77 Vasospasm and Its Management

Anil Pande, Ravi Ramamurthi

INTRODUCTION

The term "vasospasm" is used to denote an abnormal, inappropriate or unnatural constriction of the vascular lumen. Cerebral vasospasm results in a decrease in cerebral blood flow, disturbance in autoregulation and delayed cerebral ischaemia (DCI). Despite the fact that cerebral vasospasm has been the subject of the most intensive laboratory and clinical investigations, its cause still remains uncertain and the management is difficult. This angiographic narrowing is seen in cerebral[43,50,52] and spinal vessels.[107] It generally involves medium and large sized cerebral arteries and usually occurs between the 4th day and 14th day after subarachnoid haemorrhage (SAH). It is maximal during day 6–8th and spontaneously resolves by the 12–14th day and rarely may be sustained over 2 weeks.[244,262,283] Aneurysmal SAH has an incidence of 6–16 per 100,000. Early reports[216] of vasospasm as being less common in India were due to the condition being unrecognised and under-reported. Around 30–70% of aneurysmal SAH patients will develop cerebral angiographic vasospasm with delayed neurological defects manifesting in 30–50% of patients. Vasospasm causes death and disability in 12–17% of SAH patients and is the most important factor in the eventual outcome.[35,45,132,133,305] Vasospasm can also occur following traumatic brain injury[30,158,181,203] with or without SAH. It has been seen following cranial surgery,[111,154] lumbar puncture, brain tumour bleed,[67] hypothalamic injury and following cranial infections.[149] Thacker et al.[267] cited vasospasm and an autonomic storm due to the venom as a plausible explanation of the symptom complex of multiple cerebral infarcts and bilateral optic neuropathy with limb ischaemia, following scorpion bite. In women with eclampsia transcranial Doppler (TCD) regularly picks up vasospasm in all the great cerebral arteries.[27] Arterial narrowing has been seen in migraine and in non-infectious vasculitis. Vasospasm accounts for 3–7% of all strokes and carries a mortality rate as high as 40% and is more serious than re-bleeding as a cause of death and disability due to cerebral ischaemia and infarction.[64,116] Delayed cerebral vasospasm has traditionally been recognised as the most treatable cause of morbidity and mortality from SAH. The physiological and cellular events of acute brain injury, which occur during the first 24–72 hours following aneurysm rupture are also contributing factors along with delayed cerebral vasospasm to the final patient outcome.[25,26]

BRIEF HISTORICAL OVERVIEW OF VASOSPASM

Endo et al.[55] highlighted the landmarks in the study of vasospasm and this knowledge is important to understand the complexity of the problem of vasospasm and may suggest further direction of research. Roy and Sherrington,[225] in 1890, suggested that the intrinsic control of cerebral circulation depends upon the local metabolic and functional need. Richardson and Hyland,[55,250] in 1941, were advocates of the hypothesis that strokes could be due to aneurysmal vessel thrombosis. In 1951, Ecker and Riemenschneider[52] published a classic paper which began the modern era of vasospasm management and they presented six cases of vasospasm, all in patients after SAH. Vasospasm was seen to be greatest near the site of the ruptured aneurysm. They also noted that vasospasm was a self-limited process, because it was not seen in angiograms performed 26 days after SAH. They stated that "It is probable that arterial spasm plays an important role following spontaneous rupture of saccular aneurysms of or near the circle of Willis." They confirmed angiographically the spasm of cerebral arteries and its relationship to cerebral aneurysms. Vasospasm was defined as a change in calibre of arterial vessels based on two consecutive cerebral angiograms performed under identical conditions at different time intervals.[52] Denny-Brown,[43] in 1951, reported cases where neurological deterioration occurred due to hypotension and narrowing of major blood vessels. Although Denny-Brown did not directly correlate deterioration with vasospasm, he linked these changes with neurological signs in patients with strokes.[151] This significant observation was not noticed but, over time, it became evident that vasospasm was an important cause of death and disability in patients with SAH. Logue[55,250] implicated vasospasm and re-bleeding as causes of neurological deterioration in patients with aneurysmal SAH and Bebin[55,250] implicated the role of vasospasm in the mortality and morbidity in patients with aneurysmal bleed.[174,176] In 1956, the first observation of vasospasm during surgery for intracranial aneurysms was published by Logue et al.[55,250] Penfield et al.[197,250] in 1958 published an article on "manipulation hemiplegia" and attributed

vasospasm to be the cause of this untoward complication of epilepsy surgery. Pool et al. in 1958[55] demonstrated that vasospasm could be induced by surgical manipulation and counteracted by local application of papaverine. Lindsay Symon and his coworkers[250,259-261] did a lot of work on elucidating disordered cerebrovascular pathology in aneurysmal SAH and autoregulation dysfunction leading to development of focal ischaemia. Symon also demonstrated that angiographic vasospasm may be asymptomatic. Stornelli and French[55,250] reported on their experience in treating 28 patients after SAH from a ruptured aneurysm. The appearance of vasospasm on angiographic studies was more common in patients who died after surgery than in those who recovered post-operatively. These authors concluded that intracranial vasospasm was a key factor in the determination of outcome after aneurysmal SAH. In 1964, Glen Kindt and Sayeed Farhat, two residents of Edgar Kahn, began the use of hypertensive agents to reverse hemiparesis due to vasospasm. Farhat and Schneider further studied this phenomenon in clinical cases and Kindt along with McGillcuddy Keller, Pritz and Gianotta studied the addition of hypervolaemia to hypertension to treat vasospasm. In 1965, Allcock and Drake[3] presented a series of patients with SAH in whom post-operative angiograms were obtained. Vasospasm was seen in 51% of patients who underwent surgery within 3 days of haemorrhage, in 61% who received surgical treatment 6–10 days after SAH, and in 9% of patients who underwent surgery 10 days post-SAH. The interval between SAH and angiography was 3.7 days in patients with and 6.9 days in those without vasospasm. Weir[282] made measurements at 8 predetermined positions on 627 sets of angiograms from 293 patients with aneurysms. A ratio between the sum of the vessel diameters in the subarachnoid space to the sum in the base of skull and neck was calculated and plotted against time. They reported that vasospasm has its onset in man about day 3 after SAH, is maximal at days 6–8 and is gone by day 12. There was a tendency for patients in poor clinical grades to have more vasospasm. The patients with most vasospasm had a significantly higher mortality than those with the least. The idea, that vasospasm was associated with high morbidity and mortality rates, lead to the norm for delayed surgery for ruptured aneurysms. Kennedy[250] postulated that blood if removed from the subarachnoid space by irrigation, could decrease the risk of vasospasm. In 1979, Allen et al.[4] showed that acute and chronic vasospasm in dogs could be reversed by the calcium antagonist nifedipine. Based on this observation, a human trial of another calcium antagonist, nimodipine, was initiated.[119] Allen et al.[4] found that a neurological deficit due to vasospasm occurred in 8 of 60 patients receiving placebo compared with 1 of 56 receiving nimodipine. Saito et al.[226] on the significance of vasospasm in the treatment of ruptured aneurysm and the time period of vasospasm found that there were no deaths among 20 patients operated upon within the first 3 days after SAH. Post-operative vasospasm was always mild in these cases, when it occurred, probably because blood clot or blood-stained cerebrospinal fluid (CSF) was removed by operative procedures. Sundt et al.[254] advocated a delay of surgery till meningismus is gone. In 1976, Suzuki et al.[255] analysed more than 1,000 aneurysm cases and found excellent outcomes when surgery was performed during the first few days after SAH. They hypothesised that early surgery decreased the likelihood of vasospasm by removing blood products surrounding cerebral arteries. Evidence confirming the timing of vasospasm was provided by Weir and his colleagues,[283,284] Peerless,[193-196] Wilkins,[289-292] Fox,[68,69] Gianotta,[72] Batger,[15] Macdonald,[152,153] Kassell[112-117] among others have been important contributors to the study of the phenomenon of vasospasm and its management.

INCIDENCE

The incidence of vasospasm following aneurysmal SAH varies from 20% to 40% in different large series.[66,171,185,195,196,223,226,237,289] Komotar et al.[132,133] estimated an incidence of 6–16 per 100,000 populations for aneurysmal SAH and this was the aetiology in 5–15% of stroke patients with a high overall mortality ranging from 30% to 70%. There are reports that patients with vasospasm have a significantly higher mortality and morbidity,[3,226] while others[171,238,242,243,289] could not find any consistent effect on mortality and morbidity. Ramamurthi[216] in 1969, reported a low incidence of intracranial aneurysms in India and south-east Asia, but had cautioned that the reason could be due to a poor pickup rate. Aneurysmal SAH affects 10 per 100,000 populations in the Western world.[271] The incidence of SAH and vasospasm in India is comparable to the rest of the world and has to be estimated. Sengupta[238] observed that a congenital anomaly of the Circle of Willis adversely affects the surgical results in patients with vasospasm. The incidence and time course of symptomatic vasospasm parallels that of arterial vasospasm.[260] However, although 40–70% of patients have evidence of arterial narrowing confirmed by angiography (Angiographic vasospasm) or Doppler ultrasound, only 20–30% develop the clinical syndrome (Symptomatic or clinical vasospasm).

CHRONOLOGY

Angiographic spasm is usually seen on doing cerebral angiography 7 days after the SAH (it may be seen as early as 3 days after the haemorrhage), but is not seen angiographically before the 3rd day. If seen earlier after SAH it is due to an earlier episode of bleed. The vasospasm is maximal during 7–8 days (4–14 range) following bleed and usually subsides in 2 or 3 weeks. Brawley et al.[19] demonstrated a biphasic response of cerebral vasospasm in experimental SAH. The acute phase starts within minutes and lasts up to 1 hour. The chronic phase begins 4–24 hours after the bleed. Three phases in the evolution of chronic vasospasm

were proposed by Kapp et al.:[109] (1) an initial muscular contraction; (2) secondary injury to the arterial wall due to injury to the internal elastic lamina and (3) the further cascade of repair. Suzuki[256] recognised that early spasm is induced by mechanical stimulation and serotonin, and the second phase by release of oxyhaemoglobin from haemolysis of the clot. Endo et al.[55] and Suzuki[256] found that the severity of vasospasm depended on the reactivity of the vessel and prolongation of vasospasm was dependent on the quantity of vasospasmogenic substances. Oxyhaemoglobin is maximally released on the 7th day and then it gets converted to methaemoglobin which disintegrates into haeme and globulin which get absorbed by the 15th day. Thus, the onset of vasospasm and its resolution correspond to the time taken for the lysis of erythrocytes and the final clearance of the breakdown products from the subarachnoid CSF spaces. Sano and Saito[228] in their survey of 443 cases of intracranial aneurysms identified 68 cases with pre-operative vasospasm. There was no case in which vasospasm was identified during the first 4 days after SAH, while 66% of the cases exhibited vasospasm between the 6th and 9th days after SAH. Eight cases died from vasospasm before surgery and 8 cases had renewed bleeding mainly when vasospasm began to subside. The duration of vasospasm was on an average 14 days, ranging from 8 days to 24 days.

Immediate or Acute Vasospasm

Immediate vasoconstriction after SAH has been observed in a number of experimental studies.[288] The role of this sudden spasm may be protective. Westermair et al.[286] showed that acute vasoconstriction occurs even in SAH of a minor extent and may contribute significantly to a perfusion deficit in the acute stage after SAH. The oscillating pattern of regional cerebral blood flow (rCBF) in the period of early recovery after SAH resembles the pattern of synchronised vasomotion.

Early Spasm

It is the spasm seen after 25–30 minutes after SAH.[179] Early vasospasm, which is defined as arterial narrowing seen on diagnostic angiography within the first 48 hours of aneurysmal rupture, is a rarely reported and poorly defined phenomenon in patients with SAH. This early spasm, seen in animal experiments, is not often seen perhaps because imaging is rarely done immediately after the rupture of the aneurysm. Factors contributing to early spasm have been elaborated by Nagai et al.[179]

Late Vasospasm

This is the spasm which appears on day 3–14 and occasionally lasts for 2–3 weeks. Rarely vasospasm may be seen after 2 weeks of SAH.

RISK FACTORS FOR DEVELOPING VASOSPASM

Several factors including a large volume of blood on CT, an initial loss of consciousness, poor grade of SAH (poor neurological condition), pre-existing hypertension, basilar artery aneurysms, an anatomically incomplete circle of Willis and smoking, and other correlates, like age less than 50 years, hyperglycaemia, the duration of unconsciousness after SAH, the plasma level of brain natriuretic peptide (BNP), have been suggested as predictors for the development of cerebral vasospasm after SAH.[29,48,59,112,142] Hop et al.[88] found that the duration of unconsciousness after SAH is a strong predictor for the occurrence of DCI. Gonzalez et al.[76] proposed the vasospasm probability index, a combination of TCD velocities, cerebral blood flow and clinical risk factors to predict cerebral vasospasm after aneurysmal SAH. Badjatia et al.[14] studied the relationship between blood glucose levels (mg/dL) and occurrence of symptomatic vasospasm and clinical outcomes after aneurysmal SAH and they concluded that mean inpatient blood glucose value was associated with the development of symptomatic vasospasm and thus is a target for therapy to prevent vasospasm and improve clinical outcomes.

Chandy et al.[28] reported that in patients with SAH, hyponatraemia is associated with a significantly greater risk of developing vasospasm and may precede vasospasm by at least one day, but Qureshi et al.[212] found that neither hypernatraemia nor hyponatraemia was associated with the risk of symptomatic vasospasm[37]. Zhang et al.,[302] using elemental and molecular mass spectrometry (MS) detection, size exclusion chromatography (SEC), inductively coupled plasma mass spectrometry (ICPMS), reverse phase (RP)-Chip and electrospray MS, found six protein families that could be the focus areas for possible biomarkers to predict vasospasm. Goddard et al.[74] reported that the treatment method (Clipping or coiling) had no influence on the incidence or duration of TCD detected vasospasm and there was no significant difference in outcome at discharge or follow-up between those patients who had surgery or endovascular management of their aneurysms. The effect of age on symptomatic vasospasm remains controversial. In a study, Magge et al.[155] showed that a younger age is associated with an increased incidence of angiographic and symptomatic vasospasm.

SITE OF OCCURRENCE

Vasospasm occurs only in arteries and is not seen in smaller arterioles or capillaries or veins because arteries have a well developed circumferential layer of smooth muscle, the tunica media. The perivascular sympathetic plexus is well developed and these sympathetic nerves arise in the superior cervical sympathetic ganglion. DuBoulay[48] reported on the distribution of spasm in the intracranial arteries after aneurysmal bleed. The middle cerebral artery is most frequently associated with vasospasm and this has been attributed to haematomas in the

Sylvian fissure being in close proximity with the course of the vessel. Bilateral spasm occurs with anterior communicating aneurysms and other aneurysms that are closer to the mid-sagittal line. In multiple aneurysms the spasm may be used to localise the site of the ruptured aneurysm. Internal carotid aneurysms are associated with wide spread and diffuse spasm which can extend to the opposite side.

CLASSIFICATION AND GRADING OF VASOSPASM

Vessel narrowing due to atherosclerosis or an arteritic process has to be differentiated from vasospasm. Congenital hypoplasia of vessels must be borne in mind and usually is easily differentiated from vasospasm. With hypoplasia the curvature of the internal carotid artery (ICA) and the contralateral A1 segment tends to be large.

Cerebral vasospasm can be classified variously according to location, severity and symptomatology.

One classification divides vasospasm into three types, namely—'subangiographic', 'angiographic' and 'clinical' vasospasm.

1. Subangiographic vasospasm is the type that affects small caliber vessels and is not seen on standard cerebral angiography. Clinical findings, cerebral blood flow studies and perfusion imaging pick up this subtype.
2. Angiographic vasospasm is vasospasm as seen on cerebral angiography. Many patients with significant narrowing may be asymptomatic. In vasospasm due to aneurysmal SAH the vasospastic arteries tend to be close to the site of the aneurysm rupture. Distant arteries can also be affected in a "diffuse" or "generalised" manner.
3. Clinical vasospasm is the type where the patient develops neurological signs and symptoms and these may not correlate with the radiological findings.

On conventional, angiography vasospasm can also be classified as 'local', 'diffuse' or 'segmental'.

1. Local—when the spasm is limited to one vessel.
2. Segmental vasospasm affects only a part of the vessel.
3. Extensive or generalised type is when there is spasm of at least two major vessels.

Sano and Saito[228] classified vasospasm into three types: Type 1—extensive diffuse; Type 2—multisegmental and Type 3—local. Type 1 was prognostically the worst, Type 3 was good and Type 2 was located between these two types.

Classification According to Size of Vessel

Small Vessel Spasm

There is impairment of vasodilatory capacity of small vessels distal to the vasospastic basal arteries after SAH and this concept of small vessel spasm is based on haemodynamic and histological evidence.

Large Vessel Spasm

Large vessels are involved by spasm and may include the carotid, vertebral, middle cerebral arteries (MCA), anterior cerebral arteries (ACA), posterior cerebral arteries (PCA) and other cranial arteries.

Grading According to Severity

As the diameter of arteries is reduced, the velocity of blood going through them increases. A progressive increase in this velocity indicates the severity of vasospasm. Vasospasm has been graded as moderate when the velocity is 120–200 cm/sec and severe when the velocity exceeds 200 cm/sec.

Vasospasm according to its severity is usually classified into three grades:

Grade I: The vessel still has 50% of luminal flow.

Grade II: There is more than 50% of reduction of the lumen.

Grade III: The vessels are barely visible on angiography.

Angiographic vasospasm was graded by Vora et al.[279] as none, mild (less than one-third artery luminal narrowing), moderate (one-third to one-half narrowing) or severe (more than one-half narrowing). Severe vasospasm is greater than 70% vessel narrowing.

Fisher Grading System

Fisher et al.[64] studied the amount of blood on the CT scan and risk of developing vasospasm in a landmark paper in 1980 and related the density of SAH on CT scans to the chance of developing vasospasm. Patients were grouped as low risk (Grades I and II) and high-risk (Grades III and IV) for developing vasospasm. Kistler et al.[128] reaffirmed that the extent and location of blood in the subarachnoid space determined the severity and location of vasospasm and the false-positive and false-negative cases could be explained by inadequate CT technique. Smith et al.[246] revisited the grading scale to determine its validity in the era of modern management, and found that angiographic vasospasm was associated with intraventricular blood but not with the Fisher grade. Fisher grade correlated with symptomatic vasospasm in only half the patients and they concluded that a new predictive CT grading scale for vasospasm may be necessary.

EXPERIMENTAL MODELS FOR STUDYING VASOSPASM

The phenomenon of vasospasm and its therapy is studied and developed using intracranial and extracranial vessels of *'in vivo'* and *'in vitro'* models in rats, rabbits, cats, pigs, dogs[96] and primates.[42,50,51,61,217] These models use pial vessels, circle of Willis, basilar artery or the peripheral vessels, e.g. rat femoral artery model. Sonebe et al.,[250] in their bibliography of experimental

vasospasm, highlighted the important landmarks in vasospasm experimental research. Megyesi et al.[168] in a review of *in vivo* models of cerebral vasospasm identified 57 models of SAH and vasospasm dating back to 1928. These models used one of three techniques to simulate SAH: (1) an artery was punctured allowing blood to escape and collect around the artery and its neighbours; (2) an artery was surgically exposed, and autologous blood obtained from another site was placed around the artery or (3) blood from another site was injected into the subarachnoid space and was allowed to collect around arteries. The majority of animal models of SAH and vasospasm use intracranial arteries; however, extracranial arteries (rat femoral artery model) have also been used in vasospasm experiments. These studies are easier to design and implement but the vasospasm in these vessels may not reflect the actual phenomenon of cerebral artery vasospasm. Echlin et al.[50,51] in an early study on monkeys showed arteriographic and other evidence that blood, in the absence of evident mechanical stimulation or injury to intradural arteries, when injected into the anterior cervical subarachnoid space through a catheter, consistently caused acute and chronic vasospasm of the intradural arteries. Evidence indicated that vasoconstrictor agents or factors in fresh blood caused the vasospasm, since similar subarachnoid injection of saline or clear serum did not cause vasoconstriction. Other circumstances involving mechanical or other factors, such as vessel injury, may also contribute to the length and severity of the spasm.

Two-Haemorrhage Model

The model of SAH and vasospasm used most frequently is the canine "two-haemorrhage" model,[96] obtained by injecting 0.5 ml/kg of autologous arterial blood into the cisterna magna of adult mongrel dogs on day 0 and day 2. Two injections of blood into the dog's basal cistern performed 48 hours apart, result in greater arterial vasoconstriction than that affected by a single injection of blood.

Perforation Model

In this model, the major intracranial vessels, like ICA, MCA, ACA and PCA, are punctured using filaments and endovascular techniques. Lee et al.[145] found that the perforation model produced more severe pathophysiological changes than the double blood injection, and it mimicked human SAH in having an injured blood vessel and a direct haemorrhagic brain lesion under arterial blood pressure, and concluded that endovascular perforation was more suitable for study of acute SAH sequelae.

Prechiasmatic SAH Model

The prechiasmatic SAH model seems to be suitable for study of the sequelae after SAH. It produces a significant decrease in cerebral blood flow (CBF), an acceptable mortality rate and substantial pathological lesions, with high reproducibility. The CBF reduction is predominantly dependent on the amount of subarachnoid blood as demonstrated by Prunell et al.[211]

Primate Model

The best model of vasospasm seems to be the primate model in which a blood clot is surgically placed around the large cerebral vessels at the base of the monkey's brain,[168] but the use is limited by cost and animal welfare constrains.

Cultured Cells

Cytoskeletal studies of cultured arterial endothelial and smooth muscle cells can be used to study the phenomenon of vasospasm and the cellular mechanisms of oxidant injury initiated by the breakdown products of haemoglobin.

Computational and Mathematical Models

Methods using 3-D patient-specific geometries, biofluid mechanics (shear and pressure), and the non-linear mechanics of the wall (properties, biaxial stress), including cell-mediated changes in wall structure are possible.

AETIOPATHOGENESIS OF VASOSPASM

Cooke et al.[35] in a recent publication reiterated that the pathophysiology of cerebral vasospasm is complex and poorly understood and that the ischaemia and inflammation incurred with SAH affects smaller vessels differently than larger ones. Cerebral vasospasm and early brain injury (EBI) are among other causes of subsequent morbidity and mortality.[282-284] The distribution of blood in the subarachnoid space, elevation of intracranial pressure, reduced cerebral perfusion and cerebral blood flow trigger the acute injury cascade leading to microvascular injury, plugging of vessels and release of vasoactive substances[193,287] by platelet aggregates, alterations in the nitric oxide (NO) and nitric oxide synthase (NOS) pathways and lipid peroxidation.

Is Vasospasm Protective?

Du Boulay[48] and Goel [75] hypothesise that vasospasm after aneurysmal rupture may have a protective role. This is borne by the incidence of re-bleed when the vasospasm abates[226] and the problem of treating vasospasm by various means in the presence of unsecured aneurysms.

BIOLOGY OF CEREBRAL BLOOD VESSELS

Khurana et al.[122] in their exhaustive chapter on the biology of cerebral vessels and blood flow described the topographic organisation and histology of cerebral arteries, cerebral blood flow physiology and pharmacology

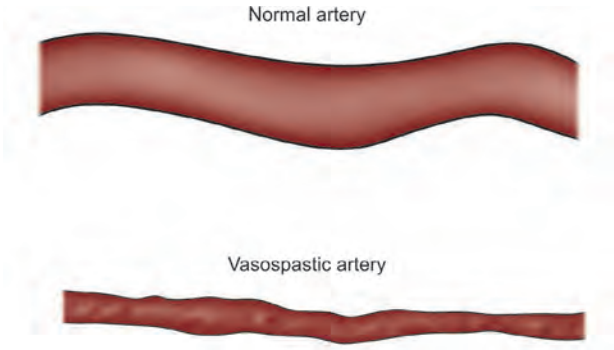

Fig. 1: Physiology of vasospasm showing the changes seen in the vessel wall following damage

especially those which are NO mediated and involved in cerebral autoregulation. Finally they present molecular biology developments leading to gene transfer technology for inhibition of angiographic vasospasm and vasospasm-associated vasculopathy. The cerebral blood vessels are characterised by a single elastic lamina, paucity of elastic fibres in the media and relatively little advential tissue.[35] The vascular smooth muscle and the endothelial cell are parts of an incompletely understood functional complex. Cerebral blood vessels are devoid of vasa vasorum. Zervas et al.[301] studied the micro-architecture of the adventitia of large feline cerebral vessels of the same size, in an effort to determine how the vessels are nourished. The cerebral vessels contain a rete vasorum in the adventitia that is permeable to large proteins and is in continuity with the subarachnoid space. This substructure may be analogous to the systemic vasa vasorum and may contribute to the nutrition of the cerebral arteries. The vasodilatory and vasoconstriction function of the vessel wall is modulated by neural, metabolic and hormonal factors and eventually by genetic factors.[123-126] The vasodilation is primarily mediated by NO and the vasoconstriction by endothelin. Peroxidative membrane damage in the arterial smooth muscle cell leads to prolonged arterial contraction that occurs during vasospasm (Fig. 1).

Genetics and Pathophysiology of Vasospasm at the Molecular Level

Genetic[49,126] and molecular changes[44,47,153] in the brain, the vascular endothelium and the vascular smooth muscle cells play an important role in the pathophysiology of vasospasm induced by SAH (Fig. 2). The SAH induces activation of immediate early genes and expression of stress proteins and heat shock proteins such as HSP70. Haeme present after SAH is metabolised by Haeme oxygenase to biliverdin and carbon monoxide. The SAH induces Haeme oxygenase-1 in the glia without affecting its isoform—Haeme oxygenase-2. Haeme oxygenase-1 is normally detectable in the neuronal populations but increases in response to oxidative stress. It is likely that Haeme itself, rather than ischaemia induced by vasospasm, plays a pivotal role in the expression of Haeme oxygenase-1. Haemolysate-induced Haeme oxygenase-1 and HSP70 expression may be used as markers for cell damage in infarcted brain associated with SAH and vasospasm.

Dietrich et al.[44] described recent developments in molecular biology to elucidate the mechanisms of SAH-induced vasospasm, and discuss the potential contribution of cerebral microcirculation regulation to the control of ischaemia. Recent findings of microvascular regulatory mechanisms and their failure after SAH suggest a role in the development and size of the ischaemia. Removal of NO produced by neuronal NO synthetase in the arterial adventitia may be important. Miyagi et al.[173] found mRNAs for Rho A and Rho kinases alpha and beta were expressed in the rat basilar artery and that they were significantly unregulated and reached their peaks on day 5. The mRNA upregulation of these proteins indicates that activation of Rho A/Rho kinase-related signal transduction pathways is involved in the development of long-lasting contraction of cerebral arteries after SAH. Peters et al.[198] stated that predisposition to intracranial aneurysm has a strong genetic component. Khurana et al.[124] indicated that endothelial NO synthetase gene polymorphisms predict susceptibility to aneurysmal haemorrhage and cerebral vasospasm.

Jayaraman et al.[99] showed that the pro-inflammatory cytokine tumour necrosis factor α and its proapoptotic downstream target, Fas-associated death domain protein, are increased in human aneurysms. In contrast, interleukin 10, which is secreted predominantly by T helper 2 cells, was absent in aneurysms. Increased tumour necrosis factor α and Fas-associated death domain protein may have deleterious primary and secondary effects on cerebral arteries by promoting inflammation and subsequent apoptosis in vascular and immune cells, thereby weakening vessel walls.

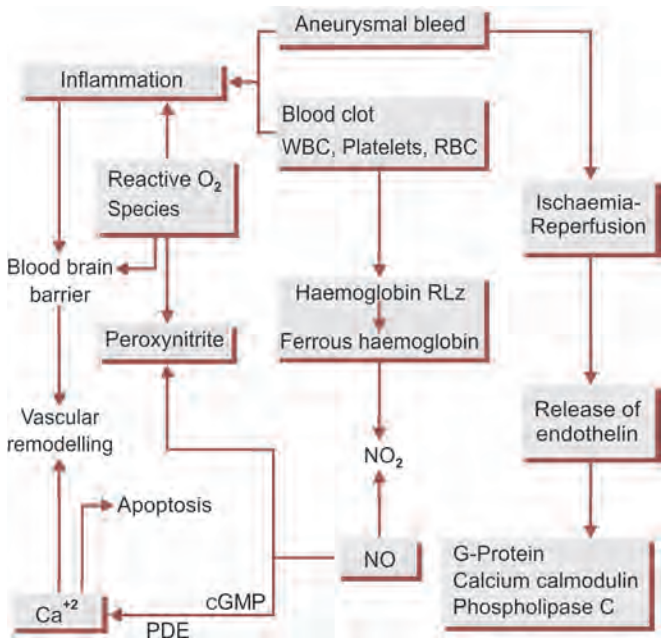

Fig. 2: Pathogenesis of vasospasm

Wang et al.[281] reported immediate early gene expression in vascular smooth-muscle cells synergistically induced by haemolysate components. Multiple high-molecular-weight components present in erythrocytes have synergistic effects on gene expression in smooth-muscle cells. The differences in patterns of gene induction suggest that multiple signalling pathways are activated. Ducruet et al.[49] presented a systematic review of 21 studies suggesting a genetic basis for clinical outcome after SAH, with a special emphasis on the pathogenesis of cerebral vasospasm and DCI. A study of genetic determinants of cerebral vasospasm, the predisposition to delayed cerebral injury, and the determinants of ensuing functional outcome after SAH has begun. The suspected genes are diverse and encompass multiple functional systems including fibrinolysis, inflammation, vascular reactivity and neuronal repair. Polymorphisms in the vasoregulatory molecule, endothelial nitric oxide synthase (eNOS), can increase susceptibility to cerebral vasospasm following brain aneurysm rupture. They highlight potential pitfalls in the interpretation of genetic association studies, and call for uniformity of design of larger multicentre studies in the future.

Red Blood Cells, Components and Other Spasmogens

The pathogenesis of delayed ischaemic neurological deficits (DINDs) after SAH has been related to products of haemolysis of the subarachnoid bood.[251,252] Fractionated plasma and white blood cells do not cause vasospasm, but even the washed erythrocytes can cause vasospasm. The breakdown of the erythrocyte is an important key event and the rate of dissolution determines the period or duration of vasospasm. Many factors are involved and the key component is haemoglobin and this acts along with a host of other factors as elaborated by Weir, MacDonald and Suzuki among others.[152,256,257,283] Vasospasm can be ameliorated by clot removal or reduction of its volume within 48 hours by surgery or by intra-cisternal t-PA and drainage. Oxyhaemoglobin is released from the 3rd day in incubated mixtures of blood and CSF and reaches peak levels after 7 days. This oxyhaemoglobin, derived from lysis of the red blood cells in the subarachnoid space, has been implicated in several cascades causing vasospasm. Pluta et al.[204] in a study provided *in vivo* evidence that the concentrations of oxyhaemoglobin and deoxyhaemoglobin increase in the cerebral subarachnoid perivascular space during the development of delayed cerebral vasospasm. Their results support the hypothesis that oxyhaemoglobin is involved in the pathogenesis of delayed cerebral vasospasm after SAH, and implicate deoxyhaemoglobin as a possible vasospastic agent. Topical brain superfusion of artificial cerebrospinal fluid (ACSF) containing the haemolysis products K^+ and haemoglobin (Hb), induces ischaemia in rats. Superimposed on a slow vasospastic reaction, the ischaemic events represent spreading depolarisations of the neuronal-glial network that trigger acute vasoconstriction as shown by Dreier et al.[47] Contraction of vessels also occurs in response to vasoactive substances released from the erythrocyte haemolysate, the key component being haemoglobin and other vasoactive factors, which include serotonin, norepinephrine, bradykinins, angiotensin, prostaglandin, thromboxanes and free radicals, or "reactive oxygen species", e.g. superoxide (O_2).[6,7] These toxic molecules damage endothelial cells, smooth muscle cells, adventitial fibroblasts and vessel wall nerve fibres. Other molecules implicated in the aetiology of cerebral vasospasm include the vasodilators NO and prostacyclin (PGI_2) which become underactive, and the vasoconstrictors endothelin-1 (ET-1) and thromboxane A_2 (TXA_2) which become overactive. Potassium channels are also thought to play an important role, as is the enzyme Haeme oxygenase. Endothelin-1 and transforming growth factor-beta increase collagen synthesis by smooth muscle cells, whereas NO and tissue necrosis factor-alpha decrease collagen synthesis. The delicate neurochemical mediated balance between vasodilatory and vasoconstrictors of the arterial wall muscle gets deranged due to some of these factors released from the red cell. These factors are usually secreted by the endothelium and include prostacyclins, NO endothelins and eicosanoids. 5-hydroxytryptamine (5-HT) and endothelin-1 (ET-1) cause constriction of cerebral arteries and upregulation of the ETB and 5-HT1B receptors is seen after SAH. Peerless and Griffiths[193] reported on release of plasma catecholamines following SAH. Sviri et al.[258] found that BNP plasma levels are elevated shortly after SAH, although they increase markedly during the 1st week in patients with symptomatic vasospasm. Their findings suggest that secretion of BNP after spontaneous SAH may exacerbate blood flow reduction due to arterial vasospasm.

Kim et al.[127] evaluated the status of thin (actin) and thick (myosin) filament regulation of smooth muscle contraction in the double-SAH canine model of cerebral vasospasm and to determine the effects of a kinase inhibitor reported to be effective in vasospasm, HA1077, on thin and thick filament regulation. Their data suggested that degradation of the thin filament-associated protein calponin plays a role in cerebral vasospasm and that the antivasospastic action of HA1077 is, at least in part, due to prevention of calponin degradation. Cytoskeletal changes in cultured vascular cells are sensitive indicators of oxidative injury. Cultured endothelial cells and smooth muscle cells showed a dose-related disruption of the cytoskeleton, particularly the F-actin and vimentin filaments, when exposed to oxyhaemoglobin. The cytoskeletal injury was prevented by the addition of deferoxamine or 1% albumin in experiments by Comair et al.[34]

Yamamoto et al.[298] examined the effects of intracarotid infusion of prostaglandins (PG) E_1 and F_{2a} on the circulation of the dog brain by fluorescein angiography, by measuring diameter changes in the epicerebral

vessels and by measuring microregional cerebral blood flow with ^{133}xenon and lithium-drift silicon detectors. Selective clipping of external and internal carotid arteries indicated that PGE_1 acts by constricting these vessels as well as the epicerebral arteries. Since prostaglandins are released from platelets as well as from stimulation of the cerebral cortex they should be considered as factors involved in the regulation of cerebral blood flow and in the mechanism of cerebral vasospasm.

It has been recognised that the endothelium plays an important role in the regulation of the cerebral vascular tone. In 1988, endothelin (ET)-1, a potent vasoconstrictor, was isolated from cultured porcine aortic endothelial cells.[302] ET-1 which is one of three distinct isoforms of ETs (ET-1, ET-2 and ET-3) has a more marked effect on cerebral arteries than do the other two isoforms. Elevated levels of ETs have been demonstrated in the CSF and plasma of patients after SAH and cerebral infarction. ETs act at least three different receptor subtypes, the ET_A receptor, which is localised in vascular smooth muscle cells and mediates vasoconstriction, and two different ET_B receptor subtypes. The ET_{B1} receptor subtype is present in vascular endothelial cells and mediates the endothelium-dependent vasodilation. The ET_{B2} receptor subtype is present in smooth muscle cells causing vasoconstriction. ET-1 acts from the adventitial but not from the luminal side of cerebral arteries. *In vivo* and *in vitro* ET-1 causes a dose-dependent and long-lasting vasoconstriction, similar to cerebral vasospasm after SAH. The vasoconstriction caused by ET-1 can be reversed by selective ETA receptor antagonists or combined ETA and ETB receptor antagonists.[302] Dehouck et al.[41] found that astrocytes can upregulate tight junction proteins and can play a critical role in blood-brain barrier (BBB) induction and maintenance. These endothelial pericyte interactions have Endothelin-1 as a mediator.

VASCULOPATHY

Inflammatory vasculopathy in response to haemorrhage has been extensively researched, but is incompletely understood and has strong genetic influences.[121,122,134] Krishna et al.[135] on studying vascular changes following experimental SAH in dogs found morphological changes in the arteries including subintimal proliferation and medial myonecrosis. It is clear that the greater the amount of subarachnoidal blood, the greater is the severity of the vasospasm. Peerless et al.[194] found structural changes in the human cerebral artery following SAH. Takemae et al.[264] found that intimal proliferation observed between 1 and 2 weeks after experimental subarachnoid blood injection to be an indicator of arterial injury. Poly (ADP-ribose) polymerase is important in modulating inflammation and inhibiting ADP-ribosylation attenuates cerebral vasospasm after SAH. The inflammatory reaction in the vessel wall causes destruction of the endothelial cells and adventitial nerve fibres, white cell infiltration, myoproliferation and eventual fibrosis leading to proliferative arteriopathy and prolonged vasospasm. Pluta et al.[206] found that cerebral vasospasm after SAH was not associated with the extent of proliferation of cells in the vessel wall, nor could the intensity of the limited proliferative changes have been responsible for narrowing of the vessel diameter.

TRAUMA OF MANIPULATION OF THE ARTERIES

Penfield et al.[197] in 1958 reported on manipulation hemiplegia—an untoward complication in surgery of focal epilepsy which they attributed to vasospasm. Harvey and Rasmussen observed general contraction of the middle cerebral arteries after manipulation and this was restricted to the vessels manipulated, but sometimes it spread to the ICA. Surgery in the presence of angiographic vasospasm was considered deleterious and leading to an increased incidence of post-operative cerebral ischaemia due to arterial narrowing exacerbated by surgical manipulation of vasospastic vessels during aneurysm dissection and clipping. Lindsay et al.[61] tested this theory in a primate model of cerebral vasospasm and found that the increased risk of post-operative cerebral ischaemia for surgery in the peak vasospasm period may be due to mechanisms other than increased arterial narrowing precipitated by surgical manipulation.

HYPOTHALAMUS

Wilson et al.[293] reported that vasospasm occurred after injection of hypothalamic extract in a dog model, hypothesising the role of hypothalamic injury in cases of vasospasm around the sellar region. Kamal et al.[106] in the experimental rat femoral artery model of vasospasm showed craniopharyngioma fluid to be vasospasmogenic.

SYMPATHETIC PLEXUS

The cerebral vessels, especially the pial vessels, are densely innervated by noradrenergic sympathetic nerves that arise in the superior cervical sympathetic ganglia and enter the intracranial cavity along the walls of the carotid artery. These cause constriction of the vessels and the interruption or temporary blockage of these causes relaxation and dilatation. The spinal arteries are also innervated by several systems that contribute to the control of spinal cord blood flow. The sensory fibres of the upper cervical nerves have a vasodilatory effect on the anterior spinal arteries (ASA). The SAH causes vasospasm by various neurochemical mechanisms. Kanat et al.[107] found the neuron density of C3DRG (Dorsal Root Ganglion) to be an important factor in the regulation of anterior spinal artery volume and spinal blood flow. They postulate that low density of C3DRG is an important factor in the pathogenesis of severe vasospasm in SAH and continuation of spinal cord blood flow. Suzuki et al.[256] were early proponents

of sympathectomy for vasospasm; many surgeons strip off the sympathetic plexus from the spastic vessels during surgery. Using minimally invasive techniques the superior cervical sympathetic ganglion can be blocked to relieve spasm.

Role of Nitric Oxide in Vasospasm

The reduction in the level of NO is a known mechanism of delayed vasospasm after SAH. Evidence for a causative role for NO includes the disappearance of NOS from the adventitia of vessels in spasm, the destruction of NO by haemoglobin released from the clot into the subarachnoid space, and reversal of vasospasm by intracarotid NO. Pluta et al.[205] sought to establish whether administration of L-arginine, the substrate of the NO-producing enzyme NOS, would reverse and/or prevent vasospasm in a primate model of SAH. Brief intracarotid and continuous intravenous infusion of L-arginine did not influence the incidence or degree of cerebral vasospasm but, after SAH, intracarotid infusion of L-arginine markedly increased rCBF in a primate model of SAH. Cerebrovascular tone is regulated by a dynamic balance of relaxing and contracting factors. Loss of the endothelium-derived relaxing factor—NO in the presence of oxyhaemoglobin and overproduction of endothelin-1 stimulated by oxyhaemoglobin have been postulated as causes of delayed cerebral vasospasm after SAH.[205] Perivascular concentrations of oxyhaemoglobin and deoxyhaemoglobin peaked on day 7 in the SAH group, at which time the concentrations in the dialysate were 100-fold higher than in any sample obtained from the control animals. Methaemoglobin levels increased only slightly, peaking between days 7 and 12, at which time the concentration in the dialysate was 10-fold higher than in samples from the control animals. Erythrocytes carry NO for release in vessels, whereas transfused erythrocytes may lack stored NO. Several converging lines of evidence also indicate that blood transfusion may exacerbate poor outcomes in some critically ill patients. Smith et al.[246] reported that development of angiographically confirmed vasospasm after SAH is associated with post-operative RBC transfusion and worse outcome is associated with intra-operative RBC transfusion. Before blood is transfused, patients with SAH should be carefully assessed to determine if they are symptomatic because of anaemia. Impairment of NO production and vasodilator function is an important mechanism associated with the pathogenesis of cerebral vasospasm, accompanied with decreased eNOS mRNA level, loss of neuronal NOS immunoreactivity and diminished cyclic guanosine monophosphate formation. Consequently, experimental vasospasm can be alleviated with NO or NO donors because of their potent relaxing function. Patients given blood transfusion during surgery for intracranial aneurysms have worse cerebral vasospasm. The explanation is that normally red blood cells deliver the NO required for vasodilatation of arteries, which is depleted in stored blood. Genetic studies have shown that eNOS gene promoter T-786C single nucleotide polymorphism (eNOS T-786C SNP) predicts susceptibility to post-SAH vasospasm. This information may be used in predicting vasospasm and developing methods for its prevention.

APOPTOSIS AND VASOSPASM

Apoptosis has been implicated in pathogenesis of aneurysmal SAH vasospasm and EBI. Following SAH causing vasospasm and resultant ischaemia, apoptosis occurs in the hippocampus, BBB and the vasculature, along with necrosis. Several apoptotic pathways are believed to be involved in SAH, including the death receptor pathway, caspase-dependent and caspase-independent pathways, and the mitochondrial pathway. Cahill et al.[24] found that p53 and associated apoptotic proteins were up-regulated after SAH and that downstream mediators of apoptosis were negatively influenced by the inhibition of p53 by Pifithrin-alpha. They found that apoptotic inhibition resulted in less cell death and an overall favourable outcome in the treated animals. There results suggest that apoptosis may be an important cause of cell death in the brain after SAH, and that p53 may play an orchestrating role regarding apoptosis in SAH. Apoptosis is important in the pathogenesis of secondary brain injury after SAH, and the apoptotic cascades present a number of potential therapeutic opportunities that may ameliorate secondary brain injury after SAH.

CASCADE OF EVENTS BEFORE AND AFTER VASOSPASM

The biology of cerebral blood vessels and blood flow is complex and genetic and molecular factors play a major role in the aetiology of SAH and vasospasm.[122-125] Immediately after SAH there is a decrease in cerebral blood flow, a CPP-independent fall in cerebral perfusion and loss of autoregulation, and this correlates with the degree of vasospasm which, when exceeds 50%, causes significant reduction of blood flow. Autoregulation is partially preserved when the flow is greater than 40% of basal flow but absent when the flow is less than 20%. Peerless[193,194] suggested that the progressive neurological deterioration was due to multiple factors including increased intracranial pressure, cerebral oedema, low perfusion pressure, low blood flow and impaired microcirculation and rheology. Following SAH, depolarisation of the vascular smooth muscle cells takes place due to depletion of energy metabolism and impaired potassium channel activity. Various agents acting on potassium channels can partially reverse vasospasm and activation of calcium channels can cause smooth muscle contraction and contribute to vasospasm. The rise of intracellular calcium observed after SAH is explained by oxyhaemoglobin-induced depletion of intracellular calcium; this leads to an influx of extracellular calcium through the voltage-dependent calcium channels. Protein kinase C is activated and may interact with other signalling

pathways such as myosin-light chain kinase, NO, intracellular calcium and protein tyrosine kinase. Takeuchi et al.[265] found impairment of autoregulation to be strongly affected by the development of cerebral vasospasm and that, in this state, a decrease in cerebral perfusion pressure easily depresses the electrical function of the brain.

EARLY BRAIN INJURY

Brain injury after SAH is a biphasic event with an acute ischaemic insult at the time of the initial bleed and secondary events such as cerebral vasospasm 3–7 days later. The EBI is a recently described term that describes the immediate injury to the brain after SAH.[11,12] The physiological and cellular events of EBI make significant contributions to patient outcomes and may even be a more significant factor than delayed cerebral vasospasm. A number of pathways have been recognised as having a role in the aetiology of EBI. Cerebral vasospasm and EBI after SAH are due to a combination of physiologic insults to the brain, resulting in global ischaemia, BBB breakdown, brain oedema and cellular death signalling. Atorvastatin ameliorated the vasospasm and EBI after experimental SAH. The underlying mechanisms may be related to its inhibition of the caspase-dependent proapoptosis pathway.[25,26] Sheba et al.[234] elaborate on the mechanisms of acute SAH-induced injury. Distribution of blood in the subarachnoid space, elevation of intracranial pressure, reduced cerebral perfusion and CBF and disturbed oxygen utilisation may be additional factors contributing to secondary brain damage after SAH,[286,287] initiating the cascades of acute injury.[232,233] Together they lead to direct microvascular injury, plugging of vessels and release of vasoactive substances by platelet aggregates, alterations in the NO/NOS pathways and lipid peroxidation. The pathophysiology of focal cerebral ischaemia is a multifactorial process[242,243] that involves the generation of free radicals, lipid peroxidation and activation of protein kinase C as well as phospholipase C and A2 with resultant accumulation of diacylglycerol and the release of endothelin-1. These events appear to create a positive feedback loop that, in turn, produces a tonic state of smooth muscle contraction and inhibition of endothelium-dependent relaxation. Serotonin, prostaglandins, catecholamines, histamine released from the breakdown of platelets and erythrocytes are also implicated as causative factors.

CLINICAL FEATURES OF VASOSPASM

Symptomatic vasospasm is the clinical syndrome of cerebral ischaemia associated with angiographically documented narrowing of a major cerebral territory.

Fox et al.[68] in an early study correlated computerised tomograms and angiograms with the clinical course. They suggested that delayed cerebral vasospasm may be preceded by relative vasodilation, or at least inhibition of vasoconstriction and concomitant increased vascular permeability of the parent vessels diagnosed by contrast enhanced computerised tomography. Schenk and Kricheffl[231] found infarcts in the brains of 65% of patients in whose angiograms vasospasm had been noted, while 82% of patients for whom vasospasm had not been reported also had infarcts. These figures suggested that there was no correlation between these two factors. However, since many of these reports were from the early days of cerebral angiography and represented the reading of many radiologists, it was felt that a more thorough study of this relationship was indicated to better assess the role of vasospasm in the production of cerebral infarcts in these patients.

Hemiparesis, hemihyperaesthesia, dysphasia, paraparesis, decreased sensorium, headache, low-grade fever and meningismus are the clinical features seen. Progressive impairment in level of consciousness or increase in focal neurologic deficit occurring after four days of any condition causing SAH should prompt investigation to rule out vasospasm and also other causes of neurological deterioration like electrolyte disturbance (hyponatraemia), infection (meningitis and sepsis), hydrocephalus and seizures (non-convulsive status). Patients can be asymptomatic despite angiographic vasospasm. The patients can present with progressive neurological signs involving cranial nerves, and ischaemic syndromes related to the arteries involved. Diffuse vasospasm may present with progressive deterioration in level of consciousness. Meningismus is also seen. The Hunt and Hess grade on admission correlates with risk of developing vasospasm. Chakravarti et al.[27] hypothesised the cerebral vasospasm in eclampsia, to be produced by a combination of reaction to hypertension, prostaglandin deficiency, defects in the e-NOS gene (coding for NOS) and endothelial damage. Vasospasm plays an important role, producing ischaemia and infarction in the brain tissue in this condition.

INVESTIGATIONS

After the history and clinical findings point towards vasospasm due to the various causes already mentioned, the clinician then has to decide on what would be the ideal set of investigations to diagnose and to treat the cause of vasospasm (e.g. aneurysmal rupture) or other rare causes of arterial spasm (e.g. tumour bleed). Once the patient has been evaluated with a haemogram, serum electrolytes, chest X-ray, USG abdomen, renal function, liver function and a complete coagulation profile is done. Angiography still remains the main modality of investigating and treating vasospasm (Figs 3A and B). Investigations to measure cerebral perfusion include cerebral blood flow studies, positron emission tomography (PET), single-photon emission computed tomography (SPECT), xenon CT and TCD among others.

Cerebral Blood Flow Studies

Various CSF flow studies are in clinical use and use radiolabelled H_2O, CO and O_2 with very short half-lives

for measurement of parameters like rCBF, cerebral metabolic rate of oxygen ($CMRO_2$) and oxygen extraction factor (OEF). The occurrence of irreversible ischaemia, penumbra, oligaemia, hyperperfusion and normal haemodynamics is investigated. In patients with vasospasm leading to ischaemic insult the regional oxygen extraction factor (rOEF) is elevated and in patients with a completed stroke the rOEF is normal. Yonas[299] emphasises that CBF technologies can help to determine whether new symptoms are caused by ischaemia, as well as define the often unpredictable manner in which ischaemia occurs in vasospasm. The CBF measurements may also help to identify the best time for surgical intervention following SAH. In addition, CBF studies may delineate when aggressive medical therapies are indicated and when they are potentially harmful. Despite the inherent limitations, as new technologies for CBF determination become more widely available, they should play an important role in the management of patients with aneurysmal SAH. Knuckey et al.[131] measured CBF during the 1st week of SAH in 46 patients who were in a good clinical grade and had a proven ruptured intracranial aneurysm. The mean initial CBF in patients who developed cerebral ischaemia was 42 ml/min/100 gm brain, which was significantly lower than in patients who did not develop cerebral ischaemia (49 ml/min/100 gm brain). This reduced CBF was not secondary to raised intracranial pressure or angiographic spasm. Patients with a reduced CBF (less than 50 ml/min/100 gm brain) and diffuse subarachnoid blood on computerised tomography had a very high incidence (78%) of cerebral ischaemia, despite a good clinical grade at the time of measurement. Serial CBF measurements are of value in monitoring the evolution of cerebral vasospasm. Yamakami et al.[297] used the xenon-133 inhalation method to clarify the relationship of vasospasm to the reduction of CBF and the DIND. Serial rCBF studies were conducted on 35 post-operative patients with ruptured intracranial aneurysms[78]. The CBF was calculated as an initial slope index (ISI) derived from the desaturation curve of each head probe, and the hemispheric mean value of the ISI (mean ISI) was calculated in both hemispheres. Their results suggest that severe vasospasm causes a reduction of CBF and that the reduced CBF brings about DIND.

Electroencephalography

Currently electroencephalography (EEG) is not commonly used, but a decline in the per cent of Alpha waves (6–14 Hz) predicts the onset of vasospasm and this is more sensitive than both angiography and TCD. A decline of EEG power or its amplitude was also a sensitive pointer to vasospasm development.

Transcranial Doppler

Introduced by Rune Aaslid in 1982, it has become an indispensable bedside test for vasospasm. Transcranial Doppler (TCD) uses the Doppler effect principle. Ultrasound signals are reflected off moving objects (RBCs in case of blood) and the frequency of the reflected signal changes in direct proportion to the velocity of the moving object. The main obstacle to ultrasound penetration of the skull is bone. Low frequencies, 1–2 MHz, reduce the attenuation of the ultrasound wave caused by bone. It is now an established method for diagnosing haemodynamically significant vasospasm in major intracranial arteries. It is safe, inexpensive and readily available. It is a cost effective, portable, non-invasive test that can be repeated as often as necessary. The TCD uses range-gated pulsed Doppler frequencies. The CBF can also be assessed with laser Doppler flowmetry (LDF) and LDF probes can be placed stereotactically over the cranial windows to allow online recording of cerebral blood flow. The utility of TCD in detecting and quantifying vasospasm has been extensively studied and correlated with angiography. In patients with moderate to large volume SAH, flow velocity (FV) rises between 3–10 days after ictus and reaches the peak between 11–20 days paralleling the natural course of vasospasm. The MCA velocity correlates best with vasospasm. The FV more than 140 cm/sec indicates angiographic narrowing and more than 200 cm/sec implies severe spasm. A rise in mean velocity by 50 cm/sec over 24 hours also indicates severe spasm. The TCD also provides the advantage of acoustic windows representing specific points of the skull where the bone is thin enough to allow ultrasound to penetrate. There are four acoustic windows: (1) transtemporal; (2) transorbital; (3) suboccipital and (4) retromandibular. Shekar et al.[236] reported that TCD examination has considerable potential in the early diagnosis of DIND (clinical vasospasm) in patients with SAH. Arslantas et al.[5] elaborated that TCD is a relatively recent advancement in imaging that enables measurement of blood FV in large intracranial arteries through temporal, occipital and orbital portions and transforamen magnum positions of insonation to check blood flow velocities (FVs) in cerebral vessels (windows where the bone is relatively thin) of the skull.

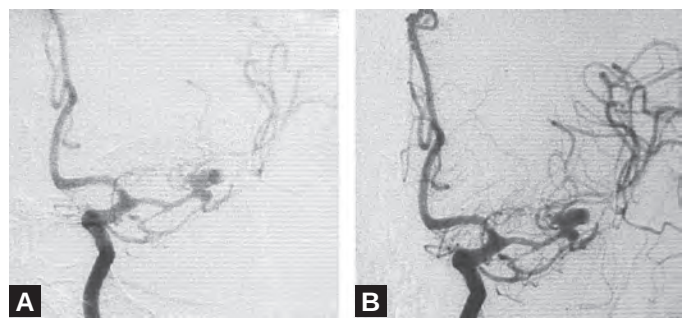
Lindegaard Index

The Lindegaard index (LI)[147] is defined by the ratio between the mean FV in the middle cerebral artery and the mean FV in the ICA. Criteria for diagnosis of a stenosis greater than 50% of an intracranial vessel with TCD include: (a) segmentary acceleration of FV; (b) drop in velocity below the stenotic segment; (c) asymmetry and (d) circumscribed flow disturbances (turbulence and musical murmur). The LI (VMCA/VICA) of more than three indicates vasospasm. Sensitivity and specificity of TCD in detecting vasospasm is high and is reported to be 84–85% and 89–98% respectively.[101]

In patients with a proven SAH, the clinical status, the amount of subarachnoid blood on a computerised tomography scan obtained within 5 days after SAH and the FVs in both MCAs measured by TCD sonography were correlated by Seiler et al.[235] All patients had pathological FVs over 80 cm/sec between day 4 and day 10 after SAH. The side of the ruptured aneurysm showed higher FVs than the unaffected side in cases of laterally localised aneurysms. Increase in FV preceded clinical manifestation of ischaemia. A steep early increase of FVs portended severe ischaemia and impending infarction. Maximum FVs in the range of 120–140 cm/sec were not critical and in no case led to brain infarction. Maximum FVs over 200 cm/sec were associated with a tendency for ischaemia, but the patients may remain clinically asymptomatic. In cases of no or only a little blood in the basal cisterns, mean FVs in both MCAs increased only moderately whereas, with thick clots of subarachnoid blood, there was a steeper and higher increase of mean FVs. Measurements of FV in defined segments of the basal cerebral arteries can be obtained through the intact adult skull using 2 MHz pulsed Doppler ultrasound. Lindegaard et al.[147] compared FV in these vessels with findings from 56 cerebral angiographies obtained in 51 patients from day 1 to day 21 after SAH. The median FV was 56 cm/sec, range 36–88 cm/sec (within normal limits). There was a clear inverse relationship between the MCA diameter and MCA flow velocity. Eleven of the 13 MCAs having diameter 1.5 mm or less showed FV in excess of 140 cm/sec. This seems a useful limit to diagnose pronounced MCA spasm (50% diameter reduction) with this method. Further clues to the severity of MCA spasm were obtained from the ratio calculated by dividing the MCA flow velocity by the FV in the ipsilateral, extracranial ICA, since spasm probably does not involve the neck vessels. This ratio was from 1.1 to 2.3, median 1.7 at day 1–2, but rose to over 10 in patients with the most severe MCA lumen narrowing. The PCA flow velocity was inversely related to the PCA diameter. Assessment of ACA spasm requires considering findings from both hemispheres combined, since the two proximal ACAs usually anastomose through the anterior communicating artery. Vora et al.[279] determined the correlation between TCD velocities and angiographic vasospasm after aneurysmal SAH.[1] For individual patients, only low or very high middle cerebral artery FVs (i.e. < 120 or ≥ 200 cm/sec) reliably predicted the absence or presence of clinically significant angiographic vasospasm. Intermediate velocities, which were observed for approximately one-half of the patients, were not dependable and should be interpreted with caution. Patients who develop clinical evidence of ischaemia from vasospasm often have mean velocities in the middle cerebral arteries of over 200 cm/sec. Daily increase of more than 50 cm/sec is a more sensitive indication of development of vasospasm. Intracranial hypertension can cause a false low mean middle cerebral velocity. Sloan et al.[245] reported TCD to be highly specific (100%), but a less sensitive (58.6%) test for the detection of angiographic vasospasm following SAH. Confirmatory angiography may be avoided if the TCD study is positive, but additional studies may be necessary if the clinical picture is suspicious and the TCD study is negative. Gonzalez et al.[76] found the use of TCD velocities, Lindegaard ratio and spasm index independently to be of limited value for the diagnosis of clinical and angiographic vasospasm.

Angiography

Angiography is still the main modality of investigation and offers the combined advantage of therapy, if necessary, in the form of mechanical (balloon angioplasty) and pharmacological angioplasty (Figs 3 to 6). Conventional four-vessel angiography is usually performed using the transfemoral route using Seldinger's technique and arterial spasm is seen as concentric narrowing of vessels, and this must be differentiated from other causes of arterial narrowing such as congenital arterial hypoplasia, pressure effect of the haematoma, hypertensive arteriosclerosis and narrowing due to increased intracranial pressure. The risk of vasospasm due to angiography is 1% and there is a 0.5–1% risk of an adverse vascular event. Spontaneous thrombosis of cerebral aneurysms demonstrated by angiography is infrequent. Kumar et al.[136] described angiographically documented spontaneous thrombosis of an intracranial aneurysm at the posterior cerebral-posterior communicating artery junction in a 40-year-old woman. The initial angiogram done on the 16th day after an episode of SAH showed a medium sized aneurysm. Subsequent angiograms done on the 30th, 40th and 60th day failed to demonstrate the aneurysm. The factors leading to this rare event remain obscure. Vasospasm can also cause the non-visualisation of a causative aneurysm and the angiogram must be repeated when such a possibility is suspected. Yamakami et al.[297] classified angiographic findings into the following five types: (1) diffuse, (2) peripheral, (3) proximal-severe, (4) proximal-mild and (5) no spasm. A retrospective analysis by Kivisaari et



Figs 3A and B: Angiogram showing vasospasm of the middle cerebral artery following aneurysm rupture. Saccular aneurysm can be seen arising from the middle cerebral artery

Fig. 4: Narrowing of the basilar artery seen after vertebral artery angiogram

al.[129,276] revealed that ruptured, posterior circulation and large/giant aneurysms are more prone to incomplete clipping. Therefore, these aneurysms require post-operative if not intra-operative evaluation with angiography. Chiang et al.[31] also found the use of routine intra-operative angiography to be safe and helpful in a significant number of cases, although it does not replace careful intra-operative inspection of the surgical field. Intra-operative angiography can be used to treat associated vasospasm. Le Roux et al.[144] explain the

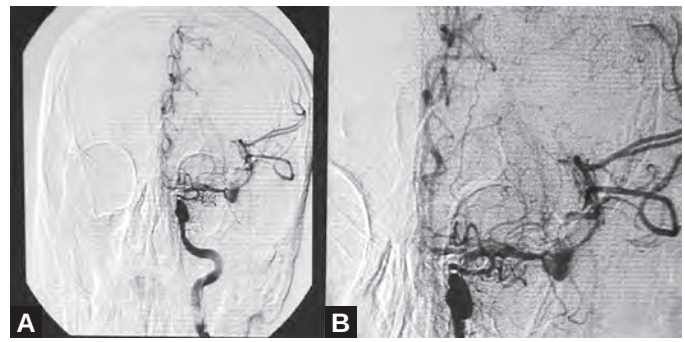

Figs 6A and B: Vasospasm involving the left MCA and posterior circulation

role of immediate post-operative angiography in severe symptomatic vasospasm.

Computerised Tomography

The computerised tomography (CT) scan is the preliminary investigation after a thunderclap headache and can help in studying all causes of vasospasm. It is indispensable in the follow-up of these patients. When delayed neurological effects due to vasospasm and resultant infarction or haemorrhage appear, it is the primary investigation guiding treatment. It can be used to predict the occurrence of vasospasm depending upon the volume of blood seen on the initial scan as per Fisher et al.[64] The scan also gives valuable clues about the location and number of aneurysms, and other causes of SAH like arteriovenous malformations (AVMs). The CT scans are repeated to rule out hydrocephalus, re-bleed, infarction and haematomas which can be the cause of neurological deterioration other than vasospasm. Nabavi et al.[178] in a prospective study assessed the feasibility and diagnostic relevance of repetitive dynamic (contrast-enhanced) CT measurements of CBF, cerebral blood volume (CBV) and mean transit time (MTT) in the first 3 weeks after aneurysmal SAH. In 15 patients with SAH, 59 dynamic CT studies including 944 regions of interest were analysed. The results were correlated with the clinical course and time after the event and the occurrence of vasospasm. Significant differences in CBF and CBV were found between ROI in grey matter (GM) and white matter (WM), with time after the event, between patients with significant and absent or minor vasospasm, and between patients with and without a presumed vasospasm-related infarct. Simone et al.[244] aimed to clarify the convenience of CT perfusion for the assessment of cerebral vasospasm caused by SAH. Significant correlations between MTT and CBF values and neurovascular findings were obtained. The CT perfusion can be performed in a short time and on a regular basis, and it, therefore, has the potential to identify cerebral vasospasm because of SAH.

Computerised Tomography-Angiography

CT-angiography is a non-invasive and cost-effective investigation and is replacing conventional angiography.

Rapid technological advances and latest generation scanners provide better quality images and can be considered an adequate stand alone modality of investigation for vasospasm and its causative pathologies. Multislice CTA can detect angiographic vasospasm after SAH with accuracy similar to that of DSA. Multislice CTA is highly sensitive, specific and accurate in detecting mild and moderate cerebral vasospasm. It is less accurate for detecting no vasospasm and marked vasospasm. The limitation is its reduced reliability when more distal and intermediate degrees of spasm are encountered. Velthieus et al.[278] attempted to determine prospectively whether and to what extent CT angiography can serve as the sole imaging method for a pre-operative workup of patients with ruptured intracranial aneurysms. They concluded that CT angiography can replace DS angiography as the pre-operative neuroimaging technique in a substantial proportion of patients with ruptured intracranial aneurysms.

Single-Photon Emission Computed Tomography

The single-photon emission computed tomography (SPECT) uses CT with radioisotopes like inhaled intravenous xenon-133 or intravenous technetium 99-HM-PAO (Hexamethyl-propyleneamine oxime) to image topographically the blood flow in the superficial and deep regions of the cerebrum. The SPECT scan shows hypoperfusion in regions with angiographic vasospasm[95]. The SPECT cannot differentiate between infarcted and ischaemic regions and can miss a bilateral hypoperfusion state as it compares one hemisphere with another to detect hypoperfusion. The SPECT should be considered as the first test for the detection of clinically suspected vasospasm and may obviate the need for invasive studies before the onset of treatment. The SPECT may also help to prognosticate patients with a poor outcome. The SPECT brain perfusion studies can contribute to the diagnosis of vasospasm complicating SAH.

Xenon-Computed Tomography Scan

Xenon-CT scan (Xe-CT) imaging technique uses the ready diffusion capacity of inhaled xenon gas across vessel walls into brain parenchyma. The amount of the xenon then attenuates the CT rays and behaves like iodinated contrast material. The amount of xenon in the parenchyma is thus proportional to the blood flow. This rCBF data is then combined with a conventional anatomic scan creating a functional image. The xenon CT has better clinical correlation than the TCD. Xu et al.[295] investigated the association of TCD and Xe-CT with the characteristics of symptomatic vasospasm secondary to aneurysmal SAH in patients who underwent euvolemic treatment without sedation. No correlation was found between CBF and mean blood FV of the MCA territory. The differences between MCA velocity and lowest cortical CBF in patients with symptomatic vasospasm were significantly different from patients without symptoms. The TCD does not help to predict regional CBF in the MCA territory in patients with SAH on euvolemic treatment.

Perfusion Computed Tomography-Scan

Perfusion CT studies involve sequential acquisition of cerebral CT sections obtained in an axial mode during the IV administration of iodinated contrast material. The DCI is related to perfusion asymmetry on admission CT perfusion (CTP). The cerebral blood flow ratio (comparing contralateral regions of interest) seems the best prognosticator for development of DCI. Perfusion CT values of CBF have proved to be accurate in animals. Kanazawa et al.[108] clarify the convenience of CT perfusion technique for the assessment of cerebral vasospasm caused by SAH. The CTP can be performed in a short time and on a regular basis, and it, therefore, has the potential to identify cerebral vasospasm due to SAH. Significant correlations between CBF values and neurovascular findings were obtained by them. Linear regression analysis by Wintermark et al.[294] showed good correlation between perfusion CT and stable xenon CT. The CBF perfusion CT studies of CBF achieved with adequate acquisition parameters and processing lead to accurate and reliable results. Lefournier et al.[146] in a study, sought to identify the best perfusion parameters in perfusion-CT (PCT) which are able to predict vasospasm diagnosed by angiography after SAH. They found that PCT can accurately identify severe vasospasm and be used as a convenient non-invasive imaging modality to monitor patients with SAH.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a very sensitive investigation and diffusion and perfusion weighted imaging and other MRI protocols are being used to pick up ischaemia due to vasospasm, which can lead to infarction if left untreated. Jadhav et al.[96] used MRI to examine the recently reported EBI after SAH. Double haemorrhage SAH model was obtained by injecting 0.5 ml/kg of autologous arterial blood into the cisterna magna of five adult mongrel dogs on day 0 and day 2, followed by imaging at day 2 and day 7 using a 4.7-Tesla (T) scanner. White matter (WM) showed a remarkable increase in T2 values at day 2 which resolved by day 7, whereas grey matter (GM) T2 values did not resolve. The apparent diffusion coefficient (ADC) values progressively increased in both WM and GM after SAH, suggestive of a transition from vasogenic to cytotoxic oedema. Ventricular volume also increased dramatically. Prominent neuronal injury with Nissl's staining was seen in the cortical GM and in the periventricular tissue. They concluded that multimodal MRI reveals acute changes in the brain after SAH and can be used to non-invasively study EBI and normal pressure hydrocephalus post-SAH. The MRI can also predict tissue histopathology and may be useful

for assessing pharmacological treatments designed to ameliorate SAH.

Magnetic Resonance-Angiography

MR-angiography (MRA) has been reported to have a sensitivity of only 46% and specificity of 70%, as there is the problem of motion artifact and difficulty in visualising distal vessels and branches. Technical hardware and software advances are rapidly increasing the role of MRA in the investigation and management of vasospasm. Ramdurg et al.[217] have used MRI and MRA for demonstration of SAH-induced vasospasm in a rat experimental model.

Positron Emission Tomography Scan

Positron emission tomography (PET) scans are available in all major cities in India, and rCBF and regional cerebral metabolic rate of oxygen ($rCMRO_2$) can be measured with PET in patients with SAH and hemiparesis due to cerebral vasospasm. Powers et al.[209] indicate that with PET studies it may be possible to prospectively differentiate patients with neurological deficits due to reversible ischaemia from patients with irreversible infarction. Frykholm et al.[70] investigated the occurrence of early haemodynamic and metabolic changes in the acute stage of SAH. Haemodynamic and metabolic disturbances proved to be common after SAH and oligaemia was the predominant pathophysiological pattern. These abnormalities probably reflect the primary brain injury caused by the initial haemorrhage. The impact of secondary insults such as acute hydrocephalus, brain oedema, vasospasm, seizures, hypotension and hypoxaemia are likely to be dependent on the degree of primary injury, which can be assessed by PET.

TREATMENT

Komotor et al.[132,133] in a recent review of advances in vasospasm treatment and prevention stated that, despite maximal medical therapy, up to 15% of patients surviving the ictus of SAH experience stroke or death from vasospasm. Causes of neurological deterioration and poor outcome after SAH, including delayed effects of acute global cerebral ischaemia, thromboembolism, microcirculatory dysfunction and cortical spreading depression, play a role. Cross et al.[36] provide compelling evidence that surviving an SAH is more likely, if the patient is admitted to a hospital with a high caseload of SAHs as multimodality treatment options, cumulative experience and technical infrastructure and personnel who are better exposed to the problem of vasospasm. Current management of vasospasm is still being defined and consists of medical therapy, including triple-H regimen and oral administration of calcium antagonists, cisternal clearance of blood after surgery or interventional procedures and endovascular balloon angioplasty and/or injection of vasodilatory agents for refractory cases. Wilkins[289-292,304] exhaustively reviewed the literature on the various approaches to the prevention and treatment of intracranial arterial spasm. Gianotta et al.[72] presented a series of 17 patients who developed severe neurologic deficit due to post-operative cerebral vasospasm. All underwent confirmatory post-operative cerebral angiography. Treatment included controlled hypertension, hyperventilation, over-transfusion of whole blood and colloids, and infusion of low-molecular weight dextran. Neurologic deficits were reversed promptly and completely in 12 patients and partially in three patients. The authors propose that methods designed to increase cerebral blood flow can reverse the ischaemic deficits of vasospasm.

Initial Intensive Care Unit Management

Patients with vasospasm are admitted to neurosurgical service and are managed within the neonatal intensive care unit (NICU). In critically ill patients or in those with compromised pulmonary function, a Swan-Ganz catheter should be in place and appropriate monitoring used to avoid circulatory overload and pulmonary oedema (PO), as well as to ensure the optimisation of cardiac output.[9,69,80,89,93,177,182,183] If vasospasm is suspected clinically or by TCD standard triple-H therapy is started after the offending aneurysm has been secured by clipping or neurointerventional methods. The patient is monitored by neurosurgeons preferably trained in both open microneurosurgery and neurovascular interventional methods. Periodically the patient is re-evaluated clinically and by TCD. Daily SPECT and digital subtraction angiography are done in a few tertiary centres when a new neurological deficit appears and other causes of deterioration like hyponatraemia have been excluded. Persisting deficit despite triple-H therapy, new or worsening vasospasm detected by TCD or SPECT[35] may require a change in the treatment modality or more aggressive methods. Gupta et al.[80] in a review on monitoring the injured brain in the intensive care unit focussed on the monitoring of intracranial pressure, blood flow to the brain (TCD), cerebral oxygenation using the methods of jugular bulb oximetry, near infrared spectroscopy and implantable sensors, and the monitoring of function using electrophysiological techniques. MacLaughin et al.[166] reported that PE occurs in 28.8% of patients after SAH, and most of the time it was delayed. Cardiac dysfunction, both systolic and diastolic, is commonly observed during SAH and could contribute to the genesis of PE after SAH. Thus all patients must be monitored by a team comprising a neurosurgeon, neurologist, intensivist, anaesthetist and cardiologist supported by excellent nursing and paramedical staff. The general measures of good intensive care, proper ventilation and provision of optimal nutrition promote faster recovery and helps in better outcome.

Triple-H Therapy

Induced Hypertension, Hypervolaemia, Haemodilution

Attempts to improve cerebral perfusion by volume expansion and induced hypertension are commonly

practiced.[196,222] This increases CBF and decreases the haematocrit. It is a safe and effective modality of treatment to prevent ischaemic neurological deterioration. Solomon et al.[249] suggested that immediate aneurysm surgery and aggressive post-operative prophylactic volume expansion in all patients can substantially reduce re-bleeding and DCI, potential causes of morbidity after aneurysmal SAH. Intensive care monitoring and close clinical supervision are indicated when patients are receiving inotropic agents such as dopamine or dobutamine with normalisation of the circulating blood volume with fluid administration or transfusion. Xenon blood flow studies have demonstrated that, rarely, patients with induced hypertension can have a reduction in rCBF. Walid and Zaytseva[280] reviewed the available evidence regarding the beneficial effects of hyperbaric oxygen (HBO) in preventing post-operative ischaemic complications due to vasospasm after surgery on ruptured cerebral aneurysms and the rationale for including HBO into the standards of care of these difficult patients. The authors' premise is that the oxygen-carrying capacity of the blood is lowered with hypervolaemic hypertensive haemodilutional (HHH) treatment and this side effect can theoretically be partially corrected using HBO therapy which appears to be the missing link in the above therapeutic regimen (Quadruple H therapy). Murthy et al.[177] state that the avoidance of hypovolaemia is perhaps more important than the institution of hypervolaemia. Individual haematocrit varies, and is maintained above 35% and haemoglobin is kept above 10 gm/dL to maintain the optimal oxygen carrying capacity. Crystalloid solutions are given to meet normal daily requirements. Glucose solutions are avoided. Human serum albumin can be used as a volume expander in a dose of 1 g/kg per day divided in 4–6 doses/day, each administered over 30–60 minutes. Gupta et al.[81] concluded that "triple-H therapy" is useful in treating vasospasm induced ischaemic deficits. The duration of "triple-H therapy" varied from 2–7 days with an average of 4.6 days and complications included hypokalaemia, haemorrhagic infarct and septicaemia which worsens brain oedema in the presence of acute infarcts and hence is contraindicated in such patients. In a study, Origitano et al.[192] utilised a protocol for prophylactic "triple-H therapy" in the treatment of SAH, and evaluated the response of CBF. The CBF remained elevated during 21 days after SAH, irrespective of neurological grade on admission, age, sex or angiographic arterial narrowing. They found a consistent method for establishing sustained improvement in CBF after SAH. The authors advocate that Triple-H therapy is a safe and effective modality for elevating and sustaining CBF after SAH. In combination with early aneurysm surgery, it can minimise DCI and lead to an improved overall outcome.

Shimoda et al.[241] investigated the frequency of various intracranial complications that may result from hypervolaemic therapy for a delayed ischaemic deficit (DID) following SAH. Around 28% developed an intracranial complication during hypervolaemic therapy—cerebral oedema was aggravated in 18, and a haemorrhagic infarction developed in 8. The authors suggested that hypervolaemic therapy is contraindicated in a patient who is found to have a massive abnormality on CT at the time when a DID is manifested, especially when it occurs within 6 days after the SAH. To avoid haemorrhagic infarction, it is important to discontinue hypervolaemic therapy as soon as the DID resolves. Demaraju et al.[38] in a validation study found that hyponatraemia with natriuresis in the neurosurgical setting responds to salt and fluid replacement guided by the patients' volume status as determined by the central venous pressure and that the syndrome of hyponatraemia with natriuresis is most often caused by "cerebral salt wasting" rather than by the syndrome of inappropriate secretion of antidiuretic hormone. The hyponatraemia post-SAH should be treated with fluids rather than fluid restriction as it is due to excessive sodium excretion and fluid restriction for hyponatraemia after SAH is associated with a worse outcome. Egge et al.[53] cite the paucity of information and important limitations in the design of the studies evaluating the efficacy of triple-H therapy.

Induced Hypertension

Kassel et al.[116] induced arterial hypertension in 58 patients with progressive neurological deterioration from angiographically confirmed cerebral vasospasm after spontaneous SAH in an attempt to improve their deficits. The most effective regimen consisted of intravascular volume expansion, blockade of the vagal depressor response, and the administration of antidiuretics and vasopressor agents. With this protocol, arterial blood pressure could be sustained at high levels for prolonged periods. Neurological deterioration was reversed in 47 patients, transiently in 4; permanent improvement occurred in 43. Complications experienced during therapy included PO, dilutional hyponatraemia, aneurysmal re-bleeding, coagulopathy, haemothorax and myocardial infarction. The presence of an untreated ruptured or intact aneurysm is a contraindication. The production of a hypervolaemic state by the use of colloid and crystalloid infusion accompanied by atropine blockade of the vagal depressor response and blunting of the diuresis with vasopressin enables arterial pressure to be elevated for longer than 1 week. Only if the aneurysm or cause of SAH has been tackled and the patient does not have cardiac contraindications like ischaemic and congestive cardiac disease, this option may be used and a systolic blood pressure of 200–220 mm may be maintained using dobutamine, or dopamine. If the patient does not respond within 60 minutes then phenylephrine or norepinephrine, or a combination of both is used. Fleischer et al.[66] successfully treated vasospasm, which resulted in cerebral ischaemia with a combination of aminophylline and isoproterenol.

PHARMACOLOGICAL PREVENTION OF VASOSPASM

The agents that have been tried include papaverine, procaine, cyclandelate, nitroglycerin, reserpine, kanamycin, platelet aggregation inhibitors, prostaglandin antagonists and serotonin antagonists among others. None of these have been found to be effective. In an experimental study on primates Sundt et al.[254] started using isoproterenol in the treatment of cerebral vasospasm. Isoproterenol acts by increasing the heart rate and cardiac output. It dilates the peripheral arterioles and decreases arterial pressure. It also increases venous return to the heart. The potential risk of cardiac arrhythmia is offset by the simultaneous use of lignocaine hydrochloride. Isoproterenol in a dose of 0.4–0.8 mg in 150 cc of 5% dextrose at the rate of 10–20 microdrops per minute is given, with simultaneous administration of lignocaine hydrochloride 2 g in 450 cc of 5% dextrose in 0.2% saline and 20 mg potassium chloride at the rate of 20 microdrops per minute. This regime was found to be effective, in treating patients with aneurysmal SAH, having symptomatic vasospasm. Brown et al.[23] advocated dopamine and mannitol. Dopamine in low doses (< 5 microgram/kg per minute) produces peripheral vascular dilatation, while in higher doses greater than 10 microgram/kg per minute produces peripheral vasoconstriction and an increase in arterial blood pressure. While using dopamine, monitoring fluid replacement and ECG and CVP is advisable.

Calcium Channel Blockers

Rinkel et al.[221] in a recent Cochrane review confirmed that calcium antagonists help to reduce spasm. The intracellular calcium ion is a key player in the development of muscle contraction of the vessel wall and calcium antagonists, like nimodipine, nicardipine and magnesium sulphate block, the slow channels of calcium which inhibit the contraction of smooth and cardiac muscles.[210] The skeletal muscles are not affected and these agents are very useful to prevent the onset of vasospasm and can help in its reversal. These agents are hypothesised to prevent brain injury by other mechanisms than blockage of slow calcium channels and also have a role in cerebral protection.

Nimodipine

Nimodipine is a calcium antagonist that has a selective CNS action and blocks the dihydropyridine sensitive (L-type) calcium channels. Other similar drugs used less commonly are nicardipine,[266] nifedipine and diltiazem. Oral nimodipine is given in dose of 60 mg four times a day and reduces infarcts and bad outcomes. Jan et al.[97] reported a 36% reduction in bad outcome in patients treated with nimodipine. Its clinical effectiveness was not based on its ability to prevent or reverse angiographically demonstrable vasospasm. Nimodipine can be used either orally or intravenously or intra-arterially. It is lipid soluble and crosses the BBB. Auer[8] demonstrated pial arterial vasodilatation by intravenous nimodipine in cats.

Although the large clinical studies have shown a beneficial effect, the mode of action is still debatable, as there is no significant reduction in angiographic vasospasm in these patients. The probable action may be protecting the nerve cells against the damaging influence of calcium.[98,121,190,200-202] Calcium channel blockers are thought to be more neuroprotective than counteractive to vasospasm itself. Their benefit may derive from their prevention of calcium entry into ischaemic cells, antiplatelet effect and ability to dilate leptomeningeal arteries. The calcium theory of neuronal damage has been recently adapted to SAH. It is proposed that haemorrhagic insult to the brain causes free radical mediated destructive reactions of membrane phospholipids, and the consequent decrease of phospholipid dependent enzymatic activities, such as Na^+-K^+ ATPase. Marazaitico et al.[156] found that nicardipine treatment reduced the TBRAS content and induced the recovery of Na^+-K^+ ATPase activity, exerting a brain protective role against the detrimental effects of the haemorrhage.

There was no significant difference in response using either two or three micrograms per hour infusion. Dorsch[46] used nimodipine infusion within 3 days of diagnosing an ischaemic deficit in 141 patients. Around 74% were in Glasgow Outcome Scale (GOS) I and 6% in II at the time of discharge, 11% died. Gilsbach et al.[73] in a European, multicentre, prospective, randomised, double-blind dose-comparison study on preventive therapy with intravenously administered nimodipine evaluated the efficacy and tolerability of two different doses: 2 and 3 mg/hr. All patients who were in Hunt and Hess grades I to III were operated upon—patients who had poor Hunt and Hess grades (IV-V) were operated upon on according to the surgeon's choice. This treatment regimen was associated with a low incidence of delayed neurological dysfunction with no significant difference between the two dosage groups: 3 patients (1.5%) remained severely disabled and 2 (1%) moderately disabled due to vasospasm with or without additional complications. Even among the patients in Hunt and Hess grades IV or V the long-term outcome was favourable (good-fair) in 40% and unfavourable in 60%. Among the patients in grades I to III, the long-term outcome was favourable in 89% and unfavourable in 11%. Mee et al.[167] found that nimodipine does not increase the cerebral blood flow or protect the heart after an SAH, but there were no side effects from nimodipine. Allen et al.[4] enrolled 125 neurologically normal patients with intracranial aneurysms in a multi-institution, prospective, double-blind, randomised, placebo-controlled trial within 96 hours of their SAH, to determine whether treatment with the calcium blocker nimodipine would prevent or reduce the severity of ischaemic neurologic deficits from arterial spasm. They concluded that nimodipine should be given to patients who are neurologically

normal after SAH in order to reduce the occurrence of severe neurologic deficits due to cerebral arterial spasm. Petruck et al.[199] concluded that nimodipine treatment in poor-grade patients with SAH results in an increase in the number of good outcomes and a reduction in the incidence of delayed neurological deterioration due to vasospasm. This effect occurs by a mechanism other than prevention of large-vessel spasm as visualised on angiography. Karinen et al.[110] in a randomised prospective clinical trial of nimodipine medication found that patients in the nimodipine group had an average of 3.46 years longer life expectancy (incremental effectiveness) than those in the placebo group. There was a significant difference in 3-month follow-up mortality and a slight difference in sickness pensions during the 10 years after SAH. Nimodipine treatment was associated with a significant decrease in mortality and its use in the management of patients with SAH seems economically justified because it increases patient life years at very low-incremental cost. Pillai et al.[203] reported that oral nimodipine given for 3 weeks did not improve outcome in patients with severe diffuse head injury even in the patients with SAH. In another double-blind placebo-controlled trial to determine the effect of intravenous nimodipine on delayed ischaemic deterioration and CT-visualised infarcts after SAH and surgery, Ohman et al.[188] found that nimodipine treatment was associated with a significantly lower incidence of deaths caused by DCI and significantly lower occurrence of cerebral infarcts visualised by CT scanning in the whole population, especially in patients without an associated intracerebral haemorrhage on admission CT scan. Hanggi et al.[85] for the first time demonstrated the feasibility and safety of intrathecal nimodipine lavage in patients with severe vasospasm resistant to the established medical and endovascular treatment strategies. Nimodipine 60 mg every 4 hours orally or via an NG tube for 21 days should be initiated within 4 days of haemorrhage as it has been shown to improve outcome in vasospasm. Patients should be monitored for renal failure, GI side effects, dependent oedema and PO, which are potential side effects of calcium channel blocker use.

Nicardipine

Flamm et al.[65] found nicardipine to be effective in a dose of 0.01–0.15 mg/kg/hr infusion. Nicardipine was found to induce the recovery of Na^+-K^+ ATPase activity, in experimental SAH thus exerting a brain protective role. High-dose intravenous nicardipine has been shown to reduce the incidence of angiographic and symptomatic vasospasm in patients with aneurysmal SAH, but treatment may be complicated by side effects, including hypotension or PO/azotaemia. Haley et al.[83,84] suggest that, from a clinical standpoint, the results of high-dose and low-dose nicardipine treatment are virtually equivalent, but administration of low-dose nicardipine is attended by fewer side effects. Nicardipine prolonged-release implants (NPRIs) have been used to prevent vasospasm in patients with SAH.[77] Kasuya et al.[118] reported on their use and NPRIs were applied principally to patients with thick clots (Fisher Group 3) through a frontotemporal or frontal craniotomy. The NPRIs were placed in the cisterns with thick clots where vasospasm was highly probable. Shibuya et al.[240] in a randomised prospective study found AT-877, a calcium channel blocker, to reduce symptomatic vasospasm.

Free Radical Scavengers

Free radicals reaction initiated by the lysis of clot has been implicated in the pathogenesis of vasospasm by Asano et al.[6] Oxyhaemoglobin has a direct effect on the vessel wall causing vasoconstriction and also causes injury due to the release of superoxide ion that injures the endothelial lining. Free radical induced lipid peroxidation has been identified as a potentially important contributor to both the arterial narrowing of vasospasm and the final cascade of ischaemic cell death.

Tirilazad mesylate[113,114,248] is a non-glucocorticoid 21-aminosteroid that exerts its anti-lipid peroxidation action through co-operative mechanisms—a radical scavenging action (i.e. chemical antioxidant effect) and a physicochemical interaction with the cell membrane that serves to decrease membrane fluidity (i.e. membrane stabilisation). It is a potent inhibitor of lipid peroxidation and also acts as a free radical scavenger. In experimental models of SAH and focal cerebral ischaemia tirilazad has been shown to ameliorate vasospasm and improve cerebral blood flow as well as reduce the size of cerebral infarction. In addition, preliminary studies with this drug have shown it to be safe and unassociated with side effects such as hypotension, mental status changes or glucocorticoid toxicities. Kassel et al.[113] found that there was a reduction in symptomatic vasospasm in the group that received the benefits of treatment with tirilazad which was predominantly in men rather than in women. Tirilazad was well tolerated at all three dose levels. These observations suggest that tirilazad mesylate at a dosage of 6 mg/kg per day is safe, and improves overall outcome in patients (especially in men) who have experienced an aneurysmal SAH. Phase III SAH clinical trials have shown a beneficial effect of tirilazad only in men. One explanation for the decreased efficacy in women is that women metabolise the drug up to 60% faster than men. However, it is also possible that other more subtle differences between the sexes alter the pharmacodynamic response of women to tirilazad. Recombinant human superoxide dismutase is supposed to act in prevention of vasospasm by blocking endothelial injury initiated by the superoxide ion.

Other drugs with similar mechanism of action are nicarven and ebselen. Asano et al.[7] reporting on hydroxyl radical scavenger synthetic nicarven found that it has no demonstrable vasoactive properties but scavenges hydroxyl radicals in aqueous environmental conditions at neutral pH. The usefulness of this therapy

for SAH was strongly indicated by the fact that the agent significantly ameliorated DINDs, leading to a marked improvement in the GOS scores at 1 month, as well as a reduction in the cumulative incidence of death by 3 months.

Endothelin

Endothelins are 21-amino acid vasoconstrictor peptides and are the most potent naturally occurring vasoconstrictors. They can be produced by the vascular endothelium and smooth muscle cells. Three endothelin genes have been identified and the proteins are called endothelin-1 to 3. Endothelin-1 is a powerful endogenous vasoconstrictor substance produced by endothelial cells, and causes significant and sustained vasospasm. Nilsson et al.[184] reported on the presence of contractile endothelin-A and dilatory endothelin-B receptors in human cerebral arteries. Endothelin receptor antagonists (TAK-044) cause prevention or reversal of vasospasm. In animal models, endothelin antagonists have been associated with reduced incidence of chronic vasospasm following clot placement. Such compounds have not yet gone to clinical trials. The NO has been tried with no conclusive results. Zimmermann and Seifertl,[303] in a review of the results of clinical and experimental investigations, support the hypothesis that ET-1 is a major cause of cerebral vasospasm after SAH. The SAH causes complex changes in the ET system and increased ET-1 levels after SAH; these are not solely responsible for the development of vasospasm but may occur after cerebral ischaemia. Endothelin receptor antagonists[269,274] (clazosentan) are still under investigation and may reduce both the frequency and the severity of vasospasm. Vajkoczy et al.[272,275] studied the safety and tolerability of the novel endothelin A (ETA) receptor antagonist clazosentan in patients with SAH and its potential to reduce the incidence and severity of cerebral vasospasm following surgical clipping of the aneurysm. In a Phase IIa multicentre, double-blind, randomised treatment with clazosentan resulted in a reduced incidence of angiographically evident cerebral vasospasm (40% compared with 88% of patients) and the severity of vasospasm was reduced in the clazosentan group ($p = 0.012$). In Part B of the study, in 50% of assessable patients who were initially treated with placebo, reversal of vasospasm was observed following the initiation of clazosentan therapy. The incidence of new infarctions was 15% in the clazosentan group and 44% in the placebo group. There was no adverse event pattern indicating a specific organ toxicity of clazosentan. Schubert et al.[232] found that prophylactic treatment with the ET receptor antagonist clazosentan prevented hypoperfusion, and has shown promise in phase 2 studies, and two randomised, double-blind, placebo-controlled phase 3 trials (CONSCIOUS-2 and CONSCIOUS-3) are underway to further investigate its impact on vasospasm-related outcome after an SAH.

Calcitonin gene related peptide, another potent vasodilator, has been used for patients with cerebral ischaemia following SAH[102]; however, adverse effects like hypotension are common. Its role in intra-cisternal administration has not yet been established.

Nitric Oxide

Vasoconstriction due to Deficiency of Endothelial Nitric Oxide

The NO donors like sodium nitroprusside and nitroglycerin are used. The NO is an extremely potent vasodilator and accounts entirely for the biological effect of endothelium-derived relaxing factor.[2,159,213] It acts through cyclic guanylic acid-dependent protein kinases and reduces the protein-dependent inflammatory response in the vessel wall in vasospasm. Intrathecal sodium nitroprusside was suggested as a treatment for cerebral ischaemia in patients with severe, medically refractory vasospasm after SAH (10–40 mg single dose and 2–8 mg/hr as infusion, 4 mg/ml,1–2 ml per dose up to three times daily for a week). Kumar et al.[136] found that intraventricular SNP therapy is effective in reversing the changes even in established cases of SAH-induced vasospasm. Intraventricular administration of nitroprusside has been shown to reduce severe vasospasm which was refractory to other therapy by Thomas and Rosenwasser.[268]

Recombinant Tissue Plasminogen Activator

It is well established, that the amount of blood in the basal cisterns has a correlation with the development of vasospasm.[255,257] Hence, continuous cisternal irrigation post-operatively to reduce the incidence of symptomatic vasospasm has been tried and an improved clinical outcome reported.[175] A single bolus of 10 mg of thromboplastin activator (TPA) injected into the basal cistern helps in clearing the subarachnoid clot post-operatively. However, the clearance of clots per se may not reduce the incidence of spasm as monitored by TCD. Intracisternal administration of TPA is also being used by some groups.[96,286,300] Usui et al.[273] reported the results of a retrospective review, between January 1986 and December 1991 of the results of early surgery and intrathecal thrombolytic therapy in 111 patients with aneurysmal SAH. Effects on clot lysis, angiographic and symptomatic vasospasm, cerebral infarction, and clinical outcome were compared in 60 patients treated with Urokinase (UK) 60,000 IU/dL for 7 days (UK group), 22 patients treated with 0.042–1 mg tissue plasminogen activator (tPA) every 6–8 hours for 5 days (tPA group), and 29 patients who did not receive treatment with either thrombolytic agent (no-treatment group). This study indicates that post-operative intrathecal thrombolytic therapies, especially with less than 4 mg/dL of tPA are effective in lysing subarachnoid clot and preventing

vasospasm and infarction safely. Findlay et al.[62] found that the intraventricular administration of recombinant tissue plasminogen activator (rtPA), in a dose of 3 mg every 24 hours, has been shown to be therapeutically efficient, significantly improving the outcome of patients with intraventricular haemorrhage. The use of rtPA also decreased the necessity for permanent VP shunt insertion in survivors. The intrathecal administration of rtPA[288] has been shown to dissolve subarachnoid clots, thereby preventing vasospasm in humans. The use of rtPA in human trials has reduced the severity of angiographic vasospasm and improved the clinical neurologic grade of the patients. Ramakrishna et al.[215] found that intraventricular tPA is a safe and effective treatment for reducing both angioplasty and shunting rates in patients with SAH in Hunt and Hess grades 3–5. Stolke and Serfant[253] in a prospective study of a single bolus injection of rtPA in patients with aneurysm rupture concluded that intrathecal thrombolysis is an effective and safe method for removal of intracisternal blood accumulations after SAH resulting in a significant reduction of symptomatic vasospasm and DID and conversion of a SAH Fisher grade III into a SAH Fisher grade II. It is sufficient for significant reduction of the incidence of post-haemorrhagic DID, avoiding the necessity of complete pharmacological blood clot evacuation and the use of higher concentrations of rtPA or continuous irrigation of the subarachnoid space. The other agents tried with varying results are streptokinase and urokinase.[229]

Papaverine

Papaverine (phosphodiesterase inhibitor) is an alkaloid and a powerful vasodilator. It acts directly on the smooth muscle cells of the arterial wall by trans-endothelial absorption. It is given in the dose of 200–300 mg over 30 minutes. Since the absorption is trans-endothelial, it is not surprising that the best results have been obtained with an infusion close to the site of spasm. Due to reported ocular complications, a supra-ophthalmic position should be used, if at all possible. An angiographic response is seen in 80–95% of cases. A clinical response is seen in 25–50% of cases. Given as intra-arterial infusion (12 mg/hr) by selective catheterisation, it was found to be effective,[105,157] without associated systemic complications.[104] Ramdurg et al.[217] compared the effects of single bolus doses of nitroglycerine and papaverine using magnetic resonance angiography in the rat model and found that papaverine is an effective drug for ameliorating SAH-induced vasospasm. Short-acting NO donors were not as effective in ameliorating vasospasm. Another endovascular treatment strategy for vasospasm is intra-arterial infusion of papaverine.[33]

Intra-arterial Papaverine

Intra-arterial infusion of papaverine is being used clinically as a vasodilator for spastic arteries after SAH, since *in vitro* experiments demonstrated that papaverine is one of the most potent vasodilators of human cerebral arteries following SAH. The proximal segment of the anterior cerebral artery, the posterior cerebral arteries and distal middle cerebral arteries are not amenable to balloon dilatation because of size or angle of take-off. The instillation over several hours of high concentrations of intra-arterial papaverine has been associated with reversal of spasm in some cases.[155] Milburn et al.[170] conducted a study to determine if there is a change in intracranial arterial diameters after papaverine infusion for vasospasm and to determine whether the change occurs in the proximal, intermediate or distal arteries. In all treatment groups an increase was found in the average arterial diameters ranging from 2.8% to 73.9%, with a mean increase of 26.5%. Increases in diameter were observed in proximal, intermediate and distal arteries. The timing of treatments ranged from day 3 to day 19 post-SAH, and there was no relationship between timing and arterial responsiveness ($r = -0.06$). There was a moderately good correlation between the degree of vasospasm in an artery and its responsiveness to papaverine. The effect of papaverine did not persist until the following day in patients who had repeat angiography performed. Kassel et al.[115] treated a series of 12 patients with intra-arterial papaverine. Arterial narrowing in the posterior circulation and middle cerebral artery distribution appeared to be more responsive to papaverine infusion than was spasm in the anterior cerebral arteries. The infusion of 300 mg of papaverine over 1 hour seemed to be an adequate and safe dose to effect these angiographic and clinical improvements.

Mathis et al.[160] describe three patients who experienced transient neurologic events associated with intra-arterial papaverine infusion in the vertebrobasilar system. Two of these involved respiratory depression and underscore the need for careful monitoring and, when required, cardiopulmonary support. Alternatively, the super-selective intra-arterial infusion of papaverine (2 mg over 10 s) has been shown to be effective in dilating spastic distal vessels not accessible to angioplasty techniques. Tsukahara et al.[270] described the successful treatment of cerebral vasospasm after SAH by intra-arterial infusion of papaverine hydrochloride and discuss the experimental background of this treatment. Livingstone et al.[148] reported that basilar artery vasospasm refractory to medical therapy in a 47-year-old man was successfully treated by the passage of a non-detachable balloon system and angioplasty after intra-arterial papaverine infusion.

The potential adverse effects of papaverine which have been reported include transient neurologic dysfunction, seizure, mydriasis, monocular blindness, drug precipitation, increased intracranial pressure and even aggravation of spasm.[160] Of these, by far the most common is elevation of the intracranial pressure.[161] Fortunately, this can usually be controlled (< 20 mm H_2O) with a mannitol infusion (25–50 gm); however, on occasion, the infusion must be either slowed or even stopped. Other complications which can occur with this form of

treatment include dissection and thromboembolism. The rate of serious complications is in the range of 5% or less. Rath et al.[219] found instillation of papaverine at the surgical site caused significant haemodynamic changes possibly because of stimulation of the hypothalamus in the third ventricle or vagal nuclei in the fourth ventricle, or even both. They recommend cautious use of intracisternal papaverine in such a scenario, especially when third ventriculostomy has been performed as an adjunct surgical procedure.

Statins

Lynch et al.[150] demonstrated that simvastatin reduces serum markers of brain injury and attenuates vasospasm after SAH. The use of simvastatin as prophylaxis against DCI after aneurysmal SAH is a safe and well-tolerated intervention. Its use attenuates serum markers associated with brain injury and decreases the incidence of radiographic vasospasm and DID. Currently pravastatin 40 mg daily orally or via NG tube for 21 days should be initiated within 4 days of haemorrhage as it has been shown to improve outcome in vasospasm.

However, McGirt et al.[165] found that the uniform introduction of simvastatin did not reduce the incidence of symptomatic cerebral vasospasm, death or poor outcome in patients with an SAH. Simvastatin was well tolerated, but its benefit may be less has been previously reported. Kramer et al.[134] reported that the addition of statins to standard care was not associated with any reduction in the development of vasospasm or improvement in outcomes after aneurysmal SAH. If there is a benefit to statin use, it may be smaller than suggested by previous studies. Further randomised controlled trials are awaited.

Miscellaneous

Fasudil is a calmodulin inhibitor and inhibits multiple kinases with maximal effect on Rho kinase, which results in inhibition of myosin light chain kinase and thus, causes smooth muscle relaxation through a Ca-independant pathway. It is given IV 30 mg thrice daily. Intra-arterial fasudil has been used. Colforsin daropate, a water-soluble forskolin derivative, is an adenyl cyclase activator with positive inotropic and vasodilatory effects. Intra-arterial injection of colforsin daropate hydrochloride (HCl) is capable of directly stimulating adenylate cyclase, which in turn causes vasorelaxation via elevated intracellular concentrations of cyclic adenosine monophosphate. Milrinone, a phosphodiesterase inhibitor, given intra-arterially, has vasodilating and inotropic properties similar to that of papaverine. Milrinone was effective and safe for the treatment of cerebral vasospasm after SAH and intra-arterial infusion with adjunctive intravenous infusion holds promise as a clinically advantageous treatment regimen. Erythropoietin has been cited to be neuroprotective by its anti-apoptotic action and systemic administration of r-Hu-EPO can significantly attenuate SAH-induced cerebral vasospasm and ischaemia. Prostaglandin E_1 (PGE1), known pharmaceutically as alprostadil—may be of value in the treatment of vasospasm.[79] Delgado-Zygamunt et al.[42] found intracisternal administration of the substance P (SP) antagonist spantide two hours and three days post-SAH significantly reduces the degree of late spasm and also decreases the degree of CBF reduction. The findings suggest that SP is involved in the development of both angiographic spasm and CBF changes post-SAH. Synthetic serine protease inhibitor FUT-175 (nafamostat mesylate) inhibits both complement pathways and the other plasma protease cascades (coagulation, fibrinolysis and the kinin system).

TIMING OF SURGERY IN RELATION TO VASOSPASM

Lawson et al.[143] found that coiling of ruptured aneurysms can be performed safely on patients who arrive on post-haemorrhage days 4–10 and treatment need not be delayed after day 10 as the results of the timing of aneurysm surgery studies initially suggested. De Ganz et al.[39] conducted a systematic review to compare early aneurysm surgery (days 0–3), intermediate surgery (days 4–7) and late surgery (> 7 days after SAH). Their meta-analysis suggested that both early and intermediate surgical treatments improve outcome after aneurysmal SAH, in particular for patients in good clinical condition at admission. Kassell and Torner[117] in a series of 2,265 patients admitted within 3 days of their first SAH found that the peak of re-bleeding occurred on the same day as the initial haemorrhage and there was no later peak. These data suggested that new management strategies for minimising re-bleeding must be considered for patients admitted soon after aneurysm rupture. Laidlaw and Siu[139] sought to determine whether the re-bleeding rate in poor-grade patients justified a period of supportive observation before selective treatment and whether unselected ultra early surgery would lead to acceptable results and the outcome results of ultra early surgery indicated that a non-selective policy did not lead to a large number of dependent survivors, even among elderly poor grade patients. The high ultra early re-bleeding rate indicated a need to urgently secure the ruptured aneurysm by performing surgery or coiling, and this indication is more pronounced for poor-grade patients than for good-grade patients. In earlier years Sundt et al.[254] and others recommended the delay of surgery till meningismus is gone. The international co-operative study on timing of aneurysm surgery had shown that patients who underwent surgery post-haemorrhage days 4–10 had worse outcomes than patients treated on days 0–3 and days 11–14 and many felt that patients who present on day 4–10 should have surgery delayed till day 10. But currently many surgeons feel that if the angiographically detected vasospasm has not produced any adverse effect on the clinical condition, its influence on the surgical outcome is not significant. Lawson

et al.[143] on analysing the effect of coiling on the clinical outcome found that coiling can be performed safely on patients who arrive on days 4–10 and endovascular treatment need not be delayed until after day 10. Sano and Saito[228] surveyed 443 cases of intracranial aneurysms operated upon within the first 3 days after SAH (the day of SAH being counted as the first day) and reported good results, minimal post-operative vasospasm and no mortality due to vasospasm. Cases operated upon 1 week after the SAH also showed good results, whereas fatal post-operative vasospasm was seen in cases operated upon on the 4–7th day after SAH. Cisternal, ventricular and epidural drainage are recommended after the clipping of aneurysms in the acute stage of SAH. Early surgery permits the mechanical removal of fresh blood clot by suction and irrigation.[246,247] Once the offending aneurysm has been secured by a clip, it is possible to place tissue plasminogen activator within the subarachnoid space, either at the time of surgery or subsequently through catheters, to facilitate early fibrinolysis of the clot, thus reducing the amount of decaying blood pressing against the arteries. This appears to be an effective way of preventing vasospasm. Gruber et al.[79] found the infarction rate was higher with endovascular treatment as opposed to surgery (37.7% vs 21.6%), as a result of a skewed Fisher Grade 4 infarction pattern in the endovascular treatment group versus the surgery treatment group (66.7% vs 24.5%). They suspected that unremoved subarachnoid/intracerebral clots contributed to the higher infarction rate with endovascular treatment. When patients with Fisher Grade 4 and Hunt and Hess Grade V were excluded from analysis, the difference in infarct incidence between the treatment groups no longer reached statistical significance. These fibrinolytic agents have a potential to cause bleeding by dissolving normal clot, so only patients at high risk of developing vasospasm should be chosen for this type of prophylaxis. Cisternal fibrinolysis using 10 mg rtPA intra-operatively and immediately following clipping using catheters was helpful in patients with thick clots. Cooke et al.[35] found that coiled patients had a greater degree of distal vasospasm than clipped patients and suggested that surgical clipping may reduce distal vasospasm as a result of direct evacuation of haemorrhage or indirectly via fenestration of the lamina terminalis, and the decompressive effect of craniotomy helps in reducing intracranial pressure and in turn reduces distal vasospasm. Varma et al.[265] have suggested that patients with aneurysmal SAH, in clinical grades I to III, should be operated upon as soon as possible irrespective of the time since ictus. Delay in definitive surgical treatment after admission to a neurosurgical unit can lead to death from re-bleeding in an additional 8.4% of patients who are in a stable neurological state. This additional mortality can be reduced if facilities for emergency cerebral angiogram, optimal theatre facilities and neuroanaesthesia backup are available, coupled with the surgeon's willingness, expertise and capability to give equally good results while operating on an aneurysm at odd hours.[277]

SURGERY

The debate on the ideal method of tackling the problems of aneurysmal bleed are unlikely to be resolved and probably clipping, coiling and angioplasty will all have indications and advantages in specific situations.[13,17,91,97,162-164,169,172,178,207,208] Fujii et al.[71] and Le Roux et al.[144] advocated immediate surgery followed by aggressive haemodynamic therapy and angioplasty in patients with an aneurysm and refractory vasospasm. Batjer and Samson[15] suggested that non-comatose patients with focal middle cerebral ischaemic deficits and secured aneurysms in whom medical management has failed or in whom these measures are contraindicated may benefit from extracranial-intracranial bypass. Patients with unsecured aneurysms remote from an ischaemic middle cerebral territory should probably be revascularised if cautious hypertension fails to improve their condition. Benzel and Kesterson[18] emphasised that extracranial-intracranial bypass surgery offers another alternative to the treatment of patients with vasospasm who have failed aggressive medical management.

Interventional Neurosurgery

Endovascular intervention is contemplated when symptomatic cerebral vasospasm is non-responsive to maximal medical management. Brisman et al.[20] reviewed the historical development and current status of endovascular techniques used in the treatment of symptomatic vasospasm following aneurysmal SAH. Neurointerventional treatment of vasospasm following aneurysmal haemorrhage has been proven to be a safe and successful technique for those patients suffering symptomatic vasospasm refractory to medical management. The techniques continue to undergo refinement as endovascular technology advances. Balloon angioplasty is better than intra-arterial antispasmodics due to the increased durability and long-lasting effects of the former and lower risk profile.[263] Schuknecht[233] summarised the indications, applications and limitations for microcatheter guided selective papaverine infusion and transluminal balloon angioplasty in patients who sustained cerebral vasospasm following SAH. They emphasised that structured neurointensive and endovascular treatment of imminent vasospasm integrating papaverine administration and balloon angioplasty are complimentary rather than alternative techniques. Percutaneous transluminal balloon angioplasty[21,22,32,56,57-59,72,92,143,218] is done with special balloon tipped catheters to dilate the proximal major cerebral arteries and must be done early when the other therapies fail to combat vasospasm. Due care must be taken to rule out cerebral infraction as a white infarct can be converted into a red one due to hyperperfusion. The PTA for high-grade symptomatic vasospasm after SAH is considered an effective treatment method for the patient who does not respond to medical therapy.[72] Immediate improvement of angiographic and clinical findings were frequently observed after PTA. Neurologic

improvement, defined as improvement in the Hunt and Hess neurologic grading scale has been shown in 60–80% of the patients so treated by Higashida et al.[86] Firlick et al.[63] studied the effects of transluminal angioplasty on CBF in the management of intractable vasospasm following aneurysmal (SAH) and reported that in the majority of patients with refractory vasospasm following SAH, angioplasty effectively dilated spastic arteries, reversed delayed neurological deficits and significantly improved CBF in areas of brain at risk of infarction. Transluminal balloon angioplasty[253] is effective in dilating larger proximal vessels, but its access for dilation of smaller distal vessels is limited and here intra-arterial vasodilating agents, including papaverine, nimodipine, nicardipine, verapamil, milrinone, fasudil and colforsin are used.

Angioplasty is performed via a femoral artery approach; usually with a 6 or 7 French sheath using wire silicone balloon microcatheter systems. Systemic heparinisation is used to minimise the risk of thromboembolic events. Brothers and Holgate[22] have described two modifications of the basic technique that have allowed increased selectivity and successful angioplasty of multiple branches, both proximal and distal, involved by vasospasm. The blind-ended, single-lumen balloon-dilatation catheter most widely used to date lacks steerability, limiting its application to unbranched stems and single branches at bifurcation or trifurcation points. Reported complications resulting from balloon angioplasty for cerebral vasospasm following SAH include perforation, aneurysm re-rupture, branch occlusion and haemorrhagic infarct. With most patients not able to co-operate, the procedure is best performed under general anaesthesia. Lakhani et al.[140,220,224,230,239] have emphasised the importance of airway safety. Le Roux et al.[144] in a subgroup of patients presenting with proven symptomatic vasospasm and an unclipped but ruptured aneurysm used urgent surgical obliteration of the aneurysm followed by immediate post-operative angioplasty and found it to be a safe and reasonable means to improve outcome. Kaku et al.[104] described the successful treatment of cerebral vasospasm after SAH with super selective intra-arterial infusion of papaverine hydrochloride. Percutaneous transluminal angioplasty was performed in two steps. First, a silicone balloon was used for dilation of the ICA and the proximal portions of the middle cerebral artery. A silicone leak balloon or Tracker-18 catheter was then introduced into or just proximal to the site of vasospasm not accessible to the angioplasty balloon catheter for superselective infusion of 0.2% papaverine. It is essential to infuse the papaverine just proximal to the spastic vessels in order to deliver sufficient concentration of drug, and infusion should be carried out as early as possible before the artery loses its ability to return to a normal luminal size. Yalamanchili et al.[296] retrospectively compared a group of 19 patients treated with craniotomy and aneurysmal clipping with a group of 18 patients who were treated via endovascular occlusion with Guglielmi detachable coils in regard to frequency and severity of cerebral vasospasm. In patients with similar Hunt and Hess grades and Fisher grades, preliminary data suggested that the frequency and severity of cerebral vasospasm may be reduced in those treated by endovascular occlusion of their aneurysm as compared with those treated by direct surgical clipping. Bejjani et al.[16] reported angioplasty to be a safe and effective treatment for symptomatic vasospasm that is refractory to hyperdynamic, hypervolaemic therapy. When used early (< 24 hour), it leads to significant clinical improvement. However the long-term outcome is good, even in cases of delayed angioplasty. The prevention of worsening of the cerebral ischaemia and its extension to other territories may be the reason. Elliot et al.[54] reported that balloon angioplasty is superior to papaverine infusion for the permanent treatment of proximal anterior circulation vasospasm following aneurysmal SAH.

Jaested et al.[100] found the frequency of infarction in the distribution of vessels undergoing TBA amounts to 7% and is significantly lower than in vessels not undergoing TBA. Nussbaum et al.[187] established the ability of intra-aortic balloon counterpulsation (IABC) to improve CBF significantly in a canine model of cerebral vasospasm. The IABC improves CBF in patients with vasospasm and is a rational treatment option in select patients with refractory cerebral vasospasm.

Cerebrospinal Fluid Drainage

Cisternal irrigation in meningitis has a role in protection of leptomeningeal and cortical structures as reported by Aydin et al.[10] They postulate that the irrigation procedure may decrease the percentage and severity of meningitic complications by way of the excretion of the inflamed purulent collection from the subarachnoid spaces. Ito et al.[94] performed enhanced cisternal drainage following early aneurysm surgery in patients with Hunt and Kosnik grades I–III, to effect continuous wash-out of subarachnoid blood clots and reduce symptomatic vasospasm.[130] Following extensive evacuation of the cisternal blood clots, Liliequist's membrane was opened extensively and a third ventriculostomy was affected by opening the lamina terminalis. They found that enhanced post-operative cisternal drainage can reduce the incidence of symptomatic vasospasm and be of benefit to the outcome of early aneurysm surgery. Usui et al.[273] in a retrospective review of the results of early surgery and intrathecal thrombolytic therapy in 111 patients with aneurysmal SAH found tPA therapy reduced the incidence of symptomatic vasospasm. This appears to be the result of the more rapid clearance of cisternal clot in the thrombolytic groups than the no-treatment group. This study indicates that post-operative intrathecal thrombolytic therapies, especially with less than 4 mg/dL of tPA, are effective in lysing subarachnoid clot and preventing vasospasm and infarction safely. Ohman et al.[189] reviewed patients receiving 3 mg,

10 mg or 13 mg of rtPA in a single intracisternal injection at the end of the operation. In all treatment groups a reduction was observed in the amount of blood seen on the post-operative CT scans compared to the pre-operative CT scans. Findlay et al.[60] administered rtPA directly into the basal subarachnoid cisterns after minimal surgical clot removal and aneurysm clipping. All patients except one demonstrated partial to complete cisternal clot clearance on CT scans within 24 hours after surgery. Intrathecal fibrinolytic treatment appears effective in clearing subarachnoid clot and reducing vasospasm, and may be associated with acceptable risks if given to patients with large-volume SAHs at high risk for severe vasospasm.

Inagawa et al.[90] studied the effect of continuous cisternal drainage on cerebral vasospasm using strict criteria in 140 patients with ruptured intracranial aneurysms. Angiographic vasospasm was less severe, the incidence of permanent symptomatic vasospasm and low-density area on computed tomography were lower, the mortality rate was lower and the rate of good recovery was higher.[137]

Cisternal irrigation therapy with urokinase is safe and effective for the prevention of symptomatic vasospasm after aneurysmal SAH. The efficacy and safety of cisternal irrigation therapy with urokinase to prevent symptomatic vasospasm was evaluated, and the optimal concentration of the drug was estimated by Sasaki et al.[229] After the aneurysm was clipped, irrigation tubes were placed in the Sylvian fissure (inlet) unilaterally and in the prepontine or chiasmatic cistern (outlet). Lactated Ringer's solution with UK (30, 60 or 120 IU/mL) was infused at a rate of 30 ml/hr. Analysis of the drainage fluid suggested that UK 120 IU/mL was effective. No abnormal changes were observed in the coagulative and fibrinolytic systems after UK irrigation.

OUTCOME

Outcome of patients with SAH and vasospasm continues to be poor, and cerebral vasospasm is still the most common cause of morbidity and mortality after aneurysmal SAH.[41] Vasospasm was the cause of 28% of all deaths and 39% of disability in the international co-operative study on the timing of aneurysm surgery. The patients with vasospasm had longer ICU stays and were more likely to be in poor grade. If the angiographically detected vasospasm did not produce any adverse effect on the clinical condition, its influence on surgical outcome was not significant. Kassel et al.[117] further elaborated that vasospasm and re-bleeding were the leading causes of morbidity and mortality in addition to the initial bleed. Predictors for mortality included the patient's decreased level of consciousness and increased age, thickness of the subarachnoid clot on computerised tomography, elevated blood pressure, pre-existing medical illnesses and basilar aneurysms. Hacket and Anderson[82] on evaluating 432 first-ever cases of SAH (76% due to confirmed cerebral aneurysm rupture) found only (56%) to be alive approximately 1 year later (mean time 1.2 years) and a high proportion of these long-term survivors of SAH experience ongoing deficits in high level (neuropsychological) functioning leading to impaired social roles. Juvela et al.[103] found that hyperglycaemia at admission seems to impair outcome, and excess weight and hypertension appear to elevate the risk of cerebral infarction after SAH and this was independent of the severity of bleeding. Rabenstein et al.[214] reported that patients with better clinical grades (WFNS Grades I–III) at hospital admission were less likely to suffer symptomatic vasospasm when treated by endovascular coil occlusion, compared with craniotomy and clip application. Nevertheless, they found no significant difference in overall outcome at the longest follow-up examination between the two treatment groups. Hoh et al.[87] found that there was no significant difference in total vasospasm or symptomatic vasospasm when patients who underwent clipping or craniotomy were compared with patients who underwent coiling. In patients with Hunt and Hess Grades I–III ("good grade"), clipping and craniotomy were associated with better outcome and less in-hospital mortality, but there was no difference in total vasospasm or symptomatic vasospasm versus coiling. In patients with Hunt and Hess Grade IV or V ("poor grade"), there was no difference in any outcome measure among the treatment groups. Niskanen et al.[186] stated that the modality of treatment of patients with SAH does not seem to affect resource use. Endovascular and surgical treatment are likely to require a similar amount of ICU resources in the year after initial treatment. Rabenstein et al.[214] found no significant difference in overall outcome at the longest follow-up examination between the two treatment groups, but patients with better clinical grades (WFNS Grades I–III) at hospital admission were less likely to suffer symptomatic vasospasm when treated by endovascular coil occlusion, compared with craniotomy and clip application. Dehdashti et al.[40] studied whether the incidence of symptomatic vasospasm and the overall clinical outcome differ between patients treated with surgical clipping compared with endovascular obliteration of aneurysms and found that symptomatic vasospasm and ischaemic infarction rate seemed comparable in both groups, even for patients with better clinical and radiological admission grades. There was no significant difference in the overall clinical outcome at long-term follow-up between both groups. Wermer et al.[285] found that only one-third of patients regain functional independence after aneurysmal SAH and despite this recovery, many of these patients experience psychosocial problems. The long-term psychosocial effects of SAH are considerable, even in patients who regain functional independence. Sengupta[237] found that there were personality changes associated with loss of interest, initiative and energy. Analysis of the different factors involved suggests that the outcome of surgery depends

mainly on pre-operative clinical condition which, in turn, reflects the severity of the haemorrhage. Lanzino et al.[141] reported no age-related differences in the overall incidence of angiographic vasospasm; however, symptomatic vasospasm was more frequently reported in the older age groups and there was a significant increased risk of poor outcome after the age of 60 years.

Lagares et al.[138] found that only the age, the level of consciousness defined by the WFNS scale and the presence of global brain hypodensity on the initial CT scan had a significant prognostic influence in the logistic regression model. Global brain hypodensity was strongly related to mortality. Salary et al.[227] reported no relation between aneurysm size and volume of subarachnoid blood. The volume of cisternal blood correlates with the Hunt and Hess grade but is not an independent determinant of outcome. Outcome is related to the following triad of well-established clinical factors: Hunt and Hess grade, age and clinical vasospasm.

Preventive Neurosurgery—The Future

Despite investigational, pharmacological, neurointerventional and surgical advances, the morbidity and mortality due to vasospasm is a huge unsolved problem. Vasospasm does not occur in all patients with SAH and obviously the aetiopathogenesis is multifactorial and incompletely understood.[120-124,126] Prevention of SAH would be the ideal step reducing its incidence, but mass screening of the population is impossible. Perhaps the high-risk patients could be imaged for prevention. The factors, like hyperglycaemia, hypertension, obesity and pre-existing medical illness, increase the risk of developing vasospasm[103,111] and these create possibilities on how the problem of vasospasm can be dealt with using principles of preventive neurosurgery. The close causal relationship between cigarette smoking and aneurysms, SAH and vasospasm[141] has been proved conclusively and lifestyle changes and health education can help to reduce the incidence of this devastating condition. Nakai et al.[180] reported that pretreatment with continuous wave ultraviolet (UV) light irradiation can lead to significantly reduced degree of vasospasm and this prophylactic effect of UV light on vasospasm was suggestive of involvement of apoptosis in the mechanism of this effect. Onoune et al.[191] studied the effect of recombinant eNOS gene expression on reactivity of canine basilar arteries to endothelin-1 (ET-1). Their results suggest that genetically modified adventitia can produce NO and cause relaxation in response to ET-1 via activation of ET_A receptors. This supports a novel concept that successful transfer and expression of recombinant eNOS gene can lead to a qualitative change in responsiveness to vasoconstrictor substances.

CONCLUSION

Mocco et al.[175] in an effort to help to clarify the current state of medical therapy for cerebral vasospasm reviewed the relevant literature on the established medical therapies used for cerebral vasospasm following aneurysmal SAH, and they discuss burgeoning areas of investigation. Despite advances in the treatment of aneurysmal SAH, cerebral vasospasm remains a common complication and has been correlated with a 1.5- to 3-fold increase in death during the first 2 weeks after haemorrhage. Weyer et al.[288] performed a systematic review of the literature on the treatment of cerebral vasospasm and made the following conclusions: nimodipine is indicated after SAH and tirilazad is not effective. More study of haemodynamic manoeuvres, the effectiveness of other calcium channel antagonists, such as nicardipine delivered by other routes (for example, intrathecally), magnesium, statin drugs, endothelin antagonists and intrathecal fibrinolytic therapy, is warranted. There is less enthusiasm for the study of steroid drugs and anticoagulant/antiplatelet agents because they entail more risks and investigations so far have shown little evidence of efficacy. The study of rescue therapy, such as balloon angioplasty and intra-arterial vasodilating agents, will be difficult. The quality of clinical trials should be improved.

78 Cerebral Protection

Ravikant Palur, Ganesh K Murthy

INTRODUCTION

The goal of every neurosurgical procedure is to achieve a preset objective whilst minimising the complications. This, however, is not the sole responsibility of the neurosurgeon. Modern neurosurgery requires a multi-disciplinary approach for a safe and successful outcome. This is where the concept of cerebral protection comes in. Cerebral protection can be described as any manoeuvre used to prevent the occurrence of a neurological deficit, or any other complication following a neurological insult. This is the responsibility of the neurosurgeon as well as the rest of the "team". The "Team" includes the neuroanaesthetist as well as the intra-operative monitoring team. This responsibility extends to the team managing the ICU since neuroprotection is equally, if not more necessary, during the post-operative or post-insult period. Protection implies improved outcome as evidenced by electrophysiologic, metabolic or histologic indices of recovery and ultimately by improved clinical neurological recovery.

In order to understand the various nuances of cerebral protection, it is essential to understand the pathophysiological processes involved in neuronal damage. This chapter has been divided for the sake of simplicity into two parts; the first half deals with the pathophysiology of cell damage, the latter half details the various modalities of cerebral protection being practiced worldwide.

PATHOPHYSIOLOGY OF INJURY TO THE CENTRAL NERVOUS SYSTEM

Neuronal cell damage in a neurosurgical setting occurs commonly intra-operatively with a varying degree of insult based on many factors. However, the pathophysiological processes in intra-operative injury are similar to those involved in other forms of injury to the central nervous system (CNS) such as stroke and trauma. Major advances in neurobiological research have outlined a cascade of cellular events that occur in injured tissue. This cascade of events involves neuronal depolarisation, excessive activation of excitatory amino acid receptors, energy depletion with ionic refluxes, and activation of catabolic enzymes and subsequent lipid peroxidation and free radical formation. These processes perpetuate the initial insult. At the same time, brain ischaemia causes the proliferation of neural stem cells/neural progenitor cells (NSCs/NPCs) in both the subventricular zone (SVZ) and the subgranular zone (SGZ) of the brain. A NSC/NPC-conditioned medium showed neuroprotective effects *in vitro*. NSC/NPC-released brain-derived neurotrophic factor (BDNF) and vascular endothelial growth factor (VEGF) are required for NSC/NPC-conditioned medium-induced neuroprotection. These data suggest that NSC/NPC-generated trophic factors are neuroprotective and that brain ischaemia-triggered NSC/NPC proliferation is crucial for brain protection.[49] Nerve growth factor (NGF) was recently characterised as an angiogenic factor inducing proliferation, migration and capillary sprouting in endothelial cells (ECs) of different vascular beds.[48] These processes lead to oedema, which compromises local perfusion and triggers further activation of the injury cascade. It is necessary to understand these events well, as they have a bearing on the multiple pharmacological strategies aimed at preventing or attenuating CNS injury.[2]

The main events leading to neuronal cell damage can be studied lucidly under the following headings.

Intracellular Calcium Accumulation

There is considerable evidence that excessive intracellular calcium is a fundamental mediator of cell death. Numerous studies have demonstrated intracellular calcium accumulation prior to ischaemic neuronal death.[76,83,85] Removal of extracellular calcium prevents hypoxic neuronal death in cell culture models.[16,36] Increases in intracellular neuronal calcium concentrations can occur from many sources including multiple membrane channels as well as intracellular storage sites. Some of these sources are unique to neurons explaining the extreme sensitivity of neurons to ischaemic and traumatic injury. The role of intracellular calcium in neuronal injury can be understood better in Figure 1.

Excessive Activation of Excitatory Amino Acid Receptors

Glutamate and aspartate are the major excitatory neurotransmitters in the brain; ironically they are also potent neurotoxins. Excitatory amino acids are present throughout the grey matter of the CNS. These amino acids are packaged inside synaptic terminals and are

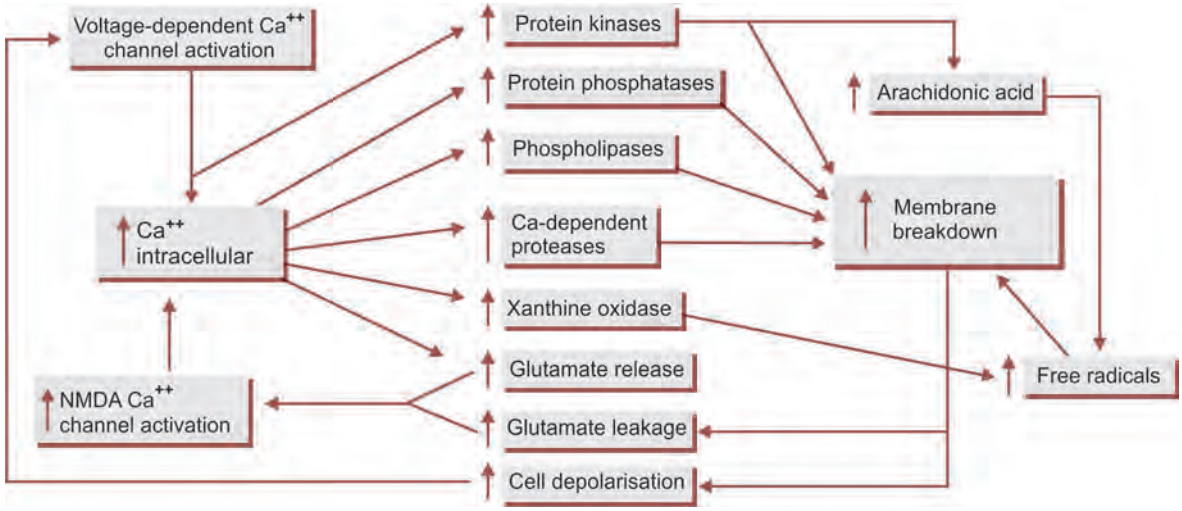

Fig. 1: Role of intracellular calcium in neuronal injury

released into the extracellular environment for synaptic transmission. Following their release into the synaptic cleft, they activate post-synaptic receptors to facilitate excitatory neurotransmission. They are then rapidly cleared from the extracellular space by energy dependent cellular uptake mechanisms.

These uptake mechanisms fail when there is hypoxia-ischaemia, leading to toxic accumulation of excitatory amino acids in the extracellular space. This accumulation has been proven to destroy neurons in cell culture (Fig. 2), and the injury thus caused appears to be mediated by excessive activation of excitatory amino acid receptors that are linked to ion channels with a high permeability to calcium. Three major families of receptor subtypes have been identified:

1. N-methyl-D-aspartate (NMDA)
2. AMPA/Kainate (also referred to as "non-NMDA")
3. Metabotropic receptors

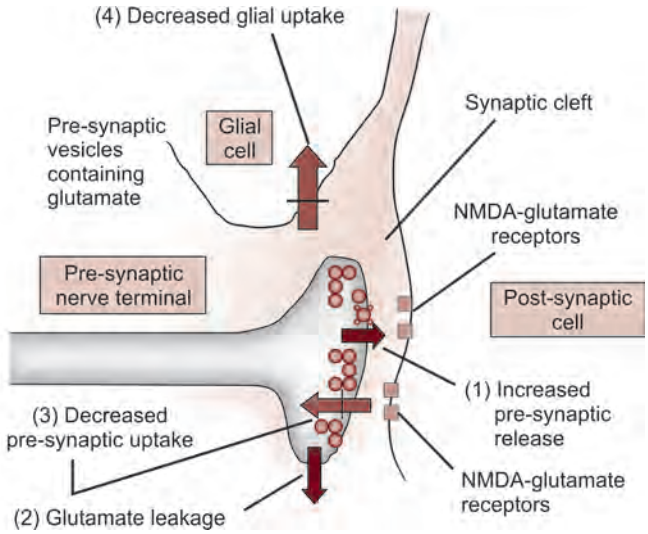

Fig. 2: Four mechanisms of increased extracellular glutamate during trauma: (1) Increased pre-synaptic vesicular release (2) Increased leakage of neurotransmitter (3) Decreased pre-synaptic neurotransmitter uptake (4) Decreased glial uptake
NMDA = N-methyl-D-aspartate

Numerous experimental studies have shown that NMDA antagonists can significantly reduce brain injury from focal ischaemia or trauma. These antagonists are also sufficient to inhibit early swelling and delayed cell death. This suggests that the NMDA-associated ion channels are of critical importance for both sodium and calcium influx into the hypoxic neuron.[16,25,41]

Voltage-Gated Calcium Channels

Voltage-Gated Calcium Channels (VGCCs) are an additional avenue for calcium to enter neurons. These channels are involved in the release of glutamate into the synaptic cleft. Hence, inhibition of these VGCCs may provide neuroprotection indirectly by decreasing excitatory aminoacid-mediated neurotoxicity.

Other Sources of Intracellular Calcium

There are numerous additional sources of intracellular calcium such as:

a. Energy depletion results in reverse operation of the sodium/calcium exchanger, leading to further increases in intracellular calcium.
b. Release of calcium from intracellular storage sites during acute injury.
c. Non-specific leakage of toxic excitatory aminoacids into the extracellular space leading to activation of receptors on neighbouring neurons and culminating in propagation of the brain injury.

Lipid Peroxidation

Excessive levels of intracellular calcium mentioned above trigger an array of neurochemical changes that eventually lead to neuronal injury. Modulators, such as calpain and protein C and intracellular proteases, are activated leading to damage of the cellular proteins. Moreover, phospholipases trigger lipid peroxidation and the generation of free radicals. Lipid peroxidation is one of the most damaging consequences of elevated intracellular calcium. This progressive process can rapidly

propagate through cell membranes leading to membrane destruction. Free radicals formed during the process of membrane destruction also attack nearby glial cells and vasculature, which causes additional injury. Brain tissue has very limited defences against these free radicals because cerebral neurons have low levels of endogenous antioxidants. This "neuronal injury" cascade following trauma, ischaemia or due to hypoxia involving the CNS, ultimately leads to cell death.

Role of Oxygen-Free Radicals

Oxygen is both a life-sustaining and a life-threatening inhalant. A free radical is defined as an atom of a molecule in a particular state with an unpaired electron in its outer orbit.[37] It is now well recognised that oxygen-free radicals are formed during the metabolism of all aerobic cells. There are several pathways in aerobic cells that lead to the production of oxygen-free radicals. The discovery of superoxide dismutase (SOD) by McCord and Fridovich[56] showed the way to research on oxygen-free radicals. Evidence supporting the deleterious effects of oxygen-free radicals in many pathological processes has grown considerably.[10,11,14,31,32,40,80,89]

The current major candidates for a source of oxygen-free radicals are,[37,54] (Fig. 3):

- Accumulation of reduced metabolites
- Xanthine oxidase
- Mitochondria
- Activated neutrophils
- Arachidonic acid metabolism
- Catecholamine oxidation

The fact that oxygen-free radicals are one of the factors responsible for cell damage is well documented in:

- Traumatic brain injury[22,29,43]
- Cerebral ischaemia-reperfusion injury
- Subarachnoid haemorrhage and vasospasm
- Peritumoral brain oedema

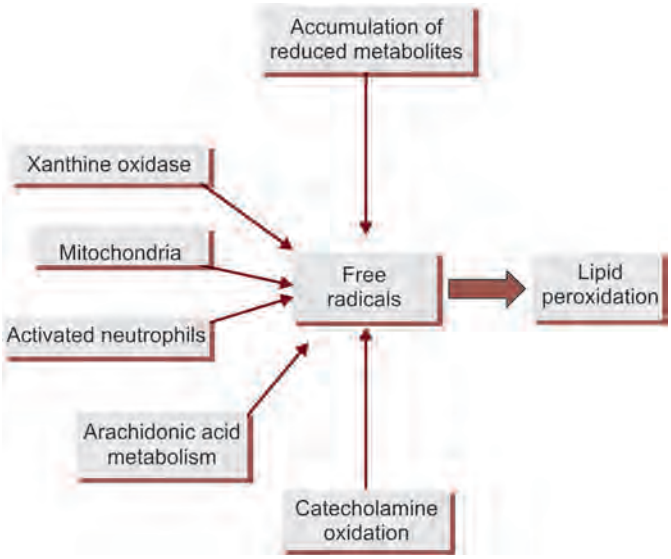

Fig. 3: Sources of free-radical release and lipid peroxidation

PROTECTIVE MECHANISM AGAINST OXYGEN-FREE RADICALS

A variety of enzymatic mechanisms have evolved which provide protection against oxygen-free radicals. SOD scavanges the superoxide, which is formed during the process of reduction of oxygen by aerobic cells. Two other enzyme systems also help in the scavenging of hydrogen peroxide; these are catalase and glutathione peroxidase.[77] Another endogenous defence exists in hydrophilic and hydrophobic regions. In hydrophilic regions, ascorbic acid, cysteine, ceruloplasmin and transferrin are the antioxidant compounds. In hydrophobic regions, several fatty acids and vitamin E are the antioxidant compounds. More details regarding protective mechanisms in a clinical setting have been discussed in the later parts of this chapter.

MODALITIES OF CEREBRAL PROTECTION

The various modalities of cerebral protection available for therapeutic use are shown in Table 1.

PHARMACOLOGICAL THERAPIES

Barbiturates

Barbiturates produce a dose related decrease in neuronal function that is accompanied by a dose related decrease in cerebral metabolism.[63] Barbiturates interfere with synaptic transmission and multineuronal networks, can exert a local anaesthetic effect on membranes, and can enhance presynaptic inhibition by facilitating

Table 1: Modalities of cerebral protection

A.	Pharmacological therapies:
1.	Barbiturates
2.	Isoflurane
3.	Etomidate
4.	Local anaesthetics
5.	Calcium entry blockers[5]
a.	Flunarizine
b.	Lidoflazine
c.	Nimodipine
6.	Diuretics
a.	Mannitol
b.	Furosemide
7.	Corticosteroids
8.	Diphenyl hydantoin
9.	Perfluorochemical blood substitutes
10.	Antioxidants/free radical scavengers
B.	Non-pharmacological therapies:
1.	Hyperventilation
2.	Hypervolaemia
3.	Haemodilution
4.	Induced hypothermia
5.	Induced hypertension
6.	Induced hypotension

the binding of gamma-aminobutyric acid. The parallel decrease in cerebral oxygen consumption accompanying the decrease in neuronal function reaches a plateau when neuronal function is abolished as evidenced by isoelectricity on the EEG.

The proposed mechanism of action of barbiturates can be outlined as follows:

- Decrease in cerebral metabolic requirements
- Improvement in distribution of CBF
- Suppression of seizures
- Suppression of catecholamine induced hyperactivity
- Anaesthesia, deafferentation, immobilisation
- Loss of thermoregulation
- Decrease in ICP
- Decrease in cerebral oedema
- Decrease in CSF secretion
- Scavenging free radicals
- Stabilisation of membranes
- Blocking calcium channels
- Alteration in fatty acid metabolism

Barbiturates help in protecting against temporary focal ischaemia. Prophylactic barbiturate treatment has been recommended for brain protection during periods of focal ischaemia when temporary clamping of a major cerebral vessel is necessary as during carotid endarterectomy,[27,33,58,92] aneurysm clipping[12,21,34] or extracranial to intracranial bypass procedures.[47,52,91] Relatively small, single doses of barbiturates have been recommended due to concern about cardiovascular compromise. Drug induced coma produced by larger doses of barbiturates may delay examination of neurological functions postoperatively.

Normal anaesthetising doses of thiopental (3–5 mg/kg) will produce burst suppression on the EEG lasting less than 5–10 min. Larger doses of thiopental (10–25 mg/kg) produce burst suppression on the EEG lasting about 10 min. Ideally, the occluded vessel should briefly be opened every 5–10 min to allow subsequent small doses of thiopental (1–2 mg/kg) to reach the ischaemic area. If this cannot be done, a continuous infusion of thiopental (3–5 mg/kg/hr) should be administered to maintain burst suppression throughout the period of ischaemia. Ideally, the EEG should be monitored to determine the correct dosage of thiopental required to produce burst suppression in each patient. Blood pressure should be maintained within normal limits. If there is need for profound hypotension during aneurysm clipping, a larger dose of thiopental (6–8 mg/kg) decreases both arterial blood pressure and cerebral metabolism.[62]

Barbiturates have two major undesirable effects. First they may decrease Mean Arterial Blood Pressure (MABP), especially in patients who are hypertensive or hypovolaemic for any reason. They are known to decrease cardiac output with either no change or an increase in heart rate. At high doses, they decrease cardiac contractility, which may lead to a need for vasopressors. A second undesirable side effect of high dose barbiturate is delayed awakening and prolonged time to extubation.

The one clear contraindication to the use of barbiturates is the patient with either acute intermittent porphyria or variegate porphyria. In these patients, the increase in porphyrin synthesis that can be provoked by barbiturates can precipitate an acute attack with widespread demyelination leading to pain, weakness and possible paralysis.

Isoflurane

While barbiturates remain the prototype for cerebral protection during focal ischaemia, it is presumed that any anaesthetic drug that decreases neuronal function with an accompanying decrease in cerebral metabolism might provide cerebral protection during focal or incomplete global ischaemia to the extent that it provides metabolic suppression without disrupting systemic haemodynamics.

Isoflurane is unique among the volatile anaesthetics in that two MAC isoflurane (2.4%) can induce a level of anaesthesia in man that is characterised by an isoelectrical EEG and haemodynamic stability.

Isoflurane increases the tolerance of the brain to low blood flows. It has the ability to lower cerebral metabolism significantly more than the other volatile anaesthetics (halothane, enflurane, innovar) at the clinical concentrations (0.5–1 MAC) used, thereby maintaining the oxygen supply-demand ratio.[57,60] In addition, isoflurane provides protection by suppression of seizures, reduction of catecholamine induced hypermetabolism and immobilisation, deafferentation and anaesthesia. It has not been demonstrated whether isoflurane can favourably redistribute rCBF.

Etomidate

Etomidate is another anaesthetic capable of producing a dose dependent decrease in neuronal function with a parallel decrease in cerebral metabolism.[64] In addition, it is a direct cerebral vasoconstrictor with the ability to significantly decrease CBF. Other mechanisms that may contribute to protection against ischaemia include redistribution of CBF,[97] reduction in intracranial blood volume, decrease in ICP,[64] membrane stabilisation and attenuation of FFA liberation.[81] Etomidate has two advantages over the barbiturates if used as a protective agent. Even large doses of etomidate, sufficient to produce maximal suppression of neuronal function and cerebral metabolism, do not produce cardiovascular depression, hence eliminating the need for isotropic or vasopressor support.[19,20,26] Due to its shorter half-life, etomidate may allow a more rapid awakening time than high doses of thiopental. Etomidate has the disadvantage of suppressing the usual adrenocortical response to stress. Etomidate in a dose of 0.4–0.5 mg/kg achieves burst suppression in 2–3 min.

Calcium Entry Blockers

Calcium entry blockers form a heterogeneous group of drugs; they block the influx of calcium into the cell[95]

and can block the intracellular flux of calcium into the mitochondria.[4,82]

Classification of Calcium Entry Blockers

A. Myocardial, electrophysiologic and vascular effects:
   - Verapamil
   - Tiapanil
   - Diltiazem

B. Predominantly vascular effects (Dehydropyridine derivatives):
   - Nifedipine
   - Nimodipine
   - Nisoldipine
   - Nitrendipine

C. Only vascular effects:
   - Cinnarizine
   - Flunarizine

D. Complex effects:
   - Lidoflazine.
   - Perhexilene

Primarily, four Ca^{+2} entry blockers have been studied for a possible role in brain protection. They were chosen for study because they produced vasodilatation in cerebral vessels *in vitro*.

Mechanism of Protection by Calcium Entry Blockers

A. Cerebral blood flow phenomena:
   - Improve ischaemic flow
   - Attenuate post-ischaemic hypoperfusion
   - Prevent vasospasm
   - Improve rheological properties

B. Cellular changes phenomena:
   - Prevent enhanced proteolysis
   - Prevent formation of FFA and free radicals
   - Antioxidation

Nimodipine: The calcium entry blocker most extensively studied for its protective effects against cerebral ischaemia is nimodipine. There are three prospective randomised double blind, placebo-controlled studies on the use of nimodipine in patients with vasospasm after SAH.[6,73,74] All patients treated with nimodipine orally for 21 days after SAH had a significantly lower incidence of delayed ischaemic deficits or death and had significantly better neurological outcome than those patients given placebo. Although a similar number of patients in each group developed vasospasm as determined by angiography, nimodipine seemed to attenuate the extent and severity of the vasospasm. Nimodipine acts through its effects on neurons by preventing Ca^{+2} entry into the cells, Ca^{+2} sequestration by mitochondria and the alterations in FFA metabolism and the arachidonic acid cascade or by free radical scavenging.

Nimodipine has also been studied for a possible protective effect in animal models of complete cerebral ischaemia. Treatment with nimodipine before or after complete cerebral ischaemia significantly ameliorates post-ischaemic hypoperfusion.[39,65,93,94] It has been demonstrated that this flow enhancement is regionally heterogeneous, but tends to redistribute blood flow such that areas of low flow receive a greater increase in rCBF than areas of high flow.[86]

Flunarizine: Studies of flunarizine have focused on possible prevention of neurological damage after complete global ischaemia. However, inconsistent results are seen in ameliorating post-ischaemic hypoperfusion or improving neurological outcome. In addition, flunarizine precipitates in the lungs producing severe pulmonary oedema. It is not likely to be useful clinically.

Lidoflazine: This has only been investigated for its use in the prevention of neurological damage after complete global ischaemia in animal models of cardiac arrest. Until definite results in the clinical trials emerge, its role in cerebral protection is not clear.

Nicardipine: Experimental studies in animal models of global ischaemia showed no neurological improvement.

Diuretics

Diuretics have been used as adjunctive therapy in brain protection primarily for their role in decreasing cerebral oedema or in decreasing ICP. The two common agents for neuro-protection are mannitol and furosemide.

Mannitol

The use of mannitol in neurosurgery has been studied for over 30 years. In spite of being widely used in neurosurgical operations involving patients with cerebral oedema, the indications and the optimum dose schedule for mannitol remains to be established.[8,15,70] Some of mannitol's beneficial effects include osmotic diuresis, decreased blood viscosity and free radical scavenging.

Mannitol has been shown to increase CBF in experimental and clinical situations. Maximum reduction in blood viscosity occurs during the first 30–60 min after rapid infusion of mannitol; however, this is largely resolved within 4 hours.[70] Decrease of ICP following mannitol administration in an experimental cat model has been shown to be similar to that of decreased viscosity. The maximum white water content reduction in the control hemisphere was at 60 min, whereas no reduction was seen in the lesioned, oedematous hemisphere.

Mannitol also effects serum sodium and potassium acutely. These changes may be of significance intra-operatively for patients with severe cardiac or renal disease, particularly in any procedure in which mannitol is given in high doses. 20% w/v mannitol (0.5–2 g/kg) given over 30 min effects osmotic diuresis. In case of aneurysmal surgery, a total dose of 2 g/kg is given when temporary artery occlusion is planned. Its action begins within 4–5 min and peaks in about 30–45 min. The classic mechanism is believed to be movement of intracellular water into the intravascular volume along the osmotic gradient (the osmolarity of 20% mannitol is 1098 osm/L); some evidence also exists that the rapid action of mannitol can be mediated by decreased production of CSF.

Lastly, despite mannitol's ability to improve CBF in ischaemic regions, it has not been shown to preserve brain or spinal cord electrical activity in ischaemia. Hence, the administration of mannitol should not be considered a substitute for appropriate electrophysiological monitoring.

Furosemide

Furosemide is the diuretic most commonly used intra-operatively in neurosurgery. It is a potent loop diuretic that decreases ICP by venodilatation and by decreasing total intravascular blood volume, and causes the diffusion of oedematous fluid into the vasculature. Furosemide selectively dehydrates abnormal ischaemic or traumatised cerebral tissue and, therefore, may act synergistically with mannitol. Large doses of furosemide also decrease CSF production. The recommended dose ranges 0.1–1 mg/kg followed by 0.3 mg/kg every 4 hours. Given its relative safety and effectiveness, furosemide should be considered intra-operatively whenever ICP reduction or fluid volume reduction is indicated.

Steroids

Corticosteroids are commonly used pre-, intra- as well as post-operatively by neurosurgeons. Although several mechanisms have been suggested for the neuroprotective effects of corticosteroids, its major action is probably inhibition of lipid peroxidation. The efficacy of steroids in reducing vasogenic peritumoral oedema is well documented, but whether corticosteroids have the same efficacy in intra-operative ischaemic cerebral oedema is uncertain. Other mechanisms by which steroids prove helpful is in scavenging of free radicals, reduction of CSF production and increasing the seizure threshold.[71,79,83] The side effects of steroids have been frequently cited as a reason for avoiding their usage. Gastrointestinal bleeding and infections are two major complications with steroids. Exacerbation of hyperglycaemia and subsequent increase of brain injury, especially in an ischaemic situation, is another problem with steroids.[51,75] In conclusion, the use of steroids remains controversial for intra-operative neuroprotection while they are effective in vasogenic peritumoral oedema. Hence, judicious usage of steroids is warranted.

A new class of steroids, 21 aminosteroids or lazaroids, have been developed that inhibit lipid peroxidation of membranes, but lack the glucocorticoid side effects.[55] When free radical destruction of membranes via lipid peroxidation contributes significantly to irreversible cell damage after ischaemia, lazaroids may provide protection from these secondary consequences of ischaemia. However, further animal studies are needed to establish the efficacy of lazaroids in preventing neurological injury after focal and complete global cerebral ischaemia.

Phenytoin

Phenytoin has been shown to stabilise membranes and slow the release of K^+ from ischaemic neurons. Increase in extracellular K^+ concentration causes contraction of vascular smooth muscle, thereby further reducing CBF and increasing glial water content resulting in cytotoxic oedema. Phenytoin has also been shown to attenuate FFA accumulation during complete global ischaemia, thereby preventing the arachidonic acid cascade leading to the production of endoperoxides, prostaglandins and free radicals, and the potential detrimental effects these could have in ischaemic cells.

Perfluorochemical Blood Substitutes

These are small biologically inert particle fluorocarbons (perfluorodecalin and perfluorotripropylamine) emulsified and suspended in an iso-osmolar mixture of intralipid, glycerol and fatty acids. The total surface area for gas exchange per unit volume is approximately 100–170 times that of blood so that gas exchange occurs twice as fast as with haemoglobin. It has been reported that treatment with one such perfluorocarbon blood substrate, Fluosol DA immediately after the onset of permanent focal ischaemia in cats resulted in significantly less neuronal damage than that in saline treated control animals.[72] Suggested mechanisms of protection include increasing oxygen availability to the tissues, decreasing blood viscosity, preventing narrowing of the vascular lumen and increasing flow to the ischaemic areas via collateral circulation because of the small particle size.

Sendai Cocktail

Suzuki[66] advocated a combination of mannitol (500 ml of 20% solution or 100 gm), Vit. E (500 mg) and dexamethasone 50 mg, often referred to as Sendai cocktail, for protection during temporary arterial occlusion. Up to 60 or more minutes of temporary arterial occlusion were possible by this regime without apparent post-operative neurological deficits.

Excitotoxic Antagonists

A major role for excitatory neurotransmitters, notably glutamate, in ischaemic cerebral injury has been well documented. The relationship between excitatory neurotransmitters and increased intracellular calcium has been established. Excitotoxic injury appears to be the result of activation of several receptors: (a) N-methyl-D-aspartate (NMDA) receptor; (b) amino-3-hydroxy-5-methyl-4-isoazole propionic acid receptor and (c) additional receptors.[17]

Although many excitatory antagonists have been studied, few have proven suitable for human trials.[3] The ones in use are dextromethorphan, its primary metabolite dextrorphan and CGS-19755. The limiting factors for the clinical trials to date are significant side effects and unproven efficacy. Continuing research in this area holds promise that an agent truly suitable for intra-operative use will be developed in the relatively near future.

Antioxidants/Free Radical Scavengers

Given that the three primary mechanisms of ischaemic brain injury are loss of calcium homeostasis, acidosis

and increased free radical production, it is not surprising that antioxidants or free radical scavengers should be a part of pharmacological neuroprotection. An oxygen-free radical scavanger is a compound that removes free radical species. A list of known oxygen-free radical scavangers that have been demonstrated to be useful in animal models[11,37,78] is shown in Table 2. Although multiple approaches to inhibit lipid peroxidation and free radical formation have been attempted, substantial clinical benefits have not been clearly documented in human trials with these agents.

Vitamins C and E have a very slow onset of action, while deferoxamine does not cross the blood-brain barrier. Only two agents are likely to be candidates for intra-operative use primarily as antioxidants in the near future, SOD and tirilazad mesylate (TM). SOD has been shown to be effective in treating the vascular changes and increased ICP that occur in several types of brain injury, such as fluid-percussion injury and cold injury.[44,69]

Since SOD has a biological half-life of only 5 min, it has been conjugated with polyethylene glycol (PEG-SOD) for human trials. In a phase II trial of PEG-SOD in patients with severe head injury, treatment was a single bolus intravenous administration, with a mean time from injury to treatment of approximately 4 hours.[69] The percentage of time the ICP was above 20 mmHg and the amount of mannitol required to control ICP were less in the moderate dose PEG-SOD (5,000 U/kg) and in the high dose PEG-SOD (10,000 U/kg) treated patients than in controls. Given these results, it is possible that PEG-SOD or a similar form of SOD may prove to be an important component of a "cocktail" to minimise free radical induced ischaemia-reperfusion injury.[30,85]

TM is an L1-aminosteroid that was developed specifically to maximise the inhibition of lipid peroxidation by glucocorticoids, such as methylprednisolone, but eliminates the unwanted glucocorticoid effects. TM is effective in both focal and global ischaemia with reperfusion.[52] It has also improved outcome in an animal model of spinal cord injury when given 30 min post injury. Its mechanism of action appears to be cell membrane preservation by inhibition of lipid peroxidation.[7] TM was well tolerated when given intravenously up to 6 mg/kg/day (in divided doses every 6 hours); it is expected that doses considerably higher may be feasible and more effective. It is also likely to be a strong candidate for intra-operative use in the near future.

Recent studies have suggested possible roles for pyruvate in protecting CNS neurons from excitotoxic and metabolic insults. Pyruvate can induce glia to up-regulate the synthesis of glutathione (GSH), an antioxidant that protects cells from toxins such as free radicals.[61]

Two well-studied protective proteins, heat shock protein 72 (Hsp72) and SOD2 were genetically targeted for expression in astrocytes using the astrocyte-specific human glial fibrillary acidic protein (GFAP) promoter. This neuroprotection was associated with significantly better preservation of astrocyte glutamate transporter-1 immunoreactivity at 5-h reperfusion and reduced oxidative stress and improving the resistance of astrocytes to ischaemic stress by targeting either the cytosolic or the mitochondrial compartment.[100]

Table 2: Oxygen-free radical scavengers

A. *Enzymatic*:
a. Superoxide dismutase
b. Catalase
c. Allopurinol, oxypurinol (xanthine oxidase inhibitor)
B. *Non-enzymatic*:
a. Dimethyl sulfoxide (DMSO)
b. Dimethylthiourea (DMTU)
c. Deforoxamine
d. Mannitol
C. *Hydrophilic*:
a. Ascorbic acid (vitamin C)
b. Glutathione peroxide
c. L-methionine
D. *Hydrophobic*:
a. Vitamin E
b. Barbiturates

NON-PHARMACOLOGICAL THERAPIES

Hypothermia

Conditions of metabolic inhibition that reduce O_2 and glucose consumption may provide protection for the ischaemic brain owing to the diminished gap between demand and supply.

Mechanism of Protection by Hypothermia

- Reduction in cerebral metabolism: Activation metabolism (neuronal function) and residual metabolism (cellular integrity).
- Membrane stabilising effect: sodium channels restriction and reduction in Na^+ and K^+ flux.
- Reduction in cerebral oedema.
- Reduction in ICP.

The therapeutic benefit of deep hypothermia against cerebral ischaemic injury is largely as a result of reduced metabolic demand and decreased cerebral metabolic rate of oxygen consumption. O_2 consumption is reduced approximately 6–9% per degree drop in temperature. On the basis of animal studies and clinical studies, it is estimated that CMRO2 is decreased 50% at 30°C, 75% at 25°C, 85% at 20°C and 90% at 15°C.

The duration of cerebral ischaemia that can be tolerated is related to the magnitude of temperature reduction and, hence, to the magnitude of metabolic suppression. Deep hypothermia of less than 27°C requires cardiopulmonary bypass, with surgery, general anaesthesia and complex equipment to provide support of the circulation since the heart commonly fibrillates at a temperature below 26–28°C. Mechanical ventilation is required

because hypothermia decreases or abolishes spontaneous respiration depending on the depth of hypothermia. Metabolic acidosis may result from decreased perfusion due to inadequate blood flow and temperature gradients between the core and the periphery. Aggregation or sludging of RBCs due to hypothermia may contribute to poor peripheral circulation.

From clinical trials and animal studies, it is clear that hypothermia alone will not provide complete protection or stimulate the repair that is necessary for normal neurodevelopmental outcome. Other agents such as xenon, N-acetylcysteine, erythropoietin, melatonin and cannabinoids are discussed as future potential therapeutic agents that might augment protection from hypothermia.[18]

Recommended Limits of Total Circulatory Arrest under Deep Hypothermia

	Circulatory arrest time	*Core temperature*
Adult neurosurgical procedures	45–60 min	15–18°C
Paediatric cardiovascular operations	60–90 min	18–20°C

Systemic Effects of Deep Hypothermia

A. Clotting defects:
   - Heparinisation with inadequate reversal
   - Thrombocytopaenia
   - Abnormal platelet function
   - Inhibition and deficiencies of factor I, II, V, VII, X and XII
B. Altered delivery, metabolism and effects of anaesthetic agents
C. Decreased O_2 availability
D. Disturbed acid/base balance
E. Decreased hepatic and renal function
F. Decreased carbohydrate metabolism
G. Reduced cerebral blood flow, increased cerebrovascular resistance
H. Increased blood viscosity
I. Cardiac arrhythmia
J. Shivering

Complications of deep hypothermia include myocardial depression, arrythmias, hypotension and tissue injury due to inadequate or inhomogeneous tissue perfusion.

Hyperventilation

Controlled hyperventilation producing hypocapnia is an effective short-term means of reducing ICP by decreasing CBF and cerebral blood volume when $PaCO_2$ decreases. Cerebral vessels vasoconstrict until the limit of vasoconstriction is reached, which occurs at a $PaCO_2$ of approximately 20 mmHg. If $PaCO_2$ decreases below 18–20 mmHg, ischaemia may occur.[84]

It is hypothesised that hyperventilation might exert a protective effect in focal cerebral ischaemia by vasoconstricting normal cerebral vessels, thereby shunting blood from the normal tissue to the ischaemic area (Robin Hood Steal phenomenon).[46] Hyperventilation begun before experimental focal ischaemia has been shown to decrease the incidence of cerebral infarction;[88] however, it has no effect if begun after ischaemia.[87] Conversely, it has been reported that increased $PaCO_2$ improved CBF in areas of ischaemia.[42] Due to these conflicting reports, hyperventilation is rarely used as a method for improving outcome from focal cerebral ischaemia unless increased ICP is present. Cerebral ischaemia-reperfusion injury (IRI) is a complex process resulting in cellular damage and death. Several recent studies confirmed that repeated hyperbaric oxygen preconditioning (HBO-PC) prior to cerebral ischaemia or spinal cord ischaemia can provide neuroprotection.[96]

Hypertension, Hypervolaemia and Haemodilution (Triple H Therapy)

Hypertension

Cerebral vasospasm occurring as a consequence of SAH is usually accompanied by ischaemia and disturbed auto regulation. Several studies have demonstrated that both CBF and abnormalities in neurological function resulting from this focal ischaemia secondary to vasospasm can be improved by increasing the arterial pressure.[13,23,38,45,67,68]

Induced hypertension may be effective in reversing the effects of focal ischaemia only if CPP is raised before the endothelial cells and the BBB have been damaged by the ischaemia.[35] If raised after damage to these structures, the raised cerebral arterial pressure may cause extravasation of blood and fluid into ischaemic tissue, which would result in intracerebral haemorrhage, increased cerebral swelling, intracranial hypertension and an excaberation of ischaemia.[35]

Hypervolaemia

Although there is little evidence to substantiate a direct relationship between intravascular volume and CBF,[50,98] expansion of intravascular volume by colloid infusion has been commonly used to treat focal cerebral ischaemia.[24,53]

Haemodilution

Blood viscosity varies inversely with the shear rate of the fluid and is, therefore, greater at lower flow rates. During and after cerebral ischaemia, blood viscosity increases as a result of shift in electrolytes and water from plasma to tissue. Haemodilution would decrease blood viscosity and improve cerebral perfusion during and after ischaemia. There are three major types of haemodilution depending on the amount of volume expansion. Hypovolaemic haemodilution is produced by phlebotomy and less fluid replacement. Isovolaemic

haemodilution is produced by exchanging fluid for blood. Hypervolaemic haemodilution is produced by infusion of fluid (colloid or crystalloid) into the circulation. Hypervolaemic haemodilution has been commonly used in patients with focal ischaemia and has been shown to improve cerebral perfusion of ischaemic brain and decrease neurological deficits.[1,28,38,99]

Agents for Volume Expansion

Crystalloids
a. Normal saline
b. Ringer's lactate
c. Hypertonic saline
d. Hypertonic Ringer's lactate
e. Dextrose solution

Colloids
a. Blood
b. Albumin
c. Dextran
d. Hetastarch
e. Perfluorocarbons

Induced Hypotension

Over the MABP range (50–150 mmHg), the cerebral blood flow (CBF) remains constant or nearly constant in the intact brain (Fig. 4). To be truly effective, induced hypotension or hypertension would need to exceed these values to affect CBF, i.e. drop below 50 mmHg or rise above 150 mmHg. In actual intra-operative practice, cerebral auto regulation for blood pressure is not fully intact in many circumstances and, thus, the relationship between MABP and CBF more closely resembles the dashed line in the figure. In regions of severe ischaemia, cerebral oedema or infarction, auto regulation may be completely lost.

Induced hypotension is employed to reduce blood loss. It is necessary to distinguish prolonged induced hypotension during procedures in which blood loss is virtually continuous (extensive spinal fusions or the resection of large vascular tumours), from temporary induced hypotension to facilitate control of unexpected profuse bleeding (premature rupture of aneurysm or AVM). In the former situation, the induced hypotension is elective and is undertaken with maintenance of adequate perfusion of neural tissue as an essential goal. In the latter situation, the induced hypotension is emergent and is undertaken at the risk of ischaemic injury to neural tissue.

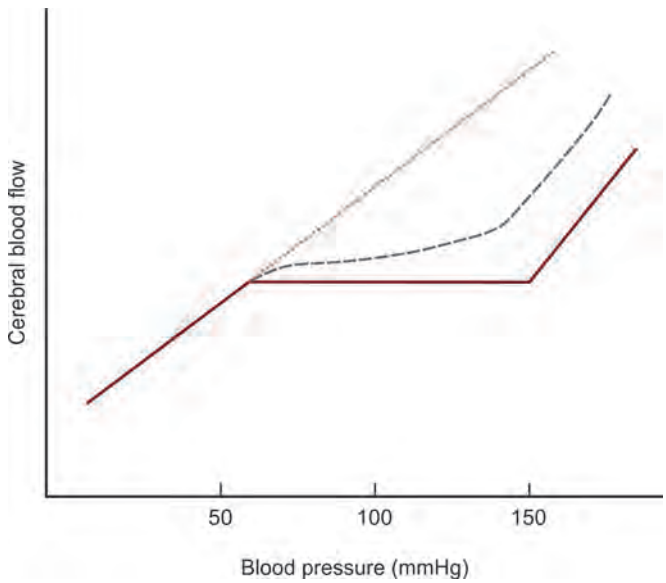

Fig. 4: Cerebral blood flow auto-regulation (solid black line); partial autoregulation of CBF to changing MABP, realistic in many clinical situations, e.g. cerebral oedema (dashed blue line); complete loss of auto-regulation of CBF to changing MABP, i.e. CBF fluctuates with fluctuations in MABP (dotted red line)

Relative Contraindications to Induced Hypotension

- Ischaemic cerebrovascular disease
- Ischaemic coronary artery disease
- Chronic hypertension
- Hypovolaemia
- High (> 45) or low (< 30) haematocrit
- Extremes of age.

Complications of Induced Hypotension

- Stroke
- Cardiac arrest or myocardial infarctions
- Hepatic failure
- Renal failure or renal artery thrombosis
- Retinal artery thrombosis.

Agents for Induced Hypotension[90]

- Inhalation anaesthetic (increased isoflurane)
- Intravenous anaesthetic (propofol, thiopental, etomidate)
- Vasodilator (sodium nitroprusside, nitroglycerine, hydralazine)
- Sympathetic blocker (esmolol, labetalol)
- Ganglionic blocker (trimethapan)
- Narcotic (sufentanyl)
- Adenosine (less commonly used at present).

Nitroglycerine would preserve brain tissue oxygenation better than sodium nitroprusside due to its venous dilating properties. Sodium nitroprusside is a peripheral arterial bed dilator (rather than a venous bed) and, thus, may produce increased peripheral vascular resistance. Following discontinuation of induced hypotension with these agents, increased CBF (hyperaemia) can be seen. With respect to the duration of sodium nitroprusside induced hypotension that can be safely tolerated, a well-established primate model of temporary middle cerebral artery occlusion provides relevant data. Hypotension from a MAP of 60 through 65 mmHg to 48 through 50 mmHg for 15 min was well tolerated, but neurological deficits occurred with 30 min or longer of occlusion plus hypotension.

Electrophysiological Monitoring

Electrophysiological monitoring, such as EEG and evoked potentials (EPs), may allow intra-operative detection of cerebral ischaemia, leading to a change in surgical technique that improves perfusion. However, they are not routinely used because their changes are

not always specific and the recording sites not always accessible.

EEG monitoring may be indicated when temporary occlusion is planned, either to determine the duration of tolerance or for titration of anaesthetic agents when burst suppression is desired.[9,59]

Somatosensory evoked potential (SSEP) has been investigated for use during procedures on both anterior and posterior circulation aneurysms, whereas brainstem auditory evoked potential (BAEP) has been primarily investigated for use during procedures on vertebral-basilar aneurysms. EPs can be recorded even when EEG is suppressed with high dose barbiturates and, therefore, the only electrophysiological monitor available when maximal pharmacological metabolic suppression is used.

Spontaneous breathing has been used in the past as an indicator of brainstem function, particularly when extreme hypotension is used. It is seldom used today, because optimal brain relaxation is difficult and extreme hypotension is no longer used. However, with aneurysms of the lower basilar artery and vertebral artery, where temporary or permanent occlusion of the feeding vessel is contemplated, spontaneous breathing may provide additional and more specific information than cardiovascular monitoring.

Cerebral protection implies providing an environment in which there is scope for maximising recovery for the damaged neuronal cells and minimising the side effects of the various therapeutic manoeuvres involved. Neuronal cell damage can follow ischaemia, hypoxia and even cerebral trauma. Many of the pathological processes, e.g. free radical release are still poorly understood and more research needs to be done in order to make rational choices about therapy either for prevention of cerebral ischaemia/hypoxia or for treatment to prevent irreversible cell damage once the pathological processes are set in motion. Lastly, as neurosurgical operations become more complex and newer technologies are introduced into the field, the need to have a team approach is very evident in order to have an optimum outcome.

79 Paraclinoid Aneurysms

Vijendra Kumar Jain, Sanjay Behari, Bernard Lyngdoh

INTRODUCTION

Paraclinoid aneurysms arise from the internal carotid artery (ICA) distal to the cavernous sinus but proximal to the posterior communicating artery.[6,9,14,24] Five to ten per cent of all intracranial aneurysms arise from this segment of the ICA.[16,24,26] Satisfactory clipping of paraclinoid aneurysms, while preserving the ophthalmic artery and maintaining the patency of the ICA, is technically challenging. A number of these aneurysms are giant and are difficult to clip due to splaying of branch vessels at the neck of the aneurysm and atherosclerosis and calcification at the neck and dome of the aneurysm. Advances in skull base techniques and endovascular procedures and their combinations have greatly improved surgical outcome. In this chapter, we review the neuroanatomy of the paraclinoid region and discuss the operative nuances involved in the surgery of paraclinoid aneurysms.

NEUROANATOMY

Paraclinoid Internal Carotid Artery

The modification of Fischer's classification proposed by Bouthillier and colleagues[4,16] classifies segments of the ICA in an anterograde sequence (Fig. 1). The cavernous segment of ICA is designated the C4 segment. After exiting from the cavernous sinus, the ICA bends twice to form the anterior loop and reverses its course by 180 degrees. Here, it is surrounded by the anterior clinoid process laterally, the optic strut anteriorly and the carotid sulcus medially.[16,26]

The intracavernous ICA is separated from the intradural space by two layers of the cavernous sinus dura, an inner membranous layer and the outer dura propria. These layers split at the anterior clinoid process (Figs 2A to C).

The inner membranous layer forms the periosteum covering the inferior surface of the anterior clinoid process. At the point at which the ICA comes in close contact with the inferior surface of the clinoid process, the inner layer encircles the ICA, forms the proximal dural ring and then further wraps the clinoidal segment of the ICA in a dural sleeve (known as the carotid collar).[24,37] The proximal dural ring does not fuse with the adventita of the ICA and can easily be separated from it. The dural sleeve fuses with the distal dural ring at the point where the ICA enters the intradural space after emerging from the cavernous sinus (Figs 2B and C).

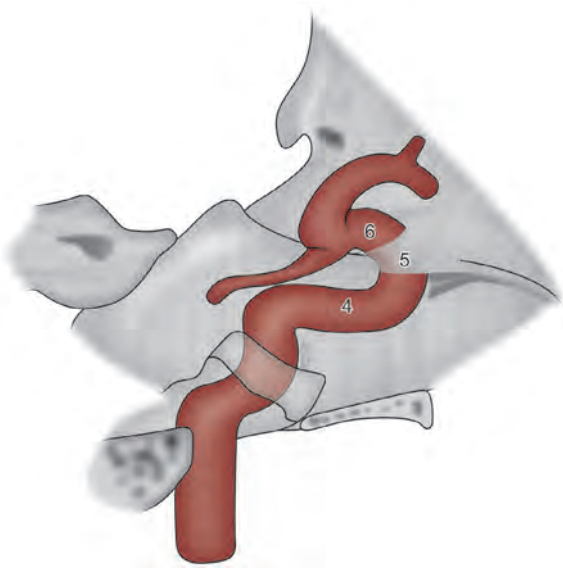

Fig. 1: Lateral view of the ICA showing the segments described by Bouthillier et al. C4 corresponds to the cavernous ICA, C5 to the clinoidal ICA and C6 to the ophthalmic ICA

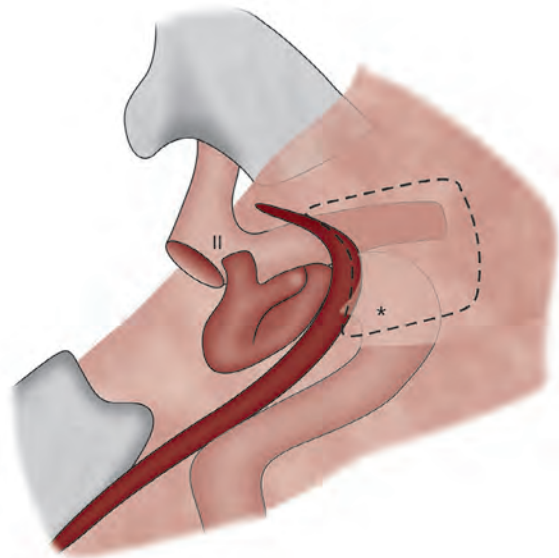

Fig. 2A: Lateral view of the left paraclinoid region showing the dura covering the anterior clinoid (*). The drilling of the anterior clinoid in order to expose the clinoidal ICA requires the reflection of the dura overlying it. The optic nerves and the chiasma are represented by II

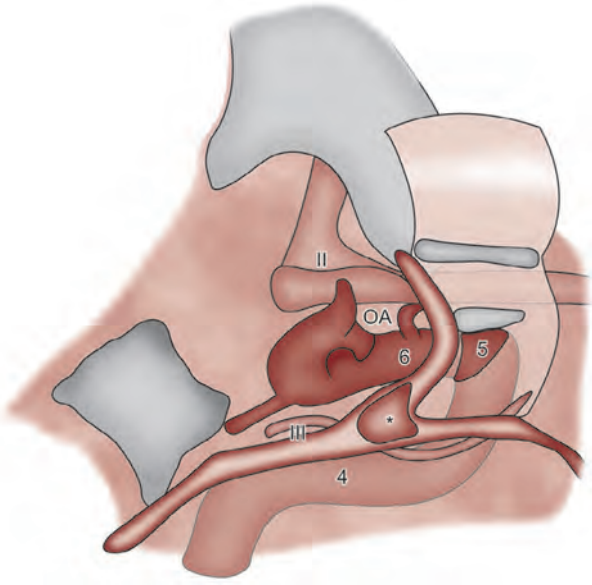

Fig. 2B: The drilling of the anterior clinoid (*) exposes the clinoidal ICA (5) between the proximal and the distal dural rings. The ophthalmic artery (OA) arises from the ophthalmic segment of the ICA (C6) just distal to the distal dural ring. The third nerve (III) is seen entering the cavernous sinus

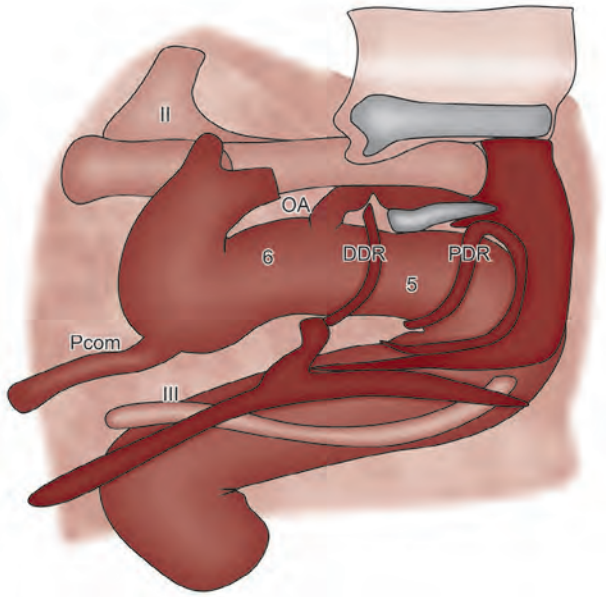

Fig. 2C: The anterior clinoid has been completely removed exposing the proximal and distal dural rings. The cavernous (C4), clinoid (C5) and ophthalmic (C6) segments of the ICA and the ophthalmic artery (OA) can be seen. The clinoid (C5) segment, situated between the proximal and the distal dural rings; and, the ophthalmic (C6) segment, situated between the distal dural ring and the origin of the posterior communicating artery together constitute the paraclinoid region of the ICA. The inner dural layer of the roof of the cavernous sinus forms a sheath over the oculomotor nerve (III) and then encircles the ICA as the proximal dural ring (PDR). It forms the carotid collar around the clinoid segment of the ICA and fuses with the distal dural ring (DDR). After removal of the anterior clinoid process, a space exists between the inner and the outer dural layer known as the clinoid space

Posteriorly, the inner dural layer forms the dural sheath of the oculomotor nerve and continues as the inner layer of the lateral wall of the cavernous sinus. The portion of the proximal ring that separates the clinoid ICA from the oculomotor nerve is termed the carotico-oculomotor membrane and is the surgical landmark for encountering the clinoidal ICA through the roof of the cavernous sinus.[24]

The clinoidal (C5) segment of the ICA is the part of the ICA from the proximal to the distal dural ring (Figs 2B and C). This part of the ICA is regarded as extracavernous and extradural. Aneurysms located proximal to the distal dural ring do not cause subarachnoid haemorrhage (SAH) and, therefore, do not produce the same morbidity as do aneurysms arising from the intradural space. The veins of the cavernous sinus may extend through the incompetent proximal dural ring up to the distal dural ring through the space between the dural rings and the ICA.[24,37]

The outer dural layer or the dura propria of the cavernous sinus forms the periosteum covering the superior surface of the anterior clinoid process, the planum sphenoidale and the tuberculum sellae. It also continues as the diaphragma sellae and the falciform ligament (the dural sheath of the optic nerve), and fuses with the adventitia of the ICA to form the distal dural ring (Figs 2B and C).[24]

The distal dural ring forms the boundary between the extradural and the intradural spaces and marks the end of the clinoid (C5) segment and the beginning of the ophthalmic (C6) segment of the ICA. The distal dural ring is adherent to the adventitia of the ICA so a blunt rather than a sharp dissection of the distal dural ring from the ICA may tear the adventitial layer of the ICA.[16,24] The distal dural ring is reinforced on its lateral aspect by the anterior petroclinoid ligament that extends from the petrous apex to the anterior clinoid process.

A small subarachnoid pouch exists at the medial aspect of the ICA at the distal dural ring known as the carotid cave.[27] This cave points towards the cavernous sinus. The apex of the cave contains connective tissue, which, if breached, communicates this space with the clinoid venous plexus. Thus, large aneurysms in this location may be both intradural and extradural. Since the cave contains the subarachnoid space, carotid cave aneurysmal rupture may cause SAH. Thus, carotid cave aneurysms, despite being located proximal to the distal dural ring, are intradural.[24]

The clinoid space is the potential space between the outer and the inner dural layers and is occupied by the anterior clinoid process. It is a potential space, since it is only created after an anterior clinoidectomy.[32,33]

The proximal ophthalmic (C6) segment of the ICA lies under the anterior clinoid process beyond the distal dural ring. The ophthalmic artery arises distal to the distal dural ring from the rostromedial aspect of the C6 segment of the ICA. It travels through the optic foramen lying inferior and lateral to the optic nerve. In 2–16% of

cases, it may also arise proximal to the distal dural ring either from the C5 or from the C4 segment.[16]

The superior hypophyseal arteries arise from the posteromedial wall of the proximal C6 segment, vary from 1–5 in number and cross over the diaphragma sellae. Occasionally, they may originate near the distal dural ring, within the carotid cave or may even be intracavernous.

The paraclinoid segment of the ICA, therefore, extends from the proximal dural ring to the origin of the posterior communicating artery and encompasses both the clinoid (C5) and the ophthalmic (C6) segments.[16,24,26]

Review of Classification Schemes

Drake et al. had described carotid-ophthalmic aneurysms as a distinct entity in 1968, but did not propose any classification.[9] In 1971, Kothandaram et al. first classified these aneurysms according to their relationship with the optic chiasma into subchiasmal, suprachiasmal and parachiasmal aneurysms.[28] In 1976, Almeida et al. divided them into lateral optochiasmatic and suboptochiasmatic[1] to which Thurel, in 1976, added the suprachiasmatic and global groups.[41] Based on arteries of origin, Day, in 1990, classified them into ophthalmic artery, superior hypophyseal-paraclinoid and superior hypophyseal-suprasellar aneurysms.[6] In 1993, Al-Rodhan et al. classified them based on the projection of the neck and dome of the aneurysm into supraophthalmic, ophthalmic, infraophthalmic/supracavernous, transitional and cavernous groups.[2] In 1994, Batjer et al. classified these aneurysms into ophthalmic artery, superior hypophyseal artery and proximal posterior wall aneurysms,[3] to which, in 1997, Fries et al. added "partially intracavernous aneurysms.[14] In 1997, Kumon et al. classified these aneurysms into five groups: the subchaismatic; lateral chiasmatic; suprachiasmatic; carotid cave and paraclinoid.[29] In 1999, De Jesus et al. divided them into four groups: clinoid; ophthalmic; superior hypophyseal and posterior paraclinoid.[7] In 2003, Barami et al. reclassified them again as per their location in relation to the ICA segments.[5]

Classification of Paraclinoid Aneurysms

This is based upon the site of origin of the aneurysm on the C5 and C6 segments of the ICA and the direction of projection of these aneurysms, and was primarily proposed by Barami et al. in 2003 (Figs 3A to D)[2,5,16,24,38] (Table 1).

Carotico-ophthalmic Aneurysms

These aneurysms arise from the origin of the ophthalmic artery (Fig. 3A).[6] They usually arise from the dorsal surface of the C6 segment, project superiorly into the subarachnoid space and displace the optic nerve superiorly and medially. Their neck as well as their dome is intradural (Ia). Occasionally, the ophthalmic artery arises from the C5 segment of the ICA proximal to the distal dural ring in which case the neck and the dome are extradural. These lesions either present with SAH, or if

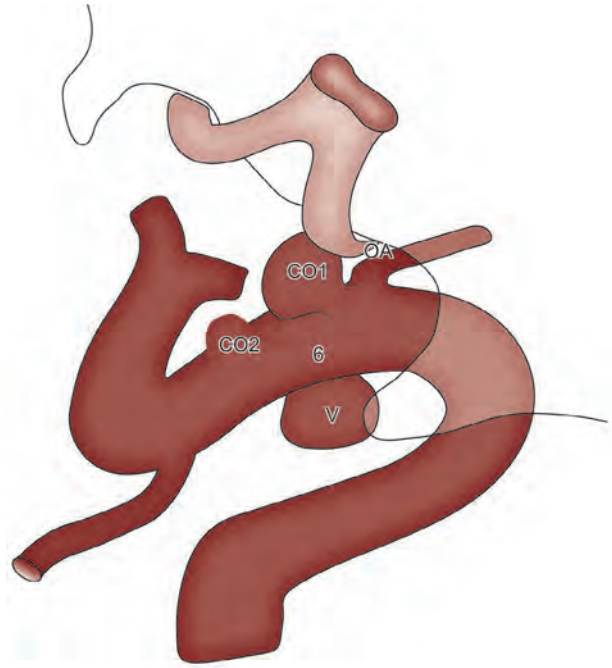

Fig. 3A: Lateral view of the ICA showing a carotico-ophthalmic aneurysm (CO1) arising from the origin of the ophthalmic artery; a blister aneurysm (CO2) arising from the dorsal wall of the ophthalmic segment of the ICA; and a ventral wall aneurysm (v) arising from the ventral surface of the ICA

they grow to a large size cause optic nerve or chiasmal compression. One variant of this aneurysm arises from the dorsal and the superior surface of the ICA, a few millimetres distal to the origin of the ophthalmic artery. The latter aneurysms are broad based, sessile and project superiorly (Ib) (Fig. 3A).[18,19,25]

Ventral or Posterior Wall Aneurysms

They originate between the ophthalmic and the posterior communicating arteries and project into the cavernous sinus (Fig. 3A).[13,32,33] The neck lies 180 degrees opposite

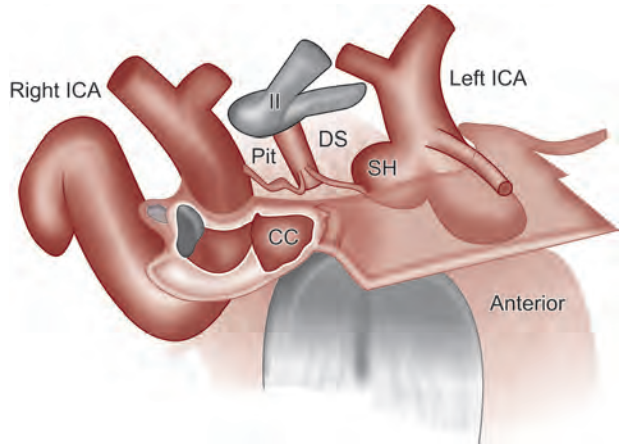

Fig. 3B: Anteroposterior view of the right and left ICA. The left ICA is showing a superior hypophyseal artery aneurysm (sh) while the right ICA is showing the sub-diaphragmatic (carotid cave) variant of a superior hypophyseal artery aneurysm (CC). The pituitary stalk (Pit) is seen entering the diaphragma sellae (DS)

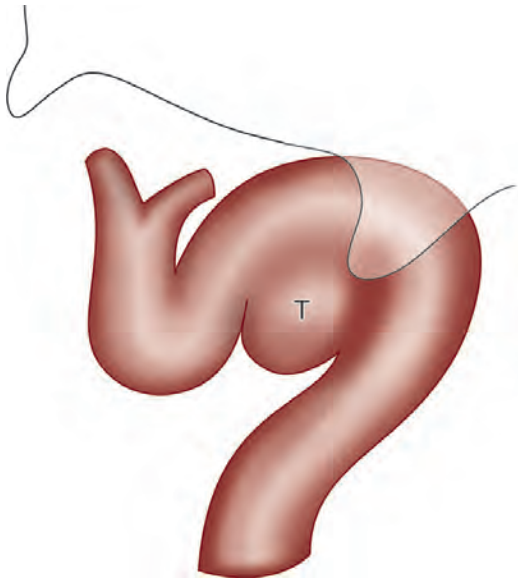

Fig. 3C: A transitional aneurysm (T) takes origin from the cavernous, clinoidal and ophthalmic segments of the ICA

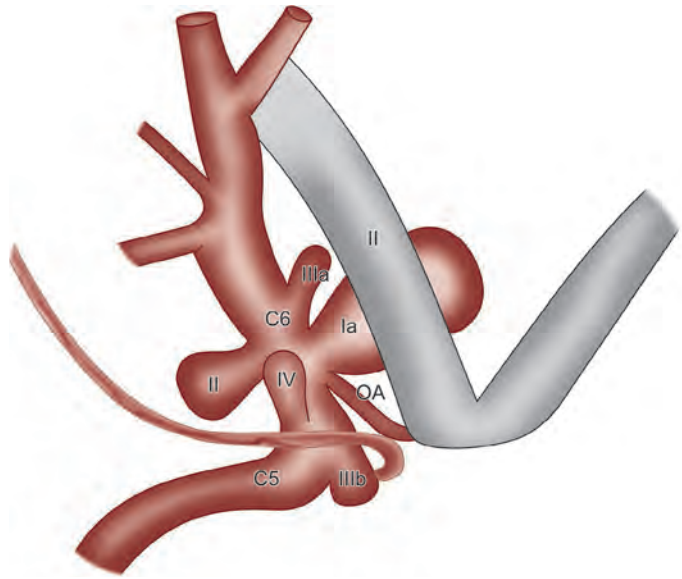

Fig. 3D: Overview of the location of paraclinoidal aneurysms

Table 1: Paraclinoid aneurysms

Classification	*Origin from ICA*	*Origin from surface of ICA*	*Relation to branch of ICA*	*Other relations*
(Ia) Ophthalmic artery aneurysm	Ophthalmic segment of ICA (C6)	Dorsal	Ophthalmic	Medial or lateral to II nerve
(Ib) Ophthalmic artery aneurysm	Ophthalmic segment of ICA (C6)	Dorsal	None	Lateral to optic nerve
(II) Ventral wall or posterior carotid wall aneurysm	Ophthalmic segment of ICA (C6)	Ventral	None	Aneurysm dome may project into cavernous sinus roof. Arise from ventral wall right opposite and just distal to origin of ophthalmic artery
(IIIa) Superior hypophyseal artery aneurysm	Ophthalmic segment of ICA (C6)	Medial	Superior hypophyseal artery	Arise distal to ophthalmic artery and are above the diaphragma sellae
(IIIb) Carotid cave aneurysms	Clinoidal segment of ICA (C5)	Medial	Superior hypophyseal artery	Arise at or below the dural ring around the ICA as it enters the subarachnoid space. They are below the diaphragm sella and may project into the sella
(IV) Transitional aneurysms	Clinoidal (C5), ophthalmic (C6) and often also the cavernous segments of ICA (C4)	Ventral	None	Often giant aneurysms extend from the cavernous sinus proximally to the subarachnoid space distally, widening the dural rings

to the origin of the ophthalmic artery. They are not associated with an arterial branch. Although they look and behave like other saccular aneurysms, they are often blister-like with a relatively thin wall and a broad base, and are extremely fragile. Therefore, during the post-subarachnoid haemorrhage period, their surgical treatment carries a high morbidity rate. The dome may project towards the roof of the cavernous sinus and involve the III nerve. Thus, large aneurysms of this type occupy both the intradural and the extradural spaces.[18,19]

Superior Hypophyseal Aneurysms

They arise from the medial surface of the proximal C6 ICA closely related to the origin of the superior hypophyseal artery distal to the ophthalmic artery (Fig. 3B).[6] The neck as well as the dome are intradural and they project medially above the diaphragma sellae (IIIa). A variant of this aneurysm arises from the carotid cave,[27] with its neck and fundus being intradural and projects inferomedially along the medial aspect of the distal dural ring. This may project below the diaphragma sellae and may be assumed to be a sellar mass on CT imaging (IIIb). It arises at or below the dural ring around the ICA as it enters the subarachnoid space (Fig. 3B).[18,19]

Siphon or Transitional Aneurysms

These giant aneurysms have a base extending from the distal cavernous to the ophthalmic segments (Fig. 3C).[8] The dome may elevate the roof of the cavernous sinus, enlarge the proximal and distal dural rings, and also extend intradurally.[2]

Clinical Presentation

These aneurysms may present as SAH with sudden severe headache, decreased visual acuity, field deficits, changes in colour vision, diplopia or retro-orbital pain.[6,12,23] Occasionally, transient ischaemic attack or stroke, dizziness, facial pain or numbness, audible bruit, panhypopituitarism and epistaxis have been described. As per the series of Hoh et al. 32% had multiple aneurysms and 10% had aneurysms in a paraclinoid location. 26% of their paraclinoid aneurysms were incidental and detected with other ruptured or unruptured aneurysms, AVMs, family screening and accompanied with other syndromic disorders such as Marfan's syndrome.[20]

SPECIAL RADIOLOGICAL CONSIDERATIONS

On CT, in patients with SAH, the extent of haemorrhage is graded using Fischer's classification. Thin section CT of the clinoidal region with bone windows determines the position of the ICA, aneurysmal calcification and clinoidal erosion. An aneurysmal calcification with clinoidal erosion may predispose to an inadvertent tearing of the aneurysm during clinoid drilling.[16]

On cerebral angiography, carotid-ophthalmic, ventral wall and transitional aneurysms are better visualised on the lateral projection; superior hypophyseal and carotid cave aneurysms are better seen on anteroposterior and submentovertical projections.[16]

Since the position of the distal dural ring determines the intradural and extradural segments of the ICA (the aneurysms located proximal to the distal dural ring, being extradural, do not cause SAH), an angiographic determination of the distal dural ring may help in planning the surgical approach. Punt proposed that the origin of the ophthalmic artery may be used as a marker for the intradural ICA,[35] but the ophthalmic artery may occasionally be situated proximal to the distal dural ring. Taptas stated that the base of the anterior clinoid process on lateral views may mark the intradural ICA.[39] Oikawa et al. stated that the medial aspect of the ring was at the level of the tuberculum sellae and its lateral aspect at the level of the clinoid process.[34] However, carotid cave aneurysms may be observed below the level of the tuberculum sellae or the anterior clinoid process. Therefore, at present, there is no reliable angiographic method to determine the precise level of the distal dural ring and, therefore, the point of transition of the extradural and the intradural ICA. However, Murayama and colleagues, using three dimensional CT angiography of the paraclinoid region, have found a concavity corresponding to the distal dural ring on the paraclinoid segment of the ICA.[30]

Carotid cave aneurysms[27] and ventral wall aneurysms[32,33] are located close to each other, so it is angiographically difficult to differentiate the two from each other. A ventral wall aneurysm originates at a nonbranching point of the ICA just distal to and opposite to the ophthalmic artery origin, while a carotid cave aneurysm arises proximal to the origin of the ophthalmic artery, next to the distal dural ring and grows ventromedially into the carotid cave. According to Zhang et al. the main differentiation between the two is the finding of an angiographic axillary space between the axilla of the ICA and the anterior or anteroinferior surface of a ventral aneurysm in the lateral projection, since the neck of a ventral aneurysm arises more distally than that of a carotid cave aneurysm. This finding was absent in all carotid cave aneurysms due to their inferoposterior projection from the genu towards the axilla of the ICA.[44] Another differentiating point is that since the carotid cave lies in the 1–6 o'clock position medial to the ICA, a carotid cave aneurysm has a prominent medial projection in the AP view when compared to a ventral aneurysm.[27,44]

Differentiating between the two is important since ventral wall aneurysms can be clipped after removal of the anterior clinoid process;[32,33] while carotid cave aneurysms can only be clipped after removal of the anterior clinoid process as well as separation from the distal dural ring, mobilisation of the ophthalmic artery and dissection of the genu and axilla of the ICA.[27,44]

Intra-operative angiography has been a useful adjunct during direct surgery for paraclinoid segment aneurysms. It may reveal either a residual portion of the aneurysm after clipping or compromise of the patency of the ICA that was not easily apparent under direct microscopic vision. Thus, clip repositioning with intra-operative angiography has improved the radiological efficacy of direct surgery.

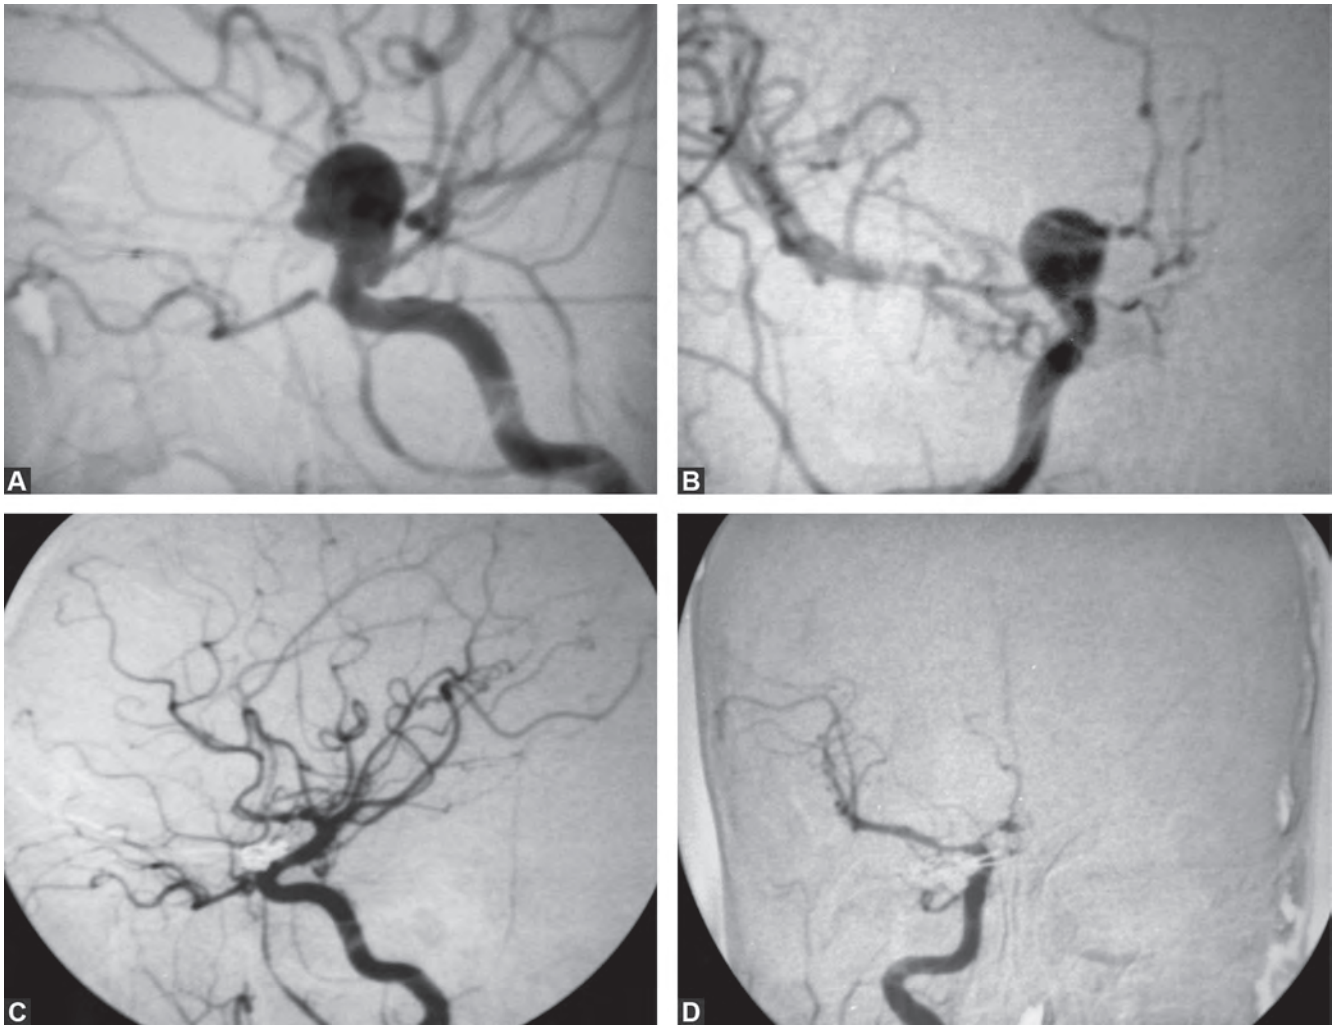
On MR imaging, the precise dimensions of an aneurysm with a thrombus may be determined. The coronal images delineate superior hypophyseal and carotid cave aneurysms. The infradiaphragmatic location of the latter is also determined on MR studies since these aneurysms can only be accessed by dividing the diaphragma sellae.[16]

Testing for collateral flow in patients with a large broad necked aneurysm before either surgery or endovascular therapy where ICA occlusion is a possible outcome: In large or giant aneurysms, the suitability of permanent ICA occlusion is determined by the balloon test occlusion (BTO) accompanied by a clinical examination that does not suggest any asymmetry of clinical signs; angiographic criterion, in which symmetry of flow in both hemispheres or in the anterior and posterior circulation throughout all phases of flow, is determined; a single photon emission computed tomography (SPECT) study, in which a decrease in perfusion during a hypotensive challenge with a mean BP 20% below the baseline is determined; and xenon computed tomography in which the symmetry of perfusion is determined.[40] In case the BTO with SPECT is well-tolerated, the ICA may be trapped. In case it is not tolerated and perfusion defects are seen on SPECT, a vascular bypass using superficial temporal to middle cerebral artery anastomosis may be required.[20,21,40]

THERAPEUTIC OPTIONS

Clip Alone

This is the ideal method of treatment since it provides a direct obliteration of the aneurysm with preservation of the carotid and ophthalmic arteries and a simultaneous decompression of the optic apparatus. Even aneurysms with a broad neck may be dealt with using a clip (Figs 4A to D, 5A to E and 6).



Figs 4A to D: (A) Lateral. (B) Anteroposterior ICA angiogram showing a carotico-opthalmic aneurysm. (C) Post-operative lateral. (D) Anteroposterior ICA angiogram showing successful aneurysm clipping

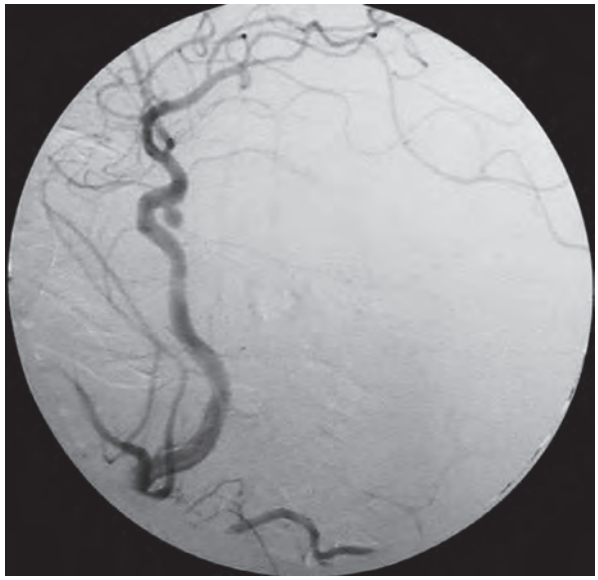


Fig. 5A: Right carotid angiogram showing a type II, ventral wall aneurysm situated opposite to the ophthalmic artery with no branch relations

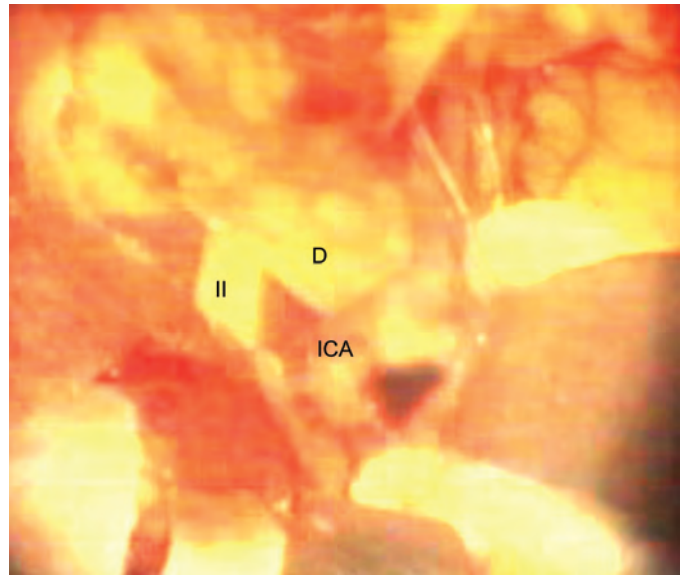

Fig. 5C: The last part of the anterior clinoid process is removed with dissectors exposing the dura (D) over the clinoidal segment of the carotid artery (ICA) and the optic nerve (II)

Ligature and Clip

The purpose of the ligature is to narrow a broad neck sufficiently to allow an easier application of the clip, but not to narrow the neck so much as to kink the parent ICA.[12]

Trapping of the ICA with or without Extracranial-Intracranial Bypass

This takes care of aneurysms with a large neck, especially involving the cavernous and clinoid carotid artery (Figs 7A to G). It is not the preferred method of treatment since cerebral ischaemia may occur after trapping of the ICA, despite a successful pre-operative BTO.

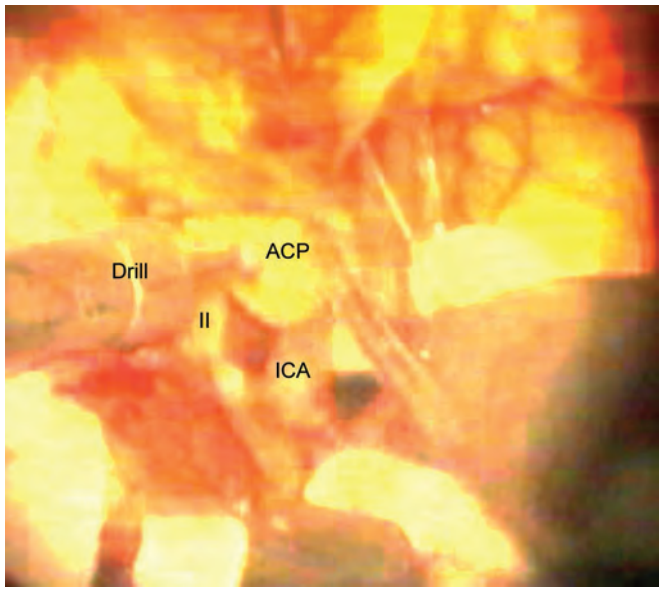

Fig. 5B: An intra-operative view showing the anterior clinoid process (ACP) being drilled. The optic nerve (II) and internal carotid artery (ICA) are exposed in the suprasellar cisterns after Sylvian fissure splitting

Circumferential Wrapping

Occasionally, in blister like aneurysms with no neck and a fragile dome, a circumferential clip graft may be applied.[12]

Cardiopulmonary Bypass with Profound Hypothermia and Circulatory Arrest

This serves as a useful adjunct to both clipping and trapping as the aneurysm neck may be identified and the fundus dissected with minimal bleeding.[12,20,21]

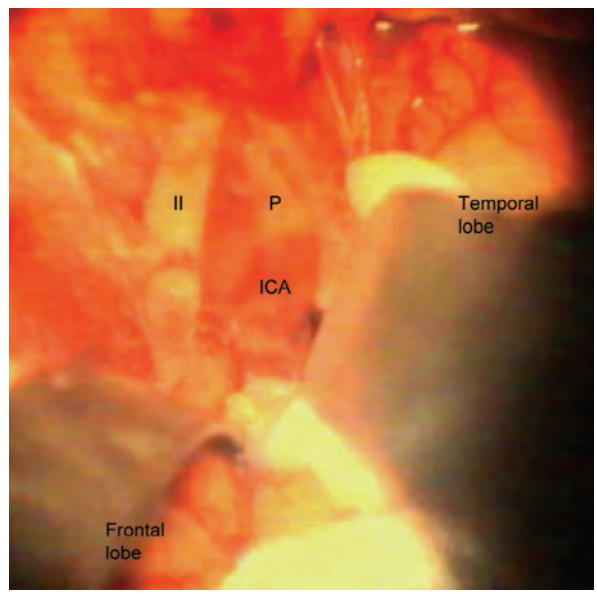

Fig. 5D: The distal dural ring and carotid collar are removed exposing the paraclinoid segment of the internal carotid artery. This was utilised both for proximal control and for achieving adequate space for the clip blades. The unroofing of the optic canal also exposes the distal optic nerve

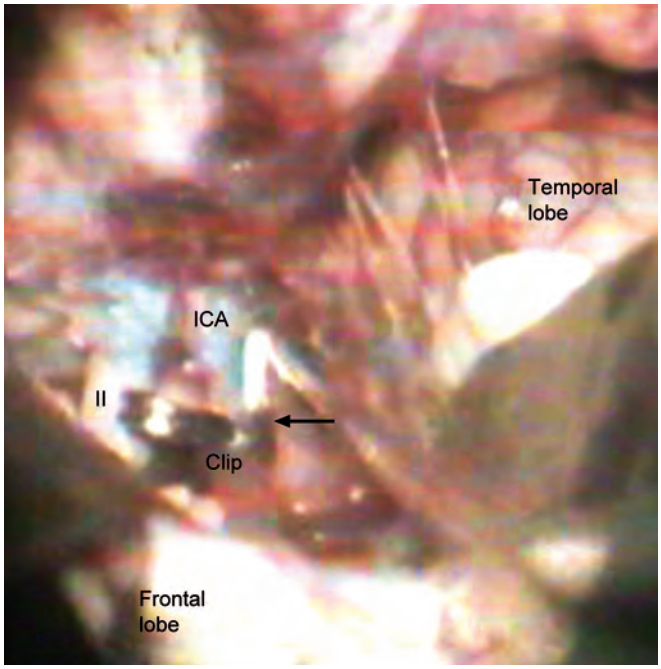

Fig. 5E: A right angled fenestrated clip applied to the aneurysm. The fenestration of the clip is looping around the clinoidal segment of the internal carotid artery

Endovascular Treatment

Since paraclinoid aneurysms are more difficult to treat surgically and have a higher surgical morbidity, endovascular treatment may have a more prominent role in their obliteration. This includes: coiling of the aneurysms with Guglielmi detachable coils while preserving the parent artery; intravascular stenting; balloons to remodel coils at the neck of the aneurysm and permanent balloon occlusion of the ICA.[20,40,42] As an adjunct to surgery for the clipping of paraclinoid aneurysms, a novel endovascular method utilised a balloon catheter with a coaxial lumen inserted via the transfemoral route as a means of proximal control, along with the provision for a simultaneous suction decompression and intra-operative angiography.[31]

Batjer and Samson have described a technique of retrograde suction decompression in clipping of large and giant paraclinoid aneurysms.[3]

Thornton et al. have estimated the amount of occlusion of the aneurysm, in terms of percentage, on follow-up angiograms after endovascular treatment as: 100%: dense coil packing with no contrast filling the aneurysm; > 95%: contrast fills a very small portion ("dog ear") at one side of the neck or within the interstices between the coils at the level of the neck only; < 95%: coil packing is less dense, contrast fills at least a small portion of the neck and there is minimal contrast filling within the interstices between the coils. Any additional filling of the aneurysm with contrast is also included in this group. Unsuccessful: no coils placed in the aneurysm.

Progression of Thrombosis

Any decrease in the amount of contrast filling at follow-up angiography.

Fig. 6: Lateral carotid angiogram showing another ventral wall aneurysm with a wide neck

Refilling

Any increase in the amount of contrast filling at follow-up angiography.[40]

The main complications of endovascular coiling include coil compaction leading to refilling of the aneurysm, blockage of parent vessel, progression of aneurysm thrombosis to parent vessel or its subsequent embolisation and aneurysm rupture during the procedure.[17,22,42]

Surgical Considerations

Craniotomy

The pterional craniotomy is the standard craniotomy for paraclinoid aneurysms. A larger craniotomy, especially extending towards the midline, provides greater manoeuvrability for clip application and suction. The Sylvian fissure should be opened widely to visualise the carotid bifurcation and the proximal middle cerebral artery. However, to approach the paraclinoid area, the other craniotomies which may be considered include the ipsilateral supraorbital, subfrontal and ipsilateral frontobasal. Occasionally, contralateral approaches may be useful.[14]

Proximal Control

For proximal control of the ICA, there are several alternative strategies: (A) The common and internal carotid arteries may be exposed in the neck. However, if there is extensive collateral flow to the aneurysm, this strategy may not work; (B) The portion of the ICA between the proximal and the distal dural rings may be exposed by dividing the distal dural ring circumferentially around the ICA after the ophthalmic artery has been dissected free.[15,16] The disadvantages of this method are that it is technically demanding since the drilling and manipulation are very close to the aneurysm sac. The carotid artery is thin and within bony confines and, therefore, is difficult to occlude. There may be substantial cavernous

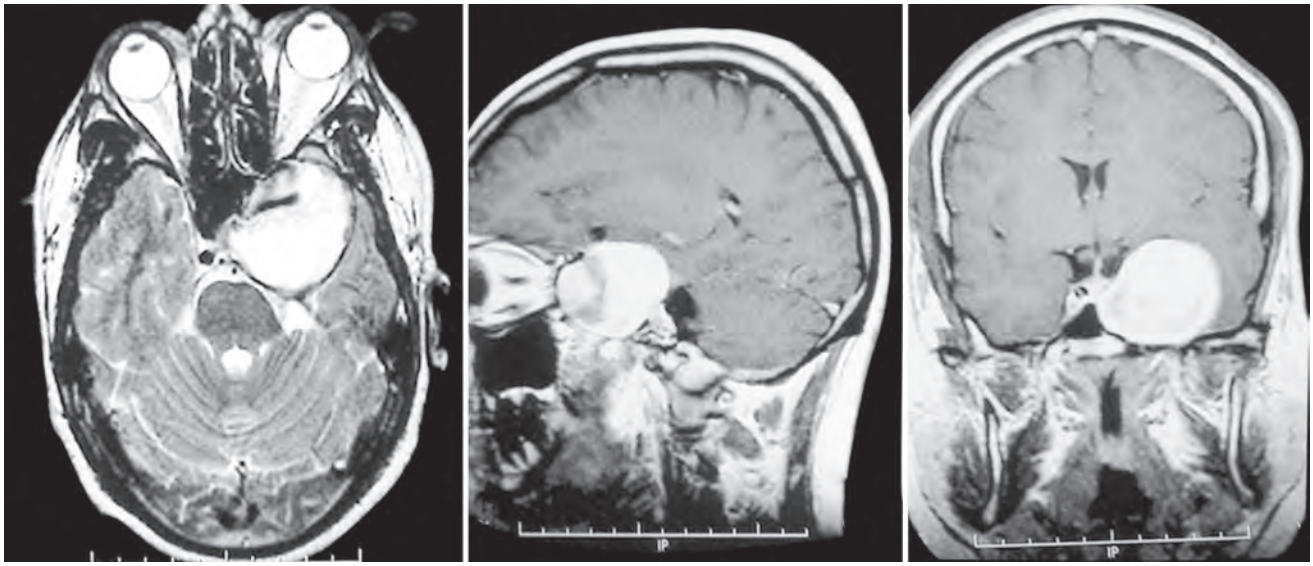

Fig. 7A: Axial T2 and sagittal and coronal T1-weighted MR images showing a giant cavernous and paraclinoid transitional aneurysm

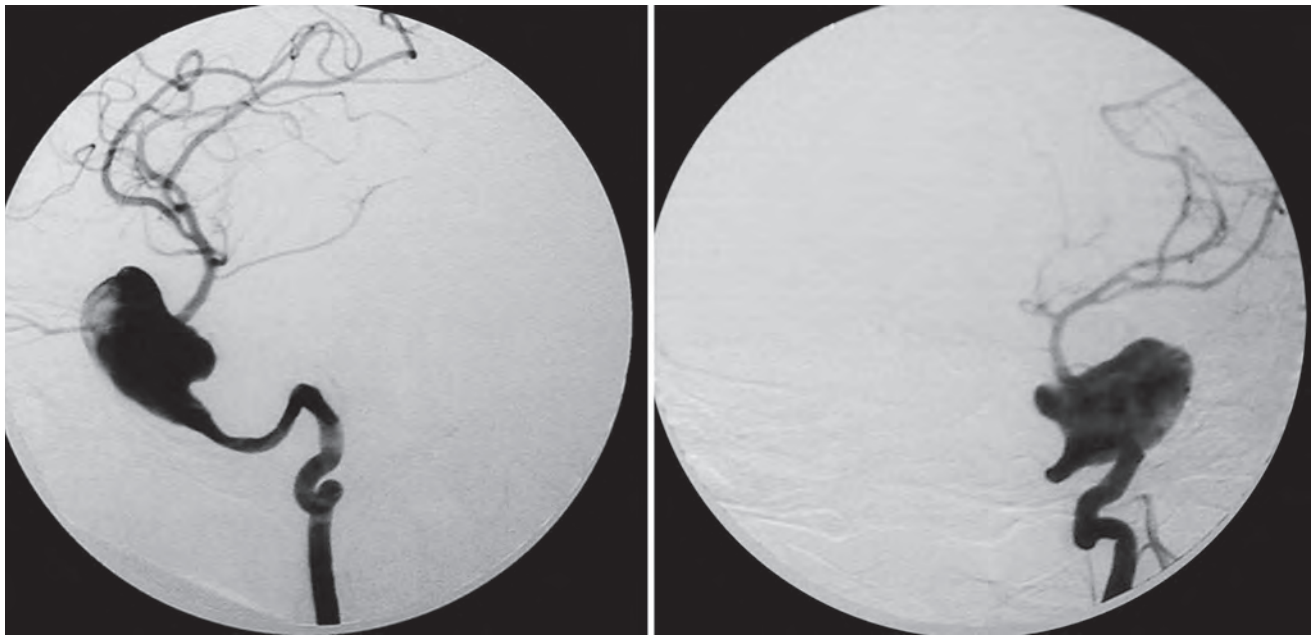

Fig. 7B: Lateral and oblique views of a left carotid angiogram showing a giant aneurysm that is occupying the cavernous, clinoidal and supraclinoidal segments of the internal carotid artery. The origin of the ophthalmic artery is from the dome of the aneurysm

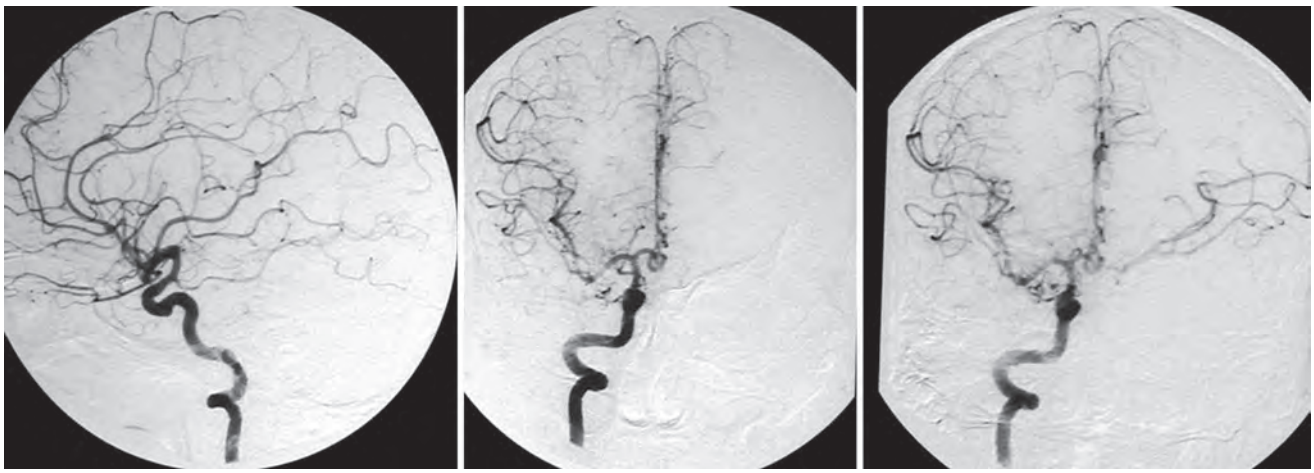

Fig. 7C: Lateral, anteroposterior and cross-compression studies showing a good cross-flow of circulation from the right to the left side. The patient also withstood 20 minutes of balloon test occlusion of the left internal carotid artery

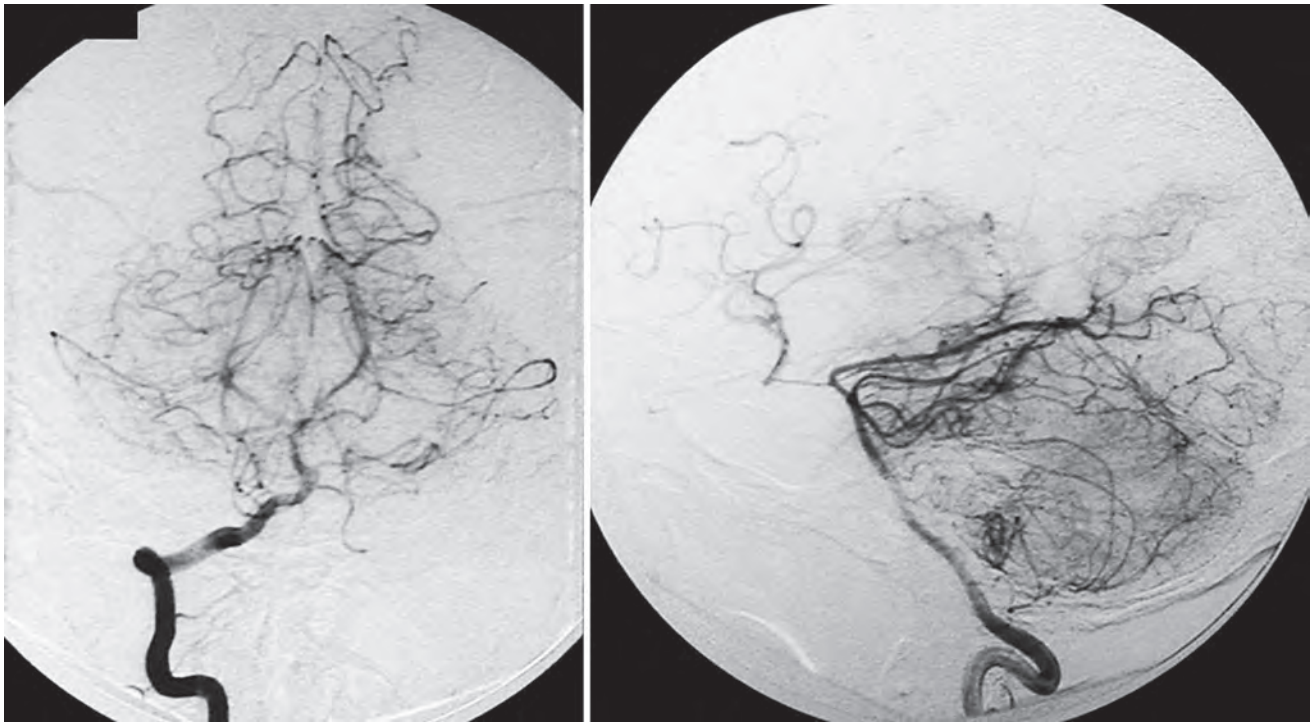

Fig. 7D: The verterbral angiogram also shows a good cross-flow to the anterior circulation through the posterior communicating artery

sinus bleeding; (C) The cavernous carotid artery may be exposed by retracting the temporal lobe laterally and incising the dural sleeve medially from the point of entry of the oculomotor nerve into the cavernous sinus up to the superior orbital fissure. The cavernous sinus is opened to extend the exposure of the ICA from the distal dural ring to the posterior clinoid process. The cavernous sinus bleeding is controlled by packing with surgicel. Within the cavernous sinus, injury to the VI nerve is prevented by remaining close to the artery, especially on its lateral aspect;[15,16] (D) Retrograde suction decompression either by the endovascular route by passing a non-detachable balloon transfemorally into the distal ICA to temporarily occlude its lumen; or, by exposing the carotid bifurcation in the neck, occluding the common and external carotid artery and applying a retrograde suction through the catheterised ICA.[11,20,31] However, in large aneurysms, the dome of the aneurysm does not collapse until it has been dissected from the surrounding structures and, (E) The petrous carotid artery may also be used for proximal control. This is located extradurally deep to Glasscock's triangle in the middle cranial fossa. The boundaries of this triangle are the groove of the greater superficial petrosal nerve coursing in an anteromedial direction in the floor of the middle cranial fossa; the mandibular nerve exiting through the foramen ovale; and, the line joining the foramen spinosum to the arcuate eminence. Exposure of the petrous ICA starts 5 mm medial to the foramen spinosum, deep and just medial to the location of the divided greater superficial

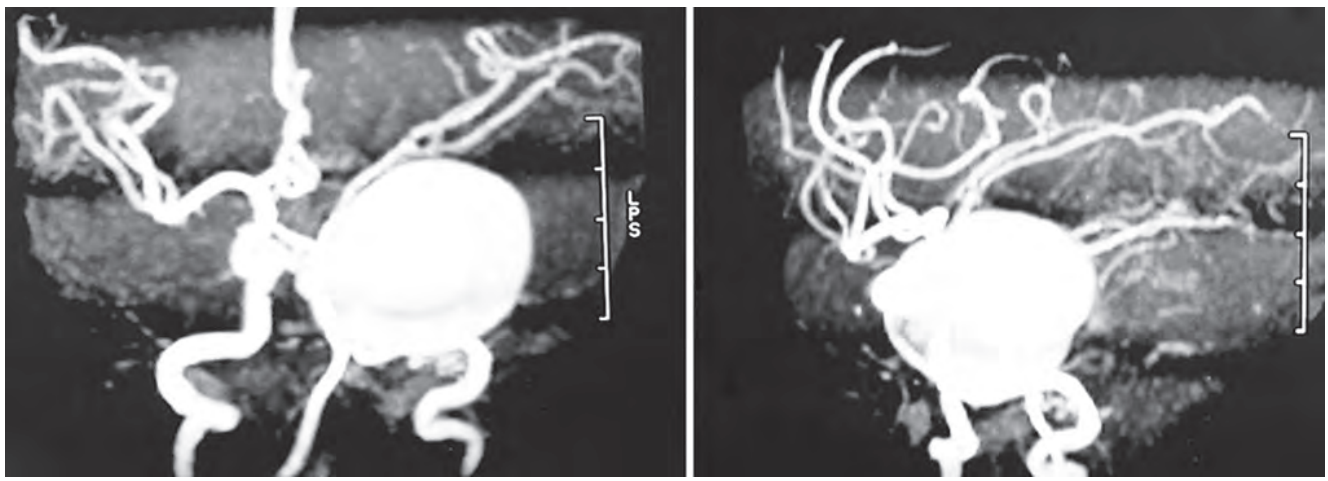

Fig. 7E: Anteroposterior and lateral images of magnetic resonance angiography (MRA) showing the giant aneurysm

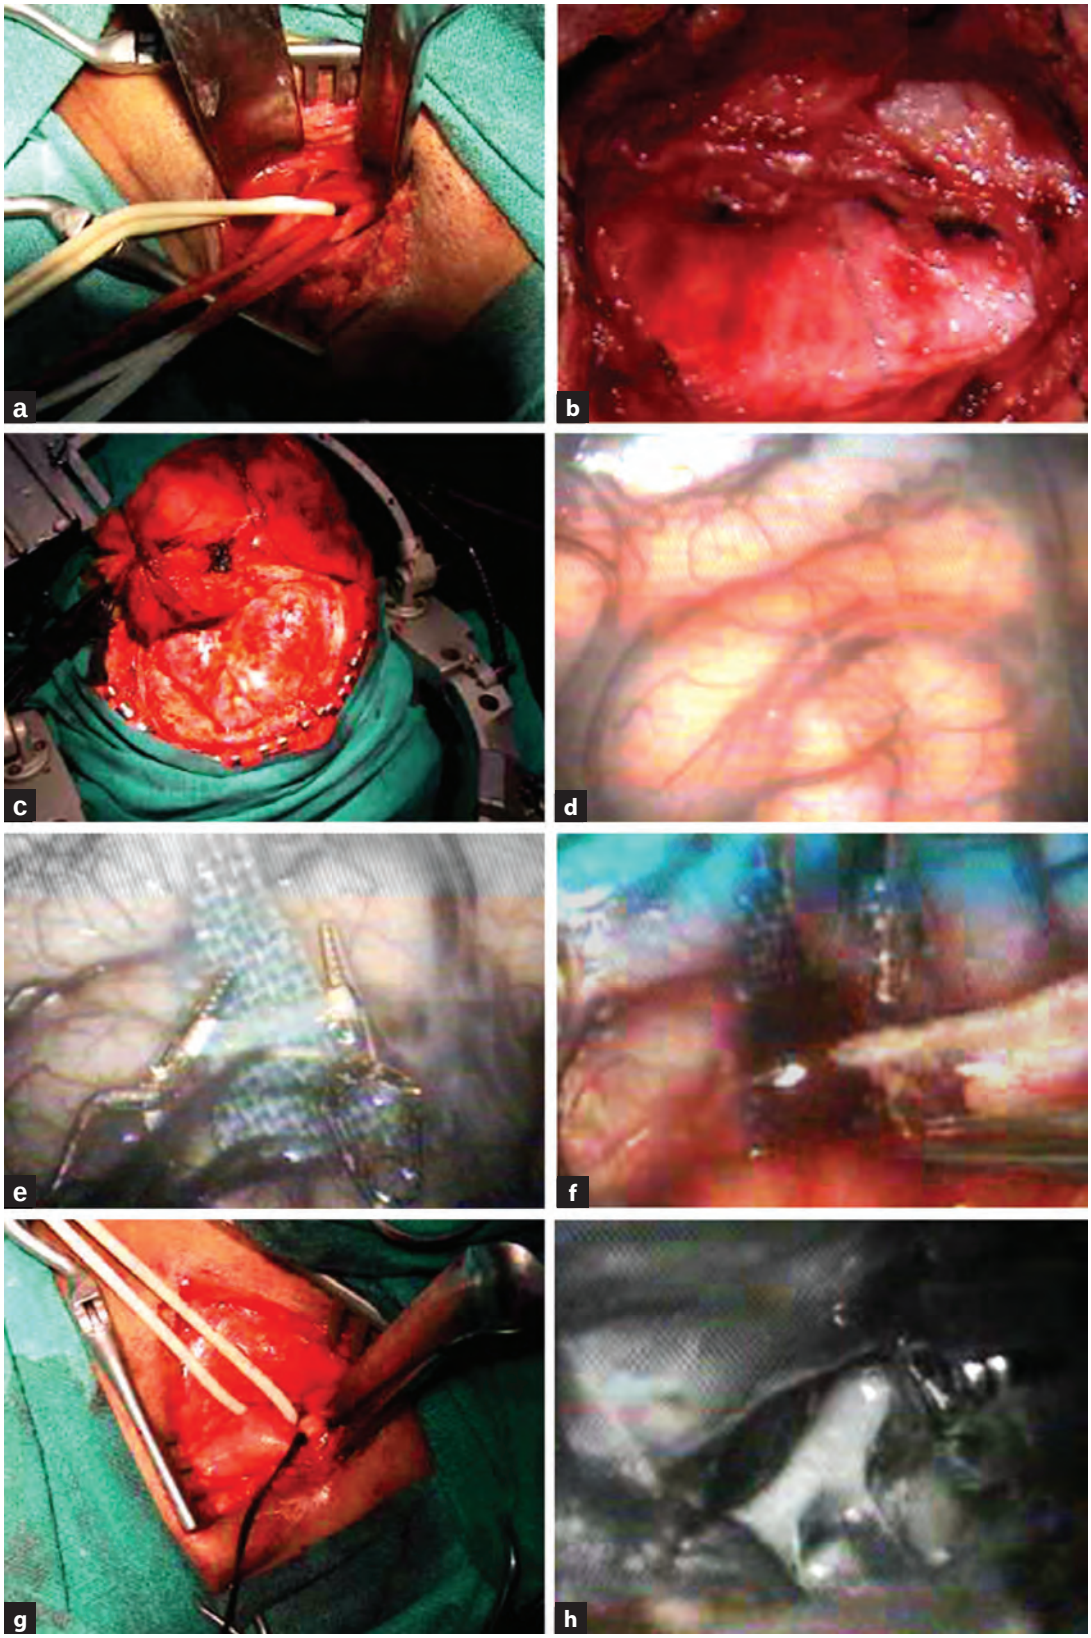

Fig. 7F (a to h): Despite a very good cross-flow to the left internal carotid artery, additional flow was also established by a superficial temporal to middle cerebral artery (STA-MCA) bypass. The operative steps of the STA-MCA bypass and left internal carotid artery trapping are shown: (a) Proximal control of the internal carotid artery in the neck; (b) Harvesting of the superficial temporal artery; (c) Performing the frontotemporal craniotomy and exposing the frontal and temporal lobes; (d) Harvesting the opercular branch of the middle cerebral artery; (e) Clamping of this artery using temporary clips, keeping it patent with heparinised saline and opening it on its side; (f) End-to-side anastomosis of this vessel with the frontal branch of the superficial temporal artery; (g) Ligating the internal carotid artery in the neck, and (h) Trapping the internal carotid artery proximal to the anterior communicating artery

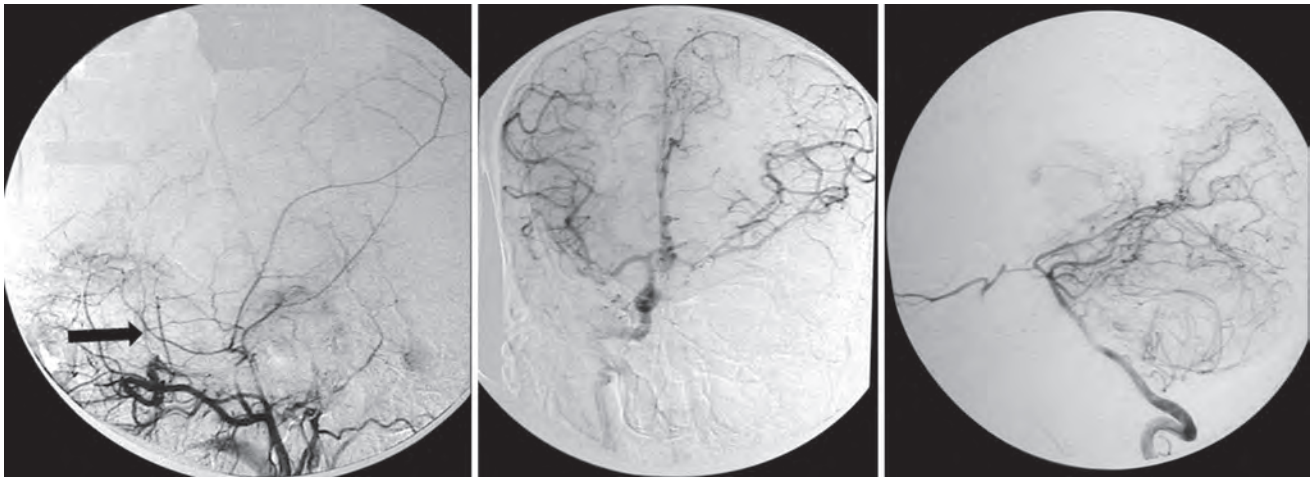

Fig. 7G: The post-operative left external carotid angiogram, anteroposterior images of right carotid angiogram and vertebral angiograms showing the supply from the external carotid artery through the bypass, and the maintenance of a good cross-flow

petrosal nerve. An extra-arterial Fogarty balloon catheter may be inflated in the carotid canal for proximal control. However, traction on the superficial petrosal nerve may cause VII nerve paresis; injury to the petrous ICA may occur, if its bony covering is not adequate; and, hearing may be lost if the drilling proceeds posteriorly towards the arcuate eminence (Fig. 8).[43]

If, despite proximal control, the sac of the aneurysm still remains turgid, then it may reflect a substantial inflow from the posterior communicating artery which requires a separate temporary clip; or, it may represent a retrograde flow to the aneurysm from the ophthalmic artery via its extensive external carotid anastomosis that may require an additional temporary occlusion of the external carotid artery. However, this occlusion, if prolonged, increases the risk of retinal ischaemia.[15]

Untethering of the Optic Nerve

One crucial feature of the approach is the unroofing of the optic canal and mobilisation of the optic nerve at its entrance to the optic canal. The dura propria over the optic nerve is incised in the centre along the long axis of the optic nerve with a hook knife; then both flaps of the falciform ligament are mobilised laterally and medially to provide an additional length of 3–10 mm of untethered optic nerve; finally, further deroofing of the optic nerve is carried out by drilling the osseous optic canal, the anterior clinoid process and occasionally parts of the tuberculum sellae (the latter procedure is applicable for a medially directed aneurysm or for a contralateral approach to carotid-ophthalmic aneurysms).[14,20]

Anterior Clinoidectomy

Removal of the anterior clinoid process along with the roof of the optic canal provides decompression of the optic nerve, provision for proximal carotid artery control and ensures that the tips of the aneurysm clips extend past the aneurysm to ensure complete obliteration of the aneurysm neck.[2,10,16] For large aneurysms and, especially

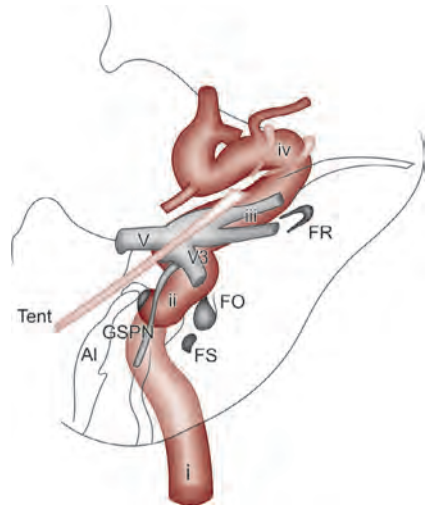

Fig. 8: Proximal control of the ICA may be obtained in the neck; (i) in the Glasscock's triangle (ii) the boundaries of which are formed by the groove of the greater superficial petrosal nerve (GSPN), the mandibular nerve (V3), and the line joining the foramen spinosum (FS) to the arcuate eminence (AE); in the cavernous sinus (iii) by retracting the temporal lobe laterally and incising the dural sleeve medially from the point of entry of the oculomotor nerve into the cavernous sinus up to the superior orbital fissure; and in the portion of the ICA between the proximal and the distal dural rings (iv). The foramen ovale and rotundum are represented as FO and FR, respectively

carotico-ophthalmic aneurysms that point dorsally, an intradural rather than extradural drilling of the anterior clinoid process is safer since it permits direct observation of the position of the aneurysm and the optic nerve during the drilling. Removal of the anterior clinoid process allows for at least 6 mm more exposure of the proximal ICA without entering the true cavernous sinus (see Figs 2A to C, 5A to F).[15,16,26]

Before starting the drilling, the anterior clinoid process is palpated with a dissector to determine whether or not it has been eroded, and also to assess the proximity of the optic nerve. The contents of the superior orbital

fissure are on the inferolateral aspect of the anterior clinoid process; the genu of the ICA is underneath and the optic nerve is medial to the anterior clinoid. The dura over the anterior clinoid process can be turned down as a flap prior to drilling or the flap can be completely coagulated to leave the bone exposed. A diamond burr is used to core out the centre of the anterior clinoid, to expose the optic nerve dural sheath and to resect the optic strut. Then a dissector is utilised to dissect out the residual shell of the anterior clinoid from the carotid artery and the cavernous sinus.[15] Bleeding from the bone can be controlled with bone wax. Removal of the anterior clinoid process may cause post-operative CSF leak, especially when the anterior clinoid is well-pneumatised and communicates with the ethmoidal sinuses. Bone wax should be applied to the open sinuses to obliterate any potential opening in them.[10,15,16]

Dural Ring Division

After removal of the clinoid process, the dural collar around the ICA is opened by slitting the lateral edge of the optic nerve dural sleeve using sharp dissection. This exposes the cave portion of the carotid artery and facilitates negotiation of the distal tips of the aneurysm clips beyond the neck of the aneurysm in order to ensure a proper clipping (see Fig. 2C).[15,36]

Dissection

Dissection of the aneurysm should not be done till the clinoid process has been removed and the distal dural ring has been opened. After the clinoidectomy, the arachnoidal dissection around the aneurysm and the branches of the ICA is performed and the ophthalmic artery identified. The ICA branches and the perforators in close proximity to the aneurysm are dissected away from it. This may be facilitated by a gentle temporary deflection of the aneurysm sac. In unruptured aneurysms, the dome of the aneurysm may be dissected from the surrounding adhesions to promote its collapse. In order to avoid traction of the optic apparatus, the aneurysm sac is dissected off from the optic nerve and chiasma before it is completely collapsed.[15,16]

Clipping

For clipping these aneurysms, the clip blades must assume a path parallel to the parent vessel. Long straight, side angled or angled fenestrated clips may be required to secure these aneurysms (with the carotid artery placed within the clip fenestration). The clip should be long enough to completely cover the neck but not to impinge upon the ophthalmic, superior hypophyseal, posterior communicating or anterior choroidal arteries.[6,14,15,16]

For aneurysms with a large neck, clips may have to be applied in a tandem fashion (Fig. 9). If the sac is large, the closing force of the clips may not be sufficient to keep the neck of the aneurysm obliterated. This may require fenestrated straight clips placed perpendicular to the tandem clips and the long axis of the ICA. In case of a long neck, neck shortening may be performed using bipolar coagulation with constant irrigation. When multiple tandem clips are being used, care should be taken that the pulsations of the sac do not force the clips down against the parent vessel, thus obliterating its lumen. Care should also be taken to see that the optic nerve is not deflected after clip placement.[15,16,36] In heavily calcified or atherosclerotic aneurysms, the clip should be placed slightly away from the neck and closer to the fundus in order to prevent rupture of the vessel wall.[16]

Accessing Bilateral Carotico-ophthalmic Aneurysms via the Same Approach

If bilateral carotico-ophthalmic aneurysms are present, after clipping the ipsilateral aneurysm, consideration for securing the contralateral aneurysm may be given only if: (1) the contralateral aneurysm is unruptured, since to obtain proximal control from the contralateral approach is difficult; (2) the aneurysm is superiorly or medially directed so that it can be accessed under the contralateral optic nerve; (3) during its expansion, the aneurysm displaces the optic nerve superolaterally and the chiasma superiorly; (4) the aneurysm is small so that only minimal dissection is required and, (5) some drilling of the tuberculum sellae is performed to completely expose the aneurysm.[14,20]

The limitations of the contralateral approach include the danger of visual apparatus damage while working through the narrow corridor between the optic nerves; the danger of opening the sphenoid sinus during drilling of the tuberculum sellae; the difficulty in opening of the optic canal and in the removal of the optic strut from the contralateral side; and the lack of proximal control of the ICA by the contralateral approach.

Precautions during Surgery

Prevention of Optic Nerve Injury

While unroofing the optic canal, the dura covering the optic nerve must not be disrupted by the drill. The field is continuously irrigated using saline in order to avoid thermal injury to the optic nerve. The artery may be retracted laterally after its complete exposure and extensive mobilisation in order to access the carotid-optic space, and a medial exposure of the optic nerve must be avoided. Before incising the distal dural ring, the ophthalmic artery must be clearly identified. The microvasculature of the optic nerve must be meticulously preserved by keeping its pial covering intact during the opening of the dura propria.[16]

Avoidance of Cerebrospinal Fluid Rhinorrhoea

The frontal sinus may be opened during the craniotomy. The sphenoidal and posterior ethmoidal sinuses may be opened during the anterior clinoid resection. Both must be properly sealed using bone wax.[10,32,33]

Avoidance of Arterial Lumen Compromise during Aneurysm Clipping

While placing the clips tangential to the ICA, care should be taken to see that the lumen of the vessel or one of its main branches or perforators is not compromised. A Doppler ultrasound or intra-operative angiography may be used to ensure the patency of vessels and the requirement for readjustment of clips.[15] In case ICA trapping is done, a saphenous vein or superficial temporal to middle cerebral bypass may be performed to prevent brain ischaemia.

Outcome

During the management of paraclinoid aneurysms, the surgical complications associated with permanent morbidity include visual deficits (approximately 3%), ICA occlusion (approximately 2%) and embolic stroke (approximately 1%). The endovascular procedures are associated with an embolic stroke rate of approximately 2.5%, and an overall immediate morbidity rate related to the GDC procedure of approximately 9% (aneurysm perforation, unintentional parent artery occlusion and embolic stroke). The overwhelming cause of morbidity and mortality in both the surgical and the endovascular groups is vasospasm-related ischaemia in patients with SAH, which may be managed with Triple H therapy, intra-arterial papavarine infusion and angioplasty.[17,22,42]

For successful management of paraclinoid aneurysms, the following are essential requirements:

- An understanding of the three dimensional anatomy of the paraclinoid region and the radiological assessment of the ICA and the aneurysm and the surrounding structures.
- The acquisition of the surgical skills for high speed drilling close to the aneurysm, drilling the anterior clinoid process, controlling the proximal ICA, mobilisation of the optic nerve, dissection of the perforating vessels, application of various complex clip configurations and the utilisation of adjunctive measures like cerebral protection and proximal ICA control.
- The development of the capability for alternative therapeutic strategies, like endovascular procedures, that can preserve the arterial lumen and provide a lasting repair, using stents, coils or both.

80 Internal Carotid Bifurcation Aneurysms

Mathuriya SN

INTRODUCTION

Non-traumatic subarachnoid haemorrhage (SAH) accounts for 5–10% of all strokes. The overall worldwide incidence of SAH is 1.1–96/100,000 population, the average being 10.5 as reported in various studies. The lowest incidence is in the Middle East, and the highest in Scandinavian countries, more so in Finland.[2] In the Indian population it is somewhere in between. A very low incidence was reported in India in the earlier years.[11,28] There is a female preponderance of 1.3–1.6. The incidence of aneurysms increases with age, and it plateaus by the fourth decade. Internal carotid bifurcation aneurysms (ICBA) constitute the main group in children (26–29.5%).[20] A familial association of SAH with intracranial aneurysms has been described. Internal carotid artery (ICA) aneurysms can be classified into seven groups based on the site of origin, wall morphology, and clinical and surgical behaviour: (a) ICA extracranial, (b) ICA petrous and ICA cavernous, (c) ICA ophthalmic, (d) ICA wall, (e) ICA-PCoA (f) ICA-AChA and (g) ICA bifurcation.[18]

Arterial bifurcations are sites of maximal haemodynamic stress, where cerebral aneurysms commonly develop. In ICBA, the neck may not necessarily exist exactly at the ICA bifurcation and it often deviates slightly to the M1 or A1 side.[27]

Most of the aneurysmal necks deviate to the side of the anterior cerebral artery (ACA). Aneurysms tend to arise at the junction of the ICA and the A1 segment of the ACA rather than at the junction of the ICA and the M1.[27]

ICB aneurysms constitute 5% (2–9%)[18] of all intracranial aneurysms. This forms 7.9% in our series. There is a male predominance.[18,20] The ICA bifurcation is the commonest site in children, and they have a better outcome than their adult counterparts. ICBA represented 18% of all ruptured intracranial aneurysms before the age of 30 years.[18]

Amongst ruptured ICA aneurysms, in the author's series, 16% were at the bifurcation of the ICA. These are relatively uncommon and frequently rupture at a younger age compared to others.[14,38] Around half of these aneurysms rupture, of which 50% are smaller than 7 mm.[18] These have an embryogenetic factor responsible for their origin.[27] Mean age of presentation at the time of rupture is 41 years. In the younger age group (less than 20 years of age) these constitute more than 40% of all intracranial aneurysms. The probable risk factor could be arterial wall defects and wider angle of the ICA bifurcation. Around 7% of ICA bifurcation aneurysms are giant. Multiple aneurysms are seen in 43% of patients and the most frequent site of another aneurysm is on the MCA. Bilateral ICA bifurcation aneurysms occur in 6%.[28] Rebleeding occurs in 30–33% before clipping. Angiographic vasospasm is present in 33–63% of ICBA.[14,16,24,25,29,35]

No clinical symptomatology is specific for ICBA. SAH is seen in the anterior cisterns in 92% of patients on CT scan.[9] There may be an intracerebral haematoma (ICH) in the orbitofrontal gyrus (9.5–20%).[16,18,25,35] Fluid attenuated inversion recovery (FLAIR) sequence of MRI has recently been shown to be effective for detecting SAH in the subacute period when CT sensitivity decreases. Lumbar puncture (LP) detects blood in 98% of SAH patients. Uncommonly, when the aneurysm grows to a large size, it can cause pressure on the medial temporal lobe leading on to seizures. Sometimes, if the aneurysm is totally medially directed, it can compress the anterior third ventricle leading to hydrocephalus. ICBA are of median size of 8 mm (range 2–60 mm) in 52% and are associated with ICH in 15–19% and SDH 1–2%.[28] The ICH, when present, is located in the frontal lobe in 73%. Intraventricular haemorrhage leads to a dismal prognosis.

Digital subtraction angiography (DSA) confirms or excludes an aneurysm. Around 2–5% of aneurysms which are missed on the initial study due to vasospasm are detected on repeat DSA. Magnetic resonance angiography (MRA) can effectively demonstrate large aneurysms. CT angiography (CTA) reveals most aneurysms larger than 2–3 mm. This has a high diagnostic accuracy with false negative results in very small aneurysms. Around 99% of ruptured aneurysms of 3–4 mm can be recognised by CTA.[6,32]

The CTA also visualises the neck from all sides and the exact relation of branches to the neck and fundus.[20] It delineates details of the fundus, neck and relations to the branches and, sometimes, this proves a better investigation than DSA in large/giant complex aneurysms (as far as visualisation of large branching vessels is concerned, but not the perforators). The CTA lacks visualisation of

dynamicity of the circulation and visualisation of perforators.[32] It is mandatory to preserve flow in all the perforators surrounding or adherent to the aneurysm dome. A detailed pre-operative knowledge of the presence and extent of atherosclerotic plaques in the parent artery, the aneurysm base and presence of associated aneurysms is required. A mental spatial view of the angioarchitecture of the ICA bifurcation and its relation to the surrounding structures is formulated, which is necessary for proper orientation during the microsurgical dissection. CTA does miss small incidental aneurysms. CTA, being a non-dynamic study, provides no information regarding collateral circulation, hence, on many occasions it may not be used as the only imaging modality for ICBA (Figs 1 and 2).

Conventional four vessel angiography, DSA or 3D DSA are the diagnostic imaging methods. Many projections and angles, e.g. anteroposterior, lateral, forward oblique, reverse oblique and basal views, are used. These are to delineate the aneurysm sac, its direction, projection, neck size configuration and straddling on to initial M1/A1, perforators and their relation to neck/sac, status of vasospasm, extent of cross circulation and any other associated aneurysms.[33] The 3D DSA provides not only 3D visualisation of the endoluminal image, but also provides most precise correlation between rotational images and actual findings at surgery (Figs 3 and 4).[33] For intra-operative navigation, 3D CTA and/or DSA should be rotated to illustrate (a) the angioarchitecture of the ICA bifurcation and its relation to the skull base, (b) projection of the ICBA dome and its relationship to the A1 and M1 segments and (c) the probable site of rupture. Sometimes, in giant complex partially thrombosed aneurysms, it may not be possible to obtain all the details particularly involvement/take off of M1 and A1 and these may be from the aneurysm sac itself. For this purpose 3D CTA may be a useful modality particularly the angioscopic views.[32]

ANATOMY

The ICA, after emerging from the cavernous sinus, traverses in the carotid cistern and gives off the ophthalmic (Oph. A.), superior hypophyseal (SHAs.), posterior communicating (P.com) and anterior choroidal (Ach) branches. The P.com can be absent altogether in up to 14% of cases. The Ach may arise as a single trunk or as multiple vessels from the posterolateral surface of the ICA. Preservation of the Ach during different steps of dissection for ICBA or temporary clipping is

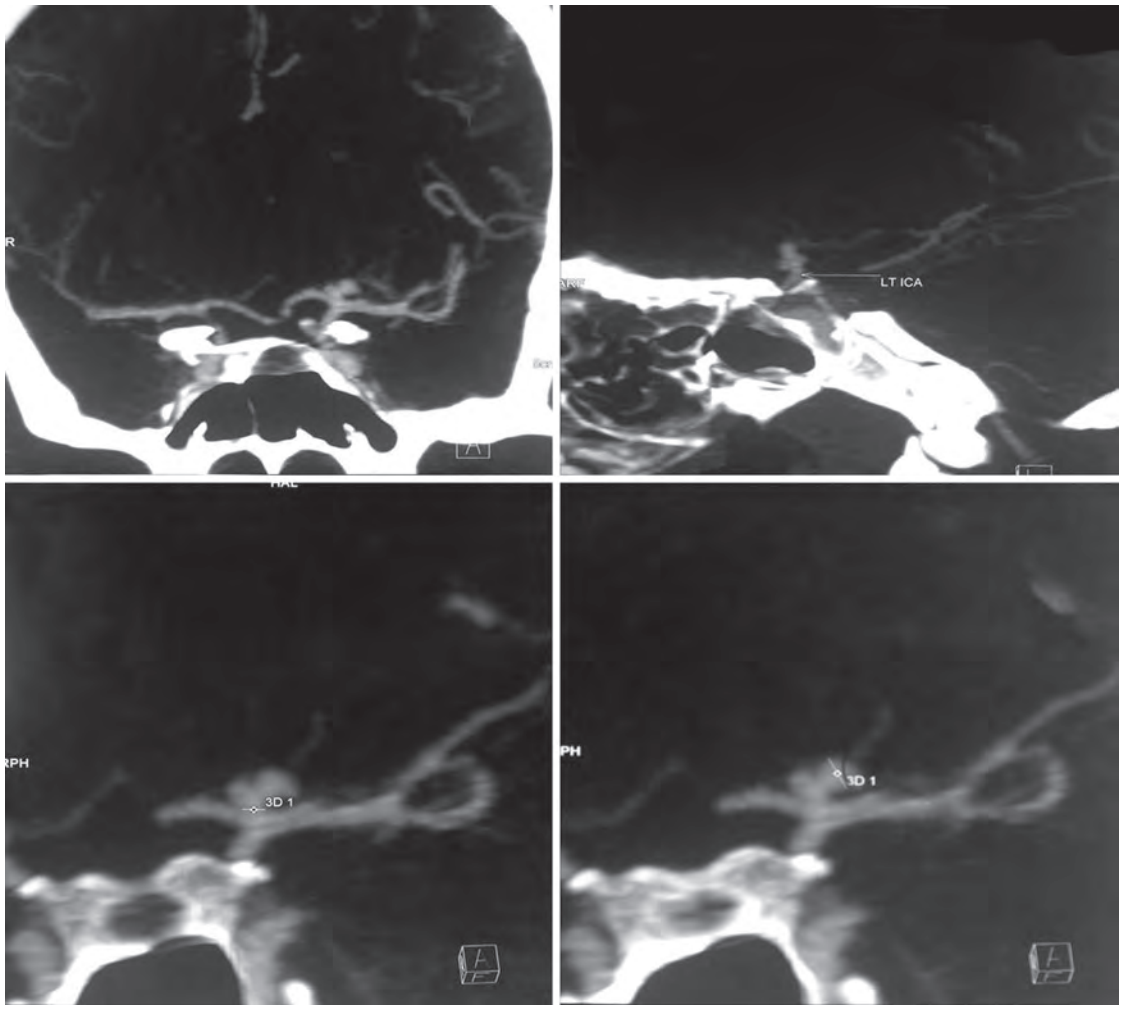

Fig. 1: CTA showing bilobed ICBA

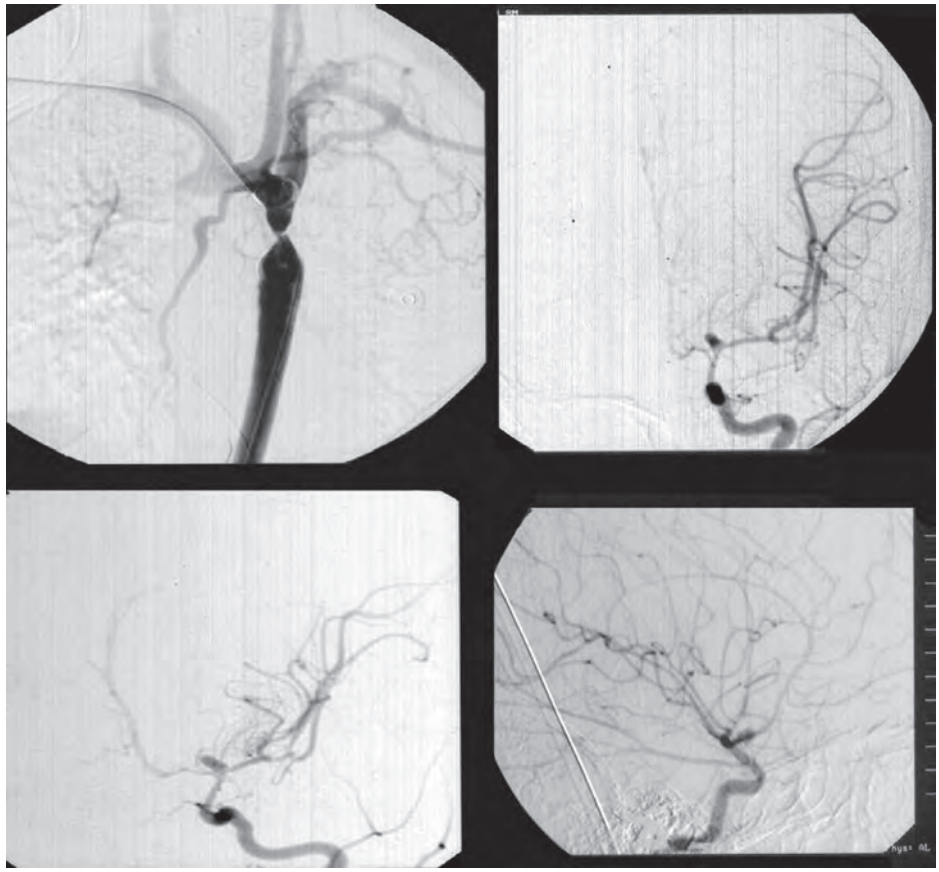

Fig. 3: DSA showing coarctation of aorta and left ICBA

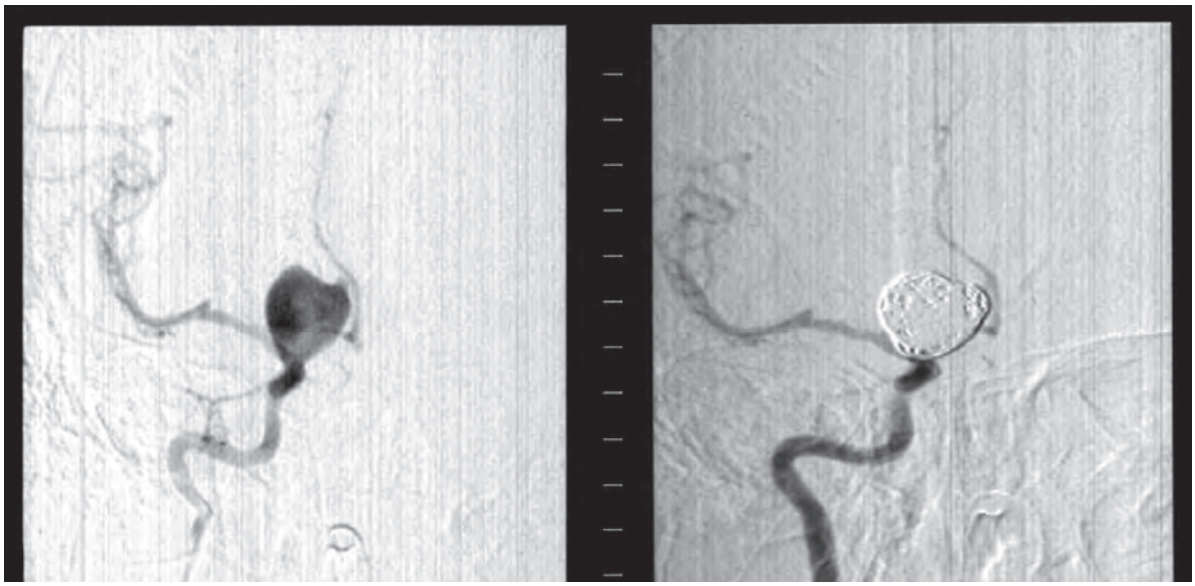

Fig. 4: DSA—large right ICBA—coiled

of paramount importance. After its origin in the carotid cistern, the Ach enters the crural cistern with a postero-medial course and is often found behind the ICA bifurcation. The Ach traverses lateral and inferior to the optic tract, passes through the wing of the ambient cistern to enter the choroidal fissure. Uncal arteries usually originate distal to the Ach, from the very proximal part of the MCA, from the anterior wall of the ICA 3–5 mm proximal to its bifurcation or rarely from the proximal A1 segment. Infrequently, up to 3 small perforators arise from the posterior wall of the ICA and pass to: (a) the optic tract, (b) the premammillary part of the floor of the third ventricle, (c) the optic chiasm and (d) the infundibulum. They rarely enter the anterior/posterior perforated substance (APS/PPS). The perforating branches of the choroidal segment (average, 4; range, 1–9) arise from the posterior half of the ICA wall, pass upward and terminate in: (a) the APS, (b) the optic tract and (c) the uncus. Some of these perforators may also arise from the ICA bifurcation. For temporary clipping in ICBA, a comprehensive knowledge of the possible sites of origin and trajectories of these small branches and perforators is of great utility and safety.[28,37] The vessel then passes postero–supero-laterally and bifurcates. The calibre, direction and tortuosity of the vessel vary, as also the length. The bifurcation can be comparatively anterior or deep. The ICB is the deepest portion of the anterior part of the circle of Willis. This usually lies lateral to the optic chiasm, inferior to the APS and at the medial most end of the Sylvian fissure. ICBAs point upwards in the direction of the long axis of the prebifurcation segment of the ICA towards the APS.[8] In case of a long ICA, the ICB may lie in the Sylvian cistern. The APS is bounded by the olfactory trigone, optic tract and uncus. This triangular field of grey matter is studded with entry sites of perforating vessels. These vessels are known to arise from M1, A1, recurrent artery of Heubner (RAH), P.com and Ach.[8] The ICB lies at the convergence of the cisterns of the anterior and middle cranial fossa.[8,20]

Arteries related to the ICB area are ICA, ACA, MCA, perforators from A1, M1 (medial and lateral striate), RAH, Ach, diencephalic branches of P.com and temporal branches of MCA.[38] There are a large number of perforating branches with their course behind the ICA bifurcation. These arise from: (a) the choroidal segment of the ICA, (b) the Ach, (c) the RAH, (d) the medial lenticulostriate arteries (MLAs) and (e) the lateral lenticulostriate arteries (LLAs).[28] Relation of the ICA and the optic nerve can vary from a parallel course of the artery and the nerve to a concave or convex course in relation to the nerve.

Anatomical variations of ICA, M1 and A1 may affect intraoperative orientation during dissection of ICBA: (a) hypoplastic ICA, (b) absent ICA, (c) ICA trifurcation, or (d) persistence of foetal remnants. A hypoplastic ICA diminishes in calibre at or shortly distal to its origin. In these cases, the petrous and sellar segments may also be absent. Hypoplasia or aplasia of the ICA occurs in less than 0.01% and only 100 cases have been described in the literature.[18]

Three major patterns of collateral circulation have been described in hypoplasia/absence of the ICA.[30] Carotid trifurcation is a unique and unusual anatomical variant where three arterial branches arise from the carotid termination.[13] This may result either from anomalies of the carotid termination itself, from accessory origins of the Ach at the ICA termination or from absent M1 portion of the MCA. When the M1 segment is absent, the MCA bifurcation is located at the ICA termination and both the frontal and the temporal M2 branches arise at the ICA termination itself. The frontal M2 may even be hypertrophied like a normal M1. The branches include the ACA and the two M2 portions of the MCA. The P.com and Ach originate at their usual

location. The other variant includes an accessory MCA arising at the carotid termination which is a residual congenital remnant of the foetal MCA. The most proximal segment of the primary cranial division of the foetal internal carotid gives off the Ach first, the second collateral is the MCA and the next segment is the stem of the ACA.

The embryonic origins of a duplicated MCA and accessory MCA are still not clear. Theoretically an aneurysm located at the carotid trifurcation may arise between any two branches arising at the trifurcation. Depending on the location and the size of the aneurysm, the perforators, especially the MLAs, may course along or wrap over the body of the aneurysm arising between the ACA and the MCA like any other standard ICBA. The perforators arising from the distal carotid, medial ACA and even the RAH may be in close relation to the aneurysm.

When the aneurysm arises between the two M2 vessels originating at the carotid termination, the MLA perforators may be in close proximity and need to be protected during dissection and clipping. These anatomical variations should be identified pre-operatively and displayed during surgery before clipping is attempted.[13]

Anterior cerebral and Sylvian veins converge in the area of ICB and reach the sphenoparietal and cavernous sinus. The deep venous system includes anterior cerebral, deep middle cerebral and basal vein of Rosenthal, and these are located inferior to the ICB.[38] The supraclinoid ICA, origins of its branches, and the fronto-orbital veins draining into the sphenoparietal sinus are all within the carotid cistern.

Aneurysms in this location vary from 3 mm to giant aneurysms. This is a common site for giant aneurysms to occur. These aneurysms are broad based and the neck extends on to the A1 or M1 side from the ICB. The relationship of the aneurysmal sac to the structures around depends on the direction and projection of the fundus, which could be superior, posterior or inferior.[4] Projection of the fundus is superior in 56%, posterior in 18%, anterior in 20% and inferior in 6%. A detailed knowledge of the ICBA which includes projection of the dome (anterior, superior, posterior), anatomy of the perforators, relation and calibre of main vessels is important for planning the approach. The anteriorly projecting ones arise from the anterior aspect to project into the lateral orbitofrontal gyrus or the base of the olfactory tract. The superiorly projecting originates from the superior aspect of the ICA bifurcation with its dome projecting into the APS, the lateral portion of the lamina terminalis cistern, or the Sylvian cistern. Posteriorly projecting ICBAs originate from the posterior aspect of the ICA bifurcation with their dome projecting into the carotid, interpeduncular or even the ambient and crural cisterns.

These aneurysms are covered by arachnoid from the carotid, olfactory, lamina terminalis and Sylvian cisterns. When the aneurysm grows, it occupies the Sylvian cistern and cistern of the lamina terminalis and compresses the M1, A1 and the perforators which are displaced around the aneurysm. Disposition of arterial branches around will depend on the direction of the fundus and its projection. A postero-inferior projection is into the IPC and crural cistern and is related to diencephalic branches of the Ach and P.com. An enlarging aneurysm widens the crotch of the ICB and may displace the A1 and M1 inferiorly or laterally depending on the direction and growth of the fundus. The dome may get buried into the surrounding brain parenchyma, and is surrounded by a large number of perforators from A1, M1, RAH, Ach and P.com. These perforators lie posterior to the aneurysm sac, but their proximity and adherence will depend on the extent and projection of the fundus. These are more bound in posteriorly directed lesions. Sometimes, the temporal arteries are also pushed and are adherent to the aneurysm wall in giant aneurysms.[31]

PRE-OPERATIVE EVALUATION

Clinical evaluation, investigations and medical management are the same as for all other patients with aneurysmal SAH in other locations. Blood pressure is maintained. CSF drainage, if necessary (through lumbar or ventricular route), is performed to lower the intracranial pressure (ICP). This is the same protocol as in patients with aneurysmal SAH in other locations. An acceptably lax brain is mandatory as the location of ICB is deep as compared to most of the other aneurysm locations.

Position and Skin Incision

The patient is positioned supine with the vertex tilted 10–15 degrees below the horizontal plane. The head is rotated from the midline by 30–60 degrees depending on the projection of the aneurysm to allow proximal control and optimal exposure of A1 and M1. As already described, these aneurysms typically point in one of the three directions: (1) superiorly; (2) posteriorly or inferiorly and (3) anteriorly.[26] In case of supero-medial projecting aneurysms along A1, the head is turned 60 degrees from the vertical plane. Posteriorly directed aneurysms accompany the MCA and occupy the Sylvian cistern and, hence, the head needs to be turned 30–45 degrees. Inferiorly directed aneurysms drape down over the posteromedial aspect of the ICA and may enter the IPC and the head tilt should be the same as for posteriorly directed ones. Anteriorly directed aneurysms are less common and are along the ICA; hence a tilt of 30 degrees is adequate.[4,18,20,23] The malar eminence is at the highest level with the lesser wing of the sphenoid perpendicular to the floor.[28] Extent of craniotomy depends on the surgeon's experience, the projection of the ICBA, and the presence of ICH.

A frontotemporal (FT) semicoronal incision is made beginning at the superior border of the zygomatic arch close to the tragus and anterior to the superficial temporal artery (STA), which should be preserved. The incision proceeds superiorly and posteriorly, curving anteriorly

to end just behind the hairline in the frontal region.[9,32,33] In 1984, Yasargil[38] described the standard pterional craniotomy and subsequently reported a modified procedure for reconstruction of the temporalis muscle avoiding facial nerve injury.[36] In the 1990s, several modified techniques were proposed. The aim of the approach is maximum surface exposure and minimum brain retraction. Facial palsy and post-operative temporalis muscle atrophy along with discomfort/pain should be avoided. A musculocutaneous flap avoids facial nerve injury, but a thick pad of temporalis is a hindrance to the basal approach. Hence, an interfascial dissection is mandatory. The interfascial approach and removal of a part of the orbital roof and sphenoid wing greatly increases the exposed area at the base of the surgical pyramid. The frontotemporal branch of the facial nerve overlies the temporalis muscle. The temporal fascia is present from the origin of the temporal muscle along the superior temporal line (where it is continuous with the galea) to the zygomatic arch. The facial nerve, after emerging from the stylomastoid foramen, courses anterolaterally over the ramus of the mandible into the substance of the parotid gland where it divides into five main branches. The frontotemporal (FT) branch can be injured during pterional craniotomy. The three twigs exit the parotid gland to run in the subcutaneous tissue. The posterior branch has a very short course. The middle and anterior branches continue in the subcutaneous tissue 1 cm anterior to the STA. The middle branch courses anterocephalad to innervate the frontalis muscle. The anterior branch courses anteriorly and 1–2 cm above the zygoma to innervate the orbicularis oculi and corrugator muscles. An attempt should be made to maximally retract the temporalis muscle from the temporal fossa without injuring the FT branch of the facial nerve. The skin incision is not extended too deep, rather continues superiorly to the temporal crest then curves sharply anteriorly. The galea is then separated from the pericranium and the temporal fascia is exposed within 4 cm of the orbital rim. At this level the anterior part of the temporal fascia divides into two layers separated by a 5–6 mm thick sickle shaped pad of fat. The two layers of fascia are attached to the outer and inner border of the zygomatic arch. The fat layer is dissected apart carefully with a knife and reflected with the superficial layer and the skin flap; hence the FT nerve coursing superficially along the fascial layer is protected. The temporal fascial attachment to the medial surface of the zygomatic arch is incised and carried anterosuperiorly along the superior temporal line releasing the temporal fascia and aponeurotica muscle periosteum. The temporalis muscle is then reflected and rotated inferoposteriorly.[36] An additional fascia periosteal cuff is made along the superior temporal line to facilitate subsequent muscle closure.[20]

The author raises a slightly larger scalp flap and further retracts posteriorly, so as to handle a very thin portion of temporalis posteriorly. A small cut is made in the temporalis lateral to the key burr hole and then raising an osteoplastic flap. This causes less handling of the temporalis and utilises the advantages of an osteoplastic flap. The key burr hole is properly centred (just inferior to the convergence of the inferior frontal bone, greater wing of sphenoid and frontal process of the zygomatic bone). The anterior cut should be flush with the supraorbital margin. In addition to the pterional flap, the temporal squama and the lateral 2/3 of the lesser wing of the sphenoid are drilled/nibbled. These manoeuvres are necessary to facilitate the opening of the anterior Sylvian fissure and minimise brain retraction. The exposure required is comparatively more for these aneurysms located in the deepest portion of the anterior portion of circle of Willis.

Brain relaxation is obtained by proper head positioning, venous drainage, normal ventilation and administration of mannitol and furosemide at the time of the last cut in the skull flap. In case the brain is not slack, the IPC and lamina terminalis are opened to release CSF. Intraoperative ventricular puncture is rarely required. The CSF can also be drained through a lumbar catheter. An adequately lax brain is mandatory to avoid excessive brain retraction.

To achieve a safe exposure, dissection and clipping the following points must be adhered to:

- Specific microsurgical approach dictated by the direction and projection of the aneurysm and length of the supraclinoid ICA.
- Wide exposure of the Sylvian fissure, parent artery, main arteries and perforators.
- The arachnoid over the Sylvian fissure is stretched with the help of a fine suction tip. This is placed on the inferior frontal gyrus on the right side and the superior temporal temporal gyrus (STG) on the left side. The Sylvian fissure may be full of blood clots or may be collapsed due to oedema. The superficial layers of the arachnoid are cut medial to the superficial Sylvian vein.
- Arachnoid is separated and cut.

The dissection in the Sylvain fissure is performed with the help of suction tip, ballpoint dissector and microscissors. The main dissection and separation is performed with the help of fine tipped bayonet or bipolar forceps. A few small bleeding points on adjoining cortical surfaces need to be coagulated. The major Sylvian veins and tributaries, even the superficial ones, are not sacrificed. There are two small veins one at the middle of the posterior limb and another at the medial end of the Sylvian fissure which cross through the Sylvian fissure. These may be coagulated and cut to obtain proper exposure of the Sylvian cistern. As an initial step, dissection of the Sylvian fissure is performed only superficially. The remaining part of the Sylvian cistern dissection, whether prior to or after carotid cistern dissection, will depend on the projection of the aneurysm fundus and length of the supraclinoid carotid.

When the ICA is short, the dissection is performed from proximal to distal (carotid cistern). This is contrary

to when the ICA is long or the aneurysm is large/giant complex and anteriorly projecting when the Sylvian fissure must be widely opened in a retrograde manner to avoid excessive retraction in exposing the ICB.

The incision in the arachnoid at the basifrontal region (between ON and frontal lobe) is now extended medially to the lamina terminalis to avoid strangulation of A1 by arachnoid bands on retraction of the frontal lobe. The Sylvian fissure is widely opened incising the arachnoid trabeculae in the Sylvian cistern. However, the MCA is not skeletonised. Thick clots in these cisterns are removed by flushing with saline. Clot removal necessary for dissecting the vessels should be picked up and removed by sharp dissection (microscissors). The laterobasal frontal lobe is elevated. A small artery from the ICA to the dura over the anterior clinoid is coagulated and cut and the carotid cistern is opened. A careful dissection of trabeculated arachnoid bands within the carotid cistern is mandatory for mobilisation of the supraclinoid origin of the P.com which may be adherent to the dura overlying the posterior clinoid.

The ICA bifurcation complex is dissected and mobilised. After dissecting the ICA, the course of the P.com and Ach arteries is determined and the relationship of their branches while dissecting the fundus is noted. Dissection is done along the antero-inferior surface of the A1 and M1 and the extent is determined by the size and exact direction of the fundus. The A1 remains often hidden behind the aneurysm dome at this stage. In posteriorly, superiorly or inferiorly projecting ICBAs or in large and giant aneurysms, the risk of premature rupture of the aneurysm is a real challenge (Fig. 5).

The temporopolar and anterior temporal arteries are mobilised for a few millimetres to avoid retraction stretch/trauma. Wide dissection of the lamina terminalis cistern, Sylvian and carotid cisterns will help in proper delineation and tracing of adjoining arteries (A1, M1, P.com, Ach) and their branches from the origin (Ach, RAH and perforators from A1, M1, P.com and Ach).

Fig. 5: Operative photograph showing a bilobed ICBA

The recurrent artery of Heubner may loop beneath the A1 and is hidden behind the aneurysm. The M1 perforators (lateral, proximal and distal striate vessels) and A1 perforators (medial, proximal and distal) must be preserved. These originate from the inferior surface of M1 and can be identified by retracting the M1. These supply the substantia innominata, lateral portion of the anterior commissure, most of the putamen, lateral part of globus pallidus, superior half of the internal capsule, adjacent corona radiata, and body and head of the caudate nucleus. Perforators also arise from the posteroinferior surface of A1 (2–5 mm away from ICB). These supply the septum pellucidum, medial portion of the anterior commissure, pillars of the fornix, optic chiasm, paraolfactory area, anterior limb of the internal capsule, anteroinferior part of the striatum and the anterior hypothalamus.[15]

The subfrontal exposure is used for posteriorly or inferiorly directed aneurysms and is subsequently followed by temporal lobe mobilisation after coagulating and dividing temporal tip veins. The superficial Sylvian vein should be preserved, although its occlusion is tolerated without any serious consequences. However, the basal vein of Rosenthal and its tributary the medial Sylvian vein must be preserved to avoid venous infarction. These are located in relation to the ICBA.

Standard microsurgical techniques are used to prepare the aneurysm for clipping the aneurysm fundus projecting in different directions. The final step of dissection involves isolation of the aneurysm neck and separation of the perforators. Mostly the sac of these aneurysms is adjacent to perforating vessels and in many instances these perforators are adherent to the sac.[32] The aneurysm base, with the adjacent arterial branches, should be visualised before clipping. Superiorly projecting aneurysms are buried in the orbitofrontal gyrus or the base of the olfactory tract and these cases require slightly more elevation of the frontal lobe. Perforators are related to the posterior and lateral walls and the base can be approached relatively safely and controlled before dissecting the entire dome free. In such cases temporal retraction is required initially, after sacrificing temporal veins. In posteriorly projecting aneurysms into the APS or lateral portion of lamina terminalis, and also in inferiorly projecting aneurysms into the IPC or ambient cisterns both frontal and temporal retraction is required. These latter are the most challenging ICBA, but fortunately are the least frequent ones. The dome is obstructed by the ICA and so proper visualisation of the perforators is particularly difficult even in small aneurysms. These are embedded in the perforators, posing the greatest risk of their injury. These may be adherent to the dome and may be severed during retraction, dissection, coagulation, kinking, compression for haemostasis, temporary occlusion or final clipping. Identification is essential as the deficit produced may be severe. Hence, this demands an astute microneurosurgical technique, skilled, painstaking and patient dissection on and around the aneurysm. Temporary clipping as and when required under full cover of neuroprotection needs to be used.

When there is an associated ICH, a small cortical incision is made depending on the location, avoiding Broca's area, and some haematoma is evacuated to gain space. The ICH in the immediate vicinity of the aneurysm should be left in place until proximal and distal control has been obtained. Finally, more ICH can be removed at the end of operation. One should be cautious in dealing with anteriorly projecting aneurysms as retraction of the frontal lobe may risk rupture, hence, this should be avoided until proximal control of the ICA has been established. Large anteriorly projecting ICBA may initially obstruct the view towards the A1 trunk, preventing temporary clipping of the A1. The pilot clip is inserted with the temporary clips on. The aneurysm sac is then opened and eventually reshaping with bipolar coagulation is performed and the final clip is inserted. If the aneurysm dome is obstructing and hiding the visualisation of perforators it may be desirable to first place a pilot clip at the aneurysm base and proceed with dissection of their details.

The aneurysm neck is dissected free of branches of P.com, Ach, perforators from the recurrent artery, A1 and M1 with the help of small cotton pledgets and guarded microsuction compression. The microscope is angled from the frontal side and the table is tilted laterally to visualise the perforators on the temporal side and vice versa. The fundus of the aneurysm is left undisturbed.

Appropriate cleavage around the neck is created so as to clear the clip passage free from the perforators' adherence. Arachnoid adhesions between the aneurysm neck and A1 are opened. The optic tract may abut the aneurysm fundus and this should be separated from the wall of the aneurysm and A1. Sometimes the sac may be partially or fully buried in the orbitofrontal cortex. Subpial tissue resection is performed through a pial opening around the sac. This is to free the aneurysm from the fronto-orbital region and release tension, which can be precipitated by frontal lobe retraction which is kept at a minimum before this dissection. If there is a haematoma in the orbitofrontal region the same should be evacuated, at least partially.

The site for proximal control should be prepared just above the origin of the Ach. Temporary clips, if needed, should be placed at this site safeguarding the perforators. If the aneurysm neck is broad, then a straight clip can cause a kink in one of the vessels or a patent dog-ear in the aneurysm. In such a situation, a curved or fenestrated angled clip can be placed in the axis of A1 and M1 to exactly reconstitute the ICB. All venous ooze close to the base should preferably be controlled with surgicel to avoid perforator insult by bipolar coagulation. While removing the temporary clips, even the slightest resistance noted should be taken as a caution as there may be a possibility that a small branch is attached to the clip or applicator.

During clipping there are certain recommendations to be followed. Ideally the bifurcation should be reconstructed without jeopardising supply to A1 and M1. The clip is best introduced across the neck of the aneurysm along the M1 trunk, slowly wiggling the blades between the neck of the aneurysm and the ACA and the MCA as well as their branches to avoid crimping of the parent artery or "dog earing" of the aneurysm. The clip is closed slowly. However, the A1 may be sacrificed if mandatory in desperate situations (when the ipsilateral A2 is perfused from the contralateral side). The size of the clip should be slightly larger or of the size of the neck of the aneurysm. The lie of the clip for wide neck aneurysms should always be parallel to A1 and M1. In case of any resistance during clip application the area is inspected to avoid injury to vessels, perforators, neck or hidden fundus. In rare cases, bipolar coagulation at low intensity by light squeeze-release manoeuvre is performed under saline irrigation. After clip placement, inspection is made to confirm the preservation of perforators and the patency of main vessels by microvascular Doppler (IMD).[10,19] Intra-operative angiography or indocyanine green angiography (ICG, if facility is available) is performed. The distal end of the clip is visualised free from any vessels or a part of it. After the clipping, the aneurysm dome is punctured and the collapsed sac can be mobilised, coagulated, transected and removed.

Inferiorly directed aneurysms need a special mention as these are embedded amongst the perforators and are pointing into the IPC or even to the ambient and crural cisterns. The clips usually required are straight or curved fenestrated ones. The final clip should preferably be small, appropriate, properly angled for neck occlusion avoiding compromise or kinking of the main vessel lumen, branches and perforators. If bipolar reshaping is not considered, then the blade of a single occluding clip should be one and a half times the width of the base as suggested by Drake. Sugita clips have a wider opening and blunt tips in comparison to Yasargil ones so one should tailor the clip as per aneurysm architecture and status noted at dissection.

Multiple clipping using two or more clips is occasionally required for wide-neck aneurysms. Previously coiled aneurysms pose additional difficulties for adequate clip placement as there may not be an adequately free base for safe application of the clip. One has to consider removing some or all of the coils under temporary clipping to provide extra room for the clip at the base.[22]

INTRA-OPERATIVE RUPTURE

Intra-operative rupture (IOR)[1] can occur during craniotomy, after dural opening, during dissection or while clipping. Morbidity and mortality is around 30% in IOR. Earlier in the surgery the rupture takes place the worse is the prognosis. Blunt dissection causes large and irregular tears extending close or may be on to the neck whereas, most of the microtears/micropunctures are small and are at a specific site, hence can be successfully tackled without ischaemia or vessel sacrifice.

In case of rebleed during craniotomy (before bone flap removal) the procedure is postponed. If the IOR

occurs just before/soon after dural opening then continuance with the aim to clip the aneurysm will add to the trauma caused by the fresh insult. Hence, the dura is opened and a large pericranial or fascial patch is sutured to reduce ICP. The bone flap is placed in the abdominal wall. In case a large ICH in the frontal lobe is detected on intra-operative ultrasound, CT or MRI then one can go ahead with haematoma evacuation, clipping of aneurysm, decompressive craniotomy, duroplasty and post-operative ventilation.

The two most common causes of intra-operative rupture soon after initiation of the procedure are retraction of the frontal lobe and dislocation of the ICA while the aneurysm dome is still adherent to the frontal lobe. The risk is highest for anteriorly projecting aneurysms. Control is obtained via suction and compression of the bleeding site with cottonoids. Short and sudden hypotension by cardiac arrest, induced by intravenous adenosine can be used to facilitate quick dissection and application of a pilot clip in case of uncontrolled bleeding. If the rupture takes place before completing the dissection, temporary clips must be applied to the parent vessels proximally and distally, and the aneurysm is prepared for pilot clipping under local flow arrest. A small and thin-walled ICBA may rupture at its neck during dissection. In such a case, under temporary clipping, reconstruction of the base by including a small part of the parent artery inside the clip should be attempted. In case the same is not effective, a clip on a mini cotton wrap can be applied. In case the rupture takes place after starting dissection (opening of Sylvian cisterns/basal cisterns) a part of the frontal/temporal lobe is excised (depending on the direction of fundus projection). The feeding artery is reached for temporary clipping with immediate institution of neuroprotective measures. Subsequent dissection is the same, though more focussed and is to be carried out in a limited time frame.

The IOR during dissection is managed by temporary clipping under cover of already administered neuroprotectants. A small hole can be managed by suction on cotton. In case of a large hole temporary clipping and dissection is performed which are followed by permanent occlusion of the neck. In case the bleeding aperture is exposed/dissected, a tentative clip can be applied on the aneurysm just proximal to the rent in the aneurysm. Tentative clipping can either be a temporary clip or a permanent clip (mostly permanent clip) depending on the force required/extent of dissection completed at the tentative clip site. Rupture at clipping could be avoided by dissection of the neck to its total extent. Status of the neck and adjacent vessels is kept in consideration in view of plaque/severe atheromatous changes. The clip ends are never forced through any resistance. If bleeding is at the time of clip closure, the clip is removed as the application will result in increase of the size of the rent in the aneurysm. The remaining steps are the same as for IOR during dissection. After successful clipping of the aneurysm, the dome is punctured and the collapsed sac is mobilised to visualise the perforators, distal end of the clip and remaining neck if any (particularly in inferiorly directed sacs). Gradually the remaining wall of the aneurysm is moved in the clip by readjustment under temporary occlusion of the proximal artery.

TEMPORARY CLIPPING[3,12,21,23,34]

(See Chapter 83 "Middle Cerebral Artery Aneurysms")

GIANT ANEURYSMS[17,31]

Giant ICBA comprise 7% of all ICBA. The dome of a giant ICBA is usually at least partially covered by the frontal lobe and extends also into the Sylvian fissure. Perforating arteries frequently follow and/or arise from the base of these aneurysms and it may be very difficult, even impossible, to dissect them free. The large size, distorted anatomy, origins of the perforating arteries and other arterial branches originating directly from the aneurysm, calcifications at the base, and intraluminal thrombus, make microneurosurgical management of giant ICBA an extremely difficult task. Proximal occlusion or trapping is difficult even if bypass is done. Comprehensive pre-operative imaging by CTA, DSA and MRI is mandatory. The 3D reconstructions of the CTA and rotational DSA help to show the aneurysm orientation with relation to the bony landmarks and to identify calcifications, thrombus, organised thrombus and their location in the aneurysm. DSA provides important information about the flow dynamics of the ICA bifurcation complex.

Direct clip occlusion remains the most effective treatment for giant aneurysms as well. The perforators are often draped over the aneurysm neck and dome. The neck is broad most of the time, and thick walled, incorporating the origins of A1 and M1. Hence, the angioscopic views of 3D CTA are quite informative for pre-operative decision making of the extent of safe clipping. However, proximal ICA occlusion is often ineffective for ICA and other aneurysms distal to the ophthalmic artery origin. Still these patients should have a balloon test occlusion (BTO) done and, in case the aneurysm is unclippable or high risk, then a bypass procedure needs to be performed. This acts either as a prerequisite for intra-operative temporary clipping of ICA or for proximal ICA occlusion directly or endovascularly to induce thrombosis of the aneurysm.[4,17] This procedure should soon follow the confirmation of graft patency. This is to obviate any risk of aneurysm rupture due to hyperdynamic circulation following bypass and stump emboli due to delaying anticoagulation.

In addition to obtaining detailed radiological work up of giant ICBA the points to be considered are:

- A comparatively larger craniotomy flap
- Extremely lax brain
- Wide roomy exposure of the Sylvian cistern
- Satisfactory exposure of ICA, M1, A1 and P.com for temporary occlusion

- A stepwise dissection and clipping of the aneurysm dome/body using a tentative clip and then proceeding towards the base to achieve the desired complete occlusion
- Assessment of size of the neck and its contents
- Relation of the neck to the origin of the M1 and A1 so as to exactly assess the safe clippable portion of the aneurysm sac. Intraluminal thrombus can be removed and a temporary clip is applied at the patent portion of the aneurysm
- Working out the location of organised clots/plaques in relation to the aneurysm neck on MRI, CT/CTA+DSA
- Disposition of vessels around are visualised at surgery and are cautiously dissected.

In addition to all neuroprotective measures, intraoperative evoked potential monitoring and IMD/ICG to assess patency of vessels after clipping are needed.

Utmost care is needed not to damage the surrounding perforators. Once the dome is decompressed and if the aneurysm wall is not heavily calcified, it is usually reduced by bipolar coagulation to allow for final dissection of the neck, before deciding how to perform the final clipping. Giant ICBA often require complex clip reconstruction. Multiple clips are applied to ensure complete occlusion of the neck preserving all the perforators and branches originating from the neck. With the neck clipped, one must ensure that there is no kinking in the A1, M1, and the terminal ICA is open.

In aneurysms which significantly involve the perforators, direct surgical clipping or trapping may not be feasible. Parent vessel sacrifice with distal revascularisation by high-flow bypass may be the only treatment option in these cases.

Subsequent to confirmation of the previously mentioned requirements, the aneurysm is isolated by temporary occlusion of ICA, M1, A1, P.com and Ach. If the aneurysm does not contain organised clots/plaques, especially near the neck, then intermittent suction decompression with a scalp vein cannula attached to the suction with intermittent trapping of aneurysm for dissection is adequate for clipping. In case the aneurysm contains clots/organised clots/plaques, more so close to the neck, then the aneurysm is to be opened away from the probable site of permanent clip and parallel to the bifurcation (the neck). The contents are peeled through the cleavage between organised clots and aneurysm wall. Sometimes, these are too tough to be removed by suction, dissector and tumour forceps. The CUSA at a lower setting is useful in this situation. The wide neck is clipped with the help of both fenestrated and nonfenestrated clips. Usually this works if organised clot has been removed off the wall at the neck. If not possible, then a Sundt booster clip can be used as the amount of pressure generated across clip jaws by giant aneurysms is incredible. A small portion of the neck is maintained patent. This is recommended to maintain a small neck proximal to the clip so as to avoid compromising the diameter of the lumen of the parent vessel incorporated during growth of giant aneurysms. In case of non-availability of a booster clip, a 2.0 suture is passed under the ICA and then around the neck after safeguarding the perforators and other branches. This is tied to oppose the wall at the neck because, a tight knot will jeopardise circulation by occlusion/kink of main artery/branches. The gentle tie is reinforced by a fenestrated/nonfenestrated clip. Ligature should be used only when really necessary as extensive dissection of the aneurysm is a prerequisite for this procedure. Chances of vessel occlusion, infection and dissolution of suture are subsequent problems. Post clip IMD to see the patency of the vessels is essential and an intra-operative angiogram/ICG is recommended. Wrapping of a giant aneurysm produces dense scar around the base but has very little effect on the dome.

Unruptured ICBA with the dome projecting anteriorly or superiorly can also be approached from the contralateral side provided that the ICA bifurcation is not too high and there are no large venous structures obstructing the view. In posterior projecting and large superiorly projecting ICBA, proper visualisation of the perforators attached to the posterior wall of the aneurysm would be very difficult from the contralateral side and would lead to perforator injury. The contralateral approach requires more retraction/lifting of the frontal lobe, and we do not recommend it in acute SAH and brain swelling. The lateral supraorbital craniotomy (LSO) is a more direct and simple approach for ICBA.[5] The LSO craniotomy is a more subfrontal and less invasive modification of the pterional approach for anterior circulation aneurysms.[25] The angle of approach towards an ICBA is a little less lateral than that provided by the pterional approach. Fusiform ICBA are extremely rare. Wrapping, trapping, excision and bypass surgery can be considered for these lesions.

COMPLICATIONS

Intra-operative non-progressive soft brain bulge in which a haematoma is not likely needs to be managed by duraplasty, avoidance of muscle closure, post-operative decongestant therapy and removal of bone flap (if required). Immediate post-operative motor deficit could result from marked ischaemia due to temporary clipping for a prolonged period in the absence of good collateral flow. All attempts must be made to enhance perfusion by Triple H therapy, antivasospastic measures, vasodilators and others. Dense deficit could result from perforator injury.

Delayed deficits can develop due to subdural/epidural/intracerebral haematoma which could result from a little lapse in haemostasis/coagulopathy. The latter needs proper investigations, CT, complete coagulogram, diagnosis and appropriate therapeutic measures. The other causes of deterioration could be hydrocephalus and vasospasm. Hence, a detailed close monitoring, leucocyte count, CT along with transcranial Doppler is mandatory to arrive at a proper diagnosis and then

institute treatment accordingly. Deterioration can also take place due to meningitis, electrolyte disturbances and seizures. Medical problems like chest infection/myocardial ischaemia/pulmonary ischaemia can lead to depressed respiration, hypoxia, hypercarbia and perfusion insults.[26]

Endovascular Treatment

Recanalisation and coil compaction remain a major limitation of embolisation therapy. A higher tendency for aneurysmal recanalisation and regrowth occurs in incompletely occluded aneurysms at initial treatment. Those at the bifurcation or wide-necked aneurysms are at higher risk. Hydrocoils consisting of a carrier platinum coil coated with a layer of hydrogel polymer have been shown to possess a potential to achieve higher rates of volumetric occlusion as a result of expansion of the hydrogel after contact with blood. High rates of delayed progressive occlusion and significantly better neointima formation at the aneurysm neck have been reported in two different animal models. Aneurysms are packed as densely as possible until angiographically complete occlusion is achieved and/or the last coil cannot be introduced into the sac.

Volumetric occlusion has been found to be significantly greater with Hydrocoils than with bare platinum coils (about 70% vs 20–30%) immediately after embolisation. A recent study comparing Hydrocoils with Matrix and platinum coils has been reported. Basilar and ICA aneurysms are subject to constant arterial pulsations, the so-called "water-hammer" effect, which may play an important role in recanalisation of these aneurysms, especially following incomplete occlusion. The regrowth rate of ICA bifurcation aneurysms is around 22%. Procedural mortality and morbidity are 2.2% each. Death or permanent neurological deficit due to thromboembolism can occur. The overall thromboembolic complication rate in the Hydrocoil is 8.1–12%.[7]

ACKNOWLEDGEMENT

We appreciate the contribution of our faculty colleagues from neurosurgery, neuroradiology, neuroanaesthesia and my stenographer for their timely support and help.

81 Anterior Communicating Artery Aneurysms

RP Sengupta, Anil Pande

INTRODUCTION

The anterior communicating artery (ACoA) complex is the most frequent site of intracranial aneurysms, and an anterior communicating artery aneurysm (ACoAA) is the commonest aneurysm a neurosurgeon tackles.[34,43,52,68,77,91,105] The anatomy of the ACoA is complex with frequent associated congenital vascular anomalies. These aneurysms are located posteriorly between the frontal lobes and their close proximity to the hypothalamus, optic nerves, chiasm and their blood supply makes surgery of these aneurysms difficult.[34,43,85] The anterior communicating artery aneurysms (ACoAAs) have a varied morphology. Saccular, fusiform,[93] blister,[8,51] multiple including kissing ACoA[12,47,113] and giant types[21,42,59,70] have been described. Hernesniemi et al.[43] analysed a database of 3,005 patients with 4,253 aneurysms, 1,145 patients (38%) had altogether 1,179 anterior cerebral artery (ACA) aneurysms; of them, 898 patients harboured 921 (78%) ACoAAs. In their series, 715 patients (80%) presented with ruptured ACoAAs with the median diameter of 7 mm. Giant ACoAAs were present in 15 (2%), whereas only 3 (0.3%) were classified as fusiform. The ACoAAs present frequently with subarachnoid haemorrhage (SAH) when of small size and luckily giant ACoAAs are rare.[43,70]

INCIDENCE

The ACoAAs form 30–37% of all aneurysms and comprise the largest percentage of ruptured aneurysms.[34,43] They are found to be more common in men with a male:female ratio of 2.3:1. These aneurysms are seen in the middle aged with a peak in the late forties.[45] The ACoAAs are very rare in children. Jain and Mehta[49] reported an ACoAA in a 3-year-old girl, who presented with subarachnoid haemorrhage. Multiple aneurysms are seen in 4.1–18.2%[47,52,79,113] of patients who present with an ACoA aneurysmal bleed. Inci and Ozgen[47] found an incidence of 4.1%. Kissing ACoAAs are variants of multiple aneurysms.[12] The inheritable connective tissue disorders like polycystic kidney disease, Ehler-Danlos syndrome, Marfan's syndrome, neurofibromatosis type 1 and alpha 1 antitrypsin deficiency may be associated. Rarely, familial occurrence of intracranial aneurysms is seen. Maramottom[72] reported the management of ACoAA in a patient with Takayasu's arteritis, a rare type of vasculitis which affects predominantly young females and involves the aorta, its large branches and the pulmonary arteries. Bulsara et al.[19] reported on the coexistence of pituitary adenoma and ACoAAs.

AETIOLOGY

Aneurysmal formation has multifactorial aetiopathogenesis with genetic, molecular, structural and flow dynamics being among the many factors involved. The genesis and increase in size of ACoAAs is due to loss of normal balance between vascular vectors, flow rheology and arterial wall characteristics. The progressive thinning and weakening of the wall finally result in aneurysmal rupture and SAH. This aetiological march is well seen in patients with ACoAAs. Aneurysms of the ACoA complex commonly have asymmetric A1 segments with one side being atretic or hypoplastic and the major flow is from the dominant A1 segment.[100] The ACoAAs have been produced in hypertensive rat models by ligation of the common carotid artery on one side and the contralateral internal carotid artery (ICA). The cross-circulation from the right ACA and hyperdynamic flow through the ACoA have been implicated in aneurysm formation. The direction of the aneurysm is determined by the direction of dominant flow. Castro et al.[22] in a study, analysed the flow dynamics in 26 ACoAAs by using image-based computational fluid dynamics methods. They found that aneurysms with small impaction zones, higher flow rates into the aneurysm and elevated maximum wall shear stress were more likely to be ruptured. The angles of the arteries at bifurcations, as well as the blood flow cause haemodynamic stress on the apical region, leading to aneurysm formation. Kasuya et al.[54] determined the angles between A1 and A2 segments of the ACA of the ACoA complex associated with aneurysms using images obtained with three-dimensional (3D) computed tomographic angiography. They found that ACoAAs are associated with the smaller A1-A2 angle junction of the ACoA complex, where higher haemodynamic stress occurs in patients with normoplastic A1 segments.

SURGICAL MILESTONES IN THE MANAGEMENT OF ANTERIOR COMMUNICATING ARTERY ANEURYSMS

In 1936, Wilhelm Tönnis[34] used a midline surgical approach to directly reach the ACoAA by splitting the genu of the corpus callosum. In 1938, Walter Dandy[26]

described the pterional (PT) craniotomy and his approach to the skull base has withstood the test of time. Hamby and Falconer[32] used the unilateral subfrontal approach to reach ACoAAs. In 1956, Vincent Logue[69] used proximal occlusion of the A1 and Hamby proposed the exposure of both carotid arteries in the neck for temporary occlusion to prevent a premature rupture. Williamson and Brackett[34] suggested temporary occlusion of the proximal anterior cerebral arteries and Pool[88] used the midline bifrontal approach with temporary occlusion of both A1 arteries. In 1962, Lyle French[35] described resection of the anteromedial part of the frontal lobe to prevent premature rupture of ACoAAs. Kempe,[57] in 1968, and Vander Ark,[56] in 1971, described the gyrus rectus approach to these aneurysms and highlighted the importance of the direction of projection of the aneurysm in the operative approach (Fig. 1). They further classified aneurysms of the ACoA into three basic categories depending upon the orientation of the dome, and based the approach on the principal of leaving the fundus of the aneurysm alone.[57] Those which pointed downwards were approached from above, anteriorly projecting aneurysms were tackled from above and behind, superiorly and posteriorly pointing aneurysms were to be approached from below. In 1964, Adams and Whitt[1] reported on the use of the operating microscope in the surgery of aneurysms and, in 1966, Pool and Colton[87] stressed the advantage of the microscope in intracranial vascular surgery. In 1969, Yasargil et al.[116] introduced concepts of microneurosurgery. The microsurgical corridor using the PT approach to ACoAAs was popularised by Yasargil[115] and Fox.[34] Sengupta[100] researched the circulatory patterns, anomalies and morphological aspects of ACoAAs and used a modified subfrontal, gyrus rectus approach. In 1986, Hakuba et al.[40] described the orbitozygomatic-infratemporal approach increasing bone removal to reduce need for brain retraction. In 1989, Smith et al.[104] described the orbitocranial approach which involved the removal of the orbital rim and roof, and the sphenoid bone. In 1991, Guglielmi et al.[39] reported on the electrothrombosis of saccular aneurysms via the endovascular approach. The use of the endoscope to assist the microsurgical clipping of cerebral aneurysm was first reported by Fischer and Mustafa in 1994. In 1982, Jane et al.[50] described the supraorbital approach for suprasellar lesions and ACoAAs and thereafter the use of Keyhole concept in aneurysm surgery has been developed and modified by many authors.[24,25,27,53,67,102] Image guided approach to these aneurysms has been described.[102]

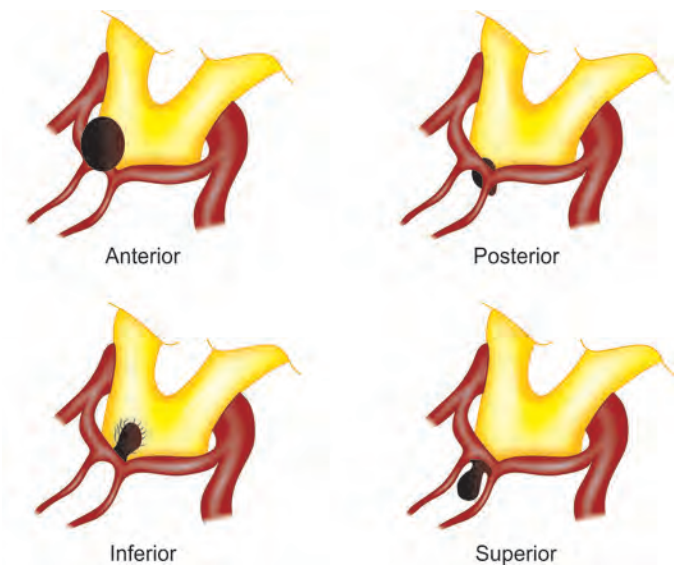

Fig. 1: Illustration showing the various directions of the ACoAA

MICROSURGICAL ANATOMY OF ANTERIOR COMMUNICATING ARTERY COMPLEX

Anterior Cerebral Artery

This artery arises as one of the two terminal branches of the ICA at the medial end of the Sylvian fissure. It runs anteriorly and medially above the chiasm (70% of cases) or optic nerve and enters the interhemispheric fissure.[86] Arteries from both sides are joined together by the ACoA at the beginning of the interhemispheric fissure. These two arteries then ascend in front of the lamina terminalis to pass into the interhemispheric fissure. The arteries make a smooth curve around the genu of the corpus callosum and pass backwards in the pericallosal cistern. The pericallosal artery continues backwards along the splenium to anastomose with splenial branches of the posterior cerebral artery. The ACA is divided into three segments.

1. The segment from the bifurcation of the ICA to the point of origin of the ACoA is known as A1 segment. This is also known as the horizontal part of the ACA.
2. The segment distal to the ACoA up to the point of origin of the callosomarginal artery is known as the A2 segment.
3. The part distal to the origin of the callosomarginal is termed pericallosal artery.

The A1 segment of the ACA runs forward and medially from the bifurcation of the internal carotid. Small perforating branches originate from this segment to supply the genu, the posterior limb of the internal capsule and the rostral thalamus. Proximal branches supply the anterior limb of the internal capsule. It also supplies the optic chiasm, hypothalamus and anterior commissure.

Proximal A1 segment aneurysms constitute less than 1% of all aneurysms. These can also give rise to bleeding into the septum pellucidum and the pre-operative computerised tomography (CT) scan can be misleading. They can be associated with fenestration of the A1 segment. Depending upon the site of origin, they are divided into the following five groups:[108]

1. Junction of the A1 segment and a perforating artery
2. A1 segment directly
3. Proximal end of A1 fenestration
4. A1 segment and cortical branch
5. Fusiform dilatation of A1 segment

The recurrent artery of Heubner arises from the A2 segment in about 80% of cases.[85,86] It then runs laterally and passes in close relationship to the superolateral aspect of the proximal ACA or A1 segment. It turns upwards and backwards to enter the anterior perforated substance.

ANTERIOR COMMUNICATING ARTERY COMPLEX

The ACoA overlies the optic chiasm at the level of lamina terminalis. The average length of this artery is 4 mm (0.3–7 mm) and it consists of a single or multiple channels. Three to four branches arise from the posterior/inferior aspect of the ACoA and supply the fornix and septal region.[92] Pai et al.[85] studied the anatomy of the ACA-ACoA complex in Indian subjects. They found variations were more in the ACoA and DACA segments rather than the A1 segments. The diameter of the ACoA (anteroposterior) ranged from 1 to 3.5 mm with a mean of 2.1 mm. The length of the ACoA ranged from 1 mm to 4 mm with a mean of 2.45 mm. All the ACoAs in their study gave rise to perforators. These ranged from 1 to 5 in number with a mean of 3. These arose from the posterosuperior surface of the ACoA and coursed superiorly. They may arise as a large stem vessel or multiple thin small vessels. In one case the ACoA gave rise to the pericallosal artery which coursed directly anterosuperiorly over the genu and then posteriorly over the corpus callosum. Rosner et al.[92] studied the microsurgical anatomy of the anterior perforating arteries, the group of arteries that enter the brain through the anterior perforated substance and observed that the ACA branches arose from the A1 segment and from the recurrent artery. Intrasellar aneurysms originating from the ACoA are located above the chiasm or optic nerves. The A1 courses above the optic chiasm or nerves to join the ACoA. The junction of the ACoA with the right and the left A1 is usually above the chiasm (70% of brains) rather than above the optic nerves (30%). Of the arteries traversing above the optic nerves, most traverse above the nerve near the chiasm rather than distally. The arteries with a more forward course are often tortuous and elongated and some of them rest on the tuberculum sellae or planum sphenoidale. The length of A1 varies 7.2–18.0 mm (average 12.7 mm). Camuscu et al.[20] describe the microanatomy of the perforating arteries arising from the ACoA complex (distal 5 mm of the A1 segment, the ACoA and the proximal 5 mm of the A2 segment). As important perforating arteries arise both from the A1 segment and the ACoA, dissection in this area should be careful while isolating the neck of the aneurysm. Vascular anomalies are common in the region of the ACoA.[6,11,60,63,71,100] These include, accessory ACA, azgous anterior cerebral, occasionally hypoplastic anterior communicating and fenestration of anterior communicating and A1 segment.[6,13,63] Avici et al.[11] studied the anterior communicating complex in 25 cadaver specimens obtained at routine autopsy. In 15 specimens (60%), an anomalous ACoA was found. The most common anomaly identified was a multi-channelled ACoA. The first channel was always the smallest channel, and all of the perforators arose from this smallest channel 45% of the time. All other anomalous anterior communicating arteries presented with concomitant anomalous perforator anatomy. In clinical practice the difference in the reported incidence depends upon the surgical approach used.[80] These anomalies are visualised better with the interhemispheric approach.[84] The pre-operative vigilance and delineation of these anomalies is necessary to avoid accidental occlusion of these vessels, especially the median artery of the corpus callosum or third distal ACA, with a poor or fatal outcome.[37] Fenestration of the A1 segment,[73] and asymmetry of the ACA[71] are commonly associated with aneurysms in this region. Kwak et al.[63] observed fenestration in the ACoA or the presence of more than two anterior communicating arteries in 17 cases (5.7%). As the anomaly was duplicated in some of these cases, the total number of cases with anomalies of the ACoA was 26 (8.8%) out of 296 cases. Perlmutter and Rhoton[86] found the origin of the recurrent artery of Heubner at the A2 segment in 78%, A1 in 14% and at the ACoA in 8%. Variations in the circle of Willis are often seen in patients with intracranial aneurysms.[60,114] Norlen and Barnum[82] described different patterns of circulation through the anterior part of the circle of Willis (Figs 2A to D). In an analysis of 100 patients with anterior communicating aneurysms, Sengupta et al.[100] found the following four types of collateral circulation:

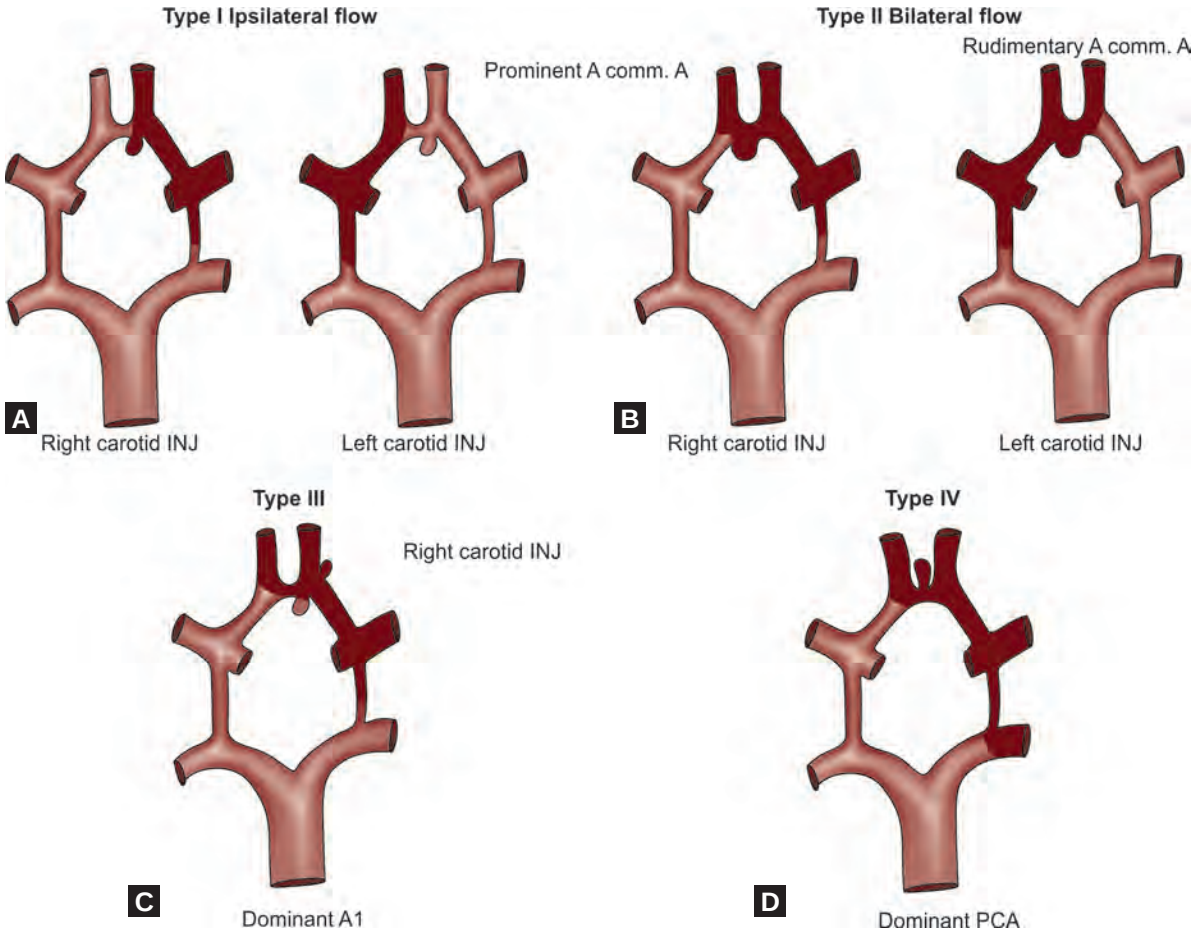
Type I: Ipsilateral (66%). In this type the aneurysm and the distal ACA fill from one proximal ACA.

Type II: Bilateral (14%). The aneurysm and both the ACAs fill from both carotid injections.

Type III: Dominant ACA (12%). The aneurysm arises from the axilla of the two anterior cerebral arteries, both of which fill from one anterior cerebral. The contralateral A1 segment is hypoplastic.

Type IV: Dominant ACA with foetal posterior cerebral artery (8%).

Murai et al.[78] reported a patient with a heterogeneously enhancing, partially calcified intrasellar mass on Magnetic resonance imaging (MRI) and the normal pituitary gland was identified at the bottom of the sella, and the optic chiasm was located superior to the aneurysm. Digital subtraction angiography (DSA) and 3D computed tomography angiography demonstrated the mass to be a partially thrombosed ACoAA. Intrasellar aneurysms originating from the ACoA are likely to present difficulty in dissecting the neck of the aneurysm from the bilateral optic nerves and pituitary stalk, impeding direct aneurysm clipping. Kawashima et al.[55] report an unusual variant of a ruptured ACoAA located on the planum sphenoidale where the course of both the A1s were not tortuous, but were rather straight. The left A1 was 20.5 mm in length.



Figs 2A to D: Patterns of circulation through the anterior part of the circle of Willis. (A) Type I circulation showing ipsilateral filling of the ACA on carotid injection. (B) Type II circulation showing bilateral filling of ACA from either carotid injection. (C) Type III circulation (dominant) with the opposite Alhypoplastic and with poor collateral circulation. (D) Type IV circulation (dominant with foetal PCA) with very poor circulation

Supreme Anterior Communicating Artery

Albert et al.[3] reported on a rare case of a ruptured pericallosal aneurysm originating from an atypical communicating segment between both distal A2 arteries, called the 'supreme ACoA'. The neurosurgeon should be aware of this rare vascular anomaly that might be angiographically occult and raise unexpected intra-operative difficulties. Rarely, an anomalous ACA can arise from the ICA at the bifurcation.[28] The aberrant artery coursed anteriorly along the ipsilateral olfactory tract and made a hairpin turn posterior to the olfactory bulb, supplying the circulation of the ACA. Persistence of the primitive olfactory artery is suggested as the embryological origin of this vascular anomaly.

CLINICAL FEATURES

Most ACoAAs present with a bleed causing the classical "thunder clap" headache described commonly by patients as the "worst headache of their life". Not taking cognisance or failing to take this history can lead to the diagnosis being missed with disastrous consequences. These aneurysms can present with loss of consciousness, seizures, anosmia, oculomotor nerve paresis,[90,94] diabetes insipidus or hypothalamic dysfunction. The aneurysm can cause a large frontal haematoma or intraventricular bleed. Acute and chronic hydrocephalus can be the cause of neurological deterioration in these patients.

The "ACoA Syndrome"

Patients with ACoAAs may present with memory disturbance,[4] confabulation, paraparesis and personality changes. This has been characterised as the "ACoA syndrome". Greene et al.[38] in a clinicopathologic evaluation of patients with lower extremity weakness following rupture and repair of ACoAAs found angiographic vasospasm in the ACA distribution in all their cases, and this paraparesis persisted beyond the angiographic resolution of vasospasm. All their patients had evidence of frontal lobe dysfunction throughout their post-operative course and deep venous thrombosis and pulmonary emboli were common causes of morbidity and mortality. Their autopsy data supported regional microvascular ischaemia within the ACA distribution as the aetiology of these motor deficits. The combination of vasospasm in the ACA distribution and lower extremity weakness associated with cognitive and affective impairment that resolves with time is common in patients with ACoAAs. They propose that this constellation of clinical,

radiographic and pathologic findings be referred to as the "ACoAA paraparesis syndrome". Sensory disturbances are also seen. Gait apraxia is defined as the loss of ability to walk in the absence of weakness. Extrapyramidal symptoms and incontinence result due to injury involving the anterior cingulate gyrus, medial superior frontal gyrus or the superolateral frontal gyrus. Altered states of sensorium similar to akinetic mutism are seen along with abulia, a decrease in spontaneous speech with increased response latency and decreased capacity to persist while doing an activity.

Vascular injury to the corpus callosum causes a type of disconnection syndrome with ideomotor apraxia, agraphia and tactile anomia restricted to the left hand. Pathological grasp phenomena or alien hand syndrome can be an associated finding. Vascular injury to the frontal lobe or basal ganglia has been linked to the pathological grasp reflex seen in these patients.

Neuropsychological Symptoms

Neuropsychological examination must be detailed and performed in all patients with a suspected ACoAA both before and after surgery. These include Mini Mental Scale Examination (MMSE), the Micro Cognitive Test, Computerised Assessment of Cognitive Function (CACF), Wisconsin Card Sort, Trail-making Test, Rey's Complex Figure Test and Recall and portions of the Wechsler Memory Scale 3 among others. Beeckmans et al.[15] correlated the neuropsychological performance of five patients with an ACoA syndrome (amnesia, confabulation and personality changes) with neuroimaging techniques and found basal forebrain and frontal lobe pathology in all patients, and all patients displayed a profound amnesic syndrome. Retrograde amnesia characterised by a temporal gradient was seen with normal short-term memory. Böttger et al.[17] hypothesised that lesions of the medial septum and nucleus of the diagonal band of Broca were closely associated with memory deficits and prefrontal lesions were associated with attentional, executive and psychopathological dysfunctions. Bilateral lesions were associated with severe disturbances. The type and severity of these deficits were independent of the side of lesion in unilateral cases of gyrus rectus resection, and of the Hunt and Hess grading system according to them. Alexander et al.[4] studied 11 patients with amnesia and personality change after surgical repair of ruptured ACoAA. The CT and clinical evidence suggested that infarction in the territory of the ACoA was responsible for amnesia and personality change. The medial septal nuclei, the paraventricular nucleus of the anterior hypothalamus and the medial forebrain bundle were the probable regions involved. Gross infarction in the frontal lobes was not a requirement for the syndrome. Diamond et al.[29] explain that in these patients amnesia is seen despite traditional cerebral areas implicated in memory disturbances not being damaged. Mavaddat et al.[74,75] support the dual lesion hypothesis (damage to both frontal lobes and basal frontal lobes) to have the ACoA syndrome. They also feel that involvement of basal frontal cholinergic and the medial temporal circuit accounts for the amnesia.

Visual Symptoms

The ACoAAs can cause visual symptoms by direct chiasmal and optic nerve pressure or due to indirect ischaemic aetiology. Chan et al.[23] described six cases of leaking anterior communicating aneurysms that caused acute monocular blindness. They explained that as the aneurysm enlarges, the down-pointing dome compresses the optic nerve from above and adheres to it. When the aneurysm ruptures through the adherent dome, it bleeds directly into the optic nerve, resulting in severe headache and monocular blindness. Direct optic nerve compression by the aneurysm is also possible. Umredkar et al.[110] reported that monocular blindness can result due to the direction of the growth of fundus of large ACoAAs and compression of the optic nerve, and also due to the haemorrhage into the optic nerve. Distortion or traction, and indirect pressure on the optic nerves at the margins of the optic foramina also play an important role. Another factor cited by them is the interference with the blood supply of the optic nerve or chiasma either by occlusion or distortion of the perforating arteries. In large ACoAAs, the intra-aneurysmal thrombus may occlude the origins of the branch vessels supplying the optic nerves and chiasm, thus causing ischaemia. An adherent optic nerve to the fundus of the ACoAA may be damaged from direct haemorrhage.

Endocrinological Symptoms

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH), cerebral salt wasting syndrome and diabetes insipidus are seen in these patients and they need to be differentiated as the treatment modalities differ significantly. Sayama et al.[95] studied the incidence and timing of hyponatraemia (Na < 135 mEq l-1) after subarachnoid haemorrhage with special reference to ruptured ACoAAs. The ACoAA group had a significantly higher incidence of mild hyponatraemia and severe hyponatraemia than other groups. Among ACoA cases, hyponatraemia occurred significantly more often in grade III and IV cases, in cases with vasospasm, and in cases with hydrocephalus. Respective days of onset for symptomatic vasospasm and for hyponatraemia were day 7.6 ± 4.4 and day 10.6 ± 5.8 following SAH, representing a 3-day delay for hyponatraemia. In most patients hyponatraemia resolved within 28 days following SAH. Hyponatraemia occurred more often with ACoAAs, possibly due to vasospasm around the ACoA or hydrocephalus causing hypothalamic dysfunction. Since hypervolemic therapy can cause hyponatraemia, particularly careful observation is required during such therapy in patients with ACoAA. Panhypopituitarism is also seen and Nukta and Taylor et al.[83] reported that the panhypopituitarism could be due to injury to the anterior pituitary or the hypothalamus.

Hydrocephalus

Cerebrospinal fluid (CSF) diversion procedures are often required in patients with an ACoAA.[9,62,103,118] These aneurysms are close to the third ventricle and lamina terminalis and often the aneurysmal bleed extends into the ventricle and can cause acute hydrocephalus causing rapid clinical deterioration within 24–48 hours after SAH. Hydrocephalus requiring shunt placement is a common complication after aneurysmal subarachnoid haemorrhage (aSAH). Komotor et al.[62] found fenestration of the lamina terminalis appears to be associated with a decreased incidence of shunt-dependent hydrocephalus of more than 80% after aSAH.

INVESTIGATIONS

Once the history or clinical features are suggestive of an ACoAA presenting as a bleed or with the varied symptoms described above the patient must be rapidly shifted to a neurosurgery centre where all investigations are carried out on an emergency basis and appropriate therapy is instituted as early as feasible to avoid the risk and devastating consequences of rebleed. Patients undergo routine haemogram, liver and renal parameters are checked along with complete coagulation profile. A physician, cardiologist and anaesthetist urgently evaluate and clear the patient followed by the neurosurgeon who decides on how to investigate further and manage the case.

Conventional Angiography

Multiple angiographic views (standard, oblique, submental vertex views) are usually required to visualise these aneurysms. Oblique views with the ACoA artery projected into the centre of the left and the right orbits are essential pre-operative studies. A basal view is helpful. These angiograms must be studied carefully for multiple aneurysms. Individual aneurysms are studied for their morphology, direction, flow features and associated vasospasm. In a few cases the aneurysm may not be visualised in the angiogram. The angiogram reveals whether the aneurysm fills from one or both sides and cross compression verifies whether collateral flow is present. In analysing the angiogram attention is paid to see if the ICA is long or short, as a long ICA makes the visualisation of the ICA bifurcation difficult and to follow the A1 to the ACoAA brain excessive retraction may be required. DSA, a 3D rotational angiogram or 4D angiogram are routine (Fig. 3). Anterior communicating aneurysms rarely arise from the ACoA itself. From a careful study of the angiograms the position of the neck of the aneurysm can be ascertained in the majority of cases. The aneurysm is usually to one side of the ACoA in relation to one of the major vessels. An understanding of this is important for successful occlusion of the neck without compromise of other vessels. The anatomical variations of the ACoA complex occasionally allow the inclusion of one half of the ACoA in the clip

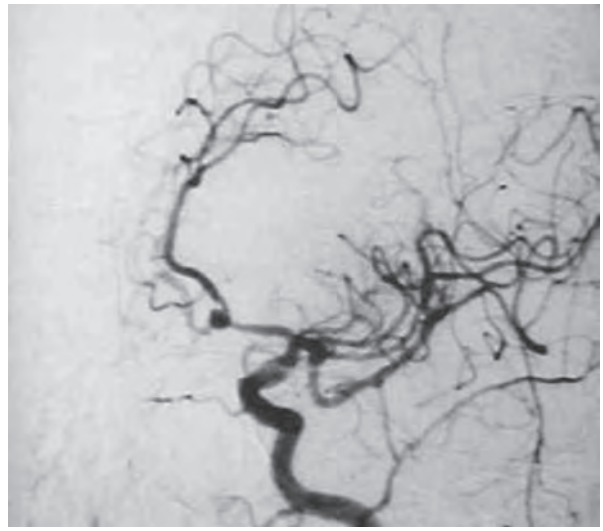


Fig. 3: Four vessel DSA showing ACoAA

without any untoward effects.[100] The small perforating vessels which arise from the ACoA (3–4 in number) will be perfused from the opposite ACA in such occasions. Jha et al.[52] reported a series of 44 consecutive patients with aneurysms of the ACoA during an 8 years period; these formed 55% of all aneurysms operated during this period. Eight patients (18.2%) had multiple aneurysms. Twenty-seven ACoA aneurysms (61.4%) were directed antero-inferiorly, 8 (18.2%) postero-superiorly, 6 (13.6%) superiorly and 3 to the side (Fig. 2). Twenty-nine (65.9%) arose at the dominant A1-ACoA junction.

Computerised Tomography

Computerised tomography (CT) of the brain is generally the first investigation ordered after a thunderclap headache. The CT shows characteristic anterior interhemispheric fissure SAH and a frontal intracerebral haematoma should raise the suspicion of a bleed due to an ACoAA. Diffuse and extensive SAH is often seen and attention is then paid to look for the usually globular hyperdense aneurysm in the ACoA region (Fig. 4). Flame shaped intraparenchymal haematomas

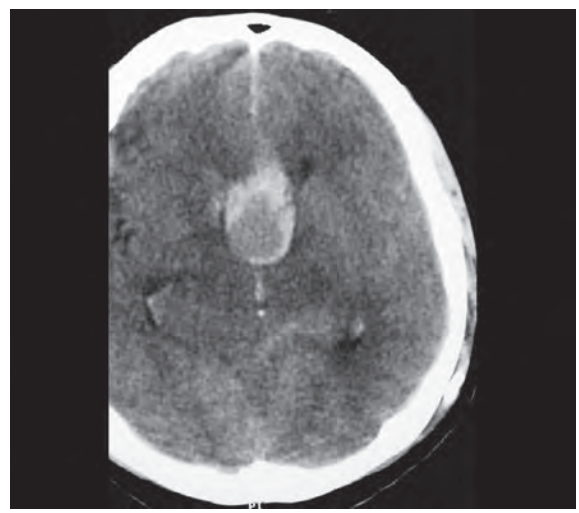

Fig. 4: The CT scan brain showing large globular ACoAA

in the gyrus rectus are characteristic of ACoA aneurysmal bleed. Yock et al.[118] analysed the CT findings in 19 cases of ruptured ACoAAs and compared these with the angiographic appearance. They observed: (a) occasional negative scans, (b) visualisation of non-giant aneurysms on infused axial scans, (c) common asymmetric subarachnoid haemorrhage, (d) involvement of the anterior interhemispheric fissure whenever subarachnoid haemorrhage is visualised, (e) "typical" septal haematoma in a minority of cases, (f) frequent infarction, particularly in the ACA distribution, (g) "meningeal hyperaemia" seen on post-contrast scans and (h) little correlation between angiographic aneurysm orientation and the location of haemorrhage on CT scan. Calcified aneurysm and atherosclerotic walls may be seen in giant aneurysms. Hydrocephalus was seen in 25% of their cases. Frontal lobe infarcts were seen in 20% of cases and bilateral anterior infarcts were seen due to associated vasospasm. A normal CT scan should be looked at with caution and if the history and clinical features are pointing to an ACoA aneurysmal bleed a lumbar puncture should be done to look for crenated RBCs and evidence of SAH.

3D Computerised Tomography Angiography

The 3D-4D CT angiography can be done in the emergency situation and provides a very good 3D idea of these complex aneurysms and adjacent structures and vessels (Figs 5 and 6). Villablanca et al.[112] evaluated the utility of volume-rendered helical CT angiography in patients with intracranial aneurysms. The CT angiography was reported to be superior to both DSA and MR angiography in the evaluation of the arterial branching pattern at the aneurysm neck, aneurysm neck geometry, arterial branch incorporation, mural thrombus and mural calcification. For surgical cases, CT angiography had a significant impact on treatment. Beck et al.[14] reported about accurate size and location of a consecutive series of ruptured and un-ruptured aneurysms taking the complex 3D anatomy and parent vessel morphology into consideration by using the newly developed 3D rotational angiography (3D-RA).

Anduluz et al.[8] reported that DSA failed to reveal an aneurysm in three patients, which were eventually diagnosed by CT angiography. 3D-CTA is a superior imaging modality to magnetic resonance angiography (MRA)

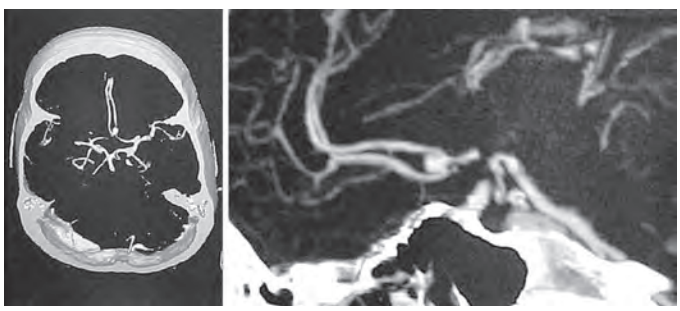

Fig. 5: Reconstruction CT angiogram appearance of the ACoAA

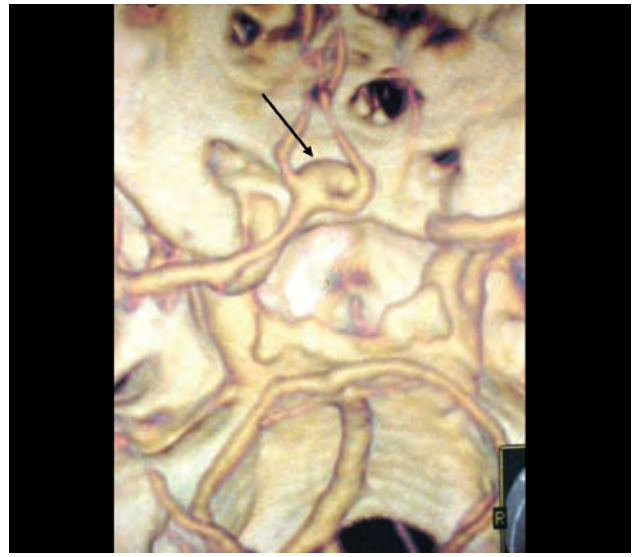

Fig. 6: 3D reconstruction of the CT angiogram showing ACoAA

and DSA in understanding the relationship between the aneurysm and surrounding structures in spite of the bony artifacts. The CT angiogram shows the regional anatomy around the ACoAA and patient specific variations in the skull shape and bony landmarks should be studied to plan the surgical corridor and manoeuvres to clip the aneurysm. In two cases, the authors found that aneurysms were initially misdiagnosed as a single complex aneurysm based on routine cerebral angiograms, but special angiographic views demonstrated double aneurysms. In one case, multiple ACoAAs could be identified using 3D-CT angiography. Double fenestration of the ACoA complex associated with an aneurysm is a very rare finding and is usually caused by ACoA duplication and the presence of a median artery of the corpus callosum. De Oliveira et al.[28] reported a patient, in whom double fenestration was not associated with ACoA duplication, representing, therefore, a previously unreported anatomic variation. The DSA images missed the double fenestration which was disclosed by 3D-RA, indicating the importance of 3D-RA in the diagnosis and surgical planning of intracranial aneurysms. Presence of bi-lobed or multilobed ACoAAs should raise the suspicion of kissing aneurysms.[12,79,113] Shekar et al.[98] found that the technique of 3D-CT angiography was useful in delineating the vascular anatomy and its relation to the cranial base structures. This helped the surgeon to plan the appropriate approach to the aneurysm. Inci and Ozgen[47] studied 146 patients with ACoAAs. Six (4.1%) of these patients harboured multiple aneurysms of the ACoA. The size of the ACoAAs ranged from 3 to 12 mm (mean 5.3 mm). In bilobular ACoAAs, special angiographic projections and 3D-CT angiography or 3D DSA should also be performed to obtain a correct diagnosis. The differentiation of two aneurysms from a bilobular aneurysm during the pre-operative period is important for surgical planning.

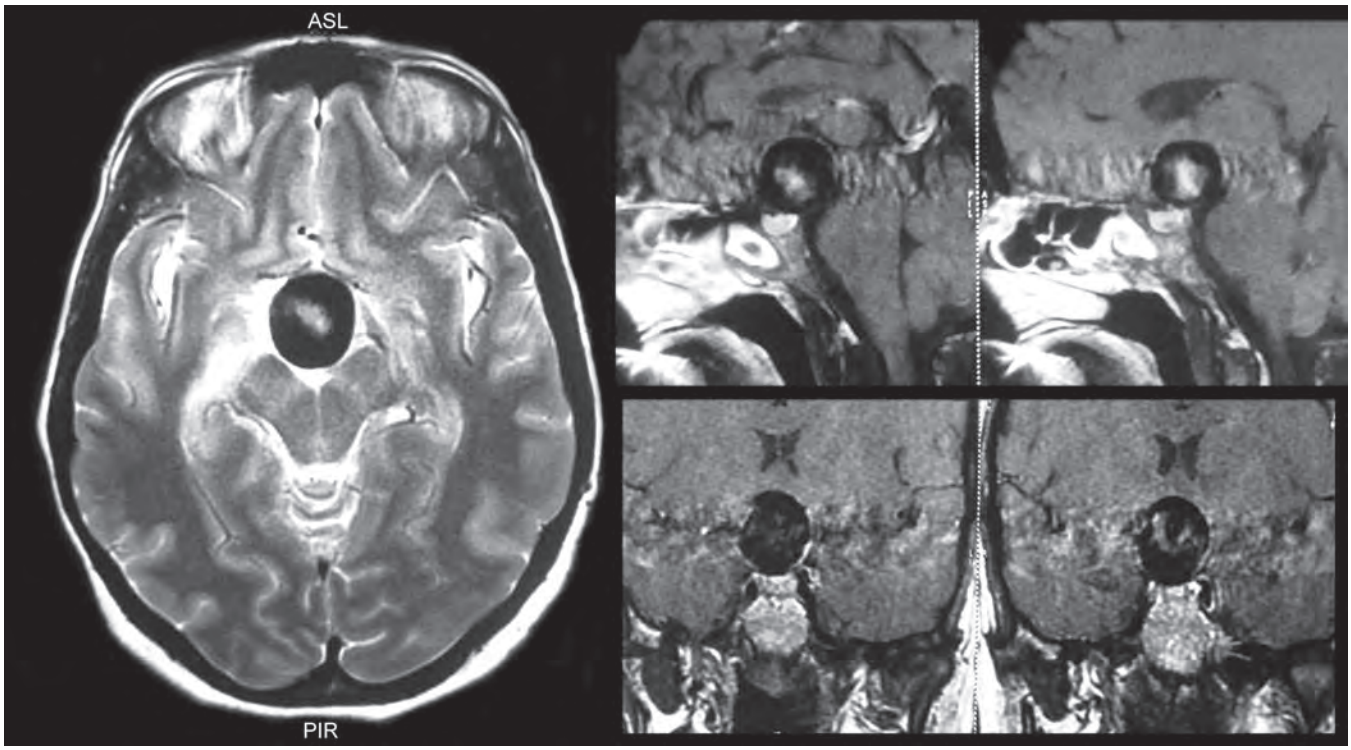

Fig. 7: MRI scan of the brain showing large ACoAA in the suprasellar region with an intramural thrombus

Magnetic Resonance Imaging and Magnetic Resonance Angiography

The MRI shows these aneurysms and the regional neuroanatomy very well. This is the best modality to visualise the infarcts and regions of ischaemia. Aneurysms missed on conventional angiography can be seen sometimes. The morphology, configuration of aneurysm and fundus direction are well observed. The MRI is indispensible in the evaluation of giant ACoAAs as angiography can underestimate the true size of the aneurysm due to a large thrombus (Figs 7 and 8). In a significant number of patients with SAH angiography can be normal.

Fig. 8: MR angiogram showing the ACoAA of the patient as in Figure 7

Currently, repeat cerebral angiography is done after 1–8 weeks, during which time a number of these patients can rebleed with considerable morbidity and mortality. Vassilouthis et al.[111] suggest that MR angiography, guided by the CT findings, probably has a place in the management of these patients with SAH of "unknown aetiology" before repeat catheter angiography is undertaken.

CLIPPING AND COILING DEBATE IN THE MANAGEMENT OF ANTERIOR COMMUNICATING ARTERY ANEURYSMS

The ACoAAs are least amenable to interventional methods of treatment due to multiple factors.[16,31,77] The endovascular techniques to treat aneurysms require that the intimal proliferation occurs over the platinum coils and the thrombus forms to obliterate the aneurysm. In ACoAAs due to the aneurysm being in the direct line of flow this intimal proliferation may be less optimal than in side wall aneurysms.[16] The ACoAAs are smaller and their sac may be too small for coil placement. Other factors complicating the treatment were when the aneurysmal neck was not clearly distinct from the adjacent or parent vessels or because the aneurysm sac was too small and treatment may be difficult due to atheroma of the cervical and intracranial vessels. The rarer variants of ACoAAs including the giant,[21,42,48,59,70] fusiform,[43,93] kissing[12,113] and blister aneurysms[8,51] require complex decision making and evaluation. Giant ACoAAs are less amenable for treatment by coiling and tend to have significant residual lumens and tendency to recanalise post coiling and these may require special

types of stents. The contention that microsurgical clip application should be the preferred option in the treatment of ACoAAs with anteriorly directed fundi and that endovascular packing is selected for those lesions with posteriorly directed fundi, depending on morphological criteria is currently followed.[16,31,77]

SURGICAL TECHNIQUE

The majority of the aneurysms in this area point anteriorly and inferiorly, and are safely clippable. The posterior and superiorly pointing aneurysms are fraught with more risks due to the proximity and involvement of ACoA perforators, recurrent artery of Heubner and A2 segments.[85] Pai et al.[85] in their study of ACoA in Indians found that the anterior border of the A1 segment was devoid of any perforators and dissection carried along this border in approaching the ACoA is advisable. The postero-superior perforators are frequently more in the lateral A1 segment than the medial portion. Hence Pai et al.[85] also advocated that during surgery the temporary clip should be placed as medially as possible to avoid perforator ischaemia.

Hernesniemi et al.[43] review the practical microsurgical anatomy, importance of pre-operative imaging in surgical planning and microneurosurgical steps in dissection and clipping of ACoAAs. As ACoAAs have a higher tendency to rupture, incidental unruptured aneurysms in size between 5 mm and 25 mm can be safely operated upon by experienced neurosurgeons with low morbidity and mortality in young and healthy patients. These authors feel that patients who are elderly and with associated co-morbidity may not benefit from elective clipping of an unruptured aneurysm. Great skills and experience are required in the surgical management of the ACoAAs due to the disproportionate fundus to neck ratio. A broad based neck which incorporates the parent vessel and mass effect that can totally alter regional anatomy may make clipping impossible at times. The ACoAAs present frequently with SAH when they are small.[43] Furthermore, unruptured ACoAAs may have increased risk of rupture regardless of size; also they may be associated with other aneurysms. The aim in microneurosurgical management of an ACoAA is total occlusion of the aneurysm sac with preservation of flow in all branching and perforating arteries. Shanno et al.[102] advocated the use of image guidance in ACoAA surgery. The surgical trajectory should provide optimal visualisation of the ACoA complex without unnecessary brain retraction. Temporary clips, pilot clips and a wide selection of fenestrated and normal clips along with a good surgical and radiological pre-planning are required in complex giant aneurysms. Cranial base approaches[98] are routinely used and give more exposure with minimal retraction. Figueiredo et al.[33] compare the angles of approach and area of exposure to the ACoAAs associated with pterional (PT), orbitopterional (OPT) and orbitozygomatic (OZ) craniotomies before and after gyrus rectus resection. The vertical and horizontal angles of approach to the ACoAA complex were significantly larger for the OPT and OZ approaches compared with the PT approach. Use of the OZ approach may decrease the need for frontal lobe retraction and resection of the gyrus rectus according to them.

PRE-OPERATIVE MEASURES

All patients with a ruptured ACoAA should be immediately admitted in a neurosurgical intensive care unit and standard guidelines[76] are useful to decide on patient management. The patient is monitored closely to treat haemodynamic and neurological deterioration. Anticonvulsants, steroids and calcium channel blockers are used as indicated. Close watch is maintained to pick up vasospasm which may require aggressive treatment. Without definitive therapy surgery 4% bleed on the first day, thereafter for two weeks the daily risk is 1.5%, and 25% bleed within 6 months and thereafter have a yearly bleed rate of 3% per year. The functional survival rate is a dismal 18% at 10 years. Early surgery is therefore commonly practiced.

Nathal et al.[80] compared the intra-operative anatomical findings of the ACoA complex in 46 patients with anatomical variations to those in an equal number of patients without variations in order to determine the visualisation of the elements of the vascular complex. Visualisation of the vascular elements was similar in patients with or without anatomical variations. The differences observed were dependent on the surgical approach selected and on the projection of the aneurysm. It was found that, even when the intra-operative anatomical field and the number of vascular elements visualised are different from those obtained in autopsy studies, the vascular microanatomical characteristics can be confirmed with each surgical approach to the extent necessary to ensure safe clipping of aneurysms in patients both with and without anatomical variations.

APPROACHES TO ANTERIOR COMMUNICATING ARTERY ANEURYSMS

The approaches to ACoAAs are: anterior, lateral and skull base approaches. The anterior approaches include the anterior interhemispheric, basal interhemispheric and the midline trephine approach.

Side of Approach

These are usually approached from the right side to prevent injury to the dominant hemisphere and because it is easier for a right-handed surgeon to approach from the right side. However, these aneurysms being in the midline are approached from the left or right side depending upon the side of the dominant A1, haematoma, direction of the fundus, pre-existant anterior cerebral territory infarct and radiographic characteristics seen on angiogram and CT angiograms. The dominant A1 is used for

achieving proximal control and also because the dome of the aneurysm is generally pointing towards the direction of main thrust of flow and away from the direction of the dominant A1. If there is a large frontal haematoma then it is advisable to operate from that side allowing for evacuation of haematoma and also preventing the possibility of bifrontal injury. Similarly, a large infarct on one side may warrant an approach from the same side.

The Subfrontal Modified Gyrus Rectus Approach

Kempe and his colleagues[56,57] popularised the original idea of Falconer[32] to approach the ACoA complex through the gyrus rectus. Gyrus rectus dissection does not cause any effect on the outcome.[46] The patient is placed supine on the table with the chest piece elevated 30 degrees and the head piece is lowered 15 degrees. During the early part of the operation the head piece can, however, be kept elevated for convenience of performing the craniotomy. The head is turned 45 degrees to the opposite side and placed on a ring to allow change of angle during surgery, if necessary. The ipsilateral shoulder is raised on a sandbag to avoid traction on the brachial plexus and facilitate venous drainage. The aim is to allow the pterion to face directly upwards. This allows the frontal lobe to fall away from the floor of the anterior cranial fossa when the arachnoid dissection is complete and the optic nerve can be seen with a little retraction.

The skin incision runs along a line starting in front of the tragus, gently curving behind the hairline medially and anteriorly to the midline and gently backwards up to the point in the plane of the mid-point of the opposite pupil. This ¾ coronal scalp flap meets all the requirements. If a cosmetic scar is not of paramount importance, a short incision curving forwards to a point about 1.5 cm in front of the hairline at the level of the ipsilateral pupil will be quicker. While incising the scalp care is taken to avoid injury to the main stem of the superficial temporal artery and the temporalis muscle. The scalp flap is reflected over the brow. While elevating the scalp flap it is wise to mark the midline for orientation during placement of burr holes. The supraorbital and supratrochlear nerves are carefully separated from the periosteum and stay with the scalp flap. Placement of the craniotomy is crucial. The bone flap should be generous and extend as close to the floor of the anterior cranial fossa as possible, and the medial limb should be in the plane of the ipsilateral pupil. If the frontal sinus is opened the mucosa should be removed and the sinus sealed with bone chips and pericranium before opening the dura. The crucial burr hole is the one above the zygomatic process which should expose the frontal and temporal fossa. Although the use of craniotome and power drills are common multiple burr holes connected with Gigli saw are also an option. Craniotomy should expose the Sylvian fissure well. The lateral half of the sphenoid wing must be removed and the bony margins waxed. In elderly persons the dura is often adherent to the bone and great care is necessary to prevent laceration of the dura and the underlying brain. The bone flap with the attached temporalis muscle is now reflected laterally and held in position with fish hooks. The dura is hinged against the bone margins with hitch sutures to prevent extradural bleeding.

On palpating the exposed dura, the brain tension can be assessed. If there is any tension, CSF is removed via a lumbar drain if already in place. When the ventricles are enlarged on the CT, the frontal horn of the lateral ventricle is cannulated and a ventricular catheter is introduced to remove CSF. The CSF should not be drained excessively as this makes subsequent arachnoid dissection difficult. Once the dura is slack a linear incision is made 1 cm above the anterior margin of the bony opening along the entire length of the exposed dura. After opening the dura, the headpiece of the table is lowered to allow maximum extension of the head, making sure the head is resting comfortably on the ring and the endotracheal tube is not disturbed. A 1.5 cm wide hand-held retractor is used to retract the orbital surface of the frontal lobe. If the optic nerve can be visualised with minimal frontal lobe retraction, the position of the head is ideal. It must be appreciated that undue retraction of the brain can cause oedema resulting in decreased blood flow.[10,41,96] The retractor is now attached to the Leyla (Aesculap) self-retaining retractor system mounted on the left side of the operating table.

The operating microscope with 300 mm objective is now brought into the operating field. The paraoptic cisterns are opened with a sharp 22 gauge needle bent 90 degree at the tip and mounted on a suitable handle. This is the cheapest and finest arachnoid knife that is available in any operating theatre. As the CSF starts to flow it is sucked out. The arachnoid is divided with scissors from the pre-chiasmatic cistern medially to the lateral limit of the exposure. The arachnoid over the medial end of the Sylvian fissure is very thick. With careful division of this thick band the frontal lobe will fall back without any tension on the temporal lobe. While dissecting the arachnoid medial to the optic nerve, care must be taken not to disturb the anteriorly projecting aneurysm or the blood clots in the pre-chiasmatic cistern. If the angiogram suggests a backward or inferiorly projecting aneurysm the arachnoid over the opposite optic nerve and A1 is divided. During these early stages, the retraction over the frontal lobe should be kept over the lateral aspect of its orbital surface to avoid any tension on the aneurysm complex. Once the proximal part of the internal carotid and the olfactory tract are exposed, this stage of the operation is complete (exposure of ICA bifurcation and A1 segment are avoided in this approach).

The brain retractor is now replaced over the medial aspect of the orbital surface of the frontal lobe just above the olfactory tract without any tension on the interhemispheric fissure. A site below (medial) the olfactory tract is now selected for corticectomy in the gyrus rectus. A 1.5 cm incision is made over the cortex with bipolar

coagulating forceps. Cortical tissue 1 cm^3 in volume is removed in such a way as to enable the interhemispheric fissure to be reached. The suction pressure is crucial at this time, as the arachnoid in the interhemispheric fissure over the aneurysm complex should not be disturbed at all. If the frontopolar or orbitofrontal arteries come in the way, they should be sacrificed. After removal of this cortical tissue, a suitable size retractor can be placed over the olfactory tract deep into the cavity created by corticectomy and the frontal lobe retracted further without any tension on the aneurysm complex.

The next stage of dissection is crucial. The risk of premature bleeding is highest at this stage. The blood pressure should be allowed to fall gradually to 80 mm systolic in a normotensive patient. Magnification is increased to a comfortable level. A second suction is kept ready and so also a temporary clip. The surgeon should be mentally prepared to tackle bleeding from the aneurysm. In spite of all pre-operative planning, the anatomy of the aneurysm complex may appear confusing at the beginning. The pia-arachnoid in the interhemispheric fissure is generously dissected using suction and bipolar forceps. This will expose the A2 or the ACoA region. The dissection is kept on the outer side, to avoid the aneurysm and the perforating vessels. If the aneurysm is found to be tense at this stage, the proximal part of A1 is cleared of arachnoid and a site free of perforators is chosen for temporary clip application. If the configuration of the circle is normal, enough blood will perfuse the brain supplied by the occluded A1. However, if a temporary clip is applied on both A1 arteries, the blood pressure should be elevated to 100 mm.

In this approach, the vasculature ipsilateral to the aneurysm complex and the adjacent ACA will be seen. Contralateral vessels remain obscured by the aneurysm itself. An attempt is made to pass a fine hook to the free border of the aneurysmal neck before dissecting the adherent side. If this should fail, coagulation of part of the sac with a broad tip bipolar forceps will shrink the aneurysm sufficiently to discover or create a cleavage for the passage of the clip. If one of the cortical vessels gets in the way at this stage, it is coagulated and divided but not separated from the sac. The Heubner's artery is always away from the sac and is not seen unless looked for. Perforating vessels from the ACoA are also not looked for, as these get separated (segregated) when the neck is shrunk all around at the final stages of dissection. After clearing the neck on the opposite side, attention is drawn to the ipsilateral side with the adjacent A2. Again, gentle coagulation of the adjacent part of the sac under hypotension will expose the potential space which is further dissected free with micro scissors. If the aneurysm is projecting laterally underneath the A2, separation of the vessel is done with a temporary clip on A1. With the sac being slack, careful coagulation of the sac will expose the ipsilateral borders of the neck. If there is a leak from the aneurysm, gentle pressure on the cottonoid with the left hand sucker will allow continued dissection or coagulation of the rent. Using bipolar coagulation, it is possible to render a broad neck small. Once the neck has been isolated all around, a crucial decision must be made as to which size and shape of clip is appropriate to obliterate the aneurysm. The length of the clip is usually 1.5 times the diameter of the neck of the aneurysm, i.e. a 10 mm neck needs a 15 mm clip to occlude it. The tip should be advanced gradually beyond the neck and released gradually to avoid a tear in the neck. Distortion of the clip by the overlying frontal lobe should be avoided. Pieces of muslin are placed around the clipped neck. Papaverine 2.5% solution is instilled over the exposed vessels.

The dura is not closed in acute cases of ruptured aneurysms. If necessary, dural graft is used to provide space for brain swelling. Ventricular drainage is continued if the ventricles are large. The bone flap is secured loosely to the pericranium and muscles. Post-operatively the pupillary size is noted. Papaverine can cause pupillary dilatation.

Pterional Craniotomy

A fronto-temporo-sphenoidal craniotomy of Dandy[26] as modified by Yasargil[115] is the most commonly used approach to ACoAAs and is especially preferred for inferiorly projecting aneurysms. This approach is also optimised by using a tailored resection of the gyrus rectus to expose the ACoAA.

The medial aspect of the Sylvian fissure is opened and the carotid bifurcation defined. The cisterns are opened to let out the CSF. The arachnoid fibres running between the olfactory tract and the optic nerve are divided to allow the frontal lobe to be retracted. The ACA (A1 segment) is exposed by opening the cistern of the lamina terminalis on the antero-superior aspect of the vessel. To avoid spasm of the perforating vessels the A1 is not exposed in its entire course. By following the lamina terminalis cistern medially, the surgeon will come to the ACoA complex. Further dissection depends upon the direction of the aneurysm, superiorly (84%) or forwards (16%). If the aneurysm is directed superiorly, the left ACA is identified and dissected medially, towards the A1 complex. This step should be postponed if the aneurysm is directed forwards. Occasionally, 1 cm of the gyrus rectus has to be resected to define the anatomy clearly, before application of the clip on the neck. A careful search should be made for the presence of a third A2 segment. In this procedure both A1 and A2 segments bilaterally, Heubner's artery and the hypothalamic perforators are identified.

Anterior Interhemispheric Approach

This is used in cases where the ACoA is located more than 12–14 mm above the anterior clinoid process and when the aneurysm projects posteriorly in between the frontal lobes. The anterior interhemispheric approach[107] is via a bifrontal craniotomy and the dura is opened in

a W-shaped manner and turned anteriorly. After ligation of the superior sagittal sinus anteriorly, the anterior interhemispheric fissure is entered to identify A2 and this is followed up to the ACoA. Frontal lobe retraction is then done to expose the A1.

Coagulation of the bridging veins may be necessary in the interhemispheric approach to ACoAAs. Most people do not develop any infarct. However, in the acute stage of subarachnoid haemorrhage, patients do not tolerate coagulation of the bridging veins and venous infarcts develop. This is more frequently seen in poor grade and elderly patients.[109]

The Basal Interhemispheric Approach

This involves the removal of more bone, and the midsection of the base of the anterior cranial fossa is resected. This extension downwards into the frontal sinus and nasal bone region provides greater exposure and limits brain retraction. In the basal interhemispheric approach[117] there is no anosmia which is a frequent complication with the interhemispheric approach.

Midline Trephine Approach

The anterior interhemispheric approach through a midline trephine has been advocated by Keogh et al.[58] This approach uses a limited forehead incision, low midline trephine, unilateral dural opening up to the interhemispheric fissure, dissection of the interhemispheric region up to the genu and basal region and then to approach the aneurysm after defining the anatomy. The sectioning of superior sagittal sinus or cutting the falx in the anterior interhemispheric region is avoided.

Other Skull Base Approaches

Shekar et al.[98] emphasise that cranial base approaches, used selectively, can provide improved exposure of deep-seated aneurysms and large or giant aneurysms, while minimising brain retraction. In the orbitozygomatic approach[40] and modified orbitozygomatic approach removal of the orbital rim and the zygomatic arch can be combined with a fronto-temporal craniotomy to gain additional space, so as to decrease cerebral retraction. As shown by Alaywan and Sindon[2] by incorporating orbitozygomatic removal the field view angle was increased by 75% in the sub-frontal approach, 46% in the PT approach and 86% in the sub-temporal approach. In patients with increased intracranial pressure, giant ACoAAs and those projecting superiorly these approaches are useful. Schwartz et al.[97] showed that area of exposure provided by the fronto-temporal transsylvian approach was increased by 26–39% by adding orbital rim osteotomy and an additional 13–22% with removal of the zygomatic arch. Significant and consistent increases in surgical exposure were obtained by using orbital osteotomy, whereas zygomatic arch removal produced less consistent gains. Both manoeuvres may be expected to improve surgical access. However, since larger and more consistent gains were afforded by orbital rim removal, the threshold for removal of this portion of the orbitozygomatic complex should be lower according to them.[97]

Orbitopterional Approach

The orbitopterional (OPT) approach is an anterior skull base extension of the PT approach that provides greater exposure to the anterior cranial fossa, supra and parasellar regions and ACoA complex. With use of the OPT approach, resection of the zygomatic arch is not needed and extension of the temporal craniotomy is considerably less.

Andaluz et al.[7] explain the better outcomes in the OPT approach to ACoAAs to be due to the following three factors:

1. Avoidance of dissection of the Sylvian fissure decreases the risk of temporal lobe injury.
2. Decreased retraction on the basal frontal lobe as significant space is gained from the removal of the sphenoid ridge and superior and lateral orbital rim.
3. Better basal access allows a better cisternal toilette which, complemented by fenestration of the lamina terminalis during ruptured ACoAA surgery, can decrease the incidence of cerebral vasospasm and post-SAH hydrocephalus, in addition to providing improved relaxation of the brain during surgery. Benefits of the OPT approach versus the PT approach in terms of exposure of the ACoA complex were corroborated by Figueiredo et al.[33] The vertical and horizontal angles of approach to the ACoAA complex were significantly larger for the OPT and OZ approaches compared with the PT approach. The authors feel the use of the OZ approach may decrease the need for frontal lobe retraction and resection of the gyrus rectus.

Orbitocranial Approach

Fujitsu et al.[36] described an orbito-fronto-temporo-basal craniotomy technique that allows excellent access to ACoAAs. This orbitocraniobasal approach is particularly useful for the surgical treatment of ruptured aneurysms in the acute stage of subarachnoid haemorrhage, when retraction of the brain needs to be kept to a minimum. With this approach, retraction of the orbital contents decreases the amount of retraction of the brain to such an extent that a brain retractor is not necessary to access to the ACoA complex.[104]

Supraorbital Keyhole Minicraniotomy

The supraorbital minicraniotomy using the eyebrow incision can be used for the management of these aneurysms.[17,19,35,50,77,81,85] Jane[50] described the supraorbital approach to approach ACoAAs in a technical note in 1982 and AL-Mefty[5] elaborated on the supraorbital-pterional surgical approach. Deep lesions can be handled via subfrontal, transsylvian or subtemporal routes

during the same operation with minimal brain retraction. Czirják and Szeifert[25] reported the frontolateral keyhole craniotomy, together with the advent of modern neuroanaesthesia, cerebrospinal fluid drainage and microsurgical techniques, to be a safe approach for an experienced neurosurgeon to use in the treatment of supratentorial aneurysms or tumours of the anterior fossa and sellar regions. Jho[53] described the steps of this approach. A small (4–5 cm) long eyebrow incision is made and the pericranium is separated. Thereafter a small basal orbital roof craniotomy (measuring 2 cm by 3 cm), including the supraorbital arch, is made as a single piece bone flap using a craniotome. The orbital roof is then opened up to the supraorbital fissure and to the optic canal by additional removal of bone in the orbital roof. This will expose the globe and the orbitofrontal dura mater. When the dural incision is made at the orbital portion of the dura mater, the orbital contents are retracted by tack-up sutures. The surgery is carried out utilising the orbital space rather than the intracranial space. The direct eyebrow incision provides an additional vital working space with a width of more than 1 cm at the skull base by eliminating the scalp flap which a coronal incision employs.[53] Dare et al.[27] reported on the successful use of this procedure in elective surgery of 10 aneurysms of the anterior circulation. The mean aneurysm size was 5.9 mm, with a range of 4–10 mm. They highlight the advantages of this approach that include minimal disruption and exposure of normal brain tissue, reduced frontal lobe retraction, and an excellent post-operative cosmetic result. The authors found that the neuroendoscope was helpful at times but was not essential and no special instruments or intra-operative image guidance was required. According to them relative contraindications include the presence of a large frontal sinus, severe brain oedema and recent subarachnoid haemorrhage. In addition, this approach was not used for the treatment of giant intracranial aneurysms.

Cheng et al.[24] have developed a small pterion keyhole approach as an alternative access to treat anterior circulation aneurysms. An oblique skin incision about 3–5 cm in length was made just from 1 cm anterior to the superficial temporal artery at the level of the zygomatic arch, curved just below the temporal line to the forehead, and stopped at the hairline over the Sylvian fissure. Then a small craniotomy (2–3 cm) was made just over the Sylvian fissure and the aneurysm was exposed through the lateral cerebral fissure.

Steiger et al.[106] describe the technique of transorbital keyhole approach to ACoAAs. This approach did not necessitate resection of the gyrus rectus and provided more ventral access than the supraorbital approaches and the ACoA complex can be controlled by splitting the basal aspect of the interhemispheric fissure.

Endoscopic Assisted Microneurosurgery

Profeta et al.[89] emphasise that, among the aneurysms of the anterior circulation, the endoscope is particularly useful in those of the internal carotid and the anterior communicating arteries. In their 3 years experience they found that endoscopes can carry out a supportive role in planning surgical manoeuvres and in verifying clip position. They feel that the endoscope has now become almost indispensable for the "difficult" aneurysms, including the large and giant ones before and after clipping. Thus, the endoscope should be kept ready for use in the operating theatre for any eventuality.

GIANT ANTERIOR COMMUNICATING ARTERY ANEURYSMS

A giant intracranial aneurysm is defined as one larger than 2.5 cm in diameter. These represent about 5–8% of all intracranial aneurysms.[68] Hauck et al.[42] emphasised that patients with very large or giant unruptured intracranial aneurysms present with ischaemic stroke and progressive disability. The aneurysm rupture risk in these patients is up to 50% in 5 years. The ACoAAs rarely grow to giant size as they rupture much earlier and only 10% of giant aneurysms occur in the ACoA.

Patients with a giant aneurysm present with mass effect that causes visual symptoms due to pressure on the optic nerves and chiasm, cranial nerve dysfunction, hemiparesis, seizure or headache. Hydrocephalus is due to pressure on the anterior third ventricle. Lownie et al.[70] reviewed their 20-year experience with giant ACoAAs and found on analysis that at least 3.5 cm of aneurysm mass effect was required to produce dementia in the patients. Dementia was usually caused by direct brain compression by the aneurysm rather than by hydrocephalus and optic apparatus compression occurred with smaller aneurysms (2.7–3.2 cm) when they pointed inferiorly. Aneurysm neck clipping was possible in half of their cases and special techniques, including temporary clipping, evacuation of intraluminal thrombus, tandem and/or fenestrated clipping, and clip reconstruction were often required. Occlusion of or injury to the ACA was the main cause of poor outcome or death. Proximal ACA occlusion, even of dominant A1 segments with small or no contralateral A1 artery, was an effective treatment alternative and was well tolerated as a result of excellent leptomeningeal collateral circulation.

Sometimes it may not be possible to safely clip these aneurysms due to multiple factors like, the neck is too small or very wide, arteries of the ACoA complex or multiple perforators being closely positioned to the aneurysm or a turgid large aneurysm over which the clip keeps slipping and there is risk of kinking and occluding the parent vessel. Appropriate clip selection and proper sequencing of multiple clips are important. Straight clips with short blades are preferred to avoid hindrance of the surgeon's operative field and interference between the clips. Multiple and fenestrated clips may be required to reconstruct the vascular anatomy. These aneurysms can be trapped, opened and the thrombus removed using a cavitron ultrasonic surgical

aspirator (CUSA) and then the reconstruction is done using various clips. Vascular clamps[81] may be required in some cases followed by definitive clipping. Cantore et al.[21] reiterate that the "gold standard" for the treatment of giant aneurysms remains surgical clipping. When direct surgical clipping or endovascular repair is contraindicated, the high-flow EC-IC bypass is a viable surgical option. Kim et al.[59] describe a giant aneurysm of the ACoA which was treated with a STA-RA graft-A3 bonnet bypass and A3-A3 side-to-side anastomosis. Inoue et al.[48] cite a case where revascularisation of the ACA was done with an A3-A3 anastomosis and a superficial temporal artery bypass using an A3-radial artery graft to trap a giant ACoAA.

Zada et al.[119] show that the fenestrated aneurysm clip can be a simple and practical tool in the operative management of ACoAAs. The ACoAAs pointing in a superior direction are more likely to require clip fenestration around the A2 vessel, whereas those pointing in an inferior direction are more likely to require clip fenestration around the A1 vessel. The parallel approximation of the fenestrated clip blades makes them especially useful in the treatment of large or giant aneurysms. Drake et al.[30] reported that Hunterian proximal artery occlusion was used in the treatment of 160 of 335 patients harbouring giant aneurysms of the anterior circulation with 90% satisfactory outcomes. They found that the ACA had very good leptomeningeal collateral flow that prevented infarction even without cross flow.

FUSIFORM ANTERIOR COMMUNICATING ARTERY ANEURYSMS

Fusiform ACoAAs are rare, and a series of five fusiform aneurysms has been reported by Sampat et al.[93] They advise a thorough review of angiograms and 3D CT angiography reconstruction images to identify the complex and fusiform entity of ACoAA. They emphasise the importance of experience in operative techniques and thorough knowledge of the ACoA anatomy in tackling these rare forms and maintain flow in all vessels while surgically recreating an ACoA of normal calibre.

BLISTER-LIKE ANTERIOR COMMUNICATING ARTERY ANEURYSMS

Blister aneurysms are rare lesions characterised by a hemispherical shape and fragile walls.[9,51,101] Blister-like aneurysms constitute technically challenging lesions that may occur at the ACoA. Andulez and Zuccarello[8] reported on a series of five patients with blister-like aneurysms of the ACoA. Usually, blister-like aneurysms have been reported to occur at non-branching sites of the dorsomedial ICA. The CT angiography is valuable in diagnosis. Blister-like aneurysms should be suspected when DSA is negative for subarachnoid haemorrhage. These aneurysms arose from the horizontal portion of the ACoA without any involvement of the branches of the ACA. All such aneurysms were thin-walled and lacked a surgical neck. On dissection, two of the lesions were ruptured. All lesions were treated with straight fenestrated clips through the A1-ACoA junction, thus remodelling the ACoA.

KISSING ANTERIOR COMMUNICATING ARTERY ANEURYSMS

The term "kissing aneurysms" refers to two anatomically adjacent aneurysms with different origins and partially adherent walls.[12,113] These require careful preoperative planning and surgical techniques like gyrus rectus resection, applying temporary clips on the A1 segment, coagulation and shrinkage of one aneurysmal sac, appropriate clip selection and sequencing. Kissing ACoAAs can be successfully clipped.[12]

COMPLICATIONS

Hydrocephalus, perforator and arterial occlusion, vasospasm, parenchymal brain injury, neuropsychological sequelae and electrolyte disturbance are common complications after aSAH from ACoAAs.

Intra-Operative Rupture

The ACoA is associated with higher intra-operative rupture risks than other aneurysmal locations in the anterior circulation. This can be partly attributed to increased dissection and retraction that is used to expose these aneurysm and the associated perforators. Most intra-operative ruptures occur during the dissection to expose the neck and clip application stage. A good mental 3D image and cautious, sharp dissection, proper magnification and illumination, keeping the surgical area wet, microsurgical technique and use of sharp instruments are essential to avoid intra-operative rupture of the aneurysm.

Injury to Arterial Branches and Perforators

Baldawa et al.[12] point out the difficult and deep surgical anatomy of these aneurysms, especially their intimate relationship to 11 crucial arteries and their perforators—paired A1 segments, paired A2 segments, two recurrent arteries of Heubner, two orbitofrontal arteries, two frontopolar arteries and the ACoA—any of which may be injured or inadvertently clipped during surgery. Pai et al.[85] found that perforators arose from the posterior and the superior surface in 90% of the cases. Occlusion of these perforators with the aneurysm clip is a major cause of morbidity and mortality in patients with ACoAAs pointing posteriorly or superiorly. They observed that a clear view of the ACoA was usually hindered by the overhanging gyrus rectus. Profeta et al.[89] reported fatal outcome of a patient with giant ACoAA due to cerebral infarction due to post-clipping stenosis of one distal cerebral artery in which it was not possible to re-position the clip correctly due to the presence of an arteriosclerotic calcific plaque near the aneurysm neck.

More commonly vasospasm can complicate the picture. The injury to the recurrent artery of Heubner results in upper limb and facial weakness with speech difficulty. Injury to the ACA commonly manifests as paraparesis. The ACoA syndrome comprises of abulia, Korsakoff-like syndrome, hypokinesis, visual field defects, affective disorders and diabetes insipidus. Gibbons et al.[37] emphasise pre-operative and intra-operative vigilance in determining the presence of anomalies prior to clip placement to avoid clip occlusion of a third distal ACA segment which can occur during the treatment of ACoAAs.

Hydrocephalus

These aneurysms are located close to the lamina terminalis and the bleed can extend into the 3rd ventricle leading to hydrocephalus. Rarely, giant ACoAAs can cause obstruction by mass effect. Sindou,[103] analysing a series of 197 consecutive cases of ruptured intracranial aneurysms, reported that opening of the lamina terminalis and Lilliequist's membrane facilitates CSF circulation in the basal cisterns and favourably influences the outcome in patients with ruptured intracranial aneurysms. Andaluz and Zuccarello[9] suggested that fenestration of the lamina terminalis is a valuable adjunct in ACoAA surgery and this was associated with statistically significant decreases in shunting rates, incidence of vasospasm and better outcomes. They recommend its routine use in patients with Fisher grade 3 ACoA aSAH.

Electrolyte Disturbance

The ACoAA management is frequently complicated by electrolyte and fluid disturbance. Hyponatraemia, hypernatraemia, SIADH, DI and cerebral salt wasting syndrome have been reported. Hyponatraemia is more common than hypernatraemia and post-SAH hyponatraemia is commonly due to cerebral salt wasting syndrome rather than SIADH. The cerebral salt wasting syndrome is due to the kidneys being unable to conserve sodium loss and this leads to hyponatraemia and fluid loss.

Brain Retraction Injury

Many complications and subsequent poor outcome in ACoAA surgery are due to excessive retraction[61] of the frontal and temporal lobes and splitting the Sylvian fissure. Andrews and Brings[10] reviewed the literature on brain retraction injury, with particular attention to the use of intermittent retraction, intra-operative monitoring techniques (brain electrical activity), cerebral blood flow and brain retraction pressure. They concluded that through a combination of judicious retraction, appropriate anaesthetic and pharmacological management, and aggressive intra-operative monitoring, brain retraction should become a much less common source of morbidity in the future.

Schaller et al.[96] emphasise that the transsylvian approach is "minimally invasive" but not "atraumatic". They used SPECT scans to demonstrate ipsilateral regions of hypoperfusion in 100% of the cases and contralateral hypoperfusion in 80%. Cerebrovascular reactivity was found to be impaired in 83.3% of the cases ipsilaterally and in 33.3% contralaterally. Thus, a significant proportion of patients who undergo microneurosurgical procedures develop bilateral alterations of their cerebral circulation. There are elevations in mean blood flow volume values caused by cerebral vasospasm. Since these changes remain asymptomatic in the majority of patients, the transsylvian approach can be considered "minimally invasive" but not "atraumatic". The authors suggest alternative surgical routes and alternative treatment modalities should be investigated in a similar manner.

Neuropsychological Sequelae

These aneurysms are associated with highest incidence of neuropsychological deficits which can be seen before and after rupture of these aneurysms or after surgical clipping due to iatrogenic injury or vasospasm of perforators. Nearly 40% of patients will have these complications. The ACoA syndrome with severe memory deficits, confabulation and personality changes, like abulia, lack of motivation and poor cognition with relative sparing of intelligence, is seen in a few patients. Cognitive impairment after surgery for ruptured and unruptured aneurysm can be due to many factors as emphasised by Hillis et al.[44] including subarachnoid haemorrhage, general effects of neurosurgery, peri-operative management. Finally, some of the post-operative deficits may be a reflection of premorbid states.

Others

Post-operative haematomas, optic nerve and chiasmal injuries and rarely optic chiasm arachnoiditis due to wrapping of the aneurysm by material, like muslin, are seen.

OUTCOMES

The outcomes in ACoAAs continue to improve due to better imaging, improvements in critical-care techniques, better management of vasospasm and newer treatment options.[16,43,64] The assessment of the outcomes after aneurysm surgery is not easy and many factors have to be taken into account. Buchanan et al.[18] point out a well known fact that despite the neurosurgeon's classification of patients as having a "good recovery" or "moderate disability", the majority of patients surgically treated for SAH reported psychosocial and neurobehavioural changes that were disabling for them and burdensome to their family. The ACoAAs have the worst surgical outcomes among all anterior circulation aneurysms. The clinical grade of the patient as measured by the Hunt and Hess or WFNS scale is still the primary factor that determines the final outcome in patients with an ACoAA after SAH. In patients with good grade the mortality is

less than 5% and most patients have a good outcome. Outcome scores, like Glasgow outcome score, Modified-Rankin scores and Disability Rating Scale (DRS), are used to access outcomes and these are evaluated by independent observers. Andaluz et al.[7] evaluated the short- and long-term follow-up of 75 patients with ACoAAs who underwent surgical treatment through the OPT approach and found overall outcomes at discharge using the modified Rankin Scale to be good in 52 (69.4%) patients, fair in 13 (17.3%) and poor in 10 (13.3%). Sengupta et al.[99] described a series of 32 patients and in 28, the aneurysms were treated by direct surgery with no deaths; 26 of these patients were studied psychometrically from 4 to 33 months after operation. There was no evidence of post-operative intellectual impairment; however, there were personality changes associated with loss of interest, initiative and energy. Analysis of the different factors involved suggests to the authors that the outcome of surgery depends mainly on the pre-operative clinical condition which, in turn, reflects the severity of the haemorrhage. Mavaddat et al.[74,75] reported that after open surgery for ruptured ACoAAs, patients who have achieved a favourable neurological outcome still exhibit significant cognitive deficits, primarily in tests sensitive to temporal lobe dysfunction. However, early surgery did not carry a higher risk of neuropsychological disability. The direction of the aneurysm at the ACA-ACoA and its bearing on surgical outcome was stressed by Jha et al.[52] and they observed that most of the posterosuperior pointing aneurysms presented in poorer grades and outcome was unsatisfactory. In comparison most of the antero-inferiorly pointing aneurysms presented in a better grade and the results were satisfactory. Le Roux et al.[65,66] found that predicting outcome based only on clinical and diagnostic criteria present at admission may have resulted in withholding treatment from 30% of the patients who subsequently experienced favourable outcomes. They emphasised that aggressive management including surgical obliteration of the aneurysm can benefit patients with poor neurological grades and should not be denied solely on the basis of the neurological condition on admission. Andaluz and Zuccarello,[9] on analysing 106 patients affected by ACoAAs, with hydrocephalus requiring shunt to be 4.25% in patients who underwent fenestration of the lamina terminalis (FLT) and 13.9% in patients who did not. Clinical cerebral vasospasm occurred in 29.6% of patients who underwent FLT and in 54.7% of patients who did not. Frontobasal hypodensity was identified post-operatively in 0% of patients who underwent FLT and in 5% of patients who did not. Good outcome was reported in 69.81% of patients who underwent FLT and in 33.96% of patients who did not. Poor outcome was associated with higher Hunt and Hess grades, need for ventricular drainage, elevated intracranial pressure and multiple interventional vasospasm therapies. No complications were linked to FLT. Hauk et al.[42] reported that patients presenting with a TIA, a poor baseline condition, an aneurysm greater than or equal to 25 mm, and/or an age greater than or equal to 50 years are at increased risk for a poor outcome. The most important predictor of outcome was a post-operative stroke. About 75% of poor outcomes were due to a major ischaemic stroke. Solomon et al.[105] also found stroke to be the most significant complication accounting for 50% of poor outcomes.

82 Distal Anterior Cerebral Artery Aneurysm

Ravi Ramamurthi, Shivaram Bojja

INTRODUCTION

Distal anterior cerebral artery (DACA) aneurysms, located distal to the anterior communicating (ACom) artery on the A2-A5 segment of the anterior cerebral artery (ACA) are less common and account for 3.1–9.2% of all intracranial aneurysms.[3] The characteristics of the aneurysm arising from distal accessory ACA are considered similar to those of distal ACA aneurysms.[5] In 1948 Sugar and Tinsley reported the first attempt to treat a distal ACA aneurysm surgically.

MICROSURGICAL ANATOMY

Most DACA aneurysms arise at the pericallosal-callosomarginal artery (PerA-CMA) junction, which is usually located in the A3 segment of the ACA around the genu of the corpus callosum. The aneurysms can rarely arise at the origin of the frontopolar artery more distally.

Aneurysms in the PerA-CMA junction are divided into two types according to their location:[4]

1. Supracallosal
2. Infracallosal

Infracallosal distal ACA aneurysms are defined as those located in the lower-half of the A3 segment, which makes it more difficult to gain proximal control.

CLINICAL CHARACTERISTICS

The average age at presentation is 50 years with a slight female preponderance.

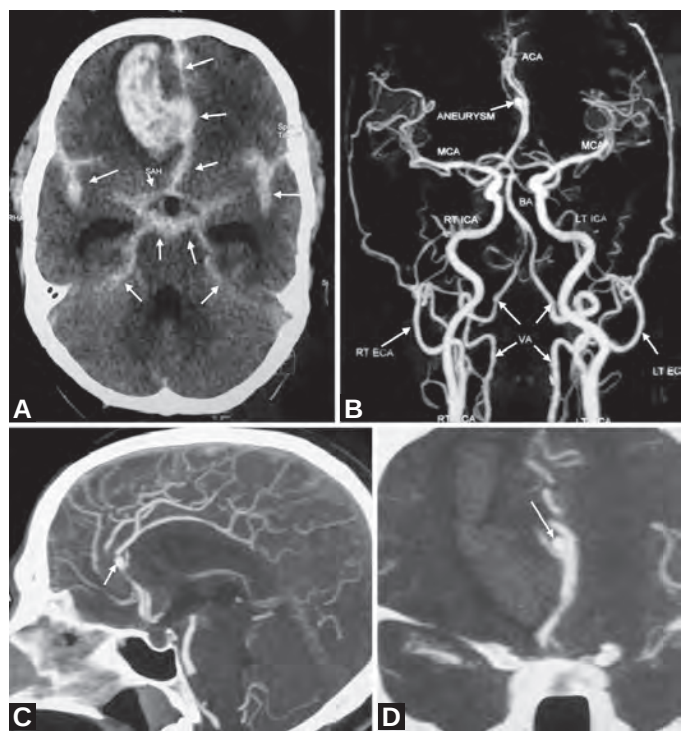
Patients with ruptured DACA aneurysms present with symptoms and signs typical of subarachnoid haemorrhage (SAH) with occasional monoparesis of a lower extremity. A hemispheric disconnection syndrome may occur if there has been a significant intracallosal haemorrhage. Intracerebral haemorrhage is a common (50%) complication of ruptured DACA aneurysms. DACA aneurysms are commonly associated with other intracranial aneurysms and may be identified in patients investigated for SAH from aneurysms at other sites.

INVESTIGATIONS

The computerised tomography (CT) findings are similar to those seen with ACom aneurysms. Hyperdense areas are seen in the interhemispheric fissure, cingulate sulcus, pericallosal cistern and cistern of the lamina terminalis in ruptured aneurysms. A four-vessel digital subtraction angiography (DSA) is the investigation of choice for evaluation of SAH from DACA aneurysms. For determining the laterality of the aneurysm a unilateral injection of contrast is done. CT angiography is also useful to detect these aneurysms (Figs 1A to D).

SURGICAL CONSIDERATIONS

As the two anterior cerebral arteries are side by side, the effect of SAH, haematoma and surgical manipulation may involve both the vessels. At surgery, if the callosomarginal artery is mistaken for the pericallosal artery, the surgery will be difficult. This happens when there is subfalcine herniation of the cingulate gyrus.



Figs 1A to D: Imaging of a patient with distal anterior cerebral artery (DACA) aneurysm. (A) Computerised tomography. (CT) scan showing subarachnoid haemorrhage and intracerebral haematoma in the right frontal lobe. (B) CT reconstructive angiogram in anterior view showing the DACA aneurysm. (C) CT angiogam in sagittal section showing DACA aneurysm. (D) CT angiogram in coronal section showing DACA aneurysm

With the patient in the supine position, a craniotomy flap is raised, with the medial limb over the sagittal sinus. Identification of the aneurysm at operation becomes easier if the bone flap is planned using some guidelines from the angiogram. A line is drawn on the lateral view of the angiogram from the nasion to the aneurysm. From the end of the line, a perpendicular is drawn to meet the vault of the skull. The point where the second line meets the vault should be the midpoint of the medial limb of the bone flap. A search for the aneurysm should be made along the imaginary perpendicular line. While retracting the medial frontal lobe, the bridging veins should be preserved as far as possible. The callosomarginal and pericallosal arteries are closely related to the neck and the fundus of the aneurysm and care should be taken to preserve the continuity of the vessels while applying the clip. Proximal control of the feeding artery is not easily possible in this approach. Resection of a portion of the corpus callosum helps in providing excellent exposure of the proximal A2 segment. No untoward effects of resection of the corpus callosum have been noticed.[1,6] Occasionally, a transfalcine approach through the side opposite to the lesion by cutting the falx, will help direct visualisation of the lesion and clipping of the aneurysm.[2]

Endovascular treatment by coiling, including parent vessel occlusion using coils or coils combined with n-butyl-2-cyanoacrylate is safe and effective.[3]

83 Middle Cerebral Artery Aneurysms

Mathuriya SN, Pathak A, Gupta Vivek, Grover VK

Aneurysms of the middle cerebral artery (MCA) pose a significant challenge to neurosurgeons. They constitute around 20% of all cerebral aneurysms. MCA aneurysms constituted 25.3% of 2,588 intracranial aneurysms operated upon by the author at PGIMER, Chandigarh, during an 18-year period. The commonest location is MCA bifurcation both in the ruptured and unruptured group. They constitute 89% of all ruptured and 30% of all unruptured aneurysms.[10] Mirror MCA bifurcation aneurysms are seen in 14% of patients. Around 45% of ruptured MCA bifurcation aneurysms caused an intracerebral haematoma (ICH).[1,54] Around 96% of aneurysms were saccular, 10–15% were located at M1 and 5–7% in the distal MCA segment.[10]

The majority of MCA bifurcation aneurysms are located between two or three M2 branches as a lateral extension of the M1 segment and they project laterally. Aneurysms in this location, more frequently than other locations, produce ICH, but have a lesser incidence of hydrocephalus. Around 24% of aneurysms have been reported to be large and 9% giant. Around 47% were located on the left side and 53% on the right.[10] They may be associated with aneurysms in other locations.[10,31,59] The size of the neck has been reported to be narrow or wide in an equal number of cases in some studies, whereas a few report that a large number usually have a comparatively wider neck which involves the origin of M2 branches. Aneurysms of the M1 segment arise at the origin of the temporopolar or anterior temporal arteries (lateral wall) or in relation to the lenticulostriate arteries [(medial wall) 10–15%].[2,4,11,20,69]

CLINICAL FEATURES

Middle cerebral artery aneurysm rupture leads to a symptom complex which is indistinguishable from subarachnoid haemorrhage (SAH) due to bleed of an aneurysm in any other location.[8] More than half of the patients with a ruptured MCA aneurysm lose consciousness, which is more than in aneurysms in other locations. Severe headache is the most prominent symptom of SAH which is usually diffuse, but one-third of patients with MCA aneurysms have unilateral headache.

Eighty per cent of patients with ruptured MCA aneurysms had focal neurological deficit at presentation in the form of hemiparesis, aphasia, visual field defects and facial weakness. These are noticed in only 34% of aneurysms in other locations and only 7% had severe deficits. Headache and vomiting were seen in 90% and 66% respectively. Seizures occur in 10% of patients. It is far less common in other locations. A patient with SAH, who is conscious with gross hemiparesis on presentation, is most likely to have an aneurysm in the MCA. Giant aneurysms are commoner in the MCA than in other locations, except the paraclinoid region.[10] These can grow to a massive size without producing deficits. Large and giant MCA aneurysms without rupture produce mass effect and can, in rare instances, lead to raised intracranial pressure (ICP). A rare presentation in these aneurysms is temporal lobe epilepsy, which is exceptional in aneurysms in other locations. These seizures result from damage and gliosis of the medial temporal lobe due to compression or repeated subclinical haemorrhages.[33] Giant aneurysms may, rarely, lead to cranial nerve compression. Ischaemic symptoms, such as TIA and stroke, are comparatively uncommon presentations of aneurysms, but these are more common with MCA aneurysms than others. Exceptionally, a major stroke can result from occlusion of the MCA or its major branches due to aneurysmal expansion and spontaneous thrombosis.

Aneurysms in the paediatric age group are uncommon (0.5–4.6%) and still more infrequent in neonates.[30] The ultimate outcome is poor due to delayed diagnosis. Clinical features include irritability, vomiting, seizures SAH and coma. SAH is the most common presentation. Mortality in patients who are not treated surgically is high. The important diagnostic modalities are cranial ultrasound and MRA.[23,30]

Aneurysms can occur at the site of arterial bypass and it depends on a disproportion between the donor and recipient vessels and the number of sutures inserted. These aneurysms result from increased haemodynamic forces and intra-operative disruption of the intima and media at the anastomotic site. These patients need periodic follow-up, specifically patients with an unusual ICH at the site. These aneurysms are relatively large, project into the frontal lobe in the direction of flow and usually present after a short interval of bypass surgery.[38]

Intracerebral Haematoma

Around 30% of ruptured MCA aneurysms present with intracerebral haematoma (ICH) (Figs 1 and 2). A

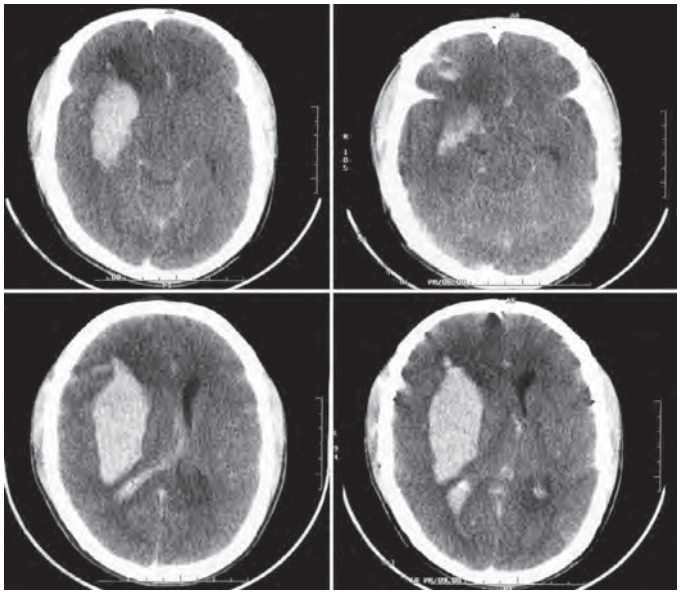

Fig. 1: CT showing Rt. frontotemporal ICH (deep) with IVH

haematoma extending into the frontal operculum and the temporal operculum, bridging the sphenoid ridge, is virtually pathognomonic of a ruptured MCA aneurysm. Computed tomography (CT) is mandatory to diagnose SAH, IVH and ICH. The location of the ICH, its size, extension and associated ischaemic areas and infarcts in the temporal/frontal lobe or associated intra-Sylvian haematoma (ISH) also help in diagnosing the site of aneurysm rupture. Management of ISH needs appropriate and precise judgement as it involves a large number of perforators in the Sylvian cistern with their variations and adhesion to the haematoma. Patients with temporal ICH are usually in poor grade or they may deteriorate fast. Hence, definitive investigations (angiogram/CTA) are required to visualise the details of the pathology.

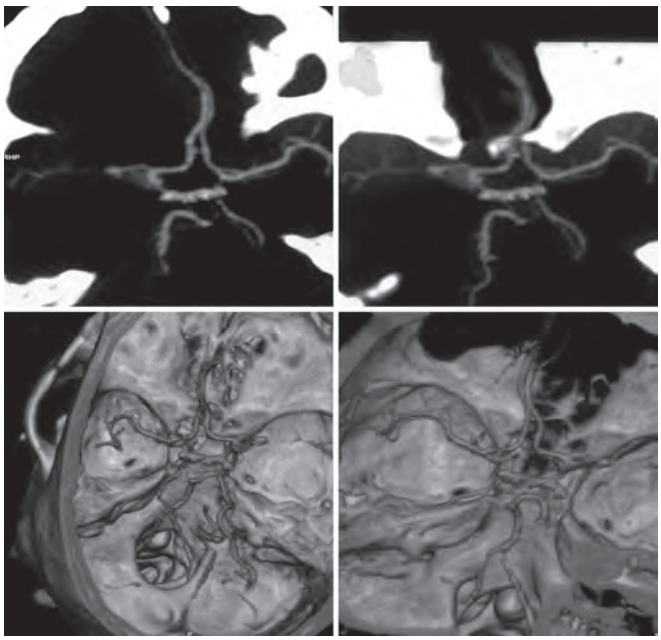

Fig. 2: CTA showing Rt. M1 aneurysm

ICH occurs maximally in laterally directed MCA bifurcation aneurysms.[1,10,39,48,54]

INVESTIGATIONS

After CT has confirmed SAH, an angiogram/CTA is performed on an urgent basis after confirming fitness for the same, mainly after assessing hydration and renal parameters. This can differentiate an ISH from a temporal ICH in which there will be elevation of M1 and increased distance between the M2 branches and the inner table of the skull.[34] Aneurysms originating at the early temporal branches project into the temporal lobe and those from the lenticulostriate arteries into the lateral frontal side.

MCA bifurcation aneurysms have three main projections: (1) anterosuperior; (2) posterior and (3) inferior.[73] These aneurysms are classified into five types: (1) Intertruncal—These have a superiorly and posteriorly directed dome and the base is usually towards the M2, and the M2 is commonly involved in the base. (2) Inferior MCA bifurcation aneurysms project inferiorly and anteriorly towards the sphenoid ridge. (3) Lateral aneurysms project in line with the long axis of M1. (4) Insular MCA bifurcation aneurysms project towards the insula in the coronal plane and medially in the axial plane. Types 2 and 4 are not intertruncal and do not involve the M2. (5) Complex MCA bifurcation aneurysms.[10]

In some dysmorphic and giant aneurysms the growth may be multidirectional in relation with M1 and M2. A detailed anatomical study, not only of the aneurysm complex (neck size, fundus, lobes, rupture site) but also the vessel of origin, branching, perforators close to the neck and fundus and their adherence, and any branches originating from the fundus/just close to the neck, origin of other vessels, type of circulation, displacement of vessels, vasospasm, any other aneurysms and any more lesions is essential for planning treatment. Information about dynamic flow is important when DSA or 4D CTA is done. All these details are useful for planning the type of treatment, type of approach, exposure of vessels, temporary clipping and dissection around the neck. The 3D DSA provides most of the information required. All angiographic studies underestimate the size of the neck as compared to what is seen at surgery, but 3D DSA is relatively accurate. This being an endoluminal contrast study it under represents all intraluminal contents (plaques, calcification, etc.).[51]

Distal MCA aneurysms arising from the second bifurcation are still in the Sylvian fissure, but not those arising beyond the M3. Almost all MCA aneurysms have a neck except fusiform, serpentine and dissecting ones. Branches usually arise close to or at some distance from the neck but, rarely, they may arise from the dome.

The CTA being a non-invasive, short procedure, not requiring much of the patients' co-operation can be used as a definitive diagnostic modality for MCA aneurysm diagnosis (Figs 3 to 10). One can construct and generate a surgeon's view on the console, rotate the image 360

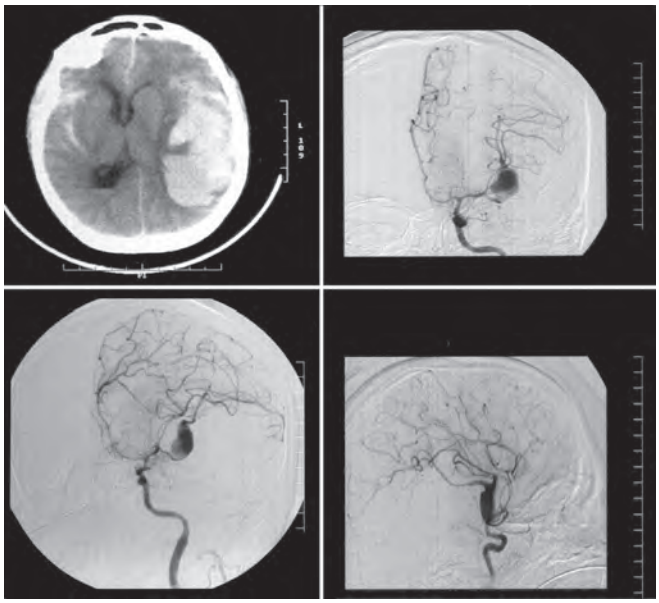

Fig. 3: CT and DSA—large Lt. temporoparietal ICH and partially thrombosed large MCA bifurcation aneurysm

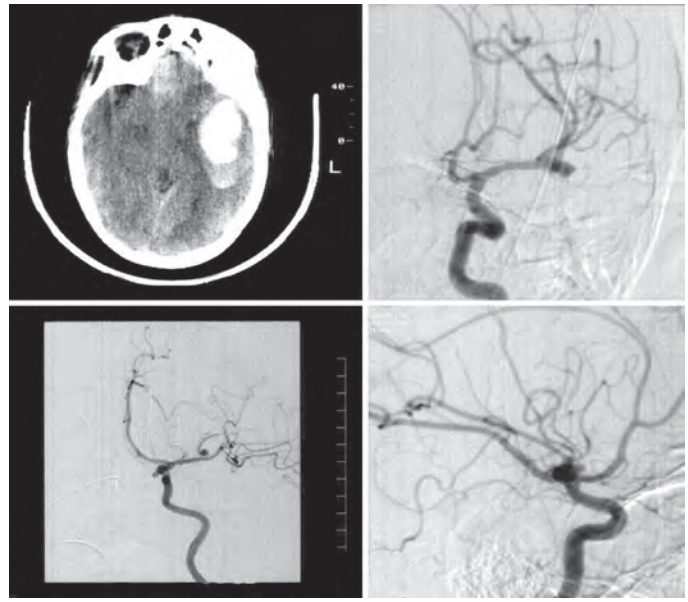

Fig. 4: CT and DSA—Lt. temporal ICH and MCA bifurcation aneurysm

degrees and visualise the aneurysm, vessels and their relation on all surfaces of an aneurysm. The operative technique: splitting of Sylvian fissure, sequence of vessel exposure and aneurysm dissection can be well planned so as to avoid premature rupture at exposure and dissection. The 2D CTA allows identification of the clot and its detailed configuration and CTA can predict a probable rupture point (3D and 2D CTA fused). An irregular aneurysmal shape or aneurysmal bleb on 3D CTA and adjacent thick high density areas on 2D CTA indicate the haematoma and clot on the dome in areas of likely rupture. Many MCA aneurysms are bulbous and broad necked. The CTA can provide information to pre-operatively decide on the size and shape of clips required, and also the need for multiple clips. The direction of the dome and its relationship to the M1 and M2 branches can be visualised in all views and on rotation, thereby helping in deciding on the approach. On CTA it can be seen whether the M1 is anterior or posterior to the aneurysm. In superiorly directed aneurysms M1 is exposed first, and the M2 in inferiorly and laterally directed aneurysms.[7,30,56]

Early branches typically arise at right angles to the main trunk of the MCA, whereas the true post-bifurcation trunks run nearly parallel, diverging only minimally before they reach the genu of the MCA. The lateral lenticulostriate arteries usually arise proximal to the bifurcation, but in 17–23% of patients, they originate from the post-bifurcation part of the MCA.[15]

The CTA is a non-dynamic study, hence, has an inherent pitfall of not providing information about collateral circulation and flow contribution from the various

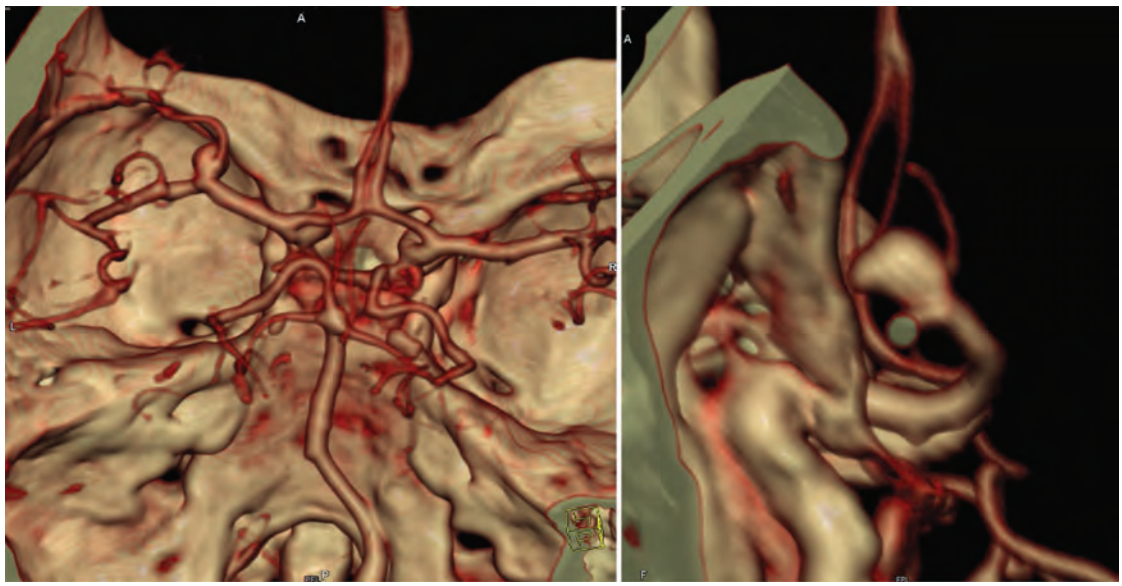

Fig. 5: CTA—Rt. MCA bifurcation aneurysm

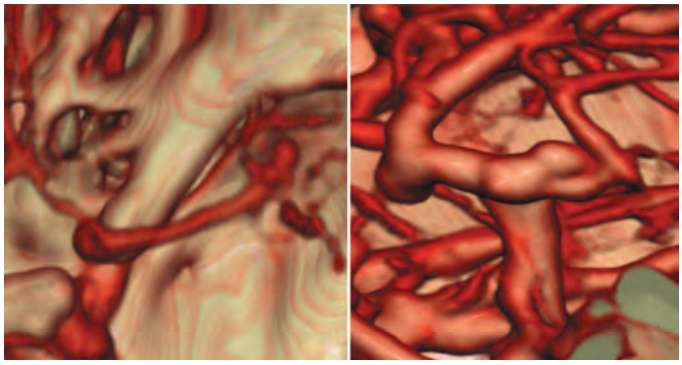

Fig. 8: CTA showing MCA bifurcation aneurysm with a ruptured bleb

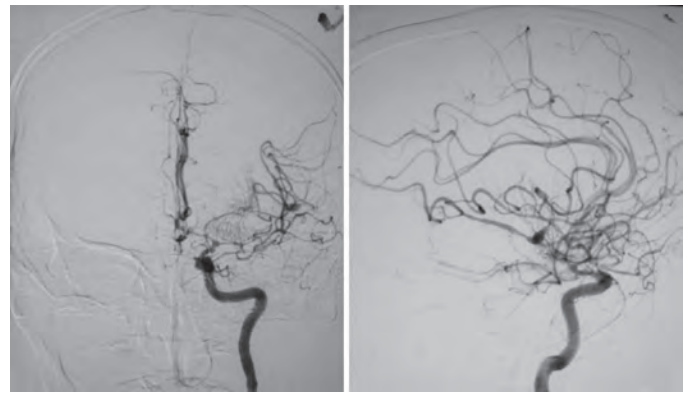

Fig. 9: DSA—Lt. distal MCA aneurysm

vascular territories, which is required for temporary clipping. The CTA cannot image definitely aneurysms less than 2 mm in size, and perforators and other very small vessels less than 1 mm diameter.[22] There are a few more drawbacks, e.g. kissing vessel artifact, wherein the exact site of origin of branching vessels originating at the neck of the aneurysm may not be visualised and may give an erroneous impression of a broad neck. A superimposed Sylvian vein and venous confluence may wrongly be interpreted as aneurysm. It may not be possible to differentiate a crooked infundibular dilatation from an aneurysm and vessel adherence to the aneurysm.[26,44] Vasospasm and its grade and extent cannot be made out. In post-operative follow-up, CTA is not an alternative to DSA due to metal artifacts of clips in the usual software, but the artifacts can be obviated by use of software for their removal.[6,63]

4D Computed Tomography Angiography

It provides details of aneurysm wall dynamics, e.g. dome pulsation, blebs and growth of aneurysm. It entails CTA with a retrospective electrocardiography-gated reconstruction algorithm by use of technology that

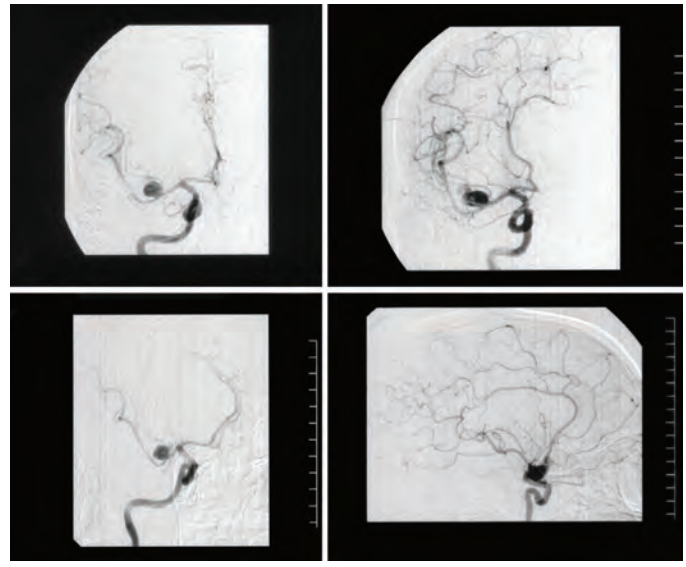

Fig. 10: DSA showing MCA bifurcation aneurysm Rt

was developed initially to examine coronary arteries. Pulsating blebs are seen in 32% of saccular aneurysms and 50% enhancement of volume difference between systole and diastole.[19] These contractions may indicate the site of rupture. The rupture points are seen in 40% of cases. This visualisation of the aneurysm wall in 3D cannot be made out even on DSA. It shows both the entrance and the exit points in dissecting aneurysms and also subacute and chronic intramural haematoma.

TREATMENT

Direct microsurgical repair is the most accepted, common, effective, and safe modality to treat MCA aneurysms, specifically with a wide neck and major branches arising at the initial portion of the dome/base. This is an accepted method even at institutions where coiling is a technique used for most locations.[46] The peripheral location and comparatively well known anatomy and characteristics are more suitable and acceptable for microsurgery. Anatomical variations are seen, but usually are well known and described. This awareness avoids untoward problems. In spite of all these positive characteristics, these aneurysms do not have that good an outcome in spite of a safe and non-complicated clipping technique. The responsible factors are: initial poor clinical grade; hemiparesis/hemiplegia; dense SAH; ISH; large temporal/sometimes frontal ICH and raised ICP. Dense SAH and ISH cause vasospasm also. Many a time a large temporal ICH demands an emergency evacuation and clipping of aneurysm/EVT.[10,22,31]

Anatomy[15,31,43,47,68,73]

These aneurysms can be classified location wise as: (1) M1 segment—(a) at lenticulostriate arteries takeoff, (b) at temporal arteries take off, (c) at frontal arteries take off; (2) MCA bifurcation or trifurcation and (3) Distal sites on M2, M3 and M4 segments. Most studies indicate that MCA bifurcation aneurysms are the commonest (80–90%).[15,31,73] Many a times proximal early branch aneurysms resemble MCA bifurcation aneurysms.

The MCA, after its origin from the ICA lateral to the optic chiasm, traverses underneath the anterior perforated substance (APS) and 1 cm posterior to the lesser wing of the sphenoid. In the Sylvian cistern, it makes a posterosuperior turn (genu) at the limen to lie on the surface of the insula. At the periphery of the insula, the branches of the MCA lie on the medial surface of the frontal, temporal and parietal opercula.

Sylvian Fissure[15,73]

This is a longitudinal cleft and has a superficial portion visible on the surface, a stem and three rami. The deep portion is hidden in the cleft between the frontal and parietal opercula above and the temporal operculum below. Laterally, the Sylvian cistern contains the MCA complex, the deep Sylvian vein and its tributaries. The sphenoid ridge projects into the stem separating the frontal and temporal lobes. The posterior ramus extends between the frontal and parietal lobes above and the temporal lobe below. The two anterior rami divide the inferior frontal gyrus into the pars orbitalis, triangularis and opercularis.

The anterior portion of the Sylvian cistern is called the sphenoidal compartment and the posterior part is called the operculo-insular compartment. Thick arachnoid bands cover the origin of the MCA and it appears like a tunnel. Many arachnoid trabeculae cross over the MCA from the frontal to the temporal lobe. These are numerous and thick on many occasions, and should be cut with sharp instruments to expose and dissect the MCA complex. The Sylvian cistern narrows down superiorly as the frontal and temporal lobes come close to each other. The width on the surface is around 5–10 mm. This is classified into four catagories:[10,73] (1) Large and voluminous with transparent and fragile arachnoid bands; (2) A small cistern with thin and fragile arachnoid bands; (3) Large cistern with thick and tough arachnoid and (4) Small cistern with thickened and tough arachnoid. The arachnoid trabeculae may be toughened by adhesions that occur after a SAH or meningitis, making dissection of the Sylvian cistern more difficult. In some patients, the frontal lobe may indent the temporal lobe within the fissure or vice versa, further complicating dissection.

Middle Cerebral Artery[10,15,31,47]

The MCA is classically divided into four segments. These are: (1) the M1 or sphenoidal segment; (2) the M2 or insular segment; (3) the M3 or opercular segment and (4) the M4 or cortical segment. The M4 segment is the parasylvian segment while the M5 segment is the terminal segment.[10,47]

The M1 extends from the origin of the MCA to the genu, which lies on the limen insulae and lies in the deep part of the Sylvian fissure. In 57–86% the bifurcation occurs proximal to the genu[10,15,31,47] and in 27% is distal to the genu. The M1 segment can be divided into pre-bifurcation and post-bifurcation segments.

Two sets of branches arise from the M1 trunk. Those from the superolateral surface supply the temporal lobe. They may include the uncal artery (usually arises from the ICA), the temporopolar artery and the anterior temporal artery. Often, the temporopolar artery is absent, with a commensurate increase in the size of the anterior temporal artery. The second group of arteries arises from the inferomedial surface of the middle cerebral trunk and consist of a variable number of striate arteries. The striate vessels can be divided into proximal, middle and distal groups. Their number ranges from 1 to 15. The lenticulostriate arteries (LSAs), particularly the more lateral vessels, are recurrent arteries forming vascular loops as they turn medially to enter the lateral two thirds of the APS. The substantia innominata, the lateral anterior commissure, the putamen, the lateral globus pallidus,

the superior half of the internal capsule, corona radiata and the body and head of the caudate nucleus are supplied by the LSAs. In rare circumstances, LSAs arise from M2 branches.[3,15,22,47]

The "early branches", include the temporopolar and anterior temporal arteries from the inferior trunk and the fronto-orbital artery from the superior trunk. These arteries supply the anterior part of the temporal lobe and orbital part of the frontal lobe. Thirty per cent of the time, the uncal artery may arise from the M1 segment instead of the ICA and proximal to the temporal branches.[73] Sometimes (5%), two temporal arteries take off as a single large-stem artery, giving the impression of an early bifurcation. This condition was coined as a "false bifurcation" by Yasargil.[73] In some cases, the temporopolar and anterior temporal arteries are hypoplastic or absent and a single temporal branch coming from the M2 segment may take over the cortical areas supplied by them. The LSAs arise from the posteromedial aspect of M1. These arteries may also arise from the M2 segment or from a large fronto-orbital artery taking off from the superior trunk of the MCA. Three patterns of origin of these vessels have been observed: (1) all LSAs arise from a single artery (40%); (2) two large arteries originate from the M1 and then divide into a number of small arteries (30%) and (3) a number of small twigs of LSAs arise from the M1 (30%).[3,15]

The M2 (insular) segment begins at the genu and terminates at the circular (peri-insular) sulcus. The MCA divides into superior and inferior trunks at the level of the limen insulae, and these trunks course over the insula as M2 segments. The superior and inferior trunks may be equal in diameter, or one of them may be larger than the other.[15,22,43,47]

According to Umansky,[68] there are four types of branching patterns: (1) cortical branches arise as collateral vessels from a single trunk that terminates in the angular artery (6%); (2) the MCA divides into the superior (frontal) and inferior (temporal) trunks (64%); (3) the MCA divides into the superior, middle and inferior trunks (29%) and (4) the MCA divides into four trunks (1%).

In a study reported by Gibo et al.,[15] 78% of the MCAs divided as a bifurcation, 12% as a trifurcation and 10% divided into multiple trunks. In contrast to these studies, Yasargil[73] stated that, when a large branch arises from the superior or inferior trunk just after the bifurcation, a false impression or "pseudotrifurcation" or "pseudoquadrification" takes place. The M2 segment gives off approximately 10 branches that arise mainly from the superior trunk. Some of these arteries constitute the main blood supply to the insula. The prefrontal, precentral, and central arteries, and sometimes the anterior and posterior parietal arteries, fan out over the insula from the superior trunk. Once they reach the superior peri-insular (circular) sulcus, these arteries make a sharp angle to become the M3 segment. Due to this sharp angle, these arteries are called "candelabra arteries". An important anatomical landmark for the central artery in the region of the insula is that it courses along the central sulcus of the insula. The inferior trunk gives rise to the middle temporal artery, posterior temporal artery and angular artery. The M3 (opercular) segment begins at the circular (peri-insular) sulcus of the insula and terminates at the surface of the Sylvian fissure. The M3 segment passes over the insula parallel to the M2 segment, but in the opposite direction. The M4 (parasylvian) segment begins at the surface of the Sylvian fissure and M5 is the terminal segment.[10]

Branches for ECIC Bypass

A cortical artery with appropriate cortical length and at least 4 mm diameter is the temporo-occipital artery. The central sulcal artery is the largest branch to the frontal lobe, the angular artery is the largest branch to the parietal lobe and the temporo-occipital and posterior temporal arteries are the largest branches to the temporal lobe. The angular, posterior parietal and temporo-occipital have the longest segment on the cortical surface.[31] A 4 cm diameter craniotomy centred 6 cm above the external auditory canal is appropriate for the same.

Variants

Duplication of the MCA has been reported in 1–3% of cases. Duplication of the MCA should especially be differentiated from early branching of the MCA, which is a more common variant. Accessory MCAs have also been associated along with aneurysms.[34,35]

Surgical Techniques [3-5,8-10,14,17,25,31,32,40,45-47,50,58,60-62,66,70-73]

Despite good technical results, these patients have surprisingly poor outcomes, primarily because a rupture often produces both SAH and ICH/ISH. The general principles are an adequate exposure and no brain retraction. These are the keys to successful aneurysm surgery.[10,61,62] Excessive retraction leads to unsatisfactory results. The critical elements of aneurysm surgery are: (1) head positioning and fixation determined by the origin of the aneurysm and direction of the fundus; (2) extent of bony exposure; (3) relaxation of the brain via drainage of cerebrospinal fluid (CSF), evacuation of haematoma or by other means like normoventilation and cerebral decongestants in acceptable doses and (4) dissection should routinely be limited within the subarachnoid space (SAS).

Three basic approaches have been described.[3,8,10,31,40,45,50,58,60,61,70,72]

1. Proximal Trans-Sylvian—Splitting the Sylvian fissure medially and following the MCA trunk distally.
2. Distal Trans-Sylvian—Following the major divisions proximally to the aneurysm by opening the fissure peripherally/distally.
3. Superior Temporal Gyrus (STG) Approach[3,17,40]—Making a small corticectomy in the STG and then

subsequently entering the distal portion of the Sylvian fissure and following the M2 branches to the aneurysm.

Skeletal fixation is painful and may cause transient hypertension even in an anaesthetised patient. In patients with a recent SAH, we prefer to inject a local anaesthetic into the anticipated pin sites before securing the device to the cranium. The head is rotated to the contralateral side so that the Sylvian fissure and sphenoid ridge are oriented vertically in the operative field. This rotation usually requires approximately a maximum 30-degree turn of the patient's head and places the malar eminence near the apex of the operative field. Excessive rotation will lead to the temporal lobe obscuring the operative field, thereby needing more retraction to obtain a required exposure. It also leads to obscuration of the medial MCA branches behind the aneurysm dome, especially in large or giant aneurysms. This in turn complicates the dissection and aneurysm clipping. The head is extended (vertex down), allowing the surgeon to see up into the Sylvian fissure. This varies by approximately 20 degrees, depending on the aneurysm's location and its depth in the Sylvian fissure and the course of the MCA. More extension is used for aneurysms deep in the fissure than for those in more superficial locations. Finally, the head and neck are elevated to improve venous drainage before the fixation device is secured.

Proximal Trans-Sylvian Approach[8,10,14,31,40,72]

The basic pterional approach[50,72,73] elaborated by Yasargil is used. For a free bone flap, the flap of skin and muscle are turned together by opening the fascia and muscle along the same line of the skin incision posteriorly and then detaching the muscle from the bone by subperiosteal dissection and leaving it attached to the skin flap. Cutting the anterior (frontal) attachments of the muscle fibres from within facilitates retraction of the muscle backward and downward towards the temporal fossa with barbless fishhooks or sutures attached to strong rubber bands. This is done to suture the muscle properly anteriorly during closure and also to avoid a cosmetically unpleasant depression over the pterional region. Injury to the frontalis nerve is prevented by starting the incision at the level of the zygoma just in front of the tragus as opposed to 1 cm or 1.5 cm in front of the tragus. By starting the incision just in front of the tragus, one spares not only the frontal branch of the facial nerve but also the superficial temporal artery. The authors prefer to raise an osteoplastic flap. It is important to expose 1–2 cm of the temporal lobe to provide access to the Sylvian fissure. The craniotomy should extend along the floor of the frontal fossa just above the supraorbital rim, exposing 3–4 cm of the frontal lobe. The lesser wing of the sphenoid is drilled medially as far as possible to make the anterior and middle cranial fossa floor flat. This helps in avoiding excessive brain retraction.

After adequate relaxation is obtained, the surgeon decides whether the exposure should proceed from medial to lateral or vice versa. In the former case, the carotid cistern is opened by sharp arachnoidal dissection, and the medial aspect of the Sylvian fissure is then opened, preferably on the frontal side of the Sylvian veins. One may have to coagulate a venous tributary at the medial end, but quite often the vein can be spared by dissection and lengthening. Whether coagulating a vein can lead to problems may be determined by applying a temporary clip on the vein and observing the flow on indocyanine green angiography (ICG). The exact location of the fissure medially is not always apparent and the fissure does not always "open" in a clean arachnoidal plane. Use of retractors at the initial part of the procedure should be avoided as the brain is usually lax with decongestants, ventilation and CSF drainage. The arachnoid is opened sharply and CSF is released from the optic and carotid cisterns. Wide opening of all the medial cisterns and separation of the frontal lobe from the optic nerves, chiasm, and lamina terminalis fenestration minimises the need for brain retraction. The Sylvian fissure usually underlies the indentation in the brain made by the sphenoid wing. The Sylvian vein generally hugs the temporal edge of the fissure. Occasionally, neither the sphenoid indentation nor the Sylvian vein will lead to the location of the fissure. Cortical middle cerebral branches are more difficult to see on the surface, but consistently mark the location of the fissure as they emerge from the depths of the fissure and travel over the surface of both the frontal and the temporal lobes. The arachnoid is best dissected sharply when it is held taut. It is safe and less traumatic to use intermittent suction retraction on a small cottonoid to accomplish this task and reserve mechanical brain retraction for the final stages of dissection. By spreading and dissecting with the fine tip bayonet and cutting with microscissors, the arachnoid of the Sylvian fissure is opened from the lateral to the medial side. One or more veins bridging the Sylvian fissure may be encountered, and these may be sacrificed. As the fissure is opened progressively, retraction can be applied immediately adjacent to the area of dissection, always keeping the arachnoid under some tension. The superficial arachnoid layer is divided before carrying the dissection deeper into the fissure. As the fissure is split, the frontal lobe can be mobilised and retracted progressively with the suction tip. The microscope view is more from the frontal lobe towards the medial temporal lobe as the opening in the fissure deepens. If the surgeon gets lost in the subpial plane, following the middle cerebral branches will lead to the fissure and the MCA. When dissection in the fissure is impossible, the surgeon should orient the dissection towards the temporal lobe and perform subpial dissection in the STG. The MCA is followed along its anteroinferior aspect, away from the perforators.

One or two temporal or frontotemporal branches will be seen before the aneurysm is reached. When the aneurysm arises from the M1 segment in relation to a perforating branch, it is necessary to achieve a limited separation of the perforators from the neck which is enough to pass a clip. Care is taken to preserve the LSAs. These aneurysms

usually are not too large and point straight upward into the frontal lobe; it is not necessary to dissect the dome completely. In some patients, the dome of the aneurysm is embedded in the temporal lobe; thus, care should be taken when applying the retractor. A potential site should be selected for placement of temporary clips avoiding the portion of the vessel harbouring the LSAs and provide enough space for deployment of the permanent clips. Dissection is begun at the aneurysm base because the body and dome of the aneurysm are invariably more fragile and one should try and keep away from the initial rupture site till the terminal step of dissection. The site of rupture is determined on CTA + 2D CT fusion and, at surgery, by adherence of the aneurysm to the arachnoid or the cortex.

MCA bifurcation aneurysms pose particular surgical challenges. In aneurysms of the bifurcation (or rarely the trifurcation) of the MCA a complete dissection of the aneurysmal complex is usually preferable. The main problems encountered are: a broad neck, calcification or atherosclerosis in the neck and adhesion of major divisions and sometimes smaller perforating vessels to the neck. When the neck is broad, it is not infrequent to have kinking following clip application. The LSAs exit mainly proximal to the bifurcation; however, some may arise distal to the bifurcation. The surgeon must ensure that they are not adherent to the aneurysm and included inadvertently in the clip. Sometimes, a third division that arises either from the bifurcation or shortly thereafter from one of the other major divisions, or a perforating vessel that arises either before or after the bifurcation and was not evident during initial and preliminary preparation of the neck may surprise the surgeon. Another advantage of dissection of the entire aneurysm complex including the dome is the increased freedom for clip application or modification in clip application. When a recently ruptured aneurysm dome is adherent to the brain, the surgeon should not hesitate to develop a subpial plane, leaving a small amount of adherent clot and brain with the dome. If felt necessary, a tentative clip may be placed proximal to the rupture point to facilitate complete dissection without the need for a temporary clip. The relation of the divisions to the dome is then worked out, and usually, at least one division must be separated carefully from the base of the aneurysm by sharp dissection to define the true neck. Care must be taken to spare the important recurrent perforators, at least one of which is usually found adherent to the aneurysm. Attempts should be made to dissect it sharply off the neck and also a deep vein invariably located there. In those cases, we score the connective tissue that binds the aneurysm to the artery by using a small, sharp knife/needle knife under high magnification. It is frequently necessary to replace the clip several times to avoid kinking of the divisions or "slippage" of the clip proximally onto the MCA. The dissection is begun to separate the divisions more proximally down to a narrower neck. The surgeon can retract the vessel gently away from the aneurysm to stretch the arachnoid bands. These must be sharply divided to separate the vessel from the aneurysm. Usually, one can control bleeding by placing a small cotton patty over the perforation in the aneurysm and applying gentle pressure with the sucker. Bleeding often stops after a few minutes of pressure. When this fails, temporary clips/trapping controls the bleeding. Deformation of the aneurysm by using the sucker, bipolar or dissector allows identification and dissection of the MCA branches hidden behind the aneurysm. In multilobulated or bulbous aneurysms with broad necks, a flawless clipping without prior shaping of the base may be difficult/not possible on many occasions. Bipolar coagulation is used to prepare these aneurysms for clipping. The current is at a low setting. The cleaned bipolar tips are held a few millimetres apart and applied to the aneurysm. This procedure eliminates some of these small blisters and makes the wall look relatively "normal".

How far to proceed in separating the adherent division from the base of the aneurysm is a matter of exquisite surgical judgment of sharply separating the divisions from the neck of the aneurysm only after the aneurysmal complex is completely exposed and a temporary clip is applied. At this juncture, a tiny puncture hole generated can be controlled readily. Due to the complex anatomy of these aneurysms, a full array of aneurysm clips must be available. Fenestrated clips are frequently beneficial to leave a division in the fenestration when the division cannot be separated fully from the base.

Distal Trans-Sylvian Approach[40,45]

This surgical technique minimises retraction injury to the brain and preparation of broad-based MCA aneurysms for clipping is better. It is preferable to open the Sylvian fissure peripherally, find the distal divisions, and dissect proximally towards the aneurysm. This approach has the advantage of facilitating exposure of the distal anatomy of the aneurysm complex, which is usually the difficult part of the dissection. An M2 branch is identified and is followed proximally on to the proximal side of the aneurysm projection until the genu and the bifurcation are exposed. Proximal control is established just proximal to the neck of the aneurysm bypassing the aneurysm complex to avoid any intra-operative aneurysm rupture (IOAR) before gaining proximal control. Then the aneurysm complex is dissected, and the aneurysm is clipped. Yasargil advocates exposure of the MCA to achieve proximal control and then moving laterally. The distal trans-Sylvian approach is associated with less risk of injury to the LSAs. Leaving the proximal MCA unexposed, the risk of exacerbating vasospasm is also minimised.

Superior Temporal Gyrus Approach[17,40]

When the distal fissure cannot be opened atraumatically, occasionally, with a recent haemorrhage or when there is a large temporal ICH, a variant of the lateral Sylvian approach, the STG approach, is considered. This

approach allows the surgeon to enter the fissure distally by subpial dissection without disturbing the Sylvian veins and the superficial portion of the frontal operculum.The only difference is that the surgeon enters the fissure not at the surface but at a depth of 1.5–2 cm from the surface through a cortisectomy in the anterior aspect of the STG. The cortisectomy is extended medially into the vertical segment of the Sylvian fissure over the insula, the arachnoid is then opened, and the fissure is entered. Peripheral branches of the MCA are identified and followed medially. From this point, dissection and clipping proceeds in the same way as done in the distal Sylvian approach. This approach offers the advantage of reducing brain retraction and manipulation of the middle cerebral trunk and its perforators. Its advantages are preservation of the Sylvian veins, minimal retraction even with a large temporal ICH and a swollen brain. A rapid procedure is performed. Its main disadvantage is its violation of brain tissue and theoretical increase in the risk of epilepsy.

For this approach, the skin incision is started at the level of the zygoma, just in front of the tragus. The incision curves slightly backward above the ear before starting to swing forward to the hairline. The cut is extended farther back on to the temporal bone to expose more of the temporal lobe. The pterion and lateral aspect of the sphenoid ridge are drilled. This step is important because it exposes the anterior aspect of the Sylvian fissure, which allows dissection of the aneurysm and clip application from an anterolateral direction as well as from a posterior direction. The exposure is obtained by suction of non-eloquent brain tissue or by removal of any existing temporal haematoma. A 1.5–2 cm incision is made in the STG beginning just behind the front of the Sylvian fissure and continuing posteriorly in a direction parallel to the fissure. The haematoma is evacuated sufficiently to achieve good relaxation, but staying away from the aneurysm. The subpial dissection is then extended medially into the vertical segment of the Sylvian fissure over the insula. Then, one may convert a STG approach to a distal trans-Sylvian approach (Fig. 11). Sometimes, it is difficult to appreciate the anatomy of the MCA, its branches and the aneurysm when approaching the aneurysm through the temporal lobe. Enough of the distal trunk of the MCA is exposed to allow the application of a temporary clip; should this become desirable. Once the distal part of the trunk of the MCA and the origin of the main divisions have been identified then one can proceed with dissection of the entire aneurysm complex. One should take the precaution of leaving adherent brain tissue and clot on the dome in the area of likely rupture (may be secured with a tentative clip). A temporary clip is used for these final stages of dissection. Most MCA bifurcation aneurysms project laterally as a direct continuation of the MCA; less commonly, they project caudally or rostrally.

In an aneurysm projecting backward over the insula, the dome of the aneurysm is in the way when the aneurysm is approached from a distal direction. Many prefer to approach such aneurysms from a medial direction by splitting the medial aspect of the Sylvian fissure first. The distal-to-proximal approach is not suited for aneurysms of the main trunk of the MCA, proximal to the bifurcation, and to those aneurysms that arise from the MCA at the point of origin of an early temporal branch. This is also not suitable for patients in whom the main trunk of the MCA is short, in aneurysms arising from an early bifurcation before the genu and those arising from the horizontal segment of the MCA beneath the insula. In these locations nothing is gained by following the M2 branches from the distal direction. The medial trans-Sylvian approach is ideal for these locations. For giant and complex aneurysms combined approaches are suitable.

Intra-Operative Rupture

Intra-operative aneurysm rupture (IOAR)[5] can occur during craniotomy or after dural opening, but usually it occurs during the final stage of dissection and clipping. Morbidity and mortality is around 30% in IOAR. Earlier in the surgery the rupture takes place, the worse is the prognosis. Blunt dissection causes large and irregular tears extending close or may be on to the neck, whereas most of microtears/micropunctures are small and are at a specific site, hence, can be successfully tackled without ischaemia or vessel sacrifice (Figs 12 to 14).

Fig. 11: Operative photo—distal trans-Sylvian approach

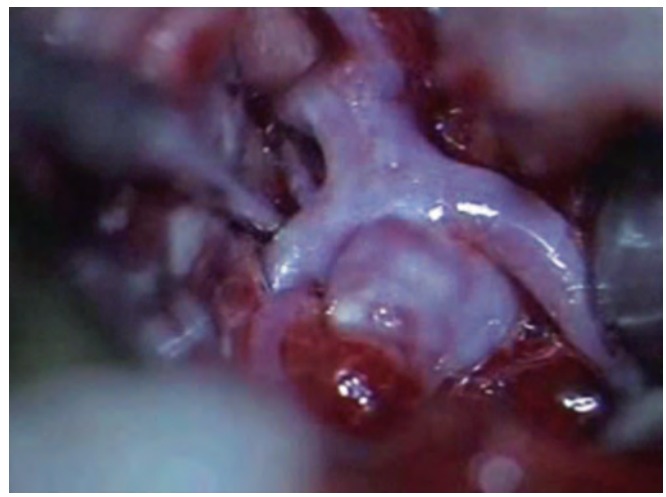

Fig. 12: Operative photo—large MCA bifurcation aneurysm

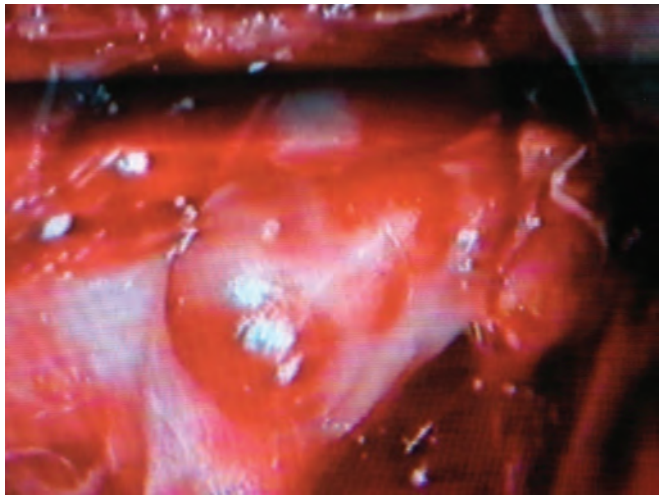

Fig. 13: Operative photo—MCA bifurcation aneurysm

- In case of rebleed during craniotomy (before bone flap removal), the procedure is postponed. If IOAR occurs just before/soon after dural opening, then continuing the surgery with the aim to clip the aneurysm will add to brain trauma caused by the fresh insult. Hence, the dura is opened and a large pericranium or fascia patch is sutured to reduce ICP. The bone flap is placed in the abdominal wall. In case of rupture after starting dissection (opening of Sylvian cisterns/basal cisterns), a part of the frontal/temporal pole can be excised, if needed, and the feeding artery is reached for temporary clipping with institution of immediate neuroprotection measures. Subsequent dissection is as described earlier, but has to be carried out in a limited time frame. IOAR during dissection is managed by temporary clipping and already administered neuroprotectants. A small hole can be managed by cotton and suction. In case of a large hole temporary clipping and dissection is followed by permanent occlusion of the neck. In case the bleeding aperture is exposed/dissected, a tentative clip can be applied on the aneurysm just proximal to the rent. Tentative clipping can either be with a temporary clip or permanent clip (mostly permanent clip) depending on the force required to occlude the ruptured site/extent of dissection completed at the tentative clip site.
- Rupture at clipping can be avoided by dissecting the full extent of the neck. The status of the neck and adjacent vessel should be considered when there are severe atheromatous changes or plaque. The clip ends are never forced through any resistance. If bleeding occurs at the time of clip closure, the clip is removed as the application will result in increase of the size of rent in the aneurysm. After successful clipping of the aneurysm, the dome is punctured and the collapsed sac is mobilised to visualise perforators, the distal end of the clip and the remaining neck if any (particularly in inferiorly directed sacs). Gradually, the remaining wall of the aneurysm is moved into the clip by readjustment under temporary occlusion of the proximal artery.

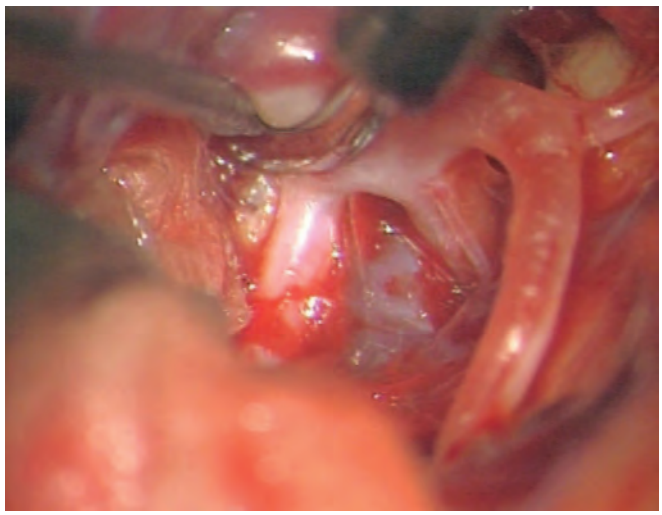

Fig. 14: Operative photo showing MCA bifurcation aneurysm

Single-Stage Approach for Bilateral Middle Cerebral Artery Aneurysms[32]

The patient's head is fixed in the supine position, not rotated but extended enough to minimise (frontal lobe) retraction. The operation table can be tilted to either side according to the requirement. The amount of tilt necessary for an approach to either side is less than 10 degrees and the head can be rotated as necessary on either side just by loosening a single screw from below in a four pin head clamp.

A bifrontal scalp flap is turned down to expose the pterional areas bilaterally. The ruptured aneurysm is approached first. The operating table can be tilted to the opposite side. A similar craniotomy is done on the opposite side and the aneurysm is clipped. This bifrontal scalp incision is symmetrical and better shaped as compared with two separate fronto-temporal scalp incisions. It carries an inherent risk of causing anosmia. This subfrontal approach with the head in almost the neutral position takes more time than for a unilateral MCA aneurysm, but this obviates the troublesome worry about the rupture of the untreated aneurysm during the peri-operative period.

Clipping of a contralateral unruptured aneurysm from an ipsilateral craniotomy can also be performed by experienced surgeons. The proximal ICA bifurcation to M1 is dissected and the aneurysm complex is located at the bifurcation area. The contralateral proximal and distal parent vessel can be exposed adequately for temporary control in case of rupture of the contralateral aneurysm. To obtain the additional working space needed to gain adequate contralateral exposure, a low fronto-orbital extension is necessary. With the Sylvian fissure opened wide, egress of CSF from the SAS allows relaxation of the brain and provides an adequate corridor into the basal cisterns containing the circle of Willis. This minimises the need for retraction of the frontal lobe and provides maximal working space at the depth of

the dissection. After clipping the ipsilateral aneurysm, dissection of the contralateral spaces is continued.[54] The unilateral approach is not always suitable, e.g. for peripherally located MCA aneurysms, a long M1 segment, or in case of large or complex MCA aneurysms. Careful study of the MRA/angiogram/CTA will always reveal if such a unilateral approach will be feasible or not.

Intra-Operative Microvascular Doppler

Intra-operative microvascular Doppler (IMD)[29] is useful in preventing incorrect placement of the clip more so in MCA bifurcation aneurysms due to the need for confirming the patency of three and, sometimes, four vessels. Mechanical arterial spasm is treated by topical sodium nitroprusside (SNP) and its efficacy is verified by IMD. This is a feasible, safe, and very reliable technique in aneurysm surgery. Compared to other procedures such as intra-operative angiography, the cost and efficiency of IMD is favourable. In complex and large aneurysms, a suspected residual neck could be detected by the typical turbulent flow. A 20-MHz 1-mm vascular probe is an appropriate module for direct insonation of the afferent and efferent vessels and the aneurysm sac before and following surgical clipping.

Indocyanine Green Chorioangiography Angiography

It is an extremely useful non-invasive technique to help in dissection to obtain a proper orientation, visualisation of perforators, wall thickness and plaques. This is a great help in delineating the remaining aneurysm neck and any vessel compromise due to the clip, the placement of which can be modified accordingly.

Giant Aneurysms[10,49,59,60]

Only about 5% of intracranial aneurysms are giant (an adequate understanding of these lesions, including the nuances of blood flow dynamics, natural history, and potential therapeutic options, is necessary when one is managing such aneurysms). The most common clinical presentations are SAH and ICH or, both. The poor natural history of these lesions is related to their mass effect on the surrounding brain tissue, to emboli that can dislodge to the downstream vascular territory, and to their high risk for rupture compared with that of other aneurysms. Detailed pre-operative planning includes MRI, CTA, angiography and balloon test occlusion (BTO) of the parent vessel. These can often provide additional valuable information for surgical planning. The treatment of complex aneurysms should be based on a balance between the risks associated with each treatment and its benefit to the patient. The procedures are direct clipping, wrapping and potential bypass. The CT is useful for evaluation of calcification. The MRI is ideal to visualise an intraluminal thrombus and its type, perilesional oedema and associated infarcts, if any. Sometimes, asymptomatic lesions may be incidentally detected on non-invasive imaging. Rotational angiography with 3D reconstruction delineates the anatomy of the aneurysm in relation to the surrounding structures and real time rotation, hence, is important for treatment planning. If BTO is tolerated, there may not be a need for a bypass or only a superficial temporal artery STA-MCA bypass is indicated. If, however, temporary occlusion evokes neurological deficits, a high-calibre conduit is needed to replace the target vessel flow with less complex lesions. Giant aneurysms have a higher rate of arterial wall calcifications, atherosclerotic plaque, and intraluminal organised thrombus along with a wide neck, incorporated branches and dysmorphic structure. These features complicate direct clip reconstruction. Occasionally, adjunctive treatment techniques, including profound hypothermia and circulatory arrest, may have to be adopted.

Direct aneurysm exposure and clip reconstruction of the parent vessel with multiple clip technique is recommended.[49] Total control of the aneurysm anatomy is necessary. With large and giant aneurysms, a small self-retaining soft and pliable retractor with very low tension is applied on the aneurysm itself. A small Rhoton-type dissector and self-retaining retractor can be used for this purpose. Temporary clips must be used in each of the divisions and on the main trunk. Closing a residual pouch sometimes results in a significant aneurysmal base remnant. Proximal anastomosis can be achieved to the external carotid artery or to the common carotid artery, depending on the anatomy in a given patient. The distal anastomosis usually is achieved to an M2 branch.

A certain degree of surgical experience is required to choose between the various options possible for dealing with giant aneurysms: (i) clipping using extra large, fenestrated or multiple clips; (ii) excision with or without interposition graft; (iii) proximal and distal vessel occlusion.

In giant aneurysms a good dissection of the ICA, A1, proximal M1, distal M1 and MCA bifurcation is required. Intra-operative angiogram and availability of endovascular help is extremely beneficial. The thrombus is removed and the aneurysm is clamped between the neck and the incision for decompression of intra-aneurysmal contents. The vascular clamp softens the aneurysm and prevents slippage of thrombus into the M1. In case the clip slides on to the vessel then several clips are used to avoid this problem.

Large, giant or globular aneurysms have thick walls that prevent the tips of the aneurysm clip from closing. In these situations one can safely use Drake's tandem-clipping technique with use of a fenestrated clip proximally; to seal the proximal portion of the aneurysm that is missed by the fenestration, a non-fenestrated proximal clip is applied. In extreme uncontrolled situations in giant aneurysms with organised thrombus and a thick wall, De Bakey's vascular clamp may have to be utilised as a rescue measure.[36] The sclerotic, calcific portion (if easily possible), and organised thrombus (with

a CUSA) are removed, followed by primary clipping, without a long duration of trapping and vessel compromise. Finally, the MCA trunk and branches are assessed with IMD, which is mandatory in large/giant/complex aneurysms.

When the amount of calcification is extensive, the only solution is to perform an aneurysmorrhaphy or to abandon efforts to clip the aneurysm and consider either endovascular occlusion if the anatomy is suitable or, sometimes (particularly in older patients), simply wrapping of the aneurysm. In general, wrapping has been proven to confer no long-term protective value in giant aneurysms.

A bypass is required when attempts to clip are unsafe/not possible. Combined endovascular therapy and revascularisation is a newer solution in these cases. Approximately 25–30% of giant MCA aneurysms simply cannot be clipped, the only possible treatment (other than no treatment) is occlusion of the afferent artery with a high-flow vein/arterial graft.

Advances in endovascular technology (EVT), such as modified stents (covered, partially covered or low porosity) and new embolic agents, will probably improve therapeutic options for these complex lesions. Newer stent technology, such as the "pipeline stent", will have a major impact on the treatment of giant aneurysms. The most important task is to choose the most appropriate management strategy for a specific patient.

Neuroprotection[13,37]

In addition to the routinely used intravenous brain protectants (IVBP, mannitol, antioxidants), the brain-protecting anaesthetic agents include propofol, etomidate, pentobarbital and isoflurane. These are administered individually or in combination. Overall infarction rate is reported to be 22.4% in the IVBP group versus 45.5% in the non-brain protected (NBP) group.

As a general guideline, temporary occlusion of the MCA up to 10 minutes is considered safe. The mean temporary clip time for patients free from infarction was significantly longer in the IVBP group than in the NBP group. Intermittent temporary clip application with periods of reperfusion had significantly less chance of developing an infarction than those who underwent one continuous episode of long occlusion. Propofol and etomidate have been shown to decrease the cerebral metabolic rate for oxygen ($CMRO_2$) and have the ability to produce a burst-suppression pattern on EEG monitoring with conclusive evidence of reduced neuronal damage following experimental ischaemia. Five minutes of reperfusion after every 10 minutes of ischaemia produced by intraluminal occlusion of the MCA in rats resulted in significantly smaller infarction volumes as compared with animals undergoing continuous ischaemia. Studies show that mild hypothermia too salvages penumbral tissue by intermittent reperfusion during iatrogenic ischaemia.

Temporary Clipping[21,53,64,65]

The safety and value of temporary clipping of the MCA are matters of considerable controversy. As per some authors, there is a 45% infarction rate associated with temporary clipping of the MCA.[33] Others have indicated that temporary clipping does not contribute significantly to peri-operative complications.[1,3,7,43]

- Temporary clipping helps in dissection of awkward necks, providing clarity of vision, reducing tension in the sac, capacity to open the sac and evacuation of clot. These render complete/near complete occlusion possible. Pentothal is administered in a loading dose of 10 mg/kg body weight (BW) 5 minutes before temporary occlusion and a maintenance dose of 5–10 mg/kg BW to produce burst suppression pattern on electrocorticography (ECOG).
- Pentothal can also be introduced as 3–5 mg/kg BW intravenously (IV) which is repeated every 15–20 minutes, if occlusion extends beyond that time. 100 gm mannitol, 20–30 minutes prior to temporary clipping, is protective. 1 gm methyl prednisolone, 50 ml/hr, low molecular weight dextran and IV vitamin E or C have also been recommended for neuroprotection.
- Hypertension is maintained at 150 mmHg systolic. Mild hypothermia of 33–34 degrees centigrade has also been found to be effective in a few isolated studies.
- The clip blades used should be of low force, the maximum being 70–80 gm (Sugita, Yasargil). Higher force, longer duration and repeated application at the same site may lead to partial endothelial damage to total desquamation and fragmentation, thereby exposing the subendothelial layers. This is followed by proliferation of smooth muscle cells, accumulation of connective tissue and lipid deposition. The changes in the smooth muscle cause changes in the adjacent nerve fascicles impairing neurogenic innervation and autoregulatory function.
- The vascular occlusion force is determined by four variables. These are vessel diameter, blood pressure, clip blade contact area and vessel elasticity.
- A few moments after MCA occlusion, the blood flow falls to 10 ml/100 gm/min in primates (normal 50 ml/100 gm/min), which is sufficient to induce infarction within 6 hours. This is sufficient to abolish electrical activity of the cortex, but reperfusion within 15 minutes restores the activity. Ischaemia induced in humans by temporary clipping depends on collateral circulation, area containing deep perforators (with poor collateral flow) and blood supply to major deep nuclei (6 min – 15 min).
- Clinical/radiographic strokes take place when occlusion lasts greater than 20 minutes. When hypertension and mild hypothermia are used, temporary occlusion is tolerated better.
- Temporary occlusion under somatosensory evoked potential (SEP) and motor evoked potential (MEP) monitoring indicate that gradual attenuation of SEPs/

MEPs takes place after temporary vascular occlusion. This does not cause ischaemic brain damage if recirculation is established within about 10 minutes of the disappearance of the potentials. These have been observed in ICA and MCA temporary occlusion.

- Observations to be made after clipping are—ensure ample room for adequate blood flow to all distal vessels from the bifurcation area and full patency of distal branches from the bifurcation. Distal tip of the clip is off any branches/perforators. Sometimes, branches originate from the sac or even the dome. Multiple clips to safeguard these branches are really mandatory. Infrequently, if it is not possible then a bypass is the answer or relying on the collaterals.

Outcome

The overall mortality and morbidity of surgery for MCA aneurysms are 6% and 11%, respectively. The presence of an ICH usually does not increase the morbidity much, but patients with ISH have a worse outcome. Patients developing vasospasm have a significantly poorer outcome, around five times more than usual. The size (not the large/giant), site and shape of the aneurysm *per se* do not have any effect on the development of vasospasm. Multinodular and multilobulated aneurysms have a poorer outcome due to therapeutic problems. In large aneurysms with an ICH, a poorer outcome has been reported in some studies. The outcome is significantly better if the surgery is undertaken within 0–3 days of the ictus as compared to the group that had late surgery. This helps in more aggressive management of vasospasm. Post-operative vasospasm is basically related to pre-operative clinical grade, patient's age, artery size and severity of SAH, rather than to the timing of surgery. Evaluation of cognitive functional outcome is an extremely important parameter in assessing the recovery.

Giant MCA aneurysms need to be opened, thrombectomy is performed and then the neck is clipped. Around 18% of the patients had poor outcome and there is a 12% morality. Yasargil[72] noted a higher incidence of hemiparesis in proximal MCA aneurysms and attributed it to the technical difficulties associated with clipping of proximal MCA aneurysms, leading to occlusion of the anterior temporal artery or lenticulostriate perforators.

M1 Segment Aneurysms[2,10,11,16,18,20,52,69]

The usual length of the M1 segment is 12.7 to 20.2 mm. Aneurysms arising along the M1 segment proximal to the MCA bifurcation from early frontal and early temporal branches have distinct anatomic features. M1 segment aneurysms make up less than 10% of the total number of MCA aneurysms. They are often small and thin walled, which makes their clipping a tedious task. They are often wide necked and are in intimate relation to important branches. Preservation of these branches is of paramount importance. These aneurysms usually project superiorly and towards the frontal lobe in contrast to MCA bifurcation aneurysms which usually project towards the temporal lobe in the axis of the Sylvian fissure. Frontal lobe retraction should be avoided as that could result in premature rupture as the projection of the dome is to the frontal lobe. The average distance of a typical MCA bifurcation aneurysm is 20.2 mm from the ICA bifurcation, for early frontal branch aneurysms 13.1 mm and for early temporal branch aneurysms 12.7 mm. After peripheral splitting of the Sylvian fissure till the limen insulae, the M1 is dissected avoiding the superior surface. Enough M1 segment is exposed to allow temporary clipping before any frontal lobe retraction that might be required to complete the dissection of the medial fissure is attempted. A cautious dissection of the neck is required as this is critical. Early frontal branch and LSAs course inferiorly en route to the APS and lie deep to the aneurysm neck and dome. These aneurysms may be hidden under the insula, sometimes burrowing into the limen. Adequate head rotation facilitates the exposure. Slightly less rotation is required for MCA bifurcation aneurysms.

Early frontal branch, early temporal branch, lenticulostriate and short M1 segment bifurcation aneurysms all arise in the sphenoidal portion of the MCA and project superiorly towards the frontal lobe in the anteroposterior (AP) view. The arachnoid adhesions between cortical branches, LSAs and small pial arteries limit mobilisation and dissection of M1.

Associated ICH may prove a hindrance in the management of these lesions. These haematomas may be located in the frontal lobe, temporal lobe, insula or putamen and have to be differentiated from hypertensive bleeds. Early frontal branch aneurysms are not uncommon. These aneurysms may sometimes be mistaken as MCA bifurcation aneurysms, which may put the M1 at risk during surgery. When giant M1 aneurysms project towards the frontal lobe or have a massively calcified wall, parent artery occlusion with pre-operative bypass is recommended.

Complete 3D visualisation of the neck, dome and branches around is necessary by whatever methods available. In giant and fusiform aneurysms a good resolution MRI is required to show a thin aneurysm wall and thrombus separately.

Mini-Craniotomy Approaches[9,12,28]

With the aid of navigation, it is possible to easily locate MCA aneurysms and perform minimally invasive surgeries such as mini-craniotomies, tailored Sylvian dissection and successful clipping of unruptured MCA aneurysms.

Navigation systems incorporate almost real-time localisation, orientation and guidance that facilitate minimally invasive techniques and enable surgeons to achieve the desired results with accuracy and safety. Minimally invasive techniques are contraindicated for giant aneurysms and are not generally accepted for recently ruptured aneurysms.

The head is rotated 30 degrees to the contralateral side so that the Sylvian fissure is oriented vertically in the surgical field and the M1 segment would appear less vertical from the surgeon's perspective. A nearly linear skin incision (approximately 4–5 cm long) is made 1 cm behind the hairline to do the craniotomy for the trans-Sylvian approach for anterior circulation aneurysms. Subsequently, a sphenoid ridge keyhole approach was also described. These two approaches are applicable to anterior circulation aneurysms, including MCA aneurysms, as minimally invasive techniques. The lateral supraorbital approach is also used by many experienced surgeons even for surgery within 24–48 hours. However, a lax brain has to be ensured by expert anaesthetic techniques, CSF drainage and neuroprotection. A basic additional prerequisite for using this approach is ensuring that the skills and adequate experience are available to dissect the Sylvian fissure and treat recently ruptured cerebral aneurysms.

The lateral supraorbital approach is more subfrontal and the head is rotated 15–20 degrees with a little tilt to optimally visualise the M1, the branches, and the neck and dome of the aneurysm at a comfortable working angle. When there is an associated ICH, an incision is made in the temporal or frontal cortex depending on the location of the haematoma, safeguarding the eloquent speech area. On many occasions, there are calcific plaques in M1 hence, a wider splitting of the Sylvian fissure and more exposure of M1 is necessary to avoid placing a temporary clip in the plaque area. The arachnoid is dissected and cut on the frontal side of the superficial Sylvian vein. The arachnoid is cut with scissors and closed scissors can be used as a sharp microdissector. Small cottonoids can be used to expand the cisternal space by dissection. The dissection is usually done on the anteroinferior surface so as to avoid dissection in relation to the origin of the perforators. In aneurysms on the frontal side, the dissection usually starts at the ICA bifurcation. Sharp dissection of the branches around the neck is crucial. The dissection of these thin walled, broad necked aneurysms which are adherent to LSAs should be painstaking and delicate to safe guard all these structures individually. In the event of rupture of these aneurysms under proximal control, a final dissection is attempted with the application a tentative clip after control of the bleeding by cotton and suction. If this fails, short time temporary clipping or trapping by small clips is attempted. Sometimes, these aneurysms are too small to clip specifically following rupture and then 8 or 10 zero suture or clip with small portion of the vessel wall in the clip or clip on wrap (in extreme situations) is attempted.

Dissecting Aneurysms[27,41,42]

These are comparatively less common intracranially, and their natural history is not clear. These are predominantly seen in the younger age group. These usually occur in the vertebrobasilar circulation and are seen in the proximal vessels in the anterior circulation. The arterial pressure is weaker in the distal branches than in the proximal branches, but dissecting aneurysms may occur in the distal branches intracranially. In distal locations they occur due to head trauma, vasculitis, atherosclerosis, neoplastic emboli, bacterial infection, and are associated with endocarditis. These are known to be related to such diseases as migraine, fibromuscular dysplasia, mixed connective tissue disease, trauma, periarteritis nodosa, syphilitic angiopathy, moyamoya disease and Guillain-Barre syndrome. They present as thrombotic and haemodynamic ischaemia correlated with atherosclerosis. It is advisable to include this possibility in the differential diagnosis of occlusive vascular disease, especially in young patients. Dissecting aneurysm of the MCA has been known to cause cerebral infarcts in young individuals. The plane of dissection is mainly in the subintimal layer. A dissecting aneurysm should be considered as a diagnosis when a saccular intracranial aneurysm is excluded in patients having haemorrhage around the MCA.

There is no specific and definite causative factor identified for intracranial dissecting aneurysms in the MCA. These are relatively rare in the MCA with only 26 reported cases. Histological studies have indicated that these may be produced by penetration of the circulating blood into the vascular wall with subsequent extensions of the effused blood for a varying distance between the layers of the vessel. These have been classified based on the condition of the internal elastic lamina (IEL) and the state of the intima as follows: type 1 has acute widespread disruption of the IEL without intimal thickening; type 2 shows extended and/or fragmented IEL with intimal thickening and type 3 manifests fragmentation of the IEL, multiple dissections of the thickened intima, and organised thrombus in the lumen.[13] The classification as per the different planes of the dissecting laminae of the arterial wall, in which type 1 (submedial dissection) is likely to cause cerebral infarction and type 2 (subadventitial dissection) causes SAH as it communicates with the true lumen through the disrupted portion of the IEL.

Angiographic characteristics of dissecting aneurysms include the pearl and string sign, narrowing, fusiform dilatation and occlusion, but these are not diagnostic. The pathognomonic sign for dissecting aneurysm may be double lumen, but this is infrequently found. MRA can substitute for intra-arterial angiography when repeated studies are necessary. Infarcts were observed not only in the territory of the MCA branches, but also in the territory of the LSAs originating from M1. Surgery, including bypass surgery, does not therefore seem likely to be effective, since it cannot improve flow through these perforating arteries.[55] The optimal surgical procedure is yet to be established, however, there is some consensus that surgical treatment such as wrapping or trapping with arterial reconstruction may be appropriate in the presence of SAH, since subsequent bleeding often leads to

poor outcomes in dissecting MCA aneurysms presenting with SAH. Most of the patients treated surgically had good outcomes. Surgery should be done promptly to prevent critical rerupture and SAH. The natural history of intracranial dissection is obscure, so surgery should be performed in patients with recurrent SAH, but may be unadvisable in neurologically stable patients without recurrent SAH.[2] The surgical methods, such as trapping with or without bypass surgery, ligation or wrapping for ruptured MCA dissecting aneurysm, have been reported.[51] The routine surgical treatment for dissecting aneurysms of the M1 portion is bleb clipping and wrapping due to the presence of perforating arteries, whereas that for aneurysms of the M2 or M3 portion is resection or trapping of the dissecting aneurysm, and if possible STA-MCA anastomosis to maintain MCA flow distal to the lesion. Despite the risk of haemorrhage, the endovascular technique may be considered in high-risk patients.

Distal Middle Cerebral Artery Aneurysms[1,24,35,57]

Intracranial aneurysms mostly occur at the main trunks of the circle of Willis. Distal MCA aneurysms are the least common of all MCA aneurysms. They constitute around 1–6% of MCA aneurysms. These are usually associated with aneurysms in other locations (56%). Their treatment is a great challenge due to location, small distal arteries, terminal branches, type of aneurysm (embolic and fusiform), wide neck, tight Sylvian fissure, and these aneurysms have more chances of rebleed. Lack of collateral circulation in these arteries may mandate bypass and revascularisation. These present as ICH in addition to SAH in 50–60% of patients, which is one of the factors for poor outcome in them. The clinical features include small diameter aneurysm (usual 7–9 mm) with wide neck and fusiform shape in more than half. These can originate just distal to the bifurcation at M2-3 or beyond. These are hidden deep in the distal Sylvian cistern amongst the distal branches of MCA. The location could be M2, M2-3 and M3. Radiology shows SAH with moderate to large ICH with increased incidence of rebleed in 50% of cases. The M3 opercular segment commences at the peri-insular sulcus, M4 at the parasylvian surface and the distal most branches are designated as M5. The distal Sylvian fissure as such is narrow and previous SAH produces adhesions and makes it tough as well. The usual aetiological factors for aneurysms in this location are infective endocarditis, neoplastic emboli, inflammation and trauma. These are located mostly on cisternal branches and are rarely seen on perforating or penetrating branches. The bleed and rebleed are determined not only by size at rupture, but more so by the thickness of the wall and diameter of the artery of origin. The smaller aneurysms have higher arterial pressure than larger ones and if the growth rate exceeds the capacity of wall repair the thinness of the wall results in early rupture.

The DSA and CTA (aneurysms larger than 2 mm diameter) have a comparable sensitivity in diagnosing these aneurysms. The CTA can help by providing a surgeon's view and one can measure the length of M1 and distance of the aneurysm from the MCA bifurcation. The T2 coronal and axial MRI are also useful for pre-operative planning in these aneurysms. The aneurysms of M2 can be approached through the same approach as for MCA bifurcation aneurysms and more distal ones need more occipital exposure over the Sylvian fissure. Patients with a large ICH present in a poor clinical state and there may even be a life threatening situation. Therefore, on many occasions these need to be operated upon immediately after CT angiography. More distal aneurysms are not only problematic to treat but even more tedious to locate, more so in the presence of ICH (responsible for swollen and even tight brain). Therefore, neuronavinagation is of great help. Intra-operative DSA, colour Doppler or 3D intra-operative ultrasound are of use in localisation and management.[54,67,68] A fifth of patients have hydrocephalus needing ventricular drainage. The pre-operative measurement of distances of M1 segment and the onward distance is beneficial to get a guide for opening the arachnoid in the Sylvian fissure, locate the aneurysm and orient the extremely complicated arterial tree in the distal Sylvian fissure. After proper localisation, the dissection may be performed under frequent, short clipping, maximally for 5 minutes at one time. Usually the required clips are small or mini clips (one and a half times the size of the neck). As the anatomy is complex in the region with small branches being present, it is better that a post clip ICG is performed to confirm complete occlusion and complete patency of vessel lumen. The haemodynamic stress is less in the distal MCA as compared to M1 and MCA bifurcation; hence, these aneurysms occasionally grow to a giant size. Fusiform aneurysms with beer belly can be tangentially clipped. In fusiform aneurysms with retrograde flow confirmed on IMD after temporary clip, it may be possible to clip the parent artery without a bypass.

ACKNOWLEDGEMENTS

We appreciate the contribution of our faculty colleagues from neurosurgery, neuroradiology, neuroanaesthesia and my stenographer for their timely support and help.

84 Posterior Circulation Aneurysms

Ashish Suri, Sachin A Borkar, Nalin K Mishra

INTRODUCTION

Aneurysms of the posterior circulation are relatively uncommon lesions, which account for about 15% of all intracranial aneurysms. These aneurysms are technically difficult to tackle as they require manipulation in the confined space in front of the brainstem and cerebellum. In 1946, Schwartz was the first surgeon who successfully clipped an aneurysm in the posterior fossa without the aid of magnification.[45] In 1965, Drake reported his experience with aneurysms of the basilar bifurcation and attributed the high mortality and morbidity in his series to injury to the perforators arising from the proximal posterior cerebral arteries.[10]

Advances in micro-neurosurgical instrumentation, development of different skull base approaches, pharmacological brain protection, modern neuroimaging and development of precise scientific neuroanaesthesia have all contributed to advancement in surgical management of posterior circulation aneurysms. Interventional neuroradiology has developed as a separate scientific discipline and has undergone recent technological advancement leading to more and more patients with posterior circulation aneurysms being treated by endovascular methods,[33] though its long-term efficacy is yet to be established.

In this chapter, we discuss the relevant microsurgical anatomy, incidence, clinical presentation, diagnostic imaging and available treatment options, surgical as well as non-surgical, for the management of posterior circulation aneurysms.

MICROSURGICAL ANATOMY

The anatomy of the posterior circulation and its relationship to adjacent neural structures can conveniently be divided into the following three neurovascular complexes (Fig. 1):

1. *The basilar apex*: Basilar artery (BA) bifurcation, posterior cerebral artery (PCA), superior cerebellar artery (SCA), BA-SCA junction, upper basilar artery.
2. *The basilar trunk*: Midbasilar artery, anterior inferior cerebellar artery (AICA).

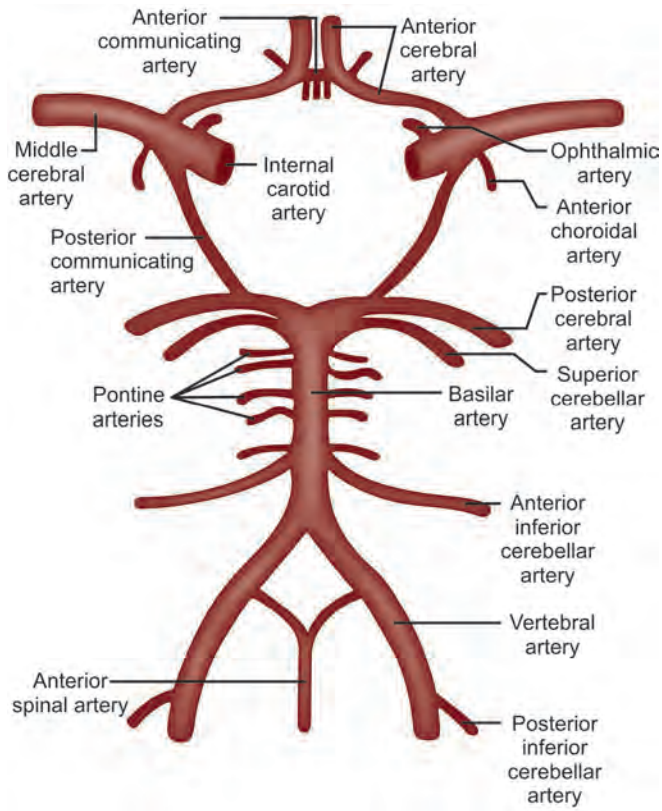

Fig. 1: Diagrammatic representation of circle of Willis showing both anterior and posterior circulation

3. *The vertebral trunk*: Vertebral artery (VA), posterior inferior cerebellar artery (PICA), VA-PICA junction, vertebrobasilar junction (VBJ).

Vertebral Artery (VA)[42]

After its exit from the subclavian artery, the VA traverses through the foramina transversaria of the lower six cervical vertebrae, arches over the posterior arch of the atlas and penetrates the dura at the level of the foramen magnum behind the occipital condyles to become intradural and intracranial.[6,7] The vertebral arteries are frequently asymmetrical in size, the left being dominant in 90%. The extradural branches are the muscular branches and the posterior meningeal artery. The intradural branches are the posterior spinal artery, the PICA, the medullary perforating arteries and the anterior spinal artery. The

vertebral trunk is the intradural portion of the artery from its dural ring to the VBJ.

Posterior Inferior Cerebellar Artery (PICA)[19,28]

The PICA represents the largest and most clinically significant intracranial branch of the vertebral artery. It arises at the level of the olive (10 mm above the foramen magnum) in around 92%. The PICA can be considered as having four segments which are defined by their relationship to adjacent cranial nerves. The anterior medullary segment begins at the origin of the PICA, lies anterior to the medulla and extends posteriorly past the hypoglossal rootlets at the medial edge of the inferior olive. The second, the lateral medullary segment, extends from the olive along the lateral surface of the medulla to the rootlets of the IX, X and XI cranial nerves at the lateral edge of the olive. The third, the tonsillomedullary segment, passes under or between the rootlets of the CN IX, X, XI triad and around the cerebellar tonsil, then it makes an inferomedial turn called the caudal (infratonsillar) loop. The fourth segment of the PICA, the telovelotonsillar segment, passes along the medial surface of the tonsil, ascends towards the roof of the IVth ventricle and curves downwards again forming a cranial loop (supratonsillar loop). The peak of the cranial loop is called the 'choroidal point' and is closely related to the floor of the IVth ventricle. The PICA may be absent in about 26% unilaterally and in 2% bilaterally. In 16%, it is hypoplastic. The PICA and AICA have an inverse relationship in size. Aneurysms in this region arise at the PICA-VA junction, but rarely from the distal PICA.

Basilar Artery[36]

This originates at the junction of the vertebral arteries at the level of the pontomedullary sulcus, runs upwards anterior to the pons to terminate at the level of the pontomesencephalic junction into two PCAs. At the bifurcation point, it is closely related to both the oculomotor nerves. The bifurcation is typically within 1 cm of the dorsum sellae in 90%. This configuration means that the BA can bifurcate as far as caudally as 10 mm below the pontomesencephalic junction or as far rostrally as the mammillary bodies. The location of the basilar bifurcation in relation to the dorsum sellae and the posterior clinoid process is important in selecting the surgical approach to clip an aneurysm. The branches of the basilar artery include the pontomedullary artery, the long lateral pontine artery, AICA, SCA, the posterolateral artery, PCA and the caudal, middle and rostral perforators. Perforating branches arise from the posterior and the lateral surfaces of the basilar artery and not from its anterior surface.

Posterior Cerebral Artery (PCA)[56]

This is the terminal branch of the basilar artery. The basilar apex, along with its bifurcation into two PCAs, constitutes the posterior portions of the circle of Willis. The PCAs can be subdivided into three segments. The P1 segment (basilar bifurcation to origin of posterior communicating artery) gives rise to the thalamoperforating arteries and long and short circumflex arteries. The P2 segment (starts at the PCA-PCom junction and extends to the posterior aspect of the midbrain) courses through the crural and ambient cisterns giving origin to the anterior temporal, hippocampal, medial posterior choroidal and posterior temporal arteries from the anterior part; and middle, posterior and common temporal arteries and lateral posterior choroidal arteries from the posterior part. The P3 branch courses through the lateral part of the quadrigeminal cistern towards the calcarine fissure and terminates into calcarine and parieto-occipital arteries which supply the occipital and posterior temporal lobes.

Superior Cerebellar Artery (SCA)[23]

The SCA arises from the basilar trunk just before its bifurcation and encircles the midbrain in the pontomesencephalic sulcus. In 20%, it may arise directly from the PCA. Cranial nerve III separates the SCA and PCA. The SCA passes between CN III and V into the cerebellomesencephalic sulcus and gives off the superior vermian and lateral hemispheric branches.

Anterior Inferior Cerebellar Artery (AICA)[20]

The AICA arises from the lower third of the basilar artery, courses around the anterior and the lateral surface of the pons below and between abducens fascicles and runs laterally towards the flocculus. It has premeatal, meatal and postmeatal parts. It gives origin to the internal auditory, subarcuate and recurrent perforating arteries. Along its course, it also sends branches to the upper anterolateral medulla, CN VII and VIII, middle cerebellar peduncle and petrous surface of the cerebellum.

Perforating Vessels[29]

The basilar apex and PCAs give rise to a large number of essential perforating arteries. These perforators can be divided into three categories.

1. The first group arises from the apex of the basilar artery itself, typically from the terminal 2–3 mm of the artery and supply the posterior perforated substance, cerebral peduncles and lateral pons.
2. The second group of perforators arises from the posterior and the superior aspects of the P1 segments of the PCA, along with long and short circumflex arteries. Together, they supply the medial and the lateral geniculate bodies (posterior thalamoperforating arteries), interpeduncular fossa, mammillary bodies, cerebral peduncles and posterior mesencephalon.
3. The third group arises from the superior and the lateral surfaces of the PCom, supplies the hypothalamus and posterior optic chiasm anteriorly or perfuses the

posterior perforated substance and the thalamus posteriorly (posterior thalamoperfoarating arteries).

INCIDENCE

Aneurysms of the posterior circulation account for around 15% of all intracranial aneurysms.[12,31,38,52] Morphologically, they can be saccular, fusiform or dissecting. Saccular aneurysms of the posterior circulation most often occur at the basilar apex (45–55%), followed by the origin of SCA (15–24%), PICA and PICA-VA junction (7–21%), PCA (10–14.5%), and lower third basilar artery, VBJ and AICA (3–4%).[14,15] Saccular aneurysms of the AICA are the least common. The frequency of coexistent multiple aneurysms range between 24% and 36%.[11,39] They most commonly present in the fifth and sixth decades of life, most often in females.

Dissecting and fusiform aneurysms are more common in the posterior circulation compared to the anterior circulation. Fusiform aneurysms account for 9% of all posterior circulation aneurysms. Fusiform aneurysms of the vertebrobasilar system frequently occur in the setting of intracranial atherosclerosis.[38] Dissecting aneurysms account for 31% of vertebral artery lesions and are found in young males.[52] Dolichoectatic aneurysms of the vertebral and basilar arteries may result from dissections that produce fusiform degeneration of the artery, progressive enlargement and luminal thrombosis.[1,34]

Giant aneurysms (>25 mm in diameter) occur in the posterior circulation as frequently as in the anterior circulation and follow the same anatomic distribution as the smaller aneurysms. Posterior circulation aneurysms appear to be less frequent in paediatric and geriatric age groups.[30,32]

Anatomic variations and vascular abnormalities associated with posterior circulation aneurysms include hypoplastic or foetal PCAs, persistent carotid-to-basilar anastomosis and arteriovenous malformation in the occipital lobes or cerebellum.[23,38,45,52,55] Connective tissue disorders (e.g. polycystic kidney disease, Marfan's syndrome, Ehlers-Danlos syndrome) can increase the likelihood of aneurysms in the posterior circulation as they do in the anterior circulation.

CLINICAL PRESENTATION

The clinical presentation of posterior circulation aneurysms depends upon whether the aneurysm has ruptured or not. Almost 80% of posterior circulation saccular aneurysms present with signs and symptoms of acute subarachnoid haemorrhage (SAH)[3,38,52] almost always without features localising the source of bleeding. Headache, nuchal pain and rigidity, nausea, vomiting and altered mental status are the most common manifestations of rupture. Intraparenchymal bleeding is rarely associated with rupture of posterior circulation aneurysms[11,38,52] due to the tough pial envelope of the brainstem. Superiorly, pointing basilar tip aneurysms, however, often rupture through the floor of the IIIrd ventricle causing intraventricular haemorrhage and obstructive hydrocephalus. Likewise, a ruptured PICA aneurysm can present with IVth ventricular bleed with hydrocephalus. Occasionally, a cranial nerve deficit points to the origin of a particular aneurysm;—oculomotor paresis (aneurysms of basilar apex, upper basilar artery and superior cerebellar artery); abducens dysfunction (aneurysms of VBJ and lower basilar trunk); VII and VIII cranial nerve involvement (AICA); IX, X, XI (PICA); XII nerve involvement (PICA and vertebral artery aneurysm).

Unruptured giant aneurysms of the vertebrobasilar system usually present with mass effect on the adjacent cranial nerves and brainstem.[3,38,52] These signs can range from isolated cranial neuropathies to brainstem compression syndromes that mimic posterior fossa tumours. These include hydrocephalus (due to obstruction of CSF flow through the cerebral aqueduct or IVth ventricle); contralateral haemiparesis with ipsilateral IIIrd nerve palsy (due to compression of the cerebral peduncle by a basilar tip or SCA aneurysm); dysphagia, dysarthria, cerebellar symptoms (by compression of lower cranial nerves and cerebellum by a giant vertebral artery aneurysm).[51,53]

Dissecting aneurysms present with occipitocervical headache, SAH, non-haemorrhagic infarction of the thalamus, brainstem, cerebellum or other signs of cerebral thrombosis, oculomotor palsy, Horner's syndrome or a mass lesion.[39]

DIAGNOSTIC STUDIES

The initial evaluation of a patient with suspected SAH invariably involves computed tomography (CT), which clinches the diagnosis; allows visualisation of accompanying infarcts, cisternal clot, hydrocephalus and a giant aneurysm. The location of the SAH can sometimes provide a clue to the location of an aneurysm, though it is not always a reliable indicator. Basilar tip aneurysms can cause a large amount of clot in the interpeduncular cistern.[13] PICA aneurysm rupture can cause IV ventricular bleed (Figs 2A to C). CT angiography may reveal a posterior circulation aneurysm with a three dimensional external morphology and its relationship to the bony anatomy of the skull base.

Magnetic resonance imaging (MRI) can be a helpful adjunct in the evaluation of giant aneurysms of the posterior circulation and its relation to the brainstem and cranial nerves.[3,52] MRI is not routinely used for the assessment of most saccular aneurysms. Magnetic resonance angiography (MRA) has superseded MRI in that respect (Fig. 3A).

High quality four-vessel digital subtraction angiography (DSA) in multiple projections (anteroposterior, lateral, oblique, submentovertical) remains the gold standard for diagnosis and surgical planning (Fig. 3B). Pre-operative angiographic studies determine the following important features:

- Aneurysm's vessel of origin.
- Aneurysm's shape, size and relationship to parent and adjacent arteries.

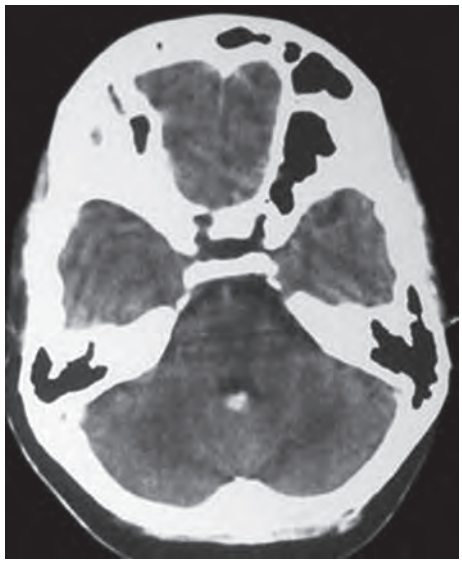

Fig. 2A: NCCT head showing IVth ventricular bleed in case of PICA aneurysm

Fig. 2B: IADSA showing left PICA aneurysm

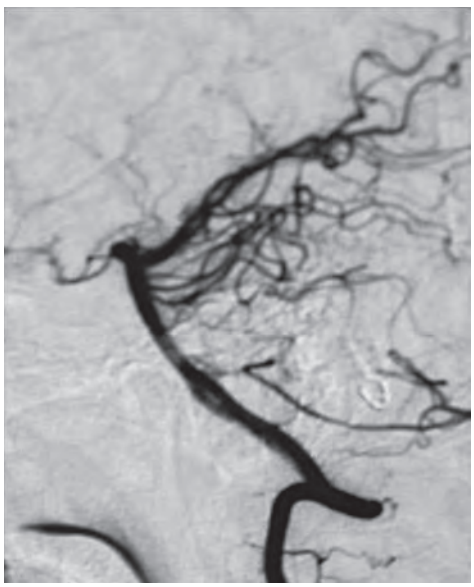

Fig. 2C: IADSA of the same patient showing well-clipped left PICA aneurysm

Fig. 3A: MR angiography showing left VA-PICA junction aneurysm

- The presence and location of vasospasm.
- The displacement of adjacent vessels, suggesting mass effect from haematoma or partial thrombosis of an aneurysmal sac whose dimensions are much larger than that seen on angiography.
- The presence of associated multiple aneurysms or vascular abnormalities.

Four-vessel angiography also delineates features of the underlying circulatory supply to the posterior fossa that may affect surgical strategy, e.g. foetal PCA, dominant vertebral artery, etc. DSA is also essential to assess the adequacy of filling of both vertebral arteries as well as possible collateral circulation via the posterior communicating arteries (Alcock Test). Dissecting aneurysms, more common in the vertebral circulation, can be recognised as a double lumen (diagnostic hallmark), a narrow tapered lumen (string sign) or an irregular post-stenotic dilated segment (pearl sign).[33]

Table 1: Surgical approaches for posterior circulation aneurysms

Aneurysms	*Trajectory*	*Approach*
Basilar top, PCA, SCA, Upper basilar artery	Anterosuperior	Subtemporal (Peerless and Drake)[11,39] Pterional transsylvian (Yasargil),[54] Transsylvian temporopolar (Sano),[44] Modified pterional transcavernous transsellar (Dolenc),[8] Middle subtemporal transtentorial (Sugita)[50] Orbitozygomatic, Orbitozygomatic infratemporal,[16] *Extended orbitozygomatic approach*
Midbasilar artery, AICA	Lateral	*Transpetrosal* (Kawase),[22] Transtemporal (Sekhar),[47] Retrolabyrinthine transsigmoid (Gianotta and Marceri),[14] *Combined supratentorial and infratentorial approaches* (Kadson and Stein),[21] Transoral transclival approach (Saito),[43] Transoral transclival with Le Fort I maxillotomy (Archer),[2] Extended middle fossa approach
VA, PICA, VBJ	Posteroinferior	Midline suboccipital, Paramedian suboccipital, *Far-lateral approach* (Heros),[17] Extended far-lateral approach

(*Italic letters* indicate the preferred approach)

It is beyond the scope of this chapter to describe the operative steps of each surgical approach in detail. Still, an attempt has been made to acquaint the reader with common approaches used for management of posterior circulation aneurysms.

SURGICAL MANAGEMENT

Principles of surgery for posterior circulation aneurysms are essentially similar to those followed for aneurysms of the anterior circulation;—shortest trajectory to the aneurysm, bone removal in lieu of brain retraction and maximum dissection of the arachnoid from brain, vessels and nerves. Several surgical approaches, viz. infratentorial, supratentorial, combined supratentorial/infratentorial and transbasal have been used for successful treatment of posterior circulation aneurysms.

The choice of surgical approach depends on the anatomical location, size and projection of the aneurysm, relationship of the aneurysm to the foramen magnum and midline, level of basilar bifurcation and the shortest possible distance from the cranial surface to the aneurysm (Table 1) (Fig. 4).

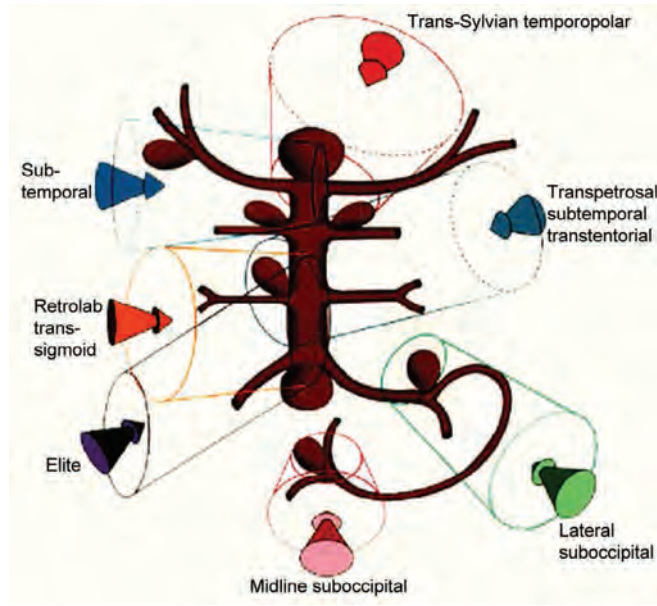

Fig. 4: Diagrammatic representation of various surgical approaches to posterior circulation aneurysms

SUBTEMPORAL APPROACH

The subtemporal approach, developed by Peerless and Drake,[9,11,39] employs a lateral trajectory with elevation of the temporal lobe. The patient is placed in the supine position with the head semi-extended and turned to the opposite side. A question-mark shaped incision is made just anterior to the tragus. A temporal craniotomy is made flush with the floor of the middle cranial fossa to minimise temporal lobe retraction. If required, the zygomatic arch may be removed, especially if the basilar bifurcation is high. The dura is opened based inferiorly. A self-retaining retractor is placed to expose the tentorial edge and the ambient cistern. The arachnoid is opened and CSF is drained; the tentorial edge is cut and the cut ends are hooked by a stitch. The arachnoid is widely opened. The membrane of Liliequist is opened and CN IVth is carefully visualised; tracing the IIIrd CN proximally permits the identification of PCA and SCA. The PCA is traced proximally to reach the basilar bifurcation. In many cases, the subtemporal trajectory parallels the

long axis of the aneurysm's neck, which is the optimal direction for placing a clip on these aneurysms. The posterior perforating arteries, whose preservation is perhaps the most crucial aspect of the procedure, can also be visualised best from this trajectory. The neck of a posteriorly projecting aneurysm has to be separated from the perforators and the opposite PCA. In technically difficult cases, cardiopulmonary bypass and hypothermic circulatory arrest can be used.

PTERIONAL-TRANS-SYLVIAN APPROACH

This approach, popularised by Yasargil,[54] is an excellent approach for basilar apex aneurysms. This approach is also a familiar approach to most neurosurgeons as it is the standard approach for most anterior circulation aneurysms. The patient is in the supine position with the head rotated approximately 30 degrees to the opposite side and extended approximately 20 degrees. Exposure of the basilar apex through this approach requires splitting the Sylvian fissure, widely opening the cisterns around CN IInd and the carotid artery, and gently retracting the frontal and the temporal lobes (Figs 5A and B). The PCom is followed posteriorly through Liliequist's membrane to the PCA, which is then followed medially to the basilar apex.

ORBITOZYGOMATIC AND EXTENDED ORBITOZYGOMATIC APPROACH

The orbitozygomatic approach is an extension of the pterional approach in which the superior and the lateral portions of the orbit are removed, thereby creating more space in the operative corridor and providing an extended upwards view of the basilar apex. The fulcrum of the trajectory drops lower across the orbit, resulting in a higher view of the basilar apex above the posterior clinoid process. Consequently, it is one of the preferred approaches for a basilar apex aneurysm. Several modifications to the orbitozygomatic approach enable an extended exposure to facilitate the surgical management of giant posterior circulation aneurysms, particularly those located below the basilar artery apex.[25] Additional inferior exposure is gained by removing three intradural bony obstacles, viz. the anterior clinoid process, the posterior clinoid process and the dorsum sellae. Removal of the upper clivus opens a window to the anterior surface of the basilar artery through which the aneurysm can be dissected (extended orbitozygomatic approach). While drilling the clivus, it is important to preserve the medial dural wall of the cavernous sinus to avoid entry into the cavernous sinus.

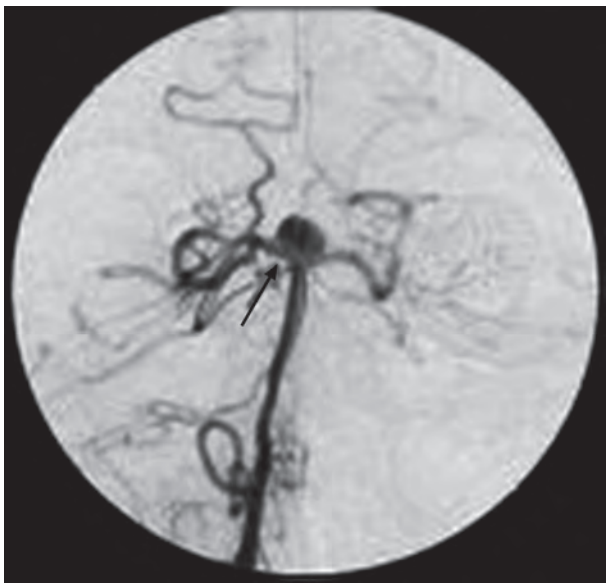

Fig. 5A: IADSA showing basilar top aneurysm

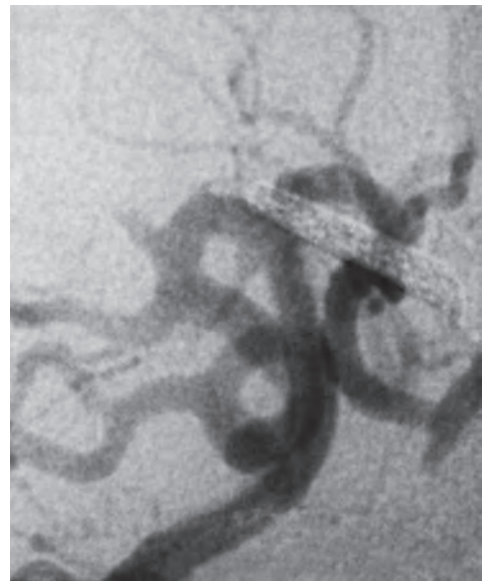

Fig. 5B: IADSA of the same patient showing well-clipped basilar top aneurysm

TRANSPETROSAL APPROACH

The transpetrosal approaches have three variations, viz. retrolabyrinthine, translabyrinthine and transcochlear.[24] The three types of temporal bone dissection represent a graduated increase in the amount of petrous bone resected with a corresponding increase in anterior exposure. Any one of these approaches can be used to access an aneurysm in the middle zone of the basilar artery.

FAR LATERAL APPROACH

[Synonyms—lateral suboccipital approach, extreme lateral approach, extreme lateral inferior transcondylar exposure (ELITE) (Fig. 6)].

The far lateral approach is the most common approach to aneurysms of the vertebral trunk.[17,48] For aneurysms in this location, the authors use a modified suboccipital craniectomy. The patient is positioned in the lateral position in three point fixation with flexion in the anteroposterior plane, rotation 45 degree away from the side of the lesion and lateral flexion of 30 degree down towards the floor. A hockey-stick incision is made in the

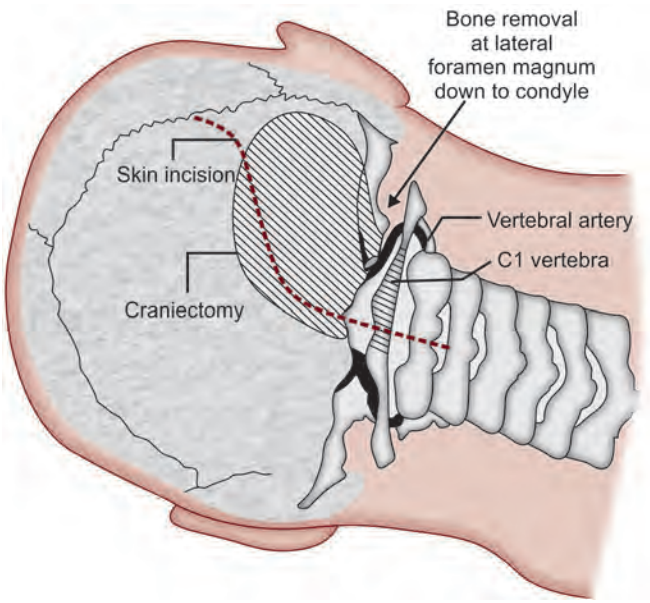

Fig. 6: Diagrammatic representation of skin incision and extent of craniectomy in Heros far lateral approach. [Courtesy: Heros RC. J Neurosurg. 1986;64(4):559-61)]

beginning of cervical midline over the C5 spinous process. It extends cephalad to the inion, courses laterally along the superior nuchal line to the mastoid bone, and finishes inferiorly at the mastoid tip. Bony removal consists of three parts: a C1 laminotomy, a lateral occipital craniotomy and a partial condylectomy. The posterior arch of C1 is also removed. Exposure is made superiorly till the transverse sinus, laterally till the sigmoid sinus, medially till the midline and inferiorly right up to the level of the jugular foramen. The dura is opened. After the arachnoid of the cisterna magna is widely opened and CSF drained, the cerebellum is retracted superomedially. The vertebral artery is identified and traced distally in front of the lower cranial nerves. The arachnoid is further cut widely from the brain, nerves and blood vessels.

ALTERNATIVE SURGICAL STRATEGIES

- Parent artery occlusion/proximal ligation/Hunterian ligation[49]—The principle of this technique introduced by John Hunter about 200 years ago for giant aneurysms is to remove the forceful flow of blood through the artery to the aneurysm and to depend upon collateral circulation to nourish the part deprived of direct blood flow. Proximal ligation is technically easy to perform; reduces the pressure in the aneurysm and subsequently the incidence of rupture and encourages thrombus formation. However, unpredictable haemodynamic complications ranging from ischaemia to thrombus formation and later, migration from the stump can occur.
- Wrapping[49]—Muscle and various substances, such as methyl methacrylate, silicone, polyvinyl and temporalis fascia, are used to wrap the aneurysms. The purpose of wrapping is to induce fibrosis in the wall of the aneurysm, thereby, decreasing the risk of rupture and rebleeding. However, the mass effect of the aneurysm is not removed by wrapping. The aneurysm can continue to grow and erode even the coating of methacrylate and rupture.
- Trapping[49]—Trapping the aneurysm involves isolating the aneurysm from the circulation. Trapping of distal aneurysms is certainly possible, e.g. distal PICA aneurysms. Proximal trapping of PICA aneurysms may be possible, but should be followed by some form of revascularisation if the vessel must be trapped proximal to the choroidal point.
- Revascularisation—If sufficient collateral flow is present, one can go for parent artery ligation. However, if revascularisation is needed, aneurysm excision with primary reanastomosis of the artery may be possible.[34] Alternatively, bypass from the extracranial circulation (superficial temporal artery or occipital artery) to the posterior circulation (SCA or PICA), or an interposition radial artery or saphenous vein bypass from the external carotid artery (ECA) to SCA or PCA, may be useful.[26,35,41,46]
- Cardiac bypass with hypothermic circulatory arrest[27]—Hypothermic circulatory arrest is a useful technique for giant and complex posterior circulation aneurysms that cannot be treated by conventional surgical and endovascular approaches. With 24 degree celsius core cooling, the brain will be protected for 1 hour of complete circulatory arrest. Draining the cerebral circulation allows the aneurysm to collapse and permits the surgeon to dissect the perforators and branches away from it. However, it is associated with significant morbidity and mortality rates related to systemic heparinisation, cardiopulmonary bypass, cardiac arrest and prolonged ischaemia. Hence, it should be used with extreme caution.

ENDOVASCULAR MANAGEMENT

The advent of endovascular techniques, particularly detachable coil embolisation of aneurysms, has added a new treatment strategy in the management of intracranial aneurysms.

Indications of endovascular treatment include aneurysms in surgically difficult locations;—basilar bifurcation, lower basilar trunk and VBJ; previous unsuccessful neurosurgical exploration and patients in whom the surgical risk is unacceptably high, or in a medically unstable patient.

ENDOVASCULAR OBLITERATION

- *Intravascular obliteration of the aneurysm along with parent artery/flow modification—*

A. Detachable balloons:
   - Silicone balloons filled with iso-osmolar contrast medium (Iohexol) or solidification agent like HEMA (Hydroxymethyl methacrylate).
   - Latex balloons filled with iohexol or silicone.

B. Flow modification techniques:
   - Extracranial-intracranial bypass excluding the aneurysm.
   - Parent artery obliteration proximal to the aneurysm with good collateral flow.

Complications of balloon embolisation include intraprocedural aneurysm rupture,[18] incomplete occlusion of sac, distal propulsion of balloon and migration of thrombus from the neck of the aneurysm.

- *Intraluminal obliteration of the aneurysm—detachable coils—*
  A. Free pushable coils (Cook).
  B. MDC—Mechanically Detachable Coils (Balt, France).
  C. IDC—Interlocking Detachable Coils (Japan).
  D. GDC—Guglielmi Electrically Detachable Coils (USA).

The most successful of all these and the one currently used by the majority of interventional neuroradiologists is the Guglielmi Detachable Coils (GDC), introduced by Guglielmi et al.[15]

The GDC coil is 0.01 inch in diameter and contains three parts, the proximal part (175 cm) is made of stainless steel wire, then the intermediate portion (3 cm in length) is made up of very soft stainless steel coil and the distal component varies from 4–40 cm in length and is made up of platinum with helical memory. Platinum is not affected by electrolysis and is radio-opaque, biocompatible and thrombogenic. When the coil is in place, electrothrombosis is generated by applying low voltage (0.5–2 millivolts) positive direct current to the proximal end of the stainless steel guide wire using battery operated current generation. The negatively charged blood particles are attracted and thus electrothrombosis is caused. By the time the thrombosis occurs, the current also dissolves the uninsulated stainless steel coil closest to the platinum coil by electrolysis. This detaches the coil from the main catheter. The number of coils required depends upon the size of the aneurysm. Coils probably provide immediate protection against re-haemorrhage by reducing blood flow within the aneurysm sac, buffering arterial pulsations within the fundus and sealing the weak portion of the wall. Eventually, organised thrombus forms within the aneurysm and the aneurysm is excluded from the parent vessel by the formation of an endothelialised layer of connective tissue that covers the neck's ostium.

Factors that limit successful endovascular aneurysm occlusion include dome-to-neck ratio less than 2, neck width greater than 4 mm, inadequate endovascular access, unstable intraluminal thrombus and if any arterial branch is incorporated in the neck.

Those aneurysms with a dome-to-neck ratio that did not favour endovascular therapy can be made more suitable for the procedure with the use of a stent.

Stents can also be used to cover the orifice of the aneurysm and to serve as a buttress to keep coils within the aneurysms from herniating into the lumen of the parent artery.[40] (Figs 7A to D and 8) Complications of coiling of aneurysms include aneurysm perforation, parent artery narrowing, parent artery occlusion, embolisation, coil migration and post-embolisation aneurysmal haemorrhage.

Although endovascular therapy is an effective modality of treatment in the short term, there are very few studies regarding its long-term effectiveness. The main challenge with endovascular treatment continues to be unacceptable rates of recurrence and the associated risks. Pandey et al.[37] in one of the largest series regarding endovascular management of posterior circulation aneurysms, have reported a 24.5% incidence of clinically significant recurrence at 3 years follow-up. Further areas of research in this regard include development of new

bioactive coil technology towards the goal of permanent occlusion of the aneurysm and the elimination of recurrences and all associated risks.

Multi-modality strategies, such as a surgical bypass with subsequent endovascular occlusion of the aneurysm, can also be designed for optimal management of posterior circulation aneurysms. A poor grade patient can be treated by partially coiling the aneurysm, obliterating its dome to protect against re-haemorrhage and leaving the neck for definitive clipping later. Alternatively, broad-necked aneurysms[4] that cannot be clipped completely might be clipped partially to create a narrower neck that would be more amenable to coiling. Although endovascular technology is promising, the management of patients with posterior circulation aneurysms can be improved by strategies that combine surgical and endovascular techniques.[5]

MANAGEMENT OF GIANT POSTERIOR CIRCULATION ANEURYSMS (FIGS 9A TO C AND 10A TO C)

A giant aneurysm is defined as one larger than 2.5 cm in diameter. Treatment of giant aneurysms has traditionally been associated with the higher morbidity and mortality than smaller lesions. Giant aneurysms represent around 5–8% of all intracranial aneurysms. Fifteen percent of these giant lesions occur at the top of the basilar artery, and approximately 5% arise from the vertebral artery.

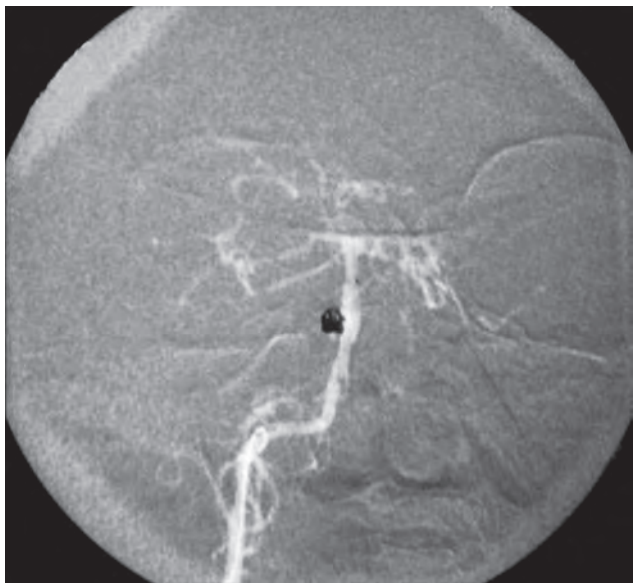

Fig. 7D: IADSA showing stent in basilar artery with well-coiled mid-basilar artery aneurysm

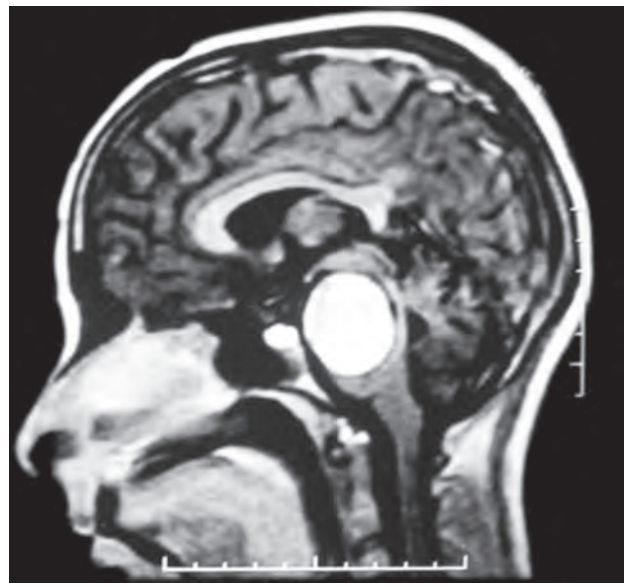

Fig. 9A: Contrast enhanced MRI of brain showing giant distal basilar artery aneurysm

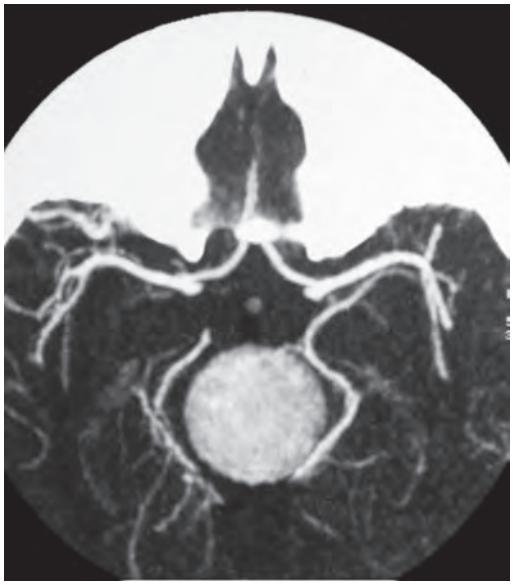

Fig. 9B: CT angiography of the same patient showing giant distal basilar artery aneurysm

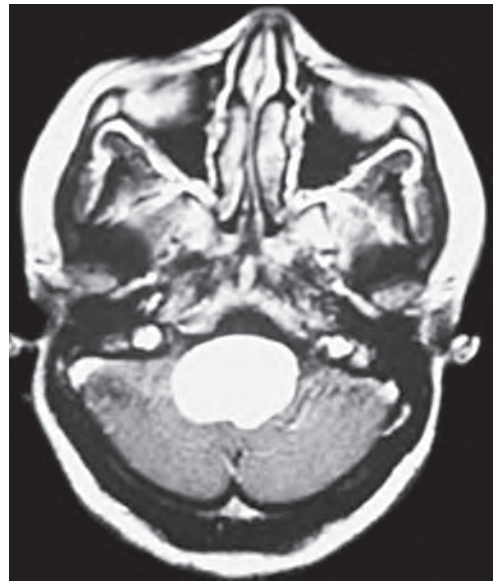

Fig. 10A: Contrast enhanced MRI of brain showing giant right vertebral artery aneurysm

Several different strategies are currently available to manage giant posterior circulation aneurysms. This stems from the fact that no single technique is absolutely effective in dealing with all giant aneurysms. Current treatment options for these lesions include direct surgical techniques, endovascular techniques and combined approaches. Regarding surgery, the aneurysm can be attacked directly with clipping and resection of the mass lesion, or aneurysmorrhaphy with vessel wall reconstruction. Indirect surgical techniques include proximal occlusion and trapping of the aneurysm using clips and ligatures above and below the lesion, parent vessel occlusion or an extracranial to intracranial bypass procedure. Endovascular management includes occlusion of giant posterior circulation aneurysm using GDC coils.

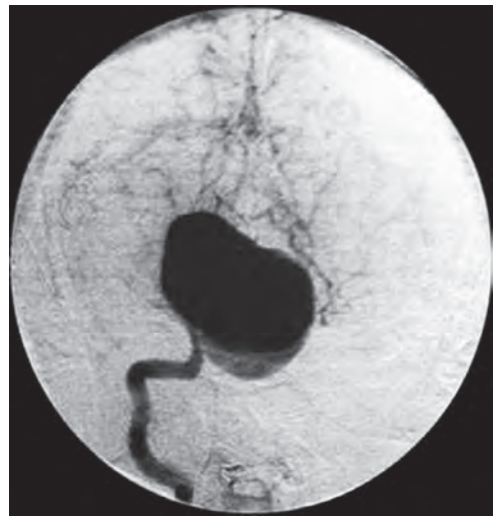

Fig. 10B: IADSA of the same patient showing giant right vertebral artery aneurysm

Fig. 9C: IADSA of the same patient showing giant distal basilar artery aneurysm

Fig. 10C: Check IADSA of the same patient showing well-coiled right vertebral artery

Other treatment options for giant posterior circulation aneurysms include combined techniques. In this approach, a surgical procedure, such as an intracranial to extracranial bypass, can be performed prior to endovascular occlusion of the parent vessel. Alternatively, bypass techniques can be combined with endovascular trapping of certain giant aneurysms or intra-aneurysmal endovascular techniques.

CONCLUSION

Posterior circulation aneurysms, due to their rarity, deep location, intimacy with cranial nerves and small vascular perforators, can be among the most difficult cerebrovascular anomalies to treat. The advent of endovascular treatment in the management of posterior circulation aneurysms has added another treatment option, which has immense potential. The challenge for vascular neurosurgeons is to embrace and integrate endovascular techniques into the management of posterior circulation aneurysms while still maintaining technical proficiency in all skull base approaches.

85 Giant Aneurysms

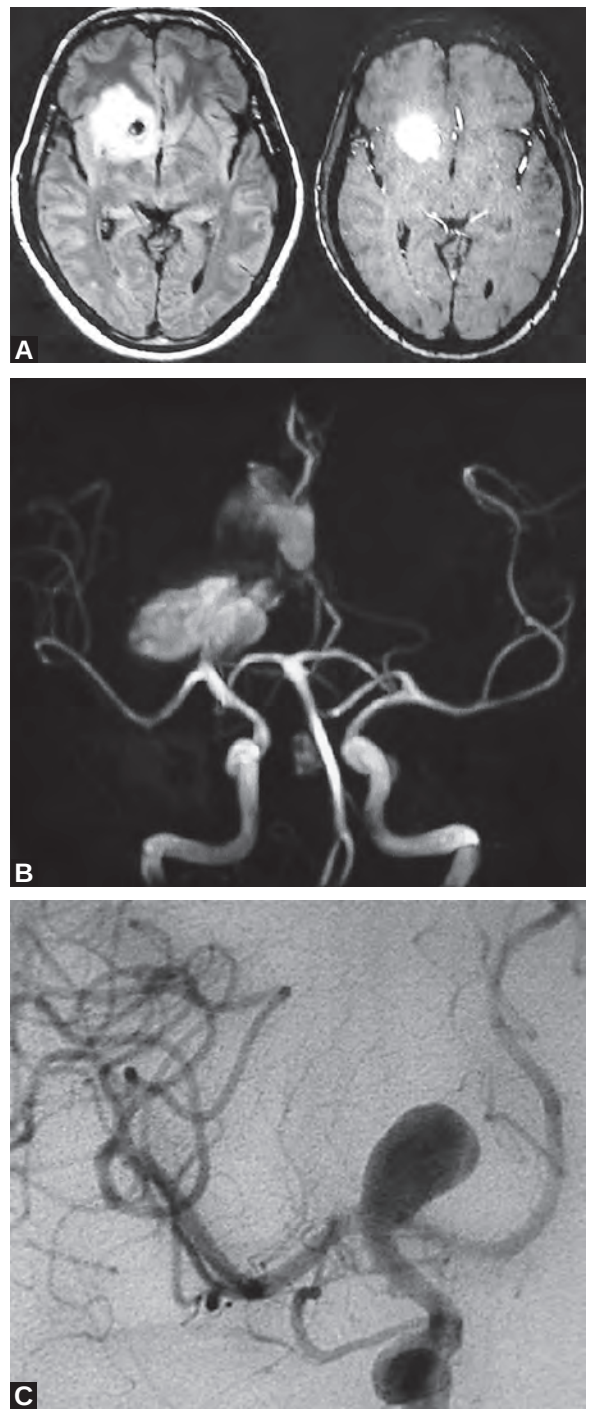
Sanjay Behari, Rabi Narayan Sahu, Rupant K Das, Vijendra Kumar Jain

INTRODUCTION

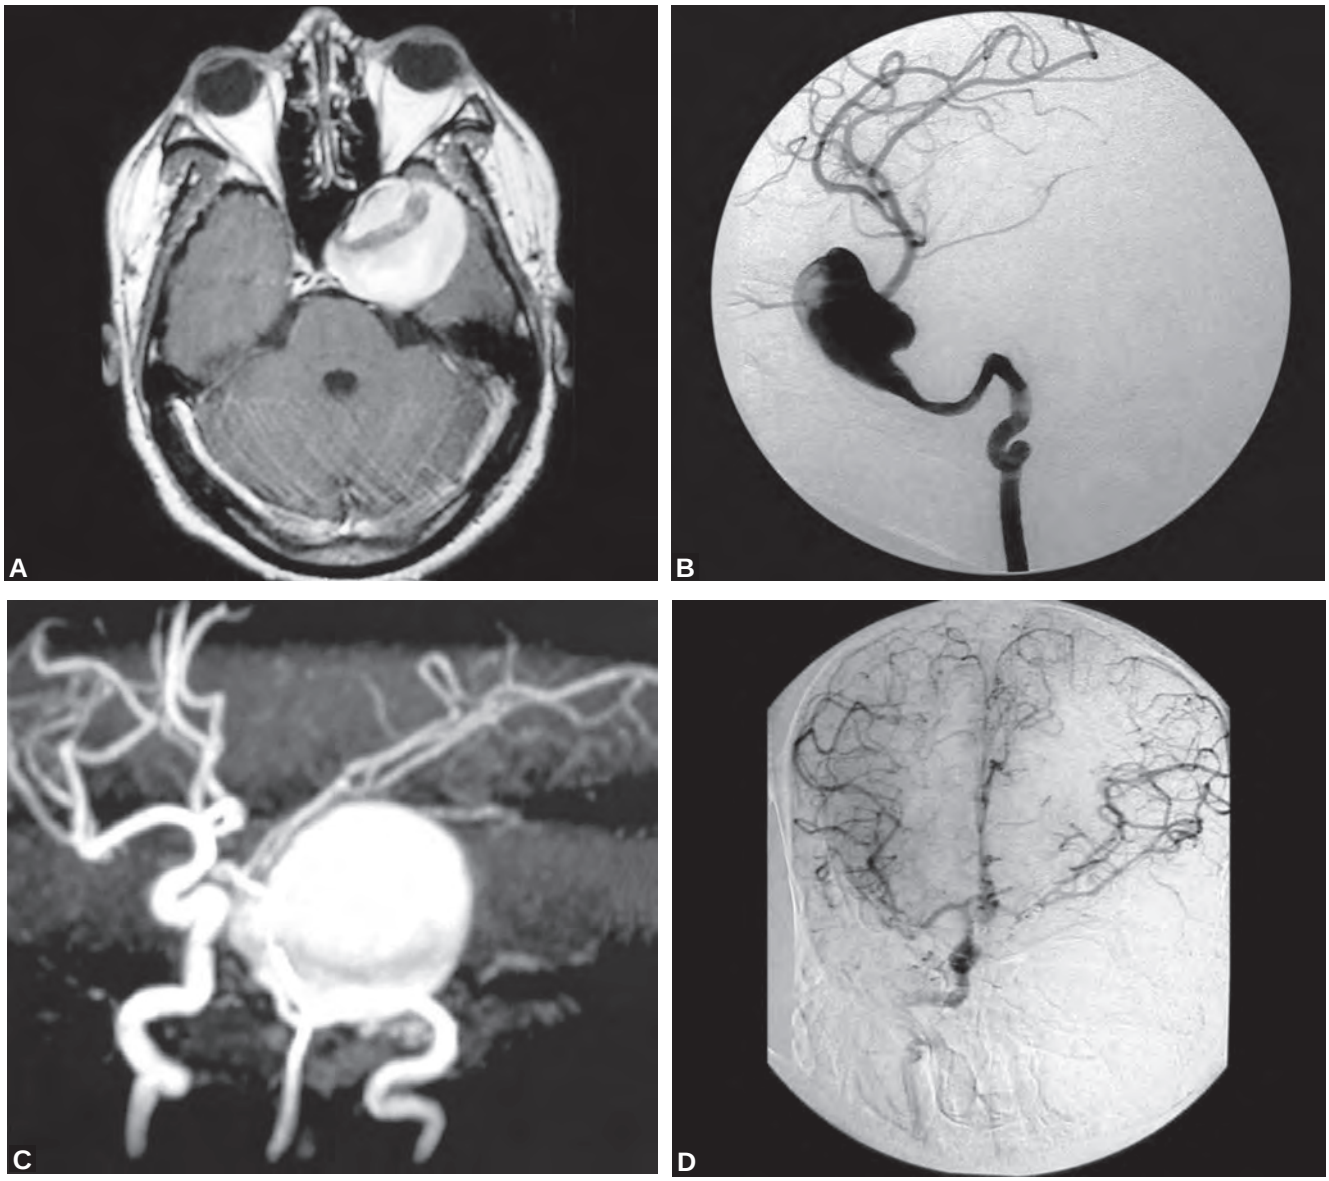
Giant aneurysms are aneurysms that are 2.5 cm or larger in size. They represent approximately 5% of all intracranial aneurysms. They most often present either in the 6th decade (in approximately 35% patients, i.e. one decade later than the smaller aneurysms) or in the paediatric age group (5–10%). Approximately 60% of giant aneurysms are seen in the anterior circulation, especially on the internal carotid artery.[18] Giant posterior circulation aneurysms comprise 1–2% of aneurysms seen in clinical practice and are often associated with much poorer outcomes than anterior circulation aneurysms.[18] In the anterior circulation, the frequently encountered giant intracranial aneurysms include intracavernous and petrous carotid aneurysms, ophthalmic segment aneurysms, posterior communicating artery aneurysms, carotid bifurcation aneurysms, anterior communicating artery aneurysms and middle cerebral artery aneurysms.[10,11,15,16,18] Giant posterior circulation aneurysms have a predilection for the basilar bifurcation, the vertebral artery at the origin of the anterior and the posterior inferior cerebellar arteries and the vertebrobasilar junction.[14,17] With growth, these aneurysms may incorporate the origin of major arterial branches as well as vital perforators. In 1875, Hutchinson performed the first proximal ligation for a middle fossa giant intracranial aneurysm.[18] Direct surgical treatment with a good outcome in nearly 80% patients and especially the need for proximal vessel ligation when direct clipping was impossible, was advocated in two classical series by Drake in 1979[7] and Sundt et al. in 1991.[16]

PATHOLOGY

Giant aneurysms may be saccular (Figs 1 to 5) or fusiform (Figs 6 and 7). Saccular aneurysms may arise from gradual expansion of berry aneurysms. Their fundus and neck grow both by growth of their wall as well as its thinning and distension. Due to the large volume within the aneurysm and resultant flow stasis, intra-aneurysmal thrombosis and distal embolisation are frequent. The turbulence of blood leading to endothelial damage within the aneurysm may also lead to thromboembolic phenomena. A thrombosed giant aneurysm may still bleed due to its thin walls. Fusiform aneurysms result from weak vessel walls or from arterial dissections (Fig. 7).



Figs 1A to C: (A) Axial MR image. (B) MR angiography. (C) Internal carotid artery DSA showing a giant middle cerebral artery aneurysm



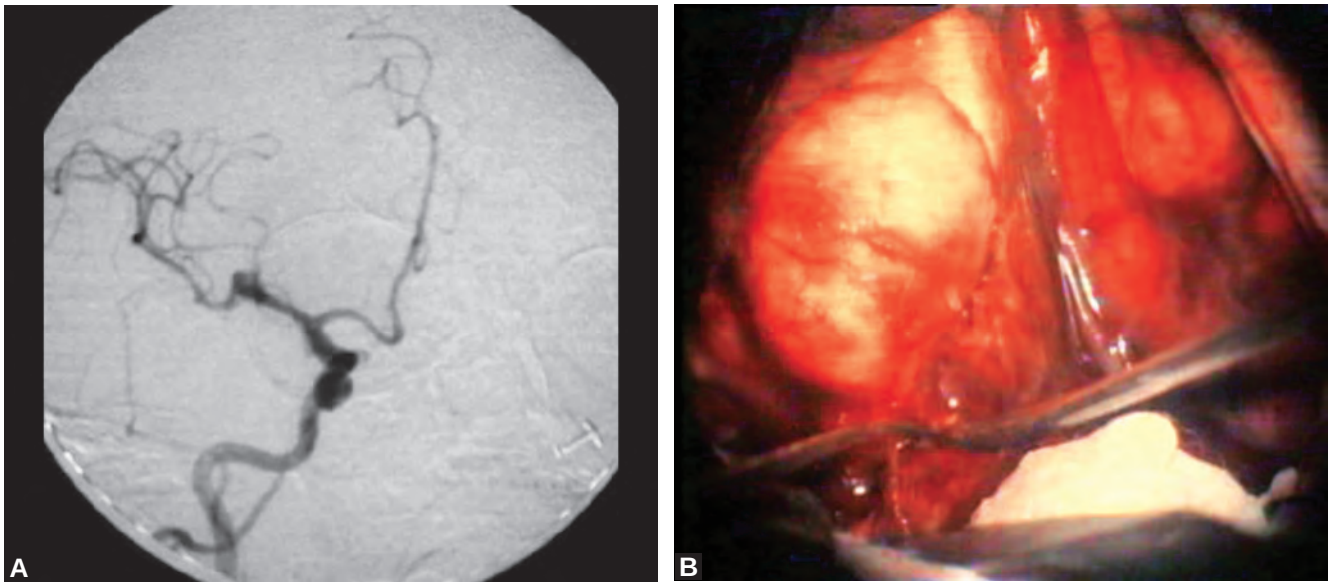
Figs 2A to D: (A) Contrast enhanced MR image. (B) Lateral view of internal carotid DSA. (C) AP MR angiogram showing a giant transitional cavernous and paraclinoid internal carotid artery aneurysm. (D) Post-operative AP internal carotid artery DSA image following trapping of the aneurysm showing a good cross flow across the anterior communicating artery

Atherosclerosis and collagen vascular disease may be the predisposing causes. The atherosclerotic plaque extending from the parent vessel to the fundus of the aneurysm may compromise the ostia of perforating vessels resulting in ischaemia of the surrounding brain.[6,18]

CLINICAL PRESENTATION

Fifty to sixty percent of giant intracranial aneurysms are either found incidentally or produce mass effect. The commonly found aneurysms produce symptoms depending upon their regional anatomy.[18] Cavernous internal carotid artery aneurysms present with retro-orbital pain, diplopia, facial hypoaesthesia, ocular nerves palsies, hypopituitarism or epistaxis.[11] Ophthalmic segment aneurysms present with retro-orbital or frontal headache, decreased visual acuity or field defects. Carotid bifurcation aneurysms present with homonymous hemianopia and other visual field defects, seizures and hemiparesis. Middle cerebral artery aneurysms may also present with hemiparesis, speech disturbances, hemianopia and seizures. Anterior communicating artery aneurysms may obstruct the foramen of Monro and cause hydrocephalus, cognitive disturbances due to bifrontal mass effect, decreased visual acuity or field defects such as bitemporal hemianopia. Posterior communicating artery aneurysms may cause IIIrd nerve palsy and trigeminal neuralgia.

Thirty to forty percent of giant aneurysms present with subarachnoid haemorrhage; 3–5% present with cerebral ischaemia due to thromboembolic phenomena, especially those in the middle cerebral artery and the internal carotid artery. Occlusion of the ostia of perforating vessels by thrombus or an atherosclerotic plaque may contribute to ischaemia. Parent vessel occlusion may also cause infarction.



Figs 3A and B: (A) Internal carotid artery DSA showing the patent part of a partially thrombosed giant aneurysm. (B) Intra-operative photograph showing the partially thrombosed giant internal carotid artery aneurysm

Nearly 80% of patients with giant aneurysms presenting with subarachnoid haemorrhage or mass effect die or develop severe morbidity within 5 years if the aneurysm is left untreated.[18] Ophthalmoplegia or visual deficits may lead to visual impairment in the involved eye.

Thirty to forty percent of posterior fossa aneurysms present with subarachnoid haemorrhage. The most common presentation of these lesions is mass effect compressing the mesencephalon and diencephalon. Basilar apex aneurysms may compromise the IIIrd and VIth cranial nerves; midbasilar aneurysms may compromise Vth, VIth, VIIth and VIIIth cranial nerves and vertebral aneurysms may compromise the lower cranial nerves. Territory infarction and brainstem syndromes may occur if the perforators get stretched and thrombosed by the pressure of giant aneurysms. Besides subarachnoid haemorrhage, severe headache may also be due to intra-luminal thrombosis or dissection within the walls of the aneurysm.[6,7,14,17]

RADIOLOGICAL EVALUATION

Skull Radiographs and Bone Windows of Computed Tomographic (CT) Scans

A ring calcification, bony erosion of sella or skull base (Fig. 5), erosion of anterior or posterior clinoid process or sellar enlargement may be found, but these are not

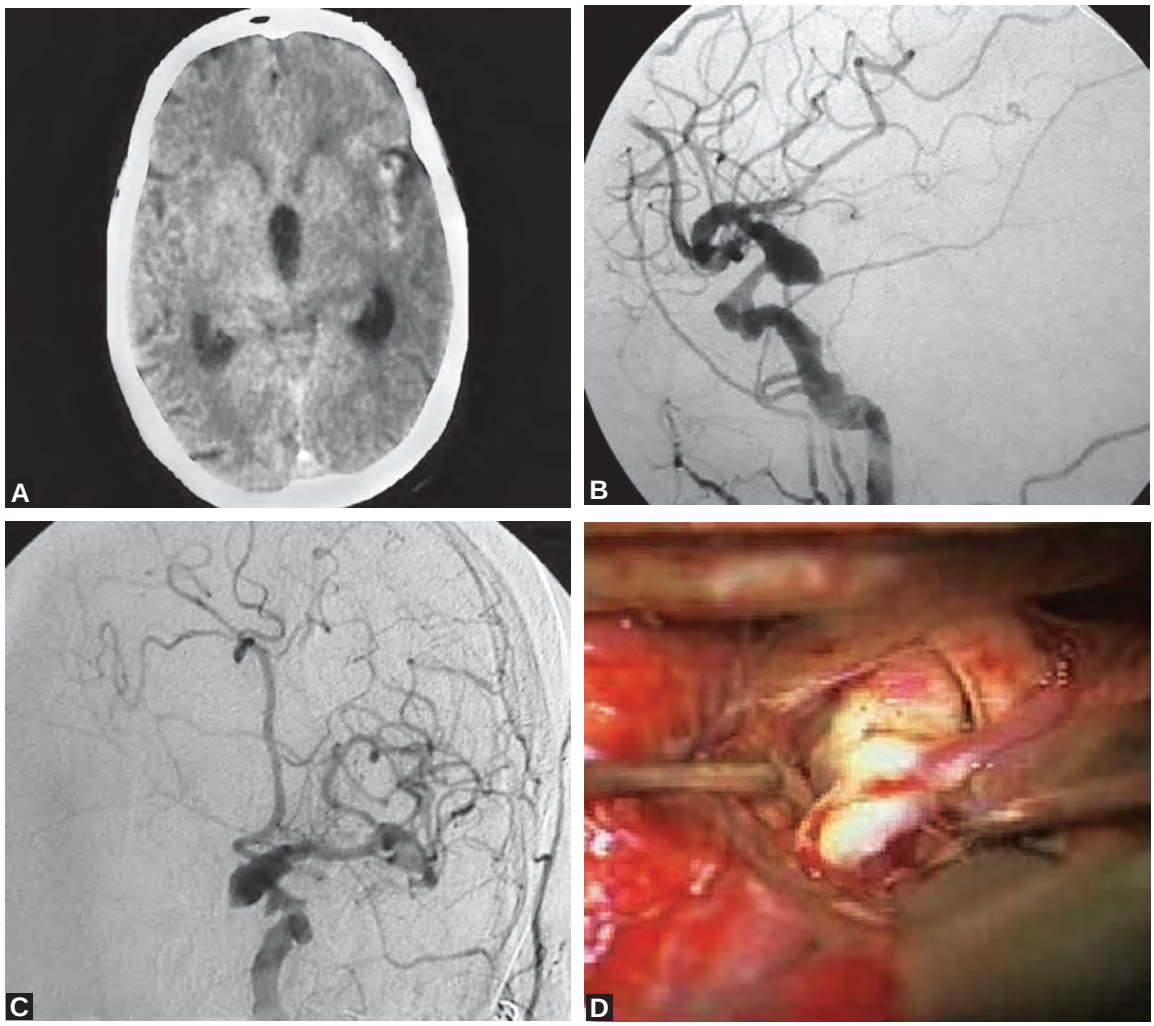

Figs 7A to D: (A) Axial CT scan showing subarachnoid haemorrhage in the Sylvian fissure. (B) Lateral angiogram. (C) AP angiogram. (D) Operative view showing a fusiform aneurysm of the internal carotid artery. The subarachnoid haemorrhage was due to bleeding from a thin walled bleb from the atherosclerotic segment. The entire segment was wrapped during surgery

characteristic of giant aneurysms and are more commonly seen in other lesions.

Computed Tomography

Non-thrombosed aneurysms are hyperdense and enhance uniformly after contrast injection. They are often round in configuration and are in close proximity to the parent vessel. Perianeurysmal oedema is rare. In partially thrombosed aneurysms, a "target" sign may be seen. This may present as a central or eccentric densely enhancing area representing the flowing blood. The peripheral thrombus may show a halo and heterogeneous or no enhancement due to the presence of various stages of blood products. The outermost rim of enhancement may be due to the vascularity of the vasa vasorum. A completely thrombosed aneurysm may be hypodense to hyperdense depending upon the age of the clot. There may be ring or intra-aneurysmal calcification. Three dimensional CT angiogram helps in defining the neck, perforators and anatomy of the skull base and may be helpful in planning clipping techniques.[18]

Magnetic Resonance Imaging (MRI)

MRI may show a thrombosed giant aneurysm where only a small part of the lumen was being filled up on angiography. The laminated thrombus may give a heterogeneous intensity on T1- and T2-weighted images. The sagittal, coronal, axial and MR angiographic images help in completely defining the aneurysm. Gradient echo flow imaging may differentiate flow voids from bony structures, calcification from thrombus and CSF pulsation induced artefacts from pulsating vessels from actual aneurysms. Thromboembolism may also be picked up on various MR sequences.[6,9,18]

Digital Subtraction Angiography (DSA)

DSA is essential to visualise the shape and size of the giant aneurysm, define the neck-fundus ratio and identify the taking up of the parent vessel by the aneurysm. Cross compression studies involve compression of the proximal portion of the internal carotid artery harbouring the aneurysm while the opposite carotid artery or the vertebral artery is injected with dye to assess the collateral circulation to the brain on the side ipsilateral to the aneurysm. The balloon test occlusion (BTO) helps in defining whether the patient will tolerate proximal vessel control or ligation during aneurysm surgery. The external carotid angiogram evaluates the status of the external carotid system for a possible superficial temporal-middle cerebral artery or an occipital artery-posterior inferior cerebellar artery bypass, if needed. Superselective angiography helps in defining the neck of the aneurysm by guiding the microcatheters to the aneurysm. With a partially thrombosed giant aneurysm, the angiographic filling of the lumen may not be a true estimate of the aneurysm size and may require CT or MR reconstructed images to precisely define the size of the aneurysm.[9,10]

Intra-operative angiography permits assessment of completeness of aneurysm occlusion and patency of parent vessel during surgery. It also serves as an adjunct to the surgical procedure since suction decompression of the aneurysm or proximal control of the parent vessel may be secured through the endovascular route; any residual neck of the aneurysm may also be coiled under the same anaesthesia and permanent proximal vessel coiling may be done after patency in the bypass graft has been ensured. To perform intra-operative angiography, the femoral sheaths are placed pre-operatively and a radiolucent operating table and head frame are used.[3,6,19,20]

AIM OF SURGICAL TREATMENT[18]

- To exclude the giant aneurysm from the circulation to prevent its rupture, while maintaining the patency of the parent vessel.
- To alleviate the mass effect caused by the aneurysm.
- To prevent thromboembolic events.

SURGICAL TREATMENT

Special Considerations for Giant Aneurysms

- *Assessment of cross flow*: In large or giant aneurysms, the suitability of a permanent ICA occlusion is determined by the BTO accompanied by a clinical examination that does not suggest any asymmetry of clinical signs; angiographic criterion, in which symmetry of flow in both hemispheres or in the anterior and the posterior circulation throughout all phases of flow, as well as a good angiographic cross flow through the anterior communicating artery (from the contralateral anterior circulation) and through the posterior communicating artery (from the posterior circulation) is maintained; a single photon emission computed tomography (SPECT) study, in which a decrease in perfusion during a hypotensive challenge with a mean blood pressure 20% below the baseline is determined and xenon computed tomography, in which the symmetry of perfusion is determined. In case the BTO with SPECT is well tolerated, the internal carotid artery may be trapped, if required. In case the BTO is not tolerated and perfusion defects are seen on SPECT, a vascular bypass using the superficial temporal to middle cerebral artery anastomosis may be required.
- *Reduction of mass effect*: Corticosteroids and various dehydrants, such as furosemide and mannitol, may be administered to alleviate the mass effect. A ventricular drain or lumbar drain may decrease the brain swelling and facilitate lobar retraction.
- *Neuro-protection during temporary clipping*: Barbiturate neuro-protection during temporary vessel occlusion involves using thiopental sodium in a dose titrated to maintain burst suppression on EEG. good hydration, oxygenation, mild hypertension, hypothermia (33–35

degrees), mannitol supplementation and calcium channel blockers have all been used as neuroprotective agents during temporary clipping. Following clipping, in cases of subarachnoid haemorrhage, hypervolaemic, hypertensive, haemodilutional therapy may be used.[3,8]

- *Proximal control*: For proximal control of the internal carotid artery, there are several strategies: (a) The common and internal carotid arteries may be exposed in the neck. (b) The portion of the ICA between the proximal and distal dural rings may be exposed by dividing the distal dural ring circumferentially around the ICA after the ophthalmic artery has been dissected free. (c) The petrous carotid artery may also be used for proximal control. This is located extradurally deep to Glasscock's triangle in the middle cranial fossa. The boundaries of this triangle are the groove of the greater superficial petrosal nerve coursing in an anteromedial direction in the floor of the middle cranial fossa; the mandibular nerve exiting through the foramen ovale and the line joining the foramen spinosum to the arcuate eminence.
- *Intra-operative assessment of patency of parent vessel and completeness of aneurysm clipping*: Intra-operative angiography and Doppler studies give information regarding patency of the parent vessel after successful clipping of the aneurysm. In case intra-operative trapping of the main artery is possible, the Doppler helps in localising the superficial temporal artery for a possible superficial-middle cerebral artery bypass.[3,5,6]

Surgical Technique

- *Exposure*: A giant aneurysm requires wide exposure often requiring skull base approaches. Wide Sylvian fissure dissection, opening of the basal cisterns to release the cerebrospinal fluid and relax the brain, use of diuretics and ventricular catheters all help in gaining a wide exposure.
- *Considerations during clipping*: In clipping of a giant aneurysm, occasionally, the neck may be very wide and not completely visualised. With the help of dissectors, it must be made sure that the clip blades are free from any perforators and arachnoidal bands. Atherosclerosis may make the aneurysm wall extremely thin and prone to rupture. An aneurysm harbouring a thrombus at the neck may be difficult to occlude unless proximal vessel temporary occlusion and opening of the aneurysm to strip the thrombus from the aneurysm wall is resorted to. A number of different clip sizes and shapes may be required for adequate clip placement. The clip may slide down and cause parent vessel occlusion unless a series of stacked clips are used for full deflation of the aneurysm prior to clip placement. Angled fenestrated clips with loops that go around the vessel wall and right angled blades that clip the neck of the aneurysm and reconstruct the vessel wall are often very useful. Booster clips and extra long clips may also be required. After clip placement, the aneurysm has to be observed for sometime to ensure that the vessel has not twisted around occluding its lumen, the aneurysm is not filling due to inadequate closing force of the clips and the clip is not sliding towards the parent vessel.[7,11,15,18]

Adjuvant Techniques

- *Temporary clipping*: Proximal and distal clipping is useful during aneurysm dissection, in case of aneurysm rupture during dissection, to deflate the fundus of the giant aneurysm prior to clipping or arterial wall reconstruction and to remove the thrombus from its neck to facilitate permanent clipping. Neuroprotective agents, induced hypertension, mild hypothermia and bypass grafts may help in increasing the ischaemia time. Distal occlusion also decreases the risk of embolisation of the thrombus.[8,18]
- *Wrapping*: This technique may be used for fusiform, thin walled aneurysms or when a perforating vessel is originating from a part of the fundus of the aneurysm that cannot be included in the clip. This, however, is ineffective unless the entire aneurysm can be exposed.
- *Suction aspiration*: After temporary clipping, the dome of the fundus may be aspirated to shrink it prior to clipping of the neck. Endovascular proximal vessel balloon occlusion followed by suction aspiration of the aneurysm also facilitates its clipping.[4,5]
- *Bypass*: The low flow superficial temporal artery-middle cerebral artery bypass or the high flow saphenous vein interposition graft are placed. The bypass may be done from the cervical internal or external carotid artery to the M2 branch of the middle cerebral artery in the anterior circulation and the occipital-PICA anastomosis or superficial temporal-P2/3 bypass in the posterior circulation. These techniques are especially helpful in case aneurysm trapping is being planned or prolonged temporary occlusion of the parent artery is anticipated considering its difficult location or large size.[18]
- *Proximal vessel ligation*: This may be associated with nearly 30–50% incidence of ischaemic complications without bypass. Its effectiveness depends upon the adequacy of the collateral circulation. Intracavernous and petrous internal carotid artery aneurysms have a 90% occlusion rate; paraclinoid segment (with collaterals from ophthalmic artery) have a 75% occlusion rate and supraclinoid aneurysms (with collaterals from anterior and posterior communicating and anterior choroidal artery) have only a 50% occlusion rate.[6,18]
- *Deep hypothermic circulatory arrest*: If the brain is cooled to 18 degrees centigrade even the brainstem can tolerate ischaemia up to one hour. At about 29 degrees centigrade, however, ventricular fibrillations are precipitated necessitating the need to bypass the heart to perfuse the brain and other vital organs while

hypothermia is continuing. Once the body temperature reaches 18 degrees centigrade, the bypass pump may be switched off for about an hour. Using circulatory arrest, the giant aneurysm may be decompressed by draining a part of the blood volume into a storage reservoir to facilitate clipping. The disadvantages of this procedure are: Perforators may look like arachnoidal bands and be inadvertently injured; ruptured perforators may bleed when the pump is restarted; the aneurysm may fill up again due to insufficient strength of the applied clips or heparinisation and platelet depletion by the pump circuit may lead to persistent oozing.[2,3]

- *Skull base approaches*: For adequate exposure, especially in posterior circulation aneurysms, these approaches have been developed.[1,6,7,22] The important ones are as follows: (A) For giant paraclinoid/caroticoophthalmic aneurysms, a frontotemporal craniotomy and orbitozygomatic osteotomy and anterior clinoidectomy provides access to the paraclinoid segment of the internal carotid artery. Removal of the orbital rim also provides access to the anterior cranial fossa base for a subfrontal clipping of giant anterior communicating artery aneurysms. Retraction of the temporal lobe posteriorly and drilling of the posterior clinoid after this approach provides access to a high basilar artery bifurcation.[15,22] (B) The transcavernous approaches are extensions of the trans-Sylvian or subtemporal approaches and provide access to the cavernous sinus, the tentorial edge and the posterior fossa giving a good view of the pons, midbrain, middle fossa and upper clivus. In Dolenc's approach, after a frontotemporal craniotomy and extradural and intradural anterior and posterior clinoidectomy, the cavernous sinus is entered into laterally along the IIIrd nerve. In the extradural temporopolar approach, an extradural resection of the anterior clinoid during a frontotemporal craniotomy and orbitozygomatic osteotomy is performed. With a trans-Sylvian exposure and retraction of the temporal lobe posteriorly, the paraclinoid segment of the carotid artery is mobilised laterally dividing the dural ring. The orbital roof is also drilled exposing the IInd nerve medially. Thus, a wide exposure to the posterior fossa may be gained via a considerably widened carotico-optic space. Access to the posterior fossa may also be gained by working lateral to the IIIrd nerve and mobilising it medially. Kawase's approach involves a subtemporal or frontotemporal craniotomy, anterior petrosectomy from the middle fossa base and opening the tentorium and lateral cavernous sinus wall to gain access to the posterior fossa at the level of the lower midbrain and pons. (C) The transpetrosal or presigmoid approaches involve removal of the petros bone in addition to temporal or retrosigmoid bone removal. This provides access to the mid pons, upper medulla, lower basilar trunk, vertebrobasilar junction and distal vertebral arteries. (D) The far or extreme lateral approaches involve drilling of the posteromedial aspect of the occipital condyle after a standard retromastoid suboccipital craniectomy to change a predominantly posterior approach to the brainstem to a more lateral one. They provide access to the lateral and ventral pons and medulla and 7–12th cranial nerves. They also provide access to the vertebral artery from its intradural entry to the vertebrobasilar junction.[6,14,17,22]
- *Endovascular techniques*: Primary endovascular treatment for giant intracranial aneurysms involves:[19] (A) Stenting of the vessel with sheathed stents to exclude the aneurysms. These ideally should exclude the aneurysm from the circulation while blood flow in the branching and perforating vessels is maintained, and be flexible and self expanding to automatically conform to the vessel lumen. (B) Endosaccular occlusion involves placement of thrombogenic metal wires or coils, such as the Guglielmi detachable coils, to totally occlude the aneurysm.[1] Liquid material, such as N-butyl cyanoacrylate, that becomes solid by precipitation or polymerisation, onyx whose solvent dimethylsufoxide is washed away in blood leaving a precipitate within the aneurysm, or neurocryl have been used.[19] (C) Proximal vessel occlusion using coils, balloons or N-butyl cyanoacrylate for aneurysms proximal to the circle of Willis which decreases the flow within the aneurysm and induces thrombosis. (D) Taking proximal control of the parent vessel intra-operatively during aneurysm clipping, the site of occlusion may be chosen based on the collateral flow distribution; a prior BTO also ensures the patient's ability to undergo proximal vessel occlusion. (E) Intra-operative endovascular suction decompression of the aneurysm to make it smaller and more amenable to surgical clipping. (F) In poor grade patients after subarachnoid haemorrhage, with a broad-based aneurysm in a location that requires a difficult exposure, partial coiling reduces the immediate danger of rebleeding. (G) Flow reversal technique: In giant fusiform aneurysms of the proximal basilar artery, proximal occlusion of both vertebral arteries reverses flow through the basilar artery and decreases the intraluminal pressure within the aneurysm leading to its thrombosis and shrinkage.[5,19,20]

Endovascular embolisation is often not the primary choice of treatment in giant aneurysms. Giant aneurysms usually have a wide neck. Total occlusion requires dense packing of the sac. The wide neck predisposes to coil herniation and compromise of the parent artery. Intrasaccular thrombus increases the risk of recurrence due to migration of coils into the thrombus. The mass effect of the aneurysm is not alleviated and GDC does not protect against thromboembolic events. The coils may rotate, compact or remodel permitting re-entry of blood into the aneurysm.[1,5,19,20]

Long-Term Outcome

The most important risk factors associated with a poor outcome of unruptured aneurysms are giant aneurysms

(>2.5 cm) and location in the posterior circulation. Giant aneurysms rupture in more than 50% of cases and the mortality is greater than 60% within 2 years. The International Study of Unruptured Intracranial Aneurysms Part 2 found that the annual rupture rates for giant aneurysms were 8% in the anterior circulation and 10% in the posterior circulation.[21] A meta-analysis on the clipping of all unruptured aneurysms found an overall mortality and morbidity of 0.8% and 1.9%, respectively; in patients with giant aneurysms of the anterior circulation, however, the mortality and morbidity were 7.4 and 26.9%, respectively; and, of the posterior circulation, the mortality and morbidity rates were 9.6 and 37.9%, respectively.[13] Nakase et al.[12] investigated the long-term outcome of patients with unruptured giant aneurysms and found that surgery significantly reduced the mortality (from 31 to 4%) but increased the morbidity (from 8 to 19%) as compared with conservatively treated patients. Thus, giant intracranial aneurysms have a poor prognosis if left untreated, but the treatment goals are also difficult to achieve with the presently available options.

86 Incidental Intracranial Aneurysms

Suresh Nair, A Mathew, G Menon

The morbidity and mortality associated with aneurysmal subarachnoid haemorrhage remain distressingly high despite advances in microneurosurgery, interventional radiology, neuroanaesthesia and critical care. Although intracranial aneurysms are common affecting 5% of the population,[59] the incidence of subarachnoid haemorrhage is relatively low (approximately 1 case per 10,000 persons per year),[16] especially in patients with small (<10 mm in diameter) aneurysms, suggesting that most aneurysms do not rupture. A great number of unruptured and often incidental intracranial aneurysms are being diagnosed today because of the increasing age of the population and improvement in imaging techniques. Patients harbouring an unruptured intracranial aneurysm (UIA) are potentially at high-risk of dying from subarachnoid haemorrhage (SAH). Prevention of this rupture with surgical or endovascular treatment is believed to be the most effective strategy to prevent mortality and morbidity. However, all current treatments carry some risks and, therefore, the natural history of UIAs must be considered carefully before formulating treatment recommendations. The decision to treat or not to treat is important because treatment related complications usually occur at or around the time of the procedure. Therefore, the cumulative lifetime risk for rupture of an untreated aneurysm needs to be evaluated to make a judgement of what is best for the patient. Also one should know the factors associated with risk of intracranial aneurysm formation and subarachnoid haemorrhage and identify the subset of people who can be screened for incidental aneurysms. With a thirty-day mortality rate following rupture reaching 50% with nearly half the survivors having irreversible brain damage,[30,65] it is understandable that discovery of UIAs should prompt a decision for expeditious treatment.

There are many growing controversies about incidental aneurysms:

1. Should we screen for incidental intracranial aneurysms in people at risk of harbouring them?
2. When is it appropriate to secure an incidental anenurysm?
3. What are the risks of rupture if the aneurysm is not treated?
4. If treatment is pursued, what treatment modality should be used?

To answer the above questions and to obtain a rationale for management of UIAs, one should have an idea of its formation.

The majority of aneurysms are saccular in shape and result from a combination of factors including degeneration and weakening of the internal elastic lamina and collagen fibres of the arterial wall, as well as the haemodynamic effects of fluid pulsations. Factors associated with the risk of intracranial aneurysm formation and subarachnoid haemorrhage can be classified as modifiable and non-modifiable. The major identified modifiable risk factors include active smoking, hypertension, excessive alcohol consumption and possibly the use of oestrogens.[1,4,6,27,28,41,58] Some case control studies also found increased risk with intake of coffee and use of cocaine.[9] The most important unchangeable risk factors are familial occurrence of SAH and autosomal dominant polycystic kidney disease (ADPKD).[8,46] Aneurysms have also been associated with connective tissue diseases, such as Ehlers-Danlos syndrome type IV, neurofibromatosis and Marfan disease, but these disorders are rare and therefore the number of patients with SAH related to them is small.[53]

POPULATION AT RISK

A family history of subarachnoid haemorrhage is the strongest risk factor and is defined as having at least one first-degree relative (parent, sibling or child) with SAH. However, because such a family history is not common, screening of people who have a family history of SAH will not have a large effect on the incidence of SAH.[47] The chance of having an aneurysm and the lifetime risk of SAH depend on the number of affected first-degree relatives.[8,46] The lifetime risk of SAH in individuals with two or more affected first-degree relatives is unknown, since there are few families with this history and because those that exist tend to seek screening for aneurysms and treatment of those detected. The chance of harbouring an aneurysm depends not only on the number of affected relatives but also on the relationships. If the affected relatives are siblings, the risk of having an aneurysm is higher than if they are parents or children.[8,46] Aneurysms are more commonly large and multiple in familial than in sporadic SAH.[50] However, since only 10% of cases of SAH are associated with a family history,

large and multiple aneurysms are more commonly seen in sporadic than in familial SAH. Patients with familial SAH tend to be younger than sporadic cases and, in families with two generations affected, the age at onset is earlier in the younger than in the older generation.[7,8,55] Risk of intracranial aneurysms and of SAH according to the number of affected first-degree relatives shows that individuals with one affected relative have a 5.5 times greater lifetime risk of SAH than the general population, but the risk of finding an aneurysm with screening in an individual with one affected relative is only 1.7 times higher than in the general population.[8,46] This suggests that familial intracranial aneurysms have a higher risk of rupture and the rate of development of new aneurysms is quicker in relatives with familial occurrence of SAH than in individuals without familial occurrence. People with two or more affected relatives and with a negative magnetic resonance angiography have a 7% risk of developing an aneurysm within 5 years of screening.[64]

Although SAH is common in patients with ADPKD, less than 1% of cases of SAH are attributable to ADPKD because the disease is rare.[14] Intracranial aneurysms are found in about 10% of patients with ADPKD.[46] Apart from a positive family history for SAH, no clinical characteristics have been identified that are associated with increased risk of aneurysm in patients with ADPKD. The position of the mutation in PKD1 is predictive of development of aneurysms, but mutation detection is not yet used in clinical practice. As for people with a positive family history of intracranial aneurysms, people with ADPKD are at risk of developing new aneurysms.

Patients who have been successfully treated for an aneurysm are at risk of developing new aneurysms. There are only few series, all with short follow-up, which have reported the risk of development of de novo aneurysms. In these reports the rate of development of new aneurysms was between 0.4% and 2.2% per year.[12,21,61] Apart from development of new aneurysms, an occluded aneurysm might reopen or a new aneurysm could develop at the site of a treated aneurysm. The rate of growth of aneurysms after clipping was about 0.5% per year in two series with high rates of follow-up angiography.[18,19] In two follow-up studies, the risk of recurrent SAH after clipping was estimated to be 2% in 10 years, and about 9% in 20 years, which is about 30–50 times higher than the risk in the general population.[12,21] A higher proportion of patients with two episodes of SAH had a positive family history of the disorder (30%) than those with SAH in general (10%).[8] Patients with recurrence of SAH were also younger at onset than those with the disorder in general. The mean time between the first and second episodes was 7.8 years, ranging 2.8–14 years for SAH from *de novo* aneurysm.[33,62] The lower limit of about 3 years for a new episode from a *de novo* aneurysm accord with other studies on rupture of *de novo* aneurysms. A new aneurysm seems to take some time to develop, although some case reports have described rupture of new aneurysms within 2–6 months after initial SAH.[33,69]

ISUIA STUDY AND CONTROVERSIES

Asymptomatic unruptured aneurysms, which constitute between 17% and 37% of all unruptured aneurysms, are less prone to bleeding than symptomatic unruptured aneurysms.[59,60,69] Their annual bleeding rate has been the subject of much controversy. Most of this controversy stems from the results of the International Study of Unruptured Intracranial Aneurysms (ISUIA) which was first published in 1998.[59] The ISUIA had two objectives. The first was to evaluate the natural history of UIA, and the second was to establish the risk of treatment. The study consisted of retrospective and prospective components. In the retrospective component, the natural history of UIAs was evaluated and in the prospective component, the morbidity and mortality related to treatment were evaluated. A total of 1,449 patients with 1,937 UIAs were included in the retrospective cohort. They were divided into two groups: 727 patients of group 1 who had no prior history of SAH and 722 patients of group 2 who had history of SAH. The mean duration of follow-up was 8.3 years. Of the 1,449 patients, 32 had documented aneurysmal rupture. In group 1, the cumulative rate of rupture was 0.05% per year for aneurysms less than 10 mm in diameter and about 1% in those over 10 mm in diameter. Aneurysms larger than 25 mm had a 6% rupture rate in the first year. In group 2, the cumulative rate of rupture was about 0.5% per year for lesions smaller than 10 mm and about 1% for those larger than 10 mm in diameter. In group 1, in addition to size, location was related to haemorrhage risk, with basilar top, vertebrobasilar, posterior cerebral and posterior communicating artery aneurysms having a higher risk of rupture. In group 2, only location (i.e. basilar tip) and increasing age predicted an increased risk of haemorrhage. The risks quoted in the ISUIA study, however, was lower than previous studies had suggested.[17,21,31] Jane and co-authors estimated that the long-term risk of rupture for an incidentally discovered cerebral aneurysm was between 1% and 2% per year.[17] Similarly, Juvela et al. found the annual rupture risk to be 1.4% per year among 181 untreated aneurysms followed in 132 Finnish patients over a 30 years period. The annual risk to patients was 2.1% because some patients had more than one aneurysm.[20,21] Results of the initial report of the ISUIA have created much controversy, and the study has been criticised based on the select nature of the retrospective cohort and the comparison between the prospectively gained morbidity data and the very low rupture rate for patients in the historical cohort who had been selected for non-operative intervention. It was suggested that the retrospective group had excluded patients with the highest risk of rupture and introduced data-collection bias, artificially lowering the estimated annual haemorrhage rate and those patients enrolled in ISUIA were pre-selected for low natural history risk and these low-risk patients represented only about 2% of the patients seen in practice.[13,22,38] This combined

retrospective/prospective ISUIA report did not make a clear distinction between the risks of symptomatic and truly incidental unruptured aneurysms and did not determine the influence of genetic factors, smoking history or concurrent diseases such as ADPKD. Subsequently, in a population based study by Juvela et al. 142 unselected patients from a defined geographic area were observed for an average of 20 years. The risk of haemorrhage was 1.3% and each millimetre increase in aneurysm size was associated with an increase of 1.11 in the relative risk of haemorrhage.[20] In addition, active cigarette smoking was found to be an important predictor of aneurysm rupture. This study, along with another study from Japan,[60] suggests that risk of rupture from asymptomatic aneurysms is probably closer to 1% than 0.1% per year and this risk is highly dependent on age, smoking, lesion size and lesion location. Surgical series show that multiple aneurysms represent about a third of unruptured aneurysms. The annual risk of bleeding of an unruptured aneurysm discovered during angiography performed for a ruptured aneurysm in another location is greater than the risk for an isolated asymptomatic lesion.[15,67] In the ISUIA, prior SAH was associated with an 11-fold increase in rupture for small (<10 mm) aneurysms.[24] No additional risk was observed for larger aneurysms. The exact additional risk of rupture from an asymptomatic aneurysm when there is a history of SAH is not certain.

There is considerable evidence in literature that the majority of ruptured aneurysms are smaller than 10 mm. In the Co-operative Aneurysm Study angiographic studies revealed a mean maximal diameter of 8.2+/–3.9 mm and a median diameter of 7 mm.[23] Seventy-one per cent of the sacs were smaller than 10 mm and 13% were less than 5 mm in diameter. The relationship between aneurysm size and haemorrhage from unruptured aneurysm is not fully elucidated. According to ISUIA, in patients with no history of subarachnoid haemorrhage, the five-year cumulative rate of rupture of aneurysms located in the internal carotid artery, anterior communicating artery, anterior cerebral artery or middle cerebral artery is zero for aneurysms under 7 mm, 2.6% for 7–12 mm, 14.5% for 13–24 mm, and 40% for 25 mm or more.[67] This rate is in contrast to rupture rates of 2.5%, 14.5%, 18.4% and 50%, respectively, for the same sizes of aneurysms in the posterior circulation and posterior communicating artery. Some authors suggest that unruptured aneurysms less than 10 mm in diameter do not bleed even though the average size of ruptured aneurysm from the same group was 7.5 mm.[37,66] Yasui et al. followed 25 unruptured aneurysms including 66% that were less than 5 mm at the time of detection. Twenty-five per cent of the aneurysms were still less than 5 mm when SAH occurred.[70] In a prospective population based study an association between increased aneurysm size and bleeding was observed.[21] The median diameter of unruptured aneurysms that subsequently bled was no different from the median diameter of those that did not rupture (4 mm). In the same study, aneurysm growth on serial examination was associated with an increased risk of bleeding. The available data suggests that, whereas increased aneurysm size is associated with increased risk of rupture, small aneurysms certainly bleed and in some patients this risk of bleeding may be predicted by aneurysm growth.

Results of a continuation of the prospective arm of ISUIA have recently been published.[67] Compared with rupture rates in the retrospective cohort, rupture rates were higher in patients from group 1 (no prior SAH) of the prospective cohort who had unruptured aneurysms at least 7 mm in diameter, and this difference was most pronounced for aneurysms 7–9 mm in diameter. Size had little predictive value in patients with history of SAH from a different aneurysm (group 2). On multivariate analysis age greater than 50 years, aneurysm size greater than 12 mm, posterior circulation location, previous ischaemic cerebrovascular disease and aneurysm symptoms other than rupture were predictive of poor outcome after craniotomy while, in patients treated endovascularly, only size greater than 12 mm and posterior circulation location were associated with poor outcome. Comparison between the surgical and endovascular groups is not possible due to the unbalanced distribution of patients in the treatment groups of this nonrandomised study. There was a high rate of incomplete aneurysm obliteration in patients who underwent endovascular therapy, although the overall treatment related morbidity and mortality at one year was lower in the endovascular group.

SHOULD WE SCREEN FOR INCIDENTAL ANEURYSMS

The benefits of screening for asymptomatic intracranial aneurysms have never been quantified. No clinical trials have been done on screening for aneurysms in patients at increased risk and presumably such trials will not be done because the follow-up needs to be 20 years or longer. The goal of screening is not to detect or to treat an aneurysm, but to increase the number of quality years of life.[3] Decisions therefore must be made from calculations and assumptions about perceived quality of life.[47] Definitely the patient gets a reassurance with a negative screening result, but it can also cause anxiety if a 3 mm aneurysm is found and left untreated or if an unrelated abnormality is found.[63] Also one has to bear in mind that even screening, repeated screening and preventive treatment cannot prevent all episodes of SAH because, in rare instances, aneurysms can develop and rupture within the regular screening interval of 5 years.[52] Conventional angiography, however, is not useful for screening high-risk groups because a single negative angiogram does not exclude the possibility of a de novo lesion developing in future. MRA is at present the most satisfactory technique for screening high-risk groups. The number of false negatives may be reduced by the simultaneous use of CT angiography. Screening should be done in individuals with two or more affected first-degree relatives, and

in patients with ADPKD. With this screening strategy, approximately 10% of individuals are found to have an intracranial aneurysm.[9,42,48,49,51] In approximately a third of these patients, the aneurysms are larger than 5 mm in diameter.[48] Since aneurysms are very rare before the age of 20 years, screening is started after this age. If a first screening is negative, repeated screening should be advised, because the risk of finding an aneurysm 5 years after the initial screening is about 7%.[64] Screening should not be advised if the life expectancy of the patient is short because of advanced age or comorbid illness and the maximum age for screening is 60–70 years depending on the individual's health status.[47] Screening should also be done in identical twins if SAH has occurred in one of the twins. In many pairs, the aneurysms are at the same site and SAH tends to occur at around the same age.[35,40] In individuals with only one affected first-degree relative, screening is not very efficient or effective as relatives of index SAH cases have only a 4% risk of harbouring an intracranial aneurysm and this low incidence may not make screening cost-effective.[43,71] To prevent one episode of fatal SAH, 300 at risk people must be screened.[47] The general advice is not to screen individuals with only one affected relative. Patients with Ehlers-Danlos syndrome type IV are advised against screening because of the fragility of the vessel wall which substantially increases risk of treatment.[34] There is no indication for screening patients with neurofibromatosis or Marfan disease, because an increased risk of SAH has not been confirmed in these groups.[47] Patients who have had an aneurysmal SAH are at increased risk for development of a new aneurysm some time after the initial aneurysm has been discovered. Each year, new aneurysms develop in at least 2% of patients with previously ruptured aneurysms and in this group of patients, the incidence of aneurysmal rupture is approximately 6 per 10,000 per year, which is substantially higher than the incidence of aneurysmal SAH in the general population.[21] Follow-up screening for aneurysms in this group might be beneficial, but evidence to advise on follow-up screening in such patients is insufficient.

MANAGEMENT ISSUES

We know that the rate of rupture of UIA is affected by factors such as aneurysm size, aneurysm location, multiplicity of aneurysms, aneurysmal growth, symptomatic aneurysms and patient factors such as age, gender and history of hypertension and smoking. The presence of severe progressive symptoms from an aneurysm within the subarachnoid space is an indication for treatment regardless of the size of the unruptured aneurysm. Symptomatic unruptured aneurysms often require treatment because of headaches, cranial nerve deficit, seizures, embolic stroke or hemiparesis. The risk of bleeding is also greater in symptomatic unruptured than asymptomatic unruptured aneurysms.[67] Symptomatic lesions represent about a third of all unruptured lesions, but account for three quarters of the cases that bleed during observation. Overall, the risk of complications from treatment is around 5% for death or persisting impairment in activities of daily living, and 10% for persisting cognitive deficits or reduced quality of life.[67] The risks are higher for neurosurgical clipping than for endovascular coiling, especially in patients older than 50 years.[5,44,45,67]

The complication rates are probably lower for aneurysms detected by screening, because they are mostly small, and risks of complication from treatment increase with the size of aneurysms.[54] In a meta-analysis by Raaymakers and co-workers, in which the treatment of 2,568 unruptured aneurysms in 2,460 patients was examined, surgical morbidity was 10.9% and mortality 2.6%.[44] Similarly, in the prospective arm of the ISUIA, among 996 patients undergoing surgery, 1 year mortality was 2% in patients with previous SAH and 3.8% in patients without prior history of SAH.[67] The morbidity for both groups was approximately 12% and much of this morbidity included subclinical neuropsychological defects that had limited functional impact. The meta-analysis of Raaymakers et al. had several caveats because of studies with varied inclusion criteria, inconsistent outcome measures, unclear information about neurosurgeon's experience and a relatively high percentage (37%) of symptomatic unruptured aneurysms were included in the analysis. In addition, a relatively large number of giant and posterior circulation aneurysms, which both have particularly poor surgical outcomes, were included in the study. When these two groups of patients were analysed separately, Raaymakers and co-workers found that the surgical mortality and morbidity among other aneurysms were 0.8% and 1.9%, respectively. To date, the most selective meta-analysis of unruptured aneurysm surgery was performed by King and associates, who observed an overall mortality rate of 1% and morbidity of 4.1%. This study, unlike the meta-analysis by Raaymakers included more aneurysms less than 10 mm in diameter (72% vs 54%) and more aneurysms located in the anterior circulation (94% vs 70%).[26]

FACTORS ASSOCIATED WITH SURGICAL OUTCOME

Increased aneurysm size is the most important factor associated with surgical complications and poor outcome. Aneurysms larger than 25 mm in diameter have a fourfold increased risk compared with 5 mm aneurysms.[25] Wirth et al. showed operative morbidity following surgery to be 2% for aneurysms smaller than 5 mm, 7% for aneurysms 6–15 mm and 14% for aneurysms 16–25 mm.[68] Among 92 unruptured giant aneurysms operated at Columbia Presbyterian Hospital, morbidity occurred in 25% and, overall, 83% experienced a good or excellent outcome, while for lesions less than 10 mm, 99% had good or excellent outcome.[54] Ninety-nine per cent of non-giant and 90% of the giant aneurysm patients returned to work. Aneurysm size was also related with

technical results with only 60% of giant lesions undergoing clip occlusion while it was 85% for lesions less than 10 mm diameter.[11] The association between increased aneurysm size and poor outcome may be explained in part by the aneurysm's intimate association with small perforators, broad aneurysm neck, intraluminal thrombosis, or atherosclerosis in the aneurysm neck or dome. In the series of Wirth et al.[68] aneurysm location affected outcome in anterior circulation aneurysms; morbidity was 5% for posterior communicating aneurysms, 8% for middle cerebral aneurysms, 12% for ophthalmic lesions, 16% for anterior communicating lesions and 17% for internal carotid bifurcation lesions. A similar relationship between anterior circulation aneurysm location and outcome was not observed by the Columbia Presbyterian hospital group.[60] In their observation basilar bifurcation lesions were associated with poor outcome and worse angiographic result with only 66% having angiographic occlusion but 81% experienced a good or excellent outcome in this group.

Even though advanced age is recognised as a poor prognostic indicator for surgery, many surgeons have reported good surgical results in patients older than 60 years.[11,54,68] Wide aneurysm neck reduces the success of endovascular procedures, but generally play a less significant role in surgery. Calcification in the aneurysm neck is associated with increased surgical difficulty and is also associated with an increased incidence of cerebral embolism and intra-operative bleeding from the aneurysm neck. Patient related factors include advanced age, ischaemic cerebrovascular disease, and medical conditions, such as diabetes mellitus, also increase the risk of unruptured aneurysm surgery.

ENDOVASCULAR TREATMENT

In some patients endovascular coil occlusion is a valuable alternative to surgery in the treatment of unruptured aneurysms, even though the long-term effect on natural history remains uncertain. Also there are difficulties in evaluating coil embolisation technology, because the procedure is constantly being refined and additional experience gained. Procedural morbidity with this technique is between 6% and 19% in the older series with overall favourable outcome in 82% and a mortality of 10%.[10,29,39] Endovascular procedures appear to be less successful than surgical procedures in occluding unruptured aneurysms with only 50% achieving complete occlusion.[29,39] A second limitation to an endovascular procedure is aneurysm recurrence, which is between 16% and 32%.[11] The results of GDC embolisation for incidentally discovered, unruptured aneurysms were assessed in a series of 120 patients by Murayama and colleagues.[32] Thirty-nine percent of the aneurysms were ophthalmic segment aneurysms and 18% were located at the basilar bifurcation. Complete GDC occlusion could be achieved in only 63% of cases and procedure related morbidity was 5.2%. Follow-up angiograms were available in only 77 patients of the original 120 patient cohort. After the original embolisation, complete occlusion was observed in 52 aneurysms, and a small neck remnant was visualised in 22 aneurysms. At follow-up angiography, none of the 52 completely occluded aneurysms had recanalised. In the 22 aneurysms with small neck remnants, 8 (36%) showed aneurysmal recanalisation due to coil compaction. A comparative study by Johnston and coworkers in a cohort of patients treated at 60 University Hospitals from January 1994 through June 1997, using the University Health System Consortium database, looked at the outcome between coil embolisation and surgical clipping for both symptomatic and incidental unruptured aneurysms.[18] Adverse outcomes were significantly more common in surgical cases (18.5%) than in endovascular cases (10.6%). In another study Johnston and colleagues compared 130 cases ideal for either technique that underwent surgery or coil embolisation during a 10 years period. Surgical complications were threefold greater than endovascular complications, probably because the surgical team did not have a dedicated cerebrovascular surgeon and low volume surgical centres were compared with high volume endovascular centres.[18]

MANAGEMENT GUIDELINES FOR INCIDENTAL ANEURYSMS

Whether or not to treat a truly incidental (asymptomatic) aneurysm remains controversial. It is clear that size of the aneurysm is important; however, it is also clear that there is no cut-off size below which rupture is not possible. Small aneurysms have a risk of haemorrhage even though this risk may be less than that of larger aneurysms. In general, the risk that small aneurysms (<7 mm) will rupture is low, particularly if they are on the anterior circulation. Small aneurysms might therefore best be left untreated.[38] However, this approach is not appropriate for patients who have two or more relatives who died from SAH. Several studies have found a higher risk of rupture for familial than for sporadic aneurysms.[46] Patients with unruptured aneurysms, whose relatives have died from SAH, know that the haemorrhages occurred from small aneurysms. A patient with a small aneurysm but a positive family history is difficult to reassure with general statements that small aneurysms have a low-risk of rupture. In patients with small aneurysms (<7 mm), the decision on whether or not to treat depends on the age of the patient, site of the aneurysm, accessibility of the aneurysm for coiling in older patients, whether or not a previous SAH has occurred and the ability to cope with the knowledge of having an untreated aneurysm.[47] In patients with very small aneurysms (3 mm or less), follow-up assessment to check whether or not the aneurysm is increasing over time seems to be a reasonable approach. The optimum period between follow-up assessments and the duration of follow-up are not known. At the University of Miami School of Medicine, each case of incidental aneurysm is considered individually and treatment offered

accordingly.[2] They recommend treatment of incidental aneurysms that are more than 7 mm in diameter if the patient is relatively young and without major co-morbidities. If the patient is very young or has a family history of aneurysms or has had a SAH from another aneurysm, they recommend treatment even for aneurysms of a significantly smaller size. With larger aneurysms, they stretch the indications for treatment and treat even patients who are older, but in relatively good medical health or younger patients with some co-morbidities who are still likely to tolerate general anaesthesia. Due to location and configuration, the decision making becomes more problematic for truly incidental large and giant aneurysms, where risk of treatment is very high. In such cases they consider age an important factor and tend to take a risk in a younger patient and to observe an older patient with periodic imaging. A more aggressive approach is pursued if prominent growth of the aneurysm is seen on follow-up imaging. They also address the issue of treating an incidental aneurysm with open microsurgery or endovascular occlusion. With unruptured aneurysms one does not have the problem of swollen, hyperaemic and friable brain that may be injured by retraction at surgery and also there is no problem of vasospasm that may be exacerbated by surgery. Therefore, they tend to lean more towards open microsurgery under equal circumstances with unruptured incidental aneurysms because of the uncertainty about the long-term durability of coiling as opposed to microsurgical clipping in experienced hands. They recommend open microsurgical clipping for most aneurysms of the anterior circulation and for vertebral artery including origin of PICA or distal PICA or distal AICA aneurysms and aneurysms at the origin of the superior cerebellar artery. For most basilar aneurysms they recommend endovascular treatment. As suggested by this group, it is very important to emphasise that the evaluation of "risk versus benefit" is an ongoing process that continues until an aneurysm is secured by either coiling or clipping. If one finds, during surgery, unexpected circumstances that clearly increase the risk of treatment, one should not hesitate to back off as may be seen during open surgery when the aneurysm neck is found calcified or if the surgeon finds vital perforators that cannot be saved. Under such circumstances the authors' advice is to back off and either treat the patient conservatively or recommend endovascular therapy.

THE AMERICAN HEART ASSOCIATION GUIDELINES

Members of the Stroke Council[63] recommended that incidental aneurysms smaller than 10 mm in patients without a previous SAH should be observed rather than treated unless the patient is young, there is a daughter aneurysm or if there are unique haemodynamic features. Patients with a family history of aneurysmal SAH also deserve special consideration for treatment. Aneurysms larger than 10 mm should be considered for treatment depending on age, health and aneurysm risk factors.

ADVANCES

Recent advances in molecular genetics have made linkage studies possible to map the chromosomal locus of a putative intracranial aneurysm gene mutation. One approach is to screen the human genome for intracranial aneurysm genes by testing linkage of a large number of distinct highly polymorphic genetic markers. Another method for studying linkage is to analyse variations in the sharing of marker alleles among affected sibling pairs only. Polymorphisms of several genes have now been investigated in patients with intracranial aneurysms. Certain polymorphisms of the angiotensin I converting enzyme, matrix metalloproteinases and endoglin genes may be associated with an increased risk for aneurysm development.[56-58,72] Olson and colleagues[36] performed a sibling-pair linkage analysis in Finnish patients with intracranial aneurysms and identified a susceptibility locus at 19q13.1-13.3.

CONCLUSION

The advent of reliable non-invasive imaging and efficacy of treatment for incidental cerebral aneurysm has aroused an interest in the medical fraternity in the management of these patients. The numbers of incidental aneurysms will continue to increase as the age of the population increases. The treating physician must understand the natural history to assess the effectiveness of treatment options. Whether or not it is proper to screen for incidental aneurysms is based on an understanding of aneurysm formation and rupture. If aneurysms develop over a brief time frame and are most prone to rupture during this period, aneurysm screening programs will identify only stable aneurysms and miss the unstable ones that require treatment. If the long-term risk of haemorrhage from an incidentally detected aneurysm is as low as that reported by ISUIA, treatment in its current form may pose a greater risk to patients than does the disease itself. Treatment of incidental aneurysms will continue to evolve. The development of intravascular stents and flow redirectors may improve the result of endovascular procedures. Less invasive surgical approaches, better neuroprotection that permits longer temporary occlusion times, and endoscopic instruments designed to identify perforators will similarly improve surgical results. The patients should have a management plan that is individualised and should consider the age of the person, life expectancy, co-morbidities and characteristics of the aneurysm.

87 Multiple Intracranial Aneurysms

Mahmoud Rashidi, Anthony Sin, Anil Nanada

INCIDENCE

Based on observations from autopsy studies, nearly 10–15 million people in the United States are largely believed to have, or will develop, cerebral aneurysms in their lifetime.[16,17] Winn and colleagues from the University of Virginia retrospectively reviewed 3,684 cerebral angiograms not related to subarachnoid haemorrhage (SAH) or known aneurysms and found only 24 (0.65%) asymptomatic unruptured aneurysms.[45] Interestingly, no case of multiple aneurysms was noted. Complex management issues arise when a patient with multiple cerebral aneurysms is encountered, especially with SAH following a rupture of one of the aneurysms.[21] The overall incidence of this entity has been reported to vary from 7 to 30% among patients with intracranial aneurysms (Table 1), although there is a study reporting an incidence as high as 45% based on angiographic findings.

A review of 23 studies revealed a prevalence of 16.6% with 3,189 multiple aneurysms among 19,268 patients. There is not a significant difference noted among various types of studies. A single meta-analysis of asymptomatic, (unruptured) intracranial aneurysms using a MEDLINE search from 1966 to 1992 revealed an incidence of 39.8%.[20] Two autopsy studies showed between 9% and 19% of deaths resulted from ruptured intracranial aneurysms.[10,13] The reported incidence among

thirteen retrospective studies with angiograms ranged from 9 to 44.9%.

It may not be feasible to determine the exact incidence of multiple intracranial aneurysms in the population; however, a literature review of various studies over the years done around the globe appears to indicate that the overall incidence is about 17%.

The difference between reported incidences in literature depends on the nature of the study, patient selection and time of study.

The incidence of multiple aneurysms is higher in women than men (20.2% vs 12.4%).[4] The cause of this higher incidence of multiple aneurysms in women is unknown. The menopausal state and high prevalence of collagen diseases may play a role in the formation of multiple aneurysms.

The correlation between increased age and multiple aneurysms is controversial.

RISK FACTORS FOR MULTIPLE INTRACRANIAL ANEURYSMS

Hypertension

Historically, the presence of chronic hypertension was a major risk factor for SAH. Some recent studies have shown a correlation of hypertension as a risk factor for multiple aneurysms.[1,18,33] The findings were significant among people less than 55 years old with post-operative hypertension and carrying more than two intracranial aneurysms. Ellamushi and co-workers found among their 400 patients with SAH to have odds ratio of 1.9 for hypertension and multiple aneurysms.[8] Some other studies have failed to find a correlation between hypertension and multiple aneurysms, and the authors hypothesised that the higher prevalence of antihypertensive therapy in their study group compared to the others may have an effect.[38] The presence of hypertension delays synthesis of collagen and elastin and causes degeneration of the internal elastic lamina to develop in the arterial wall. Subsequently, weakened walls begin to bulge under added haemodynamic stress caused by hypertension.[15]

Gender

A higher incidence of intracranial aneurysm formation has been observed in the female population, especially among post-menopausal women. Although there is controversy about the presumed mechanism for the role of female hormones in the aetiology of aneurysms, observations from a number of studies have shown that there are changes in patient characteristics once menopause takes place. Decrease in oestrogen levels has a negative effect on collagen production. In turn, this decline in collagen will cause the cerebral blood vessels to get weaker and predispose them to develop aneurysms. In one study, the difference between males and females was 17.6% versus 32.4% in multiple intracranial aneurysms.[22] Others have also observed that being a female increase the risk of developing multiple intracranial aneurysms.[8,18,38]

Arteriovenous Malformation

The association of intracranial aneurysms and arterio venous malformation (AVM) has been described for several decades. Thompson et al.[42] found 7.5% of patients with AVM had associated intracranial aneurysms. The majority of these patients had multiple aneurysms (51%), most of the aneurysms being located on the feeding vessel of the AVM (85%). The risk of haemorrhage is higher in patients with AVM and associated aneurysms than for patients with AVM alone. One hypothesis to explain association of aneurysms with AVM is that haemodynamic stress on the feeding vessel leads to aneurysm formation. It has been shown that increased blood flow leads to degeneration of arterial walls. Because of the high-risk of intracranial haemorrhage in these patients, aggressive treatment is necessary.[42] The treatment of these patients with complex vascular anomalies is challenging and needs to be individualised. Most authors agree that the aneurysms on the feeding arteries should be treated before initiating definitive treatment of AVM.[42]

Familial Aneurysms

An ongoing series of 30 patients with familial intracranial aneurysms from thirteen families in Canada has determined an incidence of 17% for multiple intracranial aneurysms in this group. Each family has been questioned and found to have 2 or more individuals with intracranial aneurysms.[23] Other authors have reported a higher incidence of around 50%.[27,31] With only a limited number of families available for study, it is difficult to conclude that there is a higher incidence of multiple intracranial aneurysms among these family members. Patients with familial aneurysms and multiple aneurysms tend to be younger, and there is a higher incidence of middle cerebral and internal carotid aneurysms.

Connective Tissue Disease and Congenital Disorders

Rare cases of hereditary connective tissue diseases, such as polycystic kidney disease, Ehlers-Danlos syndrome, pseudoxanthoma elasticum and Marfan syndrome, have been known to be associated with multiple intracranial aneurysms.[5] It has been proposed that an embryological endothelial defect in one or two embryonic segments of the neural crest or mesoderm leading to dysfunctional vessel wall remodelling in the presence of repeated or long-lasting triggers is responsible for this. Eighty-eight patients with polycystic kidney disease were screened for intracranial aneurysms. Three out of four (75%) patients with aneurysms had more than one intracranial aneurysm.[6] Although small in size, this number is significant given the rarity of the disease. Multiple aneurysms are also reported to be associated with moyamoya

disease, fibromuscular dysplasia, aortic coarctation and tuberous sclerosis.[26]

Sickle Cell Disease

The endothelium is interrupted following repeated injury from adhesion of the sickled erythrocytes to the endothelial cells. This cascade may disrupt the supply of oxygen and other nutrients throughout the entire vascular system and, in turn, the formation of an aneurysm may be initiated at multiple locations. The overall incidence of intracranial aneurysm among sickle cell disease patients is low compared to the overall population as there are only a small number of reported cases since a seven-year-old boy was diagnosed at autopsy to have the first documented case of SAH with sickle cell disease in 1930.[2,7] Oyesiku et al. reported 9 cases (60%) of multiple aneurysms in their fifteen patient series.[34] The same authors also combined their data with previously published cases and found 14 (47%) out of 30 published cases of sickle cell disease had multiple aneurysms. There were 44 cases of intracranial aneurysms among sickle cell disease patients reported more recently.[36] Fifty-seven per cent of them had more than one aneurysm, and aneurysms from patients with multiple aneurysms comprised nearly 80% of the total number of aneurysms.

Smoking

A presumed molecular mechanism for negative risk factors of cigarette smoking on aneurysm formation is based on a serum elastase/α1-antitrypsin imbalance or increased elastase activity.[3] Repetitive transient increases of systemic blood pressure have been observed for about three hours following cigarette smoking.[25] Thus, it is plausible that long-term smoking can weaken the cerebral blood vessels by promoting degradation of elastin in the blood vessel walls to initiate formation of aneurysm at anatomic sites of maximum turbulence under the load produced by hypertension. Juvela et al.[18] analysed 266 consecutive patients with SAH and found that regular smoking at any time is a significant risk factor for the presence of multiple intracranial aneurysms when adjusted for age, sex and hypertension in patients aged less than or equal to 60 years. Qureshi et al.[38] reported an estimated odds ratio of 1.7 for smoking at any time with the presence of multiple intracranial aneurysms among 419 patients. A retrospective study of 392 SAH patients between 1985 and 1997 at Queen's Square Hospital, London, showed a statistically significant correlation of multiplicity of aneurysms to smoking ($p < 0.001$).[8]

ANEURYSM DISTRIBUTION

The distribution of multiple aneurysms as reported by several studies is displayed in Table 2. The most common site for multiple aneurysms is different from patients with a single aneurysm. In patients with multiple aneurysms, the most common sites are the internal carotid artery (ICA) and the middle cerebral artery (MCA). However, in patients with a single aneurysm, the anterior communicating artery (ACoA) is the most common site. In a retrospective study by Roganovic, the incidence of ACoA aneurysms in patients with multiple and single aneurysms was 17.8% and 37.4%, respectively.

INSTITUTIONAL EXPERIENCE

Over 300 aneurysms have been treated at our institution, which has functioned as the regional tertiary referral centre for complex vascular and skull base lesions since the early 1990s. The incidence of multiple aneurysms was around 12% among the patients treated. The presence of multiple aneurysms was more common among female patients (male to female ratio of 1:4). The median age was around 51 years. Most patients had two aneurysms, and they were clipped at a single sitting, if they were on the same side. Otherwise, the second stage of the operation for the contralateral side was planned after a few weeks of the first operation. Posterior communicating artery was the most common site of aneurysms in these patients.

ILLUSTRATIVE CASE

A 60-year-old female with a history of heavy smoking and hypertension presented with the worst headache of her life to an outside hospital. She was neurologically intact except for mild confusion (Hunt and Hess Grade III). CT scan of the brain showed diffuse SAH with extension mostly into the left Sylvian fissure (Fisher Grade III) (Fig. 1). Four-vessel cerebral angiogram revealed multiple aneurysms on both sides: bilateral MCA, bilateral ophthalmic and left PCom (Fig. 2). Although the aneurysm on the right MCA was the biggest in size and suspicious for the rupture, her initial presentation of left-side periorbital headache and more concentrated SAH on the left-side confused the matter of localisation

Table 2: Distribution (%) of multiple aneurysms

Langawa et al.[14]	–	28	17	44	6

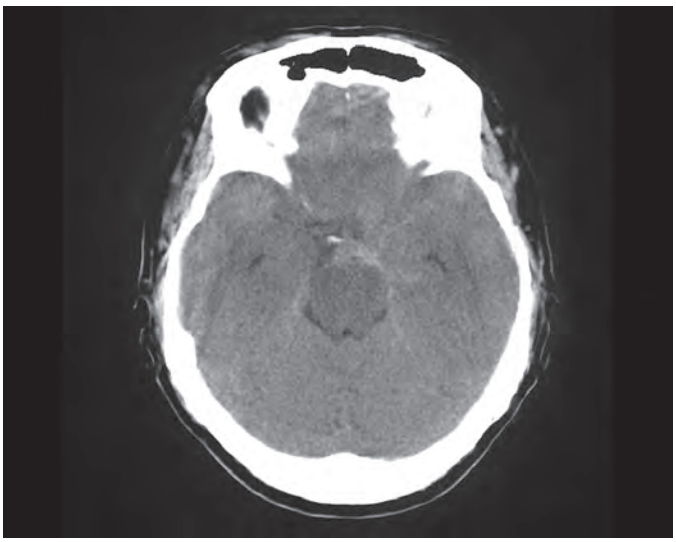

Fig. 1: There is diffuse SAH along the basal cisterns with extension into the left Sylvian fissure

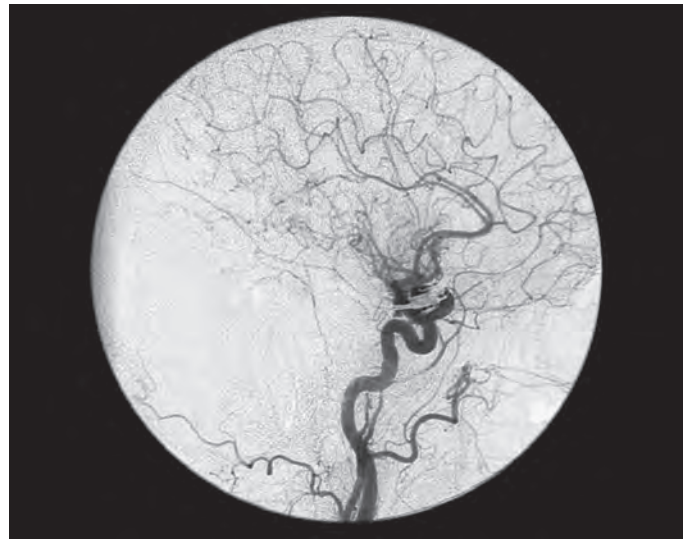

Fig. 3: Right side selective lateral view of the carotid shows presence of multiple aneurysm clips with complete obliteration of the aneurysms and preservation of the major vessels following the second stage of the operative plan

of the rupture site. A slight bulging area on the dome of the left PCom along with the above mentioned factors persuaded the senior author to clip the left sided aneurysms first. Intra-operatively, most of the blood was found around the left PCom, and a total of eight clips were applied to clip all three aneurysms without any complications (Fig. 3). She did well following the operation and the rest of the aneurysms were clipped 3 months after the initial operation (Fig. 4).

PREDICTION OF RUPTURE SITE

The most common site of rupture in patients with multiple aneurysms as compared to patients with a single aneurysm is ACoA.[28] In patients with SAH and multiple aneurysms, the ruptured aneurysm must correctly be identified, especially in cases where complete aneurysm clipping cannot be accomplished in a single operation. False localisation of the ruptured site may result in disastrous post-operative haemorrhage from the unprotected ruptured aneurysm.[12]

With clinical signs, computed tomography (CT) and angiographic findings, the site of ruptured aneurysm usually can be identified with a high degree of certainty (Hino et al. 91%; Nehls et al. 98%).[12,28] Other methods for predicting the rupture site are magnetic resonance imaging (MRI) and electroencephalography (EEG).[12,26]

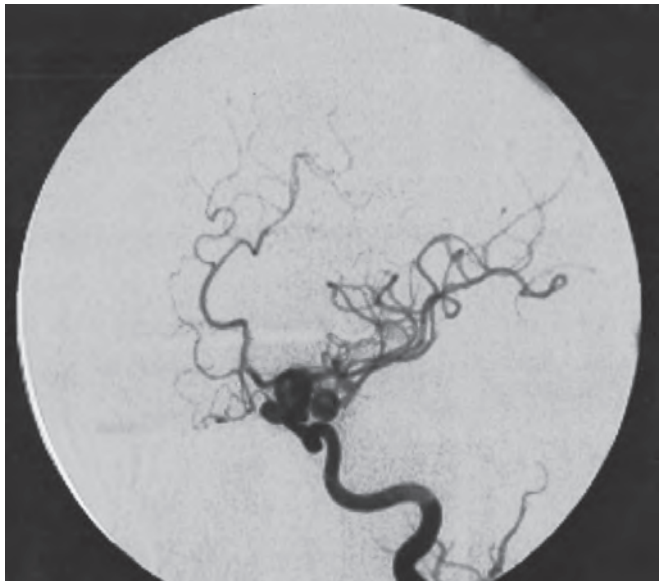

Fig. 2: AP and lateral views of carotid angiogram show the presence of bilateral MCA, bilateral ophthalmic and left PCom aneurysms. There is a slight bulging on the dome of the left PCom, which is highly suspicious for being the possible rupture site. There are no obvious signs of vasospasm on these views

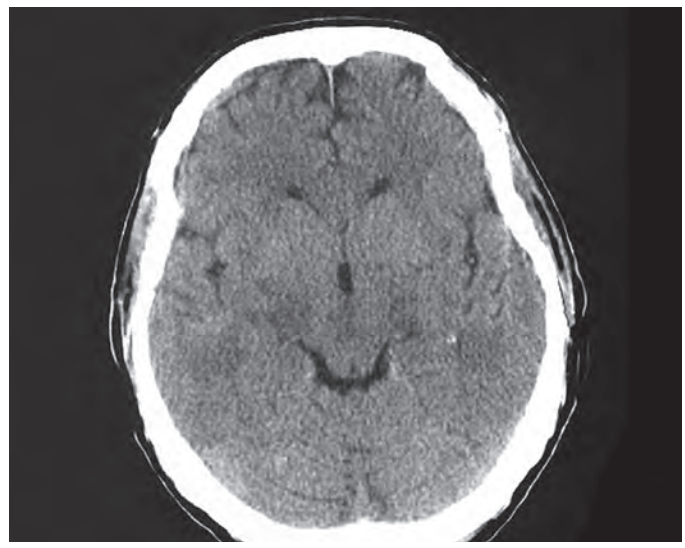

Fig. 4: CT of the brain without contrast shows no signs of infarction or hydrocephalus following the second operation

In some patients with cranial nerve palsy, the neurological examination will help in identifying the site of rupture. However, some other finding, such as hemiparesis, can be misleading. In the majority of patients with multiple aneurysms, clinical signs are not helpful for localisation of the ruptured aneurysm. In the study conducted by Zderkiewicz et al. it was helpful only in 7.6% of cases.[45]

CT plays a significant role in localising the ruptured site. The haemorrhage site in CT can provide very important information, such as focal blood collection in the specific cistern (suprasellar, perimesencephalic clot in posterior communicating artery aneurysms), interhemispheric fissure haematoma (in ACoA), intracerebral haematoma (in the temporal or frontal lobes in MCA aneurysms), and the area of intraventricular haemorrhage (isolated fourth ventricular haemorrhage in PICA aneurysm).[26]

The angiographic signs that can help in localising the ruptured aneurysm are as follows:

- Aneurysm bleb
- Irregular aneurysm contour
- Focal vasospasm
- Size of aneurysm
- Focal mass effect from blood clot
- Extravasation of contrast (rare cases)
- Changing aneurysm shape in serial angiograms.

In patients that have MRI, focal oedema or increased signal adjacent to one aneurysm may indicate a recent haemorrhage.[26] In some cases, EEG findings may help in identifying a ruptured aneurysm. To determine the site of ruptured aneurysm, one should use all the possible information from clinical presentation, CT, angiography and, in some patients, MRI and EEG.[12,26]

TREATMENT

The treatment criteria for incidental multiple intracranial aneurysms are similar to incidental aneurysms in general.[26] Studies have shown that the morbidity and mortality of patients with multiple aneurysms with SAH related to ruptured aneurysms, as well as the rebleeding, was from a ruptured aneurysm.[12] Most authors suggest treatment of multiple aneurysms using a one stage operation early post-SAH period.[43] This can be accomplished with a standard or modified approach. In some series, early surgery and one stage operations have been associated with less surgical morbidity and mortality. The favourable results with one stage operations compared to multi-stage operations may be related to easier access to aneurysms.

In SAH patients with multiple aneurysms, the symptomatic aneurysm should be treated first. The remaining aneurysms will be clipped from deep to more superficial aneurysms. In these cases, clipping the symptomatic aneurysm may obscure the view of deeper aneurysms or interfere with the clipping of the deeper aneurysms. There are three options for a successful completion: (1) clip the deeper aneurysm first with care not to disturb the ruptured aneurysm; (2) clip and aspirate the symptomatic aneurysm to allow clipping deeper aneurysms, and (3) treat the symptomatic aneurysm first and treat the deeper aneurysm through a different approach.[26]

The advantage of a one stage operation is to eliminate the need for a second surgery, to be sure that the ruptured aneurysm has been clipped, and to aggressively treat vasospasm with induced hypertension and hypervolaemia without the risk of aneurysmal rupture.[43] On the other hand, in the two stage operation, the exposure and clipping is technically easier when the subarachnoid blood has been cleared and the brain is less swollen.

Most authors suggest clipping all aneurysms in a one stage operation, if they are easily accessible and clipping the ruptured aneurysm has been completed smoothly. Otherwise, some or all asymptomatic aneurysms should be treated in second operations 6–12 weeks later. The other therapeutic option in patients with multiple aneurysms is an endovascular approach. In some cases, a combination of an endovascular approach and open surgery is a valuable option.

OUTCOME

The prognosis of SAH patients with multiple aneurysms is less favourable than in SAH patients with a single aneurysm, especially in elderly patients. In patients with multiple aneurysms, surgical complication is significantly more than that of single aneurysms.[32] Makio et al.[19] reported surgical complications of 12.1% in patients with multiple aneurysms versus 6.0% in patients with a single aneurysm. The factors that affect the outcome in patients with multiple intracranial aneurysms include: (1) misdiagnosing the site of the ruptured aneurysm; (2) failing to treat multiple aneurysms with multiple surgical approaches and (3) associated complications of surgical treatment of unruptured aneurysms.[11,29] As the number of aneurysms increases, the surgical results become more unsatisfactory.[8] In the study reported by Rinne et al.[8] there was no difference in outcome between patients having unilateral and bilateral aneurysms. Delayed neurological deficit has a major influence on the outcome of patients with multiple aneurysms. Furthermore, patients with vertebrobasilar aneurysms have a poorer outcome.[8]

CONCLUSION

Multiple aneurysms occur in about one-third of patients with aneurysms. They are more common in women and also in cases of familial aneurysms.[23,38] Other conditions associated with multiple aneurysms include connective tissue diseases and congenital disorders. The site of rupture can be determined with high accuracy using clinical signs, CT and angiographic signs.[12,26] If it is feasible, the symptomatic and asymptomatic aneurysms should be treated in a one stage operation (with a standard or modified approach). In some cases, the treatment of asymptomatic aneurysms could be done in a second surgery a few weeks later. Recently, one stage operations have become more frequent. In most series, it has been demonstrated that the prognosis and surgical outcome are worse in patients with multiple aneurysms.[19]

88 Infectious Intracranial Aneurysms

Sanjay Behari, Vivek Vaid, Awadhesh K Jaiswal, Vijendra Kumar Jain

HISTORY

Virchow, in 1847, and Osler, in 1885, discovered that bacterial endocarditis may lead to vascular disruption and aneurysmal development.[22] In 1869, Church first described an infectious aneurysm in a 13-year-old boy with mitral valve endocarditis. "Mycotic aneurysms" was the term coined by Osler for all infectious aneurysms.[21] Bohmfalk et al. recommended that those aneurysms resulting from bacterial infections be designated "bacterial intracranial aneurysms" and the term "mycotic aneurysms" be reserved for those resulting from fungal infections.[5] Ojemann recommended that all types of aneurysms resulting from infection be termed "infectious intracranial aneurysms".[21] Infectious aneurysms form about 0.5–6.2% of intracranial aneurysms, occur more frequently in the anterior circulation and may be multiple.[6,7,9,20,21,24] They clinically manifest in 2% of cases of bacterial endocarditis and 5–15% of cases are detected at autopsy.

AETIOPATHOGENESIS

In intracranial arteries, contrary to the systemic blood vessels, the internal elastic membrane provides strength to the vascular wall. The external elastic lamina is absent, the muscularis layer is thin and there is no external support in the subarachnoid space. Infection affects the internal elastic membrane leading to its damage. Hydrostatic pulsations against a weakened wall lead to aneurysmal dilatation.

Haematogenous spread occurs via large calibre blood vessels to the tiny nutrient vessels supplying the intracranial vessels, the vasa vasora. Due to the small size of these vessels, the septic emboli cannot travel any further and, therefore, block it establishing a local infection of the outer adventitial layer of the blood vessel of the brain. This leads to ischaemic necrosis and the local infection also spreads to the subarachnoid spaces via the Virchow-Robin spaces. The blood vessel progressively weakens due to establishment of infection in a centripetal fashion in the vessel wall. The hydrostatic pulsations of blood in the blood vessels cause progressive dilatation of the vessel wall. Occasionally, turbulence, atherosclerosis or trauma to the vessels may lead to stasis of flow or endothelial damage causing direct implantation of the septic emboli through the damaged endothelial surface. Direct blood vessel invasion occurs due to the presence of endogenous central nervous system infection. A paranasal sinus infection may produce a contiguous spread to the cavernous sinus or meningitis may involve the basal cisterns. The blood vessels within the basal cisterns are surrounded by the infective process leading to local invasion of the adventitia.[17] This, especially, is the pathogenetic mechanism in immunocompromised patients and patients undergoing immunosuppressive therapy following organ transplants. The transmitted blood pulsations on the luminal aspect of the weakened wall lead to its progressive dilatation.[2,9,15,19]

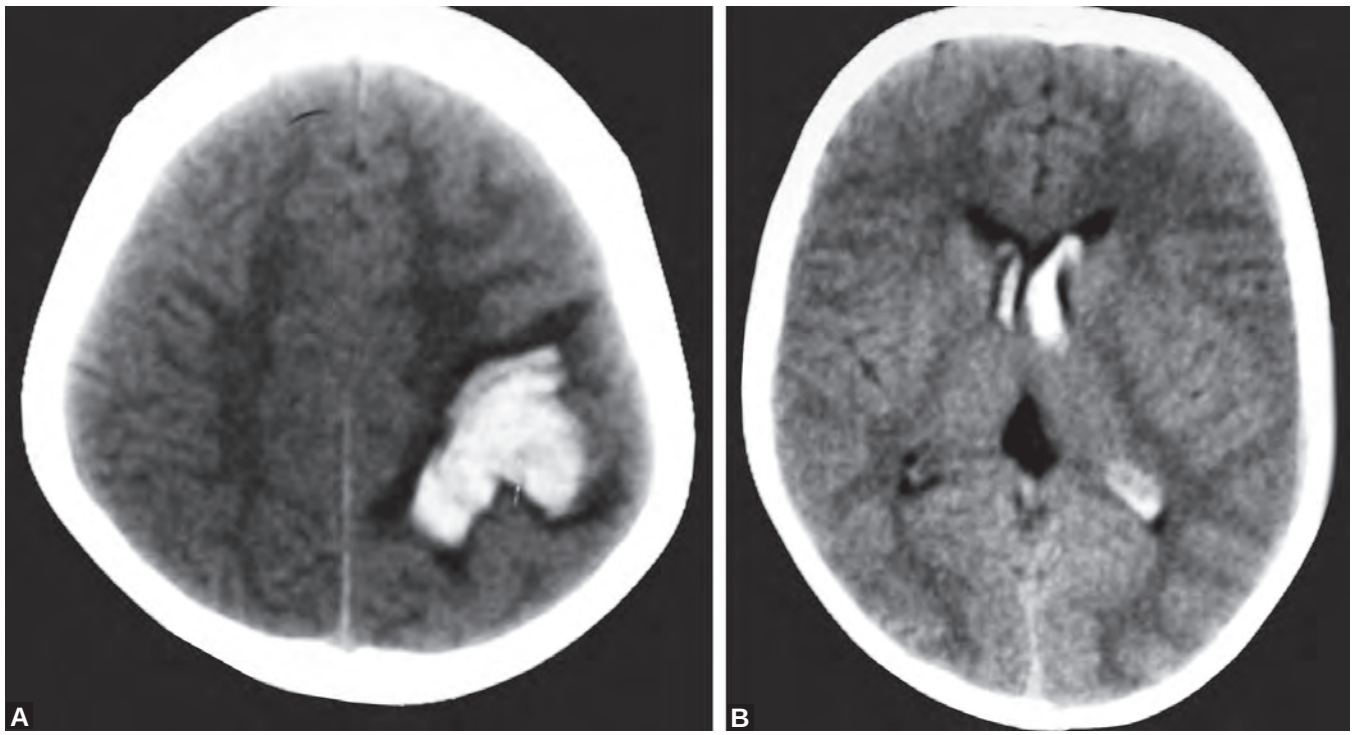
Patients with HIV infections, diabetes mellitus and immunocompromise are more likely to have fungal infections, while patients having a septic picture and multiple or distal aneurysms are more likely to be harbouring a bacterial aneurysm.[9]

CLINICAL FEATURES

The clinical profile of these patients varies. If unruptured septic intracranial aneurysms are present, then the patients may have a clinical symptomatology of sepsis without any signs pertaining to the central nervous system. In cases of spontaneous thrombosis or intracerebral haemorrhage, there may be focal signs based on territorial infarction. Subarachnoid haemorrhage may lead to sudden severe headache, neck stiffness or even obtunded sensorium. Early sentinel signs may often lead to an early identification of these lesions provided a high index of suspicion is maintained. Approximately 5% of patients with subacute bacterial endocarditis will develop an intracranial lesion, so any neurological changes warrant cerebrospinal fluid studies and CT/MR. These investigations may help in detecting a central nervous system infection, but are relatively insensitive for detecting infective aneurysms. Any abnormality in these studies in patients with neurological symptoms thus warrants angiography.

RADIOLOGICAL FEATURES

On digital subtraction angiography, the infective aneurysms may be single or multiple. The anterior circulation is involved more often than the posterior circulation. In the series by Chun et al., the commonest site was the distal middle cerebral artery (at or beyond



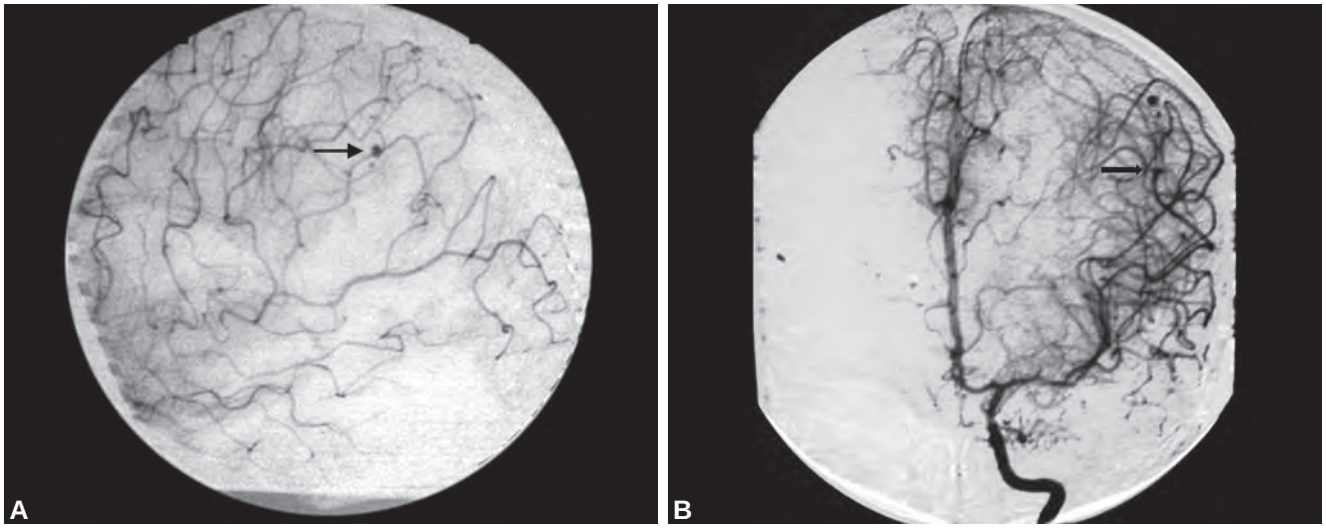
Figs 1A and B: Plain axial CT scan showing a left parietal haematoma with intraventricular haemorrhage in an 11-year-old child with rheumatic heart disease

the trifurcation), followed by the M1 segment and the distal anterior cerebral artery.[6]

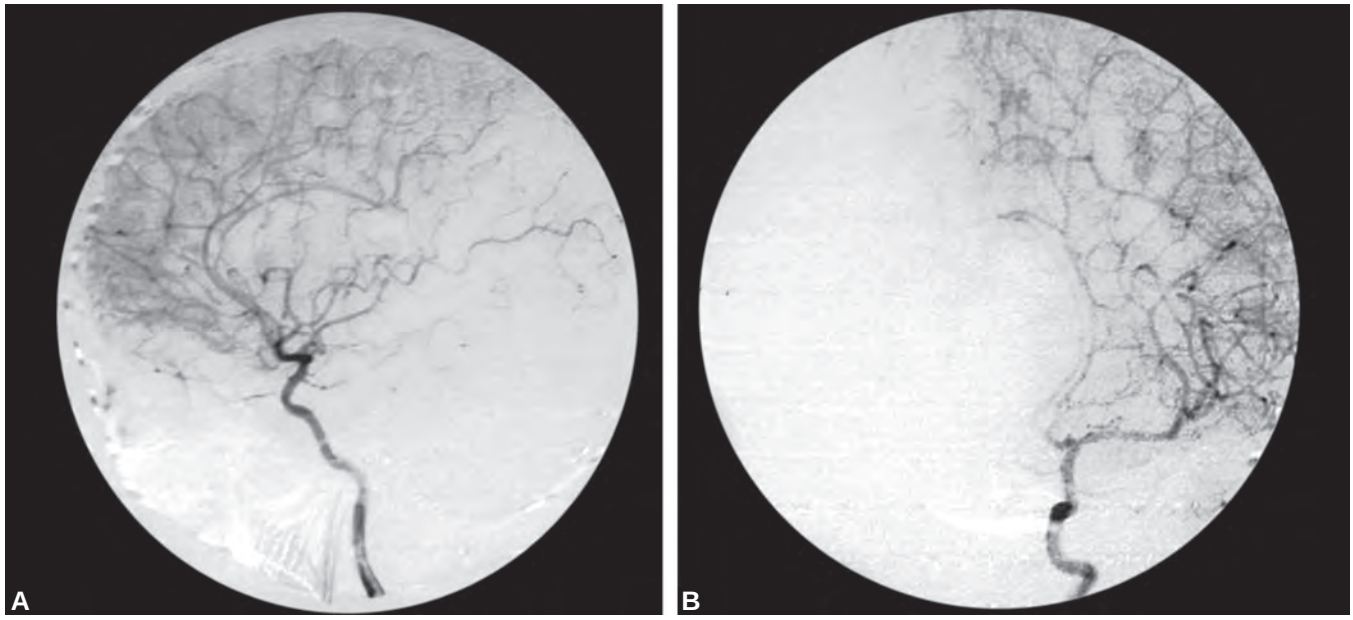
These aneurysms are typically fusiform and irregular, without the neck that characterises saccular aneurysms (Figs 1 to 4).[4,10] The diagnosis of an infectious aneurysm is fairly straightforward in the cases when endocarditis is associated with distal aneurysms. When evaluating proximal aneurysms, a combination of radiological findings may help in diagnosing an infectious aneurysm. These include arterial stenosis or occlusion close to the aneurysm, the presence of multiple aneurysms and rapid morphological changes within the aneurysm. CT angiography may be a less invasive and quicker technique to serially follow-up the infectious aneurysm.[1]

MANAGEMENT ALGORITHM

Suspecting the diagnosis helps in initiating early treatment but may be difficult in patients without endocarditis. Chun et al.,[6] Dowd and Awasthi[9] and Phuong et al.[23] have given the management algorithm for management of infective intracranial aneurysms (Flow chart 1). The clinical decision making is based upon whether the aneurysm has ruptured; whether there is a haematoma

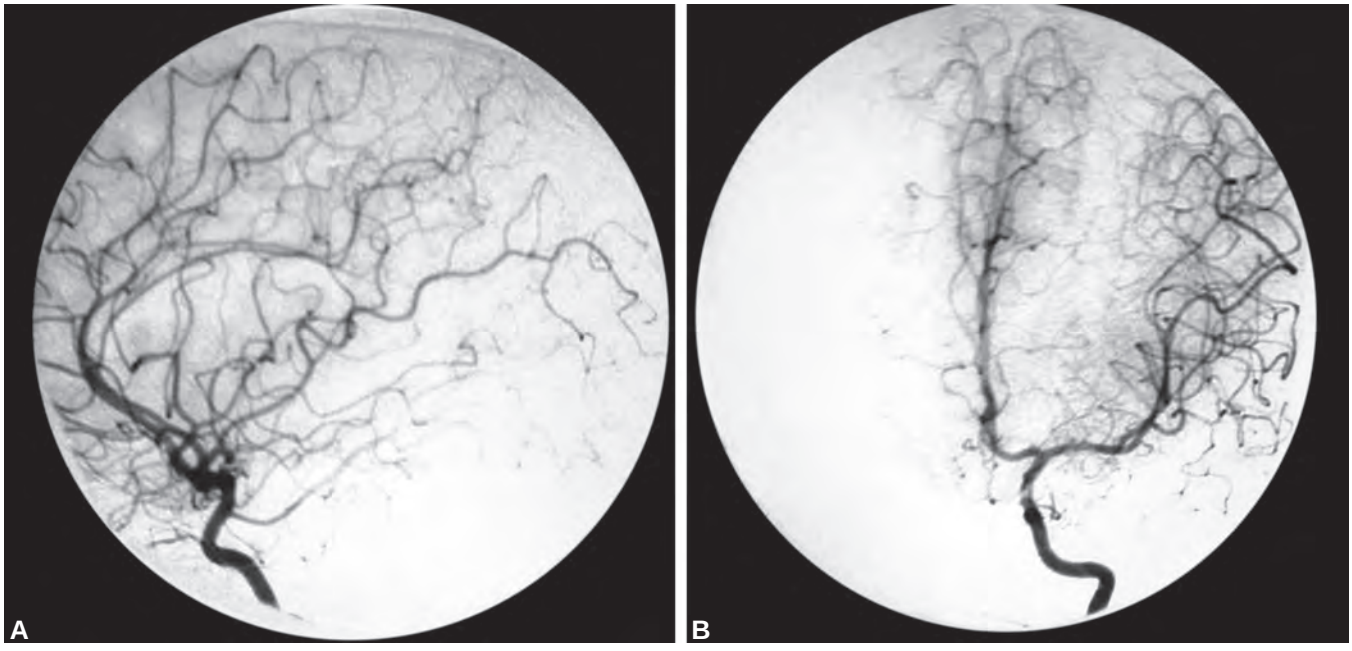


Figs 2A and B: (A) Lateral. (B) anteroposterior images of internal carotid artery angiogram showing an infected aneurysm arising from the posterior parietal branch of MCA. The aneurysm is small, sessile and situated on a peripheral vessel trunk without a branching vessel



Figs 3A and B: The angiogram after 6 weeks showing complete resolution of the aneurysm on antibiotic therapy

producing mass effect or increased intracranial pressure and whether the parent artery is supplying eloquent brain tissue. Serial angiograms are necessary in patients being treated medically after aneurysm detection, since the characteristics of infected aneurysms may change leading to six scenarios: (1) spontaneous resolution with preservation of the parent artery; (2) spontaneous resolution with thrombosis of the parent artery; (3) increase in size; (4) decrease in size; (5) unchanged size with the same morphological features (stable) or (6) unchanged size with different morphological features (unstable).[6] Thus, if there are neurological symptoms with bacterial endocarditis or sepsis (especially with the background of immunocompromise) then a contrast enhanced MR or CT scan with CSF studies is required. If it shows a positive intracranial finding, four-vessel angiography is performed to detect an intracranial aneurysm. If the angiography is negative, then medical treatment may be continued. If the angiography is positive for an infective aneurysm, but the patient has an unstable medical condition, such as severe sepsis or congestive cardiac failure rendering him unfit for surgery; or, there is no evidence of intracranial haemorrhage or neurological worsening, then he may be treated with antibiotics. In both the above scenarios, angiography should be repeated after 2–4 weeks. A patient harbouring an infectious aneurysm should be placed on appropriate antibiotics that achieve therapeutic levels in the central nervous system.



Figs 4A and B: The angiogram after 4.5 months showing that the infected aneurysm had not recurred

Flow chart 1: The algorithm for management of infectious intracerebral aneurysms
(Adopted from: Chun et al.,[6] Dowd and Awasthi[9] and Phuong et al.[23])

The correction of the cardiac disorder is also important in patients with infective endocarditis. The resolution of the aneurysm may occur on appropriate antibiotics often with preservation of the parent artery. Therefore, if an aneurysm is unruptured, or is in a difficult area to approach surgically or there are multiple aneurysms, then a trial of antibiotic therapy alone may be appropriate.[9]

Medically treated patients with enlarging or dynamic unruptured aneurysms; ruptured aneurysms in stable patients in surgically accessible areas especially in the presence of haemorrhage and mass effect causing neurological worsening are eligible candidates for surgical intervention or endovascular treatment.[4,6]

The choice of intervention between surgery and endovascular treatment may be decided by the algorithm suggested by Chun et al.[6] According to them, patients with ruptured aneurysms that are not associated with haematomas and that do not involve eloquent vascular territory are treated endovascularly. In patients who also require continuous heparinisation for their prosthetic cardiac valves, and those patients with compromised haemodynamic status, especially with acute endocarditis, endovascular intervention, is desirable. Patients are treated surgically when there is a haematoma or the risk of ischaemic complications in an eloquent territory. Therefore, endovascular therapy is the first choice for patients in stable condition with ruptured aneurysms; surgical therapy is the first option for patients in unstable condition with ruptured aneurysms and the second option for patients in stable condition who experience failure of endovascular therapy. Medically treated patients with enlarging or morphologically changing unruptured aneurysms also require direct surgical or endovascular intervention.

The aims of surgery are to eliminate the infectious aneurysms from the circulation, prevent ischaemic complications from arterial sacrifice and evacuate any associated haematoma. The surgical options available include trapping and resection of the aneurysm, trapping and bypass to the distal parent artery, direct clipping and wrapping of the aneurysm.[20,23,25] In contrast to primary aneurysms, surgery for these aneurysms is more difficult as these aneurysms are situated more often on peripheral blood vessel branches, the surrounding brain may be inflamed and oedematous (both due to the presence of infection and the haemorrhage) and the blood vessel wall is often friable. The aneurysm is often sessile and may be arising directly from the blood vessel wall without a neck. Attempted clipping of an acute, friable infected aneurysm can lead to clip erosion of the vascular wall as well as catastrophic peri-operative rupture. Occasionally, the only option left with the neurosurgeon for aneurysm exclusion from the parent vessel may be

trapping or excision of the parent blood vessel.[3] A bypass procedure may be mandatory in case the parent vessel is supplying an eloquent area of the brain. Endovascular management may also involve parent vessel occlusion after a test occlusion has negated the possibility of neurological deficits developing after the procedure. Harris et al. have described a special MRI technique to accurately localise the flow-related signal of a small infectious aneurysm masked by short T1 value/bright signal of the methaemoglobin in the intraparenchymal and extraparenchymal blood. This was done by mathematically subtracting a three-dimensional unenhanced MR angiogram from an identical < 30 seconds gadolinium bolus administered three-dimensional MR angiographic sequence. The subtraction angiographic MR image removed the high signal from the obscuring haemorrhagic components thus delineating the peripherally situated small mycotic aneurysm. With this technique, frameless stereotaxy was a useful adjunct in managing the infectious aneurysm.[12] Often, due to the small size of the infected aneurysm and the remoteness of the blood vessel that harbours it, frameless stereotactic navigation may not be helpful. In such cases, frame-based angiographic stereotactic localisation for distal aneurysms that cannot be treated endovascularly may be a useful technique.[8]

There has been a steady progress in the endovascular treatment and parent vessel occlusion is not always necessary. Improved microwires, microcatheters, stents and balloons have facilitated access to the distal circulation. Thus, balloon or stent assisted coil embolisation procedures may be used to maintain parent vessel integrity, although with some risk of rupture, given the fragility of the diseased parent vessels.[11,26]

The timing of intervention in infected aneurysms is vital. The patients harbouring these aneurysms may be systemically ill and anaesthesia may pose an increased risk; antibiotic treatment helps to reduce systemic infection as well as local inflammation in the arterial wall and facilitates clipping or coiling of the aneurysm.

BACTERIAL ANEURYSMS

In the series by Ojemann, the causative organism in bacterial aneurysms was *Streptococcus* in 51%, *Staphylococcus* in 21% and *Pseudomonas* in 3% of cases. Six per cent had multiple aneurysms and 14% had no growth.[21] Bacterial endocarditis, meningitis and cavernous thrombophlebitis have all been implicated in their causation.[4,17,23,25]

Therapy

The antibiotic therapy must be tailored to the culture and sensitivity profile of the patient's infection and the considerations of blood-brain barrier penetration of various antibiotic regimens. It should be administered for a minimum of 6 weeks.

Approximately 30–50% of infective aneurysms resolve with antibiotic therapy alone due to spontaneous thrombosis of the involved vessel. Ten to thirty per cent of patients may have a new aneurysm developing or the pre-existing aneurysm enlarging despite antibiotic therapy. Therefore, repeat angiography after 2–4 weeks is recommended to rule out new aneurysms. The risk of rupture and its consequent morbidity should be weighed against the chances of spontaneous resolution. Since the mortality from aneurysmal rupture varies between 60% and 90%,[11,23] in case an unruptured aneurysm is surgically accessible and the patient does not have septicaemia, a pre-emptive surgery or therapeutic embolisation should be considered. Patients who have clinical deterioration or in whom the angiogram shows progression of the aneurysm should also be treated surgically. Attention should also be focussed on the cardiac cause of the septic focus. A combined staged repair of the cardiac and neurological lesions with the timing based on which one is the more stable lesion often leads to a successful outcome.

FUNGAL INFECTIONS

Fungal infections are rarer and usually spread by contiguity from basal meningitis, following a surgical procedure or from paranasal infections. Therefore, they are found on more proximal intracranial vessels compared to the bacterial aneurysms. Diabetics, patients with widespread prolonged sepsis, intravenous drug abusers or immunocompromised patients are particularly susceptible to develop these lesions.[1] Embolisation from bacterial endocarditis may also occur. Finally, "a primary or cryptogenic mycotic aneurysm" occurring in the absence of an obvious inflammatory reaction may also occur. The common organisms were *Aspergillus*, *Phycomycetes* and *Candida*.[9,13,14,16,18] The antifungal therapy must be tailored to the organism identified and the considerations of blood-brain penetration. The prognosis is grave due to widespread disease or aneurysm rupture. In stable patients, surgery may be considered for taking care of accessible aneurysms, expanding lesions or those that fail to resolve with follow-up imaging and for those that demonstrate evidence of haemorrhage or mass effect.

VIRAL INFECTIONS

There is no conclusive evidence that viral infections cause aneurysm formation. However, the increasing frequency of aneurysm formation with age, the seasonal incidence of aneurysm rupture and increased incidence of aneurysm detection in children with HIV, especially during the periods of increased viral load, may point towards the implication of viral infections in aneurysm formation.[9,27] Furthermore, HIV may produce large vessel coagulopathy and intimal invasion with HIV containing mononuclear cells.

To conclude, an algorithm for the management of infective intracranial aneurysms is given. A high index

of suspicion in susceptible cases facilitates their earlier detection with early institution of antibiotic and surgical/endovascular therapy and thus prevents morbidity. Given the often changing nature of the aneurysm, repeat angiograms are mandatory during their management.

89 Intracavernous Aneurysms

BS Sharma, VS Mehta

INTRODUCTION

Intracavernous aneurysms constitute about 5% of all intracranial aneurysms. Middle aged females are affected five times more commonly than males. These aneurysms may be true or false. The true aneurysms may be purely within the cavernous sinus or transitional. In true intracavernous aneurysms, the neck and dome of the aneurysm are contained within the cavernous sinus.[1] Rupture of true intracavernous aneurysms may cause spontaneous carotico-cavernous fistula (CCF).[28] False aneurysms are secondary to head injury or following internal carotid artery (ICA) injury during trans-sphenoidal or cavernous sinus surgery.[4,10] In the transitional variety, the aneurysm extends into the subarachnoid space. Intracavernous aneurysms may be saccular or fistulous. Fistulous aneurysms may be spontaneous or traumatic. About 15–20% is bilateral and 15–20% have associated aneurysms. Intracavernous aneurysms enlarge insidiously and are frequently of giant size. Management of these aneurysms is difficult and pose a major challenge due to their intracavernous location, giant size, presence of atherosclerosis/thrombosis/calcification, broad neck and incorporation or origin of a major branch or perforator from the neck of the aneurysm.

CLINICAL FEATURES

Intracavernous aneurysms present with the clinical features as mentioned below.

Cranial Neuropathy

Cranial nerve deficit from II to VI alone or in combination occurs due to mass effect causing progressive visual loss, decreased visual acuity, field defects, diplopia, blepharoptosis and/or ophthalmoplegia. Proptosis, chemosis and bruit occur in spontaneous CCF. Parasellar syndromes[9] which consist of pain in V1 and V2 and paresis of one or two extraocular muscles are also due to mass effect. Rarely, they may present with bilateral VI cranial nerve paresis,[5] and as Tolosa-Hunt syndrome, with recurrent intolerable retro-orbital pain, ptosis and diplopia due to oculomotor nerve and abducent nerve involvement.[31] Bilateral intracavernous segment ICA aneurysm simulating pituitary apoplexy has been reported.[25]

Pain

Causes of the pain associated with intracavernous aneurysms are:

- Headache is caused by local irritation of the dura
- Retro-orbital pain which is caused by trigeminal nerve compression by aneurysm mass
- Facial pain is caused by episodes of distension or enlargement of the aneurysm and involvement of the trigeminal nerve. It may be severe, intractable and episodic.

Subarachnoid Haemorrhage

Subarachnoid haemorrhage (SAH) occurs in transitional cavernous aneurysm.

Epistaxis[13,22,24]

In false aneurysms secondary to trauma, massive, delayed and life-threatening epistaxis is a leading symptom. In the presence of blindness or blurring of vision, recurrent epistaxis and fracture of the skull base following trauma, early angiography should be performed.

Transient Ischaemic Attacks

These are caused by thromboembolism.

INVESTIGATIONS

In addition to conventional angiography, three-dimensional (3D) computed tomography angiography (CTA), slow injection angiography, aneurysmography and balloon test occlusion (BTO) are useful in determining the method of treatment. At angiography size of the aneurysm, width of the neck, origin of a branch or perforator from the neck, presence of thrombus and other aneurysms, presence of waist deformation and collateral circulation should be studied (Fig. 1). Waisting seen at angiography indicates extension of the aneurysm into the subarachnoid space,[29] either through the dural ring or eroded dural roof of the cavernous sinus. The waist indicates that rupture would be life-threatening. Deformation of the aneurysm may be due to compression against the optic nerve or anterior clinoid process (ACP) with an intact dura. Computerised tomography (CT) scan is useful in detecting bony erosion, SAH and

Fig. 1: Digital subtraction angiography showing intracavernous aneurysm

calcification. Magnetic resonance (MR) (Fig. 2) detects the presence of thrombus. Krings et al.[11] described a patient with an intracavernous aneurysm in whom the area of increased aneurysm pulsatility as demonstrated by high-temporal resolution dynamic CT angiogram using a 320-detector row CT, was identical to the area of aneurysm growth on follow-up. They hypothesise that this technique may predict aneurysm growth and may, therefore, be helpful in the non-invasive *in vivo* assessment of individual aneurysm features such as dome and bleb pulsations in both unruptured and ruptured aneurysms.

TREATMENT

Indications for Treatment

The indications for treatment are:

- Diminution of vision
- Severe intractable facial pain

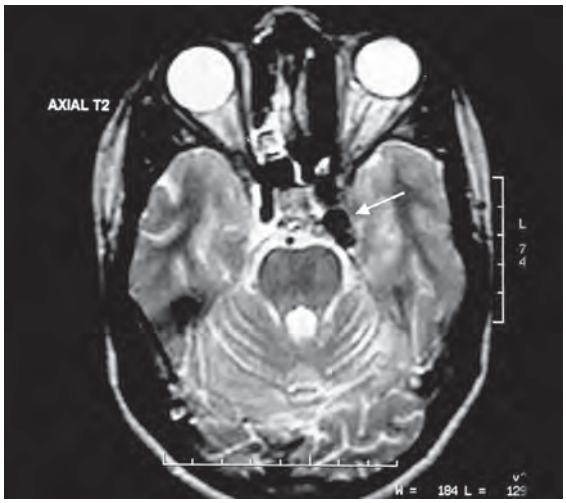

Fig. 2: Magnetic resonance imaging showing intracavernous aneurysm

- Progressive ophthalmoplegia
- Evidence of enlargement of aneurysm
- Transient ischaemic attacks
- Presence of waist in angiogram
- Risk or presence of SAH
- Risk or presence of epistaxis.

Asymptomatic or minimal symptoms of compression can be observed, especially in elderly patients.

METHODS OF TREATMENT

The aim of treatment is exclusion of the aneurysm from the circulation and preservation of efferent flow. This can be achieved by endovascular techniques or surgery. Bavinzski et al.[3] in their study divided 48 patients with cavernous carotid aneurysms into two subgroups by location. Morphological features in both groups correlated well with differences in clinical presentation and also influenced therapy.

1. Group I—In this group, aneurysms arose from the C3 portion, were small and saccular, with an epidural partly intracavernous location. This group was well-suited for endovascular obliteration.
2. Group II—In this group, aneurysms arose from the C4-5 segment, were usually large or giant and often fusiform with a true intracavernous location. These can be treated with direct or indirect surgery, or endovascular methods. Stiebel Kalish et al.[21] reported a large cohort of carotid cavernous aneurysms (CCA), comparing the neuro-ophthalmic presentation, complications and outcome with and without endovascular treatment. The results of 185 patients with 206 CCA were reviewed. Seventy-four CCA underwent treatment [endovascular, 67 (91%); surgical treatment, 6 (9%)], and 115 were followed for an average of 4 years, two of whom required treatment later. Statistical examination revealed that the treated group had a higher proportion of neurological and visual complications than people who were not treated. They concluded that endovascular treatment of CCA leads to a significantly higher rate of pain resolution compared with untreated patients, even after adjusting for initial pain severity. Diplopia may not resolve after treatment. The results of their study underscores our approach indicating treatment only in cases of debilitating pain, visual loss from compression, or diplopia in primary gaze or in patients with risk factors for major complications such as pre-existing coagulopathy or sphenoid sinus erosion. Vasconcellos et al.[27] analysed a group of patients with internal carotid aneurysms in the intracavernous segment. Patients were divided into two stratified groups, one with 19 patients who underwent interventional treatment, and another with 21 patients who were conservatively treated. Their study demonstrated that intervention is significantly correlated with a better prognosis considering evolution of pain symptoms secondary to neurovascular compression (p = 0,002).

Regarding neurological deficits, an interventionist approach was also significantly correlated with better outcome in comparison with initial presentation (p = 0,008). Their results indicate that interventional treatment determines improvement or resolution of pain symptoms in comparison with patients conservatively treated, as well as stabilisation or partial improvement of neuro-ophthalmological deficits.

Endovascular Technique[3,4,26]

Selective endovascular occlusion[28] with detachable balloon or Guglielmi detachable coils via the arterial route or electrothrombosis by detachment of platinum coils via the transvenous approach can achieve the objective. Proximal segment cavernous ICA aneurysms (C3 position) with a definable and narrow neck are better suited for endovascular treatment.[3]

Endovascular treatment of giant and large aneurysms by using a combination of stent placement and liquid polymer injection has been successful.[12] The metallic stent is first placed across the neck of the aneurysm to reconstruct a tubular arterial lumen, followed by obliteration of the fundus with ethyl vinyl alcohol polymer. This excludes the aneurysm from the circulation with preservation of the parent artery. Kadyrov et al.[10] treated an intracavernous ICA pseudoaneurysm following trans-sphenoidal surgery with stent assisted coil embolisation. Appelboom et al.[2] reported a unique case of wide-necked mycotic intracavernous large aneurysm treated with a new generation of intracranial flow-diverting, endoluminal implant placed across the aneurysm neck without coiling. Angiographic controls showed complete thrombosis of the aneurysmal sac with dramatic improvement of symptoms. Follow-up magnetic resonance imaging (MRI) and digital subtraction angiography 3 months after the procedure, confirmed total occlusion of the aneurysm with normal circulation in the parent vessel.

Surgical Treatment

Surgical treatment of aneurysms can be done in two ways:

A. Direct surgical methods
B. Indirect surgical methods

Direct Surgical Methods

These include clipping or resection followed by ICA wall reconstruction. Direct clipping is recommended in aneurysms with a definable neck arising from the anterior genu segment and in the transitional variety. The cavernous sinus can be approached intradurally or extradurally (ED). The ED approach[6] provides complete exposure and good proximal control of the ICA.

Pre-operatively, good cross-circulation through the anterior communicating artery and retrograde filling of the ICA through the posterior communicating artery is desirable, so that temporary occlusion of the ICA can be tolerated. However, this operation should not be contemplated in poor risk or elderly patients.

The cavernous sinus is approached directly using a combination of three different techniques:

1. Pterional exposure of the ICA
2. Subtemporal exposure of the ICA
3. Extradural petrosal exposure of the ICA

The sphenoid wing is removed to the ACP. The ACP, optic canal (superior and lateral aspect) and optic strut are drilled. The intrapetrous segment of the ICA is exposed in Glasscock's triangle bounded by the middle meningeal artery, the arcuate eminence and the greater superficial petrosal nerve. The middle meningeal artery is coagulated and ligated. The greater superficial petrosal nerve is interrupted and the bone over the ICA between these three landmarks is removed with a diamond burr, unroofing the anterior and superior aspect of the ICA. The bony canal of the Eustachian tube, located lateral to the ICA, is opened and its soft components are left intact. The entire circumference of the ICA inside the petrous bone is exposed for a possible temporary clipping.

The dural incision is made along the sphenoid wing and continued down to the clinoid process and extended to the optic nerve and to the foramen spinosum along the outer margin to the cavernous sinus. The temporal lobe is retracted and the tentorial edge is exposed from the clinoid process to the entrance of the IV nerve. The III and IV nerves are separated from the tentorial edge at the point where they enter the lateral dural wall of the cavernous sinus and followed to the superior orbital fissure. The outer layer of the lateral dural wall of the cavernous is dissected from the III, IV and V nerves and turned in one piece. The incision of the dura of the lateral wall of the cavernous sinus is started at the entrance point of the IV nerve, continued forward along the tentorial edge to the entrance point of the III nerve and is extended along the superior orbital fissure and inner aspect of the lateral margin of the lateral wall of the cavernous sinus to the foramen ovale. The V nerve is dissected from the Gasserian ganglion by lifting the posterior part of the dural layer consisting of the outer layer of the lateral wall of the cavernous sinus. The first division of the V nerve is followed to the supraorbital fissure, the second division to the foramen rotundum and the motor branch and third division to the foramen ovale. The ICA is dissected from the ophthalmic artery backwards along the sella turcica by packing the cavernous sinus with surgicel along the medial aspect of the ICA. Dissection of the horizontal part of the intracavernous ICA is carried out meticulously using Glasscock's techniques. This provides complete exposure of the ICA from the petrous bone to the supraclinoid portion. The neck of the aneurysm is defined and clipped. Multiple fenestrated clips are particularly useful or the aneurysm may be resected and the ICA reconstructed using sutures. The parent ICA lumen must be kept patent. The cavernous sinus is covered with the dural flap which

is sewn down along the previous incision. The bony canal of the Eustachian tube is packed with bone wax and the intrapetrous part of the ICA is covered with a muscle flap taken from the temporalis muscle. Romani et al. reported a case of intraoperative rupture of an intracavernous carotid aneurysm caused by clinoidectomy, which was repaired by using a single-clamp applicator, i.e. anastoclip vessel closure system, 1.4 mm.[15]

Indirect Surgical Methods

Proximal parent vessel occlusion or trapping is indicated in aneurysms with a poorly definable neck, origin from the proximal cavernous segment of the ICA, traumatic aetiology, fusiform aneurysms and when direct surgery is not feasible or carries a high-risk.

Before the ICA can be sacrificed, it is necessary to assess collateral flow by angiographic BTO of the ICA. This may be supplemented with electroencephalography (EEG), transcranial Doppler (TCD), cerebral blood flow (CBF) studies using direct intracarotid injection of Xenon, distal ICA pressure measurements and single photon emission computerised tomography (SPECT) studies. The BTO is performed under light sedation. The BTO is deemed successful when there is good clinical tolerance and there is adequate angiographic collateral circulation in the arterial, parenchymal and venous phases with symmetric filling of both hemispheres (Fig. 3). Additional criteria include no change in EEG, CBF of greater than 35 ml/100 gm/min, distal carotid pressure greater than 60 mmHg and symmetric perfusion in SPECT. If collateral flow is inadequate, suggested by development of neurological deficit, poor filling in angiography, changes in EEG, CBF less than 20 ml/100 gm/min and asymmetric perfusion on SPECT, an external carotid-internal carotid (EC-IC) bypass procedure is needed.

Carotid ligation is also contraindicated in patients with recent SAH, poor Hunt and Hess SAH grade, hypovolaemia, cerebral vasospasm and/or intracerebral haematoma. Relative contraindications include presence of atherosclerosis or aneurysms in the contralateral ICA.[1]

Fig. 3: Digital subtraction angiography showing good cross-circulation

Proximal Internal Carotid Artery Occlusion

Occlusion of the proximal internal carotid artery by balloon or ligation in the neck is the simple traditional method. Gradual ICA occlusion in the neck is performed with a Silverstone clamp. Adequate hydration is ensured. Aspirin is started to prevent thromboembolism. The angiogram is repeated after 3 months. If the aneurysm fills, trapping is performed. It is not a preferred method, but may be used in patients in advanced age, high medical risk and proven adequate collateral flow. After ICA occlusion, induced hypertension, anticoagulants and increase of circulating blood volume to minimise the risk of delayed thromboembolism is advocated. Common carotid artery (CCA) ligation preserves some ICA flow through the external carotid system and so the risk of ischaemia is less as compared to ICA ligation. ICA ligation provides a better reduction of aneurysm pressure and high rate of aneurysm thrombosis as compared to CCA ligation.

Trapping

ICA occlusion by balloon or ligation proximally in the neck, and distally proximal to the ophthalmic artery may be performed in patients presenting with haemorrhage or mass effect. This allows emptying of the aneurysm to reduce the mass, and minimises the risk of ischaemia caused by thromboembolism by reducing the dead space.

Immediate symptomatic relief is obtained by loss of aneurysm pulsations and pressure. Aneurysm thrombosis occurs in the first post-operative week, but retraction is maximal after several months and can be monitored by MR angiography.

External Carotid-Internal Carotid Bypass[16-30]

Indications

- In patients treated by ligation or trapping who have inadequate collateral circulation, i.e. failed BTO
- In patients with unclippable aneurysms, who have long-life expectancy or are young, hypertensive, and/or have bilateral or associated aneurysms. The EC-IC bypass preserves ipsilateral cerebral vascular reserve
- Failure of endovascular or clipping treatment
- Interposition high flow saphenous vein graft (SVG) from the proximal ICA or external carotid artery (ECA) in the neck to the middle carotid artery (MCA) bifurcation is the preferred procedure. Petrous ICA to supraclinoid ICA bypass requires temporary occlusion of the ICA during the anastomosis for 90–120 minutes and is not preferred.[18-20] Radial artery graft (RAG) from the carotid to the MCA may be used,[8] but two grafts to major MCA branches are required. Superficial temporal artery to middle cerebral artery

(STA-MCA) anastomosis itself may not be sufficient, but can supplement the already present collateral flow.

PRE-OPERATIVE EVALUATION

Cardiac functions, cerebrovascular disease, hypercoagulable states and coagulation parameters are evaluated. Angiography with cervical compression or balloon occlusion is performed to assess vascular anatomic features and collateral circulation to know the tolerance to temporary occlusion.

ANAESTHESIA

The brain should be lax. Prior to clamping the recipient vessel 2000 units of heparin, mannitol, phenytoin, methyl prednisolone, fentanyl and propofol are given. During occlusion the blood pressure is raised 20% above the baseline and mild hypothermia of 34°C is maintained.

SUPERFICIAL TEMPORAL ARTERY TO MIDDLE CEREBRAL ARTERY ANASTOMOSIS

Patients should be properly selected and careful attention should be given to peri-operative details to minimise complications.[7]

Technique

Donor (Superficial Temporal Artery Dissection)

The donor vessels should be of greater than 1 mm lumen diameter. Anterior or posterior branches of the STA are identified by palpation and Doppler ultrasonography and are externally marked. A linear incision is made directly over the distal artery. The initial cut passes through the skin and dermal fat. The edges of the wound are retracted and elevated with skin hooks and the dissection is continued proximally exposing the external surface of the STA in its entire length. A 1 cm pedicle of supporting tissue is prepared along with the artery. The pedicle is elevated from the temporalis fascia. The proximal and distal ends are left *in situ* to allow continued flow of blood. The artery is bathed in 3% papaverine saline until it is used for anastomosis.

Intracranial Exposure

Through the same skin incision used for STA dissection, the temporalis muscle and fascia are divided into anterior and posterior leaflets. A free bone flap of 5–6 cm size is raised. The proximal Sylvian fissure is exposed and split. An accessible 15 mm segment of the MCA which is free of branches is isolated over a latex dam.

A temporary clip is placed on the proximal STA pedicle and the distal end is sectioned. The entire pedicle is rotated to the recipient MCA site. An extra 1 cm length of STA is mobilised to compensate for brain displacement when cerebrospinal fluid is let out. The distal end of the STA is dissected off all the supporting tissue. A fresh cut is made across the distal end of the artery and its patency is checked by releasing the proximal STA clamp transiently. After irrigation with heparinised saline, the free end of the STA is fish mouthed to approximately twice the diameter of the vessel.

The dissected MCA segment is isolated between two temporary clips. A linear arteriotomy (two times STA diameter) is made and is irrigated with heparinised saline through a venflon. With 10-zero nylon on a BV-6 needle microsuture, the base of the fish mouth is sewn to the distal end of the MCA incision. The apex of the oblique cut end of the STA is sutured to the proximal end of the MCA arteriotomy. This directs flow towards the proximal portion of the MCA. About six to eight independent microsutures are taken through the arterial walls. Posterior wall suturing is difficult, so it is performed first. After placement of all sutures, each suture is tied with four knots. Before tying the last suture the STA clip is transiently released to allow residual debris to be dislodged through gaps in the anastomosis. The clips are removed individually to allow back bleeding of each end into the anastomosis site. Significant leaks are closed with isolated microsutures. A small amount of bleeding from the anastomosis can be controlled with surgicel or gelfoam. If the patency of the anastomosis is in doubt, a few sutures are removed and the clips are released for direct inspection of back bleeding and the fault is corrected. The STA-MCA bypass alone may be inadequate to prevent a stroke after acute ICA occlusion in patients with poor collateral circulation.

Internal Carotid Artery or External Carotid Artery-Middle Cerebral Artery Bypass Using a Graft

Saphenous Vein Graft Harvesting

The technical aspects of harvesting and preparation are crucial to long-term success. The saphenous vein may be harvested from the leg or thigh depending upon the calibre of graft required. It is harvested from the leg due to a better match for the vertebral artery (VA), posterior cerebral artery (PCA) and MCA. The lower limb is positioned externally rotated at the hip and flexed at the knee. The incision is made 1 cm anterior to the medial malleolus. In the groin, used for carotid circulation grafts, the skin is incised directly over the vein. The vein is found medial to the femoral pulse near the fossa ovalis two finger breadths lateral and inferior to the public tubercle, up to the adductor tubercle. The delicate layer of areolar tissue under the skin is incised sharply 5 mm from the wall of the vein. This leaves stumps of branches for ligation with 4-0 ligatures. Holes in the graft are repaired with 7-0 prolene mattress stitches. Prior to ligation of the branches and mobilisation, 5-0 prolene or marking pencil is used for Garrett orientation line to avoid twisting and kinking. The vein is dissected and mobilised, but left *in situ* covered with cottonoid soaked in 3% papaverine until extraction. The vein should not be grasped with forceps. After extraction, the lumen is flushed with heparinised solution and distended to

fracture of the wall. The flow rate in SVG is high and creates turbulence. Veins greater than 1 cm are more prone to thrombosis due to slow flow (Poisellile's law).[14]

Radial Artery Graft Harvesting

The arm is extended and supinated. An incision is made just lateral to the biceps tendon in the cubital fossa skirting the belly of the brachioradialis up to just lateral to the flexor carpi radialis tendon. Dissection is started at the wrist first, proceeding proximally between the muscle layers up to the bifurcation of the brachial artery. Venae comitantes are preserved except 2 cm at either end. The branches are ligated, clipped or cauterised. The artery is left *in situ* covered with moist packs of papaverine until extraction. Before extraction, a temporary clip is placed on the artery and a Doppler probe is placed on the palmar arch to confirm adequate flow. After extraction a blunt needle is introduced into the lumen of the artery and is distended with pressure using heparin solution until the artery visibly pops and distends. The artery is then plicated over a blunt needle and the procedure is repeated from the other end.

The superficial temporal, occipital and superior thyroid artery may also be extracted for interposition grafting. The VA can be used as a donor when it is of sufficient size and can be occluded for 30 minutes and the other VA is not hypoplastic or absent.[17]

The RAGs do not undergo denudation as SVG do because it has arterial endothelium. Arteries do not have valves, so remain open even at low flow rates. This low flow rate can be an advantage to avoid hyperaemia in ischaemic brain, but may not prevent stroke after acute occlusion. Flow through RAG is less (40–70 ml/minute) than through SVG (70–140 ml/minute) so a single RAG is not sufficient to prevent stroke in patients with no collaterals and in such cases two RAGs (one from ECA and other from ICA) to each major branch of MCA or SVG is required. Best diameter ratio of donor/recipient is 1.6:1 for patency. This is best matched between the posterior inferior cerebellar artery and STA. Due to a thicker wall, RAG is easier to perform. The RAG is easier to keep open compared to SVG because the arterial endothelium does not undergo denudation and can support the slower flow through them and less turbulence is created. Spasm is the most important problem responsible for failure, which can be prevented by calcium channel blocker prophylaxis and "pressure distension technique" and can be treated by angioplasty. The radial artery is a good thickness and diameter match for MCA/PCA. When the recipient artery is less than 2.5 mm, a RAG is best.

Anastomosis

Distal anastomosis is performed first because blood in the graft makes it more difficult, if proximal anastomosis is performed first. A frontotemporal craniotomy is performed and the Sylvian fissure is split. The main trunk of the MCA and its major branches are isolated. The arteries are coated with papaverine soaked cotton. A rubber dam is placed under the arteries. The MCA bifurcation is the ideal location for anastomosis because it orients blood flow along the axis of the MCA reducing turbulence. The proximal end of the vein or distal end of the RAG is obliquely divided. The main trunk of the MCA is occluded distal to the lenticulostriate perforators and its branches are also occluded. A 5 mm arteriotomy is done at the bifurcation. The lumen is flushed with heparinised saline. The vein graft or artery is anchored to the arteriotomy at both ends with 8-0 prolene/nylon sutures. During suturing only the adventitia should be held. About six to eight interrupted sutures are passed through approximating the vessel walls. Interrupted sutures take more time, but provide better approximation without leak or stenosis at the suture line. The loops are left long and tightened at the end of the procedure, allowing better inspection of the edges of the arteriotomy and venotomy. The graft is flipped over and sutures are applied through the other wall. Before the sutures are tied, the graft and arterial segment are flushed with heparinised saline.

Temporary clips on the MCA are released to allow back bleeding into the anastomosis and the suture line is inspected for leaks. Large leaks require additional sutures, whereas small leaks are controlled with gel foam. The graft is temporarily occluded close to the recipient artery and flow through the recipient artery is resumed after the distal anastomosis.

Since the pre-auricular tunnel takes a sharp turn, a post-auricular tunnel is preferred and the subcutaneous tunnel is made with Mayo's scissors. The graft is passed through the tunnel via a small diameter chest tube.[17]

Proximal anastomosis is performed with 7-0 prolene. The ECA or ICA is dissected in the carotid triangle in the neck. The ECA should be exposed at least 2 cm from the common carotid bifurcation and the ICA for at least 3 cm from the bifurcation or up to the XII cranial nerve which lies below the belly of the digastric muscle and superficial to the ECA. The ECA is used as the donor in patients with no or poor collaterals. The ICA is used as the donor, if there are at least some collaterals and the ICA can be safely occluded temporarily.

The carotid is isolated and arteriotomy performed. An oblique tear drop shaped 8 mm arteriotomy or venotomy in the free end of the graft is made by bevelling and fish mouthing. In case of size discrepancy, the graft is anastomosed to the carotid end to side to reduce turbulence. This anastomosis is performed under slight tension because the vein expands after resumption of arterial flow. The proximal clamp on the artery and the temporary clip on the graft are released. The carotid distal to the graft is occluded with a clip or ligated. If the vein graft is attached to the ECA, the ICA must be occluded or artificially narrowed by placing a tie and clamp to reduce the flow through the vessel to maintain patency of the graft. The ICA then can be occluded permanently with endovascular technique or ligated. Intraoperative assessment of flow through the graft is

done by TCD. Intraoperative angiography is performed after dural closure and the speed of flow is assessed, which must be faster through the graft than through the ECA.

If flow through the graft is poor, the graft is incised 2 cm proximal to the distal anastomosis and flow through the graft is assessed from both ends. If flow from the distal end is poor, the anastomasis must be revised.

Cervical to supraclinoid ICA bypass is performed when the MCA is not suitable for anastomosis. The ICA is occluded proximal to the ophthalmic artery and is sectioned. The cut vessel is sutured shut with 7-0 prolene. One clip is applied to the posterior communicating artery. The cut end of the ICA is fish mouthed. The vein is anastomosed end to end with 7-0 prolene. The needle should pass through both the intima and media to avoid dissection. A temporary clip is placed on the graft and the vein graft is brought out through a wide dural opening into the clinoidal space. A pexy of the graft may be required to prevent kinking.

The C5-C3 bypass for cavernous ICA is the shortest possible length and is a large calibre high flow venous graft entirely within the skull avoiding pressure on the venous graft during movement of the head. The distal anastomosis is in the ICA between the ophthalmic and posterior communicating arteries. Proximally the petrous portion of the ICA is exposed just posterior to the foramen ovale and medial to the foramen spinosum. This technique has the advantage that it is a high flow graft from one large artery to another. Trapping of the cavernous ICA is immediately adjacent to the proximal and distal ends eliminating vascular dead space, which may encourage thrombus formation leading to delayed complications. However, 90–120 minutes of temporary occlusion of the ICA is required for both proximal and distal anastomosis and is a major disadvantage.[18,19]

Closure

A cruciate dural incision is made for entry of the graft to prevent occlusion. Fibrin glue is used for a watertight seal. Careful epidural haemostasis is performed with bipolar diathermy, dural hitch sutures, gelfoam or surgicel, because considerable oozing can occur after heparinisation. The adventitia of the graft can be sutured to the dural edges. Graft flow is assessed along the tunnel after closure using a Doppler probe. The site of the tunnel is marked for further assessment.

POST-OPERATIVE MANAGEMENT

Normovolaemia is maintained. Heparin (5,000 units) is given subcutaneously for 7 days and then aspirin 325 mg orally for 1 month in RAG and for life in SVG. Graft patency is assessed by palpation with a finger behind the mastoid, TCD, MRI and MRA. Follow-up angiogram is performed within 1 week after surgery. 3D CTA and/or arteriography are advised at 3 months and then yearly (Fig. 4). Phase contrast MR is useful in evaluation of cerebral circulation in the area supplied by the bypass. In high flow grafts, mild hypotension is used to avoid breakthrough bleeding in the first 24 hours. Intraoperative angiography allows immediate recognition and correction (salvage procedures) of graft related problems.

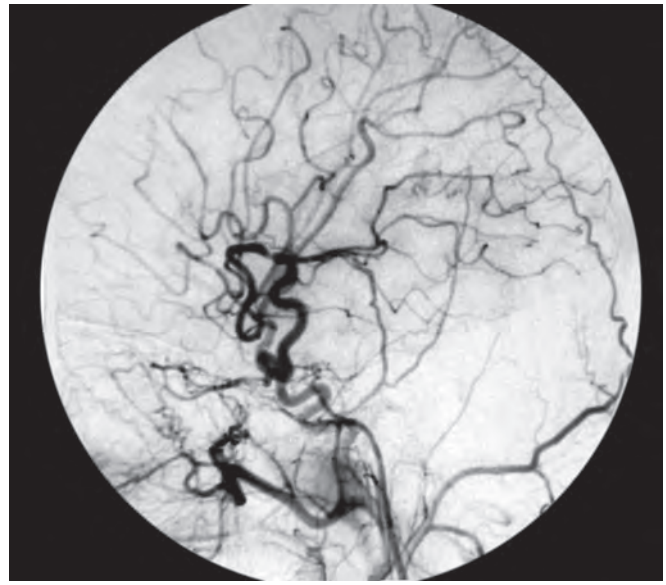

Fig. 4: Digital subtraction angiography showing functional superficial temporal artery to middle cerebral artery anastomosis

COMPLICATIONS

Epidural, subdural or intracerebral haematoma may occur due to the use of intraoperative heparin. Infarcts may be deep-perforator related from temporary occlusion or hemispheric due to hypoperfusion, embolism, graft occlusion, vasospasm or meningitis in patients with poor collateral, inadequate protection during surgery or protracted vascular occlusion. Poor outcome or ischaemic complications are highest in the posterior circulation.

GRAFT PROBLEMS[17,23]

Shortest possible length of the graft and end to end anastomosis at both ends are preferred to reduce the turbulent flow. Annual occlusion rate is 1–1.5%. The RAGs have better long-term patency rates.

Use of the operating microscope, improved perioperative treatment, brain protection agents, intra-operative angiography and improved micro-surgical techniques of harvesting, meticulous, atraumatic and perfect anastomosis have produced excellent patency results of 80–98% for bypass surgery.[17–19]

Graft Failure[23]

Early Graft Occlusion

It is most often due to thrombosis promoted by loss of native intima, slow graft flow and hypercoagulable states. Intimal desquamation or endothelial cell loss due to exposure to a high-flow high-pressure arterial

environment is accelerated by trauma during harvesting. Most problems that cause early graft occlusion are technical. Trauma during harvesting can be avoided by using delicate, non-crushing vascular clamps and forceps, grasping only the adventitia and by avoiding stretching the vein longitudinally. Meticulous atraumatic techniques of harvesting, preparation and anastomosis minimise internal damage and graft flow turbulence. The graft patency is also related to distal atherosclerotic disease, number of vessels available for run off, length of the graft, kinking and size discrepancy between the graft and recipient.

Subacute Graft Occlusion

A vein graft undergoes structural changes in response to arterial haemodynamics and the trauma of harvesting. Subintimal fibrosis (arterilisation) occurs by the end of the 1st month and so vein graft occlusions are common during this time. Steroids protect venous endothelisation. Subacute changes that threaten patency of the graft are:

- Internal hyperplasia and medial fibrosis are due to ischaemia of the media caused by interruption of the vasa vasorum. It is most prominent in the floor of the recipient artery and heel of the graft. Factors contributing to this include mismatch of mechanical properties of the donor and recipient and local turbulence. Aspirin decreases the incidence
- *Valve fibrosis*: Most valves lie flat posing no threat to patency, but fibrotic change makes them impinge on the vascular lumen generating turbulence. This is why some people advocate valvotomy
- Aneurysmal dilatation of the graft at the anastomotic site
- Clamp stenosis may occur. Delicate clamps have to be used to prevent this
- Suture stenosis.

Delayed or Late Graft Occlusion

This occurs due to atherosclerotic changes. It occurs usually 4 years after the surgery leading to late occlusion of the graft. Diabetics are at special risk. Control of serum cholesterol and low-density lipoprotein may improve graft survival. Aspirin prevents lipid accumulation in the graft. This is a progressive disease causing graft occlusion in 13% of cases in the first 5 years and an additional 26% occlude in the next 5 years. Patients with slow flow experience delayed graft occlusion.

Treatment of Graft Occlusion

- *General*: A hypercoagulable state is corrected by hydration. Slow flow is corrected by occlusion, narrowing or artificial stenosis to obtain adequate graft flow, e.g. ICA, proximal VA. Spasm is treated with 3% papaverine local application
- Proximal anastomosis end problems affect flow into the graft. It may be caused by suture line stenosis which requires revision. An anastomotic kink can be corrected by pexy
- Tunnel compression is caused by narrowing of the tunnel which requires surgical opening and dilatation
- Distal end problems occur due to a stitch applied through both walls and it requires revision.

The authors have treated 16 cases of intracavernous aneurysm in the last 3 years using various methods, i.e. ICA ligation without EC-IC bypass,[10] ICA ligation with external carotid-middle cerebral artery high flow SVG bypass[3] or RAG bypass,[1] STA-MCA bypass[1] and endovascular obliteration.[1] One patient with ECA-MCA bypass died of mismatched transfusion and acute renal failure. Two patients developed hemiparesis which improved later at follow-up. One patient each had bypass block and subdural haematoma with no neurological consequences.

SUMMARY

Intracavernous aneurysms constitute 5% of all aneurysms and predominantly affect females in their middle age. The common clinical presentation includes cranial nerve neuropathy (II to VI), pain and SAH. They are frequently giant and broad-necked. The best treatment is clipping using Dolenc's extradural approach whenever possible. Endovascular obliteration with preservation of efferent flow is useful in proximal aneurysms with a definable neck. Internal carotid ligation or trapping with or without extracranial-intracranial bypass is a viable alternative in unclippable aneurysms, failure of surgery or endovascular obliteration.

90 Contemporary Endovascular Treatment of Intracranial Aneurysms

Uday Limaye, Anand S

INTRODUCTION AND HISTORICAL BACKGROUND

Endovascular treatment of intracranial aneurysms is gaining more acceptance and is now more commonly available in India. Over the last decade, catheter technology and technical advances have taken it to a higher level of competence.

Neurosurgical clipping has been the gold standard in treatment for intracranial aneurysms since 1937, when Walter Dandy started clipping aneurysms.[20]

Fedor Serbinenko, a Russian neurosurgeon, first described endovascular treatment of intracranial aneurysms in the early 1970s. He used detachable latex balloons to treat aneurysms, either by depositing the balloon directly into the aneurysm lumen or by occluding the artery from which the aneurysm was arising.[29,30] Then came the use of free coils which did not offer any significant advantage. Detachable coils revolutionised endovascular treatment. In 1991, Guido Guglielmi was the first to describe the technique of embolising aneurysms using an endovascular approach with electrolytically detachable platinum coils, termed Guglielmi detachable coils (GDC).[12]

Endovascular treatment has been practised in India once the GDC coils became available in 1997. As the endovascular horizon widened, the management of wide neck aneurysms was tackled with the bioactive coils, stents and balloon-assisted techniques.

Recanalisation of aneurysms after coiling is still an issue, despite the low risk of rebleeding (<1% per year).[7,31] The disadvantage of coiling in our country is the high cost of the material. The equipment and expertise too are limited to a few centres in major cities.

The International Subarachnoid Haemorrhage Trial (ISAT) gave a much-needed boost to endovascular treatment of intracranial aneurysms all over the world and it has made a visible impact even in India. The results were so compelling, that recruitment was stopped after 2,143 cases. In this trial, aneurysm cases deemed suitable for treatment by both neurosurgical and endovascular techniques were enrolled. The results showed that the risk was 22.6% higher with neurosurgical technique than by endovascular means. The other advantages were the hospital stay, which was two times longer with surgery, and new deficits were four times more common with neurosurgical clipping.[21,22]

Intracranial aneurysms are common, with a prevalence of 0.5–6% in adults, according to angiography and autopsy studies. The majority of intracranial aneurysms are asymptomatic. They are diagnosed once they have ruptured and caused subarachnoid haemorrhage, a devastating type of stroke associated with 32–67% case fatality and 10–20% long-term dependence in survivors due to brain damage. For ruptured aneurysms, early treatment within 72 hours has been recommended because the risk of re-rupture is high, with approximately 20% risk of rebleed in the first 2 weeks after first subarachnoid haemorrhage and 60% by 6 months. The mortality from a rebleed is around 50%. With the availability of newer imaging, more unruptured aneurysms are being diagnosed. This is leading to the treatment of more and more unruptured aneurysms.[6,13,25,32,33,35]

INDICATIONS FOR ANEURYSM COILING[4,19,23,26]

- Posterior circulation aneurysms
- Multiple aneurysms
- Paraclinoid aneurysms
- Aneurysms with severe vasospasm
- Patients in extremes of age
- Giant/serpentine, fusiform, dissecting, mycotic and pseudoaneurysms
- Blood-blister like aneurysms (Ogawa aneurysms)
- Aneurysms with brain AVM
- ISAT supports offering coiling when there is high likelihood of success.

LIMITATIONS OF ENDOVASCULAR TREATMENT

- Tortuosity of neck vessels (Stability of arterial access is the primary step for endovascular treatment)
- Renal failure
- Non-availability of modern DSA facility
- High cost of material
- Aneurysms with large parenchymal clot may require surgical evacuation and clipping done in the same sitting.

STEPS OF ENDOVASCULAR COILING

- All procedures are done under general anaesthesia
- Transfemoral access is secured and adequate heparin is given

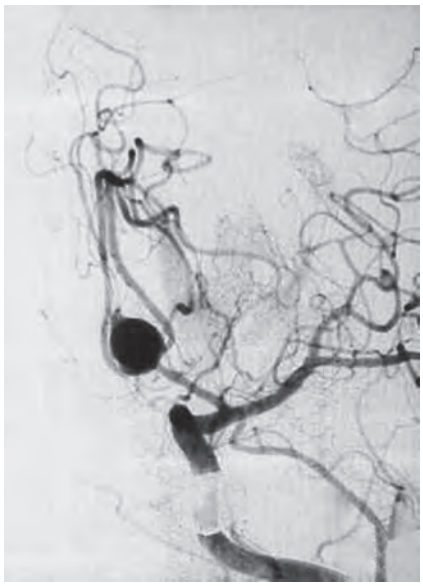

Fig. 1A: Lt ICA angiogram showing a large, wide neck anterior communicating artery aneurysm (ACoA)

- The guiding catheter is placed in the appropriate artery [Cervical internal carotid artery (ICA) or vertebral artery]
- Microcatheter over microwire is navigated into the aneurysm carefully under road map guidance
- Aneurysm coiling is carried out with detachable platinum coils of suitable sizes
- Depending on an individual case balloon or stent assisted coiling is done (Figs 1A and B).

POST-PROCEDURE MANAGEMENT

- All patients post coiling are admitted in the ICU
- Continuous monitoring of vital signs and neurological examination at regular intervals are done
- Triple H therapy and calcium channel blockers are used for treatment of vasospasm
- Patients with post-SAH hydrocephalus and intraventricular haemorrhage may require external-ventricular drainage
- Antiplatelets and low molecular weight heparin are used when indicated.

FOLLOW-UP

- Patients are clinically followed up at regular intervals
- Angiographic follow-up is done at 3–6 months, 18 months, 3 years and 5 years interval with DSA, CT angiography or MR angiography.

EQUIPMENT AND DISPOSABLE MATERIAL

- A fully equipped DSA catheter lab adds invaluable support in the endovascular technique. Biplane imaging, rotational angiograms, 3D-reconstruction techniques, flat panel and digital zooming and CT like cross-sectional images can now be obtained on high end DSA systems. Advanced imaging techniques help us understand and treat the disease better. Good quality fluoroscopy with magnification and road map facilities are basic necessities for endovascular treatment (Figs 2A and B).

  b. Guider (Boston Scientific)
- *Microcatheters*:
  a. Eschelon (EV3)
  b. Excelsior (Boston Scientific)
- *Microwires*:
  a. Transend 14 (Boston Scientific)
- *Detachable platinum coils:*
  a. 2D, 3D, 360, complex coils (Compass-Microvention, 360-Boston Scientific, Orbit-Cordis and Morpheus-EV3)
  b. Ultrasoft and hypersoft coils

Fig. 1B: Complete occlusion on post-coiling angiogram

Fig. 2A: Right internal carotid artery (ICA) angiogram (3DRA) showing MCA trifurcation aneurysm

Fig. 2B: Post-coiling

c. Bioactive coils (Matrix, Boston Scientific)
d. Coated coils (Hydrocoils-Microvention)

- *Balloon remodelling catheters*:
  a. Hyperform (EV3)
  b. Hyperglide (EV3)
- *Self expanding intracranial stents*:
  a. Neuroform (Boston Scientific)
  b. Enterprise (J & J Cordis)
- *Stentgrafts*:
  a. Graft master (Jomed)
- *Liquid embolic agent*:
  a. Oynx (EV3)
  b. NBCA glue (Histoacryl, B Braun).

DRUGS USED DURING THE PROCEDURE

- Heparin
- Protamine sulphate for reversal of heparin, if required
- Contrast media (Nonionic Ultravist, German Remedies).

DRUGS USED IN ADVERSE EVENTS

- Mannitol
- Anticonvulsants
- Abciximab
- Right-PA

TREATMENT OF VASOSPASM

- *Chemical angioplasty*: Intra-arterial nimodipine therapy (3–4 mg/arterial territory)[3,28]
- *Balloon angioplasty*: Focal spasms are treated with cerebral angioplasty balloons.[9]

SPECIAL CONSIDERATIONS IN ENDOVASCULAR ANEURYSM TREATMENT

Dissecting Aneurysms

Dissecting aneurysms are commonly seen in the vertebrobasilar circulation. All dissecting aneurysms are treated with endovascular technique. Embolising the aneurysm with coils with parent vessel sacrifice is important to prevent recurrence. If this is not feasible, stents will have to be used.[1]

Giant Aneurysms

The commonest location is the cavernous ICA followed by the vertebro-basilar circulation. Cavernous ICA aneurysms are treated with proximal parent vessel occlusion; which is done after a successful Balloon Test occlusion of the artery (Figs 3A to C). Basilar giant aneurysms may be treated by flow reversal techniques with occlusion of one or both vertebral arteries. This requires the presence of prominent posterior communicating arteries.[8]

Mycotic (Infective) Aneurysms

Mycotic (Infective) aneurysms are seen more commonly with infective endocarditis. They are treated with antibiotics. Ruptured mycotic aneurysms are treated with coils or glue with embolisation of the parent branch vessel.[23]

BALLOON REMODELLING CATHETERS

The balloon remodelling catheters are commonly used to protect the neck of the aneurysm while coiling large wide neck aneurysms. They are also used to seal the neck of the aneurysm during embolisation of aneurysm with Oynx. These balloons, on temporary inflation, occlude the neck keeping the coils inside the aneurysm. The balloon catheters available are: (a) hyperform and (b) hyperglide (EV3), which can be used depending on the type and location of the aneurysm (Figs 4A to C).

Large, wide neck and giant aneurysms can also be treated with stent assisted coiling. Generally, the stent will be deployed across the neck of the aneurysm. This is followed by cannulation of the aneurysm through the

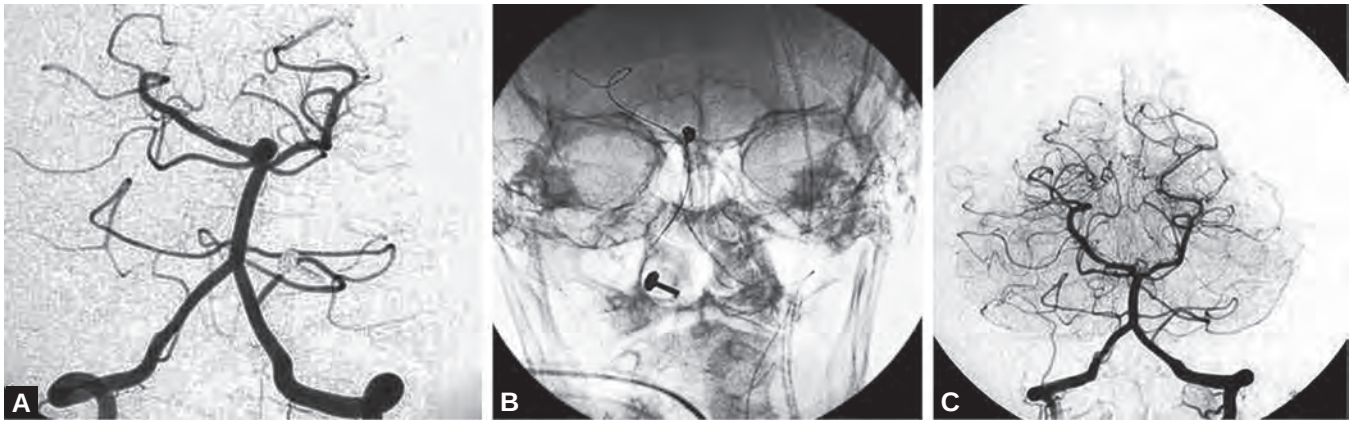
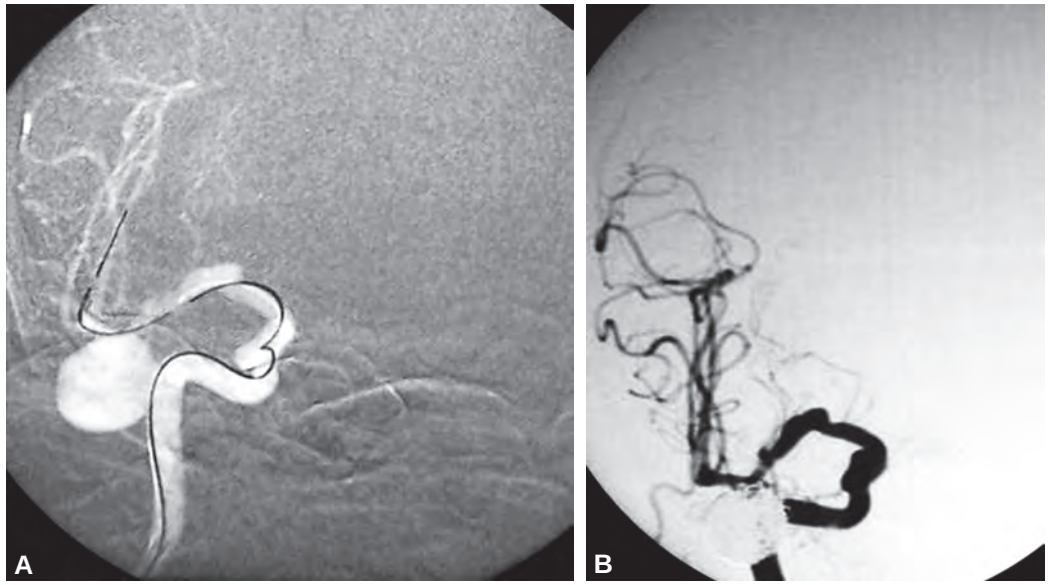


Figs 4A to C: (A) Basilar top aneurysm. (B) Balloon remodelling with hyperglide balloon. (C) Post-coiling angiogram shows complete occlusion of the aneurysm with the patent posterior cerebral arteries

stent strut for coiling. The self-expanding nitinol stents available for intracranial use are (a) Neuroform (Boston Scientific) and (b) Enterprise (J & J, Cordis). The newer stents are highly flexible and help in easy navigation into the intracranial circulation. These are preferentially used in unruptured aneurysms, taking into consideration the antiplatelet agents required to be given before, during and after the procedure (Figs 5A and B).



Figs 5A and B: (A) Giant MCA trifurcation aneurysm. Self-expanding stent has been deployed. (B) Post-stent assisted coiling, complete exclusion of the aneurysm and good patency of all MCA branches is seen

COATED/BIOACTIVE COILS

Matrix

Matrix detachable coils are platinum coils covered with a bioabsorbable polymer (90% polyglycolide, 10% polylactide) and attached to a stainless steel delivery wire. The coil consists of 70% polymer and 30% platinum.[36]

Hydrocoils

This device consists of a carrier platinum coil coupled to an expandable hydrogel material, which undergoes a ninefold increase in volume when placed into a physiological environment.

There is no concrete evidence in favour of these coils that they improve long-term occlusion or significantly prevent recanalisation.

NEWER ADVANCES

Stent Grafts

Coronary stent grafts have been used infrequently in endovascular treatment of giant or pseudoaneurysms.

They constitute a promising alternative for endovascular treatment. They have mainly been used in the carotid circulation. The stent graft seals the neck of the aneurysm. Long-term patency of the graft is an issue. A case where the arterial curvature is acceptable, side branches are absent or can be sacrificed, stent graft is an option for treatment. Their use is limited due to lack of flexibility and free availability.[15]

Oynx

Oynx (Micro Therapeutics, Inc, Irvine, CA) has been used to treat selected cases of aneurysms. It is an ethylene vinyl alcohol copolymer dissolved in the organic solvent dimethyl sulfoxide (DMSO). Oynx HD 500 has been used in selected cases of giant or large wide neck aneurysms that are not suitable for coil treatment or in whom previous treatment has failed to occlude the aneurysm.[2]

COMPLICATIONS

- Perforation
- Thromboembolism

Procedure-related morbidity and mortality rates as reported in most published series are between 1.5% and 4%. A few series report a very low mortality of 0.8% and permanent morbidity of 2.5% in ruptured aneurysms. In patients with unruptured aneurysms the morbidity is below 2% in most series. Lowest reported is 0% mortality and permanent morbidity of 1%. Complications although these cannot be avoided, are inversely proportional to the expertise and experience of the operating endovascular specialist.[2,10,11,18,21,22,34]

Perforation

During coiling the microwire/microcatheter/coil may inadvertently perforate the wall of the aneurysm. This leads to SAH, which may increase the mortality/morbidity if not rapidly controlled. Heparin is reversed and the aneurysm is rapidly packed with coils. Use of a remodelling balloon catheter for urgent tamponade is life saving. Aneurysmal rupture is depicted by the issue of the tip of the coil or the microcatheter outside the limit of the aneurysmal sac and/or extravasation of contrast media during angiography. Aneurysm rupture may also lead to large parenchymal haematomas which require surgical evacuation. Rupture of the aneurysm into the ventricle may require an external ventricular drainage to treat hydrocephalus.

Thromboembolism

It is a feared complication during the procedure leading to cerebral infarction. Clinically relevant thromboembolic complications are reported in 3.3–6% in different series. The occurrence of a thromboembolic event is dependant on several factors such as the technique used to treat the aneurysm or the medication administered before, during and after treatment. Treatment of thromboembolic complications is tailored to the specific situation of each patient. Medical treatment is modified during the procedure with an increase of the systemic heparinisation, IIb/IIIa antagonist or intra-arterial fibrinolysis with rt-PA (Figs 6A and B).

Device Related Issues

Malfunctioning of devices, rarely, may occur. Stretching of coil, non-detachment of coil, coil or stent migration, and microcatheter/balloon rupture may rarely complicate a procedure.

RECANALISATION/RECURRENCE

The long-term stability of aneurysmal occlusion obtained with coils remains the most significant limitation.

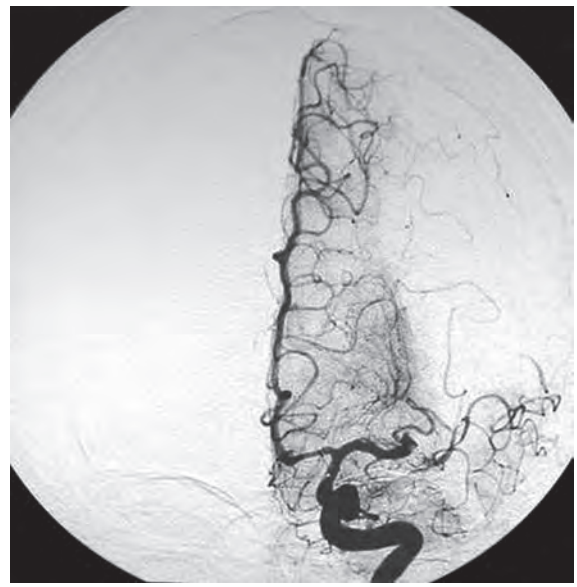


Fig. 6A: Thromboembolism during left MCA trifurcation coiling

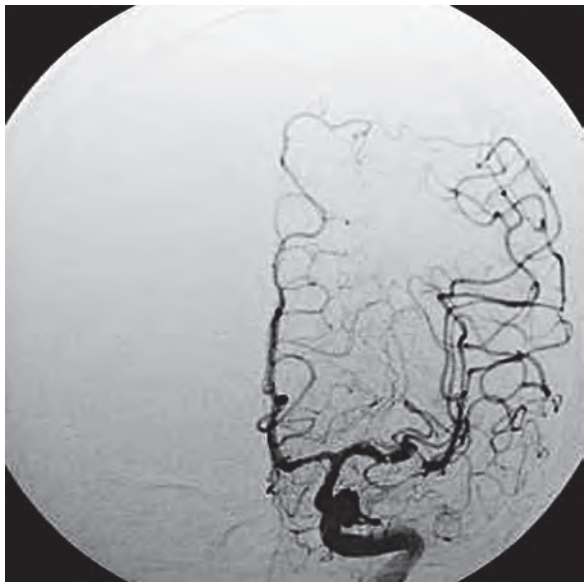

Fig. 6B: Complete recanalisation after the use of abciximab

According to the largest published series, the rate of recanalisation after selective endovascular treatment of intracranial aneurysms is between 13% and 34%. Recanalisation is commonly seen with large wide neck aneurysms or giant aneurysms. It depends on the initial packing or coil density at the time of first treatment. Recanalisation occurs due to coil compaction, incomplete packing or neck residue. Recurrence of aneurysm at the same site or at other sites is also reported. Repeated check angiograms are done to look for recanalisation or recurrence of aneurysms. The risk of rupture of these aneurysms is negligible (<1% per year). If there is significant recanalisation/recurrence of aneurysm then recoiling or a neurosurgical clipping is selected.[5,14,16,17,24,27,31]

CONCLUSION

Endovascular techniques used are constantly undergoing improvisations and modifications. With wider acceptance and newer advances in endovascular technique, most aneurysms are now amenable to endovascular treatment. Complete occlusion of aneurysms and use of a stent when indicated have improved long-term and stable angiographic cures.

Objective selection of the safest and most effective treatment option should be done for each patient. However, the issues of recanalisation and regrowth cannot be ignored. Further advances to minimise these are desirable.

91 Vascular Malformations of the Brain

Ravi Ramamurthi, Amit Kapoor

INTRODUCTION

Vascular malformations of the brain, hitherto commonly known as angiomas, are defined as congenital non-neoplastic lesions which arise from faulty embryologic resolution of primitive vascular networks. Krayenbuhl and Yasargil[143] found evidence in the literature that Egyptians had recognised the existence of cerebral vascular malformations as early as 1500 BC. However, Luschka (1854) and Virchow (1863) are credited for their pioneering efforts to describe the morphological features of these lesions. The first clinical diagnosis of cerebral arteriovenous malformation (AVM) was made by Steinhill in 1895. The earliest surgical exposure of cerebral AVMs was done by Giordano in 1890 and Krause in 1908. Following the introduction of cerebral angiography in 1927, by Egaz Moniz, the first angiographic diagnosis of cerebral AVM was reported by Bergstrand et al. in 1936.[8] Since the first successful total extirpation of a cerebral AVM by Olivecrona in 1932,[85] a number of monographs, based on large series of cases, have been published.[47,67,86,110,128] With better understanding of the natural history of cerebral AVMs, and with the application of the recent advances in diagnostic and therapeutic neuroradiology, neuroanaesthesia and microsurgical techniques, the management of cerebral AVMs has become much easier than in the past. However, it still remains one of the major surgical challenges.

CLASSIFICATION

The term "arteriovenous malformation" is commonly used to describe all types of vascular malformations of the brain. Though numerous classifications have been proposed by various authors, the widely accepted classification is that propounded by McCormick in 1966[65] and is based on the morphology of the component vessels, the existence of intervening neural elements and the biological behaviour of the lesion. This classification, subsequently modified by him in 1978, is as follows:[66]

- AVM
- Cavernous angiomas
- Venous angiomas
- Capillary telangiectasia
- Transitional forms

AVMs are the commonest of these lesions in surgical series, whereas, venous angioma is the most common type in large autopsy series.[114]

ARTERIOVENOUS MALFORMATIONS

Aetiopathogenesis

Although the definite aetiopathogenesis of these developmental vascular malformations is still unknown, a genetic factor has been considered. Familial or hereditary cases with various neurocutaneous syndromes are often associated with such lesions.[3,68,122]

Early development of the cerebral circulation has been divided into five chronological stages. AVMs of the brain are congenital lesions which develop during the late somite stage, between the 4th week and the 8th week of embryonic life. Cells (angioblasts) differentiate from the mesoderm during the 3rd week of embryonic life forming small syncytial islands. These syncytial cells develop tiny sprouts which interconnect them and form a syncytial plexus. Intercellular clefts now appear in this syncytial plexus and they later fuse to form the primitive vascular lumen. The syncytial cells enveloping these clefts become the endothelium of the vessels and these later proliferate linking the vascular lumina into an irregular endothelial vascular meshwork over the surface of the developing brain. The more superficial portion of this primordial vascular plexus forms the arteries and veins, and the deeper portion resolves into the capillary component.

The exact pathogenesis of AVMs is unknown. Capillary agenesis during the second stage was postulated as the predominant feature of congenital AVM by Olivecrona and Ladenheim.[86] However, Tonnis and Lange-Cosak,[128] thought that the developmental arrest took place during the fifth stage. Kaplan et al.[43] felt that, originally, many plexiform anastomoses exist between arteries and veins which later get reabsorbed and disappear. Arrest of development at this phase will lead to persistence of abnormal arteriovenous (AV) communications. The fact that AVMs are of congenital origin is substantiated by the absence of a history of trauma, stress and other potential causes of a vascular fistula, their development and increase in size by displacement of the maturing brain at its margin with preservation of neurological function, failure of attempts at production of an experimental model, as well as lack of evident growth of an AVM by any neoplastic process.

Incidence

In the absence of an epidemiological study, the true incidence of intracranial AVMs is difficult to provide.

Varying figures have been mentioned based on the type of material examined. Cerebral AVMs rank second to aneurysms among the intracranial vascular lesions that produce subarachnoid haemorrhage (SAH). They occur with one-tenth[22] to one-fourth[68,142] the frequency of intracranial aneurysms. The incidence of AVMs in the co-operative study[94] was one-seventh of that of intracranial aneurysms. The majority of patients present in the third decade. Earlier reports from India suggested a higher incidence of AVMs compared to saccular aneurysms.[41] However, further studies have refuted this observation. The Indian Council of Medical Research collaborative study established that the relative incidence of these two lesions in Indian patients with SAH was the same as reported from the rest of the world (Aneurysm:AVM is 5:1). With wider use of complete sequential angiography, computerised tomography (CT) and magnetic resonance (MR), AVMs may be detected more frequently. A male preponderance is reported by almost all authors. Average annual AVM detection rate of 1.34 per 100,000 person years has been reported with the incidence of first ever AVM haemorrhage of 0.51–0.55 per 100,000 person years. Estimated prevalence of AVM haemorrhage is about 0.68 per 100,000 person years. Mean age of presentation is 33 ± 18 years with no sex predisposition. Approximately half of the patients with AVM may suffer intracranial haemorrhage (ICH) during life time.[29,57] Familial occurrence is rare, but described in text.[73]

Location

Most of the medium and large AVMs extend over two or more anatomical vascular territories. Hemispheric AVMs situated in the watershed areas are usually supplied by more than one arterial pedicle. Mingrino[68] in a review of 1012 cases collected from six large series found the distribution to be supratentorial in 86% and infratentorial in 14%. The parietal lobe is the commonest region involved in supratentorial lesions. There is no significant hemispheric preference. In the series of Rout,[106] the lesions were superficial in 51.4% cases and deep in 48.6%. The majority of deep AVMs were located in the medial paratrigonal region[77] Bilateral hemispheric malformation was encountered in only one case. Vascular malformation in the internal auditory canal has been reported by Saleh et al.[112] Anterior cavernous malformation and those malformations involving the superior petrosal, transverse and sigmoid sinus region are readily recognised and diagnosed as compared to those involving basal sinuses, prominent cortical venous drainage and other drainage patterns.[1,101,102] AVMs were in eloquent location in 71% of cases and 55% cases had deep venous drainage.[65]

Pathology

Hemispheric AVMs are located in the middle cerebral, posterior cerebral and anterior cerebral territories in declining frequencies. These may derive arterial supply either from one or a combination of epicerebral (perforators arising from pial vessels), transcerebral (major parenchymal arteries and their branches) or subependymal vessels (choroidal arteries). The malformations supplied by the epicerebral vessels are confined to the cortex and are drained by cortical veins. The AVMs fed predominantly by the transcerebral vessels usually assume the shape of a wedge, based on the surface with its apex often reaching the ventricular wall. These drain into both the superficial and deep venous systems (Fig. 1). The centrally located AVMs mostly receive feeders from the anterior as well as the posterior circulation (Fig. 2). Malformations located in the watershed areas are always fed by more than one major artery. Depending upon the size, the malformation may involve one or several adjacent lobes, the entire cerebral hemisphere or, rarely, the whole brain.[3]

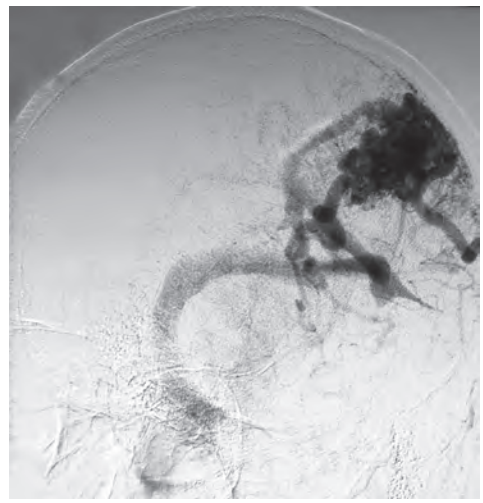

Fig. 1: Digital subtraction angiography study showing arteriovenous malformations draining into both superficial and deep venous systems

An AVM is a cluster of congenital AV communications without an intervening capillary bed (Fig. 3). Both the feeding arteries and the draining veins are tortuous and dilated. As the draining veins are arterialised, they are disproportionately enlarged and often look like arterial feeders at operation. The number of fistulous communications

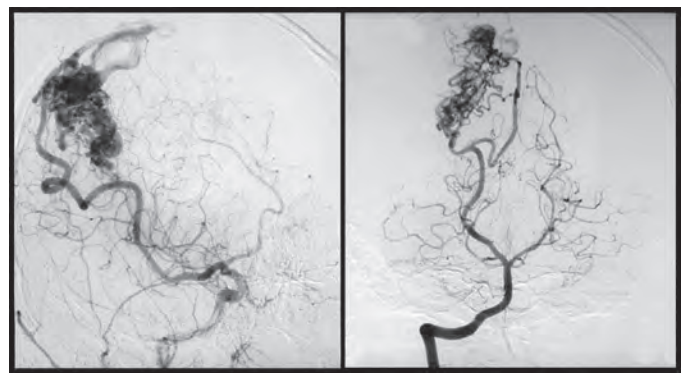

Fig. 2: Arteriovenous malformations receiving feeders from the anterior as well as the posterior circulation

Fig. 3: Arteriovenous communications without an intervening capillary bed

probably remains constant, but may enlarge in size with the passage of time due to high flow dynamics through the malformation.[21] The growth of the malformation proceeds apace with the growth of the brain. However, in exceptional circumstances, dramatic enlargement has been observed.[119] In the absence of an interposed capillary bed with diminished resistance of blood flow and deficient vasomotor control in the shunt, an increased amount of blood passes through the malformation unutilised. The malformation becomes a "parasite on the cerebral circulation", depriving the adjacent brain of normal perfusion. Increasing "shunt flow" may even embarrass the cardiac output in neonates.[124]

In the presence of large cortical draining veins, the arterial feeders are often submerged within the brain parenchyma. Large AVMs with associated varices do behave as space occupying lesions producing neurological deficits either due to mass effect or because of intracerebral steal (Fig. 4). The leptomeninges covering

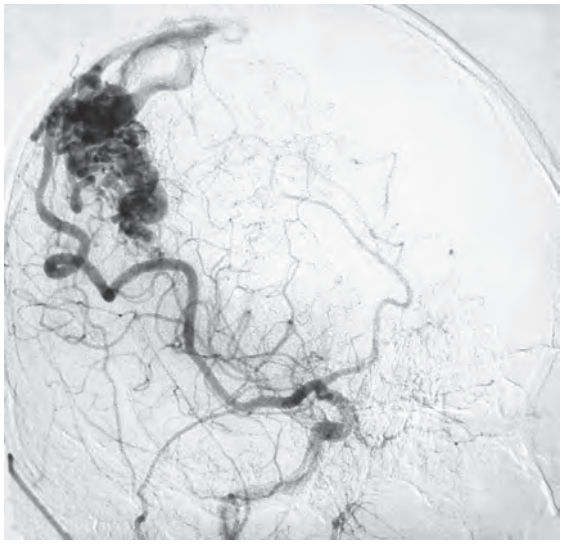

Fig. 4: Digital subtraction angiography study for arteriovenous malformations showing evidence of steal from the right anterior cerebral artery

the malformation are often thickened and opacified giving it a milky white appearance. Some AVMs, rarely, may be so compact that they even resemble a cavernous angioma in gross appearance. Most AVMs demonstrate a gliotic core associated with the nidus and a gliotic wall around the malformation forming a "pseudo capsule" which helps in surgical dissection for total extirpation. Hyaline degeneration causes collagenous replacement of the normal smooth muscle component of the media in the main arterial feeders adjacent to the malformation.[30] Smooth muscle and intimal nodules often project into the lumen of large arterialised draining veins and their walls may reveal amyloid like material. In between the component vessels, gliotic parenchyma and foci of haemosiderin laden macrophages are often encountered. Spontaneous thrombosis of component vessels with inflammatory changes leading to disappearance of the AVM is rarely seen. Calcification of the vessel in an AVM is not uncommon.

Expression of modulation of various molecules, receptors and mediators has been implicated in the pathogenesis of AVM. The IL-6 genotype is associated with increased expression of IL-6 in AVM with increased angiogenesis and increased incidence of intracerebral haemorrhage. RASA 1 defects and phosphorylated extra cellular signal regulated kinase promote abnormal vascular remodelling, thus promoting AVM pathogenesis. Similarly, VERF–VEGF receptor and integrin alphabeta I have been indicated in promoting growth of AVM. Smoothelin expression is reduced in large AVMs and has associated loss of contractile property associated with the homodynamic stress. Tie-2 expression has also been implicated in a similar manner. Smooth muscle cell specific protein marker SM2 is absent in normal vascular structures and is expressed strongly in AVM. The SAH induced vasospasm is mediated by endothelin 1 whose levels are elevated in endothelial cells from ruptured AVM.[8,11,12,47,49,50,62]

Moyamoya disease, sickle cell disease, Marfan's syndrome, Turcot syndrome, hereditary haemorrhagic telangiectasia (HHT), Beckwith-Wiedemann syndrome, high grade glioma, angioma, other vascular formations, persistent trigeminal artery and metaplasia have been associated with AVM.[4,11,28,68,79,81]

The HHT is autosomal dominant and associated with cerebral malformation ranging from AV fistula (AVF), small nidus type AVM or micro-AVM with nidus less than 1 cm in size.[7,64]

Immediate perinidal brain tissue may show dilated capillaries with severe congestion. These vessels are sometimes called "giant bed capillaries" and are associated with significant ischaemia in the surrounding brain matter.[30]

Developmental venous anomalies with an AV shunt are a risk factor for aggressive clinical behaviour rending the lesions to complications similar to AVM.[55] Cerebral AVM classified into AVFs and plexiform types, essentially exhibit similar morphology with the plexiform

type being a conglomeration of AVFs.[76] Reperfusion into unprotected capillaries of severely hypoxic cortical areas results in "break through" and vasoparalysis does not appear to be the underlying cause.[77]

Natural History

There are several long term studies reported in the literature, addressing the issues of the natural history of AVMs.[5,15,31,38,59,88,94,133,140] The onset of symptoms is maximal in the second and third decades, although these lesions are present since birth. This latency in the onset of symptoms is probably due to progressive maturation and growth of the lesion and gradual changes in the adjacent neural parenchyma. Haemodynamic factors eventually lead, either to a weakening of the vessel wall resulting in haemorrhage, or to irritation and gliosis of the surrounding neural tissue causing seizures. Growth of AVMs occurs in about 20% due to repeated haemorrhages, gradual dilatation of the vessels, expansion of feeders, and recruitment of new supply.[21,77] AVMs in the elderly may at times diminish in size,[58] especially small AVMs with a single feeder. Occasionally, an AVM may disappear spontaneously as demonstrated angiographically.[23,113]

In their extensive study of the natural history of AVMs Ondra et al.,[88] found that in an unruptured AVM, the incidence of first bleed is 4% per year. The annual re-bleed rate continues to be the same, i.e. 4% per year. This is at variance with the earlier studies of Graf[31] and the co-operative study[94] where it was mentioned that the incidence of re-bleed in the 1st year after the initial bleed goes up to 6% and drops to 2–3% from the 2nd year onwards. Kitamura[46] has stated that AVMs bleed probably more than what we expect. Ondra et al.[88] have also determined that the annual mortality rate due to an AVM is 1%, with the mortality at the initial or first bleed being 10%. Morbidity with each bleed occurs in 20–30% per episode of bleed, with long term morbidity being 2.7% per year. The mean interval between haemorrhages was 7.7 years in their study and mortality with recurrent bleeds also remained the same as that of the first bleed, i.e. 10%. A higher mortality rate of 13% for the second haemorrhagic event and 20% for the subsequent episodes has been reported.[21,31,100,140] Forster[28] had reported that in a patient presenting with seizures, there was a 25% chance of the first bleed within 15 years, whereas in patients presenting with a bleed, the possibility of a second bleed was 25% in the next 4 years, and that of a third bleed was 25% within 1 year of the second episode.

Ondra et al.[88] observed that contrary to the earlier belief, there is no change in the risk of suffering a haemorrhagic ictus in a patient manifesting for the first time with seizures or any symptom other than a bleed. The co-operative study[94] revealed that on long term follow-up, only 34% of patients harbouring an AVM remained symptom free. About 26% became minimally symptomatic, 26% were partially disabled, 11% were severely disabled and 3% were severely incapacitated. While there is a chance of a decline in the incidence of haemorrhage from an AVM after the age of 40 years,[58] there is only a 50% chance of leading a normal life after the age of 55 years. Untreated posterior fossa AVM carries a poorer prognosis.[57]

Celli et al.[12] observed that the risk of bleeding in children, as compared to adults, was approximately three times greater by 10 years and about 2.5 times greater by 25 years of age. In their series, the incidence of parenchymal or intraventricular haematoma was greater in children as compared to adults.[127] Wilkins[140] found that the risk of haemorrhage from an AVM in a child is threefold compared to adults and the incidence of re-bleed is seven times more. The size of the haematoma is larger in children, causing more focal neurological deficits and the risk of death is higher. However, in the series of Rout, the only factor that was significantly different between the paediatric and adult age groups was the initial mode of presentation, with bleed (90%) outnumbering other symptoms in children. There was no significant difference in the re-bleed rate, size of AVMs and the incidence of pre-operative or post-operative deficits.[79]

Only 18–20% of cerebral AVM are diagnosed during infancy and childhood. ICH is a presenting feature in 75–80% of cases and is associated with higher morbidity and mortality. The natural history of untreated cerebral AVM is worse in children with longer life expectancy than in adults, higher annual risk of AVM bleed [3.2% vs 2.2%] and a higher incidence of posterior fossa and basal ganglia AVM, most of which present with massive haemorrhage.[74] Spontaneous occlusion of AVM and *de novo* occurrence and growth of AVM, though rare, have been reported.[3,10,28,32,38,40,45,51,78] Haemorrhage either at original presentation or during follow-up of an untreated AVM appears to carry a lower morbidity than ICH from other causes.[5] Haemorrhage risk of grade IV and grade V AVM appear to be lower than grade I through grade III.[33] Deep seated large AVM are more prone to haemorrhage.[39]

Intracerebral haemorrhage in the paediatric age group differs from the adult and is mainly due to vein related causes.[48,52]

Clinical Features

An AVM may present with ICH, seizures, headaches, focal neurological deficits, dementia, raised intracranial pressure, congestive heart failure (especially in neonates) or unusual symptoms like trigeminal neuralgia or hemifacial spasm. In the series of Rout, 73% of patients harbouring an AVM presented with bleed, 37.6% had seizures and 57% had neurological deficits at admission.[106] The incidence of various clinical features has been reported variously as haemorrhage (43–51%), headache (14–24.9%), seizures 17.3% (generalised 75%, focal 25%), persistent neurological deficits (7%) and progressive neurological deficits in 45% of cases.[18,65]

Symptoms occur due to cortical venous hypertension, venous stasis and ischaemia.[35,41,42,53,59]

Haemorrhage

In most of the reported large series, ICH was the common-most mode of presentation of AVMs, with the majority having bled before the age of 40 years. It is the initial presenting symptom in 65–79% of cases. The peak incidence of haemorrhage is between 11 years and 35 years of age. There is no gender preference for the propensity to bleed. Although it is conventionally believed that AVMs tend to rupture more frequently during pregnancy, there is no convincing evidence to substantiate such a belief.[75] Haemorrhage may be intraparenchymal, intraventricular, subarachnoid or subdural. Spontaneous SAH due to AVMs has been reported in 2–10%.[91,94] Some authors have observed that haemorrhage from AVMs occurs more frequently during sleep, as compared to strenuous activities. Bleed from an AVM is unrelated to stress, activity, trauma or hypertension.

Patients with ruptured AVM tend to have more deficits at presentation and generally better post-operative prognosis than with unruptured AVM.[14] In comparison to ICH due to other causes AVM related ICH occurs more frequently in younger individuals, female, non-smoker, people with lower blood pressure, cholesterol and WBC counts.[31]

Predictors for a high-risk of AVM rupture are:

- *Age*: There is a higher propensity for AVM to rupture in children. Crawford[15] and Celli et al.[12] have shown that the risk of bleed from an AVM progressively declines after the age of 40 years. Increasing age increased the risk of ICH. Higher age shows higher fraction of AVM haemorrhage and these patients are more likely to harbour additional risk factors such as intranidal arterial aneurysms and small AVM diameter.[6,26]
- *Size*: Small AVMs have an increased likelihood of bleeding because of the higher pressures in the feeding artery. Small AVMs commonly present with a massive intraparenchymal bleed (Fig. 5). Micro AVM presents with large haemorrhages and significant neurological deficits.[69]
- *Location*: AVMs located in the posterior fossa have a higher risk of rupture and also have a poorer outcome. Periventricular AVMs also show a greater propensity to bleed. Infratentorial location is an independent risk factor of haemorrhagic presentation.[24,125] Choroid plexus AVMs present with intraventicular haemorrhage.[34] Border zone location is an independent determinant of lower risk of AVM haemorrhage.[63]
- *Past history of bleed*: In the study by Forester,[28] as well as in the co-operative study,[95] it is mentioned that an incidence of bleed is followed by a higher risk of second bleed in the 1st year. Forester[28] also mentions that re-bleed is inversely proportional to the neurological status at the first bleed, but both these observations have not been substantiated by any other large series. An initial haemorrhagic presentation is associated with increased incidence of re-bleeding with an annual re-bleeding rate of 2–4%.[20]
- *Intranidal aneurysm*: Demonstration of an associated intranidal aneurysm suggests a high possibility of bleed. Pedicle aneurysms on feeding vessels are frequently associated with haemorrhage. About 40–96% of aneurysms are situated on the feeding artery and 23% at an arterial bifurcation. About 9.9% of AVMs are associated with an aneurysm. Intranidal aneurysms have higher re-bleeding rates.[66,67,71]
- *Venous drainage*: Miyasaka et al.[70] observed that the venous drainage pattern is an important determinant of haemorrhage from an AVM. There is a high risk of bleed in the presence of only one draining vein (89%), deep drainage (94%) and demonstration of venous obstruction (94%). The deep drainage pattern may be associated with stenosis of the vein of Galen which increases their propensity to bleed; or else, the arterial pedicles of the deep seated central AVMs being smaller, result in high flow and pressure within the nidus, thus predisposing to their rupture. Deep venous drainage is an independent risk factor of haemorrhagic presentation.[24,39] The risk of rupture of an AVM is less in cases of peripheral or mixed venous drainage and in the presence of an angiomatous change, because this results in dilatation of cortical or leptomeningeal vessels recruited by large AVMs which have a low perfusion pressure within them.[63,105,107]

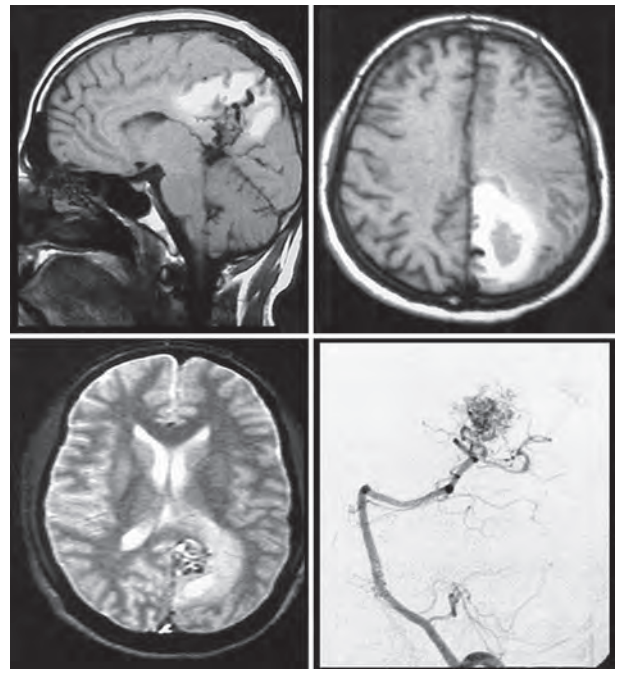

Fig. 5: Arteriovenous malformations presenting with bleed

Pathogenesis of haemorrhage: Venous obstruction resulting from either a mechanical cause like venous stenosis or a relative haemodynamic venous obstruction due to

increased venous outflow results in rupture of the thin-walled venous end, more so at the nidus-venous junction. Haemorrhage may also result from rupture of an associated intranidal aneurysm. The intranidal aneurysm occurs as a consequence of mechanical or haemodynamic venous outflow obstruction. Rarely, an aneurysm of the feeder artery, as a result of high flow through the vessel, may rupture and cause haemorrhage. Draining vein pressure and feeding artery pressure (Pfed) are significantly higher in AVM with haemorrhage.[75,108,116,118]

The Pfed is lower in distally located AVMs, large lesions and in AVMs with multiple draining veins.[9] The number of draining veins, the mean transit time (MTT) of the feeding artery and the ratio of MTT of the draining to the feeding vessels determine the incidence of ICH.[72]

Seizures

The second most common manifestation of AVMs is seizures, its incidence being 10–50% in different series. With the advent of non-invasive diagnostic modalities, more such cases are being reported. The average age of onset of seizures is 25 years. Seizures may be associated with a subclinical bleed in 6.5% of cases, as observed on MR scans as areas of haemosiderin deposits or during surgery as xanthochromic staining of the tissues. About 12% of patients presenting with features of intracerebral haematoma may have associated seizures. Seizures are more common with large, superficial, high flow malformations. In the elderly, epilepsy is less frequent with an increased incidence of infratentorial lesions.[21,93,145]

Pathogenesis of seizures: Although an AVM is a congenital lesion, the irritation and gliosis produced in the surrounding brain tissue with maturation of the lesion, may result in a seizure disorder. An epileptogenic focus may also be caused by associated cerebral ischaemia due to steal in a high flow AVM. Haemosiderin deposits and areas of intervening gliosis result from the pressure of dilated vessels and/or decreased tissue perfusion due to venous hypertension. Mass effect, due to venous ectasia or pouches and retrograde dural sinus hypertension resulting in hydrocephalus or raised intracranial pressure, may also cause seizures. Rarely, a secondary epileptogenic focus may occur in the temporal lobe.[144]

Focal Neurological Deficits

AVMs can present with focal deficits alone in 4–12% or in combination with haemorrhage or seizures in 25% of cases. Neurological deficits and mental changes are the result of arterial steal, venous hypertension causing hypoperfusion of the surrounding brain parenchyma, mass effect of the AVM or hydrocephalus. Most of the strokes in AVM are haemorrhagic.[17] Selective retrograde amnesia occurs in patients with AVMs in mediobasal and diencephalic regions.[27,43,46]

Other Features

Large AVMs produce changes in the scalp and the skull. The scalp veins may enlarge and also increase in number. In some a thrill may be palpable over the neck vessels, associated with a bruit. Bruit is more common when the malformation has connections with the external carotid system. Papilloedema and fundus changes, when seen, are mostly secondary to SAH or a haematoma. Retinal angiomas may be associated in a small percentage of cases. Intermittent exophthalmos may occur in anterior AV malformations associated with orbital varices. Posterior fossa angiomas may cause trigeminal neuralgia.[42] Mental changes are also common in posterior fossa malformation, when all the blood vessels take part in the supply to the malformation. Orbital congestion may present as chiasmal syndrome, headache or without visual symptoms.[70]

Cardiovascular Effects

In very large AVMs with enlargement of the feeding vessels, and increased blood flow, there is an associated change in the pulse pressure giving rise to a water hammer pulse. There is a proportionate increase in the cardiac output and cardiomegaly results, especially in children.[136] This may be the first sign of a cerebrovascular anomaly. In the late stages, high output cardiac failure may result. This complication is rare, except in infants with an AVM involving the vein of Galen. Cerebellar haemorrhage has been associated with neurogenic pulmonary oedema.[19]

Haematological Effects

Some AVMs have a tendency to trap platelets which adhere to the poorly formed endothelium of the malformation. This may result in thrombocytopaenia and a bleeding diathesis.

HAEMODYNAMICS OF ARTERIOVENOUS MALFORMATION

An AVM is typically an abnormality comprising direct AV shunts, characterised by the absence of the intervening capillary bed. The absence of these resistance vessels, therefore, causes a low perfusion shunt flow which adversely affects the brain parenchyma, either by altering the blood flow pattern in the neighbouring areas causing "intracerebral steal", or, by affecting the metabolism in the adjacent normal tissue which shows evidence of decreased glucose utilisation.[120] Feeding artery pressures in the AVM are an important determinant of the haemodynamic events related to the lesion. The pressure in the feeding arterial pedicle is determined by:

- *Size of the AVM*: The smaller the size of the AVM, the higher will be the feeding artery pressure
- *Length of the feeding artery*: The smaller the feeding arterial segment, the higher will be the pressure within that vessel
- *Number of nutrient arteries to the adjacent parenchyma*: The more the number of nutrient branches, the less will be the pressure head feeding the AVM

Shunt flow velocity within the AVM nidus is an important determinant of the clinical manifestations and can be measured non-invasively by using transcranial Doppler ultrasound.[55,82,83,87]

INVESTIGATIONS

Plain X-ray may occasionally show evidence of calcification and/or abnormal vascular markings on the skull, but this is not an important investigative tool in the diagnostic armamentarium available today.

The CT scan is valuable in diagnosis. In the hyperacute and acute stages, CT visualises the intracerebral haematoma and brain oedema better than MR. A plain CT scan may show an area of hypodensity within the haematoma. This is a useful guide to the location of the nidus of the AVM and was described by Wakai[134] as the "nidus sparing sign". In the presence of an acute haematoma, a contrast-enhanced CT may or may not reveal the AVM, but after resolution of the haematoma, the AVM may be visualised as a serpiginous enhancing lesion with an early draining vein (Fig. 6). The presence of associated calcification is easily seen. There may be evidence of "steal" phenomenon and hypoperfusion of the surrounding brain in the form of perilesional hypodensity, grey matter changes, disturbances of grey-white interface or cortical atrophy. Intrinsic hypodense areas within the AVM may be visualised in a high resolution scan, corresponding to the areas of gliosis or old haemorrhage.

Magnetic resonance imaging (MRI) will show areas of serpiginous flow void on T1-weighted and T2-weighted images (Fig. 7). The signal intensity of the AVM may be paradoxically increased if there is slow flow, stagnation or thrombosis within the vessels. Areas of associated haemorrhage are revealed and old subclinical haemorrhages, which are difficult to diagnose on a CT scan, can be easily visualised. The exact location of the AVM nidus, feeders and draining veins is easily established in relation to the eloquent areas of the brain because of the ease of multiplanar imaging. Areas of cortical atrophy are also easily visualised. Serial MR imaging is useful in diagnosis and management of occult AVM.[56,103,109]

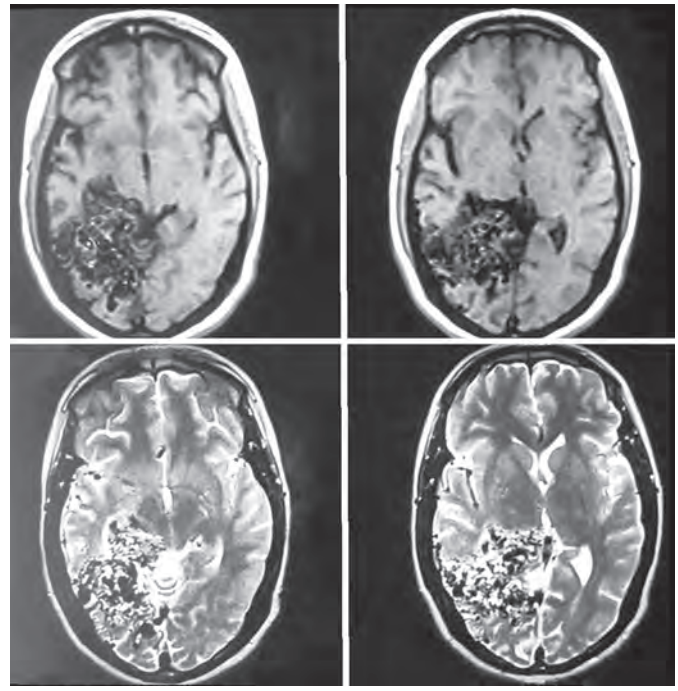

Fig. 7: Magnetic resonance imaging will show areas of serpiginous flow void on T1-weighted and T2-weighted images

Functional MRI (fMRI) is useful in identifying language activation patterns and the relative location of an AVM.[22,23,36] Brain plasticity in relation to structural abnormalities like AVM can be demonstrated by fMRI.[44] MR tractography is useful in assessing the relationship between the AVM, sensory motor fibres and tracts.[15] Magnetoencephalogram is useful in estimating an interictal paroxysmal activity source in patients with AVM.[60]

MR angiography (MRA) gives an excellent outline of the AVM with detailed information on the arterial pedicles and venous drainage pattern (Fig. 8). However, as of today, it has neither replaced nor supplanted digital subtraction angiography (DSA) which is still considered the "gold standard" in the imaging of an AVM.

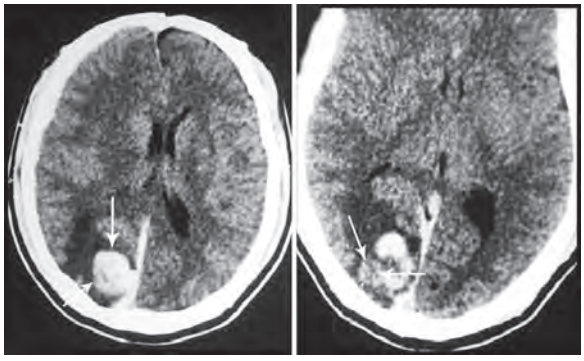

Fig. 6: Contrast computerised tomography scan showing serpiginous arteriovenous malformations after resolution of haematoma

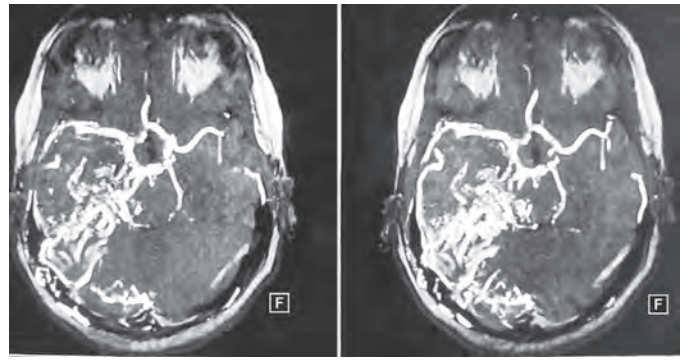

Fig. 8: Magnetic resonance angiography showing an excellent outline of the arteriovenous malformations with detailed information on the arterial pedicles and venous drainage pattern

The MRA is a beneficial supplement of DSA in patients with cerebral AVM at both initial diagnosis and at follow-up after therapy. The MRA can be performed using various techniques.[2] Volume rendered three-dimensional (3D) time-of-flight MRA helps in assessing the relationship between the components of the AVM and that of AVM with an associated haematoma. Surface anatomy scanning of the brain in a superficial AVM can non-invasively demonstrate the superficial AVM along with the brain surface and provide information useful for planning surgery.[25,37] Magnetic resonance venography may be of importance in detection and assessment of small AVMs which are difficult to diagnose with other MR methods.[54]

Conventional angiographic evaluation of an AVM, utilising subtraction and magnification techniques, should be routinely used. The angiographic definition is definitely enhanced by using super-selective techniques and stereo angiographic 3D display, though it is not really necessary for pre-operative planning. Super-selective catheterisation is certainly helpful in a pre-embolisation study.[98,99,131,132,139] Complete angiographic evaluation of an AVM consists of studying the characteristics of the arterial feeders, the nidus and the draining veins (Figs 9A and B).

The features to be noted in the feeding arterial pedicles are:

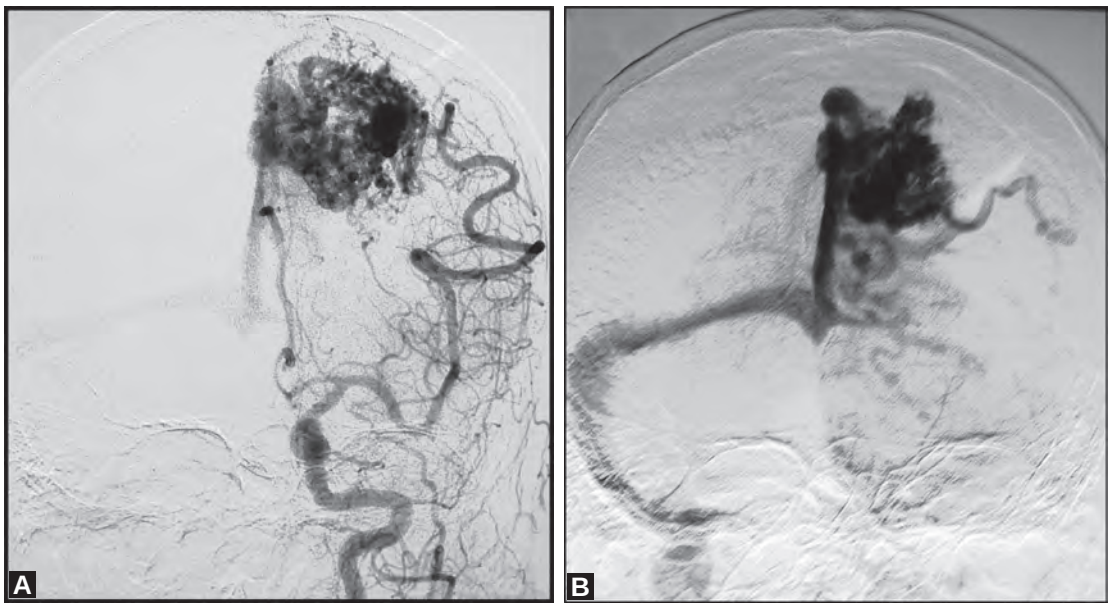
- Whether it is a direct or an indirect feeder
- Presence of stenotic segments in the arteries
- Presence of any dural supply
- Associated angiographic variations of the arteries
- Presence of associated aneurysms which may be either dysplastic or flow related
- Presence of angiographic spasm (which is uncommon in this condition).

A study of the nidus should be undertaken to evaluate:

- The type of nidus, whether it is compact or diffuse. A compact nidus should be further categorised as to whether it is single, multifocal or multicompartmental
- The size of the nidus
- The presence of AV communications and flow characteristics: whether a high flow or a low flow AVM. A high flow AVM is characterised by the presence of a large nidus, usually larger than 4 cm, a few large feeders, high shunt flow within the nidus, decreased circulation or dilated arteries in the adjacent brain parenchyma and evidence of steal from adjacent vascular territories
- Venous pouches
- Intranidal aneurysms
- Careful observation of the venous drainage pattern is mandatory to note:
- *Drainage*: Whether central, cortical or mixed
- Variations in venous anatomy
- Stenosis, thrombosis or kinking of the veins
- Ectatic dilatations of the draining veins

Studies necessary for pre-surgical planning include:

- A good subtracted and magnified angiogram showing the above mentioned features
- The relevant frames to delineate the nidus of the AVM in relation to bony landmarks like the coronal suture, external occipital protuberance and external auditory meatus
- Delineation of the cortical draining veins of both the hemispheres, when an interhemispheric approach to the AVM is planned.



Figs 9A and B: Complete angiographic evaluation of a arteriovenous malformations consists of studying the characteristics of the arterial feeders, the nidus and the draining veins

CAUSES FOR ANGIOGRAPHICALLY OCCULT ARTERIOVENOUS MALFORMATIONS

AVMs that are not visualised on angiography are termed angiographically occult vascular malformations.[84] These may be either truly occult or may not be visualised due to the various factors enumerated below:

- Truly occult AVMs such as cavernoma, telangiectasia, thrombosed AVM
- Transiently occult AVMs due to destruction or compression by haematoma and/or oedema
- Micro AVM
- Intraluminal thrombosis because of stagnation or turbulent flow
- Changes in blood vessels, e.g. fibrosis, spasm, placation or dysplastic changes
- Variable filling of the AVM during angiography.[97]

The CT or MR scan may be helpful in revealing the lesion. In case of angiographically negative AVMs, delayed angiography or surgical exploration has been reported by various authors to be positive in as high as 27–53% of cases.

CT angiography with spiral/helical CT and maximum intensity projection can be used to display vascular images in a 3D format with excellent delineation of the anatomical features. It has a lower acquisition time as compared to MRA. It may become available in the near future as a minimally invasive, low cost screening tool, especially for follow-up examination.[13,81] Volume rendered 3D CTA allows for accurate differentiation of AVM from haemangiomas and other lesions. Precise volumetric definition of an AVM is helpful in radio surgical treatment and planning.[13]

Transcranial Doppler is useful in the study of intracranial vascular malformations in neonates and children to evaluate the malformation as well as the ICH. Colour Doppler imaging can be used in pre-natal diagnosis of foetal brain malformations. It can be utilised to monitor the shunt flow velocity and the status of perfusion of the surrounding parenchyma in pre-operative as well as post-operative evaluation.[27,55] Ultrasound assessment of the volume flow in the extracranial internal carotid artery is useful to evaluate perfusion states of the brain in the presence of an AVM pre-operatively and post-operatively.[16] Transcranial Doppler can be used to demonstrate the size and shape of an AVM which may not be detected on emergency CT in the presence of massive haemorrhage.[61]

Single-photon emission computerised tomography and functional positron emission tomography (PET) scanning are useful for assessment of the extent of hypoperfusion.[54] PET activation studies are also useful in precise location of cortical functions of patients with an AVM to guide management as cortical functions may undergo translocation when a huge AVM involves eloquent areas.[58]

Scanning electromicroscopy shows shunting arterioles (150–250 microns) which can be selectively sectioned to interrupt arteriolar blood supply of the AVM in functional areas of the brain.[80]

GRADING OF ARTERIOVENOUS MALFORMATIONS

Total surgical resection of an AVM is determined by many factors:

- Age and neurological status of the patient
- Size (small, medium, large, giant)
- Location, especially with respect to eloquent areas of the brain
- Configuration of the nidus (compact or diffuse)
- Number, size, type and source of arterial feeders
- Nature of venous drainage (superficial, deep or mixed) and number of draining veins
- Haemodynamics of the AVM (shunt flow, degree of steal from the surrounding parenchyma, feeding artery pressure and participation of perforators)

Various authors have tried to evolve a grading system, which would incorporate the above mentioned factors in order to prognosticate the difficulties of surgical resection and the neurological outcome after surgery. Earliest grading systems were based only on the size of the AVMs.[21,57,58,92,95,104,111,115,123,126,129,130,135,137,138,141] Garretson in 1979[30] proposed a system based on the age of the patient and the arterial feeders. These systems, though easy to apply, did not take into account the eloquent areas of the brain or the relation of the draining vein. Parkinson and Bachers[89] divided AVMs into five types, depending on the arterial feeders and venous drainage patterns. A comprehensive grading system was prepared by Shi and Chen[117] in 1986, but the major drawback of this system was that it failed to determine precisely the eloquence of the area of the brain involved. Spetzler and Martin,[121] in 1986, proposed a system based on the size of the AVM, the venous drainage and the eloquence of the involved brain. This system is simple and easy to remember and has been found to correlate well with surgical difficulty and the post-operative deficits. However, this system ignores the arterial feeders and also makes no mention of the number of draining veins. Pertuiset[96] devised a score system for evaluation of operability and surgical strategy based on anatomic, haemodynamic and clinical factors. Pasqualin[90,91] also proposed a system for grading of AVMs based on the size (volume) of the nidus, the pattern of venous drainage, shunt flow and the arterial feeders. Comparing all these available systems, it is obvious that there is no single grading system that addresses all the important variables affecting the ultimate prognosis in a given case; therefore, they all remain far from ideal. All these systems are only applicable to surgical cases. An ideal system should be simple, uniformly applicable, able to predict operative difficulty as well as outcome, and should enable comparison and evaluation of all treatment modalities.

A simple and easily applicable grading system is described below. The Spetzler and Martin grading system takes into consideration the size, the venous drainage and the eloquence of the adjacent brain.[121] Points are assigned for each factor as follows:

1. Size of AVM:
   - Small (< 3 cm) 1 point
   - Medium (3–6 cm) 2 point
   - Large (> 6 cm) 3 point
2. Eloquence of adjacent brain:
   - Non-eloquent 0 point
   - Eloquent 1 point
3. Pattern of venous drainage
   - Superficial only 0 point
   - Deep 1 point

The grades are I to V and this is arrived at by adding the scores. Grade I, i.e. a small AVM in a non-eloquent area with a superficial drainage has the best prognosis; and grade V, i.e. a large AVM in an eloquent area with deep venous drainage has the worst prognosis. Inoperable lesions are in Grade VI and diffusely involve the brainstem or hypothalamus.

92 Surgical Management of Cerebral AVMS

Ravi Ramamurthi, Ravindranath Kapu

The management of an AVM can be a simple matter or a most challenging neurosurgical exercise. The following varieties of procedures that have been used for dealing with this condition are:

1. Excisional surgery,
2. Endovascular treatment,
3. Radiosurgery,
4. Combination of the above.

The criterion for cure of an AVM is the complete obliteration and non-visualisation of the AVM on follow-up angiography.

CONSIDERATIONS IN THE TREATMENT OF AVM

Important considerations in the treatment of an AVM are:

- Factors related to the patient—age, general condition, neurological state, occupation and psychological attitude
- Factors related to the AVM—natural history of the AVM, its mode of presentation, and anatomic and haemodynamic characteristics of the AVM
- Experience of the neurosurgical team and the available facilities.

Factors Related to the Patient

Age is an important determinant of surgical therapy. Young patients have a high-risk of bleeding from an AVM and the cumulative morbidity due to haemorrhage or seizures is very high. While confronted with an older patient, the risk: benefit ratio for the individual patient should be considered, keeping in mind the life span of the patient and also the fact that the risk of bleeding may actually decrease after middle age. A patient with a poor performance on the Karnofsky scale is unlikely to have a good outcome. Occupation of the patient and the psychological motivation are important considerations, especially in relation to the post-operative morbidity.

Factors Related to the AVM

(a) The natural history of cerebral AVMs leaves no doubt that the long-term prognosis for patients with untreated malformations is grim. The natural risk associated with most of the AVMs far exceeds the risks related to treatment.[28,29,61]

(b) *Mode of presentation:* There is no argument as far as the treatment of AVMs presenting with haemorrhage is concerned. They undoubtedly merit definitive treatment. With increasing understanding of the natural history it is becoming evident that AVMs presenting with non-haemorrhagic manifestations also deserve aggressive management. Surgery is being increasingly advocated for AVMs presenting with seizures.[11,56,76] Heikkinen et al.[27] employed radiosurgery for AVMs presenting with seizures and reported a good outcome as regards to seizure control. Patients with intractable headache alone, progressive neurological deficits or hemifacial spasm, all need to be considered for definitive treatment based on the individual merits of the case. A fixed neurological deficit from a past haemorrhage does not improve following surgical excision, but such patients, if young, are offered definitive treatment in order to prevent recurrent bleeds and further increase in morbidity. An asymptomatic AVM in a young patient definitely deserves aggressive management, whereas, in an elderly patient it may be left alone.

(c) *Anatomic and haemodynamic factors:* These are important determinants of the mode of therapy to be chosen for a specific case. While the majority of the AVMs can be surgically excised, it may be difficult to operate on certain small AVMs in deep, inaccessible or eloquent areas. The same applies to very large, diffuse AVMs occupying almost an entire hemisphere. The relative merits of radiosurgery, embolisation or any of the combinations of the available modalities need careful consideration.

Experience of the Neurosurgical Team

As each AVM is different from the other, the feasibility and the risk of surgical excision is best judged by the surgeon based on his individual experience. In addition, the availability of competent neuroanaesthetists and neuroradiologists, especially trained in interventional techniques, is helpful in the total management of difficult and challenging malformations.

SURGERY

Total surgical excision remains the gold standard in the treatment of AVM. The aims of surgical excision are to interrupt the natural history of the disease, and prevent

future haemorrhage, decrease cerebral steal, improve neurological deficits and to achieve seizure control.

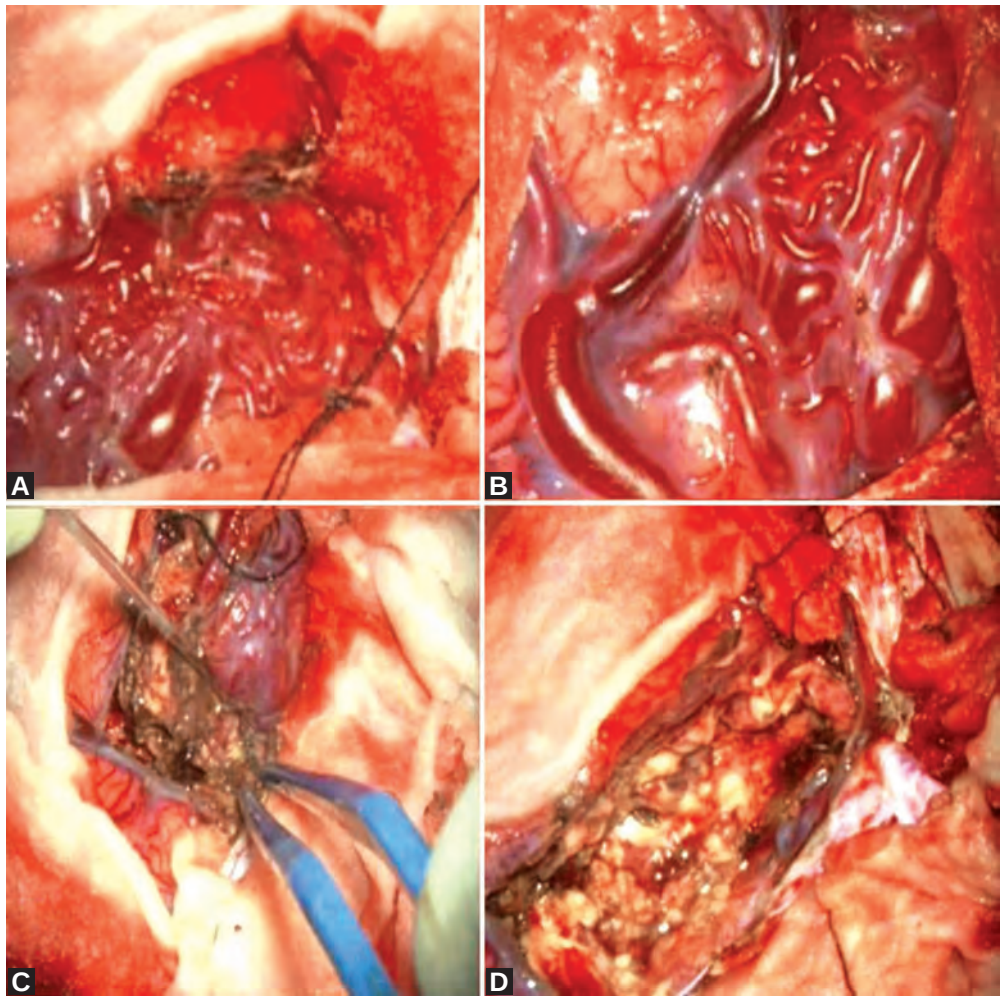
Principles of Surgical Treatment

Unlike in aneurysms, the risk of an immediate rebleed from an AVM is much less. Generally, the arterial feeders should be attacked first then followed by excision of the nidus and finally resection of the draining vein.[17,75] Care should be taken to preserve the veins (Figs 1A to D) until the very end of the operation. When an intracranial AVM is resected, the goal should be complete obliteration. The timing of angiography and elective excisional surgery is delayed 2–3 weeks for the brain to recover from the initial insult, unless a large and life-threatening haematoma warrants early evacuation. Early angiography often fails to delineate the exact morphology of a malformation in the presence of a sizeable haematoma. In the presence of a haematoma with attendant cerebral oedema and raised intracranial pressure, attempts at early surgical excision may often preclude the chances of total extirpation of the malformation. While awaiting angiographic evaluation and definitive surgery, patients are administered anticonvulsants and antioedema therapy if indicated.

Small AVMs located in the polar regions or on non-eloquent cortical surfaces, with or without a bleed, pose little difficulty for total excision. However, large high-flow AVMs or those with deep arterial feeders are often a challenge for one stage surgical excision. In such lesions, pre-operative embolisation, particularly of the deeper feeders, reduces shunt flow, minimises intra-operative bleeding and avoids post-operative autoregulation breakthrough syndrome.[54,66] Thus, it is an important adjunct to subsequent successful total excision.

For extensive malformations, certain surgeons employ planned staged surgical resection without pre-operative embolisation, depending upon sectorisation of the lesion.[50]

All patients are operated upon under general anaesthesia with the head positioned in such a way that the malformation is above the heart level to enable maximum venous drainage. Intra-arterial monitoring of blood pressure is mandatory. A generous craniotomy is made to have good access to the lesion. In patients with a dural component of the malformation, the dura should be excised and the dural defect repaired with



Figs 1A to D: Intra-operative image showing stages in excision of AVM. (A) AVM seen as a bunch of worms and surrounded by gliotic tissue. (B) Draining vein is seen entering into the superior sagittal sinus which should be preserved till the end of surgery. (C) Excision of AVM. (D) Post-operative stage

pericranium, fascia lata or lyodura. The dura is often adherent to a cortical malformation and should be separated with care using bipolar diathermy. The arachnoid over the surface of the malformation is usually thickened and often appears milky white.

Large arterialised draining veins are prominent landmarks of an AVM at surgery. However, the margins of most malformations buried in the parenchyma are usually not definable on the cortical surface. The dilated arterial feeders, when present on the surface, appear greyish-pink and are thin walled. On occasions it may be difficult to differentiate between an arterial feeder and an aterialised draining vein. In such a case, transient occlusion of the vessel helps in differentiation. The arterial feeders often lie buried in the sulci adjacent to the malformation and may be traced by dissecting the arachnoid over the sulci with the help of accurate anatomical localisation. The major arterial feeders are identified early in the dissection and are coagulated with bipolar cautery adjacent to the lesion. For reaching the arterial feeders buried in the sulci, it may be necessary to trace one or more superficial draining veins on to the nidus and the veins may often be used as a handle, as was described by Malis, for "marginal dissection" along the surrounding gliotic parenchyma.

The presence of a haematoma, as seen in 42% in Rout's patients,[57] or small cystic cavities help in delineation of the margins of the malformation, facilitating its dissection. The adjacent gliotic parenchyma often appears as a "pseudocapsule"[16] and offers a plane of cleavage for the dissection of the lesion. The "pseudocapsule" is more often found in compact lesions as compared to the diffuse malformations. It is always essential to preserve any large draining vein till the end of surgical resection.[17,75] Although most arterial feeders can be coagulated with bipolar diathermy and divided, large arterial feeders are best clipped and coagulated. As the deep arterial feeders are most difficult to reach, identify and divide, it is often essential to shrink the size of the malformation using low voltage bipolar diathermy. Sometimes, it may be required to retract the malformation to reach the large feeders. Rarely one may encounter a normal artery coursing over the lesion with its branches supplying the malformation. In such situations it is essential to preserve the parent artery and selectively coagulate only the feeding branches. In the event of bleeding from a draining vein, the rent can be coagulated or may be temporarily packed with gelfoam and cottonoids and dissection continued in adjacent areas till the arterial feeders are taken care of.

While hypertension is avoided during dissection, temporary hypotension may occasionally be required to control troublesome bleeding. Under high magnification, one may dissect through the malformation and a coil of vessels lying outside the plane of dissection may arouse the suspicion of an incomplete resection. Following resection, persistent oozing from the bed of the malformation suggests either a torn and retracted vessel in the white matter or a residual AVM nidus which should be pursued till absolute haemostasis is achieved. It is mandatory to raise the blood pressure above the normal level or even perform Valsalva manoeuvre to confirm haemostasis prior to dural closure. In the event of brain oedema supervening during dissection, it is better to abandon the procedure and plan staged resection. Advances in pre-operative embolisation techniques have made planned staged resection of large high flow AVMs unpopular, except for some extensive lesions which may need different avenues of approach. Malformations in certain locations, like the medial temporal lobe, deep nuclei, internal capsule, corpus callosum, intraventricular, sulcal, along the tentorial incisura, and the posterior fossa require special operative approaches. Intraoperative embolisation prior to an attempt at surgical excision can be adopted, if there are angiographic monitoring facilities,[62] but this procedure has its own limitations.

Advances, like stereoscopic angiography, bipolar diathermy with automatic irrigation, improved neuroanaesthetic management, application of Nd-YAG laser photocoagulation, evoked potential monitoring for brainstem lesions, intra-operative DSA facilities, intra-operative cerebral blood flow studies and fluorescein angiography, as well as cortical mapping of the eloquent areas, have profoundly expanded the limits of successful total excision of AVMs that were previously considered inoperable, with an acceptable mortality and morbidity.[71]

Post-operatively, the patient's head is kept elevated by 30–40 degrees for optimal venous drainage. Anticonvulsants and decongestant therapy, including steroids, are continued. Hypertension is avoided; patients are kept relatively underhydrated for the first 48 hours to avoid hypervolaemia, to prevent the deleterious effect of hyperperfusion around the margins of resection and the surrounding brain. Some authors have even advocated elective ventilation and barbiturate coma for 48 hours following excision of large deep seated high flow AVMs. Steroids are tapered off 1 week after surgery. Post-operative check angiography is essential to evaluate the completeness of surgical excision of the malformation. Immediate post-operative angiogram may fail to reveal a small residual nidus because of cerebral oedema and blood clot. The ideal time for performing a check angiogram is 3–6 weeks after surgery. If a residual AVM is detected, it is operated upon at the earliest available opportunity (Figs 2A to D).

In most standard neurosurgical units excisional surgery carries a mortality of less than 2% and a morbidity of less than 10%. These results offer a better prognosis than the natural history of most of the cerebral arteriovenous malformations.[12,29] However, the risks of surgical excision still remain high for AVMs located within the brainstem and deep nuclei, as also for the very large lesions.

AVMs Associated with Aneurysms

Management of AVMs in association with aneurysms deserves special mention.[35] Aneurysms in such a setting may be either flow related, developing as a result of high flow through the AVM; or non-flow related, and located at the common sites for aneurysms in the circle of Willis. Flow unrelated aneurysms located outside the angioarchitecture of the AVM are unlikely to regress after surgery for the AVM and may in fact enlarge and rupture once the "sump" effect is eliminated following extirpation of the AVM. These aneurysms should be operated upon before treating the AVM. Regression has been noted[39] in the size of flow-related or dysplastic aneurysms, of distal aneurysms or aneurysmal dilatations located on the trunk of the main feeding arteries after restoration of normal flow following excision of AVM. The AVMs are associated with aneurysms in 3% of the cases.

Haemodynamic Changes after Removal of an AVM

The immediate change that occurs following removal of an AVM is the interruption of the nonperfusion flow and the conversion of shunt flow into perfusion flow pattern. There is an increase in the arterial end pressure, and the pressure at the venous end decreases which results in an increase in the cerebral perfusion pressure. This increase in the perfusion pressure could be due to elevated plasma renin and norepinephrine levels.[7]

Post-Operative Complications

Complications that may be encountered in the early post-operative period are:

- Brain swelling which can be caused by a venous infarct, retraction oedema, haemorrhage from residual AVM, perfusion pressure breakthrough syndrome or occlusive hyperaemia[45]
- In AVMs with large sized and long feeder vessels, when there is evidence of stagnation of blood in the post-operative angiogram retrograde thrombosis of the feeding artery may occur, especially in elderly patients
- Post-operative hyperthermia is another serious complication[3] which can be exacerbated by mild, intra-operative-induced hypothermia.[8] Hence, careful monitoring of the temperature in the intensive care unit is recommended.

Normal Perfusion Pressure Breakthrough Syndrome

Two hypotheses for the cause of brain oedema and haemorrhage during or after surgery in AVM have been proposed—normal perfusion pressure breakthrough syndrome (NPPB) and occlusive hyperaemia.

The NPPB syndrome was described by Spetzler et al.[63] in 1978 and is thought to be related to dysautoregulation in the brain parenchyma adjacent to an AVM. It is, however, a rare occurrence when there is a large high-flow AVM, the surrounding brain tissue is in a state of chronic ischaemia due to vascular steal by the same parent vessel which feeds the AVM. The vessels in this ischaemic, hypoperfused area will be in a state of chronic vasodilatation in response to the persistent ischaemia and they lose their inherent capacity for rapid autoregulation. The rapid interruption in the flow to the AVM and restoration of perfusion flow may result in an increased flow in these maximally dilated vessels which are unable to contract in response to the increased flow. This results in seepage of blood from these vessels into the adjacent brain parenchyma. This phenomenon is termed the perfusion pressure breakthrough syndrome. The key factor in prevention of this malignant post-operative haemorrhage and oedema is staged reduction of blood supply to the malformation. This can be accomplished by staged surgical ligation of the feeders[16,44,47,50,59,73]

The factors that help in predicting the risk of developing NPPB are:

- Clinical evidence of cerebral ischaemia, e.g. focal neurological deficits, headaches, seizures
- CT or MR evidence of cerebral atrophy resulting from hypoperfusion
- Angiographic evidence of large, high-flow AVM, numerous large calibre feeding arteries, steal from other vessels, border zone location, flow shift towards the AVM
- Pre-operative evidence of ischaemic rim around the nidus identified by cerebral blood flow studies, low feeding artery pressure before removal of AVM, immediate normalisation of arterial and venous pressures after removal of the AVM, increased regional cerebral blood flow after removal of the AVM.

Patients at risk for developing NPPB can be identified pre-operatively and such a complication can be prevented by converting the large high flow AVMs into smaller lesions by either pre-operative embolisation or staged resection.[2,64] However, partial embolisation of the nidus and staged resection are not without drawbacks. These procedures may fail to protect adequately against NPPB because it requires time to correct dysplastic regulation. There is always a risk of haemorrhage between the stages of resection. This risk may even increase, because of the alteration of haemodynamics in the AVM. Other points against staged resection are the risk of developing acute on chronic hypoperfusion, divergence of flow to deeper or non-accessible vessels and recruitment of new collaterals which may increase the surgical difficulty during attempts at complete obliteration of the AVM.

Occlusive Hyperaemia

This hypothesis postulates that the malignant post-operative haemorrhage and oedema can be caused by either arterial stagnation and obstruction or venous outflow obstructions, which are in turn related to resection of the AVM.

Post-Operative Seizures

The incidence of post-operative seizures after removal of an AVM ranges 6.5–50%. The incidence of *de novo* seizures has been reported as 11.6%.[75] However, it is to be noted that seizures occurring in the immediate post-operative period do not usually recur. The risk of delayed epilepsy is small, especially if the patient did not have pre-operative seizures.

Results of Surgery

Immediate mortality due to surgery can be expected in 1–6% of cases. Delayed mortality has been reported as 1–2%. Morbidity in the immediate post-operative period is seen in 20–44%, whereas over a period of time, the morbidity decreases to 2–6%. The dramatic improvement in the neurological deficits in the majority of patients is because of resolution of the pre-operative intra-cerebral haematoma and restitution of normal cerebral perfusion. However, patients developing fresh neurological deficit immediately after surgery also improve during the follow-up period. Development of immediate transient neurological deficits may be because of retraction oedema or due to the phenomenon of surrounding cortical suppression described by Yasargil[75] as "Temporary blocked syndrome". Patients in poor pre-operative clinical grade may be expected to have a poor outcome.

EMBOLISATION

Interventional neuroradiologists can embolise the AVM nidus or the feeders as definitive treatment, or as a part of the multimodality approach to the management of large high flow AVMs (Figs 3A and B). Embolisation (see chapter on Embolisation) is also useful in occluding inaccessible feeders.[54] Luessenhop and Spence reported, in 1960, the first successful embolisation of an AVM using methylmethacrylate.[39] Current indications for embolisation can be divided into: (1) Pre-surgical embolisation for large or giant cortical AVMs, and (2) Embolisation before radiosurgical intervention to reduce the nidus size.

Embolic materials can be divided into solid or liquid agents. Solid agents consist of fibres, microcoils and microballoons[5,19,21,31,48,60,67] and liquid agents include cyanoacrylate monomers such as I-butyl cyanoacrylate (IBCA) and N-butyl cyanoacrylate (NBCA), ethylene vinyl alcohol (EVAl) copolymer[4,6,40,41,49,70]) absolute ethanol, with or without the use of contrast agents for visualisation under digital subtraction fluoroscopy.[15,51,74] Usually the transfemoral route is employed. When the transfemoral route cannot be employed, Gomes[25] has suggested alternate approaches like direct injection of the embolic materials into the malformation or into the central vessels of the lesion under fluoroscopic guidance and selective catheterisation and embolisation of the abnormal veins draining the malformation.

Pre-Radiosurgical Embolisation

Endovascular therapy in radiosurgical interevention for AVMs has three potential goals:[13] (1) to decrease target size to less than 3 cm in diameter, because smaller volumes have a higher cure rate with less morbidity; (2) to eradicate angiographic predictors of haemorrhage, such as intranidal aneurysms or venous aneurysms and (3) to attempt to reduce symptoms related to venous hypertension. There is no ideal embolic material identified for pre-radiosurgical use.[13,14,23] Various authors have reported on the use of intra-operative embolisation, but it is not favoured by most neurosurgeons. Tissue reaction to embolotherapy with various embolic materials is variable.[53]

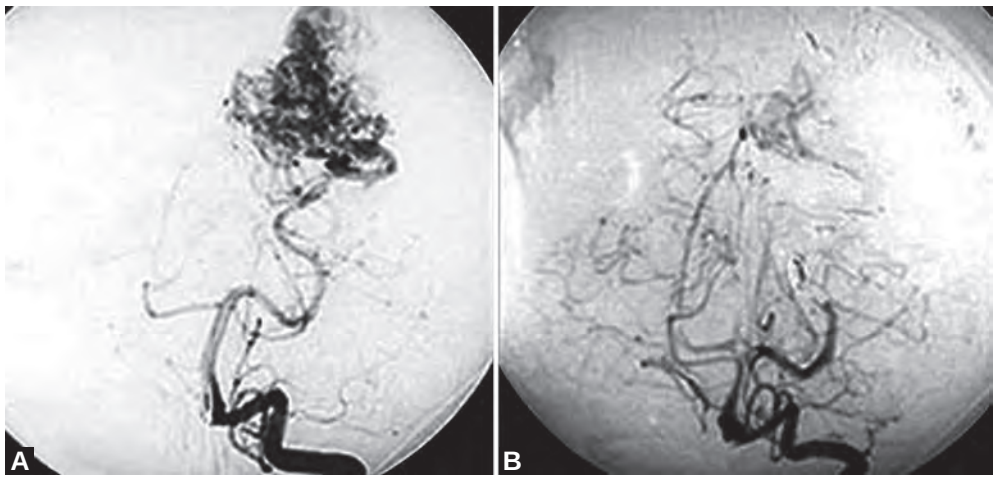
Palliative Embolisation

This may be recommended for patients who have large, inoperable cortical and subcortical AVMs and in those patients presenting with uncontrollable seizures or with progressive neurological deficit due to secondary venous hypertension and/or arterial steal phenomenon.[5,22,68]

Cyanoacrylates and polyvinyl alcohol (PVA) cause acute inflammation and angionecrosis in the early stage, followed by a late chronic inflammatory response and foreign body giant cell reaction. Avitene causes delayed endothelialisation. Hence, careful management of the coagulation profile is recommended to prevent thromboembolic complications during and after the procedures, although algorithms for anticoagulation remain controversial.[18,52,63]

Complications encountered with embolisation may be due to the haemodynamic alterations or due to the material used. Haemodynamic alterations may cause increased risk of haemorrhage because of pressure changes in the feeding artery and by recruitment of collaterals, in cases of partial embolisation of the nidus. Materials, like IBCA, may cause difficulty in dissection and retraction of the AVM during subsequent surgery, because of its hard consistency and failure of the vessels containing the IBCA cast to contract during coagulation. Rarely, the IBCA cast may dissolve, resulting in recanalisation of the AVM.

Other complications that may be encountered include neurological deficits due to occlusion of normal arteries, hyperaemia and swelling of the surrounding parenchyma, catastrophic haemorrhage due to rupture of arterial feeders or rarely, glueing of the catheter *in situ* due to rapid polymerisation of IBCA.[72] The role of partial embolisation of an AVM is limited due to the risks already enumerated; however, it may be indicated in special cases to reduce cerebral steal and hypoperfusion



Figs 3A and B: DSA image showing. (A) Left parietal AVM pre-embolisation. (B) Post-embolisation showing complete obliteration of the AVM

in patients presenting with chronic dementia or intractable headache.

RADIATION THERAPY

Conventional radiotherapy has no role in the treatment of AVMs.[36] However, stereotactic radiosurgery using charged particle beams (He, proton or neutron), Gamma knife (Co-60) or linear accelerator have all been found to be effective in the treatment of AVMs. Radiosurgery is indicated: (1) in small (<2–3 cm), deeply located, surgically inaccessible AVMs in eloquent areas of the brain with multiple small feeders; (2) in combination with surgery or embolisation for large AVMs, inaccessible or unresectable residual AVMs, and (3) in patients who are either not willing for surgery or poor surgical candidates because of concomitant medical illness. Ideal candidates for radiosurgery are the patients with small AVMs in eloquent areas, preferably with an isolated pedicle. Usually, the nidus of the AVM is irradiated in a single sitting; however, multiple sittings may be required in certain cases with large AVMs. Irradiation of the feeder vessel may also be tried in cases of large inoperable AVMs with discrete isolated pedicles of feeders. A successful obliteration rate of 62.5% at the end of 1 year, 83.2% at the end of 2 years and 94% at the completion of 3 years has been reported by Steiner[65] for Gamma knife therapy. Colombo et al.[10] reported a 100% obliteration rate after 3 years of treatment with linear accelerator radiosurgery. Fabrikant[20] reported an estimated complete obliteration rate of 90–95% at the end of 2 years using heavy charged particle (He) Bragg peak radiosurgery. Obliteration rate is determined by the volume of AVM treated, results being better for those of smaller volume. The radiobiological basis for the effectiveness of radiosurgery in the treatment of AVMs is still unknown. Changes seen in the early stage are swelling, degeneration and necrosis of the endothelial cells, followed by thrombosis, fissuring of the walls and punctuate haemorrhages which lead to progressive degeneration, fibrosis and perivascular infiltration of lymphocytes. Delayed changes over a few months or years are endothelial proliferation causing obliterative angitis leading to obliteration of the lumen, media proliferation and perivascular fibrosis.

The limiting factors in the successful outcome of radiosurgery are the size (3–3.5 cm for photons and 4 cm for charged particle) and the latency period. During the latency period of 2–3 years, till the AVM is completely obliterated, the risk of bleeding remains at 3–4% or may even be enhanced due to altered haemodynamics of the AVM. The other complication seen with radiosurgery is radiation induced damage by secondary occlusion of normal vessels causing focal neurological deficits in 3–4% of cases.[42] Major complications occur in about 2%, and rebleed is seen in about 4% of patients.[20] Transient asymptomatic white matter changes may occur in about 10% of cases, whereas, delayed radiation necrosis with permanent neurological sequelae is seen to affect about 1% of the patients. Patients' age, location and flow characteristics of the AVM, volume of the lesion, and dose and fraction schedule of radiation are some of the factors contributing to complications. Newer energy sources, such as Neon and Carbon, are being investigated to evaluate their potential as radiosurgical tools. Also, endovascular boron-neutron capture therapy,[43] as well as targeted radiotherapy using monoclonal antibodies against mesothelial cells of the AVM, is under investigation.

ELECTROTHROMBOSIS AND CRYOSURGERY

To overcome troublesome bleeding and facilitate total excision of deep seated and large AVMs, Handa et al.[26] employed electro-thrombosis using copper electrodes and direct current. If a check angiogram does not reveal disappearance of the nidus, the AVM is then excised easily. However, this procedure has not gained wide popularity and is of historical importance.

Walder[69] reported his experience of cryosurgical management in 27 cases of large, deep seated or eloquent area AVMs. The AVMs could be totally eliminated in 14 cases. It is of paramount importance that the cryoprobe should be immobile during freezing and is entirely above the freezing point when withdrawn to avoid a rupture. However Walder himself felt that this method of treatment has failed to provide a solution to the problem.

SPECIAL CONSIDERATIONS

Pregnant Patients

Most data regarding AVM haemorrhage risk during pregnancy are inconclusive. Robinson et al.[55] suggested that the risk of haemorrhage during pregnancy is similar to that at other times. The rebleeding rate during the same pregnancy may be higher than the early rebleeding rate in non-pregnant patients. Although haemorrhage during delivery is a major concern, vaginal delivery does not carry a higher risk for haemorrhage than delivery by cesarean section.[58]

Recommendations

(1) If a woman anticipates pregnancy and has a known AVM, treatment should be considered before the pregnancy.

(2) If the lesion is discovered during pregnancy, a decision should be made regarding the treatment risks versus the risk of haemorrhage during the remainder of the pregnancy. This also must include the potential risk to the foetus during intervention, whether it is by embolotherapy, surgical extirpation, or radiation and the associated diagnostic tests. In most cases, such risk-benefit analysis will not support elective treatment of AVMs during pregnancy.

Paediatric Lesions

The AVMs account for 30–50% of haemorrhagic strokes in children[9,24] and paediatric patients are more likely to present with haemorrhage than adults, with some authors like Humphreys et al.[32] and Kahl et al.[33] reporting 80–85% haemorrhage rate as their initial presentation.

Paediatric AVMs have been treated with surgical excision,[9,32,33] endovascular embolisation,[37] radiosurgery[1,34] and multimodality management.[30,46]
Humphreys et al.[32] reported a series of 160 paediatric AVMs in which the morbidity and mortality rates were 18% and 11%, respectively. Lasjaunias et al.[37] reported the largest endovascular series of 179 paediatric AVMs, in which the morbidity and mortality rates were 28% and 16% respectively. The largest radiosurgical series is, by Levy et al.,[38] of 40 paediatric AVMs, in which they found a 30% rate of permanent neurological deficits.

93 Embolisation of Intracranial Vascular Malformation

Anil Karapurkar, Nishant Aditya

Arteriovenous malformations (AVMs) are the second most common intracranial vascular malformations. They are believed to be congenital. Multiple AVMs are rare. *De novo* AVMs are rare but have been documented.[23] Familial AVMs are rare.[35] Ninety percent of intracranial AVMs are supratentorial. AVMs consist of a bunch of vessels, called nidus, which is made up of vessels of variable diameter and vessel wall thickness. Distinct vascular compartments within an AVM have been described.[109] Within the nidus there may be an arterial aneurysm[99] or an arteriovenous fistula (AVF). The nidus may be compact or diffuse. No two specialists would agree about the exact nidus of an AVM,[40] because it is usually obscured by large arterialised draining veins. The AVM may be fed by one or more branches from cortical and deep branches of all major arteries such as the ACA, MCA and PCA. If the AVM is of the high flow variety, feeding arteries are dysplastic and these dysplastic arteries may be associated with flow related aneurysms.[18,93,99] The draining veins have thick walls as they are arterialised. In high flow AVMs, with or without AVF, the draining veins may have large aneurysms or varices along their course. There may be stenosis of the draining veins. Anomalies of venous outflow are not infrequent and the deep venous system may be absent or there may be stenosis of the straight sinus or sigmoid sinuses. Haemorrhage may occur when there are venous anomalies or there are sudden changes in venous pressure.[63,64] The brain surrounding the AVM may show areas of gliosis due to ischaemia secondary to steal.[58] There may be calcification and cyst formation due to previous haemorrhage. Some parts of the AVM may be thrombosed.[55]

To standardise the management of AVMs, many classifications have been proposed. The one commonly accepted is that of Spetzler-Martin.[90] This takes into consideration three factors: (1) the size of the AVM; (2) the eloquence of the brain area involved and (3) the venous drainage. Grade I AVMs are the easiest to treat and Grade IV the most difficult. Grade V is inoperable and is best left alone. This is essentially a classification which is useful in identifying the surgical risks of AVM. However, most interventionists find this classification inadequate. The criteria which should be included in the classification are: (A) Weak spots—such as associated (1) juxta-nidal aneurysm, (2) intra-nidal arterial aneurysm, (3) aneurysm on the circle of Willis, (4) subependymal venous aneurysm, (5) stenosis along venous channels, especially when there is a (6) single draining vein, (7) congenital absence of the deep venous system which carries a higher risk of haemorrhage; (B) Associated intra-nidal A-V fistula with very high flow across the nidus which increases the risk of surgical extirpation and failure of stereotactic radiosurgery (SRS). In true intra-nidal A-V fistula, the microcatheter passes from the feeding artery to the draining vein without the intervening nidus. If there are "weak spots" even Grade IV or V AVMs according to Spetzler-Martin classification should undergo targeted embolisation to reduce the risk of haemorrhage.

The natural history of brain AVM is not precisely known despite several studies,[60] including those of captive populations.[24,36,106] The common presentations of brain AVM are: (1) haemorrhage;[63] (2) epilepsy; (3) progressive neurological deficit[55] and (4) migraine and intractable headache. Clinical signs depend on the location of the malformation[10,21,29,30,52,100,107] and the venous drainage.[49,50,63] Papilloedema due to raised intracranial pressure and venous hypertension has been reported.[21] Contralateral cerebral lesions due to raised venous pressure in the dural venous sinuses leading to impaired venous return have also been reported.[49]

Haemorrhage is the most devastating presentation in about 60% of patients [Figs 1(A to C) and 2(A to H)]. Haemorrhage is usually parenchymal, but it may be subarachnoid or intraventricular.[72] The average incidence is 2–4% per year of life. However, some studies have recorded less than 1% haemorrhage per year. The risk of re-bleeding is higher if there is a weak spot such as a false aneurysm, true arterial intra-nidal aneurysm, single draining vein with venous stenosis, or venous stenosis on a major venous outflow. Otherwise the risk is about 6–10% in the first year. Thereafter, it is the same as for other AVMs, i.e. 2–4% per year. The risk of bleeding is higher during pregnancy and parturition. If an AVM is diagnosed in the antenatal period elective caesarean section is mandatory. AVMs in some locations are prone to re-bleeding. These include those in the basal ganglia and corpus callosum.

INVESTIGATIONS

CT scan after double dose contrast and CT angiogram on spiral or multi slice CT scanning machines show the AVM nidus very well. However, feeders, draining veins, associated aneurysms and haemodynamics cannot be assessed. It is also impossible to often delineate the precise nidus because of the huge dilated early filling veins. It is difficult to distinguish arteries from arterialised draining veins. MRI sometimes is useful to show the true nidus.[11,45,88] However, it is difficult to get a true picture of the AVM on the MRI or MRA even with the latest machines. At best, static images can be obtained. No concept of the haemodynamics can be obtained.

Digital subtraction angiography (DSA) remains the gold standard in the diagnosis of AVM.[19,40,45,85] Magnification, rapid subtracted filming at 6 or 12 frames per second and multiple projections and rotational angiography provide all the desired information. For posterior fossa AVMs bilateral vertebral angiograms (VA) in addition to bilateral internal and external carotid (ICA and ECA) angiograms are mandatory. For supratentorial AVMs, bilateral ICA, ECA and at least one VA angiogram must be done. The angiogram must carefully be analysed to include: (1) the precise site and size of the AVM; (2) the arterial supply of the AVM; (3) the venous outflow, whether superficial or deep, or both; (4) associated arterial aneurysm; (5) associated venous anomaly such as stenosis, absence of deep venous system, aneurysm or varix; (6) competition between the venous outflow of the brain and that of the AVM; (7) functional antegrade flow in the superior sagittal sinus, as raised venous pressure can cause a rise in ICP [33,51] and papilloedema; (8) any evidence of mass effect due to associated clot as seen by stretching and separation of arteries and veins and (9) any supply from external carotid branches.[44,49,86]

An aneurysm may be remote from the AVM, e.g. in the circle of Willis. An aneurysm along the course of the feeding artery, remote from or close to the AVM is usually a flow-related aneurysm. Aneurysms on the feeding pedicle remote from the nidus usually need no treatment and regress after the AVM has been obliterated. Aneurysms close to the nidus need to be treated as they may rupture. There may be an aneurysm within the AVM nidus. The latter is especially common in deep AVMs of the basal ganglia, thalamus and brainstem. There may be multiple aneurysms on different branches. These may easily be missed because they are obscured by the nidus and may only be seen on super-selective angiograms. The author learned this much to his chagrin when he treated an aneurysm on the posterior cerebral artery and missed a small one on a lenticulostriate artery. The patient presented within 3 weeks with a fresh large haematoma from the second aneurysm, which had been missed. If there is an associated arterial aneurysm, whether in the circle of Willis or within the nidus it is almost certain to be the cause of the intracranial haemorrhage and must be dealt with first.[72]

INDICATIONS FOR TREATMENT

AVMs presenting with haemorrhage must be treated.[79] The mode of treatment—Surgery/Endovascular/Radiosurgery—would depend on the site, size and "weak spots" of the AVM. The management of incidental (those presenting with epilepsy) and Grade IV and V AVM remains controversial.[13,28,80,94,95] Small AVMs are thought to bleed more frequently than large AVMs.[24] They must be treated. AVMs, such as those in the basal ganglia and corpus callosum, which are prone to re-bleed should be treated. Spetzler-Martin Grade IV and V should be treated if there are weak spots, such as intra-nidal or large flow related aneurysms, subependymal venous aneurysms or significant flow limiting venous stenosis, which are likely to bleed. AVMs presenting with intractable epilepsy, severe headache which is usually due to extracranial dural arterial supply and incidental AVMs with "weakness" must be treated.

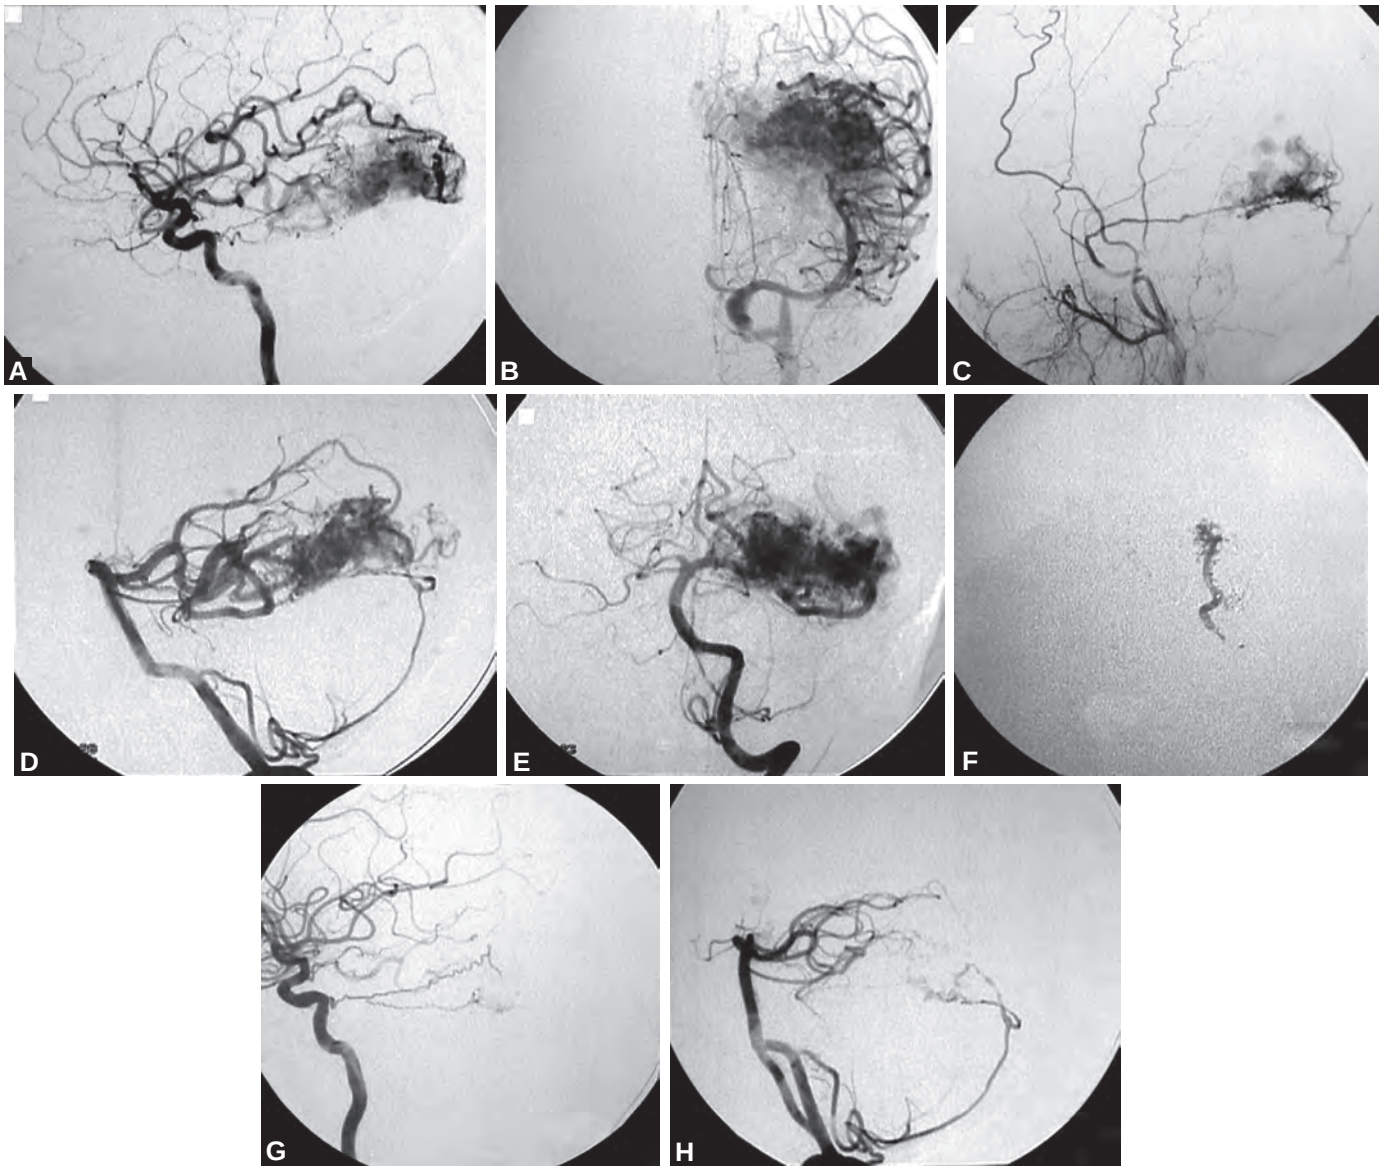
CONTRAINDICATIONS

- Spetzler Grade V
- Large diffuse AVM
- Incidental large eloquent area AVM
- Epilepsy as presenting feature in large AVM.

The results of treatment should be better than the natural history of the disease. Morbidity and mortality should be less than 4%. The actual results, whether surgical or endovascular, are far worse. In the best of hands, the complication rates are around 10–15%. Spetzler-Martin Grade I and II AVM presenting with haemorrhage must be treated. Grade VI AVMs are best left alone. Grade IV and V AVMs may also be left alone if the risk of treatment is higher than the natural history.[96,98] Only targeted treatment of weak spots such as intra-nidal or juxta-nidal aneurysm should be undertaken.[12,18,99] Targeted embolisation reduces the risk of haemorrhage.[61] It is believed that partial treatment of an AVM does not protect a patient from the risk of haemorrhage. There are reports of more devastating haemorrhage after partial treatment whether with radiosurgery (SRS) or embolisation.

Embolisation must be planned for a pati ent.[1,2,9,14,16,17,20,48,62,68,70,77,91] (Figs 3A to H) It can be: (1) definitive; (2) pre-SRS; (3) pre-surgery; (4) for remnant following microsurgery; (5) remnant following SRS; (6) targeted for intra-nidal aneurysm; (7) intra-operative embolisation followed by excision;[44] (8) targeted for other aneurysm (Guglielmi detachable coils)[18] and (9) targeted for headache.

Accessible small AVMs in non-eloquent brain with a single or multiple region of the cortical venous drainage, such as small right frontal or temporal AVMs, should surgically be excised unless there is a reasonable chance of cure with embolisation alone. A large AVM may be reduced in size by embolisation to make surgery easier.[37–39,57,93,101,103-105,110] Intra-operative angiography and magnetoencephalography are useful adjuncts.[45] Large AVMs, which are at higher risk, should be subjected



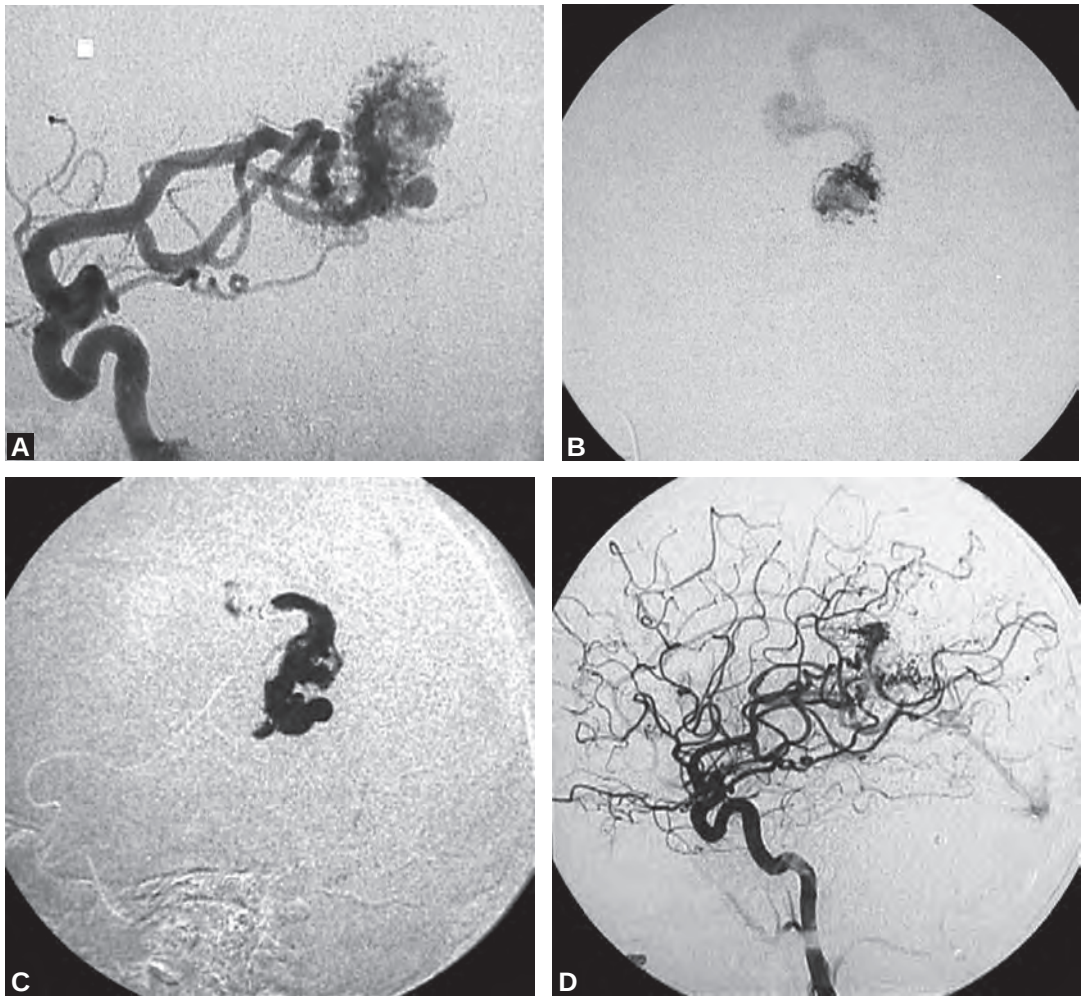
Figs 3A to H: (A and B) Lt ICA lat and AP pre. (C) Lt ECA lat Pre. (D and E) Lt VA lat and AP pre. (F) Superselective inj. (G) Lt ICA lat post. (H) Lt VA lat post

to targeted embolisation of "weak spots". A larger or deeper AVM, which is at a high risk of haemorrhage, may be treated by embolisation followed by SRS. The chance of cure with SRS is about 90% if the AVM is smaller than 3 cm in diameter. A large AVM may be reduced in size by embolisation so that it is amenable to treatment by SRS.[8,20,54,78,82,84]

EMBOLISATION

The ideal and curative treatment of AVM is to deposit liquid material like Histoacryl or Onyx inside the nidus.[22,25-27,46,67,73,102,105] If the glue is deposited in the feeding artery but not inside the nidus, it is useless, as collateral channels will recanalise the AVM immediately. Monitoring during embolisation (Figs 4A to D) is mandatory. EEG[71,83] and CSF pressure[47] have also been monitored during embolisation. Wada's test for eloquent brain is done by injecting amobarbital. Around 30 mg of amobarbital is injected through a microcatheter. If there is loss of function, embolisation is not done. Since there are false negative results, Wada's test has been abandoned. Glue is injected only if the microcatheter is within the nidus.[56,61,66,69]

For curative treatment, the entire AVM nidus including the proximal part of the draining veins must be filled with glue. Absolute alcohol has also been used for complete obliteration of the AVM.[108] Pre-operative embolisation can be with liquid embolic materials like Onyx or Histoacryl or with particulate materials such as polyvinyl alcohol (PVA), "cocktail" of PVA, absolute alcohol and Avitene, hydrogel particles,[27,75] or small pieces of surgical silk.[87] Balloons and liquid coils are useless as they only occlude the parent artery. Collateral vessels take up the supply immediately. Although the cast of glue is hard it can be easily cut with microscissors. Casts of Onyx have been found to be softer than



Figs 4A to D: AVM and intra-nidal aneurysm. (A) Lt ICA lat showing Lt parietal AVM with small posteroinferior aneurysm. (B) Superselective angio. (C) Inj of glue. (D) Post-embolisation lat view: aneurysm obliterated, small residual nidus treated by SRS

those of Histoacryl. If the AVM is large, embolisation is staged to forestall "break-through bleeding" described by Spetzler.[89] For pre-operative treatment the gap between the two procedures should be about 1 week. For definitive or pre-SRS treatment, sessions should be about 4–6 weeks apart. Pre-SRS embolisation must be with glue as particulate matter always gets absorbed and parts, which may appear to be obliterated, reappear after some weeks. Even in the best of hands, only about 35% of AVMs can be obliterated by embolisation alone. Large AVMs require multiple sessions several months apart. Angiogenesis has been reported after partial embolisation.[97] Animal models have been developed to perfect the technique of embolisation.[4,5,34,76]

The incidence of cure by radiosurgery is about 90% for small AVMs. It falls off to 70% for large AVMs.[8,20,78,82,84] Larger doses are associated with radiation necrosis. Multiple sessions of segmental SRS have recently been suggested. DSA must be done to document obliteration after SRS. Post-operative DSA is mandatory to confirm total excision, because the risk of haemorrhage persists even if there is a small remnant.

Technique

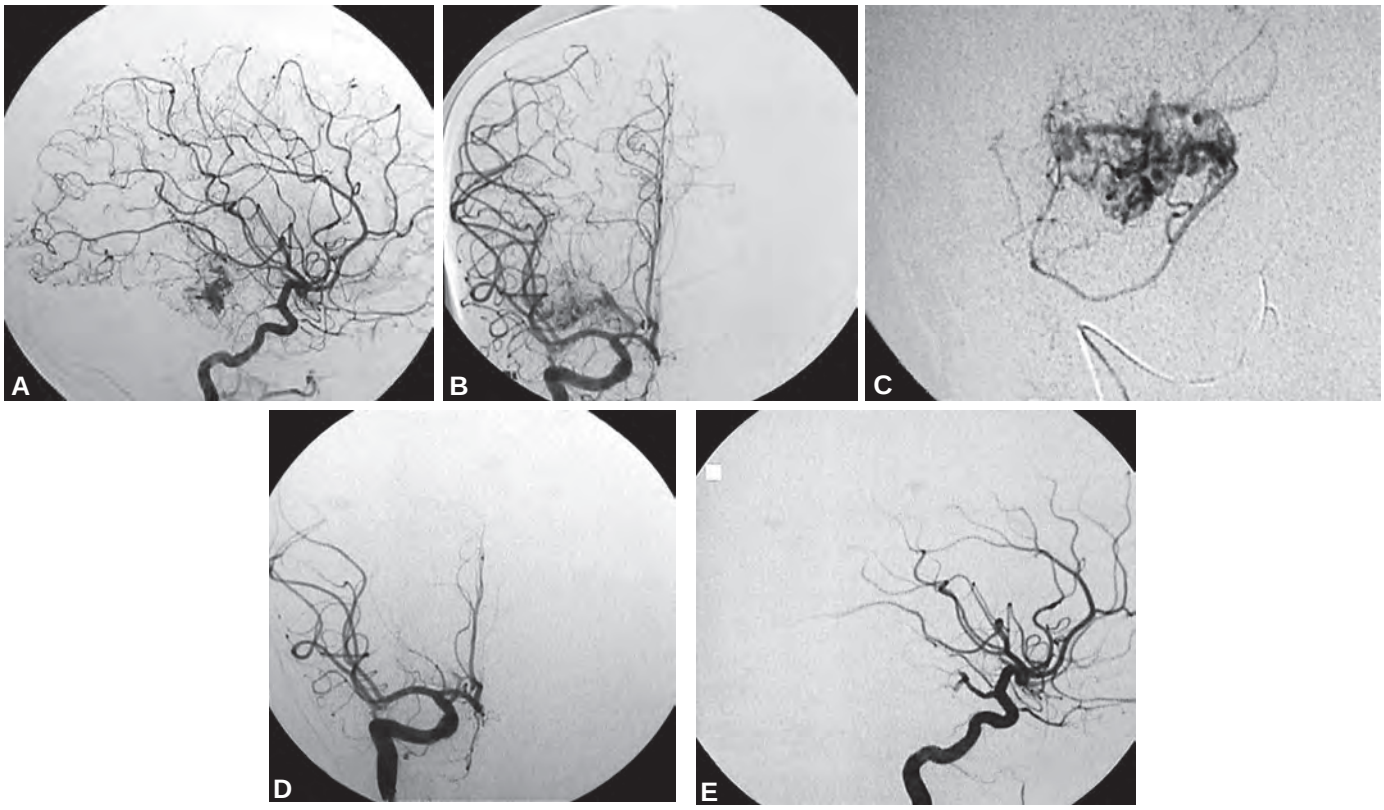
Every procedure must be planned meticulously. Simultaneous bi-plane road mapping is ideal because a true idea of the progression of glue can only be had by visualisation in two planes. Embolisation is done under general anaesthesia as the patient must be immobile for good road mapping. The transfemoral route is chosen. Rarely, especially for the left carotid artery, direct cervical puncture of the ICA may be necessary. For vertebral artery the brachial route is rarely chosen. A large lumen guiding catheter is placed in the appropriate artery.

Angiography is done at a rapid rate and in various projections. The two best projections for visualising the feeding artery and the nidus are chosen as the working positions. Under roadmapping, the microcatheter is navigated across the parent vessel into the nidus. Supple catheters of variable inner lumen and suppleness (3F, 2F, 1.8F, 1.5F or 1.2F), like the Magic (Balt SA) or UltraFlow (MIS, USA) are navigated by torque and taking advantage of flow dynamics. Catheters, such as Spinnaker (Boston Scientific), Renegade (Boston Scientific), Prowler

(Cordis), can be navigated only over guide wires. Even for supple catheters, after the first one or two segments have been embolised, the feeder becomes small and the catheter cannot be guided by flow alone. Fine, shapeable, platinum guide wires, such as Agility (Cordis), Transcend (Boston Scientific), Quicksilver (MIS), are used to navigate difficult, tight bends. Glue (Histoacryl, N-butyl-2 cyanoacrylate)[42,56,61,69,101] hardens as soon as it comes in contact with contrast, blood or saline. Adding Lipiodol, which also makes it visible, as the latter is radio-opaque, changes the polymerisation time (Figs 5A to E). If the flow is slow and there is a compact nidus, 20% glue (1 part glue : 4 parts lipiodol) is injected slowly over several minutes. If the flow is rapid, more concentrated glue, 33% or 50% is injected. If there is an associated AVF (which can be recognised when the microcatheter crosses from the artery to the draining vein), 90–100% glue is injected. It is made radio-opaque by adding tantalum powder. The glue is injected under road mapping.

The arterial supply to the nidus may be of two types: (a) End supply—The artery ends in the glomus of the AVM and (b) "En-passage". The artery goes on to supply the normal brain and gives off feeders at right angles to the long axis of the artery. End type of supply is ideal for embolisation. Glue can be injected safely. For en-passage type, if glue is injected, there is a high risk of occlusion of a normal artery. For such lesions liquid coils are injected into the arteries beyond the AVM. Once the arteries are occluded glue can be safely injected. Occluding arteries using coils proximally is safe because the pial network takes over immediately.

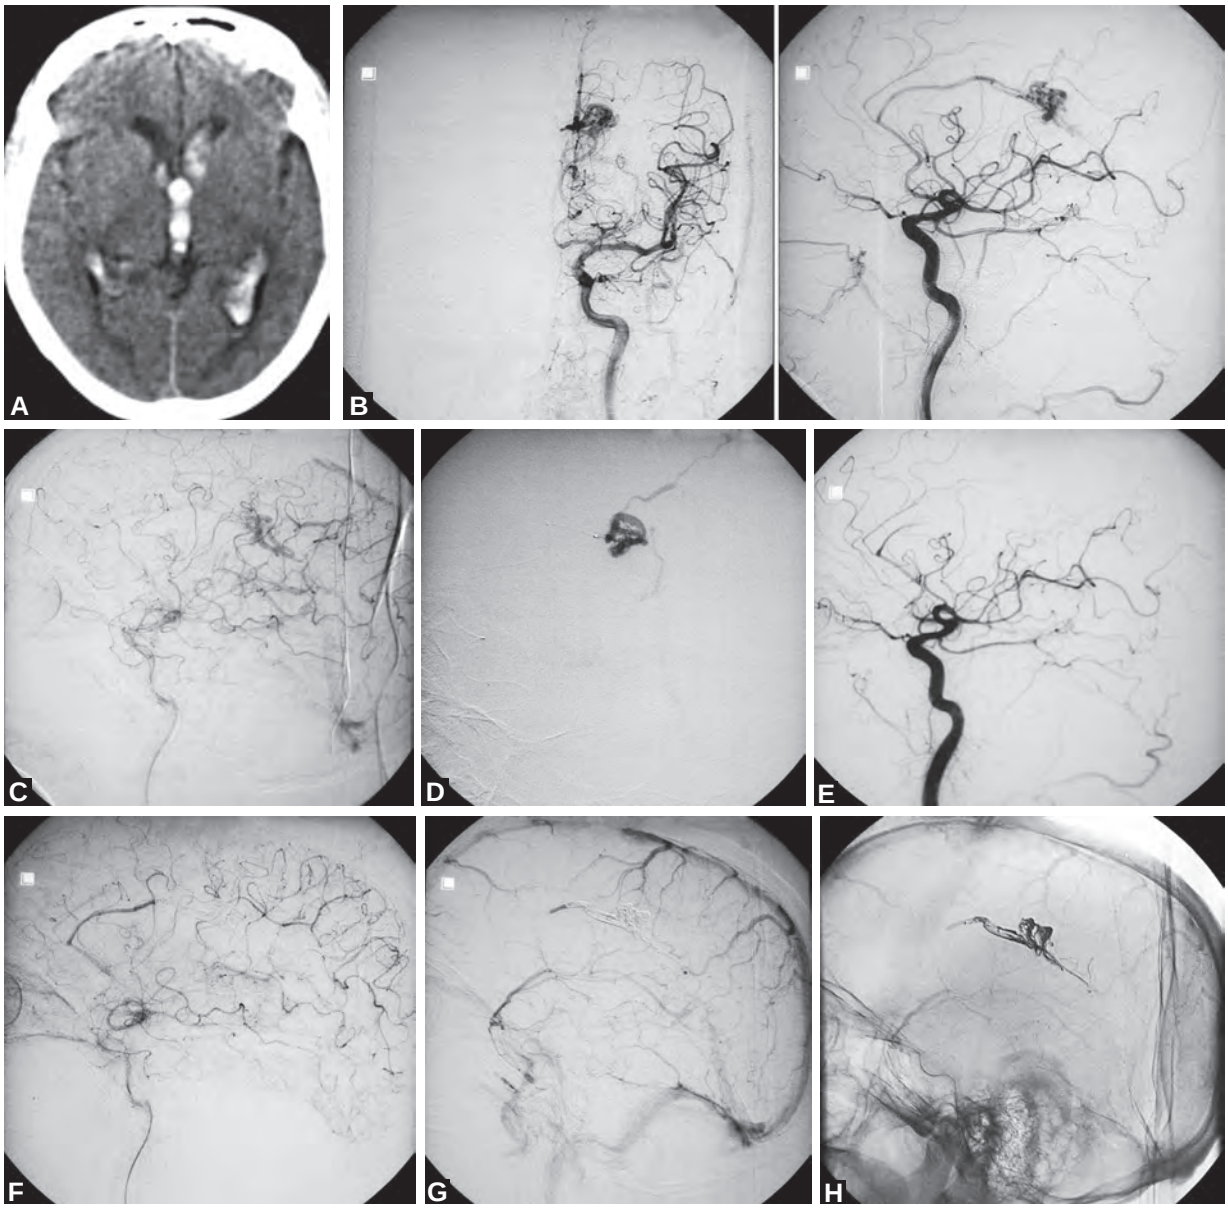
For good filling of the nidus, blood pressure may be lowered by injecting esmolol and venous pressure raised by performing the Valsalva manoeuvre during the injection. The aim is to enter the nidus and inject glue, filling the AVM from the draining vein backwards across the nidus to the feeding artery. If the vein gets occluded and the nidus escapes, there is a high risk of rupture. A large part of the AVM should be quickly embolised to prevent catastrophic haemorrhage. The microcatheter has to be pulled brutally at the conclusion of the injection lest it gets glued. Every interventionist has had catheters glued in different arteries, usually without any grievous consequences. For intra-nidal aneurysms, 50% glue is usually injected. In a single sitting 3–4 segments of the nidus may be embolised. The end points are change in the haemodynamics with slowing of passage of contrast across the nidus. If a high flow AVF has been obliterated, there may be considerable slowing with risk of venous thrombosis. If there is venous stasis, prophylactic anticoagulation with low molecular weight heparin is advisable. Whether to treat an associated aneurysm is a controversial subject. Aneurysm on the parent artery close to the AVM, or an aneurysm of the circle of Willis must be treated first whether by GDC technology or by surgery, as it may rupture after the AVM has been treated. Small, flow related aneurysms



Figs 5A to E: Small deep temporal AVM. (A and B) Pre-embol ICA. (C) Superselective. (D and E) Post-glue lat and AP

on the feeding artery, remote from the AVM, might be kept under observation. These usually regress after the AVM has been obliterated.

Onyx is the other liquid embolic agent used in the treatment of brain AVM. Onyx is ethyl-vinyl-alcohol-copolymer which is dissolved in a solvent called dimethyl sulphoxide (DMSO). After the microcatheter, which must be DMSO-compatible, is in position in the AVM nidus, it is flushed with 10 ml of normal saline to wash out the contrast. Onyx 18 is injected into a compact nidus and Onyx 34, which is more viscous, into high flow AVMs and direct A-V fistulas. Onyx has to be mixed in the solvent by placing it in a special mixer for at least 15 minutes before it is injected. In large high flow AVMs, initially, Onyx 34 is injected. This is followed by Onyx 18. One vial of Onyx contains 1.4 ml and in a single sitting a maximum of 3–4 vials may be injected. The technique of injecting Onyx is different as can be understood from the illustrations [Figs 6(A to H) and 7(A to H)]. Injections often last up to 45 minutes to an hour. There is a high risk of haemorrhage if the catheter is pulled under some circumstances. If the injection lasts for more than an hour and if the feeding artery is small and tortuous, and reflux into the microcatheter is more than 1.5 cm, the microcatheter is not removed. It is cut in the groin and left behind. Sonic catheter from Balt has a detachable tip 2.5 cm from the tip. This catheter can be removed even if there is a reflux. CT scan is done immediately after the embolisation to rule out haemorrhage. If a large part of the AVM has been embolised and there is a significant change in the haemodynamics, the patient is paralysed and ventilated for 24–48 hours, with mean blood pressure lowered by 10 mmHg to prevent break-through bleeding. If there is large haematoma it may need to be surgically evacuated. SAH or a small haematoma is treated conservatively. The cure rate with



Figs 6A to H: (A) NECT brain shows extensive intraventricular haemorrhage. (B and C) Lt ICA lat and AP pre. (D) Superselective inj. (E to G) Lt ICA lat post. (H) ONYX cast

Onyx has gone up to 50% for moderate and large sized AVMs and 100% for small AVMs. The risk of haemorrhage is also higher and is about 8–10%.

Curative Embolisation by Injecting Glue or Absolute Alcohol

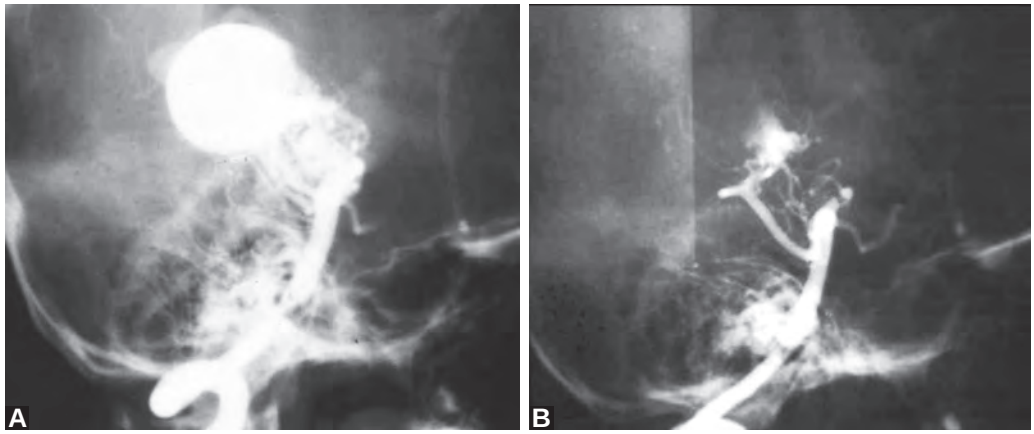
Not more than 30 ml alcohol should be injected in one sitting as there is a high risk of alcohol intoxication. Only about 35% of AVMs can be cured by embolisation alone. The rest need supportive treatment with SRS or surgery.

Following embolisation of large AVF, or large high flow AVM, the patient must carefully be monitored for "break-through bleeding" and haemorrhagic venous infarction due to venous stasis. After treatment of pial AVF in children and vein of Galen (VOG) malformation (Figs 8A and B), patients are electively ventilated for 48 hours and their blood pressure controlled with infusions of nitroglycerin (NTG), nitroprusside or esmolol to prevent bleeding.

Selecting Sections Judiciously for Pre-SRS Embolisation

Ideally, concentric peripheral embolisation should be done so that the remnant central homogeneous segment can be treated adequately. Sector embolisation also is recommended so that planning for SRS is easy [Figs 9(A to I), 10(A to F) and 11(A to G)]. If central embolisation is done, small peripheral islands make planning difficult. Also radio-opaque glue interferes with proper target localisation.

Pre-surgical embolisation can be done with glue, Onyx or particulate matter. Ideally, the less accessible deeper feeders from perforators should be targeted. However, these are difficult to catheterise because they are small and tortuous. Cocktail, surgical silk or PVA particles are injected slowly with intermittent contrast injections to monitor the progress.[59] The end point is when adequate slowing has been obtained or the AVM has been partially or largely obliterated. If the AVM is large, pre-operative



Figs 8A and B: Large vein of Galen malformation. (A) Before. (B) After embolisation using silk

sessions may be spaced a week apart. Surgery should be carried out within 1 week of embolisation as there is a risk of recanalisation.

Targeted embolisation for intra-nidal aneurysm is by injecting glue into the aneurysm and the parent artery. Every effort is made to inject into the AVM downstream. If the nidus is at some distance from the aneurysm, only the latter is targeted.

Targeted embolisation for aneurysm on the circle of Willis or on the proximal feeding artery is done using GDC technology. The aneurysm is tightly packed with platinum coils.

Embolisation for headache is confined to the feeders from the external carotid artery (ECA). Particulate matter in the form of PVA is usually used.

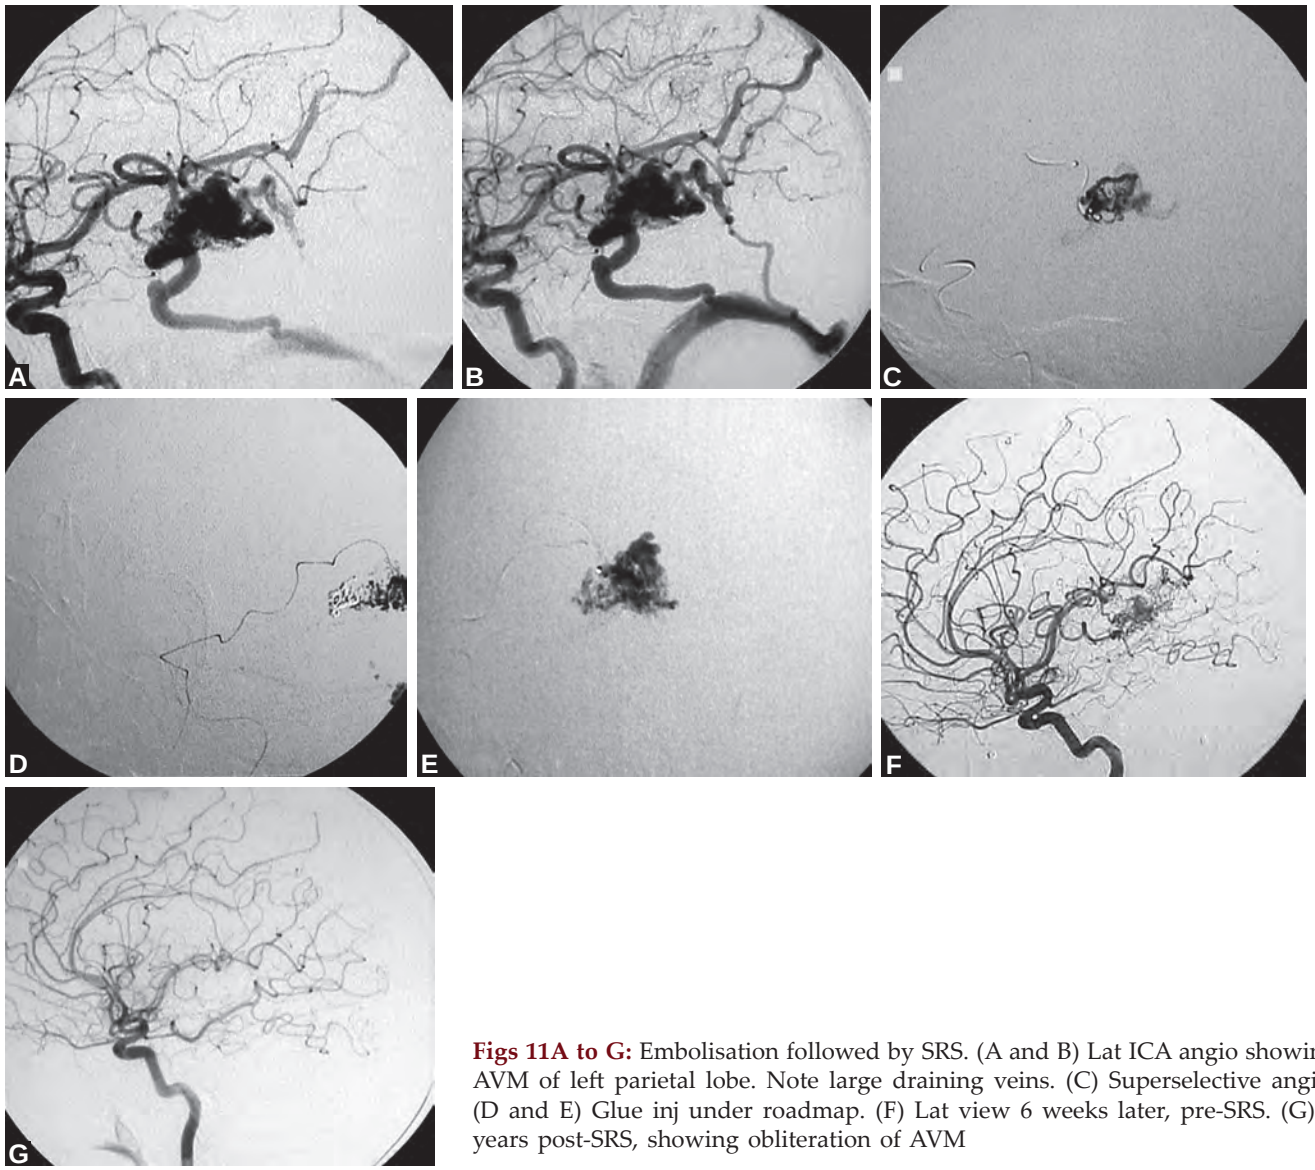
Following embolisation there may be a reduction in the incidence of epilepsy and headache. There are several reports that partial treatment offers protection against haemorrhage.[61] On the other hand, there are several reports of devastating haemorrhage after partial treatment.

COMPLICATIONS

Complications could be technical with or without any neurological sequelae. They can be neurological without any technical complication.[74]

Technical Complications

Technical complications are: (1) failure to reach nidus; (2) perforation of artery by catheter or guide wire; (3) spasm; (4) occlusion of normal branch by thrombus; (5) glue injection into normal artery; (6) passage of glue into a normal cortical or deep vein, a dural venous sinus



Figs 11A to G: Embolisation followed by SRS. (A and B) Lat ICA angio showing AVM of left parietal lobe. Note large draining veins. (C) Superselective angio. (D and E) Glue inj under roadmap. (F) Lat view 6 weeks later, pre-SRS. (G) 2 years post-SRS, showing obliteration of AVM

or the lung;[5,6,31,53] (7) catheter getting glued and breaking off; (8) catheter getting stuck in a small artery due to vasospasm; (9) perforation of microcatheter because of forceful injection; (10) rupture of missed small aneurysm; (11) occlusion of feeder without glue reaching the nidus and (12) occlusion of the draining vein without obliteration of the nidus.

Haemorrhage[3,32,41,61,65,92] and ischaemia are the two major complications. Glue should never be injected remote from the nidus. Glue should be injected only with the microcatheter inside the nidus. Rate of flow through the AVM should be estimated as accurately as possible. A careful analysis has to be made by making several injections into the microcatheter to evaluate flow to ensure adequate filling of the nidus. The concentration of glue can be varied according to the rate of flow. For low flow nidus, lower concentration of 20–25% is used, for high flow 50%, 66%, 90% or 100% glue is injected. Careful planning will prevent erratic embolisation and occlusion of normal arteries and veins. However, all estimates may be wrong as glue is more viscous than contrast and glue may pass to the venous side, occlude the feeder without passing to the nidus, or bypass the nidus and reflux to occlude a normal artery. Perforation of an artery can be a disaster, and should be quickly recognised.[15] Small perforations may be of no consequence and may be missed. These may be recognised only on post-operative CT scan. Injecting glue or depositing coils, after quickly neutralising the circulating heparin, closes larger holes. Breakage of catheter is usually of no consequence. Anybody who does interventions will have catheters broken from time to time. These catheters are left alone and need not be removed as they get endothelialised. In fact one may be able to go back into the same artery and embolise despite the presence of the catheter fragment in the lumen. Perforation of a catheter occurs at junctions of different segments, 3F–2F or 2F–1.8F because the supple catheter can get kinked. If force is used when there is resistance to injection of contrast, the catheter ruptures without any consequence. However, it is disastrous if it ruptures proximal to the tip during the injection of glue. Spasm occurs when

one is not gentle in manoeuvres and when catheters are reused. Spasm gets relieved if one just waits for 15 minutes. Sometimes, vasodilators, like papaverine, NTG or priscol, may relieve spasm.

Neurological Complications

Death may occur if a major artery or vein, such as the vein of Galen, is occluded. Rupture of a large artery or aneurysm may cause catastrophic haemorrhage and instantaneous death.[7] Neurological deficit may occur due to occlusion of a normal artery or vein. Sometimes, there may be oedema or inflammation around the glue.[81] The deficit would depend on the territory being treated and may vary from a minor deficit to major irreversible hemiplegia or aphasia. In the best of hands this is reported at 15%. If treatment is carefully planned, the risk of complications can be reduced.

CONCLUSION

Large Grade VI AVMs should be left alone except for targeted embolisation. Grade IV and V AVMs should be treated if they are at risk of haemorrhage. Targeted embolisation should be done for Grade IV and V. Grade I should be surgically excised. Grade II and III AVMs should be treated on merit, be it embolisation, embolisation combined with surgery or SRS. Grade IV and V can be treated by combining embolisation with SRS. Small remnants after surgery can be treated by embolisation or SRS. Small remnants after embolisation or SRS can be excised. Small remnants after SRS can be retreated by SRS, if safe, excised or embolised. Embolisation with Histoacryl and Onyx is permanent.[43] Particulate matter, like PVA, silk or cocktail, is not recommended, except as a pre-surgical procedure, as they get reabsorbed.

94 Stereotactic Radiosurgery for Cerebral AVMS

Ganapathy K

And when the child was grown it fell on a day
That he went out to his father to the reapers
And he said to his father—my head, my head.
And he said to a lad, carry him to his mother
And when he had taken him, and brought him,
To his mother, he sat on her knees till noon,
And then died

—Old Testament II Kings

HISTORY

The earliest reference to a possible intracranial haemorrhage is in the Old Testament. Cerebral arteriovenous malformations (AVMs) as such were, however, first studied and classified in 1854 by Luschka and Virchow. Giordano surgically exposed an AVM in 1890 while an actual excision of an AVM was done in 1932 by Olivecrona. Radiation was considered as a treatment option in the management of cerebral AVMs by Cushing even 80 years ago. To use Cushing's own words "Nevertheless, when first exposed, the lesion was still highly active and the subjective improvement experienced by the patient from his *radiotherapeutic seances* was such that he persisted in having treatment given, in excess possibly of what we would have ventured to advocate. The result has been described, namely the disclosure at the second operation three years later of a particularly avascularised tumour".[13] Several decades later, radiotherapy was still a treatment option in the management of AVMs.[106,135]

In the 1950s, Leksell, and later Larson, conceived the idea of using stereotactically guided external radiation to produce a predictable irradiation effect at an accurately defined intracranial target.[72,73] After extensive experimentation, he developed the first generation cobalt gamma unit in 1968. He called the technique "Radiosurgery". One of the early reports on the use of stereotactic radiosurgery (SRS) for an AVM with the gamma knife was that of Steiner.[123] The earliest reports on the use of heavy charged particles as a method of radiosurgery for AVMs were in 1983.[18,66,67] Subsequently, there were a few more reports, but charged particle radiosurgery for AVMs is no longer routinely carried out.[112,120-122,127] Betti and Colombo pioneered the use of Linac based radiosurgery in the management of cerebral AVMs.[7,11]

The first publication on the use of SRS for cerebral AVMs from South Asia was from Ganapathy.[30] Several publications on SRS highlighting the Indian experience in the management of cerebral AVMs are now available.[31,33-35,114] To keep this treatment cost effective, without compromising standards of excellence, is a particularly challenging task, especially in a developing country. The fifteen-radiosurgical units presently available in India cater not only to more than a billion Indians but also to several hundred million from the adjacent countries. This results in different referral patterns, different standards in pre-treatment diagnostic imaging and work up, heterogeneous clinical presentations and problems in obtaining post-treatment imaging studies. Working in this milieu, the first SRS procedure in South Asia was carried out by the author on May 30, 1995. In a short span of 12 years, more than 1,500 cases of cerebral AVMs have been treated with SRS throughout India. Several reports are available on the successful use of Linac assisted radiosurgery, the gamma knife and the cyberknife[117] in the management of cerebral AVMs.[5,11,29,30,55,64,78,80,83,125,126] Several articles have compared the efficacy of SRS vis-à-vis microsurgery.[42,74,98,105]

INTRODUCTION TO STEREOTACTIC RADIOSURGERY

Stereotactic radiosurgery refers to the method of delivering a single high dose ultra precise radiation (8–15 times that of a single conventional dose), that is about 12–25 Gray (1,200–2,500 Rads), to a well-defined lesion, using fixed stereotactic reference points. Biological effects produced by radiosurgery range from blood vessel thrombosis to reproductive cell death and frank necrosis within the treatment volume. Recently, it has been shown[128] that the endothelium of AVMs has different molecular properties and that these inflammatory molecules may be biologically relevant in the response of vascular malformations to radiosurgery and embolisation. Initially, radiosurgery was advocated for patients not suitable for open surgery. With refinements in technique and long-term follow-up data, radiosurgery is on its way to becoming the treatment of choice rather than a choice of treatment. The source of radiation can be X-rays from a linear accelerator or cyberknife, gamma rays from a cobalt unit (gamma knife) or charged particles. The

source of radiation (cobalt or X-rays) does not appear to make a significant difference.[80,93] The revolution in medical imaging in the last two decades has provided sophisticated target definition. Stancanello[117] has used functional magnetic resonance imaging (fMRI) to identify specific regions which can be considered as "functional organs at risk" (fOARs), In five cases of cerebral AVMs, consideration of the fOARs allowed quality indices of treatment plans to improve in four cases compared to plans with no consideration of fOARs. Integration of functional information into AVM radiosurgery may help further to minimise undesirable side effects.

Phenomenal advances in computer applications and better understanding of radiobiology have also resulted in the increasing use of SRS. The practice of radiosurgery demands a good knowledge of neuroimaging. Understanding the radiobiologic effects of high dose irradiation is essential. Proficiency with stereotactic techniques and computer literacy are mandatory. Equally important is a thorough knowledge of alternative treatment modalities.

Advantages of Radiosurgery in the Management of Cerebral Arteriovenous Malformations

- Safe, post-treatment complications far less than in open surgery.
- Complications are usually transient, mild and reversible.
- No procedure related mortality.
- Minimal or no hospitalisation is required.
- No post-treatment convalescence.
- Pre-treatment activities can be resumed immediately.
- No procedure related risk of infection or bleeding.

Disadvantages of Radiosurgery in the Management of Cerebral Arteriovenous Malformations

- Not suitable for all cases.
- Total obliteration only in 60–80% of cases.
- Risk of haemorrhage till obliteration occurs.
- 15–36 months waiting period.
- Limitations and difficulty in post-treatment assessment.
- Not freely available.
- Considerable expertise and infrastructure required.
- Extremely rare cases of delayed complications like cyst formation,[43,52] haemorrhage even after angiographically demonstrated total obliteration[3,87] and radionecrosis have been documented.

DECISION-MAKING IN RADIOSURGERY

When a non-invasive, safe, high-tech procedure is available, there may be a tendency to be liberal in using the technique.[32] It is essential that injudicious applications do not detract from an otherwise elegant technology. Though the facility is available in India at a reduced cost (compared to international costs), it is still not inexpensive. The minor details of the procedure have to be discussed frankly with the patient, the relatives and the referring doctor, preferably with photographs. Too often, due to the hype in the media, there is an unrealistic expectation on the part of all concerned. It has to be clearly mentioned that the primary purpose of treatment of a cerebral AVM is to reduce the chances of a disastrous haemorrhage. Comprehensive, up-to-date knowledge of the long-term natural history of the AVM is imperative. Radiosurgery is a rapidly evolving subspeciality where indications keep changing.[101] Familiarity with current published literature in peer-reviewed journals is obligatory. This alone will ensure the use of rigid criteria for selecting patients. An inadvertent bias in the use of SRS should be avoided. Radiosurgery should be withheld if the natural history of the untreated lesion is likely to be more benign than possible delayed morbidity due to radiosurgery. SRS is not a procedure to be used with impunity. Although anecdotal, and not statistically significant, long-term follow-up has revealed insignificant and significant radiation induced changes at the site of the obliterated AVM. Considerable thought, therefore, has to go into every decision before advocating SRS for an AVM. This is particularly important because there is no procedure related mortality and morbidity, if it does occur, is delayed. SRS is not a fancy sophisticated tool to be used when nothing else can be done or as a desperate salvage measure. The argument "that there is no proof that it is not useful, so why not try it out" is unacceptable and must be resisted. In India, where medical insurance is still not freely available, the economic factor also has to be taken into account. In the author's experience, AVMs have constituted the single largest indication (about 60%) for radiosurgical procedures. It may take 18–24 months to achieve total obliteration of the nidus. Total obliteration has been reported as early as 12 months and as late as 60 months. Till such time as complete obliteration takes place, the patient continues to run the risk for haemorrhage, though some reports suggest that the risk is less even with partial obliteration.[28,62,102] It follows that when the risk of haemorrhage is more, e.g. a patient who has already bled twice or more open surgery is preferable if the attendant morbidity is acceptable.

Technical suitability for SRS should not be the only criteria for carrying out a radiosurgical procedure. Morbidity following SRS is related to the location and size of the nidus. A preliminary embolisation may be necessary to reduce the size of the nidus.[14] Since most AVMs occur in the younger age group, there is a significant risk of haemorrhage over a period of time. Hence, when suitable for SRS, there appears to be no justification now, for so-called "conservative management".[92] Since considerable data and long-term follow-up are available with the use of different modalities of treatment for different types of AVMs, decision-making can be based on scientific facts.[50] Mathematical models to predict patient survival rates in microsurgery and in radiosurgery have been designed and these are useful in logical decision-making.[42]

RADIOBIOLOGICAL EFFECTS OF STEREOTACTIC RADIOSURGERY ON ARTERIOVENOUS MALFORMATIONS

Though more than 16,000 SRS procedures have been performed worldwide to treat cerebral AVMs, the underlying histopathological process leading to obliteration of the nidus is still open for discussion.[110] Inflammatory proteins in the endothelium of AVMs may play a role in the pathophysiology of cerebral AVMs and their response to radiosurgery.[128]

The underlying goal of treatment of AVMs by using high dose focused radiation is to induce an inflammatory response in the vessel walls that will result in a permanent thickening of pathological vascular channels, leading to thrombosis. AVMs are hamartomatous lesions of the brain resulting from embryogenic maldevelopment. They are histologically composed of a parenchyma with abnormal vessels embedded in a connective tissue stroma. The ionising radiation delivered by radiosurgery probably induces proliferation of spindle shaped cells in both the sub-endothelial region of the vessel wall and connective tissue stroma. According to the immunohistochemical and ultrastructural characteristics, these proliferating spindle cells are probably myofibroblasts. The contractile capacity of myofibroblasts might explain the shrinkage of AVMs after irradiation.[130] Connective tissue stroma alterations may play an important role in the shrinking process. The most characteristic pathological feature of the necrotising radiation is the occlusion of most of the small vessels within the targeted zone, leading to a coagulative necrosis of all tissue elements. The vessels of the AVM are thickened and fibrosed and the majority are occluded by connective tissue over several months. Thickening of the walls of the abnormal vessels was shown by histological analysis.[91] Autopsy studies have revealed radiation-induced changes following SRS even in arteries unrelated to the nidus.[140] More information is now available on the radiobiological effects of SRS on AVMs[1,15,71,77,79] including the use of radiation sensitisers on brain and blood vessels using primate models.[125] Gamma linolenic acid has been used in clinical trials as a possible radiation sensitiser, but with disappointing results.[113]

CLINICAL PRESENTATION

Haemorrhage (more common in smaller AVMs,) is the commonest presentation of an AVM (Fig. 1). However, in the author's experience, more cases of AVM were referred for SRS before they had bled. This is in contradistinction to the Western literature.[12,69] Seizures are more common in larger AVMs. Other clinical presentations include headache, behavioural changes or progressive neurological deficit. The mortality could be as high as 10% in the first bleed, 13% in the second and 20% in the third episode. There is a 25% risk of rehaemorrhage in 4 years after the first bleed.[26] With increasing awareness and availability of CT and MRI, AVMs are increasingly being diagnosed before they rupture.

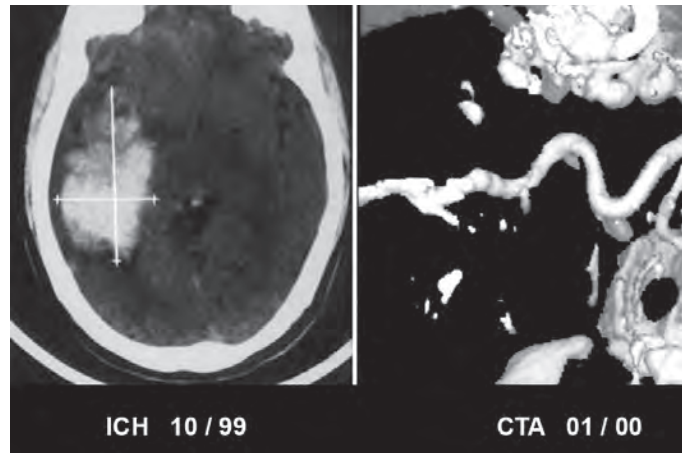

Fig. 1: CT scan showing intracerebral haematoma and CT angiogram demonstrating AVM

Investigations

Plain CT is insufficient. Double dose contrast with 2 mm slices in the region of interest is often diagnostic. Plain MRI with flow void signals and magnetic resonance angiography (MRA) are also suggestive of an AVM. CT angiography (CTA) is very informative, particularly in identifying associated arterial aneurysms. Invasive four vessel superselective angiography not only confirms the diagnosis of an AVM but also gives valuable information regarding the arterial supply, the venous drainage, presence of coexisting aneurysms, arterial and venous, and details of the nidus (Fig. 2). With increasing refinement and availability of 64 slice CT angiography even DSAs are being dispensed with for treatment planning of cerebral AVMs.[36] (Fig. 1) During the last 18 months, in 35 cases of cerebral AVM, the author has dispensed with DSA by using 64 slice CTA. Transcranial Doppler has also been used for screening and follow-up.[6]

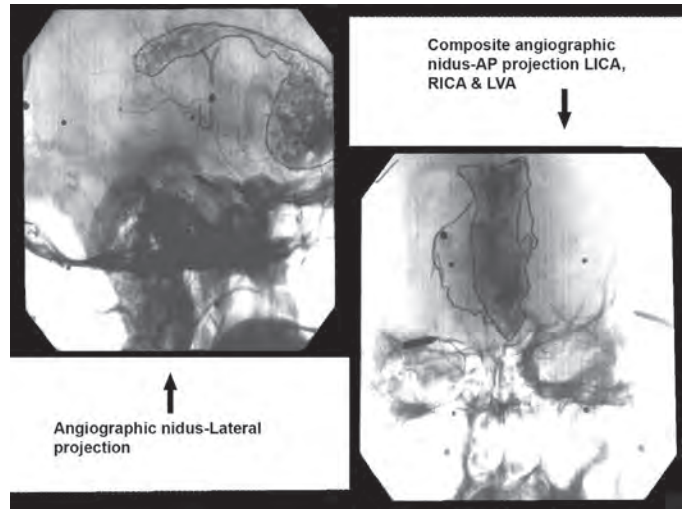

Fig. 2: Complex giant corpus callosum AVM

STEREOTACTIC RADIOSURGERY FOR CEREBRAL ARTERIOVENOUS MALFORMATIONS: THE PROCEDURE

SRS should be carried out only in a tertiary care referral centre. Well-equipped departments of imaging sciences and radiotherapy with medical physicists familiar with 3D treatment planning are a prerequisite (the latter if a Linac based system is used). The author reviews with the patient, before the procedure, the various steps showing photographs so that the patient knows exactly what to expect. An informed consent is obtained, wherein the absolute necessity for follow-up imaging studies is emphasised. The advantages and limitations of the procedure are clearly documented. Prophylactic steroids and anticonvulsants are at present no longer used as a routine. Baseline sedation with oral diazepam a few hours before the commencement of the procedure is sometimes resorted to. Occasionally, supplementary sedation may be necessary. Requirement for general anaesthesia is exceptional. In the case of patients who have already undergone open surgery, the neurosurgeon should palpate the craniotomy site and have a precise knowledge of the exact location of the burr holes or skull defect. Earrings, nose rings and even kumkum (a mark worn by Indian women on the forehead) are best not worn during the procedure. Even makeup, particularly eyeliners, sometimes produces artefacts on the MRI. The patient is instructed to keep the eyes closed all the time while undergoing CT or MRI scanning. Movement of the eyes can produce subtle changes in the position of the optic nerves. The patient gets admitted on the day of the procedure and is discharged the same day or the next day.

Step 1—Fixing the Frame

The stereotactic base ring is fixed with the patient in the sitting position. Shaving of the head is not required. Reusable screws (kept in Lysol or gas sterilised with ethylene oxide) can be used. The exact location of the screws and angulation of the base ring is crucial. The base ring has to be kept in position for periods varying from 4 to 6 hours. Hence, the screwing has to be done tightly into the inner table. The exact level at which the base ring is finally positioned would depend on the site of the lesion. The top of the ring should be at least 10 mm below the bottom of the lesion and at least 30 mm below the centre of the lesion. The artefacts produced by the screws should, therefore, be above or below the target volume (AVM). This requires considerable care. The screw is then inserted through the opening until a purchase is obtained on the inner table. When the angiographic localiser frame is used, the screws should be so positioned that as far as possible the nidus of the AVM is in the centre of the angiographic fiducials. In the future, frameless stereotaxy will be extended to radiosurgical procedures obviating this step.

Step 2—Computerised Tomography or Magnetic Resonance Imaging Data Acquisition

The CT or MRI localiser ring is placed over the base ring. 100 ml of meglumine diatrizoate (Angiografin) for CT or gadolinium for MRI is given rapidly as a bolus. One millimetre slices are taken from the vertex to the foramen magnum. MRI is desirable particularly when the optic chiasma/optic nerves/eighth nerve and other critical structures have to be identified with extreme precision. The images are transferred to the treatment-planning computer. The critical structures, like the brain stem, optic nerves and optic chiasm, are outlined besides the nidus.

Step 3—Angiographic Data Acquisition

The patient is positioned on the angiographic table so that the frame is in the centre of the table. The angiographic localiser ring is placed on the stereotactic base ring. A preliminary screening is done and fine adjustments made with the image intensifier and tube so that eight fiducial markers are seen on the PA projection and eight on the lateral projection. A four-vessel angiogram is done to ensure that different arterial systems contributing to the nidus are identified. The pictures are reviewed. The PA and the lateral picture, which displays the nidus best is chosen (Fig. 2). The nidus (the target volume) is outlined with a film marker in both the views. The images are transferred to the treatment-planning computer. Recently, with increasing availability of 64 slice CT and with the possibility of even a 256 slice CT, the use of DSA in treatment planning could progressively decline.

MRA has also been used for 3D treatment planning to identify the nidus.[17,129] Spatial distortion, if any, can be corrected[109] Stereotactic angiography alone may be an inadequate database for radiosurgery.[9,116] Blatt has pointed out that the angiographic nidus and the CT nidus may be different in as many as 75% of cases.[8] Image correlation of MRI and CT in treatment planning for radiosurgery of intracranial vascular malformations has also been done.[96] Sources of error in the angiographic nidus determination include overlapping vessels, bony structures, fine filamentous arterioles and irregular shapes. Accurate spatial representation of the nidus is essential to ensure its total coverage and to limit radiation to the surrounding brain. Treatment plans generated from the angiographic nidus interpretation need to be modified to conform to the CT nidus. Stereotaxic MRI and MRA has been used as an additional tool in defining the target.[39,40,69,108,129] Some authors believe that MRA permits semi-quantitative flow velocity assessment and may, therefore, be superior to stereotactic angiography.[95] Several attempts have been made to improve target volume definition in radiosurgery of arteriovenous malformations by stereotactic correlation of MRA, MRI, blood bolus tagging, and even functional MRI.[108] Estimation of the size of the nidus varies depending

on the imaging modality used.[90] Radiosurgery related imaging changes have been studied in detail.[21,23,141,144]

Step 4—Treatment Planning

The CT and MRI (if taken) images are studied. The anatomes (anatomical structures) normally contoured are the left and right eyes, the left and right optic nerves, the optic chiasma and the brain stem. Outlining these critical structures and the target volume (the volume to be irradiated) is the primary responsibility of the neurosurgeon. Before outlining the target volume, the entire imaging data available is studied including previous CT and MRI films. It is essential that a mental holistic 3D picture of the lesion be obtained. It is important that the clinician who outlines the lesion is familiar with vascular anatomy. Treatment planning differs depending on whether a gamma knife system is used or a Linac based system. It also depends on the specific equipment being used. In the earlier days, one or more collimators of appropriate size were chosen (Fig. 3). The author now uses the micromultileaf collimator system for ultra-conformal radiation. A set of radiation beams is devised so that all of them converge on the AVM. Their passage through critical structures (from entrance to exit) is avoided. The plans are studied and modified till the proper dose distribution within the target volume is obtained,—sparing critical structures and ensuring that the radiation dose outside the target volume is within 800 Cgy (Fig. 4).

The plan and the dose is finalised after a brain storming session. The neurosurgeon emphasises the pathology, the natural history of the lesion, the functional anatomy of the adjacent structures and the clinical status. The radiation oncologist takes into account the radiobiological effects and safety issues. This is particularly relevant if the patient has been irradiated earlier. The physicist is concerned with implementing the "prescription" and points out the technical issues in delivering the radiation. In several cases of AVMs, there may not be a perfect correlation between the angiographic nidus and the CT target volume. Considerable judgement and familiarity with the intricate details of different types of neuroimaging are required. Finally, each case will have to be judged individually and a decision taken. Optic radiation tractography based on diffusion tensor (DT) MRI has been integrated[85] into simulated treatment planning for gamma knife surgery. This appears to be a promising tool for preventing GKS-induced visual disturbances and headaches. Integration of time-resolved contrast-enhanced MRA into dosimetry planning has been reported by Taschner et al.[131]

Step 5—Treatment

The technical details of setting up a linear accelerator or the gamma knife unit are beyond the scope of this chapter. The actual treatment takes 30–60 minutes depending on the complexity of the AVM. After the radiation is completed, the frame is removed. The patient is kept under observation overnight and can resume normal activities the next day. Occasionally, the patient is discharged home after the procedure.

Procedure Related Complications

In the appropriately chosen patient and with meticulous attention to minute details, complications should be negligible. In the author's experience of 350 cases of AVMs treated with Linac based SRS, only one patient developed a procedure related major neurological deficit, which ultimately recovered. Fifteen patients,—all having grade III or IV Spetzler-Martin AVM,—developed mild neurological deficit, which responded to steroids and was totally reversible. Seizures occurred more often in the post-treatment period in AVMs than in other lesions. Hence, optimising anticonvulsant doses is essential, particularly in supratentorial AVMs. Alopecia, most often transient, occurred in a few cases in superficial lesions in the mid-nineties as part of the learning curve and

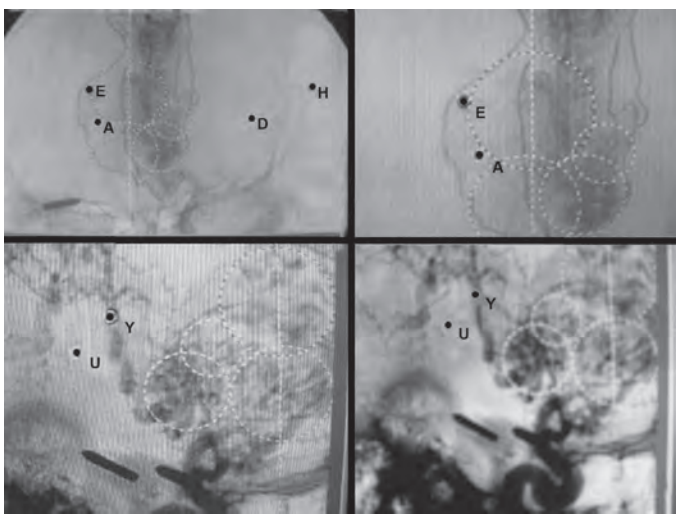

Fig. 3: Corpus callosum AVM—use of multiple collimators

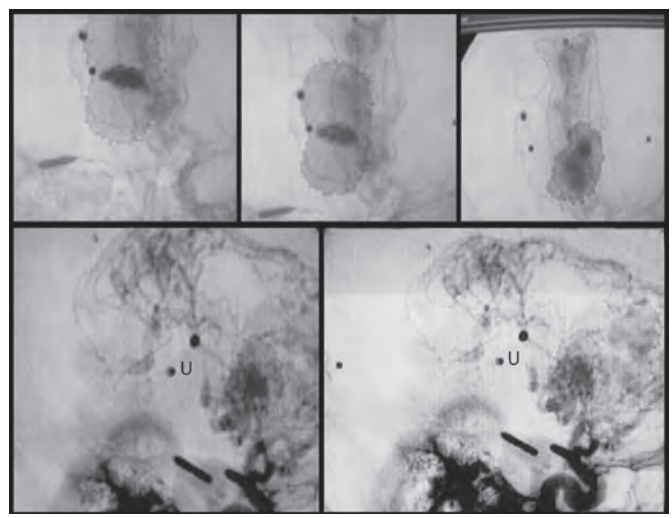

Fig. 4: Dose distribution of different portions of nidus

haemorrhage, while awaiting obliteration, occurred in 4% of cases (in the group where follow-up was available).

Follow-Up

In SRS for AVMs, unlike open surgery, results can be gauged only 12–24 and, sometimes, even 48 months later. The gold standard of successful treatment of an AVM is the angiographic demonstration of total obliteration of the AVM (Figs 5 to 9). A double dose contrast CT or MRI or CT angiogram is done initially after 12 months and then every 6–9 months. If the CT or MRI shows no nidus or is doubtful, an angiogram is done. If the CT or MRI itself shows a residual nidus, a repeat CT, CT angiogram or MRI is done later. The patient is advised angiography/64 slice CT angiography 3 years after SRS irrespective of the CT or MRI findings.

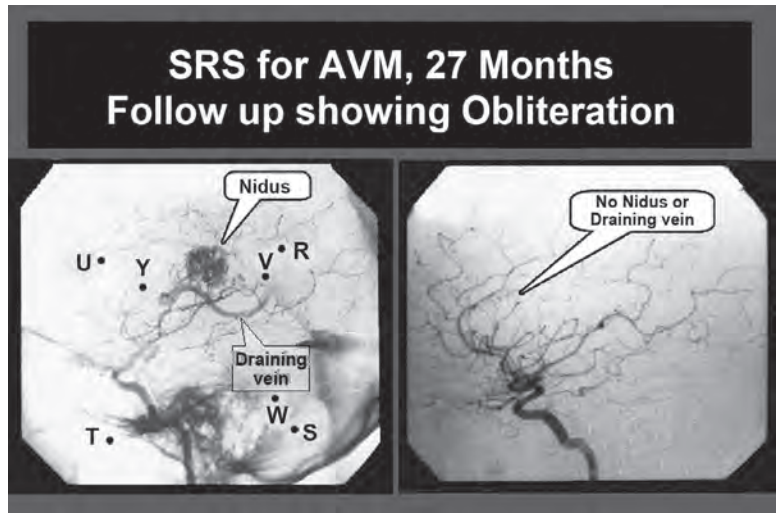

Fig. 8: Total obliteration following SRS

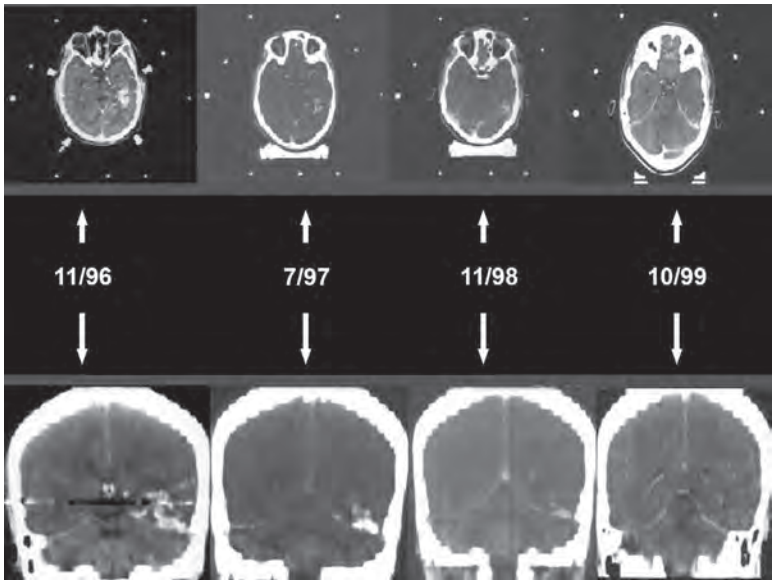

Fig. 9: Serial CT showing progressive reduction in nidus size

In the third world, where patients come from a very wide geographical distribution, including the neighbouring countries, post-treatment angiography in all cases will be difficult. Quisling et al. have used MRI to evaluate persistent nidus blood flow in cerebral AVMs following SRS.[107] In spite of the limitations, particularly in developing countries, post-treatment MRI evaluation will continue to offer some indirect evidence of "obliteration". The author, like Becker, has used transcranial Doppler in evaluating the size of cerebral AVMs. While it was useful in demonstrating lowered blood flow at the site of treatment, it was not possible to draw conclusions regarding the size and presence or absence of the nidus.[6] Heffez has stressed on the effect of incomplete patient follow-up on the reported results in the use of radiosurgery in the management of AVMs.[44] Long-term follow-up of 23 years following demonstration of complete angiographic obliteration is available.[65] Follow-up is advisable even after the treatment goal of obliteration has been achieved.

Embolisation Prior to Stereotactic Radiosurgery for Arteriovenous Malformations

Embolisation can be used as a preliminary procedure to reduce the size of the nidus and make it suitable for SRS.[2,14,41,97,99] Some authors question the value of pre-radiosurgical embolisation.[69] Embolisation is effective only if the arterial feeders contribute to the periphery of the nidus. Often, following embolisation, the blood supply is cut-off in different portions of the nidus making definition of the target volume difficult. If SRS is done immediately after embolisation, the target volume will not include portions of the nidus, which may form later following recanalisation. Presence of intranidal glue also makes outlining the target volume difficult in the CT and the MRI. The ideal time interval between embolisation and SRS is yet to be determined. Usually a 4–12 weeks' interval is preferred. Endovascular treatment of cerebral AVMs following radiosurgery has also been advocated.[84] The availability of Onyx has changed the concept of embolisation.[53,132,134]

Location

SRS is particularly suitable for AVMs located in eloquent areas. These include the post-geniculate visual pathway (to enhance the possibility of preserving visual function) and the brain stem.[10,70,86] In one series of 87 patients with brain stem AVMs, 95% improved or remained neurologically stable.[86] Re-bleeding occurred after SRS in three patients at 3, 6 and 16 months, respectively. The obliteration rate was 63% at 2 years and 73% at 3 years. A second SRS was performed in six patients with partial obliteration 3 years after the first procedure. The author has achieved total obliteration of giant AVMs following SRS in the brain stem and the corpus callosum. AVMs in the pineal region and the motor area are particularly suitable for SRS.[70,82] How the location influences the outcome is elegantly discussed by Kondziolka.[70]

Outcome

Two-year angiographic obliteration rates vary from 60% to 80%.[88] In some cases, the AVM is obliterated within a year. Several patients with a small remaining nidus, 2 years after treatment, were found to have complete obliteration at 3 years. Liscák[76] reported obliteration in 222 (74%) patients after the first round of radiosurgery and in 47 (69%) after the second. The risk of re-bleeding after radiosurgery was 2.1% annually until full obliteration and the overall mortality from re-bleeding was 1%. The risk of permanent morbidity after the first and the second radiosurgery treatments were 2.7% and 2.9%, respectively. Friedman has shown that the smaller the AVM the greater the chance of obliteration.[27] Some believe that even the smallest remnant of an AVM constitutes a risk of further bleeding.[38] Others are of the opinion that even partial obliteration offers some protection against the risk of haemorrhage.[60] There are no reports of haemorrhage occurring after angiographic demonstration of total obliteration.[75] Dose prescription and dose volume effects on the ultimate outcome have been studied.[24,81] SRS also appears to help control seizures.[19,37,49] The reduction of seizures was independent of angiographic results, suggesting that the ionising radiation by itself could lead to inhibition of epileptic activity around the AVM.[45] Headaches are a common symptom of cerebral AVMs, with a reported incidence varying from 3 to 79.2%. Headaches resolved or improved after SRS, the outcome correlating with the degree of obliteration.[47,133] Children, females and patients with deep-seated AVMs had a threefold increased risk of re-bleeding after an initial bleed. This increased risk was highest in the first year after the initial haemorrhage, and thereafter gradually decreased.[136]

Based on a prospective study of 72 patients with AVMs treated with microsurgery, Pikus concluded that microsurgery for grade I–III AVMs is superior to SRS.[98] It was also pointed out that results in microsurgery were very variable ranging from a mortality of 0.9 to 18.8% and morbidity ranging from 4.6 to 15.5%.[98] Sisti, a proponent of microsurgery, achieved total obliteration in 94% with a surgical morbidity of 1.5% and no operative mortality in a series of 67 intracranial AVMs less than 3 cm in diameter.[115] In a thought-provoking guest editorial, Steiner, a strong proponent of SRS,[124] comments on Sisti's arguments. Steiner concludes that AVMs should be managed by neurosurgeons familiar with microsurgery and radiosurgery and that both treatment options have a complementary role to play and are not exclusive of each other. The late results following surgical excision have been described by Heros.[46] Patient outcomes after SRS for operable arteriovenous malformations have also been studied.[104]

Causes of Treatment Failure

Heffez[44] has pointed out that quantifying the degree of treatment failure would itself depend on the extent of follow-up. If the analysis is limited to the patients who had follow-up angiography, the obliteration rate of AVM would be overestimated. The actual 2-year obliteration rate, if all data is considered, is in the range of 40% rather than the commonly reported 80%. Treated patients are exposed to the risk of intracerebral haemorrhage for a longer period than previously appreciated. The percentage of patients who actually undergo arteriographic confirmation of treatment efficacy 2 years after radiosurgery has ranged as low as 38%.[44] Angiography alone is not an ideal database for radiosurgery of AVMs because it can produce errors in the determination of the target centre and shape, when compared with modern CT imaging.[8,9,16,90] Other shortcomings include planar representation of 3D volume and simultaneous visualisation of feeding arteries and draining veins that overlap with the nidus and obscure its outline.[51] Stereotactically guided MRI may provide better spatial definition of the nidus and superior anatomical detail for the final design of the radiosurgical isodose distribution.

Recanalisation after embolisation, re-expansion after haematoma reabsorption and the presence of an intranidal fistula have been implicated as causes for treatment failure.[103,146] Inaccurate target definition could be due to substandard imaging equipment or operator error. Lower radiation doses used for AVMs in critical regions or when the AVM was unusually large may also contribute to treatment failure.

Statistically significant factors predictive of radiosurgical failure included higher Spetzler-Martin grade, increasing AVM volume, lower peripheral doses and a previous history of haemorrhage.[16] The maximum diameter, angiographic shape of the AVM nidus and number of draining veins are also significant. Smaller, compact AVMs with fewer draining veins respond well. Radiation dose, angioarchitectural and haemodynamic aspects, and flow pattern are also significant.[54,81] Effective radiosurgical treatment for AVMs requires accurate definition of the true tridimensional size and shape of the nidus. Over or underestimation may result in undue irradiation of normal brain tissue or suboptimal irradiation of the nidus leading to treatment failure.[116] Failure to precisely define the target volume leads to poor response. Stereotactic angiography alone, however, may not be the ideal database for radiosurgery because it can produce errors in the determination of the target centre, size and shape, when compared with modern CT imaging.[8,9] Early filling of the draining vein alone following SRS has been implicated as a risk for further bleeding.[38] Factors associated with successful AVM radiosurgery have been reviewed.[100] Gamma knife surgery for previously irradiated AVMs has been discussed by Karlson[59,63] (Table 1).

Table 1: Factors related to complete AVM occlusion

Unfavourable group	*Favourable group*
Large diameter nidus	Small diameter nidus
Multiple veins	Single vein
Higher Spetzler-Martin grade	Lower Spetzler-Martin grade
Complex shape of nidus	Compact shape of nidus
Low marginal dose	High marginal dose
High-flow pattern	Low-flow pattern
Prior embolisation	No previous embolisation
Critical location of nidus	Nidus located in non-eloquent area
Previous haemorrhage	Absence of prior haemorrhage
Presence of associated aneurysm	
Presence of associated AV shunting	
Presence of calcification	
Presence of intranidal fistula	

Complications

It is well known, although rare, that therapeutic radiation itself can produce iatrogenic radiation induced tumours.[89,111] Although occurring in very small numbers, complications following SRS for AVMs are being documented. Multivariate analysis and risk modelling studies regarding such complications have been carried out.[22] These complications may be asymptomatic, innocuous or clinically significant. Generally, the complication appears to be a result of large volumes treated, excessive dosage administered or due to use of less sophisticated treatment-planning systems. As in most neurosurgical procedures, the complications are also related to the learning curve. More complications are detected when it is looked for more aggressively. They include:

- Delayed cyst formation: This has been detected 5–23 years after SRS.[48,65,118] The clinical presentation has included hemi-Parkinson syndrome, hemiparesis and visual disturbances. Mechanisms underlying delayed cyst formation and spontaneous cyst shrinkage await clarification; breakdown of the blood-brain barrier appears to play an important role. Relatively high blood flow volumes and increased permeability of incompletely injured blood vessel walls in the treated nidus may prompt cyst formation within the area of radiosurgically induced degeneration. Coagulation necrosis leading to liquefaction necrosis may continue for several years after radiosurgery.[65]
- A new paranidal aneurysm, visualised 18 months after SRS for an AVM, in a 19-year-old woman has been described. Radiation changes in flow dynamics and vessel integrity has been implicated as a causative factor.[57]
- Asymptomatic middle cerebral artery stenosis: This has been detected 3 years post gamma knife radiosurgery. It has been postulated that the normal major artery, if located close to the target volume, may be

affected even by low dose irradiation (< 10 Gy).[138] Autopsy studies have demonstrated radiation-induced changes even in nidus-unrelated arteries.[140]

- Chronic encapsulated expanding haematoma: This has caused progressive deterioration 2 years after GKS;[48] a tough capsule containing multiple layers of organised haematoma resulting from previous bleeding was surgically confirmed. Histological examination revealed that the capsule consisted of a dense collagenous outer layer and a granulomatous newly vascularised inner layer with marked fibrosis. Haemosiderin deposits were frequently observed in the inner layer, which suggested recurrent minor bleeding from fragile vessels in this layer. An AVM was found in the haematoma, which had degenerated as the result of radiosurgery. A cross-section of the abnormal vessels showed various stages of obliteration due to intimal hypertrophy.
- Asymptomatic dural arteriovenous fistula (DAVF) in association with nidus obliteration after re-irradiation.[143]
- Haemorrhagic stroke, related to a previously irradiated, obliterated AVM.
- Radiation necrosis occurring at the site of radiosurgically treated AVMs.[48,118,126,140] These may present as a mass lesion with raised ICP or focal deficit several months after SRS. Imaging features may simulate a malignant neoplasm. Radiation necrosis appears to be a consequence of high doses employed.[48,68]
- Radiation-induced oedema detected on MRI following SRS is not uncommon.[137,142] The only major complication which the author encountered over a 7-year period while treating 170 cases of AVM with Linac based SRS was a case of "malignant" cerebral oedema resulting in post-treatment papilloedema and hemiparesis.
- Glioblastoma multiforme (GBM), histologically verified, associated with previous gamma knife radiosurgery has been described in a 20-year-old patient. Six and a half years earlier GKS had been done for an AVM. Maximum and margin radiation doses were 40 Gy and 20 Gy, respectively. In this case, complete obliteration of the AVM was confirmed by angiography. In addition to thickening of the walls of the abnormal vessels, GBM was also found in these abnormal vessels when the patient was operated upon for the tumour.[56]

Even the demonstration of complete AVM obliteration by angiography cannot be taken as a guarantee that patients will not develop delayed radiosurgery-related morbidity. Long-term neuroimaging is essential even after the "treatment goal" has been attained.[139] Additional experience with post-radiosurgical complications, potentially developing several years after irradiation, may elucidate the pathogenesis of these complications. Delayed radiation-induced complications, ranging from 3.2 to 12.5%, have been described by users of gamma knives, linear accelerator systems and particle beam systems.[145] Radiation induced oedema and haemorrhages are significantly higher in large AVMs than in small ones; however, the permanent neurological complication rate can be as low as 3.3%.[25] Gliosis and demyelination, which appeared to be dose dependent, were detected as signal changes in MRI even 23 years after complete obliteration.[65]

LARGE ARTERIOVENOUS MALFORMATION

Management of large AVMs (Spetzler-Martin grade V) has always been a daunting and challenging task. SRS has been used even for large AVMs to achieve partial obliteration, with a view to subsequent open surgery.[119] Combined embolisation and SRS for the treatment of large-volume, high-risk AVMs have also been advocated.[14,99] The advocates of open surgery concede that morbidity and mortality are higher for larger AVMs than for smaller AVMs.[98] As early as 1972, Steiner pointed out that large AVMs respond poorly to SRS.[123] Subsequently, several reports have confirmed the lower obliteration rate in larger AVMs.[24,25,51,94,137] Obliteration rate in AVMs with volumes between 10 cc and 15 cc was 77% compared to 25% for AVMs with a volume > 15 cc.[51] Staged radiosurgery, wherein portions of a large AVM are treated separately, has been considered a treatment option. The time interval between the staged radiosurgical treatments have varied from 1 to 8 months.[51,94] Although the time taken is more, complete obliteration has been achieved in many cases.[51,94,99] Karlsson[58] has suggested that a giant AVM can be treated with a low dose of radiation (≥ 10 Gy), and the treatment repeated if the AVM shrank but was not obliterated. In exceptionally large AVMs, where previous attempts at surgery and embolisation have failed following staged SRS, the nidus has sufficiently shrunk to permit subsequent surgical excision.[20] Due to the complexity of arterial feeders, embolisation alone or as an adjunct is often insufficient. A combination of SRS and stereotactic fractionated radiotherapy has also been proposed for the treatment of larger AVMs.[4] Recently, there have been reports that volumes of up to 30 cc have been treated effectively with radiosurgery with an acceptably low complication rate.[25] In patients with large AVMs, the treatment-related complication rate was 3.9% compared with 2.4% in patients with small AVMs. Larger AVMs need a longer time for obliteration. At 50 months follow-up, the complete obliteration rate of AVMs larger than 15 cm^3 (up to 26 cm^3) had increased to 58%. AVMs are radiosurgically classified as "late-responding targets embedded within late-responding normal tissue".[94] In large AVMs, the incidence of radiation induced oedema and haemorrhage is significantly higher than in small ones; however, the permanent neurological complication rate can be as low as 3.3%.[25]

Obliteration of an AVM following exposure to a single focused dose of irradiation depends essentially on total coverage of the total nidus with an adequate radiation dose. Large volumes and critical location often

necessitate suboptimal doses.[146] Lower treatment doses are also used to limit complications.[143] Since larger AVMs contain more normal brain within the AVMs towards the periphery, marginal doses also have been reduced.[61] Some have used margin doses of 18 Gy to 22 Gy in the 40–50% isodose (gamma knife) for volumes ranging from 11 cm^3 to 25 cm^3.[94] Others have kept the mean dose inside the nidus between 20 Gy and 24 Gy with a margin dose of 18 Gy (at the 55–60% isodose centres).[51]

The shape of the lesion also determines the degree to which a "tight fit" can be obtained,—that is the ability to place multiple collimators precisely over the nidus so as to generate a treatment plan, which would ensure maximal radiation to the nidus and a steep fall out resulting in minimal radiation outside the nidus. The use of a number of isocentres is particularly crucial in formulating an ultra-conformal treatment plan to cover the entire nidus. In large AVMs, different arterial systems contribute to different portions of the nidus. Accurate delineation of each portion of the nidus is to be followed by "making" a composite nidus truly representative of the giant AVM. Failure in achieving angiographic obliteration is often due to imprecise definition of the target volume due to incomplete angiography.[16] Imprecision is more when the target volume to be defined is large. Often, the entire nidus may not be included in the prescription dose.[143] For very large AVMs, staged volume radiosurgery may result in considerable size reduction making it suitable for subsequent microsurgical resection.[20] Surgical resection of large incompletely treated intracranial AVMs following SRS, is also a treatment option.[119] Large AVMs in non-eloquent areas, as over the corpus callosum,[31] can successfully be obliterated without complications with SRS, provided the angiographic nidus is accurately demarcated with pan angiography. Linear shape makes ultra-conformal treatment planning more accurate. Size and volume alone should not be the criteria for choosing or rejecting SRS as a treatment option. The shape and location should also be considered.

SRS is an elegant tool but, as Lars Leksell, the father of Radiosurgery, observed "A fool with a tool is still a fool". It is essential that the neurosurgeon planning to use SRS in the management of cerebral AVMs should be fully aware of its limitations and not only of its advantages. Considerable judgement needs to be exercised before choosing a treatment option for the management of cerebral AVMs. Today, we are in the era of evidence based medicine. Decision-making, however, has to take into account the socio-economic milieu, and the availability of the alternatives,—state of the art microsurgical and endovascular expertise,—in the management of cerebral AVMs. Ultimately, a paradigm has to be evolved for every specific clinical situation, which takes into account the several variables, which have been outlined. One should also remember that the different treatment options are not necessarily exclusive, but may even be complementary.

95 Vein of Galen Malformations

Anil Nanada

Vein of Galen malformations are rare vascular malformations. They constitute approximately 1% of all intracranial vascular lesions and nearly one-third of them are in the paediatric age group.[6,9] With increased sensitivity and introduction of specific diagnostic tools, the frequency of this diagnosis has increased over the last two decades. These malformations are usually situated in the midline, producing dilation of the vein of Galen and are sometimes referred to as "aneurysms" of the vein of Galen. The high blood flow through this fistula or shunt is responsible for the majority of symptomatology associated with these malformations.

In 1895, Steinheil described this particular malformation for the first time and referred to it as a varix aneurysm.[19] In 1937, Jaeger and his colleagues provided the first thorough description of a case of vein of Galen malformation for which treatment was attempted.[4,16] Davidoff, in 1947, and Boldrey, in 1949, subsequently described the surgical approach.[1,11] Silverman and colleagues explained the pathophysiological features of the fistula in a vein of Galen aneurysmal malformation and its causative role in prompting high-output cardiac failure in neonates and infants.[18]

ANATOMICAL CONSIDERATIONS AND CLASSIFICATION

The vein of Galen is a centrally located short venous structure formed by the confluence of the internal cerebral veins and the basal vein of Rosenthal. It passes posteriorly, emptying into the straight sinus at its junction with the inferior sagittal sinus (Fig. 1). The anatomic landmark of a vein of Galen aneurysmal malformation (VGAM) is the presence of multiple arteriovenous shunts draining into a dilated median prosencephalic vein, an embryonic vessel normally absent at the adult stage.[2] The structures drained by the vein of Galen include the thalamus, the medial temporal lobes, the occipital lobes and the superior cerebellar vermis. The vein of Galen lies in the quadrigeminal cistern and receives veins from the ambient cistern, the pericallosal and occipital veins from the corpus callosum cistern, and the precentral cerebellar vein from the superior cerebellar cistern, as well as the internal cerebral veins from the velum interpositum cistern.

Yasargil classified vein of Galen malformations morphologically based on the arterial supply pattern of the malformation into four types.[23]

Type I: Direct anastomosis between the vein of Galen and the pericallosal arteries and the P3 segments of the posterior cerebral arteries.

Type II: Direct fistula between the thalamoperforating arteries (P1 segment) and the vein of Galen.

Type III: Combinations of Types I and II.

Type IV: It is simply a pial arteriovenous malformation that drains into the vein of Galen.

In 1992, Lasjaunias proposed an angiographic classification that differentiated "true" vein of Galen malformations (Yasargil Type I–III) from the secondary malformations or dilatations (Yasargil Type IV).[6]

CLINICAL FEATURES

Patients with vein of Galen malformations have clinical presentations that can vary with age of onset. The clinical classification for the malformation involves the

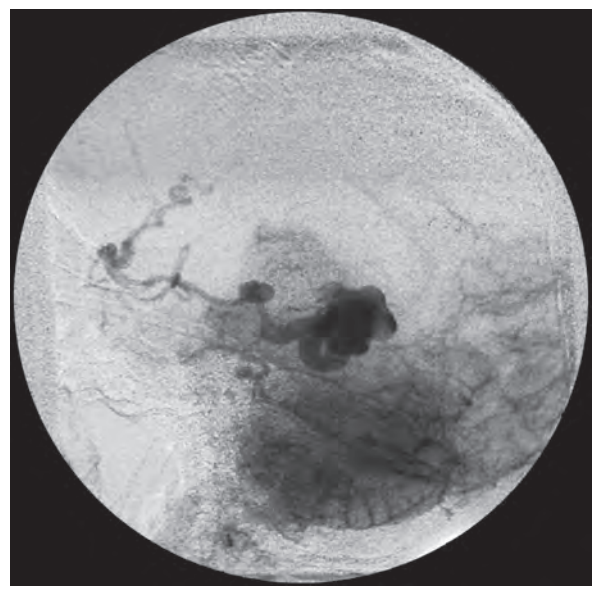

Fig. 1: A digital subtraction angiogram of the vertebral artery (lateral view) showing a dilated vein of Galen with malformation

correlation of three features: (1) age at presentation; (2) clinical syndrome and (3) pathophysiology. Three characteristic groups have been identified: (1) the neonate presenting with severe congestive heart failure; (2) the infant presenting with hydrocephalus and/or seizures and (3) the older child or adult presenting with headaches or subarachnoid haemorrhage. The basis for most clinical symptoms is not the mass effect, but rather the shunting of blood through the fistula that produces either cerebral or coronary artery "steal". There is evidence that an autosomal dominant factor caused by mutations in the *RASA 1* gene may be involved in the pathogenesis of vein of Galen malformations.[14]

Neonates

About 40% of patients with vein of Galen malformation are diagnosed during the neonatal period. The malformation typically produces congestive heart failure (hypoxia, low cardiac output, tachycardia and pulmonary oedema). Cyanosis is very common and is typically refractory to medical therapy. In addition, the cerebral artery "steal" can be associated with venous hypertension, cerebral ischaemia and infarction.

Infants

Infants have a smaller shunt as compared to newborns. Hydrocephalus and seizures are the most common presentations. Head enlargement in infants can be caused by ventricular dilatation in the presence of a distensible skull. The fontanelle is full but seldom tense. Overt signs of raised pressure (nausea, vomiting, lethargy, etc.) are rarely present. It is likely that the ventriculomegaly is a result of increased pressure in the sagittal sinus or venous system that affects CSF absorption. Typically, there is no periventricular fluid present on imaging studies.

Older Children and Adults

They typically have a low-flow fistula or may have a Yasargil Type IV malformation. They present with subarachnoid haemorrhage, intracranial bleeds, headaches or cognitive dysfunction. They, occasionally, may present with hydrocephalus, but congestive heart failure is very rare.

DIAGNOSTIC INVESTIGATIONS

Investigations of a patient with a suspected vein of Galen malformation fall into three categories: (1) imaging of the brain; (2) imaging of the cerebral vasculature and (3) various other investigations to assess the systemic effects associated with the malformation.

Brain Imaging

Computed tomography [(CT) Fig. 2] and magnetic resonance imaging (MRI) are the two definitive diagnostic modalities for this condition. On a CT scan, the characteristic features are calcification, low-density cystic spaces and post-contrast enhancement.[21] An MRI scan is more sensitive than a CT scan since it provides better information concerning the malformation and its effects on the surrounding brain. Additionally, it provides greater details about the ischaemic changes occurring in the affected brain and also depicts the patency and size of the large arteries, veins and venous sinuses.

Cerebral Angiography

The final diagnosis of the malformation is provided by cerebral angiography. This also provides information about the vascular anatomy that is essential for treatment planning. The vein of Galen forms an arc under the splenium of the corpus callosum, curving posterosuperiorly towards the tentorial apex. It is clearly seen on the lateral view, but is often obscured by the overlying superior sagittal sinus on AP projections (Fig. 3). The

Fig. 2: A plain CT scan of the head showing a large vein of Galen malformation and accompanying haemorrhage into the lateral ventricles

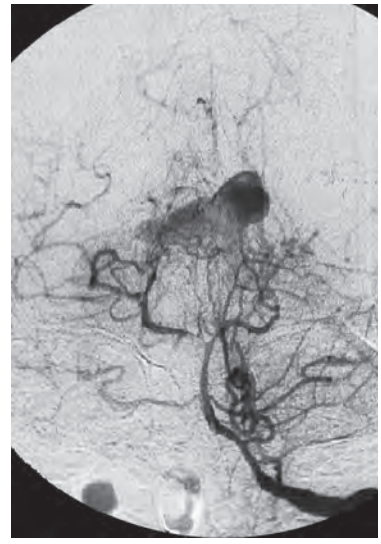

Fig. 3: AP view of a vertebral digital subtraction angiogram showing a vein of Galen malformation

two most widely referenced angiographic classifications are those of Lasjaunias and colleagues[6,15] and Yaşargil.[23]

Other Investigations

These are designed to assess systemic abnormalities associated with the condition such as hypertension, congestive heart failure and renal failure. These include studies of arterial blood gases, chest radiology, electrocardiography, echocardiography, serum electrolytes, serum creatinine and urinary electrolytes. Monitoring serial plasma BNP provides valuable information regarding the need for additional evaluation or treatment of newborns with CHF and is also helpful as a prognostic indicator.[20]

Prenatal ultrasonography shows the characteristic midline tubular anaechoic structure superior to the thalamus, which is contiguous with the dilated sagittal sinus (comet tail or keyhole sign)[17] and also reveals extracardiac left-to-right shunt, featuring as a high-output heart failure in a neonate and hypoxic-ischaemic brain lesions due to the 'steal' phenomenon. More precise anatomy and location of foetal pathology, and additional aetiologic information are the substantial advantages in doing fast MRI as an adjuvant to ultrasonography.

Doppler evaluation is important in differentiating this lesion from other cystic lesions of the brain because this is the only lesion that clearly displays blood flow within it.[13]

TREATMENT

Many series have been published that show patients with untreated vein of Galen malformation typically die from a combination of cerebral and cardiac events.[3,5] Most often, neonates succumb to their cardiac insufficiency, and older children and adults succumb to the cerebral injury. More important, despite modern treatment, the mortality rates for this condition still approaches 79% for neonates and 39% for the remaining population. Patient selection and timing remain the keys in the management of this condition. It is more important to restore normal growth conditions than a normal morphological appearance, with the primary therapeutic objective being normal development in a child without neurological deficit.[7]

Medical Treatment

In the newborn, initial treatment is usually aggressive medical stabilisation. Congestive heart failure should be aggressively treated to stabilise the accompanying pulmonary hypertension and cardiomegaly. Ideally, intervention should be delayed until the infant is 6 months old; however, if there are clinical signs of an acute deterioration, urgent definitive treatment may be indicated.

Interventional Strategies

The selection of treatment is influenced by the age of a patient at presentation and by the complexity of the malformation. These modalities may include embolisation, surgery, shunting for hydrocephalus or a combination therapy.

Treatment of Hydrocephalus

The results of most shunting procedures for ventriculomegaly in infants and neonates are disappointing because intraventricular pressure is invariably low. It is, therefore, best to avoid ventricular shunting and aim the therapy at correcting the basic pathology. This strategy has shown to normalise the head circumference.[6]

Endovascular Treatment

Sophisticated, high-resolution angiography and endovascular techniques have been applied to the management of vein of Galen malformations. This approach can be transarterial or transvenous through the torcula. The transarterial approach is considered to be most suitable for Yasargil Type I, II, or III malformations. Lasjaunias and associates recommend that the transvenous approach be limited to malformations where the arterial approach has failed.[8] Both approaches have been used with varying degrees of success for Yasargil Type IV malformations. Each technique can be used alone or in combination with surgery.[10,22]

Surgical Treatment

Surgery should be delayed until both the medical condition and the nutritional status of the patient are optimised. Many infants and children may require definitive management of the hydrocephalus before or after definitive surgery. In addition, pre-operative embolisation of the accessible feeders has been recommended to simplify the resection. The galenic region can surgically be approached by the subtemporal, transcallosal or transtentorial approaches. However, the posterior interhemispheric approach is most commonly used to adequately access a vein of Galen malformation and expose the feeding arteries.

Radiosurgery

Stereotactic radiosurgery using gamma knife has recently been tested as a treatment option for this formidable disease. Payne et al. published their series of 9 patients with vein of Galen malformations that were treated using radiosurgery.[12] They achieved a cure in four patients following a single treatment, while two others were cured after two and three sessions, respectively. In one case, the malformation failed to respond to treatment. These results, although small in number, definitely point to another potentially safe treatment modality in the future for vein of Galen malformations.

OUTCOME

Treatment for vein of Galen malformations is still evolving. Treatment modalities include surgery and endovascular

techniques. Newer modalities using focussed radiation have been suggested, but are yet to be universally accepted as definite alternatives. Although outcomes in comparison to natural history have improved remarkably, the mortality rate is still about 35% and significant morbidity is seen in another 30% of patients.

96 Cavernomas of the Brain

CE Deopujari

Developmental malformations affecting the blood vessels supplying the brain most likely develop during the late somite stages of the 4th week of embryonic life.[15] The traditionally used classification, described by McCormick,[29] divides these lesions on the basis of histopathological features into four categories: (1) venous malformations; (2) arteriovenous malformations; (3) cavernous malformations and (4) telangiectases. However, the intermediate and combined forms of these vascular malformations that do not fit simply into one of the above categories have also been described.

Cavernous malformations constitute 5–10% of all cerebrovascular malformations[28,41] and are the second most common intracranial vascular malformations responsible for haemorrhage.[27] Cavernous malformations are variously known as cryptic angioma, cavernous angioma, cavernous haemangioma, cavernoma and "angiographically occult vascular malformation" (AOVM).[18] These vascular malformations are characterised by the presence of sinusoid like capillary vessels. These capillaries are adjacent to one another, with little or no intervening neural parenchyma, while feeding arteries and draining veins are most often normal in size. The association of cavernous malformations with venous angiomas is reported to be around 20–30% in the literature.[10,42] They are known to occur anywhere in the neuraxis including on cranial and spinal nerves but are most commonly found in subcortical white matter, external capsule and pons.[8,20] Locations of the 67 lesions operated upon in our unit are shown in Table 1.

Table 1: Location of cavernous malformations operated in our series

Location	*Number*	*Percent*
Supratentorial	47	70.1
Frontotemporal	22	
Frontal	11	
Occipital	4	
Parietal	5	
Intraventricular	2	
Thalamic	2	
Optic/Hypothalamic	1	
Infratentorial	18	26.8
Brainstem	15	
Cerebellum	3	
Spinal	2	3.1

INCIDENCE

The exact incidence and prevalence of cavernous malformations are unknown, as many of these lesions remain asymptomatic. Before the introduction of modern imaging technology, cavernous malformations were considered rare lesions. These lesions are more common than are generally suspected. Based on clinical series, the prevalence of cavernous malformation is estimated at 0.5%.[43] Autopsy series by McCormick[46] and by Otten[32] revealed a prevalence of 0.4% (16 of 4,069 autopsies) and 0.53% (131 of 24,535 autopsies), respectively. Similar results were reported by two groups reviewing more than 22,000 MRI examinations,[12,43] with incidence rates of 0.4–0.5%.

AETIOPATHOGENESIS

The exact aetiology of cavernous malformations is not known. Although cavernous malformations are known to be congenital in origin, cases of de novo formation with previously documented normal MRI have also been reported.[13,48] The lesions have also been known to appear following radiation therapy[9,25] and along the path of stereotactic biopsy.[31]

Cavernous malformations are known to occur in both sporadic and familial forms.[51] Almost 30% of the patients affected have the familial form of the disease and it seems to be more common amongst the Hispanic American population. Both the sporadic and familial forms of the disease appear clinically similar, except for the fact that there is greater incidence of multiplicity and relatively lesser incidence of bleeding in the familial group.[51] Moreover, de novo development of new lesions in the familial group necessitates serial imaging follow-up at regular intervals in these patients.

The genetic basis behind the development of cavernous malformations has been elucidated. The familial form of the disease is inherited as an autosomal dominant disorder with variable penetrance.[17] Kurth et al.[24] and Dubovsky et al.[14] linked the gene for familial cavernous malformations, designated *CCM1*, to chromosome

7q. Subsequent work by them and other investigators led to the discovery that mutations in the *KRIT1* gene are responsible for *CCM1*.[45]

PATHOLOGY

Cavernous malformations are well circumscribed, discrete and multilobulated lesions of various sizes. The average size of the lesion tends to be 1–2 cm. The gross appearance is likened to a mulberry owing to its dark red purple colour. Pathologically, they are composed of sinusoidal, dilated vascular channels (caverns-lakes) lined by a single layer of endothelium devoid of elastin or smooth muscle. These vascular lakes are separated by a collagenous stroma. On cut section, they appear like a honeycomb of thin walled vascular spaces. The lack of intervening brain parenchyma is a characteristic pathologic marker. Various degenerative changes, like hyalinisation, calcification, cyst formation and thrombosis with varying degree of organisation, are common. The surrounding parenchyma exhibits evidence of microhaemorrhages of varying ages with haemosiderin laden macrophages. A gliotic reaction of the surrounding parenchyma may form a pseudocapsule around the lesion.[29,37,44,49]

CLINICAL PRESENTATION

Cavernous malformations occur throughout life but are diagnosed more often in adults. The symptoms generally start in the 20s and 30s. The lesions tend to occur equally in men and women.[12,43]

Seizures

Seizures are the most common presenting symptom, seen in 40–70% of patients with cavernous malformations.[11] All types of seizures have been described in these patients including simple partial, complex partial, focal, generalised tonic clonic or in any combination.[52] The seizures do not arise from the lesion itself but rather from the irritated cortex adjacent to the lesion.[11] The exact mechanisms by which cavernous malformations produce seizures are unknown. The iron present in haemosiderin is a well-known epileptogenic material.[50] Local gliotic reaction, extensive haemosiderin deposition, recurrent microhaemorrhages, calcification and frontal and temporal location are frequently associated with the clinical presentation of epilepsy. There are no clear data indicating the long-term risk of developing seizures but seizure control becomes more difficult with time. The risk of developing seizures in these patients is estimated to be around 1.5–4.8% in various studies.[12,30] By the time of presentation, it is medically refractory in almost half (44.7%) of the patients.[7]

Haemorrhage

Though evidence of previous haemorrhage is present in almost every lesion regardless of clinical history, overt haemorrhage is less frequent. Overt haemorrhage has been defined as "symptomatic presence of extralesional blood outside the confines of the haemosiderin ring on MRI or at surgery".[22,43] Intralesional microhaemorrhages occurring within the confines of the haemosiderin ring are rarely associated with symptoms. The risk of overt haemorrhage is definitely less than classic AVM, and has been estimated to be around 0.25–13% per patient per year.[12] Since there is uncertainty about the definition of haemorrhage, Porter et al.[34] reported event rates where they defined an event as any subjective neurological worsening with or without radiologically verified haemorrhage. In their series, the overall event rate was 4.2% per patient year, which is nearly equal to that of classic AVM. Factors associated with increased risk of haemorrhage in these patients include prior symptomatic bleed,[3,43,51] size greater than 10 mm, age less than 35 years, female sex,[30,43] pregnancy[43] and deep location of the lesion.[3]

As the cavernous malformations are low flow and low pressure lesions, haemorrhage usually displaces and compresses adjacent neural tissue rather than destroying it.

Focal Neurological Deficit

This may occur in 20–40% of patients due to compression of the critical areas of brain function.[12,43,51] The deficit may be acute and maximal at the onset, especially in cases with lesions within the brainstem. In the brainstem, where crucial tracts and nuclei are compactly arranged, even small focal haemorrhage may be tolerated poorly. However, the symptoms tend to resolve completely as the haemorrhage is absorbed. Recurrent episodes of haemorrhage are associated with progressively more severe deficits and an increased risk of permanent neurological impairment.[3,12,43]

Focal deficits secondary to mass effect may be subacute and progressive if the lesion is located in the basal ganglia or thalamus.

Incidental

Between 15% and 20% of lesions are discovered incidentally during an evaluation for headache or other unrelated neurological problems.[16] In familial patients with multiple cavernous malformations, few lesions are symptomatic.

Other rare clinical presentations reported include cranial neuropathies (trigeminal neuralgia), hypothalamic symptoms and hydrocephalus.[16,41,49]

IMAGING

Computerised Tomography

CT scan is 70–100% sensitive but less than 50% specific in detecting cavernous malformations.[16,26,40] The lesion typically appears to be well circumscribed popcorn like and

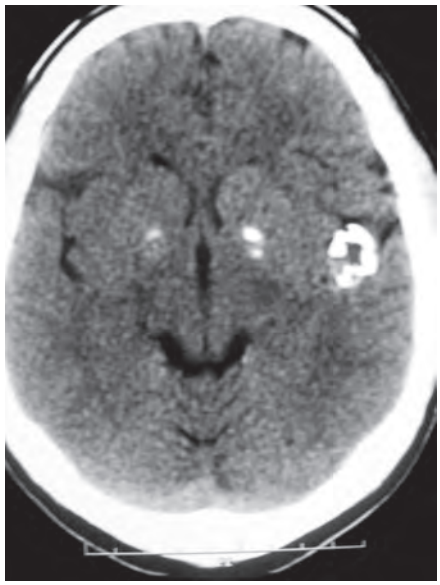

Fig. 1: CT scan of the brain plain study showing a hyperdense lesion (popcorn appearance) within the left Sylvian fissure in a patient who presented with seizures

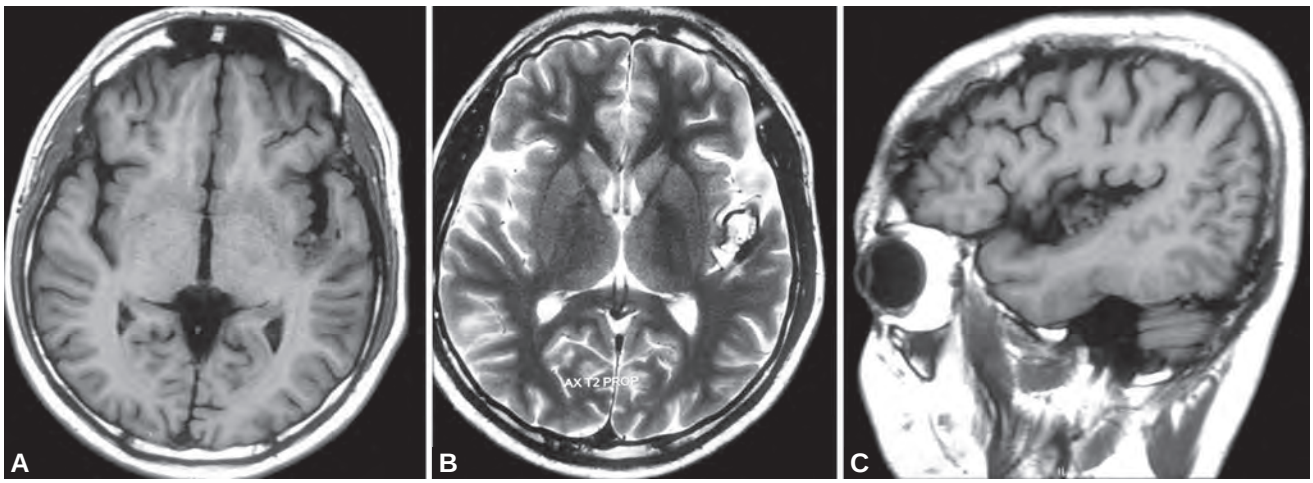
slightly hyperdense with faint enhancement on contrast. Calcification and haemorrhage may also be seen (Fig. 1).

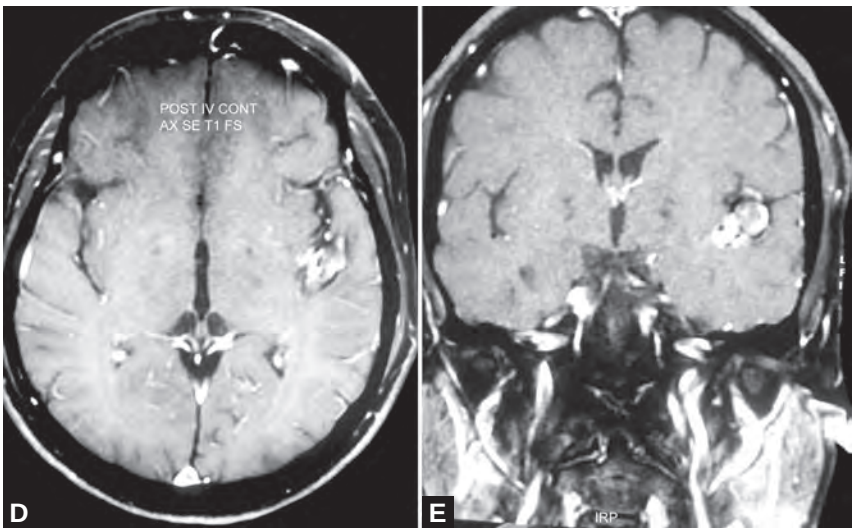
Magnetic Resonance Imaging

It is the most sensitive and specific imaging modality available for detection of cavernous malformations (Figs 2A to E). The lesion appears as a well-defined lobulated mass with a central core of mixed signal intensities surrounded by a rim of hypointensity.[5,33,38] The mixed signal reflects acute and subacute haemorrhage in different stages and the hypointense rim is due to perilesional haemosiderin deposition. The peripheral hypointensity blooms on T2 WI. Gradient-echo (GRE) images are much more sensitive than conventional sequences for detecting small cavernous malformations.

Based on the MRI appearance of cavernous malformations, Zabramski[51] classified these lesions into four types. Type I lesions are associated with subacute haemorrhage and have a hyperintense central region on T1 WI. Type II lesions contain loculated areas of thrombosis



Figs 2A to C: MRI scan of the brain in a patient having left Sylvian fissure cavernoma. (A) T1 axial. (B) T2 axial. (C) T1 coronal



Figs 2D and E: Contrast MRI scan of the brain in a patient having left Sylvian fissure cavernoma. (D)T1 axial and (E) T1 coronal

and haemorrhage of variable age. Type III lesions show the imaging correlate of chronic haemorrhage. Type IV lesions are difficult to detect on conventional imaging. Typically these lesions are small and hypointense on GRE sequences.

Angiography

Angiography is almost always normal and for this reason these lesions are also known as angiographically occult vascular malformations. Occasional abnormalities seen in association with cavernous malformation include avascular mass lesion, capillary blush or evidence of neovascularity. Other vascular malformations, like AVM or venous malformations, can be ruled out using angiography.

DIFFERENTIAL DIAGNOSIS

The MRI appearance of cavernous malformations is characteristic but not specific. Other lesions to be considered in the differential diagnosis include neoplasm with haemorrhage, especially haemorrhagic metastasis, calcified tumours like oligodendroglioma or pleomorphic xanthoastrocytoma.[26,33,40] Thrombosed AVMs which are angiographically occult may also be confused with cavernous malformations.

MANAGEMENT

Treatment options available for patients with cavernous malformations include surgical excision, observation or, occasionally, stereotactic radiosurgery. The choice of option depends on many factors like age, sex and general medical condition of the patient, number and location of the lesions and clinical presentation. The benefits and the risks associated with each treatment option need to be considered.

SURGERY

Well accepted indications for surgical excision of cavernous malformations are recurrent haemorrhage, progressive neurological deterioration, increase in the size of the lesion, intractable seizures and a large lesion surfacing near a pial or ependymal area.[12,43] Surgical resection of accessible lesions is associated with low rates of morbidity and mortality.[1,16,47,49] Surgical intervention in deep seated lesions, especially in the brainstem, should be considered only if they are approachable through an accessible surgical corridor (Fig. 3).

Intracranial cavernomas can be divided into two groups: (1) supratentorial and (2) infratentorial.

Supratentorial Cavernous Malformations

Supratentorial cavernous malformations constitute about 75% of all intracranial cavernous malformations.[12,28,43,49] They can be located superficially in either cortical or subcortical white matter or may be deep near the internal capsule or thalamus. Surgical strategies are modified based on the location of the lesion.

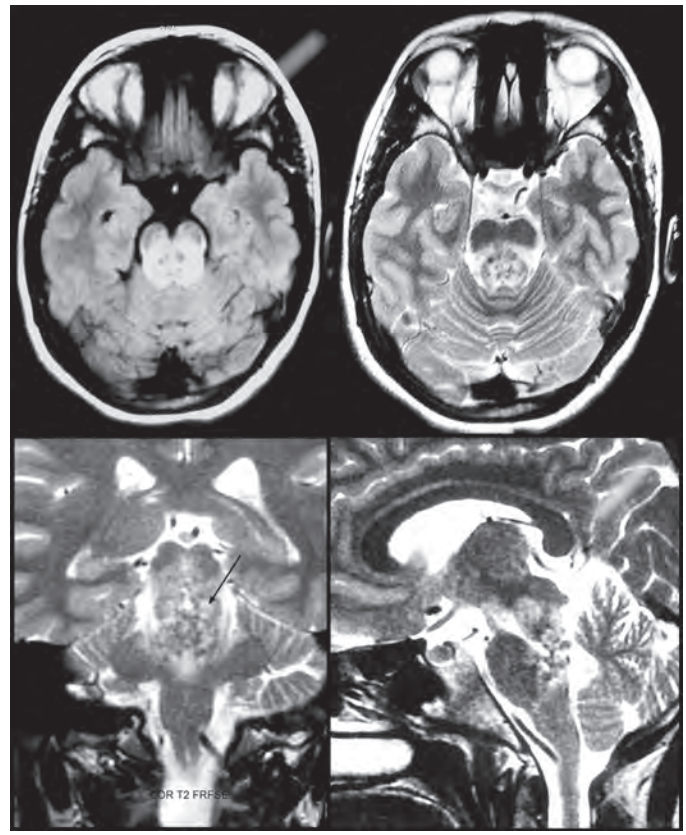


Fig. 3: MRI of the brain showing brainstem cavernoma with popcorn appearance

Pre-operative mapping of the critical brain areas using functional MRI allows better planning of the craniotomy. Frame based or frameless stereotactic devices are frequently used to minimise the size and invasiveness of the craniotomy. Surfacing lesions can be identified easily by their characteristic purple-blue mulberry-like appearance or by haemosiderin staining of the cortex. If the lesion is located deeply, intra-operative ultrasound or neuronavigation techniques can be used. Intra-operative mapping using electrocorticography or awake craniotomy should be considered while operating on lesions in eloquent areas.

The lesion can itself be entered into using a bipolar coagulator and is shrunk by emptying the larger blood filled caverns. The surrounding gliotic pseudocapsule aids the dissection. Working circumferentially around the lesion in the gliotic plane, the lesion is freed from all sides and is removed en mass. Care should be taken to inspect the resection bed under magnification for satellite like nodules.[19] Care should be taken to avoid the associated venous malformation as it may be the sole source of venous drainage for the surrounding normal brain. Damage to or resection of the venous malformation may cause haemorrhagic venous infarction.[35]

Surgical resection of capsular or thalamic cavernous malformation is associated with greater morbidity rates than for more superficial hemispheric lesions. Literature reports poor outcome for surgical treatment of thalamic lesions. Bertalanfy et al.[4] have reported around 50%

permanent neurologic complications after resection of deep seated lesions. Intervention should be reserved for lesions causing recurrent episodes of haemorrhage or progressive neurologic deficit and those that reach an ependymal or pial surface.

Surgical Strategies for Epilepsy

If the seizures can be controlled easily with medications, the indications for surgery in these patients are similar to those for patients with asymptomatic cavernous malformations. However, different surgical strategies need to be considered for patients presenting with intractable seizures. These patients should undergo a standard workup done for patients with intractable epilepsy including an ictal and/or interictal EEG, video EEG if required, neuropsychological testing, functional MRI to delineate speech and motor areas and WADA testing. Patients whose data are concordant with the lesion location by MRI may be good candidates for surgical intervention. Surgical options for these patients include lesionectomy alone, lesionectomy plus resection of adjacent gliotic tissue and lesionectomy plus resection of adjacent and even remote cortex that has been identified by electrophysiologic testing as foci of epileptogenicity. Removal of the lesion and the adjacent gliotic yellow stained tissue has shown to reduce the long-term frequency and severity of seizures.[12,39,43] Intra-operative aids, like image guidance or neuronavigation, intra-operative USG, electrocorticography or awake craniotomy for brain mapping, are helpful adjuncts. Surgery is, however, less successful if there have been more than five episodes of seizures or if the duration of symptoms is more than 2 years.

Infratentorial Cavernous Malformations

Infratentorial cavernous malformations include those involving the brainstem and cerebellum. The lesions in the brainstem are of distinct importance owing to the critical structures in the proximity.

To determine the best surgical approach for brainstem lesions, Spetzler[6] has described a "two point method" where one point is placed in the centre of the lesion and a second point is placed where the lesion most closely reaches the pial surface. Both the points are connected and the resultant straight line through the least eloquent tissue dictates the most appropriate surgical approach. Careful study of MRI scans is very helpful to plan the approach pre-operatively. The brainstem can be approached through various routes depending on the location of the lesion and pre-operative planning:[36]

- Midline suboccipital craniotomy with approach through the fourth ventricular foramen for lesions bulging into the floor of the fourth ventricle.
- Retrosigmoid suboccipital approach for lesions near the posterolateral surface of the pons, cerebellopontine angle or superior lateral medulla.
- Subtemporal approach for lesions in the anterolateral midbrain or pontomesencephalic region.
- Supracerebellar infratentorial approach for cavernous malformations of tectal plate.
- Far lateral or transcondylar approach to achieve an anterolateral trajectory to the brainstem.
- Orbitozygomatic approach to access the anterolateral midbrain and interpeduncular fossa.

Surfacing lesions are readily apparent by their characteristic mulberry appearance or by the haemosiderin staining of the overlying parenchyma. Use of the operating microscope and meticulous dissection are the key factors in determining success. Intra-operative monitoring of SSEP and BAER are useful adjuncts to help minimise complications during brainstem surgery.

Post-operatively patients are extubated only if they demonstrate good cough and gag reflex. Short-term tracheostomy and feeding tubes may be required in some patients.

OBSERVATION

For incidentally detected cavernous malformations, the rate of clinical or overt haemorrhage is very low and a first haemorrhage from a cavernous malformation rarely is life threatening. Therefore, before intervention is considered solely to prevent haemorrhage, other host-related factors need to be considered. Such patients can be managed expectantly, with follow-up imaging at regular intervals in order to detect lesion expansion or haemorrhage.

Conservative therapy is also indicated in patients who have had a single haemorrhagic episode from a lesion that does not reach the pial surface.

RADIOSURGERY

The role of stereotactic radiosurgery in the management of cavernous malformations is controversial. Kondziolka[23] has demonstrated a significant decrease in the haemorrhage rate over time; however, 26% of these patients developed neurological deterioration after the procedure. This correlated with hyperintense changes in T2 WI suggesting radiation injury. Similar results were shown by Amin-Hanjani and colleagues[1,2] and Karlsson[21] et al. As the complication rates are high and the reduced haemorrhage rate is not comparable to the zero rebleed rates after complete surgical excision, radiosurgical treatment should be reserved for lesions that are truly surgically inaccessible.

97 Other Vascular Malformations of the Brain

Ravi Ramamurthi, Harinivas

VENOUS ANGIOMA

Pfannenstiel, in 1887, first recognised this entity as composed entirely of veins. A classical anatomical and pathological description was given in 1966 by McCormick. This lesion has also been termed as "Developmental Venous Anomaly" by Lasjaunias.[5] Saito and Kobayashi et al.[14] have postulated that venous angiomas result from an intrauterine accident, during the formation of medullary veins or their tributaries, either due to thrombus or some unknown mechanism resulting in the formation of collateral pathways to drain the brain so affected. These lesions are present at birth and remain largely static throughout life, though changes in these angiomas are reported with senescence.

Venous angiomas are generally silent lesions because of their dynamic features and are low-flow and low-pressure vascular structures draining normal brain tissue.[3] Venous angiomas form the alternative venous drainage of the surrounding nervous tissue because of the non-development of the normal venous system. They are made up of veins with abnormal structure with thick walls, dilated lumen and of irregular calibre that converge radially towards a wide draining vein (caput medusae).[14]

Pathology

The causes of developmental venous anomalies are incompletely understood. It is believed that they are formed in the late stages of foetal maturation.[14] The lesion is composed entirely of veins, which are commonly thickened and hyalinised, having minimal smooth muscle and elastic tissue. The interspersed neural parenchyma is entirely normal. Venous angiomas may be subclassified according to their pattern of venous drainage into superficial (cortical) and deep (subependymal) types. Two variants of the typical venous angioma have been described. These are:

1. Venous angioma with arterial feeders also termed as medullary venous malformations with an arterial component or venous angiomas with early filling vessels
2. Varix or phlebectasia

There is a radially arranged pattern of medullary veins converging centrally on a single draining vein which is known as star cluster.[9] Histological examination shows that the capsule consists of an outer collagenous layer and an inner granulated layer with deposits of haemosiderin.[15]

Natural History and Clinical Features

The natural history depends on the topography and location whether hemispheric, deep-seated, brainstem, cerebellar or intramedullary regions.[1] These are the commonest of the vascular malformations in large prospective autopsy studies, but the least common form encountered in surgical series. Their incidence may be still higher than is generally believed, since most of these remain largely asymptomatic. Patients may present with headache, nausea and vomiting, seizures, progressive neurological deficit and haemorrhage (0.2% per year).[11] Changes due to old age, in an angioma, may increase its propensity to cause symptoms. The presence of an associated arteriovenous malformation (AVM) or a cavernoma is not unusual in a patient with a venous angioma. Coexistence of a cavernoma with a venous angioma occurs in about 8% of cases,[10] and in such a case it is usually the cavernoma which becomes symptomatic and needs to be treated, rather than the venous angioma.

Investigations

First angiographic description of these lesions was described by Wolf and his colleagues.[17] The gold standard for diagnosing developmental venous anomalies is conventional cerebral angiography. Findings include normal circulation time, normal capillary and arterial phases of study with the venous anomaly seen during the late venous phase.[17]

Computerised tomography (CT) scan without contrast administration may show a hyperdense dot, caused by the pooling of venous blood. Contrast enhancement reveals a stellate tangle of veins coursing into a sharply defined linear interstitial vein draining towards the cortical or the central system. These are commonly seen in the frontal region near the angle of the ventricles or in the cerebellum.

The first angiographic description of these lesions was by Wolf et al.[17] Conventional or digital subtraction angiography may reveal a faint capillary blush passing into the venous phase or the classical "caput medusae" or "hydra" appearance which is pathognomonic of a

venous angioma. The angiomas, showing a persistent blush, are believed to have an increased tendency to bleed. Yasargil[18] has described the following criteria for diagnosis of venous angioma on angiography:

- Absence of arterial feeders
- Appearance of the lesion in the venous phase
- Presence of dilated medullary veins draining through a dilated transcerebral or subependymal vein

Magnetic resonance (MR) is superior to CT in the identification of a venous angioma. It delineates a curvilinear streak of signal void, best appreciated on T2W1 MR imaging (MRI) scan. Hypointense areas may be visible in the body of the angioma, representing the blood pool within. These enhance brightly with contrast and the draining vein is seen well on T2-weighted imaging.[16] There may be a paradoxical high-signal intensity as the flow in the draining vein is very slow. Some of these lesions may be diagnosed on "Time of Flight" MR angiography.

Management

It is to be noted that these lesions have a very benign natural history and only rarely do they cause haemorrhage. The propensity of these lesions to cause seizures or focal neurological deficit is difficult to ascertain. These veins are anatomically aberrant, but physiologically essential and, therefore, should not be interrupted. Surgery is only indicated in the presence of a large haemorrhage causing mass effect or a clearly documented seizure or focal neurological deficit attributable to the angioma. Radiosurgery has also been advocated for these lesions, but the results are variable.[7]

CAPILLARY TELANGIECTASIAS

Capillary telangiectasia (CTS) is a vascular malformation characterised by multiple thin-walled vascular channels interposed between normal brain parenchyma. It has been hypothesised that CTS is an acquired lesion caused by other underlying venous anomalies, but this theory is still debated.[19]

This type of vascular malformation is also called capillary malformation. It is usually asymptomatic and also remains angiographically occult, making it difficult to ascertain its incidence. However, rarely, intracerebral haemorrhage has been reported. These are commonly located in the infratentorial compartment, the pons being a favoured site. Familial as well as multiple lesions have been reported.

This malformation results from vascular dilatation rather than vascular proliferation and comprises of thin-walled capillaries which are devoid of smooth muscle tissue or elastic fibres and usually drain into an abnormally large central vein. The intervening neural parenchyma is normal.

Clinical Presentation

They are mostly asymptomatic. If symptomatic, haemorrhage, seizure, cranial nerve paresis, extrapyramidal disorders and focal hemispheric syndromes have been described.[4]

Investigations

Radiological diagnosis of these lesions is very difficult, unless associated with haemorrhage. The CT scan is not sensitive enough to detect these minute lesions and in most instances, these are not visible on angiography, although rarely an angiogram may reveal an abnormal vascular blush or an early draining vein. The MR may show an area of hypointense signal in T2W1 MRI scan.[12,13] Diffusion weighted imaging seems to be a useful adjunct for the diagnosis of capillary telangiectasias which can be differentiated from tumours, inflammatory and ischaemic lesions.[2] In some cases imaging diagnosis will be difficult with conventional, MRI because the lesion will not show characteristic signal loss on conventional gradient-echo images. In those cases susceptibility weighted imaging will be useful for diagnosis as it will demonstrate marked signal loss of the lesion.[19]

Management

Capillary telangiectasis may, at times, coexist with a cavernoma, and according to Russell's original hypothesis these two represent different stages in the development of the same disease entity. As a rule, when coexisting with a cavernoma, it is the cavernoma that becomes symptomatic, necessitating treatment. No therapeutic intervention is indicated in an asymptomatic telangiectasia. If presenting with haemorrhage, surgery may be indicated to evacuate the haematoma. It is usually on histopathological examination of the evacuated blood clot and its periphery that the diagnosis of telangiectasia becomes evident.

Hereditary Haemorrhagic Telangiectasia (Osler-Weber-Rendu Disease)

Hereditary haemorrhagic telangiectasia (HHT) is a form of capillary telangiectasia characterised by the presence of multiple AVMs that lack intervening capillaries and result in direct connections between arteries and veins. Although HHT is a developmental disorder and infants are occasionally severely affected, in most people the features are age-dependent with the diagnosis not suspected until adolescence or later. The most common clinical manifestation is spontaneous and recurrent epistaxis seen usually at a younger age. Approximately 25% of individuals with HHT have gastrointestinal (GI) bleeding, which most commonly begins after the age of 50 years.

Genetics

The HHT is caused by mutations in a number of genes involved in the TGF-β/BMP signalling cascade:

- ENG, the gene encoding the cell surface co-receptor endoglin

- ACVRL1 (ALK1), also a gene encoding a cell surface receptor
- SMAD4, a gene encoding an intracellular signalling molecule
- At least two other genes that have not been identified. Molecular genetic testing of ENG, ALK1 and SMAD4 detects mutations in approximately 80–85% of individuals who meet an unequivocal clinical diagnosis of HHT and is available on a clinical basis.[8]

Diagnosis

The diagnosis of HHT is based on the presence of epistaxis, cutaneous or mucosal telangiectases, visceral AVMs and family history.

Treatment

Epistaxis is treated with humidification, nasal lubricants, topical or systemic hormones or antifibrinolytic agents, laser ablation, septal dermoplasty and nasal closure. The GI bleeding is treated with iron replacement therapy and, if needed, endoscopic ablation, surgical resection of bleeding sites, and/or hormonal or antifibrinolytic therapy. Cerebral AVMs are treated, when indicated by location or symptoms, by surgery, embolotherapy and/or stereotactic radiosurgery.

Genetic Counselling

The HHT is inherited in an autosomal dominant manner with considerable intrafamilial variability. Most individuals have an affected parent. Prenatal testing is possible for pregnancies at increased risk if the disease-causing mutation in the family is known.[8]

CRYPTIC ARTERIOVENOUS MALFORMATIONS

The term "Cryptic" was proposed by Russell to denote a group of vascular "harmartomas", predominantly small AVMs, which often remained clinically silent during the patients' life time. Cryptic AVM can cause highly variable cerebral neurological defects.[6] These lesions may present with a catastrophic and often fatal haemorrhage. The terms "cryptic" and "angiographically occult vascular malformation" (AOVM) were adapted to clinical use to describe vascular malformations that are not demonstrable on angiography. The mechanisms for failure of angiographic detection of an AVM are manifold. It is to be noted that the terms "cryptic" and "AOVM" are not synonymous. While the cryptic AVMs are a histopathological entity, AOVMs may be diagnosed by CT or MRI.

Angiographically occult AOVMs can now be readily diagnosed and managed. The AOVMs constitute a heterogeneous group of entities. Robinson et al.[12] analyzing 34 AOVMs encountered over a 10-year period, found 21 cavernous malformations, 3 AVMs, 3 venous malformations, 2 capillary malformations and 5 mixed lesions. With increased understanding of the clinical significance of cavernomas and venous angiomas, a more rational approach to their management has become possible. Rapid advances in the field of radiosurgery have made it easier to tackle the small, deeply-located AVMs. Still, surgery remains the mainstay of treatment in most instances. Injection of 142Pr microspheres into arteries feeding an AVM in order to simulate radioembolism has been proposed as a novel treatment method.[6]

98 Carotid Cavernous Fistula

Ravi Ramamurthi, Goutham Cugati

INTRODUCTION

The carotid artery in a part of its intracranial course traverses the cavernous sinus. Carotid-cavernous sinus fistula (CCSF) develops when there is an abnormal communication between the carotid artery (internal or external) or its branches, and the cavernous sinus. The cavernous sinus is not a dural sac carrying venous blood, as was thought earlier, but is a plexus of veins enclosed between two layers of the dura.

HISTORICAL

Carotid-cavernous sinus fistula was first reported by Travers[54] in 1809 and he ligated the carotid artery in the neck as part of the treatment. Later, Nunnely in 1865[40] and Rivington in 1875,[49] described the pathology, and attributed the signs and symptoms to a lesion in the cavernous sinus. Dandy and Tollis proposed that CCSF be divided into traumatic and spontaneous types.[13] Brooks in 1931 suggested using a muscle embolus introduced into the carotid artery to occlude the fistula.[42] Hamby[25] used carotid ligation intracranially, combined with a muscle embolus. Prolo et al.[46] described the use of a Fogarty balloon catheter to occlude the intracranial internal carotid and thus obviated the need for a craniotomy. Parkinson,[42] in 1965, opened the cavernous sinus and directly occluded the fistula. Serbinenko,[50] in 1974, was the first to develop and use a detachable balloon for vascular occlusion.

ANATOMY OF THE CAVERNOUS SINUS

The cavernous sinus is a plexus of veins encased in a double layer of dura and located on either side of the body of the sphenoid sinus (Fig. 1). The internal carotid artery (ICA), along with its surrounding sympathetic plexus and the VI nerve, courses through the sinus. The III, IV, V1 and V2 cranial nerves run forwards in the lateral wall of the sinus enclosed in the double layer of dura.[48]

Arteries

The carotid artery gives off three branches in the cavernous sinus:[26]

1. The meningohypophyseal trunk, a constant branch, is the most proximal and arises at the level of the dorsum sellae. This trunk gives off three branches:
   - A. The tentorial artery also called the artery of Bernasconi-Cassinari[9] which supplies the tentorium
   - B. The inferior hypophyseal artery which supplies the posterior pituitary
   - C. The dorsal meningeal artery which supplies the clival area and the VI nerve

   In about 6% the dorsal meningeal artery may arise directly from the intracavernous carotid artery.
2. The artery of the inferior cavernous sinus arises from the horizontal portion of the intracavernous

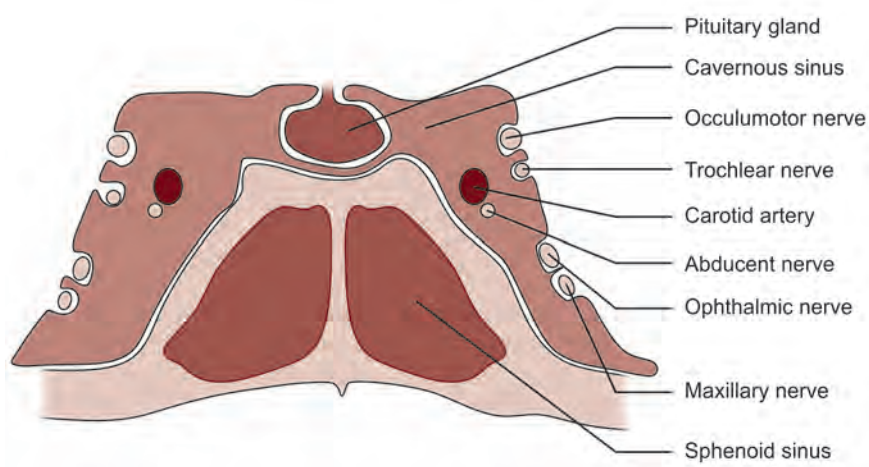

Fig. 1: Coronal section through cavernous sinus

carotid. Occasionally, it may arise from the meningohypophyseal trunk. It supplies the inferior wall of the cavernous sinus and the area of the foramen ovale and spinosum. This artery corresponds to the carotid remnant of the embryonic dorsal ophthalmic artery.

3. McConnell's capsular arteries are seen in about 30–50%. They arise on the medial side of the carotid artery about 0.5 cm beyond the artery of the inferior cavernous sinus.[33]

The ophthalmic artery may arise in about 8% from the intracavernous carotid artery. The branches of the ICA arising in the cavernous sinus anastomose with the various branches of the external carotid artery (ECA). The neuromeningeal trunk of the ascending pharyngeal artery, the recurrent and anterior meningeal branches of the internal maxillary artery and the cavernous branch of the middle meningeal artery are the arteries that commonly anastomose with the cavernous branches of the internal carotid. These arteries are important in Type C and D fistulas.

Veins

The tributaries of the cavernous sinus are many.

1. The superior and inferior ophthalmic veins and through them, the facial veins
2. The middle and inferior cerebral veins draining the cerebral substance
3. The central retinal vein, the middle meningeal veins, the superior and inferior petrosal sinuses and the emissary veins

The two cavernous sinuses on either side are connected by intercavernous communications.[1] These are:

- The anterior intercavernous sinus: This measures 0.57–5.43 mm. It may involve the whole of the anterior dura of the sella, may have a curvilinear shape or may run at the level of the pre-chiasmatic groove
- The posterior intercavernous sinus: This varies in diameter from 0.71–4.14 mm
- The inferior cavernous sinus is not always seen. It may be plexus like, a venous lake or of a mixed type and runs in the dura of the floor of the sella
- The basilar plexus is the largest intercavernous communication in the majority. It is located at the level of the dorsum sellae. There may be many irregular vascular channels or it may be heterogeneous

CLASSIFICATION

Carotid-cavernous sinus fistula has been classified in many ways which are as follows:

- Spontaneous or traumatic
- High or low-flow
- Direct or indirect (dural) fistulae according to their arterial supply determined angiographically

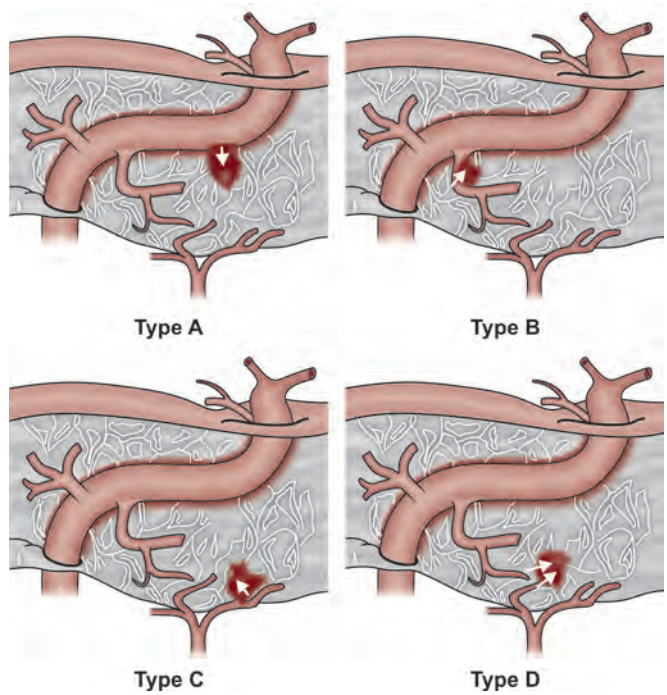
The first two do not take into consideration the factors that are required in the proper planning of the treatment of CCSF.

Barrow et al.[6] classified them angiographically into four types (Figs 2A to D). Type A are direct shunts from the ICA to the cavernous sinus. They are high-flow and are usually caused by trauma and base of skull fractures.[15] They may also be due to rupture of an intracavernous carotid aneurysm.[22,30,44] Young men are commonly affected and the majority require treatment as they do not close spontaneously. Types B, C and D are dural or indirect fistulas. They occur in middle-aged women, are low-flow and in 16–60% they resolve spontaneously.[6,17,46,56] In Type B there is a communication between the dural branches of the ICA and the cavernous sinus. These are extremely rare. Type C arises as a result of communication between the dural branches of the ECA and the sinus. Dural branches of the ICA and ECA take part in Type D fistulae which are the commonest indirect fistulae.[17]

In a study of consecutive patients having CCSF, Preechawat et al. were able to classify their 80 patients according to Barrow's classification after angiographic evaluation, as Type A (0%), Type B (14%), Type C (15%) and Type D (71%).[45]

SYMPTOMS AND SIGNS

The symptoms and signs depend upon the type of fistula, the direction of the venous outflow, either anterior or posterior, the anatomical location in the cavernous sinus and the size of the fistula. Rarely, there may be bilateral involvement.[19]



Figs 2A to D: Angiographically classification by Barrow et al. (A) Direct shunt from the internal carotid artery to the cavernous sinus. (B) Shunt from dural branches of the internal carotid artery to the cavernous sinus. (C) Shunt from dural branches of the external carotid artery to the cavernous sinus. (D) Shunt from dural branches of both internal and external carotid arteries to the cavernous sinus

Type A fistulae are direct, high-flow and mostly traumatic. They occur most frequently after a closed head injury, though they may occur as a result of direct penetrating injury or rupture of an intracavernous carotid aneurysm. A high index of suspicion is paramount in cases of polytrauma, where a CCSF can be easily missed. A relatively high incidence of traumatic CCSF occurs in patients with middle fossa fractures, especially those with transverse or oblique fractures.[32] Spontaneous non-traumatic direct CCSFs are extremely rare and an underlying predisposing factor like systemic connective tissue disorders such as Ehlers-Danlos syndrome may be seen.[58] It is probable that advancing age, menopause, hypertension and childbirth may affect some preexisting subclinical lesions in the arteriolar system like aneurysms, leading to the development of spontaneous CCSF.[14] Low-flow fistulae occurring after trauma are usually due to avulsion of a dural arterial branch.

Ocular signs and symptoms are produced when the major venous outflow is through the superior or inferior ophthalmic veins. The signs may be unilateral, bilateral or may occur only in the eye opposite to the side of the fistula due to predominant drainage through the intracavernous venous communications. The ocular manifestations are pulsating exophthalmos, chemosis, ocular nerve palsies causing diplopia, visual loss and exposure keratitis. Patients with CCSF may initially present to an ophthalmologist. There may be venous and arterial stasis resulting in decreased ocular and retinal perfusion. Retinal and choroidal changes may include venous dilatation, retinal haemorrhage, central retinal vein occlusion, central retinal artery occlusion, cotton wool patches and serous retinal detachment.[10] Facial pain may occur due to involvement of cranial nerves V1 and V2. A subjective and audible bruit will be present. Headache may occur due to dural distension, raised intracranial pressure (ICP) or subarachnoid haemorrhage (SAH). Flow through the cortical veins can produce raised ICP. Symptoms due to raised ICP, cerebral steal and SAH are uncommon. When the major outflow is posteriorly into the basilar plexus, there may only be a bruit. Rarely, lower cranial nerve dysfunction affecting the VIII, XI and XII nerves may occur.[8] In an occasional patient there may be only pulse-synchronous tinnitus.[2] Other rare presentations include brainstem compression and epistaxis.[19,28]

In the low-flow Types B, C and D fistulae the clinical manifestations are insidious in onset and include mild proptosis, chemosis, ocular pain and glaucoma. Sometimes they may lead to progressive visual loss. A bruit may be audible. The various theories and views regarding the pathogenesis of spontaneous low-flow CCSF have been described by Barrow.[7]

Differential diagnoses for CCSF include vascular lesions such as arteriovenous malformation and cavernous sinus thrombosis, cavernous sinus tumours, orbital tumours, skull base tumours and mucocoele. Thyroid eye disease, orbital pseudotumour, and orbital vasculitis resulting from Wegener's granulomatosis, polyarteritis nodosa, intracranial sarcoidosis and Tolosa-Hunt syndrome may present like CCSF.[10]

INVESTIGATIONS

Angiography is the best investigation for diagnosing and classifying CCSF. Selective external carotid catheterisation will help in Type C and D. The CT scan will be useful when there is evidence of steal or an intracerebral haematoma.

The imaging findings of carotid-cavernous fistula include dilatation of the superior ophthalmic vein, enlargement of the cavernous sinus, proptosis and thickening of the extraocular muscles. Dilation of the superior ophthalmic vein is a specific imaging sign of carotid-cavernous fistula. An engorged superior ophthalmic vein presents with a characteristic "hockey stick sign" on orbital B-ultrasound, CT and magnetic resonance imaging.[11,57] Colour Doppler imaging has been found to be useful and correlates well with the angiographic findings. Doppler also provides information about the direction and velocity of flow and is useful in post-treatment follow-up.[36,51] Transcranial Doppler is also useful in assessment,[37] as well as during balloon occlusion.[20,38] It is also useful in assessing tolerance to carotid occlusion during treatment.[5] Brain single photon emission computed tomography scanning has been used to assess the pre and post-embolisation blood flow to the brain, especially in patients with steal phenomenon.[24]

TREATMENT

Knowledge of the natural history of the disease is important in deciding whether treatment is necessary or not. Type A fistulae almost never close spontaneously, though this has been reported.[47] These require treatment. Type B, C and D are low-flow and have been reported to close spontaneously in 16–60% of cases. The indications for immediate treatment are progressive visual loss, a distressing bruit, diplopia and severe proptosis with corneal exposure. Others can be kept under observation for 6 months after investigations and angiography. Angiography itself has been reported to have promoted closure of the fistula,[39,56] though the exact mechanism is not known. Carotid compression therapy has also been successful in closure of 17% of direct and 30% of dural CCSFs.[10] Treatment is offered when the fistula does not close or there are progressive symptoms. The purpose of treatment is to occlude the fistula without occluding the carotid artery, as far as possible. The methods available include endovascular techniques, surgery and radiosurgery.

Endovascular Therapy

There have been tremendous technical advances in the field of interventional neuroradiology which have simplified the treatment and also given various endovascular treatment options while dealing with CCSF.

The majority of Type A fistulae can be treated by embolisation using balloons, coils or embolic agents. The balloons that are most favoured are silicone balloons filled with 2-hydroxyethylmethacrylate and radiopaque contrast material.[29,52]

Coils made of platinum[23,24,26] are used when balloon occlusion fails or cannot be used due to the fistula being very small, when bony spicules may puncture the balloon or when after balloon occlusion there is a small venous space into which a balloon cannot be introduced. Stent-assisted or balloon-assisted coil placement can be done. Liquid embolic agents like onyx are also used to complement balloons or coils, and rarely used as the sole strategy of management.[59]

The route of access to the cavernous sinus for embolisation can be intra-arterial through the carotid artery or intravenous through the superior ophthalmic vein or the superior or inferior petrosal sinus through surgical exposure.[16,25,53] The transvenous route through the inferior petrosal sinus is the best endovascular approach to achieve cure. Preliminary transarterial embolisation may be necessary if there are extensive ECA feeders.[27]

When endovascular techniques fail direct surgery is necessary to occlude the fistula.

Type B fistula is very rare. As it cannot be occluded with a balloon, a direct surgical approach should be considered.[5]

Type C fistula is also rare and can be treated by embolisation of the external carotid branches. The embolic materials that can be used are silastic beads, Ivalon, gelfoam and isobutyl-cyanoacrylate. Ivalon is preferred.

Type D fistula is treated initially with embolisation of the ECA feeders. This often leads to thrombosis of the fistula. In some instances the ICA feeder enlarges and if it is large enough, it can be occluded using a balloon; otherwise direct surgery has to be performed.

Covered stents have recently become available for various vascular conditions including carotid-cavernous fistulas. The CCSF can be treated while preserving the parent artery by reconstructing the arterial wall.[3,21,31,34] Li et al.[31] have reported a successful outcome in 11 out of 12 cases with traumatic CCSF. Though endoleak and spasm were among the common complications encountered, they could be dealt with easily.

Embolisation of CCSF may carry a risk of inherent complication either from the procedure or due to reopening of the fistula. Among the 80 patients treated by Preechawat et al.[45] intra-operative complications occured in three patients, which included ophthalmic artery occlusion and cerebral infarction. Eight patients experienced transient aggravation of symptoms, including increased proptosis, elevation of intraocular pressure, choroidal detachment that required suprachoroidal drainage and venous stasis retinopathy. Ophthalmic vein thrombosis resulting in central retinal vein occlusion developed in three patients and finally caused severe visual deficit. Other potential complications include uncontrolled bleeding, ophthalmoplegia and cavernous sinus thrombosis.[10]

Surgical Approaches

Surgery is indicated when embolisation fails or when it is contraindicated, or when previous procedures have occluded the ICA and the fistula is still patent. The first surgical procedure to be used was carotid ligation in the neck.[54] Various other procedures referred to under history have been tried. All these involved occlusion of the ICA. Parkinson[42] was the first to open the cavernous sinus and directly treat the CCSF. The cavernous sinus is opened between the III and IV nerves and this area is known as Parkinson's triangle.[43] Mullan, in 1979, exposed the cavernous sinus, opened it and introduced agents like gelfoam and surgicel to occlude the fistula and retain the patency of the ICA.[35] Dolenc,[18] in 1983, described exposure of the entire cavernous sinus and the petrous ICA. By removing the anterior clinoid process and de-roofing the optic canal, the entire intracavernous carotid artery can be visualised. Various methods have been used to occlude the fistula. These are direct clipping, packing with muscle or other material, or microsurgical reconstruction of the artery.

Radiosurgery

With the improved results of cerebral AVM treated successfully with stereotactic radiosurgery, CCSF is also being treated using the same principle. Stereotactic radiosurgery forms an integral part of the multidisciplinary and multimodality approach in treating carotid-cavernous fistulas. Though radiosurgery has been used in many instances for treating CCSF, its indications are still unclear. Elderly patients with medical comorbidities, failed repeated endovascular therapy and low-flow dural CCSF are among the few mentioned indications.[41]

Prognosis and Complications

The mortality associated with CCSF is 1–2%.[5] Any treatment option that is offered to the patient should not exceed this figure. CCSF being an uncommon condition, the complication and mortality rates depend on the experience of the interventional radiologist and the surgeon. Debrun achieved a 60% patency rate of the ICA in his first 54 cases[15] whereas it was 80% in the subsequent 41 cases.[17]

The complications that may occur are stroke due to ICA occlusion or balloon migration. The balloons that are used may rupture or shrink.[4,12,55] Venous rupture may occur when the transvenous route is used for emolisation.[25] False aneurysms can form due to balloon shrinkage. Cranial nerve deficits can occur due to pressure on the lateral wall of the cavernous sinus and these usually recover spontaneously.

99 Dural Arteriovenous Malformations

Ravi Ramamurthi, Nigel Peter Symss

INTRODUCTION

Dural arteriovenous malformations (D-AVMs) were first reported by Sachs,[23] in 1931. These are defined as arteriovenous (AV) shunts from a dural arterial supply to a dural venous drainage channel and constitute 10–15% of intracranial arteriovenous malformations (AVMs).[23] These occur more frequently in women.

EMBRYOLOGY AND PATHOPHYSIOLOGY

Embryologically the circulation of the brain and its coverings including dura, skull and scalp is developed from a common origin. Therefore, it can be anticipated that a vascular malformation developing in one of these layers may have vascular participation from any or all of the adjacent layers. The dura mater has an extrinsic vascular supply. Branches of the external carotid artery (i.e. middle meningeal, accessory meningeal, posterior auricular, occipital and ascending pharyngeal arteries) supply the lateral aspects and convexity of the dura. Branches of the internal carotid artery supply the floor of the anterior cranial fossa (anterior and posterior ethmoidal branches of the ophthalmic artery) and the tentorium (dorsal meningeal branch and tentorial branch of the meningohypophyseal trunk). The dura of the posterior cranial fossa is supplied by branches from the vertebral system. Minute AV shunts exist between the meningeal arteries and the walls of the major dural sinuses, which may have an important role in the pathogenesis of D-AVMs.

The AVMs of the brain may receive blood supply from the dura mater in some cases, whereas the dura alone is the seat of malformation in 10–15%. The presence of the nidus within the leaflets of the dura mater or tentorium differentiates D-AVMs from the more commonly occurring parenchymal or pial AVMs. The nidus is usually in a well-defined region of the dural leaflet, often located near a dural sinus and is the point of convergence of all arterial feeders, which mainly arise from the dural arteries or from the pachymeningeal branches of the cerebral arteries. The venous drainage can be through either dural or pial channels, with 60–75% draining exclusively into the dural sinus.[1] It is probable that increased pressure within the dural venous drainage system results in retrograde leptomeningeal venous drainage and these channels may often be noted to become tortuous or variceal. Thrombosis of the transverse or sigmoid sinus has been reported in many cases of D-AVMs. The fact that the sigmoid sinus is often blocked was observed by Sundt and Piepgras,[26] who postulated that this obstruction may be a sequel to an inflammatory process. An inflammatory hypervascularity then develops into an arteriovenous fistula (AVF). Houser et al.[9] reported stenosis or occlusion of a dural sinus in 80% of their cases and documented two cases presenting initially with sinus occlusion and then going on to develop D-AVMs a few years later.

Most AVMs associated with the meningeal artery in the anterior cranial fossa are the pure dural type, where mixed pial-dural AVMs are rare. There are two types of mixed pial-dural AVM in the anterior cranial fossa based on the shunting point:

1. One with the nidus in the brain parenchyma of the frontal lobe
2. Other with the shunting point in the dura mater

Jimbo et al.[10] reported two patients with AVMs fed by the anterior ethmoidal arteries and the persistent primitive olfactory artery with the nidus located solely in the brain parenchyma of the inferior aspect of the frontal lobe and drained via abnormal cortical veins into the cavernous and superior sagittal sinuses. They recommended occluding the venous outflow to obliterate intracranial dural AVF (D-AVF) but observed removal of the nidus in the brain parenchyma was also required. They concluded that the presence of a pial feeder should be looked for before a diagnosis of D-AVF of the anterior cranial fossa is made and a pre-operative detailed evaluation of the pial supply and shunting point is mandatory.

AETIOLOGY

D-AVMs are acquired lesions and may result from traumatic[16] or non-traumatic causes. Traumatic D-AVMs are often asymptomatic and are on many occasions diagnosed as incidental findings on angiography. These are often located at sites remote from the region of trauma. Non-traumatic D-AVMs are postulated to occur secondary to venous obstruction, usually thrombosis of one of the dural sinuses. Venous obstruction may result in the formation of D-AVM, either by enlargement of the normally present micro AV shunts within the dura or by recruitment due to "sump" effect of arterial supply

from the scalp, the meninges and the cortex through AV shunting in the wall of the sinus. This leads to secondary venous hypertension and results in retrograde drainage in the leptomeningeal veins, predisposing to their tortuosity and dilatation.

NATURAL HISTORY

D-AVMs have a highly variable natural history. Patients may remain asymptomatic for many years. Symptoms usually become manifest in the sixth and seventh decades of life. Clinical symptoms may either remain benign throughout or may rarely follow an aggressive course. This is seen (in about 27%) more commonly with lesions located at the tentorial incisura and the anterior cranial fossa.

An aggressive course in relation to D-AVMs is defined as haemorrhage or progressive neurological deficit other than ophthalmoplegia.[1,2,11-13] The D-AVMs characterised by leptomeningeal venous drainage, variceal or aneurysmal venous dilatation and Galenic drainage are especially more prone to haemorrhage. Haemorrhage may be the initial presenting feature in 17–24% of patients. The risk of haemorrhage is more common with AVMs located at a distance from a sinus, than in the lesions adjacent to a dural sinus. The D-AVMs with haemorrhage as the initial presenting feature are associated with a mortality of 30% and the incidence of recurrent lethal intracranial haemorrhage (ICH) remains high.[1] Extensive D-AVMs may cause symptoms because of venous hypertension and the resulting malabsorption of cerebrospinal fluid.[22] Spontaneous thrombosis or regression of D-AVM is also known. This results from fibrosis of the thrombus causing occlusion of the fistulous connections.[1,21] Spontaneous occlusion is seen more commonly with lesions adjacent to the cavernous sinus. In patients with polycythemia and D-AVFs that have a relatively low risk of haemorrhage, polycythaemia should be treated first before any interventional treatment, because venesections may lead to spontaneous closure of the D-AVF.

CLASSIFICATION

The D-AVMs may be classified depending on the following:

- Involved sinus (sagittal, cavernous, straight, sphenoparietal, transverse or sigmoid)
- Region of the dura involved (anterior, middle or posterior cranial fossa, tentorium)[18]
- Venous drainage pattern (dural sinus, Galenic, pial, cortical)

The above mentioned systems may be combined and a reasonable working diagnosis can be arrived at by including the anatomic location and the venous drainage.

There are many classification schemes for D-AVFs. The most useful and recent ones are the revised Djindjian and Merland[7] classification proposed by Cognard et al.[4] and the classification proposed by Borden et al.[3] both of which are based on the initial classification. Cognard et al. defined five types of D-AVFs based exclusively upon the pattern of venous outflow:

- Type I, located in the main sinus, with antegrade flow
- Type II, in the main sinus, with reflux into the sinus (IIa), cortical veins (IIb), or both (IIa+b)
- Type III, with direct cortical venous drainage (CVR) without venous ectasia
- Type IV, with direct CVR with venous ectasia
- Type V, with spinal venous drainage. They all focus on the patterns of venous drainage.

CLINICAL FEATURES

The pathophysiological consequences and clinical manifestations are related to specific stages of the evolution of D-AVMs.[11] Obrador et al.[19] reviewed 115 cases and found that symptoms fell into one of the following six patterns:

1. Bruit (35%)
2. Headache, papilloedema and visual failure due to raised intracranial pressure (15%)
3. Subarachnoid haemorrhage (SAH) (17%)
4. Ischaemic neurological deficit (10%)
5. Hydrocephalus and bruit in infants (4%)
6. Combination of more than one of these (15%)

Clinical behaviour, inclusive of initial presentation and progression of symptoms, is dependent on multiple, inter-related factors including location, arterial feeders and venous drainage. A catastrophic neurological course is primarily determined by the venous drainage pattern.

In the first stage of evolution of D-AVMs, local increased venous pressure will result in venous congestion, which may cause seizures and non-haemorrhagic focal neurological deficits. Intracranial hypertension and papilloedema may result, due to a generalised increase in venous pressure. In the second stage of evolution, with recruitment of arterial feeders, symptoms related to increased flow in the individual neural structures are encountered. These are termed "neighbourhood symptoms" and include headache, pulsatile tinnitus, cavernous sinus syndrome, trigeminal neuralgia and hemifacial spasm. The final stage in the evolution is characterised by retrograde leptomeningeal venous drainage and variceal dilatations, which are responsible for ICH. Bleeding occurs from these engorged and brittle leptomeningeal venous connections and not from the nidus.[1,14,24] Non-traumatic D-AVF/D-AVM presenting with pure subdural haematoma (SDH) is rare. Ogawa et al.[20] reported one such case and recommend considering D-AVF/D-AVM and to perform angiography if necessary when a patient presents with non-traumatic SDH without ICH and/or SAH.

INVESTIGATIONS

Although computerised tomography and magnetic resonance (MR) may suggest a vascular abnormality, detailed

cerebral panangiography, especially using digital subtraction techniques, remains the mainstay in the diagnosis of D-AVMs. Selective studies of bilateral internal and external carotid systems, along with vertebral studies are essential. Arterial branches within the dura are normally not visualised on angiography, but in the presence of D-AVMs, the concerned vessels are dilated and clearly visible. Certain meningeal vessels, like the meningeal branch of the posterior cerebral artery also called the "artery of Davidoff and Schechter", is angiographically demonstrable only in the presence of a D-AVM. The nidus is usually limited to a well-defined focus within the dural leaflet and is best visualised on ultra early arterial views, or on injection of either contralateral or more distant feeding vessels. Late arterial views, venous views and superselective injection of major feeder vessels, demonstrate engorged vascular channels which may occupy diffuse areas of the dura. The shunt flow rate can also be estimated based on the evidence of steal from a more distant artery. The pathognomonic diagnostic feature of D-AVM on angiography is the premature appearance of venous structures within or adjacent to the dura mater during the arterial phase. The presence of dilated pachymeningeal arteries often lends supporting evidence to the other angiographic data.

Dural venous sinus thrombosis will be seen on the venous phase and may reflect:

- Thrombus preceding the genesis of the AVM
- Accompaniment of spontaneous or induced thrombosis of an adjacent D-AVM
- Angiographic artefact due to "steal" through other channels.

MR angiography is helpful in the non-invasive diagnosis of D-AVMs.

MANAGEMENT

Considering the wide variability of the natural history of D-AVMs it is mandatory to define the treatment strategy based on an individualised risk-benefit ratio. This depends on the clinical features, neurological status and the nature of D-AVM as regards its location, extent and angiographic patterns. A conservative approach and observation is advisable for lesions causing only benign symptomatology. Active intervention is indicated for D-AVMs associated with features predisposing to progressive neurological deficit or for lesions with benign but distressing symptoms. This definitive treatment may be in the form of arterial embolisation, transvenous occlusion, surgical excision and radiation therapy. One or more of these modalities may be combined in specific cases.

Arterial embolisation using balloons, particulate matter or polymerising chemical agents is a good adjunct in presurgical planning and is most useful for isolated AV communications. It has only a limited application in AVMs supplied by small, multiple feeders from the internal carotid artery, e.g. D-AVMs of the tentorial incisura. Transvenous occlusion using metal coils, gelfoam or balloons may be done but is associated with significant morbidity.

Trivelato et al.[27] reported their early experience in treating nine patients by transarterial embolisation of D-AVFs with direct CVR using Onyx®. They achieved complete occlusion of the fistula in all patients with only one procedure and injection in only one arterial pedicle. On follow-up, eight patients became symptom free, one improved and no patient deteriorated. Late angiography showed no evidence of recurrent D-AVF. They recommend that transarterial Onyx® embolisation of D-AVFs with direct CVR is to be considered as a treatment option, as they found it to be feasible, safe and effective.[27] Cognard et al.[5] found Onyx® injections, were easier to control than N-butyl cyanoacrylate injections and a much larger volume could be injected over a longer time period. Also injection in a single feeder allowed obtaining arterio-arterial reflux and avoided embolisation of other feeders. They suggested that Onyx can be used as a primary treatment option for most cases of D-AVFs with direct cortical venous reflux. Saraf et al.[25] from their analysis of 99 cases of D-AVFs recommended the use of Onyx as the embolic agent of choice in the treatment of D-AVFs.

Van Rooij et al.[29] published their experience in the management of D-AVFs with CVR. Surgery being the treatment of choice for anterior fossa D-AVFs, and for all other D-AVFs embolisation with glue was the first treatment option. Five patients with an anterior fossa D-AVF underwent successful surgery without complications. In 14 patients, the D-AVF was completely occluded with embolisation alone, and in seven patients, embolisation was followed by surgery. They were able to achieve complete occlusion, angiographically confirmed in 28 out of 29 D-AVFs. Embolisation was complicated by post-embolisation haemorrhage[17] in one patient (3%). Nelson et al. in their series of 21 D-AVFs, nine of which were type III-IV Cognard, were treated transarterially under flow-arrest conditions, and cures were demonstrated in all fistulae without complications.

Kennith described a novel approach for endovascular ultrasound-guided puncture of an arterialised extracranial venous pouch with transosseous microcatheter navigation through a mastoid emissary vein for the treatment of an aggressive type 4 D-AVF. This can be offered as a useful alternative to other endovascular approaches for treating D-AVFs.[15]

Surgical methods employed are:

- Ligation of feeder vessel(s) which at best gives only transient relief of symptoms
- Excision of the entire anomaly with or without preoperative embolisation

The object of surgery is to resect the dural leaflets containing the nidus and the adjacent sinus along with disconnection of leptomeningeal draining pathways—the harbingers of fatal ICH. Careful pre-operative

angiographic analysis, judicious use of adjuncts like pre-operative embolisation and meticulous haemostasis during surgery help to improve surgical outcome. Microscope-based intra-operative near-infrared indocyanine green (ICG) videoangiography is useful as an adjunct to intra-operative or post-operative digital subtraction angiography in aneurysm surgery. Hanggi et al.[8] found microscope-integrated repetitive ICG videoangiography during AVM and D-AVF surgery is fast, easy to perform, simple, safe and is a useful additional tool that can potentially lower the surgical risk in complex AVMs and help avoid missed residuals.

Anterior cranial fossa D-AVFs are typically supplied by the anterior ethmoidal artery, sometimes bilateral, and usually drain into the superior sagittal sinus via a unilateral cortical drainer, bilateral drainers being rare.[6] Kohama et al.[12] reported a rare case of anterior cranial fossa D-AVF with bilateral cortical drainers. They recommend drainer occlusion at two points is required for complete obliteration of the drainers as the fistulous connection may not be simple.[12,28]

Successful use of conventional radiotherapy for D-AVMs is only anecdotal. However, encouraging results with the use of stereotactic radiosurgery suggest that this may be the future therapy of choice for many D-AVMs.

100 Embolisation of Spinal Vascular Malformation

Anil Karapurkar, Nishant Aditya

With the recent advances in imaging techniques, spinal vascular malformations are being diagnosed and treated frequently. Improved techniques of MRI, MRA, MR myelography[16,23] and improvement in techniques of spinal angiography have led to better understanding of the pathophysiology of the malformations and, therefore, better treatment.[39] Until the seminal papers by Kendall (1977), Merland (1980) and Symon (1984), the pathophysiology and treatment of spinal dural arteriovenous fistulae (AVF) was not understood. Dural AVF was confused with AVM of the spinal cord and extraspinal AVF with intradural venous drainage. Since, spinal AVM and AVF are complex malformations, these should be managed by specialised centres experienced in them.

CLASSIFICATION OF SPINAL VASCULAR MALFORMATIONS[5,53,63]

Spinal cord malformations are complex. Many classifications have been proposed over the years. None of them is satisfactory. The commonly accepted ones are given in Tables 1A to C.

Table 1A: Spinal vascular malformations

Type I	Spinal dural arteriovenous fistula
Type II	Spinal AVM—Intramedullary
Type III	Spinal AVM—Juvenile[51]
Type IV	Spinal AVM—Perimedullary AVF[45]

Table 1B: Casasco classification

A. Simple:
A1. Spinal canal vascular malformation:[44]
a. Intramedullary vascular lesions:
i. AVM
ii. AVF
iii. Cavernoma[25,41]
iv. Telangectasia
b. Perimedullary AV fistula:
i. Type 1-small AVF, ASA or PSA and vein
ii. Type 2-ASA/PSA and vein dilated
iii. Type 3-giant AVF, multiple feeders[43]
c. Spinal dural AVF with perimedullary venous drainage[17,30,31]
Contd...
Contd...
d. Intracranial dural AVF with perimedullary venous drainage
e. Epidural AVF and AVM:[21,22,50]
i. Single shunt
ii. Multiple shunts
A2. Perivertebral malformations:
a. Paraspinal
b. Costovertebral angle
c. Nerve root foramina
A3. Vertebral angiomas:
a. Non-progressive vertebral angiomas
b. Progressive vertebral angiomas
B. Complex:
a. AVM in spinal arteriovenous metameric syndrome (SAMS)[6] at each spinal level—involvement of all layers of integument, ectodermal and mesodermal, from skin, subcutaneous tissue, muscle, bone, dura, subdural tissue, spinal cord.[12]
b. Disseminated angiomatosis (Osler-Rendu-Weber disease).[15,20,59]

2. Intramedullary-extramedullary
3. Conus medullaris

They are usually made up of single or multiple AVF.[4] Niduses similar to those in brain AVMs are uncommon. Since there is hypertrophy of the feeding artery, aneurysms along their course are not infrequent.[7,24,46] The dilated arterialised veins may also show aneurysms along their course.

VASCULAR SUPPLY OF THE SPINAL CORD[6,57]

Three longitudinal axes supply blood to the spinal cord; the single central anterior spinal axis (ASA) and the paired posterolateral posterior spinal axes (PSA). They arise from the vertebral arteries just proximal to their junction. The anterior and posterior axes receive tributaries at multiple levels as they descend down the spinal cord. These tributaries are known as radiculomedullary and radiculopial arteries. The radiculomedullary arteries supply the anterior spinal axis and the radiculopial arteries supply the posterior spinal axes. In the cervical region radiculomedullary arteries arise from both vertebral arteries, ascending and deep cervical arteries, and in the dorsal and lumbar region from the dorsospinal branches of the intercostal and lumbar arteries. The most important contribution to the ASA is from the artery of Adamkiewicz, which may arise anywhere from T8 to L1, more often on the left side. Another prominent radiculomedullary artery arises at the cervical level and is called the artery of the cervical widening. The anterior two-thirds of the spinal cord is supplied by the ASA and the posterior one-third by the paired PSA. The anterior spinal axis is a continuous channel extending from the cervicomedullary junction to the filum terminale. The axis lies in the anterior commissure of the spinal cord and gives rise to perforators throughout its length. These perforators are known as sulco-commissural perforators. These perforators are usually not visible on angiography unless they are hypertrophied in the presence of pathology like spinal cord AVM. For embolisation, these may have to be selectively cannulated to maintain the continuity of the anterior spinal axis. Sulco-commissural arteries supply the lateral surface of the spinal cord. Accidental embolisation of a posterior radicular artery may be of no consequence, but occlusion of the ASA is followed by devastating neurological deficit.

CLINICAL PRESENTATION

The clinical presentations[37,48] of spinal cord AVM[14,26] or AVF are different from that of dural AVF (Table 2).

The clinical signs are due to: (1) SAH; (2) haematomyelia; (3) steal into AVF/AVM; (4) venous hypertension; (5) thrombosis of draining vein, (6) pressure of aneurysm, venous or arterial, true or false; (7) arachnoiditis; (8) syringomyelia and (9) Foix-Alajouanine syndrome, a result of chronic venous ischaemia of the spinal cord.[42]

Table 2: Clinical Presentation

Dural AVF	*Intradural*	*AVM/AVF*
Gender	Predominantly Male	Male or Female
Mean age	40 years	25 years
Onset	Gradual	Sudden
First symptom	Paresis or pain	SAH
Exacerbation by activity	80%	25%
UL affected	Never	Sometimes

SAH is usually due to rupture of an aneurysm or AVM nidus. Thrombosis of the draining vein results in Foix-Alajouanine syndrome. Clinical cure with disappearance of the draining vein due to thrombosis is rare.

The clinical course is often characterised by exacerbations and remissions.[2] These are due to repeated haemorrhages from aneurysms or veins. Rise in venous pressure results in clinical deterioration, e.g. after constipation, coughing, sneezing, forward bending, pregnancy and menstrual period. Claudication pain is a common presentation in dural AVF. Claudication pain and neurological deficit may be worsened by a heavy meal. Spinal SAH may be confused with intracranial SAH. However, the pain starts at the site of the spinal AVM and spreads upwards. The neurological deficit usually starts in the lateral columns then spreads to the corticospinal tracts and posterior columns. Sphincter involvement is early, if the conus is involved. The story may go on for many years, punctuated by exacerbations and remissions. Diagnosis, especially of dural arteriovenous fistula, is difficult and delayed for several months before it is made (Table 3).

Table 3: Summary of Clinical Characteristics in AVMs (Spetzler 2002)

Characteristics	*Extradural-Intradural*	*Intramedullary*	*Conus Medullaris*
Pathophysiology	Compression, vascular steal, haemorrhage	Haemorrhage, compression, vascular steal	Venous hypertension, compression, haemorrhage
Presentation	Pain, progressive myelopathy	Acute myelopathy, pain, progressive myelopathy	Progressive myelopathy
Diagnostic modality	MR imaging, Angiography High-flow, multiple feeders	MR imaging, Angiography	MR imaging, Angiography
Previous nomenclature	Juvenile AVM, metameric AVM	Classic AVM, glomus type	None

INVESTIGATIONS

Plain X-rays may show scalloping of the posterior surface of the vertebral body, if there is a large venous varix. Usually plain X-rays are non-contributory.

Myelography

Myelography with non-ionic contrast in the prone and supine positions may show the coiled vessels on the dorsal surface of the spinal cord. Arachnoiditis may also be recognised.

Computerised Tomography Scan

Computerised tomography scan with intrathecal contrast may show the large serpiginous vessels. CTA on the newer machines, if done carefully, often provides good information. The feeding arteries, nidus (if any), draining veins and aneurysms along the feeders and draining veins may be seen.

Magnetic Resonance Imaging

Magnetic resonance imaging[29] usually shows the lesion within the cord very well. In dural AVF, fusiform oedema of the conus is pathognomonic. It may extend upwards into the dorsal cord for a variable distance. The vessels may be seen on MRI myelography or T2-weighted images. Associated lesions of the cord, cysts, arachnoiditis and syrinx are well seen. Old haemorrhage may be seen as haemosiderin deposits.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA), especially after contrast, shows the vessels very well. If pains are taken one may be able to identify the site of the AVF, the feeding artery and draining vein. The coiled vessels on the anterior and posterior surface of the cord are well-seen.[36]

Digital Subtraction Angiography

DSA is the gold standard.[40,49,58] For cervical lesions, bilateral vertebral (VA), bilateral subclavian, bilateral external carotid and at least eight upper dorsal intercostal arteries must be catheterised on both sides. For lumbar lesions, bilateral intercostals, all lumbar and internal iliac angiograms must be done. For slow flow dural AVF, delayed filming up to 20 seconds is mandatory. For better subtraction the respiration is stopped during filming and bowel movements are reduced by Buscopan injections. Subtracted and non-subtracted views are necessary for proper orientation of the vertebral level and to ascertain whether it is anterior or posterior to the cord. AP views are made of all vessels. Lateral and oblique views of the feeders to the spinal cord and the malformation are made to get a complete picture of the malformation. Since the long arteries and veins may extend over several segments, it may be necessary to acquire images over several segments and fuse sequential runs to get a true idea of the extent of the lesion. For example, the ASA may start at D8 and may feed a lesion at L3. Sometimes the artery turns around the sulco-commissural segment at the conus and reascends to supply a malformation. Similarly, draining veins may begin on the posterior surface, then ascend and descend on the anterior, posterior and lateral surface. The same feeder may be supplied by many intercostal or lumbar arteries, usually on the same side, but sometimes also from the opposite side. For sacral AVF or AVM, injection into the internal iliac artery may demonstrate low-flow small feeders from the lateral sacral arteries. Despite an exhaustive study AVM may not be demonstrated, and the AVM may be occult. Sometimes it may be necessary to repeat the angiogram.

The DSA must be analysed carefully. When analysing the DSA, one must find the feeders, draining veins and the nidus. As has already been stated there may be no nidus at all. There may be single or multiple AVF. Sometimes, the transition from artery to vein in Type 1 AVF is subtle and may be easily missed. There may be one or more aneurysms on the dysplastic enlarged feeder or feeders. There may be a concomitant venous aneurysm or varix. It is mandatory to demonstrate the normal supply of the cord and identify the ASA and the PSA. The same intercostal or lumbar artery may be supplying the cord as well as the AVM. One must identify the shortest and easiest route to the feeder.

TREATMENT

Indications for Treatment

Patients presenting with subarachnoid haemorrhage, spinal cord haemorrhage, progressive neurological deficit or severe root pains need to be treated. AVMs located in the cervical[54] and upper dorsal region are clinically more aggressive, present with recurrent bleeds which cause severe neurological deficits and need urgent treatment.[6] The aim of treatment is to find "weak spots" and obliterate them. Complete cure is rarely achieved as the morbidity is much higher due to erratic embolisation when attempting to obtain obliteration of the AVM. Ligation of proximal feeders, without tackling the nidus, should be condemned as collateral circulation from adjacent arteries immediately takes over the supply. The collateral feeders are usually small and tortuous rendering further surgical or endovascular treatment impossible.

Technique[8,13,18,56,64]

Embolisation is always done under general anaesthesia[3] (Table 4). Respiration is stopped during injection, if required. Buscopan is injected to reduce bowel movements for better visualisation of contrast and glue or Onyx.[11]

Table 4: Materials required

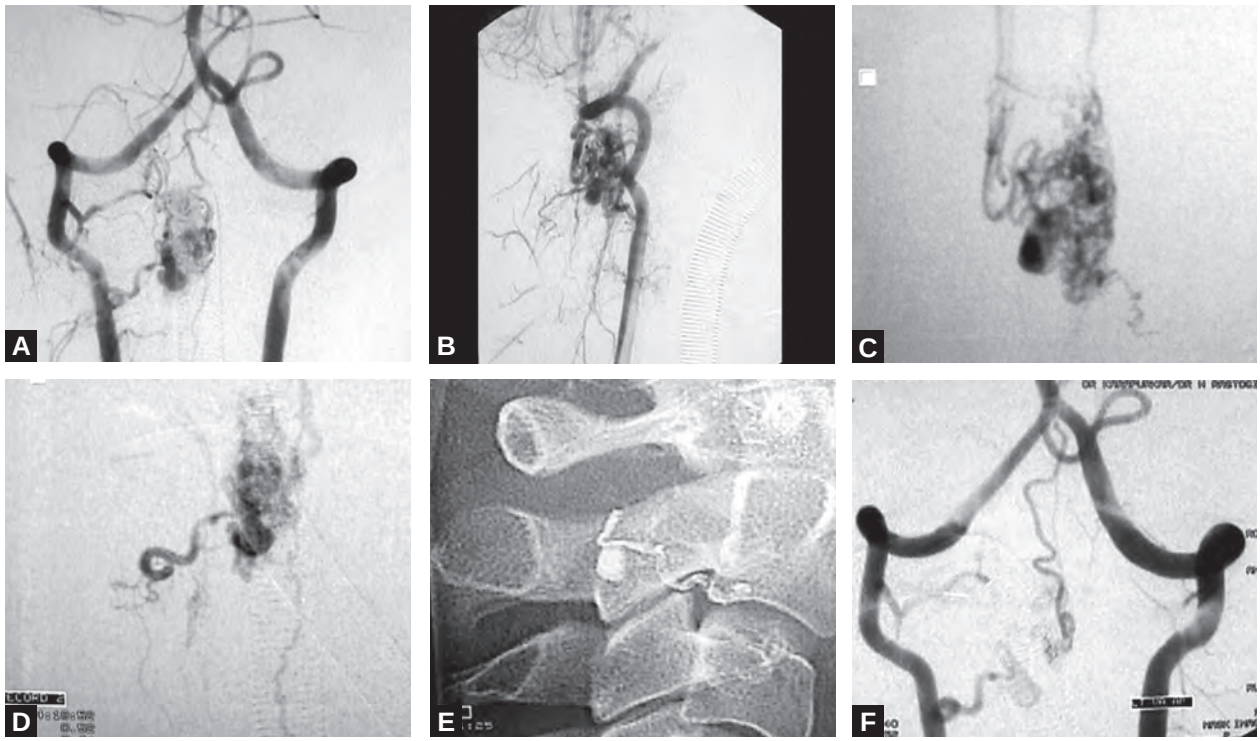
Access sheath
Spinal angio. Or Sim 1 cath
Non-ionic contrast
Microcatheter—Marathon, Magic 1.2 FM, Ultraflow
Microguide wire—Mirage 0.008"
Embolic material: Histoacryl with lipiodol, Onyx 18 or Onyx 34

Spinal Cord AVM[19,32,62]

Diagnostic angiogram and the therapeutic procedure should be carried out in two different sittings. Embolisation is done under general anaesthesia. Methyl prednisolone infusion may be started at the commencement of the procedure to protect the spinal cord. The 5F guiding catheter, usually Envoy (Cordis) or Cobra C1, is placed in the selected artery. Under road mapping the microcatheter, [Magic 1.2 FM (Balt SA), Ultraflow, or Marathon (EV3)] is advanced into the feeding artery over a microguide wire, usually the Mirage 0.008" (EV3). The catheter is navigated as close to the AVF or glomus (nidus) as possible. If there is an aneurysm, it is placed just short of it. Glue is prepared in bowls washed in dextrose. Histoacryl (glue) hardens as soon as it comes in contact with contrast, saline or blood. The polymerising time is changed by adding lipiodol which also makes it radio-opaque. For high-flow AVF 80–90% glue is injected. It is made radio-opaque by adding tantalum powder. After confirming satisfactory position, the microcatheter is washed by irrigating with 5% dextrose, so that there is no blood, contrast or saline in the catheter. Glue is injected under vision in the trace-fluoro mode. The glue is slowly injected over minutes for slow flow lesions and rapidly for high-flow lesions. For an aneurysm, the glue is deposited as close to the aneurysm as possible. An AVM or AVF downstream from the aneurysm is embolised at the same time (Figs 1A to F). For AVM or AVF the attempt is to fill the nidus with glue. Care is taken to push the glue across the nidus into the proximal few millimetres of the draining vein. The catheter is rapidly pulled out at the end of the injection, lest it gets glued. Control angiogram is performed immediately. For small lesions, if the glue does not penetrate to the vein recurrence is likely. For large lesions treatment is staged 4–6 weeks apart for fear of breakthrough bleeding.

PVA or hydrogel particles are rarely used today as recurrence is common. It is injected in saline mixed with contrast to visualise its passage. Small aliquots of 2 ml are injected gently under trace-fluoro mode or frequent runs are made to control the progress of embolisation. The endpoint is slowing of flow, stagnation in the feeder or complete obliteration. It is important not to occlude the ASA as it does not recanalise. The PSA may be occluded without any grave consequences. Particles get reabsorbed overtime.

Recently Onyx 18 (EV3) has been used to embolise the AVM nidus.[34] Onyx is a liquid embolic agent, Ethyl Vinyl Alcohol Co-Polymer, which is dissolved in dimethyl sulphoxide (DMSO) and mixed with tantalum powder to make it radio-opaque. Tantalum powder is made into a homogeneous suspension by pacing the vials in an agitator at least 15 minutes before the injection is made. Marathon, Ultraflow and Sonic (Balt SA) are DMSO compatible and can be used for injecting Onyx. Magic series of catheters cannot be used for injection of Onyx as they are not compatible. The technique of injection of Onyx is to allow reflux of Onyx onto the catheter and it may reflux for up to 2 cm, so one should have a margin of at least 2 cm between the tip of the catheter and an important branch or parent vessel. Hence, it can only be used in selective cases of spinal cord AVM. The



Figs 1A to F: Two episodes of haemorrhage. (A and B) VA angiogram, AP and lateral to show spinal cord AVM. (C) Superselective angiogram showing small intranidal aneurysm which is not seen on (A) and (B). (D) Cast of glue in nidus and aneurysm. (E and F) Control at 1 year showing small residual AVM

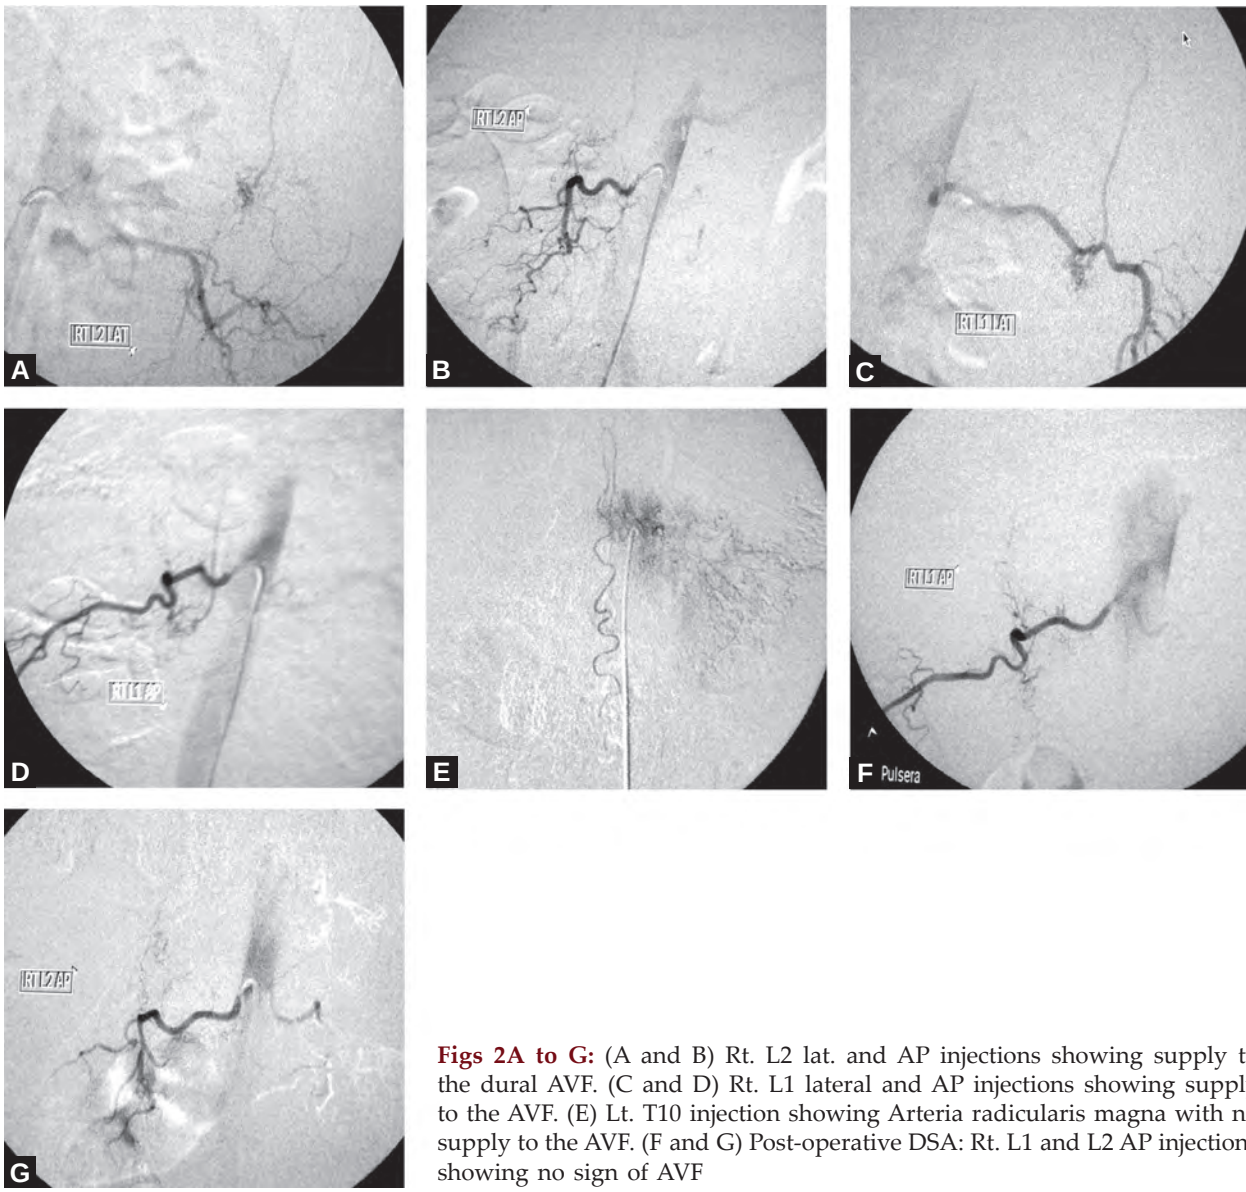
injection is made by trace-fluoro technique over several minutes, watching for reflux carefully. At the end of the injection, the microcatheter is pulled out with a jerk. As of today glue is preferred over Onyx in the treatment of spinal AVM.

Dural AVF

Dural AVF[9,33,38,55] can be treated by surgery[1] or by the endovascular route. The aim of treatment is to find and obliterate the single draining vein as it enters the spinal canal (Figs 2A to G). This is accomplished by depositing dilute histoacryl or onyx 18[60] in the draining vein and the dural malformation. Care should be taken not to let the glue or onyx reach the spinal cord veins. In dural AVF below L2 there may be a long safe length of vein available. PVA particles have no place in the treatment because it always recanalises. If there is even a small residue left, the AVF recurs. Retreatment is difficult or impossible as the adjacent lumbar or intercostals or small branches from the internal iliac supply the recurrent AVF through tiny tortuous collateral arteries. During surgery, a limited laminectomy is done on the appropriate side; the dura is exposed close to the intervertebral foramen where the bunch of vessles on the dura is recognisable. The dura is opened; the vein is identified as it enters the spinal canal. The vein is coagulated and divided. The dura containing the malformation may be coagulated and excised.

Spinal Cord AVF[10,61]

These must be treated because the long-term prognosis is poor. An attempt must be made to obliterate it completely. If cure is not possible, partial treatment is strongly recommended. Surgery is risky because the AVF may be on the anterior surface of the cord or buried within it. The angioarchitecture must be analysed. The ASA is a dangerous artery to embolise. Glue or Onyx is used only, if the microcatheter can be taken close to the AVF, so that the ASA patency is preserved. If it is not possible to catheterise the ASA, particulate matter,



Figs 2A to G: (A and B) Rt. L2 lat. and AP injections showing supply to the dural AVF. (C and D) Rt. L1 lateral and AP injections showing supply to the AVF. (E) Lt. T10 injection showing Arteria radicularis magna with no supply to the AVF. (F and G) Post-operative DSA: Rt. L1 and L2 AP injections showing no sign of AVF

PVA may be floated in very small aliquots to obliterate the AVF. The AVF may recanalise, but the ASA does not. For the PSA, onyx or glue can be used. Arterial true and false aneurysms must be obliterated with glue, onyx or by surgical clipping because they are prone to bleed again and again. For large high-flow AVF embolisation should be staged and should begin at the sulco-commissural arteries. As embolisation proceeds new segments may be identified (Figs 3 to 5). With PVA there may be recanalisation. However, with PVA, after some years the same arteries can be retreated safely. Histoacryl (glue) embolisation is permanent. Detachable balloons and coils have no place in the treatment of spinal AVM or AVF except for treatment of large high-flow direct AVF between the vertebral artery and the vertebral vein.

Giant metameric, paraspinal[28] AVF or AVM may be inoperable. The aim should be to treat the weak spots, such as false and true aneurysms, and to reduce the flow through the venous system to reduce backpressure and improve spinal cord function. Mounayer has described obliteration of a giant paraspinal AVF with perimedullary venous drainage.

Complications

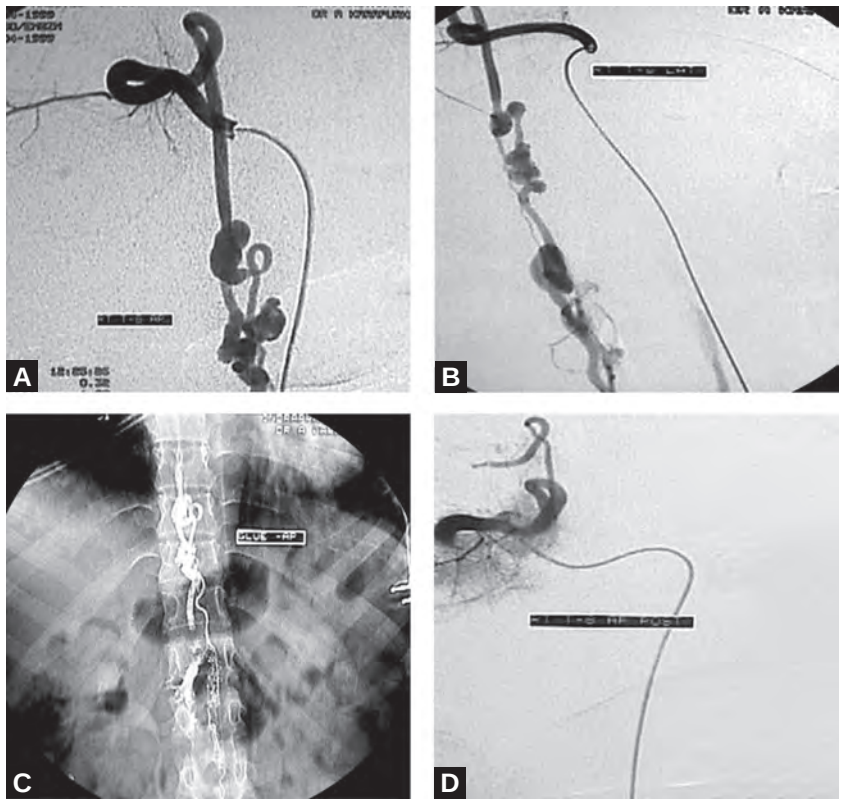
Rarely a patient may deteriorate after the diagnostic angiogram, especially, if ionic contrast is used. The cause for the deterioration is usually not found. Occlusion of the ASA is disastrous. Occlusion of the PSA may leave a small deficit. Occlusion of the draining vein without obliteration of the AVF or AVM may result in haemorrhage. Haemorrhage may occur due to rupture of an associated aneurysm. The neurological deficit is due to ischaemia of the cord or haematomyelia and may vary from complete motor and sensory paraplegia with sphincter involvement to minor problems like backache. The deficit usually recovers overtime with physiotherapy, but it may be permanent. Recovery of the sensory system, especially posterior columns, usually occurs rapidly. Motor recovery is slower. Recovery of sphincter function takes some months. Sometimes, the sphincters may not recover. Methylprednisolone, which is usually started at induction of anaesthesia, may need to be given for 5 days, if there is deterioration in function.[27] Rarely, patients may deteriorate after methylprednisolone. The author has seen three patients deteriorate after infusion of methylprednisolone before any invasive procedure was done.

Follow-Up

If partial treatment has been accomplished, annual DSA is mandatory. Retreatment may be necessary.

CONCLUSION

Spinal vascular malformation is a formidable disease.[35] It must be treated unless there is complete cord transsection with no recovery. The aim should be complete obliteration. However, safe complete obliteration may not



Figs 3A to D: Acute onset complete motor and sensory paraplegia with sphincter loss in 14-year-old girl. (A and B) AP and lateral high-flow AVF of spinal cord with multiple aneurysms. (E and F) AP and lateral views showing glue cast in nidus and aneurysm. (G and H) AP and lateral Post-embolisation Angiograms showing patent artery and no AVM. Patient had rapid complete recovery from paraplegia

be possible. "Weak spots" must be treated. Associated aneurysms must be treated with liquid embolic material like histoacryl or surgically clipped. Large AVMs are treated in a staged manner. Follow-up DSA is essential to monitor the residual AVM and to look for any "recurrence".

101 Spontaneous Intracerebral Haemorrhage

Ajaya Nand Jha, Vipul Gupta

INTRODUCTION

Intracranial haemorrhage (ICH) accounts for 10–30% of all stroke admissions to hospital, and leads to catastrophic disability, morbidity and a 6 month mortality of 30–50%.[30] Long-term outcomes are poor; only 20% of patients regain functional independence at 6 months.[30] ICH is classified as primary or secondary. Primary ICH is when the haemorrhage originates from spontaneous rupture of small arteries or arterioles damaged by chronic hypertension or amyloid angiopathy. Secondary ICH is when haemorrhage results from trauma, rupture of an aneurysm/vascular malformation, coagulopathy or other causes (Table 1).[28]

Table 1: Secondary causes of ICH[18]

Trauma
Arteriovenous malformation
Intracranial aneurysm
Coagulopathy
Haemorrhagic conversion of cerebral infarct
Dural sinus thrombosis
Intracranial neoplasm
Cavernous angioma
Dural arteriovenous fistula
Venous angioma
Cocaine or sympathomimetic drug exposure
CNS vasculitis
Anticoagulant therapy

RISK FACTORS

Chronic hypertension causes degeneration, fragmentation and fibrinoid necrosis of small penetrating arteries in the brain, which can eventually result in spontaneous rupture. Some people have discrete arteriolar microaneurysms (Charcot-Bouchard aneurysms) at the site of vessel rupture.[18] Hypertensive ICH typically occurs in the basal ganglia (putamen, thalamus or caudate nucleus), pons, cerebellum or deep hemispheric white matter.[28] Non-compliance with antihypertensive treatment increases the risk of ICH.[1]

The second most common cause of primary ICH is cerebral amyloid angiopathy, which accounts for about 15% of cases.[28] The disorder is characterised by the deposition of amyloid-β peptide in small to medium sized blood vessels of the brain and leptomeninges, which results in vascular fragility. However, spontaneous lobar haemorrhage in elderly patients with a history of cognitive decline by amyloid angiopathy is typically less severe. Recurrent haemorrhage occurs in 5–15% of patients with lobar ICH and probable amyloid angiopathy. After hypertensive ICH, repeat bleed occurs in as low as 2% of patients per year when blood pressure is well controlled.[1]

EMERGENCY DIAGNOSIS AND ASSESSMENT OF ICH AND ITS CAUSES

The classic clinical presentation includes the onset of a sudden focal neurological deficit while the patient is active, which progresses over minutes to hours.[4] The smooth symptomatic progression of a focal deficit over a few hours is uncommon in ischaemic stroke and rare in subarachnoid haemorrhage. Headache is more common with ICH than with ischaemic stroke, although less common than in subarachnoid haemorrhage.[12] Vomiting is more common with ICH than with either ischaemic stroke or subarachnoid haemorrhage. Increased blood pressure and impaired level of consciousness are common.[12] However, clinical presentation alone, although helpful, is insufficient to reliably differentiate ICH from other stroke subtypes.[4]

Diagnosis

ICH is confirmed by computed tomography (CT) scan. The volume of the haemorrhage can rapidly be estimated at the bedside from the CT with the ABC/2 method, which involves multiplying the diameter of the haematoma in three dimensions and dividing by two.[16] MRI is as sensitive as CT for the detection of ICH in the acute stage,[15] but is most commonly done as a follow-up study to detect vascular flow voids, which are indicative of an arteriovenous malformation, chronic lobar microbleeds on gradient echo imaging suggestive of amyloid angiopathy, or a contrast-enhancing neoplasm. Catheter angiography is the diagnostic test for vascular causes of secondary ICH, such as an aneurysm, arteriovenous malformation, dural arteriovenous fistula or cortical-vein thrombosis.[15]

Indications for catheter angiography include subarachnoid haemorrhage, abnormal calcifications, obvious vascular abnormalities and blood in unusual locations such as the Sylvian fissure.[4] In one study, no vascular malformations were found in people over the age of 45 years with a history of hypertension and haemorrhage in a classic hypertensive location (basal ganglia, cerebellum or pons).[43] However, angiography detected a vascular malformation in 65% of patients with primary intraventricular haemorrhage and in non-hypertensive patients with lobar haemorrhage. Angiography may also be indicated in patients with no obvious cause of bleeding, such as those subjects with isolated IVH. The yield of angiography declines in elderly patients with hypertension and a deep haematoma.[4]

PATHOPHYSIOLOGY

The two most important new concepts are that many haemorrhages continue to grow and expand over several hours after onset of symptoms—a process known as early haematoma growth—and that most of the brain injury and swelling that happens in the days after ICH is the result of inflammation caused by thrombin and other coagulation end-products.[18]

Early Haematoma Growth

Early haematoma growth is common and associated with neurological deterioration and poor clinical outcome. Even in the absence of known coagulopathy, about 38% of patients had an increase in haematoma volume of more than 33% shown by CT within 3 hours of onset.[5] Only up to 5% of patients have ICH growth when the baseline scan is done more than 6 hours after onset.[20]

Perihaematomal Brain Injury

Brain-tissue injury and swelling, which can result in increased intracranial pressure (ICP) or herniation related to compartmentalised mass effect, are the primary causes of neurological deterioration after the first day. The possible creation of an ischaemic penumbra in the brain tissue immediately adjacent to an ICH, resulting in secondary neuronal injury and cytotoxic oedema, was a major concern for many years. PET and MRI studies, done as early as 6 hours after onset of symptoms, have not shown tissue ischaemia in perihaematomal brain regions.[32] By contrast, an overwhelming haematoma-induced inflammatory response has been identified which causes less brain swelling and tissue injury.[6] Plasma, that is rich in thrombin and other coagulation end-products, released by the clotted haematoma seeps into the surrounding brain tissue, and is the primary trigger of the inflammatory process.[40]

PROGNOSIS

Mortality after ICH approaches 50% at 1 year.[38] Independent predictors for 30 days and 1 year mortality include large ICH volume, coma, older age, intraventricular haemorrhage and infratentorial location.[14,38] A useful clinical grading scale (the ICH score) that incorporates these five elements allows rapid estimation of 30 day mortality on admission (Table 2).

Table 2: The ICH score

Component	*Points*
Glasgow coma scale score	
3–4	2
5–12	1
13–15	0
ICH volume (mt)	
> 30	1
< 30	0
Intraventricular haemorrhage	
Yes	1
No	0
Age (years)	
> 80	1
< 80	0
Infratentorial origin	
Yes	1
No	0
30 day mortality at total points	
5+	100%
4	97%
3	72%
2	26%
1	13%
0	0%

MANAGEMENT

The patient's neurological status should be assessed frequently with the use of standard stroke scales such as the National Institutes of Health Stroke Scale (NIHSS) and coma scales such as the GCS. Blood pressure should be monitored adequately with an automatic cuff, whereas continuous monitoring of systemic arterial pressure should be considered in patients who require continuous intravenous administration of antihypertensive medications and in patients whose neurological status is deteriorating. Airway and oxygenation can be assessed per respiratory status and pulse oximetry. Cardiopulmonary instability in association with increased ICP is to be avoided to minimise deleterious effects in patients with limited autoregulatory capacity.[4] Monitoring and management of patients with an ICH should take place in

an intensive care unit setting because of the acuity of the condition, frequent elevations in ICP and blood pressure, frequent need for intubation and assisted ventilation and multiple complicating medical issues.[4] It has been reported that admission of ICH patients to a neurosciences intensive care unit may result in a reduced mortality rate.

Airway

Rapid neurological decline and depressed consciousness mandates immediate endotracheal intubation and mechanical ventilation. Imminent airway loss can result in aspiration, hypoxaemia or hypercapnia, which in turn can lead to cerebral vasodilatation and high ICP. Respiratory rate and tidal volume should be set to maintain a pCO_2 of about 35 mmHg and aggressive hyperventilation to pCO_2 below 28 mmHg should be avoided because of the possibility of excessive vasoconstriction and exacerbation of ischaemia.[18]

Blood Pressure

Blood pressure should be managed on the basis of individual patient factors such as prior history of hypertension on baseline blood pressure, presumed cause of haemorrhage, age and elevated intracranial pressure (ICP). The primary rationale for lowering the blood pressure is to avoid haemorrhagic expansion from potential sites of bleeding. This is particularly true for haemorrhage resulting from a ruptured aneurysm or arteriovenous malformation. However, in primary ICH, the risk of haemorrhagic expansion with mild blood pressure elevation may be lower and must be balanced with the theoretical risks of inducing cerebral ischaemia in the oedematous region that surrounds the haemorrhage.[4]
The American Stroke Association (ASA) has recommended the following guidelines for treating elevated blood pressure in spontaneous ICH:[4]

- If SBP is more than 200 mmHg or MAP is greater than 150 mmHg, then consider aggressive reduction of blood pressure with continuous intravenous infusion, with frequent blood pressure monitoring every 5 minutes.
- If SBP is greater than 180 mmHg or MAP more than 130 mmHg and there is evidence of or suspicion of elevated ICP, then consider monitoring ICP and reducing blood pressure using intermittent or continuous intravenous medications to keep cerebral perfusion pressure greater than 60–80 mmHg.
- If SBP is greater than 180 mmHg or MAP more than 130 mmHg and there is no evidence of or suspicion of elevated ICP, then consider a modest reduction of blood pressure (e.g. MAP of 110 mmHg or target blood pressure of 160/90 mmHg) using intermittent or continuous intravenous medications to control blood pressure, and clinically re-examine the patient every 15 minutes.

[SBP: systolic blood pressure; MAP: mean arterial pressure.]

Intravenous medications that may be considered for control of elevated blood pressure in patients with ICH include labetalol, nicardipine, esmolol, enalapril, hydralazine, nipride and nitroglycerin.

Management of ICP

An ICP monitor or external ventricular drain should generally be placed in all patients with ICH in coma (Glasgow Coma Scale score of 8 or less) with the goal of maintaining ICP below 20 mmHg and a minimum cerebral perfusion pressure greater than 60 mmHg. External ventricular drains have the disadvantage of a substantial risk of infection (about 10% during the first 10 days).

Emergency measures of ICP control are appropriate for stuporous or comatose patients, or those who present acutely with clinical signs of brainstem herniation. The head is elevated to 30 degrees, 1.0–1.5 g/kg of 20% mannitol is given by a rapid infusion, and the ventilation is controlled to maintain the pCO_2 at 30–35 mmHg. These measures are designed to lower ICP as quickly and effectively as possible to buy time before a definitive neurosurgical procedure (craniotomy, ventriculostomy, or replacement of an ICP monitor) can be done. Corticosteroids, such as dexamethasone, are not indicated in the management of ICH, based on the results of randomised trials that have failed to demonstrate their efficacy in ICH.[4]

Haemostatic Therapy

Eptacog alfa [recombinant activated factor VII (rFVIIa), Novoseven®, Novo Nordisk A/S] is a power initiator of haemostasis currently approved for treatment of bleeding in patients with haemophilia who are resistant to factor VIII replacement therapy. Although there is evidence suggesting that rFVIIa might improve haemostasis in patients with normal coagulation systems, results of recently published phase III Trial (FAST trial) comparing placebo with doses of 20 μg/kg and 80 μg/kg has shown that haemostatic therapy with rFVIIa reduced growth of the haematoma, but did not improve survival or functional outcome after intracerebral haemorrhage.[19]

Reversal of Anticoagulation

Warfarin anticoagulation increases the risk of ICH five to ten times.[42] Among patients with ICH, warfarin doubles the risk of mortality and increases the risk of progressive bleeding and clinical deterioration.[13] Failure to rapidly normalise the international normalised ratio (INR) to below 1.4 further increases these risks.[10] Patients with warfarin-associated ICH should be treated with intravenous vitamin K to reverse the effects of warfarin and with treatment to replace clotting factors.[4] Prothrombin complex concentrate, factor IX complex concentrate and rFVIIa normalise the laboratory elevation of the INR

very rapidly and with lower volumes of fluid than FFP, but with greater potential of thromboembolism. FFP is another potential choice, but is associated with greater volumes and much longer infusion times.[4]

rFVIIa in doses ranging 10–90 μg/kg has been used to reverse the effects of warfarin in acute ICH—primarily to expedite neurosurgical intervention—with good clinical results.[11] When this approach is used, rFVIIa should be used as an adjunct to coagulation-factor replacement and vitamin K because the effect will last only several hours. Unfractionated or low-molecular-weight heparin should be reversed with protamine sulphate,[41] and patients with thrombocytopaenia or platelet dysfunction can be treated with a single dose of desmopressin (DDAVP), platelet transfusions, or both.[18]

Fluids

Free-water given in the form of 0.45% saline or 5% dextrose in water can exacerbate cerebral oedema and increase ICP because it flows down its osmotic gradient into injured brain tissue. Solutions containing dextrose should generally be avoided unless hypoglycaemia is present, because hyperglycaemia can be detrimental to the injured brain. A state of euvolaemia should be maintained by monitoring the fluid balance, central venous pressure and body weight. Isotonic fluids, such as 0.9% saline (about 1 ml/kg/h), should be given as the standard intravenous replacement fluid.[18] Some centres increasingly use hypertonic saline in the form of 3% sodium chloride/acetate solutions as an alternative to normal saline in patients with significant perihaematomal oedema and mass effect. However, further studies are needed to clarify the risks and benefits of hypertonic saline for ICH.[18]

Anticonvulsant Therapy

Acute seizures should be treated with intravenous lorazepam (0.45–0.10 mg/kg) followed by an intravenous loading dose of phenytoin or fosphenytoin (15–20 mg/kg), valproic acid (15–45 mg/kg) or phenobarbital (15–20 mg/kg). The 30 day risk of clinically evident seizures after ICH is about 8%[27] and the risk of epilepsy is 5–20%.[27] ASA guidelines recommend antiepileptic treatment in selected patients for up to 1 month.[4] Continuous electroencephalography detects non-convulsive seizures or status epilepticus in 28% of stuporous or comatose patients with ICH.

Fever Control

The incidence of fever after basal ganglionic and lobar ICH is high, especially in patients with ventricular haemorrhage. In patients surviving the first 72 hours after hospital admission, the duration of fever is related to outcome and appears to be an independent prognostic factor in these patients. Paracetamol should be given and the body should be cooled externally in all patients with sustained fever in excess of 38.3°C (101.0°F).[33]

Management of Glucose

Evidence indicates that persistent hyperglycaemia (>140 mg/dl) during the first 24 hours after stroke is associated with poor outcomes. Insulin should be administered when the blood sugar level is >185 mg/dl and sometimes when it is >140 mg/dl.

Nutrition

Enteral feeding should be started within 48 hours to reduce the risk of malnutrition.

Deep Venous Thrombosis Prophylaxis

ICH patients are at high risk for deep vein thrombosis and pulmonary embolism. Dynamic compression stockings should be placed on admission. After documentation of cessation of bleeding, low-dose subcutaneous low-molecular-weight heparin or unfractionated heparin may be considered in patients with hemiplegia after 3–4 days from onset.

Anticoagulation after ICH

The issue of reinstitution of anticoagulation after warfarin-related ICH applies primarily to those who began taking warfarin for the prevention of cardiogenic embolism associated with either prosthetic heart valves or chronic atrial fibrillation.[4]

Recommendations for the Management of ICH Related to Coagulation and Fibrinolysis[4]

The decision to restart antithrombotic therapy after ICH depends on the risk of subsequent arterial or venous thromboembolism, the risk of recurrent ICH and the overall state of the patient. For patients with a comparatively lower risk of cerebral infarction (e.g. atrial fibrillation without prior ischaemic stroke) and a higher risk of amyloid angiopathy (e.g. elderly patients with lobar ICH) or with very poor overall neurological function, an antiplatelet agent may be an overall better choice for prevention of ischaemic stroke than warfarin. In patients with a very high risk of thromboembolism in whom restarting warfarin is concerned, warfarin therapy may be restarted at 7–10 days after onset of the original ICH.

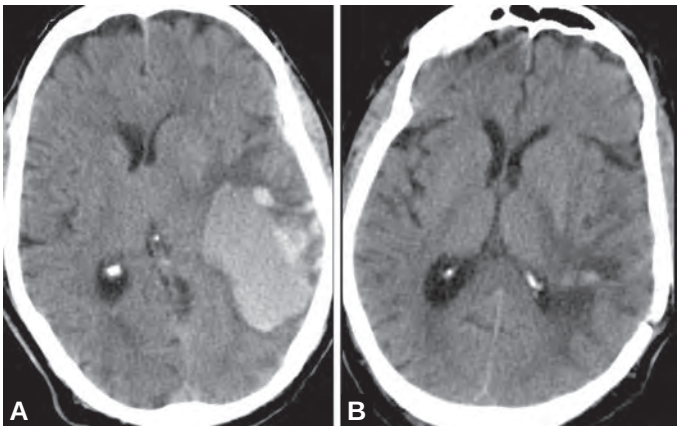
SURGICAL MANAGEMENT

To achieve the goals of surgical treatment,[23] the specific aims may include decompression to reduce or prevent elevated intracranial pressure and removal of the acute haematoma to reduce mass effect and toxicity to the surrounding brain. Several surgical options exist that vary in the degree of invasiveness and associated morbidity. These options include ventriculostomy, stereotactic aspiration of haematoma with or without rt-PA, endoscopic haematoma evacuation, craniotomy for evacuation of haematoma and hemicraniectomy for

decompression with or without evacuation of haematoma. The role of ventriculostomy is clear in patients with elevated intracranial pressure due to obstructive hydrocephalus, but no studies have directly evaluated the effect of ventriculostomy alone on the outcome of ICH patients. [Craniotomy is the most studied modality and is the most common surgical technique used. A complete evacuation under direct vision can be performed, which facilitates exploration for vascular lesions and control of bleeding sources[2]].

Of all the surgical therapies described for treating ICH, craniotomy has been the most extensively studied (Figs 1A and B) with 7 of the 9 randomised controlled surgical trials reporting results with craniotomy either primarily or exclusively.[2,4] The International Surgical Trial in Intracerebral Haemorrhage (STICH) randomised 1,033 patients from 107 centres over an 8-year period, beginning in 1995.[22] Patients were eligible if randomised within 72 hours and operated on within 96 hours of ictus for a clot >2 cm in diameter. Patients in very poor condition (GCS score <5) were excluded. Patients were randomised if the neurosurgeon was uncertain of the benefit of surgery, with 50% randomly assigned to a policy of either early surgery or initial medical management. Primary outcomes were the incidence of death and disability as measured by the extended Glasgow Outcome Scale (GOS) at 6 months, and secondary outcomes were death, the Barthel Index (BI) and the modified Rankin Scale (mRS) at 6 months.

Five hundred and six patients were randomised to surgery and 530 to medical therapy, with groups being well matched for all known variables. Twenty-six percent of the medical arm ultimately crossed over to surgery. This crossover was due to re-bleeding or deterioration in 85% of crossover subjects, and craniotomy was used in 85% in those subjects who crossed over to surgery. By contrast, only 75% of patients in the primary surgical arm underwent craniotomy, with the others being treated with less invasive surgical techniques.



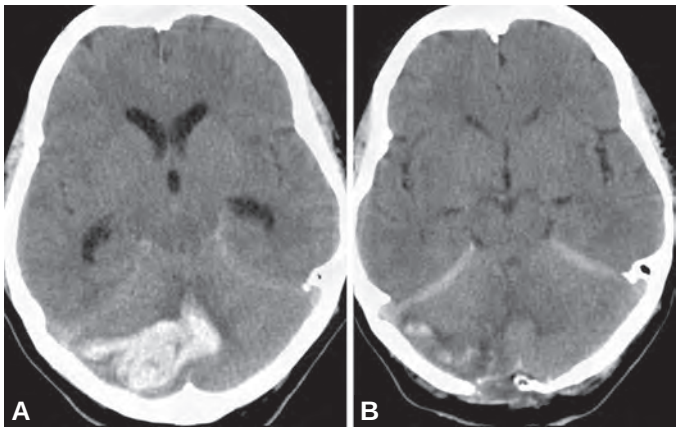
Figs 1A and B: (A) A 64-year-male patient, a hypertensive, presented with a large left temporal haematoma causing significant midline shift. (B) Surgical evacuation of the haematoma was done with complete regression of midline shift

Ninety-three per cent of patients were available for analysis at 6 months.

In an intervention-to-treat analysis, surgery within 96 hours of ictus was associated with a statistically insignificant absolute benefit of 2.3% (95% CI—3.2% to 7.7%) at 6-month follow-up. With GCS score of 9–12, those with lobar clots, and those with clots <1 cm from the surface who may have been helped by early surgery did not benefit statistically significantly. In contrast, those presenting in deep coma (GCS score 5–8) tended to do better with medical management. It must be remembered that the trial was based on the principle of clinical equipoise; patients whom the local investigator felt would most likely benefit from emergency surgery were not enrolled in the study. Thus, the STICH trial may not be applicable to certain subsets of patients who traditionally are thought to be good candidates for surgery, particularly young individuals with large lobar haemorrhages rapidly deteriorating due to mass effect. Moreover, the STICH results must be interpreted with caution because the high crossover from the medical group to surgery (140 out of 530 patients).[2]

Although the preponderance of evidence suggests that routine surgical evacuation of supratentorial haematomas is not superior to medical treatment alone, surgery may be beneficial in a subset of patients.[2] Surgery via craniotomy shows a trend towards benefit in patients with superficial clots located less than 1 cm from the surface and those with moderate initial impairment [Glasgow coma score (GCS), 9–12] and subsequent deterioration.[27] Both the American Heart Association (AHA)[4] and the European Stroke Initiative Writing Committee (EUSI)[35] guidelines recommend considering surgery in these limited situations. Otherwise, the AHA and EUSI guidelines agree on several points. Deep haemorrhages do not benefit from craniotomy, and there is limited evidence suggesting that minimally invasive treatment may be beneficial in patients with significant mass effect. Also, deeply comatose and very old patients have not been shown to benefit from surgery.

These randomised trials of surgery did not include patients with cerebellar haemorrhage. Despite a paucity of class I data regarding cerebellar haematomas, retrospective data suggest that surgical evacuation for patients with clots larger than 3 cm, hydrocephalus, or evidence of brainstem compression leads to improved outcomes (Figs 2A and B).[8,35,37] In these patients, medical management alone often results in bad outcomes. Smaller cerebellar haemorrhages without brainstem compression that are medically managed do reasonably well. For these reasons, neurosurgeons and neurologists have advocated that large cerebellar haemorrhages with compression of the brainstem or obstruction of the fourth ventricle should be surgically removed as soon as possible. Both the American Heart Association (AHA)[4] and the European Stroke Initiative writing committee (EUSI)[35] guidelines recommend considering surgery in large cerebellar haematomas.



Figs 2A and B: (A) A 47-year-old female patient presented with a large cerebellar bleed with effacement of fourth ventricle and mass effect on the brainstem. (B) CT scan done after surgical evacuation of haematoma revealed opening up of CSF spaces around the brainstem. The patient made an almost complete recovery

Minimally Invasive Surgery

The purported advantages of minimally invasive clot evacuation over conventional craniotomy include: (1) reduced operative time; (2) the possibility of performance under local anaesthesia and (3) reduced tissue trauma, especially for deep lesions. Together, these advantages may also facilitate earlier evacuation of ICH than is possible or practical with conventional craniotomy. On the other hand, the reduced surgical exposure, the inability to treat structural lesions (arteriovenous malformation or aneurysm), the potential for re-bleeding related to the use of fibrinolytics, and the possibility of an increased risk of infection related to prolonged indwelling catheters are limitations of this approach.

Endoscopic Aspiration

Endoscopic aspiration of supratentorial haemorrhage was studied in a small, single-centre randomised trial.[3] One hundred patients between 30 and 80 years of age, with haemorrhages at least 10 ml in volume, received treatment within 48 hours of onset via burr hole and continuous neuroendoscopic lavage of the haematoma cavity with artificial CSF at a pressure of 10–15 mmHg. The mixture of blood clots and blood stained CSF was removed by suction at regular intervals. More than 90% of the clot was evacuated in 15% of patients and between 70% and 90% in 30% of patients, with all patients having at least a 50% reduction in size. At 6 months, the mortality rate of the surgical group (42%) was significantly lower than that of the medical group (70%, P = 0.01). A good outcome with minimal or no deficit was also seen more frequently in the surgically treated group. In patients with large haematomas (50 ml), quality of life was not affected by surgery, but the mortality rate was significantly lower. By contrast, endoscopic evacuation of smaller haematomas led to a significantly better quality of life versus those treated medically, but survival was similar for the two groups. Moreover, the benefit was mainly limited to patients with lobar haematomas and patients less than 60 years of age.

The study by Cho DY et al. compared endoscopic surgery, stereotactic aspiration and craniotomy in non-comatose patients with spontaneous basal ganglia haemorrhage.[7] Ninety non-comatose patients with basal ganglia haemorrhages were randomised into three groups: group A (n = 30) underwent endoscopic surgery; group B (n = 30) underwent stereotactic aspiration and group C (n = 30) underwent craniotomy. There was significant delay in waiting time for stereotactic aspiration. Craniotomy had the longest operation time. Blood loss was most significant in the craniotomy group. The highest haematoma evacuation rate was seen in the endoscopic surgery group. The mortality rate was 0% in group A, 6.7% in group B, and 13.3% in group C (P = 0.21). The complication rate was 3.3% in group A, 10% in group B, and 16.6% in group C (P = 0.62). The most major complications were re-bleeding and infection. The FIM score was higher in the endoscopic surgery group than in the craniotomy group. The Barthel index score was also significantly better in endoscopic surgery than in craniotomy. However, the STICH trial suggests that subjects treated with any non-craniotomy approach in the trial had a worse outcome than those treated with conservative management (OR 1.3), but the confidence interval included 1 (95% CI—0.78 to 2.35). It is unclear whether the pathology chosen for these approaches was less ideal for intervention, because patients with deep haemorrhages and those in poor neurological condition (both of whom fared worse in the trial) were likely those most commonly chosen for minimally invasive techniques.

Thrombolytic Therapy and Aspiration of Clots

A multicentre randomised controlled trial (n = 71 patients) examined the utility of stereotactic urokinase infusion when administered within 72 hours for those patients presenting with GCS score >5 and clots of >10 ml.[36] Treated patients received 5,000 IU of urokinase every 6 hours for a maximum of 48 hours. Primary endpoints were death and degree of functional handicap (measured with the mRS) at 6 months. The median reduction in volume of ICH from baseline was 40% in the surgical group and 18% in the medical group. The re-bleeding rate was 35% in the urokinase group and 17% in the conservatively managed group. A significant reduction in death (40%) was found in the treated group, but no statistically significant difference in functional outcome scores was detected at different intervals of treatment.

Installation of tPA for clot evacuation in patients with severe IVH has been studied. Rohde et al. reported that IVH disappeared earlier (1–3 days) with tPA than with urokinase (5–8 days).[29] Compared with ventriculostomy alone, IVH treated with the addition of tPA decreased the mortality rate from a range of 60 to 90% to only 5%.

Other similar studies have indicated that the use of intraventricular tPA might improve the prognosis in patients with large IVHs.[9,21] The review of the current literature suggests that the use of intraventricular fibrinolytics carries a low incidence of complications, which usually consist of infections and haemorrhage.[9,21,26,34]

More recently, tPA has been used in the treatment of ICH. In pilot human trials, Lippitz et al.,[17] Schaller et al.,[31] and Vespa et al.[39] reported that daily administration of tPA into the haematoma cavity beginning 12–24 hours after stereotactic placement of a catheter resulted in an average 85% reduction in the haematoma volume by 2–4 days after onset.

Preliminary findings of the minimally invasive surgery plus rt-PA for intracerebral haemorrhage evacuation (MISTIE) clinical trial have been published.[24] Subjects randomised to surgery underwent stereotactic catheter placement and clot aspiration. Injections of rt-PA were then given through the haematoma catheter every 8 hours, up to 9 doses, or until a clot-reduction endpoint. After each injection the system was flushed with sterile saline and closed for 60 minutes before opening for spontaneous drainage. Average aspiration of clots for all patients randomised to surgery plus rt-PA was 20% of mean initial clot size. After the acute treatment phase (aspiration plus rt-PA), the clot reduced by an average of 46%. Recorded adverse events were within safety limits, including 30-day mortality, 8%; symptomatic re-bleeding, 8%; and bacterial ventriculitis, 0%. Patients randomised to medical management showed 4% clot resolution in a similar time window. Preliminary analysis indicated that clot resolution rates are greatly dependent on catheter placement. Location of ICH also affects efficacy of aggressive treatment of ICH.

The usefulness of minimally invasive clot evacuation utilising a variety of mechanical devices and/or endoscopy requires further testing in clinical trials; therefore, its current usefulness is unknown. Similarly, although stereotactic infusion of thrombolytic drugs into the clot cavity apparently reduces clot burden and risk of death, re-bleeding is more common and functional outcome is not improved; therefore, its usefulness is unknown.[4]

Decompressive Craniotomy

This technique has been reported to be beneficial in a number of conditions, including hemispheric ischaemia stroke and ICH associated with aneurysmal subarachnoid haemorrhage. To date, no prospective randomised controlled trials show a convincing beneficial effect on outcome for spontaneous ICH. In one series, 12 consecutive patients with hypertensive ICH were treated with decompressive hemicraniectomy.[25] Eleven patients (92%) survived, and 6 of them (54.5%) had a good functional outcome. This calls for further rigorous controlled trials, which may identify a subgroup of patients in whom this technique might prove to be worthwhile.[4]

Timing of Surgery[4]

No clear evidence at present indicates that ultra-early craniotomy improves functional outcome or mortality rate. Operative removal within 12 hours, particularly when performed by less-invasive methods, has the most supportive evidence, but the number of subjects treated within this window is very small. Very early craniotomy (within 4 hours) may be associated with an increased risk of recurrent bleeding.

102 Surgery for Stroke

Vincent Thamburaj A

Stroke is the second commonest cause of death in India with a crude overall prevalence rate of 220 per 100,000.[105] With an increasing aging population at risk, the stroke burden can be expected to reach epidemic proportions. Irreversible disability is traditionally associated with cerebral vascular disease (CVA), and it is estimated that there are two million fatalities from vascular disease every year. Its incidence is rising with increasing life expectancy.[332]

Arterial thrombosis and atherosclerosis with occlusion of the cerebral arteries is considered as the single most common cause of stroke in more than 50% of patients. Around 30–50% of the cases have had previous transient ischaemic attacks (TIAs). TIAs may be caused by embolism arising from an atheromatous carotid lesion or from reduction in cerebral blood flow due to atheromatous occlusion. Coronary artery disease and rheumatic heart diseases are responsible for most of the cardioembolic strokes. Other rarer causes include trauma to the carotid/vertebral arteries, collagen diseases, moyamoya disease, fibromuscular dysplasia, vasospastic conditions [subarachnoid haemorrhage (SAH), migraine, etc.], and the conditions which alter the rheological properties of the blood such as, polycythaemia, leukaemia, etc. Epidemiological studies involving twins, siblings or families have found evidence of a genetic influence on stroke.[37,332] The most notable difference in India from the Western countries is the predominance of intracranial rather than extracranial location of large artery atherosclerosis.[61,170,252] Therefore, there is a need to find an alternative surgical intervention for the predominantly intracranial pathology found in the Indian population.

There are risk factors such as hypertension, hypercholesterolaemia, atherosclerosis, cardiac abnormalities, diabetes mellitus, obesity and lack of physical activity. Major risk factors identified in India are hypertension (>95 mmHg diastolic), hyperglycaemia, tobacco use (smoking/chewing) and low normal haemoglobin levels (less than 10 gm).[59]

CLINICAL FEATURES

Clinical presentations of cerebral ischaemia are commonly classified into:

1. TIA is traditionally defined as an episode of focal neurological dysfunction as a result of ischaemia and resolves completely within 24 hours. Most of them last for about 10 minutes. The proposed new definition of TIA is a "brief episode of neurological dysfunction caused by a focal disturbance of brain or retinal ischaemia, with clinical symptoms typically lasting less than 1 hour, and without evidence of infarction".[7] With the new definition, patients who have transient focal symptoms of brain ischaemia and who, on diagnostic evaluation, are found to have an acute infarction, would no longer be classified as having a TIA, regardless of the duration of clinical symptoms. With this new definition, the difference between a TIA and a stroke becomes similar to the distinction between an episode of angina pectoris and a myocardial infarction. TIAs are an important determinant of stroke, with 90-day risks of stroke reported as high as 10.5% and the greatest stroke risk apparent in the first week.[151,271]
2. 'Crescendo' TIAs describe a cluster of attacks occurring at increasing frequency or duration over a few hours or days. The patients are at risk of imminent brain infarction.[283]
3. Prolonged reversible ischaemic defect is one where the signs and symptoms last longer than 24 hours, followed by complete recovery within 3 weeks. They have a stuttering or gradual onset unlike a TIA, which has an abrupt onset; they are most likely to be due to cardiogenic embolism. It is prudent to treat these patients as threatening stroke patients.
4. Progressing stroke/stroke in evolution is one where the deficit continues to progress in a stepwise fashion despite adequate medical therapy. It appears to be more common in the vertebrobasilar territory and 50% of the patients will die if untreated.
5. Completed stroke is a stable, focal ischaemic neurological deficit. There may be sudden unheralded progressive neurological deficit (embolic stroke) or the deficit, more commonly, becomes complete in a few hours (thrombotic stroke). It is usually associated with altered sensorium in a few hours (thrombotic stroke).

The earliest sign of the CVA is TIA. Monocular blindness, dysphasia, localised sensory loss and hemiparesis are some of the symptoms that strongly suggest a focal ischaemic episode, and the location of the symptoms defines the vascular distribution of the ischaemia.

Other symptoms, such as diplopia alone, syncope, etc. are far less specific symptoms.[240]

Carotid Territory

The classic history for TIA in the carotid system is one of abrupt onset of contralateral weakness or numbness of the arm or leg. Dysphasia occurs if the dominant hemisphere is involved. Impaired vision of the eye on the side of diminished carotid flow takes place.[240] There are five clinical findings which would make one suspect involvement of the carotid arteries: (1) Blindness in one eye during the TIA attack; (2) Emboli in the retinal vessels; (3) Bruit over the carotid artery; (4) Significant lowering of the retinal arterial pressure on the affected side; (5) Any sign of retinal artery ischaemia. Associated carotidynia (pain over the carotids) suggests a carotid pathology.

The more common shade or curtain altitudinal symptoms suggest reduced circulation to the posterior ciliary arteries or circle of Zinn, which is more likely to be susceptible to the effects of reduced blood flow.[256] The uncommon wedge shaped visual defects, typical of central retinal artery branch occlusion is due to an embolus.

Vertebro-Basilar Territory

Damage to this system is also characterised by a very swift onset of symptoms with neurological phenomena such as ataxia, monoparesis, hemiparesis, quadriplegia, numbness (frequently shifting from one side to the other), vertigo, defects in either visual field, diplopia, dysarthria, aphasia and, occasionally, clouding of consciousness. Vertigo is perhaps the most common symptom of TIA in this distribution.[240]

Vertebro-basilar TIAs are mainly flow related. The incidence of vertebral, subclavian, and brachiocephalic artery stenosis may be as high as 17% in patients with cerebral ischaemia, especially with posterior circulation symptoms.

Attention should be given to the tempo and localisation of the clinical syndrome, as multiple and hemispheric TIAs are associated with the greatest incidence of early stroke. Evaluation of TIAs depends on the clinical symptoms, physical examination and investigations. Attention should also be given to clinical evidence of generalised atherosclerotic disease, as death due to the complications of ischaemic heart disease is the commonest outcome in patients with TIA. Early attention should focus on risk factor modification, with emphasis on the treatment of hypertension and smoking cessation.

Investigations

TIAs should be regarded as an emergency. The risk of stroke is greatest in the weeks following TIA and patients should be referred for further investigations as the earliest.[121] The initial evaluation of a patient in whom a TIA is suspected should include laboratory tests, electrocardiography and imaging studies. Imaging of the head may reveal a non-ischaemic cause, such as a tumour or subdural haematoma, and may provide information about the cause of ischaemia.[98] It is recommended that CT or MRI of the head be part of the evaluation of all patients. Doppler ultrasonography[24] or other noninvasive investigations of the carotid arteries should be performed rapidly, ideally within 24 hours. CT will demarcate the area of ischaemia and exclude haemorrhage and also show previous infarcts, if any. Small lacunar infarcts suggest an arteriolar pathology (of the penetrating branches of major cerebral arteries). Wedge shaped infarcts suggest thromboembolism. Ill-defined border zone infarcts suggest haemodynamic ischaemia.

Fig. 1: CT angio-ICA occlusion

CT angiography[30] of cervical vessels reveals enough vascular details to be useful as a diagnostic screening method in patients with presumed atherosclerosis of the carotid bifurcation and accurately excludes and detects aneurysms and AVMs (Fig. 1).[57] MRI is more sensitive, in particular for previous vascular episodes. MR Angiography, a noninvasive test, can yield information regarding collateral blood flow and is nearly as effective as conventional angiography in estimating disease at the carotid bifurcation. It is suitable for replacing the invasive conventional angiography method in most (Fig. 2).[45,62,266]

Further technical developments with regard to spatial resolution are still required for improved visualisation

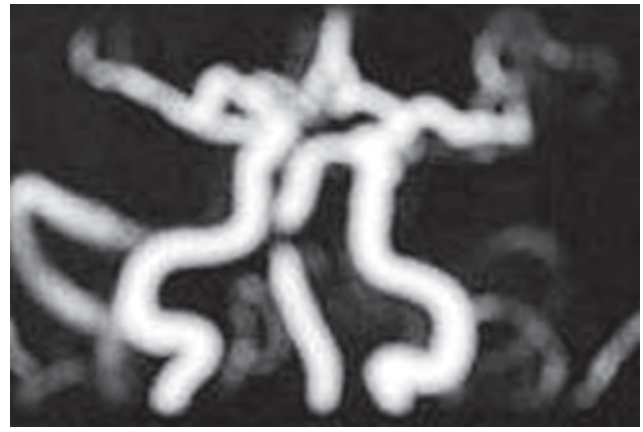

Fig. 2: MR angio-basilar occlusion

of small vessels and terminal branches of intracranial vessels.

Ultrasonography, being cost effective, should be used as a screening tool to exclude patients with no carotid artery disease from further testing. Ultrasound evaluation of carotid artery morphology and flow has been widely accepted as a noninvasive measure and has replaced ophthalmodynamometry and oculoplethysmography that offer an indirect indication of ipsilateral carotid occlusion (Fig. 3).[103,250]

B-mode ultrasound imaging provides images of various levels, or planes, enabling the creation of a 3D image of the carotid artery wall and surrounding structures.[325] This technique provides information on the type and extent of arterial damage, but blood clots sometimes do not appear and the method cannot distinguish a severely narrowed from a completely occluded artery.

Doppler testing measures the speed of arterial blood flow. Duplex ultrasound (DUS) combines B-mode imaging and Doppler to provide more detail on the condition of the arteries than either test alone can provide (Fig. 4).[310,311] DUS may be more sensitive than angiography in determining the presence of ulceration.[284] However, its reliability is highly dependent on the technician. The recent availability of ultrasound contrast agents helps to distinguish between pseudo and true occlusions, improves ultrasound images and should help to reduce operator variability.[41]

Transcranial Doppler (TCD) assesses intracranial arterial flow in the distal internal carotid artery (ICA), the middle, anterior and posterior cerebral artery stems, and the ophthalmic artery. The haemodynamic significance of extracranial and intracranial ICA occlusion and the availability of collateral circulation may be studied satisfactorily.[12,241] Transorbital (ophthalmic artery), submandibular (distal ICA), transtemporal (anterior cerebral, middle cerebral and posterior cerebral) and foramen magnum (posterior circulation) approaches are employed for a comprehensive assessment. Serial TCD examination may reveal dynamic changes in cerebral circulation that may be missed on a single MRA study.[5]

Pre-operative TCD can be used to identify patients who do not require a shunt during carotid endarterectomy.[341] In acute ischaemic stroke, TCD can be used to elucidate stroke mechanisms, plan and monitor treatment, and determine prognosis. In an era, when stroke is increasingly being recognised as an emergency requiring immediate treatment, TCD may be capable of providing rapid information about the haemodynamic status of the cerebral circulation.[265]

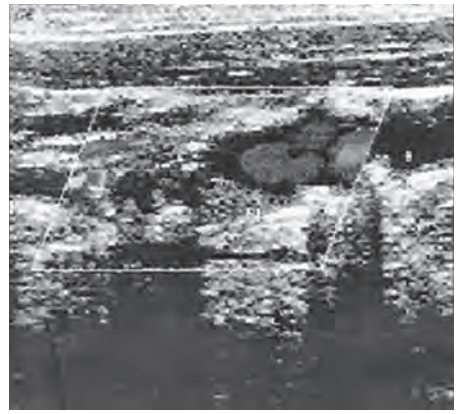

Fig. 4: Colour Doppler—grossly reduced colour flow in the left ICA

Conventional four vessel arteriography should include cerebral, carotid and aortic arch studies and with cross carotid compression. One may also find post-stenotic lesions of the bifurcation, patency of the anterior cerebral vessels, absence of the vertebral artery, occlusion of the vertebral artery and partial occlusion of the internal carotid vessels (Fig. 5). Internal carotid patency along with cross filling of the anterior, middle cerebral and the posterior communicating vessels may be evaluated. However, conventional arteriography fails to demonstrate some vascular mural changes that may be responsible for the development of clinical manifestations, such as intraplaque haemorrhage and thrombus attached to the arterial wall. These mural changes may be identified with duplex ultrasound and CT angiography.[57,80] With increasing experience with noninvasive imaging, angiography may be required less often.

Doppler C02/Acetazolamide (diamox) test: Cerebral blood flow (CBF), measured early after acetazolamide administration, could be useful to confirm the clinical

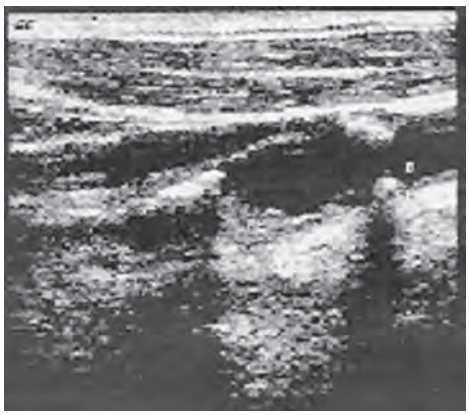

Fig. 3: Real time B mode—plaques at the bulb and left internal carotid artery ICA

Fig. 5: ICA occlusion-DSA

diagnosis of TIA. No increase in CBF during hypercapnia or following acetazolamide suggests that the cerebral arterioles are maximally dilated and the procedures to improve the blood flow, such as EC-IC bypass will not help.[286,299]

Single-photon emission computed tomography (SPECT) studies combine nuclear medicine with computed tomography. Used in the early hours after infarction, cerebral SPECT is able to reveal a deficit in local blood flow before changes appear on CT or MRI. However, SPECT does not reliably distinguish between haemorrhage and infarction. In patients who are marginal candidates for endarterectomy, the haemodynamic effect of stenosis on cerebral perfusion may be assessed with SPECT and is useful in predicting neurological outcome in ischaemic stroke patients.[57]

Positron emission tomography (PET) can be used to measure CBF, cerebral blood volume (CBV) and metabolism (CMR). Patients with low CBF and high oxygen extraction (OEF) have compromised cerebral circulation and are expected to benefit from revascularisation. These studies are helpful in an established stroke, and to differentiate between flow-related TIAs, and thromboembolic TIAs.[250] SPECT and PET are not sufficiently widely used in clinical practice.

SURGERY FOR STROKE PREVENTION

Carotid occlusive disease is the primary pathophysiological source of 10–20% of all strokes.[287] The risk of a first or recurrent stroke has been found to increase with the degree of severity of the carotid stenosis, although a linear relationship between degree of stenosis and risk of stroke has not been demonstrated.[356]

Carotid occlusive disease may be caused by a variety of disorders; but the great majority of strokes of carotid origin are related to atheromatous narrowing of these arteries.[88,198] Atherosclerotic lesions are almost invariably present at multiple sites.[88] These include the origins of the carotid and vertebral arteries, the carotid bifurcation, the cavernous ICA, the basilar artery and the middle cerebral arteries. Significant atheromatous disease in these sites is associated with the presence of similar lesions in the coronary circulation.[314] Fibromuscular dysplasia is a non-inflammatory vasculopathy and is the second most common cause of extracranial carotid stenosis[202] usually at the level of C2–C3, with sparing of the proximal ICA at the bifurcation.[54]

Dissections of the cervical carotid artery have been categorised as traumatic or spontaneous. Spontaneous dissections can be associated with atherosclerosis or fibromuscular dysplasia. Traumatic dissections typically involve the distal extracranial ICA and are thought to originate from impingement of the artery against the C2 transverse process during rotation with extension of the neck.[227]

Radiation induced stenosis is an occasional cause. Murros and Toole summarised the existing literature regarding radiation injury to large arteries and concluded that, although radiation occasionally accelerates atherosclerotic lesions, doses in excess of 5,000 Rads are required to produce significant changes.[235]

Direct Revascularisation Procedures

Carotid Territory

Carotid endarterectomy (CEA): The use of carotid endarterectomy (CEA) in the prevention of ischaemic stroke was first described in 1954[73] and has been the most widely accepted surgical procedure for prophylaxis of stroke since. By symptomatic presentation or pathological criteria, the majority of cerebral ischaemic events correspond to embolic phenomena.[85,91,96,101,247] Removal of the stenotic, atheromatous lesion eliminates potential sites of thrombi, thereby eliminating a potential source of emboli and improve cerebral blood flow.

Indications[40,63]: Carotid occlusive disease can be clinically divided into two types: (i) Symptomatic and (ii) asymptomatic. Symptomatic carotid stenosis usually refers to ischaemia in the distribution of the ipsilateral stenotic ICA resulting in TIAs, amaurosis fugax or completed stroke.[256] A diagnosis of asymptomatic disease is made in patients with any of the following:

1. Incidentally found carotid bruit.
2. Cerebrovascular symptoms referable to one carotid artery territory, and demonstration of an asymptomatic contralateral carotid artery stenosis or ulceration.
3. Patients, scheduled to undergo general or cardiac surgery with auscultatory or radiographical evidence of carotid artery disease.

Prospective co-operative studies confirm that surgery has a role in the treatment of this disease. A review of these trials is imperative if these data are to be applied to an individual patient.

In 1991, the North American Symptomatic Carotid-Endarterectomy Trial (NASCET)[238] and the European Carotid Surgery Trial (ECST)[81] concluded that carotid endarterectomy is highly beneficial to patients with high-grade stenosis greater than 70% of the ICA. A reanalysis of the final results of the ECST and NASCET suggested that CEA is highly beneficial for 70–99% stenosis and moderately beneficial for 50–69% stenosis. Patients with a stenosis less than 30% need not be operated.[282] Benefit in patients with near total carotid occlusion is marginal in the short-term and uncertain in the long term.[281] Patients with transient monocular blindness only, especially those with few risk factors, and women with few risk factors may be harmed by endarterectomy. The benefit is muted in those presenting with lacunar stroke as well.[20]

Early endarterectomy for severe carotid artery stenosis after a non-disabling ischaemic stroke can be performed with rates of morbidity and mortality comparable to those who receive delayed endarterectomy.[76,100]

The estimated prevalence of intracranial atherosclerotic disease in patients with stenosis of the extracranial ICA varies between 20% and 50%. The benefits of carotid endarterectomy in patients with both intracranial atherosclerotic disease and symptomatic extracranial ICA stenosis are uncertain.[160]

Indications for asymtomatic carotid stenosis are still unclear. In 1995, the Asymptomatic Carotid Atherosclerosis Study (ACAS)[82] looked at the benefits of surgery in patients with narrowing in the carotid artery in the range of 60–99% stenosis. The study showed that over 5 years, the risk of stroke or stroke and death caused by narrowing in the affected artery were reduced from 11% to 5.1%. There was no evidence of any more or less benefit as the narrowing approached 99%. The Asymptomatic Carotid Stenosis Trial (ACST)[113] study essentially confirms and extends the findings of the ACAS trial. ACST confirms there is overall benefit from carotid surgery in patients with asymptomatic carotid narrowing of 60–99% in patients under the age of 75 years. In patients over the age of 75 years, potential benefits are uncertain. Probably, most importantly, the ACST study clearly showed a reduction in the risk of fatal or disabling stroke following carotid surgery. The two studies together provide very strong evidence of a benefit for carotid surgery in highly selected patients with asymptomatic carotid disease.

The most recent extensive analysis[267] recommends the following for stroke prevention:

a. Patients with recent TIA or ischaemic stroke within 6 months and ipsilateral severe (70–99%) carotid artery stenosis should receive CEA by a surgeon with a morbidity and mortality of less than 6%.
b. Patients with recent TIA or stroke with moderate carotid stenosis (50–69%) may have CEA depending on comorbid factors, whereas CEA is not recommended for those with less than 50% stenosis.
c. When CEA is recommended, surgery should be performed within 2 weeks.
d. In those with symptomatic severe stenosis greater than 70% in whom the stenosis is difficult to assess, carotid angioplasty is not inferior to CEA, and may be considered.
e. Among patients with symptomatic carotid occlusion, extracranial-intracranial bypass is not routinely recommended.
f. Endovascular treatment[196] of patients with symptomatic extracranial vertebral stenosis may be considered when patients are having symptoms despite medical treatment.
e. For those with haemodynamically significant intracranial stenosis who have symptoms despite medical therapy, the usefulness of endovascular therapy is uncertain.

In clinical practice, surgeons must manage patients whose risk of stroke varies greatly. In our practice, the ideal patient for carotid endarterectomy is one who presents with a history of TIA, hemispheric[309,353] or retinal and has no neurological deficit on physical examination and who has a stenotic lesion at the origin of the ICA. Individual selection is applied in traumatic occlusion of the carotid and spontaneous dissection of the carotid, and progressive stroke despite all medical measures.

Surgical Risk Factors

To maximise the benefits of surgery, careful pre-operative risk assessment and the maintenance of low rates of major peri-operative complications are mandatory.
The risk of stroke and death from carotid endarterectomy is related to clinical and angiographic characteristics.[222] Reina Gutierrez et al.[269] suggest that the patient's risk profile has a greater influence on the results than the technique used. Several baseline patient characteristics predict surgical risk.

The patients may be classified into the following four groups to assess the risk factor:[302]

Group 1: Neurologically stable without medical or angiographic risk.
Group 2: Neurologically stable without medical, but with angiographic risk.
Group 3: Neurologically stable with medical and with or without angiographic risk.
Group 4: Neurologically unstable with or without medical/angiographic risks.

Events at presentation, recent history of stroke, stroke in progression, frequent TIAs, female sex, systolic hypertension and peripheral vascular disease are independent risk factors.[32,222] Patients with hypertension and chronic hemispheric hypoperfusion with impaired autoregulation are at risk.[259] 'Silent' cerebral infarction is found in 20–30% of patients with significant ICA disease and they seem to be at increased risk of peri-operative stroke.[119]

Evidence of ICA thrombus and ICA stenosis near the carotid siphon suggest a peri-operative risk.[216] Extensive ICA pathology and high common carotid bifurcation present a technical difficulty. Collaterals are associated with a lower risk of hemispheric stroke and TIA, both long term and peri-operatively.[120] Diastolic flow velocities within severe ICA stenosis are dependent on the level of the collateral perfusion pressure distal to the stenosis (i.e. high values indicate a low ICA stump pressure), which seems to be a risk factor for early post-operative strokes.[354] Contralateral stenosis and low stump pressures can be used in combination to identify high-risk patients likely to develop neurological complications during or following endarterectomy.[39]

As in any form of major surgery, patients with hypertension, chronic obstructive airway disease, obesity and congestive cardiac failure are at risk. Carotid endarterectomy performed in preparation for coronary artery bypass surgery with a history of angina carries a risk.[222]

There is a widespread belief, unsupported by reports, that carotid artery stenting (CAS) is advisable in high-risk patients. Lower rates of cranial nerve injury[263] and restenosis[261] have been reported with CAS. Over

all, results of carotid endarterectomy are superior to similar data regarding CAS. As of now, use of stenting in those with high risk for endarterectomy should be deferred.[165,234]

Surgical Technique

Pre-operative counselling is important as preparation of the patient mentally helps a great deal in overcoming the fear and anxiety. If the patient is on antiplatelets already, ASA may be continued through the procedure, but Clopidogrel is stopped two days pre-operatively in our practice.

In the operating room the patient is sedated with 1 mg midazolam intravenously after securing venous access and arterial pressure monitoring catheter. Arterial pressure is monitored continuously as fluctuations during the procedure can affect the cerebral circulation.

Positioning of the patient is extremely important as hyperextension of the neck may kink the vertebrals, which will be the likely source of blood supply during cross clamping of the ICA.

Intra-operative Monitoring

1. Electroencephalography is widely available and correlates well with diminished hemispheric cerebral blood flow and is a valuable tool for determining the need for shunting during carotid endarterectomy.[293] A statistically significant increase in intra-operative stroke rate is associated with the development of an abnormal EEG (1.1%), contralateral ICA occlusion (1.8%) and the combination of both (3.3%).[83]
2. Somatosensory evoked potentials (SSEP), if available, is an ideal monitoring modality under general anaesthesia, and indicates critical cerebral hypoperfusion during cross clamping, with high sensitivity and specificity. Progressive reduction of up to 50% of N20, P25 amplitude suggests cerebral ischaemia. SSEP not only helps to identify patients with insufficient collateral blood flow who benefit from specific cerebral protection, such as shunt, but also to avoid improper and hazardous application of these measures in patients with sufficient cerebral perfusion. In addition, correct shunt function is immediately indicated by recovering potentials.[68]
3. Measurement of ICA stump backpressure helps in deciding on the need for a shunt. Reports suggest that surgery without a shunt when the ICA backpressure is low (< 50 mm Hg), produces a significant deficit.[118,322]
4. Transcranial Doppler (TCD) detects high blood flow velocities. The peri-operative stroke rate can be reduced by taking appropriate measures based on findings of TCD monitoring.[242,303] The clinical significance of bilateral flow velocity increases soon after surgery is uncertain, but very high blood flow velocities might be a signal for cerebrovascular hyperfusion.[355] In those patients, increased post-operative surveillance is recommended.

The usefulness of monitoring cerebral function during the procedure is closely related to the experience of the surgical team. No one method of monitoring in selective shunting has been shown to produce better outcomes. No prospective randomised or quasi-randomised trials have been performed and the conclusions therefore remain unchanged.[22,32,33,328] Recommendations, whether to practice cerebral monitoring or not, and what method should be used for this purpose, cannot be given presently.

Procedure

We prefer regional anaesthesia as it obviates the need for extensive intra-operative monitoring for cerebral ischaemia. Assessment of cerebral perfusion can be made by direct interaction with the patient. This is by far the best mode of assessment of cerebral perfusion when compared to other modalities such as TCD and SSEP. A randomised controlled trial comparing general anaesthesia and cervical block found no significant differences in mortality or morbidity.[192] Propofol has no significant effect against neurological complications in CEA patients.[237]

Regional anaesthesia is obtained by both superficial and deep cervical block. Deep cervical block involves infiltration of local anaesthetic agents around C2, C3 and C4 at the exit foramina. Superficial block involves infiltration around the cervical plexus at the lateral border of the sternocleidomastoid muscle at the level of the external jugular vein. We use approximately 40cc of 0.375% bupivacaine as the resultant anaesthesia lasts as long as 6–8 hours. Just before making the skin incision the patient is given Fentanyl 25 mg intravenously for additional sedation.

A long high incision is made along the anterior border of the sternomastoid muscle, almost to the mastoid tip (Fig. 6). It often necessitates the division of a branch of the great auricular nerve as it crosses the anterior margin of the sternomastoid muscle, resulting in, usually, temporary ear and/or lower jaw skin numbness.

The plane beneath the investing fascia of the neck is followed under the sternomastoid muscle, and after the

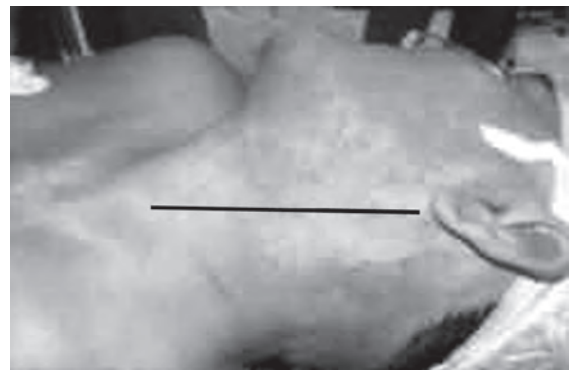

Fig. 6: Skin incision

sternomastoid muscle is mobilised, blunt self-retaining retractors are used to expose the underlying areolar tissue, beneath which lies the internal jugular vein and carotid sheath.

Sharp dissection is continued, first skeletonising the internal jugular vein and the common facial vein. The common facial vein and any nearby vein emptying directly into the internal jugular vein are divided so that the jugular vein can be retracted posteriorly, exposing the carotid arteries beneath (Fig. 7).

The carotid sheath is opened to expose the common carotid artery above the upper margin of the overlying omohyoid muscle, and dissection proceeds distally to the bifurcation and to the external and internal carotid arteries.

It is necessary at all times, but particularly at this stage to handle the tissues gently and disturb the arteries from their bed as little as possible, especially when manipulating the ICA near the plaque. It is not wise to palpate the plaque within the ICA, which is usually located at the site where the artery is most adherent to adjacent tissues, because of the risk of dislodging an intraluminal thrombus into the cerebral circulation. The sinus nerve at the bifurcation of the carotids is blocked with 1% lignocaine during carotid dissection.

During distal exposure of the ICA, care is taken not to injure or excessively manipulate the hypoglossal, vagus and accessory nerves, although the latter is high and posterior in the carotid sheath and infrequently exposed. The hypoglossal nerve, which is routinely exposed, descends deep to and beneath the digastric muscle and curves forward superficial to the external carotid artery; it often can readily be traced to this location by following a branch, the descendens hypoglossi, proximally from its course within the carotid sheath. Vessel loops are then passed around the common, external and internal carotid and superior thyroidal arteries, and heparin (75 IU/kg) is administered. Mean arterial pressure has to be maintained around 100 mm Hg before the carotids are clamped. After 3 minutes, the carotids should be cross clamped sequentially. Internal carotid first followed by common carotid and external carotid. Care should be taken to palpate the artery at the precise point where one intends to put the clamp and one should be certain that it is below a hard, calcified plaque, which could easily fracture. The superior thyroid artery, which arises from the external carotid close to the bifurcation, has to be occluded separately.

At this stage, careful neuro-monitoring is done by the anaesthetist by assessing the level of consciousness and motor activity. Any deterioration in the assessment at any stage will be an indication for shunt insertion to protect the cerebral circulation. The only method currently accepted by all surgeons to achieve cerebral protection is the use of shunt during carotid endarterectomy.[148]

However, the use of a shunt during carotid endarterectomy is controversial with various authors advocating uniform shunting,[149] no shunting,[306] and selective shunting based on monitoring.[315] The potential disadvantages of shunts are dislodgement of embolic material during placement, need for additional distal exposure, and limited visualisation at the critical distal margin of the plaque. It has been suggested that an external shunt, placed between the common carotid artery and the ICA, is safe and efficacious in cases that do not permit the placement of an internal shunt.[337]

A new type of temporary extraluminal shunt, connecting the femoral to the ICA with the interposition of roller pumps to regulate the blood flow has been reported. This method allows one to perform carotid endarterectomy without interrupting the blood flow to the brain.

An arteriotomy is extended proximally from the common carotid artery with care being taken to keep it in the middle of the lateral exposure of the ICA and away from the apex of the carotid bifurcation (Fig. 8). The internal carotid clamp is opened to assess the back bleeding, which is another indicator of cross circulation.

The atheroma is separated, particularly at the distal end of the internal carotid endarterectomy, followed by complete removal of all small, loosely adherent circumferential plaque remnants from the endarterectomy site (Fig. 9). Constant heparinised saline irrigation is recommended. The greatest care should be taken with the upper end of the endarterectomy, and if the plaque has not come out smoothly, the surgeon should be prepared

Fig. 7: Exposure of carotids

Fig. 8: Arteriotomy

Fig. 9: Removal of atheromatous plaque

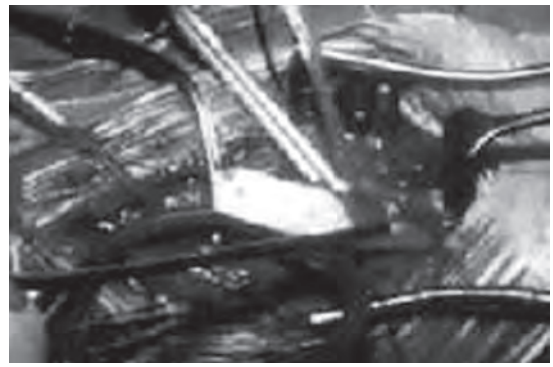

Fig. 11: Arteriotomy closure with a patch

and able to open the ICA another 5 mm in order to improve the distal repair. Any significant distal intimal step-off or shelf not firmly adherent to the arterial wall should be tacked down with 7-0 monofilament sutures. A partial or circumferential plaque should never be pulled down and away from above the level of the arteriotomy within the internal carotid, because a loose distal intimal attachment, vulnerable to subintimal dissection and carotid occlusion, can neither be fully appreciated nor properly repaired in this location. The atheroma extending up the external carotid artery is mobilised circumferentially, and the plaque is everted from the arterial lumen. Microsurgical methods increase the precision and safety of every aspect of carotid endarterectomy, including complete plaque removal, prevention of intimal flaps and non-stenosing arteriotomy closure (Fig. 10).[285]

After irrigating of the area, the arteriotomy is closed with 6.0 prolene. Before the final arteriotomy suture, the ICA temporary clip and the common carotid artery clamp are removed momentarily in turn, allowing air to be expelled from the nearly repaired arteriotomy. If the ICA is small, which is the case in small built females, a Gortex patch can be used as angioplasty (Figs 11 to 13).

Patients with complicated recurrent atherosclerosis can be treated with endarterectomy and patch grafting, but interposition vein grafts should be considered in cases in which the vessels are extensively damaged by the recurrent plaque or with an unexplained thrombus at the site of previous endarterectomy.[260]

Clamps are sequentially released after arteriotomy closure. The external carotid circulation is established first as any small debris from the operative site may be released into the extracerebral circulation. The internal carotid clamp is released last. If haemostasis is satisfactory reversal of the heparin may not be required. The wound is closed after placing a suction drain.

Post-operatively, close neurological observation is necessary by a dedicated nurse. Post-operatively the patient can be started on oral fluids after 2 hours as well as all the medications as before including antiplatelets. There is no indication for routine anticoagulant therapy. Post-operatively, our patients are put on 75 mg of aspirin. There is a suggestion that antiplatelets may increase the odds of haemorrhage, but there are currently too few data to quantify this effect.[79] Low-dose aspirin (75 mg) is effective in preventing recurrent stroke after CEA.[285] None of the newer antiplatelet agents has been specifically studied in patients requiring CEA. Further trials comparing the effects of the combination of dipyridamole with aspirin and with aspirin alone are justified.

Complications

Peri-operative complications of carotid endarterectomy are uncommon but potentially devastating. Appropriate patient selection, including careful assessment of techniques aimed at prevention and monitoring of intraoperative complications and post-operative care are mandatory.

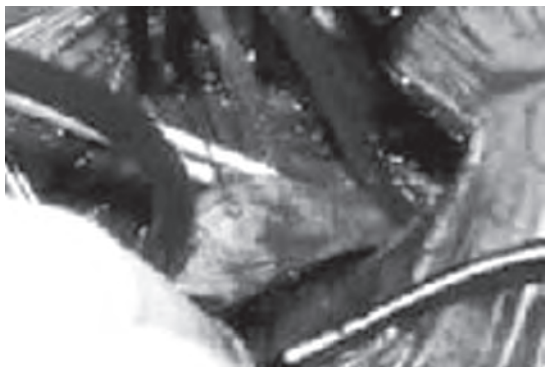

Fig. 10: Endarterectomy completed—Javid shunt being inserted

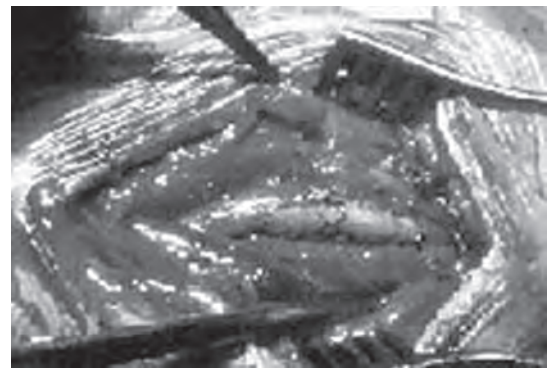

Fig. 12: Completed closure with a patch

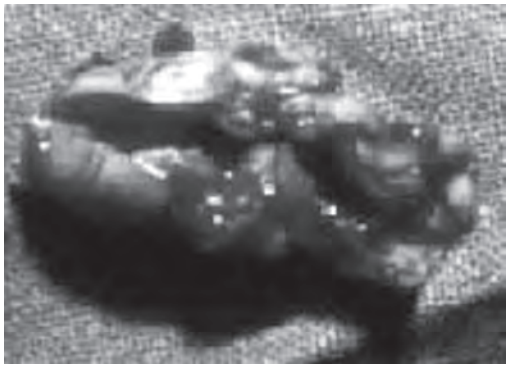

Fig. 13: Atheroma

The operative mortality and morbidity is 1–5% in various studies.[74] Reported incidence of peri-operative ischaemia after endarterectomy is about 2.5% for reversible deficits, about 1.3% for minor stroke and about 2.9% for major stroke.[209,238,314,333] Embolism is the principal cause; hyperperfusion and hypoperfusion are also important causes.[127]

Abu Rahma[3] reviewed the data on 478 consecutive patients who underwent 544 CEAs since 1976. Follow-up was complete in 83% of patients (mean 44 months). There were seven early deaths (1.3%), only one stroke related (0.2%). Peri-operative stroke rates (overall 2.9%) varied according to operative indications: asymptomatic-1.4%; TIA/amaurosis fugax (AF)-1.3%; non-hemispheric symptoms (NH)-4.9% and prior stroke (CVA)-7.1%. Five- and 10-year stroke-free rates were 96% and 92% in the asymptomatic group, 93% and 87% in the TIA/AF group, 92% and 92% in the NH group and 80% and 73% in the CVA group. Late ipsilateral strokes occurred infrequently (8 patients, 1.7%). Late deaths were primarily cardiac related (51.3%). Stroke-free rates were significantly greater. Restenosis greater than 50% according to duplex scanning developed in 13%, most (67%) within 2 years after CEA. Most of these (77%) were asymptomatic, and only 0.3% (1 patient) presented with a permanent neurological deficit. Patients with contralateral occlusion had a higher incidence of contralateral TIAs and strokes than patients without contralateral occlusion; however, the peri-operative and all late stroke rates and survival rates of CEA were comparable in patients with or without contralateral occlusion.

Intracerebral haemorrhage is an unusual complication. The incidence of intracerebral haemorrhage is increased in patients with critical carotid stenosis; this is probably related to chronic impairment of cerebral autoregulation.[27]

Restenosis occurs in about 20%. The incidence of symptomatic restenosis is in the range of 1–2%.[260] Use of dacron or vein patch during arteriotomy closure when the internal diameter of the ICA is less than 5 mm is recommended. Reoperation for carotid stenosis is a technically difficult procedure and is associated with significantly higher risks than primary CEA. Sundt et al.[312] have documented a risk of complications of 10.5%, which is four times higher than their customary rate.

Aside from technical inadequacies, the continuation of cigarette smoking post-CEA proved to be a significant risk factor; however, hypertension, diabetes mellitus, family history, lipid studies, aspirin use and coronary disease were not found to be significant risk factors.[51]

Injuries to the cervical cranial nerves are a common consequence of carotid endarterectomy. The reported incidence of cranial neuropathy after endarterectomy is 12–20%.[51,124,197] Hypoglossal, vagus, mandibular branch of the facial, and greater auricular nerves are at risk. Precise bipolar coagulation, use of magnified vision, and gentle handling of the nerves help to avoid this occurrence. Wound haematoma and infection are other possible complications.

We have operated on 67 patients between December, 2000 and September, 2006. There was no mortality. Out of 9 patients with acute stroke, one recovered his neurological deficit. One patient developed transient vagus nerve palsy, and another a marginal mandibular nerve weakness. The largest Indian series (300 patients) is from Sir Ganga Ram Hospital[298] and includes 12 patients for whom the endarterectomy was combined with simultaneous coronary bypass grafting. Sethi et al.[298] reported 3 deaths, 3% peri-operative stroke, and re-exploration due to haematoma formation was done in 6. (Figs 14 and 15).

Extracranial to Intracranial (EC-IC) Bypass

Superficial temporal to middle cerebral artery bypass (STA-MCA) is the most widely used. The first STA-MCA bypass was performed by Yasargil in 1969.[70] It involves anastomosis of the superficial temporal artery to one of the cortical branches of the middle cerebral artery.

Technique

The skin in incised over the proximal STA, just above the zygoma. The STA has at least two major branches

Fig. 14: ICA stenosis—pre-operative

Fig. 15: ICA stenosis—post-operative

(frontal and parietal) and they should both be followed distally. The STA is dissected with a small cuff of tissue to prevent vessel injury. The larger branch is freed.

A small craniotomy centred over the Sylvian fissure is made. The dural opening is fashioned in such a way as to preserve the main branches of the middle meningeal artery, as these vessels often provide critical collateral circulation to the cerebrum. Once the dura is opened, the cortical surface is examined and generally the largest diameter vessel is selected. The ideal recipient is a surface cortical vessel without significant branching. The STA is ligated and divided and the proximal STA is occluded with a temporary clip.

The recipient artery is transiently occluded between two atraumatic temporary clips and an 'end to side' anastomosis is performed with 10-0 monofilament suture. The sutures are placed under little or no tension and then tightened after ensuring the suture does not capture the back wall of the vessel. Interrupted sutures have also proven effective and remain a reasonable alternative to a running suture. Vessel flow can then be restored, with the distal MCA clip being removed first followed by the proximal MCA clip. The temporary clip on the STA is removed last.

The donor STA and recipient MCA are irrigated with diluted papaverine, to prevent vasospasm. Warm saline is used for the remainder of the operation as an additional means to reduce arterial spasm. The dura is closed leaving a large durotomy for the graft that can be covered with muscle. The bone flap is fashioned so as to prevent compression or kinking of the graft. The temporalis muscle is then reapproximated, and the scalp is closed over a subgaleal drain.

Post-operatively, aspirin (325 mg/day) is administered and normal blood pressure is maintained. This provides initial flows of 25–50 ml/min. With time, the bypass may mature, allowing enlargement of the STA leading to a higher flow. Occipital artery to the intracranial circulation anastomosis has also been tried. When the STA is not satisfactory, Spetzler et al. suggested that the occipital artery[304] can be used, and interposition vein graft is recommended by some.[142,313] Complications include aneurysmal dilatation and rupture of the graft, and emboli from the graft site.

Anecdotal reports and uncontrolled patient series suggest that STA-MCA bypass may be beneficial. Small vessel disease (about 20% of all ischaemic patients), middle cerebral artery occlusion where endovascular thrombectomy has failed or is not feasible, and total ICA occlusion may benefit from an EC-IC bypass procedure. However, National Institute of Health (NIH) study in 1985[75] concluded that these procedures do not help in preventing a stroke, despite an overall graft patency rate of 96% and low surgical morbidity. They may have a place when everything else fails in the highly selected patients where the metabolic reserve studies suggest a compromised CBF. Chronic biochemical abnormalities due to brain ischaemia may improve after cerebral revascularisation.[220] In the treatment of inoperable ICA giant aneurysms, where the risk of ischaemic complications due to ICA ligation is high, EC-IC bypass may be used as a prelude to ICA ligation.[46]

Vertebro-basilar Territory

Cerebellar infarctions carry a poor prognosis with an acute mortality rate of 20–30%. They are mostly due to diffuse atherosclerosis of the vessels with poor flow due to stenosis and poor collaterals. Medical therapy is the first line of management. Several procedures have been tried in those with persisting symptoms.[186,253] There have been no randomised studies.

The simplest procedure, perhaps, is carotid endarterectomy if a significant stenosis is found while investigating a vertebrobasilar TIA and the stenosed carotid may be asymptomatic.[280,310] It is most readily accepted if the angiogram shows filling of the posterior cerebral artery via the stenotic ICA, or filling of the posterior circulation from the ICA because of vertebral occlusion or a persistent hypoglossal or trigeminal artery.

Anson and Spetzler[10] reported good outcome with vertebral endarterectomy which is similar to carotid endarterectomy. Ausman and colleagues[15–17] have described anastomosis of occipital artery to the PICA for occlusion proximal to the PICA and a superior cerebellar artery or P1 segment of the posterior cerebral artery anastomosis for lesions at the mid or distal basilar and also recommend vertebral endarterectomy in symptomatic patients with a functioning collateral or bypass. A vein graft interposition facilitates the bypass. Hopkins and Budny[133] reviewed a major series of posterior circulation bypass. Complications occurred in 55% of patients and 20% of them were serious.

Extracranially, the left subclavian artery, next to the carotids and the vertebrals, is the most commonly involved in atherosclerosis. Subclavian steal syndrome is the most commonly treated by carotid-subclavian bypass. The cervical vertebral artery may occasionally be compressed

by cervical osteophytes. Spetzler and colleagues[305] have reported relief with anterior decompression.

Indirect Revascularisation Procedures

Intracranial occlusive diseases form a heterogeneous group with diverse pathogenesis. Moyamoya, the commonest, is a progressive occlusive cerebrovascular disorder characterised by bilateral stenosis and occlusions of the intracranial arteries with extensive neovascularisation at the base of the brain[318]. It was first described in Japan and is now reported from all over the world. The term moyamoya (Japanese for "puff of smoke") was coined by Suzuki and Takaku[317] in 1969 in reference to the angiographic appearance of these fine basal collaterals, and has since become the accepted term to define the disease throughout the world. The incidence of persistent primitive arteries is significantly higher in patients with moyamoya disease, suggesting that congenital factors may be important in the pathogenesis of this disease.[183] In paediatric-onset moyamoya disease, asymmetrical involvement of bilateral ICAs and PCAs is common, and the ipsilateral ICA and PCA tend to be predominantly involved.[233] There is some suggestion that the pathogenesis may vary between races.[106]

The term quasi-moyamoya disease or moyamoya syndrome is typically used to refer to patients who display intracerebral steno-occlusive lesions and associated collaterals in other areas of the brain (Fig. 16). Treatment of all the patients with intracranial small vessel occlusive diseases is similar to that of moyamoya patients.

Patients present with stroke or intracranial haemorrhage due to bleeding from the friable vessels with major morbidity and mortality. Children usually present with cerebral ischaemia, while intracranial haemorrhage is common in adults.

CT, MR imaging and MR angiography help in diagnosis. CT may show multiple low density areas, and general atrophy, and contrast enhancing curvilinear vessels in the basal ganglia and cortical surface.[320,342]

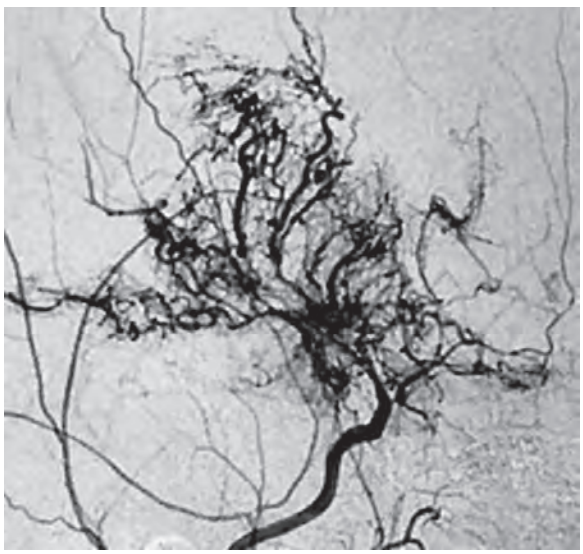

Fig. 16: Moyamoya-DSA

Conventional four vessel angiography is rarely required. 3D CT angiography is becoming an alternative. Without treatment, there is progressive deterioration of neurological function and recurrent haemorrhages.

Medical therapy with vasodilators, steroids and antibiotics is only minimally effective. Until 1975, most of the 700 reported cases of ischaemic moyamoya disease were treated conservatively. Medical therapy with steroids, vasodilating agents and low-molecular-weight dextran had been tried without success.[162]

STA-MCA bypass with or without a graft is re-emerging as a popular procedure in adults. Direct superficial temporal artery to middle cerebral artery bypass is considered the treatment of choice, although its efficacy, particularly for haemorrhagic disease, remains uncertain.[307]

Technical difficulties, especially in children, such as small STA, prompted the surgeons look for alternatives. Various surgical procedures have been tried with mixed results. All share the common goal of providing a mechanism to promote collateral blood vessels to reduce haemodynamic stress across fragile moyamoya collaterals, and ischaemia. They provide no immediate revascularisation. They rely on the subsequent formation of collateral vessels to enhance blood delivery.

Tsubokawa et al.,[334] in 1964, reported a surgery in which a dural graft containing branches of the meningeal artery was laid onto the surface of the brain of a patient with ischaemia. Suzuki and colleagues[317] suggested cervical carotid sympathectomy and superior cervical perivascular ganglionectomy with good results in improving clinical symptoms; but in most cases the procedure could not prevent the progression of the disease and the deterioration of the angiographic pattern.

Encephalo-duro-arterio-synangiosis (EDAS): In 1979, Matsushima and colleagues[207] developed EDAS with the assumption that the operation would cause the formation of spontaneous anastomoses between the arteries of the cerebral cortex, dura mater and scalp to treat moyamoya disease. The STA is mobilised and placed directly on the cortex. The free artery with a cuff of surrounding soft tissue is simply sutured to the dura.

Encephlomyosynangiosis (EMS): It involves direct placement of the temporalis muscle on the cerebral cortex. The clinical and experimental basis for using EMS in moyamoya was based on the reports of Henschen,[122] and Tsubokawa et al.[334] This may, however, induce seizures.[117, 162]

Encephalo-omental-synangiosis (EOS) may provide an alternative.[1,2] The omentum is mobilised from the abdomen in a subcutaneous tunnel and placed over the cerebral cortex as a pedicle graft or, as a free graft with microsurgical anastomosis of the gastroepiploic artery and vein to the STA and the superficial temporal vein. Karasawa and colleagues reported clinical improvement.[161] Omentum contains biologically active substances taking part in neural transmission and has angiogenic and neurotrophic action.[140]

The EMS, EDAS and STA-MCA anastomosis treatments induce vascularisation of the cerebral surface, especially in the territory of the MCA, but the vascularisation is poor in the territories of the anterior and posterior cerebral arteries.[321] Placement of multiple burr holes to improve the vascular supply has been suggested with good outcome.[78] The placement of burr holes was described as a treatment after it was noticed that neovascularisation was occurring at the site of previous ventriculostomies.[140]

Combined procedures, direct and indirect procedures or a combination of indirect procedures give the best results.[11,136,177,178,206,319] Studies such as xenon-enhanced computed tomography, single photon emission tomography and positron emission tomography can be utilised to measure regional cerebral blood flow and metabolic distribution and to the appropriate surgery, and also in post-surgery follow-ups. Follow-up evaluation with magnetic resonance angiography has advantages over conventional angiography because it is noninvasive, and the post-operative improvement of cerebral perfusion reserve show better correlation with disappearance of ischaemic attacks than does the angiographically demonstrated collateral formation.[139]

Indirect procedures are not limited by the distribution of a single major arterial division, unlike in STA-MCA anastomosis. This can be useful when both anterior and middle cerebral artery territories are affected or when there is holohemispheric involvement. Moreover, indirect procedures are technically easier to perform, as compared to STA-MCA anastomosis, and multiple indirect procedures on the same hemisphere can be performed over time, if required. Spontaneously developed leptomeningeal anastomosis might be the key factor for the efficacy of indirect bypass in elderly patients with moyamoya/stenotic cerebrovascular disease.[143] Reduction of haemorrhagic stroke is not clearly documented. There is no controlled study available. Several reports suggest that the indirect revascularisation techniques consistently lead to the development of significant collaterals in paediatric patients[135,136,274] and not in adults.[11,135,171]

SURGERY IN ACUTE STROKE

Stroke is a generic term for a clinical syndrome that includes infarction, haemorrhage and SAH (discussed elsewhere). Acute strokes may be classified into two general types: ischaemic and haemorrhagic. Approximately 80% of strokes are ischaemic.[226] Bland infarction is characterised by bland widespread leukocyte infiltration and macrophage invasion, with only scattered red cells being found. Twenty percent of strokes are haemorrhagic stroke which is due to "spontaneous" intraparenchymal haematoma in 10% of cases; in 10% it is haemorrhagic transformation of an ischaemic infarct.[6,155]

Pathophysiology

Some degree of mass effect due to brain swelling is associated in acute stroke. It ranges from very insignificant, as in lacunar infarcts, to a massive swelling due to multilobular infarcts with increase in intracranial pressure[109,295] (ICP), brain shift and uncal or cingulate herniation.

In early ischaemia, there is intracellular swelling due to derangement of Na^+/K^+ pump in the glial membrane and cell metabolism resulting in Na^+ and H_2O accumulation resulting in cytotoxic oedema. Cytotoxic oedema precedes the onset of vasogenic oedema.[93] The blood-brain barrier (BBB) is not disturbed initially. The cerebrospinal fluid (CSF) formation is not increased. Both the white and the grey matter are involved. Within a few hours, the BBB is disrupted, and there is increased cell permeability. The extracellular space is enlarged; there is abnormal diffusion of nutrients with consequent acidosis, hypoxia, and inflammatory changes. Polymorphs intensively accumulate in the region of cerebral infarction; this accumulation correlates with the severity of brain tissue damage and poor neurological outcome.[3] Endogenous substances, such as histamine, bradykinin, excitatory aminoacids, arachidonic acid, superoxide, hydrogen and hydroxyl radicals, are released and vasogenic oedema is superimposed.[20,326] Superoxide dismutase is one of the major free-radical scavenging systems that might play a role in both degenerative and acute diseases of the central nervous system; its activity in serum is reduced in acute stroke.[208] Lactic acidosis due to lactic acid accumulation, and increased pCO_2 can denature the proteins and alter the activities of pH dependent enzymes. Lactate enhances brain oedema. This oedema aggravates the mass effect which in turn aggravates the ischaemia. Cytotoxic and vasogenic oedema is maximal by 24–72 hours after the ischaemic event.[279] The '3rd day oedema' is a well known entity.[322] The critical time lasts until the 5th day in the majority, unless there is another ischaemic event.

Pressure gradients have been demonstrated in experimental models, the pressure being higher on the side of the infarct than on the opposite side or the posterior fossa.[248] Increase in ICP and subsequent reduced cerebral perfusion pressure (CPP) aggravate ischaemia. In addition, CSF flow is disturbed due to brain shifts, compounding brain ischaemia. Several studies[138,191,338] have suggested that brain swelling and herniation is an important cause of death in acute stroke.

Management[71]

Principles in the treatment of acute stroke aim to minimise secondary tissue damage caused by impaired microcirculation. One way to achieve this is to treat the brain swelling and control the rise in ICP, which improves leptomeningeal reperfusion of the medial territory.

Cerebral Infarct

Medical Therapy

Recent studies have shown a very high mortality rate despite aggressive medical treatment strategies to lower ICP, which have included osmotherapy, hyperventilation, barbiturate administration, hypothermia and anticoagulation therapy guided by ICP monitoring.[110] None of these medical treatment options have improved outcome in randomised clinical trials.[112,130,200]

The long-term effects of osmotherapy with mannitol or hypertonic solutions have not been ascertained yet. There is not enough evidence supporting a prophylactic standard therapy with hypertonic solutions.[297]

Vigorous prolonged hyperventilation has been discouraged because it may reduce the brain's ability to tolerate ischaemia and may, therefore, be more harmful than beneficial. Forced hyper-ventilation as a therapy for intracranial hypertension is obsolete. Patients with increased ICP and pre-existing ischaemia are at risk from hyperventilation, because hypocapnic vasoconstriction worsens ischaemic lesions.[346]

Barbiturate therapy has failed to be of any benefit in the treatment of oedema after severe brain ischaemia. Barbiturate coma leads to a reduction in ICP under certain circumstances.[275] The use of high doses of barbiturates, however, is associated with several side effects. The side effects include a reduction in cerebral perfusion pressure, suppressed brainstem reflexes and EEG abnormalities,[179] in addition to respiratory complications, myocardial depression with reduction in heart volume per minute, increased infection rate, disturbances in electrolyte balance, impairment of liver function and leukocyte depression.[290] The mortality rate in patients treated with high doses of barbiturate medications for raised ICP is extremely high.[107,258]

It has been reported that hypothermia induction within 14 hours of ischaemic injury and maintained for 72 hours significantly reduced ICP and mortality.[308] But side effects of this therapy are irregular pharmacokinetics, disturbances in the monitoring of vital parameters, impairment of coagulation and immunosuppression.[38,218] There are many unanswered questions concerning this therapy, such as the optimum safe brain temperature for maximum neuroprotection, and the duration of this therapy. Obviously, the centre should have the infrastructure for such therapy.

Fatal space-occupying brain oedema is rare, and occurs in 1–5% of patients with a supratentorial infarct.[129] Mortality rates are highest when lesions involve the trunk of one or more of the main cerebral vessels. In fact, occlusion of either the distal ICA or proximal MCA trunk has been characterised as a "malignant" stroke.[111] It is characterised by rapid clinical deterioration due to brain swelling and downward transtentorial herniation, and is associated with a mortality of 80%. None of the available medical therapies provide substantial relief from the oedema and raised ICP, or at best, they are temporising in most cases, and surgery has a definite role. There are a number of recent advances in the management of stroke, but here we are primarily concerned with the management of cerebral oedema which complicates ischaemic infarct and adversely affect the outcome.

Surgical Therapy

Craniectomy and decompression: Decompression of the brain by turning the closed cavity of the skull into an open one is an old neurosurgical technique and it has been applied to treat conditions of uncontrollably elevated ICP. In 1905, Cushing reported the use of this procedure to relieve the pressure caused by the growth of an intracranial tumour.[58,351] Since then, surgical decompression has been reported as a treatment option for various neurological problems. Indications included rare clinical situations such as Reye's syndrome[18] or hepatic failure,[316] as well as epidemiologically more important conditions such as head injury[330] and cerebellar infarction.[144] In the 1950s and 1960s, an increasing number of reports were published in which the authors[4,300,338] have described cases of massive cerebral ischaemia accompanied by acute and severe brain swelling. In 1968, Greenwood[108] described cases of massive cerebral ischaemia accompanied by acute and severe brain swelling and used surgical intervention in the treatment of such cases, which decreased the mortality rate to below 50%. In 1981, Rengachary and co-workers[270] reported the first case in which straightforward craniectomy was undertaken. Since then there have been regular reports of decompressive craniectomy for this condition.

A decompressive procedure in selected stroke patients is the most practiced surgical intervention in acute strokes. Any surgery should be effective, rational and safe. An ipsilateral decompressive surgery fulfils all three criteria. The procedure is, certainly, simple and safe.

Various studies support the rationale for decompressive surgery.[60,115,272] The intracranial mass effect can be compensated without an increase in ICP by resorption of CSF and by shifting CSF into the spinal canal. When the reserve spaces become completely exhausted, mass effect leads to an exponential increase in ICP. The equation is expressed by the pressure-volume curve. The studies[53,60,115,273] provide evidence that decompression leads to a shift to the right of the pressure-volume curve and, therefore, to a massive increase in compliance and a reduction of ICP.

The available results support the effectiveness of decompressive surgery as a salvage procedure. Gower et al.[107] were able to reduce ICP by 34% in seven patients by performing a subtemporal decompressive craniectomy. Jaeger et al.[146] reported that the mean ICP decreased from 59 to 10 mmHg in a two-step fashion, relating to bone flap removal and dural opening. Simultaneously, PO_2 increased rapidly from 0.8 kPa (6 mmHg) to 3.07

kPa (23 mmHg). PO_2 and ICP remained at noncritical ranges post-operatively. It is being used extensively in head trauma patients, with varying results, with a significant decrease in mortality and morbidity in comatose patients. In trauma the role of decompressive surgery is still under debate, although its use has been repeatedly reported in rather large numbers of patients.[330] It is, perhaps, more appropriate in acute stroke where the mass effect is restricted to one side only, unlike in head injury. The idea is to give room for the swollen brain, reduce the pressure gradient between the intracranial compartments, and tide over the crisis. Recent studies also demonstrate a reduction of mortality rate to less than half that reported for medical therapy alone, even using aggressive medical protocols.[110,111,272,339,352]

The technique is simple. Associated illnesses and the attitude of the family members to accept a severe neurological deficit, especially in developing countries where there are no adequate rehabilitation centres, must also be considered. As in any surgery, patient selection and meticulous post-operative management play a major role in the outcome. Associated illnesses must be attended to. Judicious timing is the key for success.

Historically, hemicraniectomy has been used as a last resort to prevent impending death after all medical therapies have been attempted. Signs of 'coning' were used to indicate the need for decompressive surgery.[270,272,296] After initial effectiveness, additional medical therapeutic efforts often fail to control or prevent herniation, and the physicians may wait too long to intervene surgically. Studies[69,94,185,296] report that craniectomy should be performed early, before severe impairment of brain perfusion occurs. A follow-up study by Doerfler and colleagues[69] compared decompression at 4, 12, 24 and 36 hours, and reported improved neurological outcome, and a significant reduction in the length of time of critical care therapy. Once the pupils are fixed and a deep coma has indicated an irreversible decline of cerebral function, surgery should not be performed.[270]

'When is early?' is still a dilemma. ICP monitoring has been recommended as a guide to surgical timing.[43,272] Increased ICP measurements are preceded by worsening clinical signs and symptoms and the usefulness of ICP monitoring in these cases has been questioned.[296]

Nausea and vomiting within 24 hours after stroke onset, a systolic blood pressure of 180 mmHg or more at 12 hours after onset, a history of hypertension or heart failure, elevated white blood cell count, an activity deficit covering the complete MCA territory on SPECT imaging, a hypodensity of more than 50% on the initial CT scan, attenuated corticomedullary contrast on CT, involvement of additional vascular territories on CT and volume of MRI diffusion-weighted imaging abnormalities of more than 145 ml have been suggested as independent early predictors of fatal space-occupying oedema formation by various small studies[29,114,166,189,251] It is generally recommended that surgical intervention should be carried out before the midline shift shows on CT. The ongoing HAMLET trial,[129] hopefully, will help us avoid unnecessary decompressive craniectomies.

There are several different types of decompressive craniectomy: (1) the lateral temporal or frontotemporal approach; (2) the bifrontal approach[182] and (3) the suboccipital approach. Traditionally, craniectomy is planned according to the area of infarct. A wide craniectomy with a duraplasty is, routinely, recommended. Bifrontal craniectomy is more commonly employed in traumatic brain injury, especially in children.

The need for a radical approach, in terms of extension of bone removal has been recommended[175] in the event of severe post-traumatic cerebral oedema, to avoid prolapse of the oedematous brain through the edges of the craniectomy defect, with possible exacerbation of brain damage. In the case of cerebral infarction, however, this phenomenon does not result in significant increase in cerebral damage or venous stasis, as in traumatic brain injury, because most likely the protruding tissue is already necrotic.[270] There are no systematic reports about quantitative analysis of the size of craniectomy required to be effective.

The author recommends a fronto-temporal craniectomy extending to the base of the middle cranial fossa, and excision of the sphenoidal ridge. Achieving decompression down to the floor of the middle fossa (subtemporal decompression) seems to be important in this surgical technique, because this procedure relieves pressure from the basal temporal lobe. Good results with this technique were reported,[8] even though there is a risk of temporal lobe herniation and necrosis.

Since the cranial vault has essentially been expanded during surgery, there is an immediate decrease of ICP. Jourdan et al.[152] have found that initial ICP values of 25–60 mm Hg decreased by 15% once the bone flap was removed and by 70% once the dura was opened, resulting in the normalisation of the ICP after surgery. A decrease in ICP allows for an increase in cerebral perfusion pressure, aiding blood flow to the ischaemic penumbra and optimising circulation to the damaged area through collateral vessels.[272]

As the dura is opened, pale infarcted brain herniates out. The herniation may subside with hyperventilation and osmotherapy. Some groups[144,156] have recommended resection of infarcted and even non-infarcted brain tissue. Some others recommend resection of the infarcted cerebral tissue and a temporal lobectomy.[205] A group of Japanese surgeons recommend additional excision of the hippocampal gyrus also to relieve peduncle compression, and blockage of CSF circulation.[335] Although resection of infarcted tissue or "strokectomy" has been associated with post-operative improvement in some cases, it is impossible to differentiate at surgery between ischaemic tissue (potentially salvageable) and necrotic tissue (irreversibly compromised). Functional MRI combined with periodic clinical follow-up suggests that the patients may experience functional recovery as a result of activation in both the infarcted and contralateral

hemispheres. Hence, excision of infarcted areas, once recommended, is avoided.[49]

Duraplasty is performed with either silastic lyodura or pericranial grafts. The graft is secured with sutures in a way that allows the initial incision to spread not more than 2–3 cm. This achieves smooth bulging rather than fungus like herniation of the brain into the craniectomy, avoiding shearing injuries, impairment of venous drainage, and enhancement of cerebral oedema, as described by Cooper et al.[53] It is also recommended that in bifrontal craniectomy, the sphenoidal ridges and the anterior walls of the middle cranial fossa be preserved to prevent temporal lobe forward migration. Csokay et al.[55,56] suggested placing vascular tunnels at the margins of a durotomy when performing decompression. This new surgical technique consists of a stellate type durotomy and the creation of a vascular tunnel by supporting pilasters made of haemostatic sponge around the main cortical veins and arteries of herniated brain with the aim that the vessels do not become compressed by the dural or bone edge to reduce vascular congestion and the subsequent ischaemia in brain tissue which herniates through the durotomy. This is reported to lead to better clinical outcomes.

The temporal muscle and skin flap are reapproximated and sutured in place. The bone flap may be preserved frozen[64, 270] or preserved in a subcutaneous pocket in the abdominal wall.[43] Cranioplasty is then performed at a later date, when functional recovery has stabilised. Artificial flaps have also been used to close the bone defect.[152,272]

The influence of hypothermia-related neuroprotection during decompressive craniectomy has been suggested.[69] Further studies are necessary to confirm its efficacy.

The author recommends subdural positive pressure drainage at the end of the procedure to help facilitate CSF drainage, if required post-operatively, and the same may be incorporated with an ICP monitor. Post-operatively, intensive medical therapy is continued.

Complications: The complication rate after decompressive craniectomy is low and has no influence on the patient's prognosis. Few complications have been reported in the literature; subdural haemorrhage as well as hygroma has occurred. Puncture was found to be sufficient for the treatment of the hygroma. Next frequent is, hydrocephalus; some may require ventriculo or lumbo-peritoneal shunt. There is no report of death or permanent deficits related to the surgical decompression itself.[67]

Outcome: Decompressive craniectomy appears most promising as a method of avoiding death from brain compression. In patients with surgical decompression, there is less risk of shifting from a fatal outcome to a vegetative state. Several studies[67,159,308,345] have reported better outcome with decompressive surgery, compared to medical therapy alone. Rieke and co-workers[272] have reported the results of a prospective, non-randomised, single institution controlled study. In this study, the mortality rate was 76.2% in the control group and 34.4% in the surgically treated group. Functional outcome, as reflected by the Barthel Index scores obtained 4–36 months after surgery, was consistent: excellent level of activity in one patient, minimal assistance required by 15 patients, and a severe disability in 5 patients. In the control group, 4 of the only 5 survivors had global aphasia.

Most reported cases are in the non-dominant hemisphere with a chance for a reasonable neurological recovery. Most recent series[167,296] suggest good outcome following craniectomy for both dominant and non-dominant infarcts. Therefore, surgery can be considered in highly selective patients with dominant hemisphere infarction, especially if some residual language function is present at admission.

A slowly developing deterioration seems to carry a better prognosis than a rapid one. The prognosis is better in patients whose midbrain symptoms developed over days instead of hours.

Recent studies have reported good outcome in patients in whom the procedure was done early and whose pre-operative Glasgow coma scale (GCS) score was 8 and above. It offered no benefit in patients whose pre-operative GCS was below 5.[95,116,268]

In theory and in practice, it would seem that younger patients with ischaemic stroke would benefit from early decompressive surgery. Individuals aged 50 years and younger have been identified as benefiting more from bilateral decompressive craniectomy in cases of subarachnoid haemorrhage because of their unatrophied brains, as compared with those over 50 years of age.[89] The young brain is less atrophied, and the ventricular system in younger persons is smaller than in older persons, allowing less room for oedematous expansion within the cranial vault.[185]

In patients younger than 50 years, recovery to a state of near-independence is possible. More than half of the surviving younger patients have a good outcome and live independently. Attention deficits are prominent in all patients; visuospatial and constructive deficits are less pronounced in patients with higher formal education.[43,194]

Craniectomy in elderly patients with space occupying MCA infarction improves survival rates compared with medical treatment alone. However, functional outcome and level of independence are poor.[132]

The author recommends that the decompressive procedure is performed prior to frank clinical deterioration despite aggressive medical therapy; the patient should be young with a GCS of greater than 5, and no serious systemic illness, and must have a supporting family. There may be occasions when patient selection needs to be individualised. The procedure is mainly to give the maximum chance to preserve life. There is a group of reluctant surgeons who feel a decompressive procedure does not alter the final outcome. Discouraging outcomes in patients do not invalidate the method; good results

confirm its usefulness. The increase in brain oedema after decompressive craniectomy led to a discussion in the neurosurgical literature and to questioning the usefulness of the procedure when treating severely brain-injured patients. Brain oedema only increases if the brain is already irreversibly severely damaged. Such patients have a poor prognosis, which is no argument against decompressive craniectomy. At present decompressive surgery might be the most promising therapeutic option to save life. Since decompressive craniectomy can be a life-saving procedure in patients who will most likely be left with a significant neurological deficit, the operation has important ethical and psychological implications. It is most essential that the family understands and be supportive.

Cerebellar Infarcts

Several treatment strategies for cerebellar infarcts (Fig. 17) have been proposed. Decompressive suboccipital craniectomy is readily accepted by neurosurgeons and physicians, unlike in cerebral infarct. Associated obstructive hydrocephalus is an added problem. Khan et al.[176] reported good results in 10 of 11 patients treated either conservatively or with ventriculostomy only. Horwitz and Ludo[134] proposed ventriculostomy in patients who do not improve with medical management and suboccipital craniectomy if there is no improvement despite ventriculostomy. Heros and Chen[47,123] recommend combined ventriculostomy and suboccipital decompression in one sitting.

Our practice is to perform a simple suboccipital craniectomy in the prone position with resection of infarcted tissue. The posterior arch of the atlas is removed for wider decompression. Ventricular drainage is established for concomitant hydrocephalus and converted to a shunt if necessary at a later stage. It must be understood that patients with brainstem infarction have poor outcome; but, brainstem compression is potentially reversible.

Revascularisation Procedures

The role of revascularisation procedures (Fig. 18) in acute stroke is still in the experimental stage. Emergency carotid endarterectomy[188,210,347] is a controversial indication, becoming less and less controversial of late. Patients must have an angiographically demonstrated lesion and no infarction on a CT. There is no randomised trial. Tissue plasminogen and interventional endovascular procedures are more often preferred. Recent reports[102,201] suggest moderate success of emergency carotid endarterectomy in patients: (a) with cresendo TIAs[125]; (b) with severe stenosis in angiography and (c) with disappearance of a previously auscultated bruit, presumably indicating acute occlusion. The presence of good collateral flow is a favourable prognostic sign.

The technique is the same as in elective endarterectomy. Clinical results are best in patients with mild-to-moderate deficit and a rapid course from onset of deficit to surgery. Although higher than elective surgery, morbidity and mortality are acceptable with urgent carotid endarterectomy, given the severity of illness in this patient population.

Despite excellent post-operative angiographic results, the outcomes in patients after STA-MCA anastomoses are not better than the results from medically treated patients.[267]

Other procedures such as posterior circulation bypass, vertebral endarterctomy, arterial anastomses and correction of subclavian steal have not been tested sufficiently. A number of experimental studies on embolectomy of intracranial vessels have also been done.[223,228] At present they remain as a few interesting attempted procedures.

Haemorrhagic Stroke

As mentioned earlier, about 20% of strokes are haemorrhagic, which is due to "spontaneous" intraparenchymal haematoma (SICH) in 10% of cases, and haemorrhagic transformation (HT) of ischaemic stroke in 10% of cases. HT may vary from patchy petechial bleeding to

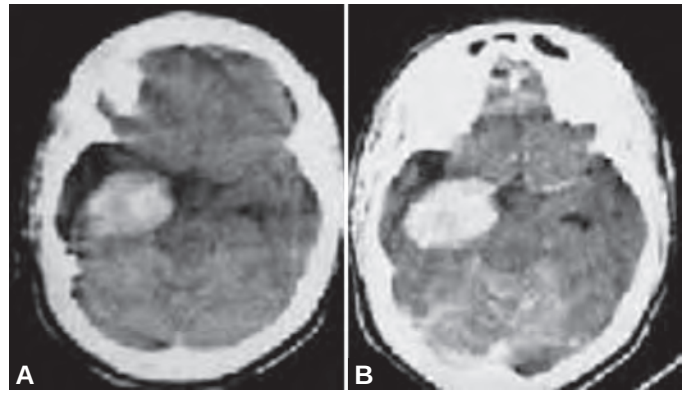
more confluent haemorrhages, representing multifocal extravasation of blood from capillaries or venules. Approximately 20% of patients with cardioembolic stroke have haemorrhagic transformation in the infarcted zone, usually occurring within 48 hours.[192,193,249] The pathogenesis of HT appears to relate to reperfusion and bleeding from recanalised but ischaemically injured vessels by the natural, dynamic dissolution of thrombi. Reperfusion into the ischaemically injured vessels can therefore result in varying degrees of blood extravasation through the damaged blood-brain barrier. It is suggested that hyperglycaemia, hypertension and restoration of blood flow to ischaemic territories were strong risk factors for a haemorrhagic infarct to develop.[248] On CT, HT appears as a discontinuous heterogeneous mixture of high and low densities occurring within the vascular territory of the infarct in contrast to SICH which appears as a discrete, homogeneous collection of blood that often exerts mass effect and may extend beyond the original infarct boundaries or even into the ventricles. The available reports suggest that haemorrhagic transformation of an ischaemic infarct is managed the same way as an ischaemic infarct is. Its prognostic value is controversial.[331]

Traditionally, non-traumatic intracerebral haemorrhage is defined as 'spontaneous' intra-cerebral haemorrhage (SICH); it may, further be classified as primary or secondary depending on the underlying cause.[219] Primary ICH accounts for approximately 70–80% of cases and is due to spontaneous rupture of small vessels damaged by hypertension or amyloid angiopathy. Secondary ICH is associated with a number of congenital and acquired conditions such as vascular anomalies, coagulopathies, tumours and various drug therapies. The common sites in order of occurrence are the basal ganglia, thalamus, subcortical white matter of the cerebral lobes, cerebellum and brainstem. Men are more likely to suffer an SICH than women and the likelihood increases with age.[35]

Cerebrovascular damage to small arteries and arterioles due to chronic hypertension is recognised as the most significant cause of primary SICH.[90] Cerebral amyloid angiopathy (CAA) is the other major cause of primary SICH and an important cause of lobar SICH in elderly populations.[340] In CAA, amyloid protein is deposited in the media and adventitia of cortical and leptomeningeal blood vessels. Histological examination of brain tissue obtained during surgery or at autopsy is necessary for the definitive diagnosis of CAA.

Vascular anomalies are the second most common cause of SICH overall. Venous malformations are the most frequently occurring vascular lesion demonstrated in autopsy and radiological series. Their clinical significance remains controversial, with some authors reporting a negligible haemorrhage risk[99] and others suggesting a higher risk.[204]

Haemorrhage is not an uncommon presentation in cases of previously unsuspected brain tumour;



Figs 19A and B: (A) Intratumoural bleed-CT plain. (B) Intratumoural bleed-CT contrast

melanoma, choriocarcinoma, renal cell carcinoma and bronchogenic carcinoma are the most frequent tumours responsible for producing ICH (Figs 19A and B). An indentation of the haematoma's surface revealed on pre-contrast CT scanning should prompt suspicion of a tumoural haemorrhage.[145] In young patients without hypertension, follow-up imaging is warranted if initial studies are unequivocal regarding cause. Hypertension continues to be the single greatest modifiable risk factor for SICH.[35] Diabetes mellitus is more commonly associated with SICH than with SAH.[154,329] Other risk factors include anticoagulants, especially in elderly patients[92] and hepatitis C virus infection as a result of subclinical clotting disorder or vessel wall friability.[163]

Pregnancy and puerperium can be associated with SICH due to dural venous sinus thrombosis and eclampsia. SICH occurs in 1–5 per 10,000 pregnancies.[215]

The clinical presentation is of a sudden onset of focal neurological deficit progressing over hours with accompanying headache, nausea, vomiting, altered consciousness and elevated blood pressure. Supratentorial haemorrhage is commonly accompanied by vomiting and altered consciousness, which is rare in ischaemic stroke.[41] Elevation in blood pressure occurs in as many as 90% of patients with SICH. Seizures occur in

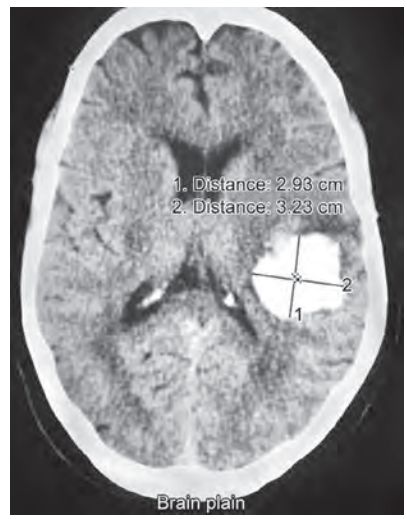


Fig. 20: Lobar haemorrhage-CT

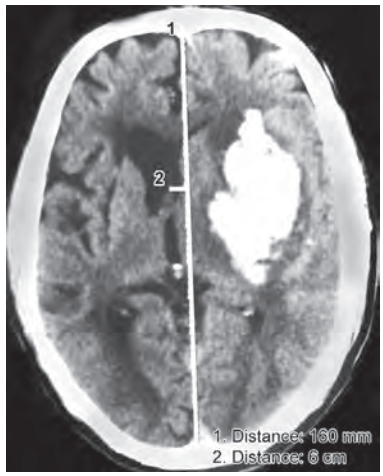

Fig. 21: Ganglio-capsular haemorrhage-CT

approximately 10% of patients.[31] The type of focal neurological deficit, of course, depends on haematoma location.

Blood may rupture into the ventricles and cause hydrocephalus. Rarely, blood finds its way into the subarachnoid space. Depending on clot location, this can result in brain herniation, compression of the brainstem and death.

Investigations

Haematomas, even just a few millimetres in diameter, are rapidly and accurately identified on CT scans (Figs 20 to 22). In addition to the size and location of the SICH, CT can also suggest potential causes, such as tumour, vascular malformation or aneurysm, and SICH related complications, such as hydrocephalus, oedema, herniation and intraventricular extension, are easily identified.[52]

Haematoma expansion and oedema formation are believed to be the major factors involved in secondary deterioration in level of consciousness, which occurs within the first 24 hours after onset.[212] Haematoma expansion, reportedly occurs in 14–38% within the first 24 hours of admission.[97,173] Fujii et al.[97] reported that repeat CT scanning within 24 hours of admission

Fig. 22: Cerebellar haemorrhage-CT

demonstrated enlargement of the haematoma in 14% of patients. Five factors were found to be associated with enlargement: (1) admission shortly after onset of symptoms; (2) heavy alcohol consumption; (3) irregular shaped haematoma; (4) reduced level of consciousness and (5) low level of fibrinogen. Kazui et al. have reported that although expansion of ICH on CT is common in the hyperacute stage, 17% of haematoma expansion occurs even after 6 hours of onset. Haematoma enlargement after 24 hours is rare.[173]

Haematoma volume calculation by CT helps in deciding on surgery. Calculation of haematoma volume is directly possible with special software. If direct volume measurements are not possible, a rapid, simplified method of determining haematoma volume has been described and validated. The formula used (A x B x C)/2 is an approximation for the volume of an ellipsoid where A is the greatest haemorrhage diameter on axial CT scans, B is the largest diameter 90° to A and C is the number of CT slices with haemorrhage multiplied by the slice thickness.[187] In clinical practice, these measurements are usually performed informally.

MRI is more sensitive in detecting cavernous malformations than CT scanning or angiography. The MR imaging appearance of SICH is complex and depends on haemoglobin breakdown products over time.[41,84] Recent reports have shown that multi-sequence MR imaging is as reliable as CT scanning in the assessment of hyperacute SICH.[254,291]

Four-vessel angiography may be needed for a definitive diagnosis of the aetiology. Based on their results, Zhu et al.[358] recommend that the use of angiography should be considered in all patients with SICH in thalamic, putaminal or posterior fossa haemorrhage except in those older than 45 years of age with pre-existing hypertension. CT scanning features in patients with SICH that warrant angiography include the presence of SAH, abnormal intracranial calcification, prominent vascular structures and perisylvian location of haemorrhage. In their study, angiography was positive in 32 (84%) of 38 patients in whom there was one or more of these CT findings. Follow-up angiography may be considered in these high-risk patients if initial studies are negative.

Histological examination of sampling of adjacent haematoma wall or preservation of tissue fragments identified at the time of surgery can be of important diagnostic value, with about a 25% rate of positive findings.[128]

Pathophysiology

Primary tissue damage and distortion occur at the time of haematoma formation when the blood spreads between planes of white matter cleavage. Haemorrhage most commonly results from rupture of the small penetrating arteries damaged by the degenerative effects of chronic hypertension. In 1868, Charcot and Bouchard described the rupture of "microaneurysms" as the cause

of SICH. Recent investigators have questioned the existence of such microaneurysms, suggesting that many of these structures are complex vascular coils, subadventitial haemorrhages, or extravascular clots resulting from endothelial damage by the haematoma.[44,90]

The vasculopathy of chronic hypertension affects the perforating arteries resulting in lipohyalinosis or focal necrosis. This helps explain the distribution of hypertensive haemorrhages in territories supplied by the lenticulostriate arteries (basal ganglia), the thalamoperforating arteries (thalamus), the perforating branches of the basilar artery (pons), and the superior and anterior inferior cerebellar arteries (cerebellum).[90] Lobar haemorrhages in the elderly are often considered to be a result of amyloid angiopathy, which preferentially involves the cortical and leptomeningeal blood vessels.[340]

Both necrotic and apoptotic neuronal death appear to play a role.[126,264] Blood and plasma products, and thrombin formation mediate many secondary processes initiated after SICH.[349] Inflammatory mediators from the blood can induce an inflammatory reaction in and around the haematoma. Neutrophils, macrophages, leukocytes and activated microglia can be found. The release of cytotoxic enzymes, free oxygen radicals, nitric oxide and products of the phospholipid cascade is thought to contribute to secondary neural injury and cell death.[350]

A delayed phase of oedema formation and injury in the 2nd or 3rd weeks after SICH in humans may be due to haemoglobin and its degradation products.[348]

Breakdown of the haematoma consists of invasion by macrophages, progression of surrounding oedema, development of microvessels at the clot margin and, eventually, gliosis.[181] The end result is a haemosiderin-stained scar or a cavity containing old blood surrounded by fibrous tissue.

An unusual form of chronic intracerebral haematoma has been defined by Roda and colleagues.[276] Their term "encapsulated intracerebral haematoma" refers to a chronically encapsulated intraparenchymal haematoma found in normotensive patients, usually caused by vascular malformations. These lesions exhibit progressive mass effect, oedema, and ring enhancement. The self-perpetuating nature of these lesions has been compared with chronic subdural haematomas.

Secondary brain injury and oedema represent potential therapeutic targets. Astrup et al.[13] proposed the term "ischaemic penumbra" to describe brain with CBF values above a lower limit of membrane dysfunction and cell death, but below an upper limit corresponding to electrophysiological dysfunction. In more recent clinical studies, evidence does not clearly support the concept of perilesional hypoperfusion without perilesional ischaemia in SICH as a result of reduced metabolic demand or diaschisis.[292,336,357] Perilesional blood flow is found to be lowest during the first 24 hours postictus, but it normalises as oedema formed over the next 2–3 days.[211] Siddique and colleagues[301] demonstrated that some of the ischaemic perilesional brain recovered its perfusion in the long term.

Management

The management of intraparenchymal haemorrhage is essentially the same and as controversial as in ischaemic infarcts; the clot is the additional problem. In general, there has been a pessimistic attitude among many medical professionals, including neurosurgeons, regarding treatment of SICH. Some surgeons prefer a non-surgical approach.[72,150,239] Their claim is the damage occurs at the time of bleeding as the blood rips through the brain and that attempts to remove the clot will only add to the trauma. Some others advocate early surgery in spite of the additional risk of damaging the intact brain tissue.[14,158,257] They claim that the neurological deterioration does not always respond to medical therapy alone, and, therefore, removal of haematoma should be accomplished as soon as possible to decompress the clot and decrease ICP to prevent secondary deterioration, and to improve perifocal vasogenic oedema and local cerebral blood flow by preventing compartmental pressure changes and consecutive reduction of the blood flow perfusion pressure or by removing the changes caused by toxic breakdown of blood byproducts.

Patients with relatively normal consciousness (GCS Scores 13–15) rarely require surgery, whereas deeply comatose patients (GCS Scores 3–5) rarely benefit from surgery. There is good theoretical rationale for early surgery. Haematoma evacuation may decrease the toxic effects of blood and plasma products, diminish surrounding oedema and ischaemia, and prevent haematoma expansion. A reduction in haematoma volume in experimental studies decreases mass effect, lessens ICP and limits the potential stimulus for oedema formation and cell death.[9,25,344] Raised ICP is also treated, when appropriate, by aggressive medical measures. Although size or volume may influence surgery related decisions,[26,232] the actual surgical accessibility of the clot is more important. Lobar haematomas and those located near the cortical surface are much more likely to be surgically treated than those located deeper in the thalamus and putamen.[86]

The ideal goal of surgical treatment of ICH is to remove as much blood clot as possible, as quickly as possible, with the least amount of brain trauma from the surgery itself. If possible, surgery should also remove the underlying cause of ICH, such as an arteriovenous malformation, and prevent complications of ICH such as hydrocephalus and mass effect of the blood clot.

Neurosurgeons and neurologists invariably advocate that large cerebellar haemorrhages with compression of the brainstem or obstruction of the fourth ventricle should surgically be removed as soon as possible. Associated hydrocephalus may require a drainage procedure. Surgical removal of large lobar haemorrhages in young patients who are clinically deteriorating has also been recommended based on anecdotal experience.[36,164]

The optimal surgical technique for haematoma evacuation is not agreed upon. Craniotomy and evacuation

of the clot has been the standard approach for removal of intraparenchymal haemorrhage and remains the most common.[89] In addition, a decompressive craniectomy with a duraplasty is performed by most, including the author. Its major advantage is adequate exposure to remove the clot. It is not difficult or time-consuming. The major disadvantage of a more extensive surgical approach is that it may lead to further brain damage, particularly in patients with deep-seated haemorrhages. In addition, the effectiveness of clot removal by craniotomy is far from ideal.[36,231]

Newer Techniques

The grim results of conventional craniotomy have stimulated a search for more tolerable, less traumatic and safer methods of clot removal. Technical advances in removal of ICH include improved localisation of the haemorrhage by stereotactic devices or intra-operative ultrasound and better surgical techniques.[14,19,36,131,157,195,244]

Stereotactically controlled endoscopic evacuation is gaining popularity. It permits localisation of the lesion, and removal of the clot is performed under optic control, which may be important in cases of cryptic arteriovenous malformations. This hightech method may be simple, fast, safe and effective. Auer and colleagues[15] conducted a randomised trial of endoscopic aspiration of haemorrhage compared with best medical treatment. More than 90% of the clot was evacuated in 15% of patients, between 70 and 90% in 29% of patients, and between 50 and 70% in 56% of patients. At 6 months, the mortality rate of the surgical group (42%) was significantly lower than that of the medical group (70%). A good outcome with minimal or no deficit was also seen more frequently in the surgically treated group. In patients with large haematomas (>50 cm^3), quality of life was not affected by surgery, whereas the mortality rate was significantly lower. By contrast, endoscopic evacuation of smaller haematomas led to significantly better quality of life compared with those treated medically, but survival was similar for the two groups. Surgical benefit was mainly limited to patients with lobar haematomas and patients less than 60 years old.

Innovations in devices to break up and remove the blood clot include, modifications of an Archimedes screw inside a cannula,[28] a specially designed ultrasonic aspirator,[243] a modified nucleotome,[168] a double track aspiration,[245] and intra-operative CT monitoring.[141]

Clot evacuation may be combined with pharmacological therapy targeting the inflammatory response, shown to develop around the haematoma and leading to delayed cellular death as observed in experimental animal models.[126]

Fibrinolysis aids rapid dissolution of the remaining blood. The aim is to achieve a mass reduction as well as to reduce the extension of perifocal oedema and minimise the amount of tissue damage. Stereotactic evacuation and thrombolysis of cerebral and cerebellar haemorrhage[194,224,225] has been reported with good results. Instillation of thrombolytics has also been used successfully for haemorrhage within the ventricular system as well.[87,214] These innovative stereotactic aspiration techniques have been used on haemorrhages in all brain locations. The most commonly used thrombolytic protocol has been administration of 6,000 U of urokinase once or twice daily via a catheter into the bed of the haematoma with subsequent drainage and aspiration. A urokinase wash out can be performed for up to 7 days after the bleeding.[169] This procedure is often repeated over several days until the majority of the haematoma has been aspirated.

Haematoma puncture and catheter placement for fibrinolytic therapy could be achieved with high accuracy and safety using frameless stereotaxy. This method, reportedly, allows unrestricted trajectory selection with catheter positioning along the main haematoma axis.[277] Some investigators have reported that aspiration with thrombolytic agents is less successful in removing clotted blood in the first hours after haemorrhage onset compared with removal of haemorrhage that has been present for several days.[168] Further studies are needed to assess optimal thrombolytic dosage, and must include controlled comparisons of mortality, disability outcome, time until convalescence and cost of care in treated and untreated patients.

Kanaya and Kuroda[157] reported that rebleeding after surgery was seen in 10% of patients who underwent craniotomy, 5% who underwent CT guided aspiration, and 6% who had ultrasound guided aspiration. On average, CT-guided aspiration removed 71% of the original haematoma, whereas ultrasound-guided aspiration removed 81%. The percentage of haematoma removed did not significantly vary with the timing of the operation. Other investigators using various CT guided aspiration techniques, including thrombolytic instillation, have reported aspiration rates ranging on average from 30 to 90% over the first several days.[131,243,245] Early evacuation might also be combined with haemostatic therapy such as recombinant activated factor VII to help prevent the risk of rebleeding.[213,229]

Outcome

The natural course of spontaneous ICH leads to a 30-day mortality rate of 45%.[35] Spontaneous ICH is associated with a higher mortality rate than either ischaemic stroke or SAH.[65,137] The patient's initial level of consciousness, haematoma size, and intraventricular extension of blood has proven to be accurate predictors of outcome. Less commonly, age, sex, hypertension and mass effect may indicate harmful effects on outcome in patients with ICH.[262]

No prospective randomised controlled study, in which surgical and medical management of SICH has been compared, has claimed a significant superiority of either medical or surgical management.[23,48,153,229,230,327,359]

However, there are non-randomised series reporting the benefits of surgery.[35,158,257] Recently, three randomised control trails evaluating new strategies for the treatment of the ICH have been completed.

The International STICH trial[219] (early surgery versus initial conservative treatment in patients with spontaneous supratentorial ICH) concluded that there is no evidence of an overall benefit of early surgery when compared to initial conservative treatment. One finding in a predefined subgroup, that patients with superficial haematomas might benefit from surgery (craniotomy), needs further exploration.

Stereotactic aspiration combined with instillation of fibryinolytic agent[327] (the SICHPA trial): The trial was prematurely stopped due to low recruitment. A cautious conclusion could be made that stereotactic aspiration of supratentorial haematoma after instillation of a plasminogen activator can be performed safely. It may reduce the haematoma volume significantly.

Ultra-early haemostatic therapy by using the recombinant activated factor VIIa[213] (the Novo-7 trial): Treatment with activated factor VII within 4 hours reduced haematoma expansion, decreased mortality, and improved clinical outcome significantly, despite slight increase in the risk of thromboembolic events.

The author recommends that patients with smaller haematomas who are alert, stable or improving should be treated medically and the patients with larger haematomas who show progressive neurological deficit, prolonged functional impairment and intracranial hypertension should be treated surgically. Patients with a GCS score less than 5 should also be treated medically because they uniformly die or have extremely poor functional outcome that cannot be improved by surgery. Easily accessible supratentorial haematomas with mass effect, especially in the young and in those with a GCS score greater than 5, must be evacuated. Patients with cerebellar haemorrhages greater than 3 cm or in whom brainstem compression and hydrocephalus are present, should undergo evacuation of the clot.

Further study of the dynamics of haemorrhage and additional results are needed prior to making a decision on how to divide patient management into the two categories of surgical and non-surgical treatment. The proposed STICH II Trial, hopefully, will solve many unanswered questions.

Pontine and Midbrain Haematomas

Pontine haemorrhages are devastating events. This haemorrhage is most commonly at the junction of the tegmentum and the basis pontis. The classical findings are those of quadriplegia, pin point pupils, paresis of horizontal eye movements and rapid progression to coma. Initially, the weakness may be asymmetrical but in the later stages, as the neurological deficits advance, quadriplegia predominates. The pupils are classically pin-point because of interruption of bilateral sympathetic fibres. Hyperpyrexia can occur but its abscense does not preclude the diagnosis.

These are unique brainstem lesions. The presentation is acute in about two thirds of the cases, and subacute and chronic cases do occur. Presentation is with neuro-ophthalmological abnormalities, loss of consciousness and headache. This may be accompanied by hemiparesis, hemisensory loss or ataxia. Vascular malformations are suspected in about a third of cases and in a similar number no underlying cause is found. Most patients improve with supportive care, although in rare instances surgery may be required if there is an underlying vascular malformation like cavernous angioma.

Cerebral Venous Thrombosis

Cerebral venous and dural sinus thrombosis (CVT) is an infrequent stroke type often described as having an unpredictable outcome.[34] A series of publications from India suggest that venous strokes, especially in women, during pregnancy and puerperium are not uncommon. Puerperal CVT may account for 15–20% of stroke victims in the younger age group. Bansal et al. reported an incidence of 4.5 per 1,000 obstetric admissions. Comprehensive reports have been provided by Chopra and Banerjee, and Srinivasan. Nagpal reported surgical treatment of primary cortical vein thrombosis in 32 selected cases.[21,50,236,308] Neurosurgeons are often involved in the care of patients with cerebral venous sinus thrombosis. Under rare circumstances, open surgical interventions may be considered, including open thrombectomy and decompressive craniectomy. Neurosurgeons should also be prepared to treat late complications of cerebral venous sinus thrombosis, including pseudotumour cerebri and dural arteriovenous fistulas[27,174]

Paediatric Stroke

The first population-based study of stroke in children from the 1970s found an incidence rate of 2.52 per 100,000 children for all stroke types.[294] The reported incidence and prevalence of stroke in children has increased over time due to improvement in imaging techniques. Neonatal/Perinatal stroke (CVAs that occur between 28 weeks of gestation and 28 days of post-natal age) is under recognised clinically. The reported causes of neonatal stroke have included cardiac disorders, infection, blood abnormalities, and/or perinatal events, yet in a large number of cases the cause remains undetermined.[77]

Cardiac disease is a common cause of childhood stroke (CVAs that occur between 30 days and 18 years of age), accounting for up to 50% of strokes, and coagulation abnormalities account for 38%.[66] Other risk factors for stroke in children include infection, moyamoya disease, arterial dissection and other rare genetic disorders.[172,180]

Haemorrhagic stroke is less common than ischaemic stroke in children as in adults. Excluding neonatal

intraventricular haemorrhage, structural vascular lesions are the most common cause of SICH in children.[199] Arteriovenous malformations (AVM) are the most common cause of haemorrhagic stroke in children. Approximately 10–20% of all AVMs will become symptomatic during childhood.[221] The most common cause of cerebellar haemorrhage in an otherwise healthy child is the rupture of a vascular malformation.[278] An underlying structural lesion should be sought in all paediatric patients presenting with SICH. We recommend that MR imaging and angiography be undertaken in all paediatric patients suffering unexplained SICH as well as follow-up imaging if no cause is found. Treatment recommendations are based on small, non-randomised trials or adult stroke studies.[42]

SURGERY IN STROKE REHABILITATION

There are no pharmacological measures available to enhance central nervous system restorative processes after acute stroke, and implantation of stem cells provides one promising approach, not only for cell replacement but also for the provision of therapeutic molecules.[104]

Stem cell therapy is still at the beginning of the road.[190] Cell transplantation is an experimental approach to restore brain function in neurodegenerative disorders such as Parkinson's and Huntington's disease.[343] Various cell types are under investigation in experimental stroke studies. Human neuronal cells can be produced in culture, delivered frozen to a hospital, thawed and processed, and implanted stereotactically into the brains of patients with stroke. Douglas Kondziolka et al.[184] reported the safety and feasibility of neuronal transplantation for patients with motor stroke and noted improvement in patients with stroke. Following transplantation, progenitor cells proliferated and differentiated into all the different brain cell types, including neurons, and they repopulated the ischaemic infarct.[288] The survival, integration and efficacy of neural transplants in stroke patients will depend on the type, severity, chronicity, adequacy of circulation and location of the stroke lesion.[289]

The first clinical trial[246] of neural transplantation in stroke patients is a milestone in stroke therapy.

While the consensus is to create a functional neuronal circuitry in the damaged host brain, there is growing evidence that trophic action of the grafts and host, as well as exogenous application of trophic factors may facilitate functional recovery in stroke. Experimental work at AIIMS, New Delhi, India, suggested a partial recovery of the vocalisation response following amygdala tissue transplantation.[147]

Stem cell research presents many ethical and scientific questions as well as future challenges. Validation of neural transplantation and any other treatment for stroke should critically be assessed in laboratory experiments and limited clinical trials. A multricentric trial, supported by the Department of Biotechnology, Government of India, on stem cell therapy is ongoing in India. Lessons learnt from earlier experimental studies on foetal neural transplant at the All India Institute of Medical Sciences need to be given heed to in this regard; and more recently highlighted by Magnus et al.[203,323,324]

CONCLUSION

Stroke is an age old problem. Sushrutha called it 'pakshavada', while Hippocrates called it 'apoplexy'. There have been many terms since. Now, the term is 'Brain Attack'. The idea is to create awareness among the public and the family physicians of not only the severity of the problem, but also the urgency, similar, in almost every way, to that of a heart attack.

Risk factor management and primary prevention continue to be key measures. Unfortunately, despite recent advances in stroke treatment and research, the general approach to caring for the acute stroke patient has been one of benign neglect and stroke continues to be the second leading cause of death and the most common cause of disability in the world. A hospital-based prospective study in North-West India,[255] evaluating the knowledge of stroke among stroke patients has shown that even after self-recognition of stroke symptoms, patients have responded late as they interpreted their symptoms as 'not serious'. For prompt treatment and prevention of stroke effective educational campaigns are necessary. While designing these programs, it should be recognised that patients often fail to identify and misinterpret stroke symptoms and this is independent of their educational status.

Tumours of the Spine and Spinal Cord

Ravi Ramamurthi

103 Clinical Features and Diagnosis

Ravi Ramamurthi, Santhosh Mohan Rao K

The most important surgical problem with reference to the spinal cord and the cauda equina is compression by lesions arising from structures outside the spinal canal, in the vertebrae and intervertebral discs or by lesions arising inside the spinal canal. The compression may be the result of congenital malformations, trauma, infection or neoplasms and the clinical syndromes are often similar.

HISTORICAL BACKGROUND

Morgagni,[31] the founder of modern pathological anatomy, referred in 1769 to the occurrence of spinal cord paralysis due to compression by a tumour. According to Elsberg,[12] the first convincing description of a primary spinal cord tumour was by Phillips[37] who described, in 1792, a tumour of the dorsal and lumbar cord.

Velpeau,[53] in 1825, published a paper in the Archieves de Medicine in which he gave a good description of an apparent cauda equina tumour and also referred to another case published by Chaussier. In 1837, Olivier[35] published his remarkable work "Traite de la Moelle Spiniera et de ses Maladies" which contains in its second volume, the complete clinical histories of four cases of extramedullary spinal tumours. In 1842, Curveilhier[8] in his pathological atlas of tumours gave an illustration of a spinal cord tumour causing 'paraplegic douleureuse'. Thus, it is seen that the entity of spinal cord tumour was recognised since the 18th century, though it was only in the latter part of the 19th century that surgical relief became possible. Victor Horsley, in 1887, was the first to successfully remove a spinal cord tumour diagnosed by William Gowers.[18] In 1883, MacEwen of Glasgow removed an epidural neoplasm in a boy aged nine, the first such operation in a child. Elsberg,[10] starting from 1911, published a number of monographs, the last one in 1940.[12]

CLASSIFICATION

Neoplasms causing cord compression may originate from structures inside the spinal canal or the vertebral column, or may spread into the spinal canal from outside.

TUMOURS OF THE SPINAL CORD

According to their anatomical location, spinal tumours are conveniently classified as extradural and intradural, although some tumours could be both inside and outside the dura. Intradural tumours could be intramedullary or extramedullary. Benign and malignant neoplasms may arise from intraspinal structures like the meninges, spinal cord, nerve roots, blood vessels and other tissues. These are ten times less frequent than intracranial tumours, with the majority of them being benign.

Primary Extradural Tumours

These tumours are relatively uncommon, accounting for 19% in the series of Elsberg.[11] Neurinomas, meningiomas and lipomas occur in that order of frequency. Rarely, a secondary malignant tumour is encountered in the extradural space without involvement of the bone. Extradural cysts, congenital or acquired, may cause cord compression as also a traumatic or spontaneous spinal extradural haematoma. The other causes of extradural compression are non-specific granulomas, tuberculomas and hydatid cysts. Cases of spinal compression due to extramedullary haematopoiesis in the epidural space have been reported.[3,7,21,28] Cord compression may also be produced by expanding aortic aneurysms.[33,42,43]

Intradural Extramedullary

These tumours are the most common intraspinal tumours (67% in the series of Elsberg),[12] neurinomas and meningiomas being the most frequent. Due to the presence of the filum terminale, intradural extramedullary ependymomas can occur in the cauda equina region. Huge tumours growing in the region of the cauda equina have been termed giant tumours of the cauda equina and include neurinomas, meningiomas and ependymomas.[5,38]

Intramedullary Tumours

Most of the intramedullary tumours (14% in the series of Elsberg)[12] are malignant and belong to the glioma group. Both astrocytomas and ependymomas are more benign

in the spinal cord than in the brain. Intramedullary tumours may become partly extramedullary when they break through the confines of the cord. Most of the developmental tumours, epidermoids, dermoids and lipomas are intramedullary lesions. Angiomas, AV malformations and haemangioblastomas also belong to the same group, though the bulk of these lesions may be truly extramedullary.

TUMOURS OF THE VERTEBRAL COLUMN

Benign tumours of the vertebral column are rare, and include haemangioma, chondroma, giant cell tumour, osteoma and fibroma. As these arise from the body of the vertebra, the spinal cord is compressed from the front. Aneurysmal bone cyst usually affects the posterior neural arch, i.e. the spinous process, the lamina and the transverse process, producing a cystic enlargement of these structures.[39] Other benign lesions are chondromas, chondromyxoid fibroma[41,46] and giant cell tumour secondary to primary hyperparathyroidism. Non-neoplastic benign lesions of the vertebral column that cause cord compression are multiple hereditary exostoses, Paget's disease,[44,49,52] fibrous dysplasia, achondroplasia, severe kyphoscoliosis and fluorosis. The diagnosis is easily confirmed on X-ray examination because of the characteristic radiological appearance.

Primary malignant tumours of the vertebrae are uncommon, and include chordoma and solitary plasmacytoma. Sarcoma is an uncommon tumour, seen most frequently in children and young adults. As the neural arches are usually involved, a swelling may be palpable in the paraspinal region.

Secondary malignant deposits are the commonest tumours of the vertebral column, being in some series more frequent than even the intraspinal neurogenic tumours. Breast, lung, thyroid and prostate are the common sites of the primary lesion. Reticuloendothelial tumours, like lymphomas and multiple myelomas, may cause multiple deposits in the bone.

Intraspinal Extension of Paravertebral Tumours

Malignant lesions, like neuroblastomas, Ewing's tumour, reticulum cell sarcoma, lymphosarcoma and Hodgkin's disease, frequently invade the extradural space through the intervertebral foramen or by destroying the bone. Benign paravertebral lesions may also cause cord compression or cord ischaemia. Tumours in the neck, mediastinum or the abdomen may rarely extend into the canal through the intervertebral foramina, for example, neurofibromas, ganglioglioma, sympathicoblastoma, dermoids and benign cysts.

PATHOPHYSIOLOGY OF CORD COMPRESSION

Like the brain, the spinal cord is also confined in a space which has no capacity for expanding. Space-occupying lesions in the spinal canal cause compression of the structures with resultant neurological deficits. Rapidly growing lesions cause severe loss of function as there is no time for the spinal cord to adjust itself. On the contrary, a slow growing tumour may attain a large size and the cord may still be viable although displaced and thinned out. The lesion may compress and occlude vascular structures on the surface of the cord or in the intervertebral foramina. As the lesion grows, the veins are compressed resulting in congestion and oedema. Arterial compression occurs at a later stage and may sometimes lead to distant effects as happens when the vertebral artery is compressed by a foramen magnum lesion. Pressure at the level of the 4th and 5th dorsal segments may cause a greater deficit because of the watershed area in the vascular supply of the cord at this level. Extradural metastatic tumours often cause symptoms by interfering with the vascular supply of the cord. Vascular tumours may produce a steal syndrome by taking away the blood from the affected region of the spinal cord.

In addition to the vascular effects, direct pressure on the cord and nerve roots leads to interference with conduction, the long tracts being affected early. Hard tumours are likely to cause early and greater disturbance than soft tumours which can exist for a long time and grow to a bigger size. This is similar to the varying effects of hard and soft acoustic neurofibroma on the brainstem.[45]

The presence of a tumour interferes with the normal movements of the cord which occur during movements of the spinal column. Such impairment contributes to cord damage. Lumbar puncture and myelography can sometimes cause a shift in the position of the tumour leading to a sudden increase in the neurological deficit. The degree and rate of recovery after removal of the compression depends on various factors like the duration, severity and location of the compression and the changes in the vascular supply of the spinal cord already produced by the lesion. In long-standing tumours, there may be gliosis in the spinal cord due to ischaemia and the recovery may be incomplete, despite complete removal of the tumour. This is more commonly seen in a meningioma where the recovery is often slow.

SYMPTOMS AND SIGNS OF SPINAL COMPRESSION

While the diagnosis of cord compression may be obvious in a few cases, it is often delayed because of variations in the presenting symptoms which may simulate other diseases and the variability of the progress of the symptoms. However, once the suspicion of the diagnosis is aroused, the symptomatology falls into place with precision because of the well-defined specific functions of the spinal cord at various levels.

The symptoms and signs include those produced by the involvement of the nerve roots (posterior and anterior), the cord segments and the long tracts, viz. the

motor, sensory, autonomic and other tracts. Some signs pertaining to the spinal column may also become apparent.

Involvement of the Posterior Root

Root pain, a symptom of posterior nerve root involvement, is the result of pressure or, more commonly, of stretching of the nerve root by the tumour. It occurs as an early symptom of an extramedullary tumour, and is usually unilateral in benign tumours and bilateral in malignant tumours. The pain radiates from the proximal to the distal region, although, occasionally, a root irritation may manifest itself as a spread of pain from the periphery to the centre. The pain is often of a burning, hyperaesthetic type in the early stages. When the thoracic roots are involved, the constricting pain is referred to as girdle pain, especially when bilateral. Root pain is increased by coughing, sneezing and movements of the spine, or by any manoeuvre which increases intraspinal pressure like compression of the jugular veins. It can persist for months before the occurrence of symptoms of cord compression, at the onset of which it may disappear. Though root pain is most commonly seen in extramedullary tumours, it may appear in about 20% of intramedullary tumours also. Elsberg[12] in his series reported root pain in 2/3rds of intradural, 1/3rd of extradural and is less than 1/6th of intramedullary growths.

In clinical practice, the proper understanding and appreciation of root pain becomes important; otherwise it may result in a wrong diagnosis. This is not uncommon in patients in whom the root pain is the sole complaint without any other clinical sign. Thus, D4 root pain on the left side may simulate heart disease. D8-D10 root pain may simulate diseases of abdominal organs, like the gallbladder, appendix and kidney, while cauda equina pain may simulate disease of the pelvic viscera. The radiation of pain, the accompanying hyperaesthesia and the worsening of pain with certain postures or with coughing or sneezing help to arouse suspicion of nerve root involvement. Irritation of the posterior root may result in pruritis in the dermatomal distribution and a rash.[25] With posterior root involvement, objective sensory loss occurs when at least two adjacent roots are involved.

Involvement of the Anterior Nerve Root and Anterior Horns

As the symptoms and signs of involvement of the anterior nerve root and the anterior horn are the same, it is clinically impossible to differentiate one from the other. While the anterior nerve roots are involved only in extramedullary tumours, the anterior horns can be involved in both intramedullary and extramedullary tumours.

Involvement of either the anterior nerve root or the anterior horn is indicated by progressive lower motor neuron paralysis, wasting and fasciculations of the involved muscles with loss of reflexes. The symptoms are more conspicuous when the cervical or the lumbosacral segments of the spinal cord or the nerve roots are compressed. In case the dorsal segments are involved, the wasting and weakness of the paravertebral muscles results in scoliosis. As the muscles have multisegmental innervation, involvement of a single anterior nerve root or anterior horn cells of one spinal cord segment may not produce recognisable weakness or wasting of the muscles. Lower motor weakness with wasting or loss of a tendon or a cutaneous reflex has an early localising value. For example, weakness of extension of the elbow with normal power in the flexors, or a loss of the triceps jerk with an intact biceps jerk indicates a lesion of C7 cord segment. Fasciculations of the muscles are more common when the anterior horn cells are involved and, thus, are more frequently seen in intramedullary tumours. With a careful and detailed search, it is possible to detect fasciculations in the wasted muscle more frequently.

Chronic irritation of the anterior horn cells by tumour or their isolation from other neuronal influences may occasionally lead to a very high rate of firing by these neurons, resulting in continuous activity or spasm of the muscles of the concerned segment[26,47] or in a localised myoclonus.[15,19] Pseudomyotonia of the hands and fingers, similar to that seen in Thomsen's disease, may occur in cervical cord compression.[13,14,48] In some rare instances, one may see the fasciculations in regions of the body far removed from the involved spinal segment due to interference with pyramidal tract function, a phenomenon termed parabiosis by Okhrimenko and Brodovskaya in 1961.[34]

Segmental Involvement

Although segmental involvement of the cord may occur in extramedullary lesions, it is common in trauma, haematomyelia and intramedullary lesions. The clinically significant areas affected are the anterior horns and the crossing of the spinothalamic tracts, in addition to the long tracts affected at that level. The symptoms of anterior horn cell involvement have been discussed. Anterior horn cells will be involved early when the tumour is situated either anterior or anterolateral to the spinal cord, and late if the tumour is situated posterior to the spinal cord.

Involvement of the Long Sensory Tracts

Subjective disturbances resulting from the involvement of the long sensory tracts are widespread unlike those caused by posterior root involvement. Subjective numbness, tingling, burning, sensation of cold and 'pins and needles' are produced by irritation of the sensory pathways in the spinal cord. Initially prominent on the side opposite to that of the tumour, the symptoms become bilateral with gradual increase in pressure.

Subjective sensory disturbances are more common in intramedullary lesions. In cervical lesions, irritation of the posterior column leads to Lhermitte's sign.[1] The patient feels a sudden electrical shock-like sensation all over the body when the neck is flexed. In 1918, this symptom was originally described by Babinski and Dubois.[4] Lhermitte, in 1924, only pointed out the value of this sign in multiple sclerosis, but somehow his name got attached to the sign. The Lhermitte's sign is seen in 38% of patients with multiple sclerosis (MS). It was first described in neck flexion. It is not specific to MS. An increase in pyramidal tract deficit caused by neck flexion and a corresponding improvement of the symptom with neck extension is suggestive of a compressive pathology in the cervical cord. This is called Bristow's symptom.[29] Lhermitte's sign in flexion is an electric shock like sensation in the trunk and limbs on neck flexion. This is seen in MS plaques at DREZ, subacute combined degeneration of the cord, cervical extramedullary tumour and radiation myelopathy. Reversed Lhermitte's sign is the same symptom seen in neck extension and is due to the buckling of the ligamentum flavum into the already compressed cervical cord as seen in cervical spondylosis.[20]

Sensory Disturbances

The objective disturbances vary according to the site of origin of the lesion and direction of its spread and, thus, many varieties of involvement may be seen. A few definite patterns are identifiable with regard to the levels of sensory loss, their direction of spread and the modalities involved. From these it is possible to differentiate between extramedullary and intramedullary lesions.

There is a lamination or grouping of fibres in the lateral spinothalamic tract, the fibres originating from the most distal parts of the body being situated peripherally and those from the proximal parts of the body situated centrally. This arrangement accounts for the differences in sensory disturbances in extramedullary and intramedullary tumours.

In extramedullary tumours the sensory disturbance is maximal in the distal parts of the body, being minimal near the level of the lesion. In other words, the sensory disturbance is of the ascending type, the sensory loss starting in the distal parts of the body and slowly progressing proximally. Depending upon the stage at which the patient is seen, it is possible to find an area of normal sensation between the band of root hyperaesthesia or anaesthesia and the main area of loss of sensation.[22] In such cases, if the more proximal root disturbance is missed, the neurological localisation of the tumour may be made erroneously at a level many segments lower.

On the contrary, in intramedullary growths the maximum sensory disturbance is at and below the segmental level of the lesion. The degree of sensory loss diminishes in a descending direction and hence 'anal sparing' or sparing of sacral dermatomes is a characteristic feature of an intramedullary growth. Ghosh et al.[17] pointed out that sacral sparing is neither a consistent feature of intramedullary tumours nor restricted to them.

In intramedullary growths, there may be dissociation between the degrees of sensory loss for the various types of sensory modalities. As the crossing of the spinothalamic fibres is affected early, pain and temperature loss may be the only sign for some time before the bulk of the lesion increases and compresses the posterior columns leading to loss of touch sensation. This dissociation of anaesthesia is not as commonly seen in intramedullary tumours as in syringomyelia. It must also be remembered that in both extramedullary and intramedullary tumours, the intensity of loss of tactile sensation is less than that of pain and temperature because of the presence of dual pathways for touch.

In advanced cases these finer differences are lost. There is neither anal sparing nor dissociation of anaesthesia in intramedullary tumours; nor is an area of normal sensation between the root lesion and the main area of sensory loss found in extramedullary lesions. Under such circumstances the clinical picture of the two lesions may be identical.

In spinal compression due to tumours there are always some differences between the sensory changes on the two sides of the body, these being more pronounced on the side opposite to that of the tumour.

MRC Classification of Sensory Nerve Dysfunction[23]

Grades:

S0—No sensation.

S1—Deep pain sensation.

S2—Skin touch, pain and thermal sensation, i.e. protective sensations present.

S3—S2 along with accurate localisation but deficient stereognosis. Cold sensitivity and hypersensitivity are often present.

S3^{+}—Object and texture recognition but not normal sensation. Good but not normal two point discrimination.

S4—Normal sensation.

Motor Disturbance

Involvement of the pyramidal tract results in loss of voluntary power, spasticity, exaggerated tendon reflexes and positive Babinski's sign on the same side. The ipsilateral limbs are affected first, followed by the opposite limbs, unless the tumour is in the midline, when both sides are affected simultaneously. Asymmetry in weakness, in spasticity and in reflex disturbances between the two sides is characteristic of a tumour, in contrast to degenerative disorders like primary lateral sclerosis or amyotrophic lateral sclerosis. By the time the compression is far advanced, the asymmetry gives place to a symmetric total paralysis on both sides resembling the picture of transverse myelitis. An extramedullary tumour in the cervical region affects the ipsilateral upper limb first, followed by the ipsilateral lower limb, the opposite lower

limb and finally the opposite upper limb. Occasionally, the motor disturbance may start in the contralateral limb first due to pressure on the opposite pyramidal tract by the bony margin of the neural arch as the spinal cord is being displaced by the tumour.

Pressure on the spinocerebellar tracts produces ataxia and tremor in the limbs of the same side. Hypotonia may occur early and may be so prominent as to suppress exaggeration of reflexes even when Babinski's sign has become positive. Unstable gait or difficulty in jumping or standing on one foot may be obvious in the early stages, before weakness sets in. But, in practice, this is seen only rarely, as by the time the patient presents, the pressure has involved not only the spinocerebellar tracts but the pyramidal tracts as well. Nystagmus has been observed as a distant sign of spinal cord tumours. Sercl and Kovarik[51] observed this in 21.3% of cervical tumours.

Though a tumour may arise from one side and cause predominant involvement of one half of the spinal cord, the Brown-Sequard syndrome is not a common finding in spinal cord tumours. Partial types of the syndrome may be seen, especially in the cervical region and are more commonly due to extramedullary than intramedullary lesions.

Sphincter Disturbances

Disturbances of micturition appear when there is a loss of function in both the pyramidal tracts, in the sacral spinal cord centres or in the corresponding nerve roots in the cauda equina. Depending upon the location of the lesion, the bladder disturbances would vary. Intramedullary tumours affect bladder function early, as the upper motor neuron fibres to the bladder lie deeper in the lateral column and occupy an area nearer the centre of the spinal cord.[32] The autonomic fibres subserving micturition travel on the dorsal aspect of the lateral columns.[24] If the tumour is situated above the level of the sacral centres of micturition and the compression is partial, uninhibited neurogenic bladder results, manifesting as urgency and precipitancy. Advanced compression results in a reflex or an automatic bladder. Pressure on or destruction of the sacral centres or the corresponding roots of the cauda equina causes an autonomous bladder.

Bowel Function

Tumours above the level of the sacral centres impair voluntary control of the sphincter and the sensation of rectal urgency is lost, resulting in constipation. Involvement of the sacral centres or the corresponding roots of the cauda equina leads to paralysis of the sphincter and faecal incontinence.

Disturbances of Autonomic Functions

Interference with the sympathetic pathways in the spinal cord leads to a characteristic dryness of the skin below the lesion. By running one's hand across the body the level of the tumour could be localised by noting the level at which the dryness of the skin starts. The skin of the involved areas is not only dry but often warm (occasionally cold) and flushed also. Segmental hyperhidrosis is an uncommon finding which is usually associated with irritation or infiltration of preganglionic sympathetic fibres or the sympathetic chain. Segmental hyperhidrosis should trigger a search for structural disease in the spinal and paraspinal region.[50] Trophic disturbances of the skin may also be seen. Interference with the parasympathetic centres in the sacral region leading to disturbances of bladder function has already been mentioned. Autonomic, sensory and motor deficits also interfere with the complex sexual function. Rarely, priapism may be seen in thoracic cord lesions, with retention of the ejaculatory mechanisms. At lower levels sexual function is lost.

Skeletal Symptoms and Signs

Gibbus and, sometimes, a paraspinal swelling may be present in malignant tumours of the vertebral column. Dumb-bell neurofibromas in the cervical region may be palpable in the anterior or posterior aspect of the neck. Obliteration of cervical or lumbar lordosis with limitation of movements may be seen in extramedullary tumours of the spinal canal and is the result of muscle spasm due to root irritation. Intramedullary tumours, when slow growing, may cause scoliosis due to weakness of the muscles supplied by the involved segments.

In primary and secondary malignant tumours of the vertebral column, the spinous process of the affected vertebra often becomes tender. On the contrary, in extramedullary tumours, the tenderness of the spinous process is felt not at the vertebra overlying the tumour, but a lower level, viz. at the vertebra supplied by the affected posterior nerve root. Thus, a tumour situated at the level of the D4 vertebra will cause tenderness of the D6 spine, as the concerned spinal cord segment is D6. In tumours of the cauda equina several spines of the lumbar vertebra may be tender, as several roots are stretched. Head compression can elicit radicular symptoms. This is known as Spurling's neck compression test.[6]

There are three methods of eliciting spinal tenderness, each with its own significance. The first is direct tenderness which is elicited by pressure over the spinous process. A pathology involving the process or an advanced stage of the pathology of the vertebral body will cause tenderness. The second is twist tenderness elicited by attempting to twist the spinous process between the thumb and the hand. Early vertebral pathology and posterior element pathology produce tenderness. The third method is deep thrust tenderness which is elicited by a guarded thrust with the proximal part of the ulnar side of the fist. This must be done very carefully.[36]

CLINICAL FEATURES OF TUMOURS AT DIFFERENT LEVELS

Because of the precise anatomical structuring of the spinal cord based on its function, careful examination of the various functions of the cord should give one an

accurate idea of the level of the lesion. In practice this is not often true and though one can predict the presence of a compressing lesion, exact localisation may not be possible in a number of cases. Ghosh et al.[17] analysing 60 cases of spinal compression, found that in 40% clinical examination failed to establish the level of the lesion. They also found that total myelographic block of the spinal subarachnoid space was compatible with intact sensations.

Errors may also occur sometimes in the diagnosis of the side of the tumour. The tumour, as it grows, displaces the spinal cord which gets compressed against the bony margins of the neural arch. In case the signs and symptoms of such compression predominate over those due to direct pressure by the tumour on the cord, then the side of the tumour is incorrectly localised to the opposite side. Thus an anterior tumour is diagnosed as a posterior one and a right sided tumour may be mistaken for one arising from the left side.

Despite these observations, a careful neurological examination helps not only to diagnose and localise the tumour but also to predict the prognosis and to evaluate improvement after therapy.

Pyramidal tract dysfunction and disturbances of the long sensory tracts are less useful in indicating the level of lesion, than root pain, root hyperaesthesia, lower motor neuron muscle paralysis or loss of reflexes, when present. At some levels, clinical localisation is more difficult than at others, for example, at the level of the foramen magnum and the conus medullaris.

Tumours at the level of the foramen magnum or cervicomedullary junction are notoriously difficult to diagnose and are often missed in the early stage. They may grow to a large size before symptoms appear, because of the relatively large subarachnoid space in the cervicomedullary region.[9,27,40] They may cause spinal cord symptoms, intracranial symptoms or both, depending on the direction of spread.

Intracranial symptoms may appear early or later and include papilloedema and hypoglossal weakness or paralysis. Sleep apnoea can be a presenting symptom.[2,54] Suboccipital headache is an early and constant feature of lesions in this region, present long before the signs of cord pressure become evident. This headache is due to spasm of the suboccipital muscles as well as to irritation of the C2 sensory nerve root. Pain in the C2 dermatome becomes clinically significant if numbness and paraesthesia develop in the same dermatome. Torticollis may occur due to unilateral muscle spasm.

Signs and symptoms, referable to a clinical level far below the tumour, may occur and confuse the clinical picture, e.g. wasting of the small muscles of the hand and of the muscles of the neck may be seen in foramen magnum tumours and is due to compression of one or both vertebral arteries or the anterior spinal artery, whose branches supply the cord down to the D4 segment. Compression of the vertebral arteries may occur on turning the neck resulting in vertigo, dizziness, unsteadiness or syncope. In 1993, an excellent review of their experience of 230 tumours at the level of the foramen magnum, collected from 21 French departments, has been presented by George et al.[16]

Lesions above C4 are said to be in the blind zone of the cervical cord. They can be elicited by the Shimizu reflex. This was first described by Shimizu in 1993. The patient is seated with the elbow flexed to 90 degrees and the forearm supinated. The examiner taps the tip of the spine of the scapula in a caudal direction with the reflex hammer. The reflex involves movement of the scapula from an abrupt stretching of the upper part of the trapezius. The reflex is said to be positive if there is scapular elevation with or without abduction of the humerus and is suggestive of cord compression between C2 and C4.[6]

Upper cervical cord lesions assume serious significance, because of interference with respiratory and vasomotor functions. Bilateral phrenic nerve paralysis may occur in the later stages or may follow surgery requiring assisted respiration. Owing to poor respiratory excursions, the patient may not be able to speak or raise his voice above a whisper. Occasionally, the respiratory paralysis may set in only during sleep, thus requiring a constant watch. The vasomotor paralysis may be extensive so as to cause sudden hypotension with change of posture.

Pain in the neck and in the occipital region made worse by movements of the neck is a characteristic feature of high cervical lesions. The pain may also radiate to the interscapular region. All the limb reflexes are exaggerated with positive Hoffman's reflex. Examination of the functions of the cervical and sternomastoid muscles and detection of sensory loss in the area supplied by the cervical cutaneous plexus helps in localisation of the level. It is to be remembered that C3-4 roots supply the region over and just below the clavicle in front of the chest up to the level of the sternal angle.

Tumours arising opposite the lower cervical segments can be localised by examination of the muscles and reflexes in the upper limb. Lesions at the 5th cervical segment cause wasting and weakness of the deltoid. When the biceps is intact but the triceps is involved, the lesion must be as high as the C6 nerve root. Inversion of the radial reflex with loss of the biceps jerk, and an exaggerated triceps reflex point to a lesion at the C5 level. The triceps is spared in C7 lesions. Examination of the hand muscles will differentiate between C7, C8 and T1 lesions. In addition, the distribution of the root pain or the presence of hyperaesthesia or subjective numbness also helps to localise the cervical root levels. While C5 sensory involvement causes hyperaesthesia or pain over the shoulder and the lateral aspect of the arm, in C6 root involvement there is pain or diminished sensation along the outer aspect of the forearm, the thumb and the index finger. Pain radiating to the middle finger indicates C7 involvement, whereas irritation of C8 and T1 causes pain along the ring and little fingers and the medial aspect of

the upper limb. Horner's syndrome may be elicited in T1 level lesions due to involvement of the sympathetic system.

Clinical assessment of the diaphragm is important in all cases of cervical spine lesions. Sniffing is an important sign which is impaired in diaphragmatic lesions. Shoulder paresthesia or tenderness is of clinical significance. Hoover's sign wherein there is epigastric angle widening with intercostal contraction; this is counterbalanced by the diaphragm and is absent in paresis of the diaphragm. Tidal percussion done in the lower border of the 5th rib in the midclavicular line gives an idea of diaphragmatic excursion. The normal diaphragm moves up to the 6th intercostal space during inspiration.

Dorsal Lesions

The level of the lesion in the dorsal region can be assessed accurately from the root pain or sensory loss. In the upper part of the trunk, the C3-C4 roots supply the infraclavicular region and the D3 root the area just below on the trunk; the D4 level is at the nipple, D6 over the epigastrium, D10 at the umbilicus and D12 over the hypogastrium. When the lesion is at D10 level, the upper abdominal muscles are normal while the lower muscles are paralysed. This results in upward movement of the umbilicus when the patient attempts to sit up from a supine position (Beevor's sign). Extensive involvement of the dorsal cord may result in wasting of the paraspinal muscles leading to kyphosis or scoliosis and is more common in intramedullary lesions.

Upper Lumbar Segments

Following compression of the first and second lumbar segments the abdominal reflexes are preserved, the cremasteric reflex is lost and the knee jerks are exaggerated. If the tumour involves the second, third and fourth lumbar segments, the cremasteric reflexes are intact, the knee jerks are diminished or lost and the ankle jerks are exaggerated. There is wasting of the quadriceps with weakness or loss of extension of the knee.

Epiconus Syndrome

This results from involvement of the L4-L5-S1 and S2 spinal cord segments. It is characterised by weakness of abduction, external rotation and extension of the thigh, and impaired flexion of the knee, and dorsi and plantar flexion of the ankle. Sensory disturbances occur in the L4 to S2 dermatomes. The knee jerk is preserved and the ankle jerk is lost. The bladder and rectum empty reflexly.

Conus Syndrome

The lower three sacral and the coccygeal segments comprise the conus medullaris. The clinical picture due to involvement of the conus is characterised by: (1) retention of urine with overflow; (2) faecal incontinence; (3) impotence and (4) perianogenital or saddle anaesthesia. Sensory disturbances occur in the S3, S4 and S5 dermatomes. There are no motor disturbances in the lower limb. The plantar reflex is flexor and the knee and ankle jerks are normal.

At the level of the conus medullaris a large number of nerve roots take origin and thus a differentiation between a conus lesion and a cauda equina lesion is sometimes difficult.

Cauda Equina Syndrome

The cauda equina consists of the five lumbar, five sacral and two coccygeal nerve roots in the spinal canal (a total of about 48 nerve roots) and extends over several vertebral levels; thus the clinical picture in tumours of the cauda equina varies according to the level and the number of nerve roots affected. If the tumour is small, only a few nerve roots will be affected with corresponding lower motor neuron signs, whereas a large tumour will implicate all the nerve roots at that level. Pain is a common symptom and occurs in 95% of cases.

At the L2 vertebral level all the nerve roots can be implicated excepting L1 which exits between the L1 and the L2 vertebrae. All the muscles of the lower limb manifest lower motor neuron weakness. Anaesthesia is present anteriorly below the level of the groin including the genitalia and, posteriorly below the upper part of the buttocks. There is retention with overflow of urine and incontinence of faeces. All the reflexes in the lower limbs are lost. At the L4 vertebral level, the L1, L2 and L3 nerve roots escape. Hence, sensations are normal over the front of the thigh, and the function of the quadriceps and the knee jerks are normal. Except for this, the picture is the same as seen at the level of L2 vertebra.

When the lesion is below S2 level, there is no paralysis of the muscles of the lower limb. A characteristic saddle shaped area of anaesthesia is seen over the buttocks, perineum, scrotum and penis, and over a small strip running from the perineum down the posteromedial aspect of the thigh. The anal reflex is lost and the reflexes of the lower limbs are normal. Retention of urine with overflow and rectal incontinence will be present. This is similar to or even identical with the conus syndrome and, therefore, neurologically it is not possible to differentiate between them.

A pure conus medullaris lesion is not seen in practice. An extramedullary tumour at the level of the conus compresses both the cauda equina and the conus. Hence, the clinical picture is mixed in the early stages, whereas, in the later stages, a pure cauda equina type of picture is seen. An intramedullary tumour of the conus will initially produce a conus syndrome, but in advanced cases the enlarged spinal cord compresses the roots of the cauda equina and produces either a mixed or a cauda equina type of clinical syndrome.

Differentiation between Extramedullary (Intradural) and Intramedullary Tumours

The clinical differences between an extramedullary and an intramedullary tumour are discussed in Table 1. No single symptom or sign is pathognomonic. The total clinical picture should be critically assessed without giving undue importance to any one symptom or sign.

ALIGNMENT OF CORD SEGMENTS AND VERTEBRAE

The spinal cord is much shorter than the vertebral column and hence the spinal cord segments are not situated opposite the corresponding vertebrae. In the adult, the spinal cord ends at the lower border of the L1 vertebral body. There is a progressive increase in the difference between the cord segments and the vertebral bodies, from above downwards. The eight cervical cord segments extend from the foramen magnum to the upper half of the C7 vertebral body. The twelve dorsal cord segments lie opposite the lower half of the C7 vertebral body up to the lower border of the D9 vertebral body. The D12, D8 and D4 cord segments are opposite the D9, D6 and D3 vertebral bodies, respectively. The lumbar cord segments are opposite the D10, D11 and D12 vertebral bodies. The sacral and coccygeal cord segments, therefore, lie opposite the L1 body.

This knowledge is essential for determining the relationship of the tumour to the level of the spinal column, thus helping in the clinical and radiological examination of the vertebral column, in focusing the site for careful examination during imaging and in helping the correct placement of the incision during surgery. In spite of all recent advances in imaging, even today, it is vital to ascertain first clinically the site of the lesion before ordering an investigation. It is not infrequent, if this dictum has been bypassed by the clinician, to see patients with missed or wrong diagnosis, and investigations ordered for the wrong level.

Table 1: Clinical differences between an extramedullary and an intramedullary tumour

S. No		*Extramedullary*	*Intramedullary*
1.	Root pain	Common and early	Late and uncommon
2.	Sensory loss at the level of the tumour	Nil or slight	Wide
3.	Dysaesthesiae and paraesthesiae (due to irritation of long sensory tracts)	Seldom, if at all	Common at all stages
4.	Subjective sensation of intense cold	Characteristic of high cervical tumour	Not seen
5.	Distant sensory loss (due to involvement of long sensory tracts)	Ascending sensory disturbance and no dissociation	Descending sensory disturbance with dissociation
6.	Muscle spasms (due to irritation of anterior nerve roots)	Fairly common	Infrequent
7.	Lower motor neuron paralysis with muscle atrophy	Absent except when nerve roots with extensive motor supply, like C8 and T1, are involved	Wide
8.	Upper motor neuron paralysis	Late	Early
9.	Sphincter disturbances	Late unless it is in the region of sacral cord	Early
10.	Brown-Sequard type of clinical picture	Late unless it is in the region of sacral cord	Early
11.	Trophic disturbances of skin	Absent	Fairly uncommon
12.	CSF protein	Marked increase	Moderate increase
13.	X-ray spine	Bone changes common	Bone changes only in a few cases
14.	Tenderness of spine	Common	Uncommon

DIFFERENTIAL DIAGNOSIS

In its early stages, a spinal cord tumour may mimic diverse diseases, the root pains in different areas of the body being mistaken for local involvement. In patients with obvious spinal cord involvement, the insidious onset, the progressive course, the initial asymmetrical involvement, the pattern and evolution of the neurological signs and an identifiable clear-cut level of involvement, usually indicate the correct diagnosis. Amyotrophic lateral sclerosis and multiple sclerosis may sometimes simulate a spinal cord tumour in their symptomatology.[30] Vascular malformations of the spinal cord may also result in progressive involvement of the cord with a well-defined level of neurological signs. Syphilitic lesions of the cord, arachnoiditis, disc lesions and syringomyelia are to be considered in differential diagnosis. Radiation myelitis may simulate a spinal cord tumour syndrome. In rare cases, a spinal cord tumour may present with papilloedema. Although this is not uncommon in foramen magnum and high cervical cord lesions, papilloedema may occur in cord tumours lower down, mimicking an intracranial lesion. Such papilloedema is due to increased CSF proteins, diminution of CSF absorption space or basal meningitis.

FUNCTIONAL SCORES IN SPINAL CORD DISEASE

In recent years great importance has been given to scoring systems which provide data about the patient's function in daily life. There are several scoring systems. The systems which are commonly used are given below.

McCormick Classification

McCormick classification[30] of clinical function in patients with intramedullary spinal cord tumours:

Class I: Neurologically normal. Mild focal neurological deficit not significantly affecting the function of the involved limb. Mild spasticity or reflex abnormality. Normal gait present.

Class II: Presence of sensorimotor deficit in the involved limb, mild to moderate gait difficulty, severe pain or dysaesthesia significantly impairing the quality of life, although the patient can still function and walk independently.

Class III: More severe focal neurological deficit with the patient requiring a cane or a brace to walk or with significant bilateral UL involvement, the patient may or may not be able to function independently.

Class IV: Severe deficit with the patient requiring a wheelchair/cane/brace with bilateral UL impairment. Patient not walking.

Nurick's Grading for Cervical Myelopathy

G0: Signs and symptoms of root involvement present, no signs of cord involvement.
G1: Signs of spinal cord involvement, normal gait present.
G2: Slight difficulty in walking, full time employment is not prevented.
G3: Difficulty in walking present which prevents full time employment. The patient is ambulant without support.
G4: The patient is not usefully employed and is able to walk only with help/support.
G5: The patient is chair bound/bed ridden.

Frankel's Grading

A- Absent motor and sensory function.
B- Sensations present, motor function absent.
C- Sensations present, motor present but not useful (corresponds to MRC grade 2 to 3).
D- Sensations present, near normal motor function.
E- Normal motor and sensory function.

104 Vertebral Tumours

Deepu Banerji, Pallav Garg, Manoj Jain, Sanjay Behari

BENIGN TUMOURS OF THE SPINE

Eight per cent of primary benign bony tumours occur in the spine.[6] Amongst primary tumours of the spine, benign tumours account for 25–35%. Benign tumours tend to occur much earlier than their malignant counterparts with the peak age of incidence being in the second and third decades of life. Benign tumours are sometimes classified according to the part of the vertebra that they affect. Osteoid osteoma, osteoblastoma and aneurysmal bone cyst tend to involve the posterior elements, whereas the anterior elements are affected by giant cell tumour, haemangioma and eosinophilic granuloma. Similarly, different tumours tend to occur at different segments of the spine with giant cell tumours usually seen in the sacrum. Haemangiomas are more commonly seen in the thoracic and lumbar spine. Osteoid osteomas are more commonly seen in the lumbar region, whereas osteoblastomas equally occur in the thoracic and lumbar spine.

Clinical Presentation

Pain is the most common presenting complaint.[13] The pain is initially focal. With progressive increase in size of the tumour, neural elements may get compressed resulting in unilateral or even bilateral radicular pain. In adults, this may be confused with the clinical manifestations of a herniated disc. In children, pain is less often a presenting complaint. Osteoid osteoma and osteoblastoma are characterised by night pain which is relieved by non-steroidal anti-inflammatory drugs (NSAIDs).[24]

The symptoms of myelopathy occur with progressive increase in the size of the tumour resulting in epidural compression. This occurs more commonly with thoracic tumours due to the narrow canal diameter at that level. Tumours at the cranial or the caudal end of the spinal axis may occasionally, present as large mass lesions due to the more capacious spinal canal at these locations, that results in a relatively delayed neurological involvement. Lesions of the lower end of the spinal canal may present with sphincteric disturbances.

Sometimes, the patient may present with spinal deformity in the form of scoliosis. If this is accompanied with back pain then it suggests a bony tumour. Along with this, the mobility of the patient is hampered with restriction of body movements in all directions. This entity needs to be differentiated from the scoliosis of idiopathic origin.

Investigations

Plain radiographs show varying features according to the type of the tumour. Sclerotic changes are evident in osteoblastoma and osteoid osteoma. Expansile-lytic lesions are seen in giant cell tumours and aneurysmal bone cysts.[25] Vertebra plana is characteristically seen in eosinophilic granulomas whereas haemangiomas are identified by their vertical trabeculae. Scoliosis can be seen on the antero-posterior films.

MRI is the investigation of choice and reveals the extent of soft tissue involvement along with the bony component.[8] It is much more helpful in demonstrating cord compression as compared to the CT image, but the bony details are best delineated by the CT scan. In osteoid osteoma and osteoblastoma, the surrounding inflammatory response may be picked up by the MRI giving an impression of a highly aggressive tumour.

A bone scan, although non-specific, is frequently used as a screening tool. In patients with sclerotic tumours, a high tracer uptake is seen. A CT guided biopsy may be performed when there is a dilemma regarding the nature of the lesion. This, however, is invasive and carries the risk of neurological deterioration.

Treatment

Surgical intervention is based upon the presentation and the type of the tumour. Enneking's Type 1 (latent) tumours refer to incidentally discovered tumours which require no treatment.[14] This category includes incidentally discovered haemangiomas and osteochondromas that are not endangering the thecal sac. Type 2 (active) lesions refer to symptomatic tumours. These need local resection with curettage and include osteoid osteoma, haemangioma, aneurysmal bone cyst and eosinophilic granuloma. Type 3 (aggressive) tumours include giant cell tumour and osteoblastoma which require wide excision. Adjuvant therapy is determined according to the surgical decompression performed.

Radiation therapy is used in cases of neurological deterioration where surgery is contraindicated or in cases of highly radiosensitive tumours. Tumours responding

well to radiotherapy include haemangiomas and aneurysmal bone cyst. Radiation therapy carries risk to the underlying neural tissue which needs to be addressed.

Osteoid Osteoma

Jackson's series revealed a 10% occurrence of osteoid osteoma in the spine.[20] Male patients are affected more than the female ones (2:1). There is no familial or racial predilection with the peak incidence being in the second decade. Usually, they tend to present within one year of symptoms. Pain is usually the presenting symptom with persistent night pain seen in more than 50% of patients. Radicular involvement is seen in less than 25% of the cases. Scoliosis is seen in up to 70% of the cases.

The lumbar spine is the most commonly affected area. Radiographic changes are seen in the lamina or the pedicle and tend to involve a single vertebral level. The tumour is seen as an isolated radiolucent area surrounded by a zone of reactive sclerosis. Soft tissue or epidural extension is unusual. Sclerotic changes are seen on the radiographs and are due to reactive bone formation. Hence, bone scan is positive in all the cases. CT is the investigation of choice to delineate this bony lesion and characteristically shows a well-defined oval area of lucency surrounded by hyperdense reactive bone. The area of lucency, also known as the "nidus", may show contrast enhancement due to the high vascularity of the lesion.

The treatment is complete surgical excision with curettage. The osteoid osteoma appears as a soft, dark red or yellowish white nodule surrounded by dense reactive bone. Remission of pain is the indicator of complete excision. In order to prevent scoliosis, excision should be undertaken as early as possible before the supporting spinal pillars are compromised by the tumour. Radiotherapy has no role in the treatment of this lesion. At microscopy, irregular and haphazardly arranged woven bone trabeculae are embedded in a fibrovascular stroma. The amount of woven and unwoven (osteoid) bone varies among lesions.

Osteoblastoma

Although the overall incidence of these lesions is less than many other bony tumours, they have a predilection for the spine with nearly 40% of them involving the latter.[21] Male patients are affected more than the female ones. These lesions share a common presentation of painful scoliosis with osteoid osteoma, yet are larger as compared to the latter with a more aggressive potential.

Patients usually present within 6–12 months of symptoms with pain that persists during the night and is relieved by NSAIDs. Radicular symptoms may occur in 50% of the cases with some cases showing signs of myelopathy. The thoracic and the lumbar segments are commonly affected. Multiple vertebral levels are more frequently affected than occurs in patients with osteoid osteoma. Another interesting feature is the higher incidence of epidural extension as compared to paraspinal soft tissue involvement.

Radiographs may miss small lesions. When seen, they usually appear to be expansile-lytic lesions. Sclerotic changes are evident in 10–15% of the cases. The lesion appears as a "hot spot" on the bone scan and, therefore, this investigative modality can be used for follow-up of patients. CT scan is the investigation of choice and is very effective in deciding the surgical plan of the patient. It shows an expansile-lytic lesion with internal bone formation within the areas of lucency and surrounding sclerosis.

At the time of surgery, the tumour gives a variable picture of a homogeneous, red to purple hypervascular friable granular mass. Histologically, rich fibrovascular stroma with abundant osteoblasts is seen. Cartilage is absent. The latter feature differentiates it from an osteosarcoma. Epithelioid osteoblastoma is an aggressive malignant variant with atypical osteoblasts.[18]

The treatment is complete surgical resection with radical curettage of surrounding normal vertebra. Patients with symptoms of cord compression need to be decompressed on an emergent basis with the expectation of a good neurological recovery. Partial excision results in persistence of pain. Radiotherapy has a role in debilitated patients who cannot undergo surgical resection. Malignant transformation following radiotherapy has been noted in some cases.

Osteochondroma

The incidence of spinal osteochondromas is not very high despite it being the most common benign skeletal tumour. Some patients have a familial background in the form of hereditary multiple exostoses[23] that usually occur in patients less than 20 years of age and have a male preponderance. All parts of the vertebra are equally affected. A solitary lesion is a cartilage-capped broad based growth on a broad base or stalk related to the epiphyseal growth plate.

Although most of these patients are asymptomatic, they usually present with mass effect in the form of myelopathy. Another characteristic feature is that these tumours tend to stop growing at skeletal maturity. In cases of persistent growth, malignant transformation to chondrosarcoma should be considered. Both CT and MRI are highly effective as diagnostic modalities with MRI being preferred since, the soft tissue margin surrounding the tumour can be better identified.

Surgery is indicated only for symptomatic lesions or for lesions which show persistent growth. Complete excision is mandatory for symptomatic relief which is possible in 70–90% of the patients. Histology shows a hyaline cartilage cap covered by a fibrous membrane, the perichondrium and an underlying pedunculated bony stalk connected to the underlying bone without any intervening cortex between the two.

Giant Cell Tumour

These tumours have certain unusual characteristics. They are rarely seen before 20 years of age since they occur after skeletal maturation. They tend to occur more commonly in females. The ends of the spinal column are the favoured sites with the sacrum being most commonly affected. In fact, they are the most common benign tumours of the sacrum.[31] Sometimes they are seen in patients with Paget's disease.

Pain at the tumour site is the chief presenting complaint. Due to their predilection for the ends of the spinal column, the duration from the initiation of symptoms to their detection is much longer, sometimes as long as 8 months. Thirty to seventy-five per cent of patients present with neurological deficits in the form of paraparesis with bladder and bowel involvement. On plain radiology, they appear as expansile, septated, lytic lesions with cortical breach and a small soft tissue component. The vertebral body is more commonly involved. They require complete en bloc resection with wide margins. Recurrence rates are high, especially following intralesional resection. Grossly, the tumour appears light brown to bloody with focal necrotic areas with a rubbery feel. The main histological features of giant cell tumours are sheets of mononuclear round cells, scattered multinucleated osteoclast type giant cells, with identical nuclei found in mononuclear and multinuclear cells.

Due to the vascular nature of the tumours that may result in large amounts of intra-operative blood loss, pre-operative embolisation is recommended. Incomplete resection mandates adjuvant therapy due to high recurrence rates. However, 5–10% of patients undergoing radiotherapy have reportedly shown sarcomatous degeneration.

Eosinophilic Granuloma

The tumour is characterised by spontaneous regression often with an excellent prognosis. This entity is the most benign form of histiocytosis X and demonstrates a solitary benign lesion. This is usually seen in patients less than 20 years of age, with the thoracic spine being the most commonly affected.[30]

The clinical presentation is like that of any other bony tumour. Sometimes, systemic symptoms of fever with weight loss may be seen. On plain radiology, these characteristically show vertebra plana with disc sparing. This needs to be differentiated from the relatively uncommon presentation of spinal tuberculosis primarily affecting the body of the vertebra. Sometimes posterior involvement may be seen. On bone scan, they reveal cold spots. MRI may give the false impression of these tumours being aggressive due to a 'Flare up' response that may often occur. Focal lytic areas with sclerosis may also be seen. At histology, histiocytic cells with characteristic cytoplasmic granules (seen by electron microscopy), known as Birbeck granules, may be seen.

Since these tumours tend to spontaneously regress with reconstitution of the vertebral body, surgical intervention is not required. Hence, the role of percutaneous biopsy is important, which can provide tissue diagnosis thereby obviating the need for surgery. Surgery is indicated in patients with spinal instability and neurological deficit. There is no role for radiotherapy. Recurrence is rarely seen.

Aneurysmal Bone Cyst

These tumours tend to affect patients less than 20 years of age. There is no predilection for either sex. Characteristically, these lesions tend to involve the posterior elements much more as compared to the vertebral body. In fact, multiple levels of involvement are commonly seen.

Pain is the most common presenting complaint along with spinal deformity in the form of scoliosis and spinal rigidity. MRI with contrast is the investigation of choice. Multiple septations may be seen within the lesion. The lesions are lytic and expansile with a thin reactive bony rim. They consist of large blood filled spaces and a network of fibrous tissue containing immature bone, giant cells and macrophages.

Surgical resection with curettage is the treatment of choice. These tumours are vascular and tend to bleed a lot. Hence, pre-operative embolisation, if possible, is recommended. Sometimes, embolisation alone is found to be sufficient for controlling these tumours.[12] Radiation therapy has no role as adjuvant therapy since even partial resections are sufficient for tumour control. Sometimes, low dose radiation is pre-operatively utilised to decrease the vascularity of the tumour which may even be curative.

Haemangioma

Haemangiomas are true benign neoplasms of the bone and may occasionally be hamartomatous in nature. They tend to occur in the third decade of life with a slight predilection for the female sex. Sometimes, they are seen in patients with systemic conditions such as Klippel-Trenaunay-Weber syndrome. When associated with multiple skeletal and extraskeletal haemangiomas, they may cause consumptive coagulopathy.[5] These tumours characteristically enlarge during the third trimester of pregnancy, resolve following the delivery, but recur during subsequent pregnancies.

They usually present with pain. Neurological compromise is also seen. Pathological fracture is uncommon. Radiographs demonstrate a characteristic vertical striated appearance of the vertebral bodies due to ossification around areas of haemangioma. This is termed as 'honeycomb' or 'coudroy cloth' appearance. On CT, these lesions give the appearance of polka dots. The vertebral body is more commonly involved than the posterior elements. Many studies have reported contiguous

multiple level involvement. The thoracic spine is more commonly affected [Figs 1(A and B) and Fig. 2].

Grossly, the lesion arises from the periosteum or the marrow spaces producing a honeycomb bloody mass. Microscopically, numerous capillary channels with large feeding vessels are seen. These tumours are usually supplied by the intercostal arteries. Cavernous vascular channels may also be seen. Angiographically, these lesions demonstrate extensive tumour blush.

Embolisation of the vessels supplying the tumour should be performed, if surgery is being contemplated. Risk of ischaemia to the cord is probable, if more than three vascular pedicles are embolised. Recent reports favour embolisation followed by radical excision in patients presenting with neurological compromise or with spinal instability. Radiotherapy has also been found to be useful. The recommended dose is 30–40 cGy in a single course over 6–8 weeks. It is often used when complete surgical resection has not been performed. If detected during pregnancy, treatment should be undertaken after delivery even though the symptoms may subside, since the tumour may recur in subsequent pregnancies. Spinal instability may require instrumentation.

PRIMARY MALIGNANT TUMOURS OF THE SPINE

Chordomas

These are rare, slow growing tumours with a peak incidence in the 5th–7th decade of life. These are considered to be the remnants of the embryonic notochord.[19] Muller was the first person to have enunciated this theory. Male patients are affected more than females. Though chordomas may occur at any level in the spine, the sacrococcygeal region is the most commonly affected region followed by the clivus.

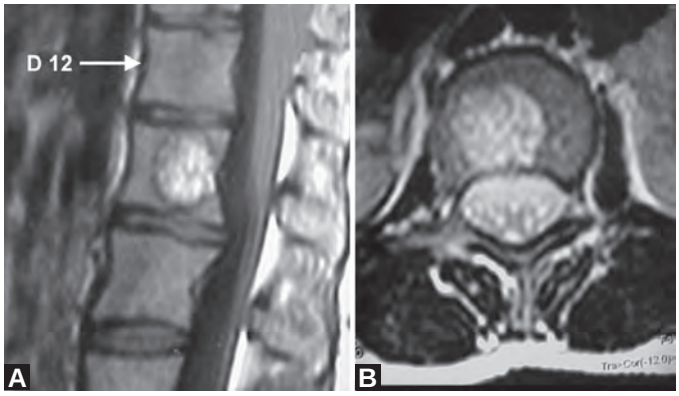
Pain is the most common presenting symptom. It is initially local becoming radicular later on with nerve root compression. In the lumbar region, the tumour may give rise to neurogenic claudication. Due to the capaciousness of the spinal canal in the sacrococcygeal region, these tumours may grow to a large size before they are detected. Bladder and bowel involvement occur late in the course of the disease. Clival tumours present with headache, multiple cranial nerve palsies and visual disturbances. Myelopathy is seen with cervicothoracic lesions that are compressing the thecal sac.

On MRI and intrathecal contrast sagittal reconstructed CT scans, they present as destructive lesions usually spanning more than one level, with disc sparing. Tumour calcification may also be seen. CT helps to define the bony destruction, whereas the soft tissue extent is shown best by the MRI (Figs 3A to E). Grossly, the tumours appear lobulated, grey, cystic or solid, firm to soft in consistency. They tend to be well-circumscribed. Microscopically, physaliphorous (soap bubble) cells are seen with a vacuolated cytoplasm. These tumours are locally aggressive with late metastasis.

Complete surgical resection is the treatment of choice, although it is often technically difficult. In such cases, the patients are advised post-operative radiotherapy. Since this tumour usually affects the sacrum, sparing of S2 root is essential for bladder and bowel control. Recurrence rates are high for incompletely resected tumours. Adjuvant therapy is essential in such cases. Sometimes, radical resections result in spinal instability which requires bone grafting with instrumentation.

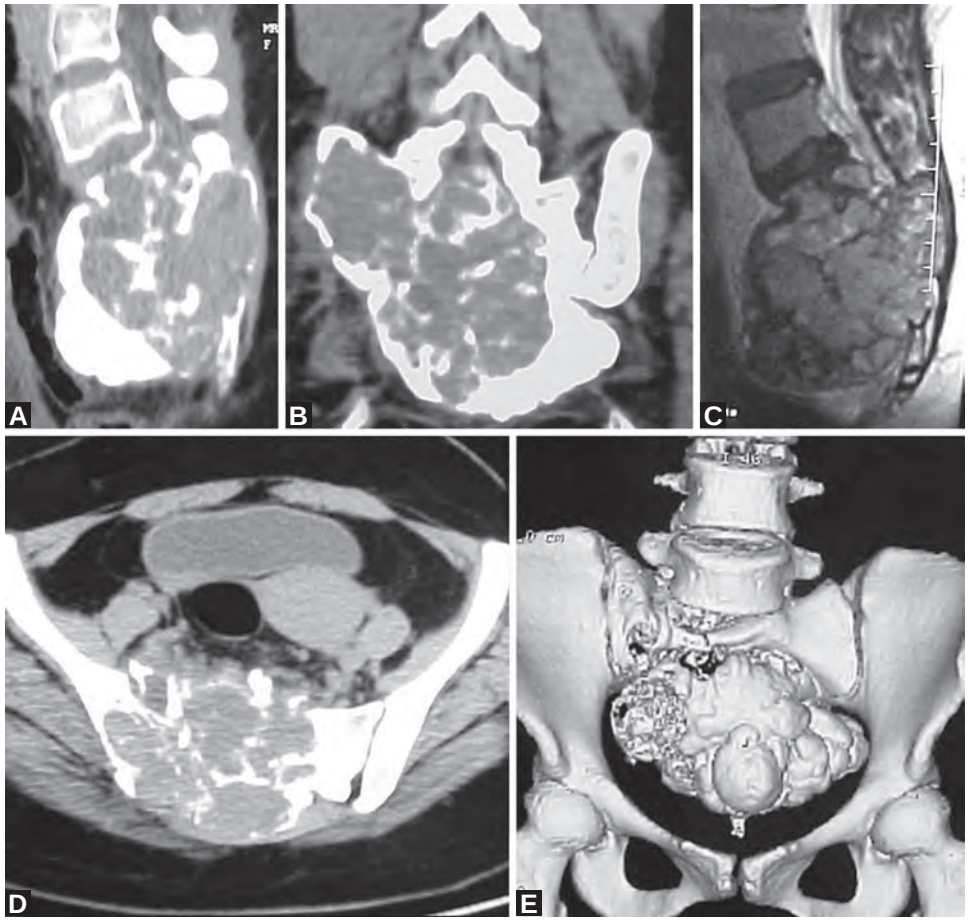
Osteosarcoma

This is the most common primary malignancy of the skeletal system other than a myeloma. The spine is relatively less affected as compared to the rest of the skeletal system. Usually these tumours show a peak in the second decade of life with spinal tumours appearing later as compared to osteosarcomas of long bones. There is no sex predilection. These tumours can occur in the spine as primaries, may be metastatic or may result due



Figs 1A and B: MRI of a patient showing vertebral haemangioma without vertebral compression

Fig. 2: MRI of a patient showing vertebral haemangioma causing cord compression



Figs 3A to E: Images of a patient with chordoma. CT scan with reconstruction (A, B, D and E) showing bony destruction. MRI (C) showing soft tissue component of chordoma

to malignant transformation in diseases such as Paget's disease, and following radiotherapy.[10]

Pain is the most common presenting complaint which is initially localised. Neurological deficits are commonly seen indicating epidural extension of the lesion.

The classical findings in patients with limb osteosarcoma are periosteal elevation and presence of Codman's triangle. These, however, are not seen in the spine. In the spine, a mixed picture of osteolytic and osteoblastic lesions is seen. Lesions usually involve the body, and posterior element involvement is much less frequent. Pathological fractures may also be seen. CT scan helps to show the bony anatomy, whereas the MRI is helpful in assessing cord compression along with the whole extent of the tumour. Bone scans are helpful in identifying multiple lesions, which may be in the form of 'skip' lesions. Biopsy of the lesion should be undertaken before surgical resection is performed.

Osteosarcomas are large vascular tumours with areas of grittiness. Grey-white tissue, suggesting fibrogenic areas, may also be seen. Microscopically, it is characterised by the presence of woven bone formed by osteoblasts, which may or may not be mineralised. There are disorganised spicules or masses, or woven bone enmeshed in a vascular bed. The bony spicules are surrounded by anaplastic spindle or polygonal cells with mitosis and atypia. Areas of haemorrhage and necrosis are common.

The standard treatment protocol is neoadjuvant chemotherapy followed by complete resection. The aim of surgery is to achieve tumour-free margins failing which the patient is subjected to post-operative radiotherapy. Treatment is started with two or three cycles of chemotherapy. Surgery is planned after 10–16 weeks, allowing the tumour to regress, following which radical excision of the tumour is done. This is usually followed by adjuvant chemotherapy. Radiation is given if negative margins are not achieved. Despite all these measures, the prognosis remains dismal.

Chondrosarcoma

It is a malignant tumour forming hyaline cartilage (without bone) composed of malignant chondrocytes. It is more common in males with a peak age of incidence in the fifth decade of life. Although it usually arises primarily in the spine, it may occasionally occur following malignant transformation of enchondromas or osteochondromas. A hereditary association is seen in some cases with Ollier's disease and familial osteochondromatosis.

Patients usually present with pain in the involved segment with an occasional radicular component depending upon the extent of the tumour. The pain is exacerbated in the supine position. Imaging characteristics depend upon the grade of the tumour. Low grade tumours result in scalloping of the bone with cortical expansion. With higher grade lesions, the lytic component increases. Calcification may also be seen, which decreases with higher grade of tumours. There are often foci of spotty calcification. There may be calcified shadows with radiating spicules arranged at right angles to the cortex. CT and MRI are done for further delineation of the tumour and its characteristics. CT of the lung should also be done due to the tendency of this tumour to metastasise to the lung. Biopsy should be performed keeping in mind the surgical plan. Needle biopsies yield little tissue, hence incisional biopsy is preferable.

Chondrosarcomas have been graded according to their histological appearance. Grade 1 tumours have mild cellular atypia with abundant hyaline matrix; Grade 2 have significant atypia with abundant cartilaginous matrix; whereas, Grade 3 have marked atypia with little cartilage matrix, mitotic figures, necrotic foci and multiple giant tumour cells.

Complete surgical excision is the treatment of choice. Instrumentation may be required for resultant spinal instability. However, it is often technically not possible to completely remove these tumours. In these cases, radiotherapy should be given to prevent the high rates of recurrence that follow incomplete resection. Cryosurgery has also been used when tumour-free margins are not achieved during surgery.[4] Long-term survival is dependent upon the histological grade of the tumour.

Ewing's Sarcoma

The overall incidence of Ewing's tumour of the bone is around 6%. Spinal involvement by this tumour has not been studied in great detail. This is a highly malignant tumour with male predominance and peak incidence in the second decade.[7] The sacrum is commonly involved with the lumbar region being the next in frequency.

The presenting symptom is pain with a variable severity of neurological deficits in the form of sensorimotor and bladder/bowel involvement. The patients may also present with cauda equina syndrome. Radiographs show lytic lesions with a thin rim of sclerotic bone around the margins. Due to the tendency of these tumours to metastasise, particularly to the lungs, CT chest should also be done. Grossly, the tumour is grey-white to blue with semi-solid to gelatinous consistency, and is extremely friable and highly vascular. Microscopically, small round cells larger than lymphocytes with scant cytoplasm are seen. Sometimes, a pseudorosette pattern may also be seen. Tumours are disposed in sheets with a uniform population of tumour cells displaying round nuclei, fine granular chromatin and a thin rim of cytoplasm.

Due to the difficulty in achieving complete excision of the tumour, which is the aim of treatment, a multimodality approach is taken combining chemotherapy, radiotherapy and surgical excision. Incomplete resection results in higher recurrence rates. Hence, post-operative radiotherapy is given in all such cases, the total dose being 4,000–6,000 cGy. The 5-year survival rate is approximately 20% after using multimodality treatment.

Plasmacytoma

These tumours are composed of malignant plasma cells and form a subgroup of plasma cell dyscrasias. These present as single bone lesions or occur at extramedullary sites. In the skeletal system, the spine is most commonly affected with the thoracic spine being the favoured site. Males are more commonly affected with the peak incidence occurring in patients older than 50 years of age. Fifty per cent of these tumours may convert into multiple myeloma, if allowed to persist for a sufficient time without treatment.

Pain is the most common presenting complaint. Radicular involvement is uncommon. However, bone destruction with collapse can result in cord compression leading to myelopathy and even paraplegia in some cases. On plain radiology, in the long bones, a characteristic "soap bubble" appearance has been described. This, however, is unusual in the spine where usually a large destructive lesion is seen. The bone scan shows minimal or no uptake. Further tumour details are obtained with the help of CT and MRI. These patients may produce paraproteins. These may be secretory or non-secretory with occasional light chain urinary excretion. Histologically, the entire spectra of plasma cell maturation may be seen with basophilic cytoplasm and an eccentric nucleus. Lesions can vary from being poorly differentiated to well-differentiated.

These tumours are highly radiosensitive. Hence, radiation therapy is the first line of treatment with the radiation dose being up to 3,500 cGy.[29] Surgical intervention is required for spinal instability and in cases of cord compression. Patients generally require stabilisation procedures. In cases of partially resected tumours, post-operative radiotherapy is given.

Patients with single lesions have better survival rates than with multiple lesions. Poor prognosis is indicated by the extent of soft tissue extension, old age and persistent paraprotein production following treatment.

Multiple Myeloma

This is the most common primary malignancy of the bone. It is a systemic plasma cell disorder where the bone marrow is first affected resulting in its replacement by plasma cells followed by involvement of the cortical surface with local extension. Destruction of the bone marrow may result in normochromic anaemia, thrombocytopaenia and neutropaenia.[26] Male and female patients are equally involved with 62 years being the peak age of

incidence. The whole skeletal system is equally vulnerable. Pain is usually the presenting feature with radicular and myelopathic features depending upon the growth of the tumour. Patients often present with pathological fractures. Patients may also develop constituent symptoms, like fever and fatigue, due to chronic anaemia. On plain radiographs, multiple destructive lesions are seen, which may result in vertebral pathological fractures with cord compression. Urinary examination is carried out for Bence Jones protein. Serum electrophoresis is also carried out to investigate for other paraproteins. Bone marrow smears reveal increased number of plasma cells which show atypical features. The beta-2 microglobulin level is measured and followed as a prognostic factor. Hypercalcaemia is reported with normal or slightly increased alkaline phosphatase. Renal function tests are also required, since this disease may result in acute tubular damage causing renal failure. Definitive diagnosis requires CT guided bone biopsy which shows fibrocollagenous tissue infiltrated by a monotonous population of mature and immature plasma cells displaying predominantly eccentrically placed nuclei with coarse chromatin, and moderate amount of cytoplasm.

Combined radiotherapy and chemotherapy form the first line of treatment. Surgical therapy is indicated only in cases of spinal fractures resulting in spinal instability or cord compression. In such cases, decompression followed by instrumentation is required. Since complete resection is not usually possible, radiotherapy should be instituted following surgery. A large number of chemotherapeutic agents are available with cyclophosphamide and melphalan being equally effective. Radiation therapy in conjunction with chemotherapy is especially helpful in relieving pain and may also result in relief of neural compression.

Lymphoma

The spine is usually affected in cases of Non-Hodgkin's lymphoma.[11] Usually multiple level involvement occurs although, occasionally, solitary lesions are seen. The peak age of incidence is after 40 years. Lymphoma tends to involve the anterior column and the posterior columns tend to be relatively spared. Lymphomas are highly radiosensitive and chemosensitive. Surgical therapy is reserved for cases with neurological deficits. In such cases, instrumentation may be required to restore spinal stability.

Metastatic Tumours of the Spine

Technical advances leading to earlier detection, and prolonged survival due to continuously improving treatment modalities have led to higher detection rates of metastatic disease in the spine. The emphasis is on 'early detection', since the prognosis is determined by the neurological status at the time of presentation. Despite recent advances in the management of various localised tumours, metastatic tumours have proven to be a surgical challenge. The present consensus is on a multidisciplinary approach involving surgery, radiotherapy and chemotherapy.

It has been widely accepted that lung and liver are the most common sites for the seeding of metastatic foci.[3] The skeletal system is the third most common site for metastatic disease with the spine harbouring the majority of these lesions. The thoracolumbar and the lumbar spine are the commonest sites of spinal metastasis perhaps due to increasing amounts of bone marrow from the cervical to the lumbar region. However, the propensity for the disease to present with neurological dysfunction is highest in the thoracic spine as the canal diameter is the narrowest in this region. Dommisse had suggested that the thoracic spine has the most critical vascular area of the spine, particularly at the levels from T4 to T9.[9] However, this fact has been refuted and the thoracic region too has a well-developed segmental blood supply.

The four common primary lesions that result in spinal metastasis are breast, lung, prostate and kidney cancers. In the paediatric population, neuroblastoma is the most common tumour responsible for neurological dysfunction.

PATHOGENESIS

The pathogenesis of the spread of the primary tumour to the spine has been studied in great detail. Four pathways of spread have been determined. The most common pathway for the metastatic spread is the venous system. Batson had demonstrated the presence of valveless veins in the spinal canal.[1] The blood from the vertebral body is drained by the basivertebral veins which connect to the epidural venous plexus. The whole pathway is devoid of valves resulting in retrograde flow of blood to the vertebral body whenever, there is a rise in the intra-abdominal pressure. This provides a pathway for the tumour cells to travel from the primary site to the spine. The vertebral venous plexus is in communication with the upper and lower extremity, the head, the neck and the trunk allowing the spread of a variety of tumours.

Arterial spread of the tumour occurs by means of the nutrient arteries. Tumours of the lung and the prostate have been known to utilise this pathway for their spread. Some tumours have shown to have perineural and lymphatic spread. Tumours that have a perineural spread tend to enter through the intervertebral foramen resulting in epidural compression.

Local extension of the tumour cells to the spine is also well-known with lung carcinoma, tumours of the retroperitoneum and the mediastinum.

In order for the tumour cells to establish themselves at the target site, two conditions need to be met. Firstly, the tumour cells should be in adequate number, which in the spine is facilitated by the valveless system of veins. The second is the availability of an environment

which allows the tumour cells to proliferate. Paget proposed his "seed and soil" hypothesis but could not provide conclusive evidence in its favour. It is now, believed that multiple factors are responsible for the spinal seedling. The cancellous bone within the vertebral body has been shown to be the favoured site for tumour deposits. Following tumour cell deposition, the metastatic foci proliferate with the aid of production of many substances that promote bone resorption. Both osteoplastic and osteoclastic activities ensue following tumour cell deposition. Indirect mechanisms responsible for tumour destruction have been the production of parathyroid hormone, PG E2, ACTH and calcitonin. Overall, osteoclastic activity predominates in the majority of the cases resulting in vertebral body destruction. In fact, the quality of reactive bone formation is the same for both lytic and blastic activities. It is merely the quantity of bone formed which differs.

The intervertebral disc tends to be involved late in metastatic disease with the cartilaginous endplates providing the barrier to the spread. Tumour spread tends to occur beneath the anterior or posterior longitudinal ligament or through the anterior and posterior body rims which are frequently uncovered by cartilage.

The neurological dysfunction resulting from spinal metastasis usually occurs in a stepwise manner. Direct compression of the spinal canal occurs due to the extension of the metastasis from the vertebral body. This results in compression of the vertebral venous plexus initially, which results in the development of vasogenic oedema due to plasma exudation and production of mediators such as prostaglandins. Indomethacin which inhibits prostaglandin formation has been shown to decrease cord oedema.[16]

Persistent cord compression results in aggravation of the vascular insult, finally resulting in arterial compromise leading to spinal cord infarction. It is the rate of development of the vascular compromise that results in slow or rapid neurological deterioration.

CLINICAL PRESENTATION

Although the clinical syndrome varies depending upon the site of involvement in the spine, pain is the presenting feature in up to 90% of these patients.[2] The pain initially is localised, being mild at the onset with progressively increasing severity. The duration of pain varies from 2 weeks to a year. The character of the pain changes to a boring or burning nature with progression of the disease. The pain tends to persist at night. Localised pain occurs due to periosteal or dural involvement. In the earlier stages, the pain is non-specific, resulting in a delay in the diagnosis of spinal metastasis. The pain may later demonstrate a radicular nature due to the involvement of the nerve roots. The radicular pain may be unilateral or bilateral and is aggravated by movements of the trunk. Recurrence of pain in patients who have previously been treated signifies tumour recurrence.

Motor deterioration tends to precede sensory or urological involvement. The pattern of motor involvement results from the site of the involvement. Anterior horn cell involvement leads to lower motor neuron weakness at that level with spastic weakness below. Similarly, asymmetrical compression of the cord by the tumour results in asymmetrical weakness with the ipsilateral side being affected earlier in comparison to the contralateral side. Lesions of the conus present with lower motor neuron weakness of the lower limbs with absent plantars and hypotonia. Sensory loss occurs much later and again the pattern depends upon the site. Saddle anaesthesia, for instance, is commonly seen in lesions of the conus. The sensory level is usually localised to one or two dermatomal levels below the vertebral levels.

Posterior column involvement may be manifested in the form of paresthesias or numbness below the level of involvement. Lhermitte's sign may occasionally be positive in patients with cervical spine involvement, especially occurring on flexion of the neck. The posterior columns may be involved early in dorsally located tumours.

Bladder and bowel disturbances often occur late in the course of the disease. Early involvement occurs in intramedullary metastasis. In lesions above the level of the conus, patients present with spastic bladder and constipation. However, patients with conus lesions have a neurogenic lower motor neuron type of bladder involvement with faecal incontinence. Conus involvement may also result in impotence in males, whereas priapism is seen with lesions above the conus.

Based on the neurological grades, various staging systems have been devised. Frenkel's system is often used for assessing the neurological involvement.

Frenkel's Classification

Grade A: Complete motor and sensory loss
Grade B: Complete motor and incomplete sensory loss
Grade C: Some motor function, incomplete sensory loss
Grade D: Useful motor function, incomplete sensory loss
Grade E: Normal motor and sensory function

RADIOLOGICAL EVALUATION

Plain radiographs are often the first investigation performed, especially since the initial presentation is that of non-specific back pain. For radiological changes to be seen, 40–65% lytic activity should have occurred. The pedicles usually show the first evidence of metastatic disease.[22] "Winking Owl sign" refers to the absence of the pedicle on AP views. Other findings are changes in the vertebral body morphology leading to vertebral collapse, osteolytic lesions or focal/diffuse osteopaenia. Sclerotic changes are suggestive of osteoblastic metastasis seen with prostate and breast secondaries. Sometimes, gastric cancers, cervical or bladder cancers may give rise to a similar picture.

Bone scans form an integral part of the work up of metastatic disease.[17] This is usually performed with technetium-99m polyphosphate isotopes. The diseased segments tend to light up following isotope administration and demonstrate the extent of metastasis in the whole skeletal system. Tracer uptake is due to reactive bone formation. In areas of highly malignant lesions, where reactive bone formation is minimal, the test may be false negative. Positive results are seen in a variety of benign lesions including inflammatory lesions making this test non-specific. However, this is useful in determining the extent of bony involvement and to identify the 'hot' spots where the biopsy is most likely to yield positive results in cases with multiple levels of involvement. In patients with recurrent lesions who have undergone spinal implants that show artefacts on radiological imaging, bone scan may be useful in defining new lesions.

MRI with contrast has been accepted as the investigation of choice and is considered superior to CT myelography. MRI is extremely accurate in identifying the soft tissue extension, paraspinal lesions and cord compression (Fig. 4). In cases of multiple levels of involvement, CT myelography tends to be ineffective in demonstrating the whole length of the block. This is overcome by the MRI. Metastatic lesions tend to enhance with gadolinium and the extent of enhancement following treatment may be utilised to evaluate the response. In the thoracic spine, however, due to motion artefacts produced by heart and lung movements, MRI becomes less accurate. Similarly, MRI cannot be undertaken in patients with steel implants, aneurysmal clips and pace makers. CT myelography is useful in recurrent cases with steel implants *in situ*. The invasive nature of this investigation and the chances of neurological deterioration are its major drawbacks. CT delineates the bony margins better than the MRI, yet the soft tissue delineation is not of the desired order.

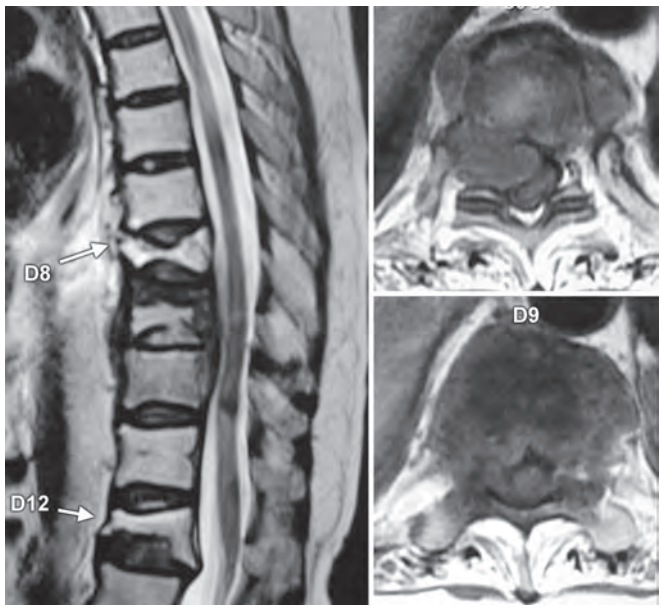


Fig. 4: MRI of the dorsolumbar spine of a patient treated for breast carcinoma showing multiple vertebral lesions with soft tissue component causing compression of the spinal cord suggestive of metastatic deposit

Tumour markers are increasingly being measured to evaluate for metastatic disease. Prostate specific antigen and carcinoembryonic antigen are routinely done and their levels are believed to correlate with treatment efficacy. Among other blood investigations serum electrophoresis, albumin to globulin ratio and gammaglobulin levels are performed for detection of myeloma. Alkaline phosphatase is usually raised in metastatic disease except in patients with multiple myeloma.

Percutaneous biopsy is useful in confirming the histological diagnosis of metastatic disease. However, the accuracy of the procedure has been found to be variable since, appropriate sampling is necessary for making the right diagnosis. This depends on accurately localising the lesion, taking the needle of the appropriate size for extracting sufficient quantity of sample and successfully evaluating the representative tissue. In cases where open biopsy is performed, the subsequent surgical plan should be kept in mind.

MANAGEMENT

The treatment of spinal metastasis has undergone modifications over the years with advancements in both the surgical and the conservative aspects. The indications for surgical intervention are being more clearly defined. With technological advancements radiotherapy can be given more effectively with lesser side effects. The other options are steroid therapy, hormonal manipulation and chemotherapy. Chemotherapy has a limited role since, it has not been found to reverse the neurological deterioration caused by compression. However, hypercalcaemia is a known complication of metastatic disease which is targeted by diphosphonates. Chemosensitive tumours such as osteosarcoma and germinoma form a subgroup where chemotherapy plays an important role in the management. Hormonal manipulation has been found useful in metastases originating from prostate tumours.

Steroids have been shown to partially reverse the neurological deficit caused by metastatic disease. Steroids are believed to prevent oedema and also have oncolytic activity. Some studies have shown that an initial high loading dose with gradual tapering is more effective in reducing oedema rather than administering low maintenance doses. However, steroids have significant side effects since, the duration of therapy tends to be prolonged. Similarly, when a patient is on steroids for a long duration and surgical intervention is being contemplated, wound complications and poor immunological responses need to be considered. Due to its high potency and salt retaining properties, dexamethasone is the drug of choice.[15]

Radiotherapy has been shown to have a definitive role in the treatment of compressive metastatic disease.

However, it is not helpful in arresting the clinical symptomatology in a patient with rapidly deteriorating neurological status. Matsubayashi et al. have shown normal bone formation in place of the tumour tissue following radiotherapy administration. Twenty to forty per cent of patients who previously were bedridden have been found to be able to walk following treatment, and this improvement was maintained up to one year.[28] There is significant relief of pain in up to 80% of the patients. The optimal dosage of radiation therapy is still not universally accepted. Approximately, 3,000–5,000 cGy given in daily fractions of 200 cGy over a 5-week period is recommended. In cases with multiple-level metastasis, the whole spine needs to be irradiated. For this, hemibody radiation is given first on one side followed by the other. With availability of proton therapy and IMRT, higher and more target specific radiation therapy can be given.

Radiation therapy has significant side effects both in the acute and long-term period. Early complications include severe neutropaenia, which is more common with upper body radiation. Radiation-induced myelopathy with poor prognosis is seen as a long-term sequel. Similarly, radiation induced malignancy is well-documented in the literature. To prevent these complications, it is important to keep the daily fraction of radiation within tolerable limits. The length of the spine to be irradiated should be defined and the interval of dosage should be reduced. The thoracic spine is more susceptible as compared to the cervical or lumbar region.

Surgical Management

Historically, posterior decompression in the form of laminectomy used to be performed for spinal tumours. Later on, it was realised that it is not more effective than radiotherapy and steroids given together. Also, this approach was helpful only for posteriorly located tumours. However, most of the tumours are anterior to the cord and cause anterior epidural compression. Gradually posterolateral, anterior and anterolateral approaches have gained wide acceptance. It has also been realised that mere decompression is not sufficient in cases where spinal instability results and spinal stabilisation is necessary.

The well-accepted indications for surgical intervention are:[27] (1) acute neurological deterioration; (2) progressive neurological deterioration while on conservative management; (3) persistent unbearable pain despite all measures; (4) extensive destructive lesions causing spinal instabiltity and (5) radioresistant tumour.

The aim of surgical intervention should not only be debulking the tumour, but also to realign the spinal elements with restoration of spinal stability. Pre-operative evaluation of the patient should be detailed and in cases having significant medical complications, which make the patient a poor candidate for withstanding the surgical procedure, conservative measures should be opted for.

For surgical decompression, laminectomy has been found to be ineffective. The posterolateral approach is often favoured as it allows tumour resection around the circumference of the dural sac and nerve roots bilaterally. This can be performed along the whole length of the spine and can be extended intra-operatively. Anterior approaches are particularly helpful for the cervical spine. In the thoracic and abdominal regions, the anterior approaches give good exposure, but anterolateral access is available on one side only.

Anterior Approaches

C1-C2 : Transoral/transmandibular
C3-C7 : Transcervical
C7-D1 : Trans-sternal/transthoracic
T3-T10 : Transthoracic/posterolateral thoracotomy
T11-L1 : Transthoracic, extrapleural, thoracoabdominal
L2-L4 : Retroperitoneal
L5-S1 : Transabdominal

Spinal stability needs to be maintained after the decompression. For this, bone grafting with instrumentation is the procedure of choice. Grafts can be autologous from the iliac crest, fibula or ribs. They can be artificial grafts made of hydroxyapatite, methylmethacrylate or ceramics. Instumentation procedures have undergone rapid development and rods, pedicle screws and cages are widely used. Spinal instrumentation, however, only provides temporary stability; bony fusion is necessary for long-term stability.

The most important factor affecting the prognosis is the ability to walk at the time of initiation of therapy, irrespective of the treatment modality. In other words, it is the pre-operative neurological status which determines the outcome. Loss of sphincter control indicates a poorer outcome.

105 Spinal Schwannomas and Meningiomas

Trimurti D Nadkarni

INTRODUCTION

Spinal cord tumours account for about 15% of central nervous system (CNS) tumours. Primary spinal cord tumours may be benign or malignant. Five to ten percent of primary spinal cord tumours originate from cells within the spinal cord parenchyma. The other 90–95% of primary spinal cord tumours arise from cells adjacent to the spinal cord, such as those of the spinal nerve roots or meningeal coverings. Meningiomas and neurofibromas are the most common benign intradural extramedullary spinal cord tumours.

HISTORICAL CONSIDERATION

The first successful surgical removal of an intradural spinal tumour is credited to Victor Horsley in 1887.[3] The tumour was a fibromyxoma and removed via laminectomy. More than 100 years later, despite vast improvements in imaging, anaesthetic care, and surgical instruments, the technique remains basically the same. At a meeting of Roswell Park Medical Club in 1908, Dr William C Krauss presented a paper, by invitation, on spinal cord tumours. The paper illustrated how nerves, motor and sensory were affected by spinal cord tumours.

The technique of intramedullary spinal cord tumour surgery as well as diagnosis and treatment of all spinal cord tumours was elaborated in detail by Elsberg in 1925.[1] After the landmark work of Elsberg in 1925, little progress was achieved in the field of spinal tumour surgery until the operating microscope was introduced. As a result of continual technical advancements since 1975 the safety and effectiveness of tumour resection has vastly improved resulting in better outcomes in patients undergoing spinal procedures.

CLASSIFICATION AND TERMINOLOGY

Spinal tumours are broadly classified as extradural or intradural based on their relation to the dura. Intradural spinal cord tumours can further be classified as intramedullary and extramedullary according to their relationship to spinal cord. A small number of spinal neoplasms can have both intramedullary and extramedullary components communicating through the nerve root entry zone. Similarly, some intradural tumours may extend into the extradural compartment through the nerve root sleeve.

Nerve sheath tumours are the most common type of intradural extramedullary (IDEM) spinal cord tumours accounting for 25–30% of all primary spinal cord tumours. Meningiomas account for 20–25% of spinal cord tumours.[15,18]

Epidemiology

Incidence

Nerve sheath tumours: Nerve sheath tumours are uncommon tumours in the general population with an annual incidence of 0.3–0.4 per 100,000 persons.[14,15] Nerve sheath tumours account for 40% of all intradural spinal cord tumours in adults.[5] In the spine, there is a male preponderance and the male to female ratio is 1.25 to 1.5:1, in contrast to intracranial and peripheral sites where there is a female predominance (1.5:1). The peak incidence of these tumours is in the fourth to sixth decade. Most are solitary schwannomas and occur proportionally throughout the spine.

With nerve sheath tumours, two tumour populations need to be distinguished which are schwannoma and neurofibroma. Schwannomas are more common and are the largest category of nerve sheath tumours. Whereas schwannomas are encountered in patients with neurofibromatosis (NF)-2 and in patients without NF, neurofibromas are found in patients with NF-1.[16] Most nerve sheath tumours arise from a dorsal nerve root. Neurofibromas represent a higher proportion of ventral root tumours and often exhibit a dumb-bell configuration.[15]

Meningiomas: Spinal meningiomas account for 25% of all primary spinal cord tumours and 12% of all meningiomas of the CNS.[11,17,18] They occur predominantly in the fourth to seventh decade; with a female to male ratio of 3.5 to 4:1. Females usually between the fourth and fifth decades account for approximately 80% of spinal meningiomas.[9,11,12,17] Spinal meningiomas occur predominantly in the thoracic region (82%), followed by cervical (15%) and rarely lumbar areas (2%).

Spinal meningiomas are mostly intradural and extramedullary in location. Extradural meningiomas account for 5% of spinal meningiomas and are more common in the younger age group. Multiple meningiomas are quite rare, but may occur in patients with NF.

Histopathology

Nerve sheath tumours: Nerve sheath tumours usually arise from the dorsal roots at various segmental levels of the spinal cord. They are avascular and globoid, and without calcification.

Neurofibromas and schwannomas merit separate consideration because of their distinct histological characteristics. Although electron microscopy and immunohistochemistry supports a common cell origin, the morphological heterogeneity of neurofibroma suggests participation of additional cell types like perineural cells and fibroblasts.

The gross appearance of a neurofibroma is of a fusiform enlargement of the involved nerve, without any identifiable nerve. Microscopically neurofibromas consist of an abundance of fibrous tissue and the nerve fibres are within the tumour substance.

Schwannomas appear as grossly smooth, globoid, eccentric masses with identifiable attachment to the nerve root from which they are arising. Microscopically, schwannomas consist of elongated bipolar cells with fusiform, darkly staining nuclei arranged in compact interlacing fascicles with a tendency towards palisade formation (Antoni-A). A loosely arranged pattern of stellate shaped cells (Antoni-B) is less common.[14,18]

Meningioma: Meningiomas usually arise from arachnoid cap cells located at exit zones of nerve roots or the entry zones of arteries into the spinal canal, accounting for their predominant lateral location.

Macroscopically they vary from smooth lobulated to a fibrous sheath like en plaque variety. Consistency can vary from soft friable, fleshy rubbery to stony calcified. The dural attachment is broader than expected. Unlike intracranial meningiomas spinal meningiomas never penetrate the pia. This simplifies surgical resection. Microscopically, meningothelial, fibroblastic and psammomatous are common histological variants found in spinal meningiomas. Atypical or malignant meningiomas are exceedingly rare in the spine.[13]

GENETIC ASPECTS

The genetic aspects of these benign spinal intradural tumours have extensively been studied during the past decade. A detailed genetic analysis of these tumours is beyond the scope of this chapter, but few points are mentioned that most researchers agree upon. Genetic alterations in the long arm of chromosome 22 play an essential role in the development of a meningioma. The chromosomal region involved has been localised to the centre of the long arm of chromosome 22 in the bands 22q12.3-qter. This is the same area that harbours the neurofibromatosis Type 2 (NF2) tumour suppressor gene. Other chromosomal abnormalities noted in meningiomas with clinical progression to malignancy include loss of heterozygosity (LOH) for foci on chromosome arm 1p, 9q, 10q and 14q.[4,8]

As with meningiomas, monosomy 22 is the most frequent cytogenetic abnormality in schwannomas. NF2 is defined by bilateral vestibular schwannomas. The NF2 gene codes for a protein called merlin (i.e. meosin-ezrin-radxin-like protein). Loss of expression of this protein was demonstrated in the pathogenesis of schwannomas and meningiomas.[4]

CLINICAL SYMPTOMS AND SIGNS

Spinal schwannomas and meningiomas are slow growing benign extramedullary tumours of the spine and typically present with slowly progressive signs of spinal cord compression. Pain is a common initial symptom in extramedullary lesions and usually is present for months before a diagnosis is established. Pain can have localising value in case of schwannomas as it arises from the dorsal sensory root producing radicular pain. Pain can also be an ill defined non-localising discomfort with multi-segmental involvement.

Most spinal cord tumours produce symptoms and signs due to a combination of local segmental and distant features. Segmental involvement of the dorsal root entry zone or anterior horn cell and roots result in specific sensory or lower motor deficit. Distant clinical features result from long tract involvement like corticospinal, spinothalamic and posterior columns. In general these tumours tend to arise eccentrically, lying on one side of the spinal cord either dorsally or ventrally. This eccentric tumour position results in asymmetric cord compression with higher incidence of Brown Sequard syndrome, i.e. ipsilateral involvement of corticospinal and dorsal columns with contralateral involvement of the spinothalmic tract. However, the clinical picture can be variable and inconsistent. Other factors, such as age, vascularity, relative size of the spinal column and tethering of structures, can modify the clinical picture.[14,18]

Specific clinical features related to the rostrocaudal location of tumours can be identified (for more details refer to chapter on Clinical Features and Diagnosis of Tumours of the Spinal Cord). Lesions of the upper cervical spine present with a unique syndrome which produces disproportional loss of dorsal column sensation in the upper limbs compared to the lower limbs, atrophy of intrinsic muscles of the hand, apart from variable involvement of long tracts below the level of lesion. Rarely, foramen magnum tumours can cause nystagmus due to pressure on sulcomarginal fibres. Increased intracranial pressure and hydrocephalus rarely occur with extramedullary tumours at any level, but are more common with upper cervical tumours. Involvement of the mid and lower cervical segments can lead to Horner's syndrome apart from long tract involvement. Involvement of the upper thoracic segments can cause girdle type pain, which is sometimes mistaken for pain of cardiac origin. Thoracic lesions produce sensory loss well below the actual level of the tumour.

Tumours of the lumbosacral and conus medullaris region of the spinal cord can affect parasympathetic innervations of the bladder, bowel and sexual organs. These symptoms can precede for months or even years the overt neurological deficits. Tumours of the cauda equina may selectively involve a single dorsal root causing persistent discrete dermatomal pain for many months and may be mistaken for disc prolapse. Worsening pain on recumbency is an important clinical feature of extramedullary tumours and is most commonly associated with large cauda equina tumours.

DIAGNOSTIC IMAGING

Magnetic resonance imaging (MRI) is the best imaging modality for diagnosis and evaluation of tumours involving the spinal cord. Intradural extramedullary masses, like meningiomas and schwannomas, compress and displace the spinal cord and cause widening of the adjacent cerebrospinal fluid (CSF) spaces. Gadolinium enhanced imaging increases the sensitivity of MRI in detecting small tumours.[18] Almost all spinal cord tumours exhibit some degree of contrast enhancement.

Spinal nerve sheath tumours, like schwannomas and neurofibromas, are difficult to distinguish on neuroimaging.[10] Both are isointense on T1-weighted images, have high signal on T2-weighted images and enhance with gadolinium (Figs 1 to 3A and B). Similarly, they can enhance faintly with iodinated contrast on computed tomography. Schwannomas can have cystic regions or fatty degeneration, whereas neurofibromas usually are homogeneous (Figs 4A, B and 5A, B). Nerve root tumours may have extradural extension through neural foramina giving them a dumb-bell shape (Fig. 6). Since these tumours are slow growing, bone remodelling can occur around them. MRI is the best imaging modality to characterise these lesions when the lesion is within the spinal canal. For lesions that extend into the plexus, MR neurography can localise and show the exact extent of nerve involvement.[7]

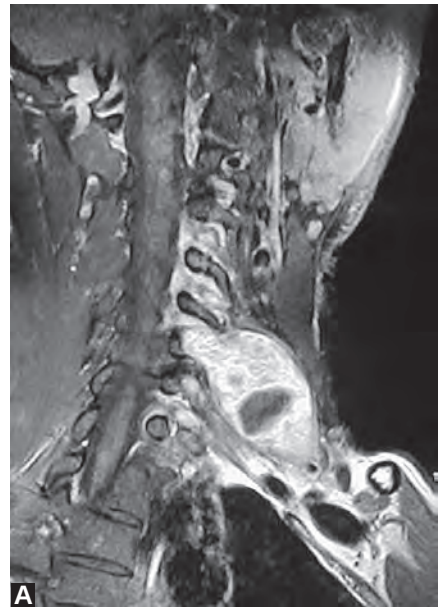
Imaging characteristics of spinal meningiomas are similar to their cranial counterparts with iso- to hypointense signal on T1-weighted images, hyper-intense on T2-weighted imaging and contrast enhancement (Figs 7 to 9). Meningiomas typically demonstrate intense uniform enhancement. Enhancement of adjacent dura strongly supports the diagnosis of meningioma. Peritumoral hypointensity is commonly seen around a meningioma which is due to CSF spaces.

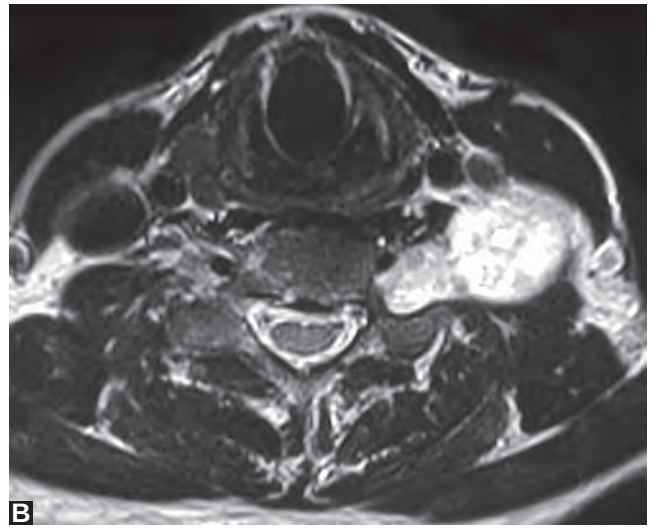
Myelography and CT myelography are rarely used presently with advancement in MR imaging.

Treatment

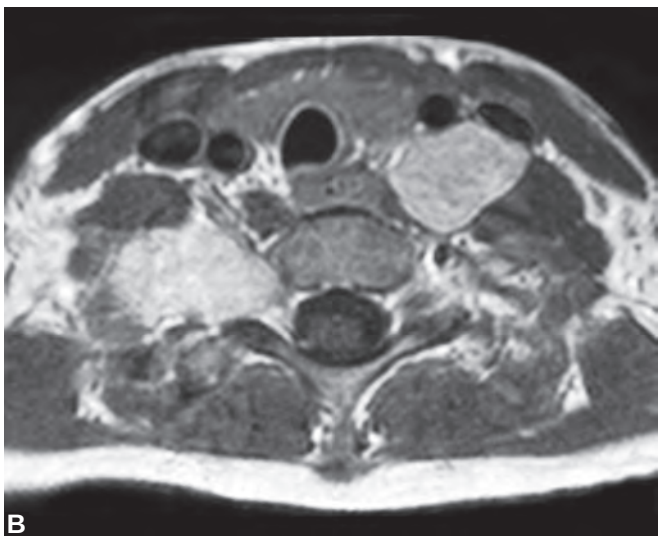
Surgical excision is the treatment of choice for benign intradural extramedullary tumours of the spinal cord. The goal of surgery is complete and safe removal, thereby

Fig. 1: Post-contrast T1-weighted sagittal MR image shows a lumbar (L4) schwannoma





Figs 2A and B: Post-contrast T1-weighted MR images. (A) Coronal. (B) Axial show a cervical schwannoma with a predominant extension along the nerve root outside the spinal canal



Figs 3A and B: Post-contrast MR. (A) Sagittal image shows multiple neurofibromas within the cranium, nerve root canals and soft tissue of the neck in a case of neurofibromatosis (NF1). (B) Axial image shows a neurofibroma within the nerve root canal on the right and another in the soft tissue of the neck on the left

decompressing the spinal cord and obtaining tissue for pathological analysis. Surgical principles employed elsewhere for removal of benign tumours also hold true for these benign extramedullary intradural spinal tumours like nerve sheath tumours and meningiomas. This includes patient positioning, optimum exposure, microscopic assistance, tumour debulking, preservation of normal neural elements and meticulous haemostasis.

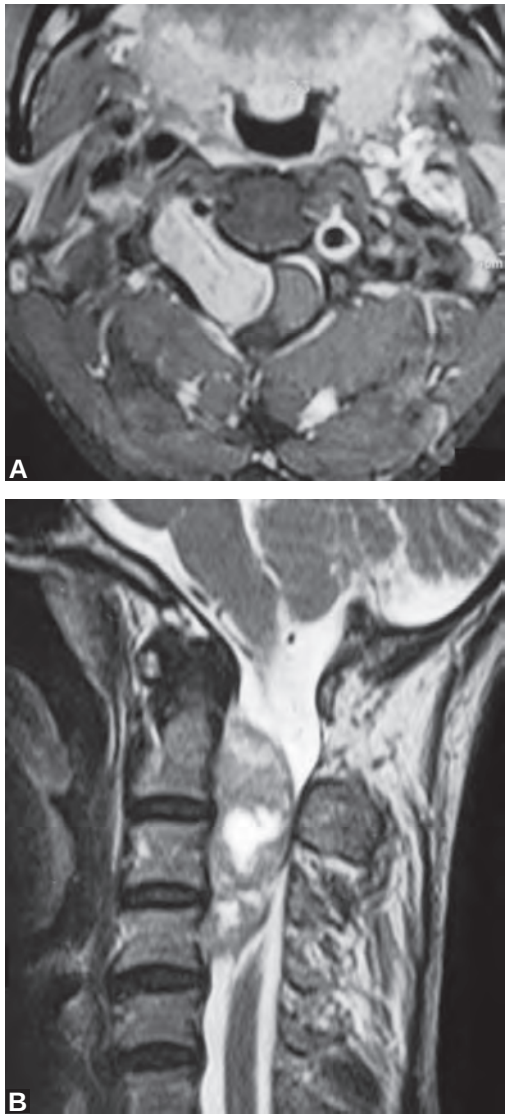
Pre-operative Preparation

Intra-operative electrophysiological monitoring of both motor and sensory tracts should be made available for the surgeon planning to resect an intradural extramedullary tumour. A Foley catheter and sequential compression device are routinely used. Pre-operative antibiotic to cover gram-positive bacteria and, steroids are routinely given.

Operative Procedure

A typical intradural extramedullary tumour is approached posteriorly through a posterior midline incision and multilevel laminectomy. This facilitates rostrocaudal extension as needed for resection of the tumour. The patient is positioned prone supported on chest bolsters. For tumours above the D2 level, the sitting position may be used as per the surgeon's preference. All pressure points should be padded adequately. There should be no compression of the genitals or abdomen in the prone position.

A standard laminectomy extending approximately one level rostral and one level caudal to the lesion usually provides sufficient exposure. Occasionally, a facetectomy or partial pedicle resection may be necessary to



Figs 5A and B: (A) Post-contrast T1-weighted axial MR image shows a cervical schwannoma extending from the spinal canal through the root canal. The tumour is entirely extradural in location. (B) T2-weighted sagittal image shows a large cervical cystic schwannoma

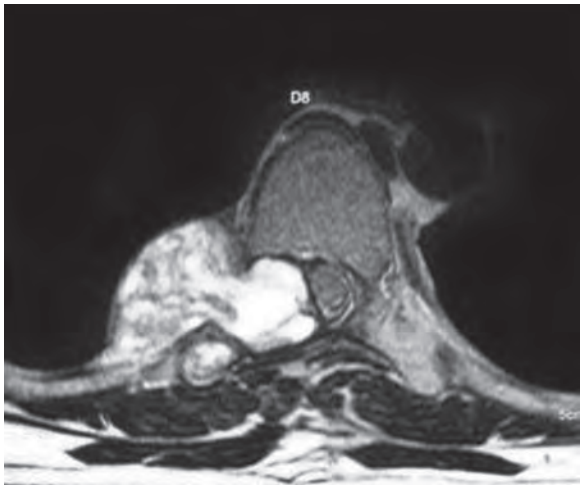


Fig. 6: Post-contrast T1-weighted axial MR image shows a dumb-bell shaped dorsal (D8) schwannoma that extends into both the spinal canal and the thoracic cavity

establish a ventrolateral corridor. Meticulous haemostasis must be achieved before durotomy. Collagen sponges (gel foam), oxidised cellulose strips (surgical) and collagen/thrombin suspension are all used to ensure a dry field prior to opening the dura.

A midline, linear dural opening is made carefully with double dura tooth forceps after making a small opening in the dura. Silk sutures are used to retract the dural sleeves by suturing them to the paraspinal muscles.

After the dura is opened, a careful inspection of the spinal cord and tumour is made. The arachnoid membrane is carefully opened over the entire extent of tumour. In a ventral or ventrolateral tumour, division of the dentate ligament would be necessary. After identification of the rostral and caudal poles of the tumour a cottonoid strip is placed to demarcate the tumour from normal spinal cord. Microdissection techniques are used to develop a plane, if possible, between the tumour and the spinal cord. Small tumours, particularly schwannomas, which tend to be associated with the dorsal roots can be removed after division of the entering and exiting roots. It must be kept in mind that temptation of having a trophy of en bloc total removal of even a medium sized tumour, specially those situated anteriorly, could result in regrettable neurological deficit. Large tumours require internal debulking and piecemeal resection. Internal debulking is done with graduated suction or sharp instruments depending upon the consistency of the tumour. The capsule is kept intact for counter traction and to keep a margin of safety from the spinal cord parenchyma. A portion of the capsule may be resected as internal volume is reduced for better visualisation of the tumour and its interface with the spinal cord. After the tumour has completely been resected the cavity is inspected to confirm complete haemostasis.

Nerve sheath tumours: Most nerve sheath tumours are dorsal or dorsolateral to the spinal cord and are well visualised once the dura is opened. Lumbar tumours may be covered by the cauda equina or conus medullaris. The nerve roots must be separated to provide adequate visualisation. Tumour removal requires identification of the proximal and distal end of the nerve root to which the tumour is attached. In large tumours, the site of origin may not immediately be apparent. The nerve root of origin usually must be sacrificed to remove the tumour. The corresponding intradural nerve root, however, can usually be preserved because the fenestrated arachnoid sheaths allow anatomic separation of the dorsal and ventral nerve roots to a point just distal to the nerve root ganglion.

Dumb-bell extension through the nerve root sleeve usually necessitates resection of the entire spinal nerve.[14] This resection rarely causes significant deficit as the function of this nerve root is already compensated by adjoining nerve roots. Significant extension into paraspinal tissues through an enlarged foramen may require an extended procedure. Although a two stage operation

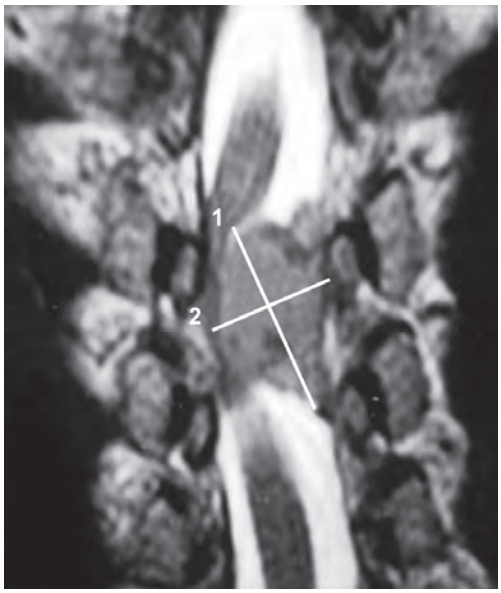

Fig. 7: T2-weighted coronal MR image shows a dural based meningioma displacing and compressing the spinal cord to the right. Note the widened adjacent cerebrospinal fluid spaces

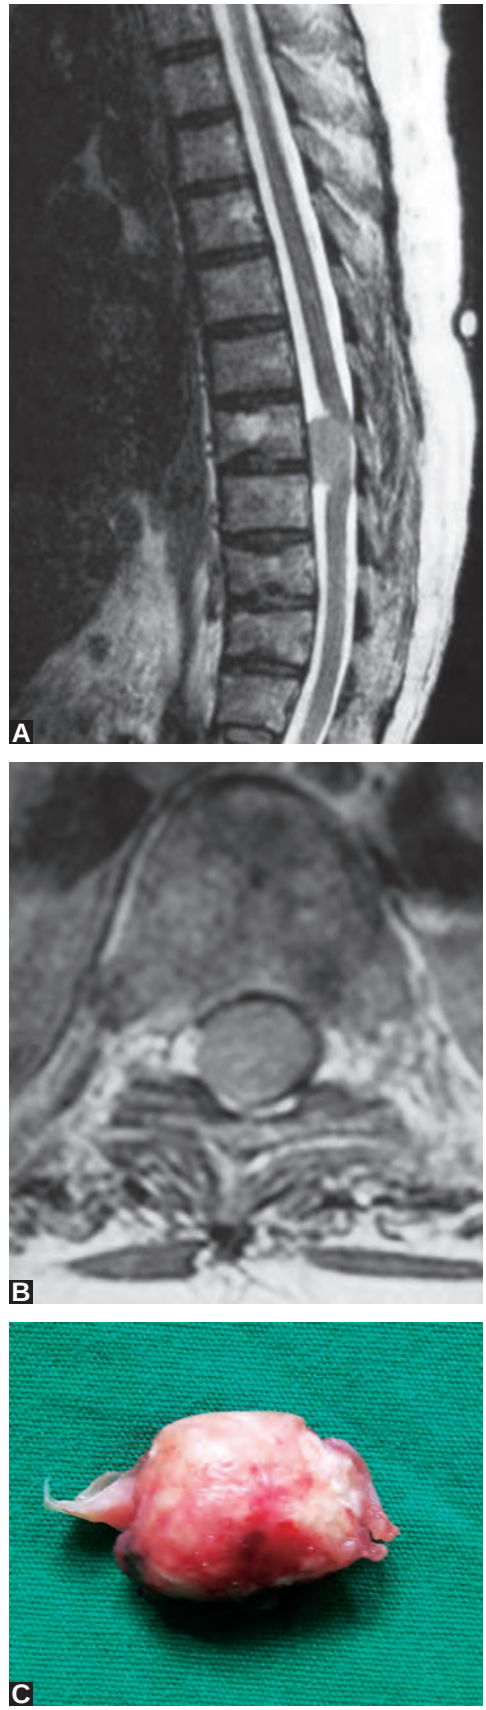
may be performed to manage separately the intraspinal and paraspinal tumour components, a single stage procedure is preferable. The cervical paraspinal region is difficult to access anteriorly due to the narrow confines of the neck and numerous neurovascular structures. Fortunately, most cervical tumours can be removed completely and safely by an extended posterior exposure. Complete unilateral facetectomy allows paraspinal access up to 3 cm. Paraspinal extension from thoracic tumour can be a small or a large mass in the thoracic cavity. A standard posterior approach provides inadequate exposure to the anterior paraspinal muscles. An anterior transpleural or extrapleural thoracotomy provides excellent visualisation of the paraspinal region. The lateral extracavitary approach is useful as a single stage operation in cases that require concomitant exposure of intraspinal and paraspinal compartments.[14] This exposure is achieved through a hockey stick incision and allows the surgeon to work on either side of the paraspinal muscles. Lumbar dumb-bell tumours can also be exposed well through a lateral extracavitary approach. Dumb-bell sacral tumours usually require both anterior and posterior exposures, which can be staged or performed simultaneously with the patient in the lateral position.

Meningiomas: A complete surgical excision is the treatment of choice for spinal meningiomas and can be achieved in more than 90% of cases. Despite favourable features, the recurrence rate of spinal meningiomas after gross total or near total excision is 10–15%.[11,17]

Posterior laminectomy provides adequate exposure in most cases. A unilateral laminectomy or facetectomy can be used for eccentrically located or ventral tumours. Most of the meningiomas displace the cord laterally and can be satisfactorily removed by the posterior route. The



Figs 8A to C: (A) T2-weighted sagittal MR image shows D8 meningioma. (B) Axial T1-weighted MR image shows the tumour to have nearly filled the entire dural sac. The cord cannot be distinguished separately from the tumour. (C) Postoperative specimen of the dorsal meningioma. A dural tail is noted on the right side

Fig. 9: Post-contrast T1-weighted axial MR image demonstrates a dorsal meningioma that has dural extensions (tail) extending on either side of the tumour

arachnoidal plane between the tumour and spinal cord can be easily identified and developed by gentle traction on the tumour away from the spinal cord. En plaque meningiomas tend to be associated with a significant amount of scarring rendering surgery more difficult.

The tumour removal involves correct identification and localisation. The rostral and caudal poles of the tumour should be identified. For lateral and ventral tumours, the arachnoid over the exposed tumour is incised and reflected so that dissection can proceed directly on the tumour surface. Large tumours are internally debulked and the tumour component adjacent to the spinal cord is delivered into the resection cavity using gentle traction and surface retraction. The remaining tumour is amputated from the dural attachment and the dural attachment is then excised wherever possible. If not possible, the involved dura is coagulated. Dural grafting may be necessary.

Management of the dural base is the most controversial aspect of treating spinal meningiomas. The options include excision of the involved dura and reconstruction with graft, or extensive *in situ* coagulation. However, in the recent literature, a significant difference in recurrence rates between the two procedures could not be established and the long-term recurrence rates range between 3% and 29.5%.[2,6,17] We prefer flush amputation of the tumour followed by coagulation of the dural origin.

Outcome and Prognosis

Spinal intradural and extramedullary tumours have a favourable immediate outcome and long-term prognosis. These tumours are benign, and if removed carefully and completely, the patient should be cured with an excellent long-term prognosis. Even patients with severe neurological deficit and cord compression can have marked improvement and long-term cure. It may take six months to two years to maximise the resolution of these deficits.

Nerve sheath tumours: The outcome of schwannoma correlates to the pre-operative neurological condition of the patient. The symptoms and signs of our patients improved in 95%. Total removal of neurofibromas and schwannomas that are not associated with neurofibromatosis is generally curative. However, tumours with extensive paraspinal involvement that are subtotally resected have a definite propensity to recur. Deficits resulting from sacrifice of the involved nerve roots are usually minor and well tolerated.[7,15,16,18]

Meningioma: The recurrence of spinal meningiomas after total extirpation is rare, and in most series the rate ranged from 1.3 to 6.4%.[9,11,12,17] The slow growth of spinal meningiomas and their presentation in patients at a late age contributed to the low recurrence rates. Significantly higher recurrence rates were found in cases of en plaque or infiltrating meningiomas, tumours with arachnoid scarring and in partially resected lesions. Klekamp and Samii have stated that patients in whom complete resection was performed, 29.5% experienced a recurrence within 5 years of surgery, whereas in all patients with partially removed tumours the lesion had recurred by that time.[6] In general, the course of a spinal meningioma appeared to be more benign than its intracranial counterpart. Mirimanoff et al. reported a recurrence rate of 13% at 10 years, which was far lower than those reported for convexity meningiomas (3% and 25% after 5 and 10 years, respectively) and parasagittal meningiomas (18% and 24% after 5 and 10 years).[11] Unlike intracranial meningiomas, there was no correlation between recurrence and resection of the dural attachment.

Although the optimal treatment for primary spinal meningioma was total microsurgical resection, some authors advocated adjunctive radiotherapy in cases of recurrent tumours. Its role as adjuvant therapy after subtotal resection is controversial due to the tumour's typically indolent nature. It has been indicated that radiotherapy should be considered after subtotal primary excision in cases of recurrent meningiomas, or as an alternative to surgery when the operative risk is too high due to co-morbidities or tumour location. Surgery is the preferred treatment in cases of spinal meningiomas because of its associated excellent functional improvement and low recurrence rates. Radiosurgery should be considered for the exceptional case of recurrent and symptomatic spinal meningioma.[6]

106 Intramedullary Tumours

Bhawani S Sharma, Manish S Sharma

INTRODUCTION

Intramedullary spinal cord tumours account for 15–20% of all intradural tumours and only 2–4% of all intrinsic tumours of the central nervous system.[34] The most common initial symptom is generalised back pain, which is very difficult to distinguish clinically from back pain due to musculoskeletal conditions. Patients are often diagnosed only after the development of neurological signs and symptoms that may occur later in the course of the disease. Early diagnosis is important, however, because surgical removal for most tumours is curative, and surgical results are best when tumours are smaller. Moreover, neurological deficits resulting from intramedullary spinal cord tumours are rarely reversible and surgical results strongly correlate with the patient's pre-operative functional status.

HISTORY

The first successful removal of a spinal cord tumour dates back to 1887. Gowers and Horsley are to be credited for this as diagnosis and localisation at that time was entirely clinical.[28,36] In 1925, Charles Elsberg in his seminal analysis of 119 laminectomies for spinal cord tumours recognised the role of cerebrospinal fluid (CSF) manometry and roentgenography in aiding clinical diagnosis. He reported 21% mortality in a cohort of 14 intramedullary tumours of whom only three could be removed completely.[12] This laid the foundation for the subsequently adopted conservative approach consisting of biopsy and adjuvant radiotherapy which lasted for more than a quarter of a century. The foundation for the current practice of aggressive surgical resection was laid by Fred Epstein who published good results after aggressive resection of intramedullary tumours in both paediatric and adult patients.[7,13] These results have further been validated by several other authors who gained enormously by the technological advances in neuroimaging, microsurgery and intra-operative neurophysiological monitoring. Aggressive resection of these lesions with acceptable peri-operative morbidity has become a more realistic treatment goal.[3,9,11,14,19,23,27,32]

AETIOPATHOLOGY

Intramedullary spinal cord tumours mostly have a glial origin as they are histologically and immunohistochemically similar to normal ependymal cells and astrocytes. The exact aetiology remains unclear but is perhaps linked to genetic mutations. This is especially so in patients with neurofibromatosis; patients with the NF1 gene may develop spinal astrocytomas, whereas patients with the NF2 gene are predisposed to spinal ependymomas. Patients who develop sporadic spinal ependymomas have also been shown to harbour somatic mutations in the NF2 gene.[32] Spinal haemangioblastomas too may occur as a consequence of mutations in the VHL gene in patients with von Hippel-Lindau disease and also in those patients without the syndrome.

HISTOLOGICAL SUBTYPES

Astrocytomas and ependymomas are the most common histological types of intramedullary tumours. In modern series', these occur in almost equal frequency in adults.[3,14,27]

Astrocytomas

Astrocytomas comprise 90% of paediatric (<10 years) and 60% of adolescent intramedullary tumours. These have a predilection for the cervical and cervicodorsal cord (60%) and are rare in the filum terminale.

This category covers all subtypes of tumours from Grades 1 through 4. These include but are not limited to low grade fibrillary and pilocytic astrocytomas, malignant astrocytomas, glioblastoma multiforme, gangliogliomas and rarely oligodendrogliomas. Most of these are Grades 1 and 2 fibrillary astrocytomas though 25% of adult astrocytomas may be malignant.[7,32]

Patients with neurofibromatosis 1 have been known to develop intramedullary astrocytomas.[21] Most astrocytomas are infiltrative. This makes tumour excision very difficult and highly morbid. Yet, some tumours may have a good plane of cleavage. This has led us not to favour the plan of a simple biopsy in all cases. A radical removal should always be the primary goal because a simple biopsy does not guarantee a fair neurological outcome. Failure to adequately sample the tumour, in the latter case, may lead to misdiagnosis.

Ependymomas

Some authors believe that ependymomas are the most common intramedullary tumours in adults.[23,18] It appears

that, as age increases, the incidence of ependymomas increases, whereas that of astrocytomas decreases. Histological subtypes include epithelial, tanycytic (fibrillar), subependymoma and myxopapillary variants.[32] Unlike astrocytomas, these tumours are associated with neurofibromatosis 2 and are usually well circumscribed.[21]

Haemangioblastomas

These benign tumours of vascular origin are commonly located in a dorsal or dorsolateral position under the pia mater. They account for about 3–8% of all intramedullary tumours and may be associated with von Hippel-Lindau syndrome in 15–25% of all cases.[32]

Lipomas

Lipomas in an intramedullary location comprise about 1% of all intramedullary tumours. These are commonly located subpially and become symptomatic in adulthood.[32]

Metastases

These account for fewer than 5% of all intramedullary tumours and are relatively rare as both the spinal cord blood supply and the volume of the cord are low. Commonest primaries are malignancies arising in the lung and breast.[10]

Miscellaneous Lesions

Melanocytomas, melanomas, fibrosarcomas, primitive neuroectodermal tumours and cavernous malformations all can occur in an intramedullary location within the spinal cord although this is exceedingly rare. Intramedullary location of dermoid, epidermoid and neurenteric cysts have also been described. Another important differential diagnosis of a mass lesion within the cord substance, especially in our country, is intramedullary tuberculoma and cysticercus cyst.[33]

Epidermoids, dermoids and neurenteric cyst can also occur. (See chapter on Congenital Tumours of the Spine)

CLINICAL FEATURES—SYMPTOMS

As elsewhere within the central nervous system, the signs and symptoms of intramedullary tumours are related to the site, level, pathology and biological progression of the disease. The initial complaints are likely to be non-specific which may explain the lag time to diagnosis of 3–4 years. The following comprise some of the more common presentations.

Pain

Pain and motor weakness are the most common presentations in adults and children. Intramedullary tumours produce an ill defined pain which is seldom radicular (except in cauda-conus lesions) but localises at the level of the lesion. It is said to be more prominent at night in the supine position. In a very young child, localisation of the pain may be difficult. A sudden onset of pain indicates either an osseous collapse or an intratumoural haemorrhage. In fact, the absence of pain in a patient with radiographic and clinical features of an intramedullary pathology may indicate a diagnosis of myelitis.

Motor Function

Intramedullary lesions classically produce a long segment lower motor neuron type of weakness at the level of the lesion with atrophy, hypotonia, areflexia and fasciculations, along with features of upper motor neuron weakness below the lesion. Weakness is maximal at the level of the lesion.

Sensory Abnormalities

Patients often complain of numbness which begins distally and then extends proximally. This often takes the form of "glove and stocking", "cape distribution" or "dissociated anaesthesia". Anaesthesia may predispose to trophic ulcerations, especially in the upper limbs in cervical lesions.

Autonomic Dysfunction

Urinary incontinence, especially in a toilet-trained child, is a significant symptom which merits a detailed clinical and radiographic examination. Myelopathic patients who develop a Horner's syndrome or early onset orofaecal incontinence should be suspected to harbour an intramedullary pathology.

Spinal Deformity

Scoliosis may be the earliest sign of an intramedullary tumour in a young child. Local lumps, spinal point tenderness and the presence of stigmata of spinal dysraphism are all indicators of underlying pathology.

CLINICAL EXAMINATION

A detailed clinical examination should narrow down the cause, possible aetiology and the level of the cause of myelopathy. Care should be taken to evaluate the fundus and cranial nerves too as intramedullary tumours may seed down from an intracranial pathology. High cervical lesions may also affect the lower cranial nerves and the spinal nucleus and tract of the trigeminal nerve. Rarely hydrocephalus may occur even in the absence of an intracranial pathology due to an elevated protein concentration in the CSF, arachnoidal fibrosis and subarachnoid metastases. This is more common in malignant spinal cord tumours.

INVESTIGATIONS

Imaging

Contrast enhanced MRI remains the investigation of choice for the patients with a suspected spinal tumour. It

is not possible using current MRI techniques to reliably differentiate between the above mentioned histological subtypes of the tumour. A few points that may help are described.

Most intramedullary tumours expand the spinal cord, are hypointense on T1- and hyperintense on T2-weighted sequences and enhance with contrast. Ependymomas are more symmetrical, enhance with contrast uniformly and are more frequently associated with polar cysts. Up to 65% of ependymomas may be associated with a syrinx.[29]

Astrocytomas tend to be poorly marginated, enhance heterogeneously with contrast and may be associated with intratumoural cysts and necrosis. Up to 20% of astrocytomas may be associated with a syrinx.[29]

Haemangioblastomas are intensely enhancing lesions located dorsally or dorsolaterally within the spinal parenchyma and may be associated with flow voids and large cysts or a syrinx out of proportion to the size of the tumour. The entire neuraxis should be screened, if this pathology is suspected.

Metastases and lymphomas may be associated with leptomeningeal enhancement. This sign also indicates tubercular, bacterial or fungal myelitis.

Lipomas are unmistakable because of their MRI signal characteristics and do not enhance with contrast.

Non-tumourous conditions to be differentiated against include syringomyelia, acute multiple sclerosis and tuberculomas.[1] A pure syrinx does not enhance with contrast and is often associated with a Chiari malformation. Acute multiple sclerosis usually does not produce cord expansion. Tuberculomas may appear hypointense on T2-weighted sequences.

Angiography

This investigation is seldom used in the investigation of intramedullary spinal cord tumours except to rule out an arteriovenous malformation. This may also be used to embolise haemangioblastomas pre-operatively.

MANAGEMENT

Rationale of Treatment

A surgeon's primary objective should be total tumour excision but this has to be tempered by the need to maintain motor, sensory and sphincter functions, especially when most patients will develop significant, possibly transient, neurological deficits after intramedullary tumour resection. Up to 20% of operated patients will develop permanent deficits.[23]

Patients have to be counselled extensively before embarking on a surgical exploration. Those with a poor functional status prior to surgery are unlikely to improve significantly. In addition, the risk of neurological dysfunction is highest in this category. Some surgeons do not consider surgery in patients with complete sensorimotor loss below the level of the lesion.

The ideal surgical candidate is a patient with a progressive neurological deficit who is still ambulant. Though the risk of inducing a significant neurological deficit in the immediate post-operative period is high (34.6–43.6%), more than half of all patients (14–31%) will recover significantly from this.[19,23,24,25,30] If left unoperated, the progress of neurological dysfunction is unceasing after motor deficits set in. This inevitably leads to total paralysis. Taking the natural history of the disease into account, the risks of surgery seem acceptable.

Surgical Management

The goals of surgery are total tumour removal with preservation of neurological function. These objectives cannot always be achieved because some tumours infiltrate adjacent neural structures and make total removal impossible without incurring an unacceptable loss of function. Even when a tumour is delineated clearly from normal spinal cord, removal may result in a permanent increase in neurological deficit.

Patients need realistic guidance, especially those who are functionally intact, continent and have minimal neurological deficits. These patients are likely to refuse surgery. They should be closely monitored for the development of new neurological deficits, the appearance of which will probably lead to consent for surgery.

Radical surgery for malignant spinal cord astrocytomas (WHO Grades 3 and 4) does not appear to be beneficial.[32] This diagnosis can only be established by histological examination of tissue obtained at surgery. It is important not to perform a limited biopsy in such a case as a sampling error, especially from the tumour-cord interface, may cause the lesion to be under graded or worse, misdiagnosed. Thus a generous decompression should be performed as it will eliminate this source of error, decrease the tumour load, diminish pain and enhance the effect of post-operative chemoradiotherapy.[26]

A realistic neurosurgeon should recognise that preservation rather than restoration of neurological function is a reasonable goal after intramedullary surgery.[32]

Pre-operative Management

Patients are usually administered intravenous steroids (dexamethasone 4 mg IV Q 6H) for 48 hours prior to surgery. Patients with high cervical lesions are instructed in incentive spirometry. The period to surgery must be used by the operating surgeon to prepare the patient psychologically for a likely post-operative neurological deficit that may potentially devastate his/her morale. We prefer to use intravenous methylprednisolone succinate in loading doses of 30 mg/kg at the time of induction followed by a maintenance dose of 5.3 mg/kg for the next 24–48 hours depending on the patient's post-operative neurological recovery.

SPECIAL INSTRUMENTS/TECHNOLOGY

Evoked Potential Recordings

At the very outset, it must be mentioned that there is no statistical evidence to support the use of evoked

potential monitoring in improving outcome after operation for intramedullary spinal cord lesions.[23] Some surgeons routinely monitor somatosensory evoked potentials (SSEP) during surgery by stimulating the median/ulnar nerves in the upper, and the posterior tibial or peroneal nerves in the lower limb with low-voltage electrical current and the evoked responses in the sensory cortex are recorded through scalp electrodes. Multiple responses recorded via scalp electrodes in the sensory cortex are averaged on a computer to generate a standard reproducible waveform. This waveform may be affected by the stimulus frequency, amplitude, patient temperature and the concentration and type of anaesthetic agent. SSEP recordings, while theoretically attractive, have several disadvantages. Patients with profound pre-operative sensory deficits may have absent or very low amplitude baseline SSEP traces to begin with. Of graver consequence is the fact that SSEP traces are generally affected 10–60 seconds after the dorsal columns are damaged. This lag period may result in irreversible surgical damage as SSEP changes are seldom irreversible unlike during scoliosis surgery when changes are frequently reversible by releasing the instrumentation. Another drawback of SSEP monitoring is that it does not correlate with corticospinal tract damage which is far more critical to the patient's post-operative functional status. Thus, injury may occur to the motor pathways without any change in SSEP. Motor Evoked Potentials (MEPs) recorded via EMG electrodes in the musculature of the upper and lower limbs after motor cortex stimulation by scalp electrodes aims to obviate this problem. Direct epidural recording of spinal cord motor and sensory pathways may be used for a more comprehensive assessment of intra-operative spinal cord function.[8] For these reasons, SSEPs are not routinely used during intramedullary surgery in our centre.

Ultrasonic Aspirator

One of the absolute indications for the use of the ultrasonic aspirator is intramedullary surgery. The advantages of this equipment are several. High-frequency ultrasonic waves are used to fragment the tumour, which is subsequently aspirated. The fragmenting intensity of the ultrasound and the suction power of the device can both be varied independently. This obviates the need to dissect the tumour sharply off the cord interface and lessens traction on normal tissue. This minimises cord manipulation and has helped to vastly improve outcome after surgery. However, great care must be exercised while using this instrument under direct microscopic vision as normal cord can easily be aspirated as well if the tumour capsule is breached. Newer models now include a pen type attachment that will only fragment tissue without aspiration. At low intensity, this device can be used as a dissecting tool, as it were, to gently peel off the tumour from its interface with the cord. Unfortunately, hard calcific tumours cannot be decompressed with this device.

Laser

The CO_2 laser has been used with varying degrees of success in the excision of intramedullary tumours. The advantage of laser is that it is haemostatic for capillaries and can help resect hard tumours impervious to ultrasonic aspiration. Its disadvantages lie in that it can indiscriminately vapourise normal tissue and often slices through larger venules and arterioles producing haemorrhage. It is also expensive and frequently cumbersome to use.

Tissue Vapouriser

This implement assists cold cautery and is used in our centre with a needle attachment to incise the pia over the dorsal midline of the cord substance. The advantage of this tool is that the incision is precise and the cut is made without charring.

Intra-operative Ultrasound (iUSG)

Ultrasound is a valuable tool which can be used intra-operatively prior to durotomy to determine whether the laminectomy/laminoplasty is adequate or else needs to be expanded. This saves time and ensures that the intradural part of the surgery is not interrupted by the need to increase the bony exposure. Likewise, after durotomy, iUSG can confirm the position, length and adequacy of the myelotomy.

SURGICAL STEPS

Positioning

The patient is positioned prone on a Wilson's frame such that he lies closer to the side of the operating surgeon. Some surgeons prefer to immobilise the head in a rigid pin fixation device to prevent pressure sores developing on the forehead and malar eminences. This system also ensures that there is no pressure on the globes of the eye. Pneumatic compression devices may also be used to prevent intra-operative deep vein thrombosis.

Bone Removal

Great care is taken to ensure that the marking of the spinous processes is correct. We rely on intra-operative C-arm to accurately map out the area of interest after the patient is positioned supine. Pre-operative marker X-rays may prove inaccurate in the prone position and the resulting inadequate laminectomy can unnecessarily prolong the operative procedure and demoralise the surgeon. Most surgeons prefer to perform an extensive laminectomy to ensure that the origins of the dorsal nerve rootlets are clearly visible on both sides and also that the lateral margins of the tumour can be adequately decompressed. Smaller tumours may be approached by a trap door laminoplasty, but the authors' personal experience with this approach has not particularly been favourable. A pneumatic drill is used in our centre to drill away the laminae till the ligamentum flavum and

epidural fat is clearly visualised. As the cord itself is bulky and the dura is compressed against bone, great care must be taken to ensure that a deficit does not result from careless bone removal itself. We use 2 mm size Kerrison upcuts to remove thin slivers of bone left behind after the use of the pneumatic drill. The laminectomy should encompass the rostral and caudal ends of the enhancing parts of the tumour as visualised on the mid-sagittal MR images. Polar non-enhancing cysts do not need to be excised but need to be encompassed by the laminectomy so that a clear plane of cleavage can be established at the outset itself. After bone removal, iUSG is used to confirm the adequacy of bone exposure.

Durotomy

We prefer to incise the dura under microscopic vision beginning from cranial and proceeding caudally using a pair of fine toothed forceps for greater control. As far as possible, the arachnoid mater is kept intact till the dura is hitched up with 4-0 silk sutures to the drapes. This prevents rapid dural decompression and the consequent epidural haemorrhage from obliterating the operative field.

Myelotomy

We perform the myelotomy using a tissue vapouriser as close to the dorsal midline as possible. This prevents inadvertent damage to the dorsal columns and the resulting severe incoordination because of the loss of proprioceptive function. We identify the midline not by the presence of the midline septum or a vein but by a line equidistant from the origins of the dorsal nerve rootlets on either side (Figs 1 and 2). This is so because the tumour might have rotated the cord and the true midline in any position is the landmark described above. This is another reason why an extensive laminectomy is preferred as we should be able to see both sets of nerve rootlets arising from an expanded spinal cord. This myelotomy is then deepened till the tumour is reached. The tumour is entered and biopsied using fine grasping or curette type forceps (Fig. 3). A part of the biopsy is sent for frozen section examination while the remainder is preserved in formalin for histopathology. The report of the frozen section is an additional guide for the surgeon regarding the aggressiveness of the contemplated surgical resection. If a large vein is present over the midline, it should be sacrificed without hesitation using either the tissue vapouriser on low coagulation mode or else with bipolar electrocautery as a paramedian incision on the cord can produce a significant neurological deficit. Unlike other experts, we do not routinely endorse the practise of holding the pia-arachnoid on either side of the myelotomy apart using 7–0 atraumatic nylon sutures as we believe this produces additional traction on an already compromised spinal cord.

Specific techniques of tumour removal are guided by the provisional radiological and histopathological diagnosis, but more importantly by the intra-operative plane of separation between the tumour and the normal cord.

Ependymomas

Ependymomas push the normal spinal parenchyma aside, are distinct from the surrounding spinal cord, usually with a well defined plane of cleavage and may be dissected from it. They are firm and reddish-grey or

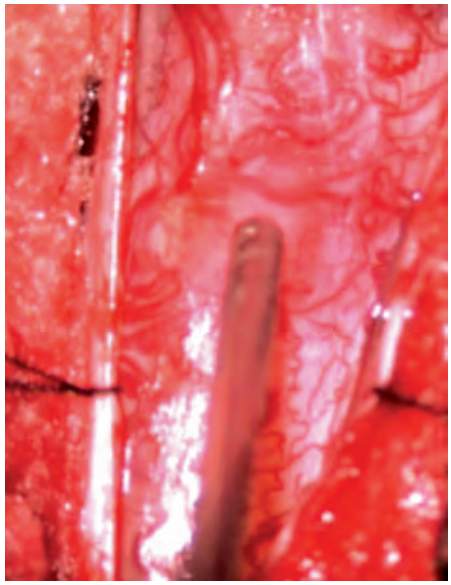

Fig. 1: Intra-operative photograph. Resection of a dorsal intramedullary ependymoma. The origins of the dorsal sensory rootlets indicate that the tumour has rotated the cord as they are not in the same plane. The suction catheter indicates the midline. The solid arrow designates the line of myelotomy over the expanded reddish spinal cord

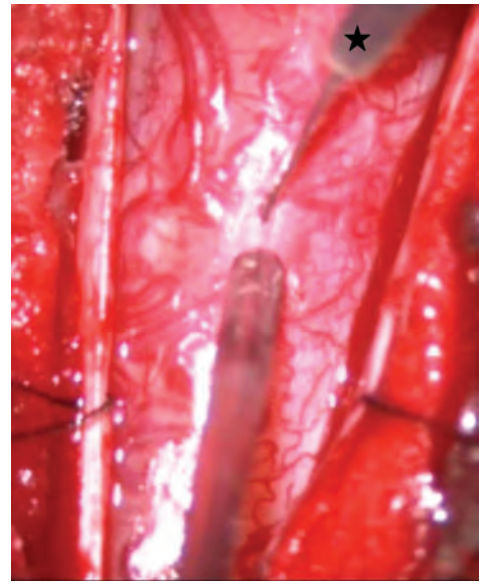

Figs 2: The tissue vapouriser (star) is being positioned to fashion the dorsal myelotomy along the midline indicated by the suction catheter. Intra-operative photograph taken at maximum zoom. The myelotomy has been commenced parallel to a large paramedian arterialised vein

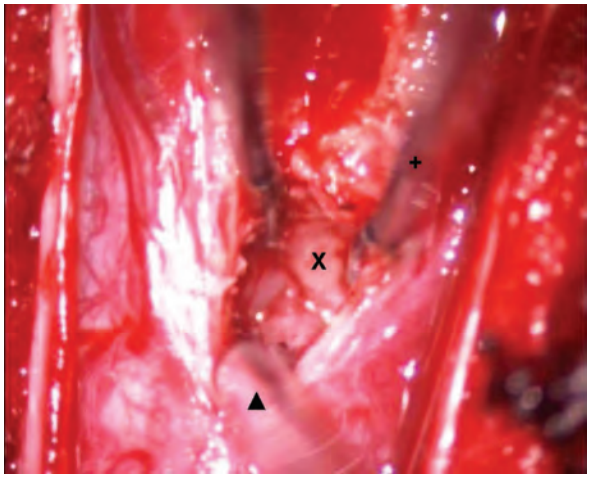

Fig. 3: A biopsy forceps (+) is being introduced through the dorsal myelotomy to grasp the ependymoma (X). The suction catheter (arrowhead) is being used to keep the myelotomy patent

yellow. Cysts may frequently be found at either end of the tumour. Smaller lesions often can be removed in one piece, but larger tumours should be debulked so that the blood supply which is located ventrally may be cauterised and cut before the tumour is finally removed (Figs 4 and 5). The ventrally located tumour should be dissected out with utmost caution using high magnification as the slightest breach of normal cord integrity will damage the ventrally located corticospinal tracts producing a catastrophic neurological deficit. If the cord-tumour interface is not clear, it would be prudent to terminate the procedure.

Astrocytomas

Spinal cord astrocytomas do not have a clear interface with the normal cord as they are infiltrating lesions. Subtotal excision is the accepted norm though some authors have found no difference in resectability vis-à-vis ependymomas. Unfortunately, recurrence after incomplete removal is common, and transformation to histologically malignant tumours has been noted to occur. Benign tumours with subarachnoid spread have also been reported.[8]

Malignant tumours (WHO Grades 3 and 4) are not amenable to complete resection. Extent of resection has not been associated with improved survival. Rapid recurrence and disabling subarachnoid spread is the norm with universal fatality before the first post-operative year.[4,5,20]

Haemangioblastomas

Haemangioblastomas may occur sporadically or in association with the VHL gene. These highly vascular lesions appear yellow-orange to bright red and are generally located subpially on the dorsal surface of the spinal cord as isolated lesions or in association with the VHL gene. These lesions have a clear demarcation from the rest of the cord and are amenable to total resection.

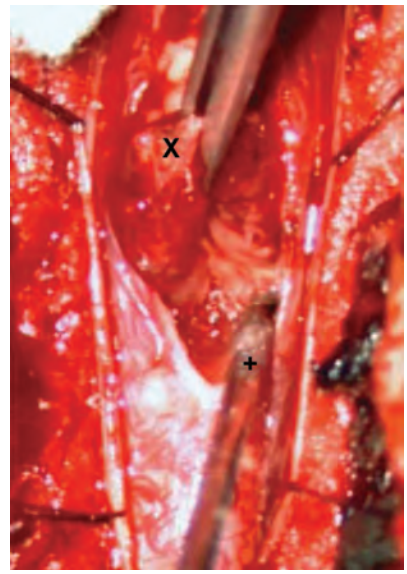

Fig. 4: The cranial apex of the tumour (X) has been grasped with the biopsy forceps and is being gently separated from the normal ventral corticospinal tracts by the suction catheter (+)

Microsurgical resection is performed along the same lines as that for AVM surgery. The lesion is not to be entered into at any cost. The arterial supply, which is usually evident, must first be interrupted before the tumour is shrunk using bipolar diathermy with copious saline irrigation. Patients have to undergo lifelong radiological surveillance to rule out recurrences locally as well as *de novo* in other parts of the cord.

Lipomas

Intramedullary lipomas are most commonly seen in the conus medullaris in association with a dysraphic spine. Isolated lipomas are very rare and are located on the dorsal surface of the thoracic or cervical spinal cord.

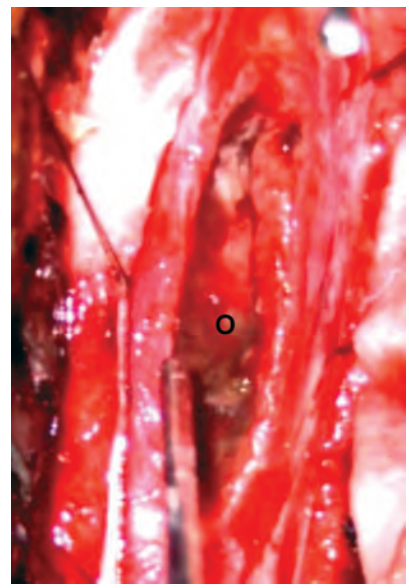

Fig. 5: The cavity formerly occupied by the tumour (O) is visualised through the myelotomy. Oxidised cellulose strips are used to ensure haemostasis

These tumours are indistinct from lipomas seen elsewhere within the human body and are clearly demarcated but densely adherent to the adjacent neural tissue. The acceptable surgical technique is a subtotal removal as these lesions are slow growing and are unlikely to recur after a generous debulking has been performed. Authors have reported using laser with great effectiveness as the performance of the ultrasonic aspirator is affected adversely by fibrous bands within the lesion.

Intramedullary Metastases

These represent less than 8% of all intramedullary spinal cord tumours.[5] The most common primaries are lung and breast carcinomas. In one third of all cases, the intramedullary metastasis may be the only sign of the primary. Progression is rapid and more than 80% of the patients die within 3 months of first seeking medical attention.[8] Operative management is similar to that for haemangioblastomas described above.

Closure

The pial hitch sutures, if used, are released. We do not close the pial incision or the myelotomy in our centre. Other authors believe this should be done to prevent cord tethering to the dura at the operative site.

A watertight dural closure is performed using a continuous interlocking 4–0 polydioxanone suture. If only debulking has been performed, a fascial patch duraplasty is essential to prevent spinal cord venous infarction. In malignant tumours, we sometimes leave the dura open to provide for an external decompression. In all cases, the wound is closed in several layers encompassing muscle, fascia and subcutaneous tissue. Vertical mattress nylon sutures are essential to close the skin incision.

POST-OPERATIVE MANAGEMENT

Methylprednisolone succinate is continued into the post-operative period for 48 hours at the rate of 5.3 mg/kg/hour. Proton pump inhibitors, antibiotics and precautions against deep vein thrombosis and pulmonary atelectasis are instituted in every patient. Patients with cervical intramedullary tumours are electively ventilated for 24 hours at the very least. Extensive physiotherapy (active and passive range of motion) is instituted from the first post-operative day. Air mattresses, two hourly change of posture, graduated compression elastic stockings, laxatives and care of indwelling Foley's catheter are routine aspects of post-operative care.

POST-OPERATIVE COMPLICATIONS

Neurological Deficit

Around 50–70% of patients undergoing intramedullary tumour surgery are likely to worsen neurologically. At least 20% of patients are expected to remain severely disabled. Patients with better neurological function fare better than those with poor function at presentation.[29]

The commonest neurological deficit that a patient is expected to experience is loss of joint and position sense as a consequence of the injury to the dorsal columns from the myelotomy.[23] The spinothalamic tracts may be injured during lateral dissection while the corticospinal tracts are vulnerable during the ventral separation of the tumour from normal cord. Though the benefits of SSEP appear intuitive, controversies abound as has been dealt with previously.

Neurological deterioration several days after surgery may be associated with tapering or withdrawal of corticosteroids. For reasons that remain unclear, a subsequent increase in corticosteroid dosage may not result in an improvement in neurological function.[8]

Wound Dehiscence

This dreaded complication occurs more frequently in patients who have either been previously operated upon or irradiated. An associated CSF leak may result in meningitis and a possible fatality. Management includes CSF diversion, debridement and primary resuturing or plastic reconstruction using rotational flaps of the trapezius or latissimus dorsi muscles.

Spinal Deformities

This delayed complication is seen more often in children and may result in thoracic or lumbar spine kyphoscoliosis or swan-neck deformity of the cervical spine. Its appearance in adults is unusual if it was not present pre-operatively. Causes include denervation of paraspinal muscles by the tumour or during surgery with a resulting unopposed flexion, especially in the cervical spine. Following a laminectomy, the paraspinal muscles also no longer have an osseous attachment. Severe flexion deformity may result in spinal cord kinking and dysfunction resulting in a delayed progressive neurological deficit which can mimic tumour recurrence. Re-exploration, instrumentation and fusion are indicated in this clinical situation.

ADJUNCTIVE TREATMENT

No study has demonstrated a beneficial effect of radiation therapy on neurological function or survival in patients with glial spinal cord tumours.[8,17] The efficacy of radiation therapy is difficult to determine because the natural history of the disease is unpredictable and long-term survival without radiation may occur. Moreover, most studies which have revealed a therapeutic benefit were not controlled.[16,35,37,38]

Most experts irradiate all adult patients with spinal cord astrocytomas, regardless of the completeness of removal or the histological grade of the tumour using 4,500 Gy given in divided doses.[8] Garcia noted improved outcomes in patients treated with 4,000 Gy compared with those treated with smaller doses.[15]

Most authorities do not irradiate paediatric patients after a gross total tumour resection. Radiation is reserved for paediatric patients with recurrent low-grade tumours or for those who have had rapid neurological progression of deficits.[8]

Patients with ependymomas should not be irradiated after documented complete excision. Recurrences should be dealt with by redo surgery and radiation if a residual tumour burden exists. When a residual tumour exists after surgery, radiation is an option if redo surgery is deemed risky.

The effectiveness of chemotherapeutic regimens using Carmustine and BCNU similar to intracranial astrocytoma management is not clear.

Regardless of tumour histology or grade of resection, all patients require lifelong surveillance with a contrast MRI of the craniospinal axis.

PROGNOSIS

Malignant intramedullary astrocytomas are considered universally fatal within one year. Median survival has been variously estimated at 6 months.[8] Patients with low-grade astrocytomas fare better but succumb to complications, such as respiratory paralysis, quadriplegia, pulmonary emboli, sepsis and pneumonia. Sandler et al. reported an actuarial survival of 68% at 5 years in 21 patients with spinal cord astrocytomas, of whom two were anaplastic.[31]

Patients with ependymomas do better than those with astrocytomas. Haemangioblastomas are benign tumours that are potentially curable if they are removed totally.

THE AIIMS EXPERIENCE

In a 4 years retrospective analysis of 75 patients operated upon for intramedullary tumours at our institute (2000–2003), 83% had motor, 77% had sensory and 41% of all cases had bowel and bladder dysfunction. Thirty-one patients had a pre-operative McCormick grade of 2. The commonest locations were cervical and thoracodorsal. All haemangioblastomas, 38% of astrocytomas and 36% of ependymomas were associated with a syrinx. Fourty-four patients (58.7%) underwent a total excision while 26 patients (34.7%) underwent a near/subtotal excision. The commonest tumours were ependymomas (33.3%), astrocytomas (28%) and epidermoids (8%). In children, the commonest tumours were astrocytomas while ependymomas occurred in the adults. There was no operative mortality. Seventeen patients (22.7%) experienced a neurological deterioration of at least one McCormick grade in the immediate post-operative period. At the time of last clinical evaluation, 33% had improved while 9.3% had deteriorated. Outcome correlated statistically only with the pre-operative neurological status. Sex, age, tumour location, histopathology, extent of tumour resection and the presence of a syrinx did not correlate with outcome. This is in agreement with other series.[8,29] Cristante et al. reported clinical improvement in 20% of the operated patients, while 50% deteriorated after surgery.[11] Constantini, in his series of intramedullary tumours in children under the age of 3 years, found that only 16% improved while 25% deteriorated.[6] Brotchi et al. on the other hand reported improvement in 53% of all cases while 10% worsened.[2] Similarly, Maira et al. in a series of cervical intramedullary tumours found that 63% of surgically treated patients got better while only 6% worsened.[22]

Illustrative radiology (Figs 6A to D) depicts total excision.

CONCLUSION

Although advances in imaging and microsurgery have revolutionised intramedullary spinal cord oncological surgery, these tumours pose a formidable challenge to most experienced neurosurgeons. Intramedullary ependymomas and haemangioblastomas are potentially curable through surgery. However, most spinal cord astrocytomas are locally infiltrative and not totally resectable. Malignant spinal cord astrocytomas are universally fatal and recur frequently. The role of adjunctive therapy still remains poorly defined.

107 Congenital Tumours of the Spine

CE Deopujari, AB Kakani

Congenital tumours of the spine usually cause progressive impairment of lower extremity and bladder or bowel function in an insidious manner through compression or by cord tethering. These tumours are a result of defective embryogenesis and may or may not be evident at birth. Surgical intervention for excision of these tumours to relieve the compression or to release the tethering of the cord is helpful in preventing or reversing neurological deficit. Tethered cord syndrome has been covered in other chapters and further discussion will, therefore, be restricted to lesions mainly presenting with compression.

Tumours or tumour-like conditions that may affect the spinal cord congenitally are dermoid and epidermoid cysts, teratomatous tumour, lipoma, neurenteric cyst, arachnoid cyst, hamartomas, cavernomas and angiolipomas. Occasionally, astrocytomas may occur congenitally.

EPIDERMOID AND DERMOID CYSTS

Epidermoid and dermoid cysts account for less than 2% of all central nervous system (CNS) lesions, the cranial to spinal ratio being 6:1.[38] However, these lesions make up to 17% of all spinal cord tumours in children. The pathogenesis of spinal epidermoid and dermoid cysts, as mentioned by Dias and Walker, is mainly congenital, the origin being epithelial tissue displaced during closure of the neural tube between the 3rd and 5th week of gestation.[19] Repeated lumbar puncture, especially multiple lumbar punctures done in the same patient, such as in the treatment of tubercular meningitis or lumbar puncture done without a stylet in the needle, is an acquired cause for occurrence of similar tumours which are then called implantation dermoids.[31,68] Such cysts are also reported to develop after surgery or trauma.

Unlike true neoplasms, which grow by progressive cell division, epidermoid and dermoid cysts enlarge by desquamation of normal cells and secretions of dermal elements into the cystic cavity. The cysts contain keratinous material arranged in a lamellar fashion. The outermost layer which is homogeneous gives this tumour its beautiful pearly sheen. Diagnosis of epidermoid and dermoid cysts is usually based on the characteristic nature of their contents revealed by histological examination.[38] Both the cysts are lined by stratified squamous epithelium supported by an outer layer of collagenous tissue. The differentiation between the two is made by the fact that the lining of the dermoid cyst also contains dermal appendages such as hair follicles, hair, sebaceous glands and occasional sweat glands. It is for this reason that dermoid cysts may contain hair. The connective tissue capsules that are located within the spinal cord are surrounded by a zone of reactive gliosis.

The location of spinal epidermoid and dermoid cysts is variable, more common sites being the lumbosacral (involving the conus medullaris and cauda equina) and thoracic area.[30] Only a few reports of cervical epidermoid and dermoid cysts have been reported.[58] These may be either extradural, intradural extramedullary or intramedullary in location within the spinal cord. These tumours are soft with a pliable capsule and grow very slowly. As the cyst increases in volume, it conforms in shape to any available cerebrospinal fluid (CSF) space and thus it attains a large size without producing any symptoms from compression of neural elements. These tumours thus become apparent usually in the second decade of life.

Around 50% of spinal epidermoid and dermoid cysts are associated with other congenital anomalies of the spinal cord, vertebrae, overlying soft tissue or skin.[48] This may be in the form of posterior spina bifida occulta, hypertrichosis and similar other dermal abnormalities, especially posterior dermal sinuses. The latter anomaly may predispose to recurrent pyogenic meningitis, and should actively be sought while operating upon a patient with an epidermoid or dermoid cyst. The presence of these cutaneous markers aids in early diagnosis of these tumours. The occurrence of these anomalies in association with these tumours further strengthens the theory of these lesions being of developmental origin.

The clinical presentation may not be different from other space occupying lesions of the cord and includes backache, progressive weakness in the lower limbs, bladder or bowel symptoms and sensory dysfunction. Leakage of the cyst contents in the CSF space is associated with recurrent episodes of aseptic meningitis.[6] Constant irritation caused by this keratinous material is also responsible for spinal arachnoiditis. This allows the capsule of the cyst to intimately adhere to the surrounding tissue and any attempt at complete removal under such circumstances carries a high-risk of neurological injury.

With the advent of MRI, the pre-operative diagnosis of these lesions has become much easier.[60,75] MRI has become the investigation of choice for early detection of these tumours. These cysts are typically isointense to slightly hyperintense compared to CSF on all sequences. Occasionally, the capsule may show enhancement on administration of contrast. The disparity in signal intensity most likely reflects variable lipid and protein composition in these lesions (Fig. 1). Other radiological characteristics of these tumours include absence of oedema in the surrounding spinal cord. Kukreja et al.[42] have evaluated the role of diffusion weighted MRI in differentiating spinal epidermoid-dermoid cysts from arachnoid cysts and have suggested that this technique may be useful in the evaluation of these lesions.

Ideal treatment of these lesions consists of complete surgical excision including excision of the capsule. Many epidermoid and dermoid cysts have a clear plane of cleavage between their lining membrane and the arachnoid membrane, enabling the surgeon to excise them totally. However, in some cases, due to the granulomatous reaction, the cyst lining becomes nodular and becomes densely adherent to the surrounding structures. Any attempt at complete excision in such cases increases the risk of neurological impairment.[11] In such circumstances, it is wiser to excise the easily separable portions of the capsule, leaving behind the densely adherent portion. Lunardi et al.[47] in his series of 16 patients, left the capsule partially *in situ* in 9 patients and in the follow-up study up to 30 years, only one of his patients showed recurrence. Maiuri et al.[49] have also demonstrated that even partial resections of spinal epidermoid and dermoid cysts to avoid neural damage results in a good clinical outcome and a very low risk of recurrence. Use of the operating microscope, good knowledge of surgical anatomy, gentle handling of the tissues, intraoperative monitoring of evoked potentials, use of CUSA and LASER allows many tumours to be excised totally. Spilling of the contents into the subarachnoid space should be avoided as the cholesterin and desquamated keratin act as irritants and cause aseptic chemical meningitis and arachnoiditis. Peri-operative use of steroids and intra-operative use of steroid containing irrigation fluid is believed to help in alleviating the chemical irritation.[6]

Fig. 1: Lumbar intradural epidermoid cyst (lipomatous lesion just above the cyst)

SACROCOCCYGEAL TERATOMA

Sacrococcygeal teratoma, the most common congenital tumour,[33,79] is a very rare tumour occurring congenitally with an incidence of approximately one in 40,000 births. Almost 75–85% of these tumours occur in females.[8,65,76] The exact aetiology for the occurrence of sacrococcygeal teratoma is not clear but it is thought that this tumour arises from totipotent cells of the primitive knot.[20,34] Another theory suggests that the teratoma is an abortive attempt at twinning. Well-defined body parts attached to these tumours suggest an incomplete conjoined twin.[20,34]

Sacrococcygeal teratomas are now increasingly being recognised antenatally with the use of foetal sonography which may reveal foetal hydrops, placentomegaly or polyhydramnios.[44] The foetal hydrops, as postulated by Langer et al.[44] results from high output cardiac failure caused by arteriovenous shunting within the tumour. They even demonstrated reversal of foetal hydrops by foetal surgical excision of the mass at 24 weeks' gestation. Danzer et al.[16] have demonstrated that ultrafast foetal MRI characterises the intra-abdomial and intrapelvic extensions of the tumour more accurately as compared to foetal sonography and provides more information on the compression of the surrounding structures. This additional information helps in better pre-operative planning in these cases.

Other reported presentations during the perinatal period include renal failure and respiratory distress,[55] trauma during delivery resulting in rupture or severe haemorrhage,[8,53,66] spontaneous rupture resulting in severe foetal anaemia,[79] consumption coagulopathy and steal syndrome.[53]

Clinically sacrococcygeal teratomas may entirely be asymptomatic or may present at birth as huge masses extending out from the sacrum and coccyx. However, a few cases may entirely be intrapelvic or presacral and can only be identified on rectal examination. Altman et al.[1] have classified sacrococcygeal teratomas into four types. Type I—primarily external with a minimal presacral component (47%). Type II—presenting externally, but with a significant presacral component (35%). Type III—tumour apparent externally, but the predominant mass being pelvic with abdominal extension (9%). Type IV—presacral without an external component (10%).

The presacral component may sometimes be large enough to cause compression of the urinary or gastrointestinal tract resulting in obstructive uropathy and chronic constipation.

Altman et al.[1] reported an 18% incidence of associated anomalies. The Currarino triad of anorectal anomalies, anterior meningocoele and presacral teratoma has also been described.[35,40] Delayed detection of teratoma in adult life has also been reported.

Pathologically a teratoma contains elements from all three primitive germ cell layers. The sacrococcygeal region is the most common site of occurrence of these tumours, the second most common being the gonads. They may be solid or cystic, but mostly are made up of both components. Actual organ formation has rarely been described, but tissues from any organ in the body can be detected in these tumours. Dehner,[17] who has described the histopathology of teratomas extensively, describes them as having "one or more somatic tissues in haphazard arrangement with little evidence of organisation".

These tumours present in three distinct forms: (1) entirely mature adult type tissue, which is clearly benign; (2) a mixture of mature and embryonic tissue, the latter often having malignant potential and (3) tumours containing frankly malignant tissue. Most series report an overall malignancy rate of 25–30%.[65,76] The longer the tumour remains after infancy, the higher are the chances of developing malignancy so that by one year of age well over 50% are frankly malignant.

Clinical diagnosis of sacrococcygeal teratoma may not be difficult; however the externally presenting tumour must be distinguished from lipoma and a low myelomeningocoele. Sacrococcygeal teratoma in the presacral region is unfortunately seldom discovered during early infancy and it needs to be differentiated from anterior meningocoele, rectal duplication or other tumours like neuroblastoma.

The only curative treatment for sacrococcygeal teratomas is complete surgical excision. The role of chemotherapy and radiotherapy in these cases is not well defined. Donnellan and Swenson have stressed the importance of complete coccygectomy in these patients.[20] None of the 51 patients with benign teratomas showed any recurrence after complete coccygectomy in their series. However, there are instances where the tumours with all mature elements have recurred despite complete excision with coccygectomy.[17] Some tumours with predominant presacral or intrapelvic components may require an additional abdominal approach for complete excision.[25] Cowles et al.[14] have described the use of pre-operative angio-graphy with embolisation and radiofrequency ablation as useful adjuncts to surgical excision of giant hypervascular sacrococcygeal teratomas. Kaneyama et al.[36] have demonstrated the use of Ligasure vessel sealing system for controlling intra-operative haemorrhage. With careful technique and a team approach including the urosurgeon, colorectal surgeon and oncosurgeon, it is usually possible to remove most of these tumours without rupture or excessive blood loss, but the obviously invasive malignant tumours cannot be removed so easily.[28]

LIPOMA

Spinal lipomas are usually associated with dysraphism, in which the intraspinal component communicates with a subcutaneous lipoma through a defect in the posterior elements of the spine.[7] Nondysraphic true intradural spinal lipomas must be differentiated from cauda equina lipomas or lipomas associated with dysraphism. The clinical, radiological and surgical problems raised by these tumours are totally different. These tumours, also known as subpial lipomas, are unique in that they may occur anywhere in the spinal canal, unlike lipomas associated with spinal dysraphism which occur predominantly in the lumbosacral region.[26] The dural layer is intact in true intradural lipomas and there is no tethering of the cord. The origin of these tumours is poorly understood but is thought to have an embryological basis. As mentioned by Finn and Walker,[26] one of the earliest theories put forwards by Virchow was based on the observation that adipocytes were present in the normal meninges and that spinal lipomas resulted from the hyperplastic overgrowth of these cells. It is postulated that lipomas develop when there is premature dysjunction of the cutaneous ectoderm from the forming neural tube.[7] The surrounding mesenchyme migrates into the developing neural tube and differentiates into fat.

True intradural lipomas are rare, accounting for less than 1% of all spinal tumours.[45] In literature, these tumours are represented as scattered case reports of 1 or 2 cases. Lee et al.[45] have reported a series of six cases where most of the patients were young adults, and the tumours were mostly located in the cervical region. Bhatoe et al.[7] have reported 14 patients with nondysraphic spinal lipoma with almost similar statistics.

Patients with lipomyelomeningocoele can generally be identified at birth because of the subcutaneous fatty masses or one or more cutaneous markers of spinal dysraphism.[9] However, in patients with nondysraphic spinal lipoma, the cutaneous anomalies are generally absent and the clinical presentation is usually with symptoms secondary to mass effect owing to the size of these lesions and not due to tethering of the cord. These tumours present with symptoms of progressive myelopathy including gait difficulties, motor weakness, dysaesthetic sensory symptoms and sphincter incontinence.[45,61] Acute neurological deterioration has also been reported. Infants and children on the other hand often develop tetraplegia or are diagnosed as floppy infant syndrome.[52] Clinical presentation simulating muscular dystrophy[21] and development of scoliosis[39] is also reported. Fujiwara et al.[27] have reported gradual deterioration in symptoms during pregnancy and after delivery.

MRI is the investigation of choice to diagnose these lesions pre-operatively.[7,27,45] Hyperintensity seen on T1-weighted images is very characteristic of fat, and further confirmation can be obtained by fat suppression studies. The lesions are usually located in the dorsal aspect of the cord in the cervical or thoracic region (Fig. 2).

The treatment of these lesions, like any other intramedullary lesion, is challenging. These tumours are not truly intramedullary but only subpial. Complete

Fig. 2: Lipoma presenting with mass effect in lower dorsal spine

surgical excision carries the risk of neurological impairment and hence partial decompressive resection is recommended.[7,27,45,50,61] Improvement in neurological status of the patient following surgery is exceptional; however, the pain disappears due to relief of pressure on the dorsal columns. Intra-operative ultrasonography may be useful to delineate the extent of the lesion as lipomas are anechoic.[7] LASER vaporises the fatty tissue without physical manipulation of the neural tissue and is an important adjunct in the surgery.[7] Long-term results of surgical treatment are satisfactory and no recurrences have been reported so far following surgery.

NEURENTERIC CYST

Neurenteric cyst,[5,15,32,41] reported in the literature by variable names as an enterogenous cyst, enteric cyst, gastrocytoma, dorsal enteric fistula, split notochord syndrome and teratoid cyst, is an infrequently reported congenital anomaly believed to be derived from an abnormal connection between the primitive endoderm and the neuroectoderm during the third week of gestation. These cysts may be found within the brain, in the cerebellopontine angle, mediastinum, abdomen and pelvis or even in a subcutaneous location, but are more frequently located in the spinal canal.[24,51] Intraspinal neurenteric cysts account for less than 0.5% of all spinal tumours.[51]

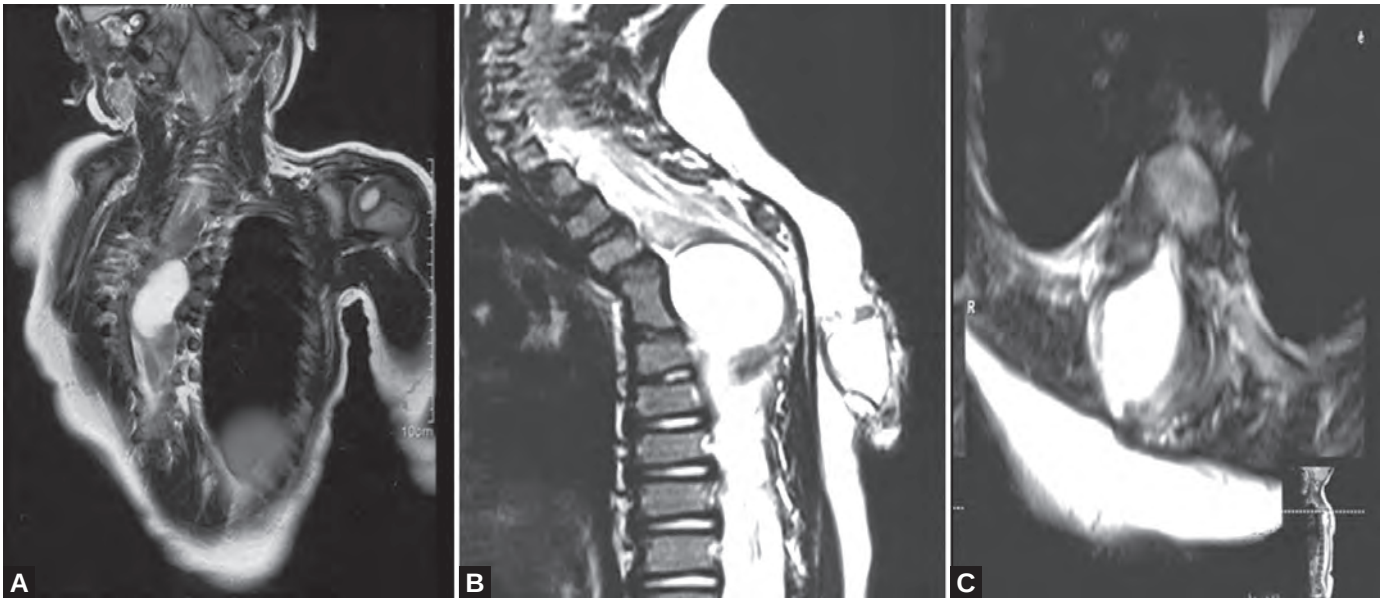
A number of theories have been proposed to explain the occurrence of endodermal tissue in the CNS. In the trilaminar germ disc formed during the third week of development, the outer layer, the ectoderm, faces the amniotic cavity and the inner layer, the endoderm, faces the yolk sac in the opposite direction. Between these two layers lies the mesoderm which gives rise to the notochord. The neurenteric canal is a temporary direct connection between the yolk sac and the amniotic cavity through the primitive pit, thus connecting the anlagen of the spine and gastrointestinal tract. Therefore, malformation at this stage of development results in combined anomalies of the vertebrae, spinal cord and the gut. The embryological basis of development of neurenteric cysts has been detailed by Rauzzino et al.[62] Patients with neurenteric cysts usually present in the first two decades of life,[43] although infrequent presentation well into adulthood is also reported.[70] The common location of these cysts is the cervical or thoracic region however, these cysts may occur at any location in the spinal canal from the craniovertebral junction[23] to the lumbosacral region.[80] Most of the cysts are located anterior or anterolateral to the cord, the dorsal location being less frequent. These may appear as intradural extramedullary masses or rarely as intramedullary lesions[70] (Figs 3A to C).

Pathologically these cysts vary in complexity and composition. Wilkins and Odum[78] have classified these lesions on the basis of the histological features of the cyst wall and its contents. The walls of Type A cysts mimic gastrointestinal or respiratory epithelium with a basement membrane supporting single or pseudostratified cuboidal or columnar cells, which may be ciliated. Type B cysts also contain glandular organisation, usually producing mucin or serous fluid. Type C cysts are the most complex containing ependymal or glial tissue within the cyst. The World Health Organization has classified these cysts under the heading of "other malformative tumours and tumour-like lesions" and has described them as cysts "lined by mucin secreting epithelium resembling that of the gastrointestinal tract".[81]

Neurenteric cysts are associated with multiple anomalies at single or multiple levels including scoliosis, fused vertebrae, hemivertebrae, Klippel Feil anomaly or spina bifida.[62] Cutaneous stigmata, as with other forms of occult spinal dysraphism, also occur in association with these cysts.[69] Other reported associations include intradural lipoma, a meningomyelocele[57] and syringomyelia.[12]

ARACHNOID CYST

Intradural spinal arachnoid cysts are amongst the rarest causes of spinal cord compression. They have been described by various names including arachnoid diverticula, subdural arachnoid cysts, leptomeningeal cysts, meningeal hydrops and arachnitis cystica. These are congenital collections of CSF contained within the arachnoidal membrane and subarachnoid space. The origin of arachnoid cysts is still a matter of debate, but most of the cysts are thought to arise as developmental anomalies. Very few are associated with other causes like neoplasm, arachnoiditis,[29] trauma[13] and surgery. Tumialan et al.[73] have reported a case of T1-T2 arachnoid cyst developing after subarachnoid haemorrhage. There are many theories in the literature to explain the development and expansion of these cysts. Basaldella et al.[4] have summarised these theories: (1) a ball valve mechanism, i.e. a possible anatomical communication between the cyst and the subarachnoid space that can act as a one way valve mechanism responsible for cyst enlargement; (2) an osmotic gradient between the intracystic and the extracystic medium responsible for a gradient driven



Figs 3A to C: Thoracic neurenteric cyst with split cord

fluid transport (this theory lacks support because of the compositional similarity between the CSF and contents of the cyst); (3) a primary malformation of the arachnoid membrane and (4) hypersecretive fluid production by cells lining the luminal cyst's wall. Ultrastructural examination of the cyst wall has revealed that it is formed from splitting of the arachnoid membrane, with an inner and outer leaflet surrounding the cavity.[63] Despite their apparent developmental origin, these cysts are not associated with spinal dysraphism or other congenital anomalies.

As the cyst expands it causes progressive compression of the spinal cord. The symptoms and signs typically progress over several years. The usual age of presentation is adolescence and young adulthood, males being more frequently affected than females. Wilkins and Odom, in their review of 66 cases, have found a nearly equal sex distribution and a peak age of occurrence in the fifth decade of life.[78] The location of the cyst within the spinal canal and the severity of cord and root compression determine the clinical presentation. These cysts occur most commonly in the middle to lower thoracic spine but are also known to occur in the lumbosacral and, rarely, cervical regions.[3] These lesions usually arise posterior to the spinal cord and can also protrude into the neural foramen. Caruso et al.[66] have also described an intradural arachnoid cyst occurring anterior to the cord in the thoracic spine.[10] Sharma et al.[67] have reported a case of an intramedullary arachnoid cyst in a 4-year-old child presenting with acute quadriparesis. A single cyst usually extends over a long segment; however, cases with multiple cysts occurring at different levels in the cord have also been reported.[71]

The most common clinical presentation is with motor weakness in the form of spastic quadri or paraparesis. Other symptoms include back pain, radiculopathy, sensory impairment and sphincter disturbances. Symptoms can be intermittent or fluctuating and may be exaggerated by Valsalva manoeuvres or positional gravitational forces. Osenbach et al.[59] and Wilkins and Rossitch[77] have reviewed the subject of spinal arachnoid cysts in greater detail.

MRI is the most effective modality for the diagnosis of arachnoid cysts. The imaging characteristics of the arachnoid cysts are similar to CSF in all sequences (Figs 4 and 5). The anatomical relationship to the surrounding structures can be well defined. Scalloping of the vertebral body and expansion of the spinal canal from osseous remodelling suggests long standing mass effect from the lesion.[46] To demonstrate a communication between the cyst and the subarachnoid space, water soluble CT myelography has been the investigation of choice which demonstrates filling of the cyst through the communicating pedicle. Nakagawa et al.[72] have reported the usefulness of constructive interference in steady state (CISS) imaging in demonstration of the communication.[54]

Treatment is usually conservative for patients with asymptomatic cysts, with clinical and radiological follow-up. The mainstay of treatment in patients with symptomatic neurological deterioration is laminectomy with complete excision of the cyst.[46] If a portion of the cyst wall appears to be fused with the pia mater, attempts at complete excision are not recommended. The patient usually shows clinical improvement even after partial excision of the cyst wall. Delayed deterioration of neurological function after initial improvement may occur, and is attributed to either spinal cord ischaemia or spinal instability. Cystoperitoneal shunt is recommended if the cyst extends over multiple spinal segments or recurs after surgical excision. Kikuta et al.[37] have described an expansive duraplasty for treatment of spinal arachnoid

Fig. 4

cyst and recommend it as an alternative option where complete resection is not possible. Histological examination of the cyst wall should always be performed to establish the diagnosis because it is difficult to distinguish an arachnoid cyst from a neuroepithelial cyst on gross inspection.

MISCELLANEOUS LESIONS

Cavernous Malformation

Cavernous malformations are a subset of vascular malformations and are variably referred to in the literature as cavernomas, cavernous angiomas or haemangiomas. These malformations are typically discrete, well circumscribed reddish lobulated masses creating an overall appearance that has been likened to "a cluster of mulberries". Microscopic examination of these lesions reveals blood containing sinusoidal chambers lined by simple endothelium and lacking mature vessel wall components. There is no intervening neural parenchyma and they are surrounded by a gliotic margin. The exact cause of cavernous malformations remains obscure but these lesions do have a familial predisposition.[2] MRI is the only confirmatory imaging technique showing salt and pepper appearance due to haemosiderin deposition caused by multiple haemorrhages (Fig. 6). Clinically these patients may present with either an acute onset of neurological compromise or a slowly progressive neurological decline.[18] The surgical principles used in the resection of cavernous malformations are the same as for other intrinsic cord lesions. Once found, the presence of a gliotic plane surrounding the lesion often facilitates resection.

Angiolipoma

These are very rare congenital lesions affecting the spinal cord, and consist of abnormally differentiated vascular and mature adipose tissue, usually located in the epidural space.[64] The diagnosis of this lesion is usually suggested by the presence of a richly vascularised component and its lipomatous contents.

Astrocytoma

Spinal astrocytomas are common tumours accounting for 25–30% of all intramedullary spinal tumours in adults.[22] In children these tumours occur with a greater frequency accounting for up to 90% of all intramedullary tumours. Spinal astrocytomas occurring congenitally are very rare. Ng et al.[56] have described a case of low grade astrocytoma in an infant and stressed on the adverse neurodevelopmental outcome despite adequate surgical resection. Infants with these tumours may also show rapid neurological deterioration. Umemoto et al.[74] have also described a congenital astrocytoma in the cervical spinal cord.

108 Paediatric Spinal Tumours

Venkatramana NK

HISTORICAL OVERVIEW

Sir William Macewen[79] of Glasgow, in 1883, removed an epidural 'fibrous neoplasm' 1/8 inch in thickness from a nine-year-old boy with relief from paraplegia. This was the first operation for a spinal tumour in a child. Gowers and Sir Victor Horsley pioneered the management of spinal tumours in 1887.[49] Harvey Cushing's refinements of Halstead's surgical technique lead him to achieve good results in surgery of spinal neoplasms.[21] The first successful removal of an intramedullary tumour was by Anton von Eiselsberg[33] in Vienna in 1907, and the first report on intramedullary tumour was by Elsberg in 1911.[34] Elsberg also described a two-stage surgical excision and pioneered the surgery of spinal tumours, and many others have contributed to this difficult field; Greenwood,[50] Cooper,[24] Guidetti,[51] McCormic, Malis, Stein,[110] Epstein[36–41] and Brotchi[12,13] among others. One of the earlier classical papers on intraspinal tumours was by Rasmusseu, Kernohan and Adson in 1940.

EPIDEMIOLOGY

Spinal tumours are rare in children with an approximate annual incidence of one per million. Spinal cord tumours account for 4–10% of central nervous system tumours in children[4,9,18,26,30,55,102,111,114,116] of which 25–35% occur within the parenchyma of the cord.[16,114] Longitudinal "holocord" tumours are very rare and comprise 1% of these lesions.[16,114] Common adult intradural extramedullary lesions, such as meningiomas, neurofibromas and schwannomas, are rarely found in children.[95] Epidural deposits are the commonest non-traumatic cause of paraparesis in children.

In children, 40% of spinal tumours are intramedullary, 20% are intradural extramedullary and 40% are extradural. The cervical spine is the region most frequently affected, followed by the thoracic and thoracolumbar spine.[112,118] Spinal tumours are evenly distributed between males and females,[22] but a slight male preponderance is noted if congenital tumours are included. Thirty to thirty-five per cent of histologically verified tumours are malignant.[22,35] Tumours of the posterior fossa in children may metastasise to the spinal subarachnoid space and may rarely present with a spinal syndrome.[63] Ingraham and Matson[56] reported that spinal cord tumours are 1/5th as common as brain tumours in childhood. Balaparameswara Rao and Dinakar[8] found the ratio to be 1:8.5. In a 25-year experience at the Institute of Neurology, Madras, there were only three neurinomas and one meningioma in children below the age of ten.[95]

PATHOLOGY

The most common paediatric spinal tumours are astrocytoma (16%), sarcoma (10%), neuroblastoma (9%), ependymoma (8%), dermoids (7%) and teratomas (7%). Medulloblastoma, neurofibroma, metastatic carcinoma and lipoma account for another 5%. Spinal haemangioblastomas are very rare in children. Ninety percent of intramedullary tumours in children are astrocytomas, whereas 60% of adult intramedullary lesions are ependymomas.[110]

The most common intradural metastatic lesion is medulloblastoma and seeding may occur in 9.4–44% of cranial lesions. Neuroblastomas are the most common cause of extradural cord compression in children.[7]

CLASSIFICATION

1. Congenital tumours: Teratomas, teratoid tumours, epidermoid, dermoid cysts and lipomas.[69,121]
2. Intramedullary gliomas: Astrocytomas,[85] ependymomas,[6] medulloblastomas, glioblastomas[15] and gangliogliomas.
3. Tumours of the meninges and nerve roots—meningiomas[75] and neurofibromas.[100]
4. Extradural extension of paraspinal tumours—neuroblastomas,[26] reticulum cell sarcoma and lymphosarcoma.
5. Vascular lesions such as cavernomas[29,72] and haemangiomas.[101]
6. CSF leptomeningeal secondaries—medulloblastomas, ependymomas, glial secondaries and germ cell tumours.[2]
7. Rare entities, PNET,[117] ependymal cyst.[68]

Most classification systems of childhood spinal tumours are based on the anatomic location of the tumour. They may be intramedullary, intradural extramedullary or extradural.[18] The most common intradural extramedullary masses are dermoid, neurofibroma, schwannoma, epidermoid, PNET and meningioma. Of these,

neurofibroma, schwannoma and meningioma are usually associated with NF type 1. Meningiomas are rare in childhood and may behave aggressively.[75,86] Extradural masses include sarcoma, neuroblastoma, teratoma, ganglioneuroma and lymphoma.[103] Extradural lesions account for about 25% of childhood spinal tumours. Primary metastatic lesions are usually sarcoma and neuroblastoma. Extramedullary tumours are quite evenly distributed throughout the spine. Sacral involvement is less common, except in developmental tumours.[18]

Of these four categories, intrinsic gliomas of the spinal cord and congenital tumours are more common in children than tumours of the meninges and nerve root. Congenital astrocytomas have been reported, the pathology being similar to astrocytomas in older children.[62] Gangliogliomas compromise 30% of tumours in children under 3 years of age. Intramedullary cavernomas are rare and there is a male preponderance (2:1) and they occur commonly in the cervical region.

CLINICAL PRESENTATION

It is difficult to get a proper history from children. It is equally difficult to get an adequate history from the parents, as they do not carefully observe the progress of the disease. In addition, there are few reliable physical signs due to the difficulty in examining the child. The diagnosis is usually long delayed and it is not unusual even to miss the diagnosis.[109] A period of close observation after hospitalisation is necessary to bring to light signs and symptoms which were not recognised earlier. Weakness of one of the extremities, usually a lower limb, and axial pain in the spine are the most frequent symptoms in children. This axial pain, which is the commonest symptom, increases during the night due to venous congestion and dural tube distension during recumbency. Radicular pain is rare and is caused by nerve root pressure, distension of the root or infiltration of dorsal root entry zone, and in extra medullary tumours. The pain can be atypical, simulating abdominal disease or disease elsewhere in the body.[99] An early and common symptom is diffuse rigidity of the spine, often out of proportion to the objective neurological signs.[53,100] In the developing countries, this sign would most commonly suggest tuberculosis of the spine. Many spinal tumours in children used to be mistaken for anterior poliomyelitis.[96] An intramedullary cervical cord tumour may be diagnosed as brachial plexus palsy. A few cases masquerade under the diagnostic label of general prostration, malnutrition, behaviour problem and polyneuritis. Hydrocephalus can be a manifestation of a spinal tumour. It is reported in 15% of cases and may be due to metastatic arachnoiditis, but 8% of benign tumours are also associated with hydrocephalus due to reactionary leptomeningeal thickening or due to increased levels of CSF proteins.[98,104]

Gait disturbance, torticollis and kyphoscoliosis have been reported. Scoliosis occurs in 25% of children with spinal tumours. Prior history of surgery, especially for spinal dysraphism, should be asked for as an intramedullary dermoid or lipoma (second tumour) may manifest after many years.[78,89] In case of lipoma, there may be a tell tale subcutaneous lipomatous mass. There may be either lower limb deformity, weakness or atrophic skin ulcerations.[69,121] Neurological deterioration years after closure of a meningocoele may be due to an intramedullary dermoid.[78,89]

Signs and symptoms depend on the location of the tumour, plane, extent of spinal cord compression and bony involvement.[18] The median duration of symptoms is 9.2 months (range 1.6–27 months).[22] Malignant tumours have a shorter prodrome (median 4.5 months). In most situations, the progression is indolent and may be associated with exacerbations and remissions. Rarely, there could be rapid progression, leading to acute paraplegia. Tenderness and paraspinal muscle spasm may be present on examination. The other symptoms include motor disturbances, sensory disturbances like paraesthesias, dysaesthesias, torticollis and sphincter dysfunction.[112,118] Detecting spinal cord compression, in an infant or a toddler, is very difficult. The only signs or symptoms may be inadequate motor milestones, irritability and frequent urinary tract infections. Children with slow growing extradural tumours may suffer from frequent urinary infections and, also loss of bladder control in toilet-trained children should raise the suspicion of a spinal lesion.

Motor deficits vary depending on the level of the lesion and the severity of the compression. Mild spasticity, increased reflexes and extensor plantar response with or without clonus occur relatively early in upper motor neuron compression. Sensory changes are infrequent and quite often difficult to assess accurately.

Dermoids, epidermoids and lipomas may be associated with a dermal sinus and present with bouts of recurrent bacterial meningitis or rarely chemical meningitis which may be confirmed by microscopic observation of keratin in CSF.

LABORATORY INVESTIGATIONS

Serum and urine levels of catecholamines: VMA and homovanillic acid levels are elevated in patients with neuroblastomas. Ewing's sarcoma may manifest with leucocytosis, increased ESR and elevated levels of LDH.

Imaging

Plain X-rays of the spine are abnormal in 70–80% of cases of spinal tumours in children, as the immature spine of children is more vulnerable to increased intraspinal pressure.[28,70,96,108] The high incidence of congenital tumours in children is also one of the reasons for the higher incidence of vertebral changes. A tomogram may disclose a diffusely widened spinal canal with relatively localised erosion or flattening of pedicles. Scalloping and scoliosis may also be present in long standing lesions.

Oblique X-rays may show an enlarged foramen as many childhood spine tumours arise as a transforaminal extension of a paraspinal lesion and loss of a pedicle through bony destruction is characteristically seen as "winking owl sign" on AP views. Plain X-rays are also very important for planning instrumentation for deformity correction and stabilisation.

CT and myelography, though performed frequently in the past, had posed problems in interpretation especially in holocord tumours, association of syrinx and in complete spinal block. CT delineates the bony anatomy and reveals osseous destruction and calcification.

MRI with or without contrast is the imaging modality of choice.[18,73,92,113] It provides excellent images of extramedullary and intramedullary neoplasms. The T1-weighted image reveals the presence of rostral, caudal and intramedullary cysts, as well as the solid component of the tumour (Figs 1 and 2). T2-weighted images give a myelographic appearance to CSF and cysts (Fig. 3). Gadolinium enhancement is mandatory in spinal tumours, which usually enhances the solid component and helps delineate the tumour from surrounding oedema.[92,106,113] In most circumstances, malignant tumours appear hypodense on T1 and hyperdense on T2 with a non-uniform enhancement.[18,107,111,113]

Ependymomas enhance brightly and homogeneously. They have polar cysts with haemosiderin caps at their poles. On axial view, they are usually located in the centre of the cord[6] (Figs 4 A to D, 5A and B). Astrocytomas[85] and gangliogliomas do not enhance as brightly and their enhancement is not homogeneous and these are commonly eccentric causing asymmetric enlargement of the spinal cord. Cavernomas appear with a target sign, with an outside rim of haemosiderin which is hypodense on T1 and T2.[29,72] Haemangioblastomas will show the brilliantly enhancing tumour nodule and adjoining cysts.[25] Neuroblastomas are usually isointense

or hypointense with areas of necrosis. Tumours, like dermoids, epidermoids and lipomas which contain fat or cholesterol, have characteristic high signal intensity on plain MRI.[87]

Positron emission tomography may help to categorise the lesions by abnormal uptake of 18F and 11C-methionine.[119]

THERAPEUTIC CONSIDERATIONS

The principles of management involve ascertaining the histological diagnosis, preservation of neurological function, tumour debulking or gross total resection, pain relief and spinal stabilisation. Often, it requires a multidisciplinary approach. The majority of paediatric spinal neoplasms are benign, low-grade astrocytomas[85] or gangliogliomas with a slow indolent course and, whenever feasible, gross total resection should be done without a neurological compromise.[83,112,118] Conservative expectant management may be an option in multiple small lesions seen in a child with neurofibromatosis and von Hippel-Lindau disease. Spinal CSF leptomeningeal seeding and disseminated disease do not warrant aggressive surgery. Modern surgical instrumentation has paved the way for successful removal of the tumours. The operating microscope, ultrasonic surgical aspirator, laser and micro-instruments are extremely useful tools to achieve this objective.[22,23,40–42,47,71]

Surgery

It is always advisable to perform a laminotomy in this age group to prevent future spinal deformity. Complications of laminectomy in children are extensive. Laminectomy in children may be followed by a deformity of the spine,[1,20,27,81,91,108,123,124] which is usually not observed in adults. In the lumbar region, an increase in lordosis, in the dorsal region, a kyphoscoliosis and in the cervical region, an exaggerated lordosis may ensue. Therefore, as a preventive measure, an ambulatory plaster jacket or a brace should be employed for at least 6–12 months when the laminectomy has been extensive in a young child, with emphasis on regular spinal exercise. The technique of osteoplastic laminotomy[1] helps to preserve the posterior elements, especially when a large area of the cord has to be exposed. Following such a procedure, complete to partial bridging of the laminar roof and reossification of the replaced bone segment occurs.

Limited laminectomy encompassing the solid component of the neoplasm is necessary. C-Arm imaging and intra-operative ultrasound help in the exposure.[23,39] Laminotomy is performed with a high speed drill. The dura is opened. The expanded spinal cord is commonly rotated and distorted. In extramedullary tumours, the arachnoid is gently opened, the tumour is debulked, the capsule is mobilised and gently removed from its attachment and care is taken to avoid injury to the neurovascular structures. In intramedullary lesions, CO_2 laser is helpful in doing the myelotomy.[47]

Conus and cauda equina lesions expand the filum terminale, which appears as a sausage shaped mass that displaces the nerve elements circumferentially around it. In such situations, it may be possible to remove the tumour en bloc taking care of the neural structures and adequately dissecting the arachnoid around.

Extradural Tumours

Primary Bone Tumours

Extradural tumours in children may be benign and include osteoid osteoma, osteochondroma, osteogenic sarcoma, osteoblastoma, aneurysmal bone cyst and eosinophilic granuloma. These are usually amenable to resection and even partial tumour removal provides excellent results.

Osteoid Osteoma and Osteoblastoma

These involve the lamina and pedicles of the cervical and lumbar spine and result from a benign osteoplastic process comprising of numerous osteoblasts which produce osteoid and woven bone. Osteoid osteoma when small may be kept under observation and spontaneous remission may occur. If symptomatic, total excision should be achieved.

Osteochondroma and Osteogenic Sarcoma

These originate from hyaline cartilage during adolescence, usually in the posterior elements of the dorsal and lumbar vertebrae. Surgical excision should be radical and gives good results. Rarely, malignant transformation to osteogenic sarcoma can occur.

Aneurysmal Bone Cysts

Aneurysmal bone cysts are benign and highly vascular lesions and can be cured with surgery and bone curettage.[5,22]

These lesions usually present in the second decade of life with local pain, swelling and rarely, spinal cord compression. They are expansile with blood-filled spaces in trabecular osteoid tissue with multiple haemosiderin containing macrophages, multinucleated giant cells and fibrous tissue. The aetiology of these lesions is yet unknown. Treatment includes pre-operative angiography with preparation for embolisation followed by complete excision. If inadequately excised, these lesions recur.

Eosinophilic Granuloma

These are benign lytic lesions that affect the anterior portions of the cervical vertebral bodies. They may be isolated or part of syndromes, histiocytosis x, Hand-Schuller-Christian disease and Letterer-Siwe disease. Many small lesions may undergo spontaneous regression. Low dose radiation or decompressive surgery with reconstruction is recommended for expansile lesions causing neurological deficits.

Malignant Tumours

The role of surgery is palliative with most malignant extradural tumours.[94] Metastatic epidural spinal cord compression occurs in 3% of all children with malignant solid tumours.[18,63] Neuroblastomas and ganglioneuroblastomas are operated upon for establishing the diagnosis or in case of a rapidly deteriorating clinical condition. These tumours are sensitive to radiation and chemotherapy. Sarcomas may require surgery in order to decompress the neural elements. Surgical decompression of neural elements significantly facilitates the neuronal recovery and outcome, especially in children. A combination of steroids, radiotherapy and chemotherapy may be suitably adopted to improve the outcome.

Neuroblastomas

In children, the most common tumour to metastatise to the extradural spine are neuroblastoma and the less aggressive ganglioneuroblastoma. This is the most common malignant paediatric spinal tumour and is derived from embryonic sympathetic neuroblasts and primordial neural crest cells. The tumours originate from the sympathetic chain and enter the spinal canal via the neural foramina taking a dumbbell shape. Surgical resection with multi agent chemotherapy and radiation is advocated.

Ewing's Sarcoma

These highly mitotic tumours arise from postganglionic parasympathetic neural crest cells. These occur

mostly in the sacrum followed by the dorsal and lumbar spine. These tumours are managed by initial biopsy. If the lesion is low grade, radical excision is followed by radiotherapy and chemotherapy. If high grade then initial radiotherapy and chemotherapy are followed by surgery. Lymphomas, chordomas and rhabdomyosarcoma also fall into the malignant group.

Weinstein described a system of surgical staging of spinal column tumours and this is currently called Weinstein, Boriani, Biagini Surgical Staging system. Boriani et al. have emphasised the importance of applying the Enneking system of musculoskeletal tumours to these spine tumours. This divides benign tumours into three stages: S1–S3, and malignant tumours into four stages: Ia, Ib, IIa and IIb. Two additional stages include metastatic high-grade intra- and extra-compartmental tumours IIIa and IIIb. Surgery can be tailored to be vertebrectomy, sagittal resection or posterior arch resection with stabilisation as necessary.[97,116]

Intradural Extramedullary Tumours

The management of these tumours is less controversial than that of intramedullary tumours. The majority of them are benign and gross total removal is the cure. Care should be taken to avoid cord manipulation. Radiation therapy is reserved only for malignant lesions.

Intermedullary Tumours

They constitute 35–40% of all intraspinal tumours in children.[57,77,90] To begin with, surgeons were more aggressive and a radical approach was adopted leading to several complications like infection, paralysis and even death. Subsequently, a conservative approach of biopsy and radiation became popular.[118] With the advent of modern neurosurgical appliances and imaging advances, i.e. operating microscope and intraoperative monitoring, laser and ultrasonic aspirator,[71] radical surgery once again has become the order of the day. The majority of intramedullary tumours are histologically benign and so a radical approach has to be adopted.[1,29,35–38,50,51,84,90]

The child is positioned prone with head fixation, if required. All the pressure points must be protected with adequate padding. Laminotomy is performed and the dura is opened over the entire length of the tumour. The opening should be just sufficient to expose the solid component of the tumour. Rostral and caudal cysts need not be exposed fully.[12,47] The spinal cord is usually expanded and often rotated. The asymmetric expansion and rotation of the spinal cord makes the identification of the midline difficult. Intra-operative ultrasound gives a two dimensional image and echogenic patterns are often helpful in identifying the cyst and the solid components.[23,39] Brotchi et al.[12,13] advocate a midline myelotomy between the posterior columns for glial tumours and for vascular lesions, like cavernomas[29,72] and haemangioblastomas,[25] which are subpial, they advocate approaching them where they are seen surfacing. The myelotomy is performed in the midline or through the dorsal root entry zone. Astrocytomas or gangliogliomas have a greyish yellow appearance with occasional calcification but without a plane between the tumour and the spinal cord. Hence, no effort should be made to develop an interface. Ependymomas are typically red grey in colour and well demarcated from the surrounding spinal cord. A good plane of cleavage can be developed in such tumours.[6,37,47,54,57] Lipomas are characterised by exceedingly poor demarcation between the normal cord and the tumour.[69] Internal debulking with ultrasonic aspirator and then gradual removal of the tumour is practiced. It is better to start at the mid-portion and then go towards the rostral and caudal poles. The surgeon should constantly be aware of the various displacements of tracts that can occur due to the expansion of the tumour.[26] Haemangioblastomas, cavernous malformations and intramedullary lipomas are uncommon intramedullary lesions.[25,29,69,101] Haemangioblastomas are associated with significant oedema and syrinx.[25] Removal of the solid tumour takes care of the associated syrinx.

The dura is closed watertight. The laminotomy is replaced and secured in position. One must close the layers without tension.[125] A transient post-operative neurological deterioration may be observed in the majority, but the deficit will improve in a few weeks.[13,48,65,67] The incidence of post-operative deterioration is related to pre-operative motor status. Total resection has a better long-term outcome than partial resection, but great care has to be taken so that the patient doesn't have an unacceptable disability even if the tumour excision remains partial.[60,90,105,115,120,122]

EVOKED POTENTIAL MONITORING

The information provided by SSEP is sufficient to assess functional integrity. However, during intramedullary tumour surgery, motor tracts may be damaged independent of the sensory system and, in addition, sensory potentials are often lost soon after myelotomy. Therefore, motor evoked potentials (MEPs), which allow direct monitoring of corticospinal tracts is preferable.[11,14,26,45,46,65,67,88] A single electrical impulse results in the direct activation of fast conducting axons leading to a potential D-Wave.[93] This can be recorded by an epidural electrode placed just distal to the intramedullary tumour. D-Wave amplitude signifies the measure of the number of functioning fast conducting corticospinal fibres. These motor potentials follow an on-off pattern and their presence indicates intact motor control. Improved electrical conductivity after tumour removal is invariably associated with a benign post-operative course. Impaired activity in comparison with the preoperative baseline is not necessarily associated with neurological morbidity. However, the majority with deterioration in activity have a greater chance of neurological dysfunction.[22]

COMPLICATIONS

Surgical morbidity is usually related to the location of the tumour, associated malignancy and the degree of pre-operative disability. In general, extensive tumours and non-cystic tumours carry a higher risk of post-operative deterioration.[45,46,83,122] Though intramedullary tumours have a relatively higher risk of surgical deterioration, it appears that the length of the tumour has no real bearing.[16] The risk of post-operative deterioration is higher in removing smaller nodules and in patients undergoing partial resection.[54] Children are more easily prone to shock when there is blood loss.

Radiotherapy to the spinal cord at this young age carries greater risks of radionecrosis[32,80] and chemotherapy carries its own complications and disabilities.[3,10]

The incidence of hydrocephalus is higher in patients with malignant tumours and up to 15% may develop hydrocephalus.[59,98]

Post-operative Spinal Deformity

The treatment of an intraspinal tumour, as in adults, is surgical excision through laminectomy. The technique does not vary from that in adults, except that, in children, because of the preponderance of congenital and malignant tumours, a comparatively greater exposure is necessary. When more than three laminae are to be removed, it is desirable to do an osteoplastic laminotomy to prevent a post-operative spinal deformity.[1,20,27,55,81,91,108,123,124] Scoliosis and kyphosis commonly evolve after surgery. Sometimes, they may be progressive and lead to myelopathy. Scoliosis usually does not cause spinal compression though it can potentiate the existing neurological disability. Several authors[1] have described that osteoplastic laminotomy is superior to simple laminectomy although it does not totally prevent post-surgical evolution of spinal deformity, especially if the tumour recurs. The causes of instability may be vertebral involvement by tumours, paraspinal muscle denervation or fibrosis, asymmetric radiation of the spine and post-surgical destabilisation.[18,81] It is reported that 24–100% of patients experience instability after laminectomy for resection of tumour.[91] Therefore, the surgeon must limit the laminectomy to as few segments as possible and care must be taken to preserve the integrity of the facet complex. The need for spinal fusion is commonest in the thoracic and thoracolumbar region. The need to remove a greater number of laminae and pre-operative kyphotic deformity are linked to spinal sagittal malalignment in children. Age less than 3 years, pre-operative scoliotic deformity (Cobb angle >10 degree), thoracolumbar region and tumours associated with a syrinx increase the odds of post-operative progression of deformity requiring fusion.[27,123,124] Osteoplastic laminectomy or bilateral laminotomy is preferred.[19]

ADJUVANT THERAPY

There is enough evidence to show that radiation is deleterious to the nervous and osseous systems.[20,32,80] The alterations in motor and sensory evoked potentials in patients who received radiotherapy have been documented.[88] Some authors do recommend radiotherapy routinely for intramedullary gliomas.[74,85,105,106,120] In a review of literature, several papers advocate RT for low-grade astrocytomas with a 5-year-survival rate of 50–91%.[19,44,58,64,74,106] Epstein, in his series, reported a five year survival of 88% with surgery alone.[45] Overall, there seems to be no evidence that radiation improves the outcome in low-grade astrocytomas or ependymomas.[38,40,46,58,106] Hence, radiation should be reserved only for malignant tumours. Survival rates of 55% at 5 years, 39% at 10 years and 79% overall 5-year-survival rate have been reported with conservative surgery and radiotherapy.[60]

Chemotherapy has rarely been used in intramedullary tumours and there are no large studies documenting its efficacy.[3,10,31,32,43,52,76,83] Temozolamide has been used but larger studies are awaited.[17]

Neurologic outcome is decided by the extent of safe microsurgical resection possible and location of the tumour. Cystic tumours are associated with a much better outcome. Early surgery before deterioration is absolutely necessary and prophylactic surgery has a role in spinal lipoma.[61,87] Patients should be operated upon early and those patients in McCormick grades 1 and 2 do much better than grades 3 and 4.[82]

There has been no difference in the long-term progression free survival period in patients who have undergone more than 80% tumour removal when compared with those who underwent 98–100% resection.[66] Hence, it may not be necessary or mandatory to achieve a total removal for an optimal outcome. Five and ten year survival has been reported as 88 and 82%. High-grade neoplasms had a 5-year survival of 18%. Minimally invasive neurosurgical microscopic techniques using lasers and CUSA,[115] improved spinal instrumentation in the form of lateral mass plates, anterior self locking plate systems, occipitocervical systems and vertebral body prosthesis allow for greater extent of excision with excellent results.[112,118]

Disc Disease and Other Spinal Pathologies

Ravi Ramamurthi

109 Pathophysiology of Disc Degeneration

Ramakrishna Easwaran

INTRODUCTION

Intervertebral discs contribute to the stability and flexibility of the spinal column. The discs normally carry out an admirable job of balancing these two opposite functions. Ageing of the population and shift to a sedentary life style, punctuated by unusual occupational or recreational strains have contributed to the increasing incidence of degenerative disc disease (DDD). In this chapter, the physiological basis for DDD and its effects are explored.

ANATOMY OF INTERVERTEBRAL DISC

The 6 cervical, 12 thoracic and 5 lumbar discs (23 in all) are basically similar in structure but they differ in size and shape according to the vertebrae in between which they are interposed. In each disc, the centrally located nucleus pulposus (NP) is contained by the outer fibrous shell of the annulus fibrosus (AF). (Note: 'anulus fibrosus' is an accepted variant spelling.) The end plates (EP) form the interface between the disc and the vertebral body (VB) above and below it. The NP accounts for 50% of the volume of the healthy adult lumbar disc but only for 33% of the volume of the thoracic disc.[26]

Nucleus Pulposus

The nucleus pulposus is a hydrated gel made up of proteoglycans interspersed by a random and loose network of fine fibrils of type II collagen and elastin. The major proteoglycan is aggrecan. This substance is composed of anionic glycosaminoglycan (chondroitin sulphate and keratan sulphate) and it contributes to the osmotic pressure in the disc needed to resist compressive loads. In infants the water content of the disc is 90% and this comes down to about 70–80% in young adults.[26] As age advances, there is progressive desiccation of the NP. The water content of the NP is reflected by the T2 signal intensity on magnetic resonance imaging. The NP is derived from the notochordal cells, which stop proliferating after infancy. The extracellular proteoglycans are secreted by the notochordal cells in foetal life and early infancy. Later in life, these cells are gradually replaced by chondrocyte-like cells with a low cell density.

Annulus Fibrosus

The annulus fibrosus is organised into about 12–25 lamellae. Each lamella is composed of spirally running collagen fibrils with randomly dispersed elastic fibres. There are also other types of collagen (notably, type IX collagen forming cross links and maintaining the network integrity) and other proteoglycans such as lumican, biglycan, decorin and fibromodulin. The direction of collagen fibrils in each lamella is tilted to the spinal vertical axis by about 60° and alternates between one lamella and the next by 120°, thus producing a woven basket appearance.[26] The lamellar arrangement is better developed in the anterior part of the disc. Elastin fibres lie between the lamellae, passing radially from one lamella to the next. The lamellae in the outer zone of the annulus attach directly to the VB above and below (Sharpey's fibres). These outer lamellae contain type I collagen, which has high tensile strength and they serve to stabilise the spine during torsional or bending movements. The lamellae of the inner zone attach to the EPs and are composed of the smoother and weaker type II collagen. The inner annulus acts as a container for the NP and absorbs the force exerted by the nucleus on compression loading. The synthesis of collagen is genetically determined but non-genetic factors, such as sex hormones or physical loads, may regulate the gene expression. The water content of the AF (about 70% of its weight) does not decrease much with age, unlike the NP. However, the annular fibromodulin undergoes age related changes. The cells in the annulus are elongated fibroblasts. The AF develops from the dark zone of the densely packed mesenchymal cells in each sclerotome.

End Plates

The vertebral EPs are entirely composed of cartilage in infancy. A rim of ossification appears in the periphery of the cartilaginous EP and this annular epiphysis fuses with the VB. By 20 years of age only a small central disc of cartilage remains. The EPs merge with the lamellae of the inner AF, completing the encasement of the NP. Unlike articular cartilage, there are no strong fibrous moorings for the EP to the cancellous bone of the VB. The vertebral EPs are derived from the light zone of the densely packed mesenchymal cells in each sclerotome.

Blood vessels penetrate the EPs during foetal life but as the disc cells involute, so do the blood vessels. The empty channels left behind by the involuting vessels are possible origins for Schmorl nodes.[26]

Blood Supply

There are no blood vessels inside the NP at any age and in most of the annulus during adult life. The intervertebral disc is the largest avascular structure in the body. The disc derives its nutrition from the capillary bed in the VB adjacent to the EP. The arterial supply to this vascular bed is derived from: (a) the centrum branches in the VB supplying the central region of the EP; (b) from the ascending and descending branches of arteries on the anterolateral surface of the VB and (c) from the anterior intraspinal arcade on the posterior surface of the body. Blood flow in the paradiscal capillaries is under humoral control, effected by acetylcholine through muscarinic receptors. This is the one mechanism by which nicotine might adversely affect the disc nutrition.

Nerve Supply

There is no nerve supply to the NP or inner annulus.[53] Unmyelinated nerve fibres, unencapsulated and capsulated nerve endings are found in the outer annulus. The nerve endings in the lateral and anterior annulus serve a proprioceptive function while those in the posterior annulus are also nociceptive. In the lumbar region, the nerve endings on the posterior annulus are derived from the sinuvertebral nerve (recurrent nerve of Luschka). The sinuvertebral nerve arises from the dorsal division of the spinal nerve root, re-entering the intervertebral foramen, dividing into a superior and inferior branch to supply the disc above and below, as well as the posterior longitudinal ligament, ventral dura, facet capsule and VB. Pain originating from the structures supplied by the sinuvertebral nerve in the lumbar region is referred to the buttock but not to the thigh or further distally (unlike spinal nerve root pain) and is known as dorsal ramus syndrome. The nerve endings on the lateral and anterior annulus are derived from the grey rami communicans. In the cervical region the fibres from the grey rami communicans join the sinuvertebral nerve. The C1 and C2 sinuvertebral nerves also supply the atlantoaxial joints and the dura of the posterior fossa.[26]

Ligaments

The anterior longitudinal ligament (ALL) with a stronger attachment to the VB and the posterior longitudinal ligament (PLL) with a stronger attachment to the posterior annulus strengthen the disc, though they are not integral parts of the disc. The ALL and PLL act as multisegmental tension bands resisting extension and flexion forces, respectively. Each disc forms a motion segment unit with the zygoapophyseal (facet) joints at that level. The facet capsules, ligamentum flavum, interspinous, supraspinous and intertransverse ligaments are important in maintaining the stability of the motion segment, while at the same time allowing motion to occur.

PHYSIOLOGY OF INTERVERTEBRAL DISC

Nutrition and Metabolism

The smaller molecules diffuse in and out of the disc through the EP. The larger molecules are transported by bulk fluid flow. Oxygen tension is low in the central region leading to anaerobic metabolism and build up of lactate. End plate permeability and, therefore, disc metabolite transport normally decrease during growth and ageing, but increase in the presence of disc degeneration and following endplate damage. The relative lack of blood supply causes limited cellular replication and this accounts for the poor repair capacity in the injured adult disc. In spite of the low blood supply, the matrix and disc cells are metabolically active. There are matrix metalloproteinases (MMP), a disintegrin and metalloprotease (ADAM) and aggrecanases that break down the matrix proteins, which are rebuilt by the disc cells. A healthy balance between breakdown and accumulation, which is regulated by genetic and non-genetic factors, is essential for maintaining the disc integrity.[41,70]

Biomechanics

The water content of the nucleus is vital for its biomechanical properties. On applying a compression force, water is expelled from the disc and it is reabsorbed into the disc once the force is removed. At low loads, the disc does not resist deformation but, beyond a certain load, the stiffness increases abruptly. This property allows the disc to remain flexible on minimal loading while it contributes to the stability as the loading increases. When the load limits are exceeded, the EPs fail first before the AF. This happens with compression loads of about 14000N in lumbar disc and 3000N in the cervical disc.[26] Water loss in the disc associated with ageing, reduces the viscoelastic adaptability of the disc making it prone to fail. The dehydrated disc behaves as a fibrous solid rather than a watery gel in its biomechanical properties. Apart from compression loads the other loads that the disc withstands are tension, shear and torsion loads. During day-to-day activities, the loads acting on the disc are a combination of these pure loads.

The pressure in the disc is studied *in vivo* by placing a miniaturised strain gauge mounted on a needle passed percutaneously into the disc, as done by Nachemson in the 1960s. A recent telemetric discometry study shows that the original studies had overestimated the intradiscal pressure on sitting. The pressure increased from 0.1 megapascal (MPa) on lying flat, to 0.46 on sitting, 0.5 on walking, 0.92 on performing Valsalva manoeuvre, 1.1 while standing up from a chair, 1.9 while holding a 20 kg weight well in front of the chest and to 2.3 on bending forwards to lift a 20 kg weight (note that 1 MPa = 10 bar = 10^6 newton/sq.m).[76]

Ageing Changes

The loss of water content in the NP with ageing has already been mentioned. The dehydration is caused by the decrease in the proteoglycan content of the matrix in the NP. There is decrease in the collagen content with replacement of type II collagen by type I collagen in the inner annulus.[65] The type I collagen fibres become coarser and become more cross-linked, thus increasing their stiffness. The collagen becomes non-enzymatically glycated, which further increases cross-linking. These biochemical changes are accompanied by histological changes such as the appearance of microstructural clefts that are seen as early as at 15 years of age. There is fissuring and clumping of parts of the NP. The EP undergoes thinning, altered cell density, formation of fissures, and there is sclerosis of the subchondral bone.[62] The histological changes of ageing are believed to be the result of reduced vascularity and they affect the EP first, then the NP, and, finally, the AF.[7] N-(carboxylmethyl) lysine (CML), a biomarker for oxidative stress has been found to accumulate in areas of maximal age changes.[45] The loss of vertebral body bone mass in osteoporosis leads to bulging of the EPs into the body and reduces the intradiscal pressure.

The changing microstructure and biochemistry alter the biomechanical characters of the ageing disc. As the NP becomes desiccated, the AF has to bear more of the compression load. The AF becomes stiffer but structurally weakened. The ageing changes are somewhat (but not exactly) similar to those due to DDD but are less intense, more or less similar at all levels and occur over longer periods. This situation is comparable to the twin conditions of senile dementia and Alzheimer's dementia, where the difference is quantitative and temporal rather than qualitative. The age-related DDD does become symptomatic. In a radiological study, degenerative disc and facet pathology in those over 65 years of age was ubiquitous, regardless of the presence or absence of pain, with greater than 90% demonstrating some level of degeneration. Higher radiographic severity scores were associated with the presence of backache but did not correlate with pain severity.[19]

DEGENERATIVE DISC DISEASE

Structural Changes

The changes of degeneration occur simultaneously in all parts of the spinal motion segment and progress over time as described by Kirkaldy-Willis.[79] The rate of progression of degenerative changes is variable. Mechanical loading in an acute or repeated chronic manner has been held as the primary factor in producing structural failure of the disc.[79] Current evidence indicates that mechanical load is only one of several factors.

The structural failure manifests as three types of tears in the AF. *Circumferential tears* occur between the laminae and are postulated to be due to interlaminar shear stresses.[15] The circumferential defects are equally distributed in the anterior and the posterior AF. *Radial fissures* progress outwards from the nucleus, usually posteriorly or posterolaterally. Biomechanical studies on cadaveric discs show that cyclic loading in bending and compression causes radial fissures. Radial fissures are associated with degeneration of NP but it is not clear which comes first. *Peripheral rim tears* are more often found in the anterior AF. Mechanical and histological considerations suggest that they are related to trauma.[51] Rim lesions are also a function of age, being commoner in older discs. Less than 15% of these tears show any tendency to heal. Only the smallest tears can seal in experimental situations and the larger tears induce progressive degeneration.[22] Blood vessels and nerves grow into the peripheral annular tear and contribute to making it painful.[72]

The NP tends to herniate along annular defects resulting in a disc prolapse. The result may be a focal protrusion, extrusion or sequestration. The biomechanical load that produces a posterior protrusion is a combination of flexion and compression. With flexion, the compressed anterior NP exerts a force on the posterior AF, which has been put under tension stress by the same flexion force. Addition of a compression force causes the NP to herniate out. Such purely mechanical disc herniations occur in the 30–40 years age group, as the discs at this age have enough hydration in the NP and are beginning to accumulate AF tears.[26] Older desiccated discs cannot extrude in this manner. In experimental settings, it requires much higher forces (than one normally encounters) to cause a NP herniation in a non-degenerated disc.[23] In fact, such loads cause injury to the VB rather than produce herniation of NP. Hence, even in mechanically induced disc hernia, there is likely to be a preceding structural degenerative change.

The EPs fail in compression and accumulate trabecular micro-damage with age. Since the EPs enclose the NP, the pressure inside the NP can no longer be maintained.[1] The load bearing shifts to the AF, causing the inner layers of AF to buckle in towards the low-pressure area of NP. This stage is spoken of as 'internal disc disruption'. The NP can then be driven up towards the VB, forming a Schmorl node. The structurally weakened outer AF bulges out radially, seen in MRI as a diffuse disc bulge. The combination of these changes in the EP, NP and AF causes loss of disc height and the disc becomes akin to a flat tyre.[8] The loss of height in the disc shifts the load bearing to the posterior elements and the stage is ripe for osteoarthritis of the facet joints and dynamic instability. Disc height loss also causes the ligaments to buckle into the canal adding to the soft tissue component of canal stenosis. Excessive annular loading also causes osteophyte formation or bony enlargement and the end result of these changes is degenerative canal stenosis. It is now possible to study the abnormal segmental motion with kinematic MRI. The lumbar functional unit with more disc degeneration, facet joint disease and flaval hypertrophy has abnormal sagittal plane translation and angulation.[31]

Biochemical Changes

Loss of proteoglycan is the fundamental abnormality in DDD. Aggrecan gets broken down to smaller molecules, thus reducing its water retaining capacity. There is elevation of decorin and biglycan, and the disappearance of 4-sulphated core region in aggrecan.[24] Undersulphation of chondroitin occurs more in the posterior part of the inner AF and this might explain the occurrence of radial fissures in this region.[41] Loss of aggrecan allows penetration of molecules, such as interleukin-1 into the disc, which accelerate the progression of degeneration.[21] The increased neural ingrowth seen in the degenerated outer AF (discussed above) is also associated with loss of aggrecan, which normally inhibits neural growth.[43] The changes in the matrix proteins are in turn caused by increased MMP activity. A recent study shows the upregulation of the MMP-3 mRNA in degenerated disc.[2] Cathepsin and prostaglandin E2 may also play a part.[28]

SA-beta-gal (senescence associated beta-galactosidase) is a marker for cellular ageing. A higher proportion of senescent cells in herniated discs has been demonstrated by this technique.[61] The herniated-free disc fragments show increased apoptosis and this might explain spontaneous resorption of herniated discs.[54] Results from human samples, mouse models and AF cell culture experiments demonstrate that the mechanical overload-induced disc degeneration is mediated through the mitochondrial apoptotic pathway in the disc cells.[60] Nitric oxide, released by the disc cells subjected to mechanical loads in an autocrine fashion, induces apoptosis.[30] Insulin-like growth factor (IGF-1), platelet derived growth factor (PDGF) and basic fibroblast growth factor (bFGF) are potent mitogens that stimulate the proliferation of disc cells.[57] These growth factors also exert anti-apoptotic effects.[16] The fact that these growth factors are overexpressed in degenerated discs indicate that there is an attempt at repair and regeneration along with the process of degeneration. In ochronosis (alkaptonuria), homogentisic acid accumulation in the elastic tissue of the disc causes early degeneration and calcification in the disc.

Vascular Changes

A fall in nutrient supply will ultimately lead to degeneration of the disc. The vascular supply can be reduced by calcific atherosclerosis of the aorta and lumbar artery stenosis and these are associated with DDD as shown by a recent systematic review.[29] Lumbar arterial stenosis has been documented by magnetic resonance angiography.[32] Even if the blood supply remains normal, nutrients may not reach the disc cells if the EPs calcify, as is known to occur in scoliosis. An elegant intraoperative study demonstrated that the concentration of diffused anaesthetic nitrous oxide into the disc was lowest in the disc at the apex of the curve in scoliosis (the most calcified and degenerated disc), indicating decreased solute transport.[71] Using contrast enhancement patterns on MRI, a group from Coimbatore, India, has demonstrated that greater abnormalities of diffusion in the end plate correlate with higher grades of DDD.[59] The adverse effects of smoking on DDD are also likely to be ischaemic, as proved by studies on animals.[25]

Inflammatory Changes

The lack of blood supply suggests that inflammation is not an important issue in the causation of DDD. However, inflammatory cells, mainly macrophages, have been found in surgical disc specimens. Both the acute and chronic herniations show activated T and B lymphocytes.[18] This may be a foreign body reaction and it can possibly result in pain, as those with inflammatory change have a better pain outcome after surgery.[77] Surgical disc specimen analysis shows inflammatory cytokines, such as interleukin-1 alpha, which in turn increases prostaglandin E2 (PGE-2) production.[67] Positive straight leg raising test has been correlated with higher PGE-2 content in the disc.[49] Antiglycosphingolipid antibodies have been detected in about 2/3rds of patients with herniated lumbar disc raising the question of an autoimmune mechanism, at least in the causation of pain, if not in the aetiology of DDD.[9] An endoscopic exploration of discs in conscious patients has shown inflammatory pathology, neoangiogenesis and neurogenesis in the AF to correlate with pain.[78]

Cause of Pain

It is simplistic to assume that pain in DDD is solely due to compression on the nerve roots. There are patients who present with back and/or leg pain without any demonstrable dural tube or root compression. Mere touching of the posterior annulus in patients undergoing surgery under progressive local anaesthesia was found to cause severe pain.[33] Substance-P nerve endings have been demonstrated deep in the AF of painful discs but only superficially in non-painful discs. This study also showed simultaneously a marker for axonogenesis in DDD, suggesting new nerve growth.[13] Experimentally acute exposure of a nerve root to NP material results in axonopathy and nerve mechanosensitisation. Chronic exposure results in mechanical desensitisation.[10] A recent MR based study shows that even the discs that reach the end stage of degeneration ('burnt out') do not become painless.[6]

Experimental Models

The animals used in laboratory experiments, such as rats, rabbits, pigs or sheep, have more cellular and vascular discs with good regenerative capacity as compared to the human disc. These animals are quadripedal and their discs do not bear the same loads, as does the human disc. Hence, inferences from laboratory studies must be made with caution. The response to standardised trauma such as needle pricks or annulus cuts have been studied in these animals. Compression loading of tail discs

in rats is another experimental model. Cadaver human vertebrae and discs dissected en bloc have been studied extensively for biomechanical properties but these lack the action of muscles or blood flow and, hence, are only a rough approximation of the *in vivo* situation.

AETIOLOGY OF DEGENERATIVE DISC DISEASE

Degenerative disc disease is multifactorial in aetiology. Ageing and mechanical stress have been implicated for long but only recently the genetic factors have gained ground as an important cause for DDD.

Mechanical Load Injury

Throughout the last century, mechanical load injury was proposed as the most important cause of disc prolapse. The higher incidence of DDD in persons doing manual work supports such a hypothesis.[39] It is now realised that the straining activity that precipitates acute disc herniation might merely be the last straw that broke the camel's back! When mechanical pressure is experimentally applied, degenerated discs herniate at lower loads.[23] Trauma seems to act by creating microscopic damage to EPs, which allows the NP pressure to get deflated, setting in motion the chain of events of DDD.[1] Nitric oxide may be the pathway mediating the suppression of proteoglycan synthesis in response to abnormal loads.[35] In sportsmen, who subject their backs to inordinate loads, MR abnormalities were found even at young age and these worsened considerably on follow-up after 15 years.[3] Weight lifters had greater DDD in the lumbar spine than other sportsmen.[73] As opposed to unusual loads, regular exercise seems to strengthen the disc by increasing the proteoglycan content.[70]

Another good example of mechanical overload is the occurrence of accelerated DDD in levels adjacent to congenital or surgical fusion. The rate of symptomatic degeneration at an adjacent segment after surgical lumbar fusion was found to be 16% at five years and 36% at ten years.[14] Of course it is difficult in such cases to separate the effects of excess loading on the one hand and a susceptibility to DDD or ageing effects on the other. The L4-5 disc is more prone to degenerate in persons with L5 sacralisation, obviously due to abnormal load distribution.[40] Yet another example of mechanical causation is DDD in relation to obesity. There is evidence from population based studies that body mass index (BMI) > 25 kg/m increases the risk of lumbar disc degeneration.[2] Being overweight at young age seems to be particularly detrimental.[36]

Genetic Factors

The first evidence for a genetic factor in causing DDD was the finding of a high familial incidence of lumbar DDD. Blood relatives of persons operated for lumbar disc disease had a significantly greater incidence of MRI abnormalities of DDD than matched controls.[42] The other clinical evidence comes from twin studies. When monozygotic twins with very different patterns of driving motor vehicles (which causes chronic vibratory stress) were compared, the degree of degeneration assessed by lumbar MRI did not significantly differ, implying that familial factors may be more important than mechanical stresses.[4] Another study calculated the heritability of cervical DDD to be 73%, as assessed by MRI in a twin study.[63] The Twin Spine Study, began in 1991 in Canada, Finland and the United States and reported in 2009, has shown only moderate influence of environmental factors such as smoking, occupation and leisure activities on the rates of DDD, but the genetic contribution was far greater.[5]

There is mounting molecular evidence for genetic factors in determining DDD. Degenerated human discs show higher expression levels of asporin gene, that codes for a small proteoglycan and this gene is known to be a susceptibile gene for osteoarthritis.[17] An association has been made with allelic variants of 25 structural, degradative and inflammatory candidate genes with lumbar DDD in humans.[74] These genes code for collagen, interleukin and MMP. Presence of at least 1 tryptophan (Trp 3) allele in the collagen IX gene (COL9A2) increased the risk of lumbar DDD about threefold, in a study from Finland.[52] Persons with little pain but severe DDD on imaging are routinely seen in clinical practice. The propensity to develop pain and response to analgesic drugs may also genetically be influenced, as shown in a recent study.[68] Peroxynitrite is a tissue-damaging molecule generated at sites of inflammation or degeneration and indicates oxidative or nitrosative stress. Peroxynitrite stimulated cytokine synthesis by increasing gene expression in an *in vitro* study of disc cells.[56] Thus, disc degeneration appears to be the end result of a complex interplay of many genetic and environmental factors.

DISC REGENERATION

It is a cherished hope of many a patient that one day medical science would be able to halt the disc degenerative process and indeed, actually effect regeneration. Two possible approaches are preventing breakdown of disc matrix and augmenting growth.

Pharmacotherapy

Anti-catabolic therapy (e.g. inhibitors of MMP), mitogens (e.g. growth factors), morphogens (e.g. bone morphogenic protein) and intracellular regulators (e.g. Sox 9) are possible classes of molecular drug therapies for the future.[80] It has recently been reported that resveratrol, a phytoestrogen found in grapes and red wine, exerts several actions to prevent disc matrix breakdown and augment disc regeneration in a bovine disc cell culture study.[34] One wonders if this compound is also responsible for the fact that moderate alcohol consumption is associated with a lower incidence of DDD, apart from the lowered rate of atherosclerosis.[81]

Cell Based Therapy

Some substances required for molecular therapy are large proteins and it is ideal to have them locally synthesised by means of cell transplants or gene therapy, rather than administered exogenously. Freeze dried whole disc allografts have been shown to maintain function and stability in the laboratory and in patients.[38] Animal experiments show that transplanted disc cells survive and produce matrix, and effect restoration of disc height. Patients who received autologous disc cell transplantation had greater pain reduction at 2 years compared with patients who did not receive cells following their discectomy surgery. Autologous disc-derived cells and adipose tissue derived cells were used in this study.[20] Bone marrow derived stem cells can migrate, survive and produce matrix in the rabbit disc.[66] Murine stem cell derived chondroprogenitors form new notochordal cells in experimentally injured rabbit discs and do not elicit an immune response.[64]

Gene Therapy

This involves the transfer of genes so that the recipient cells express these genes and synthesise the RNA and the protein they encode. The lasting effect of gene therapy is attractive as compared to exogenous replacement of the protein for chronic conditions such as DDD. Viral vector mediated transfer of genes was originally used.[69] Non-virus-mediated gene therapy is also now feasible. RNA interference technique helps down-regulate a specific gene expression (say, MMP) in the disc making it a novel avenue for therapy.[48]

Other Methods

Another possible approach is to improve the diffusion into the disc. The diffusion enhancing effect of oral nimodipine has been shown in an Indian clinical study and is yet to be exploited therapeutically.[59] Engineering and biology meet to provide hyaluronic acid nanofibrous scaffolding over which stem cells rebuild the destroyed disc.[46] It remains to be seen what the clinical efficacy and cost of these novel therapies would be.

CLINICAL CORRELATIONS

Understanding the pathophysiology of DDD helps us appreciate the wide clinical spectrum of disc disease. The young woman who develops an acute cauda equina syndrome due to a lumbar disc extrusion that occurs during labour, has *almost* a pure mechanical causation – mainly because there ought to be an element of structural weakening caused by the hormones associated with pregnancy, apart from the physical strain of labour. What about the executive who had to be operated for a far lateral lumbar disc herniation, when all he had done to precipitate it was to stoop forwards to plug in his office printer? The precipitating event served only to unmask the ongoing DDD in him, and who has not seen a patient with hardly any symptoms but with a ghastly DDD on radiography or MRI? Or a puny little thoracic disc prolapse producing paraplegia? One factor that demystifies the situation is the canal size. It is intuitive to understand that those who are blessed with a congenitally wide canal can tolerate DDD without developing neural compression. A recent report based on cervical spine kinematic MRI suggests that those with congenitally narrow canals actually have a greater propensity for DDD and not merely a greater tendency to become symptomatic.[44]

Deductions made from basic sciences have to be backed by relevant clinical data. One example is DDD occurring adjacent to a level of surgical fusion. Biomechanically, fusion is expected to wreak havoc on the adjacent disc. This fact became a strong weapon in the hands of the anti-fusion and the pro-disc replacement camps. As a radiological phenomenon, adjacent level disease (ALD) was indeed more in fused patients in a prospective randomised study. However, ALD seems to contribute little to symptoms. Simultaneous laminectomy along with the fusion seems to correlate even more strongly with ALD.[12]

IMAGING CORRELATIONS

MRI is uniquely sensitive to the changes in the biochemistry of the degenerating disc. The loss of T2 signal from the NP on desiccation has been mentioned. There is now evidence that the T1-rho relaxation time has a strong correlation to the glycosaminoglycan content and the intradiscal pressure, thus providing a means for imaging a biomechanical property.[47] By using dGEMRIC (delayed gadolinium-enhanced magnetic resonance imaging contrast), the percentage of decrease in T1 was found to correlate with the grade of DDD. Scanning at 3 Tesla with sodium based imaging helps quantify the proteoglycan content. Magic-echo pulse sequences show areas of inhomogeneity within the NP and are able to clearly distinguish the pathology in the EP from that in the NP; making these distinctions is not possible with the standard spin-echo sequences.[75]

Annular changes are also well imaged by MRI. High intensity zones (HIZ) in the posterior annulus indicate painful peripheral rim tear.[55] T2 and apparent diffusion coefficient (ADC) mapping has shown characteristic diurnal differences in the NP, inner AF and outer AF from morning to evening, again reflecting a physiological event.[37] The paradiscal vertebral marrow changes described by Modic have extensively been investigated. Type I change (T1 hypointense and T2 hyperintense) is associated with fissured EPs and oedematous, vascularised fibrous tissue in the marrow. It is significantly associated with segmental instability and low back pain. Type II change (T1 hyperintense and T2 isointense or slightly hyperintense) is due to replacement by yellow marrow. It is less clearly correlated with back pain. The

type III change (T1 and T2 hypointense) is thought to be due to bony sclerosis.[58]

CT discography is another technique that reflects the pathology in the NP and AF even before the disc herniates out. Picking up internal disc disruption with discography has helped in selecting back pain patients with near-normal MRI for fusion (in the past) or disc replacement (currently). However, there are false positives, and we should err on the side of caution.[11] Provocative discography relies on reproducing the patient's symptoms by injection. Disc block with bupivacaine is held to be better than provocative discography alone.[50] The MRI finding of disc protrusion-with-HIZ correlates better with positive provocative discography than the finding of normal/bulging disc-with-HIZ.[27] Thus, in the near future, we may be able to get the data on the altered physiology with MRI refinements alone and dispense with invasive tests such as discography.

CONCLUSION

Knowledge of the normal and altered physiology of the intervertebral disc helps the neurosurgeon to understand the patient's symptoms, interpret the imaging and plan the correct treatment. It also cautions the surgeon to think twice before performing a discectomy,—a tissue that is irreplaceable. This background knowledge is invaluable in keeping abreast with the rapid advances in the fields of disc prosthesis and molecular therapy.

110 Cervical Disc Disease and Spondylosis—Clinical Features and Diagnosis

CE Deopujari, Rajiv Kumar

INTRODUCTION

The term "cervical spondylosis" is used broadly to describe the morphologic manifestations of progressive degeneration of the spine. It is considered the most common progressive disorder in the ageing cervical spine and results from the process of degeneration of the intervertebral discs and facet joints of the cervical spine.

Several predisposing factors, such as occupations requiring repetitive motion of the cervical spine, previous injury with fracture or disc prolapse and segmentation defects like hemivertebrae or fused vertebrae, may cause acceleration of these changes.

Most people with degenerative changes of the cervical spine remain asymptomatic. Symptomatic patients are usually older than 40 years of age.[14] There are three main presentations related to cervical spondylosis: (1) neck pain and brachialgia; (2) radiculopathy and (3) myelopathy.[3]

Neck pain is the most common presentation and is frequently encountered without a precipitating incident. It may be acute or chronic and occurs more often from degenerative disc than from degenerative facet changes.

Cervical radiculopathy refers to symptoms and signs of nerve root compression and can be acute, subacute or chronic. Patients younger than 55 years are more likely to present with radiculopathy caused by herniated nucleus pulposus, whereas patients older than 55 years are more likely to have canal or foraminal stenosis caused by osteophyte formation.[11] Radiculopathy due to soft herniated disc commonly produces weakness and atrophy while a hard herniated disc produces sensory symptoms consisting of paraesthesias, hyperaesthesias or hyperalgesias. Motor and reflex changes occur less frequently and are often associated with a chronic condition.[15]

The most common roots affected are C5 and C6. This can be explained by Sunderland's[12] observation that C4, C5 and C6 roots have a strong attachment to the vertebral column while the others are relatively free. Primary compression of the nerve root without impingement of the spinal cord can result in a radicular pain pattern, loss of strength and/or sensation, or diminished to absent reflexes. Distribution of signs and symptoms in nerve root lesions are summarised in Table 1. Lesions affecting the C3 root cause sensory disturbances on the lower occiput, the angle of the jaw and the upper neck. A C3-4 disc resulting in C4 root compression does not produce motor deficit or reflex changes but will produce pain and sensory changes in the neck, scapular region and anterior chest wall. A C4-5 disc produces C5 radiculopathy with pain in the shoulder and anterior arm, weakness of the deltoid and biceps and loss of the biceps jerk. A C6 radiculopathy affects the thumb and the index finger with loss of biceps jerk. A C7 radiculopathy causes pain and sensory changes in the medial aspect of the forearm, weakness of the middle and index fingers and loss of triceps jerk, whereas C8 root affection will affect the ring and little fingers and weakness of the small muscles of the hand without reflex changes. The abduction relief sign and Spurling's sign are two examination manoeuvres that implicate compression of a nerve root at the level of the foramen.

Table 1: Distribution of signs and symptoms in nerve root lesions

Root involved	*Distribution of pain*	*Distribution of paraesthesia*	*Weak muscles*	*Reflex change*
C5	Neck, shoulder, and lateral arm	Lateral arm	Deltoid, supraspinatus, infraspinatus	Diminished biceps, brachioradialis
C6	Lateral arm and forearm, thumb	Lateral arm and forearm, thumb and index finger	Biceps, brachioradialis, wrist extensors	Biceps, brachioradialis
C7	Dorsal arm and forearm, interscapular area	Middle and index finger	Triceps and wrist extensors	Diminished triceps
C8	Medial forearm and hand, fifth digit	Medial forearm and hand, fifth digit	Intrinsic muscles of hand	Finger flexor

Myelopathy may be precipitated by a large central disc herniation, but is more commonly the result of spondylotic changes superimposed on a congenitally narrow canal. The definite time of onset of symptoms is usually not known to most patients and a change in the gait or dexterity of hand function is the most common presentation. The clinical pattern of myelopathy is characterised by the presence of long tract signs which includes hyporeflexia of the deep tendon reflexes at the level of affection and hyperreflexia at the levels below the affection in the upper limbs as well as lower extremities, increased muscle tone or clonus, and the presence of pathological reflexes, including Babinski's sign or Hoffman's sign. Inability to grip and rapidly release the fingers is an additional sign of a myelopathic hand.[9] Spillane et al.[10] noted that the early phase of cervical spondylotic myelopathy is also characterised by clumsiness and unsteadiness of gait. Severe muscle atrophy caudal to the level of stenosis is uncommon with a spondylotic myelopathy, except in the later stages.

Frequently, a combination of radicular and cord symptoms is found (radiculomyelopathy). Acute exacerbation of radiculomyelopathy can occur in spondylotic patients after minor trauma and occasionally after unrelated surgery.[5] Cervical radiculopathy may occur in a subset of myelopathic patients. In this process, the spinal canal is stenotic along with concurrent focal compression of one or more nerve roots. The majority of the patients who present with myelopathic features have concurrent axial neck pain. The most frequent clinical finding or myelopathic sign found in these patients is spasticity, followed by weakness.[4]

Various autonomic symptoms can be produced by cervical disc disease, e.g. vertigo, flushing, tinnitus and visual blurring. These may be mediated by the sympathetic contribution to the sinuvertebral nerves from the stellate ganglion. Spondylotic changes at the uncovertebral joints may cause direct kinking of the vertebral artery and produce similar changes, especially if the wall of the vessel is atheromatous.[6] Vertebrobasilar insufficiency induced by spondylotic compression of the vertebral artery is uncommon, although popularly diagnosed.[2] Autonomic pathways may also be responsible for the cervical angina syndrome. Anterior chest wall pain is described with C6-7 disc prolapse.[16] Occasionally, anterior osteophytes may cause swallowing difficulty.[8,13]

The differential diagnoses of cervical radiculopathy (Table 2A) are brachial neuralgia, carpal tunnel syndrome, vascular compression syndrome, vasospastic disorders and shoulder pathology. The pain and weakness of C5 radiculopathy is very similar to brachial plexitis which presents with early deltoid weakness. The pain and paraesthesiae of C6 radiculopathy may mimic carpal tunnel syndrome. Carpal tunnel syndrome is characterised by nocturnal dysaesthesia, weakness and occasionally thenar atrophy. The pain of lower cervical radiculopathy can mimic thoracic inlet syndrome. Conditions that can mimic spondylotic myelopathy (Table 2B) are amyotrophic lateral sclerosis, myelitis, multiple sclerosis and demyelinating conditions.

Table 2: Differential diagnosis

A. Cervical radiculopathy	*B. Cervical myelopathy*
Brachial neuralgia/neuropathy	Amyotrophic lateral sclerosis
Carpal tunnel syndrome	Primary lateral sclerosis
Vascular compression syndromes	Multiple sclerosis
Vasospastic disorders	Demyelinating conditions
Shoulder pathology	Syringomyelia
Autonomic disorder	Extramedullary tumours
Cardiac diseases	Myelitis
Gallbladder	Spinal AVM and Dural AVF

IMAGING EVALUATION

The diagnostic workup includes static and dynamic cervical spine X-rays and magnetic resonance imaging (MRI). Cervical X-rays (Fig. 1) may demonstrate loss of disc space height, spondylotic bars, foraminal osteophyte, kyphosis, subluxations, posterior compression from facet arthropathy or late autofusion of adjacent cervical segments. Flexion-extension lateral films may be useful to assess significant instability. Oblique views (Fig. 2) can also demonstrate foraminal osteophytes.

MRI is the preferred diagnostic modality for cervical spondylosis. MRI is useful for evaluating the spinal canal diameter, spinal cord and various components responsible for stenosis and compression, viz. intervertebral discs (Figs 3 and 4), ligamentum flavum hypertrophy (Fig. 5) and vertebral ligaments. Signal intensity changes on T2-weighted MRI scans (Fig. 4) at the level of spinal compression are often increased in patients with cervical spondylotic myelopathy. This represents oedema, inflammation, ischaemia,

Fig. 1: X-ray cervical spine showing loss of lordosis, decreased disc space and osteophyte formation

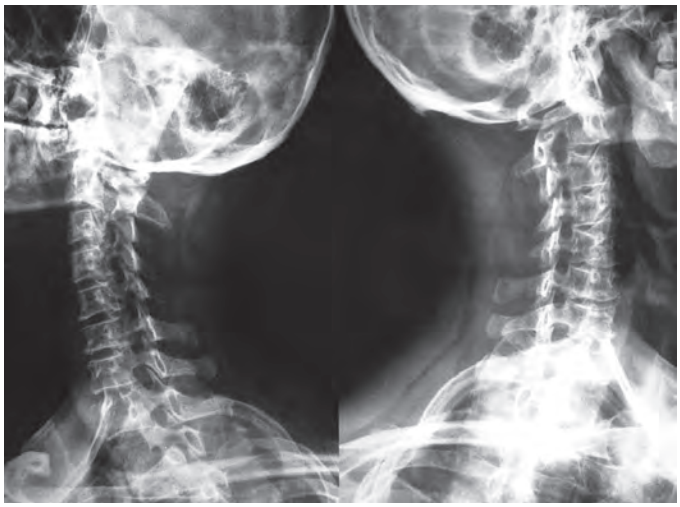

Fig. 2: Oblique cervical spine X-rays showing foraminal stenosis by osteophytes mainly at left C3/4

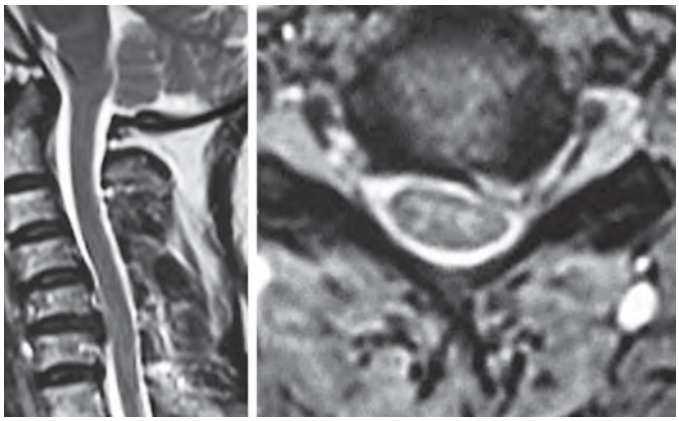

Fig. 3: MRI showing loss of lordosis with anterior compression at C5/6 disc level, axial plane confirming the left lateral (foraminal) disc prolapse

myelomalacia or gliosis.[7] However, bone quality assessment on MRI scans is not as good as with CT.

Occasionally, CT may be required for better delineation of bone anatomy such as in OPLL (Figs 6 and 7). CT is also useful for evaluating the transverse foramina, size and shape of the spinal canal, facet and uncovertebral

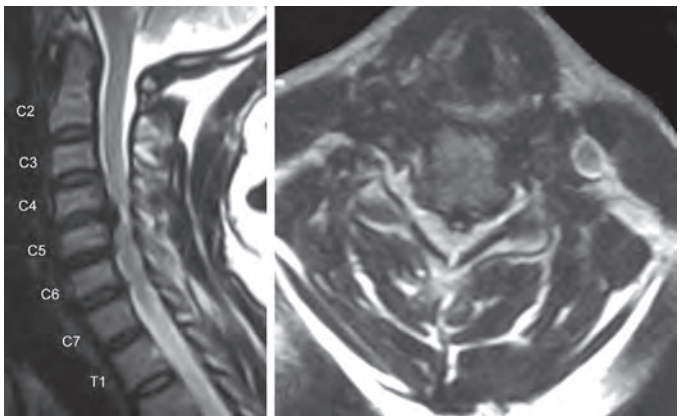

Fig. 4: MRI cervical spine showing C4-5 central disc prolapse with increased signal intensity in T2 images

Fig. 5: MRI showing cervical canal stenosis with posterior compression due to ligamentum flavum hypertrophy

joints. Dynamic CT scans are most useful for evaluation of instability (Fig. 8). CT myelography provides excellent visualisation of radicular or cord compression in patients in whom MRI cannot be performed for some reasons.

Neurophysiologic Studies

Electromyography (EMG), nerve conduction velocity (NCV) and somatosensory evoked potentials (SSEP) may be used to evaluate patients with radiculopathy or myelopathy. Brachial plexitis, carpal tunnel syndrome and thoracic inlet syndromes can accurately be diagnosed with the help of neurophysiological studies. In nerve conduction studies amplitude, distal latency and conduction velocity are measured. While amplitude corresponds to the number of intact axons, distal latency and conduction velocity reflect the degree of myelination. EMG

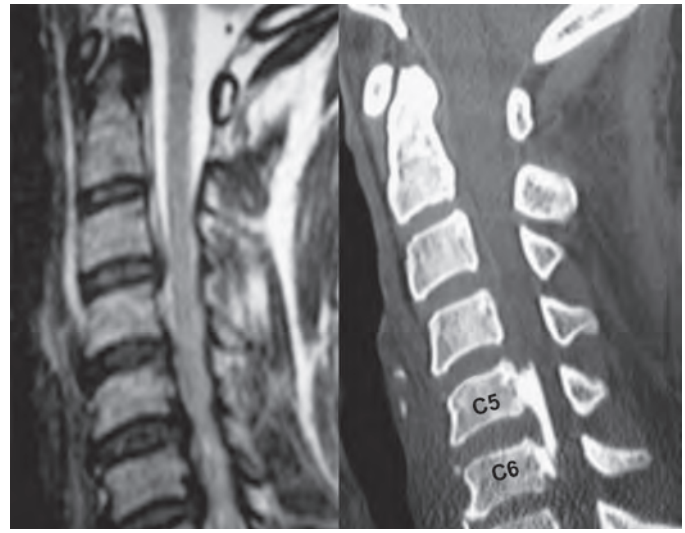

Fig. 6: MRI and CT scan showing cervical canal stenosis due to anterior compression by opacified posterior longitudinal ligament

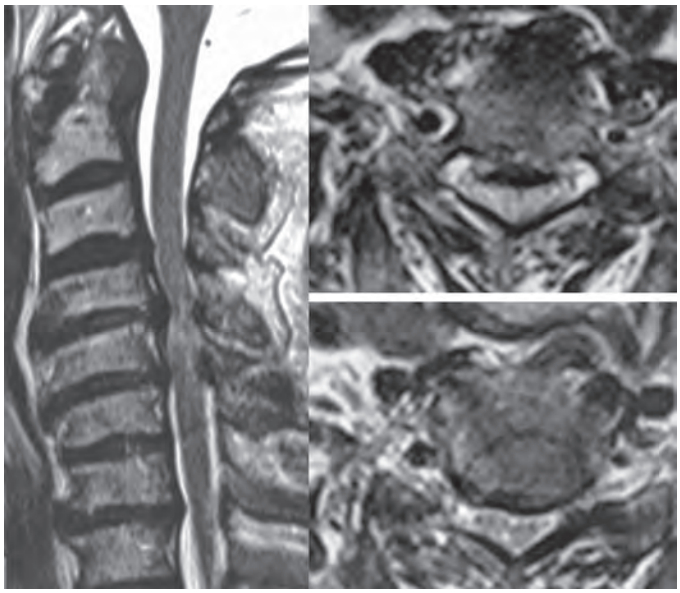

Fig. 7: MRI cervical spine showing global cervical canal stenosis, anteriorly due to opacified posterior longitudinal ligament and osteophytes, and posteriorly due to ligamentum flavum hypertrophy along with signal changes in the cord in the compressed segment

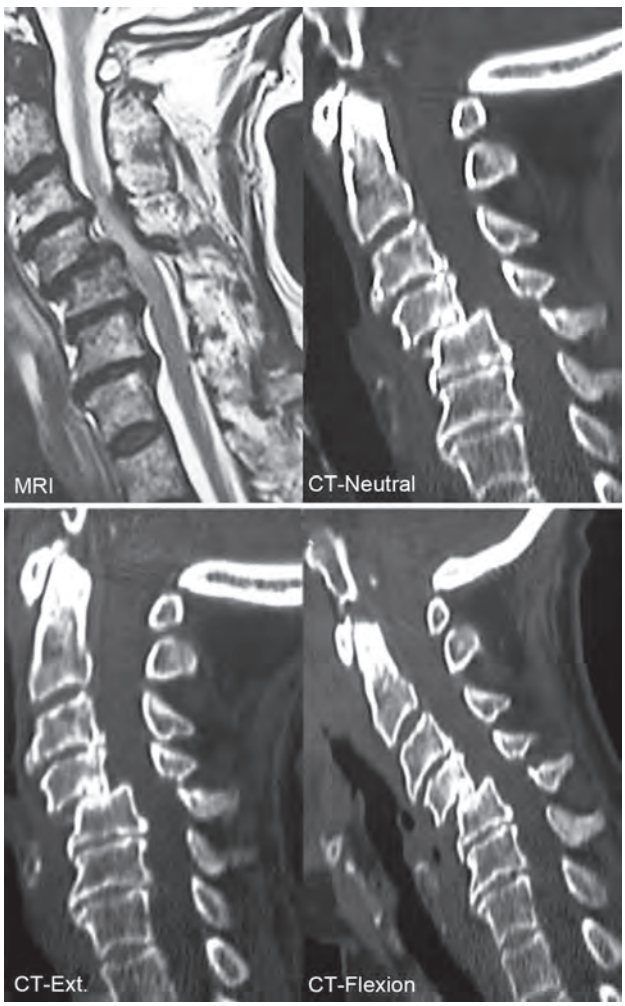

Fig. 8: MRI and CT (flexion, extension) showing degenerative C4-5 anterolisthesis with cord compression and cord signal changes. Instability is evaluated by dynamic CT

helps to establish the degree of muscular impairment and the number and the level of roots involved, and the duration of the syndrome. Motor neuron disease can accurately be diagnosed with proper EMG examination. Segmental dysfunction of the cervical cord can also be confirmed by an abnormality of the spinal N 13 potential on SSEP. Al-Mefty and co-workers,[1] in the experimental model of chronic compressive cervical myelopathy found that changes in SSEP occurred almost immediately before or at the time of neurological presentation. A combination of electromyography and somatosensory evoked potential evaluation can be very useful for confirmation in some patients presenting early with only subtle signs of upper and/or lower motor neuron dysfunction.

111 Cervical Disc Disease and Spondylosis Management

CE Deopujari, Rajiv Kumar, Rajan Shah

Cervical disc disease and spondylosis is a common pathological entity and is characterised by increasing degeneration of the intervertebral disc with subsequent changes in the bones and soft tissues. From skeletal maturity to the age of 30 years, few morphological changes occur in the cervical spine. Thereafter, the process of normal ageing in the cervical spine contributes and is difficult to differentiate from pathophysiological changes. From the fourth to the fifth decades, it is clear that the intervertebral disc undergoes progressive desiccation, becomes more compressible and less elastic, and secondary changes ensue. Although the majority of individuals over 50 years of age demonstrate significant radiological evidence of degenerative disease of the cervical spine, only a small percentage develops symptoms and neurological consequences.

In 1892, Horsley successfully operated upon a young man who developed quadriparesis after a fall, due to "a transverse ridge of bone projecting backwards from the body of the sixth cervical vertebra and pressing upon the cord".[30] In the early 1900s, the usual surgical approach to the cervical spine was through a posterior approach. In the 1940s, Spurling and Scoville[58] and Frykholm[22] described posterior foraminal decompression. In the 1950s, anterior cervical discectomy with fusion using the Smith-Robinson[55] and Cloward[13] techniques became popular and the mainstay of surgical treatment with some variations. Anterior discectomy without fusion was described in 1960 by Hirsch.[29] Since then numerous modifications have been made in the treatment of cervical spondylosis through an anterior approach. Similar advancement has been made in the treatment of cervical spondylosis through the posterior approach. Cervical laminoplasty was developed by Japanese surgeons after encountering a high incidence of post-laminectomy kyphosis.

The treatment options available for the management of cervical spondylosis are medical therapy and surgery.

MEDICAL MANAGEMENT OF CERVICAL SPONDYLOSIS

Medical management of cervical spondylosis includes pharmacological and rehabilitation components and mainly targets at pain relief. The use of these components is largely empirical as controlled studies are lacking. A systematic review of 24 randomised controlled trials of pharmacological and non-pharmacological treatment of mechanical neck pain concluded that, "in general, conservative interventions have not been studied in enough detail to assess efficacy or effectiveness adequately".[1]

Medical therapy in patients with radiculopathy and unremitting severe pain despite a full trial of non-steroidal anti-inflammatory drugs may be managed with a short course of steroids and paraesthesiae may respond to antineuralgic drugs, viz. gabapentin, pregabaline, etc. Acute neck pain can also be managed with either non-steroidal anti-inflammatory drugs or acetaminophen, supplemented with muscle relaxants in the first 2 weeks of symptoms. Development of radicular deficit and/or progressive myelopathy should be considered for termination of conservative management and surgical intervention is recommended.

Physical therapy has an important role in the management of cervical disc disease. The main objectives are to decrease the duration of disability, to reduce the use of drugs and to prevent chronicity and recurrence. The preference is to use active rather than passive modalities. Passive modalities should be used only temporarily as an adjunct. Active modalities are isometric exercises of the neck, postural re-education and strengthening exercises for the neck, shoulder and back muscles. Passive modalities are heat and cold application, ultrasound, cervical collar, traction, massage, trigger point treatment and low power cold laser.

A majority of patients with non-myelopathic cervical radiculopathy respond to non-operative care consisting of analgesic, anti-inflammatory therapy and physiotherapy. In patients with mild or subtle myelopathy, non-operative treatment can be used with regular monitoring of neurological deterioration. Traction or manipulation should be avoided.

SURGICAL MANAGEMENT OF CERVICAL DISC DISEASE AND SPONDYLOSIS

Surgical intervention is indicated for patients with spondylosis who have disabling pain refractory to conservative measures, acute cord compression, signs of progressive cord dysfunction and progressive muscular weakness or sensory impairment. Precise correlation between clinical and imaging studies is necessary before

surgical intervention. The goal of the surgical management of patients with radiculopathy or myelopathy is decompression of the nerve root and spinal cord, elimination of the anteroposterior flattening and distortion of the cervical cord. Secondary surgical considerations include realignment of the cervical spine, correction of cervical spinal instability and rectification of cervical spinal deformity. Two surgical approaches are available: the anterior approach and the posterior approach with various degrees of laminectomy and laminoplasty.

ANTERIOR APPROACH

Patients with spondylosis with osteophytes, herniated disc or in those with evidence of spinal cord compression or mechanically produced neck pain can be approached via the anterior route. The anterior approach to the cervical spine is easy and safe from levels C3 through C7. The anterior intervertebral route exposes the vertebral bodies, the discs and the osteophytes that form in the ventral aspects of the root foramina and spinal canal which can directly be removed. The anterior approach has two distinct advantages: (1) osteophytes can be removed safely and (2) fusion of the affected disc space provides permanent immobility of that joint. The disadvantage is that it affords no access to posterior elements that may be compressing the neural structures. For cervical spondylotic myelopathy, the anterior cervical approach is preferred if the compressive pathology is primarily ventral, localised to the interspace or is associated with cervical instability, spondylolisthesis or kyphotic deformity.

Anterior Cervical Discectomy

Anterior cervical discectomy for cervical disc protrusions started with the techniques described by Smith and Robinson in 1955, and Cloward in 1958. In 1960, Hirsch showed that good stability and fusion could be achieved without grafting. In 1965, Robertson used the operating microscope for removing cervical disc protrusions. He removed the disc material including the cartilaginous end plates and the posterior annulus to varying degrees. Hankinson and Wilson (1975) removed only the central portion of the disc using a high-speed drill, leaving columns of disc intact laterally. On approaching the posterior end of the disc space, the drilling was stopped and curettes and pituitary rongeurs were used for further dissection. Osteophytes were removed and the posterior longitudinal ligament usually opened. Maurice-Williams described an extended decompression with removal of posterior osteophytes, but leaving the cartilaginous end plates intact.[38] The term 'extended' refers to the removal of bone posteriorly and was described by Dunsker in 1977.[17] This involves removal of the posterior-inferior margin of the upper vertebra and for foraminotomy, the removal of the posterior-superior margin of the lower vertebra. Watters did not remove posterior osteophytes and the posterior longitudinal ligament.[38] However, he reported similar results in the anterior cervical discectomy (ACD) and the anterior cervical fixation (ACF) groups, although he stated that the satisfaction for the surgical outcome was better in the ACF group in comparison with ACD group.[38]

The rationale for removing the posterior longitudinal ligament is that following discectomy narrowing of the space could cause the ligament to buckle and produce anterior spinal cord compression. Removal of the posterior longitudinal ligament when it is involved in the spondylotic compression appears necessary and essential. However, routine removal of the stronger ligament in young patients when it is not a component of the compression seems unnecessary. Most surgeons feel that removal of the foraminal osteophytes is an essential part of the procedure, whether carrying out ACD or ACDF. However, Klaiber reported that persistence of foraminal osteophytes post-operatively did not correlate with clinical outcome.[34]

Technique of Anterior Cervical Discectomy

Exposure of the cervical spine by the anterior approach involves careful placement of the patient on the operating table with a head rest. Moderate extension is obtained by placing a small pillow or towel roll under the interscapular shoulder region. The upper cervical spine is best approached from the right side for a right handed surgeon. Although the lower cervical spine (below C6) can also be exposed well through a right sided incision, a left sided approach may be preferred for easy manoeuvrability, as well as avoiding injury to the recurrent laryngeal nerve. Crutchfield tongs are used for traction for traumatic and other cases requiring corpectomy and fusion. The head is slightly rotated to the side opposite to the skin incision. A neck skin crease incision (approximately 6 cm and medially reaching up to the midline) is adequate for single- or two-level surgeries. An incision at the level of Adam's apple is suitable for exposure of C5 and the incision can be placed above or below this level depending on the level to be exposed. However, for more extensive surgery, viz. corpectomy or plate fixation, a vertical incision is preferred running along the anterior border of the sternomastoid. The platysma is also incised in the same line and the middle layer of the fascial plane between the sternomastoid and the strap muscles is split open with blunt and, occasionally, sharp dissection. For exposure of C7 and lower down, the inferior thyroid artery and the omohyoid may need to be divided, and for exposure of C2-3, the common facial vein and the digastric tendon will need division, and retraction of the mandible may be necessary. The carotid sheath should remain on the lateral side of the dissection, avoiding injury to the sympathetic trunk.

The deep cervical fascia overlying the longus colli muscles and the anterior longitudinal ligament of the cervical spine are then visible. Once the prevertebral fascia is reached, a needle is inserted in the probable diseased disc space and the level is confirmed using a

C-arm. The needle is rostrally directed against the body above to avoid inadvertent dural penetration. The prevertebral fascia is then incised in the midline and the anterior spinal ligament and anterolaterally the longus colli muscles are exposed. The muscles are then dissected on both sides with sharp dissection well above and below the required area, to ensure that the blades of the self-retaining retractors can be placed underneath to maintain proper exposure during the entire procedure. Either Cloward or Caspar self-retaining retractors are then applied vertically.

The operating microscope is brought in at this stage. The annulus is then incised and the nucleus is entered. Anterior osteophytic ridges, especially of the upper body, may obscure the view in the presence of gross spondylotic changes and can be removed by small nibblers or Kerrison punch or burred away with a high speed drill, facilitating entry into the disc space. The nucleus is then removed with curettes and rongeurs. A vertebral spreader is then inserted in the disc space. Further disc removal is then performed and a complete disc excision can then be done in most cases of soft disc protrusion till the posterior longitudinal ligament is completely exposed. The posterior longitudinal ligament is then inspected for any tear, as the disc can sequestrate through the ligament into the spinal canal. Both the foramina can be probed with a blunt micro hook for disc fragments. In the presence of a hard disc protrusion with gross posterior osteophytic ridges, it is necessary to curette them or preferably remove them with high speed burrs after thorough removal of the hyaline cartilage attached to the vertebral body end-plates. This is important for proper decompression and frequently soft disc protrusion under these osteophytic ridges are observed. It is also necessary to create parallelism for the graft to fit precisely. Uncovertebral joint spurs projecting into the neural foramina should be curetted or burred away to enlarge the foramen till a blunt micro hook can be passed along the nerve root, ensuring adequate decompression. This is more important, and should be done generously, if a bone graft is not being used. In Figure 1, MRI of a patient has been shown who presented with radiculopathy due to C4-5 disc prolapse, and who underwent anterior cervical discectomy.

Results of Anterior Cervical Discectomy

In 1960, anterior cervical discectomy without fusion was first described by Hirsch, and is usually adequate for soft disc protrusions at one or two levels in the absence of severe spondylotic changes or significant canal stenosis.[6,40,53] Anterior cervical discectomy without fusion is followed by narrowing of the disc space and a degree of *anterior angulation (kyphosis).* Martin[37] and Dunsker[17] reported post-operative kyphosis in their study. However, they stated that it did not correlate with clinical outcome. The consensus appears to be that major kyphosis is significant, but very rare and the majority have no more than minor angulations which resolve by 1 year. Discectomy by itself leads to collapse of the disc space and subsequent *foraminal narrowing*. Strachan and West quantified this, and found that reduction in area was 12% and not statistically significant.[59] They suggested that the foraminal narrowing is not clinically significant as reported outcomes were similar after both ACD and ACF.

Complications of Anterior Cervical Discectomy

Anterior cervical surgery may have complications, viz. hoarseness, tongue paralysis, swallowing difficulty, Horner's syndrome, oesophageal perforation and fistula, spinal cord/root injury and vertebral artery injury. A post-operative infection or haemorrhage may also result.

Anterior Cervical Discectomy with Fusion

The clinical benefits of combining anterior cervical discectomy with bone grafting (ACDF) versus performing anterior cervical discectomy alone for cervical spondylosis remains controversial. Many surgical series reported over the last 30 years give consistently excellent results with ACDF.[12–15,24,29,36,45,46,48,55] However, Hirsch reported his experience with simple cervical discectomy alone

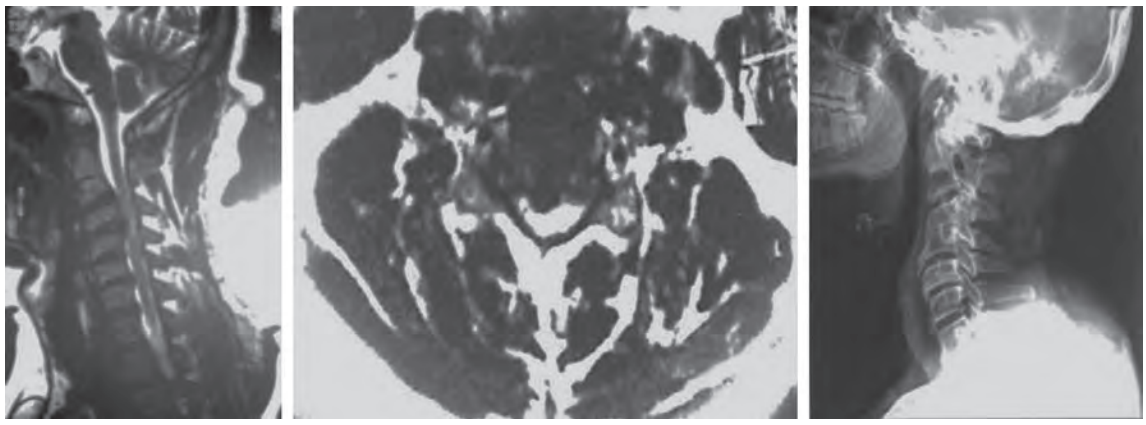

Fig. 1: Sagittal and axial view MRI showing C4-5 disc prolapse. Patient underwent anterior cervical discectomy C4-5. X-ray after 1 year showing fusion

(ACD) for the treatment of cervical spondylosis.[29] His results and those of others suggest that ACD can result in surprisingly good results challenging the need for routine arthrodesis after cervical discectomy.[5,23,24,37,44,46,57,66] Both techniques have theoretical advantages. Discectomy alone requires less surgical time is associated with fewer complications and lower cost. Discectomy with fusion results in a more rapid resolution of neck and arm pain while preventing post-operative deformity of the spine by stabilising the abnormal motion segment, arresting spur formation and preventing buckling of the ligamentum flavum and the posterior longitudinal ligament. The range of motion at the operated segment increases after anterior cervical discectomy as compared to anterior cervical discectomy and fusion. Later on, when fusion occurs in patients with anterior cervical discectomy, the biomechanics approach those of fusion. Thus, it has advantages of both, initially providing some motion at the operated segment and in later stages when fusion occurs, providing advantages similar to grafted fusion. In a prospective randomised study, Savolainen et al.[49] have shown that after anterior cervical discectomy alone, complete bony union occurs invariably.

Fusion of the Cervical Spine

The term fusion has become synonymous with insertion of the bone graft. Bony fusion, if it occurs, does so after at least a few months, and in a proportion of patients, never occurs. Some reports indicate that there is resolution of neck and arm pain quite early after fusion procedures when true fusion is unlikely to have taken place.[61] Early resolution of neck pain in this circumstance must be related to the maintenance or restoration of alignment and biomechanics. In other words, the graft is acting as a 'spacer' in the first instance and fusion has nothing to do with it.[47] There are a number of reports of anterior cervical discectomy and fusion in which a few patients who had a non-union, did not necessarily experience a poor result.[32,63] Eventually it was obvious that a good prognosis for operative intervention was not related to obtaining a bony fusion, but rather to operating on patients with classical radicular symptoms.[17] A prospective randomised study of anterior single level cervical disc by Savolainen[49] using three different methods (discectomy without fusion, fusion with autologous bone graft and fusion with autologous bone graft plus plating) had shown that ultimately all patients had complete bony union. In this study the fusion rate was slightly better with fusion and plating after 6 months, but, after an average of 4 years of follow-up, this difference vanished.

The majority of early authors assumed that fusion was necessary. They were troubled by the possibility of developing an unstable cervical spine with resultant threat to the underlying spinal cord, or of developing angulations that might lead to the chronic signs and equivalents of spondylotic myelopathy that one is trying to prevent or treat.[17] In Figures 2A and B, MRI cervical spine of a 50-year-old lady has been shown with C4-5 disc prolapse, who underwent ACDF.

The goals of the spinal internal fixation procedures are to achieve anatomical alignment, protect the neural elements and mechanically stabilise the spine while attempting to preserve the motion of normal spinal segments. These goals can only be attained by a satisfactory arthrodesis. The success of a fusion ultimately depends on satisfactory bone healing as instrumentation provides immediate but only temporary spinal fixation and is susceptible to failure due to fatigue, loosening or

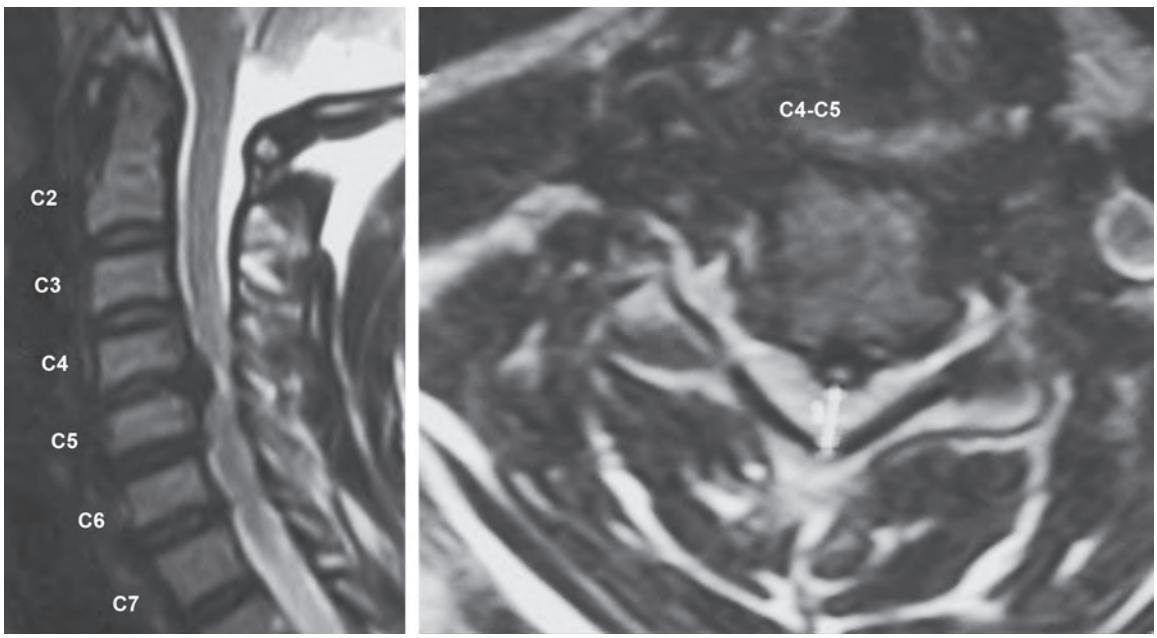

Fig. 2A: MRI cervical spine of 50-year-old lady showing C4-5 disc prolapse, underwent ACDF

Fig. 2B: X-ray on 1st post-operative day of patient (Fig. 2A) who had underwent ACDF

breakage. Surgery for fusion depends, therefore, largely on meticulous preparation of the fusion bed, and the ability of graft material to induce bone healing apart from the local fixation method and systemic factors.

When a fusion is undertaken, graft-related complications may be added to the already mentioned complications associated with discectomy such as infection, collapse, extrusion, donor site complications like pain and infection followed by failure of fusion.[25] In addition, fusion is said to predispose to accelerated adjacent level degeneration.[31]

Techniques of Anterior Spinal Fusion

The *Smith-Robinson technique* involves a thorough discectomy followed by the insertion of a tricorticate iliac crest bone graft (Fig. 3). The cartilaginous plate is meticulously removed. Bony spurs along the posterior edges are removed taking care not to remove the anterior cortical edges. The disc space is usually 1.6–2 cm deep and usually a 1.5 cm long graft is necessary. A tricorticate graft is obtained from the anterior part of the iliac crest so that its cancellous surfaces will lie against the subchondral bone above and below the space, while its cortical part forms the support between the vertebrae. Vertebral spreader is used for increased distraction before inserting the graft. The graft is inserted carefully and tapped into place. The graft is countersunk just posterior to the anterior margins of the vertebral bodies. The distractor or traction is then removed so that the graft fixes firmly. The empty space around the graft may be filled with cancellous bone chips.

The *Cloward technique* accomplishes fusion with the use of a bone dowel (Fig. 3). An autologous iliac crest graft is removed as a dowel or the allogenic bone graft may be obtained from the bone bank. All disc material is removed and the depth of the interspace is precisely measured. The drill guide is adjusted to this depth and is centered over the disc space. After completion of drilling, the remaining osteophytes can be curetted or drilled away. The bone graft is obtained from the anterior superior iliac spine by applying the dowel-cutter transversely on the ilium and a full thickness graft is obtained, leaving the crest intact. The dowel is then firmly tapped into place with a length slightly less than that measured for the interspace. The step is facilitated by first applying the vertebral spreader and removing it after placement of the graft for proper impaction.

The *Bailey-Badgley technique*[3] involves cutting a trough with a drill in the anterior aspect of the vertebral bodies, which should approximately be 1.2 cm wide and

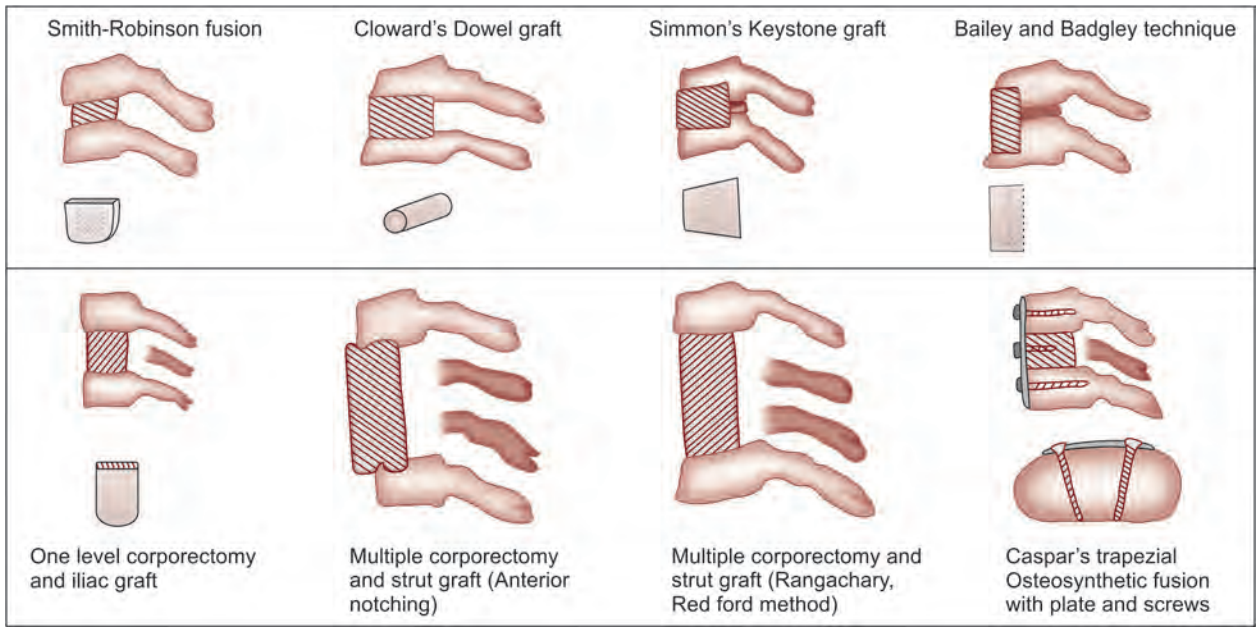

Fig. 3: Techniques of anterior cervical fusion

4.7 cm deep near the top of the upper vertebra (Fig. 3). Disc is then removed along with the cartilaginous plates of the vertebrae to be fused. Cancellous chips from the iliac bone are packed into the disc space and then an appropriate sized graft is inserted into the trough after applying traction. The graft must not project anteriorly beyond the vertebral bodies and is wedged properly after removal of traction. Suturing the fascia over the graft is important in this type of fusion, which is especially useful for multi-segmental disease.

Bloom and Raney[7] recommend reversing the orientation of the graft so that the round cortical edge of the iliac crest is placed posteriorly and the cancellous edge anteriorly so that the protruding portion of the graft can be trimmed without sacrificing the cortex and decreasing the strength of the graft. However, this may result in collapse of the graft anteriorly with some kyphosis in elderly patients.

White and Hirsch[62] have found the Smith-Robinson configuration of graft to be the strongest in compressive loading. The strong configuration of *Smith-Robinson* arthrodesis is the result of leaving the cortical shell of the vertebral body intact as 40–75% of the strength of the vertebra comes from the cortical bone, and the emphasis given to preservation of the end plate.

Simmons et al.[52] use a key stone graft for fusion (Fig. 3). A keystone square or rectangle of tissue is removed, bevelling it upwards into the vertebra above and downwards into the vertebra below using an osteotome and chisel or high-speed burr. After this, a thorough discectomy is performed. A rectangular graft is obtained from the iliac crest and shaped to fit the trough by bevelling the ends upwards and downwards to approximately 14–18 degrees. After distraction, the graft is placed into the defect and it gets locked firmly on removal of the distraction.

Bone Grafts and Other Materials Used for Fusion

Autogenous bone grafts are mostly obtained from the *iliac crest.* The advantages of autografts are that they are live, sterile and non-reactive being genetically identical to the host. *Autogenous cancellous bone* is currently the best material for its osteogenic, osteoconductive as well as osteoinductive properties. *Cortical bone* adds to the mechanical strength of the graft, but it is slowly vascularised and is minimally osteoconductive. A bicorticate or tricorticate iliac bone graft as used in most cervical fusion procedures has the advantages of both. *Autogenous vascularised bone grafts* can be obtained from the fibula, rib or iliac crest for spinal fusion as they have superior healing capabilities. These grafts hypertrophy when subjected to mechanical stress while non-vascularised grafts resorb early and weaken. Vascularised bone grafts are particularly helpful when the recipient bed is devascularised, irradiated or scarred. *Allografts* are transplanted from genetically known identical members of a species and heal in a similar fashion when used for spinal fusion as the autografts, although the vascular ingrowths are slower, lesser and new bone formation is, therefore, delayed. Allografts elicit an immunological reaction and may, occasionally, be rejected.

Cages (Fig. 4) are now available into which a bone graft can be incorporated. Cages are hollow implants that restore physiological disc height, prevent disc space collapse and stimulate bony fusion by allowing new bone growth within and around them. Cages have fusion rates similar to those associated with bone grafts.[2] Complications related to the implantation of the cages are subsidence into the adjacent vertebral bodies, cage dislocation, non-union and painful pseudoarthrosis.[65] *Methyl methacrylate* usually acts as a *spacer*, which

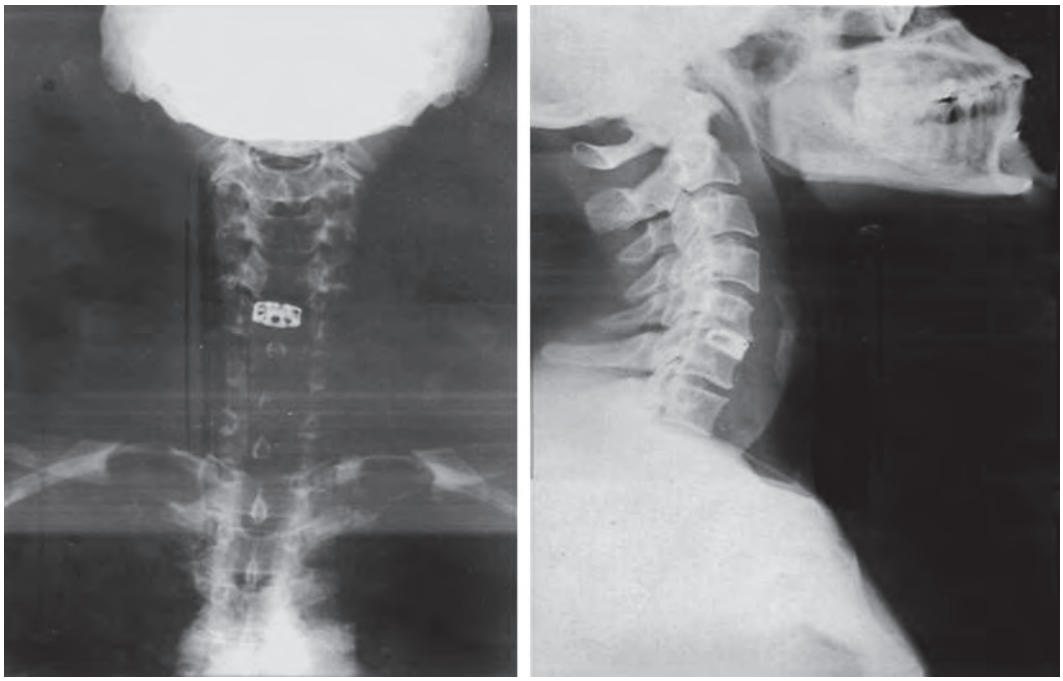

Fig. 4: Cage insertion after anterior cervical discectomy

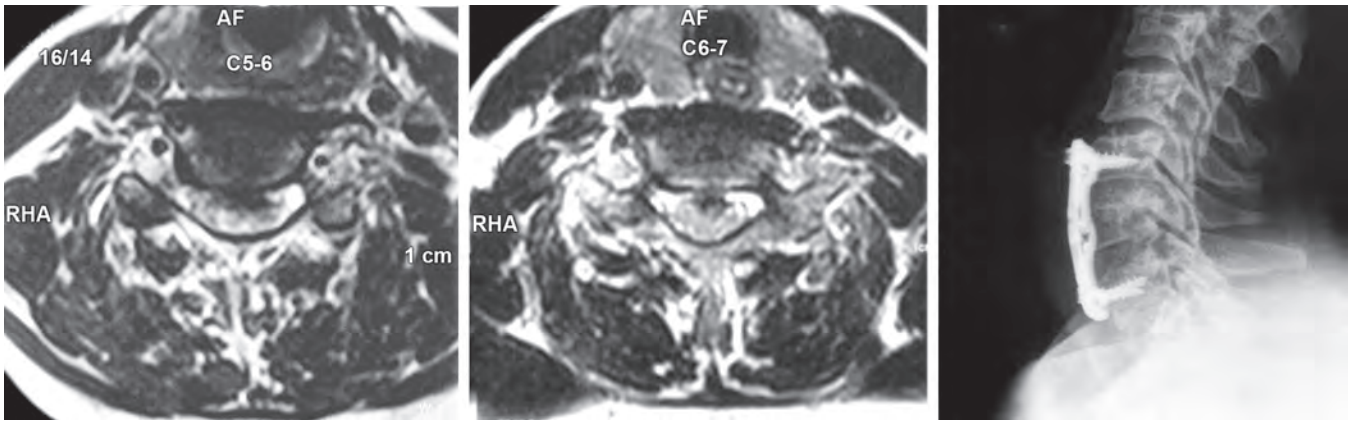

Fig. 5: MRI cervical spine axial view showing C5-6 and C6-7 disc prolapse of patient who presented with cervical myelopathy. She underwent ACDFI. X-ray cervical spine showing fusion after 5 months

resists compression and around which cancellous bone may be inserted to promote bony fusion. This is usually reserved for patients with malignant tumours or when good bone stock is not available, as it does not promote bone healing. A prospective randomised study of *polymethyl methacrylate* versus titanium cage after anterior cervical discectomy by Schroder et al.[50] had shown that the radiological result of the titanium cage is superior to that of *polymethyl methacrylate* with respect to the fusion rate. Although the titanium cage achieves a better fusion rate, there is no difference between titanium cages and *polymethyl methacrylate* with respect to the clinical outcome.[50] *Ceramics* are being increasingly used by some workers[42] as they not only act as a spacer but also have osteoconductive properties and osteoblasts form bone directly on their surface and, therefore, may be a better substitute.

Instrumented Fusion

Hardware in cervical spine surgery has been utilised for practical reasons like prevention of graft displacement, greater fusion rate, prevention or correction of scoliotic deformity and avoidance or simplification of external orthotics.[8] However, there is 10–12% short-term morbidity related to instrumentation.[60]

Casper's trapezial osteosynthetic plate technique[9] was originally described for the treatment of cervical spine injuries but has successfully been employed for treatment of spondylotic myelopathy, post-laminectomy kyphosis, infections and tumours. Deopujari et al. have found it to be a technically safe and satisfactory procedure in over 60 cases with a fusion rate of almost 100%.[8] It permits neural decompression and immediate stability, is useful for reducing spinal deformity, prevents bone graft migration and improves fusion rates. The posterior cortex should be engaged to provide immediate stability and avoid pull out observed in the Casper and the AO plate systems.

The second generation systems (e.g. CSLP from *Synthes,*[39] Orion from Sofamer-Danek, Codman plate) allow screws to lock up with the plate and engaging the posterior cortex may not be necessary. Titanium plates (Fig. 5), like in the Orion system,[49] are much lighter, easy to use and avoid difficulties in post-operative imaging. The latest, third generation systems are the dynamic semi-constrained plates to prevent stress shielding and allow subsidence.

Dynamic Fusion

Dynamic fusion or cervical total disc replacement has emerged as an alternative for the management of cervical disc herniation.[18] The goals of cervical total disc replacement are to remove the offending disc while maintaining disc height and segment motion. Although never proved, motion preservation with total disc replacement is intended to reduce adjacent-level disease.[18] Preservation of motion at the affected disc level restores normal biomechanics and offers several advantages such as avoidance of adjacent segment degeneration, donor site morbidity and early post-operative mobilisation. Inclusion criteria for cervical disc replacement includes symptomatic disc disease at a single level, and young patients (less than 60 years), while exclusion criteria includes prior fusion at an adjacent level, instability, and severe facet arthrosis at the affected level.

Total disc replacement involves anterior decompression of the disc space, similar to ACDF. The cervical disc prosthesis is then inserted into the evacuated disc space in place of bone graft. The cervical total disc replacement implants with the most extensive clinical experience are the ProDisc-C (Synthes, Oberdorf, Switzerland), the Bryan cervical disc (Medtronic Sofamor Danek, Memphis, Tennessee) and the Bristol disc (Medtronic Sofamor Danek, Memphis, Tennessee).[4] Although there are no long-term data available, these three cervical prostheses appear promising for the non-fusion treatment of cervical degenerative disc disease.[4]

Partial Median Corpectomy and Grafting

Anterior discectomy, osteophytectomy and interbody fusion by these various methods have yielded results superior to decompressive laminectomy, if the disease

process is confined to one or two levels. Surgery for more than three levels is not commonly performed because of morbidity, prolonged operating time and concern regarding kyphotic or swan neck deformity. The results are also less satisfactory, as decompression is confined to the intervertebral disc spaces, and canal stenosis is not adequately tackled. Partial median corpectomy and grafting has been recommended for such cases. The anterior longitudinal ligament and the annulus are excised from the lowest and then higher disc spaces till the posterior longitudinal ligament is visualised and the end-plates are also curetted or burred away. The intervening cancellous bone is then removed with rongeurs, curettes and high speed burrs. The central two-thirds of the body is resected to ensure decompression of the spinal canal, but not far enough laterally to disrupt the pedicles. An iliac crest, tibial or fibular bone strut is then inserted into the slots in the vertebral end plates at the rostral and caudal extremes of the resection sites.[26] The graft is locked in the slotted place with two-thirds of the graft coming to lie posterior to the anterior aspect of the vertebral column.[64] Rengachary and Redford have modified this approach where a trough is created in the superior and inferior end plates and the whole graft fitted in the slots beneath the anterior cortex, to allow good contact and compression of the graft.

POSTERIOR APPROACH

Dorsal compression is best treated by a posterior approach. Posterior approach affords easy access to the posterior elements of the vertebrae, dorsal and dorsolateral aspects of the spinal canal and its contents from C1 to D1. Cervical canal stenosis, either congenital or degenerative with hard disc protrusions or hypertrophied ligamentum flavum compressing the cord is readily removed by laminectomy. Also, decompression of the cervical roots posteriorly is easily accomplished with foraminotomy. Laminectomy was developed early in the nineteenth century and received little support initially because of a high mortality rate. The first successful laminectomy was performed in 1828, by Alban G. Smith in Danville, Kentucky.[54] The patient's paraplegia improved after three-level laminectomy. Till the 1950s, posterior approaches dominated over anterior cervical operations.

A variety of posterior surgical procedures exist, including laminectomy, laminoplasty, foraminotomy and posterior spinal instrumentation with or without laminectomy. Posterior surgical approaches have several advantages. They generally require less surgical time and they frequently do not require stabilisation, fusion or instrumentation. The nerve roots are decompressed under direct visualisation, and there is little risk to major vessels and structures. Disadvantages include post-operative neck pain, spinal instability stimulating further bone spur formation and an inability to access ventral canal osteophytes.

Cervical Laminectomy

A good decompression can be achieved by a wide and extensive laminectomy from C3-7 in cases of cervical canal stenosis, either congenital or degenerative. Northfield reported that one-third to half of the patients showed good improvement after decompressive laminectomy.[41] Snow and Weiner[56] reported improvement in 77% and Chakravorty[11] found good improvement in 64%. Chakravorty[10] felt that occasionally compression may be due to fibrous tissue only and this should be removed as far outwards as possible to decompress the neurovascular structures and relieve cord ischaemia. It may also help by release of the anchoring effect of the spinal root sleeves, permitting dorsal migration of the cord.[19,51]

Posterior decompression of the spinal cord, nerve root or both may be done with the patient in the prone or sitting position, although the prone position is preferred because of lesser anaesthetic risks. A midline incision is made to expose the spinous processes. The paraspinal muscles are stripped away subperiosteally to expose the laminae and the facets completely. The spinous processes, laminae and ligamentum flavum are then removed with either rongeurs or a high speed drill. It is better to start at the lower level, proceeding rostrally in a segmental fashion and care must be taken not to compress the already compromised dural sac.[33] Absence of epidural fat indicates lack of space within the spinal canal. The laminectomy must be wide enough to demonstrate the posterior and posterolateral aspects of the dural sac.[21] If the clinical features and pre-operative investigations indicate radiculopathy without myelopathy, segmental hemilaminectomy and foraminotomy provide excellent decompression.[33] Here, the paraspinal muscles are stripped away on one side of the spinous process only and the spinous process remains intact. The complications of extensive laminectomy are late development of spinal deformity and peridural fibrosis. These can possibly be avoided by expansive laminoplasty. Hirabayashi first described the procedure in 1977.[28] The expansive open door laminoplasty is performed by completely incising the laminae on one side and partially on the opposite side (Fig. 6). Elevation with tilting of the

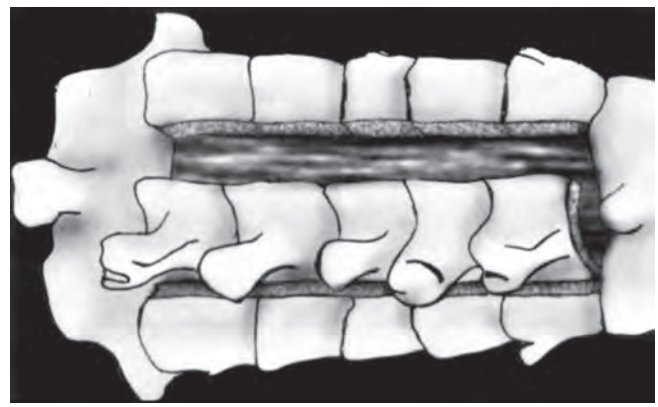

Fig. 6: Left open-door cervical laminoplasty

laminae upwards on the incised side allows enlargement of the canal. This has been used by others with success[20,27] and several modifications have been suggested with interposition of implants.[35]

Foraminotomy

Root compression in the absence of cord compression is best managed by simple foraminal enlargement at the involved level.[33] Foraminotomy is also important for radiculopathy caused by osteophytes or by an extreme lateral soft disc herniation.[16] Posterior laminoforaminotomy is also an effective option in patients with persistent radicular symptoms following an anterior procedure. Raynor has shown the limits of nerve root exposure obtained by anterior and posterior approaches.[43] He found that 30–70% facetectomy can give good root decompression by the posterior approach and a greater amount of facet removal can result in instability. The region anterior to an adequately decompressed nerve root can then safely be explored and decompressed.

The successful management of cervical disc disease and spondylosis requires proper understanding of the aetiopathogenesis and a careful analysis of the clinicoradiological features. Patient selection and adequate surgical decompression remains the key to achieve desirable clinical results. No single gold standard procedure exists for the treatment of patients with cervical spondylosis. The treatment strategies need to be tailored to match the specific changes present in a given patient.

112 Cervical Ossification of Posterior Longitudinal Ligament

Anil Pande, M Vikram, Ravi Ramamurthi

INTRODUCTION

Ossification of the posterior longitudinal ligament (OPLL) was first reported in England by CA Key in 1838[50] and, in 1960, Tsukimoto[103] reported an autopsy of a patient with myelopathy due to OPLL. Terayama et al.[100] gave the disease its name. It was reported extensively thereafter from Japan and came to be known as the '*Japanese disease*'. Hakuda S et al.,[35] on the basis of a paleopathologic study of ancient human skeletons in Japan, found that cervical OPLL was the only ossification that increased significantly in prevalence in people of the near-modern period when compared to the Neolithic gathering-hunting people. They hypothesised that socioeconomic changes from a subsidence gathering-hunting economy to the near-modern livelihood depending on rice-eating and a diet high in vegetable protein was responsible for the increased incidence of OPLL.

As the awareness of this condition grew it was seen to occur in all parts of the world.[21,22,29,52,64] In India too this condition has been known to cause compressive myelopathy quite frequently and many centres have substantial experience with its management.[2,6,8,26,42,44,59,87,95] OPLL is a distinct disease entity and should not be confused with ankylosing spinal hyperosteosis, ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis (DISH)[62,92] although nearly 50% of patients with DISH can have concomitant OPLL on cervical radiology. Sharma et al.[92] found OPLL in 12.2% of their patients with DISH (9 out of 74 patients).

INCIDENCE AND PREVALENCE

A high incidence of OPLL has been reported in the Japanese and other Asian populations.[1,51,72,101] In Japan, 4.3% of asymptomatic 60-year-old men and 2.4% of 60-year-old women had radiographic evidence of OPLL in the cervical spine.[81] The prevalence of cervical OPLL in Koreans was 0.6%, and in non-Japanese Asians, Lee et al. reported an incidence of 0.8%.[64] OPLL tends to manifest in the 5th to 6th decade of life with the cervical region[75] being the most common region followed by thoracic[98,102] and lumbar[66,92] with an incidence of less than 10% of cases.

Among patients older than 60 years of age, the prevalence of OPLL was greater than 20%. Nakanashi et al.[81] found an incidence of 11% in the sixth decade of life and the most common region was at C4 and 67% of these patients were asymptomatic. Lee et al.[64] reported it to be four times more common in men and its incidence increases with age.[104] At autopsy, OPLL was found in 20% of patients who had no earlier history of OPLL. OPLL has also been reported from North America and in Non-Asian countries.[7,21,22,29,64,88] Most patients with OPLL are asymptomatic.[39,101]

AETIOPATHOGENESIS

The aetiology is multifactorial,[39,73,90] in which complex genetic[99,101,106,110] and environmental factors interact.[39]

Genetics

The genetic background in the development of this disease has been demonstrated by pedigree survey, twin survey and HLA haplotype studies.[90] Siblings of patients who share an increased number of human leukocyte antigen haplotypes are at increased risk of developing OPLL.[39,73,98] Specific polymorphisms that may be associated with OPLL occur in several collagen genes, which encode for extracellular matrix proteins. Polymorphisms in the nucleotide pyrophosphate gene, which is involved in regulation of calcification in chondrocytes, may also be associated with OPLL.[39]

The results of gene linkage study show that patients with OPLL have a significantly higher incidence of genetic abnormalities found in the XI collagen (alpha) 2 gene (COL11A2) region of chromosome 6. From the gene mapping of this abnormality, the abnormal N-propeptide of the COL11A2 gene was found to be responsible. Wang H et al. reported that the BMP-2 gene is not only associated with occurrence with OPLL but also is a factor related to more extensive OPLL.[107] Other genetic factors, like HLA-BW40 and HLA-SA5, were found more frequently in Japanese patients.[98,99,104]

Growth Factors and Cytokines

Many growth factors and cytokines, including Bone morphogenic protein (BMP) and Transforming growth factor-beta, are involved in the pathogenesis and several transcription factors controlling cellular differentiation may also have a role.[39]

Among the cytokines that are involved in ectopic bone formation in OPLL, CTGF/Hcs24 plays a major role in endochondral ossification. TGF beta and CTGF/Hcs24 enhance the expression of ALP mRNA in OPLL cells and these are responsible for initiating osteogenesis in spinal ligament cells.[110] Epidemiological studies found that diabetes mellitus is a distinct risk factor for OPLL.[39,63] Lee et al. reported that high glucose promotes collagen synthesis in the OPLL via endogenous TGF-Beta1 resulting in hypertrophy of ligaments. The incidence of diabetes and impaired glucose tolerance test are greater in patients with OPLL and in those with DISH. They found that 18% of their patients with OPLL had diabetes mellitus.

The analysis of blood group, serum group, erythrocyte isoenzyme groups, C reactive protein, erythrocyte sedimentation rate, rheumatoid factor and HLA-B27 were inconclusive.[104] There has also been association of high growth hormone and hypoparathyroidism in cases of OPLL.[37,62,67,82]

PATHOLOGY

OPLL occurs by the process of enchondral bone formation, beginning with the most superficial layer, progressing to deeper layers and this frequently involves the dura.[89] There are many cascading events like genetic factors of polygenic character, anatomical stress, age and sex in the formation of OPLL.[89] There is heterotopic bone formation[28] Fibroblast hyperplasia and cartilaginous proliferation with increased collagen deposition occurs and this is followed by mineralisation of the thickened ligament with lamellar bone and Haversian canal formation.[83,84,105,114] The annulus fibrosus remains separate and uninvolved with ossification at certain levels. The ossified ligament is not always continuous with the vertebral body. Hypertrophy, calcification and ossification of the ligament occur segmentally. OPLL then extends beyond its posterior margin causing progressive occlusion of the spinal canal.

OPLL involves the cervical spine predominantly followed by the thoracic[98,102] and lumbar spine.[66,92] Multiple level involvement is also commonly noticed with a mean of 2.25 vertebral bodies.[29] OPLL grows with a reported annual increase in size of 0.47 mm longitudinally and 0.67 mm anteroposteriorly.[91] The enlarging mass may have a round, cuboidal, triangular or polypoid shape with its base of attachment varying from flat to broad and narrow to pedunculated.[44] Yasui et al.[114] found a difference in the collagen composition of the OPLL, OPLL containing Type I, II, III whereas normal tissue has Type I and III. Choi et al.,[11] on analysing surgical results by multiple logistic regression analysis, found that diabetes mellitus was the only statistically significant factor producing poor prognosis for patients who underwent surgery.

The encroachment of the spinal canal causes spinal cord deformation into a thin, crescent-shaped structure. Neurological symptoms and signs can be expected to develop when the lesion occupies more than 65% of the neural canal.[84,91,96]

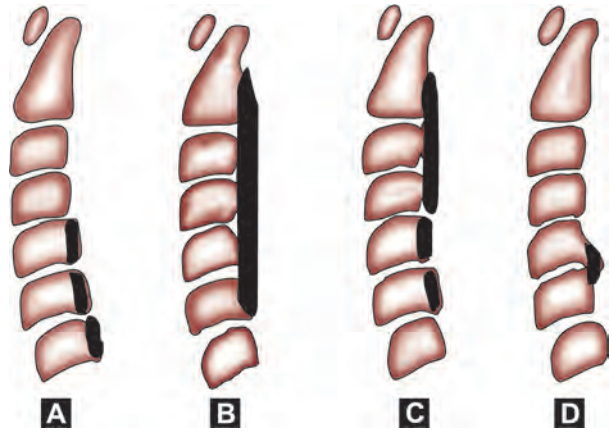
Two major mechanisms are involved in neural injury, one being mechanical compression which is both static and dynamic and the other is due to vascular compromise. Pathological changes in the spinal cord have been observed in the advanced stages. The extent of gray matter changes and the degree of spinal cord compression is proportional to the anterior horn deformity. Venous stasis, oedema, ischaemic neuronal necrosis and infarction are seen leading to cavitations and gliosis in the gray matter and spongiform atrophy, demyelination and axonal loss in the white matter. The central gray matter and the adjacent dorsal and lateral column are severely damaged. Progressive myelopathy has been explained by arteriolar degeneration of the central perforating branches of the anterior spinal artery. Demyelination, axon loss and atrophy have also been noticed in the nerve roots that have been stretched or compressed.[28,83,84]

CLASSIFICATION OF OSSIFICATION OF THE POSTERIOR LONGITUDINAL LIGAMENT

OPLL is classified as early OPLL and classic OPLL.[1] OPLL in evolution is an early variant and shows focal hypertrophy and punctuate calcification at the interspaces.

- On the basis of lateral radiographs, classic OPLL is further classified into four types: (1) segmental; (2) continuous; (3) mixed and (4) localised[13,101](Figs 1A to D).

  Segmental OPLL is located behind the vertebral bodies and not at the disc spaces. Continuous type extends from body to body, mixed has both segmental and continuous components and the localised variety is confined to the disc spaces alone. According to Tsuyama[104] 39% were segmental, 27% continuous, 29% mixed and 7.5% were localised.
- Hirabayashi et al.[31,32] suggested a CT based classification and suggested square, mushroom and hill types of OPLL to reflect its lateral extension (Fig. 2).



Figs 1A to D: Classification of OPLL. (A) Segmental. (B) Continuous. (C) Mixed. (D) Localised

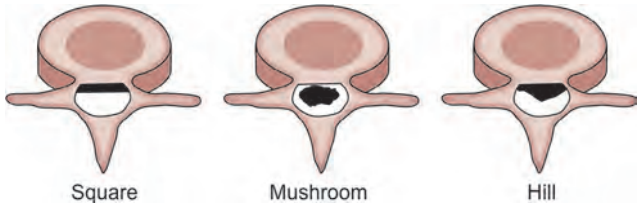


Fig. 2: Diagrammatic representation of Hirabayashi's CT based classification showing square type, mushroom type and hill type

- Hida et al.[30] described single and double layered OPLL on the basis of the ossification of the superficial and deep layer separated by the hypertrophied non-ossified layer.
- Mizuno et al. classified dural ossification in OPLL into three types: (1) isolated; (2) double layer and (3) en block type.[76]

MICROSURGICAL ANATOMY OF POSTERIOR LONGITUDINAL LIGAMENT

The posterior longitudinal ligament (PLL) is composed of collagen fibres with elastin, densely concentrated at its centre and extends from the base of the clivus to the sacrum. It is attached to the annulus of each inter vertebral disc and the posterior cortical surface of the vertebral bodies. Its thickness varies from 1 mm to 2 mm. It consists of two layers, a deep ventral layer and a superficial layer.[57] The superficial layer joins the dura at its lateral portion. It is wider at the disc level and is narrow at mid-body level. The longitudinally oriented collagen and elastin fibres are most dense centrally and thinnest at the site of the most lateral attachment to the annulus adding substantial strength and stability to the vertebral column during flexion and, mainly, extension movements. The normal ligament has both type I and type II collagen. Ossification involves replacement of the type I collagen matrix with lamellar bone structure with Haversian canals and a few bone marrow canals.[114] The posterior margin of the vertebral body where the PLL is attached is the common site of occurrence of OPLL and this extends both rostrally and caudally.[57] The internal vertebral venous plexus is located in the lateral posterior longitudinal ligament space.

CLINICAL PRESENTATION AND NATURAL HISTORY

OPLL occurs in association with degenerative disc disease or spondylosis causing radiculopathy, myelopathy and myelo-radiculopathy.[52,83,84] Asymptomatic OPLL has also been reported.[81] Patients with *early OPLL*, often in their mid-forties, present with radiculopathy or mild/moderate myelopathy.[88] Imaging shows hypertrophy of the posterior longitudinal ligament with punctate ossification opposite multiple disc spaces.

Patients with *classic OPLL* frequently become symptomatic in their mid-fifties. Symptoms include neck pain, radicular pain, dysaesthesia, arm weakness, leg weakness and urinary incontinence.[5,75] In a study of 47 Indians with OPLL, Jayakumar et al.[43] reported that 57.4% of symptomatic patients had myelopathy, 25.5% had myeloradiculopathy and 12.7% had radiculopathy alone.

Hypalgesia below segmental levels on the torso, and radicular sensory loss is also seen. Subacute development of symptoms over one to two years is common. Acute onset of symptoms or signs and exacerbation of existing neurological impairment were precipitated after trivial trauma in about 10–21% of patients.[22,27,29,56,64,70,89,117] The pathomechanism of myelopathy[56] in OPLL involves both static and dynamic factors.[67] The static factors include: spinal canal stenosis and PLL hypertrophy, and the dynamic factors include: Instability and association with a protruded disc.[118]

The pathological compression by the ossified ligament above a certain critical point may be the most significant factor in inducing myelopathy, whereas below that point dynamic factors may be more significant. Some patients with large OPLL have not exhibited myelopathy for long periods of time. Predicting the course of future neurological deterioration in asymptomatic patients with OPLL is difficult.[69,72] The mobility of the cervical spine and the type of OPLL are important factors contributing to the development and aggravation of myelopathy in patients with OPLL induced spinal canal stenosis.[69,79]

The axial ossified pattern is classified into two types: (1) a central type and (2) a lateral deviated type.[69] The incidence of myelopathy in patients with less than 60% spinal canal stenosis was significantly higher in the lateral deviated-type group than in the central-type group.[69] All patients in whom there was 60% or greater stenosis of the spinal canal developed myelopathy, regardless of a history of trauma.

The proportion of patients showing motor deficits of the lower extremities significantly increased when the sagittal canal diameter was narrowed to less than 8 mm.[56] Myelopathy has been quantified by many authors. The Nurick scale and the Japanese Orthopaedic Association (JOA) scale are frequently used (Table 1).

JOA categorises the myelopathy based on severity using a 17 point scale and the reliability of the system has been confirmed by Yonenobu et al.[115,116]

Table 1: Nurick scale of myelopathy

Grade 0	Intact, mild radiculopathy without myelopathy
Grade I	Mild myelopathy
Grade II	Mild to moderate myelopathy
Grade III	Moderate myelopathy
Grade IV	Moderate to severe myelopathy
Grade V	Severe myelopathy, quadriplegic

MANAGEMENT

Radiodiagnosis

Patients with OPLL frequently show associated ossification of the ALL, thoracolumbar PLL and yellow ligament. It has been recommended that a radiological survey of the entire spine is done in every patient with cervical OPLL.[5,23,30]

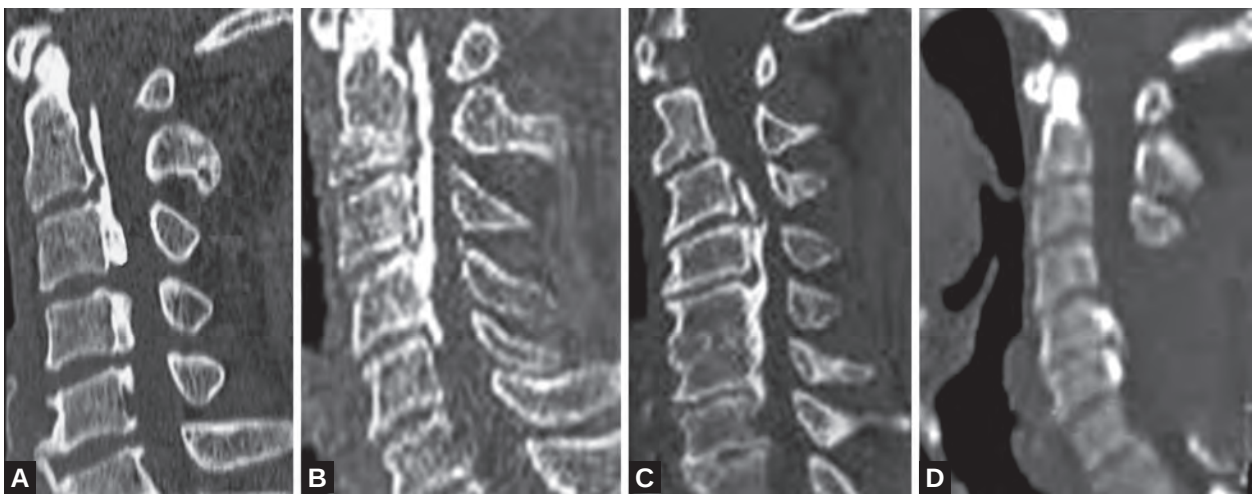
Plain X-rays

Nakanishi et al.[81] found OPLL in 11% of people in the 6th decade of life on plain X-rays. Plain X-rays are very useful in diagnosing and classifying OPLL and dynamic X-rays are useful to check for abnormal mobility. OPLL is visible as retrovertebral calcification on plain films in approximately one third of cases (Fig. 3). The normal spinal canal diameter is 17 mm from C3 to C7 on plain X-rays taken at a distance of six feet.[116] Absolute stenosis is when the diameter is 10 mm or less and relative stenosis is when it is 10–13 mm.[115,116] Occupancy ratio (OR) is obtained by dividing the thickness of the OPLL by the AP canal diameter. If the OR is greater than 40%, there is an increased risk of myelopathy. Yoo et al.[117] proposed that it may be beneficial to take a check lateral radiograph of the cervical spine as a screening tool for early detection of cervical spinal stenosis, especially in Asian people older than 40 years.

COMPUTED TOMOGRAPHY (CT) SCAN AND CT MYELOGRAPHY

The computed tomographic features of OPLL are distinctive. A 2–5 mm thick linear ossified strip along the posterior vertebral margin is usually seen at the mid cervical (C3 to C5) level. CT more readily identifies the foci of frank ossification (Figs 4A to D). Patients with OPLL frequently show concomitant ossification of the anterior longitudinal ligament and posterior longitudinal ligament in the thoracolumbar region and the yellow ligament. OPLL was most frequently observed at C5 and the number of vertebral bodies on average was 3.1.[5,23,30] Jayakumar et al.[43] in a study of 47 symptomatic Caucasoid Indians found the most frequent location to be at C3 and C4. The thickness of the OPLL ranged from 2.5 mm to 11.5 mm. Canal stenosis was most severe in patients with 'total' type of OPLL. Ossification of other spinal ligaments was seen in 50% of the patients. Chiba et al.[10] proposed a new computerised assisted measurement of OPLL where X-ray films are transformed via scanner into digital images and the length and thickness of the OPLL is measured using a computer assisted measurement system.

Bone window studies may show two signs of dural ossification: (1) the double layer or (2) the single layer sign. On pre-operative computed tomographic studies, Hida et al.[30] have described the single-layer sign characterised by a solid mass of hyperdense OPLL and the



Figs 4A to D: CT showing various types of OPLL

double-layer sign defined by two (anterior and posterior) ossified rims surrounding a central non-ossified but hypertrophied posterior longitudinal ligament. When the single layer sign is associated with a lateral C-shaped configuration of ossification, dural involvement is seen more frequently.[17,74]

The *double-layer computed tomographic sign* is more pathognomonic for dural penetration than the single-layer sign. The smooth-layer sign, indicating a clean dural plane, is more typical in North American patients. The size of the spinal canal is a factor that contributes to the neurological deficits associated with OPLL.[54] The spinal canal was narrowed by OPLL to 2.9–10.0 mm. The CT scan imaging of OPLL can miss an associated disc prolapse as highlighted by Yoshino et al.[118]

Min et al.[74] reported several differences between thoracic and cervical OPLL in regard to dural ossification signs. The incidence of these signs with thoracic OPLL was higher than that with cervical OPLL and these signs can develop in a segmental OPLL as frequently as in a non-segmental OPLL. Dural defects were present in 60% of the patients with a double-layer sign and in 50% of the patients with a single-layer sign. Therefore, surgeons should be alert for the high possibility of a dural defect when these signs are present in thoracic OPLL, although a dural defect can develop even in the absence of these signs.[74] Non-segmental OPLL is likely to be accompanied by dural ossification. Mizuno et al.[76] on retrospective analysis of neuroimaging findings found three patterns of dural ossification: (1) double layer; (2) isolated and (3) en bloc type. 2D and 3D non-contrast CT reconstructed images provide a sagittal overview of the extent of cord compression without incurring the risks associated with myelo-CT studies.[115,116]

CT myelography is recommended, especially when previous surgery has been performed or in cases of anterior spinal instrumentation with metallic implants restricting the MRI sequences. The interpedicular distance can be measured and varies from 14 to 20 mm and helps in deciding upon the width of the corpectomy. Post-operative myelo-CT studies are used to confirm the adequacy of decompression.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) should be the initial diagnostic imaging procedure in any patient with non-traumatic myeloradiculopathy. Due to the lack of MR signal from cortical bones, MRI is inadequate for diagnosing ossified lesions in the spinal canal. However, MRI provides information on spinal cord structure and associated soft-tissue abnormalities and is especially useful in the cervicothoracic junction.[55] The length of the lesion, cervical axial canal area, anteroposterior (AP) diameter of the cervical canal, spinal sagittal angles, cervical curvature index (CCI) and signal changes in the cord can be made out. MRI is valuable in studying associated cord damage and associated disc lesions prior to surgery. The T1-weighted images clearly demonstrate the spinal cord deformity caused by OPLL.

Associated disc protrusion is found to be present at the maximum compression level in 60% of the patients. A calcified central sequestrated disc is the only condition that may be mistaken for the segmental and retrodiscal forms of OPLL. The highest incidence of disc protrusion (81%) was found in patients with segmental OPLL. OPLL appears as a low signal intensity band between bone marrow of the vertebral body and the dural sac on T1- and T2-weighted images. The continuous type is easier to diagnose than the segmental type. Formation of bone marrow is shown by increased signal or intermediate signal in 56% and 11% of the segmental type. Intramedullary hyperintensity on T2-weighted imaging was noted in 43% of patients. On T1-weighted and T2-weighted images, ligamentous calcification or ossification appears as a region of low-signal intensity.[13,111,118] A sagittal image details the longitudinal extent and anatomical type of OPLL (Figs 5A to D). Axial images can demonstrate the extent of neural canal stenosis, including developmental and acquired anterior and posterior components.[96,97,109]

However, MRIs tend to exaggerate the severity of stenosis and the extent of obliteration of the subarachnoid space. Early OPLL mimicking disc disease appears opposite multiple disc spaces associated with significant retrovertebral extension, helping to differentiate it from spondylosis. MRI is often ineffective in recognising dural ossification.[76] In cases of borderline stenosis, magnetic resonance imaging during spinal flexion or extension may demonstrate compression and show where it is most severe. MRI shows signal intensity changes which may be due to cystic necrosis of the cord, which is irreversible, but sometimes the signal intensity may be due to venous infarction and this progression can be halted by early surgery.

TREATMENT

Conservative

Acute episodes of pain and the onset or increase of neurological deficits are treated with rest, external spinal immobilisation with a collar or brace and administration of analgesics, including anti-inflammatory or antispasmodic medication. Treating asymptomatic patients surgically or advising prophylactic total excision of all OPLL is not advisable as the natural history is variable.[68,72]

Operative

Surgery is aimed at enlarging the spinal canal by decompressing the bony ring and is indicated for patients with acute or chronic progression of neurological deficit. MRI showing signal intensity changes in the cord suggestive of cord oedema in T2-weighted sequence indicates sub-clinical dorsal cord compromise and warrants surgical intervention. Similarly, SSEP responses indicating

Figs 5A to D: MRI showing various types of OPLL. (A) Segmental. (B) Continuous. (C) Mixed. (D) Localised

sub-clinical dorsal cord compromise may also indicate surgical intervention.[5,23,30] Compression by a large bone mass directly on the anterior surface of a chronically constricted spinal cord causes anterior spinal artery compromise that leads to vascular myelopathy and neurological deficit, which could be irreversible. Preventive surgery may be offered to patients wishing to avoid such risks. Even indirect minor trauma to the neck can cause irreversible changes in the spinal cord if there is marked stenosis of the cervical spinal canal.[27,117] Preventive surgery prior to onset of myelopathy is generally unnecessary in most patients with OPLL.[78,79]

Selection of Surgical Procedure

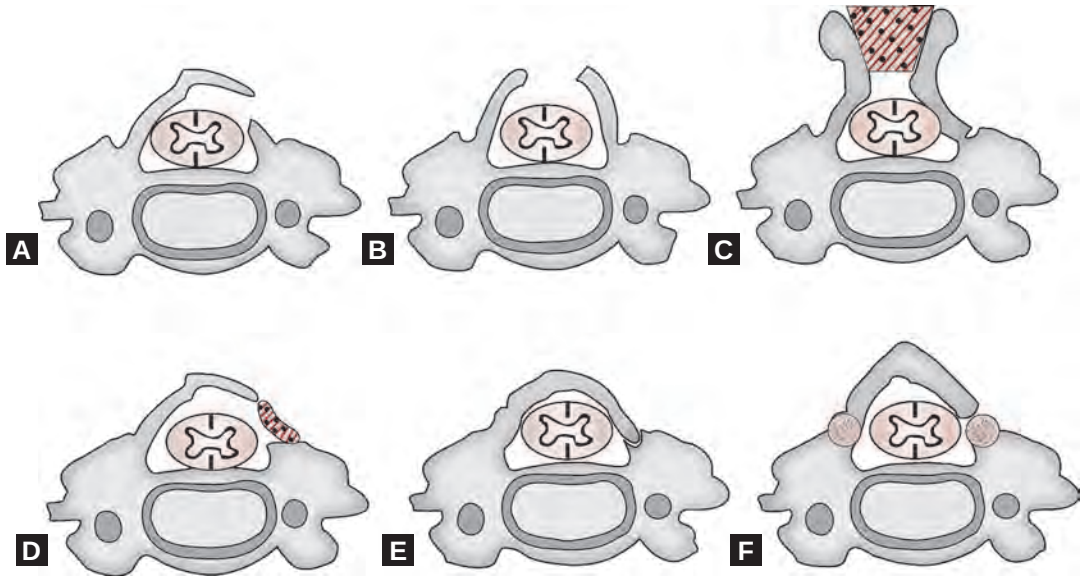
The choice of surgery depends on the age of the patient, location of the lesion and the extent of OPLL causing spinal cord and nerve root compression.[15,19,60,115,116] Developmental size of the spinal canal and the canal diameter compromise due to OPLL causing spinal cord compression are important factors influencing clinical management and the neurological state.[56] Being an anterior pathology, anterior procedures offer direct access and removal of the pathology. Posterior procedures give indirect decompression for multilevel involvement, leaving behind the progressing anterior pathology untouched. The rate of post-operative progression at two years was 56.5% and progression occurred more frequently in the younger-age group than in the older-age group.[10] Kyphotic alignment of the cervical spine and a large OPLL are major factors causing poor surgical outcome after laminoplasty for cervical OPLL.[33,40,41,47] Yang et al.[113] stated that cervical OPLL with disc protrusion is more common at C5-6 levels followed by C3-4, 4-5, 6-7. OPLL with disc protrusion causes greater spinal cord compression at the disc level.

The K-line is a simple and practical tool for making decisions regarding the surgical approach for cervical OPLL patients. The K-line[25] was defined as a line that connects the midpoints of the spinal canal at C2 and C7. The group of patients in whom the OPLL did not exceed the K-line are the *K-line (+) group*. Those in whom the OPLL did exceed it are the *K-line (-) group.* A sufficient posterior shift of the spinal cord and neurological improvement was not obtained after posterior decompression surgery in the K-line (-) group.

Matsunga et al.[72] found in a 10-year cohort study comprising of 450 patients that a significant difference in final functional outcome was not observed between non-surgical and surgical cases in which pre-operative Nurick grades were 1 or 2. In patients with Nurick grades 3 or 4 myelopathy, only 12% of those who underwent surgery eventually became wheelchair bound or bedridden as compared with 89% of those who were managed conservatively. Surgery proved ineffective in the management of patients with grade 5 disease.[72] He also found that more than 60% OPLL induced stenotic canal compromise of the cervical canal and increased range of motion of the cervical spine as the risk factors for evolution of myelopathy in OPLL.

Surgical Technique

Anaesthetic considerations: Fibreoptic pre-operative intubation is electively performed by specifically trained anaesthesiologists when deemed appropriate. Intubation is maintained during the 1st post-operative night. Patients exhibiting three or more major risk factors (repeated anterior surgery, operations lasting more than 10 hours, involving four or more levels (including C-2), obesity, asthma, and blood transfusions of more than four units (1000–1200 ml) are considered candidates for delayed extubation and, rarely, tracheostomy.[23]



Figs 6A to F: Schematic representation of various laminoplasty methods. (A) Open door. (B) Bilateral French door. (C) Splitting the spinous process and lamina with a spacer. (D) Modified open door method with a spacer. (E) Z-shaped laminoplasty. (F) Laminotomy and fusion with ceramics[30]

Posterior procedures: Posterior procedures are preferred when the OPLL is continuous, involves a long segment, in elderly high-risk patients, when the upper limit of OPLL includes C2 and in cases with a normal spinal sagittal balance. These include laminectomy alone, laminectomy with fusion,[3] laminoplasty and various newer techniques of laminoplasty, e.g. Modified Hirabayashi-type Unilateral Open-Door Laminoplasty[31] (Figs 6A to F). They offer adequate decompression in the presence of adequate cervical lordosis and the removal of multiple laminae and hypertrophied yellow ligament allows dorsal migration of the cord. The presence of kyphosis may leave the cord tethered to the anterior pathology and cause neurological deterioration.

A mean dorsal cord shift of greater than 3 mm was co-related with good clinical outcome.[94] Neurological outcome after posterior procedures was equal to multilevel anterior procedures in certain series.[34] After laminectomy, post-operative progression of kyphotic deformity was observed in 47% of patients but these changes did not cause neurological deterioration.[48] However, it is inappropriate for either older or younger patients with predominantly anterior disease, as that will fail to achieve a similar degree of neurological recovery and may promote a more rapid progression of OPLL growth with concomitant neurological deterioration.[14] Laminoplasty has about 96% of bone fusion rate, 83% of preserved range of movements and 42% increase in the canal diameter.[80] Development of the buckling-type alignment was found in 33% of patients following laminectomy and only 6% after laminoplasty.[71] These results favour laminoplasty over laminectomy from the aspect of biomechanics. Cervical range of movement (ROM) reduces after cervical laminoplasty. Post-laminoplasty cervical ROM had a positive correlation with extended motion; however, gradually it became reduced.

Surgical outcome was significantly poorer in patients with occupying ratio greater than 60%. The most significant predictor of poor outcome after laminoplasty was hill-shaped ossification, followed by lower pre-operative JOA score, post-operative change in cervical alignment and older age at surgery. Laminoplasty is effective and safe for most patients with occupying ratio of OPLL less than 60% and plateau-shaped ossification.

Agarwal et al.[2] reported that cord decompression with expansive laminoplasty using titanium miniplate fixation may improve the neurological outcome even in patients presenting late and improvement by even one grade may have major 'quality of life' benefits for these patients. Anderson et al.[3] advocated that laminectomy with fusion is an effective strategy to improve functional outcome in cervical spondylotic myelopathy and OPLL.

OPLL is a progressive disease, and an increase in the area of ossification following laminoplasty affects the surgical results. Around 21.8% had progression in the OPLL thickness. Young patients with continuous or mixed-type OPLL and C3 involvement had a risk for progression in OPLL thickness following surgery. [100,113]

Tension band laminoplasty described by Tsuzuki[105] helps to minimise the severe post-operative contractures seen in laminoplasty. In this technique, the lamina are reflected unilaterally in an open door fashion keeping the interspinous and ligamentum flavum intact and these behave as a tension band. *Double door laminoplasty* was developed by Kurokawa,[61] and in this the spinous process and laminae are split centrally and retracted symmetrically in a double door manner. Increase in segmental motion may lead to deterioration after posterior approaches which may be aggravated by the progressive atrophy of nuchal muscles. In patients with either CSM or OPLL with instability, cervical laminectomy with fusion (arthrodesis) improved the functional outcome.

Anterior procedures: The overall improvement of the neurological status of the patients were better in the anterior procedures than the posterior procedures.[1,20-22,42] Anterior discectomy, corpectomy and fusion are now considered the optimal operative treatment.[6,53] Segmental plate fixation is biomechanically better than end construct plate fixation.[93] Iwasaki et al.[40,41] opined that anterior decompression and fusion yielded a better neurological outcome than laminoplasty and is preferable in patients with occupying ratio of greater than 60%.[41]

In focal segmental lesions that do not extend above or below the disc, a simple interbody discectomy,[113] excision of OPLL and fusion may be adequate. Complete resection of the lesion requires microsurgical removal of the involved posterior longitudinal ligament and the adjacent osteophytes.

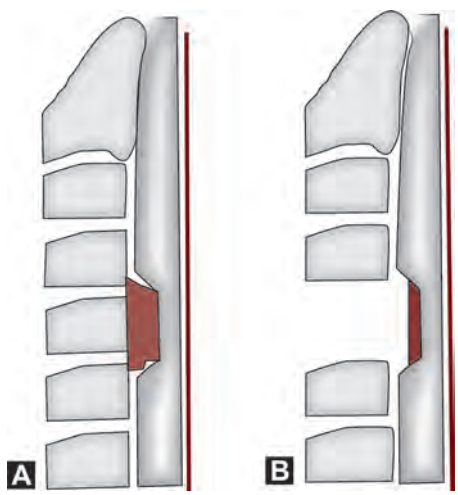
The technique of resection of OPLL with floating of dural ossification provides satisfactory decompression and avoids dural defect or neural injury in OPLL associated with dural ossification.[77] Kamikozzuru[46] and Yamaura[112] developed the original *floating method* and this technique requires more extensive corpectomy to free the ossified dura leading to a ventral migration of the OPLL mass but this procedure does not remove the OPLL and there is an increased risk to the vertebral artery and root injury while doing this extreme lateral resection technique. Hida, et al.[30] advocated the *microfloating technique* that makes the OPLL paper thin by using a high speed drill under a microscope and resecting it (Figs 7A and B).

Anterior procedures after a failed laminectomy carry a greater risk of post-operative instability due to a defective posterior vertebral column, as the ligamentous structures having already been removed.[88] Modifications of corpectomy in the form of open-window corpectomy, oblique corpectomy and floating methods have been advocated for avoiding instability and instrumentation.[26,46,85]

The high anterior cervical approach[86] to the upper cervical spine is a favourable method that provides direct and wide exposure for fusion and anterior decompression of the upper cervical spine. This is a useful surgical technique for an upper cervical lesion without severe morbidity, which allows direct anterior access to C2 and C3 while allowing extension to the lower cervical spine.

In cases where there is extensive and massive ossification, the ossification is continuous from the posterior surface of the vertebral body to the dura. Identification of the plane of the posterior surface of the vertebral body and the posterior longitudinal ligament at the level of the disc space is important, before progressing with the corpectomy and it is advisable to do a complete discectomy with osteophyte removal before corpectomy, as the placement of a vertebral spreader helps in the removal of osteophytes.

The diamond head drill should be used on reaching the posterior cortex of the vertebral body and to proceed with the decompression in a uniform manner over the entire width. This step needs to be followed as, very often, OPLL is eccentric and invaginates deep into the cord on one side and asymmetric decompression allows the cord to get hitched at the edge against the ossification leading to neurological deterioration. If there is dural involvement, careful dissection is warranted and on occasion a small thinned-out fragment of dural ossification can be left behind when the cord is completely decompressed.[77] Inadequate decompression is avoidable if the surgeon orients his corpectomy trench, depending on the MRI/CT findings of the anatomy of the OPLL. Reorienting the microscope frequently to the midline and keeping the width of the corpectomy in between the longus colli muscles facilitates adequate decompression. Continuous intra-operative somatosensory evoked potential (SSEP) monitoring also appears to limit operative morbidity.[5,22] Yonenobu et al.[115,116] suggested that anterior corpectomy results are better (Fig. 8).



Figs 7A and B: Schematic representation of microfloating methods. Before corpectomy: after corpectomy and thinning of the dura[30]

Fig. 8: Post-operative X-ray of a patient who underwent C3,4,5,6 corpectomy and fixation

Open window corpectomy: Ozer et al.[85] described this operation which involves minimal bone removal with high speed drilling, dorsal surface removal after appropriate microdiscectomy leaving the anterior and lateral parts of the vertebral bodies intact. This provides a more stable construct with three point fixation and offers better load sharing.

The oblique corpectomy:[8,26] It preserves the ventral half of the vertebral body and does not require stabilisation. Chacko et al.[8] emphasised that this is a surgical option in patients with asymptomatic OALL in the setting of progressive myelopathy due to OPLL with intrinsic stability as a result of their OALL. It avoids a multilevel central corpectomy that is associated with significant instability often requiring reconstructive procedures. Goel et al.[25] have elaborated on partial oblique strategic corpectomy involving extended midline and lateral undercutting of the vertebral body.

The skip corpectomy technique: Dalbayrak et al.[12] have demonstrated the effectiveness and safety of this technique. This is characterised by C-4 and C-6 corpectomy, C-5 osteophytectomy and C-5 vertebral body preservation; the preservation of the C-5 vertebral body provided an additional screw purchase and strengthened the construct. OPLL often coexists with cervical disc herniation and the disc may be the more important compressing factor. The area of greatest spinal cord compression is at the disc levels because of herniated cervical discs. Staged or combined anterior and posterior decompression may be necessary in a small segment of patients with mixed or continuous long segment OPLL.[32]

Anterior, anterolateral decompression and fusion for ossification of posterior longitudinal ligament in the thoracic spine by transthoracic trans-sternal approach is possible with good neurological outcome compared to posterior decompression and fusion with laminectomy or laminoplasty.[36,102] Complex cases of thoracic ligamentous ossification involving both the ligamentum flavum and the posterior longitudinal ligament may require combined procedures.[102]

Complications

Complications of anterior cervical surgery include a risk of quadriplegia of about 2–10%, root injury of about 17%, typically the C5 root, which has been attributed to rapid cord migration and the so-called "untethering effect".

Temporary paraparesis and new cervical radiculopathy may be caused due to residual foramen stenosis. CSF fistulas, bone graft displacement, pin site infection, graft site complication (iliac bone fracture, meralgia paraesthetica) implant failure, restenosis, tethering, wound infection, epidural haematoma, deformity, respiratory insufficiency, oesophageal perforation, bladder disturbances, Horner's syndrome and retropharyngeal abscess have been reported.[4,5,16,24,38,75,95,115]

Temporary recurrent laryngeal nerve and superior laryngeal nerve palsy due to retraction injury may cause hoarseness of voice and swallowing difficulty. Phrenic nerve dysfunction[24] may be due to bilateral C4 nerve root stretching, iatrogenic injury of the gray matter in the ventral horn, alteration of blood circulation related to spinal oedema or re-impingement on the spinal cord at the cranial part of the decompression site. Phrenic nerve dysfunction should be considered as a possibility when it is difficult to wean a patient from the ventilator after surgery. Kulkarni et al.[58] reported accelerated spondylotic changes in the adjacent segment in 75% of patients after cervical corpectomy and this adjacent segment disease can also develop after expansile laminoplasty.

Post-operative cerebrospinal fluid leak and pseudomeningocoeles: Patients with OPLL are especially prone to dural leaks and these are managed with dural repairs and rarely lumboperitoneal shunting procedure.[18] Post-operative pseudomeningocoele after an anterior approach to the cervical spine is an uncommon complication and may be difficult to treat.

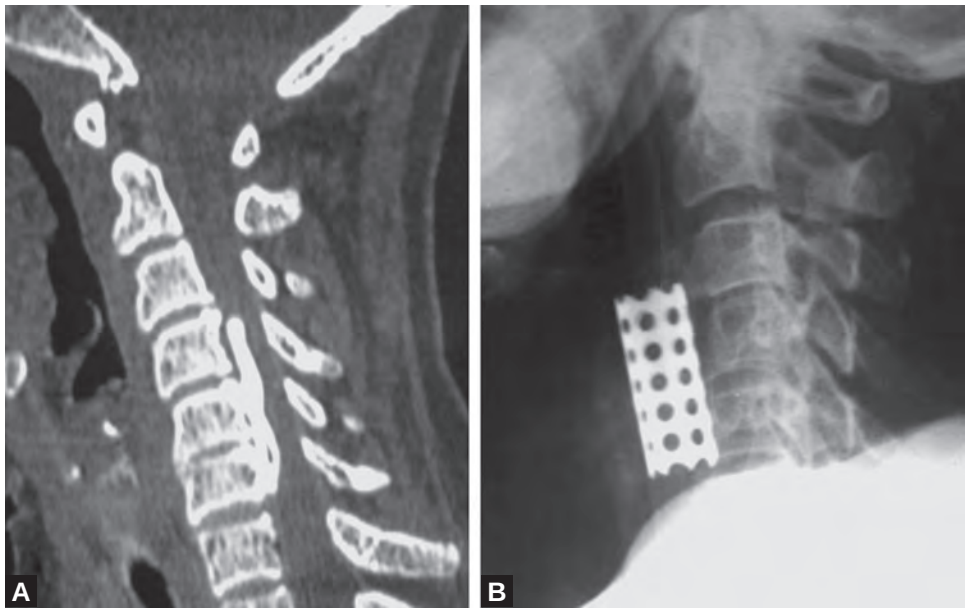
The surgeon is required to recognise dural ossification.[9] and be cautious during drilling of the OPLL. Hida et al.[30] described the (CT) findings that indicated the association with dural ossification and suggested that the 'double-layer sign' appeared more specific. The double-layer sign, as a specific indicator was sensitive in patients with mild OPLL but less frequent in those with severe OPLL. The arachnoid membrane in these cases can be preserved with the aid of the operating microscope to avoid a large area of membrane defect. The rate of dural tear is higher in patients with OPLL compared to other causes of cervical spinal stenosis. Intra-operative CSF leak[44] was encountered in 6.3% of patients in one series. The dural defect can be repaired with an onlay graft of crushed muscle/fascia and a layer of gelatin sponge. Bed rest and a lumbar subarachnoid drain are used for 5 days after surgery.

Graft Extrusion

Normally, the corpectomy defect is reconstituted using an iliac crest graft, titanium cages and very rarely fibular graft. Kumar and Rajshekhar[59] reported that when the surgical series was divided into three eras, the graft extrusion rate in the first era was significantly higher than in the other eras (6%, 1%, 1%, 0%; p = 0.01) implying a significant learning curve (Figs 9A and B). The extrusion rates for one-level, two-level and three-level CC were not significantly different (3%, 1.6%, 0% respectively; p=0.3). Wang et al.[108] emphasised that greater the number of corpectomies and longer graft fusion ending at C7 body has high rates of graft migration.

OUTCOME

Outcome analysis can be done using tools such as the Odom's criteria. Kawano et al.[49] found that the overall mean improvement on the neurosurgical cervical spine scale score (NCSS) was 78% for those who underwent anterior decompression and 46.1% for those who had a



Figs 9A and B: (A) Pre-operative CT of cervical spine showing OPLL. (B) X-ray lateral view of the cervical spine shows anterior extrusion of the cage from the corpectomy defect

posterior decompression. Yagi et al.[109] found that long-term clinical outcome was significantly worse in patients with intramedullary signal intensity changes on MRI. The other risk factors were instability of the cervical spine and severe anterior spinal compression. The long-term clinical outcome was also significantly worse in patients with post-operative expansion of the high signal intensity area.[65] The fact that cervical instability is a risk factor for post-operative expansion of the high signal intensity indicates that this high signal intensity area occurs not only from necrosis secondary to ischaemia of the anterior spinal artery but also from repeated minor trauma inflicted on the spinal cord from segmental instability. The post-operative progression at 2 years was 56.0% with progression occurring more frequently in younger patients than in older ones.[10]. In both these groups of patients at 1–2 years post-operatively it was found that mixed and continuous type OPLL grew more frequently than segmental.[10] Mizuno et al.[78] used the anterior approach in 11 patients and expansive laminoplasty in 10 patients with excellent outcome in 88% and favourable in 12%.

OPLL thickness, effective canal diameter, anteroposterior cord compression ratio, the traverse area of the spinal cord, the spinal cord-evoked potentials (SCEPs), the increase of the range of motion in the cervical spine (ROM), diabetes, history of trauma, the onset of ossification of the ligament flavum (OLF) in the thoracic spine, snake-eye appearance (SEA) and incomplete decompression may be other factors influencing outcome.[63] Age at surgery seems to be closely related to the outcome of the posterior surgical procedure.

Long-term functional outcome even in poor-grade patients (Nurick grades 4 and 5) with cervical spondylotic myelopathy (CSM) or OPLL after central corpectomy has been reported to be good by Rajshekhar and Kumar.[87] Improvement was uniformly correlated with myelopathic symptoms of 12 months' duration or shorter. The other favourable prognostic indicators for improvement after decompression were a diagnosis of CSM and pre-operative Nurick grade 5; however, patients with a pre-operative Nurick grade of 4 were more likely to experience a cure.

113 Thoracic Disc Prolapse

Ravi Ramamurthi, Nigel Peter Symss

INTRODUCTION

Protrusion of the intervertebral disc in the thoracic region is rare. In 1911, Middleton and Teacher[36] described a patient who, while he was lifting a heavy steel plate, sustained an injury to the spinal cord due to rupture of a thoracic intervertebral disc. The incidence of thoracic disc prolapse is about 0.04 of all cases of disc prolapse (1.14). With the increasing use of magnetic resonance imaging (MRI) more cases with subtle lesions are picked up, and Russell et al.[44] found a much higher incidence of 4.5%. A few cases have been reported from India.[4,25,28,46,52]

PATHOLOGY

It may occur at any age, being most frequent during middle age. Due to the resilient bony thoracic cage which permits only limited movements and the relatively small size of the thoracic disc, actual protrusion of the intervertebral disc into the thoracic canal is uncommon, although degenerative changes in the form of Schmorl's nodes and anterior and posterior osteophytes are seen frequently. Such changes are more common in people carrying loads on the back. The cause of nucleus pulposus herniations in the thoracic spine is similar to those occurring in the lumbar and cervical regions. The lower incidence of herniations is ascribed primarily to the reduced allowable flexion at the thoracic level compared with the lumbar and cervical levels and, to a lesser extent, the contribution of the ribs to weight bearing. Repeated trauma predisposes to disc degeneration and, at times, provokes an acute prolapse.[39] Svien and Karavitis[50] and Love and Schorn[35] found T-11 as the most common level affected. Multiple protrusions are rare.[47] The protrusion is commonly central, but may be centrolateral or lateral. Intradural disc herniation in the thoracic region occurs in less than 5%, but is a well-recognised entity in the lumbar region, where over 90% of all intradural herniations are seen. Almond et al. described a case where acute neurological deficit was caused by an intradural thoracic disc herniation at the T11-T12 level, the intradural nature of which was not diagnosed on pre-operative MRI.[1]

CLINICAL FEATURES

The diagnosis of thoracic intervertebral disk herniation is often missed due to its complex and variable presentation. The signs and symptoms are often of a relatively long duration, usually vague and frequently misleading. Pain localised to the back, girdle pains, pain in the abdomen, testicular pain or limb pain may be present. The symptoms may range from mild paraesthesiae to paraplegia.[46] Bladder, bowel and sexual disturbances are late features. Position sense is frequently intact.[12] Mild scoliotic or kyphotic deformities may at times be present and act as a natural protection in accommodating the prolapsed disc segment. The delay in diagnosis is often a consequence of failure to consider protrusion of a thoracic intervertebral disc as a diagnostic possibility. Bilateral drop foot due to thoracic disc herniation has been reported.[41]

Linscott et al. reviewed 78 patient charts with thoracic disc herniations, which is the largest single study in the World's literature. Injury was associated with disc herniation in approximately half of the patients, much higher than reported in previous studies. Back pain was the most common presenting symptom (73% of cases) and weakness was the most common physical finding (42% of cases). Eighty-five per cent of patients had findings consistent with neuropathy and 26% had multiple thoracic disc herniations.[32]

DIFFERENTIAL DIAGNOSIS

Ossification of the ligamentum flavum (OLF) and ossification of the posterior longitudinal ligament (OPLL), occurring in the thoracic region, may simulate cord compression by thoracic discs.[20,43] OLF is common in males and occurs at a lower thoracic level, while OPLL may occur at any level. Plain radiology, myelography, CT myelography and MR are useful for correct localisation. The approach to treatment for OLF is different from that of thoracic discs and OPLL.

INVESTIGATIONS

Calcification may be seen at the site of disc degeneration on plain X-rays. The affected disc space is narrowed. Bony spurs may be seen along its anterior and posterior surface. MR is the investigation of choice and shows the prolapse clearly, even when this is minimal. The extent of the prolapse, and the exact relationship of the bulge to the cord and roots are clearly seen.[9,19] Extradural tumours can easily be differentiated from disc prolapse.

CT and myelography are less sensitive, when compared to MR.

TREATMENT

Surgical Management

Evidence of cord compression is an indication for surgery. Various surgical approaches for the excision of a prolapsed thoracic disc have been described.[45] When indicated, discectomy may be performed via an anterior, posterior or anterolateral approach depending on the location of the disc herniation.

Posterior routes include the transpedicular,[42] lateral extracavitary approach, and the more recently described minimally invasive extracavitary approach.[31] Chi et al. have described a minimally invasive technique via a transpedicular route with the use of tubular retractors and microscope visualisation. This technique provides a safe method to identify the thoracic disc space and perform a decompression with minimal paraspinal soft tissue disruption.[13] They compared the results of this approach with clinical results after open transpedicular discectomy. Hospital stay, blood loss, modified Prolo score and Frankel score were used as outcome variables. Patients who underwent mini-open transpedicular discectomy had less blood loss and showed greater improvement in modified Prolo scores ($p = 0.024$ and $p = 0.05$, respectively) than those who underwent open transpedicular discectomy at the time of early follow-up within 1 year of surgery. However, at an average of 18 months of follow-up, the Prolo score difference between the two surgical groups was not statistically significant. Black described a technique of thoracic discectomy that has evolved from the posterolateral transfacet and the transpedicular approaches. The pedicle and most of the facet joint are spared. He found the technique safe and effective, and no specialised instruments are required.[8] The transpedicular approach also appears to be most suitable for discectomy for dorsolumbar junction disc prolapse. The approach is minimally invasive considering the size of the incision, minimal bone removal and avoidance of vital structures. Post-operative pain is minimal and ambulation can be begun within 24 hours of surgery.[6]

Decompressive laminectomy without dealing with the prolapsed disc has been described.[17,22,34,37,38] The results of such an operation are unsatisfactory and may even be deleterious, as the compressive element persists. Approaching the prolapsed segment through a laminectomy is dangerous as the thoracic disc prolapse is central or centrolateral and the dorsal cord tolerates retraction poorly.

The thoracic disc is best approached by the anterolateral route[15] through the lateral costotransversectomy approach,[54] transpedicular approach[42] or by an anterior route through a thoracotomy (transpleural or retropleural approach).[1]

Intra-operative fluoroscopy or plain radiographs are traditionally used to localise thoracic spine levels during thoracic spine operations. Unfortunately, such localisation can occasionally be difficult in the midthoracic levels due to lack of landmarks, scapular shadows and the body habitus of the morbidly obese. For efficient and accurate intra-operative localisation of thoracic spinal levels during anterior thoracic spine procedures, Hsu et al. have described a method that uses pre-operative percutaneous placement of polymethyl methacrylate (PMMA) into the vertebral body using the standard vertebroplasty technique.[24]

Video-assisted thoracoscopic microdiscectomy is gaining acceptance as a minimally invasive, safe and efficient technique suited for herniated thoracic discs from T4-T5 up to T11-T12. However, here also correct localisation is difficult and wrong level exploration is an ever-present threat. Cornips et al. present a reliable and time-efficient localising technique, which they used in 86 consecutive cases. One day pre-operatively intrathecal contrast is administered and a computed tomography (CT) scan was performed in the prone position. Using local anaesthesia, a hollow needle was advanced above the corresponding rib and through the pleura. The inner wire and corresponding pathological level were easily identified endoscopically. Myelo-CT provides detailed anatomical information, which is often helpful in determining the side of operative approach and the extent of bone removal needed. Needle localisation obviates fluoroscopy, saves OR time and allows the surgeon to focus on the technically demanding procedure. Furthermore, it is relatively a simple and safe technique.[14] During surgery the curetting of the disc must be done very carefully as the disc material might have protruded through the dura and lie embedded in the cord substance.[18,33] Singaunas et al.[49] found best results with costotransversectomy and microsurgical techniques.

Kim et al. used computer-assisted image guided costotransversectomies for thoracic disk herniation from T5-6 to T8-9 level, and found it to be invaluable in planning the corpectomy and aiding visualisation in situations in which the dura or disc were obscured, allowing successful surgical excisions in the most challenging circumstances.[29] As experience accumulates in the use of multiple approaches for the treatment of thoracic disc herniations, the role of each is becoming more clearly defined. The transpedicular approach is most applicable for lateral or centrolateral calcified or soft discs. The more anterior (transthoracic or thoracoscopic) and lateral (costotransversectomy or lateral extracavitary) approaches may be more useful for excision of central calcified discs.[7]

Another approach that has been described is the transmanubrial osteomuscular sparing approach for the treatment of T1-T2 thoracic disc herniation, and is likely to be the only one described in the literature for this disease so far.[51] Newer, minimally invasive techniques with a nearly absent learning curve are evolving. One of these techniques is the mini-TTA. Bartels et al. compared the mini-thoracotomy (mini-TTA) and

thoracoscopy for the treatment of calcified thoracic herniated disc. They found the mini-TTA has some theoretical advantages over thoracoscopy. It is also a minimally invasive approach. Thoracoscopy has a steep learning curve, whereas the mini-TTA is simple to apply. Classic microsurgical bimanual techniques can be used.[5] Sheikh et al. have described a novel minimally invasive procedure for the surgical treatment of thoracic disc herniations referred to as a minimally invasive thoracic microdiscectomy. It uses a series of muscle dilators, a tubular retractor and microscopic visualisation by way of a posterolateral approach in an effort to minimise many of the complications that are associated with the more traditional approaches.[48]

To reduce the invasiveness and risk of thoracic disc surgery, endoscopic approaches have been developed. Thoracic microendoscopic discectomy is a safe and effective treatment for surgical removal of herniated thoracic intervertebral discs.[27] This approach allows access through a minimally invasive muscle-splitting posterolateral approach that does not place the contents of the thoracic cavity at risk. In the lumbar spine, this approach has been proven effective, with a shorter length of hospital stay, less post-operative pain, decreased blood loss and shorter recovery time. These same advantages can be expected in the thoracic spine with appropriate patient selection and proper surgical technique.[11,16]

Jho has described the transpedicular endoscopic approach. The surgical technique of posterior transpedicular thoracic discectomy was modified to endoscopic transpedicular surgery. A 1.5 cm trocar was placed in the interlaminar space via a 2 cm transverse paramedian skin incision. At the ventral aspect of the spinal cord discectomy was performed under direct visualisation by using a 70 degrees lens endoscope. He found this approach to be minimally invasive and effective surgical treatment.[26]

Giant herniated thoracic discs (HTDs) can be defined as occupying more than 40% of the spinal canal. Hott et al. found that patients with giant HTDs who underwent thoracoscopic surgery had worse short-term and long-term functional outcomes than those in whom open thoracotomy was performed. They concluded that patients with giant HTDs presented more frequently with myelopathy and experienced worse functional outcomes than those with smaller HTDs and recommend open thoracotomy rather than thoracoscopy for the treatment of midline giant HTDs.[23]

Utility of interbody fusion after transthoracic discectomy is still debatable. Krauss et al., from their results, indicate that interbody fusion may not be necessary for selected patients undergoing transthoracic discectomy.[30] Ohnishi et al. recommend anterior decompression and fusion for multiple thoracic disc herniations through a transthoracic approach.[40] Further long-term follow-up is needed to evaluate the development of late spinal instability and resultant deformity after this procedure.

Complications

The procedure-related complications include death, neurological deterioration, post-operative vertebral column instability, incomplete disc resection, discectomy at the wrong level, cerebrospinal fluid leak and fistula, infection, pulmonary embolism, pneumothorax, pneumonia and intercostal neuralgia.

Unusual complications include chylorrhea. The thoracic duct along with the cisterna chyli is a major lymphatic pathway near the anterior thoracolumbar spine. Despite the fragile nature of the lymphatic system and its proximity to the spinal column, chylorrhea is rarely encountered by spine surgeons. Amini et al. reported a unique case of chylorrhea associated with a left thoracoscopic, transdiaphragmatic discectomy and fusion for a T12-L1 herniated disc.[2]

Outcome of Surgery

The differences in the surgical outcome based on disc characteristics using pre-operative CT scanning and MRI have been analysed by Yi et al. The direction of the disc was classified as either central or lateral, and disc consistency classified as either soft or hard. Clinical outcome was assessed according to the Japanese Orthopaedic Association (JOA) Score for thoracic myelopathy, by analysing motor, sensory and bladder function. Recovery rate was assessed, comparing pre-operative and post-operative status based on disc characteristics, and the correlation between outcome, symptom duration and recovery rate. Clinical outcome, according to the JOA Score, showed significant post-operative improvement, increasing from 7.0 +/- 3.1 points to 8.2 +/- 2.7 points post-operatively ($p < 0.01$). The mean recovery rate was 12.4 +/- 56.9%, and 16 patients (55.2%) showed improvement. In the soft disc group, there was improvement in all categories, but the hard disc group showed no improvement. The central disc group showed improvement in sensory function, but the lateral disc group showed little improvement. Regression analysis revealed a statistically significant correlation between the pre-operative and the post-operative score, symptom duration and recovery rate. Clinical outcome after surgery of a herniated thoracic disc proved successful, especially when the disc was considered to have a soft consistency. They concluded that in order to decide the optimal surgical strategy and prospective surgical outcome, disc characteristics, including consistency and direction of prolapse should be considered pre-operatively.[53]

Conservative Management

Conservative treatment rarely helps, as the relatively narrow dorsal canal cannot accommodate intrusions and as the thoracic cord is very sensitive to mechanical compression and vascular compromise.

Haro et al. have treated two cases conservatively. The herniated discs exhibited marked decrease in size,

corresponding to a favourable clinical outcome within a few months after the initiation of conservative treatment with prostaglandin E[3] and/or steroids in conjunction with physical therapy. The authors conclude that thoracic herniated discs are capable of undergoing natural resorption and that conservative treatment could be indicated, even in the presence of moderate myelopathy, when the myelopathy is not accompanied by bladder dysfunction or progressive muscular weakness.[21]

114 Lumbar Disc Disease

Manas Kumar Panigrahi, Rajesh Reddy S

INTRODUCTION

The term "lumbar degenerative disc disease" includes a spectrum of disorders like disc bulge, disc protrusion (central, paracentral, intraforaminal or far lateral), disc extrusion (with or without mitigated fragment) and internal disc disruption. Patients suffering from this condition present with low-back pain or radiculopathy of long duration or, acutely, as cauda equina syndrome. This chapter focuses mainly on the various management strategies of this commonly encountered condition in the outpatient department, their outcomes and the unresolved controversies.

HISTORICAL PERSPECTIVES

Thousands of years ago, Susruta (800 BC), the Father of Surgery in India and Charaka, a great physician of ancient India, identified the condition "sciatica" and named it *gridhrasi*. They attributed the pathogenesis of this condition to *vata dosha* wherein the local factors of blood, muscles, bones, ligaments and tendons are involved in a vicious manner. The symptoms of sciatica were also mentioned in the ancient Greek and Roman textbooks, but were often grouped with pain originating from the hip joint. The other notable events in the history of lumbar disc disease are summarised in Table 1.

ANATOMY AND BIOMECHANICS OF THE LUMBAR INTERVERTEBRAL DISC

The intervertebral disc (IVD) is composed of three elements which include the nucleus pulposus, annulus fibrosus and cartilaginous end-plate. The nucleus pulposus is the central portion of the disc which is composed of cells from the primitive notochord. It is composed of type II collagen and a very hydrophilic polymer called glycosaminoglycan, which is capable of absorbing a large amount of water and forming a gel-like matrix. The amount of water absorbed by the nucleus depends not only on the composition of the polymer matrix but also on the external pressure exerted on the disc. At a young age and when the disc is healthy, 80% of the nucleus is constituted by water, even under normal loading conditions, which keeps the annulus well inflated. It becomes more solid and fibrous with age (Fig. 1).

The annulus is a fibrous structure composed largely of type I collagen that restrains lateral forces produced by the compressed nucleus which is located within it slightly dorsal to the midline. It is a multilayered structure, much like an automobile tyre, composed of 10–12 concentric layers of well organised collagen fibres running in opposite directions in adjacent layers at approximately 30 degree to the horizontal plane. This arrangement provides the annulus with a high tensile modulus and strength, as well as equal torsional modulus in either direction. The annular bands are subdivided into inner fibres, which are connected to the

Table 1: Notable events in the history of lumbar disc disease[2]

1555—Vesalius described the intervertebral disc
1764—Contugno associated the symptoms of sciatica to irritation of the sciatic nerve by "acrid humors" derived from blood
1858—Luschka observed degenerative processes of the disc in autopsy specimens
1909—Oppenheim and Krause performed the first surgery, documented in literature, for disc herniation
1929—Myelography was described, Dandy attributed cauda equina syndrome to material derived from the intervertebral disc
1934—William J Mixter, a neurosurgeon at Harvard Medical College, and his orthopaedic colleague Joseph Barr elucidated the pathophysiology of lumbago and sciatica and described an intradural approach for removal of the offending ruptured disc
1948—Discography was described by Lindblom which provided an insight into the pathology of degenerative disc disease
1956—Concept of artificial disc was set forth by Van Steenbrugghe
1964—The concept of chemonucleolysis was demonstrated in a rabbit model by Smith which was later applied in humans
Early 1970s—The introduction of magnetic resonance imaging revolutionised the management of lumbar disc disease
1975—Hijikata described the first percutaneous discectomy
1977—The technique of microsurgical discectomy was described by Yasargil in Switzerland, Caspar in Germany and Williams in the United States
1984—Aschner and Heppner introduced the concept of percutaneous laser assisted discectomy with NdYAG and carbon dioxide lasers
1990s—Tubular microdiscectomy was popularised wherein a smaller incision was made with muscle splitting (MED, MEDRx systems) rather than subperiosteal dissection
2000—Saal and Saal described the concept of intradiscal electrothermal therapy

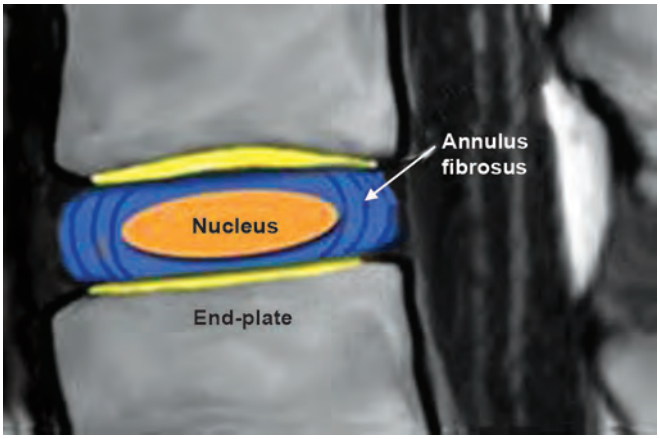

Fig. 1: Normal disc on magnetic resonance sagittal

cartilaginous end-plate, and outer Sharpey fibres, which are attached to the vertebral body.

The mechanical properties of a disc are a function of the structure and integrity of both the annulus and nucleus in combination. A change in either one of these parameters can affect the overall properties of the disc. The anterior longitudinal ligaments (ALLs) and posterior longitudinal ligaments (PLLs) further strengthen the disc space. The ALL attaches more strongly to the vertebral body edges than to the annulus and acts like a tension band to resist forces applied in extension. The PLL, which is not as strong as the ALL, strongly attaches to the annulus fibrosus and acts like a tension band to resist flexion forces. It is frequently torn in cases of free fragment disc herniation. The cartilaginous end-plate is made of thin hyaline cartilage which binds the IVD to the vertebral body above and below it. The function of the end-plate is more biological than biomechanical in that it plays an important role in allowing nutrients to pass into the disc.

The disc has a low metabolic rate and receives most of its nutrition by diffusion. The majority of the disc nutrition is supplied via the capillary beds of the cartilaginous vertebral body end-plate. The capillaries receive blood from the lumbar arteries which arise from the aorta and supply the vertebra in a segmental fashion. Vascular and lymphatic tissue is present in the annulus of young patients but the nucleus pulposus does not have blood vessels or lymphatics at any age.

A meningeal branch of the spinal nerve, known as the recurrent sinuvertebral nerve of Luschka, which arises from the posterior ramus of each nerve root, innervates the dura, PLL and the fibres of the annulus fibrosus. The outer annular regions are innervated but the inner regions and the nucleus pulposus are not innervated. Degenerated human lumbar discs have been found to contain more nerve tissue and more vessels than normal discs.

PATHOPHYSIOLOGY OF DEGENERATIVE DISC DISEASE[7,13]

The IVD performs two important but somewhat conflicting duties, i.e. it maintains spinal column stability while providing the column with necessary flexibility. By keeping the vertebral bodies separated from each other, the IVD holds the foraminal space open and prevents compression on the exiting nerve roots.

Lumbar disc degeneration and herniation are multifactorial processes to which both mechanical and biochemical derangements contribute. Disc degeneration often occurs in patients at a much younger age than knee or hip degeneration. Although the degenerative processes progress with age, the incidence of disc herniation does not; it peaks in the fourth decade. Degenerated discs show abnormal vascularity, abnormal distribution of collagen and collagen cross links and, abnormal and non-uniform elastic modulus that distributes stress to critical portions of the disc. Repetitive or continuous axial overloading is the key determinant in the pathogenesis of lumbar degenerative disease. Obese individuals, manual labourers, truck drivers and those involved in athletic activities like weight lifting and gymnastics are at risk for repetitive axial overloading of the spine. Defects in DNA for collagen have been identified in family clusters predisposed to degenerative disc disease. Multilevel disc herniation occurs at a younger age in such family clusters.

The process of disc degeneration occurs in both the annulus fibrosus and the nucleus pulposus. With advancing age, the mechanical strength of the annulus decreases and the nucleus also loses its water binding capacity. As a result, the stress in the vertebral column, which in normal individuals is transmitted to the centre of the end-plate, is transmitted to the peripheral portion of the vertebral body and the weakened annulus, resulting in disc herniation and compression on the adjacent nerve root. This, in turn, accelerates the degeneration of the facet joints (Figs 2 and 3).

Radicular pain associated with disc herniation has been attributed, in part, to the inflammatory response at the site of disc herniation, resulting in an increase in the number of macrophages and IL 1β with subsequent release of PGE_2. However, the severity of inflammatory

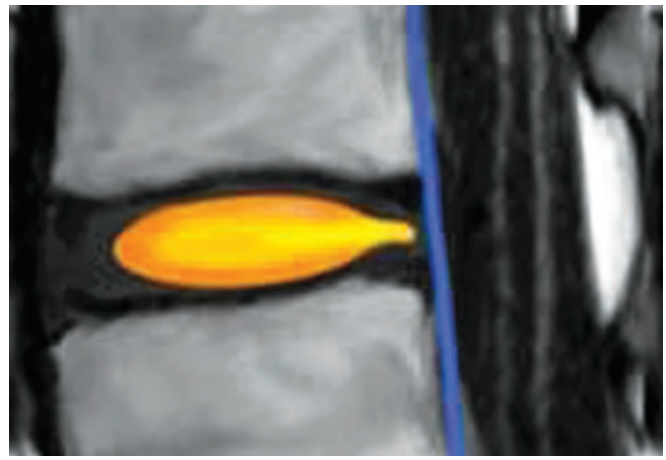

Fig. 2: Disc herniation is displacement of disc material beyond the limits of the disc

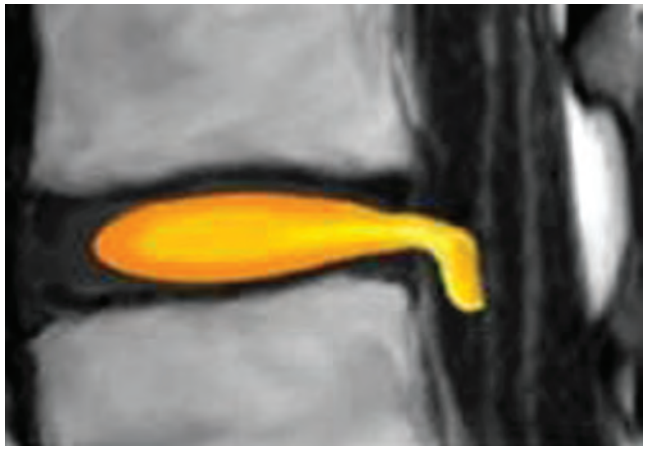

Fig. 3: Migration indicates displacement of disc material away from the site of extrusion

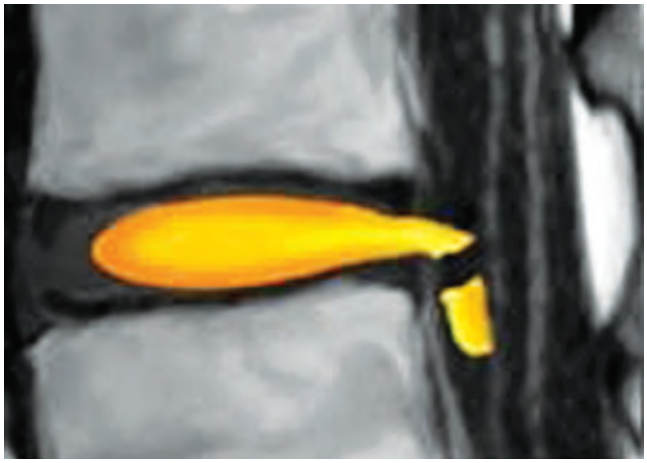

Fig. 4: Sequestration is used to indicate that the displaced disc material has lost completely any continuity

response does not correlate with the severity of symptoms. Interestingly, the presence of inflammation in patients does correlate with a better post-operative outcome when compared with those with herniated discs showing no inflammation.

An autoimmune component to lumbar disc disease has been suggested based on the findings of increase in anti-glycosphingolipid antibodies in two-thirds of patients with lumbar disc disease and radicular symptoms. However, this autoimmune theory is challenged by some researchers. The role of apoptosis in lumbar disc degeneration is not fully understood. Inappropriate disc matrix produced in degenerated lumbar discs stimulates apoptosis. It may be the possible mechanism of spontaneous resorption and remodelling of the extruded material in free disc herniations.

The majority of disc herniations occur in a posterolateral direction, i.e. corresponding to the region of the spinal canal between the midline and the neural foramen, because the nucleus pulposus is situated somewhat posteriorly within the annulus and the PLL reinforces the annulus fibrosus in the midline posteriorly. The degree of disease in the lumbar spine is characterised by the location of the abnormal portion of the disc. A disc bulge is a symmetrical extension of the disc beyond the endplates, whereas a disc protrusion is a focal area of extension still attached to the disc. An extruded or free fragment disc herniation refers to the part of the herniated disc that is no longer connected to the disc, and herniated disc material that is contained within the PLL is termed a sequestrated or subligamentous disc herniation (Figs 4 to 8).

CLINICAL FEATURES

Symptoms

A patient with a herniated lumbar disc may present with radiculopathy, neurogenic claudication or cauda equina

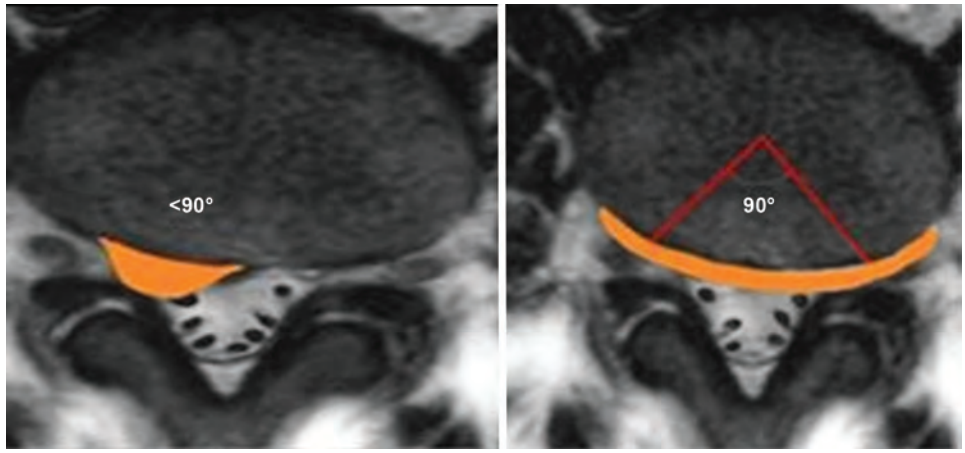

Fig. 5: Focal herniation is a herniated disc less than 90° of the disc circumference. Broad-based herniation is a herniated disc in between 90° and 180° of the disc circumference. Bulging disc is the presence of disc tissue "circumferentially" (180°–360°) beyond the edges of the ring apophysis and is not considered as a form of herniation

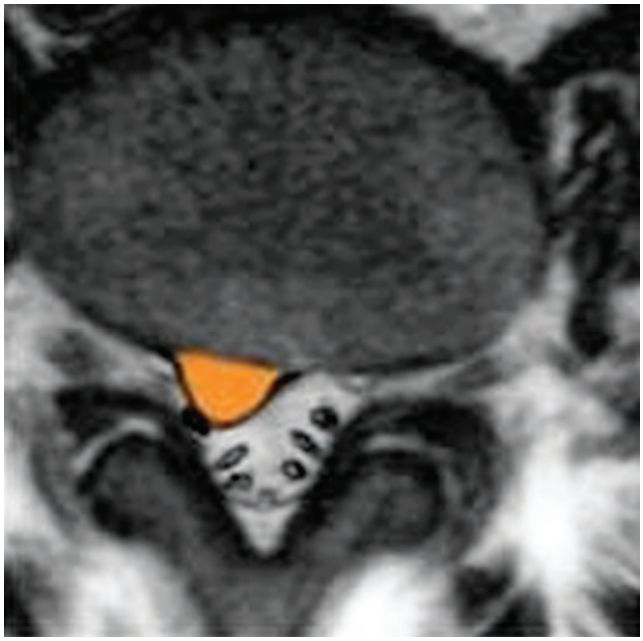

Fig. 6: Disc protrusion indicates that the distance between the edges of the disc herniation is less than the distance between the edges of the base

Fig. 7: Disc extrusion is present when the distance between the edges of the disc material is greater than the distance at the base

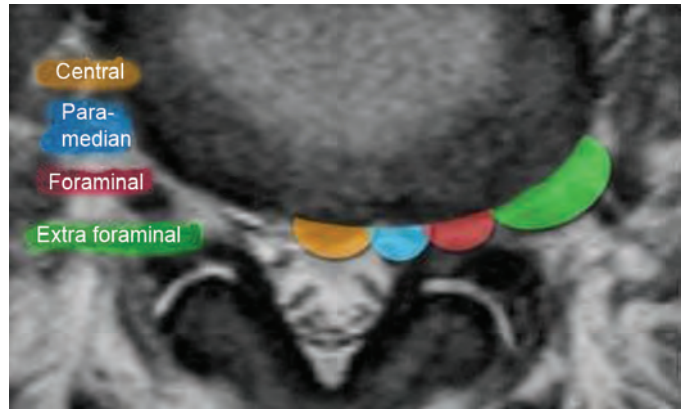

Fig. 8: Axial localisation of herniated lumbar disc

syndrome. The initial symptom in a patient with a disc herniation is pain, which may be in the back, buttock, thigh, leg or foot which is present either in all areas or a few of these areas. Radicular pain is aggravated by bending, coughing, sneezing and lifting a grounded object. The pain is usually relieved by lying down in a hip-knee flexed posture. The back pain often resolves to be replaced later in the course of the disease by weakness and numbness in the lower extremity.

The radiation of pain helps the clinician localise the nerve root that is involved and, in many but not all cases, the level of the herniated disc (Table 2). A posterolateral disc herniation compresses the ipsilateral nerve root at its exit from the dural sac (under the pedicle of the lower vertebral body) rather than in the neural foramen. For instance, a patient with posterolateral left L4-L5 disc herniation would present with left L5 radiculopathy. On the other hand, a far lateral disc herniation often affects the ipsilateral nerve root exiting through the adjacent neural foramen (under the pedicle of the upper vertebral body), i.e. a patient with left far lateral L4-L5 disc herniation would present with left L4 radiculopathy. Paraesthesias in the form of tingling, pins and needles sensation or numbness is of great value in localising the level of root compression. The more distal its location, the more reliable it is in helping with root localisation.

Patients who have large central disc herniation and resultant spinal canal stenosis present with neurogenic claudication which is asymptomatic at rest. They experience bilateral lower extremity pain after a variable duration of exertion, associated with numbness which

Table 2: Common neurologic changes in herniated lumbar disc

	Motor weakness	*Sensory loss*	*Reflex depression*	*Muscle wasting*
L2	Hip flexion and abduction	Lateral thigh	Nil	Thigh
L3	Knee extension	Patellar region	Knee	Thigh
L4	Knee extension, ankle dorsiflexion	Medial shin below knee	Knee	Thigh
L5	Extensor hallucis longus	Dorsum of foot, lateral calf	Tibialis posterior, lateral hamstrings	Calf, minimal thigh
S1	Plantar flexion at ankle	Lateral border of foot, posterior calf	Ankle	Calf

is relieved with a brief period of rest. A central lumbar disc herniation may result in cauda equina syndrome with perineal numbness, loss of bowel and bladder control and some degree of motor weakness in legs.

Signs

The clinical examination of a patient presenting with back pain is described in the chapter "Clinical Features and Diagnosis of Spinal Cord Tumours". Examination of the sensory system is the most subjective part of the neurologic examination, while assessment of muscle strength is less subjective and eliciting the reflexes is the least subjective. It is important to look for paraspinal muscle spasm, range of movements of the spine and perform a rectal examination when cauda equina syndrome is suspected. It is important to interpret straight leg raising test of Lasegue—a positive test implies reproduction of radicular pain and not back pain.

DIFFERENTIAL DIAGNOSIS

Although back pain is the most common symptom of a herniated lumbar disc, it is also the least useful symptom in making the diagnosis. The following conditions also present with symptoms similar to a herniated lumbar disc:

- Tumours involving the nerves (neurofibroma, Schwannoma, ependymoma) or metastatic deposits in the pedicle
- Peripheral neuropathy in diabetes mellitus and entrapment neuropathies involving the sciatic nerve in the pelvis
- Osteoarthritis of the hip
- Fractures involving the vertebra caused by trauma, osteoporosis or metastatic deposits
- Arachnoid cyst and Tarlov's cysts of the spinal region
- Vascular claudication

INVESTIGATIONS

Radiographs of the Lumbar Spine

Manifestations of degenerative disc disease that may be identified on plain X-ray films include IVD space narrowing, accumulation of gas within the disc (vacuum disc phenomenon), calcification of the disc, sclerosis of the adjacent vertebral body end-plates (collectively termed intervertebral osteochondrosis) and end-plate osteophytes secondary to anterolateral disc protrusion with traction by Sharpey's fibres at the site of the osseous attachment of the disc (spondylosis deformans). However, plain films are insensitive to early changes of disc degeneration and are incapable of demonstrating herniated nuclei pulposi and many cases of spinal stenosis.

Standard anteroposterior and lateral radiographs rule out other causes of back pain. Dynamic flexion and extension views are needed to rule out associated spondylolisthesis.

Myelography

It is possible to delineate the thecal sac, spinal cord and exiting nerve roots on myelography. The myelographic signs of disc herniation include:

- Compression of the nerve root and thecal sac with an angular indentation on the anterolateral aspect of the thecal sac
- Compression of the nerve root with fusiform widening of the more distal end of the involved root
- Central compression of the thecal sac by a centrally located herniated nucleus pulposus

Myelographic findings of disc herniation correlate well with operative findings at the L4–L5 level but are less accurate at L5–S1, owing to the wider epidural space and greater amount of epidural fat at this level, which minimises deformity or displacement of the sac by a disc herniation. Myelography is insensitive to the detection of lateral disc herniations and foraminal stenosis. The sensitivity and specificity of myelography have improved considerably since the introduction of water-soluble contrast agents and the use of myelography followed by computed tomography. However, in many cases, either computed tomography or magnetic resonance (MR) imaging can provide adequate information concerning degenerative disease of the spine.

Computerised Tomography

Computerised tomography revolutionised the evaluation of patients with degenerative disc disease. With myelography and plain films, only the secondary effects of the degenerative process on osseous structures, the thecal sac and exiting nerve roots are identified. Computed tomography demonstrates both the primary abnormality and the secondary effects. It is more accurate than myelography in the detection of lumbar disc herniations, owing to its ability to show lateral disc herniations and to evaluate the L5–S1 level reliably. The accuracy of computed tomography is greater than 90% in the detection of lumbar disc herniations. Computed tomography accurately demonstrates the central canal, lateral recesses, neural foraminal stenosis, facet joint disease, ligamentous hypertrophy and reactive bone changes associated with disc degeneration, including end-plate sclerosis, osteophyte formation, and facet joint narrowing or hypertrophy.

Magnetic Resonance Imaging

The development of high-resolution surface coil MR imaging, with its multiplanar capability and high contrast sensitivity, has made this the single best method for the evaluation of degenerative disease of the spine. The MR imaging is the preferred initial study for the evaluation of degenerative diseases of the lumbar spine including disc herniations and central canal, lateral recess and neural foraminal stenosis. Prospective comparisons of surface coil MR imaging, computed tomography and myelography have demonstrated that MR imaging is

as accurate as computed tomography and slightly more accurate than myelography in detecting disc herniations and stenosis. Moreover, MR imaging is more sensitive than myelography in detecting lateral disc herniations at all levels as well as disc herniations at the L5–S1 level. At this level and, occasionally at more superior levels, the epidural fat acts as an endogenous contrast agent on both computed tomography and MR imaging, allowing for the detection of small herniations. However, this fat reduces the sensitivity of myelography, since it is interposed between the opacified thecal sac or nerve roots and the adjacent herniated nucleus pulposus.

The MR imaging findings[11] of a degenerated disc are:

- Decrease in signal intensity on T2-weighted scans of the nucleus pulposus, compared with a normal disc, because of desiccation of the degenerated disc and resultant diminished water content
- Irregularity of the outline of the nucleus pulposus
- Decrease in disc height
- An intense dot like high intensity signal in the posterior annulus signifying an annular tear
- Modic changes in the cortical end-plate and the adjacent marrow.[11]

A disc herniation is best detected on axial images (either computed tomography or MR imaging) because in this plane the focal, usually eccentric posterior extension of the disc material is readily visualised. The protruding disc obliterates the epidural fat, displaces the nerve root sleeve, or both. Sagittal T1-weighted and T2-weighted MR images often demonstrate posterior bulging of the IVD. This *per se* is not conclusive evidence of a disc herniation, since this finding may be seen in degenerative disc disease in the absence of rupture of the annulus fibrosus. Sagittal T1-weighted and moderately and heavily T2-weighted images provide information regarding the level of herniation, presence of extruded or sequestrated fragments, if any. T2-weighted scans are, however, degraded by pulsation artifacts; and the axial T1-weighted scans, while providing an excellent image of the spinal cord, may be relatively insensitive to the presence of spinal stenosis and lateral spinal canal lesions, including osteophytes and herniated nuclei pulposi. Gradient-echo imaging provides excellent views of the spinal cord free from pulsation artifacts, with the high-intensity cerebrospinal fluid (CSF) and low-intensity spinal cord. On axial gradient-echo images, high intensity in the lateral recesses allows for identification of degenerative stenosis and lateral disc herniations.

Discography[14,17]

It is the technique of injecting the IVD with radiopaque contrast which provides physicians with several useful pieces of information. First, this modality provides radiographic evaluation of the integrity of the nucleus pulposus and annular rings to determine tears or other lesions that could be responsible for low-back pain. Second, and more important, is its measure of disc nociception and that targeted therapy directed at that disc is warranted. A normal disc should not cause pain when injected; however, a disc that is physiologically compromised can elicit the pain previously experienced by the patient. No more than three discs should be injected during any single study.

Significant controversy exists as to whether discography contributes any more than diagnostic information that is ascertained using the non-invasive and certainly less painful MR imaging. Discography has been viewed upon as a potential solution to the diagnostic dilemma concerning which patients to treat surgically and at what segmental level. Discography is exquisitely sensitive, but not very specific, when used to diagnose discogenic low-back pain.

The primary indication for lumbar discography is chronic low-back pain with or without radicular pain in the absence of MR imaging–documented neural compression, i.e. it can be used for identifying disc lesions and pain generators when MR images are equivocal. Discography is also indicated in the following scenarios:

- When clinical findings point to one level or one side and myelography or MR imaging indicates a different level
- When the disc protrusion is asymmetrical to the contralateral side of the patient's symptom

In some cases, far-lateral disc herniations may be confused with nerve sheath tumors or haematomas. Again, discography is indicated to resolve these diagnostic dilemmas. It is also helpful in the investigation of adjacent-level disease and the elimination of patients with psychogenic complaints from surgical therapy. In patients with a positive discography finding and equivocal MR imaging or plain radiographic findings, a thorough psychological evaluation is recommended. Such patients should not be considered for any type of surgical intervention.

Electromyogram/Nerve Conduction

This study may sometimes be required to rule out peripheral neuropathy.

MANAGEMENT

Progress made in the management of disc ailments can be divided into four distinct stages:

1. Stage I involved the correct diagnosis of the problem and the selection of surgical treatment.
2. In Stage II, advances were made in diagnostic methods and in the understanding of the physiological and biomechanical aspects of the disc.
3. Stage III consists of a period during which both progress made in stage I and II continued with new trends of disc replacement by prosthetic devices.
4. In Stage IV, more aggressive research into the field of disc degeneration and possible regeneration with stem cells is being carried on.

Table 3: Management options for a patient with degenerative disc disease

Non-operative management	*Operative management*
• Bed rest • Physiotherapy - In the acute phase: Use of hotpacks, short wave diathermy, microwave therapy. After the acute phase: graduated regime of back exercises is instituted • Use of lumbar corset whenever the patient is active • NSAIDs • Muscle relaxants • Epidural corticosteroid injections	• Open techniques • Endoscopic techniques • Microdiscectomy • Minimally invasive techniques – Chemonucleolysis – Automated percutaneous lumbar discectomy – Laser assisted percutaneous discectomy – Arthroscopic microdiscectomy – Intradiscal electrothermal therapy – Percutaneous nucleoplasty

Summary of the treatment options available in the management of patients with degenerative disc disease is given in Table 3.

Conservative Management

An important decision for the clinician is whether to advise bed rest for patients with low back pain. One rationale for bed rest is that many patients experience relief of symptoms while in a horizontal position. Another rationale is that the supine position minimises intradiscal pressure. However, the Cochrane review of nine trials with 1435 patients, comparing bed rest with other treatments or different lengths of bed rest concluded that bed rest compared with advice to stay active at best has no effect, and at worst may have slightly harmful effects on low-back pain.[4] There is no important difference in the effects of bed rest compared with exercises in the treatment of acute low-back pain, or 7 days compared with 2–3 days of bed rest in patients with low-back pain of different durations with and without radiating pain.

Microdiscectomy

Microsurgical approach for lumbar discectomy is currently the gold standard in the management of herniated lumbar disc disease (Table 3). Success rates in microdiscectomy range from 88 to 98.5% while the complication rate is around 1.5%. The biggest advantage is the shorter incision and hence reduced post-operative pain which reduces the hospital stay.

Surgical Outcomes

Between 10% and 30% of patients undergoing primary discectomy for radiculopathy continue to experience unsatisfactory results. A meta-analysis of outcomes after limited disc removal and aggressive disc removal has reported a 2.5-fold increased incidence of long-term recurrent back and leg pain after aggressive discectomy while limited discectomy resulted in 2-fold increase in incidence of recurrent disc herniation.[8,10] However, the short-term outcomes did not differ between the two techniques. The O'Connell technique of aggressive discectomy has been criticised for causing nucleus and end-plate injury, accelerating degenerative changes at the operated disc level, leading to disc space collapse with loss of foramen height, and potentially leading to an increased incidence of post-operative back and leg pain. The more conservative Williams and Spengler technique of limited discectomy emphasises removal of the disc fragment alone with little invasion of the disc space, hence is associated with a higher incidence of disc reherniation. The extent of disc removal must be based on a case by case decision regarding the intra-operative appearance of the herniated lumbar disc after discussing the pros and cons of each procedure with the patient.

Potential predictors of poor outcome include misdiagnosis (for example, diabetic polyneuropathy mistaken for radiculopathy), pre-operative psychological distress, insufficient rehabilitation, mechanical instability, impaired fibrinolytic activity, diabetes, obesity and hypertension.

The complication rate following microdiscectomy is 15–30%.

Intra-operative complications:

- Exploration of the wrong side or level
- Dural tears resulting in post-operative CSF leak, pseudomeningocoele
- Injury to the nerve root
- Retroperitoneal injury to great vessels and bowel
- Facet joint fracture
- Haemorrhage

Post-operative complications:

- Discitis (septic or aseptic)
- Arachnoiditis
- Soft tissue infection
- Failure of pain relief
- Recurrence of pain due to failed back surgery syndrome.

Minimally Invasive Spinal Surgery[16]

The traditional surgical technique of discectomy involves extensive resection of the posterior bone and muscular structures leading to increased post-operative

pain, intra-operative blood loss and morbidity. Extensive paraspinal muscle detachment from the midline osseous elements can cause weakness secondary to muscle denervation. Damage to the "tension band" consisting of the supraspinous and interspinous ligaments may lead to increased instability of the spine during lumbar flexion resulting in failed back syndrome. Hence, minimally invasive spinal surgical techniques have been developed with the idea of minimising tissue trauma without compromising the goal of a successful surgical outcome. Long-term prospective controlled data are lacking to establish the success rates of minimally invasive procedures on the spine compared with the traditional ones. Moreover, a learning curve is required to be familiar with these procedures.

Chemonucleolysis

Chemonucleolysis with chymopapain is based on the principle that depolymerisation of the proteoglycan and glycoprotein macromolecules of the nucleus pulposus reduces the water content of the extracellular matrix of the nucleus pulposus and reduction in the IVD height and bulge. In addition, chymopapain may also have an anti-inflammatory role in the nerve apart from the possibility of producing a total or partial neurectomy like effect by interacting with the sensory fibres of the annulus. It is reserved for patients with soft herniated disc as demonstrated by imaging. Contraindications include patients older than 60 years of age (poor response rate due to low mucoprotein content of the disc), migrated disc, canal stenosis, past history of discitis and allergy to papain. Success rates ranging from 82 to 87.2% have been reported. An inadvertent intrathecal injection results in hemiparesis, paraplegia, raised intracranial pressure, meningitis and haemorrhage.

Percutaneous Nucleotomy

The technique of percutaneous nucleotomy was first described by Hijikata in 1975 and popularised by Kambin and his colleagues. This procedure is most ideal for contained disc fragments. Sequestrated disc fragments, spinal stenosis, spondylolisthesis and past history of spinal surgery are contraindications. Success rates reported in literature range from 77.5 to 87% with a complication rate of 1%.

Percutaneous Laser Assisted Discectomy

It involves placement of a needle in the disc space coupled with passage of laser energy generated by carbon dioxide, Nd YAG, KTP laser or Holmium YAG laser. A 70–80% rate of long-lasting pain relief has been demonstrated with a complication rate of 3.5%.

Intradisc Electrothermal Coagulation

It is a therapeutic innovation specifically designed to treat discogenic pain.[19] Targeted thermal energy is delivered from an electrosurgery unit into the disc space by percutaneously threading a flexible heating electrode into the disc, such that the electrode passes circumferentially around the inner surface of the disc. The energy thus delivered is thought to reduce discogenic pain either by thermal coagulation of the nociceptors or by increasing the stability of the disc via contraction of type I collagen fibres. Successful relief of pain in up to 60% of the patients has been reported.

CONTROVERSIES IN MANAGEMENT

Surgery is recommended if symptoms persist after 6 weeks of supervised conservative management, although the optimal timing of surgery is still being debated. The major advantage of early surgery is quick pain relief, but the clinical results after 1 year are similar, which legitimates prolonged conservative treatment in selected patients.

The optimal treatment of patients with lumbar disc herniation and neurological deficit is not known. A study on recovery from paresis due to lumbar disc herniation has demonstrated no difference between surgically and medically treated patients.[3]

Post-operative physiotherapy was not recommended by 50% and 24% of British and Dutch surgeons respectively. These post-operative regimens are in contradiction to the literature, which has shown strong evidence in favour of active rehabilitation. However, the Cochrane review (2003) concluded that intense exercise programmes are more effective for functional outcome and lead to a faster return to work.[12] The same review also concluded that post-operative restrictions may not be necessary in most patients, and there is no evidence that it is harmful to return to activity immediately after surgery.

The spine patient outcomes research trial compared operative and non-operative care in patients with symptoms of lumbar disc herniation.[9,18] The conclusion drawn was surgery only shortens the duration of pain; if one can achieve the same with the use of analgesics, he or she can be better within 2 years without surgical risks. Numerous critics have pointed out fallacies in the study design and consider the conclusion of the randomised clinical trial invalid. One such fallacy was in the randomisation of patients in which, although treatment allocation in the trial was random, the actual treatment received was essentially stratified according to disease severity by the patient's choice.

The value of routine histopathological examination of IVD tissue has been questioned. The incidence of unexpected and important histopathological findings in tissue samples obtained during discectomy performed for a benign indication is approximately 1 in 1,000. Hence, routine histopathological examination of IVD specimens, especially those obtained in lumbar IVD procedures is justified and cost-effective according to some authors.[5]

RECURRENT DISC HERNIATION[15]

The rate of recurrent disc herniation after lumbar discectomy is 5–15% with an average pain-free interval of 8 years. The strict definition of recurrent disc herniation is the presence of herniated disc material at the same level, ipsilateral or contralateral, in a patient who has experienced a pain-free interval of at least 6 months after surgery. The clinically more appropriate definition, however, is disc herniation at the previously operated site and side. The current neuroimaging tool of choice in investigating a patient with post-discectomy recurrent symptoms is gadolinium enhanced MR imaging. The findings on imaging should be interpreted carefully and should not be confused with the post-discectomy changes. The nerve root should not enhance 6 months after the initial procedure.

Treatment options include observation and aggressive medical management (pharmacological therapy and physical therapy for rehabilitation) or operative intervention. Revision laminectomy and discectomy are the most commonly performed surgical therapies, starting at an area known to be intact, finding landmarks, beginning medially, and working out laterally to locate the pathological entity. Fusion is not routinely needed, unless spinal instability is demonstrated. There is no consensus on timing or optimal intervention in the treatment of patients with recurrent herniated discs. Higher recurrence rates and poorer outcomes have been documented in diabetic patients. Chymopapain, intradiscal electrothermal coagulation therapy and laser-assisted decompression are not options because the annulus is no longer intact in revision disc surgery.

RECENT ADVANCES

Artificial Disc Technology[1]

The two most common spinal surgery procedures, discectomy and fusion, are far from ideal for treating spinal disc degenerative disease. Although discectomy has a reasonably good short-term effect in relieving radicular pain, it causes disc height reduction in almost all patients[1] and further increases the instability of the treated disc. Scientifically, both physicians and industrial and academic researchers have been seeking better solutions for low-back pain treatment. Naturally, disc arthroplasty has been considered to be the "holy grail" of back pain treatment. The evolution of artificial disc technology is attested in part by experience in numerous patients as reported in publications over the past 50 years, especially the last 20 years.

One of the major reasons why artificial disc technology has been slow to develop is the structural and functional complexity of the disc, unlike hip and knee joints, which are composed mainly of a layer of cartilage tissue on each articulating surface. In IVD replacement, one can replace either the entire disc or only its nucleus, the former prosthesis is called an artificial total disc and the latter an artificial nucleus. Basic design concepts and component material(s) can be divided into three groups:

1. Metal
2. Non-metal
3. Metal in combination with non-metal.

The nucleus prosthesis approach has several obvious advantages over the total disc prosthesis. By replacing only the nucleus, it preserves the remaining disc tissues—annulus and end-plates—and therefore preserves their functions. Because the nucleus has a much simpler structure and function than the annulus and end-plates, the design of the nucleus prosthesis allows surgeons to leave the annulus and end-plates intact, making the surgical procedure much easier than that required to replace the entire natural disc. The major limitation of the nucleus prosthesis is that it can be used only in patients in whom disc degeneration is at an early or intermediate stage because it requires the presence of a competent natural annulus. Some of the artificial disc and nucleus available for use are the Charite device, prodisc and Raymedica implant.

Stem Cell Therapy[6]

Regenerative medicine and stem cells hold great promise for IVD disease. The therapeutic implications of utilising stem cells to repair degenerated discs and treat back pain are highly anticipated by both the clinical and scientific communities. Mesenchymal stem cells from adults are the best candidates for IVD repair. Although the avascular environment of the IVD poses a challenge for stem cell–mediated regeneration, neuroprogenitor cells have been discovered within degenerated discs, allowing scientists to revisit the hostile environment of the IVD as a target for stem cell therapy. Issues now under investigation include the timing of cell delivery and manipulation of stem cells to make them more efficient and adaptive in the IVD niche.

CONCLUSION

The complexity of the pain from the syndrome of degenerative disc disease and the fact that we do not fully understand the condition make it difficult to devise a common and effective treatment for every patient. Several controversies exist in the management of patients with herniated lumbar disc. Therefore, the treatment protocol varies from one centre to another. At the same time, newer methods like artificial disc replacement and stem cell therapy are being tried out as therapeutic options.

115 Lumbar Canal Stenosis

Manas Kumar Panigrahi, Debabrat Biswal

Changes in the diameter of the vertebral canal as a cause of neurological disturbances was first reported by Antoine Portal in 1803 and focused attention on changes in the size of the vertebral canal as a cause of compression of its contents. He noted that the abnormal curvature of the spine might produce deformity of the canal and narrowing and the second cause of narrowing was due to swelling of the vertebral bodies towards the canal. Venereal diseases and rickets were thought to be the underlying disorder. In 1864, Jaccoud, in a chapter, quoted a case of paraplegia resulting from compression of the spinal cord due to a narrow canal. In 1910, Sumita for the first time described narrowing of the vertebral canal in cases of achondroplasia. In 1911, Bailey and Casamajor described five cases of osteoarthritis producing compression of the spinal cord due to diffuse osseous growths with canal narrowing. In 1924, Vittori Putti, an Italian orthopaedic surgeon, emphasised the relevance of anomalies or acquired degenerative alterations of the intervertebral foramina and lateral recess, for causing sciatica by causing an entrapment of the exiting root. In 1925, Parker and Adson described a series of cases with hypertrophy, vascularity and sponginess of the laminae causing canal narrowing in which no diagnosis was given and infection and trauma were considered the causative factors. In 1931, Town and Reichert reported two cases with cauda equina compression due to hypertrophy of the ligamentum flavum causing intermittent claudication. In 1937, Sparling et al. described seven patients with cauda equina deficits as a result of hypertrophy of the ligamentum flavum. In 1948, Van Gerderen described an orthotic caudal nerve root syndrome and the patient deteriorated on erect posture due to compression by the hypertrophied ligamentum flavum. In 1947, Sarpyener in an article discussed congenital stricture of the vertebral canal.[27]

In 1949, Verbiest also known as the "pope of spinal stenosis", described three cases of stenosis of the lumbar vertebral canal where the interpedicular distance was normal, but the AP diameter grossly reduced. This publication became the watershed literature from which the term lumbar canal stenosis (LCS) was recognised.

In 1959, Verbiest classified stenosis into absolute and relative. The absolute were cases in which the vertebral body caused the compression, while relative in which occurrence of minor deformities would cause compression. It took considerable time before developmental narrowing or stenosis of the lumbar canal and its frequent association with intermittent claudication gained general recognition. Freidman (1961) and Epstein (1962) were the first authors to confirm the existence of this entity and from then there have been several studies and published data about LCS and its manifestation.[27]

LCS most commonly affects the middle-aged and elderly population and is one of the most common diseases in elderly persons.[31] This refers to the degenerative changes or trauma of the lumbar spine, resulting in narrowing of the spinal canal and entrapment of the cauda equina roots by hypertrophy of the osseous and soft tissue structures surrounding the lumbar spinal canal. It is often associated with incapacitating pain in the back and lower extremities, difficulty in ambulating, leg paraesthesias and weakness and, in severe cases, bowel or bladder disturbances.[14,31] It is caused by a complex process of disc degeneration, facet arthropathy, ligamentum flavum hypertrophy and spondylolisthesis. The prevalence of LCS is between 1.7 and 8% in the general population as reported by Fraser et al.[9] With increasing longevity of our population and a continually rising proportion of middle-aged and elderly persons, the problem of LCS has shown a significant increase in the patient population as reported by Kazuo Nakanishi et al. in their study.[20] Low back pain resulting from degenerative disease of the lumbosacral spine is a major cause of morbidity, disability and lost productivity. Due to the slow progression of the disease, the diagnosis may significantly be delayed. Given the potentially devastating effects of this condition, early diagnosis and treatment are essential if patients are to be returned to their previous levels of activity.

NORMAL ANATOMY

The lumbar vertebral canal is roughly elliptical, rounded, triangular or trefoil in shape and is narrowest in its anteroposterior diameter in the axial plane. The average anteroposterior diameter of the lumbar canal in adults, as determined by anatomic and radiographic studies, ranges from 15 to 23 mm and a cross sectional area of about 77 +/– 13 mm.[2,20] The canal is anteriorly bounded by the posterior edge of the vertebral body including the posterior longitudinal ligament, which is closely apposed

to the posterior vertebral body surface, laterally by the pedicles, posterolaterally by the facet joints and articular capsules, and posteriorly by the lamina and ligamenta flava (yellow ligaments).[13] Coric et al. observed that the vertebral bodies and discs account for the majority of the axial load bearing capability of the spine. The disc absorbs load and stress, provides support and resists movement. The superior facet and associated ligamentum flavum form the roof of the lateral recess, where nerve roots exit the canal and enter the foramen. The lumbar facet complex is biplanar with the medial portion oriented in the coronal plane and the lateral portion in the sagittal plane. The medial portion (coronal) limits forwards translation and the lateral portion (sagittal) resists lateral rotation. Therefore, the total facet load consists of a component responsible for sharing axial load bearing with the disc as well as components for resisting anterior and lateral shear. Ligaments play a primary role in resisting flexion rotation and posterior shear. Biomechanical studies on cadavers demonstrate that the posterior ligaments, notably the supraspinous and interspinous ligaments, exert a significant effect on tensile stiffness. The neural foramen is bordered by the superior and inferior articular processes and pars interarticularis of the superior vertebra dorsally, sequential pedicles superiorly and inferiorly, and the intervertebral disc and the posterolateral surface of the vertebral body ventrally. The nerve root exists caudal to the pedicle, and the dorsal root ganglion lies in the superior and lateral portion of the foramen.[7,10]

Lumbar stenosis has been classified anatomically as central or lateral (or mixed) and developmentally as congenital or acquired.

Central stenosis involves narrowing predominantly of the spinal canal. Coric et al. subdivided lateral stenosis as entrance zone stenosis, mid-zone stenosis and exit zone stenosis. Lateral stenosis has also been referred to as lateral recess, foraminal canal, subarticular, subpedicular, intervertebral foramen and lateral gutter stenosis (Fig. 1).[10]

The classification system proposed by Verbiest categorises the multiple causes of lumbar stenosis into two types: conditions that lead to progressive bony encroachment of the lumbar canal (including developmental, congenital, acquired and idiopathic causes) or stenosis produced by nonosseous structures such as ligaments, intervertebral discs and other soft tissue masses.

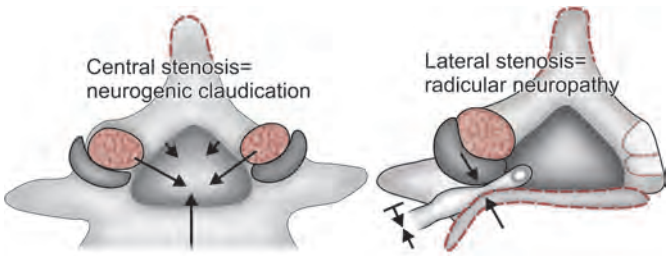

Fig. 1: Central stenosis versus lateral stenosis

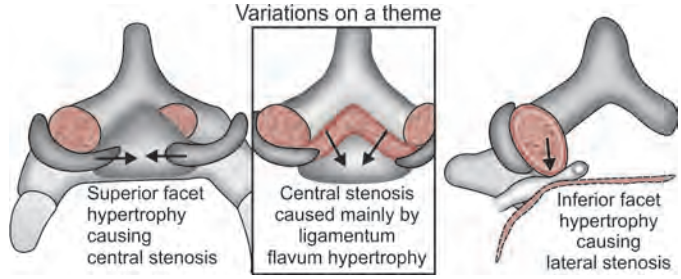

Fig. 2: Acquired stenosis due to hypertrophy of superior and inferior facets and ligamentum flavum

For practical purposes, however, the aetiologies of lumbar stenosis can be divided into congenital or acquired forms.[26,27] The two forms of spinal stenosis are described as follows:

Congenital stenosis which is primary and relatively uncommon is divided additionally into idiopathic and achondroplastic varieties. This condition is diagnosed more easily because patients are younger and usually lack other complicating medical problems such as diabetes or vascular insufficiency. Stenosis may develop at several levels of the vertebral column and may often lead to serious neurological deficits.

Acquired stenosis is a degenerative condition. The vast majority of patients present with acquired LCS. Patients generally become symptomatic at 50 years of age or older. Degenerative changes of the spine can include osteophyte formation, facet hypertrophy, bulging disks and hypertrophy of the ligamentum flavum. Any of these processes can result in canal or foraminal narrowing. Degenerative spondylolisthesis can further compromise the canal (Fig. 2).[1]

In some cases, the patient has acquired degenerative changes that augment a congenitally narrow canal,[29] which are classified as complex lumbar stenosis and present concurrently with other spinal deformities such as spondylolisthesis, scoliosis or lumbar kyphosis (flatback deformity). These lesions may be idiopathic, degenerative or surgery induced.[9]

PATHOPHYSIOLOGY

Nadalo reported that spinal stenosis results from progressive narrowing of the central spinal canal and the lateral recesses. The essential content of the spinal canal includes the spinal cord, the cerebrospinal fluid (CSF) of the thecal sac and the dural membranes that enclose the thecal sac. The spinal canal may become narrowed by bulging or protrusion of the intervertebral disc annulus, herniation of the nucleus pulposus posteriorly, thickening of the posterior longitudinal ligament, hypertrophy of the facet joints, hypertrophy of the ligamentum flavum, epidural fat deposition, spondylosis of the intervertebral disc margins, uncovertebral joint hypertrophy in the neck, or a combination of two or more of the above factors.[19]

The spine responds to physiological stresses with bone growth at the superior and inferior margins of the vertebral body (osteophytes). Osteophytes can form anteriorly or posteriorly. Posterior osteophytes narrow the intraspinal diameter and also cause lateral recess stenosis. This results in spinal cord or nerve root impingement. Furthermore, arthritic degeneration causes formation of synovial cysts and hypertrophy of the facet joints, which further compromise the patency of the spinal canal and the neural foramina.[13]

Fraser et al. noted that during ageing the discs dehydrate and can get compressed and bulge. This process can cause tilting, slippage or rotation of the vertebral bodies. The ligamentum flavum may also ossify and becomes hypertrophic. The compressed discs result in shortening of the spinal column, which causes the ligamentum flavum to buckle inwards and compress the spinal sac and nerve roots. Lumbar intervertebral disc degeneration represents a cascade of events involving bulging of the disc, disc herniation and ligamentum flavum into the canal, and resulting chronic facet arthrosis, sclerosis and osteophytic growth. Hypertrophy of the ligamentum flavum is also an important element in the development of spinal stenosis. Lumbar spinal encroachment induces ligamentum flavum hypertrophy, which further aggravates stenosis. Disease of the nerve roots and cord, however, does not typically result directly from compression of the nerves. Rather, the resulting stenosis causes decreased flow of CSF (which represents approximately 60% of the nutritional supply to the cauda equina) and increased venous pressure.[9]

SPINAL CLAUDICATION SYNDROME

The narrowing of the spinal canal leads to a compression of the cauda equina and its nerve roots. However, there is no direct relationship between the extent of the stenosis and the clinical symptoms. This finding remains unexplained. Furthermore, patients are usually asymptomatic when sitting and lying indicating a strong functional influence. There are the following two prevailing theories that try to explain intermittent claudication.

Neurogenic Compression Theory

Prolonged compression of a peripheral nerve followed by mechanical stimulation is known to produce abnormal electrical discharge,[12] thereby causing pain in experimental animal studies.[3] Long-standing direct mechanical compression of nerve roots leads to decreased CSF supply to the nerve root. Impaired nutritional supply results in microvascular changes, and causes oedema, accumulation of noxious substances, deterioration and fibrosis. The combination of these changes may explain neurological dysfunction. This theory does not explain all the functional aspects of neurogenic claudication.[22]

Vascular Compression Theory

The vascular compression theory suggests that spinal stenosis has pathological effects on the blood supply of the cauda equina. Particularly, multiple-level central stenosis is associated with spinal claudication. It is assumed that venous congestion between the levels of stenosis compromises nerve root nutrition and results in clinical symptoms. Additionally, the compressed nerve root arterioles may lose the ability to respond to exercise by vasodilatation. This compromise explains that walking produces back, buttock and leg pain as well as heaviness and discomfort in the lower limbs. During rest the vascular (nutritional) supply may suffice and the patient may be asymptomatic. However, a critical look indicates that some aspects of the clinical syndrome still are not explained well. This is particularly valid as patients with severe stenosis can be asymptomatic.[22]

CLINICAL PRESENTATION

Epstein, in her detailed article, noted that patients with severe congenital lumbar stenosis begin to show symptoms in their 30s and 40s, whereas those with acquired stenosis develop complaints in their 50s through 80s. Low back pain is often accompanied by asymmetrical, unilateral more than bilateral, radicular or claudication complaints. Standing and walking, which causes an acute increase in lumbar lordosis and infolding of the ligamentum flavum, precipitates claudication that can readily be reversed on flexion (by sitting or lying down).[6]

The characteristic syndrome associated with lumbar stenosis is termed neurogenic intermittent claudication. This condition must be differentiated from true claudication, which is caused by atherosclerosis of the pelvofemoral vessels.[13] Compression of the microvasculature of the lumbar nerve roots, resulting in ischaemia, is believed to be a major contributing factor in the development of neurogenic claudication. Wilson[11] classified neurogenic claudication into two major types based on the putative pathophysiological mechanism: postural or ischaemic. Postural neurogenic claudication is induced when the lumbar spine is extended and lordosis is accentuated, whether at rest or during exercise in the erect posture. With extension of the spine, degenerated intervertebral discs and thickened ligamenta flava protrude posteriorly into the lumbar canal, producing transient compression of the cauda equina. In the ischaemic form, it is theorised that transient ischaemia occurs in compressed lumbosacral roots when increased oxygen demand occurs during walking.[1]

Kobayashi et al. in their experimental study, observed that intermittent claudication in patients with LCS, which occurs during walking and subsides with rest, cannot be explained solely by mechanical compression of the nerve roots. These radicular symptoms associated with degenerative disease of the lumbar spine reportedly are attributable to a combination of mechanical nerve root

compression and resultant circulatory disturbance, but the dynamics of nerve root circulation are still poorly understood.[17]

It is not unusual not to find significant neurological deficits in patients with stenosis. Positive mechanical findings of entrapment are the Lasègue's sign and femoral stretch test and these can be elicited in 60% of patients with absolute and 43% of patients with mixed stenosis.[16] Mild motor dysfunction most frequently involves the extensor hallucis longus and peroneal muscle groups (L-5), and reflexes may diffusely be diminished or absent, mostly the ankle reflex. Sensory deficits, usually noted in the L-5 or S-1 distributions are rarely seen in more cephalad L2-4 or more caudad (sacral) distributions.[16] At the initial examination no neurological deficit may be elicited but a brief period of exercise often uncovers the deficit. Symptoms and signs are related to the age of the patient but not to the radiographic data (i.e. site and degree of the narrowest part or number of stenotic sites).[16] Patients with canal stenosis tend unconsciously to assume a style of gait that precludes the development of symptoms,[25] and this is one reason why the style of walking noted in these subjects immediately after they start walking is different from that in normal subjects.[10]

IMAGING STUDIES

Older patients in whom spinal stenosis is suspected should be examined using conventional spinal radiology, including AP, lateral, oblique and lower lumbar-centred views. Lateral views are most sensitive for central spinal stenosis, while oblique views of the cervical and lumbar areas demonstrate lateral stenosis syndromes better. Younger patients and all patients in whom conventional radiology findings are negative should be evaluated using either spinal CT scanning with reformatted images, spinal MRI, 3D CT or CT myelography.

Spinal MRI is the most suitable technique for the diagnosis of spinal stenosis. Spinal MRI should include imaging sets obtained in the axial and sagittal planes using T1-weighted, proton-density and T2-weighted techniques.

Plain radiographs of the lumbar spine reveal multilevel spondylotic changes with osteophytes, facet hypertrophy and disk space narrowing. Interpedicular and sagittal measurements of the canal on plain films are helpful in defining the stenosis. Flexion-Extension radiographs help demonstrate motion occurring at a potentially unstable segment.

CT scan helps in viewing facet hypertrophy, especially of the superior process, leading to constriction of the transverse diameter of the canal. Ventrally located osteophytes and hypertrophied laminae narrowing the canal in its AP diameter are readily demonstrated. Together, these changes narrow the lateral angles of the canal, diminishing the height of the lateral recess. The limitation of CT scan is in its poor demonstration of the ligamentous hypertrophy and disk protrusion (Fig. 3).[27]

Fig. 3: CT scan axial cut showing the medialised hypertrophied facets causing canal narrowing

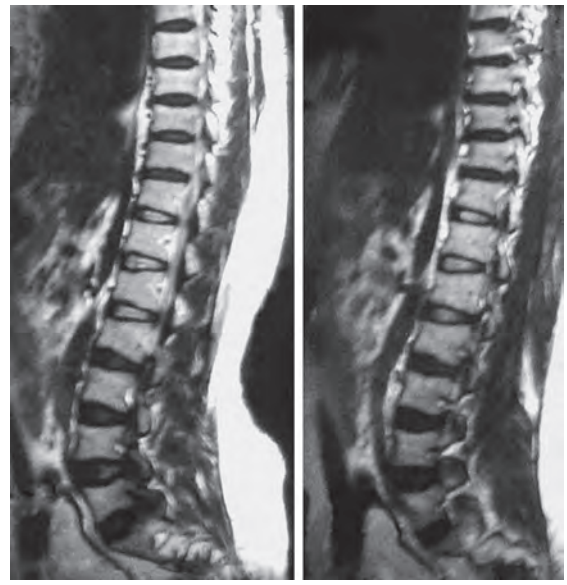

Fig. 4: MRI sagittal view of a patient of achondroplasia showing severe canal stenosis

Magnetic resonance imaging studies better delineate the soft tissue changes laterally, in the foramina and far laterally. MRI with Gadolinium DTPA affords a near myelographic view of the entire subarachnoid space. It also identifies tumours, demyelinating syndromes, adhesive arachnoiditis and infection. Compared to CT, MRI has a significant advantage because of its better soft tissue resolution (Figs 4 and 5).

CT Myelography

The benefits of CT over plain films are that it can provide greater resolution in terms of an increased ability to appreciate density differences. A second advantage of CT is its ability to image in different planes, either directly

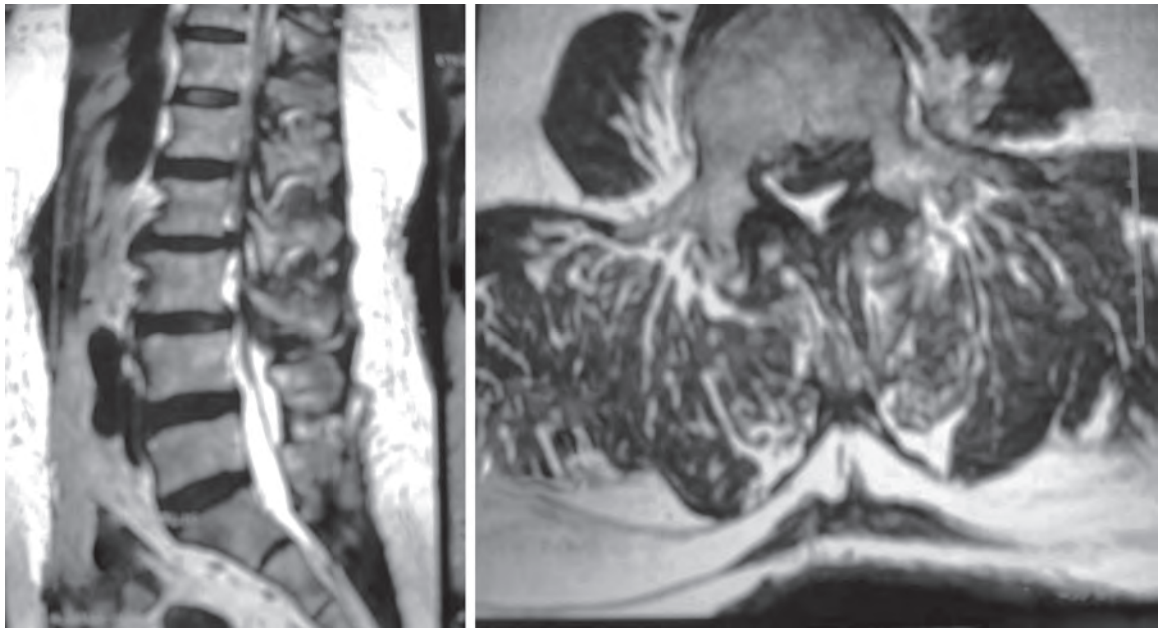

Fig. 5: MRI of the lumbar spine showing sagittal and axial view of a degenerative spine with ligamentum flavum hypertrophy, disc protrusion and facet hypertrophy causing severe canal narrowing

or by multiplanar reconstruction. On CT, midsagittal lumbar canal diameter less than 10 mm is regarded as absolute stenosis and midsagittal lumbar canal diameter less than 13 mm indicates a relative stenosis.[21]

Compared to MR imaging, the disadvantage of CT is that it does not allow good visualisation of the nerve roots and exposes the patient to radiation. If MRI is not possible (e.g. pacemaker, metallic artefacts), CT myelography provides the best alternative to confirm nerve root involvement. However, CT myelography may not display foraminal stenosis because the dural root sheath ends at the entrance of the foramen.

MANAGEMENT

Decompression of the spinal canal relieves the symptoms of lumbar stenosis in a considerable proportion of cases, but the results have been inconsistent. Patients must be chosen carefully for surgery, and success is likely if the clinical features conform to the typical syndrome, mainly pain that altered in various positions and is at least partially relieved by rest, with definite evidence of root compression by imaging.[28] Medical treatment alternatives, such as bed rest, pain management and physical therapy, should be reserved for use in debilitated patients or patients whose surgical risk is prohibitive as a result of concomitant medical conditions.[13]

Favourable indications for non-operative treatment would be mild claudication symptoms, concomitant back pain, mild to moderate radiculopathy, minimal interference with lifestyle and absence of motor deficits.

Conservative treatment options may consist of medication like analgesics, NSAIDs and muscle relaxants. The administration of calcitonin has been reported to improve the symptoms of neurogenic claudication.[23] Some patients may improve their function as a result of postural education and instructions for physiotherapy. As extension worsens the symptoms by reducing the size of the spinal canal, it is obvious that extension exercises must be avoided. Epidural injections anecdotally have a temporary beneficial effect and may be considered as a treatment in elderly patients in whom surgery would be too risky or who refused surgery. However, the therapeutic value of epidural injections in all lumbar spinal disorders and particularly in spinal stenosis remains controversial. The administration of intravenous infusion of PGE1 (60 mcg/d) for approximately two weeks has been found to be useful for treating intermittent claudication in patients with lumbar spinal canal stenosis. The effect of PGE1 was not related to the degree of stenosis obtained with images, age or claudication distance, but was correlated with baseline disease severity.[20]

However, studies comparing non-operative and surgical treatment demonstrated the better overall results of surgery.[30] Moreover, only one single randomised study compared short-term and long-term results of medical and surgical therapy. Amundsen et al.[2] concluded that an initial conservative approach is advisable for oligosymptomatic patients because those with an unsatisfactory result can be treated surgically later without impairment of the prognosis.

Surgery for lumbar spinal stenosis is generally accepted when conservative treatment has failed or if the stenosis substantially impacts on the patient's lifestyle. The general goals of operative treatment are to improve quality of life by reducing symptoms. Indications for surgery are moderate to severe claudication symptoms, significant interference with lifestyle, progressive neurological deficits and cauda equina syndrome. With the

exception of a cauda equina syndrome or progressive neurologic deficits, the indication for surgery remains relative and is dominated by the subjective interference with the patient's quality of life.

The surgical technique is largely dependent on the type of stenosis, which may be central, lateral recess or foraminal and the presence of concomitant back pain. The principal surgical options for decompression of central and/or lateral spinal stenosis are decompressive unilateral or bilateral laminotomy or laminectomy, decompression with non-instrumented fusion and decompression with instrumented fusion.

Laminotomy or Laminectomy

The objective of decompression is to create more space for the cauda equina and nerve roots by liberating the neural structures from compressing soft tissues such as disc herniation, hypertrophied ligamentum flavum, thickened facet joint capsules and osseous structures like hypertrophied facet joints and osteophytes. Until recently, total laminectomy was the standard method of decompression in central spinal stenosis. However, the recognition that total laminectomy may increase or cause segmental instability has led to a more conservative approach, preserving the lamina and only removing those parts which actually cause the stenosis.[15]

Selective decompression is the surgical technique of choice in patients presenting with neurogenic claudication without relevant back pain. A technical detail is related to the preservation of the facet joint capsules when an undercutting medial facetectomy is required to decompress the thecal sac. In selected cases, a unilateral approach suffices to bilaterally decompress the thecal sac (over-the-top technique) by undercutting of the laminae, preserving the interspinous ligaments and the contralateral muscles.[5]

Endoscopic interlaminar decompression in cases of lateral recess stenosis and its superiority over the microsurgical technique has been claimed in a study by Sebastian Ruetten. He concluded that the rate of complications and revisions was significantly reduced in the endoscopically managed group. Endoscopic techniques are advantageous in the following areas: operation, complications, traumatisation and rehabilitation.[24]

Total laminectomy is still indicated in cases in which the thecal sac cannot sufficiently be decompressed or the access to the foramen is obliterated (foraminal stenosis). In rare cases of cauda equina syndrome, total laminectomy is indicated to ensure adequate neural decompression. Laminectomy alone should be avoided in cases with pre-existing instability such as degenerative spondylolisthesis, isthmic spondylolisthesis with secondary degenerative changes and degenerative scoliosis.[4]

Inverse laminoplasty[32] is a canal enlargement technique with ligamentum flavum excision, foraminotomy and lateral recess decompression with preservation of the osseous structure. This leads to a more stable lumbar spine after re-enlargement of the canal than after laminectomy. The lamina is cut just medial to the facet joints with a high speed drill, and cuts are made in a caudal to rostral direction. The ligamentum flavum is cut and the lamina is elevated, separating it from the dura mater carefully. After excision of the laterally remaining ligamentum flavum, for decompression, widening of the lateral recess and excision of the foraminal roof and the medial rim of the facet are performed bilaterally. The removed laminae are then inverted and reattached with titanium mini plates in all patients. Disc excision is performed in patients who have disc protrusion or extrusion. Inverse laminoplasty has three advantages: (1) prevention of instability and re-construction of spinal osseous structures (2) enlargement of the spinal canal diameter and (3) prevention of neural elements from peridural scar formation.

Decompression and Spinal Fusion

The addition of fusion with or without instrumentation to surgical decompression is generally recommended when segmental instability is assumed. However, the radiological assessment of segmental instability remains a matter of debate. Decompression and fusion are considered by many spine surgeons in case of segmental instability like degenerative spondylolisthesis and scoliosis, concomitant severe back pain, necessity for a wide decompression and recurrent spinal stenosis. In patients who had a concomitant fusion, the results were significantly better with respect to relief of pain in the back and lower limbs.[8]

Use of instrumentation like pedicle screws and rod stabilisation may lead to a higher fusion rate, but clinical outcome shows no improvement in pain in the back and lower limbs.[6] However, Kornblum et al.[18] demonstrated the long-term (5–14 years) benefits of a successful fusion over non-union with respect to back and lower limb symptoms in patients with degenerative spondylolisthesis and spinal stenosis. There is no evidence in the literature that an additional interbody fusion by an anterior (ALIF) or posterior (PLIF, TLIF) approach improves outcome.[6] Newer techniques, such as interspinous spacer stabilisation, are still evolving and conclusions on clinical effectiveness are premature.[2]

Indications for implantation of the interspinous spacer are: (1) resistance to conventional medical treatment; (2) age older than 70 years or, if younger than 70 years, a high operative risk and inability to tolerate lengthy surgery; (3) lumbar stenotic symptoms of greater than moderate severity, especially intermittent claudication; (4) pain relief in flexed lumbar and exacerbation when in an extended position and (5) dural compression, primarily caused by the ligamentum flavum. The paraspinal muscle is dissected from both sides of the spinous processes to the level of the facets and laminae. The supraspinous ligament is preserved mostly to prevent posterior divergence of the spacer after surgery. The advantage of the spacer is its ease of insertion into the interspinous process space. After opening an appropriately sized window by using dilators of increasing size and insertion of the

spacer with the aid of a dedicated inserter and retainer, which are then removed, the surgery is completed. This manipulation requires little effort.[31] Many types of spacers are now in use, such as Titanium and Ceramic, and the overall results with them are early, but quite encouraging.[31]

116 Spondylolisthesis

Ramakrishna Easwaran

TERMINOLOGY

Spondylolisthesis is defined as a displacement of one vertebra over the next lower vertebra in the sagittal plane. Since the superior vertebra is usually displaced anteriorly and, as the problem is most frequent in the lumbar region, the unqualified term of 'spondylolisthesis' generally, refers to forward slipping of a lumbar vertebra. The word 'spondylolisthesis' coined by Kilian in 1854 is derived from two Greek words 'spondylos' (vertebra) and 'olisthanein' (to slip). The etymologically correct abbreviated version should be 'olisthesis' and not 'listhesis'. Spondylolysis refers to an acquired defect in the pars interarticularis. Spondyloptosis is an extreme degree of spondylolisthesis, where the upper vertebral body appears to be not in contact and is placed anterior to the lower body.

CLASSIFICATION AND AETIOLOGY

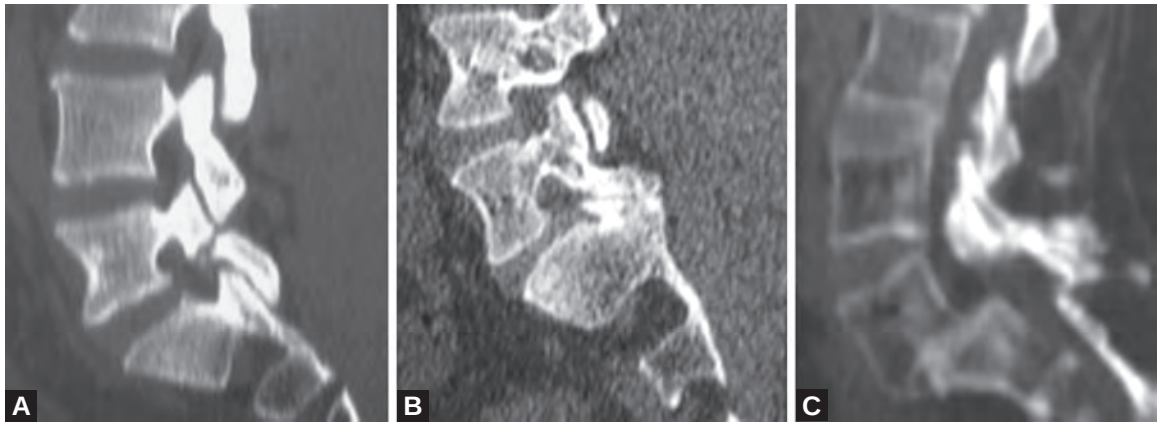
An aetiological classification that is widely accepted was proposed in 1976 by Wiltse, Newman and MacNab (Table 1).[65] Isthmic spondylolisthesis (ISO) is commoner in the 20–40 age group, while degenerative spondylolisthesis (DSO) is common above the age of 40. These two types are discussed in detail as they account for the majority of cases in clinical practice.

Isthmic Spondylolisthesis

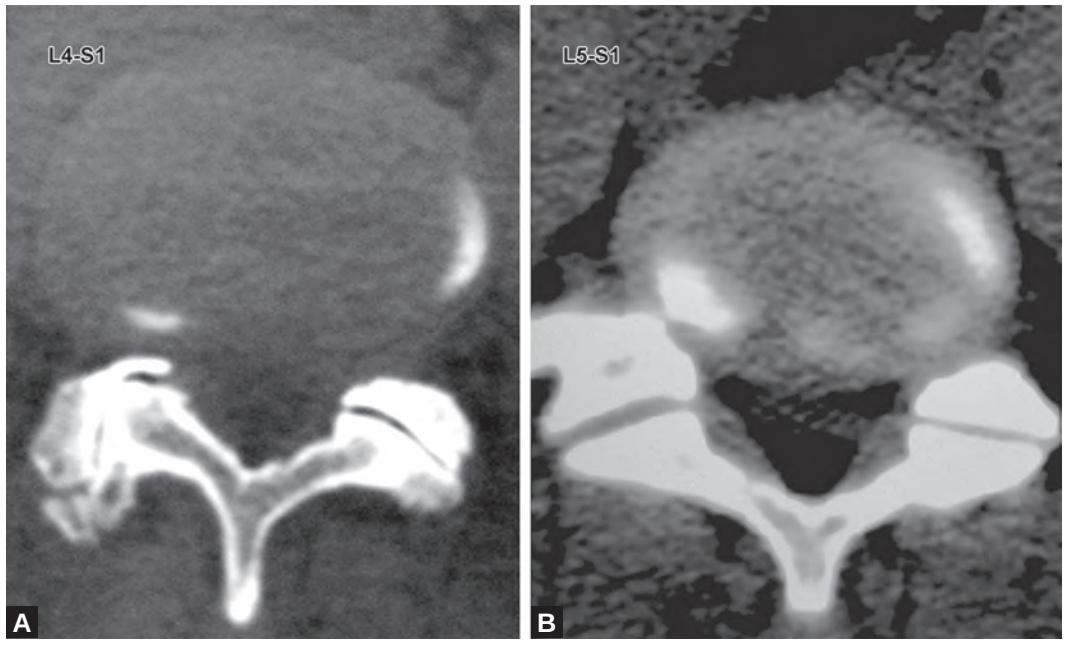
The pars interarticularis is an isthmus of bone that connects the superior and inferior facets. The pars appears to be the weakest point in the neural arch and yet it faces the highest stress.[23] Repeated stress fracture of the pars results in isthmic spondylolysis. Such stress fractures have been demonstrated by SPECT imaging and may be a cause of low backache in young athletes even without spondylolisthesis.[69] Right arm cricket pace bowlers tend to fracture their left isthmus.[9] Stress fractures start in the inferior or inferomedial cortex of the pars and propagate superiorly or superolaterally, as shown in a serial CT study.[13] A fracture that goes into non-union produces a wide smooth defect with edge sclerosis resulting in the subtype A of ISO. If there is healing and remodelling at the stress fracture site, the pars becomes elongated with alteration of the biomechanics of the motion segment, which leads to the subtype B of ISO (Figs 1A to C). These two subtypes are illustrated by sagittal CT reformation

Table 1: Wiltse-Newman-MacNab classification of spondylolisthesis[65]

Type	*Aetiology*	*Comment*
Isthmic	Defect in pars interarticularis (isthmus)	Commoner at L5-S1 level and in younger patients
Subtype A	Bilateral chronic spondylolytic defect in the isthmus	
Subtype B	Healed spondylolysis with elongated isthmus	
Subtype C	Acute bilateral fracture of isthmus	Type 4 of Aihara classification of lumbosacral dislocation (Table of chapter *Sacral Spine Injury* in this textbook)
Degenerative	Abnormal motion due to disc and facet joint degeneration	Commoner at L4-5 level and in older patients
Dysplastic	Congenital abnormality of neural arch such as malformed L5 inferior or superior S1 facet, abnormal sacral surface	Elongation of pars (mimicking isthmic subtype B) or fracture of the pars (mimicking subtype A) might occur secondarily. Horizontal orientation of L5-S1 facet joint and wedging of L5 body help distinguish dysplastic spondylolisthesis
Traumatic	Acute fracture of the neural arch at a site other than the isthmus	Type 1, 2, 3, 5 of Aihara classification (*see above*)
Pathological	A. Generalised bone disease	Example: Paget's disease, Marfan syndrome, achondroplasia, neurofibromatosis
	B. Localised bone disease disrupting the integrity of the neural arch	Example: Tuberculosis, metastasis. Fracture of the pars cephalad to a site of surgical posterior (laminar) fusion is also included (spondylolisthesis acquisita)



Figs 1A to C: Subtypes of spondylolisthesis (sagittal CT reformation). (A) Spondylolytic defect in the isthmus-subtype A of ISO. (B) Elongation of pars with normal orientation of the L5-S1 facet joint—subtype B of ISO. (C) High-grade dysplastic spondylolisthesis with pars elongation mimicking subtype B of ISO. Note the horizontal orientation of the L5-S1 facet joint and rounding off of the S1 body anteriorly



Figs 2A and B: Orientation of lumbar facets (axial CT). (A) Left facet joint has sagittal orientation which predisposes to DSO, whereas the right has a normal oblique orientation. Note the degenerative changes in the abnormally oriented joint. (B) Both the facet joints are coronally oriented and this predisposes to ISO

in Figures 1A and B. Acute fracture of the isthmus causing olisthesis constitutes the subtype C.

The roentgenographic studies of spondylolysis in the general population had suggested an incidence of 4.4% by age 6, increasing to 6% in adulthood. L5 was affected in 90% and L5 spina bifida was seen in 30%. Those with bilateral pars defects progressed to low-grade ISO but were not necessarily symptomatic.[22] A CT based Japanese study showed 6% incidence of spondylolysis in asymptomatic adults and a 2:1 male preponderance.[53] Females are however, four times more prone to developing symptomatic ISO. There is a five-fold higher incidence of spondylolysis in near relatives of patients with ISO suggesting a heritable tendency.[66] The lumbar facet joints appear to be more coronally oriented in patients with ISO (as opposed to a sagittal orientation which predisposes to DSO—see below).[11] Examples of abnormal facet joint orientation are shown in Figures 2A and B. A more horizontally oriented sacrum has been shown to increase the stress on the L5 pars from the repetitive stress due to daily activities such as standing or sitting.[46] ISO is a uniquely human disease and it is likely to be due to our bipedalism. The rare reports of spondylolysis in a 3.5-month-old infant and ISO in a non-ambulatory patient bespeak of yet other mechanisms at work.[6,23] ISO appears to increase in degree radiologically (although not necessarily in symptoms) until 25 years of age.[27] Older adults only rarely have worsening of the degree

Table 2: Factors predisposing to DSO (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

Female sex
• Oophorectomised women—3 times greater incidence
• Osteoporosis—leading to elongation of the pars
• Sagittal orientation of facets (sagittal facet angle > 45° increases risk 25-fold)
• Specific factors for L4-5 level DSO
• Narrow L4 inferior articular process
• Sacralisation of L5
• Horizontalisation of the lamina and the facets
• Specific factors for L5-S1 level DSO
• Slender L5 transverse process
• Greater inclination of sacral table
• Less deep location of the L5 vertebra in the pelvis

of slip but they progress more often to have symptoms.[19] Acute clinical and radiological progression of ISO in adults has been noted with trivial trauma.[58] When ISO occurs at L4-5, greater degree of progression has been noted and this has been noted also with a biomechanical study showing greater motion at L4-5 as compared to L5-S1 level ISO.[25]

Degenerative Spondylolisthesis

This was first described by MacNab in 1950, as 'spondylolisthesis with intact neural arch' or pseudospondylolisthesis.[39] DSO is found most commonly at the L4-5 level, followed with decreasing frequency by L3-4, L2-3, L5-S1 and L1-2 levels. Women aged 40–60 years exhibit slippage in a 2:1 to 10:1 prevalence compared with men.[15] Male patients are typically older, in the 6–8th decades. Table 2 lists the factors associated with an increased incidence of DSO.[14] DSO may be associated with translatory slips in the coronal plane or degenerative kyphoscoliosis.[21]

Dysplastic Spondylolisthesis

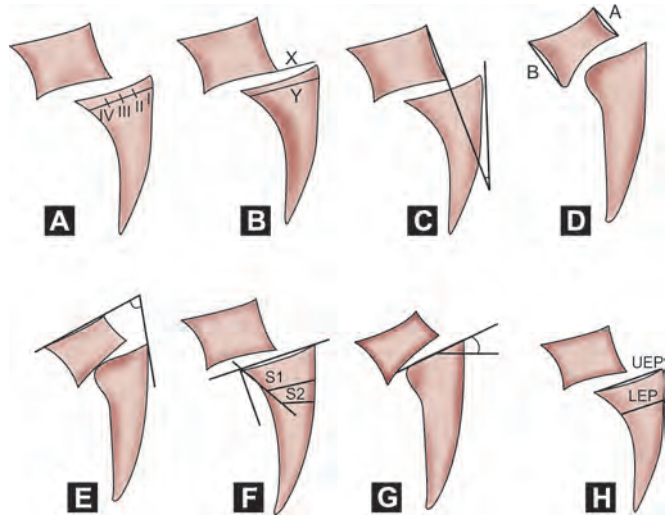
This spondylolisthesis occurs at L5-S1 level. If L5 is sacralised, dysplastic spondylolisthesis can occur at L4-5 level. Dysplastic spondylolisthesis needs to be distinguished from ISO subtypes A and B, as there might be a secondary isthmic defect or elongation in dysplastic cases too. The key is the horizontal orientation of the L5-S1 facet joint in dysplastic spondylolisthesis[66] (Fig. 1C). A higher incidence of associated spina bifida is noted with dysplastic spondylolisthesis.

Traumatic and Pathological Spondylolisthesis

Traumatic and pathological spondylolisthesis are mentioned in Table 1.

GRADING

Grading describes the severity of the vertebral slip. Meyerding, in 1932, divided the upper surface of the



Figs 3A to H: Measuring spondylolisthesis. (A) Meyerding grades. The upper surface of the lower body is divided into four equal parts to grade the forward slip: grade I: up to 25%, grade II: 26–50%, grade III: 51–75% and grade IV: > 75%. (B) Ratio X/Y represented as % gives the percentage slip. (C) The angle between the posterior borders of the bodies gives the sagittal plane rotation or roll. (D) The ratio A/B represented as % gives the lumbar index. (E) Lumbosacral angle of Boxall (normal = 90–110°) becomes more acute with high-grade olisthesis. (F) Sacral angle measures the inclination of the sacrum. (G) Sacral slope measures the sagittalisation of the upper surface of the sacrum. (H) The ratio between the width of the upper and lower endplates of S1 (called S1 index) is less than 1.35 in high-grade olisthesis

inferior vertebra into four equal parts and depending on the degree of slip of the superior vertebra, described four grades of spondylolisthesis (Fig. 3A). Grades 1 and 2 are considered low-grade and grades 3 and 4 as high-grade spondylolisthesis. This time-honoured grading system appears to have good inter-observer and intra-observer reliability.[60] What is striking on the lateral radiograph is the slip on the anterior border, but what is relevant to neural compression is the slip on the posterior border of the vertebra. Since radiographs are not always taken with parallel beams from a tube-patient distance of 6 feets, any system that relies on measurement by millimetres must not be trusted, because of non-uniform magnification of different structures within the same film and between two different films. It is necessary to specify the percentage of slip to describe slips of intermediate grades (Fig. 3B). When there is a sagittal plane translation (slip) there must be an accompanying sagittal plane rotation (roll), which becomes obvious in high-grade olisthesis. This rotation is measured by the angle between the posterior or the anterior surfaces of the two vertebrae (Fig. 3C). In high-grade olisthesis, there is rounding off of the anterior border of the upper surface of the lower body and sagittalisation of the disc space. The sacrum appears more inclined forward in L5-S1 olisthesis. The subpedicular posterior border in the slipping upper vertebra loses its height. This results in a wedge-like shape of the slipping vertebra. The ratio of the anterior and posterior heights

of the slipping vertebra is the lumbar index (Fig. 3D). The remaining measures used in studies on spondylolisthesis are shown in Figures 3E to H.

CLINICAL FEATURES AND THEIR BASIS

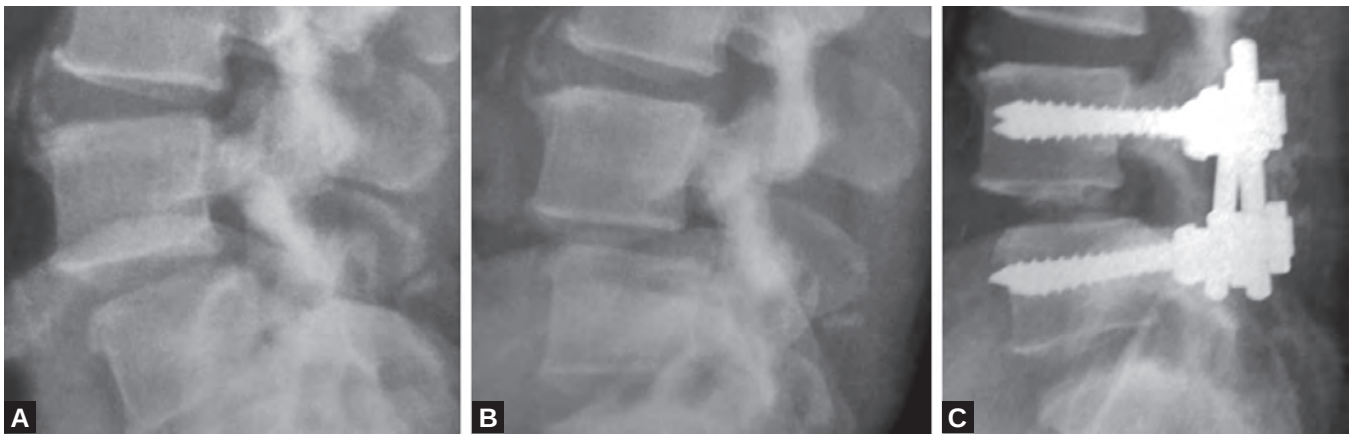
Spondylolysis and spondylolisthesis may entirely be asymptomatic. This is so in young low-grade ISO patients with good muscle tone and wide canals. Mild grade DSO might also behave similarly. Such patients do not have significant neural compression or instability. Their risk of progression is very low.[41]

Symptomatic spondylolisthesis presents with various combinations of low backache, restriction of back mobility, radicular leg pain (sciatica), neurogenic claudication, postural abnormality and neurological deficits referable to the caudal roots, roughly in that order of frequency. The back pain is poorly localised, central and sometimes is referred to the sacral and perineal region. It is worse on standing. It is believed to arise from the pseudarthrosis, ligamentous or facet joint strain or degeneration in the disc or facet joint. Many patients with ISO who have had minimal or no symptoms during young age, develop disablement only when spondylotic degeneration sets in.[19] Leg symptoms of sciatica and neurogenic claudication arise from compression or stretch on the spinal roots. In L5-S1 ISO the compression is on the exiting root, i.e. the L5 root that is stretched over the L5-S1 disc by the forward displacement. The root compression is at the foraminal level, the foramen having lost its height due to the loss of height of the L5 subpedicular body. The root is stretched by the undersurface of the L5 pedicle. The callus or pannus at the pseudarthrosis also contributes. The S1 roots and the central canal are usually free in L5-S1 ISO. Neurological deficits are rare in ISO but are seen in dysplastic spondylolisthesis.

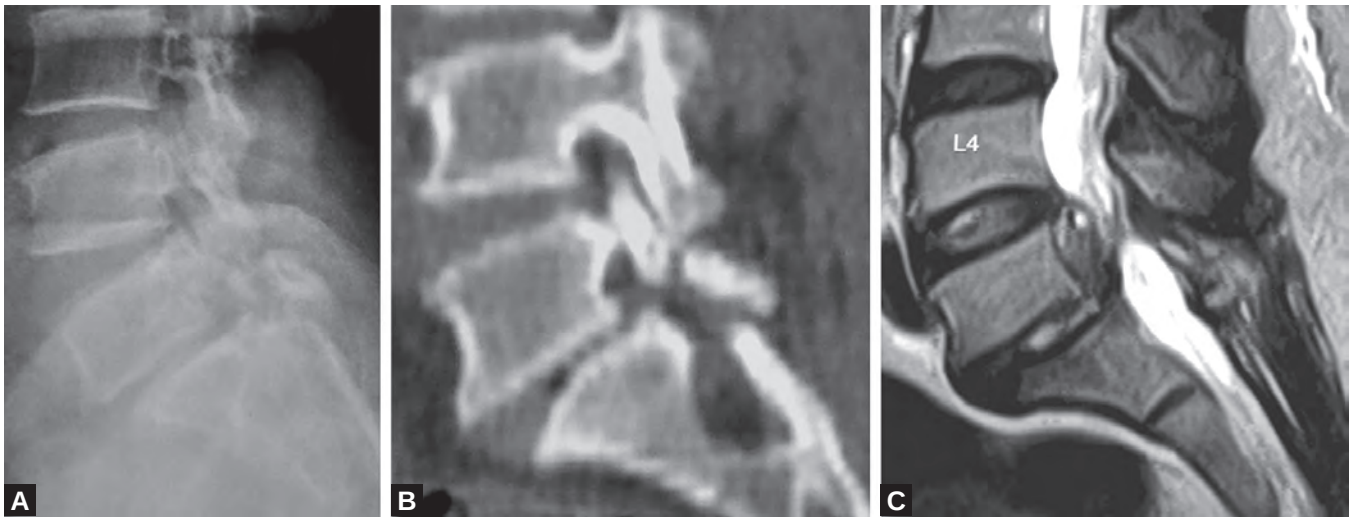
DSO is most common at L4-5 level and this again causes L5 root compression which is the traversing root. However, the compression is not, so much because of the slip as due to the lateral canal narrowing caused by the spondylosis deformans producing facetal bony hypertrophy, thickening of the facet capsules, synovial cysts from the facet joints and flaval ligamental hypertrophy. The bulging disc or a frank prolapse of the disc also narrows the space in the lateral canal. At surgery, one finds the medial enlargement of the L4 inferior facet narrowing the roof of the cranial part of the lateral canal over the L5 root and the hypertrophy of the upper part of the L5 superior facet biting into the undersurface of the L5 root, lower down in the canal. There is additional compression on S1 roots from the spondylosis deformans, even though this is not the level of slip. The symptoms do not improve on forward bending, unlike in the case of pure spinal stenosis. The patients tend to support the back of the trunk with their arms.[38] Clinical examination may show wasting of extensor digitorum brevis, weakness of toe-grip, sensory loss in the L5 and S1 segments and absent ankle reflexes. Acute worsening of pain and unilaterality of symptoms suggest an additional disc prolapse in both DSO and ISO (Figs 4A to C).

In high-grade L5-S1 olisthesis, the lumbar spine becomes hyperextended giving a foreshortened appearance of the trunk. The upper surface of the sacrum becomes vertical and the caudal sacrum juts out. The buttocks appear flat and there is a prominent transverse crease in the flanks and anterior abdomen. The hips and knees become flexed with tight hamstrings. The gait has a characteristic waddle. There may be an associated scoliosis.[43] The neurological findings are due to narrowing of the central canal where the caudal roots become pinched between the leading L5 lamina and the lagging upper posterior border of S1 body, even to the extent of producing sphincteric dysfunction. Understanding the basis for the symptoms helps the surgeon plan the decompression and stabilisation procedure better.

It is important in clinical examination to feel the leg pulses to rule out an additional vascular claudication. Neurogenic claudication is brought on by standing or walking; the pain is associated with numbness of the legs and is not felt while riding a bicycle. The "walk test" may bring about a new sensory, motor or reflex deficit that was not present at rest in a patient with neurogenic claudication. Vascular claudication is brought on by walking or cycling but not by standing.



Figs 4A to C: Large extruded disc in a patient with isthmic spondylolisthesis causing acute foot drop. (A) Lateral radiograph. (B) Sagittal CT reconstruction. (C) Sagittal T2 MR showing extruded, upmigrated L5-S1 disc prolapse



Figs 5A to C: Role of dynamic radiographs. (A) Lateral radiograph in extension shows hardly any spondylolisthesis. (B) Radiograph in flexion shows grade I L4-5 DSO. (C) Symptoms resolved with decompression and *in situ* instrumented PLIF (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

Additional diabetic neuropathy is common with DSO which causes overlapping clinical signs and will need to be ruled in or out prior to surgery with nerve conduction studies.

INVESTIGATIONS

Plain Radiographs

Plain radiographs tend to be overlooked in these days of high-tech imaging. It is humbling to see spondylolisthesis missed by MRI (done in the supine position) and picked up by a standing or dynamic lateral radiograph.[34] Figures 5A to C shows an example. The standard projections we use are: (1) anteroposterior view, which also covers the sacroiliac joints and both hip joints; (2) lateral view in the standing posture in neutral, flexion and extension. Since CT is much better at detecting the break in the pars interarticularis (Fig. 1A), we have stopped asking for oblique views to display the 'Scottie dog collar' sign. Worsening or appearance of the vertebral slip in flexion indicates a dynamic olisthesis. Around 15% of vertebral slips reduce on lying down.[38] Reduction, even if partial, in extension, suggests that such positioning of the patient is essential to improve the reduction during surgery. A forward movement of up to 2 mm in flexion is acceptable in normal persons.[28] There is often a retrolisthesis at a higher level, say L2-3 (Fig. 6). Lumbar scoliosis and degenerative disease at the adjacent levels are often found. These must be recorded to know, if the adjacent level disease seen during post-operative follow-up is a new development or not. Recognising the very common sacralisation of L5 or the much rarer lumbarisation of S1 is vital to prevent wrong level surgery.

Computerised Tomography Scan

CT scan is a *sine qua non* in our pre-operative planning. Multiplanar reconstruction of helically acquired data from a multi-detector CT done without intravenous or intrathecal contrast is our routine. Elongation of the pars and sclerosis/callus arising from healed pars defects are also seen (Figs 7A to D). CT shows spondylolysis better than oblique X-rays (Figs 1A, 7A to D and 8A to D). Our technique of CT pediculometry is shown in Figures 8A to D and it helps avoid nasty surprises on the operating table such as too narrow a pedicle or one with a very wide angle. Sagittal reconstruction can show the subtle slippage at the posterior vertebral border, without the overlap from the hypertrophic facets or iliac crests as would happen with a lateral X-ray. The sagittal reconstruction done at the levels of the facets bilaterally shows the spondylolytic defect that may be missed on lateral X-ray or MRI. This is vital in adult ISO as there is always an element of degeneration in the discs and facets, which might mislead one to think that the patient has DSO (Figs 9A to E). Coronal reconstructed images show any side-to-side translation but they are most useful for assessing the fate of the intervertebral bone graft in post-operative imaging of spinal fusion. Measuring the bone mineral density by volumetric quantitative CT can be done for osteoporosis assessment simultaneously.[37] This gives information about the osteoporosis in the vertebrae that are going to be operated upon rather than a generalised skeletal score as obtained with dual-energy X-ray absorptiometry. Intrathecal contrast CT myelography is used for those in whom MRI cannot be done (generally, because of metal artefact in the post-operative patient or severe scoliosis).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) gives a wealth of information about the soft tissues such as intervertebral discs, synovium, ligaments and nerve roots. The ability to produce whole spine imaging is useful for picking up additional levels of disease and ascertaining the exact

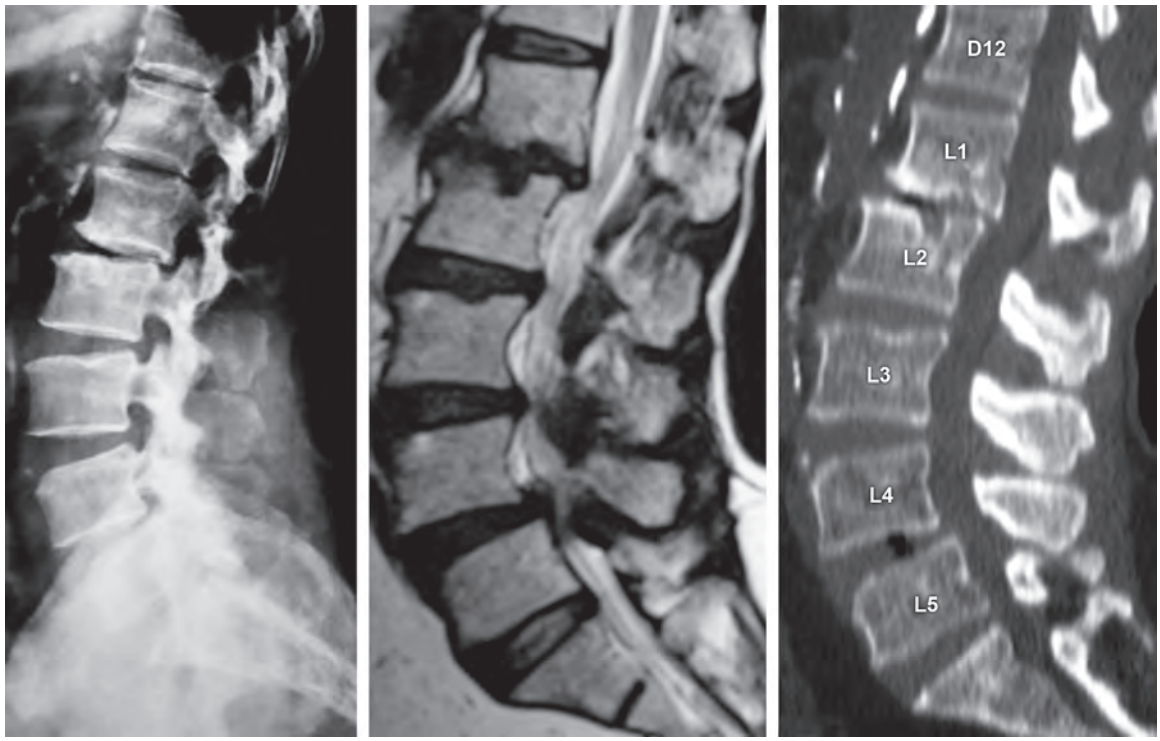


Fig. 6: Retrolisthesis at a higher level is often seen with anterolisthesis at lower level. In this patient L4-5 symptomatic anterolisthesis is accompanied by asymptomatic L1-2 retrolisthesis (lateral radiograph, MRI and CT)

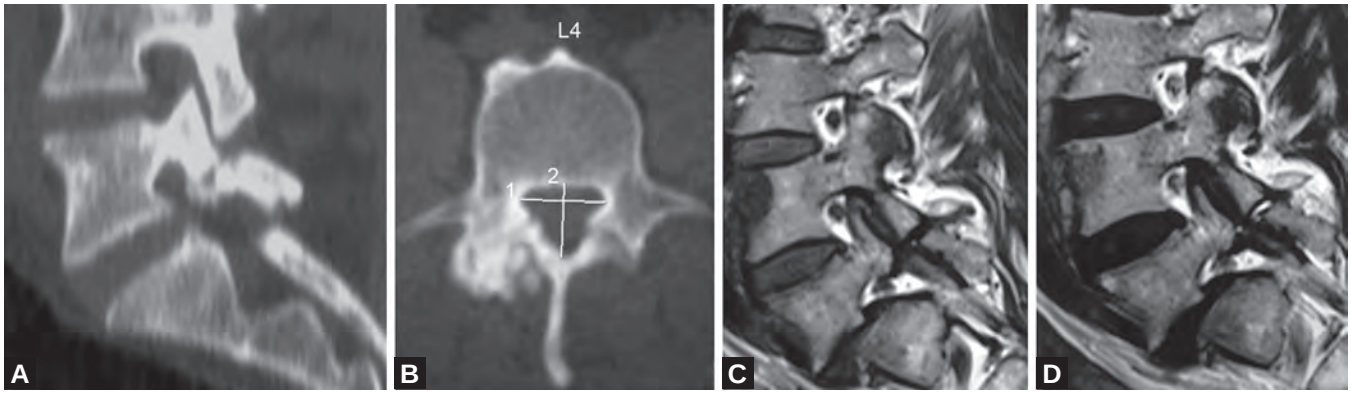
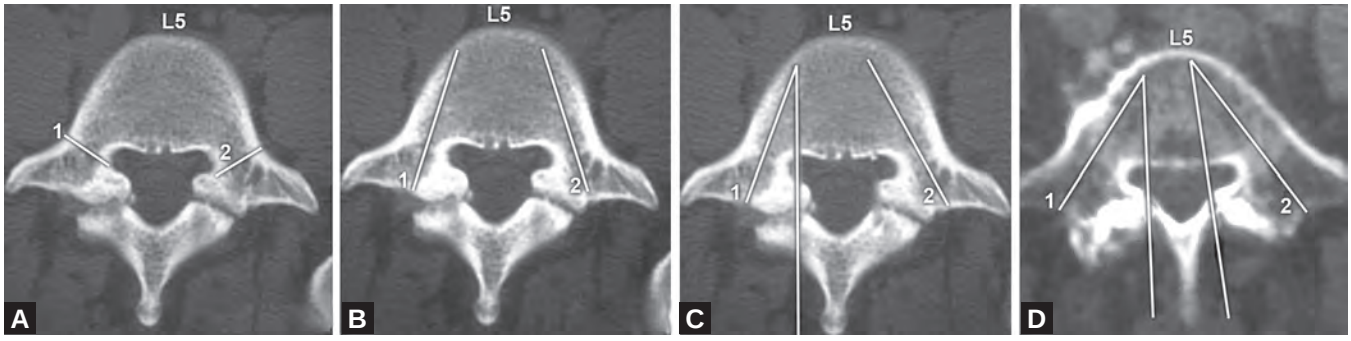
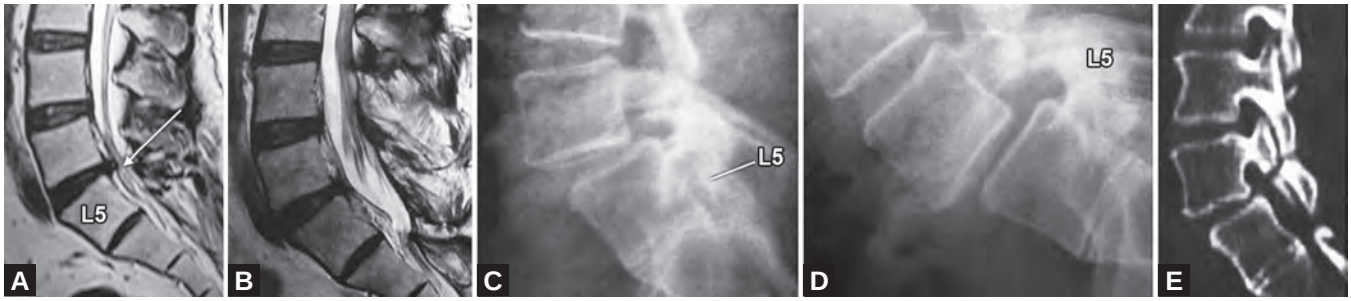


Figs 7A to D: (A) Sagittal reconstructed CT showing pars break and callus. (B) Axial CT showing exuberant callus at spondylolytic defect. (C) Sagittal T2-weighted MR showing dark band at the site of spondylolysis due to loss of marrow signal. (D) Sagittal T2-weighted MR showing bright signal at the site of spondylolysis due to ingrowth of soft tissue



Figs 8A to D: CT pediculometry. (A) Pedicle width in axial plane gives the diameter of the pedicle screw needed. (B) Oblique length of drill channel gives the length of the screw needed. (C) The inclination of the pedicle to the sagittal plane (24° in this patient) gives the correct orientation for drilling. Note bilateral isthmic spondylolysis. (D) Unusually wide and varying angulation of pedicle at L5 in another patient: 29° (left) and 34° (right)



Figs 9A to E: Adult occult isthmic spondylolisthesis. (A) A 57-year-old man with L4-5 disc prolapse and canal stenosis. He underwent L3,4,5 laminectomy and L4-5 discectomy elsewhere but had worsening dynamic and static back pain and sciatica. (B) MRI 2 years later showed adequate canal restoration but did not show spondylolisthesis. (C) Standing radiograph in extension showed grade 1 L4-5 slip. (D) On flexion it increases to grade 2. (E) CT shows the defect in the L4 isthmus missed by MRI and radiographs (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

level by counting down from C1. Coronal plane imaging shows associated vertebral translation (Fig. 10). The distended facet sign has been described to be associated with position dependent spinal stenosis in dynamic DSO.[3] Axial loaded MRI and dynamic MRI can be done in a few centres only and unless this is done MRI will continue to miss subtle spondylolisthesis.[29] Normally, the marrow signal in the pars is uninterrupted from the superior to the inferior facet. Spondylolysis is suggested on sagittal MR images by a dark signal on all imaging sequences in the pars resulting from marginal sclerosis at the site of the break (Fig. 7C). If there is a gap at the site of the break then there will also be an increased signal in the gap resulting from the presence of soft tissue (Fig. 7D).[30] Presence of oedema in the pars indicates an acute stress fracture.[13] The wide canal sign on midline sagittal MR images is present in ISO but not in DSO (Figs 11A and B).[61] The paradiscal vertebral marrow changes described by Modic generally, indicate facetal instability.[47] These changes are discussed in greater detail in the chapter on the *Pathophysiology of Disc Degeneration* in this textbook. Large (>1.5 mm) facet effusions are predictive of L4-L5 DSO even though the slip is not seen in the MRI and only seen in erect dynamic radiographs.[7] Synovial cysts indicate disruption of facet joint function and were associated with greater progression of olisthesis after decompression in one study.[16]

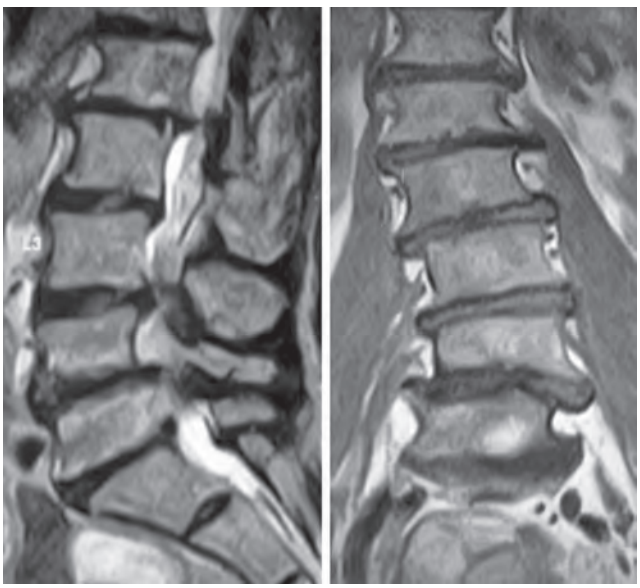


Fig. 10: Coronal plane translation in a patient with L4-5 DSO (MRI)

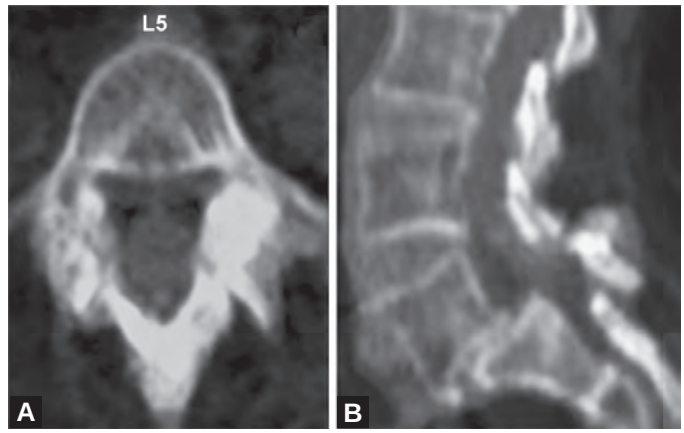
Discography

Discography is used to study the internal disruption of the disc by analysing the contrast diffusion patterns. It also aims to provoke the patient's pain. The invasiveness, rare chance of infection and poor patient acceptance of contrast discography have made many centres rely on MRI for the structural information. Modic type 1 MR changes have a high positive predictive value in the identification of pain generator and may help avoid discography.[59] Discography might help decide, if fusion surgery needs to be extended beyond the level of the olisthesis.[2]

MANAGEMENT

Conservative Management

Conservative management is indicated in patients with minimal or no symptoms. This is offered to young



Figs 11A and B: Wide canal sign is seen in ISO. (A) And is not seen in DSO. (B) Axial and sagittal CT reconstruction

patients with spondylolysis or low-grade spondylolisthesis and to the older patients with non-disabling DSO. The modalities consist of 3–5 days of rest till the acute episode of back pain resolves. Longer periods of bed rest are counter-productive. Oral analgesics, bracing, various physical therapies, epidural/facetal steroid injections and spinal flexion exercises are also prescribed but none of these have been validated by controlled trials. The wait-and-watch policy for patients without leg pain has been supported by a 10–18-year follow-up study of non-surgically managed patients with DSO.[41] Limitation of claudication producing activity is all that is needed for some elderly persons with DSO. Lack of medical fitness for surgery may rarely force one to settle for conservative treatment.

Surgical Management

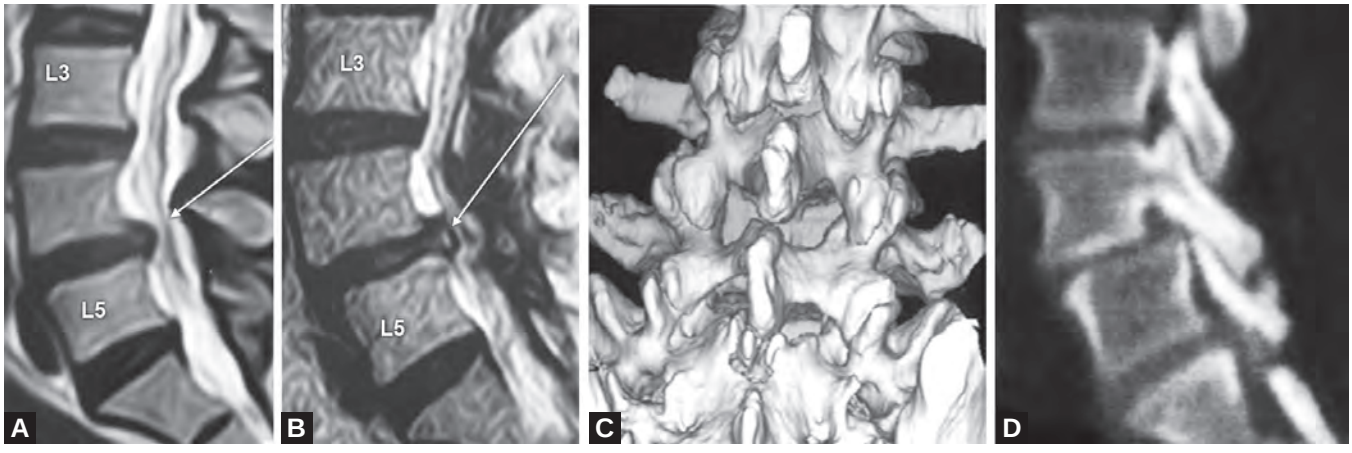
Surgical management is indicated in patients with disabling symptoms that are unrelieved by conservative management. Surgery could be offered to asymptomatic olisthetic patients with a high-risk of progression, if only we could identify that subset of patients. Unfortunately, there is no sure-shot method to do so. Factors such as spina bifida, younger age at detection, higher degree of slip at detection, female sex and dysplasia in the posterior elements have all been associated with symptom progression, but none of these are consistent markers.[8] Hence, it is prudent to wait and watch an asymptomatic patient. Clinical and/or radiological progression occurring during the observation period constitutes a strong indication for surgery.

The twin aims of olisthesis surgery are: (1) to relieve symptoms and (2) to prevent progressive worsening or recurrence of symptoms. One or more of the following is/are done at surgery for spondylolisthesis, so as to achieve these twin aims: (1) decompression; (2) reduction; (3) fusion and (4) instrumentation.

Decompression

Decompression of the nerve roots addresses the spinal stenosis and is traditionally the most important treatment for DSO and adult ISO. It may not be needed at all in young ISO patients as their neural canals are wide and they have no neural compression. In fact decompression without fusion (Gill's procedure) may be hazardous in the young patient with ISO as it leads to worsening of the olisthesis.[45] Figures 9A to E show an example of progression of adult ISO after decompression and Figures 12A to D show an example of progression in DSO after minimally invasive decompression. The decompression can take the form of unilateral laminofacetotomy, undercutting mesial facetectomy, foraminotomy, coronal hemilaminectomy (trumpet laminectomy of Kanamori) or complete laminectomy and facetectomy.[15] Partial pediculectomy, removal of osteophytes from the vertebral edges and excision of the ossified annulus may be needed.[56] Excision of thickened ligamentum flavum or hypertrophic synovium, drainage of synovial cysts, discectomy and epidural scar release are the soft tissue manoeuvres to relieve root compression. Restorative laminoplasty has also been described.[1] Over the years, decompressive surgery has become less invasive and more focused. Spinous process base osteotomy[64] and the ipsi-contra procedure[10] preserve the spinous processes and ligaments attached to it. Refinements, such as use of the operating microscope, endoscope[35] and high-speed drills, have enhanced the safety and added to operator ease. It is vital to find out what is being compressed by what and tailor-make the surgery so as to relieve it. This can be planned pre-operatively by correlating the clinical and imaging findings.

The arguments favouring a 'decompression-alone' strategy are summarised in Table 3. These are more fully discussed in an article in *Progress in Clinical Neurosciences*.[48]



Figs 12A to D: Progression of spondylolisthesis after laminotomy for DSO. (A) MRI of 61-year-old woman with L4-5 disc prolapse and grade 1 DSO. (B) Sagittal T2 MR 1 year after bilateral laminotomy/discectomy (done elsewhere)—the patient had unrelieved back and leg pain. (C) CT reconstruction to show the small laminar fenestrations and intact facets. (D) Parasagittal CT reconstruction clearly shows intact pars and grade 1 DSO. Note loss of foraminal height. Symptoms were relieved by instrumented PLIF (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

Table 3: Arguments favouring a 'decompression-alone' strategy in DSO

Arguments FOR performing non-fusion surgery (decompression alone)	*Arguments AGAINST performing fusion surgery (decompression + reduction, fusion instrumentation)*
Symptoms are due to nerve root compression alone and it is sufficient to relieve the compression	Spinal instability is a poorly defined entity
Decompression does not destabilise the spine	No proof that fusion gives better results
DSO is low-grade and does not progressively worsen to higher grades	Fusion surgery has more complications, has a steep learning curve and is poorly tolerated by the elderly. Convalescence is longer
Post-decompression progression of slip on radiographs may not be clinically symptomatic	A good post-operative X-ray does not equate to asymptomatic patient. On the contrary, even those with pseudarthrosis at a fusion site might be asymptomatic
Non-fusion surgery is simple, has low complication rate with shorter convalescence and is cheap	Even patients with radiologically successful fusion might have progression of spondylolisthesis
	Higher risk of adjacent level degeneration
	Higher cost and complications of instrumentation. No proof that instrumentation improves the clinical outcome. Instrumentation failure occurs
	Morbidity at iliac bone donor site is high

Reduction

Reduction of olisthesis is seldom necessary to achieve the twin aims stated above for patients with low-grade ISO or DSO. Complete (or at least partial) reduction is a fervently wished for goal in high-grade olisthesis, but it is rarely achieved in adults. Appropriate positioning of the patient on the operating table is vital for achieving reduction. The patient who has reduction on extension of the spine can be placed over bolsters under the chest and pelvis, allowing the weight of the hanging abdomen to force the lumbar spine in to extension. For others, some reduction occurs on breaking the operating table as in Figure 13. Reduction is easier to achieve and becomes neurologically safer when it is attempted after the decompression is completed, than before it. Manual traction on the vertebra applied to the neural arch or levering up the superior vertebra through the disc space can be done, but use of excessive force must be avoided. Achieving reduction is an important advantage of using metal instrumentation. Distraction force applied to pedicle screws can help achieve reduction (Fig. 14). Precontouring the vertical rod (or even better a plate) into lordosis can also force some reduction.[50] The vertical connector is fixed firmly to the caudal pedicle screw first and then the act of tightening the cranial (olisthetic) screw pulls up the slipped vertebra to at least some degree of reduction. Reduction pedicle screws bring about some additional reduction and also make it easy to place the rods through the screw heads which are at different depths due to high-grade olisthesis. It is acceptable to fuse *in situ* without making heroic attempts at reduction as long as the decompression is adequate.

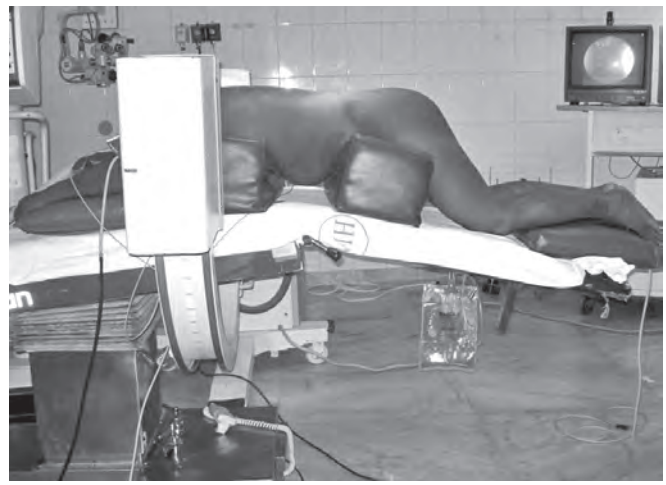


Fig. 13: Table position to maximise reduction in spondylolisthesis surgery

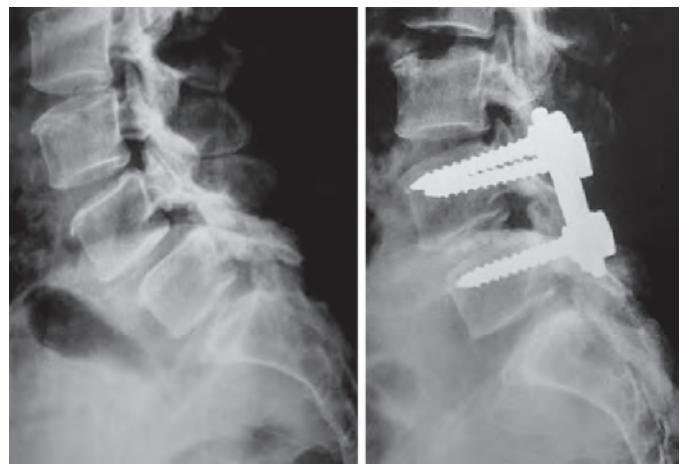

Fig. 14: Reduction of grade 1 DSO with pedicle screws in (pre- and post-operative radiographs)

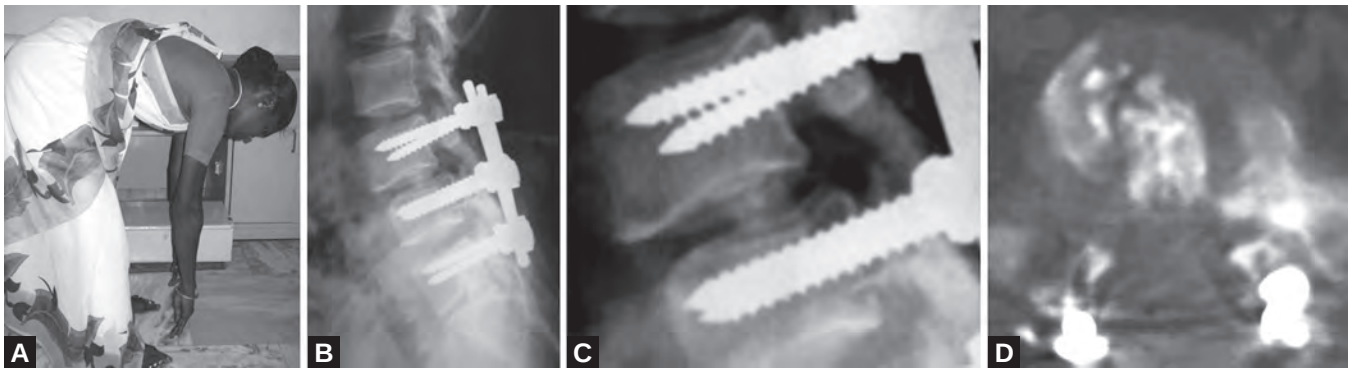
Fusion

The aim of fusion is to obtain a stable spine and a pain-free patient. Fusion addresses the instability caused by



Figs 15A to D: Results 6 weeks after 2-segment instrumented PLIF for DSO. (A) Range of lumbar flexion. (B) Lateral radiograph. (C) Note onset of fusion of the chip PLIF grafts in L3-4 space. (D) Consolidation of graft in CT radiographs (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

the disease and aggravated by the decompression procedure. Successful fusion avoids motion at that segment and halts progression of degeneration. One or two level fusion does not greatly reduce the range of whole spine movements (Figs 15A to D). A variety of fusion procedures are available. These include intertransverse fusion (ITF), posterolateral fusion (PLF), posterior lumbar interbody fusion (PLIF), transforaminal lumbar interbody fusion (TLIF), anterior lumbar interbody fusion (ALIF) and circumferential (270° or 360°) fusion. Autografts, allografts (locally banked cadaveric bone or commercially available femoral rings) and xenografts (bovine bone) are used in various combinations. The autograft may be obtained from the lumbar spine during decompression or separately from the iliac crest. Morbidity at the iliac crest donor site is considerable. Persistent iliac pain was reported by a third of the patients 2 years after surgery in a recent prospective study.[54] This has prompted a switch to the use of local bone or cages. Cages for interbody fusion are made of titanium, carbon fibre, ceramic or polyethyl ether ketone. They come in various shapes such as threaded cylinders, spiked cuboids, tapered cuboids or the expandable variety. Anterior interbody fusion relies more on cages as the neural structures do not come in the way of implanting large cages. With instrumentation becoming nearly universal, it may not be necessary to get blocks of bone; morsellated chips obtained during decompression fuse just as well (Figs 15A to D). Good results have been reported with chip grafts in both PLF and PLIF.[33,57] Recombinant human bone morphogenic protein has been used to increase the chances of fusion and it might even obviate the need for a bone graft.[32] Progression of degeneration at the level adjacent to the fused segment is seen in about 15% of patients at 3–4 years at follow-up imaging.[17] It must be remembered that not all adjacent level degenerations are symptomatic.[42]

The arguments favouring fusion surgery are outlined in Table 4 and are fully discussed in an article in *Progress in Clinical Neurosciences*.[14] There is now evidence from 13 small randomised trials and comparative observational studies showing that a satisfactory outcome is more likely with fusion than with decompression alone for DSO.[52] A meta-analysis of retrospective series up to 1993 indicated success rates of 69%, 86% and 90% for decompression, non-instrumented fusion and instrumented fusion respectively for DSO.[40] Long-term (11–17 years) follow-up studies and patient satisfaction studies have also demonstrated superiority of fusion over non-fusion procedures in both DSO and ISO.[14] In 47 patients of DSO followed up for 5–14 years the clinical outcome was excellent to good in 86% of patients with a solid arthrodesis but only in 56% of patients with a pseudarthrosis.[36] Failed posterior surgery is an indication for anterior lumbar interbody fusion.[12]

Instrumentation

There is no consensus on the use of instrumentation in lumbar fusion. The reasons for performing instrumented fusion are summarised in Table 5. The fusion rate was higher (82%) with the use of instrumentation as opposed to the non-instrumented cases of DSO (45%) in a prospective randomised trial but it is not certain, if that automatically means better clinical outcome.[18] In a study of 44 patients of DSO followed for a minimum of 2 years, the rate of progression of spondylolisthesis was least with instrumented fusion, intermediate with non-instrumented fusion and highest with decompression alone.[5] The previously used posterior instrumentation using sublaminar wires and Luque rods or Hartshill rectangles is now supplanted by transpedicular screws.[44] Since they provide three column support, pedicle screws are the stablest of devices.[24] The vertebral slip can be corrected by distraction-lordosing. It is acceptable to obtain *in situ* fusion in low-grade olisthesis as long as the nerve root space is well-decompressed. The decompression and, therefore, the instrumentation and fusion might need to extend to adjacent stenotic levels in DSO (Figs 16A to C). The recent advances include use of neuronavigation for proper placement of the screw and percutaneous placement of pedicle screws.[20,51] Use of navigation helps minimise radiation exposure of the operating room personnel. Pedicle screw placement is an exacting technique with a steep learning curve. Complications of pedicle screws and ways to avoid them

Table 4: Arguments favouring fusion surgery in DSO (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

Arguments AGAINST performing non-fusion surgery (decompression alone)	*Arguments FOR performing fusion surgery (decompression + reduction, fusion instrumentation)*
Decompression adds to biomechanical weakening caused by established and ongoing degeneration, leading to worsening of symptomatic instability	Pain is not only due to static nerve compression, but mainly due to dynamic instability. Successful fusion relieves symptoms better and prevents further progression
Root pain may be relieved for sometime after decompression, but disabling back pain due to instability persists and root pain recurs	Recent advances make fusion surgery safe, simple and patient friendly. Increased experience reduces the complication rate
Surgeon hesitates to do the required degree of decompression for fear of inducing further instability. Inadequate lateral canal decompression is a common cause of failed back surgery syndrome	While adjacent level degeneration does occur after fusion, it is overestimated and not clinically relevant
Should the patient ultimately need a fusion, it is two operations, greater cost and longer convalescence	Literature evidence favouring fusion surgery
Not fusing an unstable or potentially unstable spine may be a ground for litigation	Use of instrumentation increases chance of good fusion
	Increased cost of instrumentation is offset by a quicker return to occupation
	Alternatives are available now to rigid fixation

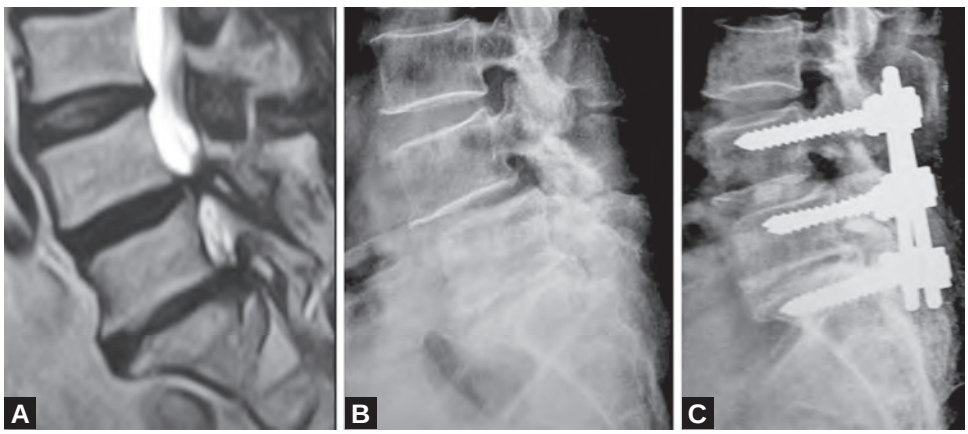
Table 5: Reasons for using instrumentation in lumbar fusion (Reproduced with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

- Immediate stabilisation
- Quicker ambulation and return to work
- Reduction of spondylolisthesis
- Correction of kyphosis or scoliosis
- Maximise chances of fusion
- Use in situations where fusion chances are lower (osteoporosis, smokers)
- Minimise the chances of recurrence of spondylolisthesis or stenosis
- Better clinical outcome

are listed in Table 6 but significant complications are rare in experienced hands.[31] In mild grade DSO, interbody cages might even obviate the need for pedicle screws (Fig. 17). There is a small randomised Chinese study that shows as good results with unilateral decompression and cage placement as with a bilateral procedure.[68]

Surgical Techniques

The details of the operative approaches, their merits, complications and results can be obtained from textbooks of operative techniques in spine surgery.[38] Only some salient facts are mentioned in this chapter. In our centre, the neurosurgeon and the orthopaedic surgeon perform spondylolisthesis surgery as a team. This has enabled us to bring together our unique training, attitudes and skills in managing spondylolisthesis. Thus, we are able to safely offer instrumented fusion for patients who have been denied surgery or offered only decompressive surgery elsewhere. Pre-operative percutaneous transpedicular external fixation has been tried in some centres to predict the response to fusion surgery, but we do not use it.[62] The obese patient is motivated to lose weight and the need for exercises to maintain back



Figs 16A to C: L4-5 DSO with L4-5 and L5-S1 canal stenosis. (A) MRI. (B) Erect lateral radiograph before operation. (C) The patient was relieved of back pain and claudication after canal decompression, partial reduction and pedicle screw instrumented PLIF. L5-S1 had to be included as there was significant degeneration and need for wide decompression at this level even though this level was not olisthetic

Table 6: Complications of and avoidance of complications in lumbar pedicle screw surgery

Intra-operative complications	*Avoidance*
Screw misplacement in pedicle Medial breach-dural tube injury, CSF leak Inferior breach-nerve root injury Lateral breach-screw loosening All walls—pedicle fracture Screw misplacement in body Excess screw length—aorta injury Insufficient screw thickness-loosening High placement-entry into disc space	Careful study of radiographs prior to surgery, CT pediculometry, correct identification of anatomical landmarks, precision drilling under lateral image intensifier control, checking of drill path position in AP view before tapping or screw placement, using paraspinous transmuscular approach rather than the midline approach, use of neuronavigation
Inability to mate the screw heads Sagittal plane-due to olisthesis Coronal plane-medial or lateral pedicle entry point	Use of reduction screws, contour the rod or plate, place screw in next higher level Use of polyaxial screws
Osteoporotic bone Screw loosening Iatrogenic fracture	Pre-operative bisphosphonate therapy, undertapping of pedicle, use of larger diameter screw, avoidance of excess force, PMMA bone cement in drill hole, inclusion of additional levels, use of transverse connectors, post-operative orthosis
Blood loss during exposure	Use of paraspinous transmuscular or percutaneous approach, avoiding too much transverse process exposure, lighting and magnification, use of bipolar cautery, hypotensive anaesthesia
Muscle and skin edge damage from retraction	Use of paraspinous transmuscular approach, releasing retraction from time-to-time
Post-operative complications	*Avoidance*
Screw back-out Small diameter or length of screw Lack of convergence Stress fracture, osteoporosis Infection Lack of bone fusion, progression of olisthesis	Choose correct screw dimensions Start drill path laterally for convergence Orthosis, avoid straining the back Antibiotics, meticulous technique Place adequate bone, bone morphogenic protein
Screw breakage	Use standard implants, ensure that threaded portion is fully in the bone
Slipping of rod	Adequate tightening of 'inny' nut and 'outy' bolt, avoid soft tissue interposition, use rod of adequate length
Neurological deficit	Avoid root injury
Wound infection	Antibiotics, meticulous technique
Chronic pain	Avoid root compromise, adequate decompression, additional anterior fusion
