Preface

Since the publication of the second edition of this Textbook in 1996, phenomenal advances have been made towards improved understanding of the pathophysiology of various neurosurgical disorders, their diagnosis and therapy. Advances in molecular biology and genetics on one hand, the refinements of imaging technologies, introduction of image-guided techniques for neuronavigation, and refinements in endoscopic and minimally invasive procedures on the other hand have markedly reduced the morbidity and mortality of neurosurgery. Simultaneously, better availability of radiosurgery and safer endovascular approaches have led to the development of non-surgical therapy for a variety of lesions.

Recent years have witnessed a rapid increase in the number of well-equipped neurosurgical departments across the country providing both state-of-the-art services to the patients and training to specialists in the diverse subdisciplines of neurosurgery. It has been our endeavour to meet their needs for an updated account of the current knowledge of the subject.

The third edition of the textbook includes a comprehensive account of all the recent advances succinctly provided by a galaxy of outstanding contributors especially selected on the basis of their expertise and experience. Care has been taken to include relevant published literature both from India and abroad.

As in earlier editions, special attention has been given to tropical disorders not often adequately covered in publications of the West. This may be an additional attraction for neurosurgeons in other developing countries as also to those in the developed ones who often encounter such conditions in their practice.

The present editors deeply miss the invaluable, wise and experienced guidance of the Senior Editor Prof B Ramamurthi who was the moving spirit behind the earlier editions. The editors would like to thank all the contributors, their associates and the secretarial staff for their co-operation. The Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India deserve our special thanks for the excellent quality of the publication.

PN Tandon
Ravi Ramamurthi

Caraka Samhita

The early medical writer Caraka tells us that when setting out to learn about Indian medicine, we should have certain criteria in mind for choosing the texts we wish to study (Caraka. 3.8.3):

"A discerning person who wants to become a physician should start by selecting a text based on a consideration of his ability to cope with hard or easy tasks, the results he is after, the likely aftermath, the place and the time. After all, there are numerous physicians' manuals in circulation in the world, so he should apply himself only to a text which is extremely famous, which is used by scholars, which covers a lot of topics and is respected by qualified people. It has to be good for pupils of all three levels of ability, and it should not be flawed by repetitiousness. It should be derived from the tradition of the saints. The connection and the sequence of the text and commentary should be well organised. It should be solidly based, and have no corrupt or missing words. It should be full of significance, its ideas should follow in sequence and it should give importance to the exactness of what ideas really refer to. Its ideas should be coherent and its topics should not be haphazard. It should have both definitions and examples.

This type of text is like a flawless sun; it dispels darkness and throws light on everything."

The Roots of Ayurveda
Dominik Wujastyk

INTRODUCTION

Medical Practice in Ancient India

The history of medical science in ancient India takes us back to antiquity. Recorded history of medical science is as old as the "Vedas". It is based on the practical experience and careful methods pursued by the sages in the olden days. The ancient writings of the Hindus, which give us an idea of the culture and traditions at that time, were classified as "Srutis" and "Smritis". Smritis are the scriptures, written by the sages, who have recorded the eternal truths as revealed by the Brahma, "The Creator". The Srutis stand as primary in point of authority, being taught through generations by word of mouth only and learnt by rote. The real systems of medicine which developed indigenously in India included "Ayurveda" and "Siddha". These are all pervasive health sciences and are not for medical purposes only. Ayurveda is considered as an essential part of the "Vedas". The primary aim of Ayurveda is to enable a person to maintain normal health by prescribing diet, medicine and a regimen of life. Ayurveda is a science of life and teaches mankind how to lead a healthy life and live long happily. Daily methods of good living known as "Dinacharya" are particularly emphasised. It also deals with physical and mental diseases and their cure. "Dhanavantri", "Charaka", "Atreya" and "Sushruta" have been considered the great masters in this science. The Siddha system of medicine is said to have originated in the days of Mohenjodaro, even thousands of years before the Vedic period, possibly between 3000 and 5000 BC. The word "Siddha" means the one who has attained perfection. According to the mythological sources, the origin of Siddha medicine is attributed to Lord Shiva, who gave the first discourse on this subject to Nandi Thevar, the celestial physician. These would indeed be valuable additions to our modern pharmacopoeia. Both Ayurveda and Siddha are similar and are based on the theory of "Tridosha". The third system of medicine—The Unani or the Greco-Arabian system—was introduced when Mohammedans came from Arabia and Persia. This includes blood as the fourth humour. The Siddha systems contain many valuable therapeutic agents, which should be studied scientifically. These three systems are taught and widely practiced in India and command much influence even today. The modern system of medicine was introduced in India by the Portugese and developed further by the British from the 16th and 17th century onwards.[7]

Medical Education in Ancient India

The educational system of ancient India was based on a personal relationship between the pupil and the teacher. The idea of organisation in education and its application to the methods of collectivism were emphasised by Buddhism. There were many Universities or "Viharas" in Ancient India that were famous, among which were Nalanda, Takshila and Kashi. The ruins of the ancient University of Nalanda are situated at Baragaon in Bihar. The best account of this university has been provided by two Chinese pilgrims, Yuon Chwang and I Tsing (5th to 6th century AD). Nalanda was known to be the largest residential university that India ever had and was a great centre for learning. Education was free, made possible by liberal grants by royal and private philanthropy. It had a large population of 8,500 pupils and 1,500 teachers. It was in such an academic atmosphere that Ayurveda was taught. The Takshila University was also a great centre of medical education, the remains of which can still be found in Rawalpindi, Pakistan. The course of training extended over a period of 7 years, at the end of which the student had a thorough severe test of his knowledge before he went into practice. The Banaras University (Kashi) flourished from 7th century BC to 12th century AD. The most outstanding feature of this university was its school of surgery.[7]

Medical Ethics in Ancient India

In admitting students to the study of medicine, as much importance was attached to moral fitness as to the intellectual and physical fitness of the pupils, for it was considered axiomatic that moral excellence was the basis of all true education. The object of education was not merely to prepare the student to earn a livelihood but also to infuse into him a strong desire to lead a good and virtuous life altogether. It was stressed that the study of medicine was solely for the purpose of showing compassion to all beings and not for selfish purposes. Various oaths have been described in "Charaka Samhita" and "Sushruta Samhita" to inculcate such habits amiably. For instance, one of such oaths in Charaka Samhita states "Thou shalt behave and act without arrogance and with

care and attention and with undistracted mind, humility, constant reflection and with ungrudging obedience."[7] Please note that this preceded the Hippocratic Oath by several centuries.

NEUROSURGICAL TECHNIQUES IN ANTIQUITY

Neurosurgery in Ancient India

Surgery had advanced a great deal in ancient India, the various wars being chiefly responsible as wounds and other injuries inflicted on the battlefield had to be treated effectively and expeditiously. The Indian people, generally speaking, possessed a progressive and enterprising mind and this along with their extensive knowledge of pharmacopoeia consisting of herbal, mineral and other drugs, helped a great deal in this process. The greatest name in the surgery of ancient India was that of Sushruta who probably flourished around 1000 BC that was in the pre-Buddhist period. This is supported by the fact that the "Atharva Veda", which is pre-1000 BC, agreed with Sushruta's system of describing the bones of the human body. The Mahabharata, the great Indian Epic, also refers to Sushruta as one of Vishwamitra's sons. At that time, surgery was taught at Banaras (Kashi) and medicine by Punarvasan Atreya at University of Takshila (Taxila). It was in Banaras where Indian surgery reached its highest point. "Sushruta Samhita" was written here by Sushruta, who for the first time brought together the existing knowledge of surgery.[7] Sushruta (Fig. 1), unlike his Greek contemporaries who were morbidly reluctant to perform human dissections, has vividly described the cranial nerves, including the optic and vestibulocochlear nerves in cadavers. He also described various surgical procedures like excising, probing, puncturing, suturing and evacuating fluids. His method of management of spinal injuries in itself reflects his great knowledge on the subject. For instance, on treatment of dislocation of the neck and downwards, the surgeon was instructed to grasp the head at the nape of the neck along with the angle of the jaw and lift it up. On the whole, however, he believed that the treatment of fractures of the spine was hopeless.[4,60]

Fig. 1: Sushruta—The practice and teaching of medicine by Sushruta from an Indian print of the 18th century AD

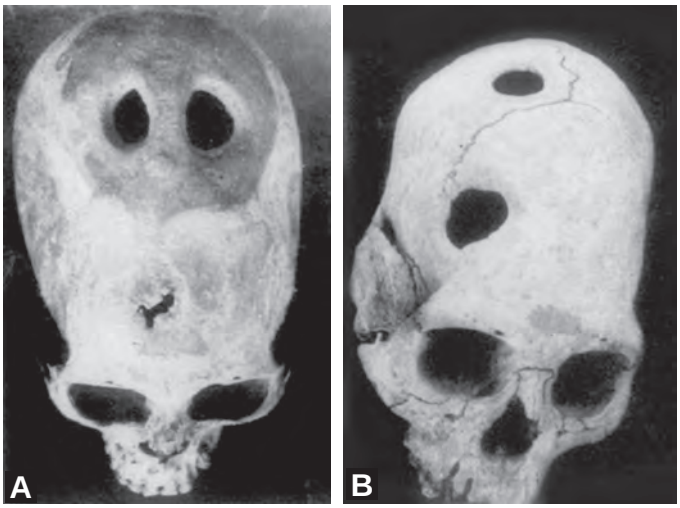
Charaka was another master of ancient Indian medicine. He was said to be the incarnation of Shesha, the serpent God with thousand heads, who is supposed to be the repository of all sciences, especially medicine. He was the son of Visudha, a learned sage, and is said to have been born at Banaras around 320 BC. His book Charaka Samhita is still used as the standard book on Ayurvedic medicine. Buddhist tradition makes him a contemporary of the great Indo-Scythian King Kanishka, to whose court he was attached in the capacity of a physician. He described various ailments like hemicranial headache, facial paralysis, spasm of the throat, and diseases of the mouth, nose and eyes. Management of all these was based usually on correcting the humors of the body.[7]

Atreya, Dhanvantri, Agnivesa and Vagbhata are a few other names of famous physicians of antiquity. Jivaka, the personal physician of Gautama Buddha, is reported to have removed intracranial masses using trephine holes. In the 10th century AD, two physicians were asked to attend King Bhoja of Dhar. All medical therapy for his severe headache had failed. The physicians advised surgery. A drug called "Sammohini" rendered the King unconscious. The head was then trephined and a pearly tumour was removed from the brain. He made a complete recovery.[7]

Trephining in Neolithic Period

In 1875, two historians of great repute, Prunières and Brocard, discovered that trephining of the skull was frequently carried out in the Neolithic period, many millennia before our historic period (Figs 2A and B). Trephining was then probably performed to remove foreign bodies, as well as splinters of fractured skull, and also perhaps for mystic reasons, e.g. to release evil spirits from the skull, which were thought to unbalance the humors in the body and ultimately lead to diseases. Graveyards from the Paracas and Parachamac regions in Peru provide ample evidence that pre-Incan surgeons were performing trephination in great numbers as early as in 3000 BC. Neolithic Celtic remains have revealed the presence of round or oval skull pieces, presumably removed by trephination. Trephination was also performed in England as discovered in a skull excavated at Crichel Down in 1938.[71]

Such trephined skulls were found in all parts of the world demonstrating the similarity of medicine of ancient civilisations. New growth of the bone about the edges of the trephines proved that these procedures were often followed by survival. The patient was usually, perhaps always, dulled or made unconscious

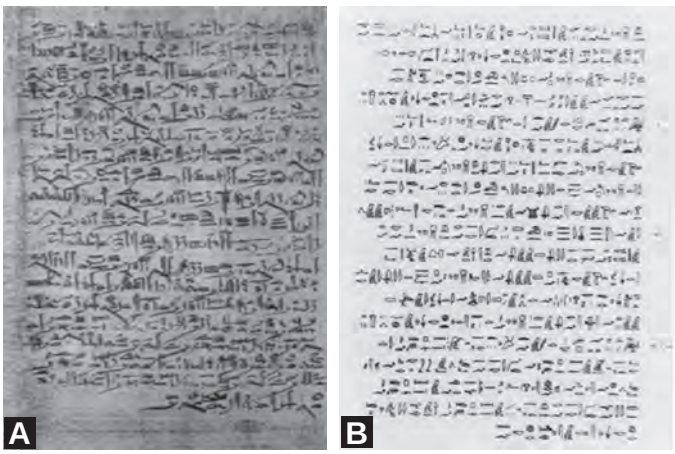


Figs 2A and B: Skull trephine as performed during Neolithic period (Anthropologic Institute of Florence)

with soporific potions. Trephining is still practiced among some primitive races for instance, the Kabyles of Northern Africa, the hill tribes of Dagestan and in many parts of Melanesia. All these operations owe their origin more from a demonical or magical concept rather than rational therapy.[4,47]

The Edwin Smith Surgical Papyrus

The Edwin Smith surgical papyrus, dating from the 17th century BC, is one of the oldest of all known medical papyri (Figs 3A and B). Edwin Smith was an Egyptologist who bought this ancient manuscript roll at Luxor, Egypt, in 1862, from unknown sources. Though he understood the importance of this manuscript, it was not until 1930 that James H Breasted, then Director of the University of Chicago Oriental Institute, translated the treatise and established its importance. More interestingly, this ancient composite manuscript, as discovered by Breasted, was a copy made by an Egyptian scribe from a still earlier document based on the contributions probably of several earlier authors dating to perhaps as early as 3000–2500 BC.[8]



Figs 3A and B: Edwin Smith papyrus—case 47 and 48 taken from Edwin Smith papyrus along with hieroglyphic interpretation shown on the right side (Plate XVII from Breasted)

The papyrus, apart from being the oldest one of its kind in existence, has many more unique features. It contains actual cases and not recipes. The treatment of cases is rational and mostly surgical. Each case had been given one of the three different verdicts: (a) favourable, (b) uncertain, and (c) unfavourable. It is of special interest to neurosurgeons because it contains the first descriptions of the cranial sutures, the meninges, the external surface of the brain, the cerebrospinal fluid and intracranial pulsations. Also of great interest are the different modes of treatment described for various types of head injuries. The frustration in treating spinal injuries was recognised even then.[8]

Hippocrates and Neurosurgery (460–377 BC)

Hippocrates is considered the father of Western medicine and his writings have influenced the practice of medicine for more than 20 centuries. Littre, who is an authority on the work of Hippocrates and his students, had collected more than 53 subjects in 72 books.[1,4] Surprisingly, most of the Hippocratic workers seem ignorant of structural anatomy and most of their writings prove to be confusing, if not wrong. The observations of Hippocrates on head injuries and their treatment are recorded in the work "On injuries of the head". The clinical acumen of Hippocrates is well demonstrated by his descriptions of aphasia, unconsciousness, pupillary inequality and ophthalmoplegia. He was aware of the fact that a blow on one side of the head could lead to convulsions and paralysis of the limbs on the opposite side. It is very interesting to note the meticulous instructions he gave for surgery of head injuries. His instructions for the use of the trephine were the most precise. ".....The opening should not be made over the cranial sutures, for the dura being adherent, was likely to be damaged", "... the trephine should repeatedly be removed from the skull and cooled with water during the procedure and the incision examined to be sure that the dura mater was not reached".[57]

Celsus (30 BC) further described the treatment of head injuries and pointed out the occurrence of contrecoup fractures and advised trephining for fractures.[4] Galen (130–201 AD) was a disciple of Hippocrates and went far beyond his master. Unlike his master, who had great humility and would often say, "I don't know", Galen had an explanation for almost everything.[4]

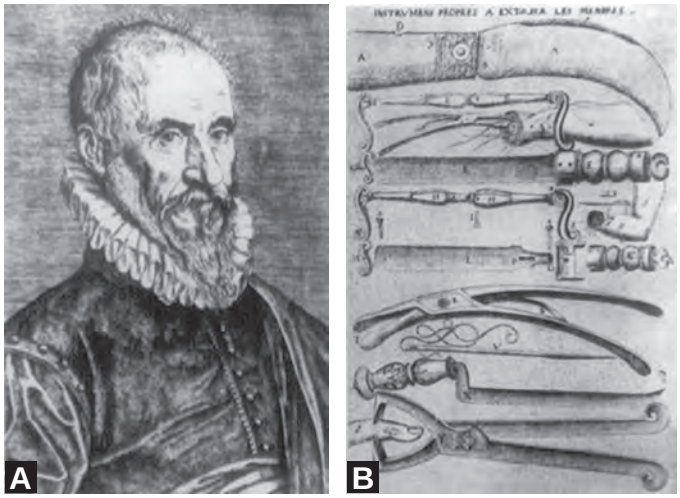
Galen's descriptions for trephination were similar to that of Hippocrates, e.g. ".....the trephine should be rotated slowly and carefully, with frequent inspections so as not to breach the dura mater.....". He emphasised upon the description of the 5 types of skull fractures listed by Hippocrates. He described dressings in great detail, including a dressing of wool with oil of roses, with a warning not to put pressure on the dura. Other Greeks who further added to knowledge, during this period were, Aretaeus the Cappadocian (150 AD), Oribasius (325–403 AD) and Heliodorrus.[1,4,57,60]

Neurosurgical Techniques in the Medieval Period (500–1500 AD)

During this period, not much was added to the techniques of management of skull fractures than what was already known. However, significant contributions were made during the later part. Paul of Aegina (625–690 AD) advocated exploration and extraction of broken pieces of bone in spinal fractures. Roger of Saleron (1170 AD) described in detail the surgical management of skull fractures. Lanfrane compiled his textbook of surgery in 1296 and was the first surgeon who advocated suturing of divided peripheral nerves. Guy de Chauliac (1300–1360 AD), who has been called "the father of modern surgery", described repair of peripheral nerve injuries, and classified head injuries according to their management very much similar to present day management. Jacopo Berengano da Carpa (1470–1530 AD) described cranial fractures in detail and advised early surgical intervention.[4,17]

Neurosurgical Techniques in the Renaissance (1500–1700 AD)

Two key figures deserve mention during this period. Ambroise Pare of the French army (1510–1590 AD) described elevation of depressed fractures and debridement of wounds in detail (Figs 4A and B). He described the use of traction for spinal injuries and like his predecessors realised the futility of treatment of cord injuries. He, however, advised removal of splinters of broken vertebra impinging on the cord as a last resort. Fabricus Hildain (1560–1634) perhaps gave the earliest description of laminectomy.[4,17]



Figs 4A and B: (A) Ambroise Pare was unquestionably one the greatest surgeons of the Renaissance. He was born in 1510 at Bourghersent in Meyenne and acquired his initial surgical skills from a barber shop. He knew no Latin and thus wrote in French to the considerable opposition of the Professors of Sorbonne, who could not conceive of a member of the college not knowing Latin. He was surgeon to Henry II, Francis II and Charles IX who also protected him during the massacre of St Bartholomew. He has been described as a man of genius, an infatiguable worker and being honest to the highest degree. He introduced various radical changes in surgical procedures like giving up the method of hot iron cautery used by Arabians, marked improvement of amputation surgery, surgery for hare lip, etc. (B) Here shown on the right are some of the instruments being used by him

Neurosurgical Techniques in the Pre-Listerian Period (1700–1846 AD)

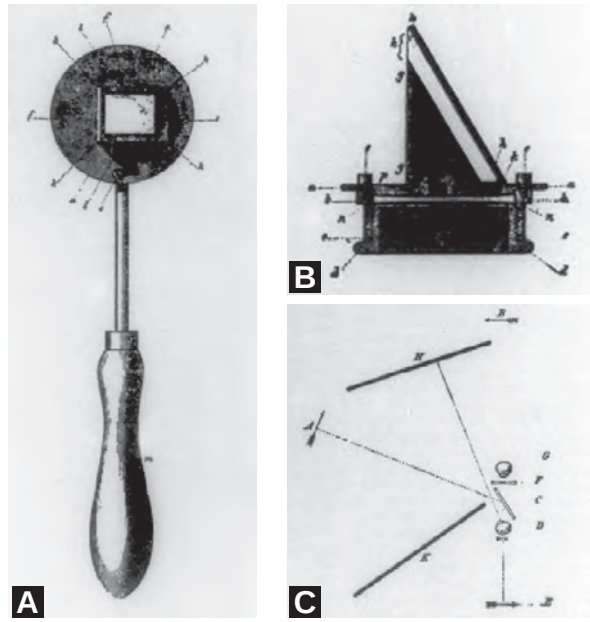
Neurosurgery was still limited to head injuries till the beginning of the pre-Horsley era in view of the lack of knowledge of antisepsis in the Western world and of anaesthesia. There were, however, a few surgeons who cannot be ignored. Jean Louis Petit (1674–1750 AD) advised trephining in all cases of scalp wounds with fractures. SF Morand in 1792[10] was the first to operate successfully upon a temporal abscess. Sir Percival Pott (1713–1788 AD) used a trephine for treatment of brain abscesses. Gurthrie (1785–1856 AD) realised the importance of epidural haematoma and advocated its urgent management.[4,17]

Neurosurgical Techniques in the Pre-Horsley Period (1846–1890 AD)

Dramatic developments started to take place in this era. Various discoveries laid down a strong foundation for the development of contemporary neurosurgical techniques. The era of painless surgery was ushered in with the discovery of chloroform and ether (1846–1848 AD). The antiseptic principles described by Lister in 1867 reduced the infection rate significantly and gave a boost to the surgeons to proceed beyond the dura mater (Fig. 5). Almost simultaneously, clinical localisation was improved markedly by neurologists like Fritsch, Hitzig, Ferrier, Gowers and Hughlings Jackson.[34]

In 1884, Sir Rickmann Godlee operated upon a brain tumour for the first time solely on the basis of clinical localisation by Hughes Bennet.[30] The patient unfortunately died a month later due to meningitis. This, however, did not discourage the other surgeons and only increased their determination to cross the last frontier. Sir William Macewen carried out his first surgery on a brain abscess in 1881.[31] He published his monograph on "Pyogenic Infective Diseases of the Brain and Spinal Cord" in 1893, where he reported 94 cases of "infective intracranial lesions". Of the 19 cases of cerebral and cerebellar abscesses in total, 18 had total recovery, a record that remains unparalleled even today.[10] In 1887, Van Bergmann, an outstanding German surgeon published a monograph on cerebral surgery containing case histories, diagnosis and operative management of over 189 patients most of them with brain abscesses.[4,10,59] PC Knapp and EH Bradford in 1889 finally summarised the situation in an article that documented 23 cases of brain tumours, which were operated upon based on purely clinical localisation.[4,10,60]

Fig. 5: Joseph Lister (1827–1912 AD) was born at Upton in the county of Essex and is considered as one of the greatest figures in the history of surgery. He is best known for his antiseptic principles, including introduction of carbolic acid spray in the operating room, the results of which were published in the Lancet in 1867. He was the first physician to sit in the House of Lords. Part of the Glasgow ward where he carried out his work and most of his publications are still preserved at Welcome Historical Medical Museum in London



Figs 6A to C: Helmholtz's ophthalmoscope—Photographic reproduction of the original illustration of ophthalmoscope published in German in 1851, and later translated into English by Shastid TH in a monogram titled "The Description of an Ophthalmoscope—Being an English translation of von Helmholtz's—Beschreiburg lines Augenspiegels" in 1916

DEVELOPMENT OF CONTEMPORARY NEUROSURGICAL TECHNIQUES

Before proceeding on this fascinating journey, it would be useful to look at the development in other branches of medicine, which have made this journey possible.

In 1851, Hermann von Helmholtz invented the ophthalmoscope (Figs 6A to C). To quote from his work on visualising the retina "... I had the great joy of being the first who saw before him a living human retina".[84]

The Development of Techniques for CSF Access and Analysis

The puncture of the subarachnoid space for a therapeutic purpose was made for the first time in 1885 by Corning when he injected cocaine for anaesthesia. Six years later, Quincke described lumbar puncture for relief of raised intracranial pressure.[22]

The first edition of Keen's "An American Textbook of Surgery" described the use of ventricular puncture using the landmarks outlined in 1890. However, the usefulness of ventricular puncture was fully realised in 1918 when Walter Dandy described pneumoencephalography and ventriculography for the purpose of localisation of cerebral masses.

Development of Neuroradiology

Roentgen discovered X-rays in 1896 and within a year, its use in medicine was well established. This constituted the main tool for diagnosis based on bony erosion, sutural diastases and pineal shift and calcification.[35,70]

Diagnostic radiology took a great leap forwards in 1918 with the introduction of pneumoventriculography and pneumoencephalography by Dandy. This discovery came about when Dandy noticed air under the diaphragm in the X-ray film of a patient with intestinal perforation.[13]

In 1921, myelography was introduced when Jean Sicard, a French clinician, and his pupil, Jacques Forestier, injected analgesics into the spine of a patient suffering from low back pain and subsequently found that the oil they used as a carrier for the analgesic, lipiodol, was radiopaque.[72]

The invention of myelography encouraged the outstanding Portuguese neurologist, Egas Moniz, to develop "Arterial Encephalography".[48]

Neuroimaging attained its pinnacle with the invention of the CT scan and MRI. In 1967, Godfrey Hounsfield of EMI Laboratories working on the interpretation of data derived from X-ray transmission hit upon the idea of simplifying data by sectioning the object into a series of "slices" for a complete diagnostic picture.[33]

The MRI scan was based on the Nobel Prize winning work of Block and Purcell in the 1940s, which was applied to medical imaging in the 1970s.[59]

More recently, functional imaging, like positron emission tomography (PET), functional MRI and SPECT, has been introduced. It may be noted that though the principle of PET was suggested as early as in 1951 by Wrenn and his colleagues, it was introduced in clinical

practice in 1970. All these inventions collectively gave a tremendous boost to the development of neurosurgical diagnosis and techniques, which also evolved more or less simultaneously.[75,85–87]

Patient Positioning

Victor Horsley was the first to stress the need for proper cranial immobilisation. Harvey Cushing (Fig. 7) was the first surgeon to devise a horse shoe shaped head rest which kept the patient's eyes, nose and mouth free and provided access for administration of anaesthetics. He also introduced the practice of shaving just prior to surgery.[60]

De Martel, in 1913, introduced the sitting position. He constructed a special chair in which the patient's head could firmly be fixed. The hazards of the sitting position were later described by Bailey.[4,60] Frank Henderson Mayfield (Fig. 8) introduced the three pinhead clamp, which made patient positioning safer and easier.[76] Victor Horsley was the first surgeon to use the operator worn headlight to illuminate the operating field.[60]

Surgical Gloves

As late as 1900, operations were performed with bare hands, asepsis being achieved by continuously dipping the hands in a bucket of carbolic acid. Halsted (Figs 9A and B) was the first surgeon to introduce the use of gloves during operations. There is a romantic edge to the story of its origin. Halsted's scrub nurse was allergic to carbolic acid and he devised the gloves primarily for her. She later on became his wife.[4]

Fig. 7: Harvey Cushing (1869–1939) was perhaps the greatest neurosurgeon of all times. Results in neurosurgery before him were dismal. As found out by Cushing at Johns Hopkins, ten years before 1901, antemortem diagnoses were made in only 32 cases of 36,000 admitted. Of these, only two cases were operated with fatal results. From this stage, Cushing introduced most painstakingly, various methods like maintenance of ether chart, absolute haemostasis, gentle use of cotton pledgets, use of silver clips and electrocautery for haemostasis and above all slow and gentle handling of tissues, which he inherited from Halsted, all of which reduced the mortality significantly. His operative mortality during the last years of his practice was only 8.7% for a total of 635 surgeries. He was also the author of a series of brilliant monographs: The pituitary body (1912), Tumours of nervus acousticus (1917), A classification of the tumours of the Glioma group (1926, with Percival Bailey) and so on down to Meningiomas (1938). His "Life of Sir William Osler" (1925) obtained the Pulitzer Prize, which was a classic in medical biography and a best seller

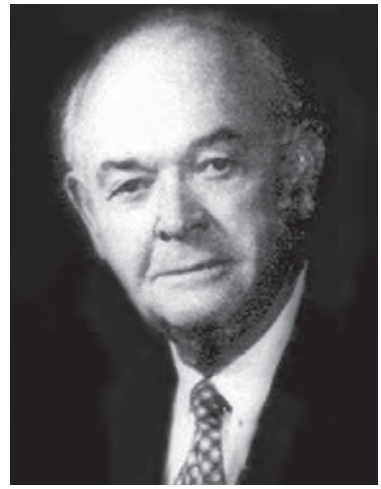


Fig. 8: Frank H Mayfield was born in 1908 in South Carolina and underwent his medical graduation from The College of Virginia. He was fortunate to have had the guidance of the eminent surgeons of that time, Drs Cushing, Dandy and Coleman. Apart from designing the three pin head clamp to which his name is attached, he is also known for this pioneering work in lumbar disc surgery, development of aneurysm clips and many surgical instruments. He was the first recipient of The Harvey Cushing Medal in 1977 by the American Association of Neurological Surgeons

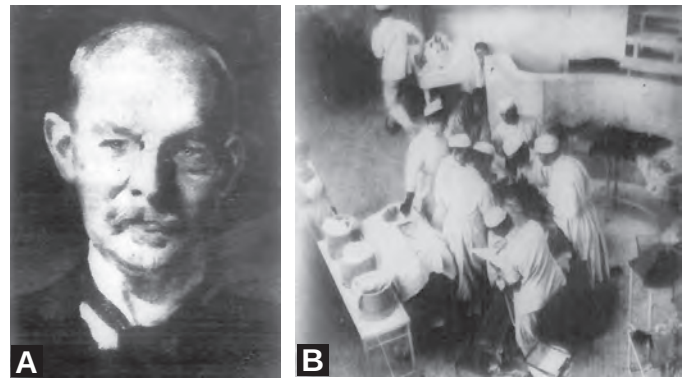

Figs 9A and B: (A) WS Halsted (1852–1922) was the first professor of surgery at Johns Hopkins. He was a quiet but effective force in transforming surgery from a series of dramatic events into a less conspicuous, painstaking and scientific study of disease. In addition to introduction of surgical gloves, use of silk ligatures and of infiltration anaesthesia with cocaine, he also devised numerous operative procedures and technical improvements often based on previous experiments on animals. (B) Photograph of Halsted in the so called "All star operation theatre" being assisted by Cushing and Finney (opposite), Bloodgood (at his right), Young (at the instruments) and Follis (leaving the theatre). Note the use of gloves and caps but no masks. The technique of handling tissues gently and slowly formed the basis on which Cushing developed neurosurgical techniques to set a standard for the future generations of neurosurgeons

Craniotomy

Earlier, the skull was opened with a trephine and the opening was enlarged with a mallet and chisel to the extent required. It was traumatic to the brain and often produced unacceptable deformities.[4,5]

In 1889, Wilhelm Wagner introduced the osteoplastic craniotomy, which allowed access to large areas of the brain without a disfiguring cranial defect. This was introduced after several years of painstaking studies on cadavers. Taison, in 1894, suggested that the bone be divided from within outwards using a chainsaw between burr holes. Almost simultaneously, Leonardo Gigli described an ingenious yet simple instrument for sawing the bone, which was initially intended to perform symphysiotomy in obstetrical surgery (Fig. 10).

D'Vilbiss, in 1896, designed a bone cutting forceps for making linear cuts in the bone from within outwards. De Martel, in 1908, introduced the metal guide for introducing the Gigli saw between burr holes. He also introduced a power-driven perforator with an automatic disengaging gear, which stopped the motor as soon as the perforator penetrated the skull. Poirier, in 1891, advocated that the dural flaps should be cut with the base towards the midline to reduce bleeding from dural emissary veins.[4,5,11,84]

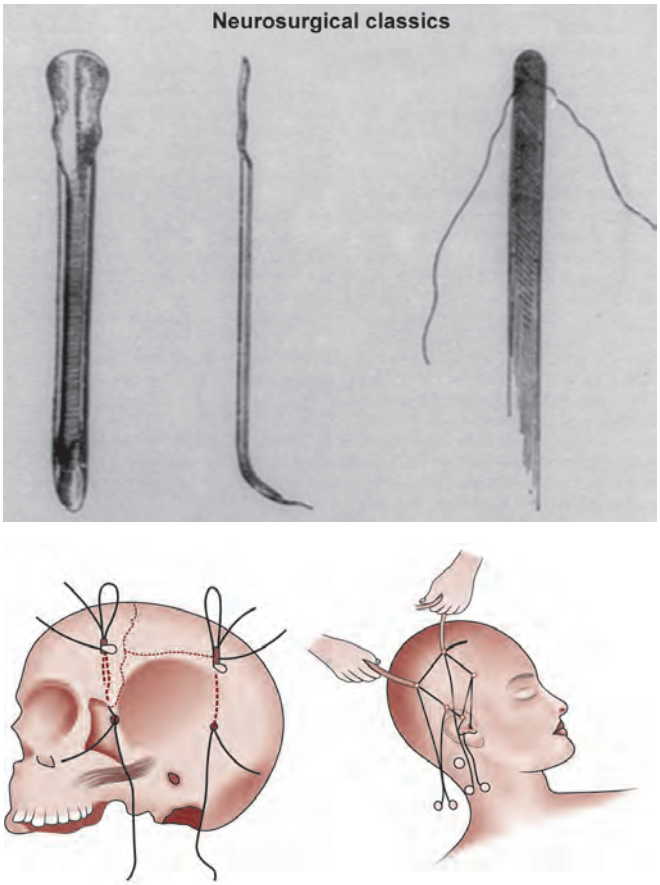

Fig. 10: The Gigli saw was devised by Leonardo Gigli in 1898. He devised a grooved probe, which he named as a "whalebone" to introduce the wire between burr holes

Suction and Irrigation

Cushing was the first surgeon to utilise a hand bulb syringe attached to a rubber catheter to cleanse the tracts of brain wounds in the First World War.[11] Power suction was introduced many years later by Herbert Olivecrona.[60]

Brain Retractors

The malleable self-retaining retractor fixed to the edge of the cranial defect was introduced by De Martel.[11] Yasargil later introduced the currently popular Leyla retractor. He named the retractor after his daughter when he saw her playing with a doll, which maintained its new position whichever way it was twisted. Many modifications and improvisations were made later by various innovative neurosurgeons like Suzuki, Rhoton, etc.[11,60]

HAEMOSTASIS

One of the most important reasons why early surgeons were discouraged from performing neurosurgery was bleeding and the difficulty of controlling it. Cushing himself, after having witnessed Victor Horsley, perform one of the surgeries, seriously contemplated against continuing this profession.[3,24,42]

Scalp Haemostasis

Brown, in 1909, introduced the practice of infiltrating the scalp with a mixture of local anaesthetic and diluted adrenaline solution. Cushing advocated the use of firm digital pressure along the edges of the proposed incision and the technique of everting the galea with artery clamps—a practice followed even today.[3,11,42]

Victor Horsley, in 1892, invented bone wax, which was initially made of bee's wax and had haemostatic qualities by virtue of its tamponade effect on bone bleeding.[3,42] Later, absorbable gelatin sponge (Gelfoam) was also found to be useful in controlling bleeding from the bone.

Cerebral Haemostasis

Various ingenious methods were devised in the past including packing with cotton, wool, oil of olive and caustics. Presently, three basic methods are used.

Thermal Methods

Galen popularised the use of hot irons for cautery as a primary method of haemostasis. Pare abandoned this method around 1500 years later. Thermal cautery was reintroduced by Cushing and Bovie in 1928 in the form of electrocautery (Fig. 11). Greenwood introduced the bipolar forceps in 1930 and this was further modified by Malis. More recently, a variety of lasers which were initially introduced by Maimman in 1960 have been used for haemostasis.[3,42,60,84]

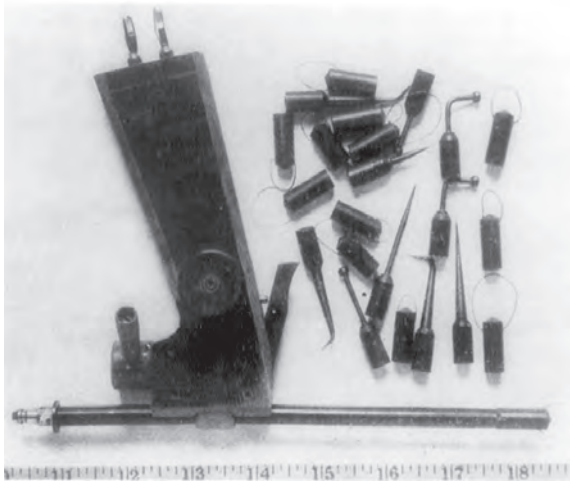

Fig. 11: Photograph of original hand-made model of the pistol-grip with pencil attached and a cluster of terminal electrodes of various types. This was initially devised by Bovie in 1927 and later modified by Cushing in the form of only a pencil to improve the precision

Mechanical and Chemical Methods

Since the time of Hippocrates, the use of caustics, like copper sulphate, was in vogue but these fell out of favour as they caused indiscriminate destruction. Horsley, and later Cushing, introduced the use of crushed muscle. Correll and Wise first introduced Gelfoam (absorbable gelatin sponge) in 1945. Yackel and Kenyon of Eastman Kodak Laboratories first produced oxidised cellulose (Oxycel) and oxidised regenerated cellulose (Surgicel) in 1942, but these came into clinical use much later. The use of microfibrillar collagen (Avitin) as a haemostatic agent was first demonstrated by MR Hait in 1969.[3,42,85]

OPERATING MICROSCOPE IN NEUROSURGERY

The operating microscope was used by otologists to perform middle ear surgery as early as 1921. For the use of the microscope in neurosurgery, it required many adaptations in the form of improved illumination, manoeuvrability and magnification. Hans Littmann of Carl Zeiss Company was one of the pioneers in developing such a suitable model. Since then many more models have been introduced. Almost simultaneously micro instruments have been developed by neurosurgeons, including Yasargil, Rhoton, Maroon, Hardy, Suzuki and many others.[85]

DEVELOPMENT OF NEUROSURGICAL TECHNIQUES IN SURGERY FOR BRAIN TUMOURS

Gliomas

Bailey and Cushing were among the first to classify gliomas according to their histological features. Cushing and Eisenhardt started the practice of examining the biopsy specimen during surgery. Early efforts by Horsley in 1893 and Cushing in 1909 consisted of external decompression with or without partial removal and this soon proved to be unrewarding.[12,33] Dandy, in 1921, advocated radical internal decompression.[14] Cushing (Fig. 7) later greatly improved the operating techniques in glioma surgery. His methods of achieving haemostasis with cotton pledgets, reducing brain swelling by increasing head elevation and painstaking closure of the dura, greatly contributed to reduce the morbidity and mortality in such patients. He also stressed the importance of excision of the mural nodule to achieve a permanent cure for cystic gliomas. The use of intravenous hypertonic solutions was introduced by Sachs and Bailey to reduce intracranial pressure before the dural opening.[11,24,80]

Meningiomas

William Macewen probably performed the first surgery for meningioma in 1879. However, Franceso Durante performed the first successful surgery for an intracranial tumour in 1885 when he removed an olfactory groove meningioma.[2] The principle of replacing the diseased bone after autoclaving was first introduced by Naffziger.[2]

Pineal Tumours

Krause (1926) was the first surgeon to explore this ominous territory. He described his supracerebellar infratentorial approach in three patients and surprisingly all patients did well.[37] Van Wagenan, in 1931, described a transventricular approach, which never gained wide acceptance.[78] Walter Dandy used the parafalcine supratentorial interhemispheric approach, which was the culmination of extensive studies on experimental animals. He used either the sitting or lateral position to allow the hemisphere to fall by gravity. However, in the absence of steroids, operating microscope and advanced anaesthesia, the surgical mortality was quite high.[16] James L Poppen, in 1966, described his classical paraoccipital supratentorial approach (Fig. 12).[21,58] The introduction of the operating microscope greatly improved the quality of outcome.

Acoustic Tumours

Sir Charles Ballance was the first to successfully remove an acoustic neuroma in 1894. He used a suboccipital craniectomy and removed the tumour with a finger. The patient surprisingly survived.[6] Cushing subsequently developed the technique of subtotal internal decompression, which reduced the operative mortality significantly. Based on his experience and that of previous authors, Cushing felt that total excision should not be attempted.[11] Dandy, in 1925, developed the technique of internal decompression followed by total excision. He also described the importance of unroofing the internal acoustic meatus for complete excision. His techniques laid down the principles for contemporary acoustic surgery [Figs 13(A and B) and 14].[15] Givre and Olivecrona, in 1949, developed the technique for preservation of the facial nerve.[26] Rand and Kurze, in 1968, described preservation of both facial and cochlear nerves.[61] The

Fig. 12: James L Poppen was born in 1903 at Drenthe, Michigan. He embarked on his neurological career in 1933 at the Lahey Clinic after having completed his 2 years surgical residency at the Illinois Research and Educational Hospital. Apart from having described numerous surgical techniques and also publishing his well-known "Atlas of Neurosurgical Technique", he was highly regarded by his colleagues and residents for his unique and exceptional operative skill. He was very much appreciated for his mark of character that he had always treated the most minor operation or procedure with just as much care and dignity. One of his favourite quotes was "The same challenge exists to complete a lumbar puncture accurately and painlessly as to clip an intracranial aneurysm"

use of the middle cranial fossa approach for acoustic tumours was described by William F House in 1961.

The translabyrinthine approach for cerebellopontine angle tumours was first suggested by Panse in 1904 and then subsequently first performed by Quix in 1911 and later by Schmieglow. However, it lost its popularity after Cushing discouraged this procedure in 1921. With improvement in instrumentation and magnification, it was reintroduced by House and Hitselberger in 1960.[33]

Fig. 14: Walter Dandy

Pituitary Tumours

Harvey Cushing was the first to coin the terms hypopituitarism and hyperpituitarism. He mentioned these in his monograph on the subject in 1912. In 1932, he wrote an exhaustive review on basophilic adenomas.[11]

Trans-sphenoidal Surgery

The first successful removal through the transsphenoidal route was performed by Schloffer in 1907. Hirsch from Vienna pioneered an inferolateral endonasal approach in 1909. Harvey Cushing modified this surgery and standardised an oronasal rhinoseptal transsphenoidal approach. He used this approach for the next 20 years.[80] Norman M Dott (Fig. 15) used the same approach, which he learned from Cushing throughout his career.

Guiot from Paris learned this method, from Dott, and popularised it in Europe in the 1960s.[27] Per-operative fluoroscopy in transsphenoidal surgery was introduced by Guiot. In 1962, Jules Hardy, after having learned

AN OPERATION FOR THE TOTAL REMOVAL OF CEREBELLOPONTILE (ACOUSTIC) TUMORS*

By WALTER E. DANDY, M.D., Baltimore
From the Department of Surgery, The Johns Hopkins Hospital and University

POTENTIALLY benign lesions, usually easy of recognition, not difficult of operative approach or even of enucleation, nevertheless tumors of the cerebellopontile angle[1] have presented surgical problems which have seemed well-nigh insuperable. Surely few lesions have enticed

B

Figs 13A and B: (A) Photograph of the article by Dandy published in Surgery, Gynaecology and Obstetrics in 1925, advocating total excision of acoustic tumours. Prior to this, most of the surgeons were following Cushing's method of intratumoural decompression, as total excision was associated with high morbidity and mortality. (B) Photograph of the patient who underwent total excision of tumour by Dandy. Note the improvement of facial palsy in the photograph on the right following a spinofacial anastomosis

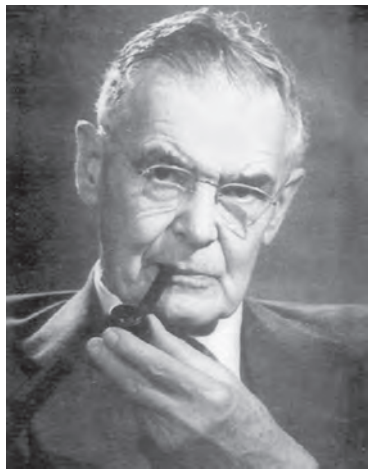

Fig. 15: Norman M Dott was born in Edinburgh in 1897 and graduated from The University of Edinburgh. He came under the influence of Harvey Cushing in 1923, when he had the opportunity to work under him at Boston under the Rockfeller Travelling Fellowship. It is interesting to note that in the initial years, he began practicing neurosurgery privately as this speciality was not recognised at Edinburgh Hospital. Among his many contributions include performing the first angiogram in the United Kingdom using Thorotrast to demonstrate a saccular aneurysm, he also worked on cerebrospinal fluid and its circulation, study of brain displacements, cerebral ischaemia, spinal cord compression, the treatment of facial paralysis by extrapetrous nerve graft and use of hypothermia during surgery. He also invented many instruments and designed operating tables and theatres

this procedure from Guiot, re-introduced it in North America. He further improved the technique by introducing per-operative fluoroscopy, the operating microscope and micro-instrumentation. He was also the first to recognise small intrapituitary lesions, which he later named as microadenomas.[27,82]

Transcranial Surgery

The subfrontal approach to pituitary tumours was devised by Krause and subsequently modified by Frazier in 1913.[23] Cushing, in later years, favoured this approach. Bronson S Ray popularised a midline subfrontal approach. The consequences of heavy retraction led Ray and Patterson to devise the pterional approach.[67,68] The subtemporal approach, initially suggested by Horsley, is used today though not frequently.[85] A large number of skull base approaches are based on this subtemporal approach.

Spinal Cord Tumours

Credit goes to Victor Horsley for having excised an intradural extramedullary tumour in 1887 at the young age of 30 years. The surgery was performed on the basis of clinical localisation by William Gowers.[17] Elsberg in his masterpiece monograph "Tumours of Spinal Cord: The Symptoms of Initiations and Compression of the Spinal Cord and Nerve Roots: Pathology, Symptomatology, Diagnosis and Treatment", emphasised on the importance of careful neurological examination and the use of spinal manometric study to establish the presence and location of intraspinal blocks. He also described a case of central cervical disc herniation usually misnamed as a "chondroma". In subsequent publications, he described in detail the clinical localisation of spinal cord and extradural tumours.[18-20] The first operative description of these tumours was accompanied by a beautiful colour illustration in Fedor Krause's masterpiece, "Surgery of the Brain and Spinal Cord". Krause referred to the mass as an "enchondroma" also a misnomer.[36] Although Cushing is given the credit for the first successful removal of an intramedullary ependymoma, the technique of intramedullary spinal cord surgery along with the management of other spinal tumours was described in detail by Charles Elsberg.[19] Rasmussen, in 1940, described the pathological features of intramedullary tumours along with surgical considerations in great detail.[65]

CEREBROVASCULAR SURGERY

Hutchison was the first physician to diagnose a saccular, non-traumatic intracranial aneurysm clinically in 1875. This was confirmed at autopsy 11 years later.[80] The development of cerebrovascular surgery would not have been possible but for the various developments which took place, including haemostatic clips by Cushing, angiography by Egas Moniz, and the use of the operating microscope.

Norman Dott performed the first planned surgery for an aneurysm in 1933. He used a muscle patch and achieved a good long-term outcome.

Walter Dandy, in 1937, clipped an aneurysm for the first time using a metal clip and shrivelled the sac with electrocautery. He also reported, in 1939, treatment of an intracavernous aneurysm by ligating the internal carotid artery in the neck, as well as intracranially, thus trapping it. However, carotid insufficiency and hemiplegia were soon noted to be the major complications of carotid ligation. Matas emphasised the importance of testing the efficiency of collateral circulation. Surgery for aneurysms developed by leaps and bounds, thanks to innovative neurosurgeons. Yasargil of Zurich, Drake of London, Ontario and Norlen of Goteborg are prominent amongst them.[49,80]

The first successful surgery for intracranial AVM was performed by Olivecrona in 1932 (Fig. 16). Results improved with the use of magnification and increased illumination provided by the operating microscope, making surgery more refined and accurate. Haemostasis improved with the introduction of bipolar forceps.[80]

In 1960, Julius Jacobson, a vascular surgeon, produced a very important paper "Microsurgery in anastomosis of small vessels". In 1967, guided by the inspiration of Prof. Donaghy, MG Yasargil of Zurich performed the first extracranial to intracranial bypass. Pool, in 1966, reported on the use of the microscope for the first

Fig. 16: Herbert Olivecrona (1891–1980) was one of the eminent students of Cushing. He was the chief founder of Swedish Neurosurgery and trained many outstanding neurosurgeons, to name a few; Wilhelm Tonnis, Sjoquist Lundberg, Lars Leksell and Edward Bucsh. Apart from doing pioneering work in vascular surgery, he developed numerous neurosurgical techniques. He was the first to excise an acoustic schwanomma, preserving the eighth nerve. Sjoquist developed medial tractotomy for trigeminal neuralgia under his guidance

Fig. 17: Wilder Graves Penfield born in 1897 at Spokane, Washington, was a man of many facets, and an excellent academic record. He graduated from Johns Hopkins Medical School in 1918. He was selected as the head of the Department of Neurology and Neurosurgery in 1928 at the McGill University at Montreal on the formation of its Neurological Centre. Apart from his numerous contributions and his pioneering work on epilepsy and brain mapping, he was the author of the novel "No Other Gods", a fictionalised version of Abraham's search for a monotheistic religion

time in aneurysm surgery. Rand had, however, used the microscope for aneurysm surgery in 1964 but had reported it only in 1967.[69,80]

SURGERY FOR EPILEPSY

Victor Horsley was the first surgeon who demonstrated that excision of a lesion responsible for focal epilepsy could lead to cure. Foerster and Penfield did creditable work in defining the structural basis of traumatic epilepsy and, in 1930, published their results with radical operations. Gibbs, Davis and Lennox, in 1935, established for the first time the correlation of clinical epileptic seizures with EEG studies. Electrocorticography was first performed in humans by Foerster in 1935 and Penfield and Jasper in 1941. Penfield was one of the chief pioneers for the development of epilepsy surgery (Fig. 17). He outlined the motor and sensory homunculus using stimulation studies in awake patients and described in detail the various types of seizure phenomenon. However, the most intriguing observation, both laudatory to reviewers and to Penfield himself, was the production of "psychical hallucinations" in the form of vivid recollections of past events on stimulation of certain areas of the temporal cortex, which threw light on the symptomatology and pathophysiology of temporal lobe seizures. He was responsible for establishing the value of cortical excision in the treatment of medically refractory focal epilepsy, especially that due to temporal lobe lesions. Falconer developed the technique of en bloc temporal lobectomy along with excision of the uncus, the hippocampus and amygdala.[32,50–55,62-64,66] In the early 1970s, B Ramamurthi introduced the concept of making lesions in the medial temporal epileptogenic areas, stereotactically.[40] Rasmussen introduced a series of modifications of the surgical technique to reduce the morbidity and mortality and improve the outcome of epileptic surgery.

SURGERY FOR MOVEMENT DISORDERS

Parkinson's observation of a patient in whom tremor disappeared following a stroke on the same side provided the idea of surgically interrupting the motor system at various levels. Victor Horsley, at the beginning of the 20th century, resected the pre-central gyrus of a boy with hemiathetosis and achieved dramatic results. Paul Bucy (Fig. 18) and his colleagues, in 1930, acquired considerable experience in unilateral subpial resection of areas 4 and 6 of the cortex in patients with various types of dyskinesias. Earl Walker was the first to suggest pedunculotomy as a mode of treatment for Parkinson's disease. In 1952, Irving Cooper, while performing a pedunculotomy, accidentally damaged the anterior choroidal artery. The surgery was terminated, but surprisingly, the patient had an excellent result. Following this, clipping of the anterior choroidal artery became an accepted form of treatment for some time, but the results were variable, as the anterior choroidal artery had a variable distribution, and it was realised that lesions in the basal ganglia may be more useful. This experience encouraged Cooper to develop chemopallidotomy.[60,80]

In 1948, Spiegel and Wycis modified Horsley's animal stereotactic apparatus and made a great advance in providing a suitable and stable stereotactic technique applicable to humans. Thus, stereotactic thalamotomy as a mode of treatment was laid on firm grounds for functional neurosurgery.[25] The globus pallidus was

Fig. 18: Paul C Bucy was born in 1904 at Hubbard, Iowa. He earned his MD and MS degrees in Neuropathology from State University of Iowa and later in 1928 joined Bailey's newly created neurosurgical staff at University of Chicago. He became in charge of Neurological Surgery at the same institute in 1939. Among his various contributions include writing of the classic volumes, "Intracranial tumours of Infancy and Childhood" and "The Precentral Motor Cortex and Neurology". He described the Kluver-Bucy syndrome in monkeys

the stereotactic target of choice for the treatment of Parkinsonian tremors in the early 1950s.[38] In 1954, Hassler and Reichert reported dramatic mitigation of Parkinsonian tremor after a lesion was made in the ventrolateral thalamus.[28] In 1949, Leksell described his stereotactic apparatus. He also developed stereotactic radiosurgery with the gamma knife.[41]

More recently, transplantation of neural tissues within the brain was described as a mode of treatment for Parkinson's disease though the concept was an old one.[43,77] Mammalian neural transplant was attempted by Thomson as early as 1890. Le Gros Clark successfully transplanted embryonic neocortical tissue in the cerebral ventricle of a six-week-old rabbit.[39] Since then, there has been an explosion of research in this field all over the world, and successful transplants into practically every region of the central nervous system have been reported both in lower mammals and primates. In India, the Department of Science and Technology[73,74] established a National Neural Transplantation Unit at the All India Institute of Medical Sciences in 1986 under Tandon and Gopinath. Bjorklund et al.[9] and Perlow et al.[56] first suggested neural transplantation for Parkinson's disease. Suspensions of chromaffin cells of the patient's own adrenal medulla were stereotactically implanted into the caudate nucleus. The transitory improvement, though it established the validity of the approach, dictated a review of strategy. Madarazo et al. from Mexico carried out open surgery where they implanted the adrenal medulla into a cavity made in the caudate nucleus and demonstrated excellent results.[46] Only a few others could duplicate the same results. After a critical review of adrenal medullary transplants in humans, Lindvall et al. concluded that there was not enough evidence to justify the claims made earlier.[44,45] For all practical purposes, this procedure has been given up now, owing to the unpredictable nature and unacceptable surgical risks. More recently, foetal substantia nigra transplants in the striatum have been shown to relieve at least partly the manifestations of Parkinson's diseases.[79,83] The latest trend is a trial of implantation of stem cells into the brain for various neural disorders. This is still experimental.

SURGERY FOR INTRACTABLE PAIN

Section of the posterior spinal roots was first performed by Bennet in 1888 for relief of pain. Foerster subsequently performed the same surgery for relief of tabetic pain. Cushing transected the spinal cord in a patient suffering from intractable pain due to metastatic malignancy.[29] Martin performed the first cordotomy in 1911. Van Wagenen and Earl Walker performed the first frontal lobotomy for relief of intractable pain.[80,85]

SURGERY FOR TRIGEMINAL NEURALGIA

Since 1880s, the standard operative approach for trigeminal neuralgia was retrogasserian neurotomy. In fact for many years, Victor Horsley used to perform the surgery at the patient's residence itself. In 1891, Frank Hartley devised an extradural temporal approach to the Gasserian ganglion. About 6 months later, Fedor Krause, unaware of Hartley's surgery, performed the same operation. Cushing modified both the techniques and reduced the mortality considerably. In 1901, Charles Frazier performed a rhizotomy using the Hartley-Krause approach. This was subsequently modified so that only differential sectioning of the sensory root was done sparing the motor root. Walter Dandy used the suboccipital approach for rhizotomy which, however, did not become very popular. Dandy, however, made a very interesting observation of the nerve being frequently compressed by a blood vessel. In 1937, Sjoquist introduced trigeminal tractotomy for relief of facial pain. In 1930, Kircshner developed the technique of percutaneous electrocoagulation of the Gasserian ganglion. Various other authors have modified and perfected this approach. Gardner, in 1959, reported treatment of neuralgia by separating the compressing blood vessel over the nerve. Jannetta subsequently developed and popularised the technique of microvascular decompression.[80,85]

PSYCHOSURGERY

The idea of psychosurgery first came to Egas Moniz in 1935 while attending the Second World Congress of Neurology. He had come there to present his pioneering work on angiography when he heard from John Fulton and his associates the effects of brain lesions on animals. On his advice, his young neurosurgical colleague, Almeida Lima, began performing frontal lobotomies. Very soon psychosurgery became an accepted mode of therapy. This work earned Moniz the Nobel Prize in 1949.[25,80,85]

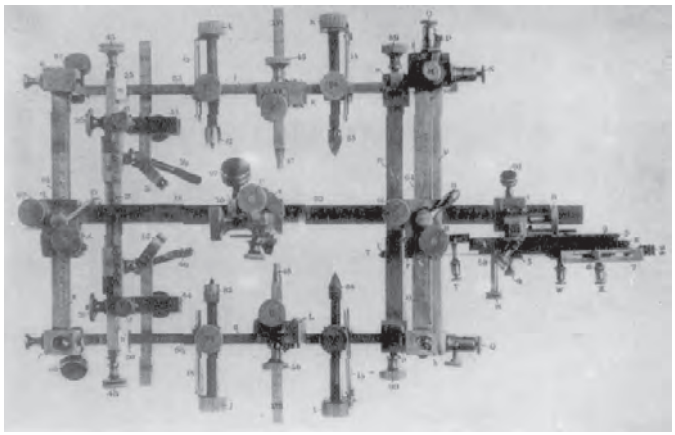

Fig. 19: Clarke and Horsley's stereotaxic apparatus—This was being used on Rhesus monkeys. Accuracy was not very good as the direction of the probe depended on the calvarial measurements, rather than in relation to the ventricles. The apparatus (only part of which is shown here) was bulky and cumbersome

STEREOTACTIC SURGERY

The concept for development of stereotaxy was born in 1908 when Horsley and Clarke (Fig. 19) designed a frame for laboratory experiments that would direct a probe to a pre-determined location in the animal's brain with the help of a previously designed brain atlas.

Even earlier to this Zernov, a Russian neurosurgeon built a guidance frame to aspirate intracranial abscesses, which he called as an encephalometer. However, stereotaxy came of age only with the pioneering work of Spiegel and Wycis who designed an apparatus, which measured distances in relation to the ventricular anatomy rather than to the calvarium. This markedly improved the accuracy. Based on the same principle, a large number of frames were created, to name a few those designed by Leksell, Riechert, Talairach, Bertrand and Narabayashi.[25] In India, Arjun Sehgal developed his own machine.

With the introduction of CT and MRI, the technique of stereotactic surgery was modified avoiding invasive investigations. With CT and MRI compatible machines, the localisation of a point in space was directed by coordinates given by computer applications. Stereotactic surgery has further advanced with the introduction of stereotactic radiosurgery and frameless stereotaxy.[25]

ENDOSCOPIC NEUROSURGERY

The concept of neuroendoscopy is not new. L'Espinasse, a virologist from Chicago, in 1910, used a small rigid cystoscope to cauterise the choroid plexus for the treatment of congenital hydrocephalus. This encouraged Walter Dandy in 1918 to develop a technique to treat communicating hydrocephalus by extirpating the choroid plexus using cystoscopes. The results were disastrous but he predicted with great foresight that this would evolve into a useful diagnostic and therapeutic tool with improvement of imaging techniques. Fay and Grant in 1923, using a small cystoscope, photographed the ventricle and choroid plexus for the first time. They also attempted to create a fistula through the corpus callosum to permit the escape of ventricular fluid into the subarachnoid space. The first successful endoscopic third ventriculostomy was reported in 1923 by Jason Mixter. Over the next few years, Putnam and Scarff reported better results with endoscopic plexus coagulation although this procedure had been abandoned earlier as a primary treatment for hydrocephalus. Renewed interest in neuroendoscopy developed with improvement of illumination, magnification and computer software along with the development of a flexible fiberoptic apparatus.[85]

DEVELOPMENT OF HIGH SPEED DRILLS

The use of drills in medical practice in fact dates back to 100 AD when Romans used a finger-operated drill to treat painful teeth. In the 18th century, a French dentist developed a drill turned by a bow, similar to the bow of a violin. A foot-powered drill for dental procedures was developed by George Greenwood in 1790. About 70 years later, George Harrington developed the first motor-driven drill for dental work, which was operated by a windup spring. George Green, a dentist in Kalamazoo, developed the first electrical dental drill and later developed an air-powered drill operated by foot bellows. In neurosurgery, Victor Horsley and William MacEwen were the first to experiment with various drills with mixed success. De Martel, in 1925, designed a cumbersome but effective drill. Jordan and Day later developed an electric drill, which operated up to 50,000 rpm. A water turbine drill, which eliminated the use of belts and gears of earlier electrical devices was devised by Nelson in 1953 at the National Bureau of Standards, this reached up to speeds of 61,000 rpm. Air-driven turbines were built independently by Iseman in 1941 and Borden in 1950. This led to the development of even higher drill speeds. Barber developed the "turbobit" in 1962 and the Robert Hall drill was introduced in 1963. After many modifications of the "turbobit", a vane-type motor was introduced in 1967 by the Midas Rex Company, which remains the standard against which all other high-powered pneumatic drills are measured.[81,85]

Neurosurgery is a rapidly evolving speciality today. Many people have contributed various developments painstakingly over many years. Its development is still very much in the steeper part of the learning curve and we are fortunate to have been born to witness this era of change. Let us experience, enjoy and contribute towards this change.

2 History of Microneurosurgery

Thimmappa Hegde, Sarat Chandra P

Modern neurosurgery came of age with the advent of microneurosurgery. The development of the operating microscope opened a whole new world of anatomy. The history of microneurosurgery is not complete without mentioning the pioneering work of various anatomists whose painstaking work laid down the foundations for the development of microneurosurgery.[33]

Galen and Vesalius were the first to mention about the membranes over the brain. Vieussen, in 1690, described in detail the pia and arachnoid membranes. Ruysch, in 1697, showed that the arachnoid extended over the convexity of the brain. Pacchioni (Fig. 1), in 1729, recognised the fluid around the brain, but this was considered to be pathological until 1770, when Cotuguo showed that its presence was physiological. In 1802, Bichat showed that the arachnoid formed a serous cavity similar to the peritoneal cavity. Magendie (1822) gave the first detailed description of the subarachnoid space containing cerebrospinal fluid that circulates under pressure and perfuses the entire surface of the brain. Various anatomists like Kolliker (1850), Virchow (1854) and Luschka (1855) later confirmed this.[33] In 1875, Key and Retzius published a monumental work in which there are detailed diagrams of the subarachnoid space injected with a blue dye, Berliner-Blau. Much more surprisingly, they demonstrated that even the subarachnoid space was compartmentalised and demonstrated the relationship of cerebral vessels to the arachnoid and numerous trabeculae suspending these vessels from the walls of the cisterns. The importance of such intricate anatomy was only realised after the development of microsurgical techniques.

Fig. 1: Antonio Pacchioni was an Italian anatomist who described the dura mater, along with small bodies adjacent to the sinuses which bear his name. He published many anatomical plates in collaboration with Malpighi and Eustachius. He believed that the dura mater was a muscular tissue which served to push the nervous fluid to the periphery and considered cerebrospinal fluid as pathological

In the contemporary period, the contribution of Albert L Rhoton cannot be ignored. Even though a neurosurgeon, he is best known for his articles along with excellent drawings on microsurgical anatomy demonstrated on cadavers.[3,7,10,15,17,18,22,24-29] Bisaria from India gave a detailed description of the microsurgical anatomy of the posterior communicating artery along with its anomalies.[1] His work was among the first from our country to provide a detailed study on cerebral microsurgical anatomy.

In the mid 1950s Leonard Malis found the microscope helpful in experiments on the cerebral cortex of cats.[5] He observed that surgical trauma was much less when he used a microscope. Also, along the way, he modified the bipolar coagulator developed by James Greenwood and this later came to be known as Malis bipolar coagulator.[9]

Loughead and Tom, in 1960, began using a microscope for experimental studies on the effect of subarachnoid blood on blood vessels of dogs.[16] Almost simultaneously, Theodore Kurze along with William House demonstrated the importance of the microscope in operating on acoustic schwannomas.[5] Julius Jacobson, in 1960, published a landmark paper "Microsurgery in anastomosis of small vessels" in Surgical Forum, which outlined the importance of the use of the surgical microscope in neurosurgery.[12] Nothing can overstate the contribution of MG Yasargil to the cause of microneurosurgery. He was instrumental in popularising the concept of total microsurgery and in the development of microscopes and microsurgical instruments.

In India, microneurosurgery had a late start. Although Dr Ramamurthi was well versed with microsurgical techniques (having attended the microvascular workshop in 1969 at Burlington arranged by Dr Donaghy), he concentrated more on the development of stereotactic surgery without actually realising the enormous future possibilities of microsurgery in India. The other

problems facing our country included the difficulty of procuring a good microscope and the resistance by other practicing physicians to accept microneurosurgery. In 1973, Huw Griffith of Bristol demonstrated the transethmoidal approach to the pituitary fossa at the Institute of Neurology, Madras, using a locally manufactured operating microscope. Professor HW Pia and Professor E Grote from Giessen W Germany, conducted workshops at New Delhi and Mumbai in 1978 to strengthen microneurosurgery for more regular use. Several years before this, a beginning of microsurgery, using an indigenously built microscope, had already been made at the AIIMS. The first Indian paper on the subject was published in 1977.[22] Since then, there has been a slow but steady progress.

DEVELOPMENT OF VARIOUS MICRONEUROSURGICAL TECHNIQUES

Aneurysms

Perhaps in no other area were microsurgical techniques more effectively applied. Pool and Cotton, in 1966, published their encouraging experience with the use of the operating microscope during aneurysm surgery.[21] Even earlier to this, Robert Rand operated on an aneurysm under the microscope in 1964.[23] Adams and Witt published their experience on intracranial aneurysm surgery with the use of the microscope.[5] Charles Drake published his experience with aneurysms of the posterior circulation in 1965 and excellently documented his subsequent improvement[6] (Fig. 2). In 1965, Yasargil (Fig. 3), then Assistant Professor of Neurosurgery, along with his teacher Professor Krayenbuhl (Fig. 4), started performing microsurgery in the laboratory.[4] The magnitude of initial difficulties can be comprehended by Yasargil's frustration and conclusion at one time that microsurgery was not practical and more time should not be wasted on it! From this stage, he moved towards perfection. In 1973,

Fig. 2: Charles G Drake was born in 1920 at Windsor, Ontario and received his medical education from The University of Western Ontario. He received his neurosurgical training at Toronto General Hospital, under the supervision of McKenzie and Botterell, who encouraged him to focus his energies on management of aneurysms and arteriovenous malformations. Since then, he operated on more than 1000 aneurysms, 60% of which were in the vertebrobasilar territory. In collaboration with Allcock and Aitken he did pioneering work on vasospasm and stressed the usefulness of magnification and illumination. He openly shared his failures and successes which provided useful learning for others

Fig. 3: M Gazi Yasargil was born in 1925 at Lice, a village in Eastern Turkey. He did his medical schooling from Frederick Schiller University in 1944 and later transferred to Basel, Switzerland, from where he obtained his medical degree in 1950. He was very much influenced by Professor Hugo Krayenbuhl who headed Neurosurgery at University of Zurich. His interest in microvascular surgery encouraged Krayenbuhl to send him to the Microvascular Laboratory at the University of Vermont where he painstakingly learned the methods of various microvascular techniques. He will be perhaps ever be remembered for his excellent study on various subarachnoid cisterns[3]

Fig. 4: Hugo A Krayenbuhl was born in 1902 at Zihlschlacht, Switzerland and received his neurological training under the guidance of the outstanding German neurologist Karl Bonhoeffer and later worked under Sir Hugh Cairns, the eminent pupil of Harvey Cushing. In addition to the large number of publications, he was the author of the book "The Cerebral Angiography" along with Yasargil and undoubtedly neurological surgery in Switzerland owes its high level of competence to this surgeon

upon Krayenbuhl's retirement, he was elected Professor Ordinarius of neurosurgery at University of Zurich and director of the Neurosurgical Clinic at Kantonsspital in Zurich. From then onwards, he continued to amass the largest experience on microneurovascular surgery in the world. His monographs on microneurosurgery, along with his excellent anatomical description of the various subarachnoid spaces are considered as classics in contemporary neurosurgical literature.[33]

Arteriovenous Malformations

In 1965, Yasargil invited Robert Rand to join him in an operation upon a patient harbouring an arteriovenous angioma of the spinal cord.[5] This surgery was performed with the aid of the surgical microscope and the Malis bipolar coagulator, which greatly increased the precision and ease. Since then, a large number of microsurgeons from Europe, Japan and America have contributed in evolving the various techniques in surgery of arteriovenous malformations. Malis was one of the surgeons who suggested the useful technique of following a venous structure back to its origin at the centre of an arteriovenous malformation.[5]

Arteriovenous Fistulas

Carotico-cavernous fistulas were being treated in the 1930s by simple ligation of the cervical carotid artery. This was obviously not always successful. Subsequently, embolisation with a number of materials including skeletal muscle, gelatin sponge and plastic was tried. Serbinenko[31] and Mullan[19] reported balloon embolisation. In 1973, Dwight Parkinson reported his famous case of direct surgical closure of the rent under conditions of cardiac arrest.[20] Dolenc has performed this surgery by temporarily interrupting the carotid intracranially, thus making cardiac arrest unnecessary.[5]

Occlusive Cerebrovascular Surgery

Attempts to revascularise areas of ischaemic brain dates back to the 1930s. From then onwards, various surgeons performed surgical procedures, consisting of placing pedicled muscle grafts or omental patches over the cortical surface.[8,11,14] This met with limited success.[5]

In 1960, Jacobson and colleagues performed the first embolectomy in a patient using the operating microscope.[13] Patency was, however, not established adequately. Over the next few years, more than half a dozen cases of embolectomy were reported with only limited successes. Shelly Chou[2] performed the first totally successful embolectomy at the University of Minnesota in 1963. In the same year, Woringer and Kunlin sutured a saphenous vein graft between the internal carotid artery in the neck and the supraclinoid carotid artery.[32] Since then, many authors have performed this procedure. In 1965, Yasargil performed for the first time successful anastomosis between the superficial temporal artery and the middle cerebral artery in a dog. Donaghy and Yasargil performed this procedure for the first time on a human being in 1967. In both the patients the anastomosis remained patent.[5] Speculative debate regarding the rationale for and against EC-IC bypass has been reduced sharply by the emergence of data from the EC-IC bypass multicentric study in 1985. There has been widespread criticism that this study has been biased in many ways and that the conclusions are not fully relevant and that ST-MC or EC-IC bypass surgery has unfortunately been not practised enough to help deserving patients.

Peripheral Nerve Surgery

In 1964, Chaffee and Numoto demonstrated a more complete return of motor units, when the sciatic nerve of rats was sutured under the microscope, rather than with the naked eye.[5] Exceptional work was done in peripheral nerve injuries by Madjid Samii who demonstrated very high recovery rates.[30] David Kline from America, in collaboration with various plastic and orthopaedic surgeons, reconfirmed the usefulness of the microscope.[5]

Microneurosurgery is not just limited to the areas mentioned above but has also been effectively applied to surgeries for acoustic tumour, para-third ventricular tumours, sellar/suprasellar areas, anterior cervical microdiscectomy, intramedullary spinal tumours and skull base surgery, to mention a few. The techniques have developed and evolved from surgeon to surgeon and from generation to generation. Over the course of time microneurosurgery developed its own unique methods, standards and rules different from any other surgical branch.

Diagnostics

Santhosh Joseph

3 Electrodiagnosis

Manjari Tripathi, Priya Gupta, Sarat Chandra P

As of today, there are a number of diagnostic procedures available both outside as well as inside the operating room utilising electrodiagnostic techniques. As these techniques are more commonly used, it becomes imperative for the practising neurosurgeon to be at least familiar with the basic techniques, their indications and interpretations. This chapter provides a brief review of all the existing techniques.

MUSCLE AND NERVE ELECTROPHYSIOLOGIC STUDIES

Electromyographic evaluation in combination with nerve conduction studies is the gold standard for assessing the neurophysiologic characteristics of neuromuscular diseases.

Electrodiagnosis, as an extension of the neurologic examination, employs the same anatomic principles of localisation, and searching for evidence of motor and sensory compromise.

Nerve Conduction Studies

Physiologically, the nerve transmits an electrical impulse across its axon both antidromically and orthodromically. Each stimulus has a proximal as well as distal transmission. This property is used to assess compound muscle action potential (CMAP), sensory nerve action potential (SNAP), F response, H reflex and SSR. Each potential is described by its latency, amplitude, area and configuration. To obtain the velocity, the nerve is stimulated at two different sites and recording is done on the same muscle, and the difference in response latency is multiplied by the distance between these two stimulation sites.

Definition of Related Terms

Latency: This is the time in milliseconds from the application of a stimulus to the initial deflection from the baseline either positive or negative, and is the time required for the action potentials in the fastest conducting fibres to activate the muscle fibres (Fig. 1).

Conduction velocity: It is calculated by measuring the difference in distance and latency between sites of stimulation in metres per second.

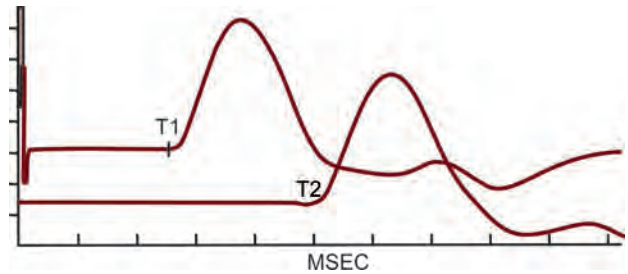

Fig. 1: Response latencies from stimulation of the median nerve at the wrist (T1) and elbow (T2)

Amplitude: It is measured in height in millivolts from the baseline to the peak of the negative phase (upwards deflection). It is proportional to the number of muscle fibres activated and gives an estimate of the amount of functioning nerve and muscle.

F response: It results from the backfiring of antidromically activated anterior horn cells. It is especially helpful in assessment of motor conduction of the proximal segment of a stimulated axon along with the entire length of the peripheral axon (Fig. 2).

H reflex: It is an electrically elicited spinal monosynaptic reflex and bypasses the muscle spindles. The group 1A sensory fibres and alpha motor neurons form the respective afferent and efferent arcs of this reflex. The H reflex latency and amplitude are helpful in diagnosis of mild S1 radiculopathy (Fig. 3).

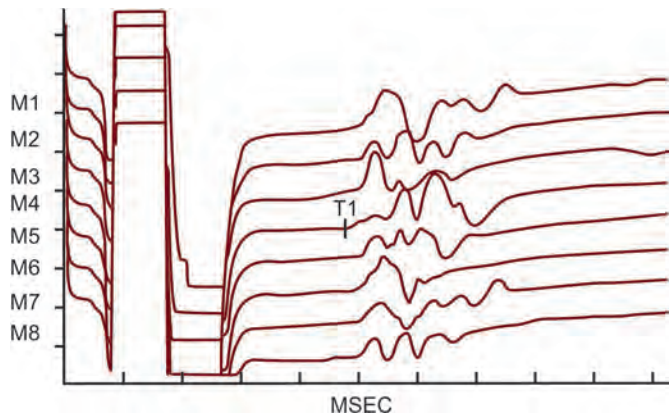

Fig. 2: Typical F-wave responses recorded from the abductor pollicis brevis with median nerve stimulation at the wrist

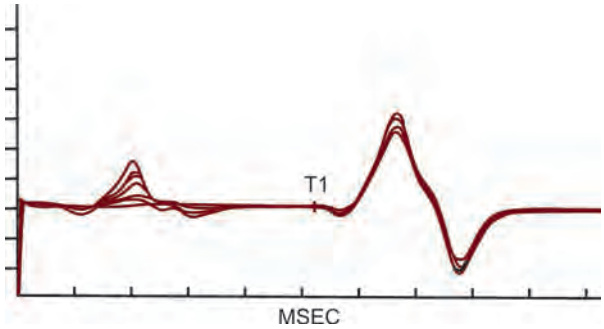

Fig. 3: Typical H-wave reflex (second peak)

Types of Neuropathy

The following are the types of neuropathy:

- *Demyelinating neuropathy criteria*: Distal latency (DL) greater than 125% of upper limit of normal (ULN) and nerve conduction velocity (NCV) less than 80% of lower limit of normal (LLN).
- *Axonal neuropathy*: Decreased CMAP/SNAP amplitude with either normal or mild prolongation of DL, and normal or mild slowing of NCV.
- *Mixed demyelinative/Axonal neuropathy*: Demyelination is present if—
  NCV < 80% (LLN) if amplitude > 80% (LLN)
  NCV < 70% (LLN) if amplitude < 80% (LLN)
  Distal latency > 125% if amplitude > 80% (LLN)
  Distal latency > 150% if amplitude < 80% (LLN)

Technical Limitation while Interpreting Nerve Conduction Study (NCS)

- *Nerve conduction study (NCS) adds to the clinical diagnosis*: It means if there were no symptoms or definite signs then most of the time NCS should be normal, and if it is abnormal in the absence of signs of any disorder the findings should be interpreted only after correcting technical limitations.
- *Age*: Decreased amplitude of sural SNAP is seen in almost 25% of individuals older than 65 years. The CMAP amplitude may also be in the lower range of normal.
- *Temperature changes the latency and conduction velocity*: Lower temperatures slow down impulse propagation, thus increasing distal latency and increase the amplitude of nerve and muscle potential. The conduction velocity increases almost linearly, by 2.4 m/s, or approximately 5% per degree, as the temperature measured near the nerve increases from 29°C to 38°C. Conduction velocity changes nonlinearly with increase in skin temperature, showing a more pronounced effect in the lower temperature range.[47]
- Inappropriate placement of recording electrodes can change the waveforms, e.g. mixing of ulnar-related waveforms while recording on APB for the median nerve.
- *Submaximal stimulus*: Usually a motor potential requires 200–300 mV of stimulus and sensory 150–250 mV and submaximal stimulation can lead to decreased amplitude of CMAP/SNAP.
- In case NCS shows axonal neuropathy of the common peroneal (CP) or posterior tibial (PT) nerves in an asymptomatic individual then always look for atrophy of the extensor digitorum brevis (EDB) or abductor hallucis brevis (AHB).
- In bare foot persons, there is atrophy of the EDB and CP-CMAP amplitude is thus reduced. In such cases, CP-CMAP on the tibialis anterior should be performed.
- Presence of fat, oedema and an open wound interferes in the recording and leads to false values.
- Normal anatomical variations, e.g. Martin Gruber anastomoses (MGA), may, in some individuals, lead to decreased amplitude in NCS in the hypothenar muscles on stimulation of the ulnar nerve at the wrist and elbow.[35]

Important Points to Remember

- Do not trust electrophysiological studies (EPS) if they do not match your clinical examination finding.
- The role of EPS is to corroborate clinical history and examination, and is not a substitute for the latter.
- While interpreting NCS, normative data of the concerned laboratory should be available before interpretation.

Electromyography

The pattern of electrical activity in muscle [i.e. electromyography (EMG)], both at rest and during activity, may be recorded from a needle electrode inserted into the muscle. The nature and pattern of abnormalities relate to disorders at different levels of the motor unit. Before planning to start EMG, the clinician should have relevant NCS and clinical details of the patient.[34]

Electromyography Findings

At rest:

- Insertion activity
- Spontaneous activity.

At voluntary movements:

- Assessment of individually recruited motor unit action potential (MUAP)
- Size
- Shape
- Stability
- Assessment of activation pattern of MUAPs
- Recruitment
- Interference pattern (IP).

Insertional Activity

It is a single burst of activity arising when the needle is inserted, slightly outlasting the moment of the needle insertion. It is thought to occur due to mechanical stimulation or injury of the muscle fibres. It lasts for a few hundred milliseconds, usually 300–500 ms. They appear as a cluster of positive or negative repetitive

high-frequency spikes, which make a crisp static sound over the loudspeaker.

Increased insertional activity indicates instability of the muscle membrane indicating:

- Denervation, usually an early finding 1–2 weeks after nerve injury
- Myotonic disorders
- Necrotising myopathies, such as inflammatory myopathies.

Decreased insertional activity suggests either fibrotic or severely atrophied muscles or functionally unexcitable muscles (e.g. during attacks of familial periodic paralysis).

Spontaneous Activity

Normal

- Normally no spontaneous activity is seen except at the motor endplate region.
- Two types of normal endplate spontaneous activity are present. (1) Endplate noise and (2) Endplate spikes.

Abnormal

- Fibrillation potentials
- Fasciculation potentials
- Complex repetitive discharges
- Myotonic discharges
- Myokemic discharges
- Neuromyotonic discharges
- Cramps.

Endplate noise: These are extracellularly recorded miniature endplate potentials and non-propagating depolarisations. It is caused by spontaneous release of acetylcholine quanta. These are negative potentials, irregular in rhythm, with amplitude of 10–50 uV and duration of 1–2 milliseconds (sounds like a "sea shell held to the ear").

Endplate spikes: These are discharges of single muscle fibres generated by activation of intramuscular nerve terminals irritated by the needle. They may originate in the intrafusal muscle fibres. They are irregular having an initial negative deflection, firing at 5–50 impulses per second, with amplitude of 100–200 pV with duration of 3–4 milliseconds (sounds like "clacking or buzzing").

Fibrillation potentials: These are spontaneous action potentials of denervated single muscle fibres. They result from the resting membrane potential of the denervated fibre and usually appear 10–21 days after muscle denervation. They are brief spikes (usually triphasic with initial positivity) or positive waves (initial positivity with slow negativity, sawtooth appearance), fire regularly at 1–30 Hz, with an amplitude of 20–200 pV; gradually decreasing with time, with a duration of 1–5 milliseconds (sounds like "crisp and clicking" and "tick-tock of a clock").

Causes

- *Common*: Denervation; Based on their distribution, useful in localising lesions affecting motor neurons, spinal roots, plexus or peripheral nerves; late in the course of denervation, muscle fibres that are reinervated, fibrotic or severely atrophied show no fibrillation potentials.
- May persist in paraspinous muscles for years after surgery.
- Inflammatory myopathy.

A grading system is used (from 0 to 4) to semiquantitate fibrillation potentials as their density is a rough estimate of the extent of denervated muscle fibres:

0 no fibrillations
+1 persistent single trains of potentials (> 2 seconds) in at least two areas
+2 moderate number of potentials in three or more areas
+3 many potentials in all areas
+4 abundant spontaneous potentials nearly filling the oscilloscope.

Fasciculation potentials: Fasciculation potentials are spontaneous discharges of a motor unit. They originate from the motor axon anywhere along its length. Their size and shape are like MUAPs, have an irregular rhythm and a lower firing rate than voluntary MUAPs (sounds like "corn popping").

Causes

1. Diseases of anterior horn cells (MND)
2. Radiculopathies
3. Entrapment neuropathies
4. Peripheral polyneuropathies
5. Cramp fasciculation syndrome
6. *Others*: tetany, thyrotoxicosis and overdose of anticholinesterase medication.

They may also occur in healthy people. Benign discharges tend to fire more quickly, whereas grouped fasciculation potentials from multiple pairs are more common in MND.

The association of fasciculation potentials with fibrillation potentials or other neurogenic MUAP changes is strong evidence of a lower motor neuron disorder.

Complex repetitive discharges: These result from the nearly synchronous firing of a group of muscle fibres. One fibre in the complex serves as a pacemaker, driving one or several other fibres so that the individual spikes in the complex fire in the same order as the discharge recurs. One of the late-activated fibres re-excites the principal pacemaker to repeat the cycle. They are shaped containing 10 or more distinct spikes, regular in rhythm, firing at 5–100 Hz, typically begin abruptly, with an amplitude of 50 pV–1 mV, with a duration of 50–1000 milliseconds (sounds like "machine gun" on the loudspeaker).

Complex repetitive discharges are non-specific and seen in many chronic disorders, including chronic neuropathies and myopathies. They may also be found in the iliopsoas or cervical paraspinal muscles of apparently

healthy people, probably implying a clinically silent neuropathic process.

Myotonic discharges: Abnormal insertional activity of recurring single-fibre potentials wax and wane in the range of 10 LIV–1 mV, varying inversely with the firing rate of 20–150 Hz (accelerating or decelerating motorcycle or chainsaw). Myotonic discharges may occur with or without clinical myotonia in the myotonic dystrophies (types I and II) and other myopathies.

Myokymic discharges: These originate ectopically in motor nerve fibres and result from complex bursts of grouped repetitive discharges in which motor units fire repetitively, usually with 2–10 spikes with a firing rate of 30–40 Hz, each burst recurs at regular intervals of 1–5 seconds (sounds like "marching soldiers" on the speaker).

Neuromyotonic discharges: Here, the muscle fibres fire repetitively at high frequency (150–250 Hz) and produce a pinging sound on the speaker. They continue during sleep and diminish in intensity with distal nerve blocks.

Cramp discharges: These include sustained involuntary muscle contraction during cramps. The discharge consists of MUAPs, with a firing rate of 40–60 Hz, with abrupt onset and cessation.

Motor Unit Action Potentials

The MUAP is the extracellular electrode recording of a small portion of a motor unit. They are triphasic in shape, measured as total peak-to-peak amplitude. It normally varies from several hundred microvolts to a few millivolts.

Duration: It is measured from the initial signal's deviation away from the baseline to the final return to baseline. It indicates the degree of synchrony among many individual muscle fibres and is a rough indicator of the number of fibres in a motor unit. It normally varies 5–15 milliseconds.

Long-duration MUAPs with high amplitude are best indicators of reinnervation.

Short-duration MUAPs with low amplitude are seen in disorders associated with loss of muscle fibres, like myopathies.

Phase: This is the deviation of the signal from its beginning until its return to the baseline. The phases equal the number of negative and positive peaks extending to and from the baseline, or the number of baseline crossings plus one. A MUAP having more than four phases is considered polyphasic. Around 5–15% of MUAPs may have five or more phases and proximal muscles may have around 25% MUAPs with five or more phases. Increased polyphasics is a nonspecific abnormality seen both in myopathies and neuropathies.

Late component (satellite or linked potential): This is a time locked waveform to the main MUAP, but separated from it by an isoelectric interval. (The duration measure does not include such potentials.) It implicates early reinnervation of muscle fibres by collateral sprouts from adjacent motor units.

Complexity: The MUAP with greater than 4 phases or a satellite potential is said to be complex.

Variability: These include changes in shape of the MUAP on consecutive discharges. It indicates deficient neuromuscular transmission. They may indicate NMJ disorder, MND, polyneuropathy or radiculopathy and early stage of reinnervation.

Characteristics of Activation Pattern of Motor Unit Action Potentials

Recruitment

Normally only 1 or 2 motor units excite semirhythmically during constant contraction. At greater muscle force, additional units are recruited and previous units fire more rapidly. The firing frequency of a motor unit, when additional units are being recruited, is known as *Recruitment frequency*. In normal muscles, mild contraction induces isolated discharges at a rate of 5–10 Hz. *Recruitment ratio* is the average firing rate divided by the number of active units, which should not exceed five. *Reduced recruitment* is seen in lower motor neuron weakness and advanced myopathies with extensive muscle loss. *Early recruitment* is seen in myopathy.

Interference pattern (IP): It is the pattern of discharge of motor units firing rapidly on applying increasing force so that individual MUAPs are not recognisable. It depends upon descending inputs from the cortex, number of motor neurons capable of discharging, firing frequency of each motor unit, waveform of individual potentials and phase cancellation. Incomplete interference pattern is seen in poor voluntary effort or upper motor neuron disorder, and with reduced recruitment.

Electrodiagnostic Findings in Nerve Injury

The electrodiagnostic findings (EDX) provide information about:

- Site of the injury
- Underlying pathophysiology
- Rate of recovery.

Timing of the Test is Important

If performed too soon after the injury, there may not have been sufficient time for EDX signs of axon damage to develop so it cannot be determined whether a nerve lesion is caused primarily by demyelinating conduction block or axon loss.

In the case of a severe axon loss injury (axonotmesis and neurotmesis), CMAPs and SNAPs are entirely normal for the first 2 days despite the presence of an obvious clinical deficit and an inability of the patient to voluntarily recruit motor units during EMG.

By day 3, wallerian degeneration starts causing some loss of the distal CMAP amplitude.

By day 9, the CMAP is further diminished and may even disappear.

By days 11–12, the SNAP amplitude is also diminished (the reason for the earlier loss of CMAP amplitude relates to the early failure of neuromuscular junction transmission).

Finally, after a few weeks, there is evidence of active denervation in the form of fibrillation potentials and positive sharp waves during EMG.

If the lesion is caused by conduction block (neuropraxia), significantly (e.g. > 50%) lower proximal as compared with distal CMAP amplitude, with abnormal neurogenic MUAPs or even their complete absence can be seen.

The distal CMAP amplitude (if stimulating and recording beyond the site of conduction block) should be within normal limits in cases of conduction block. There may be a limited amount of axon loss if injury has occurred to some axons at the site of the conduction block. Therefore, there may be some positive sharp waves or fibrillation potentials on NEE. It is important to remember that many nerve injuries involve components of both conduction block and axon loss.

There is no way to clearly differentiate a predominantly demyelinating conduction block process from an axon loss lesion on the basis of clinical symptoms, signs or of an EDX performed within 7 days of the injury.

An avulsion injury that involves both anterior and posterior preganglionic segments may produce a characteristic EDX pattern involving loss of CMAP amplitudes but preservation of SNAP amplitudes. This is because the lesion affects the dorsal root proximal to the ganglion that lies outside the spinal canal in the intervertebral foramen.

A repeat examination should always be performed to assess for electrophysiological recovery or worsening. One must assess for recovery of SNAP and CMAP amplitudes; during regeneration the SNAP amplitude characteristically recovers before the motor amplitude.

Furthermore, one may appreciate some degree of normalisation of motor unit recruitment and morphology. One particularly important EMG feature is the appearance of low-amplitude, polyphasic, unstable nascent motor unit potentials, which is important EDX evidence of early motor unit reinnervation. Some of the important features of the various types of nerve damage are discussed here.

Neuropraxia

- No axonal degeneration, only conduction block: focal site of demyelination.
- Aetiology: Compression or traction injury.
- Large myelinated fibres are more susceptible to compression and ischaemia (motor).

EDX

- Nerve conduction is normal distally, but altered across the injury site (consider axonal loss if amplitude decreased proximally and distally).
- Needle EMG shows decreased recruitment, but no abnormal spontaneous potentials.
- Normal conduction returns in days/weeks (due to remyelination of the damaged segment).

Axonotmesis

- Axonotmesis implies axon damage with preservation of the endoneurium, perineurium and epineurium, and there will be wallerian degeneration of the axon.
- Motor NCS lost day 4–7 (NMJ fragmentation).
- Sensory NCS lost day 8–10.
- Preservation of endoneurium allows for regeneration with reinnervation.
- Recovery time dependent on distance for reinnervation.

EDX

- Day 0–3: same as neuropraxia.
- Day 4–7: decreased motor amplitude.
- Day 8–10: decreased sensory amplitude.
- Day 10–14: abnormal spontaneous potentials on EMG (PSW, Fibs).
- Month 6–12: "nascent pot's (S > M) and "jitter".
- Performing EDX too early may lead to misleading information (wait 2–4 weeks).
- An early sign of axonotmesis is decreased CMAP amplitude (30–40% lower than the contralateral side).
- Repeat testing will be required in about 2–3 weeks.

Neurotmesis

- Disruption of axon, endoneurium and connective tissue (perineurium and epineurium).
- Poor prognosis for reinnervation.
- EDX finding are same as above.
- Findings for entrapment neuropathy [carpal tunnel, thoracic outlet syndrome (TOS)] are discussed elsewhere.[25,58,61]

EVOKED POTENTIALS

Sensory Evoked Potentials

Recording of spinal or cerebral potentials elicited by stimulation of specific afferent pathways helps in monitoring the functional integrity of these pathways although it does not indicate the pathologic basis of lesions involving them.

Somatosensory-Evoked Potentials

The somatosensory-evoked potentials (SEPs) are obtained by multiple electrical stimulations of peripheral nerves. The electrical signals generated are measured at the level of the peripheral nerves (over the brachial plexus or popliteal fossa), spinal cord (lumbar as well as high cervical), and cortex (scalp). These recordings are made over the scalp and skin on the neck and the back (over the spinous processes of the vertebrae) to monitor these signals in the cortex and the spinal cord.

This method relies mostly on the stimulation of the large myelinated somatosensory fibres, which transmit the impulses to the spinal cord by the posterior column system.

Median nerve stimulation at the wrist or posterior tibial nerve stimulation at the popliteal fossa or medial malleolus (ankle) is commonly used.

These evoked potentials (EPs) are so small compared to the background EEG activity that the responses to a number of stimuli have to be recorded and averaged with a computer in order to permit their recognition and definition. The background EEG activity, which has no fixed temporal relationship to the stimulus, is averaged out.

Methodology[1]

- Electrode sites on the scalp are marked using the 10–20 international system (Figs 4A and B). The recording sites preferred by the authors are C3, C4, CZ, FPZ, FZ, A1 and A2.
- The recommended stimulus is a monophasic pulse of 10–20 mA and 100 μs duration.
- The stimulus is applied to the median nerve at the wrist or the posterior tibial nerve at the ankle near the site where the nerve passes posterior to the medial malleolus. Spinal cord intra-operative SEP monitoring often involves the posterior tibial nerve; but, when surgery is above the eighth cervical spinal cord level then median nerve intra-operative SEP monitoring is used.
- Rates of stimulation of 5 Hz for median nerve and 2 Hz for the posterior tibial nerve have been used. Each limb should have evoked potential testing separately. Generally, 350–500 repetitions are generated, but up to 2,000 repetitions may be necessary.
- An analysis time of 30–120 ms is sufficient for this type of testing.
- The filter settings undertaken are 30 Hz (low pass) and 3,000 Hz (high pass).

Role of Somatosensory-Evoked Potential in Neurosurgical Diseases

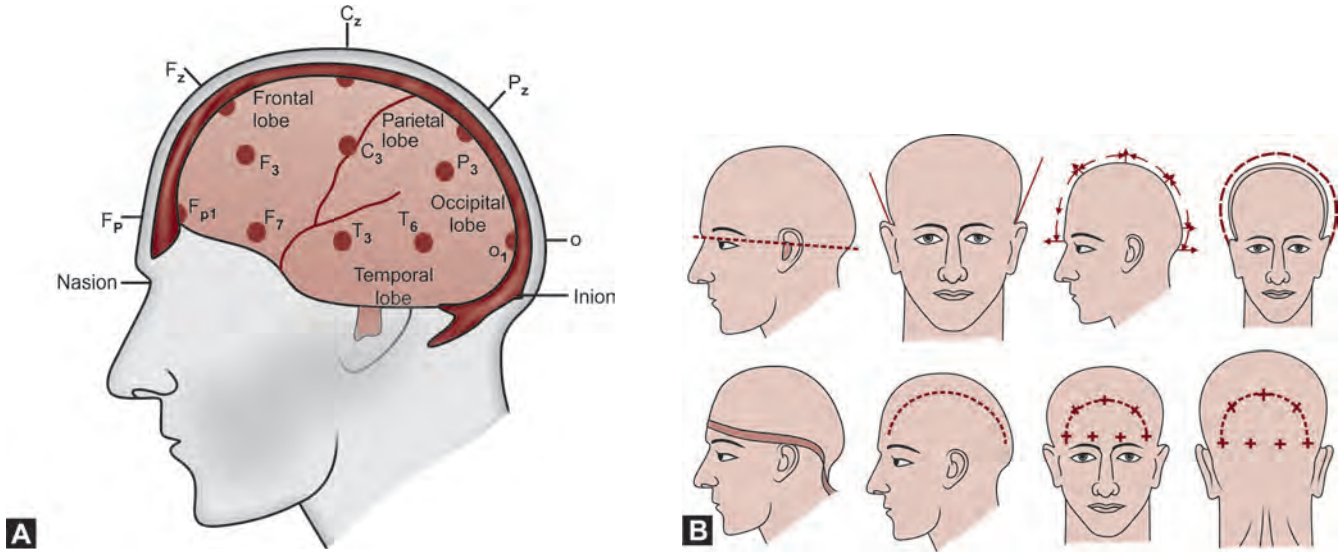
- Disorders of the peripheral nerves
- Plexus lesion
- Radiculopathy
- Thoracic outlet syndrome
- Cervical myeloradiculopathy
- *Malingering*: Some patients have sensory symptoms but no objective clinical deficits, suggesting that symptoms may not be organic in origin. In such a circumstance, an abnormal SEP indicates that symptoms have an organic basis.[43]
- Intra-operative assessment of the functional integrity of neural pathways.

Intra-Operative Monitoring

This consists of monitoring and continuous 'on-line' assessment of the functional integrity of neural pathways and mapping (functional identification and preservation of anatomically ambiguous nervous tissue) techniques.

Intra-operative SEPs are obtained by repetitive measurement of SEPs in order to monitor functionality of the posterior spinal cord tracts, resulting in detection of spinal cord damage during surgery and prevention of post-operative neurologic deficits.

Monitoring provides services beyond simply warning of ensuing complications. It offers insight towards prompt intervention. A surgeon can feel reassured about the integrity of the spinal cord and can, therefore, extend



Figs 4A and B: (A) Actual representative areas of the brain in the 10-20 system. (B) Landmarks and measurements of the 10-20 system

the procedure to a greater degree. Further, some patients may receive procedures that would have been avoided in the absence of such feedback about the status of the nervous system. Surgical correction of scoliosis is the most common procedure for which intra-operative SEP monitoring is used.

Limitations of intra-operative SEP monitoring include its monitoring only the posterior-column somatosensory system and the input being provided when the actual damage may have already taken place.

Abnormality Criteria

It is important to obtain baseline data, including pre-incision tracings and early (surgical site preparation) intra-operative data. All subsequent data, as collected, are then compared to the baseline findings. The subjects serve as their own 'internal' control.

The patient's underlying condition may prevent the recording of intra-operative SEPs in 5% of the cases. The most frequent conditions leading to the problem of poor data acquisition are neural tube defects and severe spastic quadriparesis with atrophy of the lower extremities.

Other disorders associated with unrecordable intra-operative SEPs include:

- Sequelae of spinal cord trauma
- Advanced spondylosis with myelopathy
- Scoliosis with myelopathy
- Peripheral neuropathy
- Spinal cord tumour.

Abnormality criteria for intra-operative SEPs include: (1) potentials to be monitored (cervical and cortical); (2) increase in latency equals more than 10% of the baseline value and (3) decrease in amplitude is greater than 50%.

Transient and relatively less significant changes in the amplitude (30–50% of baseline) or latency (< 2 ms) of intra-operative SEPs may be seen during surgery due to hypotension, haemodilution, hypothermia or irrigation with cold saline. Return to the baseline values is seen when these alterations are corrected. These alterations often occur gradually over a period of 30–60 minutes.

More significant changes, such as intra-operative SEP amplitude reductions of greater than 50% of baseline or increases in latency of less than 2 ms, tend to be acute and not associated with any change in temperature, blood pressure or the amount of anaesthetic administered.

It is important to note that increasing concentrations of halothane can quickly produce a decrease in the amplitude of the cortical potentials, which is directly proportional to the end tidal concentration of that gas. Patients less than 10 years old are particularly susceptible to the effect of high concentration or boluses of general anaesthetics producing attenuation of the cortical potentials. Cortical potentials in children are also more likely to be attenuated by a combination of anaesthetics, such as isoflurane and nitrous oxide, especially in high doses.

The best scalp recordings are obtained by avoiding the combination of anaesthetics or keeping the concentration of nitrous oxide at less than 50% and isoflurane at less than 0.6% when these agents are used together.

When one uses the latter range of anaesthetic doses and adds narcotics (i.e. fentanyl) during the induction, intra-operative SEPs remain unaltered.

When interpreting intra-operative SEP abnormalities, one has to be attentive to the factors that can cause recording artefacts. These include electrical stimulator failure, electrode problems (high impedance, detachment from the skin) and electrical or magnetic interference from other equipments in the operating room. Additionally, certain physiological factors, such as obesity, diabetes with neuropathy, peripheral vascular disease, seizure disorders and closed head injuries, have been associated with less than optimal responses.

Somatosensory-Evoked Potentials (SSEPs) in Peripheral Nerve Trauma

It gives information about the integrity of the posterior sensory tracts in the spinal cord and is therefore useful in evaluating suspected posterior nerve root avulsion.

However, the presence of an intact SSEP does not reliably indicate satisfactory nerve root function. The SSEPs are so sensitive that they may yield positive waveforms in the presence of only a few hundred intact nerve root axons. Furthermore, they do not provide enough localising information to be of great assistance in post-ganglionic peripheral nerve injuries and do not provide information about injury to anterior (motor) rootlets in the spinal canal.

Brainstem Auditory-Evoked Potentials

Brainstem auditory-evoked potentials (BAEPs) are elicited by monaural stimulation with repetitive clicks and are recorded between the vertex of the scalp and the mastoid process or earlobe (Fig. 5). The presence, latency

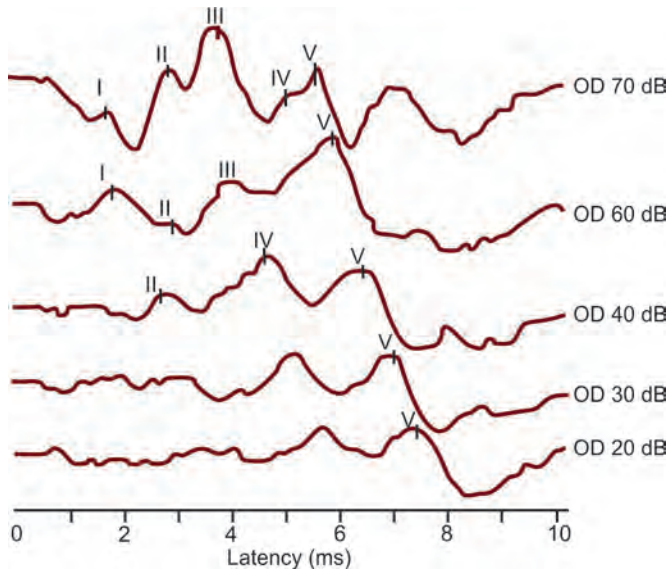


Fig. 5: Normal brainstem auditory-evoked potential wave

and interpeak latency of the first five positive potentials recorded at the vertex are evaluated.

Brainstem Auditory-Evoked Potential Wave Generators

Wave I: Distal acoustic nerve
Wave II: Proximal acoustic nerve/cochlear nucleus
Wave III: Superior olivary complex at the level of the lower pons
Wave IV: Lateral lemniscus
Wave V: Inferior colliculus or upper pons

The findings are helpful in screening for acoustic neuromas, detecting brainstem pathology and evaluating comatose patients. The BAEPs are normal in coma due to metabolic/toxic disorders or bihemispheric disease, but abnormal in the presence of brainstem pathology. Intra-operative BAEP monitoring has been shown to be useful for preservation of hearing and vestibular nerve function during the resection of acoustic neuroma and other posterior fossa surgeries.[30]

The types of surgeries in which BAEPs are used include not only acoustic neuroma resections but also posterior fossa and petroclival skull-base tumours, arteriovenous malformations, aneurysms and decompressive procedures in patients with Chiari malformation.

Intra-Operative Brainstem Auditory-Evoked Potential Monitoring

As in the non-intra-operative approach, the patients receive auditory stimulation delivered by a series of clicks at intensities of 60–70 dB hearing level keeping the frequencies of the clicks at 5–50 per second.

Earphones, transducers or even direct middle ear inserts deliver the sounds. The signals from several stimuli are averaged due to the low amplitude of each individual auditory-evoked response, which is often less than 0.1 μv. The recording can be done on the scalp during the non-operative BAEPs or directly from the acoustic nerve with special cotton wick electrodes. The scalp electrodes are placed on both ears or mastoids and vertex, and ground. A contralateral (to the side of stimulus) ear-mastoid to vertex montage can help differentiate the waveform IV and V peaks that may be fused in the ipsilateral channel.

The signal phase (rarefaction, condensation or mixed) should be chosen to maximise BAEP waveforms. Overall, the goal should be the identification of the most important components of the BAEPs, namely wave I and wave V in the shortest time possible. The effects of surgery on BAEPs are interpreted noting the generators of the waveforms to help localise where the problem is taking place.[12]

The BAEP changes seen during surgery can be divided into three types:

- *Type 1*: Gradual and persistent prolongation of the waveforms of 1 ms or more. This type of abnormality may or may not be followed by a return to the baseline values. Post-operative type 1 BAEP abnormalities are not accompanied by clinically significant hearing deficits, but careful audiological testing may reveal some minor hearing loss.
- *Type 2*: When there is a sudden loss of wave I through wave V ipsilateral to the side of the surgery without return to the baseline. Hearing impairment is often observed post-operatively on the same side of the surgery when type 2 changes are seen during surgery.
- *Type 3*: When the contralateral BAEP waveforms become abnormal during posterior fossa surgery, the prognosis is poor. Type 3 changes are often associated with other signs of brainstem dysfunction. When this pattern is not accompanied by return to the baseline, it has been correlated with poor outcome, such as death or post-operative survival with severe neurologic deficit, including hearing impairment.

Visual Evoked Potentials

The visual evoked potential (VEP) is an evoked electrophysiological potential that can be extracted using signal averaging from the electroencephalographic activity recorded at the scalp. The VEP can provide important diagnostic information regarding the functional integrity of the visual system.

Elicited by monocular stimulation with a reversing checkerboard pattern they are recorded from the occipital region in the midline and on either side of the scalp.

The VEP peak latency, amplitude and waveform are age dependent. The VEP peak latency refers to the time from stimulus onset to the maximum positive or negative deflection or excursion; thus, the term VEP peak latency corresponds to the term implicit time used to describe the time from the stimulus to the maximum deflection of electroretinograms. The VEP peak latency may also be referred to as 'time to peak' or 'peak time'.

The component of major clinical importance is the so-called P100 response, a positive peak having a latency of approximately 100 ms. It's presence, latency and symmetry over the two sides of the scalp are noted. Amplitude may also be measured, but changes in size are much less helpful for the recognition of pathology (Fig. 6).

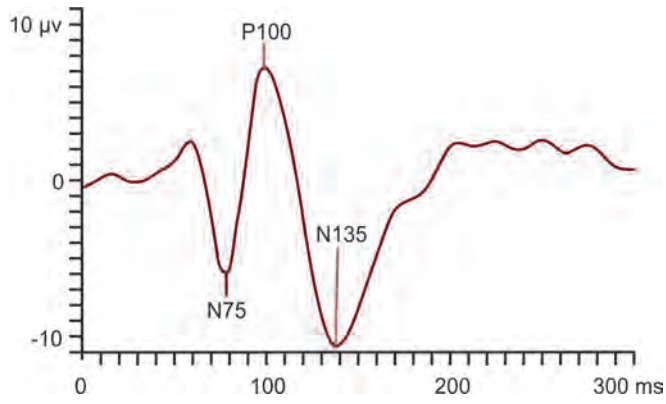

Fig. 6: Normal pattern reversal visual evoked potential

The VEPs are most useful in detecting dysfunction of the visual pathways anterior to the optic chiasm. In patients with acute severe optic neuritis, the P100 is frequently lost or grossly attenuated; as clinical recovery occurs and visual acuity improves, the P100 is restored but with an increased latency that generally remains abnormally prolonged indefinitely. The VEP findings are therefore helpful in indicating previous or subclinical optic neuritis. They may also be abnormal with ocular abnormalities and with other causes of optic nerve disease such as ischaemia or compression by a tumour. Normal VEPs may be elicited by flash stimuli in patients with cortical blindness.[58]

ELECTROPHYSIOLOGY FOR SOME CLINICAL CONDITIONS OF INTEREST TO NEUROSURGEONS

Carpal Tunnel Syndrome

Electrophysiology

Aim of nerve conduction study (NCS) and EMG:

1. To demonstrate a distal lesion of the median nerve.
2. To exclude other peripheral conditions that can result in similar symptoms like high median neuropathy, C6-C7 radiculopathy, lesions of the brachial plexus or even polyneuropathy.
3. To assess severity of carpal tunnel syndrome (CTS) and for therapeutic decisions.
4. Baseline to assess the outcome after intervention.

Electrodiagnostic Grading of Carpal Tunnel Syndrome

Grade 1: Very mild CTS—normal standard tests, abnormal comparative tests.
Grade 2: Mild CTS—abnormal sensory with a normal motor response.
Grade 3: Moderate CTS—abnormal median sensory and motor response.
Grade 4: Severe CTS—absence of sensory response, abnormal distal motor latency.
Grade 5: Extreme CTS—absence of median motor and sensory responses.

Electrophysiological Findings

Sensory Latency

- Most important, most sensitive and earliest indicator of CTS is prolonged sensory latency.
- May show diminished amplitude and is often absent.
- Latencies of 1–2 ms are considered mild, whereas latencies more than 6 ms are considered severe.

Distal Motor Latency

- Prolonged, but is not as sensitive an indicator as sensory latency.
- Motor latency abnormalities tend to occur later in the course of the disease.
- Latencies of 1–2 ms are considered mild, whereas latencies more than 6 ms are considered severe.

EMG may show loss of motor units and presence of denervation potentials in the thenar muscles. Although these abnormalities are present before clinically evident muscular atrophy sets in, they usually occur after distal motor latency is prolonged. Insertional activity may be increased in CTS. The EMG/NCS is incomplete unless the ulnar nerve of the same arm is also evaluated to rule out the possibility of peripheral neuropathy.

Post-Operative Changes

There is an immediate increase in motor conduction velocity following release of the carpal tunnel. After one week this value decreases to an intermediate value and then gradually returns to normal in the next 8–12 weeks.

Criteria for the Electrodiagnostic Evaluation of Unilateral Neurogenic Thoracic Outlet Syndrome[61]

All three of the following criteria must be found in the affected limb:

1. Amplitude of median motor response is reduced.
2. Amplitude of ulnar sensory response is reduced.
3. EMG evidence of denervation in muscles innervated by the lower trunk of the brachial plexus.

Details Regarding the Above Criteria

Criterion 1:

a. Using standard surface electrodes with active pick up over the APB, the amplitude of the median motor response on the affected side should be less than 50% of that obtained on the unaffected side.

Criterion 2:

a. Using standard ring electrodes on the fifth digit, the ulnar sensory amplitude on the affected side should be less than 60% of the amplitude on the unaffected side.

Criterion 3:

a. Muscles innervated by the lower trunk of the brachial plexus include the APB, pronator quadratus, flexor pollicis longus, first dorsal interosseous, abductor digiti minimi, flexor carpi ulnaris, extensor pollicis brevis and extensor indicis.
b. The EMG abnormalities in TOS are most commonly seen in median and ulnar innervated intrinsic muscles of the hand, especially the APB.
c. Positive waves and fibrillations may be found, but chronic denervation changes are more common, i.e. increased motor unit amplitude, increased motor unit duration, and decreased recruitment with rapid firing of motor units are activated.

The electromyographer should rule out neuropathic conditions that might mimic TOS, specifically cervical radiculopathy, CTS, ulnar neuropathy and polyneuropathy.

Acoustic Neuroma

The results of pre-operative brainstem auditory-evoked response (BAER) studies were useful in predicting the outcome of hearing preservation attempts. Patients with intact BAER waveform morphology and normal or delayed latencies had a higher probability of hearing preservation in comparison to those with abnormal pre-operative BAER morphology.[25]

A characteristic finding on ABR in a person with an acoustic neuroma would be a wave I with nothing after it—no waves 3 or 5 (10–20% of cases). A wave I–III interval delay is common, and a wave V delay occurs in 40–60% of cases.

The place of intra-operative BAER audiometry in improving hearing outcomes is still uncertain, largely due to the known difficulties in obtaining reliable recordings. However, on empirical grounds, it is likely that if hearing preservation rates are to improve, BAER audiometry will play a significant part in this improvement. The only pre-operative factor that may predict a favourable hearing preservation outcome is the presence of normal pre-operative BAER morphology.[29]

ELECTROENCEPHALOGRAPHY

The electroencephalogram (EEG) was developed by the German psychiatrist, Hans Berger, in 1929. Its potential applications in epilepsy rapidly became clear, when Gibbs and colleagues in Boston demonstrated 3 per second spike wave discharge in what was then termed petit mal epilepsy. The EEG continues to play a central role in the diagnosis and management of patients with seizure disorders—in conjunction with the now remarkable variety of other diagnostic techniques developed over the last 30 or so years—because it is a convenient and relatively inexpensive way to demonstrate the physiological manifestations of abnormal cortical excitability that underlie epilepsy (Smith, 2005).[50]

The electroencephalograph records spontaneous electrical activity generated in the cerebral cortex. This activity reflects the electrical currents that flow in the extracellular spaces of the brain, and these reflect the summated effects of innumerable excitatory and inhibitory synaptic potentials upon cortical neurons. This spontaneous activity of cortical neurons is influenced and synchronised by subcortical structures, particularly the thalamus and upper brainstem reticular formation. Afferent impulses from these deep structures are probably responsible for entraining cortical neurons to produce characteristic rhythmic brain wave patterns such as alpha rhythm and sleep spindles.

The EEG provides confirmation of Hughlings Jackson's concept of epilepsy—that it represents a recurrent, sudden, excessive discharge of cortical neurons; but like other ancillary tests, it must be used in conjunction with clinical data.

How Can Electroencephalography Help in Epilepsy?[47]

Diagnosis of Epilepsy

- Differential diagnosis of paroxysmal neurological events.
- Distinction between a focal and generalised seizure disorder.
- Identification of specific epilepsy syndromes.
- Recognition of photosensitivity and reflex epilepsies.

Management of Epilepsy

- Assessing risk of recurrence after an unprovoked seizure.
- Selection of antiepileptic treatment.
- Likelihood of seizure relapse if medication is withdrawn.
- Identification of irritative zone in epilepsy surgery candidates.
- Investigation of cognitive decline, especially when rapidly progressive.
- Monitoring in the management of status epilepticus.
- Detection of non-convulsive status.

Although the diagnosis of seizures and epileptic syndromes is primarily made from careful history and examination, the EEG remains an important investigative tool. The EEG often provides supportive evidence of seizure disorder and assists in classification of seizures and epilepsy. Moreover, EEG findings are important for determination of seizure focus and may also help with prognosis under certain circumstances.[53]

Minimum Technical Standards

Digital recording machines are rapidly replacing the traditional "paper" systems.

Advantages

- Digital EEG is particularly useful for detecting and analyzing epileptic discharge (ED) as the waveforms in question can be reformatted in various montages after the recording is completed.
- Very little storage space requirement; elimination of paper costs; automatic event detection and the ability to network different recording stations.
- Filter and paper speed settings with digital recordings are accurate and automatic, thereby avoiding technician oversight.
- Problems due to pen alignment and curvilinear effect are not seen with digital systems.

Disadvantages

- The incompatibility of systems made by different vendors, often forcing one to resort to paper printouts for transmission of EEG data between two centres.

- Comparing two separate epochs is somewhat cumbersome, as only limited data can be observed simultaneously on the monitor.[34]

Standardising Electroencephalography Recording, Lab Infrastructure and Electroencephalography Reporting

The International Federation of Clinical Neurophysiology (IFCN) has certain standards for recording of clinical EEG. These recommendations are discussed under the following headings:[42]

Patient Information

Patient's demographic details, such as name, age and clinical diagnosis, state of the patient, medications, test number and other remarks, have to be entered.

Documentation during Recording

Prior to starting the recording, square wave calibration signals of 100 μV, of 1–2 sec duration in the referential derivation must be carried out to assess the integrity of the amplifiers and analog-to-digital (A-D) conversion. The technologist should be able to annotate comments, such as eye opening and closing, hyperventilation (HV), photic stimulation (PS), drowsiness, sleep, artifacts, etc., and there must be provision for entering free text.

Recording

Amplification and channel acquisition must be available for at least 24 channels and preferably 32 channels of recording EEG along with artifact channels. The sampling rate must be at least 200 samples and preferably more. The low-frequency filter (high-pass filter) should be set at 0.16 Hz or less for recording. The low frequency filter function can also be expressed as a time constant in seconds. The high-frequency filter is good at 70 Hz. The 50 Hz notch filter must be available to cut off external electrical disturbances, but should not be used routinely, as it distorts sharp waves. Proper earthing and positioning of equipment and checking impedances eliminate this artefact. Recording should be made on a referential montage. Digitisation with 12 bits will provide a dynamic range from 0.5 μV to ± 1023 μV. Electrode impedances must be below 5k ohms and preamplifier input impedances must be more than 100 mohms. Common mode rejection ratio must be at least 110 dB for each channel.

Display

Digital EEG equipment must be able to display the EEG with the same temporal and spatial resolution traditionally used for paper recordings. Remontaging with bipolar and referential montages should be possible. Digital low frequency (high pass) filters of 0.5, 1.0, 2.0 and 5.0 Hz and digital high-frequency (low pass) filters of 15, 35 and 70 Hz must be available. For the majority of EEG investigations, the recorded signal ranges 1–70 Hz. The screen display scaling should be set such that 1 sec occupies 30 mm with a minimum display resolution of 120 data points per second, per channel. Varying the time scale should also be available, e.g. 5, 15, 30 or 60 mm/s. For 60 mm/sec display, at least 200 data points per second should be presented for each channel. The standard inter channel separation is 10 mm. The standard video screen must have a minimum resolution of 4 pixels per vertical millimetre. For paper printouts at least 300 dots per inch (dpi) resolution are needed.

Electrode Nomenclature

When additional scalp sites are required, these must be placed between the traditional 10–20 electrode system sites and are named the 10% system or the extended 10–20 electrode system[4,32] (Figs 4A and 4B). In the coronal row, AF lies midway between rows Fp and F; FC between F and C; CP between C and P; PO between P and O and so on. Thus, CP1 will be between CPz and CP3; C5 will be between C3 and T3. Extra electrodes increase the yield of the EEG. Sphenoidal electrodes are particularly useful for detecting mediobasal temporal discharges and are inserted under the mandibular notch (approximately 2.5–3 cm anterior to the tragus) and directed posterosuperiorly towards the foramen ovale.[18,46] Anterior "cheek" electrodes (placed on the maxilla approximately 2 cm anterior to the site of entry of the sphenoidal electrode) and anterior temporal electrodes (placed 1 cm above one-third the distance from the external auditory meatus to the external canthus) are also useful for demonstrating epileptiform discharges (EDs) from the temporal lobe, and the yield appears comparable to that from sphenoidal electrodes.[36]

Montages to Be Used?

Montages are different connections and combinations of electrodes.

Bipolar Derivation

In this widely used method, rows of electrodes are connected to consecutive channels, such that an electrode is attached to lead 2 of 1 channel and lead 1 of the next channel (e.g. Fp2-F4 in channel one and F4-C4 in channel 2, F4 is connected to lead 2 of channel 1 and lead 1 of channel 2). This arrangement is good for seeing phase reversals.

Common Reference Derivation

Every electrode is connected to one input of the amplifiers (usually lead 1) and all the lead 2 inputs are joined together and connected to another electrode. The common reference electrode is thought to lack electrical activity, but this assumption is not true, because no area over the scalp can be totally inert. This can be made

out in the recording, as an active reference will have its potential appearing in many channels.

Common Average Reference Derivation

A common average reference should be used to circumvent the problem generated by an active reference. This uses the average of the electrical activity at all electrodes as reference against which individual activities are compared. The average reference will be near zero in its activity. No single method of derivation is ideal and each has its upside and downside. Unipolar derivations are good to view small potentials which get amplified due to the distance between the electrodes. CZ and PZ can be used as the average reference.

Sensitivity and Specificity of the Electroencephalography

The diagnostic sensitivity of a single awake EEG with PS and HV is about 50% in adults with epilepsy. This increases to 92% after four EEGs. A single awake plus sleep record will be positive in about 80%. The diagnostic specificity of the EEG depends on the proper interpretation of the EEG. Misinterpretation of normal variants, such as benign sporadic small spikes (BSSS), 14 and 6 positive spikes, wicket waves, 6 Hz phantom spikes as well as artifacts, can lead to a wrong diagnosis of epilepsy and unnecessary antiepileptic drug therapy. It is also important to understand that a normal EEG does not exclude epilepsy. The EEG may remain normal despite repeated EEG recordings in 5–10% of patients. Such patients usually have only simple partial seizures (sensory more than motor).

Reading the EEG should be unbiased, but interpretation of the EEG must always be done in the clinical context. To summarise, the interictal EEG cannot exclude epilepsy, and the amount of epileptiform activity does not provide a guide to seizure frequency or therapeutic response despite widespread belief to the contrary.

Role of Brain Mapping

Brain mapping is a frequently misused tool but, when judiciously used, can display electrical fields that can be understood more easily than the primary EEG. It cannot however replace careful analysis of the primary EEG data by the epileptologist. Every effort must be made to get an awake and sleep EEG. Patients should be asked to be sleep deprived too.

Activation Procedures

Hyperventilation

Forster,[21] in 1924, first demonstrated that hyperventilation (HV) may precipitate absence seizures in children and this method of activation has since become routine during EEG recordings. Although HV is particularly useful for demonstrating generalised EDs, it may also activate focal ED in up to 10% of patients with partial epilepsies.[40] The neuronal irritability during HV is considered to be due to brainstem mediated cerebral vasoconstriction induced by hypocapnia.

HV should be avoided in patients with potential for brain damage from further vasoconstriction, e.g. malignant hypertension, subarachnoid haemorrhage, sickle cell disease or trait and myocardial infarction.

Photic Stimulation

Photic stimulation (PS) is useful for activation of generalised EDs. Testing is generally done with stepwise increase of frequencies up to 30 Hz with a strobe light at a distance of 20–30 cm from the eyes. At low frequencies, PS is recommended with eyes open and then closed. At medium and higher frequencies, stimulation should start with the eyes open, and the patient is asked to close the eyes during PS, thereby continuing with PS for a few more seconds with the eyes remaining closed. Eye closure during PS is particularly useful for augmenting ED and should routinely be used. The ED outlasting PS strongly suggests generalised seizure disorder, whereas those confined to the train of PS may be an incidental finding in non-epileptic subjects, especially in the setting of drug withdrawal or toxic metabolic encephalopathy, or simply represent a genetic trait.[41]

PS is particularly useful in the diagnosis of primary generalised epilepsy and ED may occur during PS in up to 40% of these patients.[23] Recent evidence indicates that approximately a quarter to a third of EEGs with photic related ED also contain spontaneous focal or generalised ED elsewhere in the records.[24]

Sleep Deprivation

When the first EEG fails to show ED in patients with epilepsy, sleep deprived recording often helps. Several studies have convincingly documented that the chances of finding ED increase with sleep deprived recordings in both partial and generalised seizure patients of all ages.[16] The ED following sleep deprivation occur both in the awake and sleep portions of the EEG.

Clinical Significance of Interictal Epileptiform Discharges

Epileptiform Discharges in Non-Epileptic Subjects

Although the presence of interictal ED generally supports the diagnosis of seizure disorder, caution is necessary in interpreting the clinical significance as ED may occur in subjects without seizures. Among healthy adults without seizure history, the frequency of ED is approximately 0.5%.[45] Practically none of these healthy subjects subsequently develop seizures. "Incidental" ED occur slightly more often (approximately 2%) in subjects with a history of previous neurological insults such as trauma, stroke, craniotomy, infections, cerebral palsy or during migraine.[62] Up to 14% of these patients

subsequently develop seizures. In children without prior seizures, ED may occur in up to 5% and this may be as high as 8% if adequate sleep is recorded;[44] these tend to be benign Rolandic or occipital spikes or generalised 3 Hz spike-wave discharges and likely represent an incidental genetic trait. Risk of subsequent seizures in these children is around 6%.[11] Certain EEG patterns, however, almost always indicate associated clinical seizures and these include Hypp's arrhythmia and 1 or 2 Hz generalised slow spike-wave complexes.

Epileptiform Discharge in the First and Serial Electroencephalograms

First standard EEGs in patients with a reasonably certain diagnosis of seizure disorder contain ED in approximately 50%.[2] Yield from the first EEG in children with absence seizures, however, is higher, around 75%.[27] Apart from sleep, several other factors have been shown to increase the likelihood of ED and these include: (i) recording within 48 hours of a seizure and (ii) ongoing seizure frequency of at least one attack per month. The yield, however, is not significantly altered by neurological status, aetiology of seizures, age of the patient and antiepileptic drug therapy. Serial EEGs are often necessary for demonstrating ED. Most patients who eventually show ED do so by the fourth EEG. Recordings are persistently negative in only 8% of epileptics although there is evidence that a higher proportion of patients with partial seizures may have persistently negative serial EEGs.

The above observations suggest that:

- The ideal time for obtaining an EEG is the first day or two after a seizure;
- Long-term monitoring should be considered if four routine recordings have remained negative in patients with ongoing "seizures".

Ictal Video-Electroencephalography (Long-Term Monitoring)

While interictal ED generally provide support for the diagnosis of seizure disorder, electrographic or clinical seizures during EEG confirm seizures and suggest their localisation. Although the EEG remains the gold standard for confirming seizures, an actual attack or event is rare during a standard 20–30 minute recording. Even serial EEGs may fail to reveal ED in up to 10% of epileptics. When the nature of attacks or the exact seizure focus cannot be ascertained with several routine EEGs, video-electroencephalogram (VEEG) monitoring often provides necessary additional information. With current systems, EEG data may be collected continuously for several days or even weeks.

Indications for Video-Electroencephalography Monitoring

Diagnosis

- Identification of epileptic paroxysmal electrographic and/or behavioural abnormalities. These include epileptic seizures, overt and subclinical, and documentation of interictal ED and in the differential diagnosis between epileptic disorders and conditions associated with intermittent symptoms due to non-epileptic mechanisms (e.g. syncope, cardiac arrhythmias, transient ischaemic attacks, narcolepsy, other sleep disturbances, psychogenic seizures and other behavioural disorders).
- Verification of the epileptic nature of the new "spells" in a patient with previously documented and controlled seizures.

Classification/Characterisation

- Classification of clinical seizure type(s) in a patient with documented but poorly characterised epilepsy.
- Characterisation (lateralisation, localisation, distribution) of EEG abnormalities, both ictal and interictal, associated with seizure disorders. Characterisation of epileptiform EEG features, including both ictal discharges and interictal transients, is essential in the evaluation of patients with intractable epilepsy for presurgical evaluation.
- Characterisation of the relationship of seizures to specific precipitating circumstances or stimuli (e.g. nocturnal, reflex, catamenial, situation-related and activity-related). Verification and/or characterisation of temporal patterns of seizure occurrence, either spontaneous or with respect to therapeutic manipulations (e.g. drug regimens).
- Characterisation of the behavioural consequences of ED as measured by specific tasks.

Quantification

- Quantification of the number or frequency of seizures and/or interictal discharges and their relationship to naturally occurring events or cycles.
- Quantitative documentation of the EEG response (ictal and interictal) to a therapeutic intervention or modification (e.g. drug alteration).
- Monitoring objective EEG features are useful in patients with frequent seizures, particularly with absence and other seizures having indiscernible or minimal behavioural manifestations.[28]

Partial Seizures

Partial seizures, in scalp EEGs, are metamorphic, i.e. they show two or more distinct phases.[48] The most common patterns consist of a series of rhythmic waves, sequential spikes/sharp waves, a mixture of spikes and rhythmic waves or regional voltage attenuation. Most often the initial frequency of temporal lobe seizures is in the alpha or theta range with slower frequencies occurring in a lesser proportion. Extratemporal seizures, however, often start in the beta frequencies rather than slower frequencies. With scalp EEG, the frequency may diminish or augment, but as the seizure ends, rhythmic waves or sequential spikes change to a slow spike-wave pattern

that gradually decreases in frequency. Focal electrodecremental events are of excellent localising value, reflecting intense neuronal depolarisation or high-frequency firing. Following metamorphic seizures, there is often postictal delta slowing and suppression or activation of focal spikes. These postictal changes also have good localising value for seizure origin and should be carefully sought.[33]

It is important to recognise that simple partial seizures, especially those with sensory rather than motor symptoms, may not be associated with discernable changes in routine scalp EEG in up to 80% of patients.[17] However, the yield in these patients may be augmented by using additional closely spaced electrodes.[5]

Generalised Seizures

Typical absence seizures are characterised by isomorphic and stereotyped patterns that do not evolve as partial seizures. However, the spike-wave discharges may change from 3.5 or 4 Hz at the onset to 2 or 3 Hz as the seizure progresses. Also, the spike amplitude may decrease during the later part of the seizure. Atypical absence attacks frequently show gradual onset and offset with spike-wave discharges occurring at frequencies less than 3 Hz.

Generalised tonic-clonic seizures may be preceded by diffuse polyspike-wave complexes. Ictal recordings during the tonic phase typically show generalised attenuation with or without high-frequency rhythmic waves that gradually increase in voltage ("epileptic recruiting rhythm") and evolve into polyspikes. The clonic phase is characterised by paroxysmal spike activity mixed with slow waves and the postictal period shows generalised attenuation followed by gradual recovery of rhythms.[22]

Myoclonic seizures are associated with 10–15 Hz polyspikes with or without slow waves, whereas tonic seizures show generalised paroxysmal fast activity or diffuse voltage attenuation preceded or followed by sharp and slow wave complexes. Generalised atonic seizures may show 2–3 Hz spike-wave discharges or may not be associated with any scalp EEG change.

Can Electroencephalography Help in the Prognosis of Epilepsy?

Routine EEG is useful for prognostic purposes in at least the following three situations:

1. Assisting in epilepsy syndrome classification.
2. Predicting recurrence after the first seizure.
3. Providing information on seizure relapse after anticonvulsant withdrawal.

Classification of Epilepsy

The EEG provides important information for classification of various epileptic syndromes and thereby assists in predicting the natural history of the syndrome. For example, a child with normal neurological examination and Rolandic spikes in EEG has a high probability of "outgrowing" seizures and may not even need treatment following isolated, infrequent seizures. Similarly, generalised 4–6 Hz spike-wave and polyspike discharges in an adolescent with seizures suggest juvenile myoclonic epilepsy of Janz: a condition with a high-response rate to valproic acid.

First Seizure

Prediction of recurrence after a single seizure is clinically important and many studies have addressed this question. However, differences in methodology make comparison of these studies difficult and the results still remain somewhat controversial. A meta-analysis of sixteen published reports suggests that EEG abnormalities may increase the risk of recurrence after the first seizure.[8]

A recent large prospective study of children with single unprovoked seizure in those without obvious aetiology ("idiopathic"), showed that the presence of ED in the EEG was associated with a recurrence rate of 54% whereas the rate was only 25% when the first EEG was normal.[49] In the above study, the EEG was not of any predictive value in children with remote symptomatic seizures.

Several prospective studies suggest that the EEG is useful in adults with first seizure, especially among those with idiopathic seizures.[57] The Italian first seizure trial group (1993)[20] also showed a 1.7-fold increase in seizure recurrence when the EEG contained ED. Some controversy still exists in this area as some authors maintain that the EEG findings are of no predictive value after the first seizure.[31]

Anti-Epileptic Drug Withdrawal

The role of EEG in predicting relapses after anti-epileptic drug withdrawal remains more controversial. A recent meta-analysis discussing in depth about various factors in predicting relapses after anti-epileptic drug withdrawal indicates that any EEG abnormality (epileptiform activity or slowing) is associated with a relative relapse risk of 1.45.[7] Other factors found to increase the relapse rate in the above meta-analysis were adolescent or adult epilepsy onset (rather than childhood onset) and known remote aetiology.

Summary

After almost 80 years since Hans Berger showed the usefulness of EEG in man, this procedure still remains the "gold standard" for the diagnosis of seizures and epilepsy. The role of EEG has expanded in recent years and the test now plays an important role in predicting seizure recurrence among patients with newly diagnosed epilepsy and during anti-epileptic drug withdrawal. Rapid advances in technology have made digital equipment and continuous monitoring more widely available and at the same time providing better quality recordings than ever before.

ELECTROCORTICOGRAPHY

This is a technique of placing grids or strips directly on the brain for recording EEG activity to localise the epileptogenic focus during surgery for epilepsy. Electrocorticography (ECoG) along with cortical stimulation mapping was first described by Penfield in 1939. Using this procedure, they demonstrated that stimulation of the supplementary area resulted in simultaneous movements and tonic posturing of both proximal and distal muscles along with speech arrest.

The hypothesis for successful epilepsy surgery is based on the principle that removal of both lesional as well as the surrounding epileptogenic area is necessary for achieving seizure freedom.[37,38] Hence, it is important that both should be delineated before surgery. However, epileptogenic zones are often difficult to identify, because they may be found in and around the margin of, or remote from a lesion.[10] The scalp EEG is helpful but may not be precise enough to localise the epileptogenic area.[59] For greater precision either intra-operative or extra-operative subdural ECoG is often used to guide surgical resection of both the lesion and the epileptogenic zone. The area of interictal spiking or the irritative zone is often wider than the ictal onset zone (area where the seizure originates) which is considered as a gold standard for localising the epileptogenic zone.[38]

Intra-operative ECoG is widely utilised for electrical mapping of the epileptogenic zone during epilepsy surgery. It is useful to delineate the margins of the epileptogenic zone, guides the surgeon in achieving resection and is also of value to evaluate the completeness of resection. It has been found to be particularly useful in resective surgeries of neocortical foci (especially developmental lesions like cortical dysplasias) and for tailored resections in hippocampal sclerosis.[13,14,51] The ECoG can be a valuable tool during multiple subpial transections (MST).

The obvious advantages of intra-operative ECoG are: (i) they allow placement of recording and stimulation electrodes; (ii) recordings can be performed before and after each stage of resection to assess the completeness of surgery; (iii) it allows direct electrical stimulation of the brain so that the regions involved in functions may be spared by the resection (e.g. eloquent cortex); (iv) no risks associated with long-term placement, e.g. infection.

The major limitations of ECoG are: (i) the limited sampling time; (ii) spontaneous epileptiform activity consists exclusively of interictal spikes and sharp waves, and seizures are rarely recorded. Thus, in most of the cases, localisation of the ictal focus is based on a hypothesis that it corresponds to the interictal activity, which is yet to be proven; (iii) it is difficult to distinguish primary ED from secondarily propagated discharges arising at a distant epileptogenic site; (iv) both the background activity and the ED may be altered by the anaesthetics, narcotic analgesics and by the surgery itself. About 80–84% of epilepsy surgery centres around the world still perform ECoG in some or all of their patients with partial epilepsy.[19]

The ECoG in all cases should be performed under standard anaesthetic conditions with induction using isoflurane. After craniotomy and dural opening, anaesthesia must be maintained with nitrous oxide and intravenous narcotics with reduction (0.5% of isoflurane) of inhalational agents. Core body temperature should be maintained above 35.5°C. The low-frequency filter is set at 1 Hz, the high-frequency filter at 70 Hz, and sensitivity should be between 300 and 5,000 μV/mm depending on the amplitude of the background and discharges.[54-56]

ECoG score 1: Normal background of mixed gamma, beta and alpha frequencies of moderate to low amplitude (i.e. usually < 20–30 mV). A few low-amplitude spikes are observed.

ECoG score 2: Loss of fast (> 20 Hz) background frequencies, but otherwise a background of mixed alpha, beta and delta frequencies of low to moderate amplitude. Repeated but non-continuous, spikes, polyspikes or paroxysmal fast activity of medium amplitude are often observed.

ECoG score 3: Mostly 6–20 Hz background frequencies with some localised nearly continuous interictal epileptiform features of moderate amplitude or persistent repetitive spiking. Very rarely, electrographic seizures are captured.

ECoG score 4: Slow (< 6 Hz) background frequencies with continuous synchronous features of moderate to high amplitude. Multiple independent epileptiform abnormalities (polyspikes, paroxysmal fast activity and electrographic seizures) are recorded.

ECoG score 5: Slow, rhythmic, usually synchronous background (< 4 Hz), often of high amplitude. Continuous synchronised or independent high-amplitude epileptiform abnormalities in multiple cortical sites are observed.

An ECoG score of 2–5 is considered abnormal and these areas should always be included within the resective zone.

An ECoG score 1 is considered relevant depending on its relation to the lesion. For instance, if there is widespread activity consistent with ECoG score 1 activity, then "chasing the spikes" is avoided and the maximally abnormal area is resected. If this activity is more focal and amenable to surgical resection, then it is utilised to guide surgical resection. Surgery always includes wide resection, making sure that the subcortical white matter is also included in the resection. A post-resection ECoG should always be performed as, often, significant activity may be noted from the margins.

Potential Advantages of Electrocorticography

ECoG recordings are more magnified: The ECoG activity is similar to that recorded from the scalp EEG, consisting of isolated spikes, brief bursts of spikes or runs of sharp waves. However, they look more magnified as they are recorded directly from the surface of the brain. They are often multifocal with a wide distribution and have been commonly recorded from the temporal cortex. More

commonly, the ED were reported to have been recorded from the hippocampal structures and inferiomesial surfaces of the temporal tip. To a much lesser extent, they were recorded from the lateral temporal cortices and more so from the posterior temporal cortices.[51,52]

New information is often seen on ECoG: Devinsky et al.[18] found new ED on ECoG in 24% of temporal lobe epilepsy, which were not previously found by scalp EEGs even with the use of sphenoidal electrodes. On the other hand, Engel et al.[19] did not obtain any additional information from the ECoG compared to the pre-operative scalp EEG.

The interictal zone recorded on ECoG correlates with the 'ictal zone': The ECoG seldom records ictal events, but rather interictal epileptiform activity. The relationship between the epileptic zone (area of origin of the epileptic seizure) and the irritative zone (area of maximum interictal ED) is not completely understood. In particular, the degree to which the two zones overlap, especially on the ECoG recording is unclear. It has been hypothesised that the frequency of this activity is proportional to the proximity to the "epileptogenic area". Alarcon et al.[3] found that the removal of this area leads to a good surgical outcome, even if areas of less frequent discharges were left untouched. If the area of maximal discharging was not completely resected, the surgical outcome was more likely to be poor. An earlier study[55] had found no such association. However, it should be noted that the latter study has used visual analysis of the ECoG as compared to the former study which used a computerised spike detection program.

In our own study of 165 patients,[56] 73% of the patients who have a good clinical outcome showed improved ECoG scores in 90%. The ECoG seemed to correlate better in temporal lesions with regard to clinical outcome (95%). It should, however, be noted that most of the patients in the present series were lesional epilepsies.

Electrical stimulation of the cortex further increases localisation: Electrical stimulation of the cortex at the time of ECoG is useful for further localisation of the epiletogenic zone.[26] The area of brain producing an aura on electrical cortical simulation has been reported to have strong correlation with the epileptic zone. This was, particularly the case when the area from which the responses matched closely with the area exhibiting the greatest ED, seen on ECoG.[9,60] However, this hypothesis was not agreed upon in a study,[26] where they proposed that the clinical symptomatology may not be related to this area of stimuli, but reflects a distant area to which the discharge has spread.

Post-resection ECoG abnormality may have a correlation to outcome: Bengzon et al.[6] noted a significant difference in the surgical outcome between patients with residual spikes compared to spike-free post-resection recordings. Around 36% of patients who were seizure-free post-surgery had residual spikes; whereas 75% of patients who were not seizure-free had residual spikes on post-resection ECoG. These findings were similar to those reported by others.[15,39,54]

Concluding, ECoG, though being widely used in epilepsy surgery, there is controversy regarding its efficacy and utility. This is particularly so as there are no prospective randomised studies. Despite its limitations, it remains a necessary tool in epilepsy surgery. In our study,[56] of a total of 73% (116/157) who had a good outcome following resective surgeries, 90% showed electrical improvement in post-resection ECoG.

CONCLUSION

Electrodiagnostic studies, both intra-operative and pre-operative, have become an integral part of the diagnostic armamentarium for both neurosurgeons and neurologists. Thus, it becomes important for every neurosurgeon in training to be familiar with their principles, techniques and interpretations.

4 Intracranial Pressure

Ravi Ramamurthi, Nigel Peter Symss

HISTORY

The mechanics of intracranial pressure (ICP) has intensively been studied over the last 100 years or so. Quincke, in 1891, first reported the measurement of ICP through the lumbar route. Later studies by Quickenstedt, Ayala and Ayer established the range of normal ICP and demonstrated the effect of changes in position and respiration, especially the Valsalva manoeuvre. Quickenstedt also described the discrepancy between cranial and spinal pressures in the presence of a spinal block, with higher pressures being recorded above a spinal block. In 1951, Guillaume and Janny carried out the first continuous recordings of ICP on a strip chart recorder. Lundberg,[42] in 1960, published his classic monograph on the continuous recording of ICP using an indwelling intraventricular catheter in a large series of 130 neurosurgical patients (Fig. 1). He described three waveforms and sought to correlate the clinical features with changes in the pressure wave pattern. His work established the usefulness of ICP monitoring in clinical neurosurgery. However, it was not before the 1970s that ICP monitoring came to be routinely used in clinical neurosurgery. It is presently accepted as an important basic technique in the management of patients with a variety of intracranial diseases.

ANATOMY AND PHYSIOLOGY

The cranium can be likened to a rigid sphere. The three main components of this sphere are brain, blood and cerebrospinal fluid (CSF) occupying 1400 ml, 75 ml and 75 ml of space, respectively.[59] The contents of the intracranial space are bound by the dura and communicate with the spinal canal through the foramen magnum. Since the thick bones of the calvarium are essentially

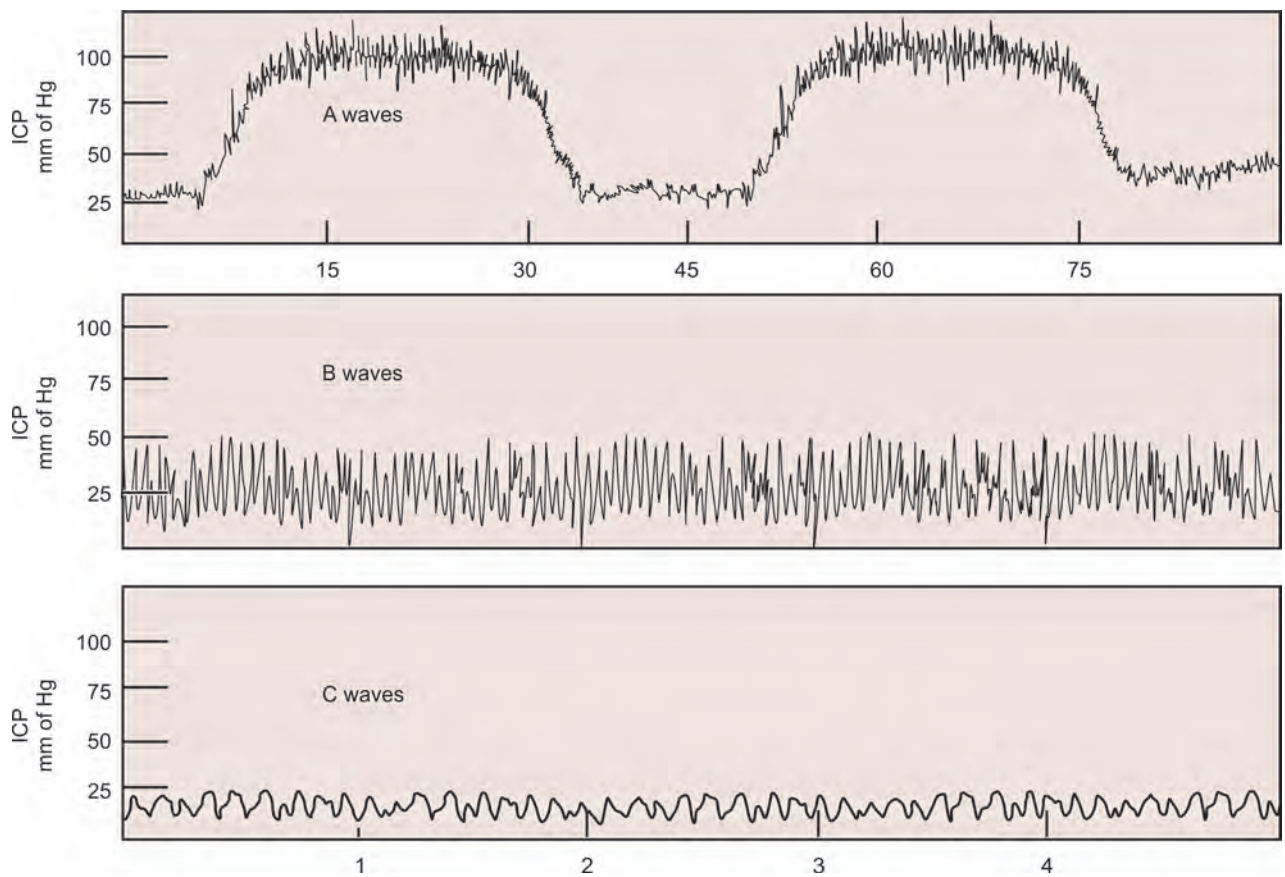

Fig. 1: Lundberg's CSF pressure waves

non-distensible, the volume of the intracranial space is virtually constant regardless of the pressure generated within it. Therefore, any change in the volume of the brain causes a reciprocal change in the volume of other intracranial components, i.e. either blood or CSF. This is the basis of the modified Monro-Kellie doctrine introduced into neurosurgery by Cushing. However, the Monro-Kellie doctrine does not hold true in infants because the skull is not rigid.

The normal ICP is pulsatile due to the respiratory and cardiac cycle. The cardiac pulsations are reflected in the ICP through pulsations of the choroid plexus, and the cerebral and spinal arteries. The variations in venous return and cardiac output with respiratory excursions possibly account for changes in the ICP with the respiratory cycle. The normal CSF pressure measured through the lumbar route ranges from 50 to 200 mm of H_2O in the lateral decubitus position. The amplitude of the pressure wave can be as much as 5 cm of H_2O due to the combined effect of the cardiac and respiratory cycles.[2,10] As the ICP increases, the pulse pressure generally increases. A transient increase in lumbar CSF pressure occurs on shifting from the lateral to the sitting position. This is due to an auto-regulatory dilatation of the cerebral blood vessels in response to a transient drop in cerebral arterial blood pressure on assuming the sitting position. Once the cerebral arterial blood pressure returns to normal, the resistance vessels constrict leading to a decrease in the cerebral blood volume and the lumbar CSF pressure.[43] In patients with raised ICP, this transient rise in CSF pressure can be prolonged.

In addition to the pulsatile character of the ICP wave, rhythmic oscillations in the pressure also occur. Lundberg[42] described three pressure waves namely: A waves; B waves and C waves (Fig. 2).

A waves are pathological and develop over a background of raised ICP. There is a rapid rise in ICP up to 50–100 mmHg followed by a variable period during which the ICP remains elevated followed by a rapid fall to the baseline. The A waves that persist for longer periods (usually 5–20 minutes) are called plateau waves. A study of patients with raised ICP due to various pathological causes suggested that plateau waves are closely associated with disturbances of CSF circulation or absorption.[24] Smaller A waves termed "atypical" or "truncated" A waves,[31,80] that often do not exceed an elevation of 50 mmHg, are also clinically important early indicators of neurological deterioration. The A waves are accompanied by clinical features of raised ICP, e.g. headache, vomiting, decerebrate posturing, pupillary changes, bradycardia and hypertension, and respond to CSF drainage, hyperventilation and osmotic diuretics.

B waves occur at the rate of 0.2–2 per minute and are related to respiration. From the studies of patients being monitored by transcranial Doppler and ICP, it appears that B waves may be vasomotor in origin.[56] Lundberg[42] initially described them in patients with intracranial hypertension, though they can also occur in normal individuals. B waves are said to be one of the best predictors of outcome after surgery for normal pressure hydrocephalus. Raftopoulos et al. suggested that the presence of B waves may have positive prognostic value in deciding if a patient being evaluated for occult hydrocephalus would benefit from a CSF diversion.[63]

Stephensen et al. analysed the relationship between the percentage of B waves and their diurnal variations and outcome in patients with hydrocephalus. They found no linear correlation between improvement after surgery in 55 patients and the total percentage B waves, but a correlation was found between improvement and percentage of B waves during sleep ($r = 0.39$, $p = 0.04$). The percentage of B waves was the same during sleep and wakefulness, and patients with NPH had the same proportion of B waves as the non-communicating patients. They concluded that B waves are commonly observed in patients with both communicating and non-communicating hydrocephalus, but are only weakly related to the degree of post-surgical improvement.[71]

C waves are of low amplitude with a frequency of 4–8 per minute. These waves are thought to be related

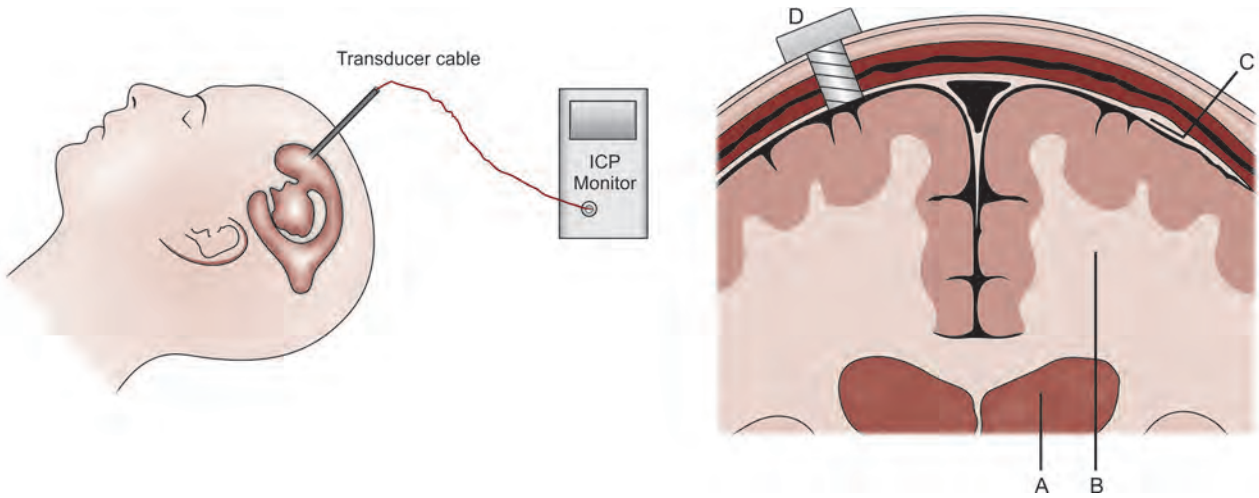

Fig. 2: Diagrammatic representation of ICP monitoring. Figure showing various methods of monitoring the ICP. (A) Intraventricular catheters. (B) Intra-parenchymal catheters. (C) Epidural catheters. (D) Subarachnoid bolt

to Traube-Hering-Mayer waves. These waves are of little clinical significance. Increased ICP is indicated by a sustained elevation in pressure above 15 mmHg or when intermittent A or B waves are recorded.

VOLUME-PRESSURE RELATIONSHIP

The cranium being rigid and non-distensible, any increase in the volume of a component would be accompanied by a reciprocal decrease in the volume of the other two components. Once the volume buffering capacity is exhausted, the ICP would begin to rise. During gradual expansion of a mass lesion, the volume displaced may be CSF, intravascular blood or brain tissue water. Of the three components, CSF appears to be the main buffer and is the first to be displaced as evidenced by compressed ventricles and obliterated subarachnoid spaces. Reduction in cerebral blood volume may occur, but is accompanied by serious sequelae. Longstanding compression of the brain can produce atrophy and loss of volume, as seen in large meningiomas, but changes in solid brain contents are very small in terms of total volume.

The rate of expansion of an intracranial mass is also important. A rapidly growing intracranial mass lesion may outpace the compensatory shift of CSF and then even the smallest increase in mass could produce a life-threatening increase in ICP. Foldes and Arrowood[15] infused the spinal subarachnoid space with saline and found that pressure remained constant at elevated levels during continuous infusion, indicating that at higher pressures, fluid infusion was being matched by fluid egress from the subarachnoid space. Their observations suggest that as much as 1 ml of CSF per minute, or 60 ml per hour, can be expressed out of the intradural space in the presence of elevated ICP. Thus, a large haematoma could be accommodated within a few hours without a dangerous rise in ICP. Langfitt et al.[38] studied the volume-pressure relationship in the rhesus monkey (Fig. 3). The ICP was measured by means of subarachnoid catheters during controlled gradual expansion of an extradural balloon. As the balloon was expanded at a rate of approximately 1 ml per hour, there was no increase in ICP during infusion of the first few millilitres of water (horizontal limb of the curve). With further expansion of the balloon, the ICP began to rise and at a volume of approximately 6 ml in the monkey, it began to rise very rapidly (vertical limb of the curve). The flat portion of the curve was termed the period of spatial compensation, and the vertical portion was called the period of spatial decompensation. In other words, in the presence of an expanding intracranial mass lesion, a rapid rise in the ICP would occur once the amount of displaceable volume within the intracranial space has been reduced to the point that any additional volume added to the cranium exceeds the volume of fluid displaced. The curve may shift to the left if the intracranial mass expands very rapidly or if there is a pre-existing pathology in the brain reducing the amount of displaceable volume. The classical pressure-volume curve is exponential. In a semi-logarithmic co-ordinate system, the curve would be linear.

Various mathematical models have been described to define the volume-pressure relationship (Fig. 4). Compliance is defined as change in volume per unit change in pressure (dV/dP). It is a measure of the distensibility of the intracranial space. The higher the compliance, the larger is the extra volume that the cranium can accommodate without a precipitous rise in pressure. Elastance is inversely related to compliance (dP/dV). It is a measure of the resistance offered to an expanding intracranial mass.[41] The slope of the volume-pressure curve is the elastance. In the horizontal limb of the volume-pressure curve, compliance is high and the elastance is low while in the vertical limb, compliance is low and the elastance is high. Volume-pressure response (VPR) is the change in ICP on injection or withdrawal of 1 ml of fluid from the ventricle in 1 second.[49] The normal VPR is 2 mmHg/ml. This response is a measure of the elastance and increases in parallel with the ICP in experimental animals and in human patients with intracranial disorders.[48] It is not certain if measurement of brain elasticity would provide useful clinical information pertinent to the management

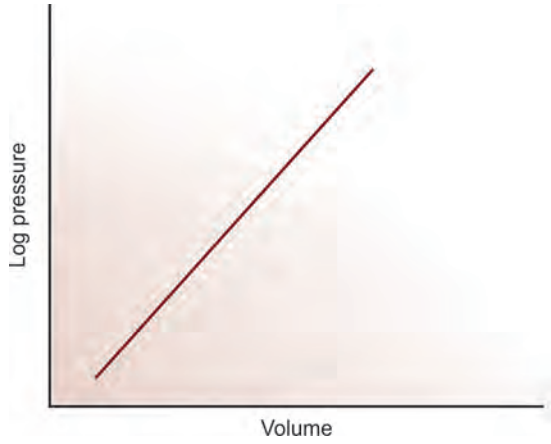

Fig. 3: The lineal relationship between the volume and the pressure semi-logrithmic co-ordinate systems

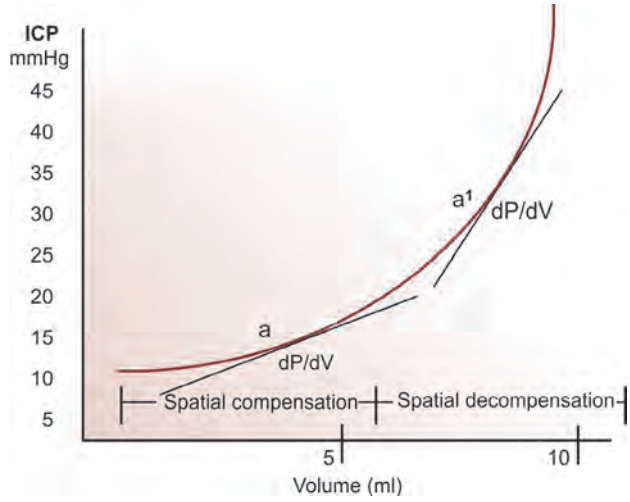

Fig. 4: Intracranial volume-pressure relationship. Note that the elastance at point 'a¹' is more than at point 'a'

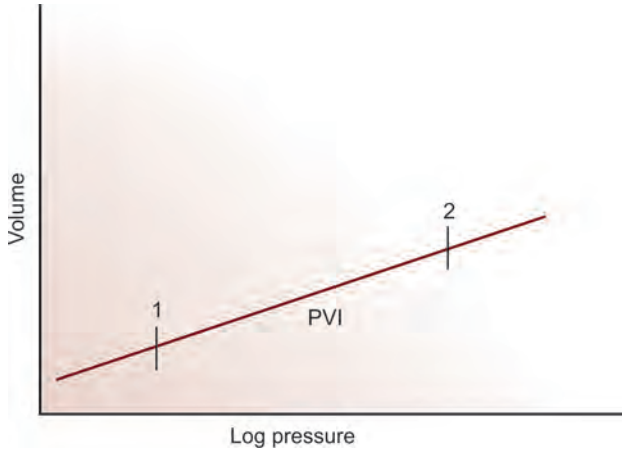

Fig. 5: The pressure-volume index is the slope of the curve between log pressure (abscissa) and volume (ordinate) between points 1 and 2

of critically ill neurosurgical patients, as such measurement provides information about only a small part of the pressure-volume curve, and gives no indication of the remaining compensatory capacity.[70] The pressure-volume index (PVI) is the volume in millilitres that is necessary to raise the ICP to a level 10 times the opening pressure.[45] The slope of the curve drawn between log ICP (abscissa) and volume (ordinate) is the PVI (Fig. 5).[33] As originally described, the test could potentially be dangerous for use in humans and a series of variations of the PVI have been described by various authors. Tans and Poottvliet[72,73] studied PVI in a heterogeneous group of 40 neurosurgical patients and concluded that measurement of the PVI is useful only in patients with normal or minimally elevated ventricular fluid pressures who do not exhibit A waves or runs of B waves. Patients with abnormal waveforms can be assumed to have abnormal pressure-volume indices. They further concluded that a PVI of less than 10 always required measures to reduce the ICP. Wilkinson et al.[78] described the ICP reserve test. A maximum of five 1 ml aliquots of fluid are injected into the subdural space over 5 minutes. The fluid aliquots are infused rapidly at 60-second intervals, with the pressure response defined as the mean ICP 60 seconds following each bolus injection. This test attempts to quantify the overall capacity of the brain to adapt to increased intracranial mass ("reserve") more than simply to determine the elastance of the brain. Guertin et al.[22] reported that abnormalities of the ventricular reserve test were as accurate as the baseline mean ICP elevation in identifying patients at risk of subsequently developing severe intracranial hypertension. Furthermore, when both observations were abnormal, they observed an 80% risk of the patient developing severe intracranial hypertension within 4 hours. Robertson et al.[66] have described a computerised frequency analysis of the ICP waveform. Any change in the shape of the waveform would indicate changes in the compliance of the brain. According to the authors, this method is a safe substitute for the fluid injection techniques to measure the PVI.

PATHOLOGY OF INCREASED INTRACRANIAL PRESSURE

Intracranial hypertension can lead to secondary changes by interfering with the cerebral blood flow (CBF) and by producing brain herniation and pressure on critical structures. Transtentorial herniation with brainstem compression can lead to clinical deterioration even when the blood flow through the cerebral hemispheres is still adequate for tissue oxygenation. A critically located temporal lobe mass may produce uncal herniation and compression of the brainstem without a rise in ICP sufficient to reduce blood flow in the cerebral hemispheres. Similarly, a frontal mass can cause sufficient axial distortion to impair perfusion of brainstem structures.

The average normal CBF is 50 ml/100 g/min. The CBF is influenced by a host of factors like arterial pressure, ICP, arterial blood gases and metabolic demands of the brain. A complex interaction between these variables determines the CBF. Ischaemic changes can develop when the CBF drops to 20 ml/100 g/min. The ICP influences the CBF through changes in the cerebral perfusion pressure (CPP). The CPP is defined as the difference between mean arterial pressure (MAP) and ICP, i.e. CPP = MAP – ICP. A rise in ICP would lead to a fall in CPP unless buffered by a rise in MAP. In a patient with intracranial hypertension, it is important to complement decongestive measures with maintenance of adequate MAP so as to continuously obtain a CPP of 50 mmHg or more. ICP and CPP monitoring are important in the management of head injury patients. However, there are other brain-related measures defined as 'pressures', such as cerebral intra-tissue pressure, critical closing pressure, 'optimal' CPP, non-invasive CPP (nCPP) and non-invasive ICP (nICP), and interhemispherical pressure gradients, which currently draw more attention in the management of head injured patients. Czosnyka et al. found that "Optimisation" of CPP provides a rational compromise between the "Critical Closing Pressure-oriented protocol" and the "Lund concept", thereby allowing individualised tailoring of cerebral haemodynamics. The nICP and nCPP are practical alternatives for invasive monitoring, especially in the early stages of trauma management, and CCP and pressure gradients are prognostic tools.[9]

Raised ICP can cause arterial hypertension (the Cushing response), bradycardia and respiratory changes. There are still a number of uncertainties about the origin of the Cushing response. Traditionally, it has been attributed to an increase in systemic vascular resistance produced by either ischaemia of or pressure on the brainstem. Hoff and Reis[28,29] postulated that ischaemia of the cerebral hemispheres could also elicit the Cushing response. According to them, cerebral ischaemia secondary to intracranial hypertension results in removal of supratentorial inhibition of brainstem vasopressor

centres, resulting in the release of sympathomimetic factors, which in turn cause peripheral vasoconstriction. Increased cardiac output may also be a factor responsible for intracranial hypertension.[19] Severe bradycardia may be the principal alteration in vital signs in patients with acutely expanding lesions such as an extradural haematoma.* The bradycardia produced by intracranial hypertension in experimental animals is unaffected by denervation of the carotid sinuses, is abolished by section of the vagi and is independent of the rise in blood pressure.[11] The occurrence of respiratory irregularities is due to release of the respiratory centres in the medulla as a result of damage to the supramedullary mechanisms. The changes in respiratory pattern depend upon the level of involvement of the brainstem. Damage to the midbrain is associated with Cheyne-Stokes or, rarely, normal respiration. As the pressure head increases to affect the midbrain and upper pons, the patient develops sustained hyperventilation. When the level of dysfunction reaches the upper medulla, breathing becomes more rapid and shallow, and in the final stages of medullary involvement breathing becomes ataxic.[47] The changes that occur in experimental animals in response to an expanding supratentorial mass are a decrease in respiratory rate, bradycardia, cardiac arrhythmias, pupillary constriction followed by unilateral dilatation, increase in pulse pressure and finally an increase in arterial blood pressure.[26] Neurogenic pulmonary oedema is a rare but serious complication of raised ICP. It seems to be mediated by the effects of intracranial hypertension on the hypothalamus, medulla or cervical spinal cord with a resultant increase in sympathetic activity with beta and alpha adrenergic discharge.[4,37,44] The former leads principally to increased cardiac output and decreased systemic hypertension, and plays little role in the production of neurogenic pulmonary oedema. On the other hand, alpha receptor stimulation leads to systemic and pulmonary arterial constriction with an increase in the pressure gradient across the alveolar membrane.

Brain injury biomarkers may have clinical uses in classifying injury severity level, predicting adverse secondary events and monitoring the effectiveness of therapeutic measures. Hergenroeder et al. analysed pooled serum samples obtained from severely injured traumatic brain injury (TBI) patients [Glasgow Coma Scale (GCS) ≤ 8] and age, sex and race-matched volunteers. Samples were immunodepleted for 12 highly abundant serum proteins, and then labelled with mass-balanced isobaric tags (iTRAQ), and analysed by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Their study revealed 31 biomarkers whose serum abundance was altered after head injury. Changes in three candidate biomarkers [serum amyloid A, (SAA), C-reactive protein (CRP) and retinol binding protein 4 (RBP4)] were verified using independent TBI and healthy volunteer serum samples. Receiver operating characteristic (ROC) curve analysis of CRP and SAA indicated they were potent indicators of injury even at very acute time points. Analysis of serum RBP4 levels at 24–36 hours post-injury may predict subsequent increases in ICP with a sensitivity of 86% and specificity of 88% at 11.6 mμg/mL (n = 7, ICP <20 mmHg; n = 8, ICP >25 mmHg). Their results support the use of serum as a source for identifying TBI biomarkers, and indicate that these biomarkers may have uses for predicting secondary pathologies such as elevated ICP associated with TBI.[27]

*It may be mentioned that in clinical practise severe bradycardia is infrequently observed in patients with rapidly increasing ICP.

INTRACRANIAL PRESSURE MONITORING

Intracranial hypertension commonly precedes clinical deterioration.[77] ICP monitoring can forewarn the clinician of impending deterioration and remedial action can be taken before severe or irreversible brain damage can take place. In neurosurgical patients who are paralysed for elective ventilation, it is a reliable method of assessing the neurological status (see Fig. 2). Continuous ICP monitoring, where indicated, helps to optimise brain protection. ICP monitoring has extensively been used in patients with head injury. It is most useful in neurologically stable (GCS 9 or more) patients with a traumatic intracranial haematoma, in whom the decision to surgically evacuate the haematoma is equivocal. A patient with persistently high ICP or a progressively rising ICP not responding to decongestants would merit surgical intervention. According to Galbraith and Teasdale,[18] patients with an ICP of more than 30 mmHg often require surgery. ICP monitoring is also indicated in patients undergoing elective ventilation for traumatic brain swelling. Today, ICP monitoring is only a part of CNS monitoring. CBF studies, continuous transcranial Doppler studies and jugular arteriovenous oxygen difference help to give a better understanding of cerebral perfusion and brain metabolism in TBI.[3]

Lobato et al. studied the incidence of pathological and ICP changes during the acute post-traumatic period in patients with severe head injuries. The aim was to define the most appropriate strategy of serial CT scanning and ICP monitoring for detecting new intracranial mass effect and improving the final outcome. Considering the high incidence of ICP and CT deterioration through the clinical course, along with the absence of strong predictors and the discordances between CT and ICP changes (which were seen in 30.3% of their cases), they recommended ICP monitoring after admission in all patients and serial CT scanning at 2–4, 12, 24, 48 and 72 hours after injury with additional controls as indicated by clinical or ICP changes in all cases.[65] The current Brain Trauma Foundation recommendation of ICP monitoring in those patients presenting with a GCS score <8 with an abnormal CT scan or a normal CT scan with age >40 years, systolic blood pressure <90 mmHg or exhibiting posturing should be followed.[51]

Some neurosurgical centres monitor ICP in patients with aneurysmal subarachnoid haemorrhage (SAH).[1]

A rise in ICP may indicate aneurysmal re-bleed, while neurological deterioration without initial increase in ICP or even an initial reduction in pressure, should alert the neurosurgeon to the likelihood of development of vasospasm rather than an intracranial mass lesion.[75] Continuous ICP monitoring in patients with suspected arrested hydrocephalus and normal pressure hydrocephalus can help to choose patients who may benefit from a CSF diversionary procedure. The detection of transient periods of intracranial hypertension or pathological pressure waves suggests the presence of symptomatic hydrocephalus and a greater likelihood of a successful outcome.[7,20,23]

Torbey et al. reported on the uses of continuous pressure CSF monitoring in establishing the diagnosis of idiopathic intracranial hypertension without papilloedema (IIHWOP) in patients with chronic daily headache (CDH). Pcsf was measured via a lumbar catheter and analysed for mean, peak, highest pulse amplitude and abnormal waveforms. A 1–2 day trial of continuous controlled CSF drainage (10 cc/h) followed Pcsf monitoring. Response to CSF drainage was defined as improvement in headache symptoms. Patients with abnormal waveforms underwent a ventriculoperitoneal shunt (VPS) or lumboperitoneal shunt (LPS) insertion. All patients had normal resting Pcsf (8 ± 1 mmHg) defined as ICP <15 mmHg. During sleep, all patients had B waves and 90% had plateau waves or near plateau waves. All reported improvement of their headache after surgery. Demonstration of pathological Pcsf patterns by continuous Pcsf monitoring was necessary to confirm the diagnosis of IIHWOP, and provided objective evidence to support the decision for shunt surgery. They concluded increased Pcsf was seen mostly during sleep and was intermittent, suggesting that Pcsf elevation may be missed by a single spot-check LP measurement.[74]

Neurosurgical patients who are paralysed and are being electively ventilated in the post-operative period should undergo ICP monitoring. Even in patients who are not being artificially ventilated, post-operative ICP monitoring can be beneficial if the haemostasis was difficult or the brain was not lax at the end of surgery. Constantini et al.[5] in a heterogeneous group of 514 neurosurgical patients reported an average time gap of 5 hours between a rise in the ICP and subsequent clinical deterioration in the post-operative period. In certain non-neurosurgical conditions, like Reye's syndrome and fulminant hepatic failure, ICP monitoring and control can be beneficial. ICP monitoring can also provide an additional objective measurement in assessing brain death.[77] The ICP drops and the waveform dampen. Contraindications to ICP monitoring include widespread scalp infection, any intracranial infection, open compound injury and bleeding diatheses.

Monitoring systems can be divided into fluid coupled and non-fluid coupled systems.[34] The former involves a fluid-filled catheter or a hollow bolt placed in the ventricle, subarachnoid space or the subdural space, connected to a pressure transducer through a fluid-filled line. The transducer converts the hydraulic pressure into an electrical signal which can be displayed digitally or on an oscilloscope. In the non-fluid filled systems, the transducer is mounted on the monitoring device itself. The monitoring devices have variously been designed for use in the ventricle, brain parenchyma, subdural and epidural space. Wheatstone bridge, inductive and capacitate-coupled oscillating circuits and optical transducers have been used. Optical transducers sense changes in the amount of light reflected off a pressure-sensitive diaphragm located at the tip of the catheter. The mean pressure is then displayed digitally. This design has the advantage of being solid state and can be used in the ventricle, parenchyma or in the subdural space. It compares favourably with the fluid-filled ventriculostomy catheter in terms of the pressure recordings; however, it cannot be recalibrated once inserted and needs to be changed every 5 days because the zero drift increases significantly after this period.[8] The cost of this system is high.

The telemetric system consists of an implanted transducer which is telemetered through the intact scalp. This system should particularly be useful for long-term ambulatory monitoring.[21]

Long-term monitoring of ICP is limited due to the lack of an implantable sensor with low drift. Kroin et al.[35] demonstrated a new capacitative transducer system which will produce accurate and stable ICP records over extended periods. The mean ICP and cisterna magna (CM) pressure were compared for months to demonstrate that the transducer system produced minimal drift over time. The change in the ICP sensor record closely duplicated that of the CSF waveform in the CM in response to well-known physiological stimuli. Mean ICP remained within 3 mmHg of CM pressure for months, with a mean difference of less than 0.3 mm Hg. Histological examination of the dog brains revealed only minimal tissue reaction to the presence of the sensor. They advocated the clinical use of this sensor and its telemetry for long-term monitoring of patients with head injury, mass lesions and hydrocephalus.[35] Advancements are being made for developing sensor systems based on microtechnologies and nanotechnologies which allow continuous monitoring and control of therapeutic procedures using wireless pressure monitoring systems.[17]

Efforts have been made at non-invasive monitoring. Totally nICP monitoring would avoid many of the risks of monitoring. Heifetz and Weiss[25] have used modified skull tongs with sensitive strain gauges to measure the ICP by detection of minute skull expansions. They have been able to demonstrate changes in skull expansion that correlate with the results of jugular compression or intraventricular fluid administration. Several devices have been described for measuring ICP through the open fontanelle of infants.[61] However, variable artifacts can be produced by the interposed tissues, depending on the pressure used to apply the sensing device to the

scalp.[30] Newer design modifications have been claimed to have overcome this problem.[69]

The ICP is normally transmitted to the perilymph of the cochlea via the cochlear aqueduct. Tympanic membrane displacement, due to changes in perilymphatic pressure, has been found to correlate with changes in the ICP. This technique is not suitable, if the cochlear aqueduct is not patent or the stapedial reflex is absent. In a clinical study, the tympanic membrane displacement measurement technique was reported to be useful in young patients with hydrocephalus and idiopathic intracranial hypertension.[65] It may prove to be a useful tool in the assessment of acute and chronic shunt malfunction in children.[54]

Although the ICP can be monitored from the ventricle, brain parenchyma, subarachnoid space, subdural space, epidural space and the operative cavity itself, it is important to realise that the pressure is not equal throughout the intracranial space. It is unclear if acute changes in the posterior fossa would be reflected in supratentorial monitoring as surgery, brain shifts and occlusion of the basal cisterns may radically alter the equilibration of the two compartmental pressures and the compliance of the supratentorial and infratentorial compartments may differ.[67] Similarly, the type of pathology producing intracranial hypertension can also influence the distribution of pressure in the cranium.[40] Pressures that involve CSF dynamics are more likely to alter the intraventricular pressure, compared to rapidly forming masses that tend to increase tissue pressure near the mass more than the intraventricular pressure.[50]

Eide described a new method for processing of continuous ICP signals. The amplitude and latency values of the accepted single ICP waves were determined. For accepted 6 second time windows, the mean ICP wave was computed as mean ICP wave amplitude and mean ICP wave latency. The mean ICP wave parameters provide information about the single ICP waves that is not given by mean ICP. Their method has been implemented in software to be used during online ICP monitoring, revealing mean ICP wave amplitude, mean ICP wave latency and mean ICP as numerical values every 6 seconds. The clinical significance of their method was illustrated in four patients by observations that mean wave amplitudes corresponded better to the acute clinical state than the mean ICP; mean wave amplitudes could be elevated despite a normal mean ICP. They suggested that the mean ICP wave parameters are related to ICP-volume compensatory reserve capacity (compliance).[12]

Eide also simultaneously compared continuous ICP signals from two different sensors: Codman ICP MicroSensor; Johnson and Johnson, and Camino OLM ICP; Camino Laboratories, San Diego. They were placed within the brain parenchyma in three patients as part of the management of severe SAH. For each 6 second time window mean ICP was computed, showing large differences in mean ICP values between the signals. Differences above 5 mmHg were observed in 13% of the 128,425 time windows derived from 24 hours ICP recordings in these three patients. Comparisons of 675,503 individual single pressure wave pairs of these 128,425 time windows revealed marginal differences in single wave amplitude (dP, i.e. pulse pressure) and latency (dT, i.e. rise time) values, suggesting that differences in mean ICP were caused by differences in baseline pressure. He concluded that changes in baseline pressure affect mean ICP but not single pressure wave characteristics such as amplitude (dP) and (dT) latency values.[13]

Epidural Monitoring

This is performed by placing the device in the epidural space via a burr hole. These are simple to insert with a low infection rate. It is relatively safe in conditions, like fulminant hepatic failure, where haemostatic abnormalities may coexist and insertion of a parenchymal or ventricular device could be dangerous.[32] However, in this system, there is no provision for CSF drainage and epidural pressures tend to be inaccurate. In a study carried out in a canine model, Sahay et al.[68] found that during continuous intraventricular fluid infusion, the ventricular pressure (VP) initially rises followed by a fall (the latent phase) and again begins to rise (the monotonic phase). The latent phase is not reflected in the extradural pressure (EDP), which remains constant during this phase and begins to rise during the monotonic phase, but remains consistently less than the VP. Some studies in the 1970s have reported that EDP is often lower than that recorded from subdural or intraventricular sites.[6,64] On the other hand, there have also been reports of higher recordings from the epidural sites as compared to the intraventricular pressure.[39] The inelasticity of the dura may be responsible for this discrepancy. More recently, epidural pressures have been reported to be systematically higher than ventricular fluid pressures. This has been attributed to the characteristics of the sensor and to the anatomy of the epidural space. Poca et al. studied these two causes and better explained higher epidural readings. They compared pressure values obtained during simultaneous epidural and lumbar pressure monitoring in 53 patients and during simultaneous subdural and lumbar pressure monitoring in 22 patients. The same non-fluid coupled sensor device was used in all compartments. Their conclusion with epidural ICP monitoring produces artifactually high values not related to the type of sensor used, but to the specific characteristics of the epidural intracranial space.[62]

A permanently implanted epidural sensor permitting long-term telemetric ICP monitoring, consisting only of an inductance and a pressure-sensitive capacitance, has been implanted in 127 patients by Güçer et al. Of these 127 patients, 13 continued to have the sensor in place for 4–9 years. The remaining patients were lost to follow-up or the sensor was removed. The sensor has been evaluated on the basis of accuracy, longevity, safety and

stability. Longevity was proven by successful monitoring over periods of years (in one patient, at least 9 years). They found the sensor to be a safe tool; the only morbidity has been two asymptomatic peri-sensor blood clots in two patients. There have been no infections in any of the 127 cases. The stability of the sensor was evaluated by measuring baseline drift over time. This rate was 1.0 +/- 0.2 mm H_2O/day.[21]

Subarachnoid and Subdural Devices

The subarachnoid and subdural devices are similar. The most commonly used devices for fluid coupled subdural pressure monitoring are the hollow screw or bolt devices, the "subdural cap catheter" and simple catheters placed in the subdural space. The first subdural subarachnoid device was introduced by Vries et al.[76] in 1973, and is also called the Richmond screw. This is a hollow self-tapping screw that is inserted into the skull through a 1/4 twist drill hole after the dura has been incised. The screw is inserted until it protrudes just under the dura in the subarachnoid space but not in contact with the brain. The screw is easy to insert and has an infection rate of about 2% after an average 5 days monitoring.[79] This device can be difficult to insert in very young infants and CSF drainage is possible only occasionally. It has a higher rate of osteomyelitis at the twist drill site (I) and may underestimate the ICP at higher levels as brain tissue may herniate into the device and dampen the waveforms.[57] The failure rate is about 8% over a 5-day period of monitoring.[79] Occasionally, CSF leakage from the twist drill site may develop after removal of the bolt.

The cup catheter is a ribbon-shaped device with a larger and shallower opening on its face for pressure transmission. The design seems to offer a smaller chance of cortical injury, and the choice of exiting the device remotely from the site of monitoring reduces the potential for post-removal spinal fluid leakage or infection compared to the subarachnoid bolt.[57,77] Being fluid coupled, this device is also dependent on frequent fluid flushing to maintain an adequate volume for pressure transmission.

Intracranial pressure can also be measured from a subarachnoid catheter. A subarachnoid catheter has been reported to be more reliable compared to the subarachnoid bolt and has a lower failure rate.[52] However, the method does not permit removal of the CSF.

The use of the Camino fibreoptic subdural device for the measurement of ICP in patients has been found comparable with recordings from the intraventricular fluid-filled catheter. Studies have also demonstrated accuracy for the Codman MicroSensor ICP Transducer, a miniature strain gauge mounted on a flexible nylon catheter.[53] Fernandes et al. conducted a comparative study in patients between the Codman MicroSensor and a Camino Transducer which was fitted immediately adjacent to it. A computerised system was used to continuously record both ICP readings. The readings from the two ICP transducers were compared on time series, logistic regression and Altman-Bland plots. Drift of the ICP, recorded by the Codman MicroSensor, was noted in two patients, one in the positive direction (maximum 30 mmHg) and one negative (maximum 20 mmHg). In both cases, the Camino ICP recording was relatively stable. In 24% of the readings, the Codman MicroSensor recorded ICP as 5 or more mmHg greater than the Camino, this difference was 10 mmHg or greater in 9% of readings. Conversely, the Camino recording was 5 mmHg or more than the Codman in 5% of all recordings, and 10 mmHg or more in 3%. They concluded that these differences, in the majority of cases (excepting the negative drift), could be explained by a constant offset of the Codman transducer.[14]

Parenchymal Monitoring

This has become popular in some centres since the availability of non-fluid filled devices, like the fibreoptic system and the piezoresistive microtransducers[60] which can easily and safely be implanted into the brain parenchyma. A parenchymal fluid-filled catheter coupled with a transducer frequently gets clogged with brain matter and clots.[8] Parenchymal monitoring has been reported to be useful in patients with small ventricles or large shifts, in large craniectomies or open compound injuries with dural loss where placement of an epidural or subdural device may be difficult.[8,60] Parenchymal monitoring is again handicapped by the inability to drain CSF.

Intraventricular Monitoring

This remains one of the most popular techniques and is probably the procedure of choice in patients with ventriculomegaly. It is very accurate, and is the current gold standard against which other methods are compared. A variety of sets are available commercially, but basically they all consist of a ventricular catheter which is fluid coupled to a strain gauge transducer. The placement of the catheter is simple and the standard landmarks for a ventricular tap are followed. It is usually placed in the frontal horn and tunnelled from its site of exit from the skull to the point of exit from the scalp. Placement of the catheter is verified by the drainage of fluid and an adequate waveform on the monitor. It offers the added advantage of therapeutic drainage of CSF to lower the ICP, and can also be used to perform CSF dynamic studies. The major disadvantage is that it may be difficult to insert in patients with small ventricles or significant shifts. The risk of infection varies from 8% at 5 days to 40% at 12 days.[46] Other studies have also shown that the risk of infection increases if the catheter remains at the same site beyond 5 days, and therefore it is advisable to change the site every 5 days if the patient requires a ventriculostomy catheter for a longer period. Intracranial haemorrhage was seen in about 2% of the cases in a large series.[55] The failure rate is considerably lower than with the subarachnoid bolt.[57]

ICP monitoring from the operative cavity in the posterior fossa using a fluid-filled catheter has been reported to be safe and more accurate than supratentorial monitoring after posterior fossa surgery.[67] It also has the added advantage of allowing drainage of CSF or collected blood whenever required.

Catheter tip transducer systems using strain gauges or fibre-optical pressure sensing techniques are currently in clinical use. With these devices, zero drift and calibration cannot be checked *in vivo*. All the present ICP monitoring devices in clinical use require a physical connection between the brain and the external environment. This becomes a source of infection, limiting the duration of monitoring. A number of telemetric monitoring devices, in which data is transmitted transcutaneously, have been developed over the last two decades. All the present ICP monitors are temporary percutaneous implanted devices. Placement of these devices carries significant morbidity, particularly infection. Apart from decreasing the risk of infection in patients with severe head injury, the clinical value of an accurate telemetric ICP monitoring system which maintains its reliability over a long period of implantation is high.[16]

O'Neill et al. conducted a survey, sent to 3,100 practicing neurosurgeons and a similar survey to 720 neurosurgery residents, to assess the current practice patterns of these procedures. Basic demographic information and estimated rates of proper ventriculostomy placement were sought. A total of 934 practicing neurosurgeons and 100 neurosurgery residents responded to their survey. Their study revealed a mean of 1.4 passes per ventriculostomy procedure for practicing neurosurgeons, 1.4 for senior residents and 2.4 for junior residents, with a rate of successful cannulation of the ipsilateral ventricle ranging from 72% to 84% for these groups. Both residents and practicing neurosurgeons admit to frequently using multiple passes and frequent catheter placement outside the ipsilateral frontal horn. Despite these imperfections, survey respondents were reluctant to embrace technology that could improve placement accuracy if it increased procedure time.[58]

Lumbar Monitoring

Kusaka et al. reported a new lumbar method for monitoring ICP in rats. A PE10 catheter connected to a pressure transducer is placed into the subarachnoid space of L5 through the dura following laminectomy to record lumbar CSF pressure (lumbar-ICP). Simultaneously, ICP at the CM (cisterna-ICP) was recorded using a catheter placed in the subarachnoid space at the CM. Anaesthetised adult male rats were subjected to baseline recording followed by experimentally induced SAH or intracerebral haemorrhage. Baseline lumbar-ICP and cisterna-ICP varied between 6 mm and 8 mmHg, and respiratory variation could be detected. Then an acute response to SAH was recorded in both the lumbar-ICP and the cisterna-ICP in all rats. They found that the lumbar catheter continuously and accurately monitored lumbar-ICP, and reliable pressure tracings were obtained for up to 24 hours after SAH. They concluded this new lumbar-ICP method is simple, safe, easy and reliable in rats.[36]

5 Neuro-Ophthalmology

Tandon R, Saxena R, Phuljhele S

It has been said that the eye is the window to the brain. Neuro-ophthalmology, which includes examination of the optic nerve, fundus, ocular movements, pupillary and corneal reflex, along with charting of the visual fields, contributes a great deal to the neurological evaluation. In this chapter only the examination of the visual field is discussed with particular reference to the various types of field defects that can occur with brain tumours.

Brain tumours may affect the visual pathway by direct compression or indirectly, through various mechanisms (Table 1).

THE NORMAL FIELD OF VISION

The visual field is a three dimensional area which is visible through each eye when fixating at a central target. The field of vision is centred at a fixation point of each eye, as an asymmetric oval shape extending maximally on the temporal side for about 90 degrees. The superior and inferior fields have an extension of 40 and 60 degrees, respectively. Nasally it is restricted by the nasal bridge and measures up to 40 degrees. There is binocular representation of the visual fields for 60 degrees to the right and left of a common fixation point.

THE NORMAL VISUAL PATHWAY

The visual pathway begins with stimulation of photoreceptors of the retina and processing in the ganglion cells. The axons of the ganglion cells converge to form the optic nerve. The nerve then travels through the optic canal and emerges in the intracranial cavity at the sellar region. At this juncture the nasal fibres of the optic nerve cross to form the optic chiasm. The contralateral nasal fibres and ipsilateral temporal fibres continue together as the optic tract, which provides for one-half of the binocular visual field. The optic tract is relayed in the ipsilateral lateral geniculate body (LGB) where sorting of fibres occurs. The third order neurons commence from the LGB and continue as the optic radiation that terminates in the visual cortex (area 17) of the occipital lobe (Fig. 1).

Table 1: Effect of brain tumours on visual pathways

Brain tumours	
Direct effects	*Indirect effects*
• Direct compression	• Papilloedema • Impact of tumour resection • Post-radiation neuropathy • Toxic effects due to chemotherapy • Metastatic lesions to retina or infiltration of optic nerve • Haematological effects like ischaemia, venous engorgement

ASSESSMENT OF VISUAL FIELD

Any form of deviation or loss in extension and pattern of the field from normal is considered a defect and has

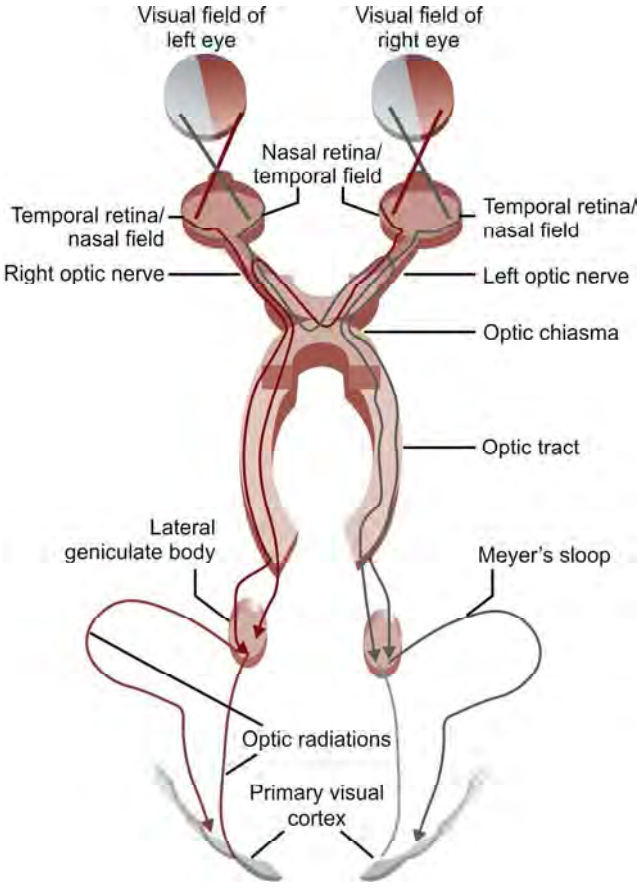

Fig. 1: Visual pathway

clinical implications in the management of brain tumours. The pattern of field defect can give information regarding the localisation of lesions along the visual pathway, while monitoring of field defect would help in determining the progression or recurrence of a brain tumour.

The process of estimating and mapping the field of vision is called perimetry. The field of vision of a patient can be assessed by various methods; the easiest and convenient for bed side examination is confrontation examination. This is a crude and subjective evaluation, wherein the examiner compares the visual field of the patient to his own field of vision. More sophisticated methods used routinely in clinical practice include Goldmann perimetry and automated perimetry, which are objective and hence more reliable methods. These techniques can precisely map and record the peripheral (full extent) as well as central (central 30°) field of vision, respectively (Figs 2A to D).

INTERPRETATION OF VISUAL FIELD

Terminologies

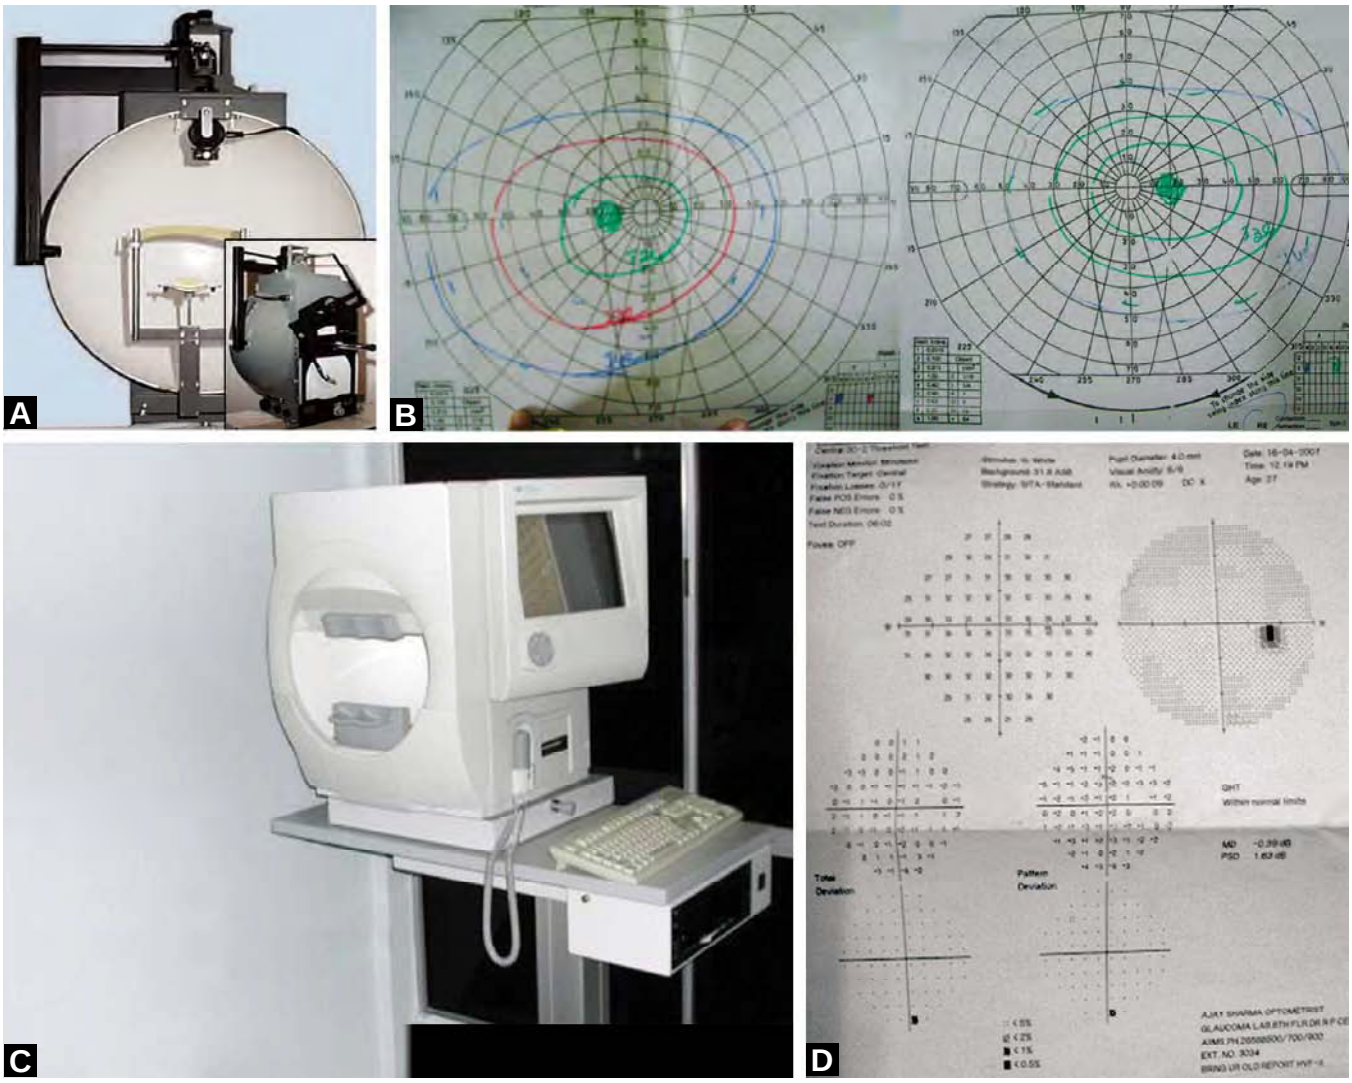
Isopter: It is a line joining the retinal points of the same sensitivity.

Constriction: Implies that there is generalised decrease in sensitivity of the retina and on kinetic perimetry it encloses a smaller area than normal.

Hemianopia: When one-half of the visual field is involved either in one or both eyes.

Homonymous: When the defects are present in the visual fields of both eyes and are on the same side of the vertical meridian.

Heteronymous: When the defects are present in the visual fields of both eyes but are on the opposite sides of the vertical meridian.



Figs 2A to D: (A) Goldmann perimetre. (B) Extent of normal visual field on Goldmann perimetry. (C) Automated perimetre. (D) Extent of normal field of vision on automated perimetry

Scotoma: It is a localised area of decreased sensitivity. It may be absolute, when the patient cannot see even the brightest possible stimulus or it may be relative if some of the stimuli are seen. They can be classified either by their location or by shape.

Congruency: The extent to which the homonymous field defect in one eye resembles that in the other eye in terms of shape, size, depth and slope of the margins.

VISUAL FIELD DEFECTS

The arrangement of visual fibres in a particular region of the visual pathway determines the characteristics and shape of visual field defects. In general, lesions anterior to the optic chiasma produce monocular defects, while lesions affecting the chiasma and beyond are always bilateral. Heteronymous defects are seen in chiasmal lesions, while all lesions affecting the visual pathway beyond the chiasma produce homonymous lesions. The more posterior a lesion is in the visual pathway, the more congruent field defect it will produce. For example, a lesion of the occipital lobe will produce a more congruent field defect than that of the optic tract. Table 2 summarises the pattern of field defects produced by various brain tumours.

Retina

Anatomy

The visual field and the retina have an inverted and reversed relationship. Thus, light rays from the temporal visual field stimulate the ganglion cells of the nasal retina. The axons of these ganglion cells form the nerve fibre layer and finally converge at the optic nerve head and exit as the optic nerve.

Organisation of Retinal Nerve Fibre Layer

The inner most layer of the retina; retinal nerve fibre layer (RNFL) bundles converge in a specific pattern to form the optic nerve head. The papillomacular bundle is formed by macular fibres that enter the temporal aspect of the disc. The arcuate nerve fibre bundle contains the axons that arise temporal to the fovea and arch superiorly and inferiorly to the fovea, to enter the superior and inferior poles of the disc, respectively. The axons from the nasal retina enter radially in to the optic nerve head, as the nasal nerve bundle. Thus, the macular fibres are centrally placed, while fibres from the upper part of the retina lie superiorly and those from the lower retina are placed inferiorly in the optic nerve (Fig. 3).

Table 2: Visual field defects according to the location of the tumour

Location of tumours	*Structure involved*	*Type of field defect*
Orbit • Optic nerve glioma • Optic nerve meningioma	• Optic nerve	Total field loss (early lesions may present with central or centrocecal field defect)
Sella • Pituitary adenoma • Craniopharyngioma • Meningioma	• Chiasma • Chiasma • Willebrand's knee	• Bitemporal field defect • Bitemporal field defect • Junctional scotoma
Mid brain • Craniopharyngioma • Meningioma • Large pituitary adenoma • Aneurysms • Hamartomas	• Optic tract • Lateral geniculate body	• Homonymous hemianopia (macular splitting) • Sectoral defects
Parietal lobe • Meningiomas • Gliomas • Metastasis • Vascular	• Superior part of optic radiation	• Inferior quadrantic field defect • Homonymous hemianopia (macular splitting)
Temporal lobe • Gliomas • Metastasis • Vascular	• Inferior part of optic radiation	• Superior quadrantic field defect (usually incongruous in nature)
Visual cortex • Gliomas • Meningiomas • Metastasis • Vascular	• Occipital lobe	• Homonymous hemianopia sparing macula. (Complete or Partial depending upon the size of the tumour)

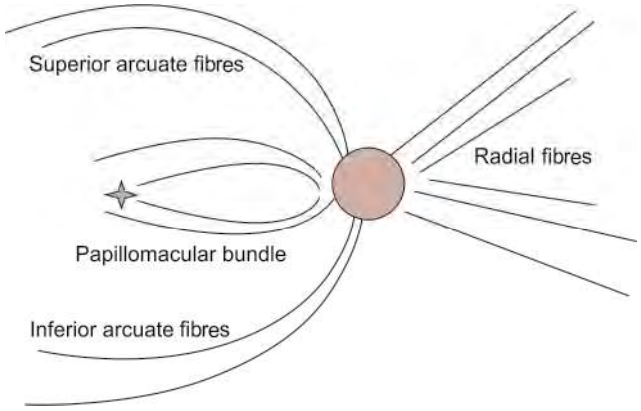


Fig. 3: Arrangement of nerve fibres as RNFL

Fields Defects

The layer of the retina that is affected by the disease process determines the pattern of field defect. Lesions in the outer retina have no particular definite boundaries, so they can produce field defects of varying shapes and sizes, while involvement of the RNFL produces a field defect corresponding to the particular pattern of the nerve fibre bundle affected (Fig. 4). The field defects produced by the involvement of RNFL are well demarcated and respect the horizontal meridian. They characteristically either involve the blind spot or point towards it. These defects should be differentiated from the sectoral defects and quadrantic defects produced by the LGB and the cortex, which respect the vertical meridian and start from the fixation point.

Papillomacular bundle involvement results in a central scotoma (Fig. 5A), centrocecal scotoma or paracentral scotoma.

Arcuate nerve fibre bundle lesions may cause a variety of field defects like: Bjerrum or arcuate scotoma, Seidel scotoma, Nasal step of Ronne, depending on the site of the lesion. Arcuate field defect (Fig. 5B) is seen in many conditions, apart from anterior optic nerve lesions (see the following box):

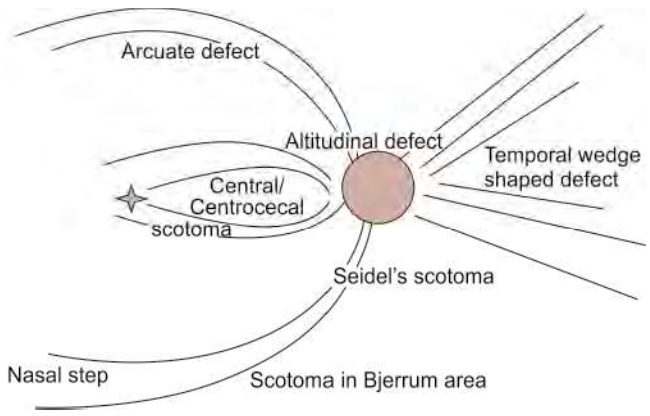

Fig. 4: Field defects produced by involvement of a specific nerve fibre bundle

1. Glaucoma
2. Chorio-retinal lesions
3. Juxtapapillary choroiditis
4. Myopia with peripapillary atrophy
5. Central retinal artery occlusion
6. Branch retinal artery occlusion
7. Ophthalmic artery or carotid artery occlusion
8. Drusen
9. Optic nerve pit
10. Chronic papilloedema
11. Anterior optic nerve lesions

Involvement of the nasal fibre bundle leads to temporal wedge shaped defects.

Optic Nerve

Anatomy

The optic nerve is formed by the axons of retinal ganglion cells that converge to form the nerve fibre bundles. It is about 50 mm in length and can be divided into four parts: optic nerve head (intraocular part 1 mm), intraorbital (25 mm), intracanalicular (10 mm) and intracranial (15 mm).

Organisation

The above described arrangement of the nerve fibres is maintained throughout the optic nerve, such that even lesions involving the posterior part of the optic nerve produces a pattern corresponding to the nerve fibre bundle involved (Fig. 6).

Field Defects

In addition to the field defects described above, the involvement of axons at the superior or inferior pole of the optic disc produce *altitudinal defects* (Fig. 7).

The Chiasma

Anatomy

The chiasma is formed by the crossing of the nasal fibres of each optic nerve. It is located over the diaphragm sella and is posteriorly related to the wall of the third ventricle. There may be variations in the location of the chiasma that have important clinical significance for localisation of the lesion. In 80% of the population, it is located directly over the sella (central); in such cases, pituitary lesions involve the chiasma first. In about 10% of the normal population, it is located more anteriorly over the tuberculum sellae (prefixed); here pituitary lesions will involve the optic tract first. In the remaining 10% of cases it is located more posteriorly over the dorsum sella, where pituitary lesions involve the optic nerve first.

Anteriorly, the chiasma is related to the anterior cerebral arteries and their communicating branches. Posteriorly, it is related to the hypophyseal stalk and the pituitary body. It is immediately inferior to the floor of the third ventricle and lies above the hypophysis.

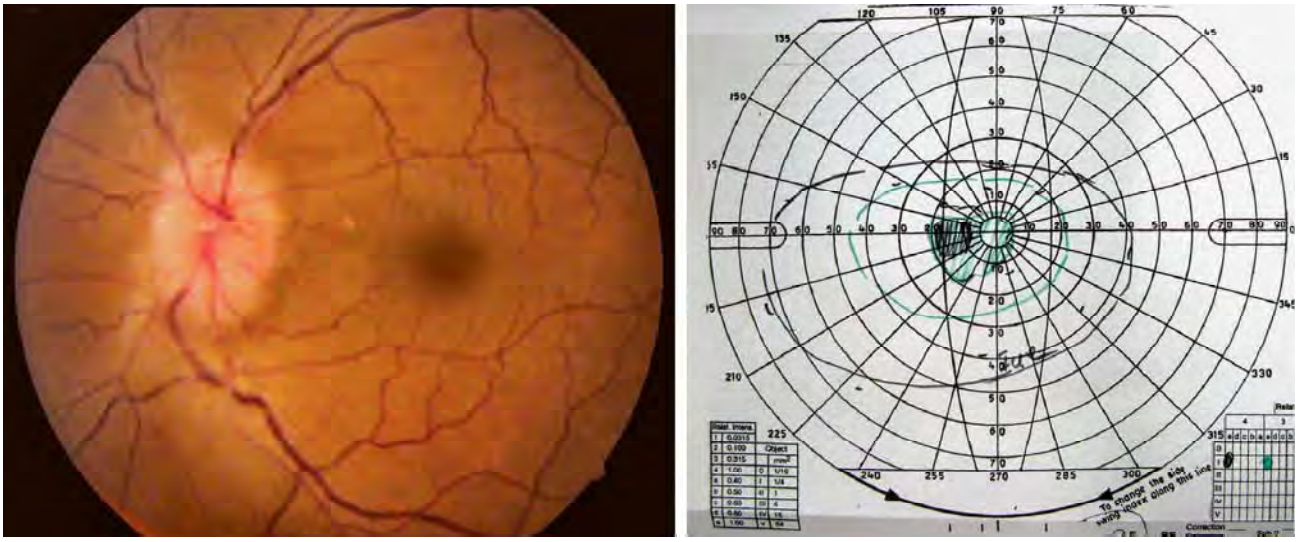

Fig. 5A: Fundus picture. Central scotoma in case of optic neuritis

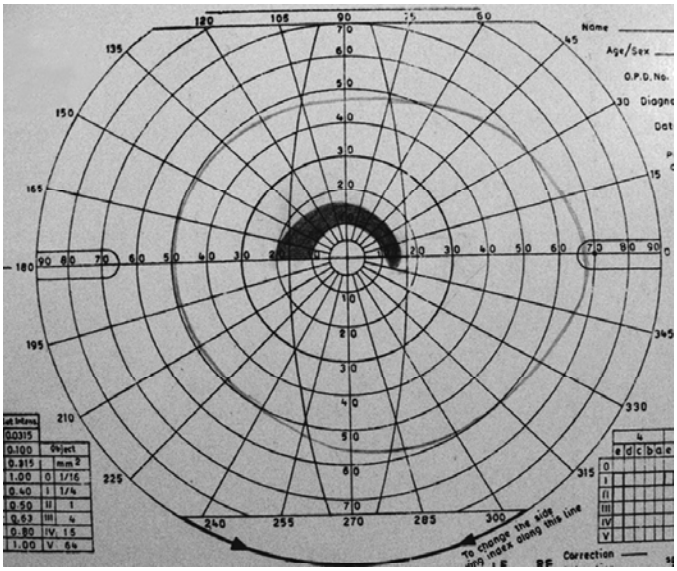

Fig. 5B: Arcuate field defect

Laterally, it is related to the internal carotid artery and the cavernous sinus.

Organisation

At the chiasma, the fibres representing the nasal visual field (temporal fibres) are present in the lateral part. The

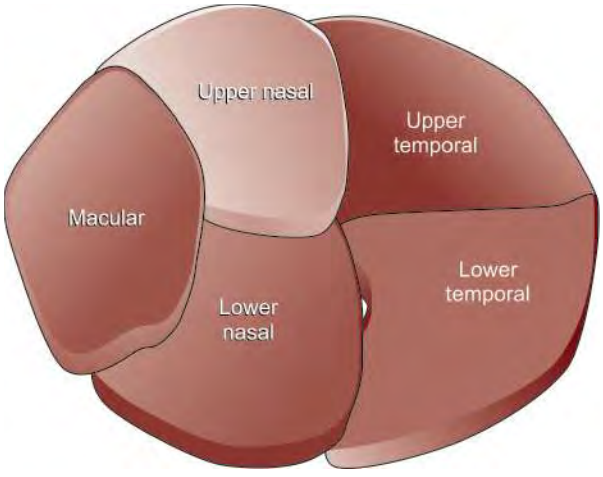

Fig. 6: Arrangement of nerve fibres in optic nerve

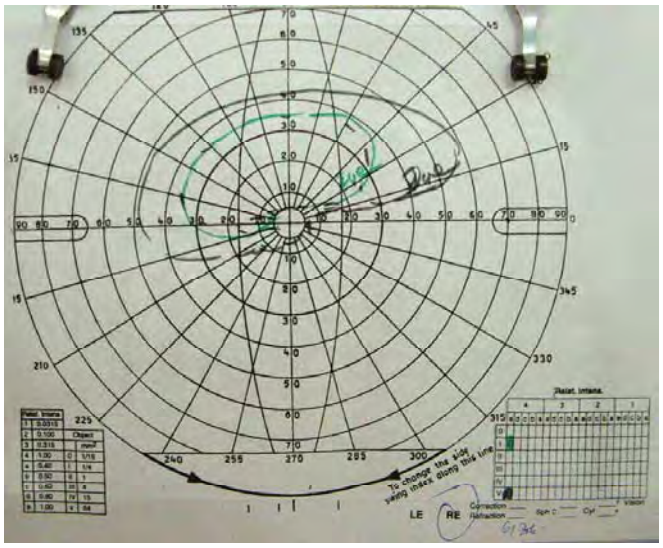

Fig. 7: Altitudinal field defect in a case of non-arteritic ischaemic optic neuropathy

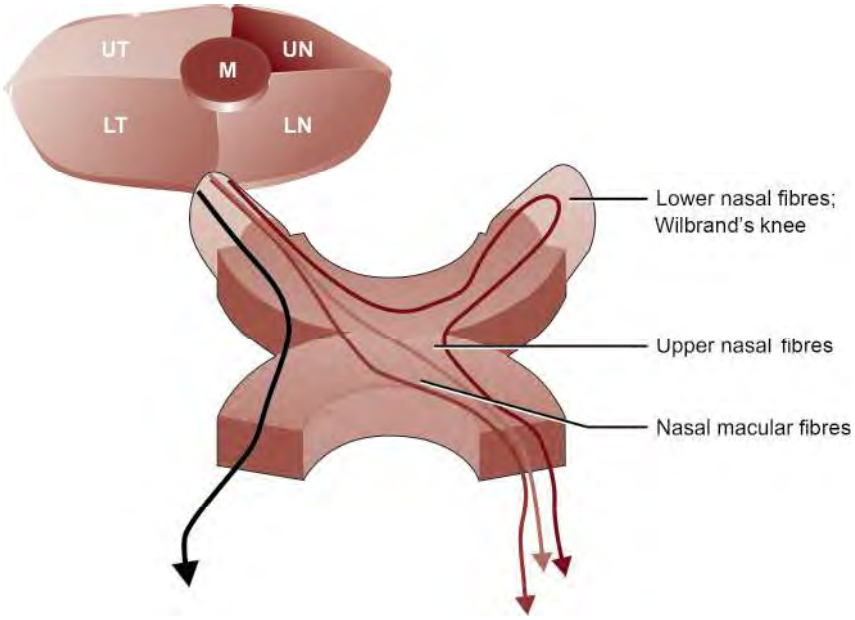

Fig. 8: Decussation of optic nerve fibres at the chiasma

inferonasal fibres (superior temporal field) cross anteriorly in the chiasma and loop forward into the contralateral optic nerve, forming von Willebrand's knee and then continue in the contralateral optic tract. The nasal macular fibres decussate most posteriorly. The upper nasal fibres (inferior temporal field) cross in the middle (Fig. 8). Thus, the right optic tract constitutes the right nasal field (right temporal axons) and the left temporal field (left nasal decussated fibres) representing the left half of the visual space.

Clinical Features

A patient with a chiasmal lesion presents with varying signs and symptoms, depending upon the type, size and site of the lesion. Pituitary adenoma presents with signs of compression of the visual pathways, as well as other features of hormonal disturbance. There may be unilateral or bilateral loss of vision, as a result of concurrent compression of the optic nerve by the tumour. Relative afferent pupillary defect may be present in unilateral lesions. Lesions of the cavernous sinus and large pituitary adenomas compress the motor nerves of the eye, leading to ocular motility disorders. See-Saw nystagmus and oscillopsia are features of tumour or trauma.

Field Defects

The axons in the chiasma are arranged in such a way that they are limited by a vertical meridian, which passes through the fovea of each eye. Thus, a lesion of the chiasma and the proximal visual pathway will have the following features:

- Hemianopic defect (bilateral defect)
- Originates from the fixation point
- Respects the vertical meridian
- Patients with retrochiasmatic lesions do not have decreased visual acuity

The field defect produced by a lesion involving the chiasma depends upon the location of the chiasma, site of the lesion and part of the chiasma affected.

Bitemporal hemianopia: Lesions that affect the body of the chiasma produce bitemporal hemianopia (Fig. 9A). Lesions of the pituitary gland, i.e. tumours, inflammation or haemorrhage are the common conditions that can affect the body of the chiasma and produce classical bitemporal

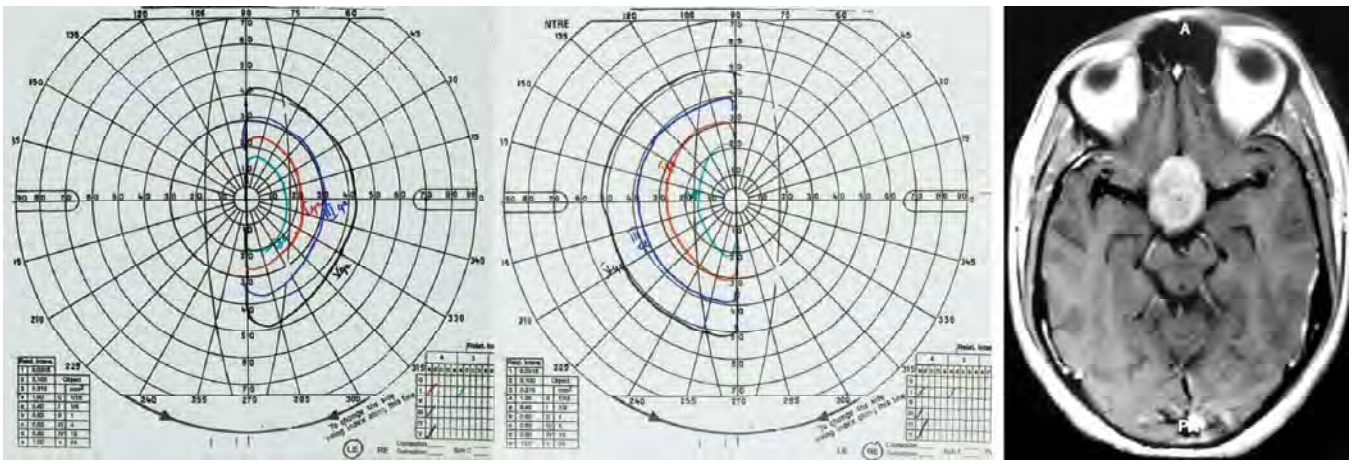

Fig. 9A: Bitemporal hemianopia in a case of pituitary adenoma. MRI of large pituitary adenoma

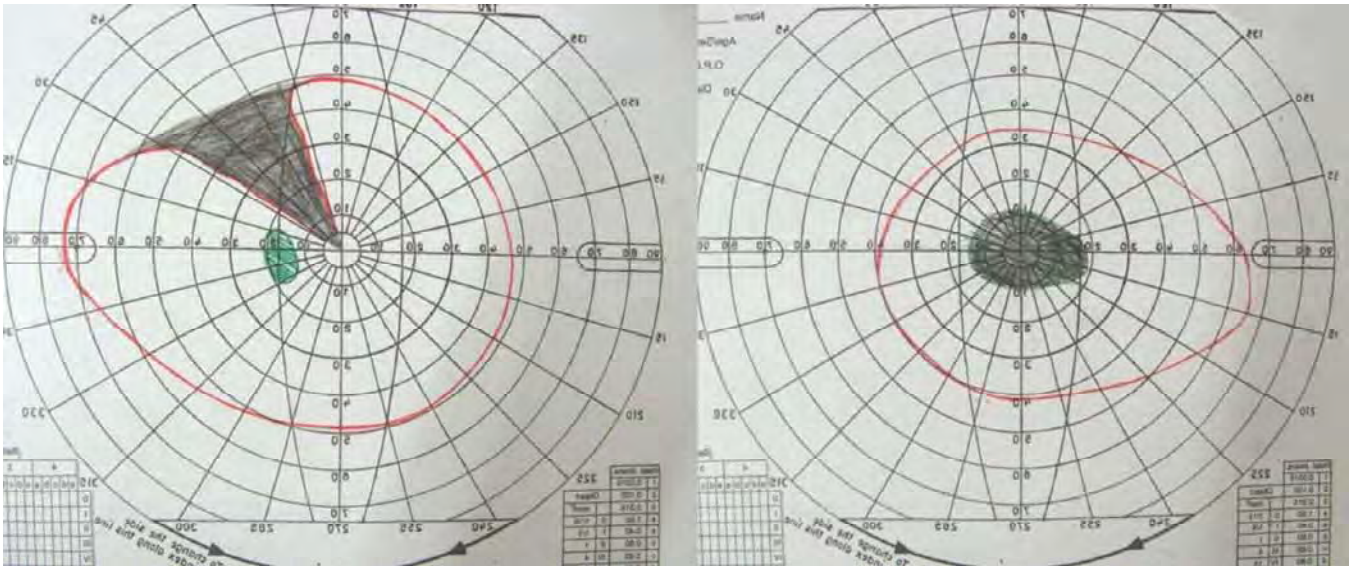

Fig. 9B: Junctional scotoma

hemianopia. Inferior bitemporal hemianopia is characteristic of craniopharyngioma. Saccular aneurysms of vessels in the circle of Willis can also lead to bitemporal hemianopia. Other ophthalmic conditions that can cause a similar field defect are bilateral glaucoma and other optic neuropathies, disc anomalies and psychogenic visual loss.

Junctional scotoma: It is produced when a lesion involves the junction of the optic nerve and chiasma, leading to an optic nerve defect in the ipsilateral eye and superior temporal (involvement of von Willebrand's knee) defect in the contralateral eye (Fig. 9B). A lesion involving the hemichiasma would cause total blindness in one eye (optic nerve of ipsilateral eye) and temporal hemifield defect in the contralateral eye (decussating nasal fibres of the contralateral eye). Lesions like meningioma, that arise from the dura of the tuberculum sellae and adjacent structures compress the optic nerve, as well as the chiasma. Depending upon their site and size they may lead to asymmetric involvement of both eyes. Craniopharyngiomas can also lead to asymmetric visual field defects. Meningiomas and craniopharyngiomas, when small in size, lead to compression of the posterior part of the optic nerve or anterior part of the chiasma, leading to mono-ocular field defect in the ipsilateral eye, most commonly in the superotemporal quadrant (inferonasal decussating fibres). A proper and careful field evaluation will expose the subtle involvement of the contralateral eye.

Binasal field defects: A large mass lesion compressing one side of the optic chiasma, on further enlargement, causes a midline shift of the chiasma with subsequent compression of the other side as well, leading to a binasal field loss presentation (Fig. 9C). This pattern of field loss can also be seen with empty sella syndrome, arachnoiditis and after surgery for pituitary tumours.

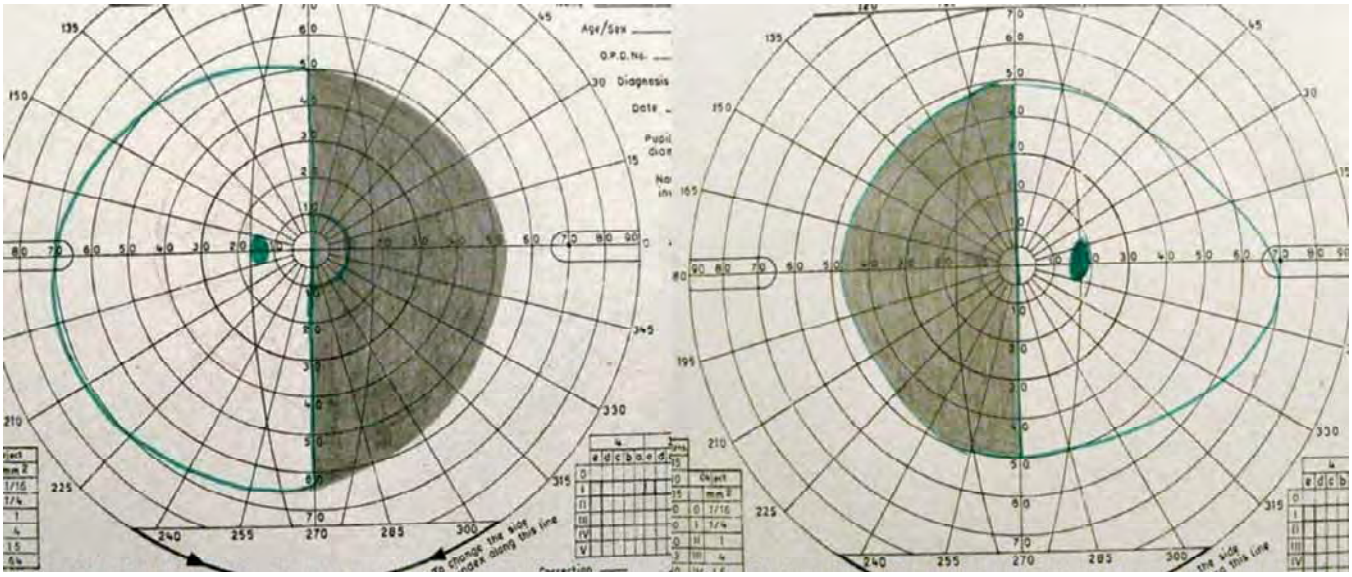

Fig. 9C: Binasal defect

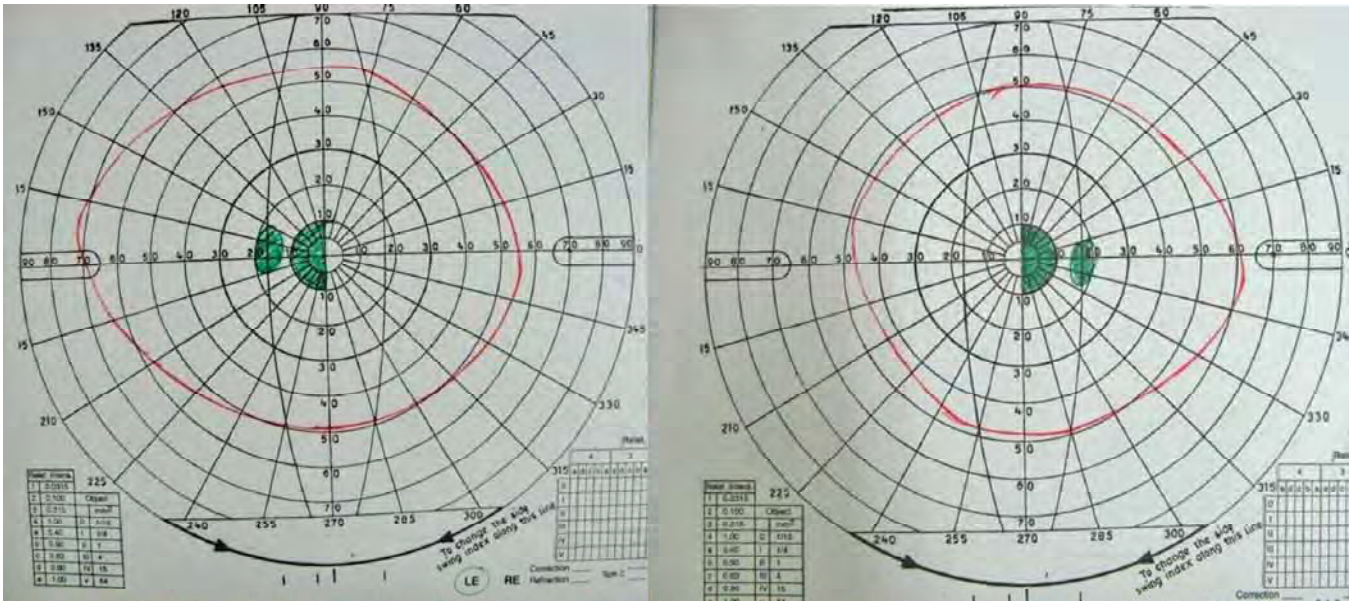

Fig. 9D: Central bitemporal hemianopia

Homonymous hemianopia: This type of field defect is commonly seen in cases where the chiasma is prefixed. Thus, any lesion which affects the chiasma can also affect the optic tract, leading to homonymous hemianopia. Large pituitary adenomas and craniopharyngiomas are the most common causes.

Lesions that affect the posterior part of the chiasma cause *central bitemporal hemianopia* (Fig. 9D).

Optic Tract and Lateral Geniculate Body

Anatomy

The optic tract runs superiorly and posteriorly from the optic chiasma and curves around the brainstem to terminate in the LGB. The LGB is a part of the thalamus and is situated along the lateral aspect of the midbrain. Each geniculate body consists of six layers of neurons and second order fibres, travelling through the optic tract, are relayed in different layers of the LGB. It receives dual blood supply from the anterior and lateral choroidal arteries, which nourish the fibres from the superior and the inferior homonymous quadrants of the retina, respectively. The optic tracts lie between the tuber cinereum and the anterior perforated substance.

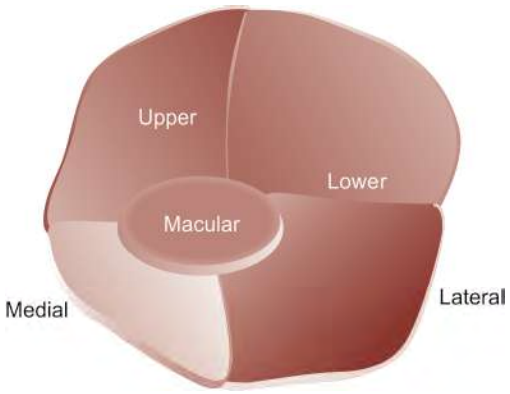

Fig. 10: Arrangement of fibres in the right optic tract

Organisation

Each optic tract is formed by the temporal fibres of the ipsilateral eye and the nasal fibres from the contralateral eye. Thus, each optic tract represents the contralateral half of the binocular visual field. The arrangement of axons present in the optic nerve takes a 90 degree turn through the chiasma into the optic tract (Fig. 10). Thus, the axons from the lower retina lie in the lateral aspect; the axons from the upper lie in the medial aspect, while the macular fibres lie in the dorsolateral aspect.

The axons from the ipsilateral eye are relayed in nuclei layer 2, 3 and 5, while the axons from the contralateral side relay in 1, 4 and 6 nuclei layer. The fibres from the upper part of the retina occupy the medial half of the anterior one-third of the LGB. The lower retinal fibres occupy the lateral half of the anterior one-third of the LGB, while the macular fibres are relayed in the posterior two-third of the LGB (Fig. 11).

Clinical Features

The characteristic hemianopic atrophy or Bow tie pattern of optic atrophy is seen in longstanding lesions of the optic tract and LGB. The most useful sign of localising a lesion between the optic tract and LGB is involvement

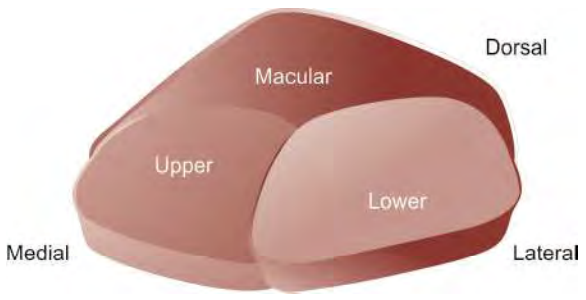

Fig. 11: Arrangement of fibres in the lateral geniculate body

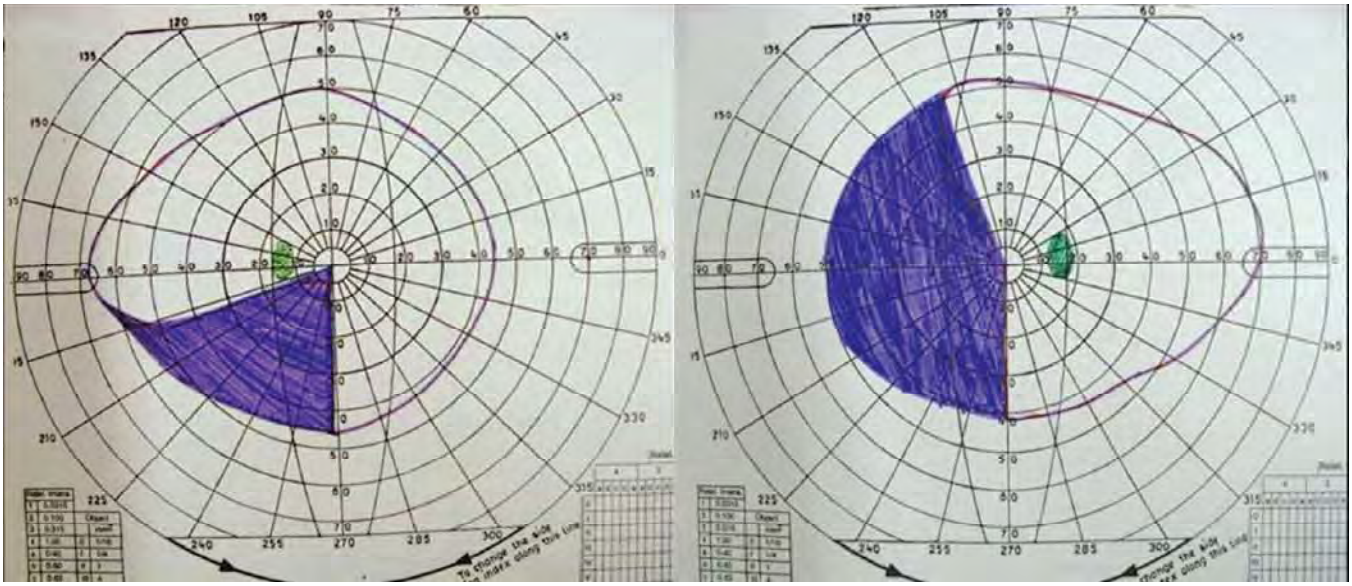

Fig. 12: Incongruous field defect in optic tract lesion

of the pupil. Optic tract lesions are associated with various pupillary abnormalities including RAPD on the contralateral side, Wernicke's hemianopic pupil[1] and Behr's pupil[2], while in lesions of the LGB, pupillary reactions are spared.

Lesions affecting the optic tracts are craniopharyngiomas, meningiomas, and large pituitary adenomas, demyelinating diseases, vascular lesions such as aneurysms, arteriovenous malformations and hamartomas. Lesions affecting the LGB include infarction, tumours, trauma and inflammatory disorders.

Field Defects

Complete optic tract disruption on one side leads to complete macular splitting homonymous hemianopia, while partial involvement will cause an incongruous field defect (Fig. 12). Similarly, a defect in one LGB will produce complete homonymous hemianopia, while partial lesions of the LGB cause a sectoral field defect (Fig. 13).

Optic Radiations

Anatomy

The optic radiations are geniculocalcarine pathways that extend from the LGB to the visual cortex. They cross the Wernicke's area as optic peduncles and travel in the retrolenticular part of the internal capsule.

[1]Wernicke's hemianopic pupil refers to the condition when the pupil does not react to the light projected from the direction of hemianopic field defect.

[2]Behr's pupil refers to the larger pupil seen in an optic tract lesion. It is seen on the contralateral side of the lesion and is usually associated with hemiparesis, particularly in cerebrovascular accidents.

Organisation

The fibres, after exiting from the LGB, rotate by 90 degrees again to regain their original arrangement. Thus, the superior fibres lie in the upper part of the radiation, the inferior fibres in the lower part and the macular fibres lie in the centre (Fig. 14).

Arrangement of fibres in the temporal lobe: The inferior fibres from the corresponding superior visual fields of both eyes commence from the anterolateral part of the LGB, sweep anteriorly and then laterally along the temporal horn of the lateral ventricle to form Meyer's loop, then extend posteriorly to end in the area below the calcarine fissure of the occipital cortex (Fig. 15).

Arrangement of fibres in the parietal lobe: The superior fibres that carry the inferior field travel directly through the lower portions of the parietal cortex to the occipital lobe area above the calcarine fissure (Fig. 15).

Clinical Features of Temporal Lobe Involvement

The clinical features of temporal lobe lesions are seizures, paragnosia, involuntary movement of the mouth, and visual and auditory hallucinations. Aphasia is characteristic of left temporal lobe lesions. The most common temporal lobe lesions are tumours which include glioma and metastasis. Surgical resection of the tumour (when more than 8 cm), itself may produce field defects. Anterior choroidal artery occlusion may affect the optic radiation in the temporal lobe and LGB. In such cases, hemianaesthesia along with contralateral hemiplegia occurs. Other lesions are trauma, demyelination and abscess.

Clinical Features of Parietal Lobe Involvement

The two most important localising signs of a parietal lobe lesion are loss of normal optokinetic response and

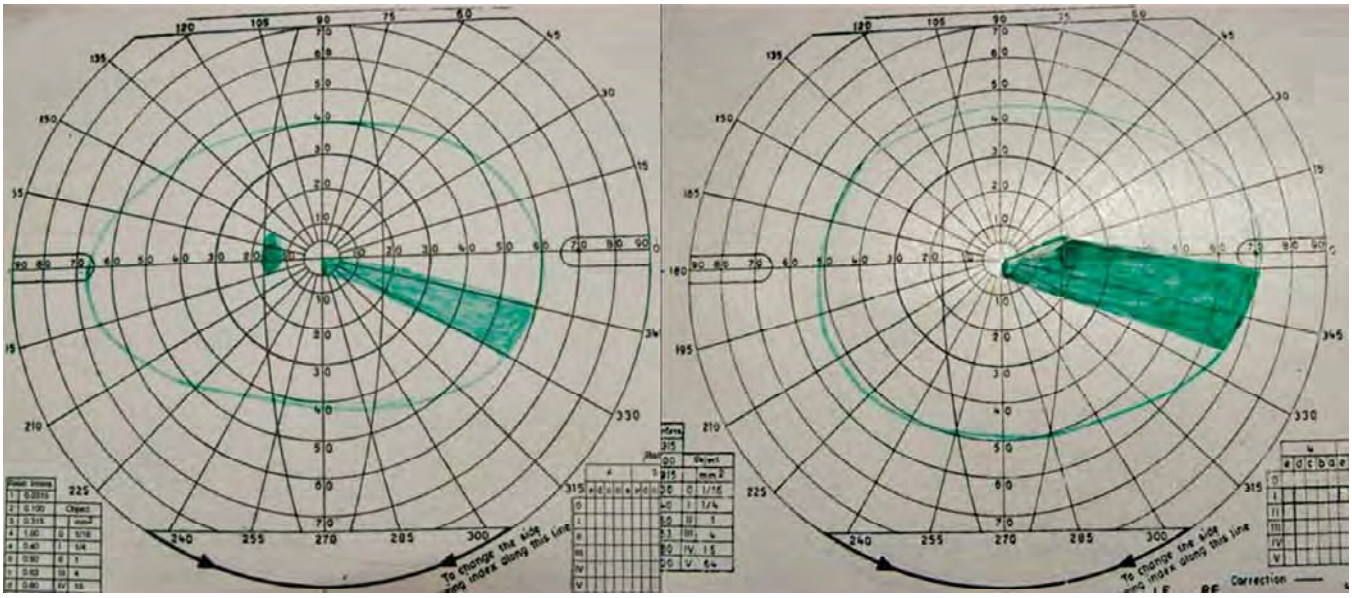

Fig. 13: Right sectoral homonymous defect in left lateral geniculate body lesion

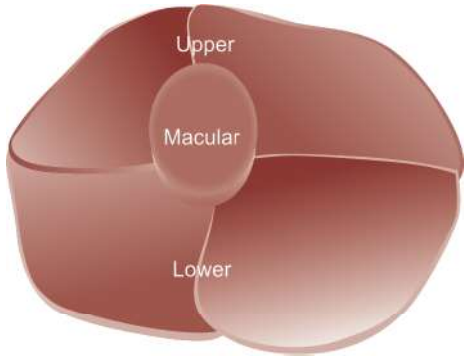

Fig. 14: Arrangement of fibres in optic radiations

conjugate deviation of the eyes. The involvement of the right parietal lobe leads to deficit of spatial orientation of the left space, thus the patient may neglect the left half of the body. Involvement of the left parietal lobe is associated with Gerstmann's syndrome (agraphia, acalculia and visual agnosia). The differential diagnosis of lesions involving the parietal lobe, include infarction, haemorrhage, AVM and tumours.

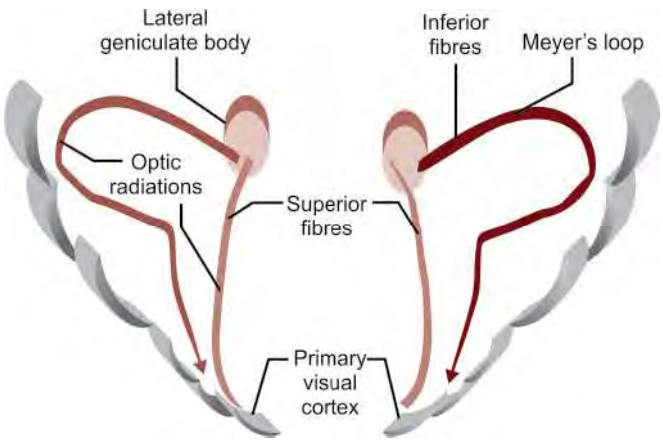

Fig. 15: Arrangement of optic radiations

Field Defects

Lesions involving the optic radiations produce field defects which are homonymous and more congruous. The involvement of the anterior temporal lobe will produce contralateral homonymous superior quadrantanopia (Fig. 16). In more extensive lesions, the defect may extend inferiorly but the hemianopia will be denser superiorly. The defects are wedge shaped defects of varying sizes and are homonymous and incongruous.

Lesions involving the parietal lobe produce an inferior homonymous field defect that is classically described as pie on floor (Fig. 17). These defects are usually more extensive and more congruous than temporal lobe defects. The homonymous hemianopia of the parietal lobe is always associated with macular splitting (Fig. 18).

Visual Cortex

Anatomy

The primary visual cortex (area 17) is located on the medial surface of the occipital lobe near the calcarine fissure. Brodmann's area 18 and 19 are associated visual areas which help in further processing of visual information.

It is now a well established fact that from the primary visual cortex, the visual pathways extend forward into two branches, a dorsal via the parietal lobe to the frontal lobe and a ventral to the temporal lobe. These sub-serve distinct cognitive functions. These are, however, not directly relevant for visual field testing.

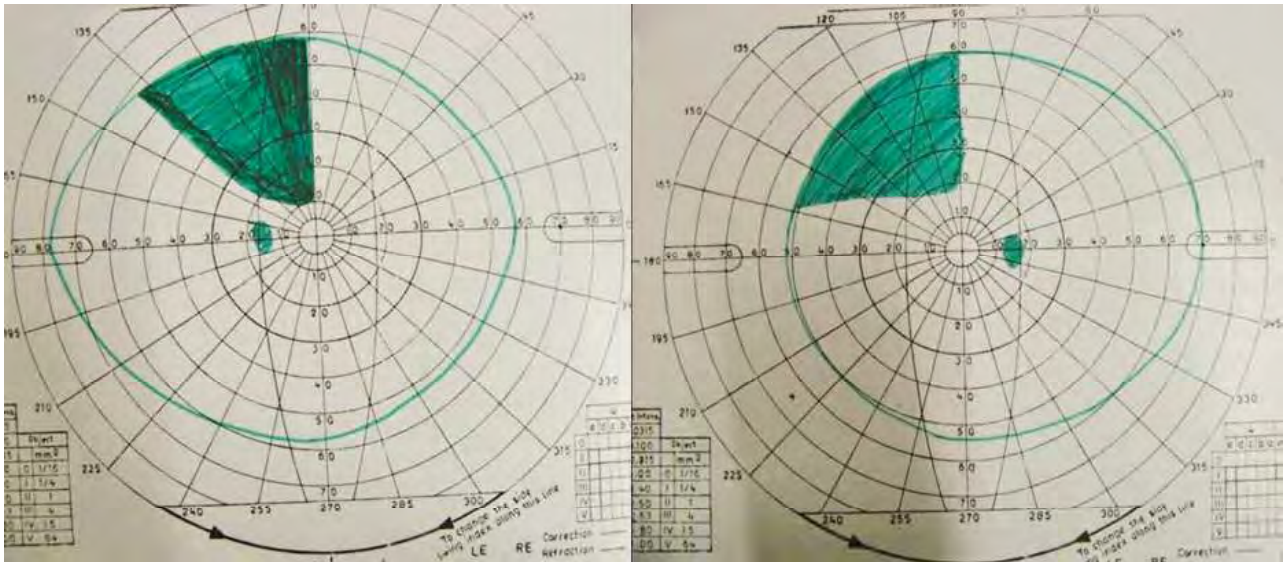

Fig. 16: Left homonymous superior field defect in right temporal lobe lesion

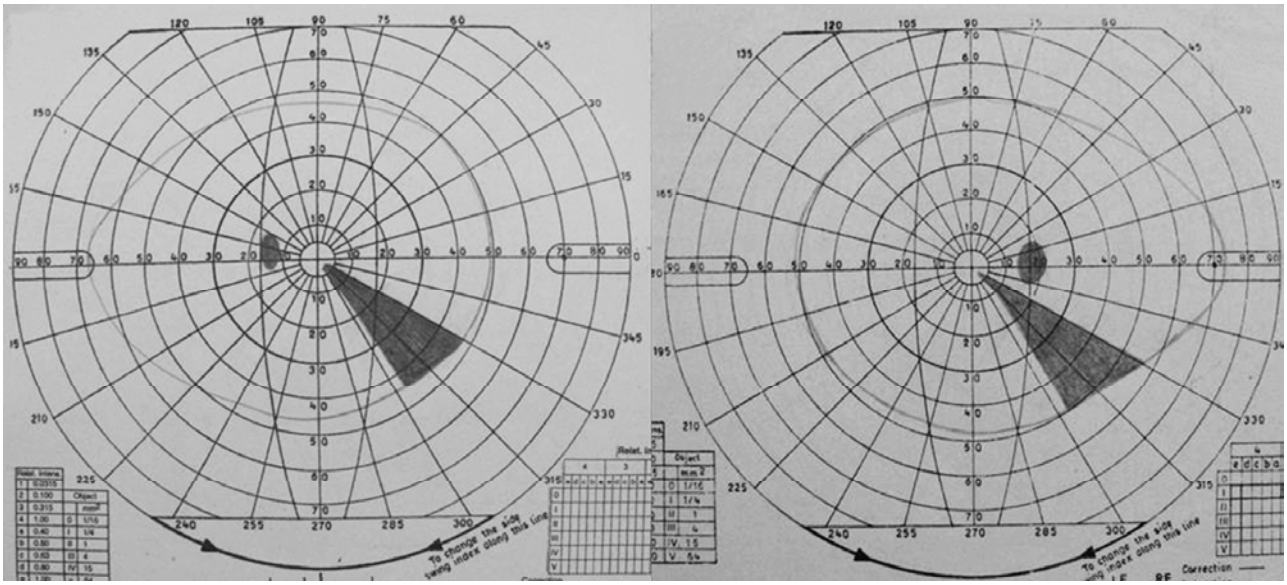

Fig. 17: Right homonymous inferior field defect in a left parietal lobe lesion

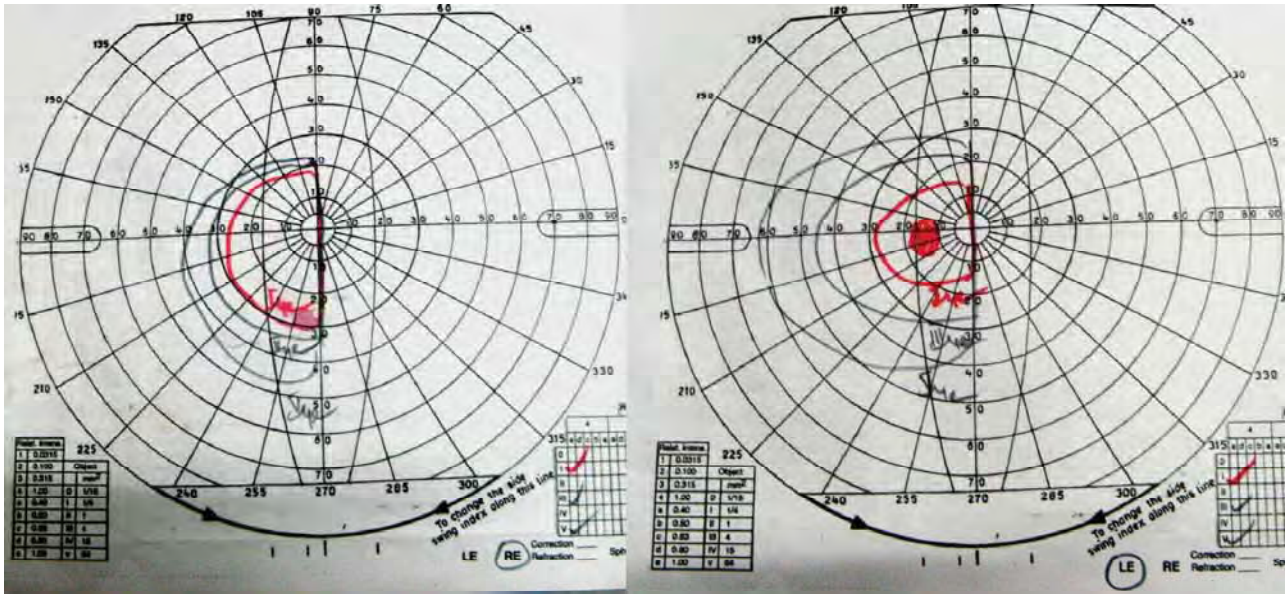

Fig. 18: Right homonymous hemianopia in a left parietal lobe granuloma

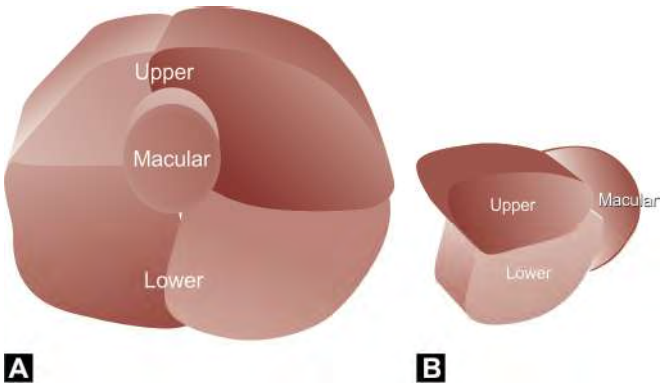

Figs 19A and B: Arrangement of fibres in occipital lobe

Organisation

The right visual cortex receives impulses from the left temporal field and the right nasal field. The orientation of fibres in the optic radiation is maintained in the visual cortex (Fig. 19A). The central field is represented at the occipital tip and is separated from the representation of peripheral fibres. The superior fibres (representing inferior field) are relayed in the area superior to the calcarine fissure while the inferior fibres (superior field) are projected to the area inferior to the fissure (Fig. 19B). In each eye there is an isolated temporal crescent in the visual field, for which there are no overlapping points in the other eye. This temporal crescent perceived by the nasal retina is represented in the anterior most portion of the calcarine cortex.

Clinical Features

Occlusion of the left posterior cerebral artery causes infarction of the left calcarine cortex, along with the splenium of the corpus callosum, which produces field defects in the right side and alexia without agraphia. Other signs include headache, visual agnosia and dyschromatopsia, which are mainly secondary to the infarction. Tumours lead to isolated visual field defects and palinopsia. Tumours affecting the occipital lobe are gliomas, meningiomas and metastasis. Bilateral occipital disease is usually due to vascular lesions which include thromboembolism, haemorrhage, hyperviscosity syndromes and vasculitis. This is also a feature following bilateral tentorial herniation, which results in bilateral occipital infarct resulting in blindness.

Fields Defects

Occipital lobe lesions produce field defects that are homonymous and highly congruous.

Complete homonymous hemianopia sparing the macula: The macular area is a watershed zone of anastomoses between the middle and the posterior cerebral arteries. Ischaemia of the occipital lobe results in sparing of the central 3–5 degrees of the visual field due to its dual blood supply (Fig. 20).

Central homonymous hemianopia: A lesion affecting the tip of the occipital lobe would produce a field defect in the macular area which is homonymous (Fig. 21). In such cases, at least 5 degrees of the central field is spared in both eyes on the side of hemianopia.

Quadrantic field defects: Lesions of the area below the calcarine fissure would give rise to a homonymous superior quadrantic defect. Similarly, a lesion involving the area above the calcarine fissure would lead to an inferior homonymous defect. Because of their anatomical and vascular separation, these defects always respect the horizontal meridian and they should not be confused with optic nerve related visual field defects. The former are always homonymous and congruous and respect the vertical meridian as well.

There could be asymmetry in field defects in cases with bilateral occipital lobe involvement. Involvement of the occipital lobe bilaterally may lead to *bilateral*

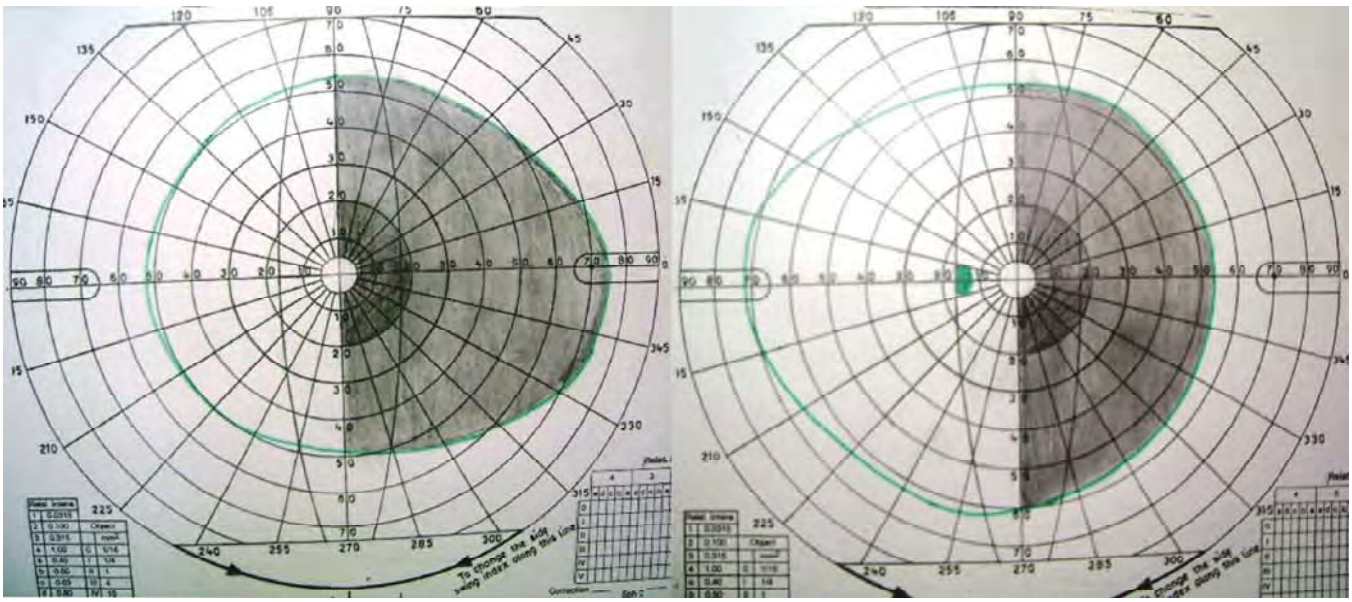

Fig. 20: Right complete homonymous hemianopia sparing macula

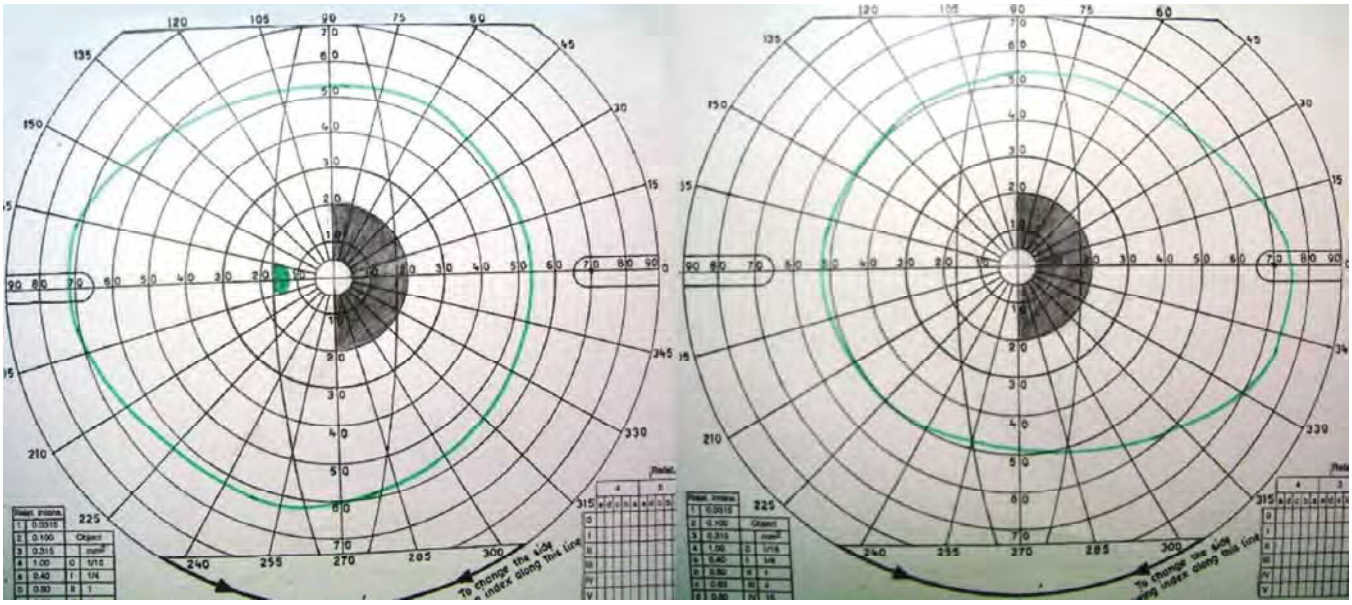

Fig. 21: Right central homonymous hemianopia

homonymous hemianopia with sparing of central tubular vision. This should be differentiated from other causes of constricted visual field like malingering, glaucoma and retinitis pigmentosa.

Lesions involving the occipital pole bilaterally would cause *bilateral central homonymous hemianopia*.

A checkerboard pattern field defect results from involvement of the occipital lobe below the calcarine fissure on one side and above the fissure on the opposite side.

Temporal crescent: The binocular field of vision is formed by superimposition of corresponding visual points of the central 60 degrees visual field of both the eyes but, then, in each eye there is a peripheral area which has no corresponding points in the other eye. This area is perceived by the nasal most retina of the eye and is represented in the anterior most portion of the calcarine cortex. Any lesion involving the anterior most part of the calcarine cortex leads to monocular temporal crescentric field defect in the contralateral eye.

SPECIAL VISUAL FIELD DEFECTS

Baring of Blind Spot

When a small degree of field is mapped, the isopter may be constricted and any scotoma outside the isopter may be continuous with the blind spot causing true baring of the blind spot. False baring of the blind spot is seen when the isopter is just outside the blind spot.

Pseudobitemporal Hemianopia

They are field defects that do not respect the vertical meridian.

Binasal Hemianopia

They are bilateral nasal defects usually caused by involvement of arcuate fibres of both eyes. Rarely, it may be caused by pressure upon the temporal aspect of the optic nerve or anterior portion of the chiasma, as in cases of aneurysm, pituitary tumour and vascular infarction.

CONCLUSION

Binocular visual field charting is an important part of ocular as well as neurological examination. It not only aids in differentiating an ocular lesion from a neurological lesion, but serves as an important diagnostic tool for localising the site of lesion and assessing the extent of damage.

6 Neuro-Otology

Sathiya Murali, Srividya, Mohan Kameswaran

Investigations for neuro-otological systems may broadly be classified into investigations for the vestibular system and investigations for the auditory system.

QUANTITATIVE TESTS FOR VESTIBULAR FUNCTION

Quantitative tests of physiologic processes under vestibular control can be useful in identifying the cause of a patient's symptoms, confirming a finding noted on clinical examination, planning a therapeutic intervention and monitoring the response to that intervention.

Electronystagmography

Electronystagmography (ENG) remains the most useful laboratory test in the evaluation of patients with complaints of dizziness or vestibular disturbance.[17] ENG can provide diagnostic information when there is a suspicion of unilateral or bilateral vestibular hypofunction.

Electro-Oculography

Electro-oculography (EOG) is typically used to record eye movements during ENG testing based on the corneo-retinal potential (electrical charge potential between cornea and retina). The eye acts as an electrical dipole along its long axis. Movement of this dipole relative to the surface electrodes produces an electrical signal corresponding to eye position. Horizontal eye movements can typically be resolved to an accuracy of 0.5°C. The sensitivity of EOG is less than that of direct visual inspection (approximately. 0.1°C). Visual inspection of small amplitude eye movements directly or with Frenzel's lenses or an ophthalmoscope is important for documentation of low amplitude nystagmus. Vertically aligned electrodes sense voltage associated with eye and lid movements, so EOG cannot be used in the quantitative assessment of vertical eye movements. Torsional eye movements cannot be measured with EOG. For this reason it is important for the person performing the study to look at the eyes either directly or with Frenzel's lenses in place, during positioning testing so that vertical torsional nystagmus caused by posterior canal "Benign Paroxysmal Positional Vertigo" is not missed. Calibration is accomplished by asking the patient to look at targets that are placed at the centre of the oculomotor range and at 10° and 15° eccentrically in the horizontal plane. Errors can occur if there is a restriction of ocular motility on calibration testing or if the patient is unable to follow instructions for the calibration tasks. The corneo-retinal potential, which provides the basis for EOG, varies with the amount of light striking the retina and necessitates keeping the room illumination constant. Surface impedance of the skin, which has an influence on recorded electrical potentials, changes with perspiration and the calibrations have to be checked frequently.

Video-Oculography/Videonystagmography

Video-oculography (VOG) is infrared (IR) imaging analysis which uses the conventional black and white camera. The eyes are illuminated with IR light. Eyes are not reactive to IR light, and hence can be viewed while in total darkness, thus eye fixation is eliminated. The eye movements are recorded by an IR video camera and converted into a digital format through software that documents the eye movements (Fig. 1). Horizontal and vertical tracings of eye movements are produced by the camera tracking the pupil of the eye.

Advantages of VOG include accuracy of 0.1–0.5°, contact free recording of eye movements and ease of handling. Rotatory eye movements in benign paroxysmal positional vertigo (BPPV) can be detected only in VOG.

Static tests include spontaneous nystagmus and gaze nystagmus. Spontaneous nystagmus is suitable for recording non-evoked eye movements with eyes closed

Fig. 1: Video-oculography

Figs 2A and B: Electronystagmography showing spontaneous nystagmus with (A) Eyes open. (B) Eyes closed

and with eyes open (Figs 2 and 3). The effects of fixation suppression can be determined.

Gaze Nystagmus

Here the eye movements are measured while the patient is fixating on a target. Nystagmus caused by CNS lesions can be differentiated from that caused by peripheral vestibular lesions. CNS nystagmus may be horizontal, vertical or rotatory. It often shows considerable variations in amplitude and tends to decline slowly, if at all, with time. If horizontal, CNS nystagmus usually beats to the right in rightwards gaze and to the left on leftwards gaze, and is usually not suppressed by ocular fixation. This is in contrast to nystagmus caused by a peripheral lesion (Fig. 4). Here it is horizontal, always beats in one direction (usually towards the normal side and suppressed by ocular fixation).[24] Nystagmus is named after the direction of the fast component which is the corrective movement of the eyes generated by the CNS. The vestibular system generates the slow phase of nystagmus which is directed to the opposite side (Table 1).

DYNAMIC TESTING

Saccade Testing

The patient is instructed to fixate a series of randomly displayed dots or lights at eccentricities of 5–30° saccades. Saccades typically begin with a latency of 180–200 milliseconds after presentation of a target. Saccade velocity increases linearly with amplitude up to about 20° but remains relatively constant for higher amplitudes. Healthy subjects consistently undershoot the target for saccades more than 20° (Fig. 5). Asymmetries in saccade amplitude or peak velocities can provide localising

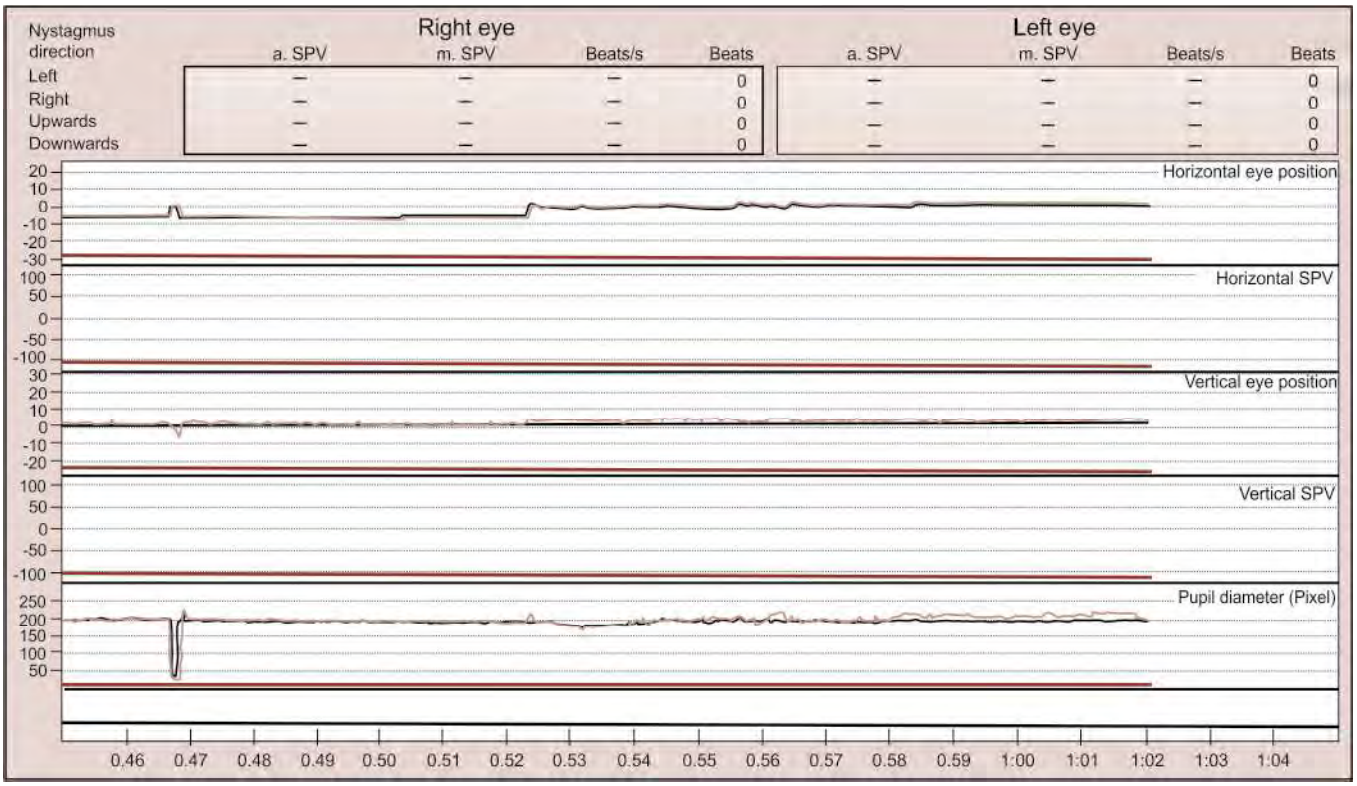

Fig. 3: Video-oculography showing absence of spontaneous nystagmus

Fig. 4: Left acute vestibular neuronitis

Table 1: Features differentiating central from peripheral causes of vertigo

Features	*Central*	*Peripheral*
Imbalance	Severe, mostly constant	Mild to moderate, mostly episodic
Neurologic symptoms	Frequent	Rare
Nystagmus	- Changes direction in different gaze positions - No change with visual fixation	- Unidirectional in all gaze positions - Decreases with visual fixation
Hearing loss	Rare	Frequent
Nausea	Variable, may be absent	Severe
Recovery by central compensation	Slow	Rapid

information (Fig. 6). With EOG, the speed of abducting saccades seems to be lower than that of adducting saccades, although recordings with search coil and IR technique suggests that the opposite is actually the case.

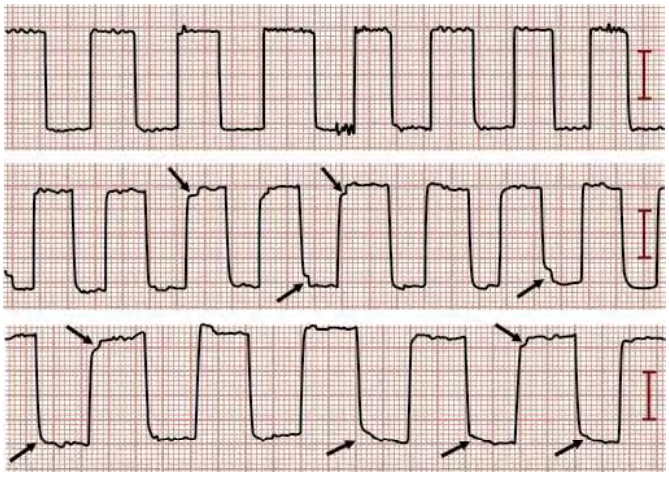

Fig. 5: Normal saccades

Smooth Pursuit

The patient is asked to watch a target that moves horizontally in a sinusoidal fashion at a low frequency with position amplitude of 20° in each direction (Fig. 7). Inspection of the waveform of the tracking eye movement is often of greater diagnostic use than absolute measure of gain and phase. "Catch up" saccades are typically made when pursuit responses are decreased. Saccadic pursuit is characterised by the occurrence of these saccades in a "stair-step" pattern. Such patterns are seen in cerebellar disease and also may occur with decreases in pursuit gain that occur with ageing.

Saccadic substitution of smooth pursuit is seen in neurological lesions (Fig. 8).

Disorganisation of pursuit eye movements with wandering slowed inaccurate tracking is seen in brainstem lesions (Fig. 9).

Optokinetic Testing

Testing is often performed with the subject surrounded by a visual scene that moves completely in one direction at

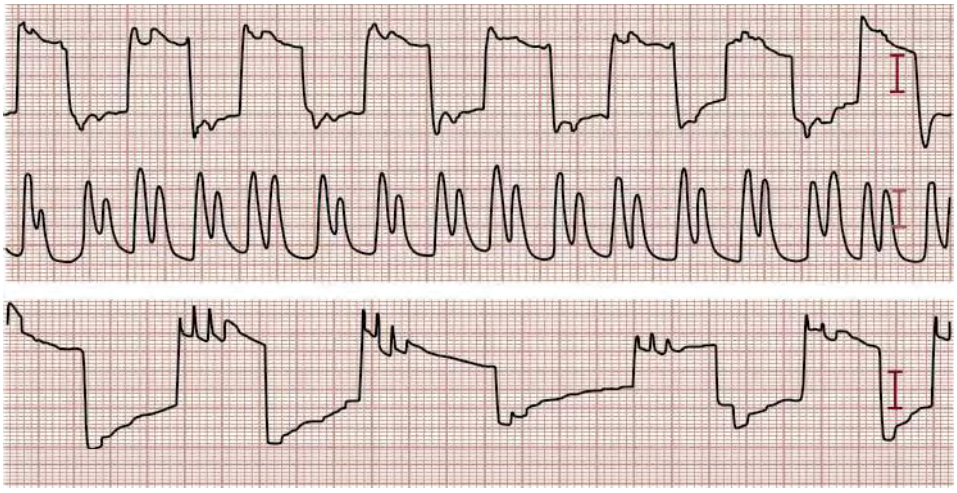

Fig. 6: True overshoots in brainstem encephalitis

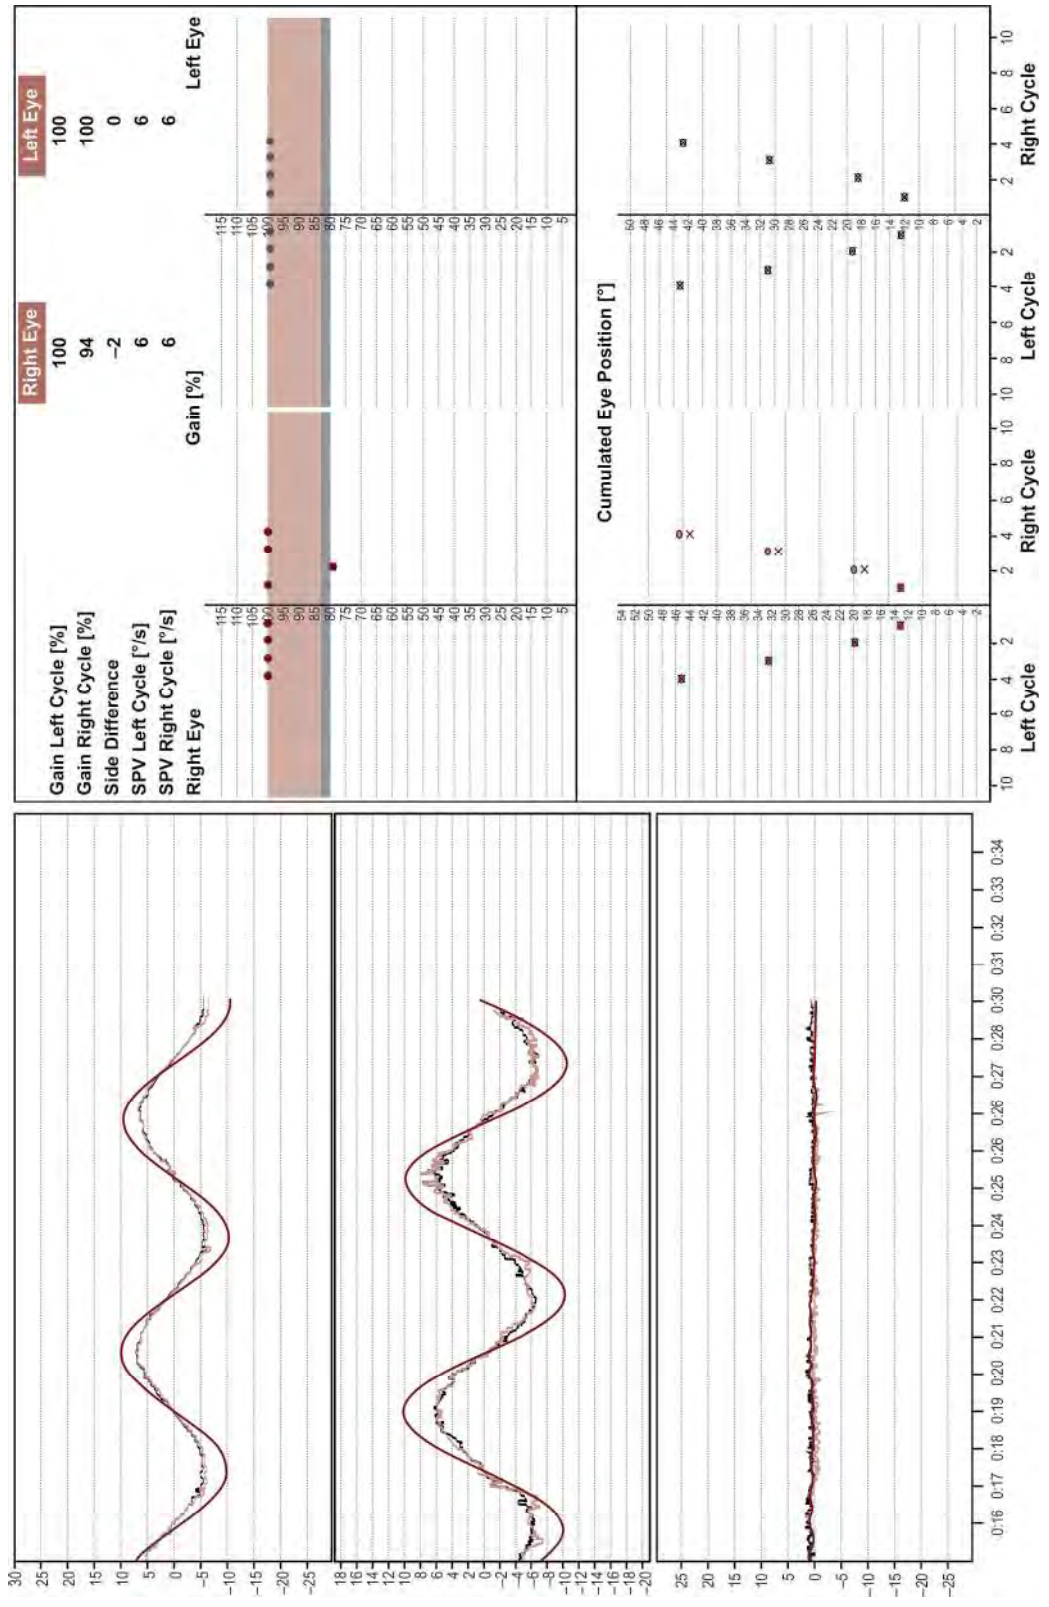

Fig. 7: Normal smooth pursuit—video-oculography recording

velocities of 30–60° per second (Fig. 10). The optokinetic tracing response is a nystagmus in the plane of motion of the visual scene (Fig. 11). Response gain (slow-phase eye velocity/velocity of the visual scene) is measured, and the profile of slow-fast component interaction is assessed. In general, slow-phase abnormalities on optokinetic tests parallel those detected with smooth pursuit testing, whereas fast-phase abnormalities are correlated with those detected on saccade testing. OKAN is a nystagmus that persists immediately after the room lights and illumination of optokinetic stimulus are extinguished. It is attributable to central velocity storage mechanisms that perseverate vestibular and optokinetic responses. Asymmetries in OKAN have been reported

Fig. 8: Saccadic substitution of smooth pursuit

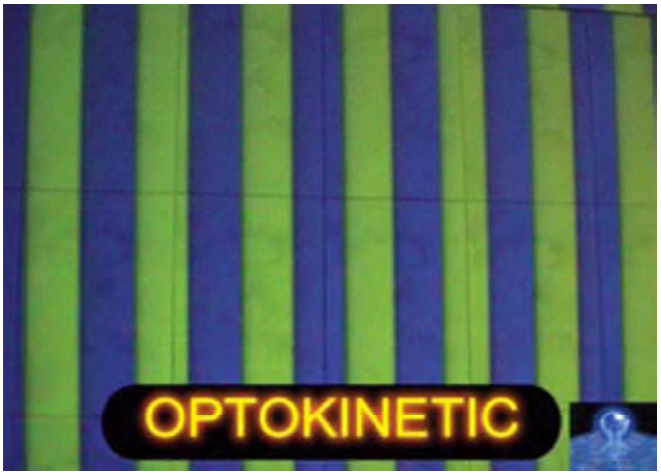

Fig. 10: Optokinetic stimulus in video-oculography

in patients with unilateral vestibular hypofunction induced by removal of an acoustic neuroma and other CNS lesions (Figs 12 and 13). Responses are greater in amplitude and longer in duration for stimulus and eye movement towards the side of the lesion.[23] Although a true optokinetic stimulus requires full-field movement of a visual surround, similar diagnostic information can usually be obtained from motion of a drum or bars of light that occupy only a portion of the visual field.

Caloric Testing

Caloric testing remains the most useful laboratory test in determining the responsiveness of a labyrinth. It is one of the few tests that allow one labyrinth to be studied independently of the other. The stimulus can be applied relatively easily with techniques that are commonly available. Caloric testing relies on stimulating or cooling the vestibular system by alternately heating and cooling the external auditory canal with water or air. The horizontal canal is affected most by such temperature effects, because it is located closest to the external auditory canal and is oriented in the plane of the temperature gradient

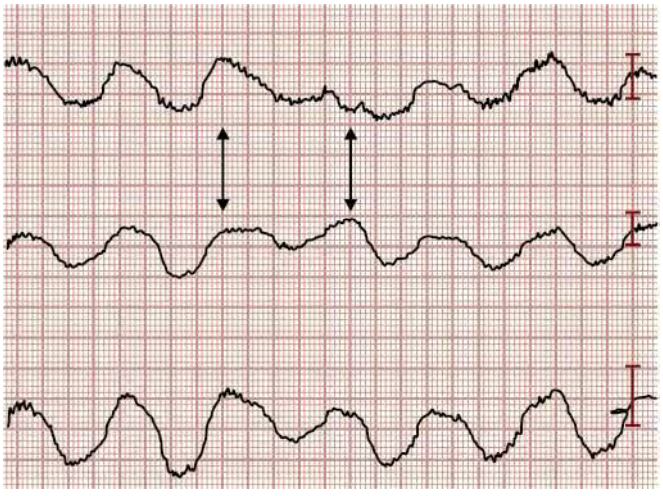

Fig. 9: Wandering slow inaccurate tracking in brainstem lesion

that is produced in the temporal bone from irrigation with water.

Calorics cause a response in two ways. The first is a convective component, with the temperature gradient across the horizontal canal resulting in a density difference within the endolymph of the canal. When the horizontal canal is oriented in the plane of gravity, the more dense fluid falls to the lower position in the canal, whereas the less dense fluid falls to the upper portion in the canal. In the presence of gravity, there is a flow of endolymph from the cooler (more dense) region to the warmer (less dense) region. This movement of fluid within the canal deflects the cupula, thereby leading to a change in discharge rate of vestibular nerve afferents. Endolymph flows towards the ampulla for warm irrigation and away from the ampulla for cold irrigation. This effect depends on head position.

The second component does not vary with head position and results in an excitation of the horizontal canal when the ear is warm and in an inhibition when it is cooled. The non-convective component may be a result of a direct temperature effect on hair cells or vestibular nerve afferents[9] or cupular displacement resulting from pressure changes in the membranous duct.[20]

Alternate binaural caloric testing as pioneered by Fitzgerald and Hallpike[19] is the most commonly used testing protocol. Cool water (30°C) and warm water (44°C) are administered for 60–90 seconds to each ear in a set order such as right warm, left warm, right cold and left cold. Such a stimulus results in heating effect in the temporal bone that lasts for 10–20 minutes, although nystagmus frequently decays over a much shorter time course (2–3 minutes) because of the effects of adaptation.[5] The prolonged heating effect of a single temperature irrigation requires that at least 10 minutes be allowed between successive irrigations. Biphasic caloric irrigations can reduce nausea and shorten the wait between stimuli for about 2 minutes by irrigating with water at 43.5°C for 45 seconds, 30.5°C for 65 seconds and 43.5°C for 23 seconds.[30]

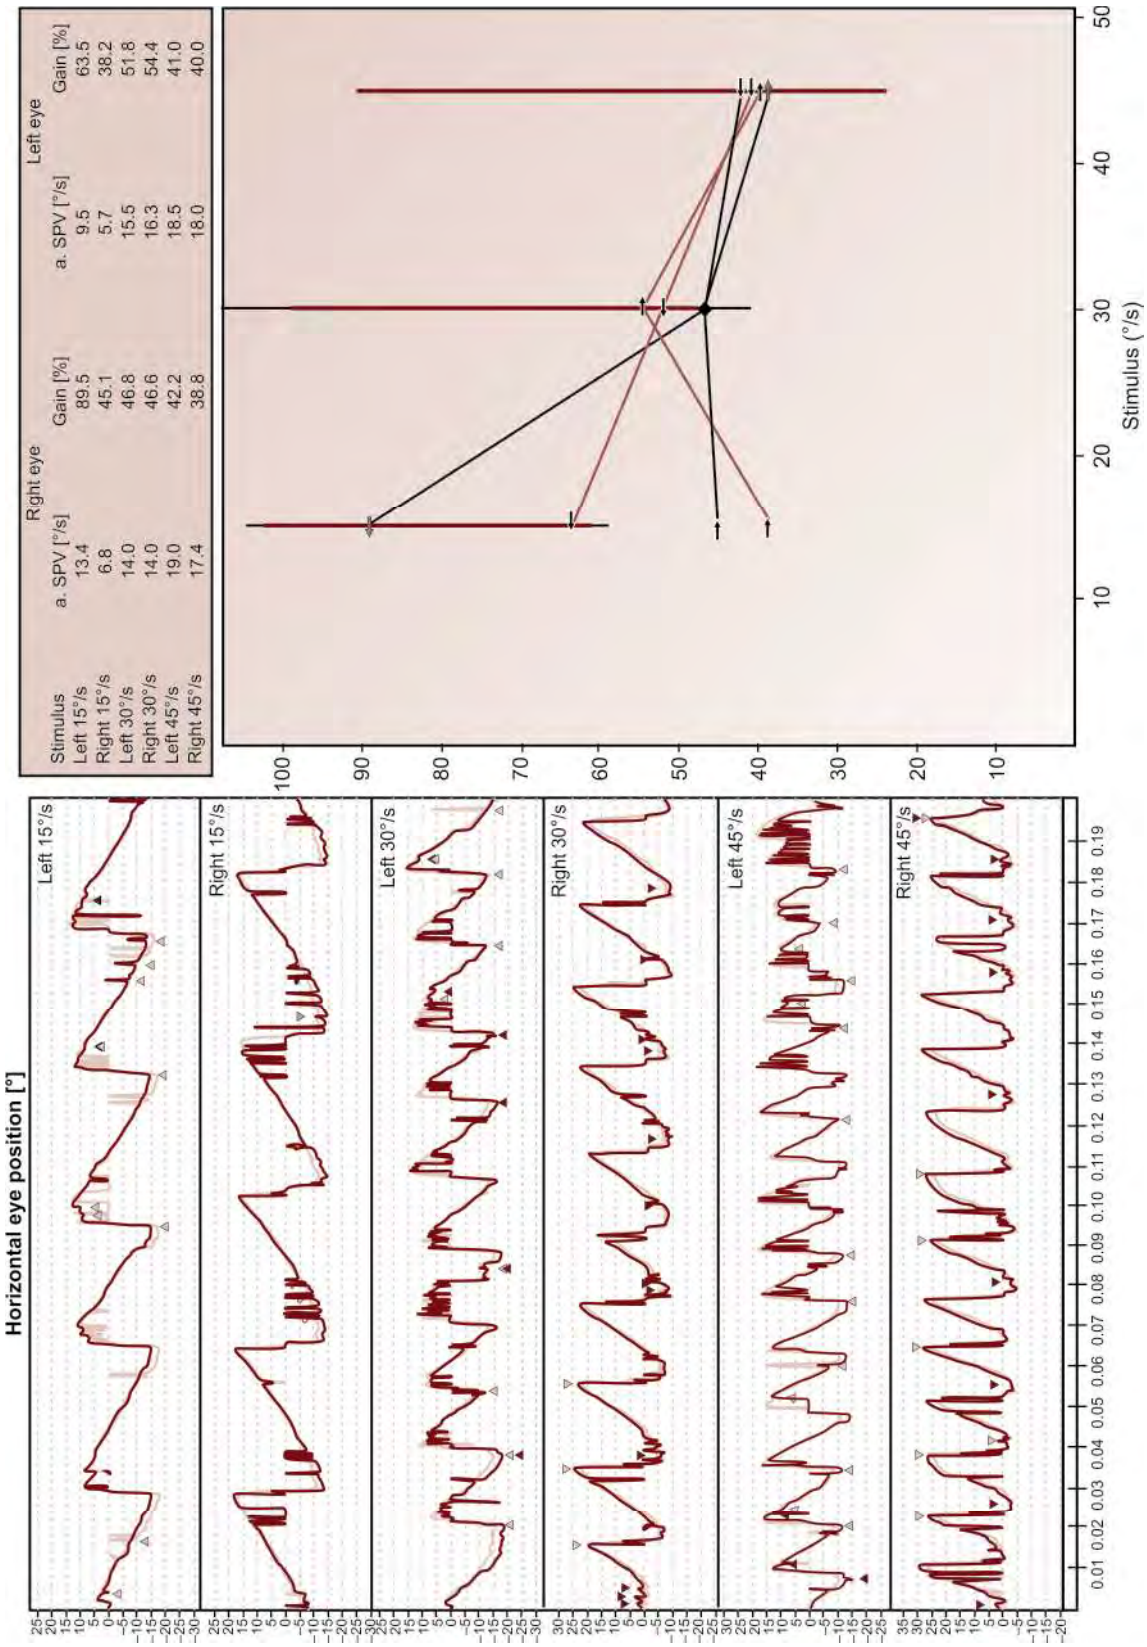

Fig. 11: Normal OKAN on video-oculography

Interpretation

In the normal vestibular system, adequate, equivalent responses should be obtained from each ear. A normal caloric response does not rule out a vestibular pathology however, since this test only measures a response from part of the labyrinth at a very low frequency of stimulation.

Slow-phase velocity is determined for each recording for use in the following calculations:

- Unilateral weakness (UW) is used to evaluate symmetry. In many clinics, a UW greater than 25% is significant.

  % UW = [((RC + RW) – (LC + LW))/(RC + RW + LC + LW)] × 100[27]

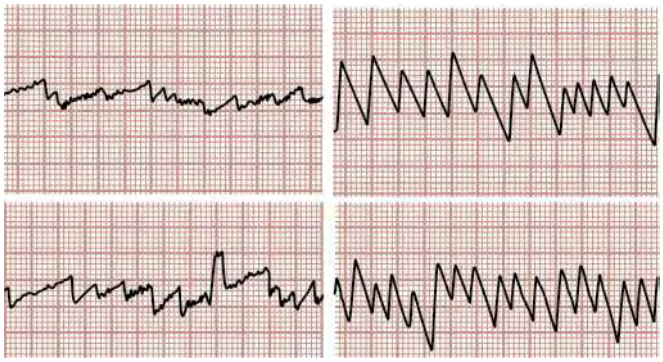

Fig. 12: Asymmetric optokinetic nystagmus in medullary compression—Arnold-Chiari malformation

Where RC is right cold; RW is right warm; LC is left cold and LW is left warm.

A negative number indicates right unilateral weakness, and a positive number indicates left unilateral weakness. Unilateral weakness is indicative of a peripheral vestibular lesion that involves the nerve or end-organ on the side of the weakness.

- Bilateral weakness: Average caloric responses of 6° per second or less are consistent with a bilateral weakness. Borderline bilateral weakness is noted when the average responses are between 7° and 9° per second. Abnormally weak bilateral responses may be due to bilateral peripheral vestibular pathology or central interruption of the vestibulo-ocular reflex (VOR).[22] When a borderline bilateral weakness or bilateral weakness is observed, drug effects should be excluded.
- Directional preponderance (DP): If the patient has spontaneous nystagmus, DP is evident. In general, a DP greater than 20–30% is considered significant. In the absence of a spontaneous nystagmus, DP may be a central sign indicating asymmetric sensitivities of central vestibular neurons to inhibitory-excitatory stimuli or asymmetries in the inputs from these central vestibular neurons to extraocular motor neurons.

  % DP = [((LC + RW) – (RC + LW))/(RC + RW + LC + LW)] × 100.[27]

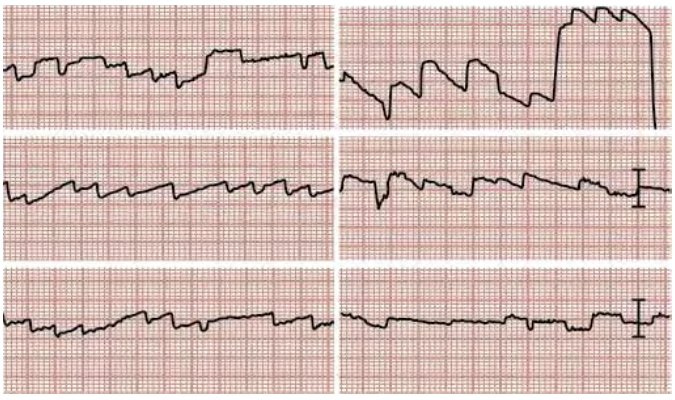

Fig. 13: Multiple sclerosis

Rotatory Chair

Unlike caloric tests, rotational tests analyse the responses of both labyrinths together. They require a high torque motor-driven chair and relatively advanced software to analyse the results. Rotatory chair testing is useful in assessing vestibular function in patients with suspected bilateral vestibular hypofunction, in patients receiving vestibulotoxic medications and in children who may not tolerate caloric testing. Clinical situations in which findings on rotatory chair may provide useful information in paediatric patients include determining whether a failure to achieve normal developmental milestones is in part based on absent vestibular function, evaluating vestibular function after meningitis and determining the presence or absence of vestibular function in patients undergoing genetic evaluation for hearing loss. Cerebellar abnormalities produce specific changes that can be evaluated with rotatory chair testing. Velocity storage mechanisms that are responsible for prolonging the VOR time constant compared with that of vestibular nerve afferents are sensitive to the orientation of the head with respect to gravity. In healthy subjects, tilting the head downwards at the onset of post-rotatory vertigo results in an immediate suppression of the stored velocity response, but patients with midline cerebellar lesions near the uvula and nodulus have VOR time constants that are normal in the upright position and are not affected by post-rotatory tilt.[10] Patients with cerebellar lesions caused by Arnold-Chiari malformation have tilt suppression that is intermediate between that of healthy patients and patients with midline cerebellar lesions. Abnormally high gain on rotational testing also has been noted in cases of cerebellar atrophy.[4]

Parameters that are commonly examined include gain, phase and symmetry. Gain is the ratio of the amplitude of eye movement to the amplitude of head movement (stimulus). Phase is a parameter that describes the timing relationship between head movement and reflexive eye response. When the head and eyes are moving at exactly the same velocity in opposite directions, they are said to be exactly out of phase or 180°. If the reflex eye movement leads the head movement, a phase lead is present, and if the compensatory eye movement trails the head movement, a phase lag is present. Symmetry is a comparison of the slow component of the nystagmus when rotated to the right compared with rotation to the left. A fourth parameter that may be studied is the time constant. This is a measure of the time (in seconds) required for the VOR gain to exponentially decrease by 63%. It is measured in step-velocity testing after the chair is rapidly stopped and is reduced in patients with vestibular dysfunction. Note that the time constant and gain may be reduced in inattentive patients as well.

Each of these parameters is useful in diagnosing and localising vestibular lesions. Studies have shown that patients with a unilateral peripheral vestibular lesion may exhibit asymmetric responses to rotation. On the other hand, patients with a compensated unilateral

lesion show a characteristic pattern of decreased gain and increased phase lead at low-frequency stimulation. Bilateral peripheral vestibular lesions are characterised by low gain and phase lag with sinusoidal testing. Rotational chair testing is ideal in the assessment of these patients because, unlike caloric testing, higher frequencies are also tested and both labyrinths are stimulated spontaneously.

This allows for accurate determination of remaining vestibular function. In fact, Arriaga et al. determined that rotational chair testing has a sensitivity of 71% for diagnosing peripheral vestibulopathies, as opposed to only 31% sensitivity for caloric testing/ENG.[3] Although it is a more sensitive test for peripheral vestibular disorders, rotational chair testing has a specificity of only 54%, compared with the 86% specificity of ENG. Both tests are, therefore, complementary and should be used in the diagnosis of peripheral vestibular dysfunction. Finally, abnormalities may be observed with central vestibular deficits. Thurston et al. showed that gains may be increased in some individuals with cerebellar deficits.[37] Cerebellar atrophy, on the other hand, may result in a disorganised nystagmus pattern with beat-to-beat variability in the amplitude.

Shortcomings of Conventional Vestibular Function Tests

- Only assess lateral semicircular canal function
- Do not assess overall balance
- Relatively insensitive
- Lack of correlation with symptoms.

Vestibular Evoked Myogenic Potentials

Vestibular evoked myogenic potentials (VEMP) is a sound-evoked muscle reflex, or sonomotor response that can be recorded using evoked potential techniques by acoustical stimulation of the saccule (Fig. 14). VEMP has become an important investigative modality in the evaluation of patients with balance disorders.

Recent studies have demonstrated that healthy subjects exhibit a burst of activity in the ipsilateral sternocleidomastoid (SCM) muscle in response to auditory

Fig. 14: Vestibular evoked myogenic potentials

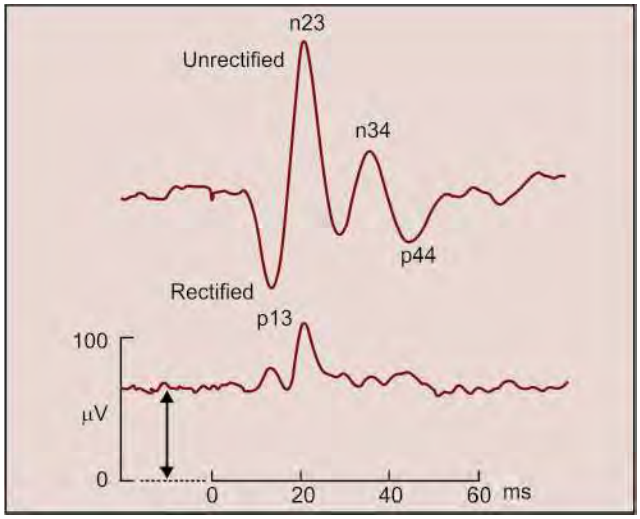

Fig. 15: Normal vestibular evoked myogenic potential recording

stimulation [100–200 msec rarefaction clicks, 95 dB sound pressure level (SPL)].[10] These click evoked responses are recorded with electromyography (EMG) and occur at a short latency (12 msec) relative to the onset of the click stimulus (Fig. 15).

The responses are abolished on the side of surgery after unilateral vestibular neurectomy.[11] In a study of patients who had previously experienced an episode of vestibular neuritis, Murofushi et al.[28] identified 10 of 47 patients who went on to experience an episode of posterior canal BPPV on the side with vestibular hypofunction. These patients had intact sound evoked myogenic responses whereas many of the patients who did not have BPPV developed no responses to the click stimuli on the affected side. Since, the posterior canal receives innervation from the inferior vestibular nerve, these investigators interpret this study in conjunction with electrophysiologic evidence of click evoked activation of saccular afferents,[29] to indicate that responses are a result of selective activation of vestibular nerve afferents innervating the sacculus. In addition to aiding the diagnosis of otolith function, patients with superior canal dehiscence syndrome also seem to have an approximately 20 dB increase in sensitivity to VEMPs.[35]

VEMP may be absent in basilar artery migraine, Ménière's disease, idiopathic bilateral vestibulopathy (IBV) and vestibular schwannoma. VEMP may be increased in superior semicircular canal dehiscence syndrome (Fig. 16) and perilymphatic fistula. Asymmetrical amplitudes may be seen in Tullio's phenomenon and spasmodic torticollis. Delayed VEMP is seen in cases of technical error, central lesions like brainstem stroke, multiple sclerosis (Fig. 17), spinocerebellar degeneration and migraine.

Computerised Dynamic Posturography

Computerised dynamic posturography (CDP) is a series of vestibulo-spinal tests for quantitatively assessing balance function in different set-ups which simulate

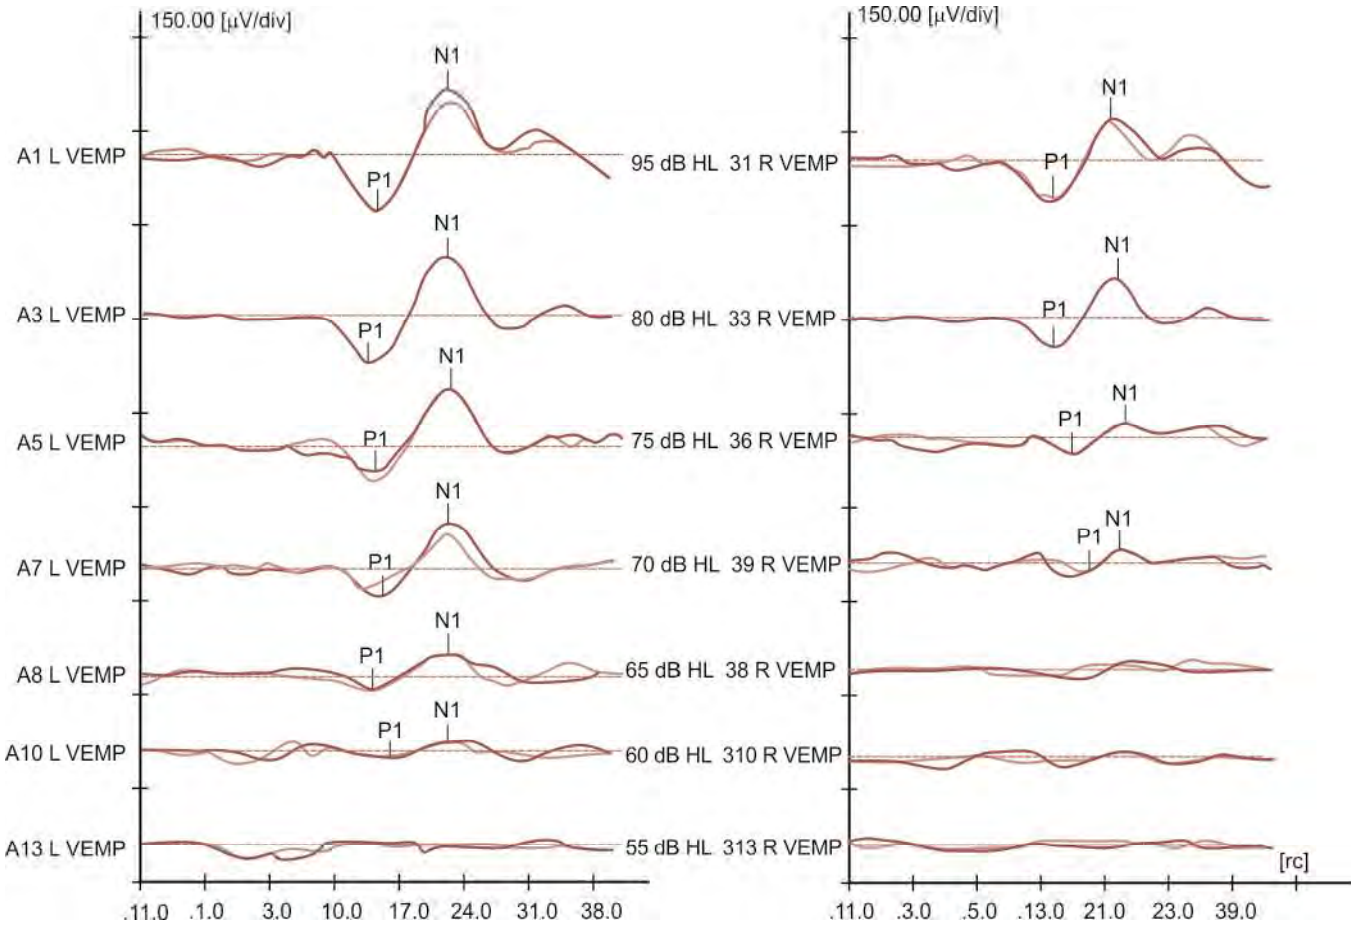

Fig. 16: Increased vestibular evoked myogenic potential in superior semicircular dehiscence

conditions encountered in our day-to-day life. In our daily life we come across various circumstances in which our vestibular system is assaulted and challenged. A person with a normal balance function can effectively counteract these challenges and maintain equilibrium, whereas a person with a deranged balance function fails to do so. For this, our balance system must be able to do two things:

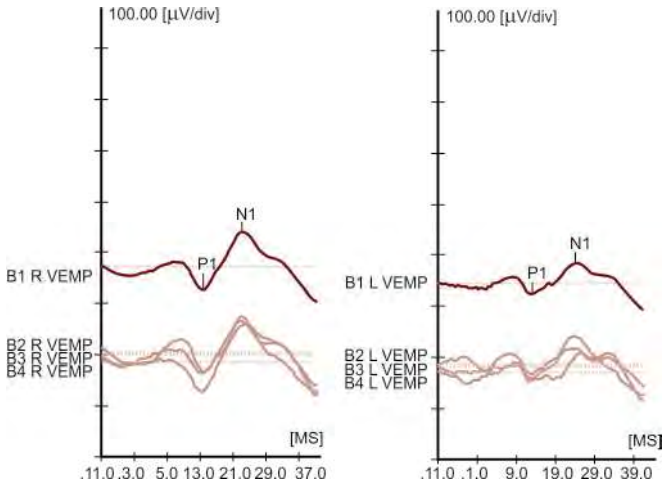

Fig. 17: Delayed vestibular evoked myogenic potential in multiple sclerosis

- To determine the position of centre of gravity relative to the base of support.
- To execute automatic movements in the body muscles such that the centre of gravity is brought back to a balanced position in a timely manner and effectively.

CDP tests these two faculties of the balance system separately. The first portion is tested by the Sensory Organisation Test (SOT) and the second portion by Motor Coordination Test (MCT).

The functional integrity of the sensory system (i.e. the inputs to the balance system, viz. the visual, proprioceptive and vestibular) is assessed by the SOT. This test detects any defect in the subject's ability to effectively use the somatosensory/visual/vestibular inputs to maintain balance and the ability of the CNS to select the appropriate input when contradictory and conflicting information is sent through these three input systems.

The second part of the CDP test is the Motor Coordination Test or Motor Control Test (MCT). It is useful in assessing the integrity of efferent motor pathways in the control of balance. That is, whether the requisite motor activity for the maintenance of balance is being properly executed after sensory information from the somatosensory/visual/vestibular senses have been received by the CNS.[1]

Cranio-Corpography

Cranio-corpography (CCG) basically consists of photographically recording the patient's head and body movements as he or she performs the Unterberger's stepping test and the Romberg's test.[1] CCG is a very quick, non-invasive and very simple objective test of vestibular and balance function. It is totally physiological, easily repeatable and provides a photographic and quantifiable record, and can even be done in children and in patients with perforated ear drums.

It was, however, found that CCG too has some inherent limitations, and though CCG helped to partially widen our view of the balance system, CCG was found to be a crude test of the vestibulo-spinal system and quite fallacious at times. It was due to these shortcomings of ENG and CCG that posturography became relevant. However, posturography or its present modification called computerised dynamic posturography is a test of systemic balance function and it does this by examining the vestibulo-spinal reflex mechanism.

INVESTIGATIONS FOR THE AUDITORY SYSTEM

Investigations for the auditory system aim to evaluate the integrity of the auditory system from the peripheral organ which is the ear to the auditory cortex. Audiological investigations have recently gained sophistication both with the accuracy as well as in their use as a neuro-otological tool. The tests that are currently available aim to answer the following questions:

- Is there a defect in the auditory system?
- What is the quantity of the defect?
- What is the site of the defect?
- Are multiple levels involved?

Answering these questions will eventually help the clinician understand prognosis. The tools in the armamentarium include:

- Bedside tests (see chapter on Acoustic Schwannoma)
- Puretone audiogram
- Impedance audiometry
- Electrophysiological tests:
  - Otoacoustic emissions (OAE)
  - Electrocochleography (ECoG)
  - Auditory brainstem response (ABR)
  - Auditory steady state response (ASSR)
  - Middle latency responses (MLR)
  - Long latency response (LLR)

Puretone Audiogram

Puretone audiogram is a subjective test, which is used to detect if there is definite hearing loss, the type (sensorineural/conductive) and quantity of the hearing loss. It helps in measurement of hearing threshold at various frequencies. Hearing threshold is the minimum sound that a subject may hear for a given frequency. The disadvantages of the test are that it is purely subjective, cannot be performed in a child, a patient who is not co-operative and in unconscious patients.

Impedance Audiometry

Impedance audiometry has been one of the major advancements in the field of otology and neuro-otology in recent times. The uses of impedance can briefly be summarised as:

- Objective differentiation between conductive and sensorineural hearing loss.
- Measurement of middle ear pressure (tympanometry) and evaluation of Eustachian tube function.
- Differential diagnosis of whether the lesion is cochlear or retrocochlear.
- Identification of site of lesion in facial palsy and certain brainstem pathologies (stapedial reflex test).

Impedance audiometry being a very useful objective test, it is mandatory to include this test in the routine diagnostic test battery.

ELECTROPHYSIOLOGICAL TESTS

Otoacoustic Emissions

Otoacoustic emissions (OAE) are biological sounds from the normal cochlea. This sound is generated in the outer hair cells of the cochlea. This is another objective test for hearing screening in neonates and young children which has now become popular.

Electrocochleography

Auditory evoked potentials are classified according to the time window within which they are recorded. Electrocochleography (ECoG) is a short latency evoked potential that reflects the summed activity of a large number of peripheral auditory nerve fibres as well as the response of generators located within the cochlea itself. The ECoG consists of three distinct evoked potentials:

1. The cochlear microphonic (CM)
2. The summating potential (SP)
3. Compound action potential (AP)

The CM and the SP are both intracellular potentials. The CM is a potential that mirrors the stimulus and it reflects the instantaneous displacement of the basilar membrane[6] (Fig. 18).

The SP is characterised by a baseline shift in the CM and it is also thought to originate from within the hair cells of the organ of Corti.[13,14,36]

The AP is the third evoked potential of the ECoG complex. It is a recording of the synchronous response of a large number of auditory nerve fibres to the acoustic stimulation. It is an onset response that is recorded using click stimulus.

Procedure

The ECoG is recorded either extratympanically or intratympanically. It is rerecorded extratympanically via an active electrode placed within the ear canal or on the drum itself and a reference electrode placed on the contralateral mastoid process. Intratympanically the

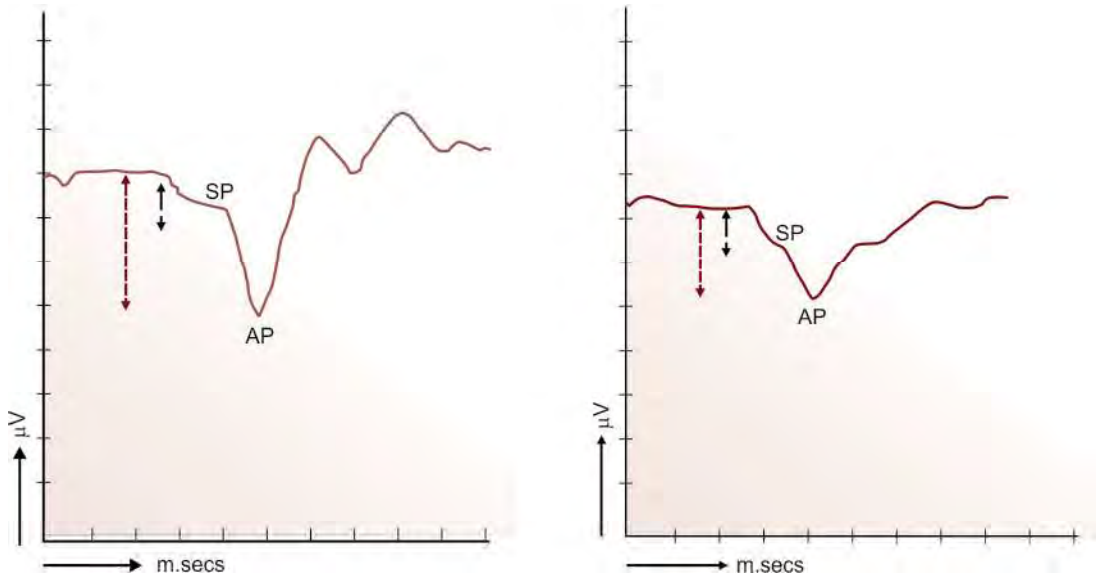

Fig. 18: Normal ECoG and ECoG in Ménière's disease—comparative increase of summating potential

ECoG is recorded using a transtympanic needle electrode placed on the promontory of the middle ear.

Clinical Applications

- To assess hearing in the paediatric age group.[12,18]
- Tool to assess auditory status in patients suspected of having Ménière's disease.
- As a part of retrocochlear assessment.
- During otoneurologic surgery.

Auditory Brainstem Response

Auditory brainstem response (ABR) is a recording of the synchronised response of a large number of neurons in the lower portions of the auditory pathways. While first described by Sohmer and Feinmesser in 1967,[31] later Jewette and colleagues gave detailed descriptions of ABR (Fig. 19).[25,26] Origin of various waves has been described in Table 2.

The ABR is recorded using differential amplification with the active electrode positioned at the vertex or high forehead with reference electrodes positioned at the mastoids or the ear lobes. It requires brief acoustic stimulus with a relatively rapid onset. The most common stimulus used to evoke the ABR is a 100-msec rectangular pulse or click. A click is the ideal stimulus for eliciting the ABR as it results in a large number of auditory nerve fibres firing at approximately the same time.

Table 2: Origin of various waves of auditory brainstem response[2]

Wave	*Site of origin*
I	Cochlear nerve (distal end)
II	Cochlear nerve (proximal end)
III	Cochlear nucleus
IV	Superior olivary complex
V	Lateral lemniscus/inferior colliculus
VI and VII	Neural generators, not definitely known

Clinical Applications

It is a tool for estimating auditory sensitivity as well as for a range of otoneurologic applications.

It is by far the most commonly used of the auditory evoked potentials, due to the fact that it can be recorded by non-invasive techniques and is easy to record, not strongly affected by attention, sleep state, sedation and anaesthesia or age.

Neuro-otological Applications

Historically, the recording of ABR has been to assist with detection of lesions affecting the auditory pathways between the cochlea and the inferior colliculus. Such lesions include space occupying lesions,[15] such as vestibular schwannomas and pathology, caused by factors such as multiple sclerosis, stroke or trauma. Generally, this is accomplished by examining the morphology of the click evoked ABR measures using a high-level stimulus.

Assessing Neurological Disorders

There are several different ways in which the click-evoked ABR is altered by the presence of retrocochlear pathology (Table 3). In some cases, the ABR recorded in the ear with retrocochlear pathology will have absent or distorted components. For example, an ABR that is absent in an ear with audiometric thresholds in the normal to moderate range, an ABR that is characterised only by early peaks or an ABR with a wave V amplitude that is smaller than the amplitude of wave I have all been interpreted as evidence of potential abnormality.[32] Such grossly abnormal ABR morphologies are thought to reflect partial conduction block or significant loss of cross fibre synchrony along the neural pathways between the cochlea and the inferior colliculus.

A second measure which is commonly used to diagnose potential retrocochlear pathology is prolonged

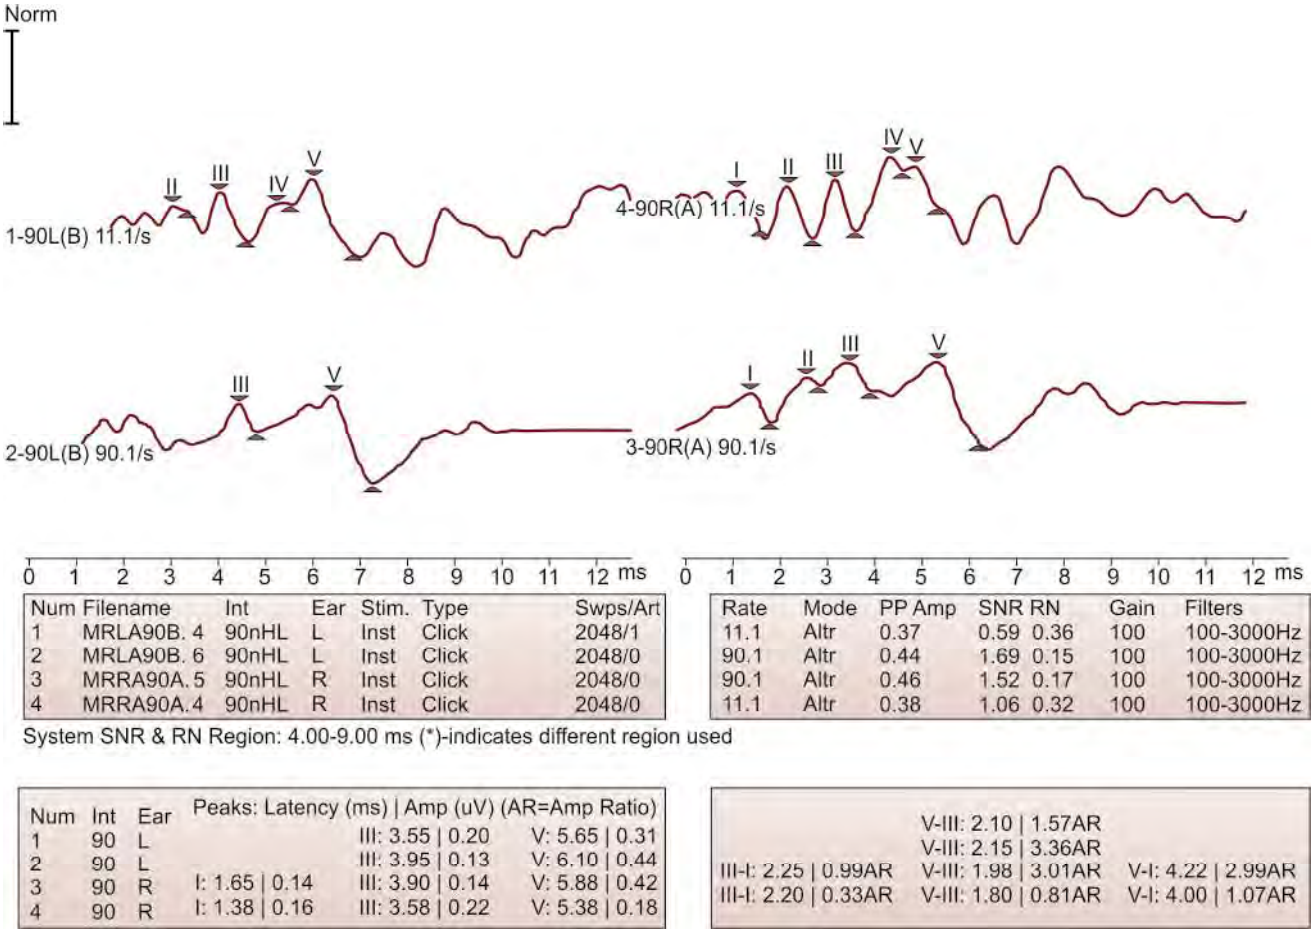

Fig. 19: Normal BERA tracing showing I to V waves

Table 3: Different parameters of auditory brainstem response for abnormality criteria

Parameter measured	*Normal value (millisecond)*	*Criteria for abnormality (millisecond)*
1. I-III IPL	2	More than 2.2
2. III-V IPL	2	More than 2.2
3. I-V IPL	4	More than 4.4
4. Interaural latency difference of wave V	Less than 0.3	More than 0.3
5. Morphology of wave V	Present	Absent

inter-peak or absolute latencies. In most persons, a high level click stimulus will generate an ABR with a wave V latency of approximately 5.5 msec and with an I-V latency of approximately 4.0 msec.[34] The presence of a tumour growing within the internal auditory canal may be slow neural conduction velocities. When the absolute latency of wave V is longer than 6.3–6.4 msec or when the interval between wave I and wave V of ABR is longer than 4.4–4.5 msec, the presence of retrocochlear pathology must be suspected.

Finally, since tumours occurring on the auditory nerve are typically unilateral, a very commonly used technique for identifying potential retrocochlear lesions is to compare the latency of wave V and the length of the inter-peak latency between ears.

A difference of more than 0.3–0.4 msec between the latency of wave V of ABR in the two ears or an interaural difference in the length of the I-V interval of greater 0.3 msec can also be considered indicative of potential retrocochlear pathology.

Several investigators have attempted to quantify the sensitivity and relative specificity of ABR as a tool for identifying ears with vestibular schwannomas.[8,21,33,38] The results of these studies vary. Some of these variants can be attributed to the choice of parameters used to categorise the ABR as normal or abnormal. Additionally, recent studies have revealed lower degrees of sensitivity. This trend may reflect the fact that the increased resolution and availability of imaging techniques allow for the identification of tumours while they are still small. There is some indication that the accuracy of ABR as a predictor of retrocochlear status may be related to tumour size,[8,21] and some authors have proposed a derived response technique that they call a stacked ABR that may be able to identify small tumours with a greater degree of accuracy than is possible using conventional techniques.[16]

It is used to monitor the status of the auditory nerve during skull base surgery, because ABR is not strongly affected by anaesthesia. It provides continuous feedback

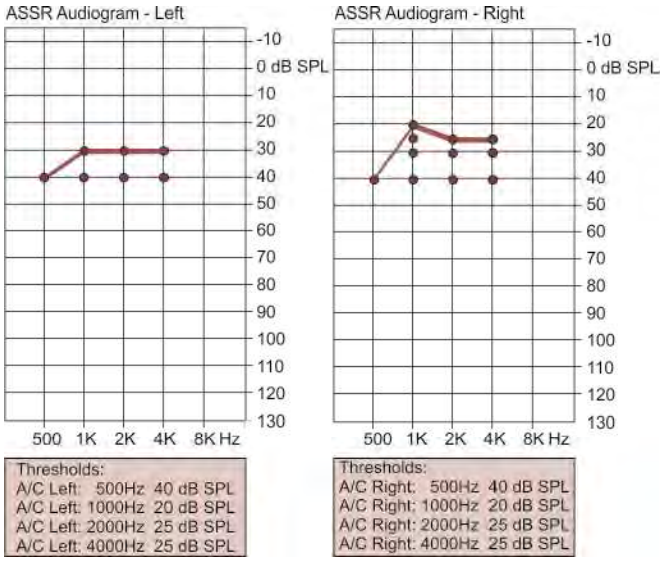

Fig. 20: Auditory steady state response

about the status of the auditory nerve during surgery. The major drawback to using ABR as a monitoring device is that it has a small amplitude potential that cannot clearly be identified in the on going electroencephalographic activity. Rather, resolutions of ABR require averaging. Thus, even in ideal situations, where the ABR is relatively robust and the noise levels are manageable it is not possible to provide the surgeon with instantaneous feedback relative to auditory nerve function.

Auditory Steady State Response

Auditory steady state response (ASSR) is a far-field auditory potential that is evoked using continuous stimulation. As a potential clinical tool, it has several advantages over the more commonly used ABR. For example, with ASSR it is easier to distinguish between severe and profound hearing loss as opposed to ABR (Fig. 20).

ASSR is a reasonable alternative to the ABR as a tool for estimating frequency-specific thresholds in paediatric populations.[7]

Middle and Long Latency Evoked Potentials

Although the ABR and the ASSR reflect neural activity at the level of the brainstem, there are a series of responses that can be recorded which reflect the synchronous activity of large groups of neurons located at the level of the auditory midbrain and cortex. Two of these responses are the auditory middle latency response and long latency responses. They can be elicited using more frequency specific stimuli and are not as dependent on neural synchrony as are the ABR and ECoG, hence MLR may be used for estimating low frequency sensitivity or to evaluate auditory function in persons in whom auditory dys-synchrony/neuropathy is suspected to be present. The LLR has an additional advantage that it can be evoked using speech rather than tonal stimuli. The disadvantages of these are that, the responses are adversely affected by sedation/ anaesthesia and responses are not fully developed until or after 10 years of age.

The audiological test battery which includes the above mentioned tests is mandatory rather than a single test to arrive at a reasonable correct diagnosis.[7]

Editorial Comments

Vestibular Function Test in Unconscious Patients

Vestibulo-ocular reflex elicited by irrigating the external auditory canal with ice cold water has proved to be a very reliable bed-side investigation to evaluate unconscious patients. It not only provides objective indication of the depth of unconsciousness, evidence of ocular nerve palsies, internuclear ophthalmoplegia but is also a guide to prognosis.

Cochlear and Brainstem Implants

Mohan Kameswaran, Kiran Natarajan

Auditory neural prostheses, such as cochlear implants and brainstem implants, have proved to be extremely significant innovations in neuro-otology in the last decade. This has been made possible due to advances in biomedical engineering and the development of materials that are biocompatible. These neural prostheses are devices, which help to restore lost or deficient neural function by integration of external circuitry with neuronal circuitry. Cochlear and auditory brainstem implants offer safe and effective hearing habilitation and rehabilitation for profoundly deafened adults and children.[21] Rather than repairing diseased organs, the emphasis has changed to bypassing them using bionic prosthetic devices. Auditory neural prosthetic intervention must be done as early as possible due to the phenomenon of neural plasticity. Neural plasticity is the ability of the central nervous system to be programmed to learn a new task. This fades between 6 years and 8 years of age.

Electrophysiological tests and imaging modalities are now available to accurately pinpoint the level of lesion in the auditory pathway. In 99% of sensorineural hearing loss, including congenital hearing impairment, the primary pathology is in the cochlea. In the past, patients with profound sensorineural hearing loss unresponsive to amplification with hearing aids had to cope by lip-reading or learning sign language. The first attempt to electronically stimulate the auditory system occurred nearly two centuries ago. The auditory system is unique in its organisation which gives it the opportunity to receive and integrate external electronic circuits. This is due to the low rejection potential of the inner ear as well as the nervous system.

COCHLEAR IMPLANTS

A cochlear implant is a surgically implantable device that helps restore hearing in patients with severe or profound hearing loss, unresponsive to amplification by hearing aids. Cochlear implants are electronic devices designed to detect mechanical sound energy and convert it into electrical signals that can be delivered to the cochlear nerve, bypassing the damaged hair cells of the cochlea. The cochlear implant represents the most successful attempt by man, till date, to interface a prosthetic device with the nervous system. The implant helps convert sound into electrical signals. These signals are then sent to an array of electrodes implanted surgically in the cochlea. The implant system preserves the tonotopic map of the cochlea (Fig. 21).

History of Implants

Djourno and Eyries published the first description of cochlear implants in 1957. In 1961, House used a single channel cochlear implant and in 1984, Clark developed a multichannel implant. Initially, 22 channel implants were used which have now been replaced by 24 channel straight arrays followed by the 24 channel contour implants. The first paediatric cochlear implantation was done in the United States in 1987.[14]

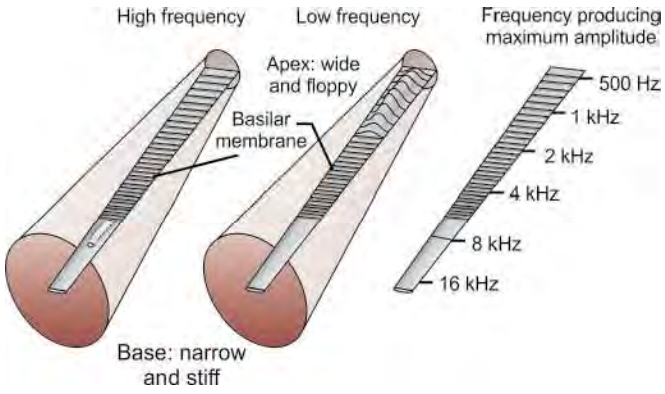

Fig. 21: Tonotopicity of the basilar membrane

Components

The implant has external components consisting of a microphone which receives sound and transduces it into an electrical waveform, a speech processor which divides the signals into components for each of the electrodes and a transmitting coil which sends the signals across the scalp to the internal components. The internal components include a receiver-stimulator which receives the signals from the transmitting coil and sends it to the electrode array which is implanted in the scala tympani of the cochlea. Speech processors are currently available as body worn and ear level speech processors (Fig. 22).

Selection Criteria

Bilateral profound cochlear hearing loss unresponsive to amplification by the most powerful hearing aids is the indication for an implant. All children below the age of 10 years who have congenital or acquired profound hearing loss and who will not benefit from conventional hearing aids and all adults who have lost hearing after acquisition of language are candidates.[9] The only true pre-requisite is an intact auditory nerve (Fig. 23).

Post-lingual candidates do extremely well with an implant and in pre-lingual and per-lingual candidates, an important factor influencing candidacy is neural plasticity and the emphasis is now on implantation as early as possible to maximise speech understanding and perception. In very young children, language acquisition is easier, hence the need for early implantation. Owing to the loss of neural plasticity in older pre-lingually deaf

Fig. 22: Components of cochlear implant

people, the response to implantation may not be optimal and extensive pre-operative counselling regarding realistic expectations is crucial. Candidacy criteria have changed and benefit has increased as cochlear implant technology has advanced.[1] Today not only patients with profound deafness, but also patients with severe hearing loss are considered candidates for implantation.

The expanded indications for implantation are related to age, additional handicaps, residual hearing and special aetiologies of deafness. The minimum age for implantation in children has come down and children as young as 6 months of age have been implanted. As the cochlea is at full size at birth, there is no anatomic difficulty with electrode insertion in very young children.[2]

Medical and radiological criteria have expanded to include significant cochlear abnormalities, including additional handicaps, as in syndromic deafness.

A multi-disciplinary approach is required involving the surgeon, audiologist and speech therapist and auditory verbal habilitationist. The patient and his family must highly be motivated for the implant.

Contraindications

Cochlear aplasia (Fig. 24), absence of auditory nerves, retro-cochlear cause of deafness, central deafness, presence of external or middle ear infections and co-existent severe medical illness are contraindications.

Pre-Operative Evaluation

Pre-operative evaluation includes a complete ENT and head and neck examination, including assessment for additional handicaps, haematological tests, TORCH serology, if required, and skiagram of chest and ECG for assessing fitness for surgery.

An audiologic assessment is the primary means of determining implant candidacy.[12] Audiological and electrophysiological investigations include pure tone (Fig. 25) and impedance audiometry (Fig. 26), otoacoustic emissions (OAE) (Fig. 27), brainstem evoked response audiometry (BERA) (Fig. 28), auditory steady state response (ASSR) (Fig. 29), aided audiometry (Fig. 30) and a hearing aid trial. Promontory stimulation testing can be done in older children and adults to assess the response of the cochlea to electrical stimulation.

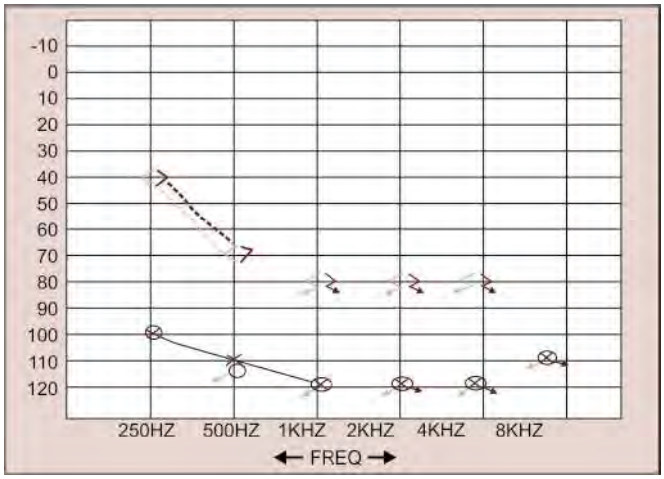

Fig. 25: Puretone audiometry showing profound hearing loss in both ears

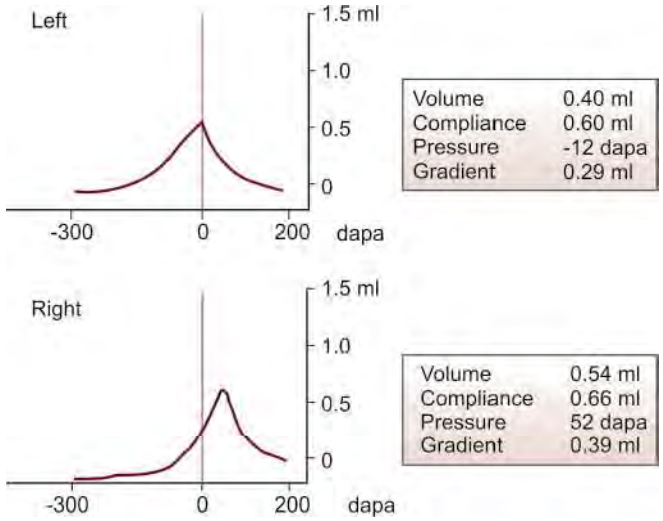

Fig. 26: Impedance audiometry showing bilateral 'A' type with absent reflexes

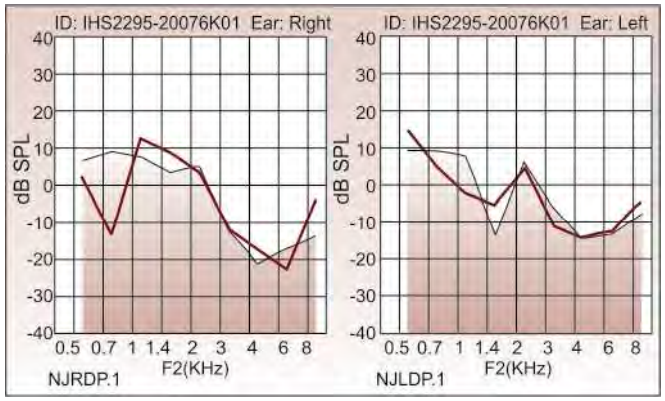

Fig. 27: Absent otoacoustic emissions

Magnetic resonance imaging is the gold standard investigation for the assessment of cochlear anatomy and the vestibulocochlear bundle (Figs 31 and 32). It reveals anomalies like Mondini's and Michel's aplasia, labyrinthitis ossificans and absent eighth nerve. Specialist referral, e.g. to an ophthalmologist or cardiologist, may be required in case of an additional handicap or syndrome where cochlear implantation involves a number of unique issues. Rapid advances in genetics and molecular biology are revolutionising our understanding of congenital deafness and genetic counselling should play an important role in prevention.[19] Pre-operative rehabilitation is important before surgery. Counselling patients and parents, prior to implantation to develop realistic expectations of the likely outcome, is vital.

Surgery of Cochlear Implantation

The goal of cochlear implant surgery is to insert the entire electrode array into the scala tympani with as little damage as possible to the structure of the inner ear.[23] The success of cochlear implantation depends on scrupulous attention to technique at all the various steps of the procedure. Implantation is a 1.5–2.5 hour procedure performed with strict aseptic precautions and is done under general anaesthesia. Surgery is essentially the same in children and adults because the anatomic

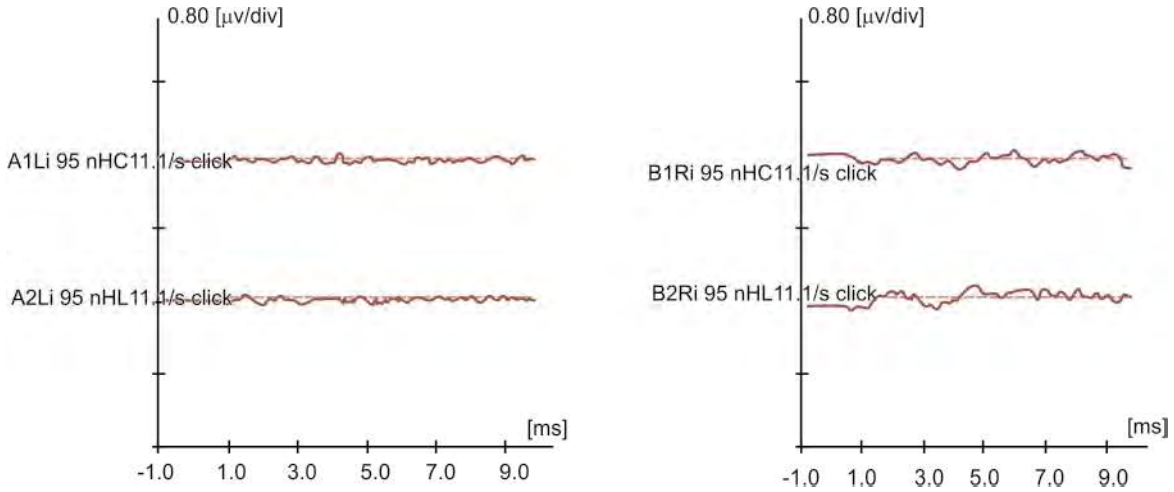

Fig. 28: Brainstem evoked response audiometry showing no peak at maximum intensity in both ears

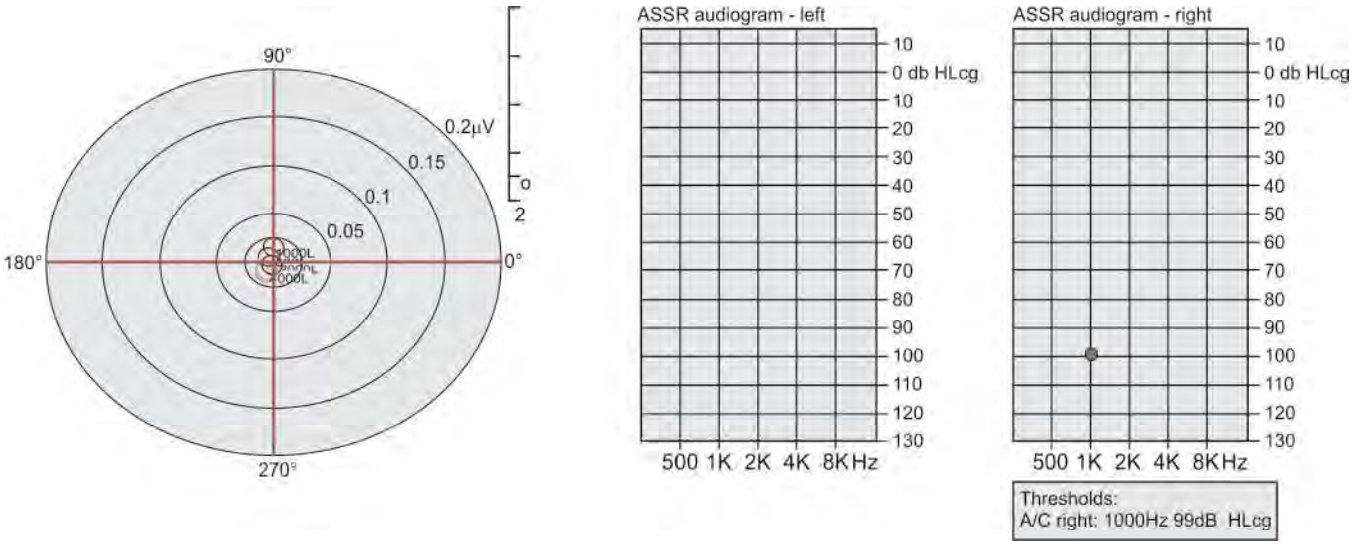

Fig. 29: Auditory steady state responses

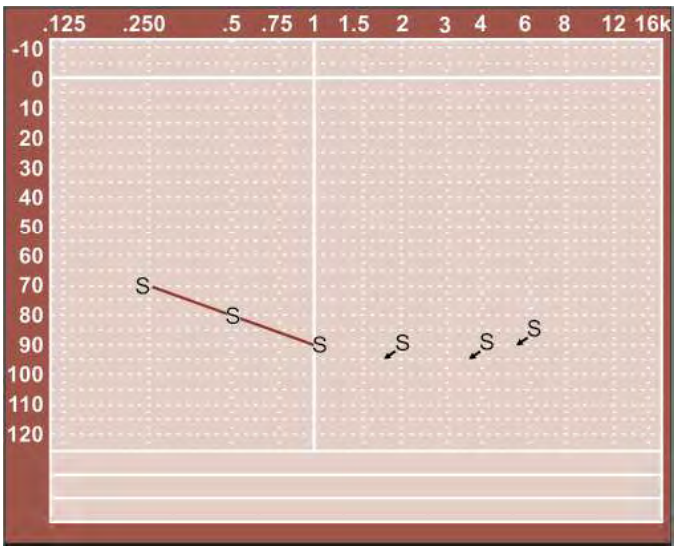

Fig. 30: Aided responses out of speech spectrum

structures are of adult configuration at birth. However, in very young children, there is a slightly increased risk of facial palsy.

The steps of surgery are:

- *Incision*: Usually an extended post-auricular incision is made to expose the mastoid cortex. The incision should be made more than 1 cm from the body of the implant.
- *Simple mastoidectomy*: The mastoid is drilled out to expose the mastoid antrum. Saucerisation of the cavity is not done (Fig. 33).
- *Posterior tympanotomy*: The facial recess is opened and the promontory and round window niche are exposed without exposing the facial nerve (Fig. 34).
- *Well for receiver-stimulator*: This is fashioned in the skull behind the mastoid cavity using a template as a guide and a groove is made to connect it to the mastoid cavity. Tie-down holes are made on either side of the well for securing the implant.

Fig. 31: MRI showing bilateral normal fluid-filled cochlea—comma sign

Fig. 32: MRI showing bilateral vestibulocochlear bundles

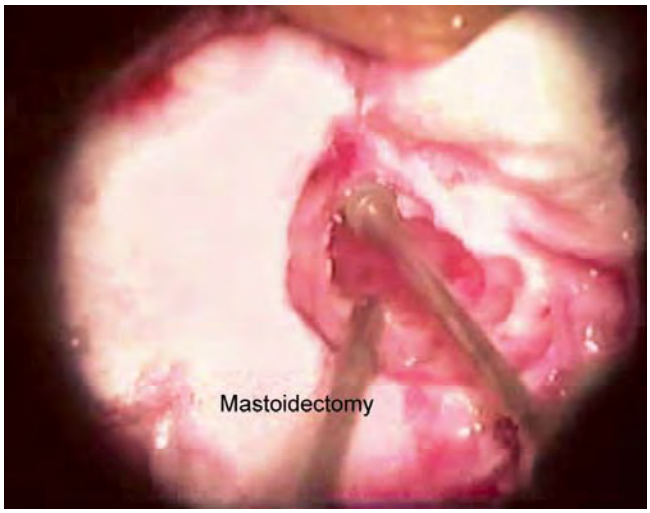

Fig. 33: Cortical mastoidectomy

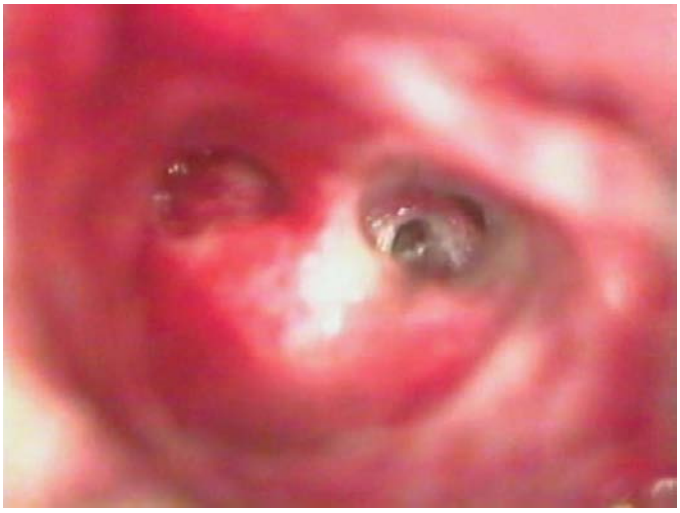

Fig. 35: Cochleostomy in progress

- *Cochleostomy*: The basal turn of the cochlea is opened anterior to the round window to make the axis of introduction of the electrode array straighter (Fig. 35).
- *Insertion of electrode array*: The electrode array is inserted atraumatically into the scala tympani using a claw (Fig. 36). Once the electrodes are inserted, diathermy should not be used.

Fixation of the device and electrode array and wound closure is done.

Electrophysiologic Testing or Neural Response Telemetry

Neural response telemetry (NRT) is performed after implanting the electrode array. This assures the team that the device is functioning and that the patient is receiving an auditory stimulus and responding appropriately.[4]

Post-Operative Care

A pressure dressing is applied for 3–4 days. Antibiotics and analgesics are administered in the post-operative period. The patient is called for review three weeks post-operatively for switch-on of the device (Fig. 37). Frequent mapping sessions are required and prolonged and intensive rehabilitation after implantation is essential. Rehabilitation aims at improving receptive language skills and expressive skills. Post-implantation rehabilitation can be important for some adult recipients, but appears critical for children to optimise the usefulness of an implant.[15]

With increasing experience in cochlear implantation, the indications for implant surgery have widened to include cochlear anomalies and multiple handicapped individuals. Implantation is beneficial in such situations. However, the surgeon must anticipate challenges during implantation and also the subsequent habilitation may be challenging.

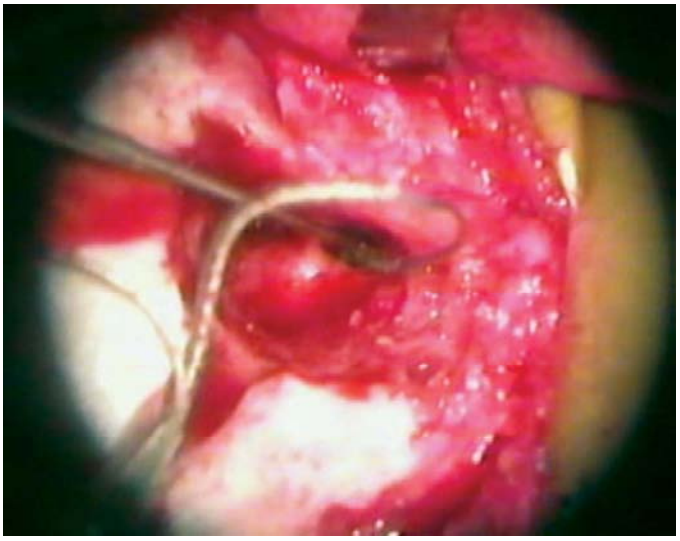

Fig. 36: Insertion of electrode array into the scala tympani of the basal turn of the cochlea

Fig. 37: Cochlear implantee

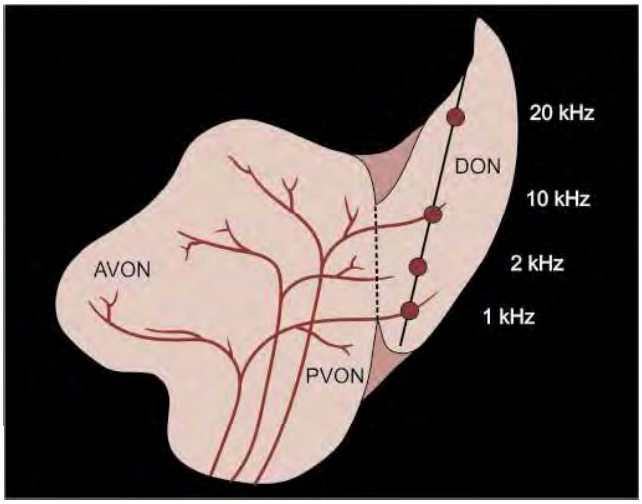

Fig. 39: Tonotopicity of the cochlear nucleus

Complications of Cochlear Implantation

Major complications include facial palsy, and implant exposure due to flap loss and wound infection. Other complications include facial nerve stimulation, device failure, deterioration of hearing, tinnitus, temporary balance problems, numbness of the scalp, loss of taste, electrode/device extrusion, CSF leak and meningitis.

The Future

Cochlear implant surgery and technology continue to evolve.[22] In the future, fully implanted devices, improved speech coding strategies, and cochlear hair cell and nerve growth factors used in conjunction with an implant may be available.[17]

AUDITORY BRAINSTEM IMPLANTATION

Auditory brainstem implant (ABI) is an effective means of hearing rehabilitation in patients with neurofibromatosis type 2. In such patients with damaged cochlear nerves on both sides, the brainstem implant bypasses the cochlear nerves and directly stimulates the cochlear nucleus[16] (Fig. 38). The cochlear nucleus has tonotopicity (Fig. 39).

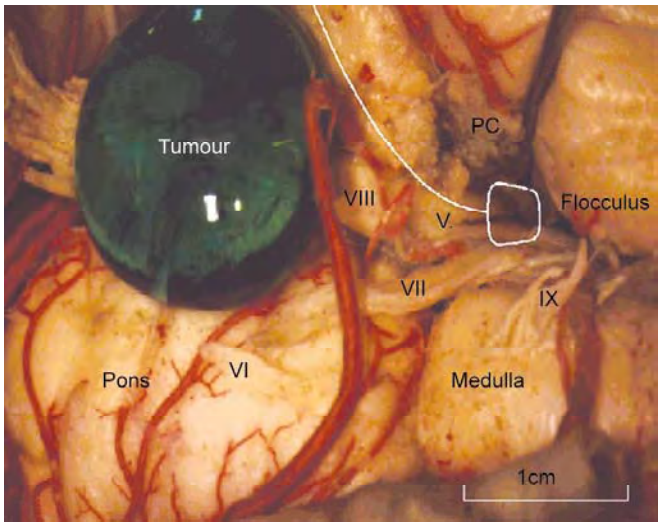

Fig. 38: Auditory brainstem implant placement in the lateral recess

Components

The ABI system commonly used is the Nucleus 24 ABI, which can be used with the Sprint body worn/Esprit behind the ear speech processor. It consists of a receiver-stimulator that receives and decodes the electrical signal from the speech processor and an electrode array, which delivers the signal to the surface of the cochlear nucleus within the brainstem. It has 21 electrodes, arranged in three of seven rows over a silicone electrode carrier. There are two ground electrodes; one plate electrode on the receiver-stimulator package and one ball electrode attached to a separate electrode lead. The receiver-stimulator is placed at least 10 mm behind the edge of the auricle and above the canthomeatal line and is angled 30–45 degrees posterosuperiorly. The stimulus is delivered by an external component comprising a microphone, a signal processor and a transmitter coil similar to a cochlear implant (Figs 40 and 41).

Indications for Auditory Brainstem Implant

Multichannel ABIs are currently indicated for patients with neurofibromatosis type 2 (NF2) and schwannomas involving the internal auditory canal or cerebellopontine angle.[10] Increasingly, ABI is being considered for non-tumour patients and even in children with congenital hearing loss before the loss of neuronal plasticity. In the near future, it may be used in bilateral temporal bone fractures and demyelinating diseases affecting the eighth cranial nerves, but sparing at least one cochlear nucleus.[18] Auditory brainstem implantation has also been recommended for use in cases of bilateral totally ossified cochleae in which a cochlear implant cannot be used.[8] It has also been reported to be useful in cases of bilateral absence of auditory nerves.[5,6]

The current criteria for ABI include evidence of bilateral seventh and eighth cranial nerve tumours involving the IAC or cerebellopontine angle, language competency, age > 12 years or older, psychologic suitability, willingness to comply with research follow-up protocol and realistic expectations.[18] Several factors can affect the

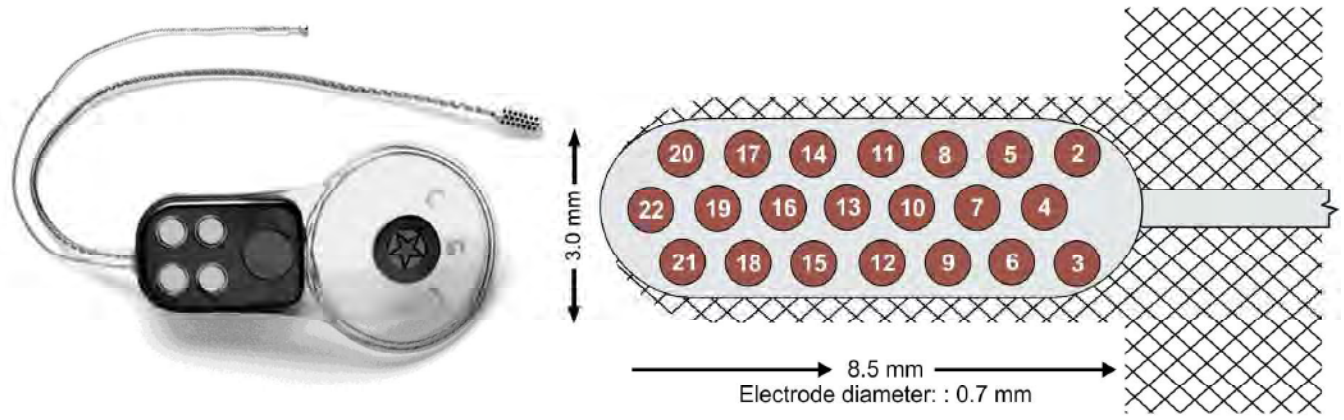

Fig. 40: Internal components of auditory brainstem implant

Fig. 41: External components of auditory brainstem implant

benefit received from an ABI. These factors may include size and location of auditory nerve tumours, degree and duration of hearing loss prior to surgery, and commitment and motivation to use the ABI.

Pre-operative counselling regarding the importance of such factors as expectations, personal motivation and family support is invaluable and the importance of regular use of the implant has to be stressed in order to maximise the benefits from the implant.

Pre-Operative Evaluation

Extensive pre-operative evaluation prior to ABI surgery is essential and a multi-disciplinary approach involving neurotologists, neurosurgeons, audiologists and anaesthetists is required. Prior to planning the surgery, assessment of the tumour and the hearing is vital. Comprehensive audiological tests, including pure tone audiometry, brainstem evoked response audiometry, otoacoustic emissions and auditory steady state response (ASSR), are required. Pre-operative MRI is very important because it may signal potential problems leading to non-stimulation such as a large lateral recess or tumour damage to the cochlear nucleus region and also helps to rule out other intracranial and spinal tumours (Fig. 42).

Auditory Brainstem Implant Surgery

For successful ABI surgery, a few important issues, such as patient selection, choice of device, choice of approach, technique of tumour removal, knowledge of micro-anatomical variations, intra-operative identification of the cochlear nucleus and prevention of complications, have to be considered.[20]

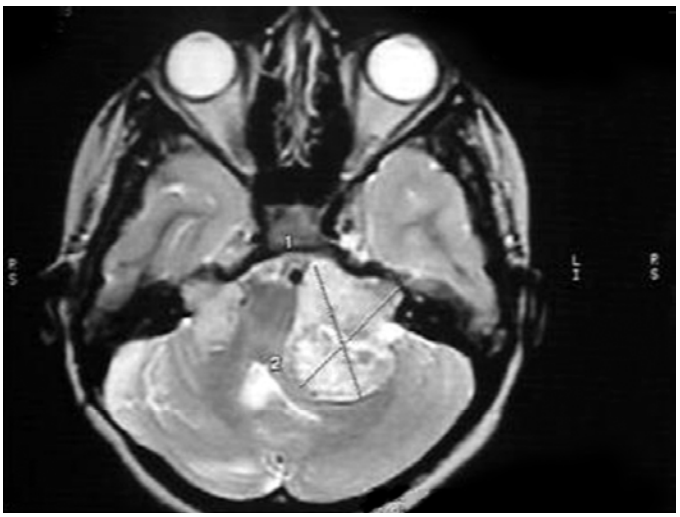

Fig. 42: MRI of neurofibromatosis type 2

During surgical removal of small NF, preservation of auditory nerve has to be attempted not only for auditory preservation but also to retain the option of using a CI in cases of total hearing loss.[13] Nerve monitoring is required and neuromuscular blocking agents should be avoided during monitoring. EMG monitoring of V, VII and IX nerves is done.

There are several approaches described for tumour removal and placement of ABI. Trans-labyrinthine approach provides optimal access for both removal of the tumour and placement of the electrode array. A trans-labyrinthine approach is used by ENT surgeons and has the advantage of offering the best lateral angle to the exit of the cochlear nerve, which allows the early identification of the facial nerve and does not require cerebellar retraction. Disadvantages with trans-labyrinthine approach are limited exposure of cranial nerves and vessels in the posterior fossa. The lateral suboccipital approach is preferred by most neurosurgeons as it is fast, safe and offers very good exposure of the lateral posterior fossa. The problems are cerebellar retraction and late identification of the facial nerve. The angle to the lateral recess and direct vision of the entrance are more difficult in comparison to the trans-labyrinthine approach.[20] The middle cranial fossa approach is only possible with angled endoscopes; however, it is technically the most difficult and places the facial nerve at greatest risk.

After craniectomy is performed, a seat for receiver-stimulator is created in the area postero-superior to the craniectomy. Tie-down holes are then placed on either side of the receiver-stimulator for securing the implant. During tumour removal, a stump of the cochlear nerve is preserved to aid in identification of the cochlear nucleus. After tumour removal, the cochlear nerve is followed medially as it enters the lateral recess of the fourth ventricle. The ABI is inserted in the lateral recess of the fourth ventricle, which is adjacent to both cochlear nuclei.

Knowledge of micro-anatomy of the cochlear nucleus complex and its variations is essential for successful implantation. Constant anatomical landmarks are very helpful in finding the cochlear nucleus. The exits of the cranial nerves 7, 8 and 9 form a triangle of about 5–6 mm (Fig. 43). If the first of these nerves is identified, the others and the entrance of the lateral recess will be found within an area of 6 mm. Between the bulging of the cochlear nucleus and the ponto-bulbar body, a small straight vein is a constant finding and an important landmark. The typical straight vein at the cochlear nucleus heading to the entrance of the foramen of Luschka is found in 76%.[11] Its positive identification gives the best security for an optimal implantation. Normally, an intact choroid plexus marks the entrance to the lateral recess (foramen of Luschka) and the taenia obliquely traverses the roof of the lateral recess, marking the surface of the ventral

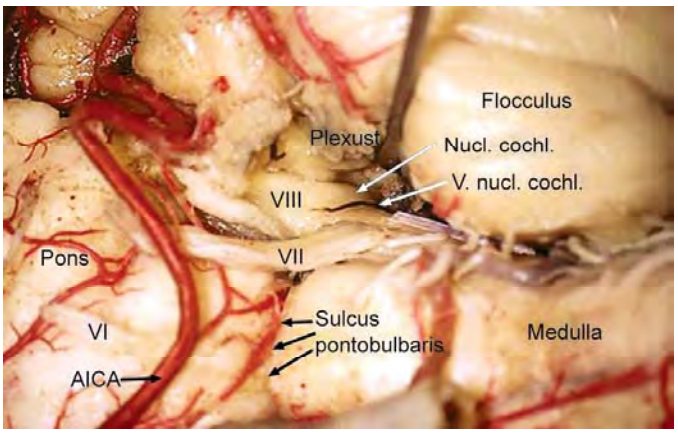

Fig. 43: Cochlear nucleus

cochlear nucleus. Location of the lateral recess can be confirmed by noting the egress of CSF during Valsalva manoeuvre.[18]

The taenia of the choroid plexus at the entrance of the fourth ventricle is dissected and the device is advanced into the lateral recess of the fourth ventricle over the surface of the cochlear nuclei (Figs 44 and 45).

Placement of the electrode completely within the recess gives the fewest side effects and preserves auditory stimulation. After placement, the electrodes are stimulated to confirm their position over the cochlear nucleus and electrically evoked brainstem responses (EABRs) are recorded (Fig. 46).

Activity in adjacent cranial nerve nuclei and vital sign changes are also noted. After the electrode array and receiver-stimulator are secured, the dura is re-approximated. The patient has to be under constant neurologic monitoring in the post-operative period.

Activation of the device is done 3–6 weeks later. The device position may be verified by X-ray/CT scan (Fig. 47). The switch-on is done with monitoring of vital signs and also non-auditory effects (tingling, jittering of the visual field, facial movement, vertigo, motor responses) are specifically looked for. Several programming sessions are required before the most suitable setting is achieved. At each follow-up visit, the patient undergoes an extensive neurologic examination to monitor any changes in neurologic status.

Penetrating ABI (PABI) electrodes have also been tried on the cochlear nucleus. This implant has the

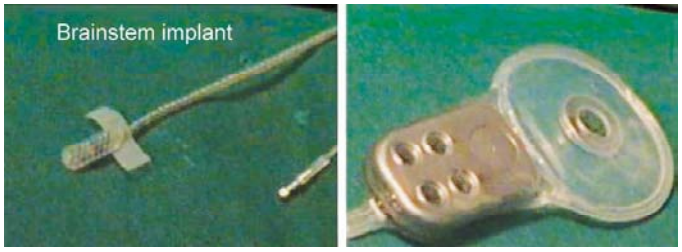

Fig. 44: Two ends of the auditory brainstem implant

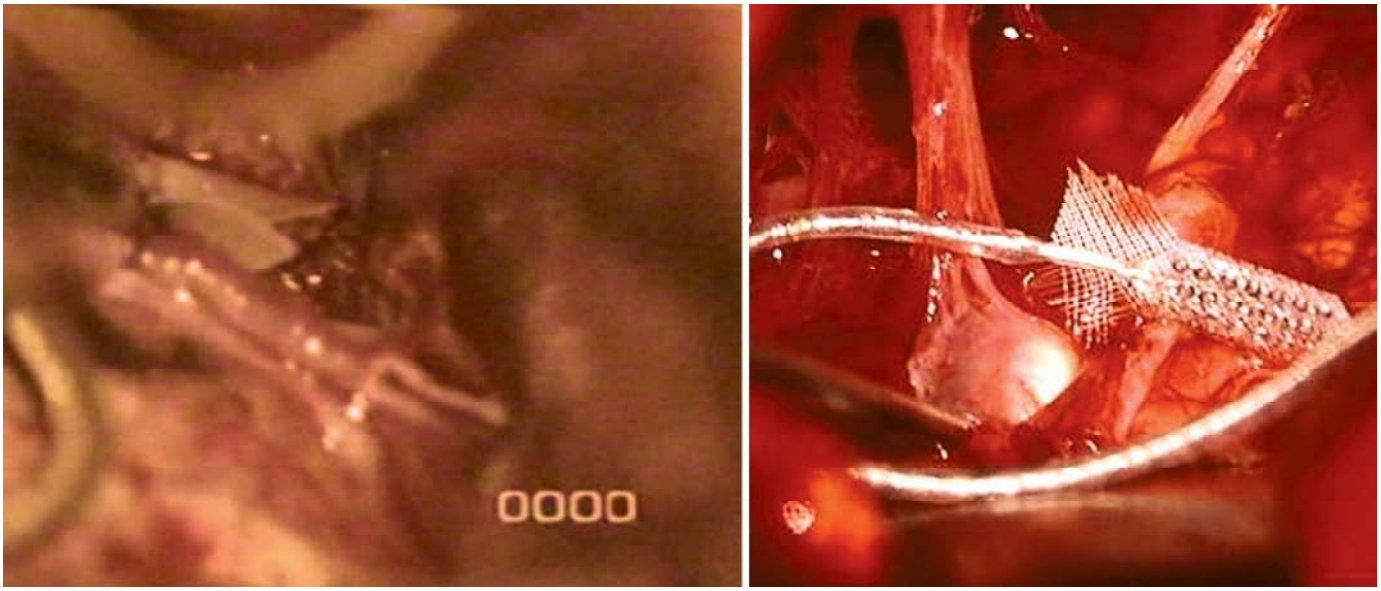

Fig. 45: Intra-operative picture of auditory brainstem implant electrodes

potential of offering improved performance due to better access to the complex tonotopic organisation of the cochlear nucleus.[18] Endoscopic-guided placement of electrodes through the retro-sigmoid approach may also be helpful in reducing the morbidity of surgery.[7] Sleeper implants may be placed at the time of removal of the first tumour and activated after removal of the second side tumour.

Contraindications to ABI include previous stereotactic radiotherapy which has the risk of radiation necrosis of the cochlear nucleus region and anatomic distortion and fibrosis. ABI may not be possible in very large tumours which cause distortion of the brainstem.

Auditory Midbrain Implants

The auditory midbrain implant (AMI) is a new hearing prosthesis designed for stimulation of the auditory midbrain, particularly the inferior colliculus central nucleus (ICC).[3] AMIs are placed in the ICC. They may prove to be a safe and potential alternative for hearing restoration in NF2 patients and may help in enhancement in lip-reading capabilities and environmental awareness and some improvement in speech perception performance.

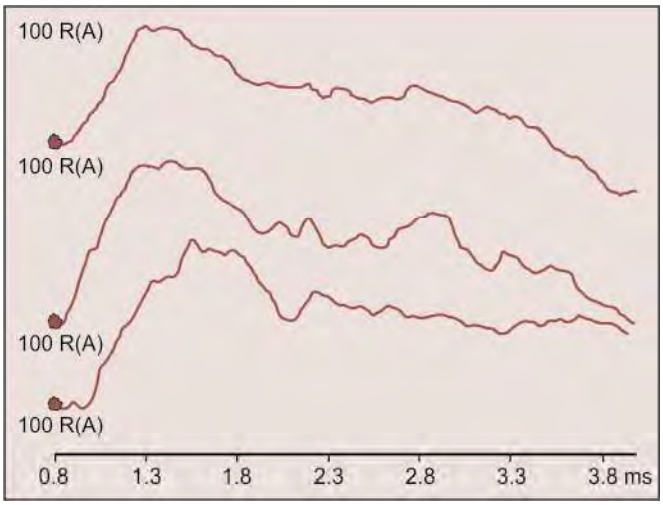

Fig. 46: Intra-operative electrically evoked brainstem responses

CONCLUDING REMARKS

Advances in biotechnology and the development of materials that are biocompatible have resulted in development of prostheses that help in rehabilitation of hearing loss unresponsive to conventional amplification. Cochlear implantation represents the single most important advancement in the rehabilitation of unaidable sensorineural deficits. Early identification and intervention, careful patient selection, and counselling of families regarding realistic expectations are crucial.

In retro-cochlear disorders in which a cochlear implant is contraindicated, the auditory brainstem implant is the only option available for hearing rehabilitation. The primary aim of treatment of patients with NF2 is the recovery of hearing after reducing or extirpating the tumour. The ABI has few side effects and allows most patients with NF2 to experience improved communication as well as access to environmental sounds. Patient selection is important and appropriate pre-operative counselling regarding realistic expectations is necessary and the importance of regular usage must be emphasised. The biosafety of cochlear and brainstem implants has been established and no long-term deleterious effects have been reported with their usage. Developments in technology will expand the benefit of these devices and offer new treatment for otologic disorders.

7 Neuroendocrinology

Ravi Ramamurthi, Ravindranath Kapu

INTRODUCTION

The anterior pituitary secretes the following hormones: (1) prolactin (PRL), (2) growth hormone (GH), (3) adrenocorticotropic hormone (ACTH), (4) thyroid-stimulating hormone (TSH), (5) gonadotrophic hormones which are follicle stimulating hormone (FSH) and luteinising hormone (LH). The posterior pituitary secretes the antidiuretic hormone (ADH or vasopressin) and oxytocin.

Pituitary hormones are measured by radioimmunoassay (RIA), immunoradiometric assay (IRMA) or enzyme-linked immunosorbent assay (ELISA). It is necessary to measure the levels of these hormones and also some substances released from the target organs, in patients suspected of harbouring a pituitary or a parasellar lesion. The reserve capacity of the pituitary gland, in its response to stress, must be tested with provocative tests (dynamic testing). The basal levels of the circulating hormones may be normal even with very little functioning pituitary tissue. The normal basal levels are given in Table 1.

PROLACTIN

Prolactin is secreted by lactotrophic cells located in the lateral wings of the anterior pituitary. These cells constitute 20% of adult anterior pituitary cells and are derived from acidophilic stem cells, which are also the precursor cells for somatotrophs. Physiological hypertrophy of lactotroph cells occurs in states where there is excess oestrogen as in the foetus and in women during the second and third trimester of pregnancy.

Prolactin contains 198 amino acid residues which were identified in 1977.[53] Different molecular forms have been recognised, the commonest being the monomeric (21.5 kd) accounting for 90% of circulating PRL. There is a "big" form with a molecular weight of 45–50 kd and a "big-big" form weighing more than 100 kd.[12,15,55,69] The polymeric forms have very little biologic activity as compared to the monomeric form. Prolactin receptors are present in the ovaries, mammary glands, pituitary gland, heart, thymus, lung, spleen, liver, pancreas, kidney, adrenal gland, uterus, skeletal muscle and areas of the central nervous system. PRL causes activation of Janus Kinase 2, a tyrosine kinase that initiates the JAK-STAT pathway and also activation of mitogen-activated protein kinases and Src kinase.[35]

The secretion of PRL is spontaneous in the absence of hypothalamic or hypophysiotropic influences. The following substances inhibit the release of PRL: dopamine, gamma-aminobutyric acid (GABA), gonadotropin-releasing hormone (GnRH)-associated peptide and somatostatin. There is also a negative autoregulatory effect of PRL itself.[29,51] The predominant control of PRL is inhibitory, but three substances, thyrotropin releasing hormone (TRH), vasoactive intestinal peptide (VIP) and serotonin are PRL releasing substances. Oestrogens increase the secretion of PRL and are responsible for the increase in pituitary size and PRL production during pregnancy.[14] T3 and glucocorticoids inhibit PRL release. Epileptic seizures can also increase the PRL levels.[38]

The basal level of PRL is 5–20 ng/ml. The average is 10 ng/ml in women and is 20–25% lower in men and in postmenopausal women. PRL levels vary through the day with a circadian rhythm and the highest levels are noted during sleep.[66] Stress induces variations in PRL levels. Physical activity, general anaesthesia, surgery, myocardial infarction, seizures, and nipple and chest wall stimulation may increase PRL levels. During pregnancy and lactation, PRL levels increase to 200–300 ng/ml.

Routine dynamic testing of PRL levels is not of much use, except in the research setting. The TRH stimulation test is the most effective. Baseline fasting TSH and PRL levels are measured and 500 ng of TRH is given intravenously over 30 seconds. The serum levels are measured at 15-minute intervals up to an hour. Any rise of over 100% is normal. Anything less is indicative of inadequate lactotroph reserve. The other substances that can be used for dynamic testing are chlorpromazine and metoclopramide to increase PRL secretion and L-dopa and nomifensine to reduce PRL secretion.

GROWTH HORMONE

This is a 191 amino acid polypeptide with a molecular weight of 22,124 daltons. It is secreted in a pulsatile fashion with surges of secretion occurring at 3–5 hour intervals[39] and the serum levels vary with the time of day.[39] The normal serum level of growth hormone is up to 5 ng/ml. Young adolescents secrete human growth hormone (HGH) at the rate of about 700 μg/day, while healthy adults secrete HGH at the rate of about 400 μg/day.[18] It is secreted by the somatotroph cells within the

lateral wings of the anterior pituitary gland. The most predictable levels of these GH peaks occur about an hour after the onset of sleep.[58]

Growth hormone secretion is controlled by two polypeptides which are secreted by the hypothalamus and reach the pituitary through the hypothalamo-hypophyseal portal circulation. Growth hormone-releasing hormone (GHRH) stimulates the secretion of GH, while somatostatin (SRIF) suppresses the release.[37] The pulsatile release of GH is controlled by SRIF rather than GHRH.[60] The hypothalamic control of these peptides is regulated by the brainstem and the limbic system. The effects produced by GH are due to stimulation of insulin-like growth factor 1 (IGF-1), which is also known as somatomedin C. IGF-1 stimulates chondrocytes and induces replication of epithelial cells. In the circulation it is bound to a protein (growth hormone binding protein, GHBP) which is a subunit of the growth hormone receptor, and an acid labile subunit (ALS).

Substances that stimulate GH secretion are encephalin, glucagons, alpha melanocyte stimulating hormone, vasopressin, diazepam, oestrogens, norepinephrine, L-Dopa, clonidine, apomorphine and ghrelin. In human corticotroph cell cultures, interleukin-1(IL-1) and tissue necrotic factor (TNF alpha) stimulate the release of GH in GH3 cells.[16,21,22] Stress, hypoglycaemia and exercise also stimulate GH secretion. Serotonin precursors, such as L-tryptophan or 5-hydroxytryptamine (5HT), enhance GH secretion. The substances that suppress GH secretion are SRIF from the periventricular nucleus,[23] hyperglycaemia,[34] isoproterenol, glucocorticoids and elevated levels of free fatty acid.

GH levels are measured in the serum in the basal state as well as after provocative tests. The basal level is tested in a fasting patient at 8.00 am. The blood may also be drawn at 12 noon, 4 pm and 8.00 pm. Normally all values must be below 2 ng/ml. The normal range is 0–5 ng/ml.

The dynamic tests used to determine GH reserve are:

1. *Insulin-induced hypoglycaemia*: After overnight fasting, hypoglycaemia is induced by a bolus injection of human insulin at a dose of 0.15 IU per kg body weight. Blood samples are taken at 30-minute intervals. A normal response is said to occur when the GH level increases to more than than 7 ng/ml, but there is absolute proof of adequate reserves only when the value reaches 20 ng/ml and above.[11] The insulin-induced hypoglycaemia test has to be done under closely monitored conditions, especially in patients in whom the adrenal reserve is low. It is contraindicated in patients with ischaemic heart disease, cerebrovascular disease, seizures and adrenal insufficiency.
2. *The arginine test*: This is used when there is a contraindication to the insulin-induced hypoglycaemia test. A 500 ml of 6% solution of arginine is infused intravenously over a 30-minute period. Blood samples are taken, initially, at 15-minute intervals and then at 30-minute intervals up to 2 hours. The glucose level should increase to more than 20% of the original value and the GH level to more than 7 ng/ml to conclude that the test is normal. L-Dopa is another substance that can be used.

The dynamic tests that are used when there is acromegaly are:

1. *Oral glucose tolerance test (OGTT)*: After overnight fasting, 75 grams of glucose is given orally. Blood samples are taken at 30-minute intervals for up to 2 hours. The glucose, GH and somatomedin C levels are measured. In normal persons, the GH is suppressed to undetectable levels. Failure of suppression indicates acromegaly. This is true in 93% of acromegalics.[62] For practical purposes, if the GH is below 2 ng/ml acromegaly can be excluded.
2. *TRH test*: The test is done between 8.30 am and 10.00 am. A basal sample is drawn and then 200 ug of TRH is injected. Two samples are taken at half-hourly intervals and the GH levels are measured. Normally there is no increase of GH. A more than twofold increase above the basal levels is called an "inappropriately high response" and is often associated with active acromegaly. Dopaminergic agents, such as laevodopa and bromocriptine, normally cause a rise in GH, but in about two-thirds of acromegalics they cause a reduction.

Somatomedin C estimation is done by RIA. The normal fasting value is 0.67 u/ml (range 0.31–1.4) and the mean in acromegalics is 6.8 u/ml (range 2.6–21.7). This assay is useful in the post-treatment follow-up of acromegalics.

ADRENOCORTICOTROPIC HORMONE AND CORTISOL

Cortisol is essential for the physiological and biochemical response to stress, both endogenous and exogenous. Cortisol is secreted from the zona fasciculata, the second layer of the adrenal cortex. Cortisol secretion is controlled by ACTH, which is secreted by the anterior pituitary and is in turn controlled by corticotropin-releasing hormone (CRH) from the paraventricular nucleus of the hypothalamus. Corticotrophs in the anterior pituitary produce ACTH and these constitute 10–20% of the cells. They are concentrated in the central portion of the gland, though some cells are also present in the lateral wings and in the pars intermedia.[2]

Corticotropin-releasing hormone secretion is modulated by positive influences from other parts of the brain and negative feedback from circulating glucocorticoids.[17] The afferents to the paraventricular nuclei arise from the nucleus of the tractus solitarius, the hypothalamus, the nucleus of the subfornical region, the medullary reticular formation, the locus ceruleus and the limbic system, especially the lateral septal region.

Adrenocorticotropic hormone secretion is stimulated by CRH and vasopressin and inhibited by negative

feedback from circulating cortisol.[28] CRH, ACTH and cortisol are secreted in a periodic and rhythmic manner with the maximum secretion at 8.00 am and the least at midnight. This diurnal variation is due to the transfer of information about the light/dark cycle from the retina to the paired suprachiasmatic nuclei in the hypothalamus. The pattern is not present at birth.[6] In normal humans, bursts of ACTH and cortisol secretion occur about 15 times in a 24-hour period.[64] ACTH levels can vary 10-fold in a day and cortisol is actively secreted only during one-fourth of a day. ACTH secretion is modulated by many neurotransmitters.[32] ACTH is stimulated by acetylcholine, serotonin and IL-1 and is inhibited by catecholamines, beta-endorphin and dopamine.[5]

It is difficult to measure ACTH in the serum as its half-life is only 20 minutes. Generally, basal levels of plasma and urinary cortisol are measured. Since there is a lot of diurnal variation, the average of 4–6 samples taken over a 24-hour period should be measured. Cortisol secretion is highest in the morning and lowest at midnight. The mean plasma cortisol level should be 5–25 ug/dl. The urinary-free cortisol level should be less than 100/ug per 24 hours and 17-hydroxysteroids should be 3–8 mg per 24 hours. Dynamic tests are used to evaluate the status of the hypothalamic-pituitary-adrenal (HPA) axis, in its response to stress and in hyper-functioning states.

Measurements of cortisol in serum, saliva and urine reflect systemic cortisol levels at the time of sample collection, but cannot assess the past cortisol levels. Hair cortisol levels may be increased in patients with Cushing's syndrome, and, as hair grows about 1 cm/month, measurement of hair cortisol can provide historical information on the development of hypercortisolism.[59]

Urinary-free Cortisol Excretion Rate

It is one of the best methods for quantifying hypercortisolism in which unmetabolised cortisol is measured. Urinary-free cortisol (UFC) is measured in a carefully collected 24-hour urine sample. The normal range is between 30 nmol/day and 150 nmol/day. The sensitivity of the UFC method in the diagnosis of Cushing's syndrome is between 95% and 100%.

The tests used for assessing normal function are:

1. *Insulin-induced hypoglycaemia (Insulin tolerance tests, ITT)*: The blood glucose levels should drop to below 40 mg/ml. An increase in cortisol level to more than 12 ug/ml is considered an adequate response and demonstrates an intact hypothalamic-pituitary-adrenal axis.[1]
2. *ACTH stimulation test*: The test is done in the morning and fasting is not necessary. After drawing blood for a basal sample, 0.25 mg of ACTH is injected and another sample is drawn after 30 minutes. Plasma cortisol should be more than 18 ug/ml and the increment should be more than 7 ug/ml.
3. *Metyrapone test*: Metyrapone inhibits 11-beta hydroxylase in the adrenal cortex and blocks the conversion of 11-deoxycortisol to cortisol. The drop in serum cortisol stimulates ACTH secretion which in turn stimulates the synthesis of 11 deoxycortisol and the metabolites of this compound can be measured in the urine. In normal people, 24-hour urinary 17 hydroxycorticoid levels are two or three times above the baseline level in 1 or 2 days after the administration of metyrapone.

The dynamic tests used in hypercortisolaemia are:

1. *Low-dose dexamethasone test*: The low-dose dexamethasone suppression test is a good screening procedure. A 9.00 am blood sample is drawn and 2 mg of dexamethasone is given at 10.00 pm. Blood is again drawn at 9.00 am the next day. Cortisol is measured in both the samples. The cortisol should normally be suppressed to below 2/ug/ml. This response practically excludes Cushing's syndrome. This test is also useful in postoperative assessment. A positive dexamethasone test and a markedly increased UFC are diagnostic of Cushing's syndrome in patients who are not under severe stress.[27]
2. *High-dose dexamethasone test*: This is used in the differential diagnosis of Cushing's syndrome and where the low-dose dexamethasone test is abnormal. The test is carried out similar to the low-dose test except that 8 mg of dexamethasone is given instead of 2 mg. Cortisol will be suppressed to less than 50% of the basal value in Cushing's disease, but not in ectopic ACTH syndrome or adrenal tumours.
3. *CRH stimulation test*: This is also a test for differential diagnosis of Cushing's syndrome. After overnight fasting and taking a baseline sample, 100 ug of bovine or human CRH is injected intravenously as a bolus and blood samples are taken at 15-minute intervals up to 90 minutes. Normally the cortisol levels should rise to 15–30 ug/ml and ACTH levels to 28–230 pg/ml. Patients with Cushing's disease exhibit a normal or exaggerated response, whereas there is no response with ectopic ACTH syndrome or adrenal tumours.
4. *Venous sampling for ACTH gradient*: This is done when the results of other tests are not definitive and computed tomography (CT) and magnetic resonance imaging (MRI) images do not reveal a microadenoma. If an ectopic source of ACTH cannot be excluded, then venous sampling is done at various levels including the internal jugular vein, the right ventricle and the inferior vena cava at the level of the diaphragm and the coeliac, the renal and the femoral veins. Simultaneously, two catheters are placed in the inferior petrosal sinus on either side and if this is not technically possible they are placed in the internal jugular vein as high as possible. A bolus injection of 100 ug of CRH is given intravenously and blood samples are collected from various sites at 5-minute intervals for 25 minutes. The source of ACTH can

be reliably identified from the elevation of ACTH in various samples. Inferior petrosal vein sampling also helps in locating the site of a pituitary microadenoma when there is a doubt.

Tests for Hypocortisolism

Morning Plasma Cortisol Level (Between 8 am and 9 am)

Cortisol levels more than 500 nmol/l at this time practically exclude adrenal insufficiency, while a level less than 100 nmol/l is almost diagnostic of adrenal insufficiency.

In a patient with such a low plasma cortisol, measurement of ACTH in the same blood sample allows the distinction between primary (elevated ACTH) and secondary (normal or low ACTH) adrenal insufficiency.[46]

All patients who are suspected to have adrenal insufficiency with morning plasma cortisol levels between 100 nmol/l and 500 nmol/l require "dynamic" testing in which 250 μg of synthetic corticotropin or less is injected intravenously or intramuscularly, and plasma cortisol is determined before injection and 30 or 60 minutes after injection. If the cortisol rises to a level more than 550 nmol/l, primary adrenal insufficiency is excluded.[46]

THYROID

Tetraiodothyroxine (T4) is the major hormone secreted by the thyroid gland, but tri-iodothyronine (T3) is the metabolically active hormone.[52] Thyroid hormones control development, growth and metabolic rate. Thyroid hormone secretion is controlled by TSH secreted by the anterior pituitary. TSH was first identified by Crew and Weisner.[4] It is a glycoprotein with two subunits, alpha and beta.[47] The alpha subunit is common to other glycoprotein hormones, LH, follicle-stimulating hormone (FSH) and human chorionic gonadotropin (HCG). Thytrophin releasing hormone tonically stimulates the release of TSH.[20] Dopamine, SRIF, neurotensin, serotonin, norepinephrine, cholecystokinin, oestrogens and cortisol directly or indirectly affect the release of TSH.

Thytrophin releasing hormone is synthesized in the paraventricular nucleus of the hypothalamus. TRH is also found in other neuronal and non-neuronal tissue. The hypothalamic-pituitary-thyroid axis is controlled primarily by the circulating thyroid hormone in a negative feedback system.

Hypothyroidism and hyperthyroidism are diagnosed on the basis of determination of T3 and T4. Free T4 is a good screening test of thyroid function, because it takes into account both T3 uptake and total T4 in the serum. Radioactive iodine uptake should not be used as a screening test of thyroid function. When T3 and T4 are low, TSH stimulation will enable differentiation between primary and secondary hypothyroidism. This differentiation is also possible by the TRH stimulation test. Mass spectrometry is a new advanced technique by which the hormones can be quantitatively assessed in biological fluids.[57]

Thyrotropin-releasing hormone stimulation test: Blood is drawn for basal levels and then 200/ug of TRH is injected and blood samples are drawn 30 and 60 minutes later. TSH assay is done on the blood samples. The normal basal values range from 0.3 IU/ml to 3.5 IU/ml. The increment should be more than 2.7 IU/ml after 30 minutes. In a patient with low thyroid hormones, impaired TSH response to TRH indicates deficient TSH at the pituitary level. A delayed TSH response to TRH, i.e. when the TSH level is higher at 60 minutes than at 30 minutes, is characteristic of hypothalamic dysfunction. It may also be seen in pituitary disease or primary hyperthyroidism. In primary hyperthyroidism, the basal TSH level is suppressed and fails to rise after TRH administration.

Basal TSH level in the upper normal range, or slightly elevated in the presence of raised T3 and T4, is called inappropriate secretion of TSH and is characteristic of TSH secreting pituitary adenoma. The TSH alpha subunit is measured by a specific RIA. This is elevated in TSH secreting pituitary adenoma.

Newer Methods

Index Methods

These are free hormone estimate tests.[24] They are of two types. The first test is a total hormone measurement (TT4 or TT3) and the other is an assessment of the thyroid hormone binding protein (THBP) concentration. These tests use either an immunoassay for thyroxine-binding globulin (TBG) or a T4 or T3 "uptake" test called thyroid hormone binding ratio (THBR).

Alternatively, indexes may be calculated from a TT4 measurement paired with an estimate of the free T4 fraction determined by isotopic dialysis. The quality and purity of the tracer (radiolabelled T3 or T4) used impacts the accuracy of the index.[31,43,45]

Indexes Using a Thyroid Hormone Binding Ratio or "Uptake" Test

"Classical" uptake test is a method in which a trace amount of radiolabelled T3 or T4 is added to the specimen and it is allowed to distribute across the thyroid hormone binding proteins like the endogenous hormone.[24,30]

"Classic" T3 uptake or THBR tests are dependant on the endogenous T4 concentration in the specimen. Currently used THBR tests produce normal FT4I and FT3I values when TBG abnormalities are mild (i.e. pregnancy). However, some of these tests may produce inappropriately abnormal index values when patients have grossly abnormal binding proteins [congenital TBG high or low, familial dysalbuminaemic hyperthyroxinaemia (FDH), thyroid hormone autoantibodies or NTI] and in the presence of some medications that influence thyroid hormone protein binding.

Ligand Assays

Types: Types of legend assays are as follows:

1. Two-step, labelled-hormone/back-titration methods

2. One-step, labelled hormone-analogue methods
3. Labelled antibody methods.

One-step ligand assays attempt to quantify free hormone in the presence of binding proteins whereas two-step assays use a physical separation of free hormone from protein-bound hormone before measuring the free hormone by a sensitive immunoassay, or by using an antibody to immunoextract a proportion of ligand out of the specimen before quantification.

One-step methods may become invalid when the specimen and the standards differ in their affinity for the assay tracer[7,9,54] whereas two-step methods are less prone to non-specific artifacts. The physical isolation of free from protein-bound hormone is accomplished with either a semi-permeable membrane using a dialysis chamber, an ultrafiltration technique, or a Sephadex LH-20 resin adsorption column.[10,42,56,61,67]

Labelled antibody methods measure free hormone as a function of the fractional occupancy of hormone antibody binding sites. This competitive approach uses specific immunoabsorbents to assess the unoccupied antibody binding sites in the reaction mixture.

The only reason to select a free thyroid hormone method (FT4 or FT3) in preference to a total thyroid hormone test (TT4 or TT3) is to improve the diagnostic accuracy for detecting hypothyroidism and hyperthyroidism in patients with thyroid hormone binding abnormalities that compromise the diagnostic accuracy of total hormone measurements.[24] Free hormone tests should be performed at 37°C since tests performed at ambient temperature show falsely increased values when specimens have a very low TBG concentration.[50,65]

GONADOTROPINS

Luteinising hormone and FSH are the gonadotropins and they are synthesised by gonadotrophs in the anterior pituitary. They have a common alpha subunit with TSH and HCG. The beta subunits confer the biologic specificity of all these four hormones.[21] LH and FSH are controlled by the hypothalamic-pituitary-gonadal axis.[48] LH and FSH release is controlled by GnRH, which is a decapeptide synthesised in the hypothalamus. GnRH release is regulated by several molecules including neurotransmitters, glial cell factors, sex steroids,[25,26] kisspeptin (Kp) and neuropeptide.[3] Plasma FSH levels also increase after Kp stimulation.[40,41] LH and FSH travel through the systemic circulation and in turn stimulate the gonadal steroids testosterone, oestradiol and progesterone. They also stimulate the peptides, inhibins and activins, as also gametogenesis. A negative feedback is exerted on the pituitary and hypothalamus by the gonadal hormones.

LH and FSH are secreted in a pulsatile fashion over 24 hours. The pattern in men is fairly constant at 90–120 minutes whereas, in women, it changes with changes in the menstrual cycle.[13,36,63] This pulsatile secretion is due to the pulsatile release of GnRH from the hypothalamic neurons.

Various other substances also regulate the hypothalamic-pituitary-gonadal axis. Prolactin inhibits GnRH secretion and causes hypogonadism.[63] Exogenous and endogenous opiates reduce GnRH secretion and produce hypogonadism. The other substances that decrease gonadotropin release are corticosteroids, dopamine and SRIF.

The normal values of FSH, LH, oestrogen, progesterone and testosterone are shown in Table 1. In a premenopausal woman, low serum oestradiol with elevated gonadotropin levels is suggestive of gonadotropin deficiency. In post-menopausal women serum oestradiol is low and LH and FSH may be high. In men, if the testosterone is low and there is no corresponding increase in gonadotropins, then there is gonadotropin deficiency.

Gonadotropin-releasing Hormone Stimulation Test

After drawing blood for a basal sample, 100 ug of GnRH is injected intravenously and a sample of blood is drawn after 30 minutes. LH and FSH estimations are done. A normal response is when the basal values of LH rise fourfold or fivefold and FSH values rise twofold. Utilising the LH RIA 2nd HMG-IRP, a cut-off of 10 IU/l was used as a marker for evidence of activation of the reproductive axis.[31,68] A reduced response is suspicious of pituitary failure. A normal response of gonadotropin secretion is sometimes seen in patients diagnosed to have gonadotropin deficiency based on low values of sex steroids and basal gonadotropins.

Gonadotropin-releasing Hormone Analogue Stimulation Tests

Recently stimulation tests were conducted using leuprolide. The dose of leuprolide is 20 μg/kg SQ. Leuprolide is about 20 times more potent than GnRH. A dose response curve showed that maximum peak LH is reached roughly about 4 hours after the leuprolide dose is given; and by 24 hours, peak sex steroid is reached.[19]

The Buserelin Stimulation Test

This is a highly specific and sensitive GnRH agonist test. It is used for investigating males with delayed puberty.[8]

ANTIDIURETIC HORMONE (VASOPRESSIN)

The prohormones, a neurophysin and a glycopeptide, which are enzymatically converted into ADH are synthesised in the hypothalamus. This occurs in the magnocellular neurons of the supraoptic and paraventricular nuclei.[49] The prohormones are contained in neurosecretory granules and transported to the posterior pituitary through the axons in the infundibulum. The neurophysin and glycopeptide are secreted along with ADH and have no known biological activity.

Table 1: Normal basal levels

Free Tri-iodothyronine (T3)		2.2–5.0 pg/ml
Free Thyroxine (T4)		0.7–2.2 ng/dl
Thyroid stimulating hormone		*ND–9 u IU/ml
17 OH Progesterone		50–180 ng/dl
Progesterone	Post-ovulatory	Above 5 ng/ml
Testosterone	Male	360–990 ng/dl
	Female	15–110 ng/dl
Prolactin	Male	ND–15 ng/ml
	Female	ND–20 ng/ml
Growth hormone	Fasting adults	ND–5 ng/ml
	Fasting children	ND–10 ng/ml
Cortisol	Morning sample	5–25 ug/dl
	Evening sample	2.5–12.5 ug/dl
17 Ketosteroids	Male	9–24 mg/24 hrs
	Female	5–17 mg/24 hrs
DHEA	Male	80–560 ug/dl
	Female	35–430 ug/dl

	Follicle stimulating hormone (m IU/ml)	*Luteinising hormone (m IU/ml)*	*Oestradiol (pg/ml)*
Male	ND–20	ND–20	5–50
Female			
Follicular	5–20	2–15	20–200
Luteal	2–10	5–25	20–120
Mid cycle	15–30	50–200	80–375
Menopausal	Above 40	Above 20	Below 30

*ND: Not detectable

Antidiuretic hormone secretion is controlled by osmotic as well as volume regulation. Osmotic regulation is most sensitive.[33,44] These receptors are located in the anterior part of the hypothalamus. ADH is released even if there is a 1% increase in the plasma osmolality. The normal plasma osmolality is 285–295 mOsm/kg water. The osmotic receptors respond mainly to extracellular sodium. The volume regulation receptors are found in the aorta, carotid sinus and left atrium. The impulses reach the brainstem through the glossopharyngeal and vagus nerves and ascend through multisynaptic pathways to end in the magnocellular neurons of the hypothalamus. ADH is released only when there is a 10–15% reduction in blood pressure.

Through the blood stream, ADH reaches the kidneys and binds to the receptors in the renal collecting ducts. Adenyl cyclase is activated and cyclic adenosine monophosphate (AMP) is generated that acts as a second messenger. This leads to increased reabsorption of water from the nephron back into the circulation.

The substances that reduce the action of ADH are endogenous prostaglandins, hypocalcaemia, hypokalaemia, lithium, demeclocycline, water, ethanol, phenytoin and anticholinergic drugs. The conditions and substances that stimulate the release of ADH or enhance its action are hypothyroidism, hypoadrenocortisolism, nicotine, chlorpropamide, cholinergic drugs, clofibrate, barbiturates, morphine, carbamazepine and anaesthetic agents.

The two syndromes that are produced by disorders of ADH secretion are syndrome of inappropriate ADH secretion (SIADH) caused by excessive ADH and diabetes insipidus (DI) caused by diminished secretion of ADH. These are dealt with in detail in the chapter on "Fluid, Electrolyte and Metabolic Disturbances".

The water deprivation test is used in suspected DI. Reduced water intake should normally reduce the urine output and increase the urine osmolality. This test should not be done in established DI and when the serum osmolality is high. The patient is made to pass urine as completely as possible and samples of urine (10 ml) and blood (8 ml) are collected and stored after centrifugation at 4 degrees Celsius. The weight of the patient is noted. Water is not ingested by the patient from 7.00 pm to 12 noon the next day. Three blood and urine samples are drawn 13, 15 and 17 hours into the water deprivation. The osmolality is measured in all the samples.

In central DI, the urine osmolality does not rise and the urine output remains high. The plasma osmolality becomes higher than 295 mOsm/kg. Urine osmolality below 400 mOsm/kg is diagnostic of DI and if it is more

than 700 mOsm/kg in any of the morning samples of urine, it rules out DI.

Administration of deamino-delta-d-arginine vasopressin (DDAVP) can also help in differentiating central and nephrogenic DI. In nephrogenic DI there will be no changes in the urine output and serum and urine osmolality on administration of DDAVP, whereas in central DI changes will occur.

8 Intra-Operative Monitoring

Babu KS, Rajasekar V

It is just over a century since the first brain tumour was resected successfully. Since then, diagnosis, imaging, and management of brain tumours have improved, in large part due to technological advances. Similarly, the operation theatre (OT) for brain tumour surgery has increased in complexity and specificity with multiple types of equipment, now considered necessary as technical adjuncts. It is evident that advanced image-guidance techniques and sophisticated technologies (e.g. robotics and nanotechnology) will drive changes in the current OT environment for the foreseeable future.[9]

Our body generates many electrical signals. Heart, skeletal muscles, peripheral muscles and different segments of the central nervous system generate these electrical signals, while the brain generates spontaneous electrical activity, which is recorded as an electroencephalogram (EEG). The central nervous system also produces an electrical response to specific stimuli. The type of stimulus varies depending on the sensory modality that is being stimulated. Flashes of light are used to evoke visual evoked potentials (VEP), auditory clicks for auditory evoked potentials (AEP) and electrical stimulation of the peripheral nerves to evoke sensory responses, along their ascending pathway called somatosensory evoked potentials (SEP). Motor evoked potentials (MEP) are evoked by transcranial electrical or magnetic stimulation of the cortex. These are the most common types of intra-operative monitoring (IOM) techniques used in the OT.

Evoked potentials (EP) have been used in the OT for the past three decades. Many centres routinely use IOM of neurosurgical cases. However, this has not become popular in our country for many reasons, such as finding suitable personnel for IOM, added cost to the patient, technical problems associated with electrical interference, reproducible wave forms, lack of equipment and IOM training centres. IOM is a dynamic process where the status of the neural structures needs to be continuously monitored and correlate the changes with the status of the patient. This would require a considerable amount of practical experience than what is needed in the electrophysiology laboratory. Having dedicated personnel will go a long way in understanding EP changes and fixing technical problems that arise during surgery. As Nuwer pointed out, false positive type of changes in the potentials are bothersome in the OT.[32] They are substantially more common for inexperienced monitoring teams who have not yet learnt how to minimise the causes of technical and clinical variability. False negative monitoring cases are those in which the potentials remain relatively stable, but the patient wakes up with a new neurological deficit. At other times, there are considerable changes during monitoring and these are wrongly interpreted. There have been cases where the monitoring team has followed just background noise or artefacts throughout the course of surgery (Fig. 1). Reliance on equipment without experienced personnel may result in failure or even worse, lead to inaccurate and misleading feedback to the surgeon. Inappropriate application of monitoring techniques has potentially catastrophic consequences. IOM is a means to monitor peripheral nerves, spinal cord, brainstem, optic nerves and cerebral cortex during the course of surgery. The prime objective of IOM is: (1) to identify new neurological dysfunction early and prevent it before it becomes irreversible and (2) to provide reassurance to the surgeon that no damage has occurred till that point in surgery, so that more radical excision of masses can be performed.

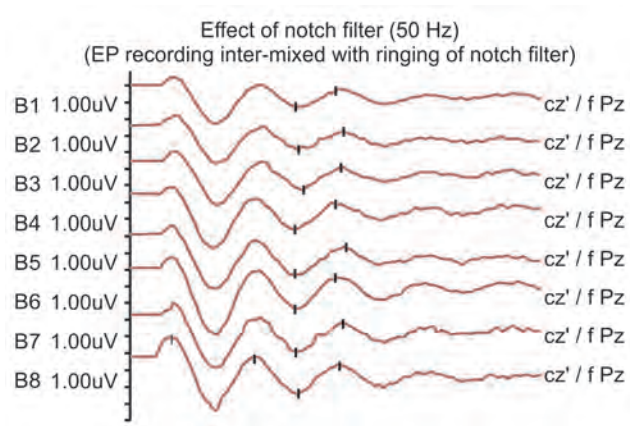

Fig. 1: Effect of 50 Hz notch filter. Notch filter caused ringing that has been erroneously followed throughout the course of surgery

CHOOSING AN INTRA-OPERATIVE MONITORING MACHINE

The majority of models which are currently available in the market for IOM have facilities to do AEP, VEP, SEP, EEG and electromyography (EMG). Some of them have

specialised features for microelectrode recording during pallidotomy and thalamotomy. However, to be cost effective, some companies give the choice of choosing certain features like SEP and AEP only or other combinations. It is important to remember that machines can malfunction if used improperly. Hence, it must be ensured that the IOM machine that is used in the OR is isolated from the wall current and from the patient in several ways. Each type of IOM machine has its own features. Users must be familiar with their own equipment and follow the safety instructions prescribed by the manufacturers (Table 1).

HARDWARE

It is to one's advantage to have a number of channels for recording. We have two dedicated machines for IOM; one has a twenty channel recording system and another an eight channel recording system. These machines are very similar to the ones that one sees in the EEG and EP-diagnostic labs. However, one must remember that the operation theatre is a hostile environment for electrophysiological recordings. The EP voltages that one records in the operation theatre are of the order of a few microvolts. The sources of high voltage interference in the OR are many, such as bipolar and monopolar cautery, AC mains, ECG, patient table, etc. Hence, amplifiers are the most important part of the IOM machine. These amplifiers must be able to withstand high electrical voltage fluctuations. The machines that one sees in the diagnostic labs are not designed for such a purpose. It is important to have amplifiers that have good rejection of noise occurring at both the inputs (common mode rejection). They should be able to withstand diathermy frequencies. A signal (wave form or trace) of interest will comprise of many different frequencies hence, one must not set filters too severely, as it will result in rejection of need frequencies and would lead to attenuation of the responses and may even result in abolishing it completely. Digital filtering is better than analog filtering, as the latter can change latency and distort the signal. A compromise must be reached between rejecting unwanted frequencies from the EEG and other sources and allowing only the signals of interest.

Ideally, the IOM machine must have its own electrical outlet. The outlet should have a separate ground that is not linked with other OT equipments. This way, the machine will have its specific place in the OT. Since, the OT is always crammed with equipment, it will not be possible to keep the machine close to the operation table. So, it is important to consider the length of the cables between the machine and the amplifiers, stimulators, etc. that are placed close to the patient before purchasing the equipment.

SOFTWARE

A feature, which enables the operator to change the electrodes or channels through the software, is useful. During surgery, the electrodes that are hooked on to the

Table 1: Intra-operative monitoring in various surgeries and their parameters

Types of surgeries/ monitoring		*Stimulus*	*Intensity*	*Rate*	*Montage*			*Low filter*	*High filter*	*Window*	*Repetition*
					Active	*Reference*	*GND*				
Spinal cord, aneurysm	SEP median nerve	Electrical 300 msec	1 ma above motor threshold	4.7/sec	C'3,4	Fpz	Non-cortical	10 Hz	1.5 KHz	40 ms	300
Spinal cord, aneurysm	SEP posterior tibial nerve	Electrical 300 msec	1 ma above motor threshold	4.7/sec	C'Z	Fpz	Non-cortical	10 Hz	1.5 KHz	60 ms	300
CP angle, MVD	BAEP	Insert ear phones clicks	70 dB	11.1-19.1/ sec	Cz	A1, A2	Fz	100 Hz	3000 Hz	10 ms	2000

patient will be buried under the drapes and would be out of reach. If there are standby electrodes, it will be possible to switch to these electrodes and, similarly, the active and reference electrodes can be switched through the software. The software must also have the facility to display the averaged data (e.g. SEP), triggered data (identification of nerve roots, etc), free running format (e.g. EEG, EMG) and also to be able to visualise the raw data. It will be useful to view the raw data to understand any technical difficulties or artefacts. Some manufacturers provide for display of either the raw or the averaged data but not both simultaneously. This will definitely be a disadvantage to the user. The facility to display all the previously averaged traces is an important feature. Changing the time base, rescaling the amplitude of the traces, performing simple digital filtering, such as smoothening, correct baseline shifts due to DC potentials, ability to measure peak and inter peak latencies and amplitudes are important. The facility to enter comments such as anaesthetic changes, stage of surgery or any other events that occur during the course of surgery is also a very important feature.

Very often, it may be necessary to perform multimodality monitoring, e.g. monitor AEP and SEP at the same time. This would also mean that the machine must have the ability to run dual time bases. Similarly, it may be desirable to monitor both the right and left sided responses at the same time (e.g. left and right median nerve stimulation where the stimulus is given at the same time and responses are also recorded at the same time). This is possible, as the cortical responses are recorded from different electrodes on opposite hemispheres. On the other hand, if the posterior tibial nerve is stimulated for the right and left leg, where the responses for both are recorded from the same spot, it will be necessary for a time interval between right and left leg stimulation to record individual responses. Similarly, for localisation of eloquent areas where subdural strip electrodes can be used for bipolar stimulation, it may be necessary to switch the stimulating points to localise the functional areas. All these features should be software controlled.

Modern machines have ready-made protocols to perform a wide variety of monitoring procedures. However, many electrophysiologists develop their own protocol; hence the software should have a facility to store such customised protocols. Each vendor offers certain advantages in their machine over others. Hence, one must take into account these various features before choosing the machine.

RECORDING ELECTRODES

Standard 8 mm EEG reusable gold disk electrodes are the most popular, as they are non-corrosive and need less maintenance. These electrodes need to be properly anchored to the patient, as most of these electrodes will be out of reach during surgery. Therefore, skin preparation and proper application of electrode cream is very important. We keep the electrodes in place by putting

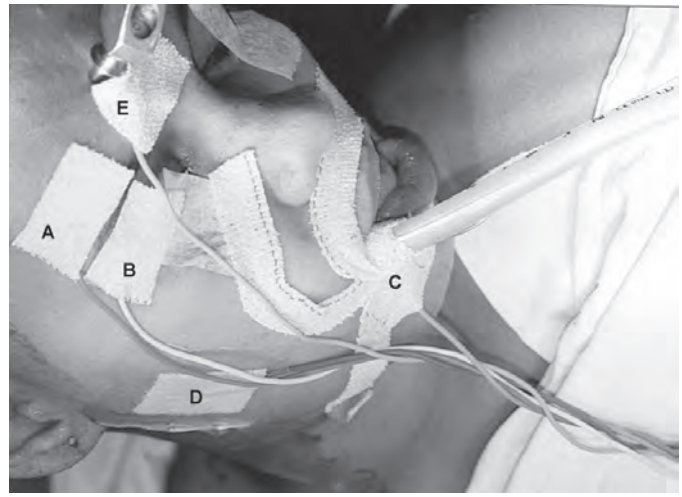

Fig. 2: Photograph showing electrode placement for facial nerve monitoring. Subdermal needle electrodes are placed in the (A) Frontalis muscle. (B) Orbicularis oculi. (C) Oris, with a common reference electrode in (D) The masseter. (E) Ground electrode in the Fpz. Note how the cables are twisted together to reduce artefacts. The electrode close to cleaning area is covered with transparent adhesive

an adhesive on top of the electrode and covering it with a sterile transparent sheet (Fig. 2). This is important as, during cleaning of the surgical area, the cleaning fluids will drip down and the electrodes will get soaked and get dislodged. Many centres also use collodion for sticking electrodes. The collodion needs to be applied in a well-ventilated room before surgery, as it has an obnoxious smell (acetone solvent). Once the electrodes are stuck with collodion, the electrode cream is injected through the hole in the middle of the disc electrode; this acts as the conducting material between the scalp and the electrode. It is cautioned not to use an electrode gel or paste that contains calcium chloride, as it can cause a type of chemical burn called calcinosis cutis, particularly in children.[43] For a corticogram, subdural strip electrodes are used. They are useful in epilepsy surgery, cortical localisation of the central sulcus, recording "after discharge" during cortical stimulation of eloquent areas, particularly the speech areas during awake craniotomy. They come in different shapes and sizes. They could be custom made, depending on personal needs, such as the number of electrodes, density, inter-electrode distance and shape of electrode array. These electrodes could be made of silver/silver chloride (Fig. 3, SLE Electronics and Accessories, UK) or platinum discs (Fig. 4, Ad Tech, Wisconsin, USA).

Similarly, depth electrodes are also commercially available; again they vary in the number of electrode points and the inter-electrode distance. They are usually made of platinum (Fig. 5, Ad Tech, Wisconsin, USA). For spinal cord surgeries epidural electrodes are very useful for recording over the scalp electrodes. These are commercially available as thin wires, usually ranging from one pole to five poles for recording. These are inserted into the epidural space through a 16 gauge catheter. Some labs have used a blunted stainless steel

Fig. 3: Silver/silver chloride plate array of 25 electrodes (5 × 5 cm). These are used for corticograms to localise central sulcus or epileptic foci

Fig. 4: Strip electrodes: platinum electrodes used for localising central sulcus and also for monitoring after-discharge during cortical stimulation

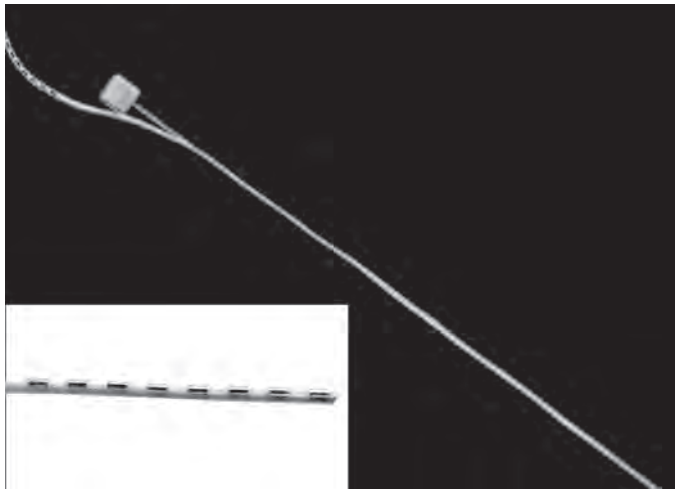

Fig. 5: Depth electrodes: these are eight contact 5 mm spacing platinum electrodes used for epilepsy surgery. The stylus with the electrodes is introduced into the brain. Once the site is determined the stylus is withdrawn so that the tube attached to the electrode will be flaccid and out of the surgeon's operating area

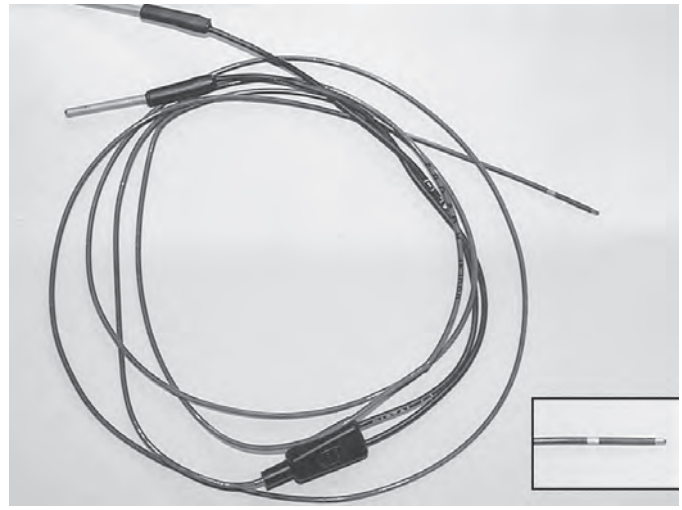

Fig. 6: Epidural electrodes: used for spinal cord surgery. These recording electrodes are introduced into the epidural space. Interelectrode distance is 1 cm

needle 0.9 X 3 mm connected to a fine wire[15] for epidural recording. We use a two pole intra-cardiac electrode (Fig. 6, Bard, Galway, Ireland). They are easy to insert directly into the epidural space without the need for a catheter (Fig. 7). These are held in place by stitching the cable at the exit to the exposed muscle and covering it with a cotton strip, such that it is out of the surgeon's operating area. They are insulated, except at the tip. These are available as a single wire or as a pair. A hypodermic needle is used to introduce the hook wire into the target muscle. Subdermal needle electrodes (Fig. 8, Nicolet, Wisconsin, USA) of 27 gauge are also very useful for recording EEG, EP and compound muscle action potentials (CMAP). They are inserted tangentially into the skin. Needles have inter-electrode impedances, which are about five to ten times that of stick-ons and, because of this they are more liable to produce noise-contaminated records in electrically hostile environments. Needle electrodes distort waveforms below 5 Hz if the input impedance of the amplifiers is less than 1 Mohms. Because of differences in both electrode potential and

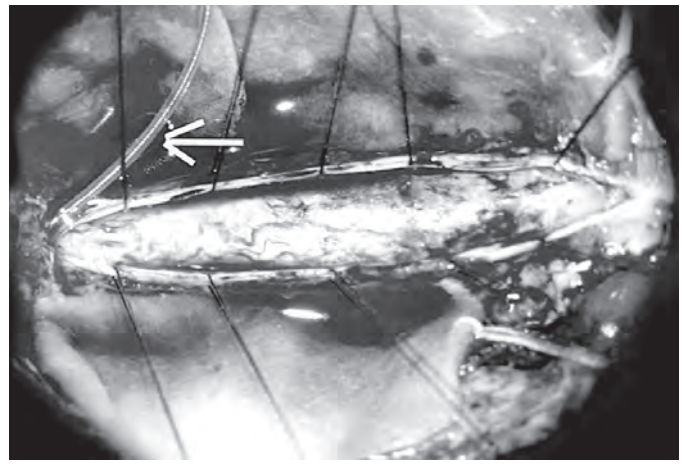

Fig. 7: Placement of epidural electrodes: photograph shows operating area with the epidural electrode moved out of the operating field

Fig. 8: Subdermal needle electrode: 1 cm steel electrodes used for EEG, EP and AMAP

recording characteristics, one should avoid recording between electrodes made of different metals.

BIPOLAR AND MONOPOLAR ELECTRICAL STIMULATION

Both bipolar and monopolar electrical stimulation are popular and they have their advantages and disadvantages. In bipolar stimulation, the spread of the stimulating current is limited between the two electrodes, which are adjacent to each other, while, in monopolar stimulation, one probe is placed on the neural structure that is to be identified, while the second electrode is placed indifferently, which is usually the exposed muscle at the operating site. In contrast to monopolar stimulation, bipolar stimulation requires orientation of the probe tips longitudinally along the nerve.[28] Therefore, in cases in which the course of the nerve is not known (i.e. nerve encased by tumour), a monopolar stimulus design is useful. Bipolar probes are useful to know which nerve it is rather than to know if it is a nerve or connective tissue. We have successfully employed monopolar stimulation for facial nerve stimulation, brainstem mapping of the motor nuclei,[29] spinal nerves in tethered cord and cortical stimulation under general anaesthesia.[27] We employed bipolar stimulation in awake craniotomy cases for mapping of the eloquent areas, so that the spread of the current is local and specific responses could be obtained and determined.

VISUAL EVOKED POTENTIAL

Flashes of light emitting diode (LED) fixed in goggles are the most common type used for intra-operative stimulation of the eyes. In these, the contours of the rubber edges fit well against the bony structures surrounding the orbit and a strap around the head can help to hold the goggles in place. The patient's eyes are kept closed with an adhesive and the light is flashed on to the closed eyelids. These are found to be convenient even for transsphenoidal surgeries. However, care must be taken to avoid the goggles slipping out of place and pressing against the eye. Contact lenses have also been used for stimulating devices. Contact lenses are fitted with a fibre optic cable that delivers light from a remote source.[39,45] In some devices the LEDs are implanted into special contact lenses and these are connected by a fine wire to a remote electrical source.[17,44]

VEP is used in patients with a tumour or aneurysm pressing on the optic nerve or chiasm. We have used VEP monitoring for pituitary tumours.[12] However, intraoperatively, we found that VEP is not as useful as other EPs and, hence, have abandoned it over time. For VEP monitoring, the active electrodes are placed at O1 and O2 with a common reference at Cz. In this, the low filter is set at 10 Hz and the high filter is set at 100 Hz. The rate of stimulation is 1.9/sec. The time base is set at 500 msec. The number of trials is set at 150. The principle peaks lie between 75 msec and 100 msec. Due to a longer recording time, these recordings are very easily susceptible to artefacts. Monitoring during trans-sphenoidal surgery for pituitary tumours showed a drop in VEP amplitude during infiltration of the nose (during which there is rise in BP), suggesting that VEP is susceptible to cerebral blood flow changes (Fig. 9).

Intra-operative monitoring of visual evoked potentials (VEPs) has been regarded as having limited significance for the preservation of visual function during neurosurgical procedures, mainly due to its poor spatial resolution and signal-to-noise ratio. Cortically recorded VEPs, instead of the usual scalp VEPs, as intra-operative monitoring, focusing on the posterior visual pathway is better. Direct recording from the visual cortices under general anaesthesia achieved satisfactory detectability of the visual response to a light-emitting diode flashing light. Intra-operative cortical VEP monitoring is a potentially useful procedure to monitor the functional integrity of the posterior visual pathway.[33]

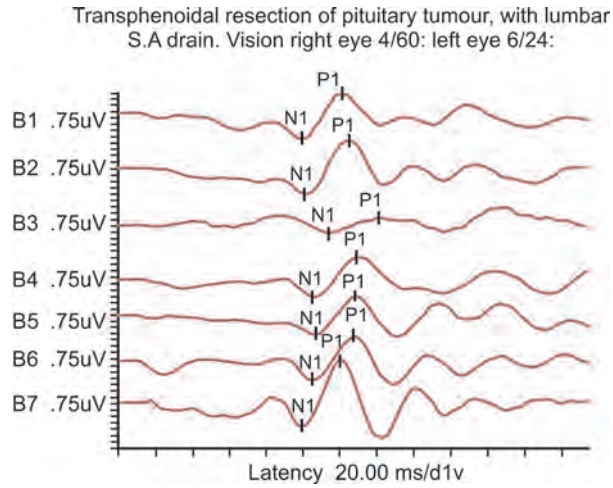

Fig. 9: Visual evoked potential (VEP) recordings taken during the course of trans-sphenoidal surgery. When the BP increased, VEP showed drop in amplitude during nasal infiltration (B3) which recovered in due course of time when BP returned to normal

BRAINSTEM AUDITORY EVOKED POTENTIAL

Neurophysiologic intra-operative monitoring of brainstem auditory evoked potentials (BAEPs) is a widely used method to assess the functional integrity of the central auditory system, during surgery involving the brainstem or the cranial nerves. The stimulus is a brief click delivered through tubal insert earphones. The stimulator is connected to silicone tubes, to which are attached disposable polyurethane foam tips, which are inserted into the ear. For better recording of wave one, gold TIPtrodes serve a dual purpose: they are used for delivering the sound and as a recording electrode.

BAEP is useful in surgery for CP angle tumours, brainstem surgery, microvascular decompression and in stereotactic biopsy of some brainstem tumours. In these, the active electrode is placed on the CZ and the reference electrodes are placed on the ear lobes. The rate of stimulation is 11.1/sec. The filter settings are set for low filter at 100 Hz and high filter at 3000 Hz. At least 2000 trials are averaged. The time base is set as 10 msec. The principle peaks are wave I, III and V. We monitored BAEP in 21 cases during stereotactic biopsy of brainstem tumours. We found only in two cases transient changes in BAEP, suggesting that stereotactic biopsy of intrinsic brainstem masses does not cause significant disruption of the auditory pathways.

Brainstem auditory evoked potentials (BAEP) monitoring is a useful tool to decrease the danger of hearing loss during cerebellopontine angle surgery, particularly in microvascular decompression (MVD). Critical complications during MVD surgery are the stretching of the VIII nerve—the main cause of hearing loss—labyrinthine artery manipulation, direct trauma with instruments or a nearby coagulation and at end of the surgery neocompression of the cochlear nerve by the prosthesis positioned between the conflicting vessel(s) and the VIIth-VIIIth nerve complex. All these dangers warrant the use of BEAP monitoring during the surgical team's training period.

Based on delay in latency of peak V, establishing warning thresholds that can provide useful feedback to the surgeon to modify the surgical strategy is essential. The initial signal at 0.4 ms is considered the safety limit. A second signal threshold at 0.6 ms (warning signal for risk) corresponds to the group of patients without resultant hearing loss. The third threshold characterised by the delay of peak V is at 1 ms (warning signal for a potentially critical situation). BAEP monitoring provides the surgeon the information on the functional state of the auditory pathways and should help avoid or correct manoeuvres that can harm hearing function. BAEP monitoring during VIIth-VIIIth complex surgery, particularly in MVD of facial nerves for HFS, is very useful during the learning period.[36]

SOMATOSENSORY EVOKED POTENTIAL MONITORING

SEPs are used for spinal cord monitoring, in surgery for cortical masses and cerebral aneurysms, cortical localisation of the central sulcus and in surgeries in and around the brainstem. The stimulating electrodes can be discs, bars or needles. Care must be taken when needles are used to ensure that they are not inserted into the nerve itself. It will be sufficient if the needles are placed subcutaneously. Needle electrodes have certain advantages in that they do not dry out during surgery, as compared to surface stimulation. Percutaneous stimulation is non-invasive and easy to use for peripheral nerve stimulation. The surface area is larger allowing a more even delivery of current. Drying of the electrode paste is a problem to be considered during long surgeries. For surgeries less than five hours, we found that percutaneous stimulation is adequate.

SEP monitoring is more commonly employed than AEP and VEP monitoring. SEP monitoring is used for spinal cord surgery, surgery in and around the brainstem and in aneurysm surgery.[25] Depending on the location of the lesion and type of surgery, either the median nerve at the wrist or the posterior tibial nerve at the ankle is stimulated at a rate of 4.7/sec. The filters are set between 10 Hz and 1500 Hz. For the median nerve, the time base is set at 40 msec, while for the tibial nerve it is set at 60 msec. Recordings are obtained from scalp electrodes; C3′ or C4′ for median nerve, Cz′ for tibial nerve and referenced to Fpz. Three hundred trials are averaged. The principle cortical peaks for median nerve are N20 and P30 and for tibial nerve are P37 and N45. In some spinal cord surgeries, we have used epidural electrodes. Epidural electrodes are not useful below the L1 level. Whenever scalp recordings are found to be unreliable, either due to artefacts or amplitudes are of low magnitude, epidural electrodes are used (Fig. 10). Bipolar epidural electrodes provide certain advantages over the scalp electrodes. Epidural electrodes are less susceptible to cerebral blood flow changes and anaesthesia. The rate of stimulation can be higher (10.7/sec), as compared to scalp recording. An average of 100 responses is more than adequate. This would drastically reduce the time. Besides this, the faster ascending EPs are from the spinocerebellar tract and not from the

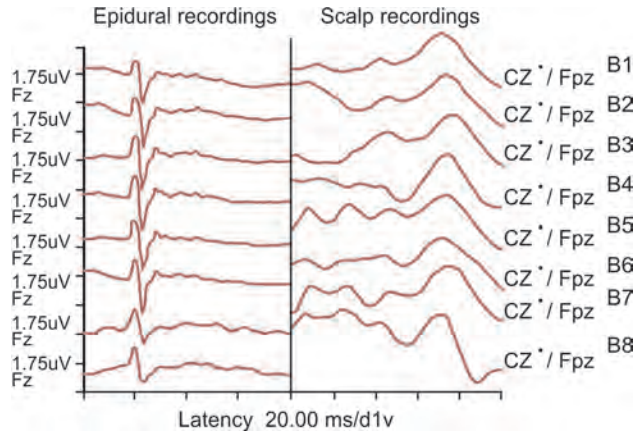

Fig. 10: Comparison of epidural and scalp recordings during spinal cord surgery of intramedullary tumour. Note scalp recordings intermixed with artefacts

posterior column. Using epidural electrodes, it would be possible to record from both these tracts and, hence, may reflect any damage or ischaemia to the cord more reliably than the scalp recordings.

MOTOR EVOKED POTENTIAL

Intra-operative motor evoked potential (MEP) monitoring in patients with spinal and cranial lesions is thought to be a valuable tool for prevention of post-operative motor deficits. MEPs provide the possibility for monitoring anterior and lateral spinal cord tracts. Responses can be recorded directly from the motor tracts or muscle. Recently, transcranial electrical stimulation (TES) and transcranial magnetic stimulation (TMS) techniques were introduced for IOM of the corticospinal pathways. For intra-operative monitoring we found TES is more convenient than TMS. In TES, the stimulus is delivered through a silver disc of 2 cm diameter, which is the cathode and the FPz is the anode. For TMS, the coils are big and difficult to position in the OT. Besides this, for TMS, care must be taken to see that there is no metal close to the coil. However, some centres have successfully used TMS for intra-operative monitoring. For both TES and TMS, a proper anaesthetic regime plays a major role in obtaining stable and reproducible waveforms.

Sustained vascular dynamics (vasospasm, congestive oedema) may cause delayed paresis which are missed or hardly reflected by intra-operative MEP changes. Even minor MEP changes must therefore be observed to prevent impending motor deficit.[31]

MEP monitoring, as opposed to SEPs, is a valid indicator of corticospinal function in brainstem-related surgery, independent from the type of lesion operated on. New deficit occurs only after more pronounced MEP changes than in supratentorial surgery, but complete loss, as in spinal surgery, is not seen. MEPs may help to prevent permanent new paresis.[30]

Intra-operative monitoring of facial nerve motor evoked potentials (FNMEPs) elicited by transcranial electrical stimulation during skull base tumour surgery is useful for predicting facial nerve function outcome.[18]

Intra-operative neurophysiological monitoring (IONM) with motor-evoked potentials (MEP), elicited by transcranial electrical stimulation and somatosensory-evoked potentials (SSEP) used in pregnant women, did not lead to any changes in either uterine muscle tone or foetal heart rate. Hence, IONM can be safely used in pregnant women.[35]

MOTOR NUCLEI AND NERVE STIMULATION

During brainstem surgery it is important to identify various nuclei, so that the surgeon can avoid manipulating or cause injury to them.[14,15] Identifying the facial nerve and mapping the course of the nerve fibres during cerebellopontine angle (CP) tumour surgery is also very important. We have used custom-made platinum monopolar electrodes. The indifferent electrode is stitched to the exposed muscle near the operating area. The tip of the platinum electrode is made into a ball that can be bent. We found this to be useful, particularly for CP angle tumours during drilling of the porus acousticus, where the facial nerve is out of view and under the bone. The electrode can be bent into a hook and the surgeon can "feel" for the nerve. We employ the same technique for spinal nerves in patients with a tethered cord. Here again, the indifferent electrode is stitched to the exposed muscle. Our starting current strength is 2.5 mA and we usually go down to 0.2 mA, keeping the rate of stimulation at 4.7/sec. The filters are set between 30 Hz and 3000 Hz. The time base for these is set at 20 msec for recording CMAP.

MAPPING ELOQUENT AREAS

Central sulcus mapping is done using somatosensory evoked potentials.[4,5,7,8,13] This is followed by cortical stimulation for further confirmation of the eloquent areas under general anaesthesia.[6] This technique is useful in planning the course of surgery for subcortical lesions. For a corticogram, subdural electrodes are used (Fig. 11). The contralateral median nerve is stimulated at 4.7/sec. The filters are set between 10 Hz and 1000 Hz, time base at 40 ms and 200 responses are averaged. The sulcus, where a phase reversal (Fig. 12) occurs, is considered the central sulcus.[11] This is further confirmed by monopolar cortical stimulation.[6] Monophasic square pulses of 300 microseconds duration at a rate of 50 Hz are used. The indifferent electrode is placed on the exposed muscle in the operating area. Current strength in steps of 1 mA starting from 3 mA is used. A maximum of 15 mA of current strength is used.[21] In awake craniotomy, bipolar stimulation is used. The stimulus is a monophasic square pulse of 1 msec duration stimulated at the rate of 50 Hz.[20] Subdural strip electrodes are placed in the vicinity of the stimulating area to record after discharge. Current strengths, starting from 2 mA to a maximum of 10 mA, are used. However, we could get responses within 4 mA of current strength. The strip electrodes are used to record after-discharge. Usually current strengths

Fig. 11: Photograph showing placement of an array of plate electrodes across the identified central sulcus. To ensure contact wet cotton strips are placed over the array of electrodes

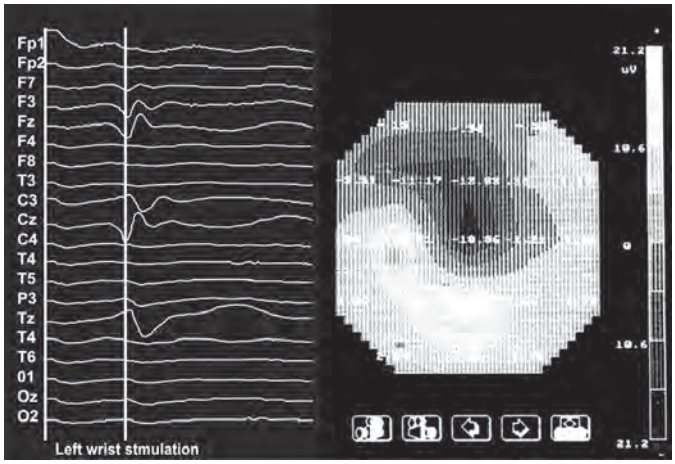

Fig. 12: Corticogram: using grid electrodes twenty channels recordings are obtained. Channels F7, F3, Fz, Cz show negative responses N20 (sensory gyrus), while Channels C3, Pz show positive responses P20 (motor gyrus) at 19.75 ms. In between them is the central sulcus. The gray scale on the right indicates voltages at 19.75 ms

are maintained 1 mA below the level of after-discharge. In our series, we have not used higher current strengths to see the after-discharge; this is to avoid any seizures that can occur due to stimulation.

INTRACRANIAL MONITORING USING ELECTROENCEPHALOGRAPHY

Intracranial monitoring using electroencephalography (IC-EEG) continues to play a critical role in the assessment of patients with medically intractable localisation-related epilepsy. Intracranial monitoring using EEG allows detailed definition of the region of ictal onset and defines the epileptogenic zone, particularly with regard to adjacent potentially eloquent tissue. Recent developments of IC-EEG include the co-registration of functional imaging data, such as magneto-encephalography to the frameless navigation systems. IC-EEG remains the gold standard for localisation of the epileptogenic cortex. Intracranial electrodes take a variety of different forms and may be placed either in the subdural (subdural strips and grids, depth electrodes) or extradural spaces (sphenoidal, peg and epidural electrodes). Each form has its own advantages and shortcomings, but extensive subdural implantation of electrodes is most common and is most comprehensively used.[10]

INTRA-OPERATIVE ELECTROMYOGRAPHY

Intra-operative monitoring, by stimulated electromyography (EMG) of the facial nerve to predict the completeness of microvascular decompression (MVD) for hemifacial spasm (HFS), is useful. The disappearance of an abnormal muscle response in the facial nerve EMG indicates the completeness of MVD. Intra-operative facial nerve EMG provides a real-time indicator of successful MVD during an operation, while BAEP monitoring may provide an early warning of hearing disturbance after MVD.[23]

INTRA-OPERATIVE DOPPLER ULTRASONOGRAPHY AND ULTRASOUND ANGIOGRAPHY

In treatment of brain arteriovenous malformations (AVMs), there is a correlation between the change of resistive index (RI) of the feeding artery and the completeness of resection of brain AVMs. The resistive index (RI) of the feeding artery was recorded so as to identify residual AVM. Intra-operative Doppler ultrasonography is a reliable tool for intra-operative localisation and complete resection of AVMs. Providing real-time flow pattern of AVMs, intra-operative ultrasound angiography combined with RI effectively indicates the completeness of resection of AVMs.[27,47]

NEURONAVIGATION

Currently, neuronavigation is an indispensable part of neurosurgical procedures in the majority of centres. The history of neuronavigation is quite short (less than three decades). The advent of neuronavigation would be unimaginable without the development of imaging technology, electronics, robotics and space technology.[16]

Intra-operative neuromonitoring includes motor mapping by direct cortical stimulation (CS) and subcortical stimulation (sCS) and localisation of the central sulcus, by using cortical multipolar electrodes and the N20 wave inversion technique. The location of all cortically and subcortically stimulated points with positive motor response is stored in the navigator and correlated with the cortical and subcortical motor functional structures, defined pre-operatively. Multimodal navigation allows integration and correlation among pre-operative and intra-operative anatomical and functional data. Cortical motor functional areas are anatomically and functionally located pre-operatively, thanks to MR and fMR imaging and subcortical motor pathways with DT imaging and tractography. Intra-operative confirmation is done with CS and N20 inversion wave for cortical structures and with sCS for subcortical pathways.[37]

Frameless stereotactic neuronavigation provides tracking of surgical instruments on radiographic images and orients the surgeon to tumour margins at surgery. Bipolar electrical stimulation mapping (ESM) delineates safe limits for resection of brain tumours adjacent to eloquent cortex. These standard techniques could complement the capability of intra-operative MR (iMR) imaging to evaluate for occult residual disease during surgery and promote more complete tumour removal. The presence of residual neoplasm is evaluated using iMR imaging; resection is continued until eloquent areas are encountered or iMR imaging confirms complete removal of any residual tumour.[42]

Preservation of motor function is very important in patients who require resection of tumours adjacent to the primary motor cortex and pyramidal tract. Electrical stimulation of the tumour cavity is necessary to prevent post-operative neurological deterioration in these cases.

A NY Tract Finder bipolar needle electrode, which enabled the identification of motor pathways by inserting it into the white matter, was developed and has been used. Motor-evoked potentials are induced by electrical stimulation with this electrode, when it is inserted toward the estimated motor pathway from the resected tumour cavity, with guidance by a neuronavigation system. The scale on the needle indicates the approximate distance from the tumour cavity wall to the pyramidal tract. This technique may be a feasible method to detect and spare the motor pathways. However, further studies are needed to determine reliability and limitations.[46]

NAVIGATED BLOOD FLOW IMAGING

Blood flow imaging (BFI) is a new 2-dimensional ultrasound modality that offers angle-independent visualisation of flow. When integrated with 3-dimensional (3D) navigation technology, BFI can be considered as a first step toward the ideal tool for surgical needs: A real-time, high-resolution, 3D visualisation that properly portrays both vessel geometry and flow direction. The neurovascular flow direction is properly visualised in all cases using BFI. Navigation technology allowed for identification of the vessels of interest, despite the presence of brain shift. BFI allows for quality control of sufficient flow in all distal arteries during aneurysm surgery and makes it easier to discern between feeding arteries and draining veins, during surgery for arteriovenous malformations. BFI seems to be a promising modality for neurovascular flow visualisation that may provide the neurosurgeon with a valuable tool for safer surgical interventions.

FLUORESCENCE-GUIDED RESECTION

Fluorescence-guided resection (FGR) of brain tumours is an intuitive, practical and emerging technology for visually delineating neoplastic tissue exposed intra-operatively. It detects surface fluorescence as a biomarker of the current surgical margin. Implementation of deformation modelling for brain shift compensation in protoporphyrin IX FGR and updated MR image information provide maximal surgical benefit.[41]

INTRA-OPERATIVE MAGNETIC RESONANCE IMAGING IN NEUROSURGERY

Intra-operative MRI (iMRI) has been incorporated into modern neurosurgical operating theatres as a guide for neurosurgical interventions. This technology has been shown to be a useful modality in brain tumour surgery and biopsy. Its use in spine, vascular and epilepsy surgery has been evolving. It is particularly useful in low-grade gliomas, pituitary adenomas and paediatric tumours.[2,3]

The addition of iMRI to the surgical armamentarium for treatment of patients with GBM improves the degree of tumour resection while minimising complications and thus may positively impact survival in this patient population. However, even with such technology, complete resection may not always be possible because of tumour location near critical brain structures or involvement of surrounding vascular structures.[26]

The intra-operative combination of an open magnetic resonance imaging (MRI) system with neurophysiological localisation and continuous monitoring techniques allows for the best available anatomic and physiological orientation, as well as real-time functional monitoring. MRI-compatible platinum/iridium electrodes for intra-operative neuromonitoring are attached to the patient's head. All other electrodes located outside the magnet are stainless steel needle-electrodes for recording of motor evoked potentials and for stimulating somatosensory evoked potentials. Intra-operative magnetic resonance scanner, neurophysiological monitoring for evoked potentials and direct cortical stimulation can be performed with standard quality within a low-field intra-operative MRI system. Electrodes fixed to the head should be of low magnetic susceptibility to guarantee optimal imaging quality. The combined use of an open ultra low-field MRI system and intra-operative monitoring allows for resection control and continuous functional monitoring.[40]

The use of the intra-operative ultra low-field MRI scanner helps to evaluate the extent of resection in glioma surgery. Further, tumour resection after intra-operative scanning leads to an increased rate of complete tumour resection, especially in patients with contrast-enhancing tumours. However, in non-contrast- enhancing tumours, the intra-operative visualisation of a complete resection seems less specific, when compared with post-operative 1.5 T MRI.[38]

Precise identification and preservation of the pyramidal tract during surgery for parenchymal brain tumours is of crucial importance for the avoidance of post-operative deterioration of motor function. The technique of intra-operative diffusion-weighted imaging (iDWI) using an intra-operative MR scanner of low magnetic field strength (0.3 T) has been developed. iDWI is very useful for localisation of the pyramidal tract and for clarification of its spatial relationships with the tumour. The use of iDWI, in addition to structural iMRl and subcortical functional mapping with electrical stimulation, can potentially result in a reduction of the post-operative morbidity after aggressive surgical removal of lesions located in the vicinity of the motor white matter tracts.[34]

INTRA-OPERATIVE MONITORING OF CEREBRAL BLOOD FLOW BY LASER SPECKLE CONTRAST ANALYSIS

Laser speckle contrast analysis (LASCA) is performed in patients undergoing cerebral revascularisation procedures for the treatment of haemodynamic compromise and complex aneurysms. LASCA offers non-invasive and rapid intra-operative assessment of relative CBF,

which can be used for optimising neurovascular procedures. The portable LASCA device is centred over the surgical field and continuous 5 minutes recordings of relative CBF are obtained. In the case of flow augmentation for haemodynamic compromise, CBF monitoring is performed before and after completion of the anastomosis. LASCA allows immediate visualisation and measurement of relative CBF in excellent spatiotemporal resolution.[22]

WIRELESS INSTANTANEOUS NEUROTRANSMITTER CONCENTRATION SYSTEM

Wireless Instantaneous Neurotransmitter Concentration System (WINCS), which couples digital telemetry with fast-scan cyclic voltametry (FSCV) is used to measure extracellular concentrations of dopamine. With the extended capability of the WINCS to use fixed potential amperometry (FPA), it is possible to measure extracellular concentrations of dopamine, as well as glutamate and adenosine. FPA offers superior temporal resolution and in combination with enzyme-linked biosensors, the potential to monitor non-electroactive analytes in real-time. The WINCS design incorporates a transimpedance amplifier with associated analog circuitry for FPA, a microprocessor, a Bluetooth transceiver and a single, battery-powered, multilayer, printed circuit board. The WINCS was tested with 3 distinct recording electrodes: 1) a carbon-fibre microelectrode (CFM) to measure dopamine; 2) a glutamate oxidase enzyme-linked electrode to measure glutamate and 3) a multiple enzyme-linked electrode (adenosine deaminase, nucleoside phosphorylase and xanthine oxidase) to measure adenosine. Because many neurotransmitters are not electrochemically active, FPA in combination with enzyme-linked microelectrodes represents a powerful intra-operative tool for rapid and selective neurochemical sampling in important anatomical targets during functional neurosurgery.[1]

INTRA-OPERATIVE ELECTROCORTICOGRAPHY

Wilder Penfield and Herbert Jasper, in the 1950s, developed the technique of intra-operative electrocorticography for localisation and surgical treatment of epilepsy. It has been used in the surgical management of medically refractory epilepsy to localise anatomic areas of focal seizure onset, guide the extent and completeness of resective epilepsy surgery, aid in functional mapping of cortical anatomy and predict epilepsy surgery outcome. The usefulness is often dependent on the underlying pathology and type of resective surgery.

It seems to be valuable in the following circumstances: (1) tailoring the extent of hippocampal resection during temporal lobectomies; (2) guiding resection of cortical brain malformations, low-grade tumours and other neocortical lesions, especially those involving eloquent cortex and (3) monitoring for after discharges during functional cortical mapping. Cortical stimulation can identify cortex with reorganised function secondary to congenital lesions and cerebral plasticity. These lesions include brain tumours, cortical dysplasia resulting in intractable epilepsy and cavernous angioma causing epilepsy. It has the disadvantage of being invasive but the advantage of being highly accurate, allowing for surgical tailored resections. The weight of the uncontrolled data at this stage is such that in children, electrocorticography remains to be a useful test in some cases of cortical resection and that cortical stimulation is usually indicated when resection in or near eloquent cortex is needed.[19] Electrocorticography (ECoG) monitoring in the microsurgical treatment of cavernous angiomas can direct the surgical procedure and control the post-operative epileptic seizure.[24]

9 Conventional Radiology

Ravi Ramamurthi, Goutham Cugati

PLAIN X-RAY OF THE SKULL

Careful examination of well-exposed plain radiographs often helps to give a clue to the possible diagnosis and points to the line of further investigation. It is useful to have anteroposterior (AP) and lateral views. Special views like posteroanterior (PA), Towne's, perorbital, tangential or stereoscopic are required for special indications. An inspection of the plain radiograph of the skull includes the examination of the vault with its outer table, the diploe, the inner table and the structures at the base. The thickness of the vault varies in different areas and in different individuals. Anteriorly, the frontal sinuses extend into the frontal bone on both sides to a varying extent. In some, the frontal sinuses extend high up into the frontal bone and also laterally almost to the outer margin of the orbit. This is more common in acromegaly and has to be taken note of when planning surgery. Occasionally, the air sinuses may extend along the orbital plate on either side. Similarly, pneumatisation of the mastoid may be so extensive as to include the squamous part of the temporal bone or even the petrous tip.

Arterial markings in the skull are usually visible as thin wavy lines and may become well marked when the external carotid branches supply a vascular lesion like a meningioma or an arteriovenous malformation. The venous channels of the skull are usually more prominent. The confluence of veins in the parietal bone has been termed the "parietal spider". At times, this is strikingly prominent and should not be mistaken for a vascular lesion of the skull. The foramina of the emissary veins may be well visualised in some X-rays, but this happens more often in patients with increased intracranial pressure.

In the base of the skull, the pituitary fossa is one of the most important structures. In the lateral view, the anterior clinoid process, the planum sphenoidale, the chiasmatic sulcus, the tuberculum sella and the posterior clinoids are usually recognisable. It is important to be aware of the normal variations in the shape and size of the sella. Zagga et al. found three types of sella namely oval, round and flat among which oval shaped sella was seen in 83%. Among the three types of sella floor namely the concave, flat and convex, the concave type of sella floor was seen in 75% of the Nigerian population.[11] Occasionally, the pituitary fossa may be deep and extend more in the vertical than in the AP direction. This has been termed "J-shaped sella" and has no special pathological significance.

In the lateral view, it is also possible to visualise the floor of the middle cranial fossa; a difference in the level of the floor on either side may indicate hypoplasia or a space-occupying lesion dating from early childhood.

Posteroanterior View

The greater and lesser wings of the sphenoid bone and the anterior clinoid processes are seen through the orbit in the PA view. As normal variations are often present in the thickness of these structures, care is necessary before diagnosing any pathology. The anterior clinoids and the planum sphenoidale may be eroded by carotid aneurysms or thickened by a meningioma. Occasionally, the sphenoid wings may be so thin, as to suggest their absence.

Fronto-Occipital

In the AP view the frontal bone, frontal and ethmoid sinuses, crista galli, ridge of the petrous bone, the posterior clinoid processes, the sides of the sella turcica and the foramen magnum can be inspected.

Caldwell View

The petrous bones are projected through the orbits and along with the internal auditory canals are well visualised in the Caldwell view (Per-orbital view) (Fig. 1).

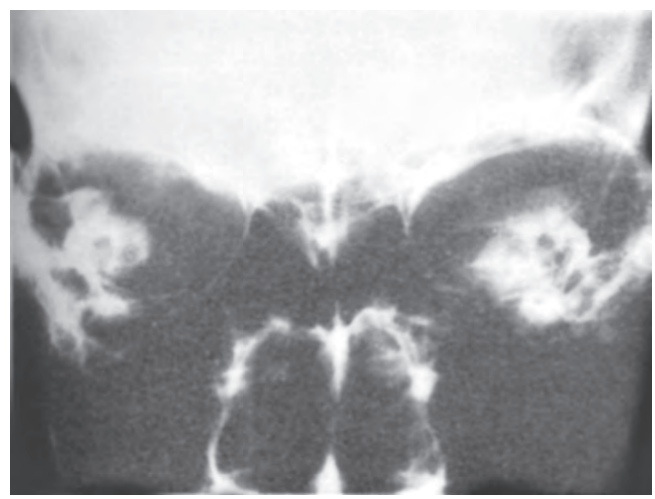

Fig. 1: Per-orbital view of the skull showing erosion of the apex of the right petrous bone

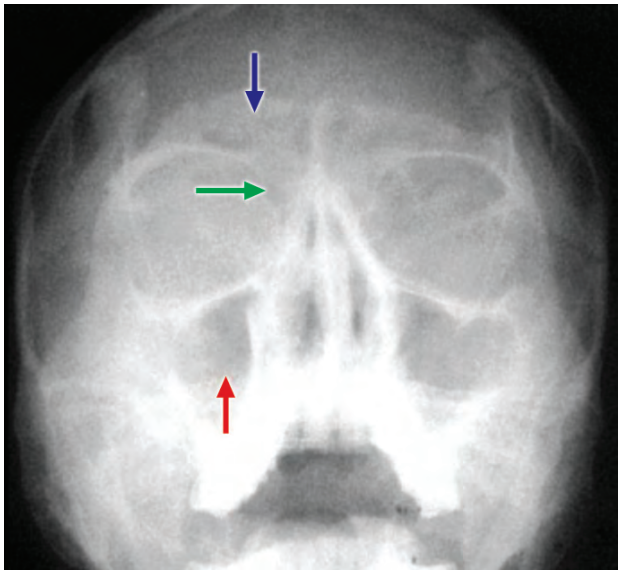

Fig. 2: X-ray Towne's view showing frontal (blue), ethmoidal (green) and maxillary (red) sinuses

Towne's View

The occipital bone, petrous pyramids, foramen magnum, dorsum sellae and posterior clinoids are seen well in this projection (Fig. 2).[5] Normal variations in the thickness of the petrous ridge must be remembered before diagnosing an erosion of the petrous bone or an enlargement of the internal auditory canal in the Towne's view.

Submento-Vertical View

Lesions involving the base of the skull can be demonstrated by a special basal view (submento-vertical view) (Fig. 3). The floor of the anterior, middle and posterior cranial fossa may be outlined. Erosion of the orbital roof, the lesser wing, the floor of the middle cranial fossa and the petrous bone are well seen. Although unilateral enlargement of the foramen spinosum would indicate an enlargement of the middle meningeal artery and the presence of a meningioma, normal variations do occur in the size of the foramen spinosum on either side. Occasionally, the foramen spinosum and the foramen ovale may coalesce and present as a single large foramen. Nasopharyngeal growths, chordomas and chondromas show appropriate changes in the base of the skull. The basal view is also used to visualise the foramen magnum and the odontoid process.

Plain X-rays of the skull may also reveal signs of systemic disorders. In hyperparathyroidism, there appears a peculiar but characteristic granular demineralisation of the vault, along with accentuation of the temporal line (the marginal line for the attachment of the temporal muscle to the skull) on frontal radiographs.[3] In Paget's disease, thickening of the bone is characteristic. In haemolytic anaemias, the diploic space widens with thinning of the tables of the skull vault (especially the outer table) and a radial disposition of the diploic trabeculae, giving rise to the so-called "hair-on end" appearance.

Multiple, rounded radiolucent areas suggest deposits of multiple myeloma or osteolytic metastases (Fig. 4). Larger well-defined areas of radiolucency may indicate deposits occurring in reticulosis which, in older children and adults, usually manifests as the solitary "eosinophilic granuloma" (Fig. 5). In very young patients, these areas may be confluent as in the Letterer-Siew disease or the Hand-Schuller-Christian syndrome. An important cause of multiple, rather ill-defined radiolucent areas in the skull of an infant or a child, is metastases from a neuroblastoma. As in this condition intracranial metastases are also fairly common, the combination of multiple rather ill-defined radiolucencies in the skull vault with signs of raised intracranial pressure, strongly favours the diagnosis of neuroblastoma.

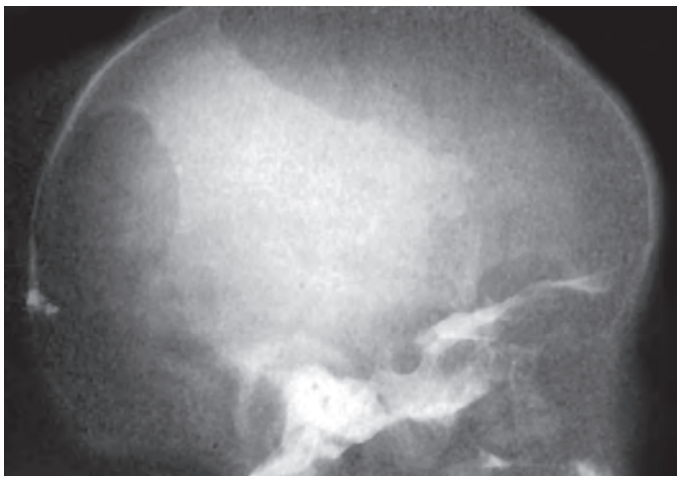

Fig. 5: Geographic skull—large osteolytic areas with irregular shape but sharp margins—findings typical of histiocytosis

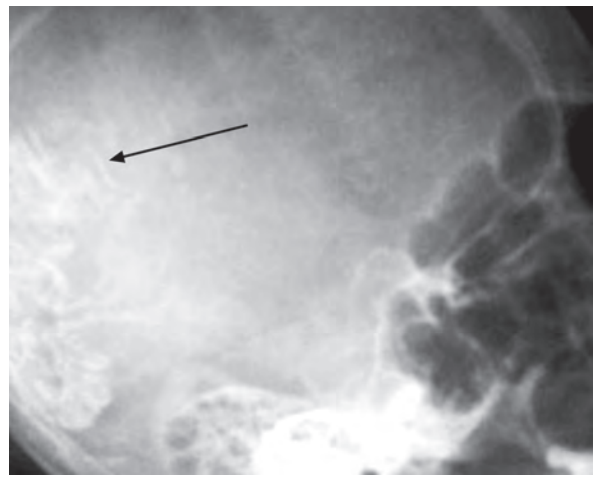

Fig. 6: Sturge-Weber Syndrome: characteristic, thin, parallel lines of gyral calcification ("rail-road") involving the atrophic occipital cortex

Intracranial Calcification

Calcification within the skull may be normal or abnormal. The structures in the midline that calcify are the pineal body, the falx cerebri, the Pachionian granules and the habenular commissure. The normal structures away from the midline that do so are: the choroid plexus, the petroclinoid ligament, the lateral edge of the diaphragma sellae and the carotid artery. The carotid siphon may show calcification in arteriosclerosis and may simulate a suprasellar calcification and is identified by its curvilinear shape and parallel streaks. Calcification of the midline structures is of clinical importance as they may be shifted to the opposite side by a space-occupying lesion in the supratentorial region, thus providing an important lateralising sign. Of the three, pineal and habenular calcifications are of much greater importance, as these structures shift readily, whereas the much more rigid falx cerebri does not lend itself very easily to a shift. Apart from a lateral shift, the pineal shadow may be shifted superiorly in the lateral radiograph of the skull by a space-occupying lesion near the dorsum of the midbrain, e.g. a tentorial meningioma. According to McRae,[4] the habenular commissure is calcified almost as often as the pineal gland and its location may be more precisely determined.

The incidence of calcification of normal intracranial structures is low in India compared to figures from Western countries. Pillai,[6] Varadarajan and Ramamurthi[10] and Shrivastava[9] reported the incidence of pineal calcification to be 5.8% and that of the choroid plexus 0.5–3%. It is suggested that this low incidence of calcification may perhaps be related to the type of nutrition. It is interesting to note that Pillai[6] reported an incidence of 23.5% from Kerala State in the south western corner of India. In general, abnormal calcification tends to be less dense in our patients, as compared to patients from developed countries. Contrary to popular belief, tuberculomas show radiologically visible calcification only in 6–7% of cases.[7] Dense irregular calcification is more often seen in healing brain infarcts that result from vascular occlusion in tuberculous meningitis and should not be mistaken for a tuberculoma. In some instances of abnormal calcification, the shape and type of calcification may be diagnostic, as in the case of the double-line wavy ("rail-road") calcification, seen in the Sturge-Weber-Dimitri syndrome (Fig. 6); or its position and shape may suggest the nature of the lesion, as in the case of the suprasellar oval or speckled calcification seen characteristically in a craniopharyngioma. Other instances of abnormal calcification occur in tuberose sclerosis, toxoplasmosis, oligodendroglioma, an aneurysmal sac, chronic subdural haematoma and dermoids. Of all brain tumours, oligodendrogliomas show the highest incidence of calcification. In the vast majority of cases, however, the type of calcification is not pathognomonic.

Increased Vascularity

An increase in vascularity, as indicated by increased and widened diploic vascular markings, is of clinical significance only if found to be localised or unilateral. Such vascularity may point to an underlying vascular neoplasm such as a meningioma, an arteriovenous malformation or a metastatic deposit.

Localised Areas of Bony Erosion or Sclerosis

Irregular areas of hyperdensity in the inner table of the frontal bone, as seen in hyperostosis frontalis interna, are not of any pathological significance. Erosion is associated with increased vascularity in the bone, whereas sclerosis occurs with decreased blood supply or as a reaction to tumour tissue infiltrating the bone. Direct pressure may also expand or erode the bone, as happens at the internal auditory meatus in an eighth nerve tumour or the tip of the petrous bone in a trigeminal neurinoma (Fig. 1) or in the pituitary fossa due to an intrasellar tumour. Local areas of bony erosion may be caused by an adjacent surface tumour like a meningioma. The inner table is more widely affected and there may be an associated increase in the local vascularity. A

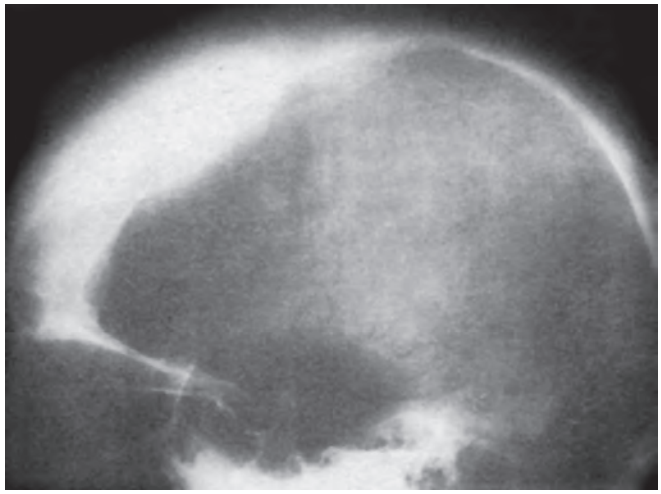

Fig. 7: Increased density of both tables of the frontal bone due to fibrous dysplasia

combination of sclerosis and erosion or sclerosis alone may occur, e.g. reactive sclerosis produced by a meningioma of the sphenoid ridge. Another condition that causes localised changes in the cranial vault is fibrous dysplasia of the bone (Fig. 7). This condition, usually seen in young patients, is of obscure aetiology. In the skull vault, it commonly presents as a cystic expansion of the diploic space, usually in the direction of the outer table, with a coarsening of the diploic pattern. Lesions in the base of the skull, however, present as a diffuse fairly dense, sclerotic thickening of the bone which is often bilateral. The sclerosis often extends to the infratemporal and maxillary regions, giving rise to the condition described as "leontiasis ossea". When unilateral, it may closely mimic a meningioma of the sphenoidal ridge. It can be differentiated from the latter by the more diffuse bone formation and associated cystic expanding lesions, seen in other parts of the skeleton.

Raised Intracranial Pressure

In infants and children, raised intracranial pressure is manifested by separation of the sutures and increased convolutional markings with thinning of the bone. Although the sutures in infants normally tend to be somewhat wide in the neighbourhood of the fontanelles, any separation beyond 2 mm is indicative of raised intracranial pressure. Such sutural diastasis may also be seen in young adults, occasionally up to the age of 20 years. Prominent convolutional markings with premature fusion of the sutures are seen in craniosynostosis. By contrast, the fully ossified skull of adults, with sutures partly or completely fused, does not allow sutural separation. Likewise, abnormal convolutional markings also fail to develop in adults even with marked increase in intracranial pressure.

Under these circumstances, the changes occurring in the sella turcica constitute by far the most important manifestation of raised intracranial pressure. In the earliest phase, there is demineralisation of the subcortical bone leading to a loss of the normal "lamina dura" (white line) of the sellar floor. This is followed by a thinning of the dorsum sellae and the posterior clinoid processes. The dorsum sellae later becomes foreshortened and pointed, resulting in a shallow sella turcica. In extreme cases, the sella becomes very shallow and flattened with its floor and anterior wall demineralised and the posterior clinoid processes and the dorsum sellae destroyed. The pituitary fossa may balloon-out in some cases of increased intracranial pressure associated with hydrocephalus. In such cases, the infundibular recess of the enlarging third ventricle acts like an expanding intrasellar lesion and the X-ray appearances resemble those of a pituitary adenoma. Another useful sign of increased pressure is the enlargement of the emissary foramina of the occipital region. This is due to increased intracranial venous pressure which is transmitted to the exterior, through the emissary and diploic veins. When there is a localised increase in pressure inside a portion of the intracranial cavity, in children and young adults, the skull may show localised thinning with a bulge. This may happen in a cystic lesion in the temporal region or in unilateral or loculated dilatation of the ventricles. Superficial expanding intracranial lesions like a congenital cyst or a chronic subdural haematoma may cause a localised thinning and bulging of the overlying bone.

Craniostenosis syn. Craniosynostosis

In craniostenosis, one or more sutures of the skull fuse prematurely during infancy or early childhood. This requires early recognition and treatment. Craniosynostosis is classified into the complete or partial types. In the complete variety all the sutures are fused, the head assumes a rounded (oxycephalic) or pointed or tower-like (turricephalic) shape. There is a marked increase in the convolutional markings due to the pulsation effect of the normal brain on the vault of the abnormally small skull. Deformity resulting from a combination of complete craniostenosis and hypertelorism, proptosis and hypoplasia of the maxillary antra is called "craniofacial dysostosis" or Crouzon's disease. The growth at the fused sutures is arrested, whereas it continues normally at the open sutures in partial craniostenosis. When the sagittal suture is prematurely fused, the growth occurs at the coronal and lambdoid sutures and the skull grows in an anteroposterior direction, resulting in a dolicocephalic or scaphocephalic type of craniosynostosis. If the coronal or lambdoid sutures fuse abnormally, the skull is foreshortened in its AP diameter, resulting in brachycephaly. In another variety of incomplete craniosynostosis, fusion of one half of the coronal or lambdoid sutures results in an asymmetrical skull, i.e. plagiocephaly.

Microcephaly

The skull is small due to an under-developed brain. The sutures are normal and the fontanelles closed. There are virtually no convolutional markings on the skull vault. There is usually some degree of "shelving" of the frontal

bone. In a few cases due to lack of growth stimulus, the sutures fuse prematurely leading to "secondary craniosynostosis". From the point of view of treatment, early differentiation between the small skull due to primary premature craniosynostosis and microcephaly with or without secondary craniosynostosis is of vital importance. The former needs surgical intervention, whereas surgery has no role for true microcephaly. An early decision is necessary, as the operation should be undertaken in the first year of life when the brain has its maximum rate of growth. The differentiation is easy if the sutures are normal, the small skull then obviously being secondary to the underlying microcephaly. If, however, secondary craniosynostosis has supervened, the absence of convolutional impressions in microcephaly differentiates it from the characteristic excessive convolutional markings seen in primary cranisynostosis.

"Hemiatrophy" of the Skull

In infantile hemiplegia when one cerebral hemisphere fails to develop fully, the skull on the affected side appears smaller than the opposite side and the bones are thicker. The crista galli is also shifted to the atrophic side. In the AP view, the atrophy of one half of the skull is well seen and is commonly known as "hemiatrophy of the skull".

Platybasia and Basilar Invagination

Platybasia is the term applied to the condition in which the base of the skull is flat. This is assessed by measuring "Welcker's angle", i.e. an angle subtended by the lines joining the nasion to the tuberculum sellae and that joining the tuberculum sellae to the anterior margin of the foramen magnum. The normal limit of the angle is 125 degrees. If the angle measures more than 140 degrees, platybasia is said to exist.

Basilar invagination and basilar impression are terms used to indicate elevation of the median part of the floor of the posterior cranial fossa; this condition may coexist with platybasia and developmental anomalies of the craniovertebral junction, such as occipitalisation of the atlas and atlanto-axial dislocation.

A number of radiological lines and measurements are available to determine the presence and degree of basilar invagination.[8] A few of the more important ones are mentioned here: 1) Chamberlain's line extends from the posterior end of the hard palate to the posterior lip of the foramen magnum. If more than one-third of the odontoid process extends above this line, basilar invagination is present; 2) McGregor's line joins the posterior end of the hard palate to the lower margin of the occipital squama. If the tip of the odontoid process extends more than 5 mm above this line, basilar invagination is suggested; 3) Bull's angle is subtended between the line extending the hard palate backwards and the line joining the centre of the anterior and posterior arches of the atlas extended forwards. If this angle measures more than 13 degrees, basilar invagination is indicated and 4) the clivus-canal line is a line which is extended along the plane of the clivus into the spinal canal. The odontoid tip normally lies anterior and inferior to this line and if the tip of the odontoid projects superior and behind this line, basilar invagination is present. For all the above, a strict lateral view of the skull is necessary.

In the AP projection, basilar invagination may be diagnosed by the use of Fischgold's line or the interdigastric line which joins the digastric grooves of the two sides. If the atlanto-occipital joint lies less than 7 mm below this line, basilar invagination is suggested. McRae's line joins the anterior and the posterior margins of the foramen magnum. Basilar invagination is said to exist if the upper margin of the occipital squama on either side of the foramen magnum is convex upward or if it lies above the line of the foramen magnum or if the condyles are above the foramen magnum. It may also be observed in the AP projection that the petrous pyramids are directed medially and upwards, instead of medially and slightly downwards as seen in the normal skull.

Sellar and Parasellar Neoplasms

The size and dimensions of the sella are quite variable in the normal skull X-ray. It is more useful if careful examination of the sella is done, rather than taking elaborate measurements. The upper limits of normality are: a) A-P diameter 17 mm; b) depth 14 mm and c) width 15 mm.

The dorsum sella is markedly thinned (but not destroyed) and is concave forwards and the anterior clinoid processes are thinned and sharpened by erosion from below (undercutting). The sella is deepened; a depth of more than 15 mm and an AP diameter of 20 mm are definitely abnormal.[1] The floor may be so demineralised that the tumour actually appears to project into the sphenoid sinus. Irregular growth may cause a step to be visible in the floor of the sella, "Double floor" in a "strict lateral" view (Fig. 8). The enlargement of the sella in some cases of raised intracranial pressure may simulate a pituitary

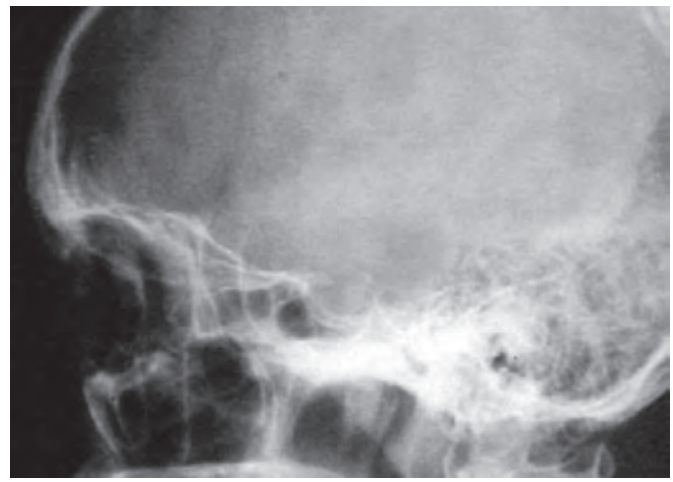

Fig. 8: X-ray lateral view in a patient with pituitary adenoma showing double flooring of the sella

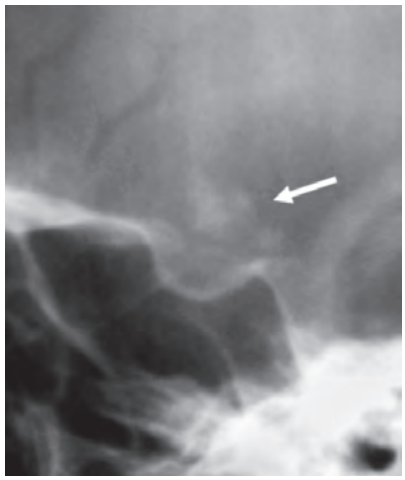

Fig. 9: X-ray lateral view in a patient with craniopharyngioma showing suprasellar calcification

tumour due to the infundibular recess of the third ventricle acting like an intrasellar lesion.

The X-ray changes in pituitary tumours have been graded by Hardy.[2] Grade I: The sella turcica is normal in size, although there may be a lowering of the floor on one side as revealed by strict lateral X-rays of the skull. Grade II: The sella turcica is enlarged to various degrees but the floor remains intact. Grade III: When the erosion is well localised to an area of the floor of the sella. Grade IV: When all the boundaries are barely visible and the entire floor of the sella is diffusely eroded or destroyed, having the aspect of a 'phantom' sella.

In addition to the sellar changes, however, there may be radiological changes, characteristic of gigantism or acromegaly. In acromegaly, the paranasal sinuses are large, the bones thick and coarsely trabeculated and the bony prominences and ridges accentuated. The skull vault is usually thick and the mandible is also thick, with everted edges. There is fairly well-marked prognathism with malocclusion of the teeth. There is also a 'tufting' of the terminal phalanges of the fingers and toes.

Craniopharyngiomas are usually suprasellar and about two-thirds of them show some calcification. (Fig. 9) Classically, the calcification is of the curvilinear or "egg-shell" variety situated just above the sella. More often one sees a diffuse speckled calcification. The majority of these tumours enlarge the sella to some extent with some truncation of the dorsum sellae.

IMAGING OF THE SPINE

Plain X-rays

Plain X-rays of the spine are valuable in all cases of suspected spinal cord lesions. Different techniques are necessary for proper visualisation of the various components of the spinal column at different levels of the spine. Special views are necessary to demonstrate changes in the atlas and the odontoid process. In the cervical region, in addition to the AP and lateral views, oblique views are necessary to show clearly the intervertebral foramen. Lateral views in flexion and extension help in determining minor subluxations between the cervical vertebrae and may also demonstrate abnormal mobility. Obliteration of the cervical lordosis itself is a useful sign. Proper visualisation of the lowermost cervical and upper four thoracic vertebrae is often difficult, especially in obese patients. The AP view alone is not informative because of the cervicothoracic curvature.

While viewing radiographs of the spine, the structures to be examined are the upper and lower borders of the body, the trabeculae in the body, the intervertebral disc space, the pedicles, the inter-articular joints, the laminae, the transverse processes and the spinous processes. One should also look at the paravertebral shadow, the head, neck and the body of the ribs and other shadows like that of the lateral border of the aorta, etc. The interpedicular distance varies from the cervical to the lumbar spine, with an enlargement in the cervical and lumbar regions corresponding to the origin of the brachial and lumbosacral plexuses. The interpedicular distance increases from C2 to C6 and then narrows from C6 to T4, below which there is a progressive increase. In the lateral view, a progressive narrowing of the AP diameter of the spinal canal may be seen from above downwards. The capacity of the spinal canal varies in different individuals according to its shape. In developing countries with resource constraints, a careful study of plain radiographs of the spine still occupies an important place in diagnosis. Congenital, traumatic, inflammatory and other abnormalities are dealt with in detail in the concerned chapters.

10 Basic Principles of CT Scan and MRI Scan

Veena Norhona

Basics of Computed Tomography

INTRODUCTION

The first computed tomography (CT) scanner was developed by Sir Godfrey Hounsfield in 1972; since then this modality has become an important tool in diagnostic radiology. Since the first scanner to the present day multislice helical scanner, CT technology has revolutionised the world of imaging and enhanced patient management.

BASIC PHYSICS

Computed tomography uses X-rays to obtain cross-sectional, two-dimensional (2-D) images of the body. The cross-sectional image is produced by 360° rotation of the X-ray tube around the patient. The transmitted radiation is measured by the detectors located inside the gantry like a ring around the patient. The final image is generated from these measurements. The gantry of the CT machine houses the X-ray tube and the detectors (Fig. 1).

TYPES OF SCANNING TECHNIQUES

Axial (Sequential) Scanning

In sequential scanning, a single slice is obtained with a single 360° rotation of the tube (Fig. 2A). The disadvantage is that the time taken for an individual study is long, hence prone to motion artifacts and the quality of reformations is suboptimal.

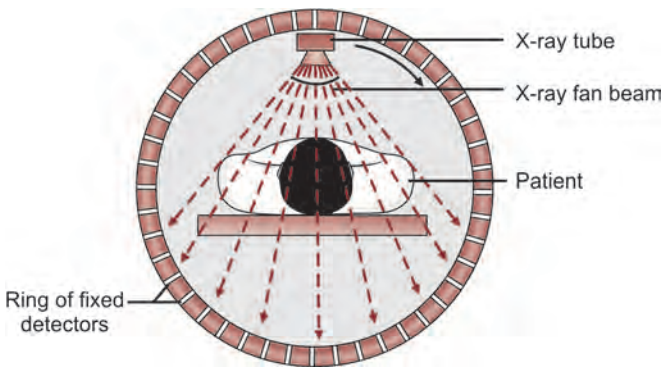

Fig. 1: Cross-sectional view of the gantry showing the orientation of the X-ray tube and detectors in a fourth generation CT scanner

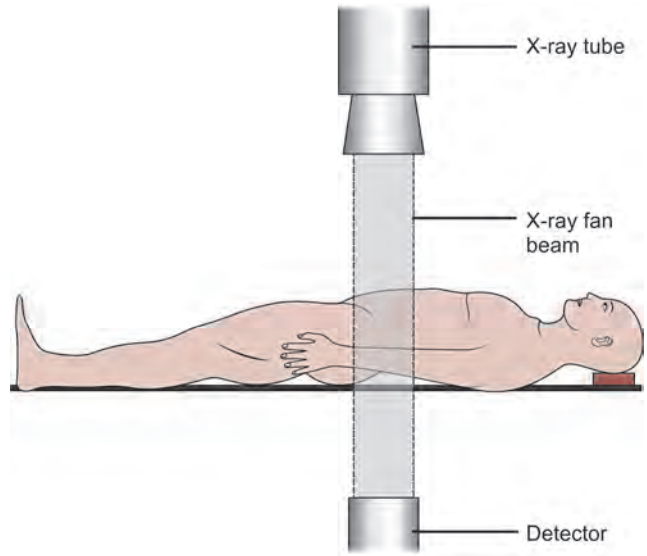

Fig. 2A: Sequential scan—single cross-sectional slice of the patient in a single rotation

Helical (Spiral) Scanning

With the advent of slip ring technology, the continuous rotation of the X-ray tube around the patient is made possible during continuous patient table movement. This led to the development of helical scanning (Fig. 2B). The transmitted radiation thus, takes the form of a helix or spiral around the patient acquiring a large volume of data. This allows larger anatomical regions of the body to be imaged during a single breath hold, thereby reducing the

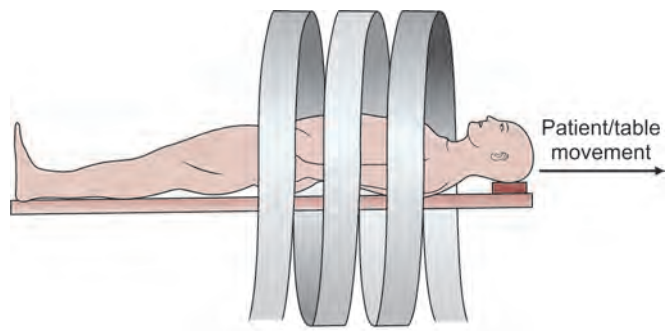

Fig. 2B: Helical scan—rotation of the tube around the patient with continuous table movement

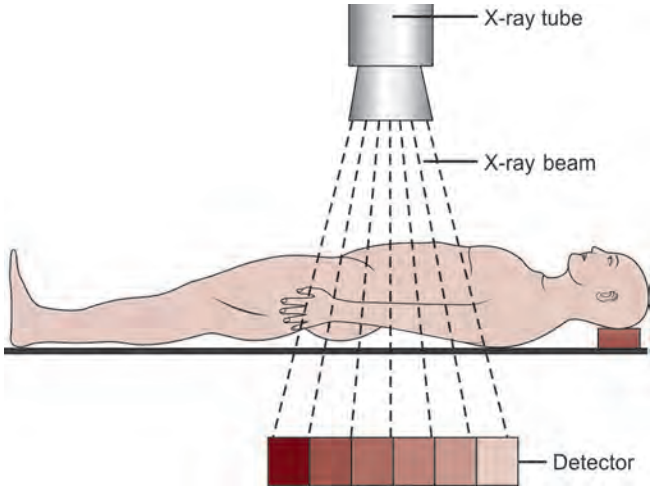

Fig. 3: Multi-slice imaging—generation of six slices per rotation of the tube in a multi-detector scanner

possibility of artifacts caused by patient movement. Faster scanning also increases patient throughput.

Multi-slice or multi-detector machines utilise the principles of the helical scanner but incorporate multiple rows of detector rings. They can therefore acquire multiple slices per tube rotation, thereby increasing the anatomical coverage in a shorter time (Fig. 3).

COMPUTED TOMOGRAPHY TERMINOLOGIES

Pixel and Voxel

Every CT image is made up of a square of picture elements called the pixel and volume element called the voxel (Fig. 4). The obtained CT image is subdivided into a matrix of up to 512 × 512 or 1024 × 1024 elements. The pixel width is determined by the field of view (FOV) and matrix size, i.e. FOV/matrix. The voxel volume = pixel area × slice thickness.

Hounsfield Unit or Computed Tomography Number

Each voxel is traversed during the scan by numerous X-ray photons and the intensity of the transmitted radiation is measured by the detectors. From these

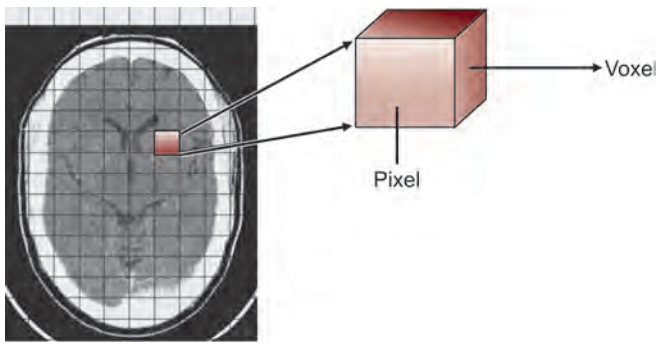

Fig. 4: Pixel—represents the matrix and voxel represents the slice thickness

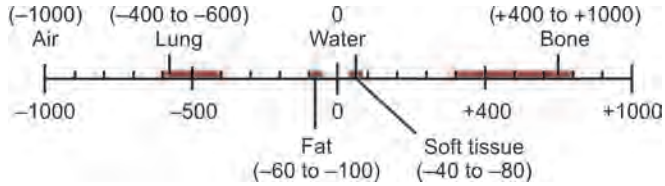

Fig. 5: Scale representing the range of Hounsfield numbers of the tissues seen in the body

intensity readings, the density or attenuation value, viz. Hounsfield unit (HU) or CT number is calculated and assigned to every tissue.

Each pixel is assigned a numerical value (CT number), based on the attenuation of X-rays by the tissue. This number is compared to the attenuation value of water and displayed on a scale of arbitrary units named HU after Sir Godfrey Hounsfield. This scale assigns water an attenuation value (HU) of zero. Each number represents a shade of grey with +1000 (white) and –1000 (black) at either end of the spectrum (Fig. 5).

The CT number of various tissues in the body is as follows:

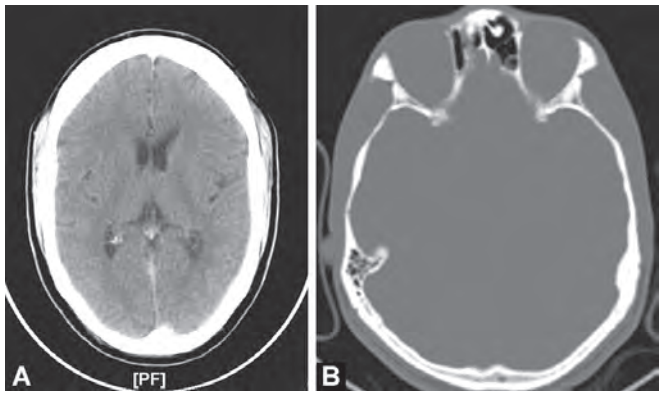
- Brain grey matter — 35–40 HU
- Brain white matter — 30–35 HU
- Blood—Flowing blood — 40 HU
- Acute haematoma — 70–90 HU (density depends on the haemoglobin concentration and coagulation profile)
- Calcification — + 80 and above
- Fat — – 100
- CSF — 0–10 HU
- Bone — + 800–1000 (depends on the type of bone).

WINDOW LEVEL AND WINDOW WIDTH

The term "window level" (WL) represents the central Hounsfield unit of all the numbers within the window width (WW). The WW covers the HU of all the tissues of interest and these are displayed as various shades of grey. Tissues with CT numbers outside this range are displayed as either black or white. Both the WL and WW can be set independently on the computer console and their respective settings affect the final displayed image (Figs 6A and B).

SLICE THICKNESS

It is the collimation of the X-ray beam as it emerges from the X-ray tube. The slice thickness can be varied depending on the anatomical region to be covered by varying the beam collimation. For example orbit scanning is done using 2–3 mm slice thickness, posterior fossa 4–5 mm slice thickness and supratentorial brain parenchyma 10 mm slice thickness.



Figs 6A and B: (A) Soft tissue window settings of an axial CT scan of the brain (WW = 100, WL = 30). (B) Bone window setting of an axial CT scan of the brain (WW = 2,000, WL = 220)

Fig. 8: Coronal reformations of the face showing fractures involving the lateral wall of the left maxillary sinus, zygoma, lateral wall of the left orbit and frontal bone

PITCH

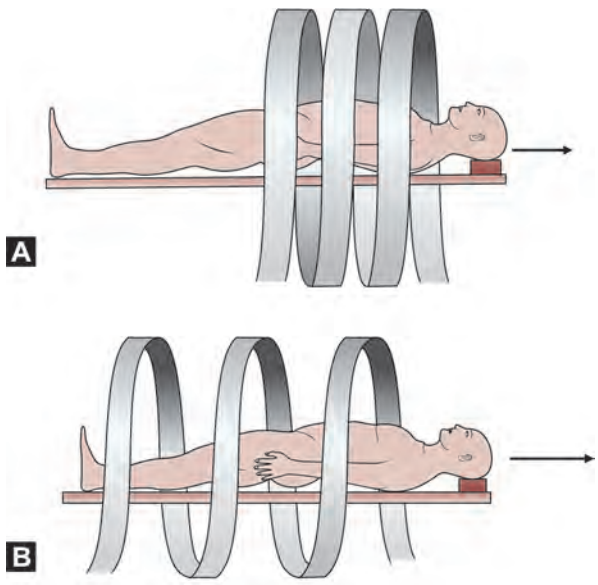
Pitch is the terminology used in helical scanning and denotes the distance travelled by the table (in millimetres) during one complete rotation of the X-ray tube, divided by the slice thickness (millimetres). Increasing the pitch by increasing the table speed reduces dose and scanning time, but at the cost of decreased image resolution (Figs 7A and B).

$$\text{Pitch} = \frac{\text{Table distance per } 360^\circ \text{ rotation (mm)}}{\text{Slice thickness (mm)}}$$

IMAGE POST PROCESSING

Post processing the acquired volumetric data during spiral CT is done in ways appropriate to the clinical situation such as:

- *Multiplanar reformatting*: After obtaining the serial axial volumetric data, the computer reconstructs the data in sagittal and coronal planes. With the current multi-slice CT scanner it is possible to obtain isotropic sagittal and coronal reconstructions. These are useful in paediatric and trauma patients who cannot be positioned for direct coronal scans (Fig. 8).
- *Three-dimensional (3-D) imaging*: The acquired data can also be post processed to obtain a 3-D model to display spatial information or surface characteristics (volume and surface rendering). This is useful in paediatric craniofacial anomalies and maxillofacial injuries to guide the surgeon in treatment planning (Fig. 9).
- *CT angiography (CTA)*: This involves injection of 100–120 ml of contrast medium, rapidly, using a pressure injector at a predetermined rate of injection. Serial axial images are obtained. These images are then used for reconstruction of the data using maximum intensity projection to get a display of the vascular tree. By altering the time of image acquisition and contrast injection, we can obtain only the arterial or venous phases (Figs 10A and B).



Figs 7A and B: (A) Shows a low pitch—tight helic. (B) A pitch of more than 1 – loose helic – shorter scan time at the cost of image resolution

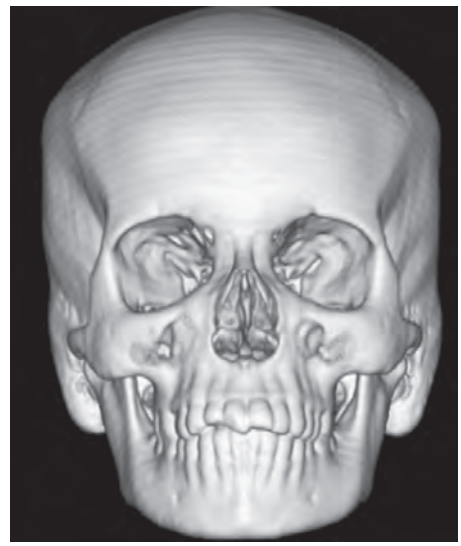


Fig. 9: CT of the skull

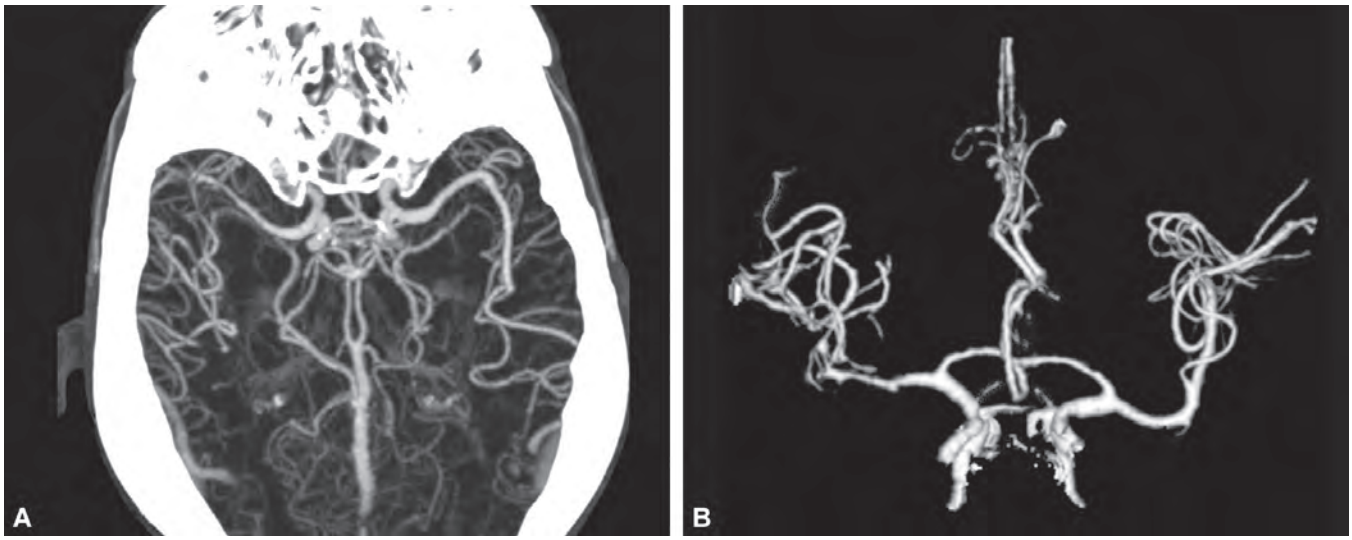

Figs 10A and B: CT angiogram of the brain showing. (A) Axial MIP image. (B) Volume rendering

COMPUTED TOMOGRAPHY CONTRAST MEDIA

These are iodine containing compounds. Iodine absorbs X-rays within the CT range (120 KVp) since iodine has an atomic number of 53 and atomic weight of 127.

There are two types of contrast agents used:

1. *Ionic contrast*: These are sodium or methylglucamine combined with a tri-iodinated benzene ring to form soluble salts. These are hyperosmolar and hence are likely to cause severe contrast reactions. These are contraindicated intrathecally.
2. *Non-ionic contrast*: These are near iso-osmolar and hence tend to produce fewer side effects and considered relatively safe for patients.

Absolute contraindication for contrast:

1. Previous contrast sensitivity
2. Abnormal renal parameters

Patients with diabetes and multiple myeloma are more likely to develop altered renal function post IV contrast injection. Patients with myasthenia gravis, sickle cell anaemia and pheochromocytoma are at risk of developing contrast-induced symptoms.

ADVANTAGES AND CLINICAL USE OF COMPUTED TOMOGRAPHY

- CT is readily available in most hospitals and is cost-effective.
- It is a rapid imaging modality with excellent image resolution, hence useful in trauma, paediatric and uncooperative patients.
- Patients in whom magnetic resonance imaging (MRI) is contraindicated.

DISADVANTAGES OF COMPUTED TOMOGRAPHY

- Radiation—The effective doses from diagnostic CT procedures are typically estimated to be in the range of 1–10 mSv.

Physical Principles of Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is based on the principles of nuclear magnetic resonance (NMR).

BASIC PRINCIPLES OF MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is based on the absorption and emission of energy in the radiofrequency (RF) range of the electromagnetic spectrum. The human body is primarily made up of fat and water, which have many hydrogen atoms (almost 63%) (Fig. 11). The hydrogen atom (1H) consists of a single positively charged proton that spins around its axis. These charged particles create an electromagnetic field, similar to that of a bar magnet.

The proton possesses a property, called spin, which has a small magnetic field. These spinning particles have a net magnetic moment which has both magnitude and direction. In the absence of an external magnetic field, these protons are randomly oriented.

When placed in a magnetic field of strength B, the protons align themselves parallel or antiparallel to the external magnetic field. There is a low energy state where the poles are aligned N-S-N-S and a high energy state N-N-S-S. This particle can undergo a transition between the two energy states by the absorption of a photon. A particle in the lower energy state absorbs a photon and ends up in the upper energy state. The energy of this photon must exactly match the energy difference between the two states.

Application of a RF pulse of appropriate duration and amplitude excites these protons from the lower energy state to the higher energy state.

The MRI signal results from the energy difference of the spins emitted during transition from the higher energy state to the lower energy state. The signal is thus proportional to the population difference between the states (Figs 12A and B).

When the RF pulse is applied, the protons are tipped into the horizontal or X-Y plane by an angle termed as the flip angle or tip angle depending on the type of RF pulse. The rate at which the protons precess is termed as frequency and the angular position of the precessing spin is called the phase of the spin.

The frequency of precession (f) is called the Larmor frequency and is characteristic of the specific nucleus and strength of the external magnetic field and is expressed as:

$$f = \gamma B$$

Where f = mHz/sec, B is expressed in Tesla and ã is the gyromagnetic ratio of the specific nucleus and expressed as mHz/T. Hydrogen has the highest gyromagnetic ratio and is the most abundant body element, hence is the natural choice for H signal.

Radiofrequency Field

Every nucleus in the body precesses at its own Larmor frequency and will produce an MR signal only when the RF energy is delivered at the correct frequency. The excitation RF pulses are delivered by coils that produce an RF field perpendicular to the external magnetic field. The RF is absorbed by the nuclei and the magnetic moment is tipped away from the Z axis, i.e. axis of the external magnetic field depending on the duration and amplitude of the RF pulse.

Free Induction Decay

When the RF pulse is switched off, the magnetic momentum of the nuclei begins to return to its original position, thereby transferring the absorbed energy and inducing alternating current signal in the receiver coil. This is termed as free induction decay (FID). As this occurs immediately after the RF pulse, this signal is not used for image data. The magnetisation is manipulated to generate a useful signal termed as echo, which produces the image.

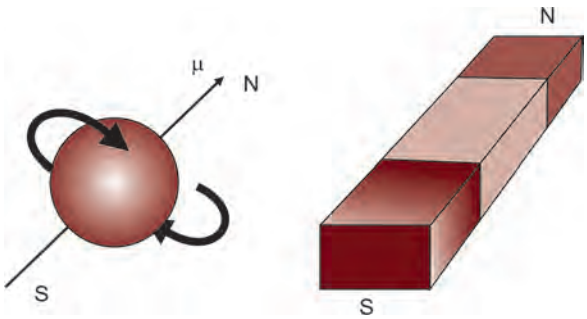

Fig. 11: Every spinning particle possesses a magnetic moment (μ) and creates a magnetic filed similar to a bar magnet

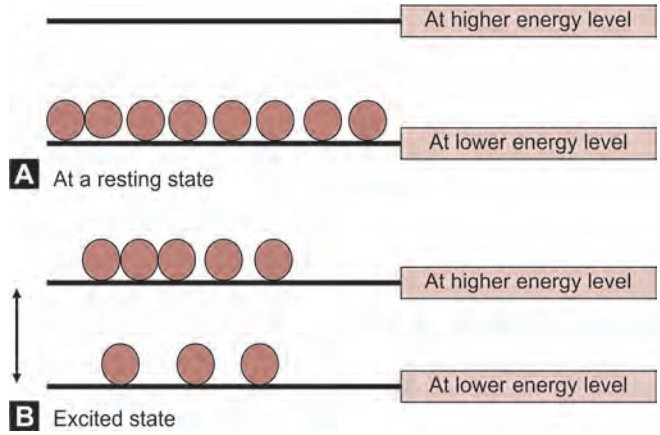
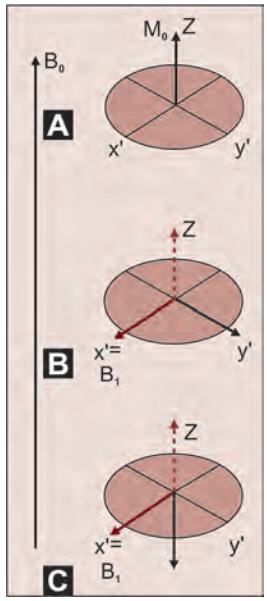


Figs 12A and B: (A) Showing protons outside a magnetic field. (B) showing excited protons in a magnetic field moving from a lower energy level to a higher energy level with two distinct energy levels. The population difference is directly proportional to the magnetic field strength



Figs 13A to C: (A) Alignment of the protons along the direction of the external magnetic field (B_0) in the z-axis. (B) After applying the RF pulse of an appropriate frequency, the magnetisation (M_0)/ protons are tipped away from its equilibrium in the x-y plane. (C) If a longer pulse lasting twice as long is applied, the magnetisation is inverted

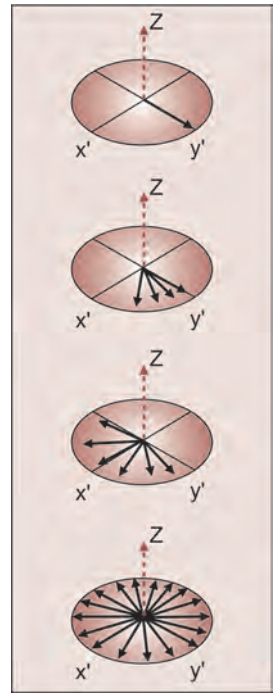


Fig. 15: Spin – spin relaxation–T2 relaxation-Loss of magnetisation in the x′-y′ plane is faster than the loss of magnetisation in the z- direction due to loss of phase coherence of the microscopic components

T1 and T2 Relaxation

When the RF pulse is switched off, two processes take place simultaneously

A. Recovery of the net magnetic moment in the Z axis—termed as longitudinal or T1 relaxation. T1 is the time required for the buildup of 63% of the original magnetisation along the Z axis (Figs 13A to C).
B. Loss of phase coherence in the X-Y plane or transverse plane—termed as T2 relaxation.

The nuclei while returning to the ground state dissipate their excess energy to their surroundings, which is called the lattice. This process is named as spin-lattice relaxation (Fig. 14). Smaller molecules reorient more rapidly than larger molecules. The medium-sized molecules, such as lipids, relax faster as their frequency of rotation is closer to the Larmor frequency than that associated with pure water or larger molecules such as proteins. Thus, T1 relaxation times depend on magnetic field strength because the latter affects the Larmor frequency. Thus water has a long T1.

Transverse magnetisation occurs because the magnetic field generated by the surrounding electrons exposes the precessing nuclei to different field strengths. Loss of transverse magnetisation (phase coherence) occurs as the magnetic moments get out of phase as a result of their mutual interaction. Anything that changes the magnetic field strength also changes the precessional frequency and causes a loss of phase coherence (dephasing) and shrinking of the transverse magnetisation. This is called T2 relaxation or spin-spin relaxation (Fig. 15). It denotes the loss of phase coherence caused by interactions between neighbouring magnetic moments. T2 is the time required to reduce the transverse magnetisation to 37% of its original value.

In biological tissues, the main contribution to T2 relaxation is from the relatively static magnetic field from neighbouring protons. Large molecules, which tend to reorient more slowly than small molecules, promote T2 relaxation and have shorter T2 times. Free water has a longer T2 than water associated with macromolecules. The T2 is relatively independent of the field strength.

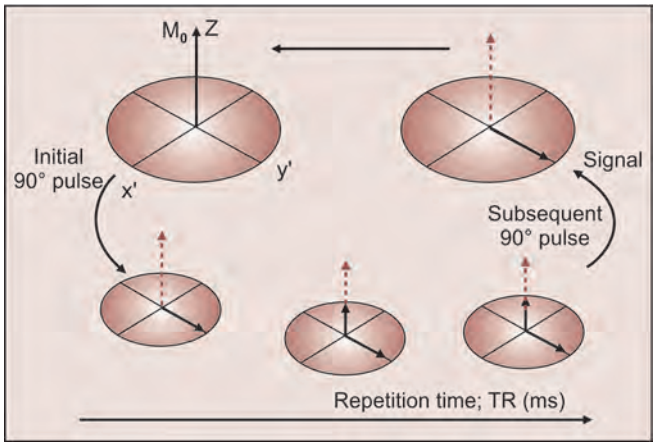

Fig. 14: Spin-lattice relaxation time

Repetition Time

The time between two RF excitation pulses is called the repetition time (TR). The TR can be chosen from a certain minimum value, depending on the imaging technique and the MR system, to very long times.

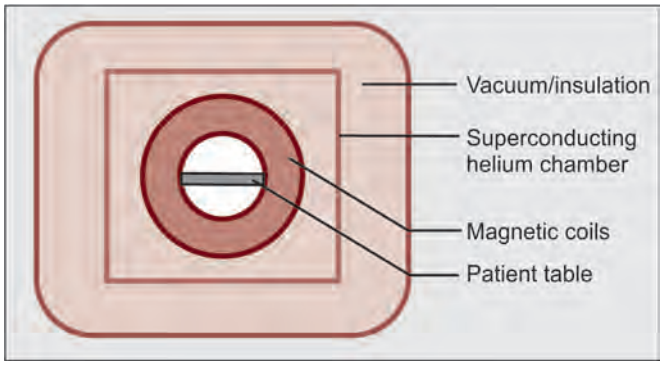

Fig. 16: Showing schematic representation of the superconducting MR systems. The bore is surrounded by the coils of the wire through which electric current is passed and cooled by liquid helium to achieve magnetisation and desired field strength

Longer values of TR allow more T1 relaxation to occur, and this property can be exploited to manipulate the contrast between tissues with different T1s or the signal-to-noise ratio in an image.

Echo Time

The time from the centre of the RF excitation pulse to the centre of the echo is the echo time (TE). The amplitude of the transverse magnetisation at the echo peak depends on TE and T2 of the tissue. As TE is prolonged, the transverse magnetisation becomes weaker. Adjusting TE influences the contrast between tissues that have different T2s.

Slice Orientation

The orientation of a slice, i.e. axial, coronal or sagittal, depends on which of the three magnetic field gradients is activated during the RF pulse. An RF pulse in the presence of the z gradient creates a transverse slice. The x and y gradients select slices in the sagittal and coronal orientations, respectively. Oblique slices are created by activating two or more gradients during an RF pulse.

Slice Position

Slices are located where the Larmor frequency matches the frequency of the RF pulse. The slice-selection gradient lowers the Larmor frequency on one side of the centre of the magnet and raises it on the other side. Slice position is controlled by changing the frequency of the RF pulse because changing the amplitude of the slice-selection gradient would inadvertently alter the thickness of the slice.

INSTRUMENTATION

The key components of an MR system are the magnet, the gradient, the RF subsystem and the computer.

The Magnet

The magnet is the main component of the MR system. There are three types of magnets in common use for

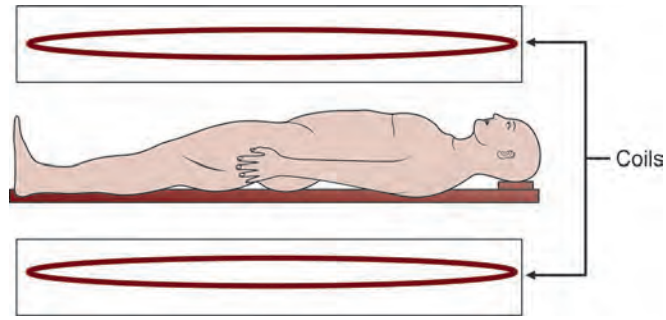

Fig. 17: Schematic diagram of a permanent MR system showing the generation of the magnetic field in a vertical direction by magnetised ceramic blocks

MRI—permanent magnets, resistive electromagnets and superconducting electromagnets. The higher the field strength the better is the signal-to-noise ratio. The strength of the magnetic field is measured in Gauss (G) or Tesla (T) units (10,000 G = 1 T). Diagnostic MR systems usually employ magnets with operating field strengths ranging from 0.02 to 3 T. Research systems operate above 3T up to 9T.

Superconducting Magnets

These are the most commonly used magnets and operate at field strength above 0.5 T. Some metals (e.g. Hg) and alloys (e.g. niobium/titanium, Nb/Ti; niobium/tin, Nb3Sn; and vanadium/gallium, V3Ga) lose their electrical resistance at very low temperatures and become superconductors. The superconductor most widely used in the construction of clinical magnets is Nb/Ti. This alloy becomes superconducting at 10° Kelvin (K) in the absence of an external magnetic field. This temperature is provided by a bath of liquid helium (4° K) (Fig. 16).

Resistive Magnets

A resistive magnet is an electromagnet in which the magnetic field is generated by the passage of electrical current through a wire. The disadvantage is their high-power consumption, limiting field strength.

Permanent Magnets

It uses a horse-shoe magnet. An advantage of these low field permanent magnet systems is that their C-shaped design is patient friendly and therefore useful in claustrophobic patients. Their field strength is limited to 0.5 T (Fig. 17).

Magnetic Field Gradients

Magnetic field gradients are activated as pulses for a short duration at timed intervals. It is a magnetic field that increases in strength along a particular direction, e.g. x, y and z gradients, according to the direction of change of the magnetic field strength. The strength of a gradient refers to the rate at which its magnetic field changes with distance.

Radiofrequency System

The excitation of the nuclei is done with a short duration RF pulse close to or at the Larmor frequency of the nuclei. The desired frequency is produced by a frequency synthesizer. The receiver detects signals in the high and very high frequency (HF and VHF) range. The magnetic resonance signals are typically a few μV in amplitude.

Transmitter and Receiver Coils

The body part to be examined is placed inside a coil. Separate coils can be used for transmitting and receiving or a single coil can be used for both excitation and detection (transceiver coil). A coil is a winding of low-resistance wire, usually made of copper. Volume coils are used for large body parts. Surface coils are used to study small regions such as the eye. The advantage of surface coils is that their signal-to-noise ratio is better as the part is close to the coil. Surface coils can receive a good signal from the tissues within the depth of half its diameter.

COMMONLY USED PULSE SEQUENCES

Spin-Echo Pulse Sequence

In a spin-echo pulse sequence two RF pulses, i.e. 90° and 180°, are applied spaced by a time interval of TE/2. After the nuclei are excited by a 90° pulse, the spins dephase in the x′-y′ plane and this is followed by a refocusing 180° pulse. The faster spins lie behind the slower ones, but at time TE/2 they make up, thus producing an echo.

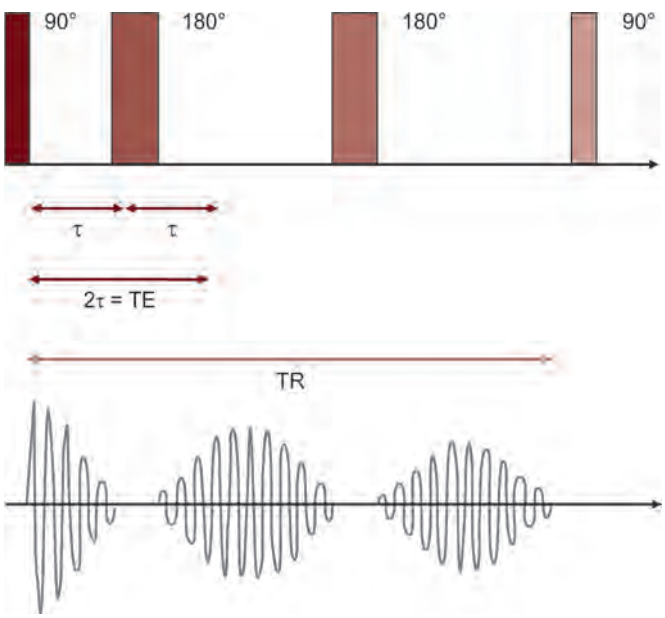

Fig. 18: Diagram of a spin-echo pulse sequence. The spin system is excited by a 90° pulse. After a time delay, one or several 180° pulses follow. This leads to the formation of an echo. The time between the 90° pulse and the peak of the echo is called echo time (TE). TR is the repetition time between two complete pulse sequences

The 180° pulse results in reversal of the phase of each spin. The position of the spins has not changed, so they will continue to rotate in the same direction. However, the 180° pulse causes the spins to return towards their starting point, rather than rotating further away from it. This 90°–180° pulse sequence is called spin-echo sequence (Fig. 18). By altering the echo delay time, and the sequence TR, the spin-echo sequence can be used to obtain T1, T2 or proton density images. The spin-echo sequence has been largely replaced by faster sequences such as fast spin echo and fast gradient recalled echo (GRE).

Gradient Echo Imaging

Gradient echo imaging is an imaging technique by which images can be acquired in much shorter times than conventional pulse sequences. The basic difference between spin-echo and gradient echo imaging is that gradient echo uses gradient reversals to get an echo, and spin echo uses 180° rephrasing pulse and gradient echo uses flip angle less than 90° (Fig. 19).

Inversion Recovery Imaging

The inversion recovery sequence uses a 180° inverting pulse, a 90° pulse and a rephrasing 180° pulse. The inversion time (TI) is determined by the TR and T1 of the tissue needed to be suppressed (Fig. 20). Commonly used inversion recovery pulse sequence are:

1. Fluid attenuated inversion recovery (FLAIR) whereby the cerebrospinal fluid (CSF) bright signal is suppressed. It is now a routinely used sequence in

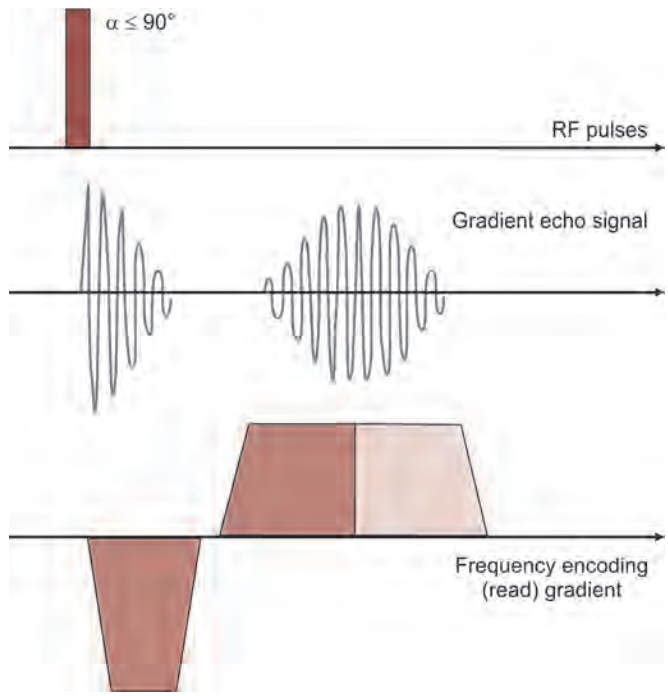

Fig. 19: Formation of a gradient echo. Instead of the 180° pulse, a gradient pulse (-G) is used followed by a second gradient pulse of opposite polarity (+G). In gradient echo sequence, the signal decay is determined by T2*, which is always less than T2

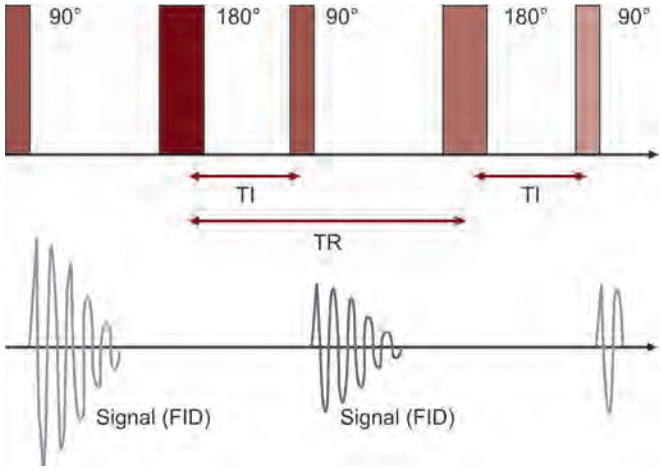

Fig. 20: Pulse sequence diagram of an inversion recovery pulse sequence. The 180° inverting pulse is followed by a 90° pulse and 180° rephasing pulse

brain imaging and especially to image periventricular plaques in multiple sclerosis.

2. Short tau inversion recovery (STIR) sequence is mainly used in imaging the optic nerves. It suppresses the orbital fat and highlights the lesions within the optic nerve, mainly in optic neuritis.

MAGNETIC RESONANCE CONTRAST

Most of the contrast agents in clinical use enhance tissue relaxation. Gadolinium is a rare earth element and toxic by itself, hence it is chelated with multi-dentate ligands for safety such as diethylenetriamine pentetate (DTPA) and tetraazacyclododecane tetraacetic acid (DOTA). It is a paramagnetic substance that shortens the T1 relaxation and hence makes the tissues with contrast appear bright.

Safety

- These contrast agents are considered safe with a rate of adverse reaction such as nausea and vomiting (1–2%) and hives (1%). Severe anaphylactoid reactions have been reported with an estimated rate of 1 in 200,000 and 1 in 400,000.
- These contrast agents can be safely used in children above 2 years.
- They should not be used in patients with compromised renal function. There have been cases reported of nephrogenic systemic fibrosis in patients with compromised renal function.
- Should not be used in pregnancy as its bioeffect on the foetus has not been established.

MAGNETIC RESONANCE ANGIOGRAPHY

Advantages of magnetic resonance angiography (MRA) versus catheter angiogram are:

- Non-invasive or minimally invasive
- Three-dimensional information can be obtained

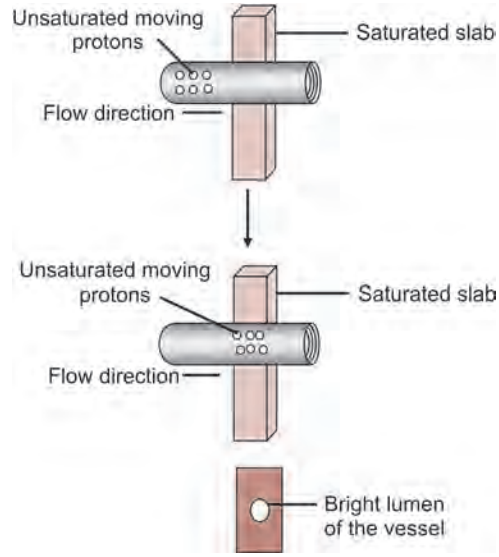

Fig. 21: Schematic representation of time-of-flight angiogram

- Can give surrounding soft tissue details

Disadvantages include:

- Flow dynamic information is lacking

Techniques of Magnetic Resonance Angiography

The commonly used techniques in clinical practice are:

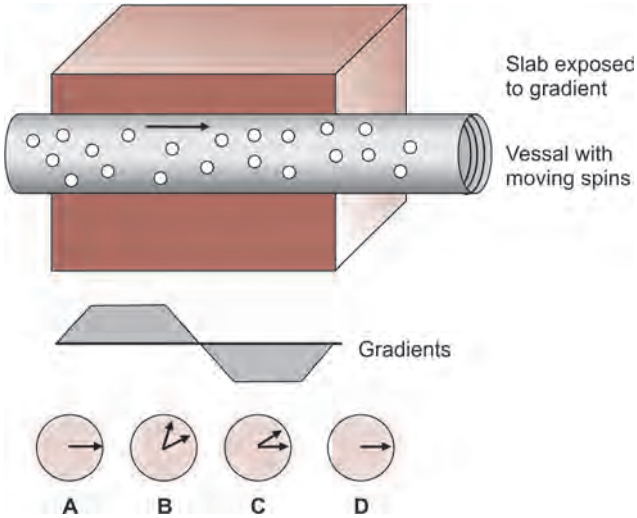
- Time-of-flight (TOF) MR angiogram
- Phase contrast (PC) MR angiogram
- Contrast-enhanced (CE) MR angiogram

Time-of-Flight Magnetic Resonance Angiogram

This is the most widely used MR angiography technique for imaging the intracranial circulation. It gives reliable vascular information without the need for intravenous contrast.

The basic principle involves suppression of the static background tissue and retaining the signal from the flowing blood. The saturation of the stationary tissue is done by using very short TR so that the stationary spins do not have enough time to regain their longitudinal magnetisation. The flowing (unsaturated) spins which enter the slice are unaffected by the slice selective RF pulse and will be fully magnetised producing a bright signal (Fig. 21). The signal produced is directly proportional to the velocity of the flowing blood. Flow saturation will occur when the spins in the imaging volume are not entirely replenished after each pulse.

The TOF angiogram can be obtained using 2-D or 3-D sequences. In a 2-D sequence, sequential thin sections are obtained whereas in 3-D a slab of tissue is excited. Each of them has their advantages and disadvantages. Two-dimensional angiograms are used to evaluate slow flowing blood, but are susceptible to turbulent flow. There is less spatial resolution. Three-dimensional angiograms have high spatial resolutions and are less susceptible to turbulent flow.



Figs 22A to D: Schematic diagram of a phase contrast MR angiogram. (A) Spins in the stationary tissue at time 0. (B) Spins dephasing after exposed to gradients. (C) Spins rephasing after switching off gradient. (D) Stationary spins rephased while moving spins are out of phase

Fig. 23: Contrast- enhanced time-resolved imaging of contrast kinetics angiogram image of the brain

Phase Contrast Magnetic Resonance Angiogram

Moving spins undergo a phase shift in the presence of paired opposing gradients. This phenomenon is utilised in phase contrast magnetic resonance angiogram (PC MRA) The amount of phase shift increases with increasing flow velocity. When the flowing blood (moving spins) moves along the direction of the gradient field, it precesses faster as the field increases and undergoes a phase change. Thus, the motion is phase encoded giving it both direction and magnitude (Figs 22A to D).

The amount of phase shift is directly proportional to the flow velocity, gradient strength and time interval between the gradient applications. By choosing an appropriate velocity encoding value (VENC), fast or slow flowing blood can be imaged. Phase contrast MRA can be acquired as both 2-D and 3-D sequences.

Advantages of phase contrast magnetic resonance angiogram: It gives:

- Flow quantification
- Flow direction
- Excellent background suppression
- Can be used for imaging areas of slow flow

Disadvantages of phase contrast magnetic resonance angiogram: The disadvantage is as follows:

- Long scan time.

Contrast-Enhanced Magnetic Resonance Angiography

The limitations of TOF and PC angiograms, such as flow saturation, flow-related artifacts, breathing and pulsation artifacts, made depiction of blood vessels in the body, especially the abdomen, difficult. By using intravenous contrast and rapid gradient imaging, it is now possible to obtain MRA images almost at par with conventional angiogram. The technique involves capturing of high magnetisation strength during the first pass of the vascular contrast, i.e. gadolinium, by appropriate timing using 3-D acquisition (Fig. 23).

Advantages: The advantages are as follows:

- Insensitive to saturation effects of the RF pulse as against TOF angiogram and therefore can cover vessels over a larger FOV.
- Useful in large aneurysms where flow is complex.

NEWER ADVANCED MAGNETIC RESONANCE IMAGING TECHNIQUES

Diffusion-Weighted Imaging

It is based on the principle of Brownian motion, which is dispersion or random translation of a molecule in a liquid due to thermal agitation.

Motion of molecules in biological tissues is complex. Neuronal tissue consists of tightly and coherently packed axons surrounded by glial cells. The movement of water molecules is hindered in a direction perpendicular to the orientation of the axonal fibres. Thus motion of molecules in biological tissues is anisotropic. The cell membranes are thought to be responsible for anisotropic diffusion rather than myelin. The restricted diffusion appears as a bright signal on diffusion-weighted images (Fig. 24).

Applications

- Stroke
- Multiple sclerosis
- Tumours
- Trauma
- Abscess

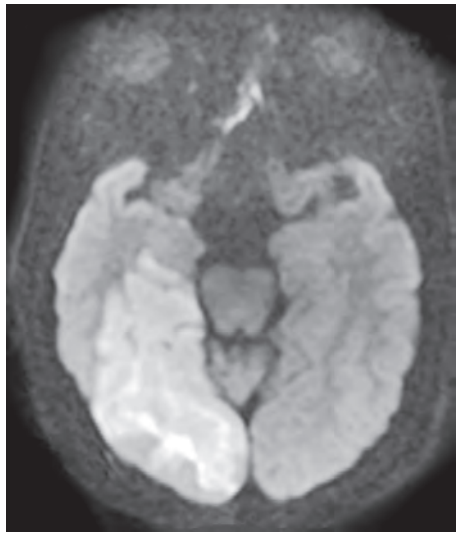


Fig. 24: Axial diffusion-weighted image showing restricted diffusion in the right occipital lobe suggestive of acute right posterior cerebral artery infarct

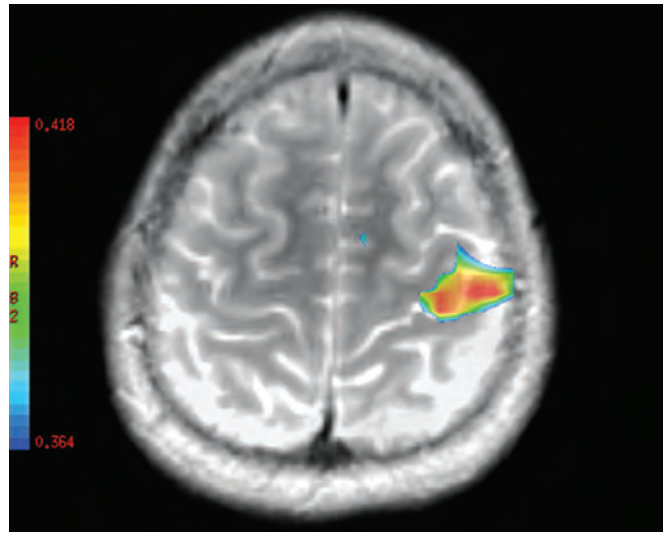

Fig. 25: MRI showing activation of the left motor cortex after right finger tapping

Lesions Bright on Diffusion Images

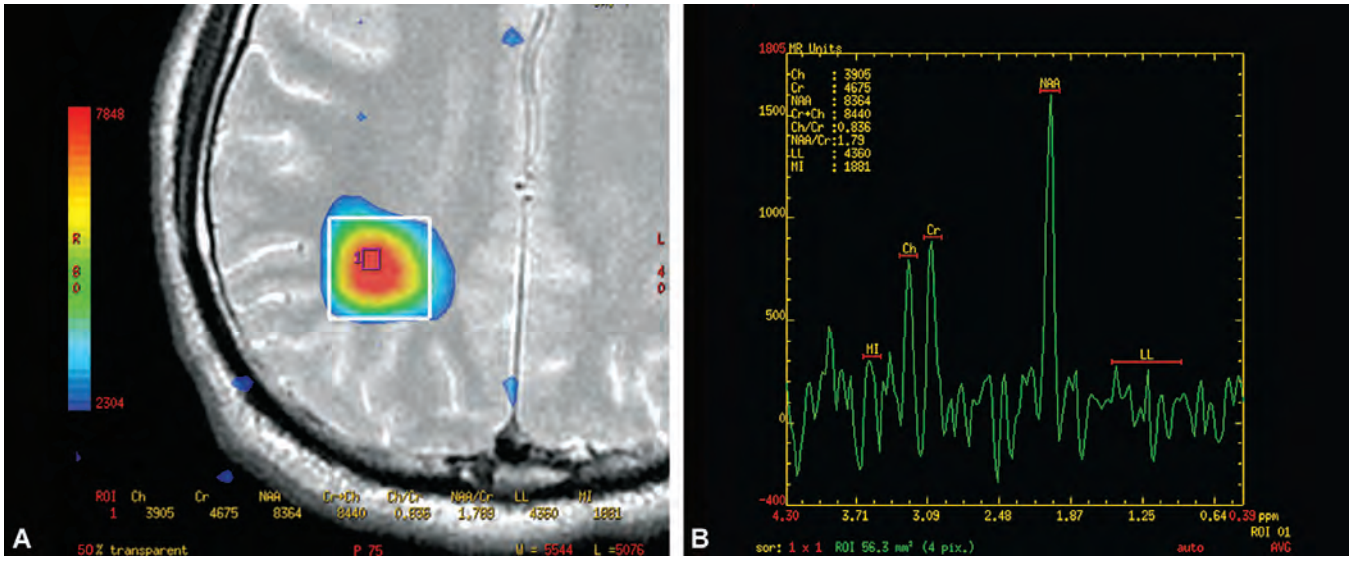
- Acute infarct
- Bacterial abscess
- Acute demyelination
- Epidermoid cyst
- Tissues with high cellularity
- Subacute haemorrhage

Functional Imaging

It is the demonstration of brain activation to a specific stimulus based on the functional anatomy of the brain, e.g. the primary visual cortex is activated using a flicker display or alternating checkerboard pattern as a visual stimulus. Once the brain is activated using a stimulus, there is change in the blood flow to the particular region due to the increased demand for oxygen and glucose. This increase in oxygen, i.e. deoxyhaemoglobin concentration causes local susceptibility effects which are used to receive the signals using appropriate pulse sequences. This is termed as blood oxygen level-dependent (BOLD) contrast imaging (Fig. 25).

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy utilises the differences in the resonance frequency of nuclei due to their different chemical bond. This is also termed as chemical shift imaging. The frequency difference varies with the magnetic field and is directly proportional to the external magnetic field. It is expressed in parts per million (ppm). The advantages of higher field strength, while performing spectroscopy, are that it provides better signal-to-noise ratio and better separation of metabolite peaks.



Figs 26A and B: Multi-voxel MR spectroscopy TE=1044 ms (A) Showing the voxel placed in the normal parietal white matter with NAA colour map. (B) Showing normal spectrum

1H (proton) spectroscopy is used for brain imaging as it is easy to perform and gives a better signal-to-noise ratio as compared to 23Na and 31P. Of all the atomic nuclei, 1H has the strongest response and is found in all biochemicals. MR spectroscopy thus provides details of the brain chemistry (Figs 26A and B). The spectrum is read from right to left and the metabolites detected on brain spectroscopy are:

- Lipid 0.9–1.4 ppm
- Lactate 1.3 ppm
- N-acetyl aspartate (NAA) at 2 ppm
- Creatine (Cr) 3.0 ppm
- Choline (Cho) 3.2 ppm
- Myo-inositol 3.5 ppm

The TE affects the metabolites detected, thus short TE ~30 ms shows metabolites with short and long T2 relaxation times and with long TE ~ 270 ms only metabolites with long T2 relaxation times are detected, therefore the spectrum primarily consists of NAA, Cr and Cho. Another advantage of long TE ~ 144 ms is that the lactate peak at 1.3 ppm gets inverted. Rather than absolute concentrations, one should rely on the various ratios to give a clinical diagnosis.

Ratio	Normal	Abnormal
NAA/Cr	2.0	< 1.6
NAA/Cho	1.6	< 1.2
Cho/Cr	1.2	> 1.5

Indications

- Tumours
- Radiation necrosis versus recurrence
- Infections
- Neurodegenerative disorders
- Metabolic brain disorders
- Stroke

Magnetic resonance spectroscopy should be carefully interpreted and correlated with MR images to make a final diagnosis.

11 Radiology: Intracranial Tumours

Kesavdas

IMAGING MODALITIES

In the management of patients with suspected or confirmed intracranial tumours, imaging of the brain is often indicated at different stages and usually has a significant role in each of them. The role of imaging includes localisation and assessment of the extent of abnormality, characterisation of the abnormality, distinction of neoplasms from non-neoplastic processes, assessment of the nature of tumour, planning for surgery or other types of therapy, intra-operative control of resection progress and finally monitoring of response to therapy.

Computerised tomography (CT) is a good screening method for the demonstration of supratentorial abnormalities, because it is accurate and the imaging method, most often available. It takes a much shorter time and is less costly. It is superior in depicting the presence of calcification and bone abnormalities such as destruction, erosion, penetration and hyperostosis. However, imaging of posterior fossa lesions is limited due to bone artifacts. The definition of the extent of oedema is poor and the neuroanatomical depiction is poor in comparison to magnetic resonance imaging (MRI).

MRI has a higher sensitivity in the demonstration of oedema and is better for earlier detection of tumours. It gives a more accurate definition of the extent of surrounding oedema and mass effect. Brainstem structures are better identified. It gives a better characterisation of brain tumours and hence is extensively discussed in this section. Along with the advanced techniques (discussed below), MRI has become the most useful pre-operative imaging tool.

Intra-operative ultrasonography is useful in real-time update for the detection of brain and/or tumour shift during surgery. It is inexpensive compared to intra-operative magnetic resonance (MR) imaging. Both these techniques are being used by neurosurgeons for image-guided surgical procedures and have led to improved surgical results. Positron emission tomography imaging of brain tumours with F-18-fluorodeoxyglucose is helpful in prognostic stratification of patients and detection of early tumour recurrence following surgery and radiation/chemotherapy.

APPROACH TO BRAIN TUMOURS

Intracranial tumours must be analysed considering the patient's age and in recognising the most frequent histologies that occur in various age groups. Approximately 15–20% of all intracranial tumours, mostly primary lesions, occur in children below 15 years of age. A higher proportion of paediatric intracranial tumours occur in the posterior fossa. A tumour in the cerebellum in the elderly is usually a metastasis. The histologic spectrum and location of intracranial tumours vary considerably between children and adults. The specific location of the mass becomes equally important in imaging analysis because certain types of intracranial tumours tend to occur with a higher frequency in specific locations. Accurate compartmentalisation of the mass will limit the differential diagnosis to a few relevant possibilities.

The radiologist must first determine whether the mass arises from within the brain parenchyma (intra-axial) or from outside the brain parenchyma (extra-axial, in which case symptoms are usually due to compression of subjacent brain). Intra-axial tumours are twice as common as extra-axial tumours. Radiologic clues that a tumour is extra-axial include:

- Widening of the ipsilateral subarachnoid space
- Cerebrospinal fluid (CSF) cleft between the mass and the brain parenchyma
- Deviation of pial vessels between the mass and the brain tissue
- Buckling of the grey matter (GM)/white matter (WM) junction
- Broad base along the dural or calvarial surface
- Adjacent bony changes such as hyperostosis in meningioma or erosion in acoustic neurinoma.

The prognosis and treatment of intracranial tumours are highly dependent on tumour histology. The signal characteristics of the tumour may provide clues about its histology. Tissue characterisation is better possible with MRI than CT. However, the latter is definitely better in showing calcification within the tumour. Histologic features, such as calcium and fat, are readily identified on cross-sectional imaging. T1 hyperintensity

in MRI may represent haemorrhage (methaemoglobin), melanin (in metastatic melanomas), fat, calcification or slow vascular flow. Haemorrhage within a tumour is usually seen in glioblastoma multiforme (GBM), anaplastic oligodendroglioma, ependymoma, etc. Metastases from renal cell carcinoma, choriocarcinoma, breast carcinoma, melanoma, lung carcinoma and thyroid carcinoma may have associated haemorrhage. T2 hypointensity may represent haemorrhage (haemosiderin), calcification, proteinaceous material or flow. Cell composition and relative water content are suggested by imaging. Tumours that show CT hyperdensity and T2 hypointensity often have high nucleus-to-cytoplasm ratios with decreased relative water content. This is suggestive of densely cellular tumours such as lymphoma, primitive neuroectodermal tumour (PNET)/medulloblastoma, pinealoblastoma, metastases from adenocarcinoma/prostate and, sometimes, meningioma. Tumours, such as GBM and higher grades of glioma, metastases and lymphoma in an immunocompromised patient may show necrotic areas within the tumour. Hypervascular tumours, such as GBM, haemangioblastoma and metastases from renal cell carcinoma, may show flow voids within the lesion.

Compressive effects on adjacent brain tissue, extent of vasogenic oedema, accompanying the mass and obstructive hydrocephalus are easily and non-invasively assessed. Intravenous contrast agents augment lesion conspicuity and reveal enhancement characteristics that can help improve specificity. Enhancement reflects the breakdown of the blood-brain barrier (BBB), which is normally absent in structures such as the pituitary gland, pineal gland, choroid plexus and meninges. Several criteria are important for the differential diagnosis of brain tumours: signal contrast with normal brain, tumour structure, the presence or absence of tumour margins, extent of perifocal oedema, indirect tumour signs, relation of tumour to blood vessels, richness of tumour blood supply and degree of contrast enhancement.

ADVANCED NEUROIMAGING OF BRAIN TUMOURS

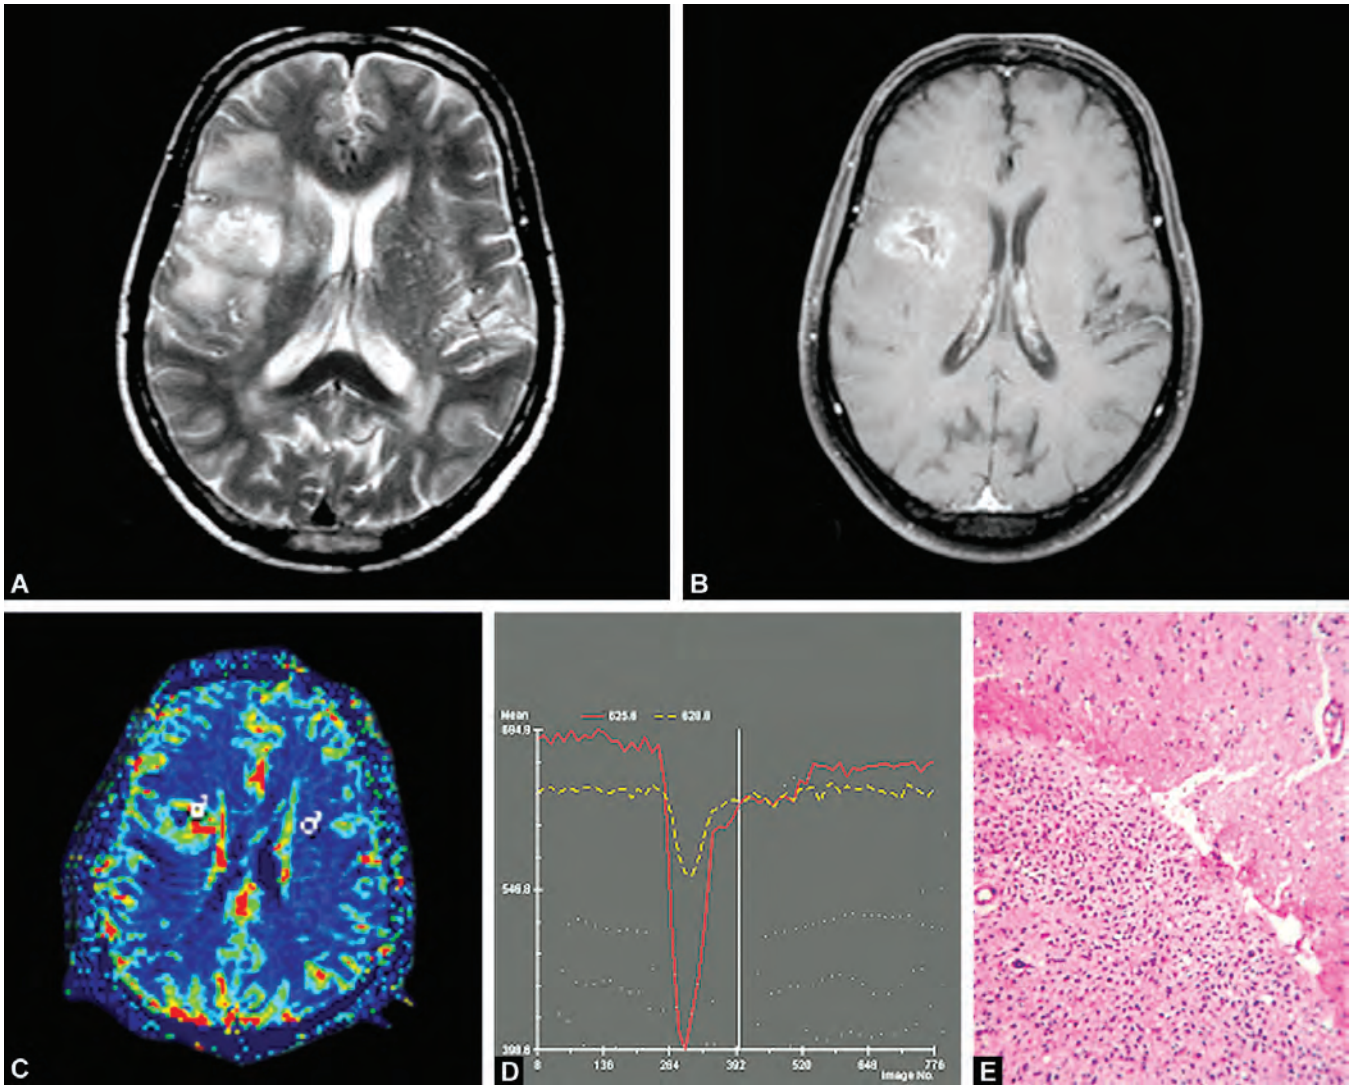
The imaging of brain tumours has significantly improved with the use of advanced MR techniques such as perfusion, spectroscopy, functional imaging, diffusion tensor and conventional MR imaging (MRI) provides mainly anatomical or structural information about the brain. Unlike conventional imaging, advanced MR techniques also provide physiological information concerning metabolism and haemodynamics.

Perfusion Imaging

Brain tumours can induce angiogenesis or the formation of new blood vessels. Hypoxia occurs as the tumour, which outgrows its blood supply, can produce angiogenic cytokines; these cytokines are responsible for angiogenesis.[21] Tumour vessels that are produced in this manner are histologically abnormal and more permeable than normal. They are also disorganised and tortuous. These vascular abnormalities and altered flow dynamics lead to changes in blood volume and flow, which are seen in MR perfusion images. The most frequently used measure of perfusion is the cerebral blood volume (CBV). The CBV (or the volume of blood passing through a portion of the brain) is measured in millilitres of blood per 100 grams of brain tissue (ml/100 g).

The most common perfusion technique is T2 dynamic susceptibility imaging.[4] The T2 effects of gadolinium result in decreased signal intensity during the passage of gadolinium. The change in signal intensity is plotted against time to form a signal intensity time curve. The CBV is estimated from the area encompassed by the curve, which is inverted in this case, since there is signal loss. Repetitive imaging is performed shortly before, during and after the passage of gadolinium. Generally, 0.2 mmol/Kg of gadolinium is injected at a high rate using a power injector. The CBV is normalised to uninvolved portions of the brain. The cases in which an arterial input function is not determined, only a relative CBV (rCBV) can be calculated. Dynamic susceptibility perfusion imaging is based on the premise that contrast material remains within the intravascular compartment. High permeability or leaks in regions of marked breakdown of the BBB results in intravascular gadolinium extravasating into the interstitial space. Extravasation can significantly affect calculations and alter CBV values. Using T1-weighted dynamic perfusion imaging, one can eliminate the problem with the breakdown of the BBB and permeability.[3,17,18] In this technique, tumour enhancement or transendothelial permeability is measured using the *Ktrans* parameter.

In general, high-grade brain tumours have greater rCBV than low-grade lesions (Figs 1A to E).[14] MR perfusion can help identify and localise higher grade components of a tumour for guiding stereotactic biopsy and can also provide a non-invasive estimate of tumour grade. Since the enhancing or even the T2 borders of gliomas do not represent the true margins of the tumour, MR perfusion can be more sensitive in defining the true extent of a glioma than anatomic MR imaging. Better delineation of tumour borders can help in radiation and surgical planning. In the future, MR perfusion imaging will probably play a role in better defining tumour margins for radiation and surgical planning. Differentiating tumour recurrence from radiation necrosis is a problem that clinicians and radiologists face frequently. The advantage of MR perfusion CBV data is its high positive predictive value for the presence of high-grade malignancy. In other words, if the CBV maps reveal elevated perfusion, it indicates the presence of a tumour. The specificity of the diagnostic task can be increased when perfusion imaging is combined with MR spectroscopy.



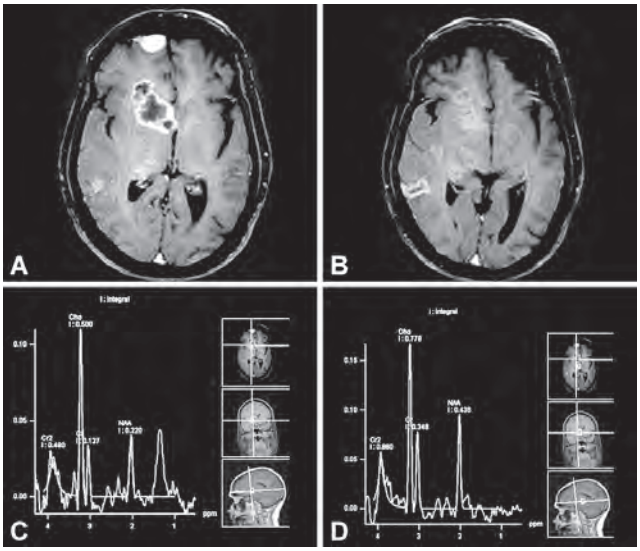
Figs 1A to E: (A) Axial T2-weighted image shows a hyperintense mass with surrounding oedema in the right frontal lobe. (B) Post-contrast axial T1-weighted image shows enhancement of the lesion except in the central area. (C and D) rCBV map and time intensity curve of the T2* dynamic susceptibility weighted perfusion imaging shows increased CBV within the lesion. (E) Haemotoxyline and Eosin staining of the resected mass lesion was suggestive of glioblastoma multiforme

Spectroscopy

Clinical applications of proton magnetic resonance spectroscopy (1H-MRS) are increasing as the techniques and hardware have become more robust and user-friendly. Proton MRS provides biochemical and metabolic information about tumours and normal brain. Spectroscopy can be done in single or multi-voxel (MRS imaging) forms. The two most commonly used methods for volume selection/excitation are stimulated echo acquisition mode and point-resolved spectroscopy sequence.

The advantage of single-voxel 1H-MRS is its short acquisition time (approximately 5 minutes). The downside is that it lacks spatial resolution and cannot be used to better define the true extent of a glioma. Histologically, gliomas are heterogeneous and, therefore, single-voxel spectroscopy cannot be used to map regional metabolic variation. In the spectroscopy literature, the most commonly used echo times are 144 msec and 270 msec. At these long echo times, the spectrum is dominated by five different metabolite peaks: choline (Cho)-containing compounds; creatine (Cr); N-acetylaspartate (NAA); lactate and lipid. The choline peak reflects cell membrane turnover. Creatine is a good surrogate for energy synthesis, and NAA is a marker that is exclusive to neuronal cells. Lactate results from anaerobic metabolism and is detected in necrotic tumours and infarcted tissue. Cellular and myelin breakdown products result in prominent lipid peaks. In tumours, choline-containing compounds are increased, and NAA is decreased relative to uninvolved or normal brain tissue. This pattern of metabolic change is the spectroscopic hallmark of brain tumours.

Combined with MRI, MRS can aid in the evaluation of tumour type and grade.[11] The higher-grade gliomas tend to exhibit higher Cho/Cr and Cho/NAA ratios (Figs 2A to D). The high-grade gliomas also tend to have lipid and lactate as the result of necrosis. MR spectroscopy can help differentiate enhancing tumour



Figs 2A to D: (A and B) Axial post-contrast images show a peripheral enhancing mass lesion close to the right frontal horn with central area of necrosis. Enhancing lesions are also noted in the right thalamus and surrounding parenchyma. (C and D) Multi-voxel spectroscopy (TE: 135) reveals elevated choline in the mass and the surrounding parenchyma suggesting spread of the lesion in the surrounding parenchyma. Pathological diagnosis was GBM

from other causes of enhancement (mainly necrosis) and is more specific in differentiating non-enhancing tumour from oedema and other causes of T2 prolongation. These qualities have been exploited in order to better define the true extent and morphology of gliomas. MR spectroscopy is utilised more and more by different groups in assessing response to therapy in patients with primary brain tumours or metastases. MR spectroscopy can non-invasively enable the distinction between a solitary metastasis and high-grade gliomas, particularly when combined with perfusion MR imaging.

Functional Magnetic Resonance Imaging

Functional MRI (fMRI) provides activation maps that reflect haemodynamic variations related to neuronal activity and identify the eloquent cortex. Blood oxygen level-dependent (BOLD) imaging examines changes in local tissue oxygenation to exploit the magnetic property changes of haemoglobin as an intrinsic contrast agent. An increase in brain activity causes an increase in oxygen consumption and an over-compensatory increase in regional cerebral blood flow (CBF), with a net effect of increased diamagnetic oxyhaemoglobin and decreased paramagnetic deoxyhaemoglobin. Paradigms may be tailored for language, speech, comprehension, memory and motor testing. Pre-operative fMRI may be used to better determine the relationship between tumour margins and the eloquent cortex, interrogate the supplemental cortex or test bilateral haemispheres (Fig. 3).[12] Another technique that is coming up for mapping the eloquent cortex is magnetic source imaging

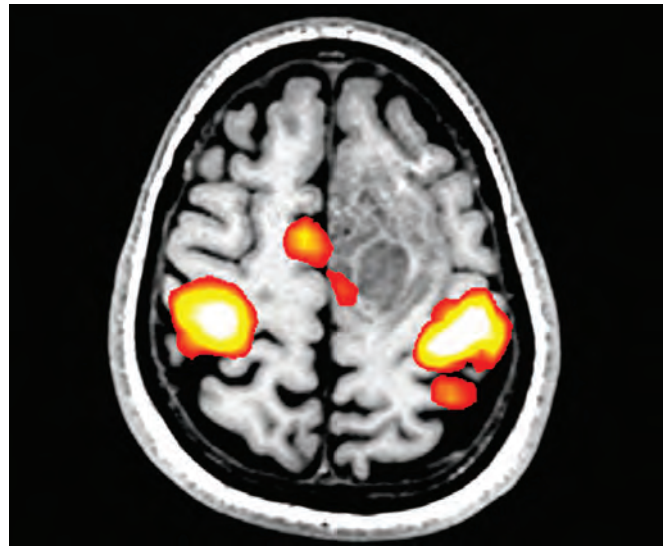


Fig. 3: Real-time blood oxygen level-dependent functional MRI done during bilateral hand movement shows the relation of the tumour with the primary motor hand area. Note the supplementary area is placed very close to the lesion

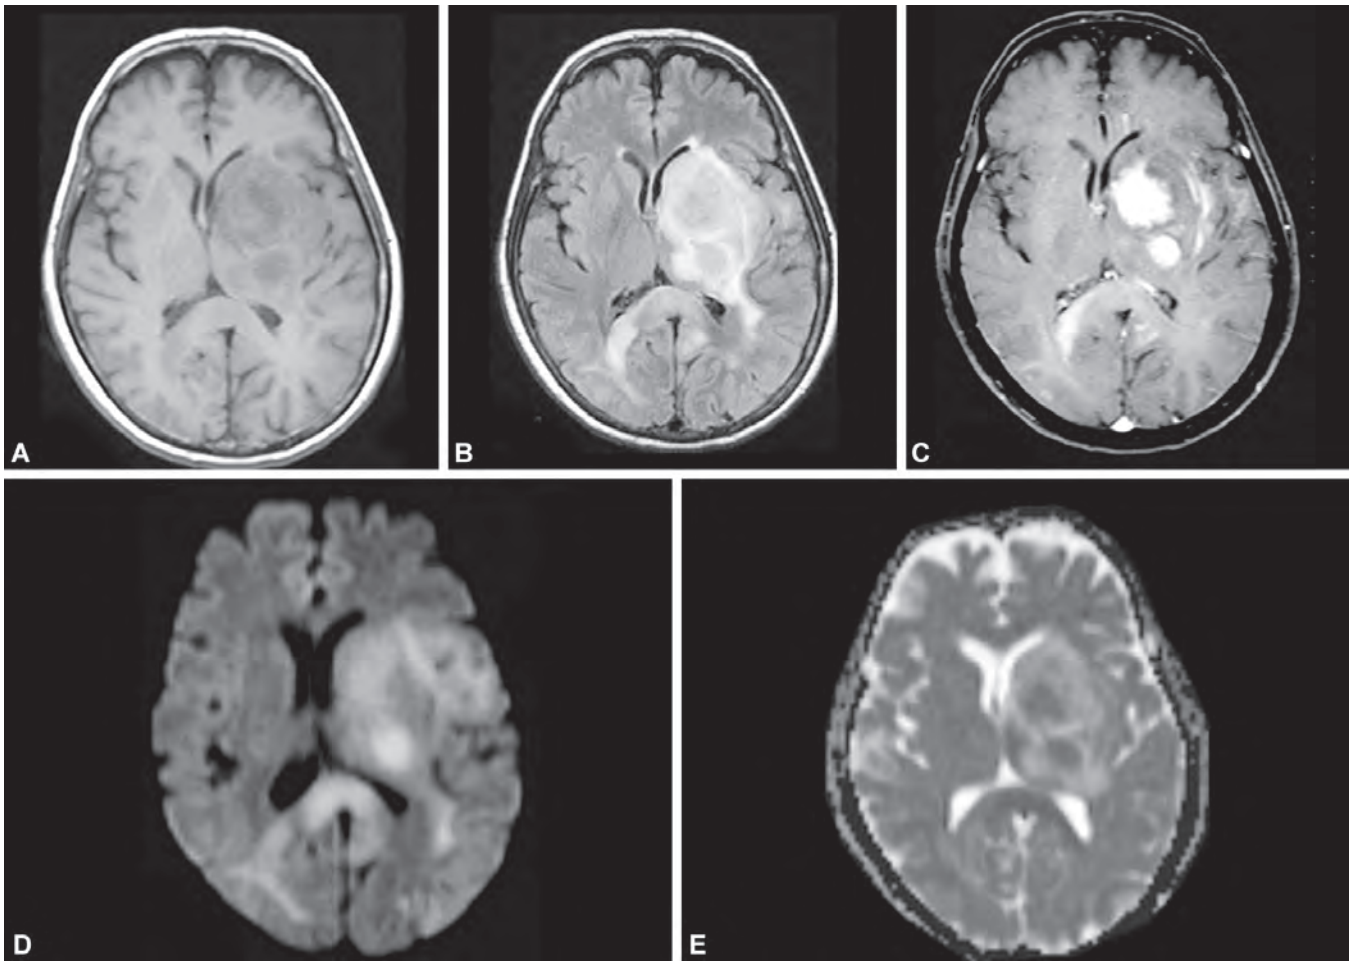
where the information from magnetoencephalography is combined with MRI.

Diffusion Weighted Imaging and Diffusion Tensor Imaging

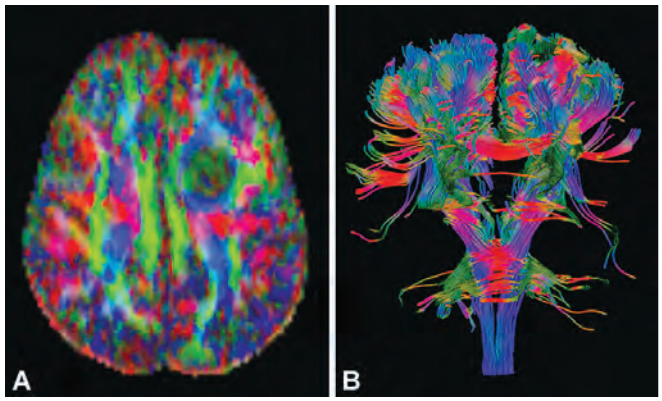
Diffusion weighted and diffusion tensor imaging is an MRI technique that is sensitive to directional movements of water molecules and that allows the identification of functional WM tracts *in vivo*. Diffusion weighted imaging can give information about the cellularity of the tumour (Figs 4A to E) and can also differentiate infective brain abscess and a necrotic tumour which may both look alike in the conventional MRI.[2] Diffusion tensor imaging has the potential to establish spatial relationships between eloquent WM and tumour borders and provide clinically valuable information to assess the progression and regression of WM tracts as a result of tumour growth or resection (Figs 5A and B). There are two main reasons why pre-operative identification of WM tracts is important. First, accurate localisation of important WM tracts can affect the decision of whether or not to operate. Secondly, pre-operative localisation of important WM tracts is essential in surgical planning.

In GM, it is usually sufficient to characterise the diffusion characteristics with a single apparent diffusion co-efficient (ADC), because measured water diffusivity is largely independent on the orientation of the tissue. However, in an anisotropic area, such as white matter, where the measured diffusivity is known to depend upon the orientation of the tissue, a single ADC is not able to describe the orientation-dependent water mobility in the tissue. Diffusion tensor imaging, which is based on the orientation-dependent water diffusion, can be obtained using a single-shot diffusion-weighted (DW) spin-echo



Figs 4A to E: (A to C) Axial T1-weighted, axial FLAIR and post-contrast T1-weighted images show a T1 isointense, FLAIR hypointense and intensely enhancing mass lesion in the left basal ganglia and thalamus. (D and E) Diffusion weighted image and ADC map show restricted diffusion within the lesion suggesting high cellularity. The lesion was proved to be a primary CNS lymphoma

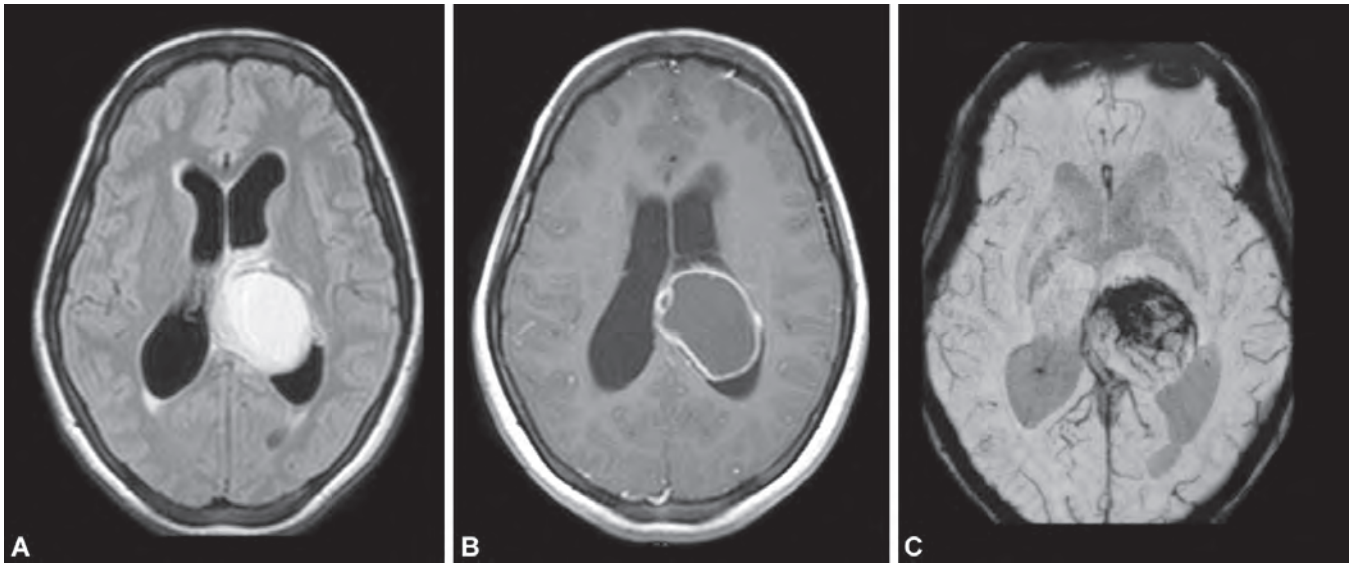
echo-planar imaging (EPI) pulse sequence, in which two symmetric trapezoidal gradient pulses are added around a 180° re-focusing pulse in the required gradient channel. Sets of DW-EPI images are collected with diffusion gradients applied sequentially along three directions for diffusion weighted imaging (DWI) and at least six predetermined directions for DTI. In DTI, the elements of the tensor obtained are used to yield a mean diffusivity map (D) and the fractional anisotropy (FA). Previous studies have shown that neoplasms and surrounding oedematous brain have an increase of free water fraction (high D value) and loss of structural organisation (reduced FA value).[16] A number of recent developments have led to a new application of DWI termed diffusion tractography. This application uses diffusion tensor data to identify specific white matter tracts as opposed to white matter tracts in general.



Figs 5A and B: (A) Fractional anisotropy map. (B) Fibre tracking in a patient with glioma demonstrate displacement of white matter tracts

Susceptibility Weighted Imaging

Susceptibility weighted imaging (SWI) is a sequence that is sensitive to T2 effects. It uses magnitude or phase images, the combination of the two image sets, obtained with a three-dimensional, fully velocity-compensated, gradient echo sequence. SWI has exquisite sensitivity to the venous vasculature, blood products and changes in iron and calcium content. In tumour imaging, it has a role in picking up micro-haemorrhages and the venous vasculature within the tumour (Figs 6A to C).[20]



Figs 6A to C: (A) Axial FLAIR image shows a hyperintense mass lesion. The mass is in the left thalamic region and is seen extending to the level of the left lateral ventricle. (B) Post-contrast T1-axial image shows enhancement of the periphery. (C) Susceptibility weighted image shows bleeds within the mass lesion. Pathological diagnosis was high grade glioma

SPECIFIC TUMOURS

Glioma

Astrocytomas are the most common primary intra-axial masses in adults. According to the World Health Organisation (WHO) three-tier classification scheme, grade I tumours are either pilocytic or fibrillary. These are diffusely infiltrative tumours that may show CT hypodensity and very mild T1 hypointensity with T2 hyperintensity in MRI and usually no enhancement. Grade II tumours are anaplastic with evidence of vascular hyperplasia and mitotic figures. They have an aggressive appearance with prominent enhancement and mass effect. Grade III tumours are GBM with areas of necrosis and haemorrhage, and are highly aggressive tumours that have outgrown their own blood supply. De-differentiation from lower to higher grade tumours is usually associated with contrast enhancement.

Pilocytic astrocytomas are histopathologically distinct from the more infiltrative low-grade astrocytomas. Patients usually present at less than 1 year of age (80% at less than 20 years). Nearly two thirds of these tumours arise from the cerebellar hemisphere with a dominant cyst and avidly enhancing mural nodule. Most of the remaining tumours occur in the hypothalamic-optic region. On MRI, the solid component shows T1 isointensity to hypointensity and T2 hyperintensity, while the cystic component shows T1 hyperintensity relative to CSF. Elevated protein in the cyst fluid may cause slight T1 hyperintensity to CSF.

Brainstem gliomas account for 1% of tumours in adults and 10–20% of tumours in children. MR shows T2 hyperintensity with mass effect and variable enhancement, which does not correlate with prognosis. Diffuse brainstem gliomas are the most common, at 58–75%. These are usually fibrillary astrocytomas that are centred at the pons and show ill-defined margins, T2 hyperintensity and mass effect. Focal tumours of the mid-brain, medulla and cervicomedullary junction have distinct margins, may be solid and/or cystic, and usually do well after aggressive resection, which is easier to perform for dorsal or lateral exophytic tumours.

Oligodendrogliomas

These tumors originate from the oligodendroglia. CT demonstrates calcification in more than 80% of cases. The tumours tend to be subcortical in location with T1 hypointensity and T2 hyperintensity. Similar to the more common astrocytomas, oligodendrogliomas vary from low grade to high grade.

Glioma Tumour Evaluation to Differentiate Low and High Grade Tumours

In terms of predicting a high grade glioma (HGG), conventional imaging has 73% sensitivity, 65% specificity and 44% negative predictive value (NPV) as compared to perfusion MRI, which achieves 95% sensitivity, 57% specificity and 79% NPV.[14] MR spectroscopy using Cho/Cr and Cho/NAA can also help predict HGG, although their addition may not improve the utility of perfusion MRI. Given the inherently heterogeneous nature of these tumours, one can use CBV maps to guide stereotactic biopsy of the area of maximal angiogenesis to target the highest-grade portion rather than rely on contrast enhancement, which only reflects BBB breakdown. During chemotherapy and radiotherapy, rCBV values have been shown to correlate better with a patient's clinical course than conventional images, and perfusion MRI has shown similar success in patients treated with anti-angiogenic agents.[1] Perfusion MRI may be able

to better predict outcome in patients with low grade tumours (LGGs).

Evaluating Peri-tumoural Region to Differentiate Metastases from Primary Tumour

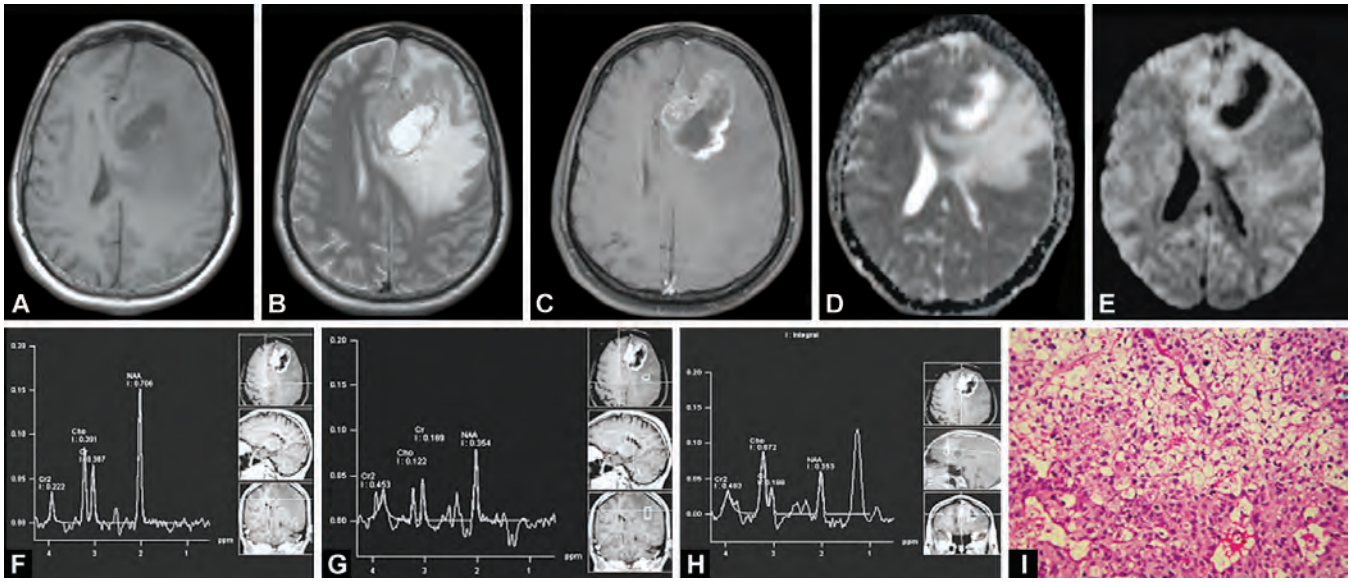
The peri-tumoural region of metastases represents vasogenic oedema caused by increased interstitial water (Figs 7A to I), in contrast to the peri-tumoural region of gliomas, which consists of tumoural infiltration into the brain parenchyma and accompanying neovascularity beyond the contrast-enhancing margins of the tumour (Figs 1 and 2). Due to the presence of these infiltrating tumour cells, peri-tumoural perfusion MRI and MR spectroscopy of gliomas as compared to metastases show increased rCBV and increased Cho. Peri-tumoural MD (mean diffusivity) of metastases is greater than that of HGGs, probably because of the contribution of infiltrating tumour cells to the glioma peri-tumoural signal abnormality. Primary brain tumours are infiltrative by nature, and perfusion MRI/MRS of normal-appearing brain tissue beyond the peri-tumoural region of T2 hyperintensity may also show hyperperfusion and abnormal metabolites related to tumour cells.[5,15]

Gangliogliomas

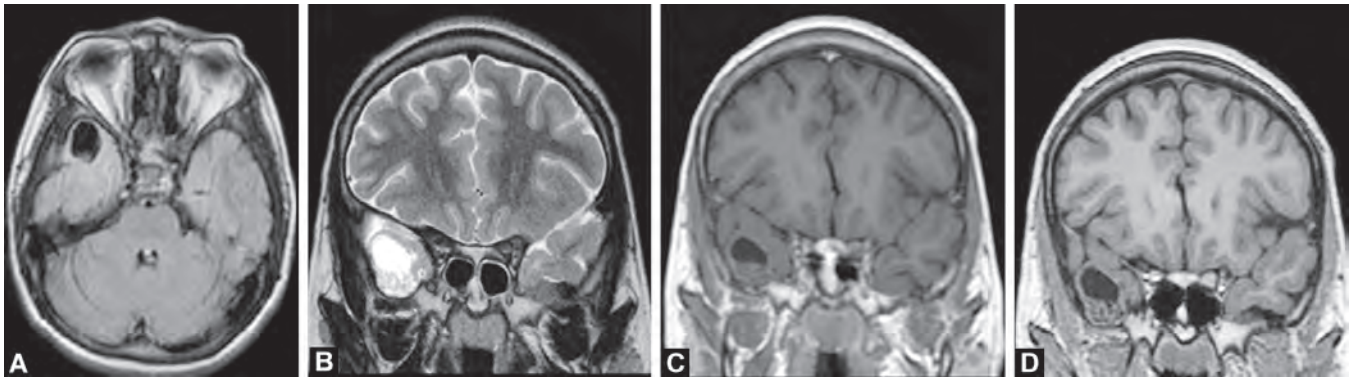
Gangliogliomas are mixed tumours whose cells originate from both glial and neuronal lines. They tend to be of low grade and have a good prognosis, although some may have more aggressive features and de-differentiation into higher-grade lesions. The lesion is usually cortical, especially in the temporal lobes. These are slow-growing tumours with a longstanding course, which may result in thinning of the overlying bony calvarium (Figs 8A to D). Tumours may also present in the brainstem. They are commonly cystic well-delineated lesions which may also have a solid component. They appear homogeneously hyperintense on T2-weighted images. CT in these tumours is of value in picking up calcification alone.

Meningioma

Meningioma is the most common extra-axial neoplasm of adults, representing 20% of all primary intracranial tumours. These are twice as common in females and occur most often in middle-aged patients. Meningiomas originate from neoplastic meningothelial (arachnoid cap) cells, and their distribution parallels that of the cap cells, which are most abundant in arachnoid granulations. Predispositions to meningioma development include neurofibromatosis type 2, familial susceptibility, hormonal factors and previous ionising radiation. Common sites are the parasagittal and convexity dura, sphenoid ridge, and parasellar and cerebellopontine angles. Parasagittal meningiomas have a propensity to invade the dural venous sinuses and cavernous sinus meningiomas cause encasement and narrowing of the internal carotid arteries. The varying histologic types and composition lead to some variability in imaging features. The majority of histopathological subtypes are benign (80–90%); atypical (5–15%) and anaplastic/malignant (1–3%) grades are uncommon.[13] Recurrence is likely after incomplete surgical resection and with atypical or anaplastic pathology. Calcification can be detected by CT in roughly 20% of cases. There may be a bony reaction in the adjacent skull, usually hyperostosis due to stimulation of a bony reaction

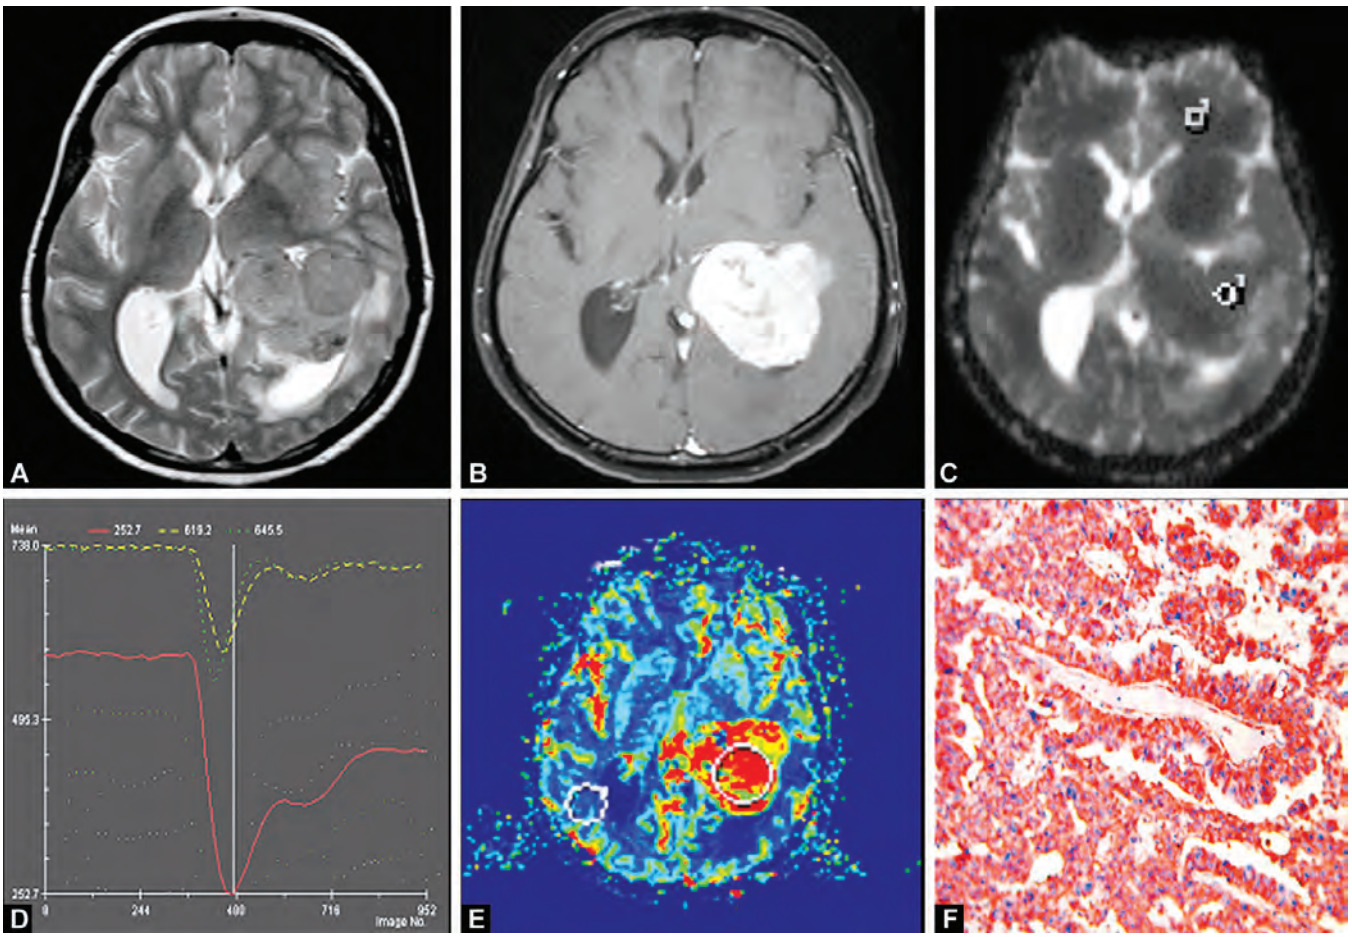


Figs 7A to I: (A) Axial T1-weighted image shows a hypointense mass lesion with central necrotic area. (B) Axial T2-weighted image shows hypointense peripheral area which in post-contrast image. (C) Shows enhancement. (D and E) ADC map and diffusion images show that the necrotic area has facilitated diffusion while the surrounding area has restricted diffusion. (F) Multivoxel spectroscopy (TE: 135) from a normal area in the opposite hemisphere shows normal spectrum. (G) Spectrum from the surrounding oedema does not reveal raised choline. A small inverted lactate is seen. (H) Solid area of the tumour shows raised choline and lipid. (I) H and E staining of the resected mass shows the lesion to be a metastasis from squamous cell carcinoma



Figs 8A to D: Patient with longstanding intractable epilepsy. (A) Axial FLAIR image shows a well defined cystic lesion in the right temporal lobe. (B) Coronal T2-weighted image shows the solid areas within the tumour. A bony scalloping of the temporal bone is also noted. (C and D) Coronal post-contrast images do not reveal enhancement within the lesion. The lesion was a ganglioglioma

through growth into the Haversian canals, and less frequently to bone destruction. They show T1 and T2 isointensity relative to the cortex. Enhancement is usually relatively homogeneous with occasional cystic components, areas of necrosis or calcification. Oedema in the brain adjacent to a meningioma is variable and more frequent in larger lesions. Demonstration of indistinct tumour margins with adjacent brain parenchyma should suggest more aggressive tumours. Perfusion MRI shows hypervascular tumours (Figs 9A to F) with greater elevations of the endothelial permeability constant *Ktrans* in atypical and anaplastic meningiomas as compared to typical meningiomas.[23]



Figs 9A to F: (A and B) Axial T2-weighted image and post-contrast image show a T2-hypointense mass lesion enhancing intensely after contrast administration. (C) Restricted diffusion is noted within the mass. (D and E). Time intensity curve and rCBV map shows marked increase in rCBV. (F) The pathological diagnosis was papillary meningioma

Choroid Plexus Papillomas

Choroid plexus papillomas and carcinomas may be present at birth, and the former is twice as common as the latter. In children, these tumours are typically located in the trigone of the lateral ventricles, usually on the left side. In adults, they are more common in the fourth ventricle. The tumours have fine, lobulated or papillary margins. They are homogeneous with mild T2 hyperintensity, although they may contain focal hypointensities from calcifications or enlarged flow voids from branches of the anterior and posterior choroidal arteries. Although hydrocephalus may occur due to tumour overproduction of CSF, it more commonly occurs due to mass effect and mechanical obstruction, similar to other intraventricular tumours.

Central Neurocytomas

These are heterogeneous masses with cystic areas, calcifications and haemorrhage. These tumours show neuronal differentiation and tend to occur in young patients at the age of 20–30 years. These tumours were previously mistaken for intraventricular oligodendrogliomas, and are characteristically attached to the septum pellucidum and located in the body of the lateral ventricle (Fig. 10). They have a well-circumscribed smooth or lobulated margin with solid and cystic components and heterogeneous enhancement.

Chordomas

Chordomas arise from remnants of the primitive notochord. These tumours are most common in the sacrum (50%), with intracranial tumours occurring almost exclusively in the clivus (35%). They are benign, but locally aggressive tumours that destroy bone and may grow into the nasopharynx, parasellar region, or pre-pontine cistern.

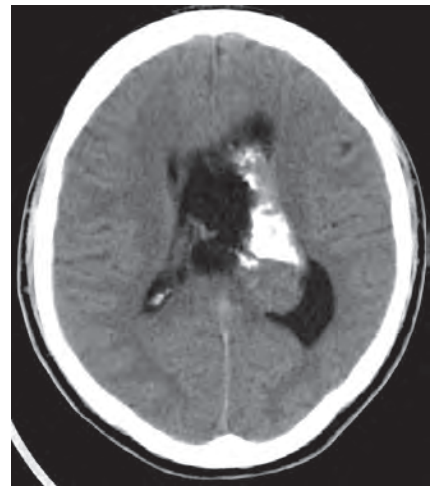


Fig. 10: Contrast CT shows a mass lesion within the left lateral ventricle extending below to the level of foramen of Monroe (not shown). The lesion shows calcification and cystic areas and minimal peripheral enhancement. The lesion proved to be a central neurocytoma

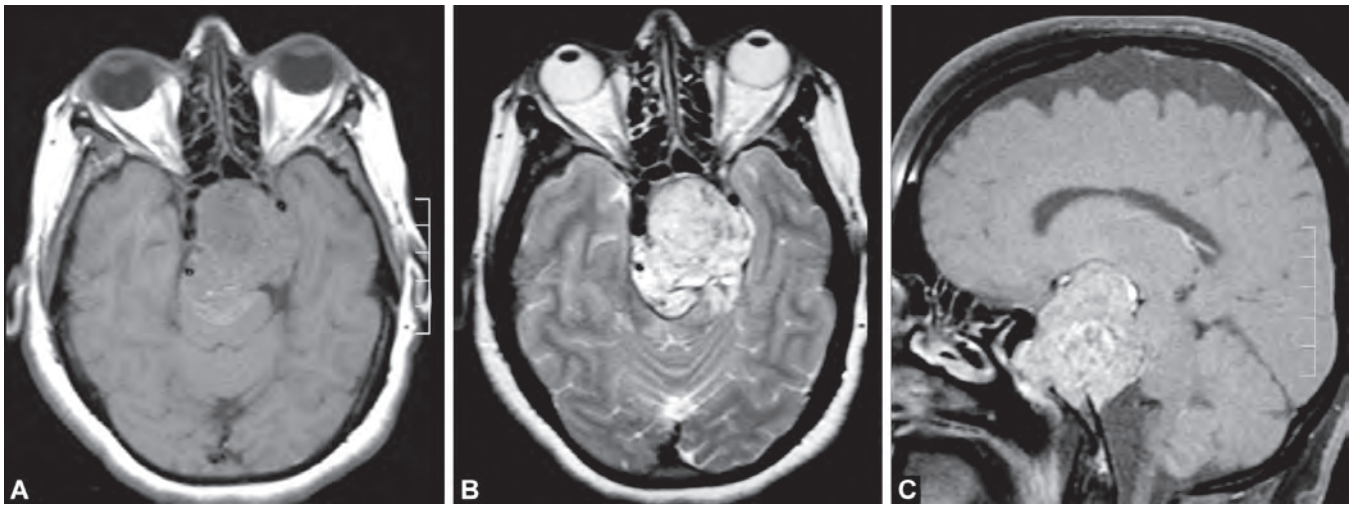
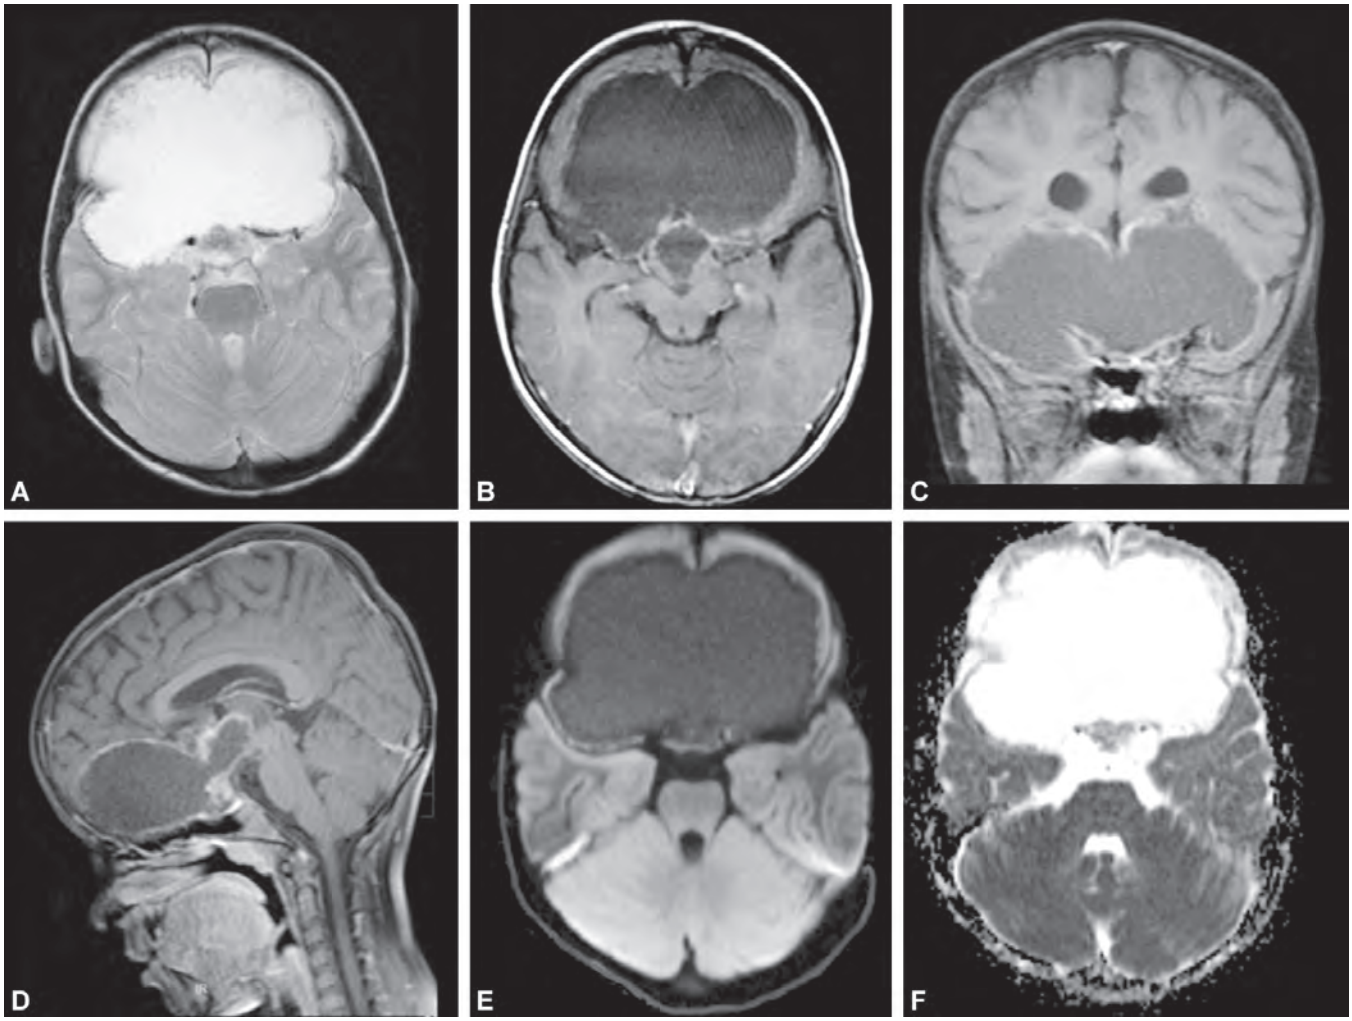
Imaging shows a lobulated enhancing soft-tissue mass centred on the clivus exhibiting bone destruction and areas of calcification, which are better seen on CT. MRI shows marked T2 hyperintensity that reflects the high water content of these tumours, and may exhibit internal reticulations or septations (Figs 11A to C).

Craniopharyngiomas

Craniopharyngiomas arise from metaplasia of squamous epithelial remnants of Rathke's pouch, from which the anterior pituitary develops. These tumours are usually centred in the suprasellar cistern and may extend into the sella, retroclival region and third ventricle; 5% may be purely intrasellar and rarely may be located in the third ventricle. They have a bimodal distribution, with a



Figs 11A to C: (A) Axial T1-weighted image shows an isointense mass lesion in the sella, suprasellar region extending to the left cavernous sinus. (B) Axial T2-weighted image shows the lesion to be predominantly hyperintense with minimal inhomogeneties. (C) Sagittal post-contrast image shows the lesion extension in the clivus and sphenoid sinus. Lesion shows enhancement after contrast. The lesion was a chordoma

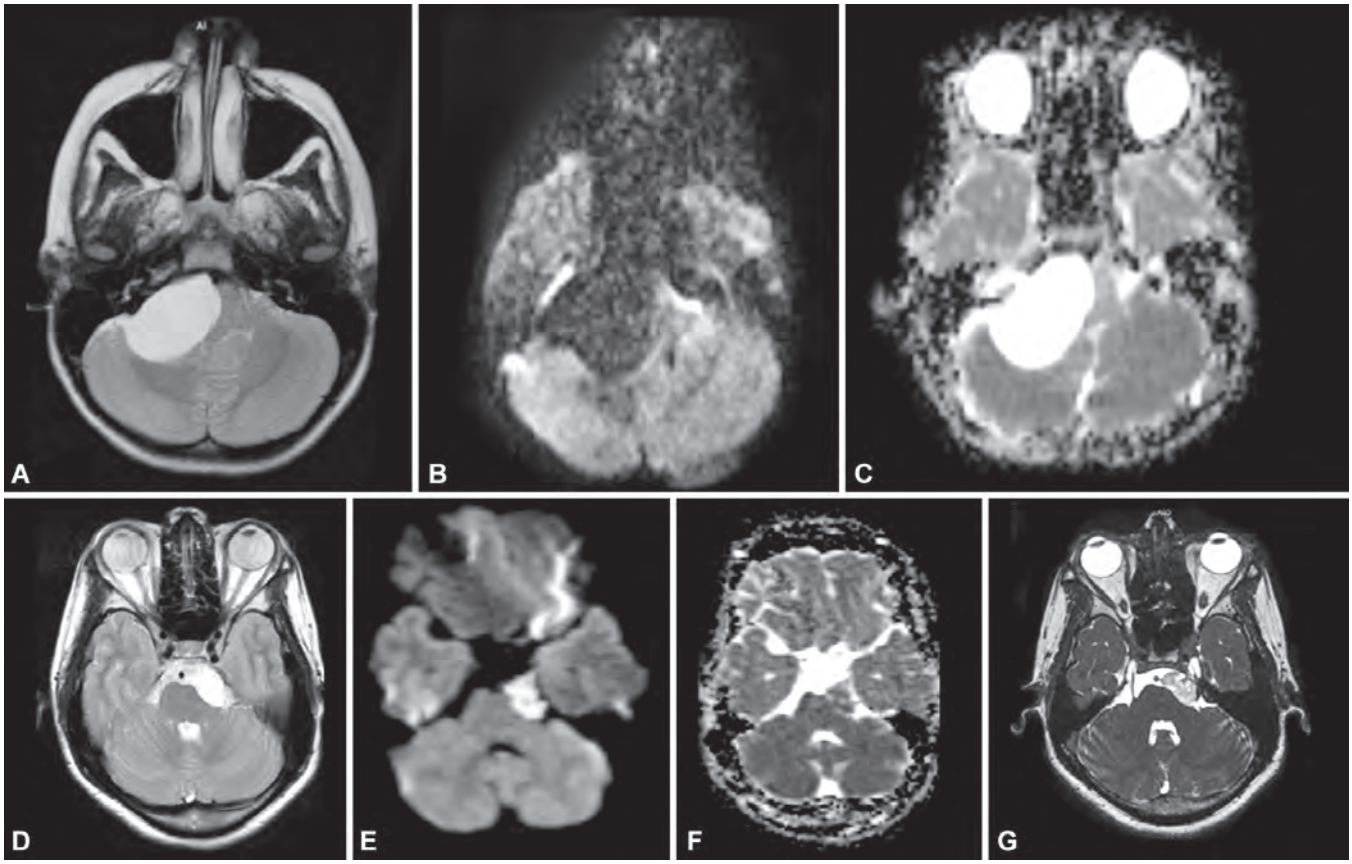


Figs 12A to F: Thirteen-year-old boy. (A) Axial T2-weighted image shows a hyperintense mass lesion in the suprasellar region extending to the anterior cranial fossa. The hyperintense mass is bordered by linear hypointensity. (B to D) axial, coronal and sagittal post-contrast images show enhancement of the periphery of the cystic lesion. (E and F) DWI and ADC maps show that the lesion is cystic and shows facilitated diffusion. The lesion was diagnosed as craniopharyngioma. Cystic areas of craniopharyngioma usually show facilitated diffusion

larger peak at 5–15 years than at 50–60 years. They may be cystic, solid or mixed cystic and solid. Nearly half of paediatric suprasellar tumours are craniopharyngiomas. These tumours are of the adamantinous variety, with lobulated contours, predominantly cystic or mixed cystic and solid with calcification, intensely enhancing solid components, and encasement of the circle of Willis vessels (Figs 12A to F).[10] The squamous papillary craniopharyngiomas tend to occur in older adults and present with predominantly solid tumours. Calcifications and recurrence are both less common in adults. MR often shows heterogeneous signal intensity with T1 isointensity to hyperintensity, fluid-attenuated inversion recovery (FLAIR) and T2 hyperintensity.

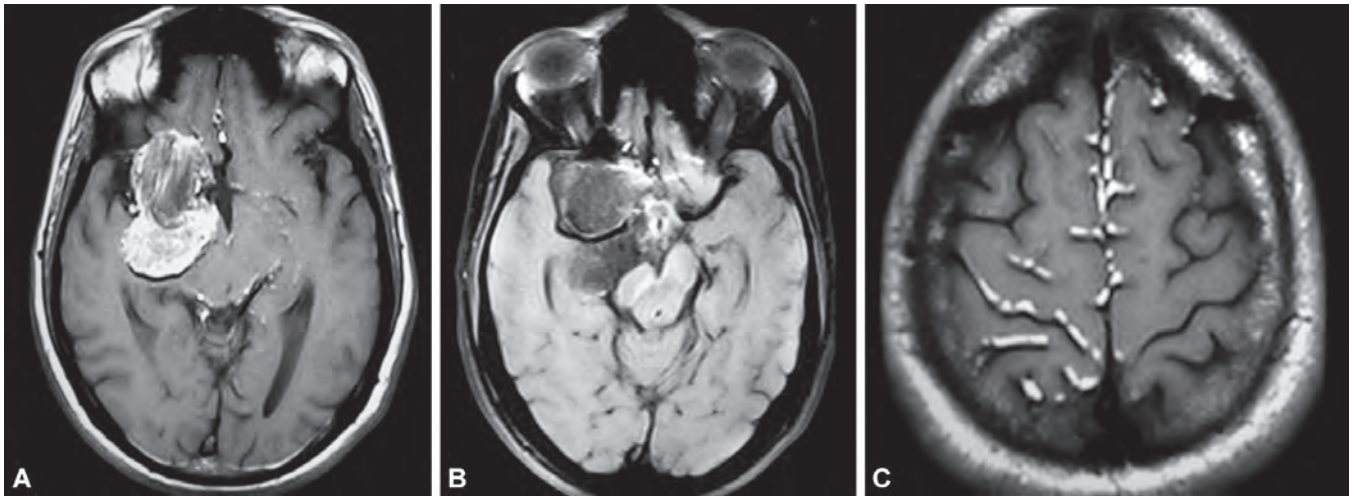
Dermoids and Epidermoids

These tumors represent non-neoplastic inclusion cysts that presumably arise from ectodermal cell rests during embryogenesis. Epidermoids are composed of desquamated cyst wall contents from an ectoderm-derived epithelial lining. They are most frequently found off the midline with insinuation into cisternal spaces and fissures, most often in the cerebellopontine angle (CPA), and less frequently around the sella. Their hyperintensity on FLAIR and DWI allows them to be readily distinguished from arachnoid cysts (Figs 13A to G).[26] Dermoids are similar to inclusion cysts, but their lining may also contain ectodermal-derived appendages (e.g. hair, teeth and sweat glands). They are more typically found near the midline and may be associated with a dermal sinus. The contents are oily with lipid metabolites that give rise to imaging features similar to those of fat, while ectodermal appendages contribute to heterogeneity. Fat characteristically results in chemical shift artifact, with spatial misregistration shown as bright and dark bands along the frequency-encoding direction. Ruptured dermoids may simulate acute subarachnoid haemorrhage as the oily contents are released into the subarachnoid space (Figs 14A to C).

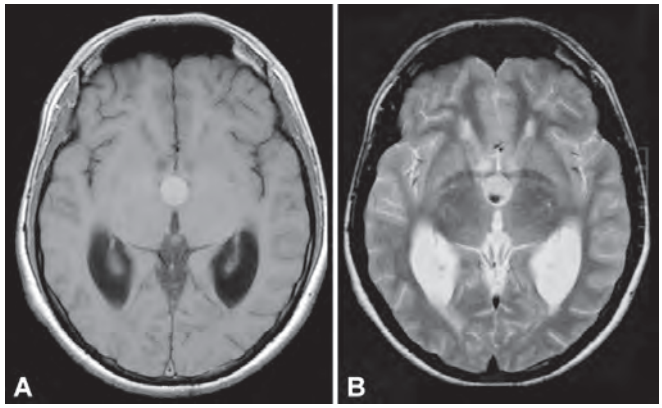


Figs 13A to G: (A) Axial T2-weighted image shows a well defined hyperintense mass lesion in the right cerebellopontine (CP) angle cistern. (B and C) Diffusion weighted image and ADC map show the lesion to have increased diffusion like that seen in the CSF. The lesion was diagnosed as arachnoid cyst. (D) Another patient in whom the MRI reveals a left CP angle mass, hyperintense in T2-weighted image. (E and F) Diffusion weighted image with ADC map shows the lesion to have mild restriction of diffusion. (G) 3D CISS sequence showing the mass is well localised in the right CP angle. This sequence is useful in defining the boundaries of intraventricular and intracisternal mass lesions

Other non-neoplastic extra-axial lesions include arachnoid cyst (a CSF-filled cavity within the arachnoid membrane that follows CSF intensity on all sequences), colloid cyst (anterior third ventricle at the foramen of Monro) (Figs 15A and B), neuroepithelial cyst (most likely intraventricular with choroidal origin), ependymal cyst and neurenteric cyst (cyst wall composed of gut/respiratory epithelium, remnant of the neurenteric canal during embryogenesis). A tall peak at 2 ppm in MR spectroscopy will help diagnosing cysts lined with ciliated columnar epithelium.[17]



Figs 14A to C: (A) Axial T1-weighted image shows a hyperintense mass lesion on the right side of the suprasellar cistern extending to the right Sylvian fissure. (B) The hyperintense signal is getting suppressed in fat saturation sequence. (C) The hyperintense fat is seen in the sulci and cisterns suggesting the possibility of a ruptured dermoid



Figs 15A and B: (A) Axial T1-weighted image shows a well defined hyperintense mass lesion in the anterior third ventricle suggestive of colloid cyst. (B) Axial T2-weighted image shows the lesion to be hyperintense with a hypointense area within. A colloid cyst shows varying intensity depending on the protein content of the fluid within the cyst

Ependymomas

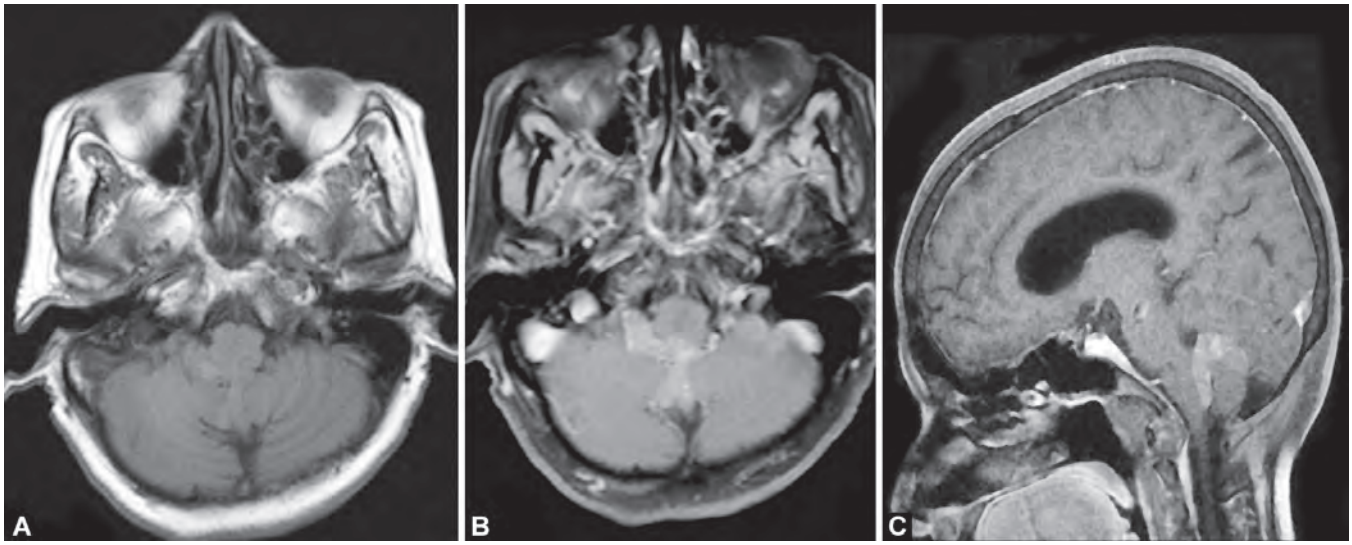
Ependymomas are glial tumours derived from differentiated ependymal cells along the ventricular system. In 60–70% of cases, these tumours occur in the infratentorial compartment and are intraventricular as they arise from the floor of the fourth ventricle. Most occur in children below 10 years old, and characteristically exit through the foramina of Lushka or Magendie (Figs 16A to C). The supratentorial tumours occur in patients 30–50 years old and may be transependymal, intraventricular or more commonly intraparenchymal. Extraventricular tumours are thought to arise from ependymal cell rests, which are predominantly located at the angled margins of the ventricles. The signal characteristics are nonspecific, with T1 hypointensity and T2 isointensity to hyperintensity, cystic changes in 74%, and haemorrhage in 13–21%.[6,7] Calcifications occur in half of these tumours, as opposed to the PNET/medulloblastomas, in which calcification is uncommon. The tumours show intense but heterogeneous enhancement with little or no peritumoural oedema.

Germ Cell Tumours

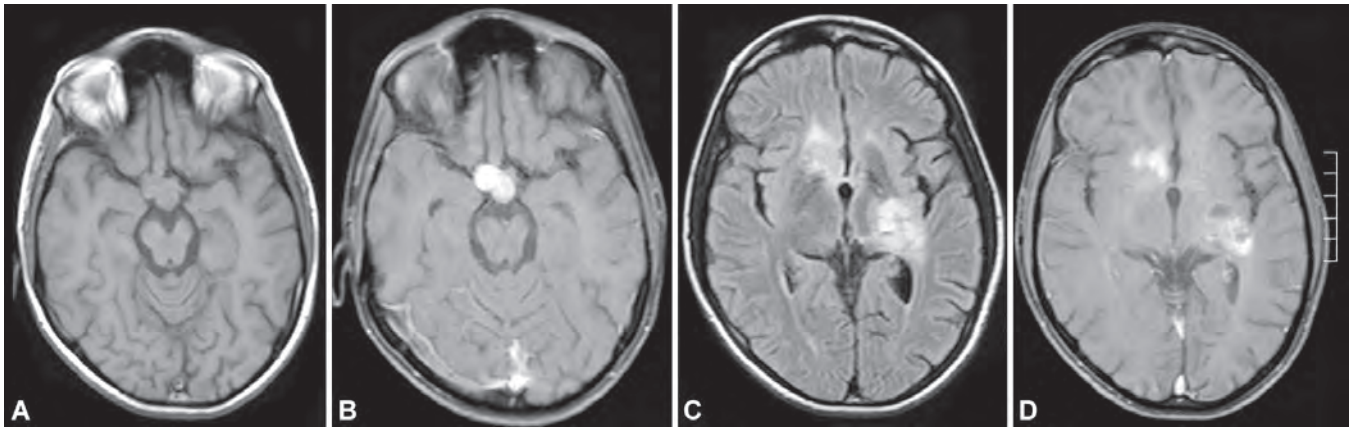
Germinomas are the most common intracranial germ cell tumours (GCTs), accounting for 60% of pineal GCTs and 40% of pineal masses. Around 90% of patients with GCTs are below 20 years of age. Clinically, suprasellar germinomas often present with diabetes insipidus. Germinomas are twice as common in the pineal region as in the suprasellar region, although 5–10% involve both areas simultaneously. Other possible midline locations include the thalamus, and fourth ventricle. Suprasellar germinomas are more common in females, while pineal germinomas have a marked male predominance (9:1). CT demonstrates a hyperdense, vividly enhancing mass that can be described as engulfing the pineal gland calcification. MR shows T1 isointensity and slight T2 hypointensity similar to that of GM because of the high nucleus-to-cytoplasm ratio. There is strong enhancement (Figs 17A to D). Metastases may occur due to dissemination via the CSF or ependymal surfaces. MRI is highly sensitive for diagnosing pineal or suprasellar mass lesions, but has limited specificity for distinguishing GCTs from other tumours. In these situations, evaluation of the CSF for specific protein markers can help establish the diagnosis and discriminate germinoma from nongerminoma lines (i.e. teratoma, choriocarcinoma, mixed germ cell, endodermal sinus and embryonal carcinoma).

Hemangioblastomas

Hemangioblastomas are the most common primary intraparenchymal infratentorial tumours in adults. These benign tumours represent 10% of all posterior fossa



Figs 16A to C: Axial T1 weighted, post-contrast axial and sagittal image show a T1-isointense mass lesion extending from the fourth ventricle to the foramen of Luscka and Magendie, which shows enhancement after contrast administration. The lesion is suggestive of ependymoma



Figs 17A to D: Young male patient showing. (A) A suprasellar isointense mass lesion in the T1-weighted image. (B) The mass enhances intensely after contrast administration. (C) Another FLAIR hyperintense mass is seen in the left basal ganglia. (D) This lesion also shows contrast enhancement. The lesion was proved to be germinoma

masses, with 83% occurring in the cerebellar hemispheres and characteristically contacting the pial surface. They present as a cystic mass with a highly vascular, solid mural nodule in 60% of patients. Enlarged, serpentine flow voids representing feeding vessels may be seen with MRI. The tumours are well defined and may induce a minimal surrounding parenchymal reaction. The cyst wall does not enhance, is not neoplastic, and does not have to be resected at surgery. Excision of the solid mural nodule is usually curative. Hemangioblastomas usually occur in young males. The principal differentiating feature between these tumours and similar-appearing juvenile pilocytic astrocytomas is age, [since the latter tend to occur in children (5–15 years old)] and their vascularity. Up to 25% of hemangioblastomas are associated with von Hippel-Lindau syndrome, in which case the tumours present at a younger age and are multiple, occurring in the cerebellum, brainstem and spinal cord (Fig. 18).

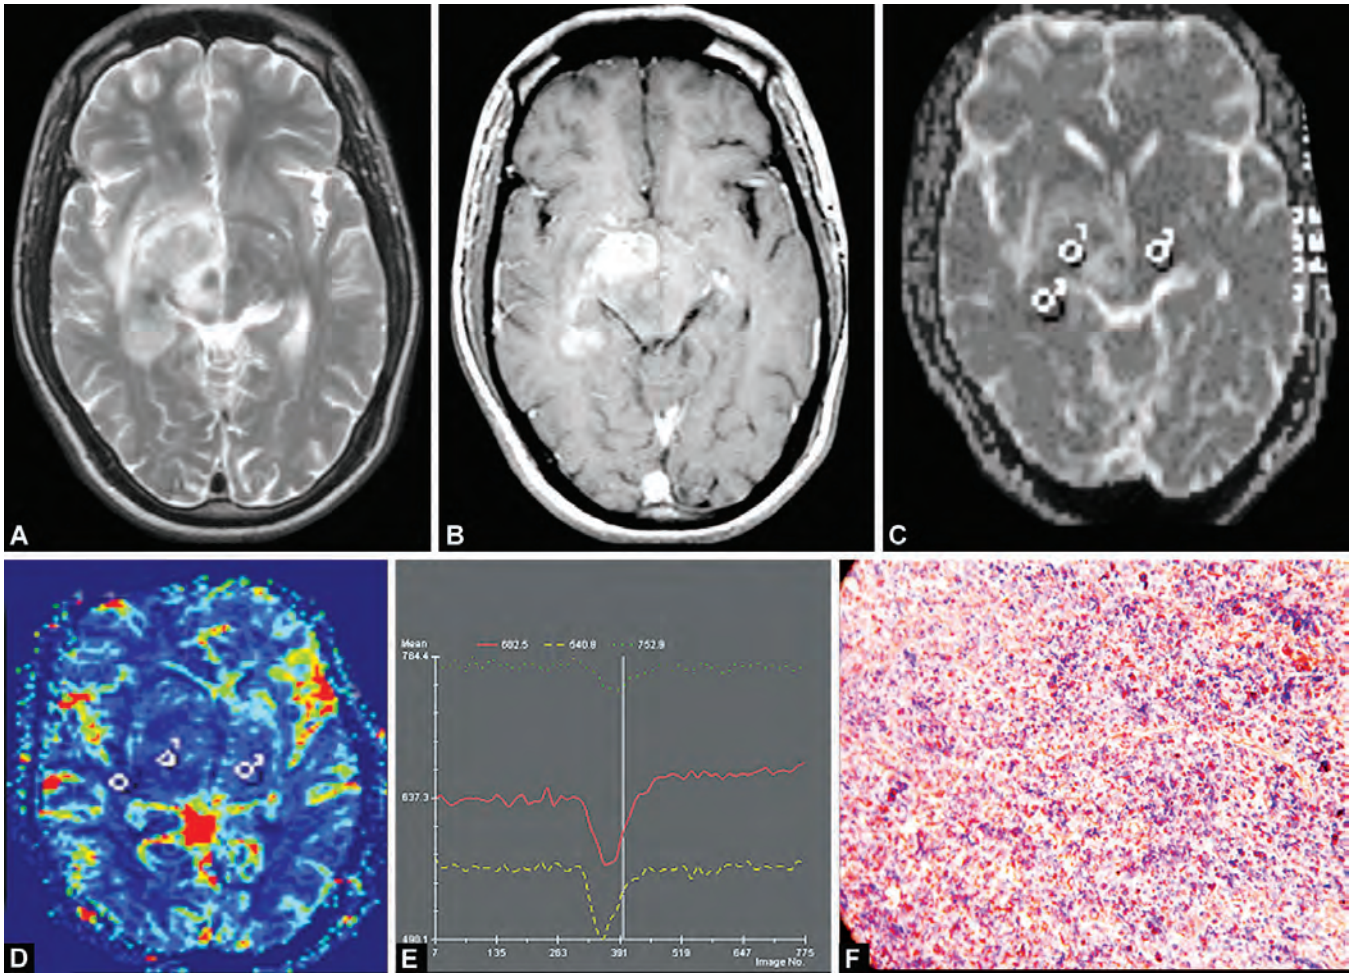
Fig. 18: Patient with Von Hippel-Lindau syndrome. Post-contrast sagittal T1-weighted image shows an enhancing mass lesion in the cerebellum. Note multiple enhancing lesions in the spine with syrinx and serpiginous flow voids. Findings are suggestive of multiple hemangioblastoma.

Lymphoma

Lymphoma has increased in incidence over the past two decades, largely due to an increased incidence in patients with acquired immunodeficiency syndrome (AIDS). However, the incidence of lymphoma has also risen in immunocompetent patients with no identifiable environmental or behavioural causes. A pre-operative diagnosis of primary cerebral lymphoma is of paramount importance to the neurosurgeon. These tumours are exquisitely sensitive to chemotherapy and radiation therapy. Conventional images often show multiple enhancing masses that often involve the deep GM, periventricular white matter, subependymal region, corpus callosum or are located adjacent to CSF spaces. They show T1 hypointensity to isointensity and are hypointense on T2WI with isointensity to mild hyperintensity because their dense cellularity leaves little interstitial room for water accumulation. Diffusion restriction with diffusion hyperintensity and ADC hypointensity may occasionally mimic an infarct. Homogeneous enhancement is absent in AIDS patients, whose tumours are more likely to have central necrosis. Despite conventional imaging features that may suggest a highly malignant neoplasm, perfusion MRI will often show only modest increases in perfusion that are much less than expected for high grade glioma.[4] This is because neovascularity is not a prominent feature of lymphomas, since the tumour cells instead grow around blood vessels in an angiocentric pattern (Figs 19A to F).

Paragangliomas

Paragangliomas may arise at the jugular foramen (glomus jugulare) or in the middle ear cavity (glomus tympanicum). These tumours arise from glomus bodies (neural crest derivatives) and often present with pulsatile tinnitus. Glomus jugulare tumours originate in the adventitia of the jugular foramen and may occlude the jugular vein with growth. At the time of diagnosis, there is usually infiltration of the tumour into the bony margins of the jugular foramen with a pattern of



Figs 19A to F: (A and B) Axial T2 weighted and post-contrast T1-weighted images show a hypointense lesion in T2 W1 image with intense post-contrast enhancement. (C) ADC map shows a low ADC in this lesion. (D and E) rCBV map and time intensity curve show that rCBV is not increased. (F) H and E staining of the resected mass was suggestive of lymphoma

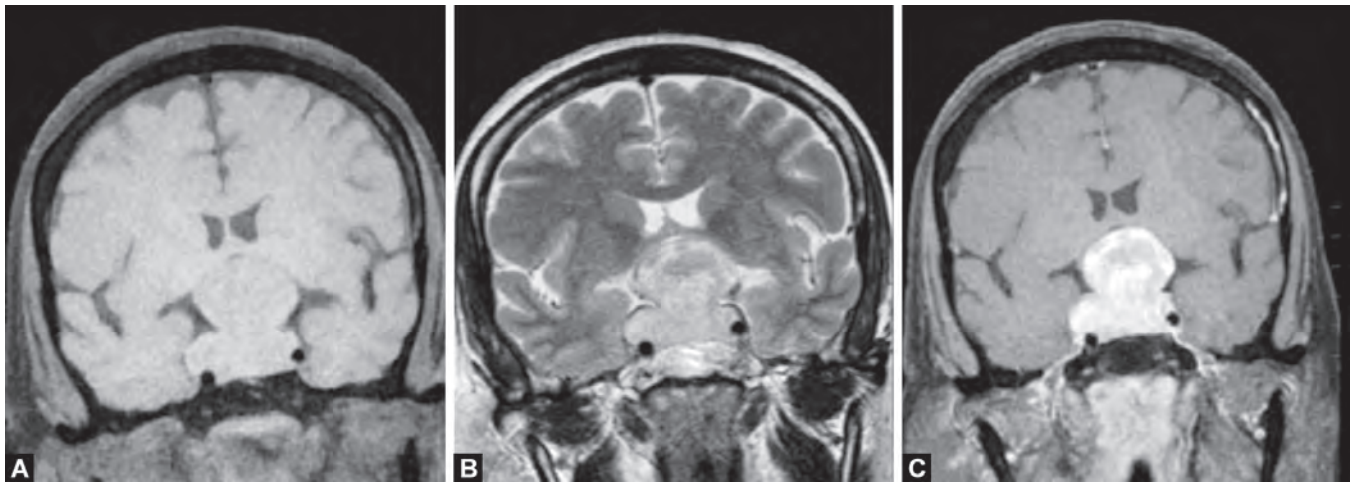
permeative bone destruction that is best seen with CT scan. MRI shows an enhancing soft-tissue mass centred on the jugular foramen (jugulare) or inferior portion of the middle ear cavity (tympanicum), or spanning both (jugulo-tympanicum). A soft-tissue component may grow intracranially towards the cerebellopontine angle. These highly vascular tumours are characterised by direct visualisation of prominent vessels within a mass evidenced by MRI "flow voids" or a "salt and pepper" appearance.

Metastases

Metastases are the most common supratentorial and infratentorial neoplasms in adults, accounting for more than 40% of all tumours. About half of these lesions are reported to be solitary; however, with the use of higher doses of gadolinium (as well as higher field strengths), the number of lesions detected is increasing. In decreasing order of numbers, metastases tend to arise from the lung (50%), breast (15%, in women), melanoma (11%), kidney and gastrointestinal primaries, although rarely metastases from primary CNS tumours may also occur. They are often located at the GM/WM junction, reflecting the normally high perfusion of the cerebral cortex. Lesions often have a fair amount of vasogenic oedema (recognised by the sparing of the arcuate fibres along with its frond-like appearance). Foci of T1 hyperintensity (seen in 3–14%) may represent blood products (from melanoma, thyroid, renal, breast and lung primaries) or melanin (in melanomas). These may be distinguished from benign haemorrhagic lesions by their relatively delayed haemoglobin evolution and incomplete haemosiderin periphery. Mucinous metastases tend to show T2 hypointensity, especially in metastatic colon adenocarcinomas. Calcification typically occurs in lung or breast metastases. Cystic lesions are associated with metastatic squamous cell carcinoma. Leptomeningeal metastases are more commonly due to adenocarcinomas and melanoma than haematological malignancies. These are best evaluated by both contrast T1-weighted images (T1WI) and contrast FLAIR images,[25] which show curvilinear or nodular pial enhancement (35%), hydrocephalus (13%) and cranial nerve deposits (11%).[8]

Pituitary Adenomas

Pituitary adenomas represent 33–50% of all sellar and parasellar masses (Figs 20A to C). In 66–75% cases, the



Figs 20A to C: (A) Coronal fat suppressed T1-weighted sequence shows an isointense sellar, suprasellar mass lesion. (B) Coronal; T2-weighted image shows the lesion to be isointense to hypointense. (C) Post-contrast image shows enhancement within the lesion. The pituitary gland is not seen separately. The right cavernous sinus and carotid artery is encased, the optic chiasm could not be visualised separately. Suggestive of pituitary macroadenoma

tumours are hormonally active and likely to present earlier with endocrine dysfunction. The hormones include growth hormone, adrenocorticotropin, prolactin and thyrotropin. Hormonally-inactive tumours present with larger sizes due to mass effect on adjacent structures. Adenomas usually demonstrate T1 hypointensity; however, variable signal intensities may occur due to intratumoural haemorrhage, which is more common after medical treatment with bromocriptine. Complicated macroadenomas may present with cystic changes and haemorrhage, including fluid-fluid levels. Coronal DCE-MRI is the most sensitive method for detecting pituitary adenomas, particularly microadenomas. There is avid, immediate enhancement of the normal anterior pituitary tissue, infundibulum and cavernous sinuses due to the pituitary's lack of a BBB and the adjacent hypothalamo-hypophyseal venous plexus. The adenoma shows delayed enhancement, with the differential most apparent in the first minute after injection. Secondary signs of a small, usually laterally located mass include increased gland height, eccentric superior convexity, contralateral deviation of the infundibulum and focal erosion of the sellar floor.

Medulloblastomas/Primitive Neuroectodermal Tumours

Medulloblastomas/PNET are the most common posterior fossa neoplasms in children (more than 33%), although they may also occur in the supratentorial compartment and have a second incidence peak in adults. PNETs classically originate in the midline cerebellar vermis in children and are more common in males, with a 2:1 ratio. They represent a spectrum of disease with a varied degree of aggressiveness, the most aggressive being the atypical teratoid/rhabdoid tumour. Desmoplastic medulloblastomas in adolescents and adults are often eccentrically located, and arise from the cerebellar hemisphere rather than the vermis. CT shows homogeneously hyperdense vermian masses. MRI reveals well-circumscribed T1 hypointense and T2 intermediate/isointense tumours that distort the fourth ventricle, which is usually displaced in an anterior-inferior direction. The site of origin may be obscured by large tumours. For distinction from fourth ventricle ependymomas, MRS of medulloblastoma shows high choline, low NAA and no lactate peak. Contrast MRI of the entire neuraxis must be performed because subarachnoid drop metastases occur in 15–50% of cases. Supratentorial PNETs are also aggressive malignancies with areas of cystic change, calcification, haemorrhage, heterogeneous enhancement and relatively little surrounding oedema. They have a similar propensity for leptomeningeal and CSF dissemination, and a poor outcome.

Rathke's Cleft Cysts

These originate from persistent remnants of Rathke's pouch. They are composed of a fibrous wall lined by a single layer of ciliated cuboidal or columnar epithelium. CT shows a hypodense cyst. Depending on the fluid composition and concentrations of protein, cholesterol and triglyceride, MR demonstrates variable T1 and T2 signal intensity. Forty percent of these cysts are intrasellar and intra-pituitary, and larger cysts extend into the suprasellar cistern. The cyst wall should show no calcification and no enhancement; however, an enhancing rim of compressed normal pituitary tissue or reactive granulation tissue may be observed.

Schwannoma

Schwannoma is the most common type of neurogenic tumour, and neurofibroma is much less common. Schwannomas originate from Schwann cells whose myelin processes surround axons of cranial nerves. They are most frequently found at the transition zone

between oligodendroglial and Schwann cell coverings of the axons. The peak incidence occurs in patients 50–60 years old, and they are slightly more common in females than in males. They originate much more frequently from sensory than motor nerves, and thus, identification of a nerve root signature can help improve diagnostic certainty. Since these tumours are well delineated and encapsulated, they affect the cranial nerve of origin and adjacent brain by compression rather than invasion. The vestibular division of the eighth cranial nerve (i.e. in the internal auditory canal and CPA) is the most frequently affected, followed by the fifth and seventh cranial nerves. MR usually demonstrates a T1 isointense to hypointense and T2 hyperintense extra-axial mass. Even very small intra-canalicular vestibular schwannomas can easily be seen with high-resolution (512 matrix) T2WI or 3D constructive interference in the Steady State (CISS) images. The presence of microbleeds within the tumour in the T2 gradient sequence or susceptibility weighted image helps in diagnosing schwannomas (Figs 21A to C), especially when placed at unusual locations.[19] Schwannomas show intense enhancement that is usually homogeneous in smaller tumours and more heterogeneous in larger tumours due to necrosis or cyst formation.

TUMOUR-MIMICKING LESIONS

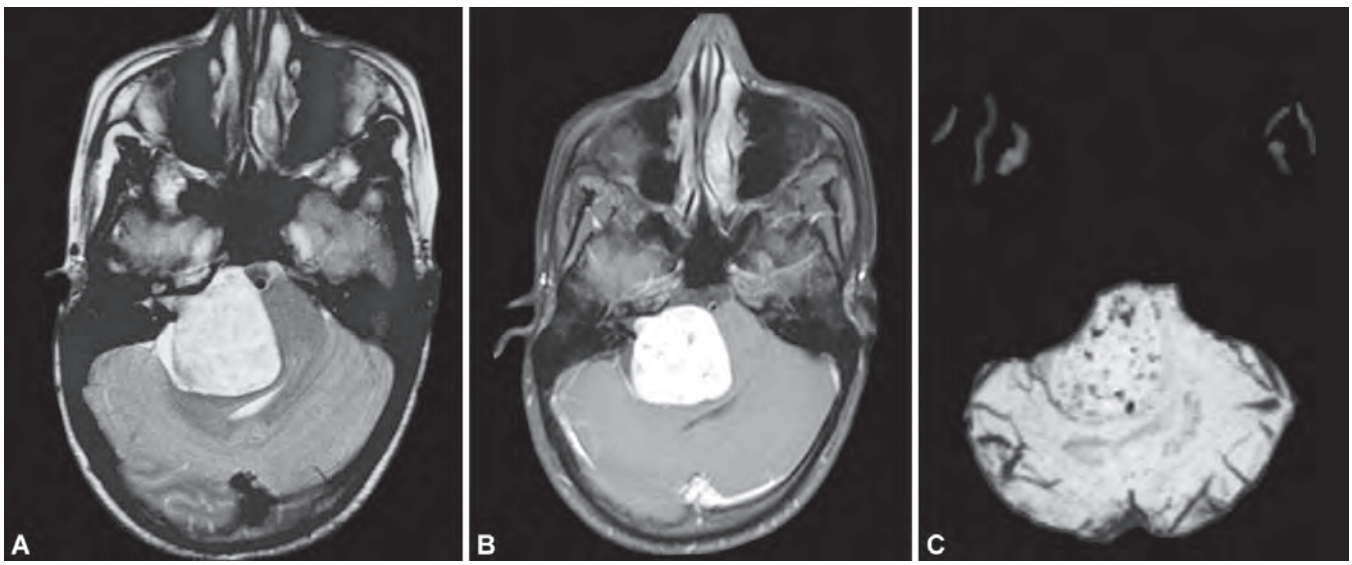
Some non-neoplastic entities may mimic malignancy due to overlapping signal abnormalities, enhancement patterns and mass effect with conventional imaging. Advanced MRI, particularly perfusion MRI and MR spectroscopy, may be very helpful in these situations. Lack of angiogenesis should suggest a tumour-mimicking lesion. A peripherally enhancing mass lesion that shows diffusion restriction and surrounding T2 hyperintensity may represent a brain abscess or metastasis. The abscess often shows a thin peripheral T2 hypointense rim, which is thought to represent free radicals caused by the inflammatory process, but this is not always readily apparent. Perfusion MRI of the capsular portion of these lesions will show significantly decreased perfusion for the abscess compared to the neoplasm.[9]

Tumefactive demyelinating lesions (Figs 22A to E) may present with enhancement, central necrotic change, mass effect and surrounding T2 hyperintensity similar to brain tumour findings based on conventional images. Perfusion MRI of these lesions may show mild hyperperfusion, although a conspicuous absence of hyperperfusion is more typical. Blood vessels in the areas of demyelination are intrinsically normal in comparison to the tumoural neovascularity. An examination of the source T2 images often reveals the presence of small venules streaming through the lesions without mass effect, which is a highly specific sign.[5]

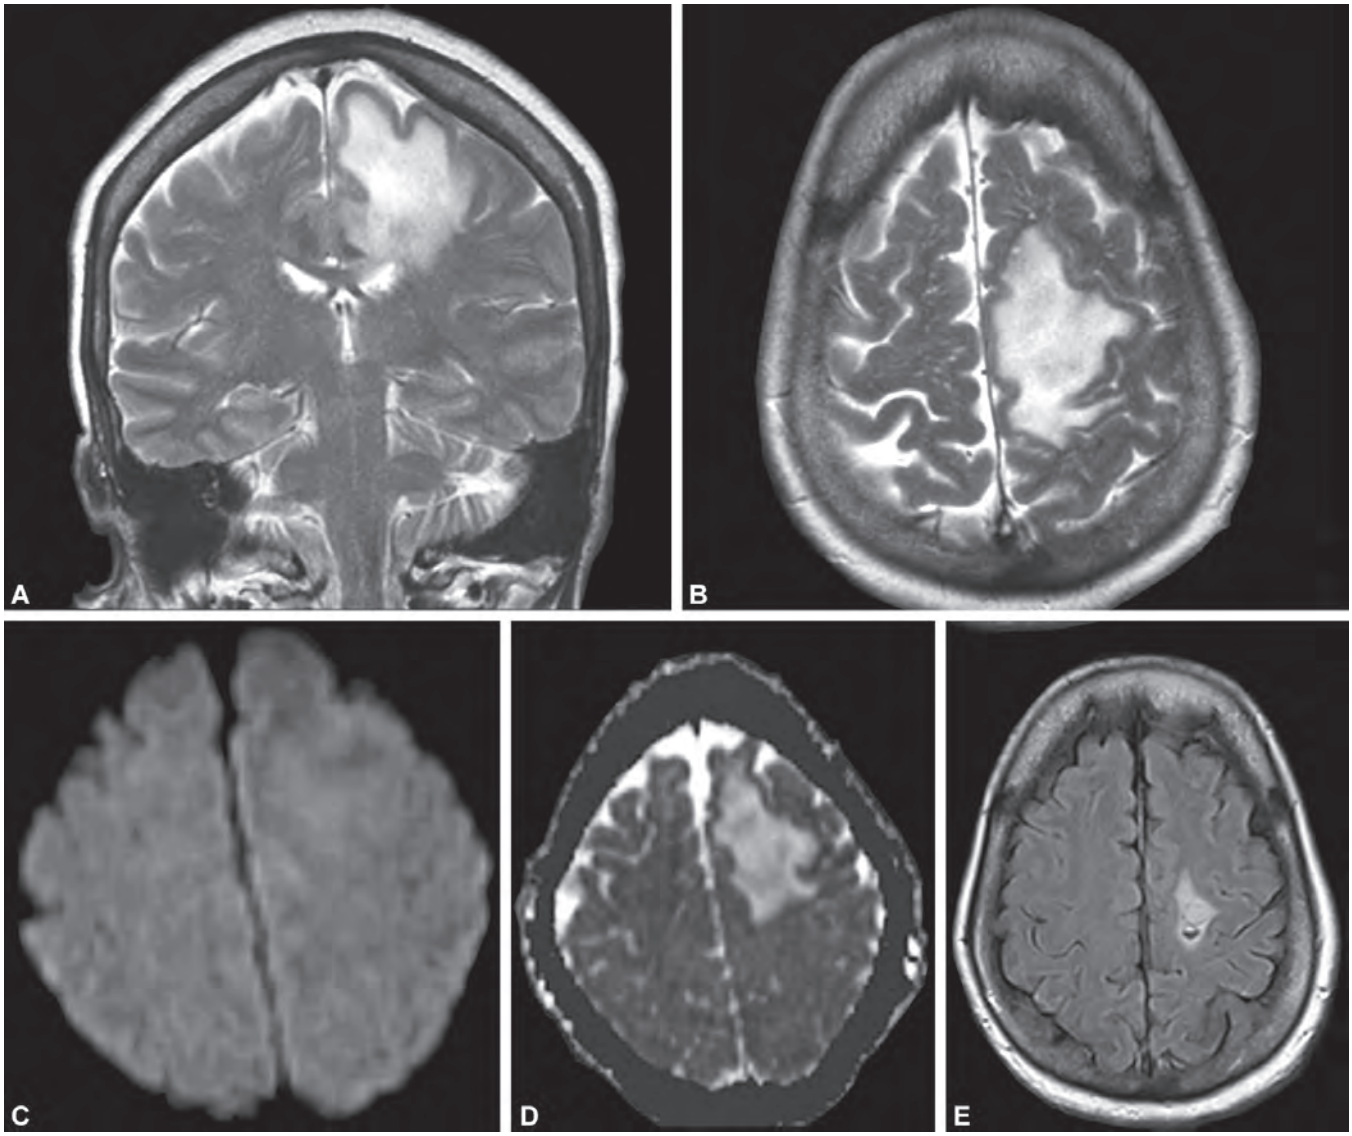
Acute to subacute infarcts may occasionally present with an atypical location or history and mimic a tumour, especially if there are DWI/ADC discrepancies. Ischaemia should decrease to absent perfusion with decreased CBV and CBF; however, the CBV may also be increased if there are adequate collaterals or luxury perfusion.

POST-SURGICAL IMAGING

Imaging is performed after surgical resection to evaluate for residual tumour and assess potential complications. MRI is the preferred modality though most of the centres still perform CT.[24] The initial post-operative scan is obtained within 24 hours using conventional sequences. In this time frame, post-operative changes affecting the BBB are not manifest, and any enhancement is thought to represent residual enhancing tumour rather than post-operative changes in the tissue. Non-contrast T1WI is essential because a fair amount of hyperintense



Figs 21A to C: (A) Axial T2-weighted image shows a hyperintense mass lesion in the right CP angle extending into the internal auditory meatus. (B) Mass shows intense enhancement after contrast administration. (C) Susceptibility weighted image shows micro-haemorrhages within the tumour

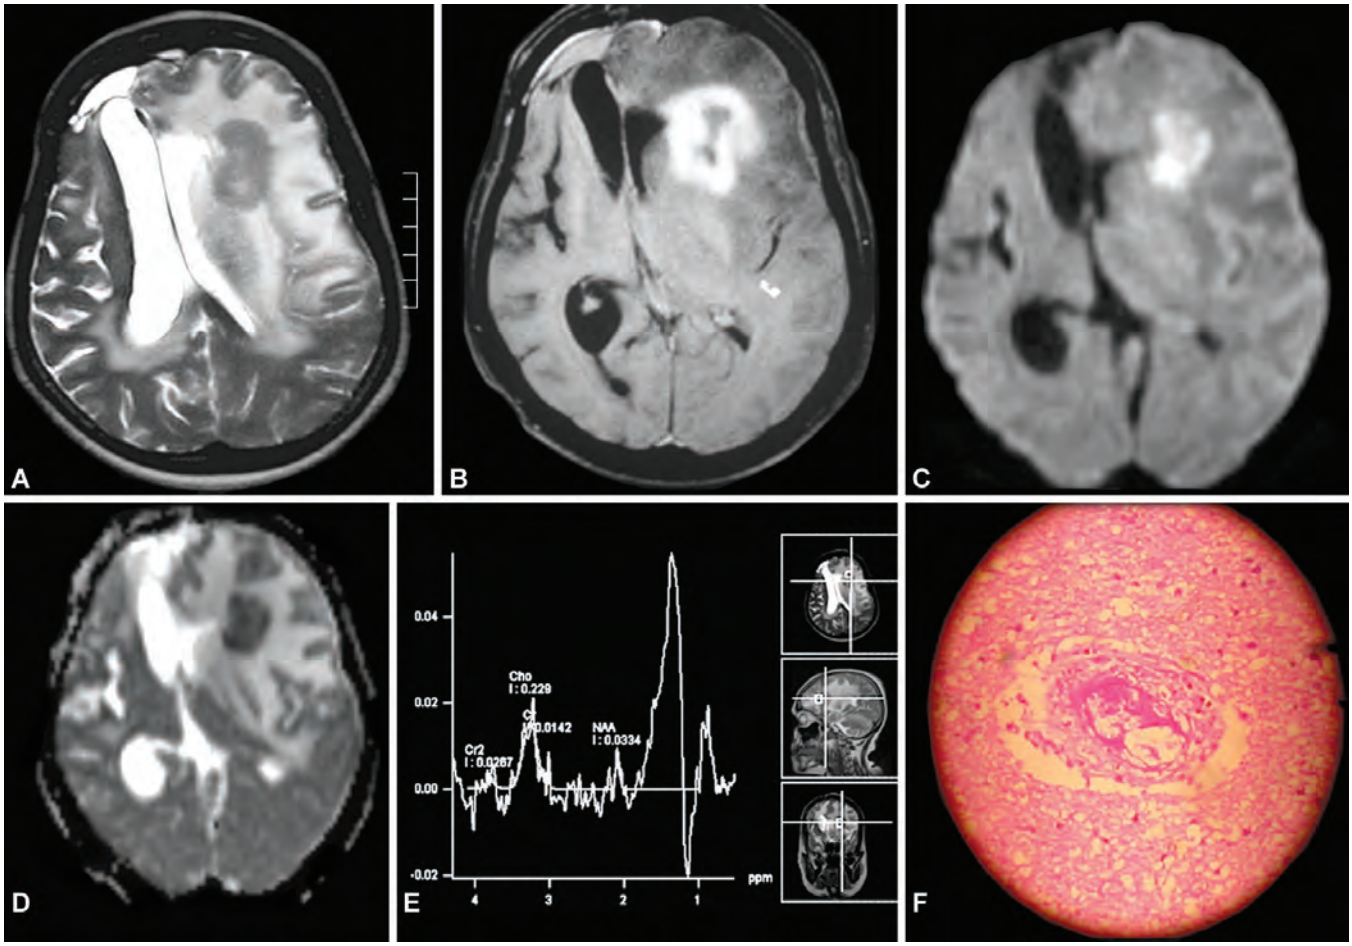


Figs 22A to E: (A and B) Coronal and axial T2-weighted images show a lesion with white matter oedema with mass effect on the left frontal horn. (C and D) Diffusion weighted image and ADC map do not slow diffusion restriction. A biopsy revealed the lesion to be demyelination. Patient was put on steroids. (E) Axial FLAIR image taken after therapy shows lesion resolution

blood product may be present. DWI is useful in the post-operative period for patients complicated by acute neurologic deficits, since the cytotoxic oedema of acute infarction is characterised by restricted diffusion (DWI hyperintensity and ADC hypointensity), in contrast to vasogenic oedema of tumour, which has elevated diffusion due to increased extracellular water (DWI hypointensity to slight hyperintensity and ADC hyperintensity). The first follow-up examination occurs 6 weeks after surgery. Scanning earlier than this can be fraught with difficulty due to exuberant post-operative contrast enhancement. If the tumour did not enhance pre-operatively, however, it will not enhance in the month following surgery. Further follow-up will be dictated by the clinical therapeutic protocol. Tumours after gross total resection tend to be followed at 3 months, 6 months and then annually. In patients undergoing medical therapy, examinations are typically performed at 4–6 weeks, with courses of chemotherapy in-between. Follow-up in patients receiving chemotherapy and/or radiation therapy should include at least one advanced imaging method (perfusion or spectroscopy) in order to differentiate between therapeutic effects and disease progression. When patients are no longer actively receiving aggressive treatment, follow-up occurs at 3-month intervals. The presence of any imaging changes with mass effect should prompt further investigation with advanced methods.

RADIATION NECROSIS VERSUS TUMOUR RECURRENCE

Therapeutic necrosis (secondary to radiation therapy or chemotherapy) cannot be distinguished from residual or recurrent tumour by conventional imaging methods, which show enhancing mass lesion(s) in the radiation bed due to disruption of the BBB with surrounding



Figs 23A to F: Known case of high grade glioma, the patient had undergone surgery and irradiation. (A) Axial T2-weighted image shows hypointense mass lesion with surrounding oedema and mass effect. (B) Except for a small central area, the lesion shows enhancement. (C and D) Restricted diffusion is noted in the diffusion weighted image. (E) Multi-voxel spectroscopy (TE: 135 ms) shows decreased choline and NAA. A large lipid peak is seen. Possibility of radiation necrosis was considered. (F) H and E Staining of the specimen revealed radiation necrosis

oedema and mass effect. The contrast enhancement simply reflects a breakdown of the BBB, which may occur in both tumoural disease and therapeutic necrosis. For this common clinical scenario, advanced imaging can be very helpful.

Perfusion MRI will show significantly reduced or even absent capillary volume in areas of therapeutic necrosis, which manifests as a "cold" region on an rCBV map. MR spectroscopy will reveal decreased metabolites manifested by reduced Cho/Cr and NAA/Cr ratios (Figs 23A to F), and mild NAA increases are often seen with successful therapy.[22] These techniques may be misleading, however, if inflammatory cells in the areas of radiation necrosis are hypermetabolic, leading to false-positive studies, and comparison with normal-appearing brain may be difficult due to radiotherapy and/or chemotherapy-induced metabolic depression.

12 Radiology: Intracranial Infections

Bejoy Thomas

INTRODUCTION

In spite of the eradication of many infective diseases due mostly to better immunisation strategies, general improvement in health and hygiene and development of effective antimicrobial therapy, the incidence of central nervous system (CNS) infections, especially opportunistic infections appears to be on the rise worldwide. This has many reasons, including the occurrence of widespread epidemics of acquired immunodeficiency syndrome, use of immunosuppressant medications and emergence of new and variant strains of the micro-organisms causing intracranial infections. With the advent of newer diagnostic methods, especially advanced applications of MRI, imaging plays a crucial role in the early diagnosis of many infective lesions of the brain and the spine.

CNS infection can result from bacteriae, viruses, fungi and parasites. It can manifest as cerebritis, cerebral abscesses, meningitis, encephalitis, subdural empyema and effusions, and ventriculitis. The pathogen can reach the brain via the haematogenous route and rarely by direct spread from an adjacent infective focus, e.g. infection in middle ear or paranasal sinuses.

Various imaging modalities can be used to diagnose the manifestations, as well as sequelae of infective lesions of the CNS. However, MRI is the most advanced method for diagnosing and characterising infective lesions.

Computerised tomography (CT) scan appears to be a less sensitive alternative in detecting early lesions. Intravenous administration of gadolinium based contrast agents improves the sensitivity of detecting them, especially meningitis and cerebral abscesses. Diffusion weighted imaging (DWI), diffusion tensor imaging (DTI), proton magnetic resonance spectroscopy (MRS), magnetisation transfer imaging and perfusion imaging may help in early detection and finer sub-classification of CNS infections.

In this chapter, we will discuss various infective conditions of the brain and their imaging characteristics.

PYOGENIC INFECTIONS

It can manifest as cerebritis, cerebral abscesses, meningitis, encephalitis, empyema and ventriculitis.

Cerebritis

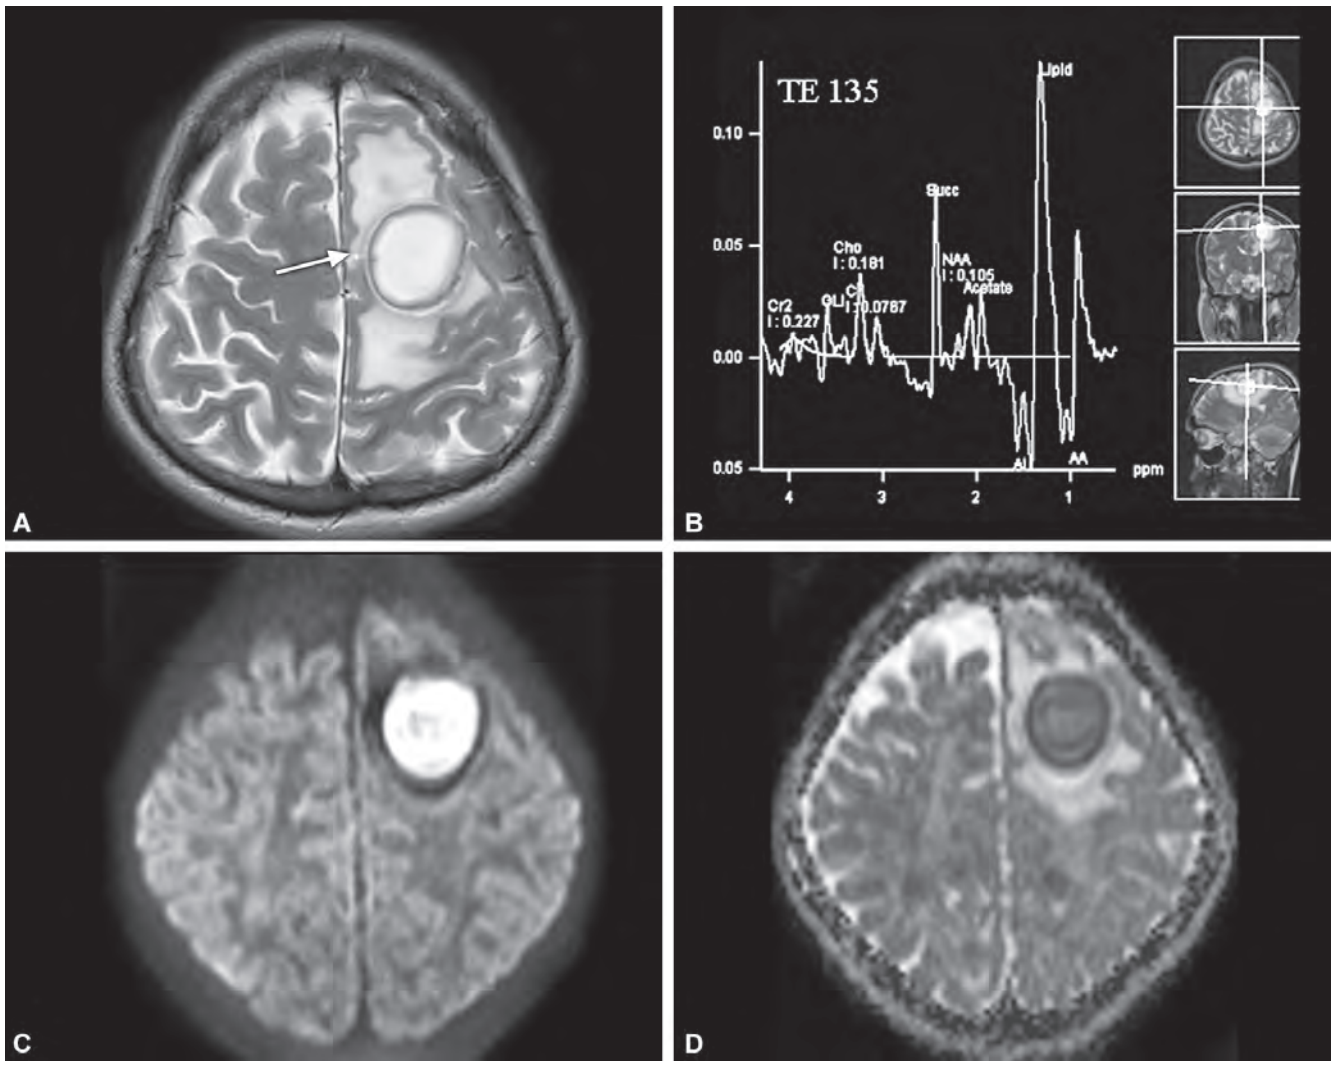
It is the earliest manifestation of a cerebral infection that may progress to the formation of a brain abscess. Usually it occurs 2–3 days following pathogen inoculation. Pathologically, localised yet poorly demarcated areas of parenchymal softening with scattered coagulative necrosis, oedema, congestion, petechial haemorrhages and perivascular inflammatory infiltrates can be noted at this stage. It results from direct spread of infection (head and neck infections/meningitis) or from haematogenous spread.

Magnetic resonance (MR) is more sensitive than CT in detecting cerebritis.[16] MR imaging shows an ill-defined area of isointensity or hypointensity with subtle mass effect (sulcal effacement or ventricular compression) on T1WI and contrast enhancement is absent or minimal. On fluid-attenuated inversion recovery (FLAIR) and T2WI, the infected tissue is hyperintense. In the absence of purulent fluid, DWI may show restricted diffusion in early cerebritis. It might be attributed to hypercellularity, brain ischaemia or cytotoxic oedema. Spectroscopy also may show abnormality, especially the presence of lactate, but the changes could be non-specific.

Cerebral Abscesses

Evolution of an abscess is characterised by four stages: early cerebritis; late cerebritis; early capsule formation and late capsule formation. In the final stages, the surrounding area of cerebritis extends only minimally beyond the capsule and the capsule is well formed on its cortical side than on its ventricular side. The length of time required for formation of a mature abscess varies from a few weeks to several months. In haematogenous spread, lesions are usually seen in the grey-white matter junction of ACA and MCA territories. Cerebellar abscesses constitute 2–14% of all cases.

The central liquefied portion is slightly hyperintense to cerebrospinal fluid (CSF) on T1WI and would be isointense to CSF on T2WI. The peripheral rim is hypointense to CSF on T2WI and hyperintense on T1WI and shows peripheral contrast enhancement on contrast enhanced T1 weighted sequences. This property of the rim has been attributed to collagen, haemorrhage and paramagnetic free radicals, within the macrophages which are peripherally distributed. This hypointense rim usually resolves with successful surgical and/or medical treatment. So, the rim may be a better indicator of response to treatment than the residual enhancement. The differential diagnosis for ring



Figs 1A to D: Pyogenic abscess involving the left frontal lobe. (A) T2 weighted axial FSE shows a cystic mass lesion with a hypointense rim (arrow) and surrounding oedema. (B) Proton MR spectroscopy at TE 135 ms shows the characteristic peaks. (C) Diffusion weighted image. (D) ADC map show restricted diffusion within the lesion

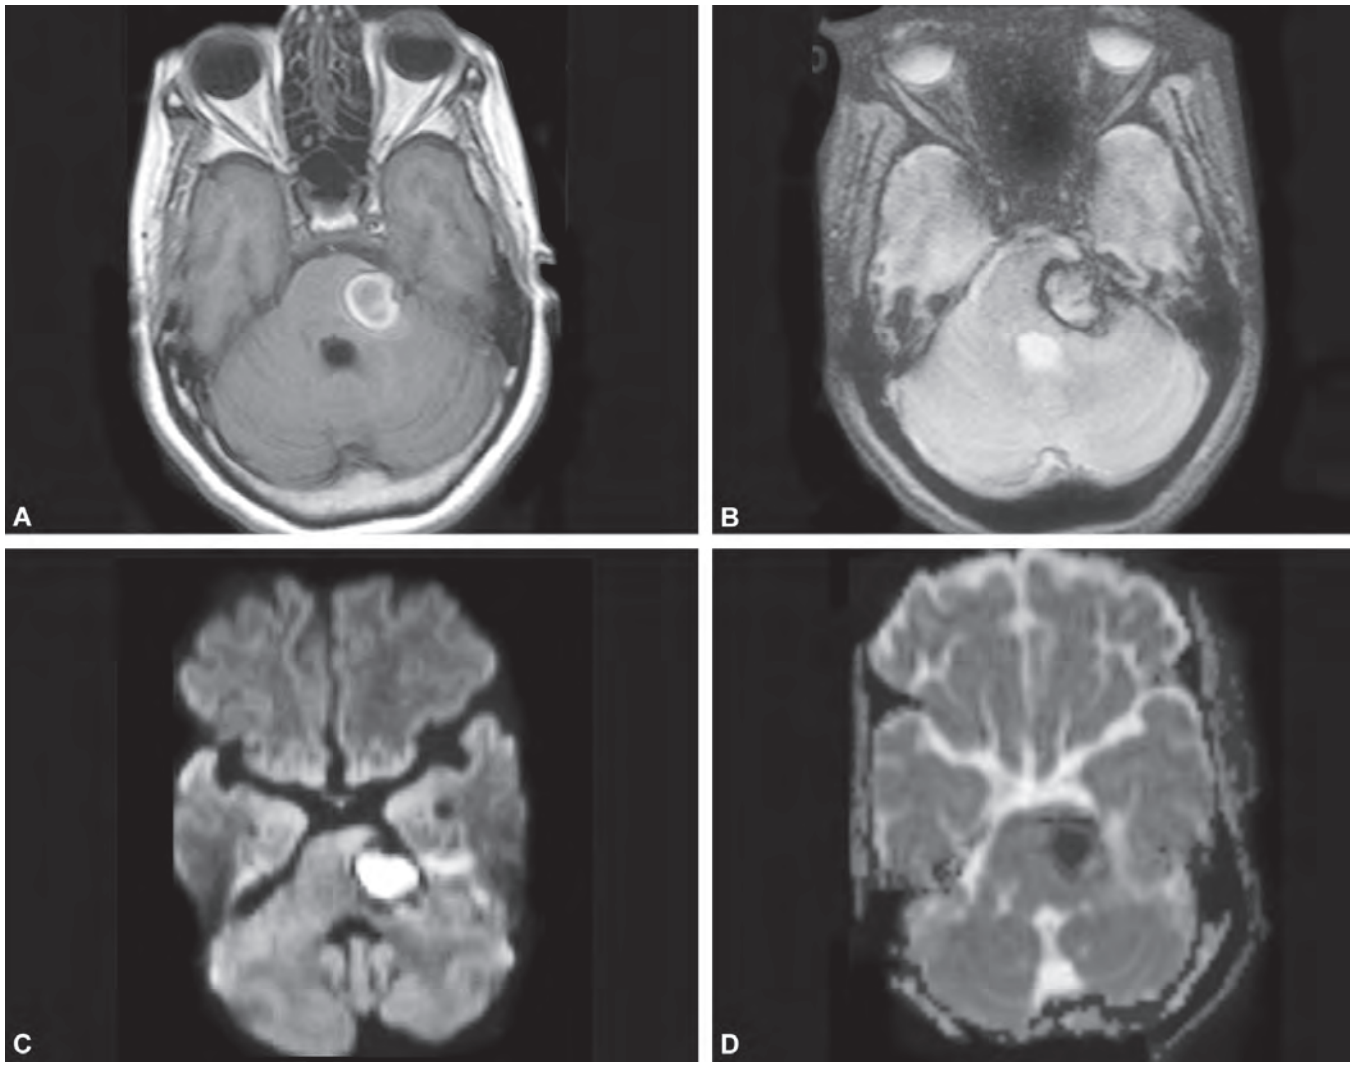
enhancing lesions includes primary brain tumours (e.g. necrotic glioblastoma), metastases, resolving haematoma, infarction and demyelinating diseases. DWI and MRS may help in the differentiation[21] (Figs 1A to D).

Ring enhancement of an abscess is usually thin and smooth, thinner along the medial margin. Sometimes, nodular or solid enhancement, incomplete thin rings or thick and irregular rings may be seen. Contrast enhancement may be reduced in patients receiving steroid or antibiotic treatment. Daughter abscesses appear as small adjacent rings, often along the medial margin of the parent abscess. Oedema surrounding the abscess may be greater in volume than the abscess itself. If the abscess ruptures into the ventricles, it results in ventriculitis or ependymitis, which carries a bad prognosis.[24]

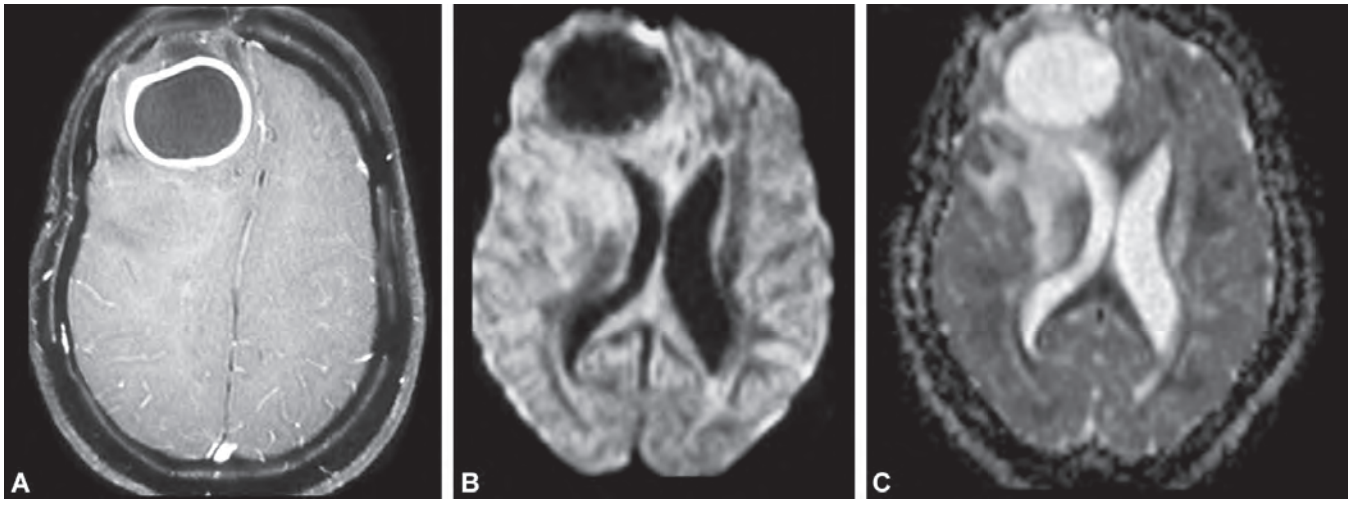
DWI shows restricted diffusion in the abscesses with calculated apparent diffusion coefficient (ADC) values in the range of 0.21–0.31. The structure of pus with its high cellularity and viscosity is responsible for the restricted diffusion. The presence of large molecules, like fibrinogen, also may play a key role in restricting the diffusion of pus. The closest differential diagnosis will be an acute infarct, which could be differentiated with other clinical and imaging features. However, hyperacute haematoma also may show diffusion restriction and should not be mistaken for an abscess (Figs 2A to D). It should also be noted that some of the abscesses may not show diffusion restriction (Figs 3A to C) and necrotic tumours very rarely show diffusion restriction.[18]

Diffusion tensor imaging, shows in addition to low diffusivity, a high fractional anisotropy (FA) in some parts of the abscess cavity.[14] FA value as high as that of the normal white matter is seen in the abscess with "orientations", apparently caused by organised inflammatory cells in the cavity. Recently, it has been shown that the 'pseudo-fibres' constituted by these cells produce high planar anisotropy (CP) on calculating the "diffusion metrics" in these abscesses.[20]

Magnetic resonance spectroscopy appears to be very useful in differentiating and characterising cerebral



Figs 2A to D: Pontine cavernoma with recent bleed. (A) Axial T1. (B) T2 GRE images show haematoma with blood in oxy Hb stage (hyper acute) in the central portion. (C) Diffusion weighted image. (D) ADC map show restricted diffusion within the lesion



Figs 3A to C: Right frontal cystic lesion. (A) Axial contrast enhanced fat saturated T1 weighted image shows a ring enhancing cystic mass lesion. (B) Diffusion weighted image. (C) ADC map show facilitated diffusion within the lesion. It proved to be a chronic sterile abscess

abscesses. MRS shows acetate (1.92 ppm), lactate (1.3 ppm), alanine (1.5 ppm), succinate (2.4 ppm) and complex peak at 0.9 ppm indicating cytosolic amino-acids like valine, leucine, isoleucine. With the characteristic imaging features, acetate and succinate are fairly specific for cerebral abscesses. In addition, necrotic or cystic tumours do not show peaks at 0.9 which usually inverts at TE 135. However, they can show lactate/lipid peaks. Acetate and pyruvate/succinate peaks were found to disappear within 1 week after instituting therapy for an abscess. Amino-acid peaks were found to disappear within days with persistence of only lactate. MRS also helps in differentiating aerobic and anaerobic abscesses.[10] DWI and MRS also may help in differentiating pyogenic abscesses from tubercular and fungal abscesses.[23]

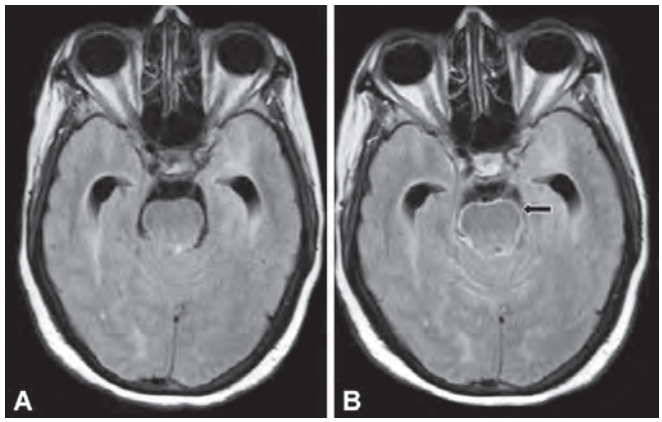
With treatment, an abscess may resolve with decrease in oedema, mass effect and degree of enhancement. However, enhancement might persist even after a full course of antibiotics, yet the lesion usually resolves within the succeeding 3–4 months. Focal gliosis or calcification may remain.

Septic Embolism and Mycotic Abscesses

This can occur in patients with history of intravenous drug abuse, bacterial endocarditis or children with congenital cyanotic heart disease. It can result in major arterial branch infarction, as also multiple small abscesses located at the grey-white matter junction. Mycotic aneurysms involve intermediate to small branch arteries and are usually located in more peripheral arterial branches. They are usually small and are difficult to be detected with cross-sectional imaging and often require digital subtraction angiography for detection.

Meningitis

Meningitis is acute or chronic inflammation of the leptomeninges. It occurs either secondary to haematogenous spread, direct spread from the adjacent focus of infection or from penetrating injury to the brain. Pathologically, the affected region shows congestion and hyperaemia of the pia-arachnoid and distension of the subarachnoid space by exudates.



Figs 4A and B: (A) Pre-contrast. (B) post-contrast FLAIR images show pial enhancement along the brain-stem with dilatation of the temporal horns suggestive of meningitis

Magnetic resonance imaging forms the most sensitive method for detecting meningeal inflammation. Unenhanced scans may be unremarkable in the acute stage. Post-gadolinium images show leptomeningeal enhancement. Pre-magnetisation and post-magnetisation transfer Gd increases the sensitivity of displaying leptomeningeal enhancement (Figs 4A and B). Magnetisation transfer ratios (MTRs) from the affected meninges may give clues to the aetiological nature of meningeal inflammation.[15] Recently, it has been shown that contrast enhanced FLAIR imaging helps in detecting subtle meningeal enhancement and many medicines, including ibuprofen can produce aseptic inflammation of the meninges which can mimic infective meningitis.[29,30]

Complications

Meningitis can result in several complications and include arterial and venous infarcts, abscess and cerebritis, subdural collection and empyema. Hydrocephalus and rarely ventriculitis may also follow meningitis. Venous infarcts are seen as hyperintense areas in the subpial cortex and underlying white matter, usually near the vertex due to superior sagittal sinus thrombosis. MRI with MR venography may help in detecting such complications (Figs 5A to C).

Subdural Collections

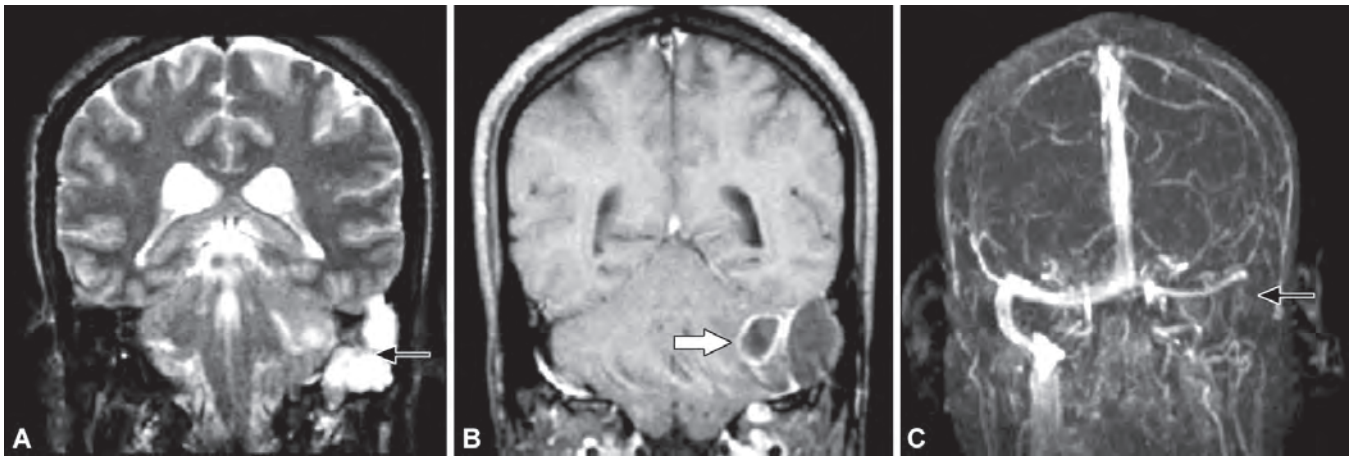
These could be subdural effusion or subdural empyema. Subdural effusion secondary to *H. influenzae* is usually bilateral and is seen as crescentic collections along the frontal and parietal cortices. They are isointense to CSF in all sequences. The underlying cerebral cortex does not show signal changes. Post-Gd images usually do not show enhancement. Calcification of the margins of the effusion may be a sequel. Subdural empyema usually shows enhancement of the periphery with restricted diffusion within it on DWI.[32]

Hydrocephalus

Hydrocephalus can be communicating or non-communicating, more frequently seen in children than in adults. It occurs due to adhesions or loculations secondary to meningitis. Ventricular dilatation with transependymal periventricular CSF seepage (T2 hyperintensity) is seen especially on FLAIR sequences. Basilar and supratentorial enhancement of the subarachnoid spaces could be seen in association with communicating ventricular enlargement.

Empyema

They represent purulent collections in the subdural and/or epidural space. In 65–70% of cases, it is secondary to otorhinologic infections with a very rapid clinical course. In the remainder it is due to previous head trauma, neurosurgical procedure or secondary to bacteraemia or meningitis. There can be either epidural or subdural empyema.



Figs 5A to C: Left mastoiditis complicated with cerebellar abscess and venous sinus thrombosis. (A) Coronal T2 FSE shows the collection in the left mastoid cavity (thin arrow). (B) Coronal contrast enhanced fat saturated T1 weighted image shows ring enhancement along the cerebellar abscess (thick white arrow). (C) MR venogram shows occlusion of the left distal transverse and sigmoid sinuses (thick arrow) with no flow in the left proximal internal jugular vein

Epidural Empyema

It shows lentiform collections, continuous across the midline with a hypointense margin on both the T1WI and T2WI (medially displaced dura).

Subdural Empyema

These are crescentric or lentiform in shape, located on cerebral convexities and are frequently bilateral. On T1WI they appear hyperintense to CSF which becomes iso to hyperintense on T2WI and PD (high protein content). Abnormal signals in the underlying brain parenchyma can be noted. Sulcal effacement and dural venous thrombosis may be associated. Prominent enhancement of the margins of the empyema may be noted.

Pyogenic Ventriculitis

Gram-negative bacteria, in particular, resistant to standard antibiotics are the most common cause of infective ventriculitis. Ventricular debris was the most characteristic finding which is irregular in contour because of the high protein content and possibly, necrotic material. Elevated protein content in CSF might be related to a decrease in CSF production. Tufts of glial tissue projecting through areas of denuded ependyma into the ventricular exudate also might contribute to the intraventricular debris. Hydrocephalus has been documented in many cases. Periventricular signal abnormality, detected in 78% of cases with MR imaging, likely reflects the periventricular inflammatory change. Periventricular signal abnormality includes swollen subependymal astrocytes and perivascular infiltration with lymphocytes and plasma cells. Chronic infection might result in subependymal astrocytic and microglial proliferation.

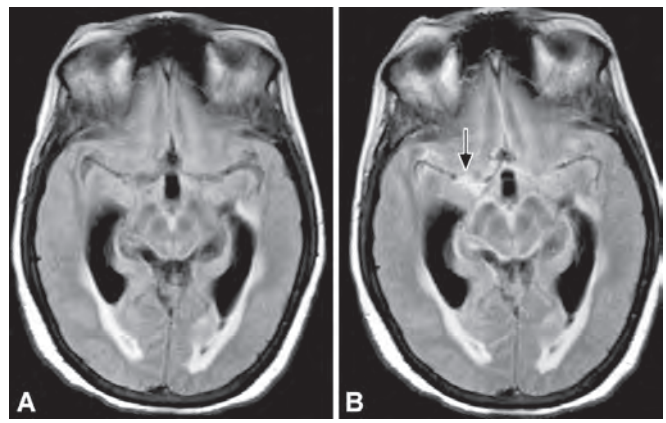
MYCOBACTERIUM TUBERCULOSIS INFECTION

Adult tuberculosis often results from post-primary infection and most cases of childhood TB are due to primary infection. Intracranial TB can present as meningitis, abscess, focal cerebritis and tuberculomas.

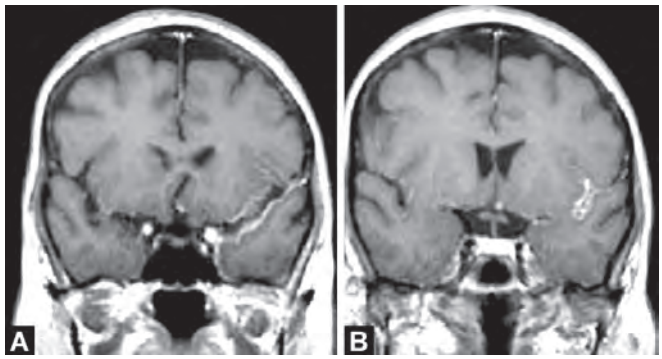
Tuberculous Meningitis

Tuberculous meningitis (TBM) usually shows enhancement of basal cisterns, meningeal enhancement, hydrocephalus and parenchymal infarctions usually of the perforator territory (e.g. basal ganglia) both on CT[4,5] and MRI.

The basal meninges are involved early in the course of the disease with thick gelatinous exudates. Circle of Willis vessels may be involved resulting in arteritis, thrombosis and infarction. Hydrocephalus, usually communicating, occurs in most cases. Hydrocephalus can be occasionally obstructive due to mass effect. MR imaging, especially Gd enhanced scans help in demonstrating the extent of exudates (Figs 6A and B, 7A and B). MTR from the meninges may help in differentiating TBM from pyogenic meningitis. The MT ratio of TB meningitis could be in the range of 19.49 +/- 1.22, in contrast



Figs 6A and B: (A) Pre-contrast. (B) post-contrast FLAIR images show thick exudates with enhancement along the basal cisterns, especially the right MCA cistern (arrow) with dilatation of the ventricles suggestive of the possibility of tuberculous meningitis



Figs 7A and B: Coronal contrast enhanced T1 weighted images show enhancement along the left MCA cistern and the Sylvian fissure in tuberculous meningitis

to viral meningitis with MTR of 8.2 +/- 0.8; pyogenic meningitis of 30 +/- 0.17; and cryptococcal meningitis of 27.2 +/- 1.7.[15]

Chronic sequelae include mental retardation, paralysis, cranial nerve palsy, seizures, and speech or visual deficits.

Tuberculomas

They may develop secondary to haematogenous spread or extension into the adjacent parenchyma, via cortical veins or small penetrating arteries. They can show various stages and are composed of central solid/liquid caseation, surrounded by a capsule of collagenous tissue, epithelioid cells, giant cells and phagocytes. They usually occur in the grey-white junction, periventricular regions, subarachnoid, subdural and epidural spaces. On CT, the immature forms appear as small discs and rings with massive oedema, while the mature forms appear as large rings or lobulated masses. The large rings enclose a mass, whereas the lobulated masses represent coalesced small discs and rings forming a large tuberculoma.[6] Target sign may be seen on CT scan. MR imaging shows variable findings, depending on the stage of the tuberculoma.[13] On T1WI it is usually isointense to grey matter with a slightly hyperintense rim. T2WI shows signals iso to hypointense to brain parenchyma, due to paramagnetic free radicals or high cellular density (Figs 8A to C). If hyperintense on T2, it is due to liquefactive necrosis of the centre. Perilesional oedema is less compared to pyogenic abscess which can be intense in the early stages. Post-Gd images show intense nodular or ring like enhancement. Healed tuberculomas may show calcification. Healing time depends on the size of the initial lesion. Tuberculomas may have distinctive MRS and MTR findings. Prominent lipid peaks (0.9, 1.3, 2.0 ppm) and phosphoserine peaks (3.7 ppm) have been noted on proton MRS. The MT ratio of tuberculomas could be in the range of 19.49 +/- 1.22. Neurocysticercosis (NCC) in contrast can show a MTR of 32 +/- 1.8.[15]

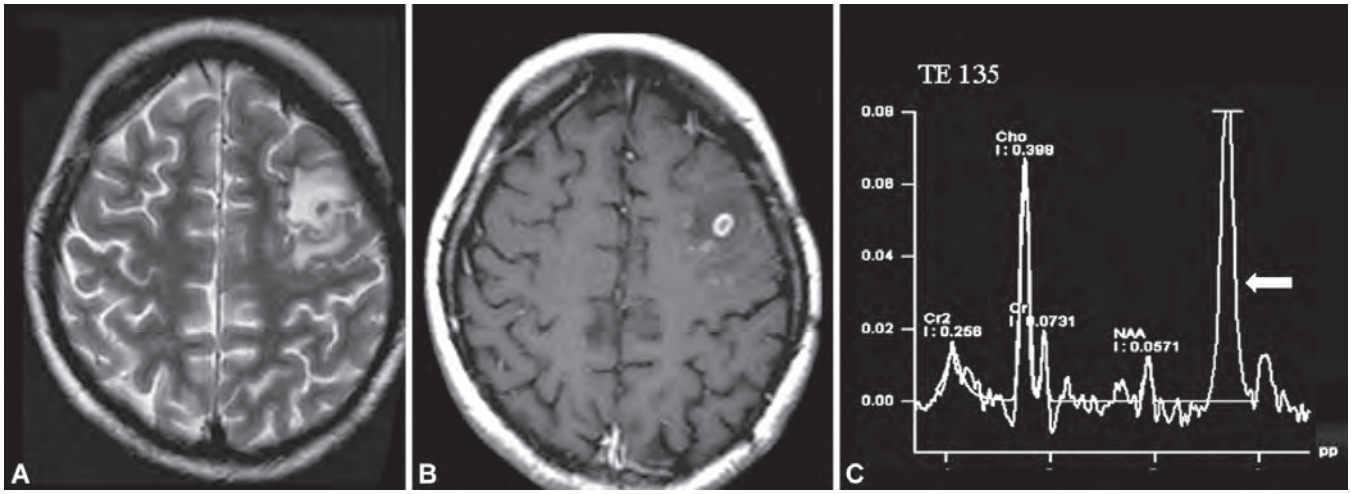
Tuberculous Abscess

Tuberculous abscess may develop due to liquefactive breakdown of caseated tuberculomas. They are usually larger than a tuberculoma. On CT they appear hypodense, with surrounding oedema and mass effect and ring enhancement.

MRI shows central hyperintensity on T2WI with post-Gd ring enhancement. DWI shows restricted diffusion with MRS showing a strong lipid lactate peak and sometimes a phosphoserine peak.

NEUROCYSTICERCOSIS

Neurocysticercosis is a common parasitic infection of the CNS. This disease is prevalent in developing countries and particularly affects the socially and economically deprived classes of society, where hygiene is often poor. Man gets afflicted by the parasite when he consumes infected pork or vegetables contaminated with parasitic eggs. NCC is caused by the larvae of *Taenia solium*, *Cysticercosis cellulosae* and less frequently by *Cysticercosis racemosae*. *C. cellulosae* is characterised by a small cyst of



Figs 8A to C: Left frontal tuberculomas in the solid caseation stage. (A) Axial T2 weighted FSE shows hypointense lesions with surrounding oedema. (B) Axial contrast enhanced T1 weighted image shows ring enhancement of the lesions. (C) Proton MR spectroscopy shows a prominent lipid peak (arrow)

5–15 mm, the cyst wall is thin and transparent and the cyst contains clear fluid with a pearly white invaginated scolex. *C. racemosae* are often large, measure 4–12 cm and are devoid of a scolex. Occasionally, a solitary cyst, especially one in the fourth ventricle can acquire a large size.[25,33] Based on the location of the cysts, five forms are recognised: parenchymal; spinal; arachnoid; ventricular and mixed.[13]

The cysts can remain viable in the CNS for several years depending on the immune status of the individual. Morphologically, four stages of disease are identified, namely vesicular, colloidal, granular nodular and calcific stages. In the vesicular stage, the cyst is well defined, contains a scolex and is viable. The colloidal stage is characterised by death and disintegration of the cyst, the cyst fluid becomes turbid and there is an associated inflammatory process. In the granular nodular stage, the cyst wall retracts with thickening of the capsule. Chronic inflammatory infiltrates are seen around the cyst with moderate to intense fibrillary astrocytosis. In the calcific stage, the lesion retracts to a fraction of its initial size, fibrosis gradually replaces the lesion and often it gets calcified.[9,13]

Neurocysticercosis can present clinically with a wide spectrum of symptoms. Epilepsy is the most common and often, the only symptom of parasitic infestation. Other manifestations include headache, arachnoiditis, focal neurological deficits, hydrocephalus, raised intracranial pressure and rarely encephalitis.[9]

MRI is the investigation of choice for evaluation of NCC. Contrast MR and advanced imaging like spectroscopy helps in further delineation and can aid in the diagnosis when there is a diagnostic dilemma. One disadvantage of MR is that small calcific nodules may be too subtle and are often missed in conventional MR and, sometimes, even in gradient echo sequences. Detection of these calcifications is important, as it can act as epileptogenic foci and can present with intractable seizures. However, the novel susceptibility weighted imaging sequences can detect these calcifications easily,[30] as is also the case with CT.

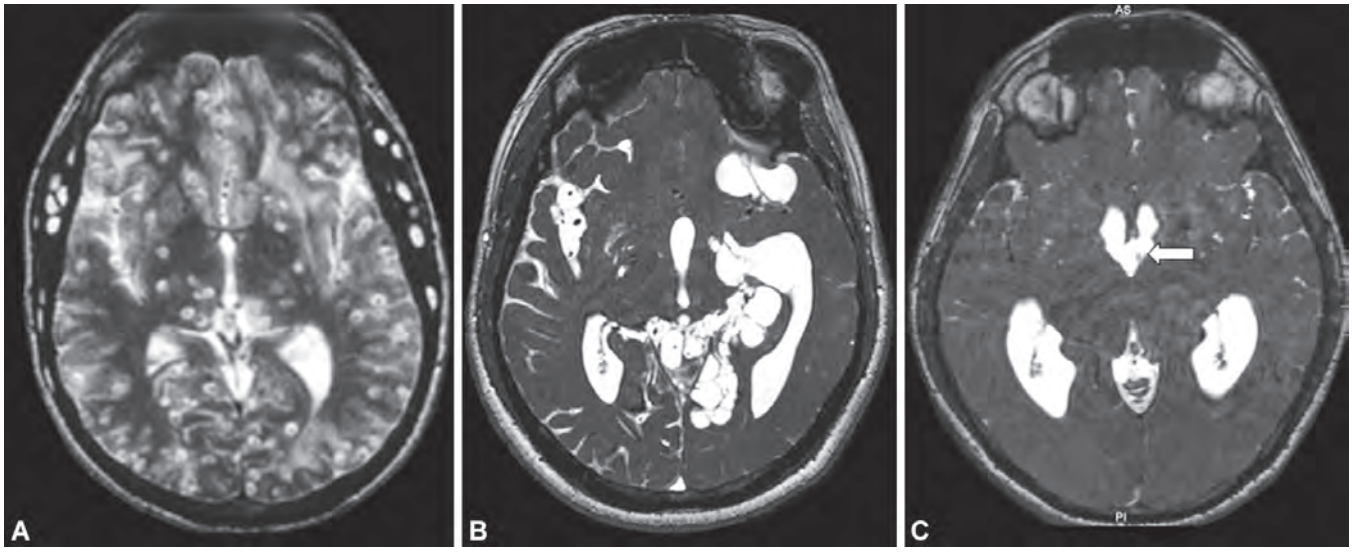
MRI can identify various stages of NCC and this reflects evolution of the parasite through different pathological changes.[13] In the acute phase of invasion, MR may show a focal non-enhancing hyperintensity or small contrast enhancement, due to mild inflammatory reaction. In the vesicular stage, a typical 1–2 cm cyst is demonstrated, which appears as a well defined hyperintense lesion on T2W and hypointense on T1W sequences similar to CSF (Fig. 9A). The larval scolex may be identified which is seen as a 1–2 mm mural nodule which appears hyperintense on T1 and hypointense on T2W. The demonstration of a scolex is pathognomonic of cysticercosis. There is no oedema, mass effect or enhancement at this stage.[9,13]

The colloidal stage is characterised by the death of the parasite which invokes a surrounding inflammatory reaction. The cyst contents become turbid due to increased protein content, which is seen as hyperintense on T1W and T2W. There is adjacent moderate to marked oedema and there is solid or ring enhancement. The cyst capsule is thickened and appears hypointense on T2W images. In the granular nodular stage, the cyst shows uniform ring enhancement and there is reduction in the oedema and mass effect. In the final stage, the cyst becomes calcified and may not be detected with conventional MR. Gradient and susceptibility weighted sequences are sensitive to calcified lesions.[9,13] These lesions do not show contrast enhancement or mass effect, although there are reports describing enhancement in calcified NCC.[28]

The cisternal form of NCC involves the subarachnoid spaces and basal meninges. They are commonly located in the cisterna magna, cerebellopontine angle cistern or sellar cisterns. Cysts are usually large and may attain giant proportions. These are racemose cysts and lack a scolex. Usually, these are single cysts, but imaging may show these cysts to be multi-loculated, which may be due to the infolding of the cyst wall or agglomeration of multiple cysts presenting as a nodular mass (Fig. 9B). Sometimes, this may be seen as asymmetrical CSF spaces and a high index of suspicion is needed to identify this. FLAIR imaging with 100% supplemental oxygen improves the conspicuity of cisternal cysts,[7] so also with the use of thin heavily T2 weighted sequences like CISS or FIESTA. These cysts can provoke inflammatory reaction, resulting in severe basal arachnoiditis, communicating hydrocephalus, vasculitis and basal ganglia infarcts.[3,9,13]

Intraventricular NCC occurs in 20% of the cases.[9] This is most commonly detected in the fourth ventricle due to dependant gravitation of the cysts. Other less common sites include the aqueduct of Sylvius and the third and lateral ventricles (Fig. 9C). Early diagnosis is important as the mobile cysts can cause acute obstruction to the ventricular outflow, resulting in sudden death. The cyst is often similar to CSF in all sequences; however, the identification of the cyst wall or scolex, if present, helps in the correct diagnosis. These cysts often conform to the ventricular wall and may be mistaken for a dilated ventricle.[25,33] Sometimes, the cyst can cause ependymal inflammation which may be seen as a high intensity rim in FLAIR images or as thin contrast enhancement of the ependymal wall. O_2 supplementation does not improve the conspicuity of these cysts. 3D CISS has been shown to be more sensitive and specific than conventional MR to detect the cyst wall and scolex of intraventricular cysts.[12] Intrathecal iodinated contrast administration and imaging with CT may identify these cysts as filling defects. Intrathecal gadolinium administration has also been tried.

Spinal cord involvement is reported in 2–5% of NCC.[9,31] Extramedullary cysts are more common than intramedullary forms and usually these patients have the manifestations of this parasite elsewhere in the body, which helps in the diagnosis. The cysts can be solitary or conglomerated, commonly located in the thoracic



Figs 9A to C: Neurocysticercosis. (A) Axial T2 weighted FSE showing the brain parenchyma and the temporalis muscles studded with cysticercal cysts in the vesicular stage. (B) Axial T2 weighted 3D-CISS demonstrating racemose cysticercosis in another patient. (C) Axial T2 weighted 3D-CISS showing cyst within the third ventricle in a third patient (arrow)

cord and may show non-specific imaging findings. Co-existant CNS infection or CSF analysis may resolve the issue.

MR spectroscopy of NCC may show lactate (1.3 ppm), acetate (1.98 ppm), cytosolic amino acids (0.9 ppm), alanine (1.47 ppm) and succinate (2.4 ppm). The presence of strong succinate with a smaller acetate peak may help in differentiating NCC from pyogenic brain abscess.[1] Choline, n-acetyl aspartate (NAA) or creatine peaks are not observed within the cysts. DWI of NCC show high ADC consistent with the cystic lesion.[1,26]

In developing countries, apart from NCC, several other prevalent neurological diseases, for example, tuberculosis, can present with a similar clinical and radiological picture. In order to improve the specificity, diagnostic criteria have been put forth based on clinical, radiological and epidemiological parameters proposed by del Brutto et al. which is given in Table 1. Modifications have been suggested for Indian patients.[8,11]

Table 1: Diagnostic criteria and degree of certainty for human neurocysticercosis

Absolute criteria	1. Histological demonstration of parasite
	2. Direct visualisation of parasite by fundoscopy
	3. Visualisation of scolex on CT/MR
Major criteria	1. Lesions suggestive of neurocysticercosis (NCC) on CT/MR
	2. Positive immunological studies
	3. Plain X-ray shows calcifications in muscles
Minor criteria	1. Subcutaneous nodules
	2. Soft tissue or intracranial calcifications
	3. Clinical history suggestive of NCC
	4. Disappearance of NCC with anti-helminthics
Epidemiologic	1. Living or hails from endemic regions
	2. Frequent travel to endemic areas
	Household contact with *Taenia solium*

- *Definitive*: (1) one absolute criterion; (2) two major criteria; (3) one major + two minor + one epidemiologic.
- *Probale*: (1) one major + two minor; (2) one major + one minor + one epidemiologic; (3) three minor + one epidemiologic.
- *Possible*: (1) one major; (2) two minor + one epidemiologic.

Differential diagnosis includes tuberculosis, brain abscess, cystic tumours and hydatid cysts. Tuberculosis is an important differential diagnosis which needs to be excluded as both are widely prevalent in developing countries and the therapeutic options are entirely different for both the conditions. Clinical and CT criteria have been suggested to differentiate both the diseases, however they are not reliable. NCCs are usually small, less than 2 cm, round and uniformly enhance with contrast and there is absence of severe mass effect. Newer techniques like magnetisation transfer, DWI and MR spectroscopy can settle the issue to a greater extent.

Electro-immuno transfer blot assay for the detection of *T. solium* antibodies has sensitivity of more than 90% and specificity of 100%. But, this test can be frequently false negative in single cysticercal lesions and its sensitivity and specificity decreases with calcified lesions.[11]

NEUROBRUCELLOSIS

It is a rare zoonotic disease with the primary hosts being camels, sheep and goats and humans act as the secondary host. This disease is usually transmitted through consumption of uncooked meat or unpasteurised dairy products. Neurobrucellosis occurs in 5–10% of cases of brucellosis and affects both the central and

the peripheral nervous systems. It preferentially affects the auditory system with occurrence of sensorineural hearing loss. Three types of imaging abnormalities can be seen[2]: inflammation, white matter changes and vascular insults. Inflammation may result from granulomas or enhancement of the meninges (basal meningitis), perivascular space or lumbar nerve roots. White matter changes manifest as hyperintense lesions on T2WI in the form of diffuse involvement of the arcuate fibres or periventricular regions (corpus callosum) or as focal demyelination. Vascular insult is likely to be due to one of two mechanisms: (a) inflammatory process (vasculitis) of the small vessels or venous system causing lacunar infarcts, small haemorrhages, or venous thromboses; (b) a haemorrhagic stroke caused by rupture of a mycotic aneurysm, a likely sequel of embolic stroke from brucellar endocarditis.

ANTHRAX MENINGOENCEPHALITIS

Infection with the *Bacillus anthracis*, a large gram-positive, spore-forming bacillus is transmitted to humans by contact with infected animals or contaminated animal products. CT and MRI show multiple haemorrhagic lesions at the grey-white matter junction of the cerebrum and diffuse meningeal enhancement. Haemorrhage in the deep grey matter, ventricle, supra and infratentorial subarachnoid spaces and diffuse meningeal enhancement can also be seen. However, no parenchymal enhancement has been reported.

VIRAL INFECTIONS OF THE BRAIN

Viral infections of the brain result usually in aseptic meningitis or viral encephalitis.

Pathological features include neuronal degeneration and inflammation. It can range from diffuse brain congestion and oedema to haemorrhage and necrosis. MRI shows scattered or confluent areas of hyperintensity on T2WI and iso to hypointense on T1WI. Haemorrhage may be present. Localised or generalised atrophic changes may be seen.

Herpes Simplex 1 Encephalitis

Herpes simplex 1 (HSV-1) encephalitis initially involves the cerebral cortex, causing neuronal destruction and cytotoxic oedema. A characteristic pattern of distribution is exhibited by the pathogen, with the anterior and medial aspects of the temporal lobes and the inferior portion of the frontal lobes initially being affected. The process may then extend to include the insular cortex. The lentiform nucleus is typically spared. Bilateral mesial temporal involvement is almost pathognomonic for HSV encephalitis, particularly when asymmetric.

CT is usually normal during the early stages of infection and abnormal parenchymal or meningeal enhancement is rarely detected before the 2nd week of clinical symptoms. MR imaging, especially DWI is more sensitive during the initial course of the disease. The involved areas appear hypointense on T1WI and hyperintense on T2WI. DWI can show restricted diffusion in the early course of the disease. Focal areas of haemorrhage may be detected on gradient images in areas of herpetic involvement, but is a rare finding. The leptomeningeal and gyral enhancement associated with HSV encephalitis typically occur along the temporal lobes, insular cortex, subfrontal area and cingulate gyrus (Figs 10A and B). These lesions are more conspicuous if magnetisation contrast pulse is turned.

If the patient has HIV infection, the white matter is predominantly affected, especially in the occipital lobe and exceptionally in the cerebellum. The hippocampi, frontobasal, insular and temporal cortices are spared.[27]

MRS shows reduced NAA between 7 weeks and 14 weeks after onset, whereas choline can be elevated, with the presence of lactate. Glial proliferation in HIV-related herpes simplex encephalitis can be associated with progressive myoinositol increase.

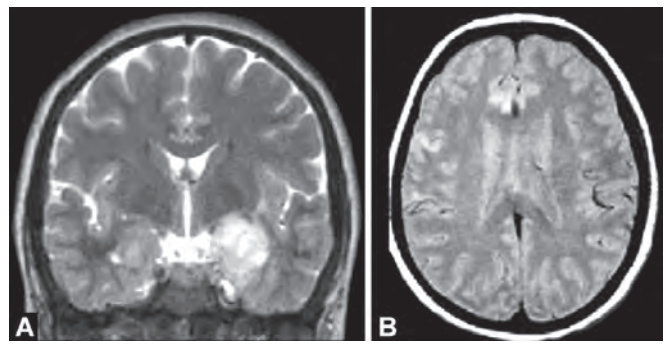
Japanese Encephalitis

The natural transmission cycle of the Japanese encephalitis (JE) group involves infection of a mosquito vector alternating with viral amplification in a variety of vertebrate hosts. Human disease is incidental to this cycle. It presents after a brief, non-specific prodromal febrile illness. Seizures are a prominent manifestation in children.

Adults usually present with more obviously encephalitic symptoms. Cranial nerve palsies, particularly of the VII nerve, occur in 50% of cases. Movement disorders are a major feature in 40% of patients and include choreiform movements, Parkinsonism and other tremors.

Thalamic lesions are most frequently hypointense on T1-weighted images and hyperintense on T2-weighted images, but high signal intensity on T1-weighted images, consistent with subacute haemorrhage, has also been described.

The basal ganglia and midbrain are frequently involved by JE. These lesions are more likely to be



Figs 10A and B: Herpes simplex encephalitis. (A) Axial. (B) Coronal T2 weighted FSE showing mesial temporal and cingulate hyperintensity

asymmetric than are those within the thalami. Co-infection with NCC is also known in endemic areas.[17]

Rabies Encephalitis

It is an acute infection involving the CNS in humans and other mammals caused by an RNA virus of the rhabdovirus family. Human rabies presents in two forms: encephalitic and paralytic. The passage of the virus to the CNS occurs axonally through retrograde axoplasmic flow of approximately 12–24 mm per day, until the virus reaches the next neuronal cell body.

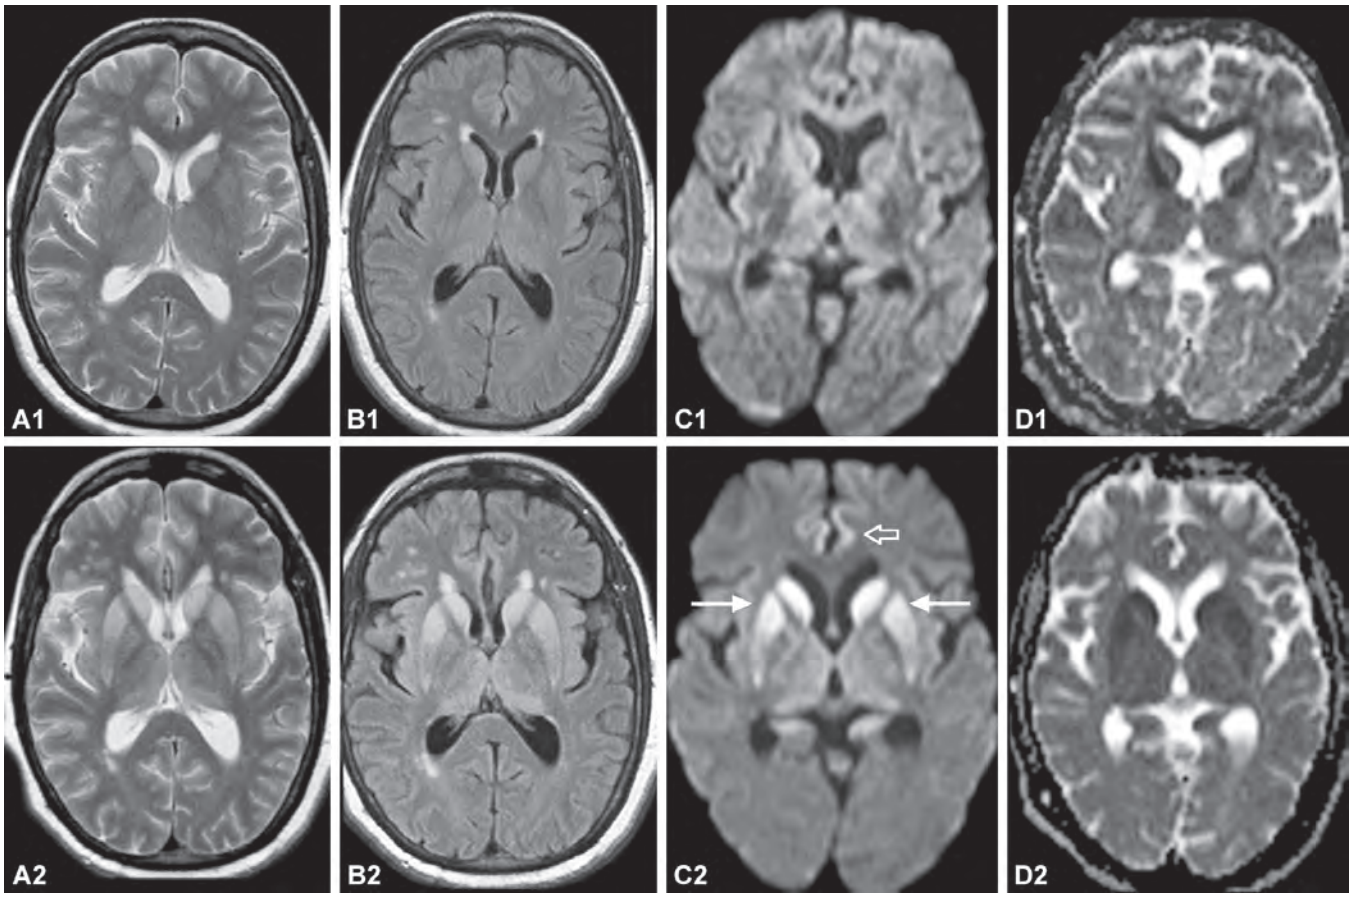
In paralytic rabies, the medulla and the spinal cord are mainly involved by extensive neuronal damage and inflammation, whereas in the encephalitic form, it is the brainstem and the cerebrum, particularly the limbic system. Involvement of the basal ganglia and the thalamus are usually seen late in the disease. CT scan shows focal or diffuse areas of decreased attenuation and, as areas of hyperintensity on T1- and T2-weighted MR images in the basal ganglia, periventricular white matter, hippocampus and brain stem.[22] Diffuse cerebral oedema may be seen in advanced stages.

Creutzfeldt-Jakob-Disease

Creutzfeldt-Jakob-Disease (CJD), a fatal neuro-degenerative disorder, is diagnosed by the detection of an accumulation of an abnormal form of the human prion protein (PrPSc) in the brain. Brain biopsy or autopsy is required for a definitive diagnosis. In sporadic CJD, diagnostic MR examinations are performed frequently and reveal typical findings. Hyperintense signal-intensity abnormalities, initially reported on T2-weighted and proton attenuation (PD)-weighted images, are also detectable on FLAIR and diffusion-weighted images (DWI) involving the head of the caudate nucleus and in the putamen (Figs 11A to D). In addition, the cortical ribbon can also show hyperintensity. DWI shows a decrease of the ADC in the affected areas, most probably because of the characteristic neuropathologic spongiform neuropil changes.[19] The disease has a fatal course.

Acute Disseminated Encephalomyelitis

It is a monophasic post-infectious (varicella, measles and rubella) or post-vaccinial inflammatory disorder that is pathologically characterised by an acute perivenous lymphocytic inflammation with confluent demyelination. It presents with seizures, focal neurologic signs and



Figs 11A to D: Creutzfeldt-Jakob-Disease (CJD). (A) Axial T2 weighted FSE. (B) FLAIR. (C) DWI. (D) ADC 3 months apart (1 and 2, upper and lower rows, respectively) showing the involvement of the head of the caudate nucleus and the putamen with diffusion restriction more evident on the second row (thin arrows). Note also the cortical ribbon sign (thick arrow)

alteration of consciousness that develop days to weeks after the onset of presumed viral infection. CSF analysis reveals mild pleocytosis.

MR imaging usually shows T1 and T2 prolongations, typically bilateral and asymmetric, in the deep and subcortical white matter of the cerebrum, cerebellum and brainstem with no mass effect. The corpus callosum may be involved in acute disseminated encephalomyelitis (ADEM) and these patients nearly always have asymmetric callosal lesions and their white matter has lesions as well. After contrast material infusion, the lesions in ADEM will show various patterns of enhancement, depending on their acuity. Improvement of white matter lesions may take a long time and part of the white matter damage may be permanent.

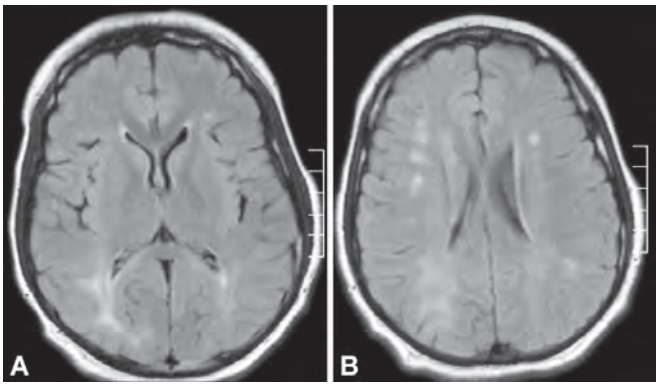
Subacute Sclerosing Panencephalitis

This is attributed to slow progressive infection by measles virus. Children between the ages of 5 years and 12 years who had clinical measles 3 years before are affected. Clinically, four stages are recognised from initial mental or behaviour abnormalities to loss of cerebral cortical function. Death usually occurs within 2–6 years. White matter abnormality seen in the centrum semiovale is either patchy or diffuse and there is minimal inflammation. Gliosis can occur in the grey matter, basal ganglia, pons and thalamus. MR shows bilateral periventricular white matter hyperintensities on T2WI (Figs 12A and B). No mass effect is seen. Frontal and/or occipital involvement can be more extensive.

FUNGAL INFECTIONS

They are divided into those that predominantly infect the immuno-compromised (Aspergillus, Candida, Mucormycosis) and those that infect immuno-competent individuals.

Cryptococcus and Histoplasma spread haematogenously, reach the microvasculature of the meninges, penetrate the vessel walls and result in an acute or chronic leptomeningitis.



Figs 12A and B: Subacute sclerosing panencephalitis. (A and B) Axial FLAIR images showing the characteristic parieto-occipital involvement

Cryptococcus Neoformans

It is the most common fungus to affect the CNS and to cause meningoencephalitis and is usually associated with HIV infection or AIDS and rarely seen in immuno-competent healthy persons.

It reaches the CNS through the haematogenous route from a peripheral focus in the lung. It extends into the parenchyma, either through the choroid plexus or through the Virchow-Robin spaces. Expansion of these spaces forms the pseudocystic lesions, characteristic of this disease.

It evokes minimal inflammatory response and does not release any exotoxin and thus causes little tissue necrosis. Therefore, secondary changes such as fibrosis, calcification, infarction or haemorrhage are rare and symptoms are caused by compression of the surrounding structures, as the infective focus enlarges. The avascular pseudocysts are seen as well circumscribed, round to oval hypointensities on T1WI and hyperintensities on T2WI, which fail to enhance after administration of contrast medium.

Granulomatous lesions enhance with contrast medium administration and are hyperintense on T2WI. They are located preferentially on the ependyma of the choroid plexus. Meningeal involvement often is inferred from the progressive ventriculomegaly on sequential images, but neither meningeal enhancement nor ventricular dilatation is specific for cryptococcosis. Periventricular oedema appears to result from altered CSF dynamics and seeping of the CSF into the interstitial space across the subependymal gliotic layer.

Candidiasis

On T2WI candida abscess appears as an area of a well demarcated hypointense signal surrounded by a larger area of high signal intensity. Meningitis, meningoencephalitis and granuloma may also result.

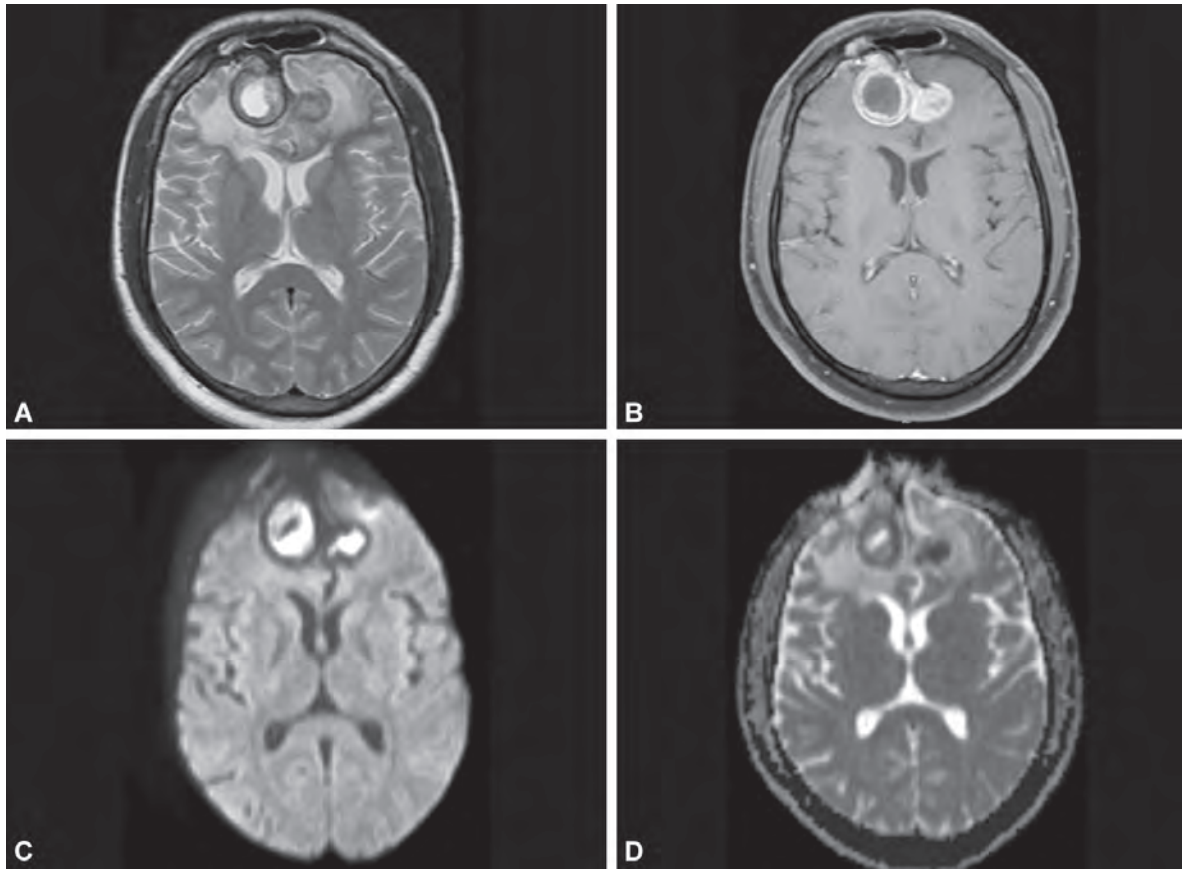
Aspergillus Infection

Aspergillus infection occurs by direct extension from the nasal cavity or paranasal sinuses or by the haematogenous route.

With direct spread, vascular invasion is often observed resulting in angiitis, thrombosis and infarction. Meningitis can result with extension into the subarachnoid spaces. With haematogenous spread, the vessels get occluded, producing infarction, septic infarction, cerebritis and cerebral abscess.

The presence of haemorrhage gives a clue to the diagnosis of aspergillosis. Fungal organisms were detected in the encapsulated lesion, but they were not commonly found in vessels or in the parenchyma outside the abscess.

Usually abscesses are hypointense on T1WI and hyperintense on T2WI with or without mass effect.



Figs 13A to D: Right frontal fungal abscess extending to left side. (A) Axial T2 weighted FSE showing the lesion with hypointense rim. (B) Axial contrast enhanced fat saturated T1 image shows ring enhancing cystic mass lesions. (C) Diffusion weighted image. (D) ADC map show the characteristic restricted diffusion

Hypointensity on T2WI also can be seen (Figs 13A to D). DWI show centrally restricted diffusion. The changes in diffusion are a likely reflection of proteinaceous fluid and cellular infiltration in the lesions.

Mucormycosis

Mucormycosis occurs in uncontrolled diabetic or immunocompromised patients. It spreads from the PNS along perivascular and perineural channels, through the cribriform plate into the frontal lobe or through the orbital apex into the cavernous sinus. It causes either infarction or fungal abscess and involves the base of the brain and cerebellum after invasion of the infratemporal fossa or orbit. It appears hypo or hyperintense on T2WI and hyperintense on T1WI and may demonstrate peripheral post-Gd enhancement.

CONCLUSION

Infections of the brain can be best imaged with MRI and advanced MR applications help in management decisions.

ACKNOWLEDGEMENT

The author wishes to thank Dr. Aravinda HR and Dr. Santhosh Kannath for the many meaningful discussions and valuable suggestions. The author also thanks the Director, SCTIMST for the permission to publish this manuscript.

DEVELOPMENT OF THE VERTEBRAL COLUMN

The vertebral column consists of 33 vertebrae, which include 7 cervical, 12 thoracic, 5 lumbar, 5 sacral and 4 coccygeal. There are regional differences in the anatomy of the vertebrae. However, despite these regional differences, the development of the vertebral column conforms to a general plan with some regional variations.[4,9,12–15]

Each vertebra passes successively through three different stages of development, which are as follows:[2,4,17]

1. Blastemal or membranous
2. Cartilaginous
3. Bony

As the notochord forms, the mesoderm condenses on either side of the notochord as two parallel longitudinal columns known as the paraxial mesoderm (Fig. 1). Initially, this mesoderm exists as a pair of unsegmented, longitudinal strips along the rostro-caudal axis. Later, the paraxial mesoderm begins to undergo segmentation resulting in the formation of the somites. The *somite* formation occurs first in the rostral end and then progresses sequentially caudally. The rate of formation of the somites has been estimated to be one pair every three hours. Initially, a cavity known as the *somitocele* (Fig. 2) is present within the somite which later disappears as the somites mature.

Each somite differentiates into a ventro-medial part known as the *sclerotome* and a dorso-lateral part known as the *dermo-myotome* (Fig. 3).[2,16,17] The dermo-myotome then forms the dermatome (forms dermis) and the myotome (forms muscle). The myotome differentiates to form two components, dorsally the epimere and ventrally the *hypomere*. The epimere gives rise to the epaxial muscles (dorsal skeletal muscles) and the hypomere gives rise to the hypaxial muscles (ventral skeletal muscles and the limb muscles) as shown in Figure 4.

During the 4th week the polymorphous cells of the sclerotome migrate ventro-medially around the notochord and form the rudiment of the centrum of the blastemal vertebra. Thereafter, the cells extend dorsally around the developing neural tube. These bilateral dorsal extensions meet in the midline dorsally to form the neural arch. The mesenchyme that intervenes between adjacent somites is related on either side to an intersegmental artery. Subsequently, each sclerotome is divided by a horizontal fissure known as the *sclerotomic fissure* (also known as von Ebner's fissure) into a less dense cranial half and a more dense caudal half (Fig. 5). The caudal half of one sclerotomic segment fuses with the cranial half of the subsequent sclerotomic segment to form the definitive centrum of the vertebra. The sclerotomic fissure and the mesenchymal condensation around it form the *perichordal disc* which persists into adult life as the *intervertebral disc* (Fig. 6). The nucleus pulposus of the intervetebral disc is notochordal in origin whereas the annulus fibrosus is mesenchymal in origin. The neural arches are related to that part of the centrum, which is derived from the cephalic part of the sclerotome. Thus, the vertebral body is derived from two adjacent sclerotomes. Close to the neural arch, each centrum gives rise to a costal element that extends laterally through the segmental myotomes.

The boundary of the head and neck corresponds to the boundary between the 5th and 6th somites. The first true somite disappears and somites 2–5 (known as occipital somites 1–4) fuse to form the basioccipital bone. The vertebrae are formed from the 6th somite onwards caudally. C1 (atlas) is formed by the fusion of the caudal half of the occipital somite 4 with the cranial half of the cervical somite 1. The shift of the somite number accounts for the production of seven cervical vertebrae from eight cervical somites.[17] The 1st to 28th pair of

The sclerotomal cells migrate to surround the notochord and the neural tube to form the vertebra. The myotome differentiates into the epimere, which gives rise to the epaxial muscles and the hypomere, which gives rise to the hypaxial muscles

somites is formed from the primitive streak by a process known as *primary gastrulation*. All the other caudal somites are formed from the tail bud by a process known as *secondary gastrulation*. It is believed that in humans, the boundary between primary and secondary gastrulation lies at the level of the 5th lumbar vertebra.

During the 6th week, chondrification starts in the membranous vertebra. Two cartilaginous centres appear in the centrum and fuse to form a single mass. Each neural arch is chondrified from one centre and fuses later with the centrum. Ossification begins in the 7th week. The vertebra is ossified from three primary centres and five secondary ossification centres. There is one primary centre for the centrum and one centre each for the neural arch. At puberty, five secondary ossification centres appear; one for the spinous process, one each for the transverse processes, two ring-like epiphyseal centres for the upper and lower surfaces of the centrum.

Regional Variations in the Development of the Vertebral Column

Cervical

The costal elements of the upper three cervical vertebrae are connected to each other in front of the corresponding centrum by bands of mesenchymal condensation. Later, this mesenchymal condensation persists only in the first cervical vertebra and forms the *hypochordal bow*, which

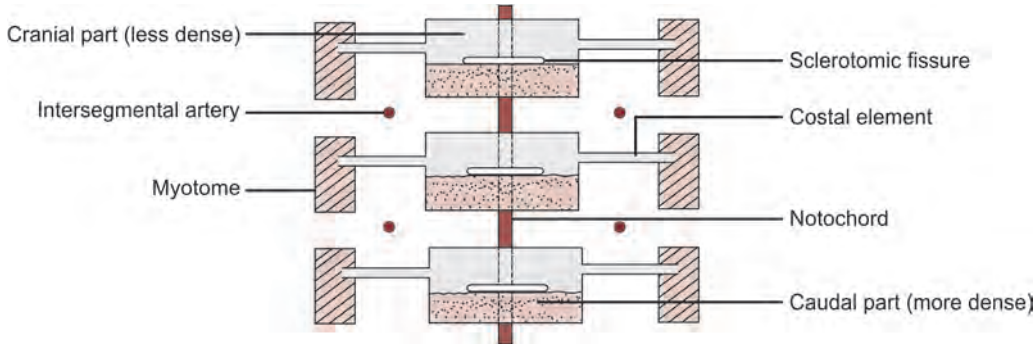

Fig. 5: Schematic representation of the division of the sclerotome, into cranial and caudal halves, by the sclerotomic fissure and the relationship of the sclerotome to the intersegmental artery and the developing myotome

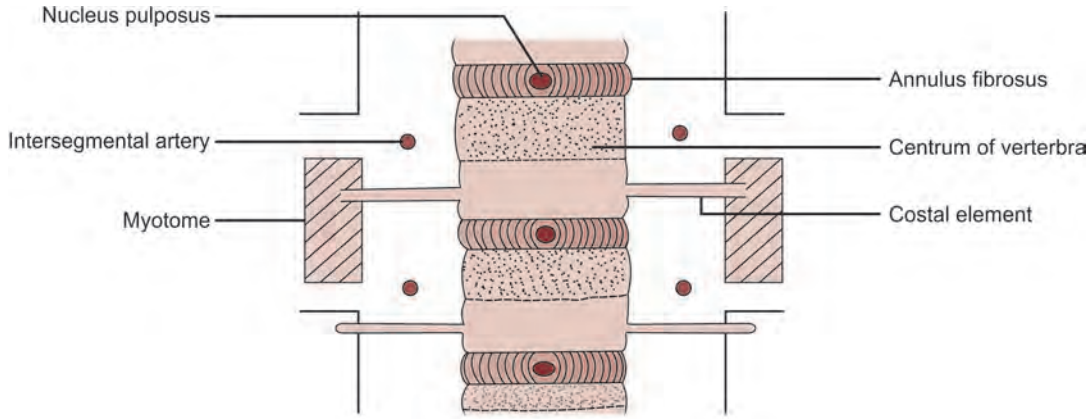

Fig. 6: Schematic representation of the development of the vertebra and the intervertebral disc

later gives rise to the anterior arch of atlas.[4] The centrum of the atlas is detached from the anterior arch and fuses with the centrum of the axis and forms the odontoid process or dens. In the cervical region, the costal element and the transverse elements of the developing vertebra are fused around the foramen transversarium. The costal element is represented by the anterior root, anterior tubercle and costo-transverse bar. The transverse element is represented by the posterior root and the posterior tubercle. In the cervical vertebrae, the distal portions of the costal elements do not develop. However, occasionally, when the distal portion of the costal process develops in the seventh cervical vertebra, it results in the formation of a cervical rib.

Thoracic

In the thoracic region, the costal elements form the ribs. As the ribs grow outwards through the segmental myotomes, they form the costal arches. The ventral end of the upper seven or eight arches unites to form the sternal plates. Finally, the sternal plates fuse in the midline to form the sternum.

Lumbar

The transverse processes of the lumbar vertebrae are formed from the costal elements and the true transverse elements are represented by the mamillary and accessory tubercles.

Sacrum

In the upper sacral vertebrae, the costal and transverse elements are fused to form the lateral mass of the sacrum. The anterior two-thirds of the lateral mass are derived from the costal elements and the posterior one-third from the transverse elements. The lateral surface of the lateral mass of the sacrum bears an articular surface through which it articulates with the ileum.

Molecular Basis of Vertebral Column Development

The authors of recent molecular studies have elucidated the genetic specification of the mammalian body plan, including, the axial skeleton. They have identified a number of developmental control genes and their role in segmentation. It is imperative for a contemporary clinician to be aware of the molecular and genetic perspectives of development so that he/she can integrate the modern molecular knowledge with problems of clinical dysmorphology as future developments in molecular biology may lead to genetic/molecular manipulations to treat many neurological illnesses.

It has been shown experimentally that the somites, and even the unsegmented paraxial mesoderm, are already skeletogenically predetermined with respect to morphological features characteristic of their axial level. For example, it has been shown experimentally that thoracic somites that are heterotopically grafted to the cervical region give rise to ribs in the host embryos. Consequently, the developmental fate of the sclerotomal cells must be specified long before the identity of the individual vertebral segment is morphologically apparent. This morphogenetic specification of the vertebral phenotype is controlled by a number of genes. These genes involved in embryogenesis encode a set of instructions or rules of assembly. Implementation of these one-dimensional rules via gene expression and protein interaction produces the three-dimensional structure, viz. the vertebral column.

Hox Genes

These are also known as *homeobox genes*. These genes were originally identified in the fruit fly, *Drosophila melanogaster*. Hox genes encode transcription factors which act as regulators of downstream gene activity and are characterised by a highly conserved 180-base pair sequence called the *homeobox*. The homeobox encodes a 60-amino acid helix-loop-helix DNA motif within the encoded transcription factors. The Hox genes play a fundamental role in the establishment of the body plan, including specification of the axial skeleton.[5,6,16,17] All vertebrates, including human beings, contain 39 Hox genes that are distributed on four linkage groups or clusters designated as Hox A, B, C, and D on chromosomes 6, 11, 15 and 2 respectively (Fig. 7). One of the interesting features of these genes is that the linear order of each gene, from the 3′ end to the 5′ end, is the same as its expression, along the cephalocaudal axis of the embryo, a feature referred to as *collinearity*. Those at the 3′ end have a more rostral expression and those at the 5′ end have a more caudal expression. In addition, those at the 3′ end are expressed earlier than those at the 5′ end. Thus, there is both a spatial and temporal pattern of expression of the Hox genes. The Hox genes are numbered sequentially from 1 onwards, with 1 corresponding to a cephalic gene and 13 a more caudally located gene. Hox A-6, Hox B-6, Hox C-6, and Hox D-6 are located at the same relative positions in their respective clusters and are referred to as a paralogous group.[17]

Hox Codes

Hox genes are expressed in developing ectodermal structures, such as the rhombomeres and neural crest, and in a wide variety of mesodermally derived organs, such as the somites, heart, kidney, testis, etc., but not in any endodermally derived structures.[5,16,17] The striking feature of Hox genes is that they have overlapping expression domains, but with clear cut cephalic boundaries. Thus, at any point along the cephalocaudal axis of the embryo, cells of the central nervous system (CNS) and paraxial mesenchyme (which later form the somites) have a characteristic complement of gene expression. This complement of Hox gene is believed to form the Hox code that specifies the position along the cephalocaudal axis.

Hox genes are necessary to establish the correct positional specification within the craniocaudal sequence of

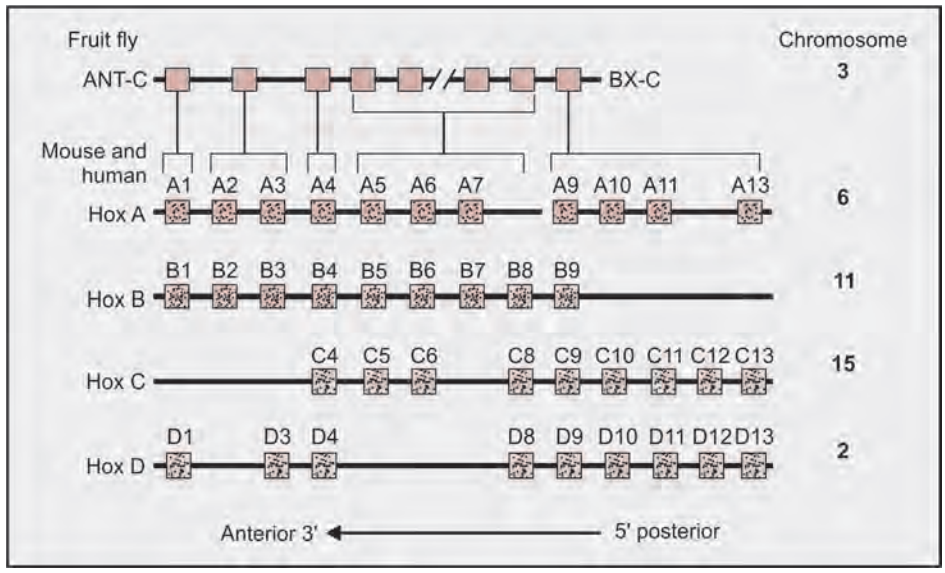

Fig. 7: Diagram representing the chromosomal organisation of Hox genes in the mouse and human and their derivation from the ancestral complex equivalent to that found in the fruit fly: 1. There are four clusters (A,B,C,D) on different chromosomes; 2. There are four paralogous groups defined vertically across the clusters and consisting of up to four genes, each on a different chromosome; 3. The expression of the genes along the craniocaudal axis of the embryo maps in a 1:1 fashion, those in the 3′ end are expressed cranially and earlier than those in the 5′ end which are expressed more caudally and later, thus the expression of these genes has a spatial and temporal pattern (Adapted from Neurosurgical Focus. 1999;6(6):Article 1.)

somites. The axial expression of Hox genes follows a general principle: the more 3′ the position of a gene in the chromosomal cluster, the more anterior is its boundary of expression in the neural tube and prevertebrae. Mutations in the Hox genes, and teratogen-induced disturbance of Hox gene expression, can both cause alterations of the number and identity of the vertebrae that form at or near the anterior limit of their expression domain. For example, in experimental studies, it has been shown that inactivation of homeobox-containing gene HoxD3 results in mutant mice in which the atlas assimilates into the basiocciput. Thus, by losing the function of a Hox gene, the first cervical vertebra is transformed into a more rostral identity, which is termed as "*anterior homeotic transformation*".[5] Conversely, extension of an expression domain rostrally can transform structures into a more caudal identity, a phenomenon known as "*posterior homeotic transformation*". The common form of craniovertebral junction anomaly, assimilation of atlas, is believed to be a form of anterior homeotic transformation.

Pax Genes

These are also known as "*paired-box*" genes.[5] These genes possess a phylogenetically well-conserved DNA sequence called the paired-box. The Pax genes also encode DNA-binding domains, which is a typical feature of a regulatory protein. This family of Pax genes contains nine genes divided into four classes that are widely dispersed around the genome and are not clustered (unlike the Hox genes). Mutations in Pax genes are believed to be responsible for some major birth defects in humans. Two genes, Pax-1 and Pax-9, control segmentation of the somites and sclerotomes to establish intervertebral boundaries. In particular, the Pax-1 gene has been found to be pivotal in the reorganisation of the sclerotome.

Initially, the Pax-1 involved in the primary segmentation of the paraxial mesoderm into somites. Subsequently, a peptide signal encoded by *Sonic hedgehog gene* (Shh gene), emanating from the notochord and the ventral floor plate of the neural tube, acts on the somites to induce sclerotomal differentiation (Fig. 8). The sclerotome itself then differentially expresses Pax-1, with expression ventrally reflecting the dorsoventral specification of each vertebra.[5,16] Within this ventral expression domain of the sclerotomes, much more intense expression is demonstrated at those axial levels at which the intervertebral discs will form, and this appears to function in the resegmentation of the vertebrae. Thus, the Pax-1 gene acts like a "*resegmentation gene*".[5] Impaired or reduced expression of Pax-1 gene will result in local or widespread fusion between the sclerotomal primordia. The perturbations in the expression of Pax-1 gene may be due to mutations or may be due to non-genetic causes like teratogens. Irrespective of the cause, impaired expression of the Pax-1 gene results in vertebral fusions, the localisation and extent of the congential anomaly along the craniocaudal axis reflecting the timing and duration of the teratogenic insult.[5]

Sonic Hedgehog Gene

The Sonic hedgehog gene acts as a signalling switch that is used in differentiating subpopulations of cells throughout the embryo.[5,16] Its actions will vary depending upon where the signal is being secreted, how far away the responsive cell population is and how Shh is proteolytically cleaved. Shh acts by binding to the

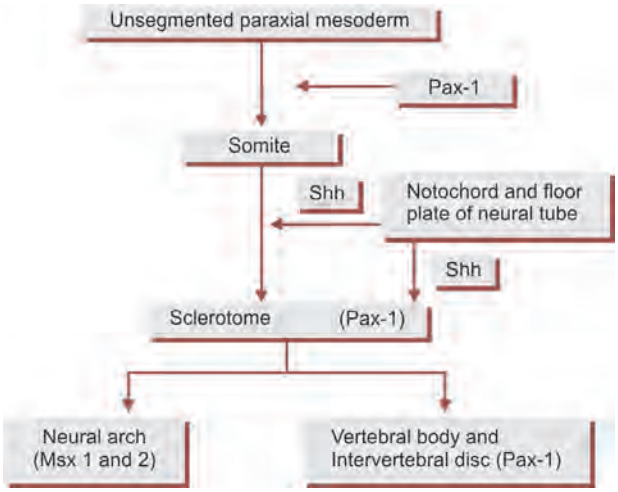

Fig. 8: Schematic representation of the cell-signalling events necessary to build a vertebral body. Initially, expression of a regulatory gene, Pax-1, is involved in primary segmentation of the paraxial mesoderm. Subsequently, a peptide signal encoded by the Sonic hedgehog gene (Shh), emanating from the notochord and the ventral floor plate of the neural tube, acts on the somite to induce sclerotomal differentiation. The sclerotome itself then differentially expresses Pax-1, with expression ventrally reflecting the dorsoventral specification of each vertebra. The formation of the neural arch is under the influence of Msx1 and Msx2 genes which are expressed under the influence of BMP-4 signals emanating from the surface ectoderm and the roof plate of the neural tube (Adapted and modified from Neurosurgical Focus. 1999;6:(6):Article 1.)

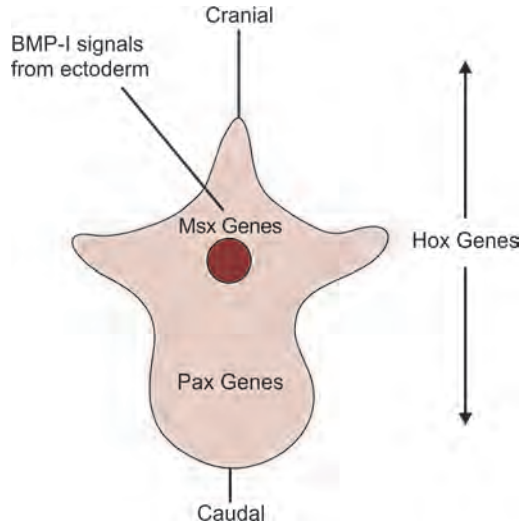

Fig. 9: Schematic representation of the genetic events controlling the development of the vertebral column. The rostrocaudal differentiation of the vertebral column is under the influence of Hox genes. The dorsoventral differentiation of each vertebra is under the influence of Pax and Msx genes (Refer text for further details)

membrane receptor patched (ptc). As mentioned in the preceding paragraphs, Shh signals emanating from the notochord and floor plate of the nerual tube act on the somites to induce sclerotomal differentiation. The Shh gene is strongly expressed in the primitive node, suggesting that this gene plays a key role in gastrulation. Additionally, the Shh gene is expressed in a left-right asymmetric pattern during gastrulation, which makes it a candidate agent that normally establishes left-right differences. Thus, during gastrulation, Shh is at first uniformly expressed in the primitive node and the primitive streak. Later, another gene known as "*Activin receptor IIa*" is expressed in the right half of the primitive node and this restricts Shh expression.[16] Activin receptor IIa gene activates other downstream genes which become localised to the mesoderm on the right side of the primitive node and streak. The Shh, which is now restricted to only the left side of the node acts on the other genes also, which are known as *nodal* and *lefty* which become lateralised to the mesoderm on the left side.[16] Faulty signalling by the Shh across the embryonic midline may be responsible for the split vertebral bodies or hemivertebrae that are often encountered in clinical practice.[5]

Msx1 and Msx2

These genes are expressed by the sclerotomal cells that migrate dorsally around the neural tube to form the neural arch. The expression of these genes is controlled by the roof plate of the neural tube and the surface ectoderm via *BMP4 signals* [Bone Morphogenic Protein (BMP)].[5,16] In experimental studies, it has been shown that interruption of the function of these genes results in spina bifida.

The development of the vertebral column is a consequence of a balance between proliferation, apoptosis and differentiation of cells. Sclerotomal differentiation is positively regulated by signals from the notochord, the neural tube and the myotome. Chondrogenic differentiation of the ventral mesoderm also requires inductive signals from the notochord. The function of different gene families is controlled by signals from adjacent structures. The very complex network regulating diverse events of vertebral column development is not fully understood. However, a brief summary of the genetic control of vertebral column development is diagrammatically represented in Figure 9. Clinical classification of vertebral anomalies and scoliosis is shown in Figure 10. Table 1 summarises the genes involved in congenital vertebral disorders.

Development of the Skull

The skull has two distinct portions: the one which surrounds the brain and organs of special senses, viz. the *neurocranium* and that which forms the lower face and jaws, viz. the *viscerocranium*. The neurocranium consists of vault of the skull and the base of the skull. The vault of the skull is *membranous* in origin and the base is *cartilaginous* in origin.[3,4,17]

Vault of the Skull

The membranous neurocranium which goes to form the cranial vault is mesenchymal in origin. This mesenchyme is derived from the neural crest.[7] All the sutures

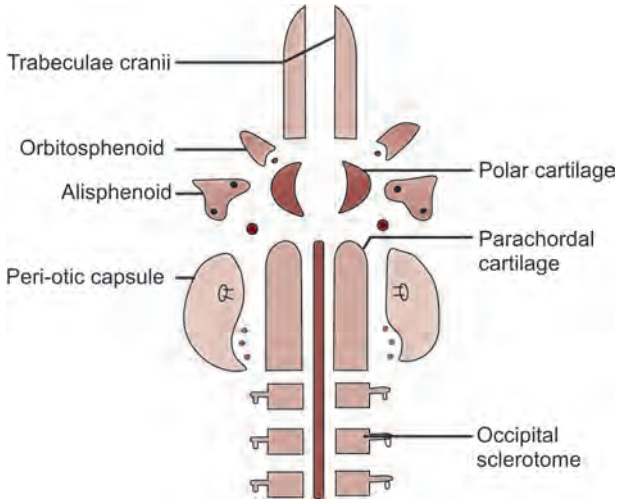

Fig. 10: Clinical classification of vertebral anomalies and scoliosis proposed by International Consortium for Vertebral Anomalies and Scoliosis (ICVAS)[17]

of the calvarial bones are also derived from the neural crest.[7,11] The bones that go to form the cranial vault are sometimes referred to as dermal bones. These include the frontal bones, the parietals, the squamous parts of the temporal bones and the upper (interparietal) part of the occipital squama. These bones first appear at about the 30th day of gestation when they begin to form curved plates of mesenchyme at the sides of the developing brain and gradually extend cranially to blend with each other. They also extend towards and reach the base of the skull. The bones of the cranial vault are formed by a wave of osteodifferentiation moving radially from ossification centres within the desmocranial mesenchyme.[17] When the adjacent bones meet, proliferation of the osteogenic front ceases and sutures are induced to form. Once sutures are formed and the fibrous desmocranium is replaced by mineralized bone, a second phase of development occurs in which growth of the cranial bones occurs at the sutural margins. Growth of the calvarial bones is closely related to the development of the dura mater. It has been shown in experimental studies, that when the sutures are transplanted with intact dura, it results in a continuous fibrous suture between developing vault bones, whereas in transplants in which dura mater is removed bony fusion occurs.

Base of the Skull

With the exception of the orbital plate of the frontal bone and the lateral parts of the greater wings of the sphenoid which are membranous in origin, the rest of the base of the skull is preformed in cartilage. Thus, the bones of the base of the skull that are preformed in cartilage include: the occipital (except the interparietal part), the petromastoid part of the temporal, the body, lesser wings and the roots of the greater wings of sphenoid, and the ethmoid.

The formation of the cartilaginous base of the skull occurs in three main regions, viz. caudally, in relation to the notochord known as the *parachordal cartilage*, intermediately, in relation to the hypophysis known as the hypophyseal cartilage and rostrally, between the orbits and nasal cavities and known as the *interorbitonasal cartilage*.

The parachordal cartilage (Fig. 11) is developed from the paraxial mesenchyme related to the cranial end of the notochord and the first five (occipital) somites. The cephalic part of the notochord extends up to the future dorsum sellae of the sphenoid bone. The parachordal

Table 1: Congenital vertebral disorders and the genes involved as per Giampietal et al.[6]

Disorder	*Predominant vertebral disorders*	*Genes*
Spondylocostal dysostosis	• Loss of normal vertebral morphology throughout the entire spine	• Delta-like 1 (DLL3)
	• Non-progressive scoliosis	• Mesoderm posterior 2 (MESP2)
	• Symmetric thoracic cage	• Lunatic fringe (LFNG)
Spondylothoracic dysostosis	• Fusion of all ribs at the costovertebral junctions bilaterally	• MESP2
	• Vertebral segmentation and formation defects	• E103X
Alagille syndrome	• Butterfly vertebral anomalies (errors in somitogenesis)	• JAG1 • NOTCH2
Congenital scoliosis	• Fused vertebrae	• DLL3
	• Vertebral body formation defects like hemivertebrae and mixed defects	• CHD7
Split cord malformations	• Spina bifida	• MTHFR gene • VANGL1 gene
Klippel-Feil syndrome	• KF1-C1 fusion is the most rostral	• KF1: Autosomal recessive
	• KF2-C2-C3 fusion is dominant and most rostral	• KF2: Autosomal dominant
	• KF3-C3 (C2-3 or C3-4) most rostral fusion. Isolated fusions	• KF3: Autosomal recessive and autosomal dominant
	• KF4-Wildervanck syndrome	• KF4: X-linked dominant

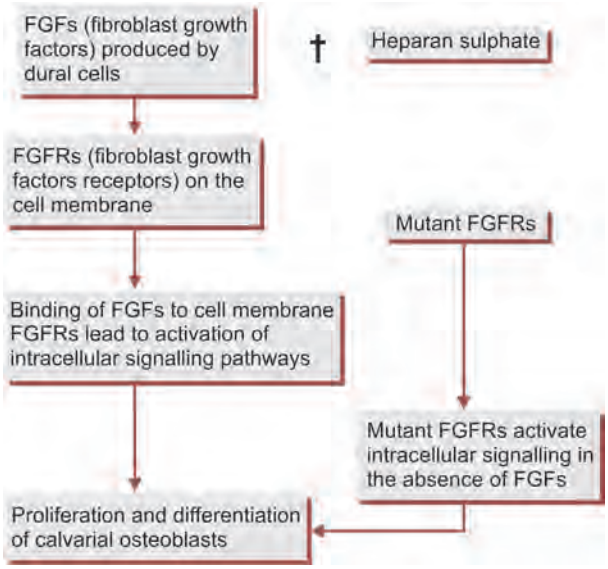

Fig. 11: Schematic representation of the development of the base of the skull

cartilages are paired structures that subsequently unite to form the *basal plate*. The basal plate is continuous behind with the four occipital sclerotomes. The centres of the sclerotomes fuse to form the *basiocciput*; the rudimentary transverse processes unite to form the ex-occiput which persists as the jugular processes; the laminae of the sclerotomes meet behind forming the foramen magnum and continue further upwards as the supra-occiput which forms the lower part of the occipital squama. The hypoglossal nerve, the nerve of the occipital myotomes, passes through the occipital bone; this canal is sometimes divided by a bony spicule and represents the fused intervertebral foramina of the occipital sclerotomes. On each side of the basal plate a cartilaginous *periotic capsule* envelops the membranous otocyst. Each capsule is perforated medially by the facial and the vestibulocochlear nerves. The otic capsule is separated from the cranial-most occipital sclerotome by a space which forms the *jugular foramen* for the transmission of the glossopharyngeal, vagus and accessory nerves. The periotic capsule is later ossified to form the petromastoid part of the temporal bone. It is notable that the region of fusion between the rostral part of the occipital bones and the portion of the parachordal plate that is of somitomeric origin corresponds to the spheno-occipital synchondrosis that is the site of growth until 20 years of age.

The *hypophyseal cartilage* ossifies to form the postsphenoid part of the sphenoid bone. It is derived from the paraxial mesenchyme and the neural crest. The paraxial mesenchyme contributes to the caudal part of the sella turcica, whereas the neural crest forms the more rostral portion of the sella turcica. A pair of *polar cartilages* appears by the side of the developing hypophysis cerebri, and encircle the developing pituitary gland in front of and behind the stalk. The fused mass thus forms the posterior part of the body of the sphenoid bone. The polar cartilages are continuous behind with the parachordal cartilages at the basiocciput. A pair of cartilaginous elements, known as, *alisphenoids* develop on either side of the polar cartilages. The alisphenoids form the greater wing of the sphenoid bone, and is perforated by the maxillary and the mandibular divisions of the trigeminal nerve.

The *interorbitonasal cartilage* (also known as the trabecular cartilage) is a bilateral structure with two separate centres of chondrification. It is of neural crest origin. At the rostral end of the developing base of the skull, a cartilaginous plate known as the *trabeculae cranii*, appears in the median plane and gives rise to the cribriform plate of the ethmoid bone. The trabecula is continuous behind with the fused polar cartilages. A *nasal capsule* is formed by the chondrification around the olfactory placode. The nasal capsules give rise to the labyrinth of the ethmoid bone and most of the nasal septum. Lateral to the trabeculae cranii, a cartilaginous element known as the *orbitosphenoid* develops on each side. The orbitosphenoid grows medially around the optic nerves and fuses with the polar cartilage to form the lesser wing of the sphenoid bone, and is separated from the alisphenoid (from which the greater wings of sphenoid bone develop) by the superior orbital fissure.

The development of the base of the skull (chondrocranium) is summarised in Table 2. The ossification of the chondrocranium starts during foetal life continues after birth and is completed after puberty.

Molecular Biology of Skull Development

Rapid advances in molecular biology in the last decade have uncovered some of the clues to the complex molecular mechanisms underlying normal and abnormal formation of the cranial bones and sutures. An understanding of these molecular mechanisms may eventually lead to manipulations of the molecular milieu by modifying specific gene activities or signalling pathways thereby altering the growth of the craniofacial skeleton. This also has important implications for understanding the various craniosynostosis syndromes and their treatment.

Table 2: Development of the base of the skull (chondrocranium)

Embryonic primordium	*Post-natal structure*
Trabeculae cranii	Cribriform plate of ethmoid
Orbitosphenoid	Lesser wing of sphenoid
Fused polar cartilage	Body of sphenoid
Alisphenoid	Greater wing of sphenoid
Basal plate (fused parachordal cartilages) and fused centra of the occipital sclerotomes	Clivus
Peri-otic capsule	Petromastoid part of temporal bone
Fused laminae of the occipital sclerotomes	Lower part of the occipital squama

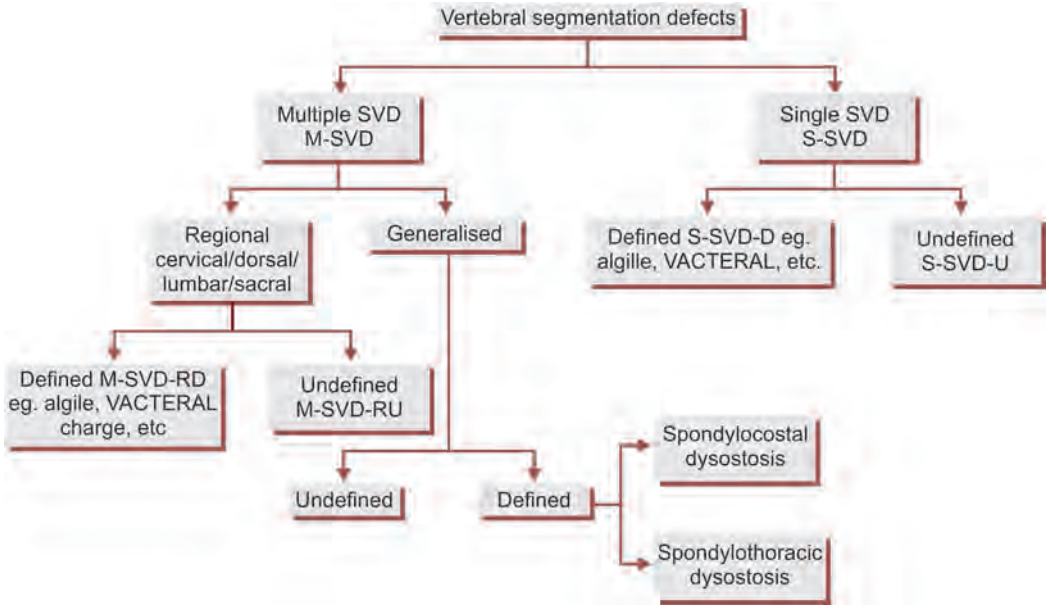

Fig. 12: Schematic representation of the mode of action of fibroblast growth factor (FGF) signalling mediated by normal and mutant fibroblast growth factor receptors (FGFRs) in calvarial osteoblasts. FGFRs consist of extracellular ligand-binding, transmembrane, and intracellular kinase domains. Upon binding to the FGF and heparin sulphate complex, normal FGFRs activate intracellular kinase domains and the resultant intracellular signalling leads to proliferation and differentiation of calvarial osteoblasts. However, mutant FGFRs activate the intracellular kinase domains even in the absence of FGFs thereby activating the intracellular signalling pathways and resulting in the proliferation and differentiation of calvarial osteoblasts

Fibroblast Growth Factor Receptors

Fibroblast Growth Factor Receptors (FGFRs) are cell surface receptors for fibroblast growth factors (FGFs), which elicit a variety of cellular functions in different cell types, including cell proliferation, differentiation, migration, and pattern formation. FGFRs belong to a family of proteins known as transmembrane tyrosine kinases.[1,8] So far, four FGFRs (FGFR 1-4) have been identified. They all have an extracellular ligand-binding domain, a transmembrane domain, and an intracellular kinase domain (Fig. 12). These receptors differ in their ligand specificity and tissue distribution. For example, in calvarial bone, FGFR1 is mainly expressed in differentiated osteoblasts, while FGFR2 is expressed in preosteoblasts. On the other hand, FGFR3 is mostly found in cartilaginous tissues, and FGFR4 expression has not been identified thus far in craniofacial bones. The principle function of FGFRs is to transduce extracellular FGF signals to the intracellular compartment, where a cascade of specific biochemical events lead to activation or repression of target genes and proteins. Ultimately, cellular behaviour, such as proliferation and differentiation, is modified. It is now believed that signals generated by FGFs that are synthesised by dural cells regulate suture development via the FGFRs present in the advancing osteogenic front (Fig. 12).

The importance of FGFR function in normal suture development is amply demonstrated in molecular genetic studies of craniosynostosis syndromes associated with FGFR mutations. Mutations of FGFR genes lead to activation of FGFRs in the absence of FGF thus initiating an intracellular signalling pathway (Fig. 12). For example, it has been shown that in Apert's syndrome, mutations of the FGFR2 have an effect on the phenotype of the calvarial bone cell. In patients with Apert's syndrome, there is accelerated ossification and increased thickness of subperiosteal bone compared to normal calvarial bone. Thus, it can be concluded that FGFR2 mutation is the reason for increased osteogenic activity in the cells at the calvarial bony margins that leads to premature suture closure.[10]

Msx Genes

The Msx genes belong to a family of homeobox containing genes. The exact role of Msx genes in skull bone and suture development has not been fully elucidated. Similar to other homeobox containing genes, it plays an important role in pattern formation in the developing embryo. It is also involved in other important developmental events, such as programmed cell death (apoptosis) and tissue interaction. Therefore, it is believed that Msx2 gene product might influence suture development by altering the apoptotic rate in suture cells or by interaction between sutures and adjacent tissues or both. The homeobox domain of the Msx2 is believed to bind to specific DNA sequences of specific target genes and determine if and when they should be expressed, e.g. in Boston-type craniosynostosis, the mutation of Msx2 gene leads to the mutant Msx2 to stay bound to the target genes for a prolonged period, resulting in enhanced Msx2 activity in cells. Therefore, gain of function of Msx2 could be the underlying molecular basis of Boston-type craniosynostosis. Members of the Msx gene family (Msx1 and Msx2) are normally strongly

expressed in the neural crest derived mesenchyme of the developing facial prominences, and there is now strong evidence for a role of these genes in the specification of the skull and face. In experimental studies, targeted disruption of Msx1 gene function produces a number of defects in facial structures and mutations of Msx2 produce defects in skull ossification with persistence of calvarial foramina.

TWIST Gene

The protein product of the TWIST gene is a transcription factor.[1] The TWIST gene regulates the expression of a number of genes by binding to regulatory regions of the target genes. It is expressed in a wide variety of embryonic tissues and in the neonatal calvarial osteoblasts. Mutations in the TWIST gene are responsible for the Saethre-Chotzen syndrome (SCS), a form of autosomal dominant craniosynostosis. TWIST genes are also believed to act as upstream regulators of FGFRs.

Transforming Growth Factors (TGFs)

Transforming growth factor-beta (TGF-β), 1 to 3 belong to a family of related heparin-binding peptides.[1] They are involved in diverse biological activities in normal growth and development of various organs, including regulation of osteoblast and chondrocyte differentiation, proliferation and matrix gene expression. These activities are mediated by high affinity receptors that are associated with intracellular signalling. Experimental studies have shown the importance of TGF-β in suture formation. Expression of TGF-β1 and β2 is shown in association with obliterating sutures, while increased expression of TGF-β3 is found in non-fusing sutures. All the three isoforms of TGF-β are expressed in the dura mater. Recent studies have shown that the different isoforms of TGF-β might determine calvarial bone growth at the sutures as well as their patency.

14 Embryology: Brain and Spinal Cord

Muthukumar N

INTRODUCTION

Neurosurgeons are often confronted by embryological development gone awry in the form of various congenital malformations of the nervous system. A working knowledge of the normal embryogenesis is essential to understand the complexities of various congenital malformations. This chapter reviews the normal processes occurring in the development of the central nervous system and the developments in this field, especially, the developments in molecular biology as applied to embryology.

For the purposes of clarity, the development of structures during normal embryogenesis of the nervous system is described in series; in reality, the formation of these structures is concurrent.

DEVELOPMENT OF THE CENTRAL NERVOUS SYSTEM

The Embryonic Disc

The union of the sperm and the egg creates the single-celled zygote and subsequent repeated divisions form the 12-cell morula to 16-cell morula, which enters the uterus. A cavitation within the morula creates two cellular groups, the outer trophoblast, which contributes to the formation of the placenta and a group of centrally located cells, the internal cell mass, which gives rise to the embryo. At 7–12 days of development, this structure, now called the blastocyst implants into the uterine wall. With further development, the internal cell mass separates from the overlying trophoblast to create a slit-like amniotic cavity, which progressively enlarges and ultimately contains the embryo. Simultaneously, the internal cell mass becomes the flattened and circular embryonic disc with two layers, the bilaminar embryo (Fig. 1). The outer layer adjacent to the amniotic cavity is called the epiblast, which gives rise to all or nearly all the cells of the embryo. The inner layer adjacent to the yolk sac is called the hypoblast and does not contribute to embryonic development.

At 13–15 days of development, the hypoblastic cells near the future rostral end of the embryo form a thickened circular area called the prochordal plate (future site of the mouth) and in the caudal end, the cloacal membrane (future site of anus). In both these regions, the outer and inner layers of the embryo are fused. The prochordal plate is important because it is an organiser of the head region. At these two areas where the bilaminar disc is fused, the interposition of the mesoderm, which takes place during the next stage, is limited.

Gastrulation and the Trilaminar Embryonic Disc

Gastrulation is the process by which the bilaminar embryonic disc is converted into a trilaminar embryonic disc by the interposition of a mesoblastic layer between the epiblast and hypoblast. At about 15 days of development, a linear thickening called the primitive streak appears in the caudal midline of the embryo. The primitive streak is limited caudally by the cloacal membrane. Progressively, the primitive streak increases in length and a thickening forms at the rostral end of the primitive streak known as the primitive knot or Hensen's node (Fig. 2). A longitudinal groove then appears in the primitive streak and deepens at the level of the Hensen's node to form the primitive pit. Cells from the epiblast migrate into the primitive streak and groove, separate from the epiblast and migrate rostrally between the epiblast and hypoblast to form the mesoblast, thus creating the earliest stage of the trilaminar embryo. The epiblast (ectoderm) is destined to form the CNS (neurectoderm) and the epidermis (cutaneous ectoderm); the mesoblast

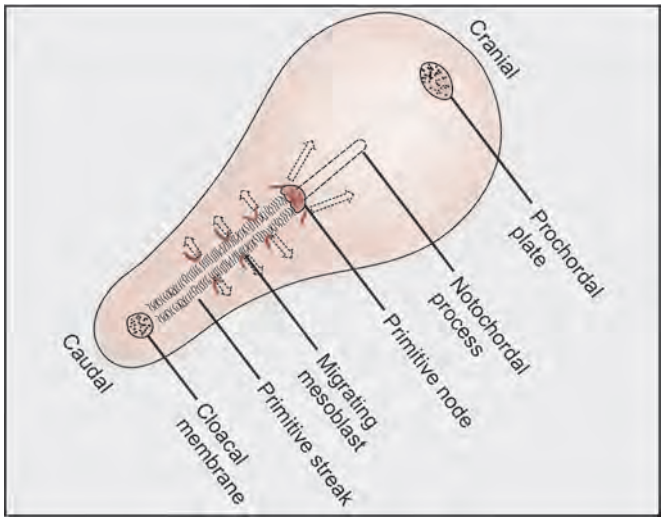

Fig. 2: Schematic representation of the embryonic disc at the commencement of gastrulation. Cells from the epiblast migrate into the primitive streak and pass between the epiblast and hypoblast. Formation of the notochord is also seen

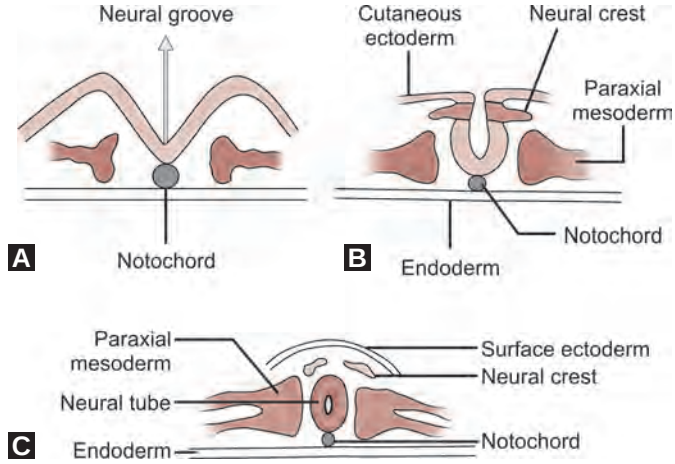
(mesoderm) forms the skeleton, striated and smooth muscles, connective tissues, blood vessels, blood cells and bone marrow and the reproductive and excretory organs. The hypoblast (endoderm) is the source of the epithelial linings of the respiratory and digestive tracts and glandular cells of the liver and pancreas. The primitive streak is the source of the intraembryonic mesoderm until approximately the 4th week of development, and then it rapidly regresses in size and disappears. During its functional lifetime, the embryo increases in length 5-fold, by the complex development of the embryo rostral to the primitive streak.

Development of the Notochord

At about 16–17 days of development, some of the mesoblastic cells migrate in the midline rostral to the Hensen's node between the ectoderm and the endoderm, all the way to the prochordal plate to form a solid rod-like structure known as the notochord. The notochord is represented during life by the nucleus pulposus of the intervertebral disc. However, the notochord is the structure around which the skull and the vertebral column will eventually form and, moreover, during development, the notochord plays an important role as an embryonic inducer, which is important for the formation of the neural plate from which the neural tube develops. Changes in the notochord (to be described below) take place almost concurrently with the changes in the neural tube (also to be discussed later). As the notochord extends cranially towards the prochordal plate, the intraembryonic mesoderm originating from the primitive streak forms two parallel streaks on either side of the developing notochord, to form the paraxial mesoderm (Figs 3A to C). Initially, the notochord remains as a solid cord of cells known as the notochordal process. Subsequently, the primitive pit extends into the notochord and converts



Figs 3A to C: Formation of the neural groove: (A) Notochord. (B) Paraxial mesoderm. (C) Neural crest

the notochord into a tubular structure known as the notochordal canal (Fig. 4). Later, the notochordal canal becomes incorporated with the underlying endoderm by a process known as the intercalation of the notochord (Fig. 5A). During this process, the amniotic cavity is transiently in communication with the yolk sac through the neurenteric canal (Fig. 5B). This neurenteric canal is a transient structure. Subsequently, the notochordal plate, which had become fused with the underlying endoderm once again, forms an infolding to form the notochordal process. This is known as the excalation of the notochord (Fig. 5C). This process of intercalation and excalation of the notochord is the period during which three different types of occult spinal dysraphism are known to develop, viz. neurenteric cyst, split cord malformation, and combined anterior and posterior spina bifida.

Formation of the Neural Tube

The neural tube is the primordium of the brain and the spinal cord. The process by which the neural tube is formed is known as neurulation. Primary neurulation is the process by which the brain and the spinal cord up to L1 level are formed. The portion of the spinal cord

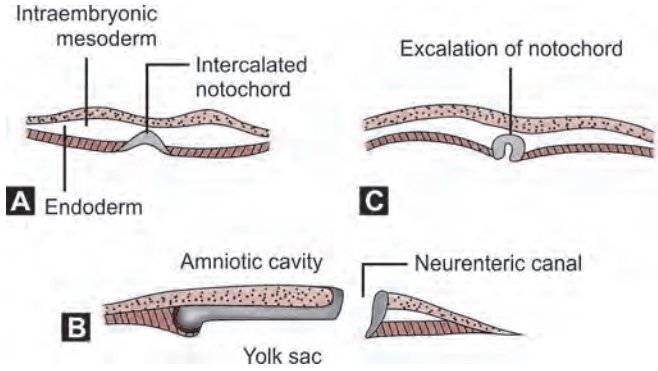

Figs 5A to C: Schematic representation of the (A) Intercalation of notochord. (B) Formation of the neurenteric canal which forms a transient communication between the yolk sac and amniotic cavity. (C) Excalation of the notochord

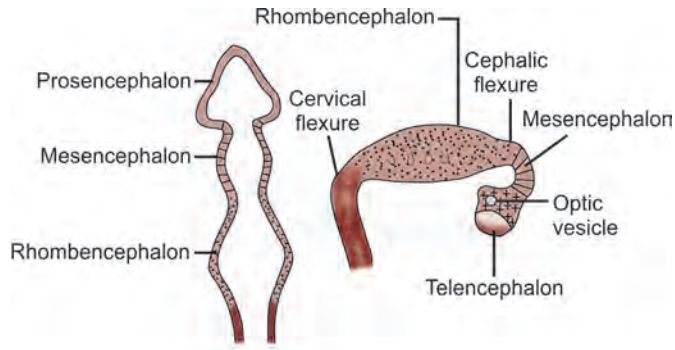

Fig. 6: Schematic representation of the development of the three primary brain vesicles and the formation of the cervical and cephalic flexures

distal to L1 is formed by a process known as secondary neurulation, which involves two stages, viz. canalisation and regression. Disorders of primary neurulation are responsible for the various forms of open dysraphism and disorders of secondary neurulation are responsible for the various forms of closed spinal dysraphism.

Neurulation

As mentioned previously, the notochord is an important embryonic inducer. In response to the notochord, the overlying ectoderm begins to thicken and forms the neural plate. A longitudinal depression develops in the neural plate to form the neural groove, the sides of which are elevated to form the neural folds. The neural folds then fuse in the midline to form the neural tube. With the formation of the neural tube, the cutaneous ectoderm once again becomes continuous in the midline and the neural tube subsequently detaches from the cutaneous ectoderm and comes to lie dorsal to the notochord (Fig. 3). The fully formed neural tube has two openings, the anterior and posterior neuropores, which remain temporarily open at the cephalic and caudal ends of the embryo. Through these openings, the neural tube communicates with the amniotic cavity. The amniotic fluid circulates through the neural tube and provides nourishment to the neural tube. The anterior neuropore closes by the middle of the 4th week at about the 20-somite stage and the posterior neuropore closes by the end of the 4th week at about the 25-somite stage. The position of the anterior neuropore is represented in the adult by the lamina terminalis. The posterior neuropore closes at the level of the spinal cord segments L1 or L2 with a range of error of two segments above or below (T11 or L4).

Development of the Brain

At the time of closure of the anterior neuropore, the rostral end of the neural tube shows three dilatations known as brain vesicles. The three early subdivisions are known as the "prosencephalon" or forebrain, "mesencephalon" or midbrain, and the "rhombencephalon" or hindbrain (Fig. 6). These three vesicles are demarcated by two constrictions between them. The constricted region between the mesencephalon and the rhombencephalon is known as the isthmus. The prosencephalon subsequently is subdivided into two parts: the telencephalon or the cerebral hemispheres and the diencephalon or thalamus. The mesencephalon or the midbrain shows less change during development than the other divisions. The hindbrain vesicle is subdivided into two parts: the "metencephalon" from which develop the pons and the cerebellum; and the "myelencephalon" from which develops the medulla oblongata (Fig. 7). The primitive cavities of the brain vesicles are the forerunners of the ventricular system. The cavities of the telencephalon become the lateral ventricles and the cavity of the diencephalon persists as the third ventricle. The cavity of the mesencephalon becomes progressively narrowed to form the aqueduct of Sylvius and the cavity of the hindbrain becomes the fourth ventricle.

Flexures of the Brain

Two prominent flexures occur in the rostral portion of the neural tube at an early stage. The "cervical flexure" develops at the junction of the rhombencephalon and

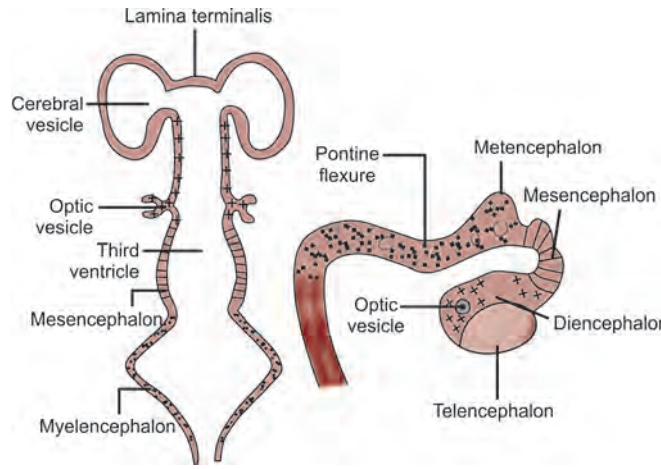

Fig. 7: Schematic representation of the development of the brain vesicles and the formation of the pontine flexure

the spinal cord, with its concavity directed ventrally and the "cephalic flexure" occurs at the junction of the mesencephalon and rhombencephalon (Fig. 6). At about the 6th week of development, a third flexure, known as the "pontine flexure", develops in the rhombencephalon with its concavity directed dorsally and divides the rhombencephalon into two segments, viz. the metencephalon and the myelencephalon (Fig. 7). It is believed that these flexures develop as a result of differences in the rates of cell proliferation and cell movement. At this stage, the developing brain has five different subdivisions: (1) the telencephalon; (2) the diencephalon; (3) the mesencephalon; (4) the metencephalon and (5) the myelencephalon. Each of these five subdivisions undergoes distinct developmental changes. In the following discussion, these developmental changes are considered separately for the purposes of clarity. However, it should be noted that these changes take place simultaneously.

The developing neural tube is divided into a dorsal "alar lamina" and a ventral "basal lamina". The alar lamina is sensory in function and the basal lamina is motor in function, the two being separated by the "sulcus limitans".

The Hindbrain

The development of the pontine flexure with a ventral convexity during the 6th week stretches the roof plate of the hindbrain to form a diamond-shaped outline, as a result of which the alar lamina comes to lie almost in the same plane as the basal lamina, resulting in the rhomboid shape of the fourth ventricle. As a result of these changes, the alar and basal laminae come to occupy the ventral wall of the hindbrain, the former being dorsolateral and the latter ventro-median in position. The portion of the hindbrain in the caudal slope of the pontine flexure is known as the myelencephalon and that in the cranial slope of the flexure is known as the metencephalon.

The basal lamina of both the myelencephalon and metencephalon gives rise to the motor neurons, which are arranged in three elongated but interrupted columns (Fig. 8). They are from medial to lateral:

- the "somatic efferent column" which supplies the striated muscles which are myotomic in origin
- the "branchial or special visceral efferent column" which supplies the muscles derived from the branchial arch
- the general visceral efferent column which provides pre-ganglionic fibres to the parasympathetic ganglia, supply the secreto-motor fibres to various glands and innervate the unstriped muscles of the alimentary and respiratory systems and the heart.

The alar lamina of the hindbrain differentiates into the sensory neurons, which form the following longitudinal, but interrupted columns from lateral to medial:

- the "general visceral afferent column" receives sensations from the viscera

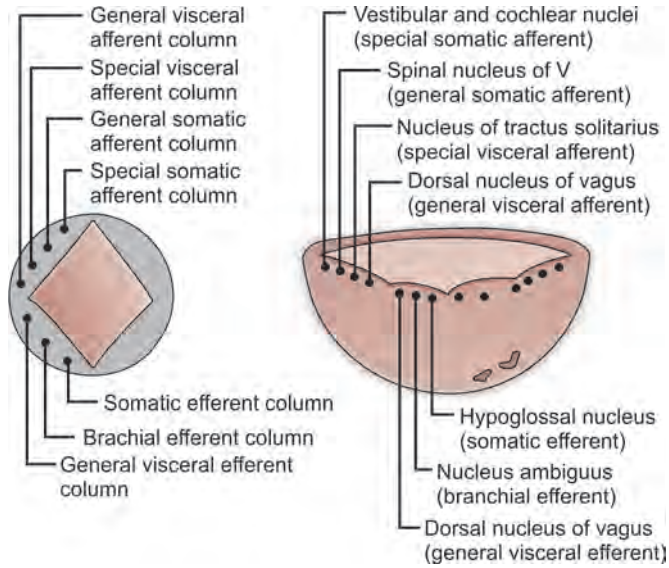

Fig. 8: Schematic representation of the development of the basal and alar laminae of the metencephalon and myelencephalon

- the "special visceral afferent column" receives taste sensations from the tongue, palate, etc.
- the "general somatic afferent column" receives exteroceptive sensations from the face, scalp and external ear
- the "special somatic afferent column" concerned with the sense of hearing and equilibrium.

Myelencephalon

The myelencephalon develops into the medulla oblongata. It extends from the first spinal nerve root of the cervical cord to the beginning of the pontine flexure. It consists of a lower closed part and an open upper part, which forms the caudal part of the floor of the fourth ventricle. Because of the development of the pontine flexure, the roof plate expands and as a result the alar lamina is displaced laterally and comes to lie almost in the same plane as the basal lamina. The sulcus limitans continues to mark the boundary between the alar and basal lamina. Derivatives of the basal lamina form the motor nuclei of the cranial nerves and come to occupy positions in the floor of the fourth ventricle medial to the sulcus limitans. The most medial cell column gives rise to the general somatic efferent fibres that form the hypoglossal nerve. Lateral to this are located the special visceral efferent and general visceral efferent fibres. The special visceral efferent column gives rise to the nucleus ambiguous which contributes fibres to the glossopharyngeal, vagus and accessory nerves to supply the muscles derived from the third, fourth and sixth branchial arches, respectively. The general visceral efferent column, which is also located medial to the sulcus limitans is represented by the dorsal motor nucleus of the vagus and the inferior salivatory nucleus. These supply pre-ganglionic parasympathetic fibres that are widely distributed.

Derivatives of the alar plate form the sensory relay nuclei lateral to the sulcus limitans. The most lateral of these nuclei are the special somatic afferent represented

by the auditory and vestibular nuclei and the general somatic afferent represented by the trigeminal complex. Medial to this group lie the solitary nuclei representing the general and special visceral afferent cell columns. Some cells derived from the alar lamina migrate ventrally to form the inferior olivary complex, which is the largest cerebellar relay nucleus of the medulla. Cortically derived fibres of the medulla come to occupy the ventromedial regions near the midline and form the medullary pyramids.

In the upper portions of the developing myelencephalon, in the region of the fourth ventricle, the roof plate consists of a single layer of ependymal cells covered by a thin layer of piamater. These two layers form the tela choroidea and prolongations of these into the ventricle form the choroid plexus. Openings in the roof plate (foramina Magendie and Luschka) appear by the 4th to the 5th months and, thereby, establish communication between the ventricular system and the subarachnoid space.

Metencephalon

The metencephalon gives rise to the pons and the cerebellum. The pons consists of two parts, viz. a dorsal portion lying in the floor of the fourth ventricle known as the pontine tegmentum and a ventral portion in which some cortical efferent fibres terminate, while others continue to more caudal regions. The pontine tegmentum is derived from the basal plate. The general somatic efferent column is represented by the medially placed nucleus of the abducens nerve. The special visceral efferent column is represented by the motor nuclei of the trigeminal and facial nerves, which supply the muscles of the first and second branchial arches. The general visceral efferent column is represented by the superior salivatory nucleus, which supplies secretomotor fibres to the submandibular, sublingual and the lacrimal glands. In addition, cells of the basal plate also contribute to the pontine reticular formation. Ventromedial portions of the alar plate form cell groups similar to that of the medulla. These cell groups include the special somatic afferent (vestibulocochlear), general somatic afferent (trigeminal) and the special and general visceral afferent (solitary nucleus). The pontine nuclei, which are located in the ventral portions of the pons, are derived from the alar plate.

Development of the Cerebellum

The dorsolateral portions of the alar lamina of the metencephalon form the rhombic lips from which the cerebellum is derived. At first the rhombic lips are widely separated from each other. Later, as the transverse rhombencephalic sulcus deepens at the pontine flexure, the cerebellar rudiments of both sides fuse in the midline caudal to the roof of the mesencephalon to form the transverse cerebellar plate. At 3 months of age, the cerebellar primordia have a dumb-bell shaped appearance. The unpaired central part of the cerebellar primordia represents the vermis and the paired lateral knobs represent the developing cerebellar hemispheres.

As the development progresses, numerous fissures appear on the surface of the cerebellar primordia and divide into lobes. The earliest of these fissures is the posterolateral sulcus, which separates the nodule from the vermis in the midline and the flocculus from the cerebellar hemispheres (Fig. 9). Thus, the flocculonodular lobe is formed. The flocculonodular lobe is otherwise known as the archicerebellum, which establishes connections with the vestibular system and plays an important role in the regulation of equilibrium and posture. As the cerebellar rudiment grows in a dorso-caudal direction, the flocculonodular lobe comes to occupy the anterior part of its inferior surface. During the 3rd month, three fissures develop; the primary fissure that develops on the cephalic slope of the cerebellum separates the anterior lobe from the rest of the cerebellum; the secondary fissure and the post-pyramidal fissure develop on the caudal slope of the cerebellum and demarcate the uvula and pyramid. The uvula and the pyramid, along with the anterior lobe, form the paleocerebellum. The paleocerebellum is also known as the spinocerebellum because it regulates the tone and posture of the limbs and is phylogenetically later in appearance than the archicerebellum. That portion of the cerebellum between the primary and posterolateral fissures represents the neocerebellum, which is phylogenetically the latest and helps in co-ordination of voluntary movements.

Histogenesis of the cerebellar cortex: The cerebellar primordia initially consist of a germinal zone at the surface of the fourth ventricle. This germinal zone gives rise to the Purkinje and Golgi-II cells that migrate outward to form the Purkinje cell layer. The germinal zone of the fourth ventricle also produces neuroblasts that migrate outward to the pial surface and form a second germinal zone called the external granular layer. The neuroblasts of the external granular layer produce three distinct types of cells (interneurons), viz. the basket and stellate cells of the molecular layer and the granule cells of the granular layer. The newly formed granule cells migrate

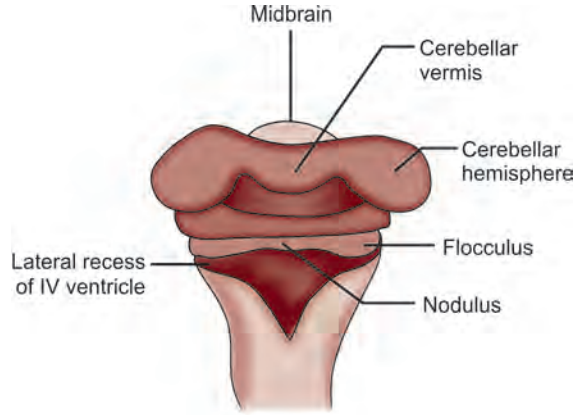

Fig. 9: Schematic representation of the development of the cerebellum

across the molecular and Purkinje cell layers to reach the granular layer. This migration of granule cells is guided by the radial glial fibres of the Bergman astrocytes. The neuroblasts of the mantle zone form the deep cerebellar nuclei.

Mesencephalon

The mesencephalon is the smallest brain vesicle which ultimately forms the midbrain, the shortest division of the brainstem. At the time of formation of the pontine flexure, the midbrain forms a conspicuous projection on the dorsal side of the flexure. However, the prominence of the midbrain is subsequently overtaken by the growth of the cerebral hemispheres. The cavity of the midbrain vesicle is markedly reduced during development and ultimately forms the cerebral aqueduct. The portion of the midbrain dorsal to the aqueduct forms the midbrain tectum and the portion ventral to the aqueduct has two subdivisions: a dorsal midbrain tegmentum and a ventral crus cerebri.

In the midbrain too, the alar and basal laminae are separated by a well-defined sulcus limitans. The motor neurons derived from the basal lamina give rise to the general somatic efferent column and ultimately form the nuclei of the oculomotor and trochlear nerves, which innervate the extraocular muscles derived from the preotic somites. Motor neurons that go to form the general visceral efferent column migrate dorsally and form the visceral component of the third nerve complex, supplying pre-ganglionic parasympathetic fibres to the pupil. The general somatic afferent column is represented by the mesencephalic nucleus of the trigeminal nerve, which invades the alar lamina of the midbrain from the isthmus rhombencephali and this nucleus receives proprioceptive impulses from the muscles of mastication, facial muscles and probably, the ocular muscles. The cells of the special somatic afferent column are represented by the superior and inferior colliculi, which act as relay centres concerned with vision and audition, respectively. These are formed from the alar plates. The inferior colliculus is formed by proliferation of neuroblasts to produce a small central homogeneous cell mass surrounded by a narrow cortical rim. The superior colliculus is a stratified structure formed by waves of migrating neuroblasts. Here, the cell migrations follow an "inside-out" sequence in that the cells forming the deeper layers are formed first followed by the cells forming the more superficial layer. As a result, cells destined for the superficial layers have to migrate through the deeper layers. The exact origin of the red nucleus, substantia nigra and midbrain reticular formation is not clearly understood at present.

Diencephalon

That portion of the prosencephalon caudal to the interventricular foramen constitutes the diencephalon. During early embryonic development, the prosencephalic vesicle gives rise to the optic vesicles. The optic vesicles are attached to the prosencephalic vesicle at the region of the developing diencephalon. The diencephalon consists of two lateral walls, and thin roof and floor plates.

Each lateral wall presents a hypothalamic sulcus, which extends from the region of the aqueduct of Sylvius to the interventricular foramen. Most of the structures of the diencephalon are derived from the alar lamina. The basal lamina is not represented in the diencephalon. The hypothalamic sulcus divides the lateral wall into the dorsal and ventral areas. The anterior part of the dorsal area develops into the thalamus and the posterior part gives rise to the metathalamus, viz. the medial and lateral geniculate bodies, which are important relay centres concerned with audition and vision. Because of the exuberant growth of the thalamus, the cavity of the diencephalon becomes obliterated to form the third ventricle. In 80% of humans, the two thalami are connected by the interthalamic adhesion or the massa intermedia. Early in development, the thalamus is separated laterally by an extra-neural cleft. Later, this cleft becomes obliterated by the projection fibres of the internal capsule. The ventral area below the hypothalamic sulcus differentiates into groups of hypothalamic nuclei. The floor plate of the diencephalon forms the following structures. Posteriorly, the cells of the floor plate proliferate to form the mamillary bodies. Anterior to the mamillary bodies, another cell proliferation results in the formation of the tuber cinereum. The floor of the diencephalic vesicle forms a tubular extension, which grows towards and fuses with Rathke's pouch. The diencephalic component of this fused structure forms the posterior lobe of the pituitary and the Rathke's pouch component forms the anterior lobe of the pituitary. The lamina terminalis, which forms the anterior wall of the third ventricle, represents the site of closure of the anterior neuropore. The lamina terminalis, however, is believed to be a telencephalic derivative. Its ventral part gives rise to a matrix from which the optic chiasm develops.

The roof plate of the diencephalon becomes thinned out and its rostral parts invaginate to form the choroid plexus of the third ventricle. The caudal portion of the roof plate thickens and evaginates posteriorly to form the pineal body. Rostral to the pineal body are situated the following: the posterior commissure, the habenular commissure and the habenular nuclei. These three structures, along with the pineal body, constitute the epithalamus.

Telencephalon

The telencephalon is composed of a median part and two lateral diverticula known as the cerebral vesicles. The anterior part of the median portion forms the lamina terminalis, which represents the site of closure of the anterior neuropore and thus the cephalic end of the primitive neural tube. The cerebral vesicles represent the rudiments of the cerebral hemispheres and develop as bilateral evaginations from the lateral wall of the forebrain during the 5th week of development. The cavity of the cerebral vesicles forms the lateral ventricles,

which communicate with the third ventricle through the foramen of Monro. The cerebral vesicles expand at first forwards, then upwards and finally backwards. As the vesicles grow backwards, they successively overlap the diencephalon and the mesencephalon. The lower part of the medial wall of the cerebral hemisphere remains thin and consists of a single layer of ependymal cells covered with the overlying vascular mesenchyme. It is continuous medially with the upper margin of the foramen of Monro. From the tela choroidea of the third ventricle, the choroid plexus projects laterally through the medial wall of the lateral ventricle through a cleft known as the choroidal fissure. The choroid fissure follows the downward and forward growth of the temporal lobe and thus assumes a C-shape.

The pallial tissue of the developing hemisphere consists initially of ependymal, mantle and marginal zones from inside out. The cells of the ependymal zone migrate outwards to become neuronal and glial cells upon maturation. The mantle zone becomes the white matter of the cerebral hemisphere. The marginal zone forms the cortical plate. Migration takes place first in the phylogenetically older areas, viz. the archipallium constituted by the hippocampal formation, followed by the paleopallium constituted by the piriform area and finally in the neopallium. The cortical layers develop in an "inside-out" fashion. The cells destined for the deeper layers are formed first followed by those destined for the superficial layers. Thus, the newly formed cells must migrate past the older cells to reach their destination and they are guided in their migration by the radial glial fibres. In the human foetus, this migration of cortical cells takes place between 7 and 16 weeks of gestation. In the early weeks of gestation, the surfaces of the cerebral hemispheres are smooth. During the 6th and 7th months of gestation, the surfaces of the cerebral hemisphere grow rapidly and develop convolutions (gyri) separated by deep furrows (sulci). The development of the sulci also takes place in an orderly fashion, viz. the phylogenetically older sulci appear first followed by the more recently acquired sulci. As a result of the formation of sulci and gyri, two-thirds of the cerebral cortex becomes buried in the walls and floor of the sulci when the brain attains its adult size.

Histogenesis of the Neural Tube

Histogenesis of the nervous system conforms to a general plan with regional variations in some parts of the nervous system. The lumen of the neural tube forms the ventricular system of the brain and the central canal of the spinal cord. Initially, the neural tube is lined by a single layer of undifferentiated neuroepithelial cells or stem cells. The continued proliferation of these neuroepithelial cells makes the single-layered neural tube into a multilayered neural tube with three distinct zones. The innermost zone is called the germinal or ependymal zone, the intermediate zone is called the mantle zone and the outer zone is the marginal zone. In the single-layered neural tube, the cells are limited by an external limiting membrane and an internal limiting membrane. The neuroepithelial cells are wedge-shaped and possess cytoplasmic processes, which reach the internal limiting membrane. Nuclei of these cells undergo characteristic oscillatory movements. First, the nucleus of an actively dividing cell migrates towards the external limiting membrane and then moves back towards the internal limiting membrane. DNA replication occurs only when the nucleus is near the external limiting membrane. Once the DNA replication is complete, the nucleus moves towards the lumen of the neural tube. Mitotic division occurs only when the nucleus reaches close to the internal limiting membrane. The divided daughter cells move from the germinal or ependymal zone into the matrix zone for further differentiation. These migrating cells are either immature neurons (neuroblasts) or glial cell precursors (spongioblasts). Some cells remain in the ependymal zone and eventually become the ependymal cells that line the ventricles of the brain and the central canal of the spinal cord. In the mantle zone, further differentiation into spongioblasts and neuroblasts occurs. The spongioblasts differentiate into astrocytes and oligodendrocytes. The microglia, however, are mesodermal in origin and appear in the mantle zone and marginal zone from the blood histiocytes when the vascular system grows around the neural tube.

The differentiation of the neuroblasts into neurons takes place in the following sequence: the neuroblasts migrating from the ependymal zone lose their cytoplasmic processes and become apolar neuroblasts. Subsequently, these cells develop two cytoplasmic processes and become bipolar neuroblasts. One of these cytoplasmic processes elongates and becomes the axon while multiple other cytoplasmic extensions increase in number and form the multipolar neuroblast. During the earlier stages of histogenesis of the neural tube, there is an overproduction of neurons. Eventually, the neurons that do not reach their appropriate locations in the CNS or those that do not reach their intended targets die, so that the total number of neurons is reduced to the normal population size. Movements of neurons to their intended locations and targets are guided by the proteins known as cell adhesion molecules and substrate adhesion molecules.

Neural Crest and its Differentiation

The neural crest cells are derived from the neuroectoderm. Initially, the crest cells border the tips of the neural folds and are continuous at the periphery with the cells of the surface ectoderm. When the two neural folds fuse dorsally to form the neural tube, the neural crest cells intervene in a wedge-shaped area between the surface ectoderm and the neural tube (Fig. 3). Neural crest cells extend from the region of the mesencephalon to the caudal somites. Neural crest cells are a highly pluripotent

Table 1: Derivatives of the cranial neural crest

	Derivatives
Nervous system	Sensory ganglia
	Sympathetic ganglia (V, VII, IX, X)
	Parasympathetic ganglia of the neck
	Neuroglial cells
	Schwann cells
Skeletal system	Maxilla
	Mandible
	Palatine
	Facial complex
	Cranial vault
Connective tissues	Cranial musculature
	Adenohypophysis
	Lingual glands
	Thymus
	Thyroid and parathyroids
	Corneal endothelium and stroma
	Vascular and dermal smooth muscles
	Melanocytes and melanophores

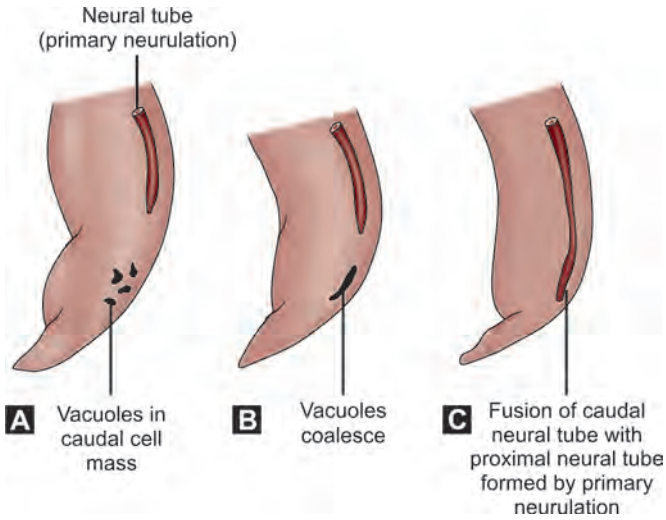
cell population that plays a significant role in the development of various structures. Neural crest cells migrate extensively throughout the embryo in four overlapping domains (cephalic, trunk, sacral and cardiac). The structures that are derived from the cranial neural crest are summarised in Table 1.

Development of the Spinal Cord

As can be understood from the preceding discussion on neurulation, the portion of the spinal cord up to the lumbar segments is formed by a process known as primary neurulation (discussed earlier). The distal portion of the spinal cord is formed by a process known as secondary neurulation. This process of secondary neurulation consists of two stages (Figs 10A to C): (1) canalisation of the tail bud and (2) regression or retrogressive differentiation.

Canalisation of the Tail Bud

Canalisation of the tail bud takes place during embryonic stages 13 through 20 (days 28 to 48). Caudal to the posterior neuropore, the tail bud contains an undifferentiated mass of cells known as the caudal cell mass, derived from the primitive streak. Under an intact covering of the cutaneous ectoderm, the caudal cell mass develops vacuoles around which cells assume a neural appearance. Subsequently, the vacuoles coalesce to form the neural tube, which then fuses with the more proximally placed neural tube formed by primary neurulation. The ventriculus terminalis, which marks the level of the future conus medullaris, becomes identifiable during days 43 to 48. Certain forms of occult spinal dysraphism, such as lumbosacral lipoma and lipomyelomeningocoele, are believed to have their origin during this period.



Figs 10A to C: Schematic representation of the development of the caudal spinal cord by secondary neurulation

Regression

The process by which the filum terminale and cauda equina are formed from that portion of the neural tube formed by canalisation and by which the conus medullaris eventually comes to lie at its adult level is termed as regression or retrogressive differentiation. This process begins as early as 43–48 days of gestation and continues throughout the foetal period and into the early postnatal period. The ventriculus terminalis is a localised dilatation of the central canal in the conus medullaris and can be identified to lie opposite the second coccygeal vertebral level early in development. At this stage of development, the spinal cord and the vertebral body levels corresponds segment for segment. During the process of regression, the ventriculus terminalis "ascends" both by regression of the caudal neural tube, as well as by the disproportionate growth of the vertebral column, resulting in the formation of the filum terminale. At birth, the conus lies opposite the third lumbar vertebral body and eventually reaches its adult position at the L1-L2 interspace by the 3rd month of life. As a result of these changes, the lumbar and sacral nerve roots which, early in their development, exit directly opposite their segmental spinal cord levels of origin become elongated as the conus "ascends", thus forming the cauda equina. Abnormalities during this stage of development result in "tight filum terminale", one of the most common causes of tethered cord syndrome.

Like other parts of the central nervous system, the developing spinal cord also has three layers: the germinal or ependymal layer, the mantle layer and the marginal layer. Cell proliferations in the mantle layer produce anterior and posterior thickenings known as the basal lamina and the alar lamina (Fig. 11). The basal lamina gives rise to the anterior horn of the spinal cord and the alar lamina gives rise to the posterior horn of the spinal cord. Neuroblasts of the basal lamina become the efferent peripheral neurons. Their axons penetrate the marginal layer and emerge from the spinal cord as the

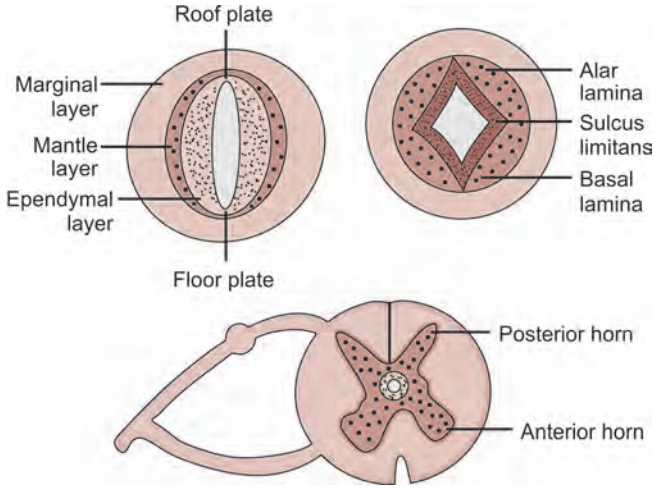


Fig. 11: Schematic representation of the development of the basal and alar lamina of the spinal cord

ventral root fibres to innervate the skeletal muscles or the autonomic ganglia. Some of the neuroblasts of the basal plates also give rise to the neurons which contribute to the local neuronal circuits forming the association cells and commissural cells, the axons of the former remaining on the same side of the spinal cord and the axons of the latter crossing over to the opposite side. Both cells contribute to ascending and descending pathways in the spinal cord. Cells of the alar lamina have axons that remain within the nervous system. Parts of these axons arch anteriorly, cross through the basal lamina to the opposite side, and reach the marginal layer, where they ascend or descend for variable distances. The expansion of the alar plates in a medial direction brings these plates into close opposition resulting in the formation of the posterior median septum. However, in the region of the basal plates, an invagination forms resulting in the formation of the anterior median fissure.

As development proceeds, the proliferation of the germinal cells of the ependymal zone gradually decreases and ultimately stops altogether. As more and more stem cells are transformed into neuroblasts, the germinal zone progressively diminishes in size and ultimately is reduced to a single layer of columnar epithelial cells lining the central canal of the spinal cord. The mantle layer progressively increases in size and becomes the grey matter of the spinal cord, which is surrounded by the marginal layer, which contains the descending and ascending axons and ultimately becomes the white matter of the spinal cord.

Development of the Meninges

The meningeal layers in the spine and in the cranium up to the midbrain are derived from the paraxial mesenchyme. The meninges overlying the cerebral hemispheres are derived from the neural crest. The dura mater constitutes the pachymeninges, and the pia and arachnoid, together, constitute the leptomeninges. All the three meningeal layers are derived from a loose mesenchyme known as the meninx primitiva or primary meninx that surrounds the primitive neural tube. Once the cerebrospinal fluid starts egressing from the ventricles it passes through the meninx primitiva and separates the meninx primitiva into the pia mater and arachnoid.

Molecular Basis of Brain Development

During the latter part of the last century, the study of embryology has led to significant advances in our understanding of the many processes that are involved in the formation and development of an embryo. Recently, the underlying mechanisms involved at a molecular level are beginning to be elucidated. Recent advances in molecular biology have allowed biologists to uncover, characterise and ultimately manipulate the genes that make up the genome of the fertilised egg. These advances have helped us in understanding the fundamental principles of development; how genes control cell behaviour and, thus, how they determine the pattern and form of an embryo. These advances are helping clinicians to understand the multitude of malformations encountered. Therefore, it is imperative that neurosurgeons, because of the wide variety of congenital malformations of the nervous system encountered by them, keep abreast of these developments. Only by understanding the processes involved during normal development we can begin to unravel the mechanisms that are responsible when things go wrong. These developments in basic sciences should be utilised for clinical benefit, principally to aid with pre-natal diagnosis and, ultimately, to enable therapeutic intervention.

Molecular Regulation of Neural Induction

Induction of neural plate formation is controlled by several factors. In the developing embryo, bone morphogenetic protein-4 (BMP-4) is elaborated by the developing ectoderm and mesoderm. Under the influence of BMP-4, the ectoderm becomes epidermis and the mesoderm differentiates into intermediate and lateral plate mesoderm. However, in the region of the ectoderm destined to become the future neural plate, the activity of BMP-4 is blocked by three molecules, viz. noggin, chordin and follistatin. These molecules are secreted by the primitive node, notochord and the paraxial mesoderm. However, these neural inducers form only the neural plate that goes to form the forebrain and midbrain regions. Induction of the neural plate regions that go to form the hindbrain and spinal cord depends upon two proteins, Wnt-3a and fibroblast growth factor (FGF). In addition, retinoic acid and homeobox genes play an important role in organising the craniocaudal axis of the developing nervous system.

Homeobox Genes (Hox Genes)

The Hox genes were originally identified in the fruit fly *Drosophila melanogaster*. These genes are a family of regulatory genes (with a phylogenetically highly conserved

domain called the "homeobox"), which appears to play a fundamental role in the establishment of the body plan. All vertebrates, including humans, contain 39 Hox genes that are distributed on four linkage groups or clusters designated Hox A, B, C and D on chromosomes 6, 11, 15, and 2, respectively (For a detailed discussion on homeobox genes refer the chapter on Embryology of the Skull and Vertebral Column).

During early development, the hindbrain is transiently partitioned into eight transverse neuroepithelial segments called rhombomeres (r1-r8), each of which adopts a distinct set of molecular and cellular properties and ordered domains of Hox gene expression (Fig. 12). These rhombomeres give rise to well-defined regions of the adult brain and their segmental organisation is critical for the establishment of cranial ganglia, branchiomotor nerves and pathways of neural crest migration. For example, the motor nerves of the first three branchial arches (trigeminal, facial-acoustic and glossopharyngeal) are respectively derived from nuclei confined to rhombomeres 2, 4 and 6. In addition to patterning the cranial nerves, the rhombomeric organisation of the hindbrain is also linked to the patterns of cranial neural crest cell migration. Hindbrain derived neural crest cells migrate ventrolaterally as three segmental streams adjacent to r2, r4 and r6, which enter the first, second and third branchial arches, respectively. Substantially fewer neural crest cells delaminate from r3 and r5 compared to the even-numbered rhombomeres. Thus, hindbrain segmentation is a conserved strategy used by vertebrates for organising diverse craniofacial features such as cranial ganglia, branchiomotor nerves and neural crest. The Hox genes play an important role in hindbrain segmentation as well as in the neural crest cells derived from the hindbrain region. The neural crest cells derived from various rhombomeric segments also exhibit the same Hox gene expression as their corresponding rhombomeric segments. This patterned Hox gene expression is carried to the branchial arches populated by the neural crest cells. In summary, the positional information that controls pharyngeal arch patterning is first contained in the rhombencephalon and then transmitted to the pharyngeal area via the neural crest cells. Thus, Hox genes are important for conferring anteroposterior identity of rhombomeres and for the normal development of the branchial arch structures.

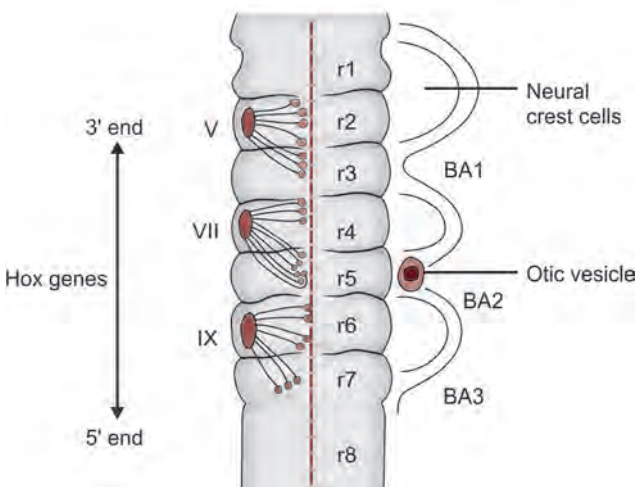

Fig. 12: Schematic representation of the division of the hindbrain into eight rhombomeres and the derivation of the pharyngeal arches from the hindbrain related neural crest cells. This patterning of the hindbrain and the pharyngeal arches is determined by the Hox genes. The Hox code is carried from the hindbrain segments into the pharyngeal arches through the migrating neural crest cells

Sonic Hedgehog Gene

Sonic hedgehog (SHH) gene is a signalling switch used in differentiating subpopulations of cells throughout the embryo. SHH function is determined by where the signal is being secreted, how far away the responsive cell population is and how SHH is proteolytically cleaved. SHH acts by binding to the membrane receptor patched (ptc). Abnormal expression of SHH is thought to lead to holoprosencephaly. SHH induced patterning of the embryo is found in the ventral neural tube, parts of the developing brain and developing limb buds.

Otx, Emx, LIM 1 and EN Genes

Otx genes (orthodenticle genes), Otx 1 and Otx 2, empty spiracle genes (Emx-1 and Emx-2) and LIM 1 genes are involved in the specification, regionalisation and terminal differentiation of the rostral central nervous system, especially, the forebrain. It is believed that modification of their regulatory control may have influenced the morphogenesis and evolution of the brain. The Engrailed 1 and 2 (EN1 and EN2) are two homeobox containing genes and are expressed at the junction of the developing hindbrain and midbrain. EN1 regulates the development of the dorsal midbrain (tectum) and cerebellum, whereas EN2 is involved only in cerebellar development. Other genes that are involved in brain development are WNT1 and NKX2.1.

Molecular Regulation of Cortical Development

Cerebral cortical development consists of three major processes: cell proliferation and apoptosis (programmed cell death), neuronal migration and cortical organisation. Cell proliferation is the process that takes place in the germinal zones of the developing prosencephalon. Before neurogenesis, the pool of progenitor cells is expanded through a series of cell divisions in which both the daughter cells re-enter the cell cycle as progenitors. Eventually, under the influence of signals that are not yet known, the fraction of post-mitotic cells that exit the cell cycle to become neurons or glia gradually increases until the proliferative potential of the germinal zone is exhausted. Certain proteins that have a role in this differentiation have been identified.

Neuronal migration requires the migrating young neuron to attach to radial glial cells that span the developing hemisphere from the germinal zone to the pia, to

Table 2: Genes and site of action

Genes	*Site of Action*
Hox genes	Segmentation of the hindbrain; hox codes are also carried into the pharyngeal arches through the migrating neural crest cells
EN1 and EN2	EN1 regulates the development of the midbrain, tectum and the cerebellum; EN2 regulates the development of the cerebellum
Otx 1 and 2, Emx 1 and 2	Specify the identity of various forebrain and midbrain regions
LIM1	Specifies the identity of forebrain and midbrain areas by supporting Otx2
Fibroblast growth factor–8 (FGF-8)	Induces the expression of Brain factor-1 (BF1), which regulates the development of the cerebral hemispheres, especially, the basal telencephalon and retina
SHH	Plays an important role in the ventral patterning of the entire central nervous system
NKX2.1	Regulates the development of the hypothalamus
WNTI	Assists in the development of the cerebellum
Filamin-1, LIS1 and doublecortin	Neuronal migration from the germinal zone of the neural tube to their final positions in the cortex
Reelin and mDab1	Termination of neuronal migration

migrate along the radial glial cells and to detach when they reach the proper layer of the cerebral cortex. Some proteins have been identified that play important roles in these steps. The filamin-1, LIS1 and doublecortin genes encode proteins that play an important role in the migration of neurons along the radial glial cells. Mutations of these genes are known to result in various types of neuronal migration disorders. Two other proteins, neureglin and astrotactin, have been identified regulating the interactions between the migrating neurons and radial glial cells. Termination of neuronal migration is brought about by an extra-cellular protein known as reelin and the cytoplasmic protein known as mDab 1. The molecular mechanisms that are involved in cortical organisation are gradually being elucidated.

A brief summary of the molecular control of brain development is given in Table 2.

Molecular Regulation of Spinal Cord Development

At the neural plate stage in the spinal cord region, the entire plate expresses genes that encode transcription factors, viz. PAX3, PAX7, MSX1 and MSX2. This expression pattern is altered by the sonic hedgehog gene (SHH) and bone morphogenetic proteins 4 and 7 (BMP 4 and 7). Expression of SHH by the notochord results in the ventralisation of the neural tube and formation of the floor plate, which also subsequently expresses SHH. The latter represses the expression of PAX3, PAX7 and MSX1 and MSX2. This results in the formation of the floor plate and basal lamina from which the motor neurons of the spinal cord originate. At the same time, BMP-4 and BMP-7 expressed from the surface ectoderm close to the neural plate up-regulate the expression of PAX3 and PAX7, resulting in the formation of the roof plate and the alar lamina, which are sensory in function. PAX3 and PAX7 are also necessary for the formation of neural crest cells.

Post-natal Growth of the Brain

At birth the volume of the brain is approximately 25% of the volume in adult life. The greater part of the increase occurs in the 1st year at the end of which the volume of the brain increases to 75% of the adult volume. This growth can be accounted for by an increase in the size of the nerve cell somata, the proliferation and increase in the dimensions of their dendritic processes, axons and their collaterals and by the growth of the neuroglial cells and cerebral blood vessels and by the acquisition of myelin sheaths by the axons. The great sensory pathways (visual, auditory and somatic) myelinate first, and the motor fibres later. During the second and subsequent years, growth progresses more slowly, reaching the adult size by the 17th or 18th year largely due to continued myelination of the various fibres.

15 Congenital Malformations of Cerebrum

Venkatramana NK, Ravi Shankar S

The development of the central nervous system (CNS) is very complex. Neurogenesis, apoptosis, neurulation, neural crest separation, cell migration, axonal path finding, dendritic sprouting, synaptogenesis, neurotransmitter biosynthesis and myelinisation are the various steps involved.[34,64] Each of these processes should be proper for normal development. Brain malformations are congenital deviations in form and/or structure of the developing CNS.[63] Congenital malformations of the brain are common clinical conditions which are one of the leading causes of infant morbidity, mortality and foetal loss.[29] Even in the general population they are the leading causes of clinical presentations like epilepsy and cerebral palsy.[32,34]

So far, only descriptive terms have been used for most CNS malformations with their clinical and radiological features. However, detailed neuropathology studies have paved the way for precise diagnosis and cause analysis. Prenatal brain imaging has aroused the interest in foetal neuropathology and significantly transformed the concepts of brain malformations.[13,31,32,35,51] Primary malformations are due to genetic or chromosomal mutations and secondary malformations to exogenous causes.[32] By definition, inherited factors can only cause primary malformations and secondary malformations cannot be inherited, but inherited factors can predispose to secondary malformations. Genetic screening plays a significant role in distinguishing the two classes of malformations. Recent neuropathological studies have made it clear that brain malformations are phenotypically unique and causally heterogeneous. Understanding the molecular cascades of the signalling pathways and developmental neuroscience have shed light on the diversity, heterogeneity and the role of mutations involving different genes. In addition, these signalling pathways could be the target of toxic agents which can produce similar malformations.[32]

DEVELOPMENT AND PATHOGENESIS

The morphological abnormalities are directly derived from alterations of the morphogenic processes. Identification of these features will help in the diagnosis of lesions which are due to the distortion of the normal embryogenic process. During the 1st week after fecundation, the egg divides and migrates from the fallopian tube and gets implanted in the uterine mucosa. During the 2nd week, the amniotic cavity develops and the inner cell mass has a two-layer organisation—epiblastic and endoblastic layers. During the 3rd week, the invagination of the epiblastic cells between the epiblast and the endoblast produces the mesoblast. During the 4th week, the neural plate will form and fold itself along its long axis to form the neural tube which closes. During this process the surface ectoderm gets separated allowing the interposition of mesenchyme. If the process of closure of the neural tube fails, the resulting malformations belong to the group of open dysraphisms. Failure of closure of the calvarium and anterior cerebrum results in cranial encephalomeningocoele. Exencephaly is an extreme form and if the herniated brain is destroyed by necrosis, it will lead to anencephaly.[18] The minor equivalent of this disorder is the atretic parietal encephalocoele.

During the 5th week, a defect in the anterior end of the neural plate can lead to a group of malformations affecting the brain, the placode derived organs and the face. The anterior neural crest develops into most of the facial skeleton, the telencephalic meninges, calvarium and superficial covering.[19] Adjacent portions of the neural plate give rise to the hypothalamus, neurohypophysis and optic chiasm in the midline and the cerebral hemisphere laterally. When the neural tube closes, its cephalic end develops flexures and dilatations resulting in three primary cephalic vesicles namely: prosencephalon; mesencephalon and rhombencephalon. They further differentiate into five vesicles: the telencephalon forming the lateral hemispheres and laminae terminalis; the diencephalon forming the forebrain; the mesencephalon forming the midbrain; and the metencephalon and myelencephalon forming the hindbrain.[60,69] At the forebrain level, lack of differentiation can result in a single prosencephalic vesicle leading to various forms of holoprosencephaly.[5–8] Septo-optic dysplasia is a variant which presents with no continuity between the hemispheres, with normal commissures and a single ventricular cavity without a septum.[22] During the 6–8th weeks, the rhombencephalon develops a significant evagination resulting in the development of the cerebellum and opening of the fourth ventricle,[10] synchronising with the transformation of solid meninx primitiva into rigid dural layers and the fluid-filled subarachnoid space.[49,60,67,68,70–73] During this process cystic cavities can develop in the posterior

fossa and if only the posterior membranous area of the rhombencephalic roof is involved, malformations such as enlarged "Blake's pouch" with abnormal location of the tentorium can occur.[2,79] When the anterior membranous area is defective, it will lead to the entire spectrum of Dandy-Walker malformations.

- Embryonic period—First 8 weeks, post-fertilisation
  - o Gastrulation and notochord formation — 2–3 weeks
  - o Dorsal induction — 3–4 weeks
    - – Primary neurulation
    - – Secondary neurulation
  - o Ventral induction — 5–6 weeks
- Foetal period—8 to 38 post-fertilisation weeks
  - o Neuronal proliferation, differentiation and histogenesis — 2–4 months
  - o Migration — 3–5 months
  - o Myelination and organisation — 3rd trimester–post-natal

Commissural Agenesis

There are three telencephalic interhemispheric commissures namely: paleocortical anterior commissure; archicortical hippocampal commissure and the large neocortical corpus callosum connecting most of the neocortex. The agenesis could be complete or partial with cysts including lipoma of the corpus callosum or isolated agenesis of a single commissure.[58,59]

Malformation of Cortical Development

Malformation of cortical development includes all varieties of cortical malformations previously described as cortical dysplasias or neuronal migration disorders. They can be classified based on the pattern of cortical formation as defects of:

a. Cellular multiplication
b. Cellular differentiation
c. Cellular migration
d. Cellular organisation.[7,55,56]

Cellular Multiplication

It starts as soon as the neural tube is completed in the periventricular layer. The primitive germinal cells divide symmetrically and produce pairs of daughter cells. The faulty multiplication can result in an abnormal size of the brain.[16]

Cellular Differentiation

As the cells are dividing, one cell will remain the germinal matrix and other cells get differentiated and become neuronal or glial cells and migrate towards their final position in the cortex. When there is a defect in this process due to any mechanism, the cells will have the characteristics of both neurons and glia, and they fail to migrate and segregate properly. They look abnormal, as giant dismorphic neurons or huge balloon cells. If this defect is localised, it leads to focal cortical dysplasias and if it is large, it can lead to hemimegalencephaly.

Cellular Migration

The neuronal cells migrate towards the cortex in a radial pattern established by the radial glia, which act as a guideline from the ventricle to the pial surface. Defects in this process will lead to neurons in abnormal locations forming masses called "grey matter heterotopias", which could be nodular or laminar, and depending on the location could be periventricular or subcortical. Subcortical laminar heterotopia is a band of grey matter located in the white matter just below the normal looking cortex and described as double cortex. It has a genetic horizon with a defect on chromosome X and also chromosome 17. Excessive migrations into superficial molecular layers may occur, leading to the Walker-Warburg syndrome, where the neurons pass the brain surface to invade the meningeal space.

Cellular Organisation

Intrinsic organisation of the cortical layers occurs with the development of the intracortical connections and then the extracortical connections mediated by the transitory subplate during the 20th and 25th weeks of gestation. Disorders at this stage will result in abnormal folding of the cortex and lead to microgyria, polymicrogyria, etc.

Cysts in the extracerebral spaces may be related to cerebral malformation or may be purely intrameningeal. They are classified according to the histology of the membrane as arachnoid cyst, neuroglial cyst and glioependymal cyst. They are usually located in the suprasellar cistern, middle cranial fossa or posterior fossa.

Schizencephaly

It is characterised by the presence of unilateral or bilateral, symmetrical or asymmetrical transcerebral clefts. The lips may be opposed or largely open with the presence of a cyst. The walls of these clefts are lined with cortex, usually dysplastic, with its pial covering. This extends all the way to the ventricular ependyma which is the hallmark of the malformation. The exact process of this malformation is not clear.[81,82]

Most CNS malformations isolated or associated with other malformations are usually identified by the descriptive terms such as microcephaly, lissencephaly, polymicrogyria and hydrocephaly. However, this description does not help us to understand the mechanism. They are classified as:

a. Abnormal brain size (microcephaly/megalencephaly).
b. External form (holoprosencephaly/lissencephaly).
c. Internal configuration (hydrocephaly/agenesis of corpus callosum).

CONCEPTS, CAUSES AND CLASSIFICATION

There are many causes of congenital malformations (Table 1) which include, chromosomal abnormalities, gene defects, foetal infection, exposure of the foetus to harmful chemicals, radiation, foetal hypoxia and often more than one of these factors may play a role and, therefore, the resultant malformation may not follow a specific pattern.[40,41] Further, the malformations are closely linked to the development stage at which time one of these aetiological factors may induce the malformation. Since many of the structures of the brain form at the same time, the resultant malformation may lead to defects in multiple structures of the brain. Due to these factors, classification and grouping are often difficult and less rewarding. In spite of this, a classification system is required for better understanding, prognostication, counselling and management of these conditions.

Table 1: Different causes of congenital malformations

Anomalies of dorsal induction	*Anomalies of ventral induction*
• Primary neurulation (neural tube defects)	
o Encephalocoeles	• Holoprosencephaly
o Craniorachischisis totalis	• Septo-optic dysplasia
o Anencephaly/exencephaly	• Agenesis of septum
o Chiari malformation[52]	• Diencephalic cyst
Anomalies of neuronal proliferation and differentiation	*Anomalies of neuronal migration*
• Micro/megalencephaly	• Lissencephaly
• Phakomatoses	• Pachygyria
• Colpo/porencephaly	• Schizencephaly
• Hydranencephaly	• Polymicrogyria
• Cong tumours/vascular malformations	• Heterotopias
	• Dysgenesis of corpus callosum[1]

Morphogenic Classification

- Defects in neural tube closure
- Forebrain growth failure
- Midbrain malformations
- Hindbrain malformations
- Abnormal cortical development
- Miscellaneous.

Classification Based on Developmental Stages

- Weeks 1–3 – Early stages of layer formation
- Weeks 4 – Neurulation
- Weeks 5 – Disorders of the anterior neural plate, abnormal diverticulation
- Weeks 6–8 – Dandy-Walker spectrum, cystic malformation of posterior fossa

Classification Based on Structural Process

- Commissural agenesis
- Malformations of cortical development
- Cellular multiplication symmetrical divisions
- Cellular differentiation
- Cellular migration
- Cellular organisation
- Extracerebral cysts
- Vascular malformations
- Uncertain process—schizencephaly.

Molecular Genetics

Each single process of CNS development is under genetic control, most often including various genes with different modes of transmission. The distinction between dominant, recessive and X-linked disorders is extremely useful for clinical diagnosis, linkage analysis and for genetic counselling. Dominant diseases manifest in the heterozygous state, that is, when only one abnormal gene is present and the corresponding allele on the homologous chromosome is normal. By definition, the responsible gene must be located on one of the 22 autosomes. So, there is a one in two chance that half of the offspring will inherit the disease. The recessive diseases require inheritance of a mutant allele of the same genetic locus from each parent. X-linked disorders and X inactivation is the third pattern of inheritance. During embryonic development, one of the two X chromosomes in each somatic cell of a female is irreversibly inactivated. The inactivated X chromosome is made permanently non-functional. If a mutation occurs on one of the X chromosomes, one half of the cells will be normal and the other half will express the mutant genotype. The actuarial risk for brain malformations evaluated by frequency may vary from a 50% recurrence risk for autosomal dominant, 25% for autosomal recessive and under 1% for a new mutation. Molecular genetics has brought new insights into the aetiology and pathogenesis of nervous system malformations and, in addition, provided tools for accurate genetic diagnosis and prenatal detection. Many malformations previously thought to be single mutant disorders are now commonly recognised to result from many independent genetic mutations. Gradients of genetic expression along the axis of the neural tube established at the time of gastrulation may explain many varieties and clinical expressions of cerebral malformations.[34]

Prenatal screening also involves ultrasound examination and foetal MRI to achieve accurate morphological diagnosis.[32,36]

STRUCTURAL IMAGING

Congenital cerebral malformations commonly manifest as epilepsy and neurodevelopmental deficits. Numerous studies have shown that MRI scan is superior to CT scanning in detecting the abnormality and associated

structural defects. Gross abnormalities, such as lissencephaly or schizencephaly, may be identified on CT scan, but are more clearly seen using MRI and also in greater detail. Multiple techniques, like fat-suppression sequences and magnetic resonance venography, give additional information required for diagnosis and surgical planning.

Normal magnetic resonance studies do not exclude neuronal migration disorders, especially focal cortical dysplasia.[23] In a recent series of malformations of cortical developments (MCDs), 68 out of 100 individuals had normal CT scan and 19 out of 36 patients had normal previous conventional MRI.[74] The presence of cortical dysplasia is best established by application of the following sequences:

1. Multiple sequences, including T1-weighted, T2-weighted, fast FLAIR and proton density, help to confirm the nature of ectopic tissue, allow good discrimination of grey and white matter and identification of foci of T2 prolongation (seen typically with polymicrogyria and focal cortical dysplasia).
2. Volumetric acquisition with thin (≤ 1.5 mm) partition enables complete coverage and reformatting in any plane, for detailed visualisation of data and 3-dimensional constructions.
3. The use of surface coils improves discrimination by increasing the signal-to-noise ratio. Magnification techniques and phase-array coils enable detection of subtle abnormalities.

FUNCTIONAL IMAGING

Functional imaging techniques include single photon emission computed tomography (SPECT), positron emission tomography (PET) and functional MRI (fMRI) techniques. These techniques are becoming increasingly important in the evaluation of patients with congenital malformations. They provide information regarding the epileptic focus, functional status, ictal activity, blood flow changes, metabolism and neuroreceptors, and also delineates the function of abnormal ectopic grey matter which is important in surgical planning.

CLINICO-RADIOLOGICAL FEATURES

Microencephaly

It is a descriptive term for a small brain (weight and size less than three standard deviations for age) which may or may not be associated with microcephaly. It is usually a silent familial trait or may be associated with mental retardation in several syndromes with autosomal recessive inheritance. It is relatively a common finding in chromosomal and metabolic diseases. Abnormal brain growth, faulty neurogenesis, brain atrophy and abnormal programmed cell death are the usual proposed causes. Pathologically, there may be gyral retraction ranging from pachygyria to agyria. Histology shows a four-layered cortex with chaotic polymicrogyria, inverted cortical layering, heterotopias, neuroglial ectopia and lack of maturation.[21,43]

Megalencephaly

It is a large brain (by size and weight) which is above two standard deviations for age. It may affect a single hemisphere (hemimegalencephaly or may be associated with ventriculomegaly), could be isolated or in association with other developmental disorders like Soto's syndrome or osteochrondral dysplasia. It could be silent or manifest with seizures and psychomotor impairment. In hemimegalencephaly (Fig. 1) the large hemisphere usually shows an abnormal gyral pattern with abnormal cortical plate organisation. In addition, abnormal angiogenesis may be seen in Klippel-Trenaunay syndrome.

Hydrocephaly

It is ventricular enlargement caused by excessive production of CSF, insufficient absorption or disturbance in the circulation. Depending on the pathology, it could be monoventricular, biventricular, triventricular or tetraventricular enlargement. Aqueductal stenosis due to Bickers-Adams syndrome or atresia (forking) is well known.

Lissencephaly

It describes the morphologically smooth brain (Fig. 2). The term is also used for agyria/pachygyria due to abnormal corticogenesis. Total absence of convolutions leads to agyria (smooth brain). Pachygyria is an intermediary form with less frequent broad gyri and shallow sulci. These two can coexist in the same brain. More than 25 syndromes, associated with this anomaly in association with mental retardation, and epilepsy have been described.[76]

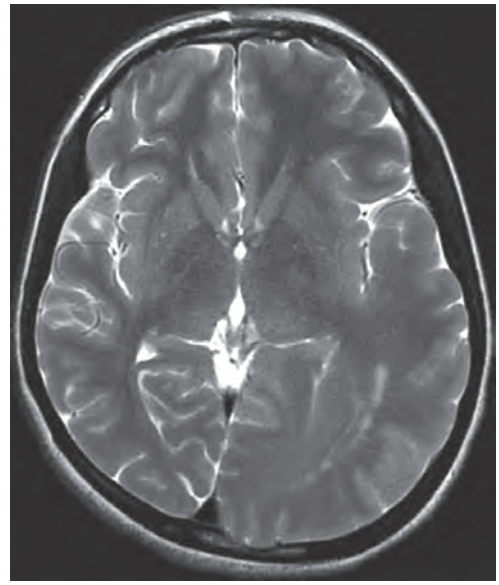

Fig. 1: Hemimegalencephaly involving only left parietal lobe

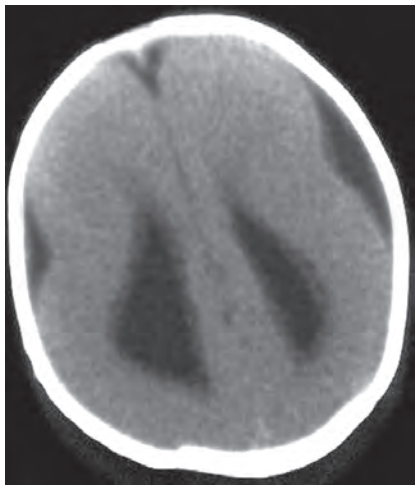

Fig. 2: Lissencephaly

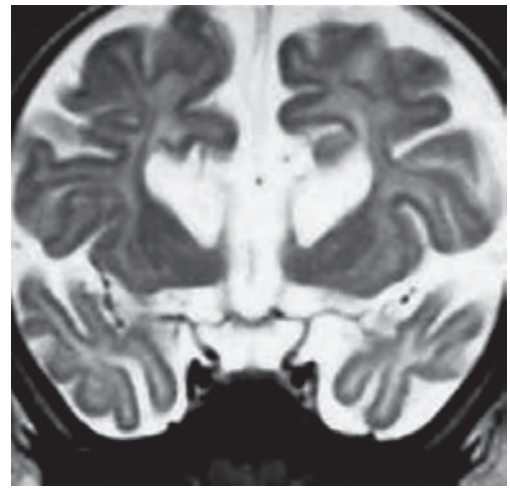

Fig. 3: Corpus callosum agenesis

Classical Lissencephaly or Type 1

It is due to abnormality in two genes, namely LIS 1 gene mapping on chromosome 17p 13.3 and DCX gene mapping on abnormal XQ 22.3. Radiologically, there could be reversal of grey-white matter ratio. Histologically, there is a four-layered cortical organisation made up of the following:

1. Superficial hypocellular layer
2. Cellular zone of hypertrophic large pyramidal cells
3. Underlying pachycellular layer
4. Large rim of ectopic neurons.

Cobblestone Lissencephaly or Type 2

It is a distinct cytoarchitectural disorder occurring in a group of autosomal recessive disorders like Walker-Warburg syndrome, Fukuyama muscular dystrophy and muscle-eye-brain disease usually associated with early hydrocephalus and agyric nodular brain surface.

"Cobblestoned" disorder is usually associated with cerebellar dysplasia, brain stem disorganisation, microophthalmia and retinal dysplasia. In addition, encephalocoeles and genital malformation in males have also been reported.

Walnut Type Lissencephaly or Type 3

It is described in relation to Neu-Laxova syndrome. Severe microcephaly, joint deformities and skin abnormalities are the usual features.[12,24–28,30]

Holoprosencephaly

It morphologically refers to a spectrum of forebrain malformations characterised by failure of the prosencephalon to form two lateral telencephalic vesicles.

It is usually associated with a spectrum of craniofacial abnormalities. Single calculi, atresia of the aqueduct, single medially fused cerebellar hemispheres and spina bifida have also been described.[15] Based on the severity, it has been divided into three groups: (a) lobar; (b) semilobar and (c) lobar with numerous transitional forms. The histopathology is usually diagnostic. Chromosomal aneuploidy accounts for 24–45% cases involving chromosomes 13 and 18. Septo-optic dysplasia (de Morsier syndrome) is also a midline developmental field defect. CNS malformations are characterised by an abnormal septum pellucidum, dysplasia of the optic chiasm or optic nerves and pituitary abnormalities. This anomaly is usually sporadic and is commoner in females.[17,37,53,58]

Agenesis of Corpus Callosum

It may be total or partial due to failure of the corticocortical tracts to cross the midline. In total agenesis, the medial surface of the hemisphere shows the characteristic absence of the cingulate gyrus and radial arrangement of the convolutions with an abnormal callosal artery. The callosal fibres that have failed to cross remain on either side of the lamina terminalis and form anteroposterior bundles called "Probst bundles" in association with the fornix. In partial agenesis, the body and splenium will be missing. Anterior agenesis is extremely rare. In severe hydrocephalus, the roof of the third ventricle may bulge into the interhemispheric region resembling the wall of a cyst. Corpus callosum agenesis[54] (Fig. 3) may be isolated or associated with an incredible number of syndromes like golden hour syndrome, Aicardi syndrome, Apert syndrome, etc. The isolated ones are usually clinically asymptomatic. The chromosomes 18 and 8 are the most commonly involved in this condition, in addition to many metabolic diseases.[20,32]

Schizencephaly

Schizencephaly is a developmental disorder of cortical migration that was first described in 1946 by Yakovlev and Wadsworth.[78,79] Schizencephaly is a cerebrospinal fluid-filled cleft extending from the ependymal surface of the brain to the pia (Fig. 4). The clefts are lined with thickened four-layered grey matter oriented parallel to the major sulcus. Other cortical areas may also show disordered migration with pachygyria, polymicrogyria and heterotopias.

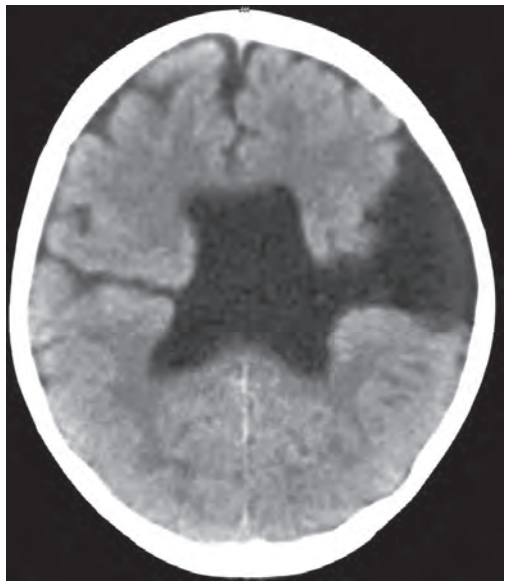

Fig. 4: Schizencephaly

There are two types of schizencephaly:

(1) *Closed-lip (type I) schizencephaly*: These are grey matter lined clefts which are in apposition to each other. Usually the ventricular margin shows an outpouching at the site of closed-lip schizencephaly, acting as an important clue.

(2) *Open-lip (type II) schizencephaly*: These are larger, grey matter lined clefts which are separated with an obvious defect in ventricular margin.

Schizencephaly can be unilateral or bilateral. Associated findings may include heterotopias, absence of septum pellucidum, hippocampal abnormality, pituitary hypoplasia and callosal dysgenesis.

It usually develops before the end of the 2nd month of gestation. The description of a few familial cases of schizencephaly raised the possibility that genetic factors could play an important role in the pathogenesis of this malformation. This possibility has strongly been supported by the presence in some schizencephaly patients of germ line mutations of the homeobox gene EMX 2.[38]

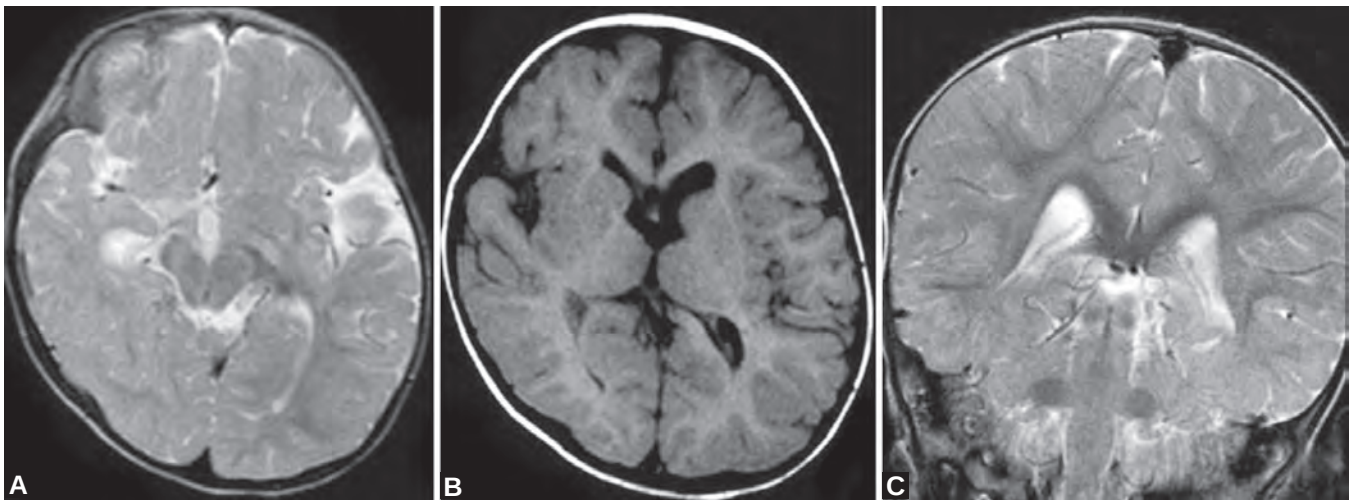
Patients with schizencephaly may present with features resembling those of polymicrogyria. Patients can be divided into those with bilateral and unilateral schizencephaly. Bilateral are less common than unilateral. Approximately 30–40% of patients have bilateral schizencephaly. Bilateral lesions are often asymmetric, with type I schizencephalic lesions in one hemisphere and type II lesions in the opposite hemisphere. The localisation of these lesions follows the vascular supply territory, with the majority of clefts localised in the fronto-temporal regions. Occasionally, these lesions are also localised to the occipital or precentral frontal regions.[48]

Clinical observations have identified that patients with bilateral schizencephaly often have moderate to severe motor dysfunction, characterised as spastic quadriparesis, marked developmental delay, mental retardation and language disorders. The seizure disorder in the unilateral group of patients is focal motor, but often sensory, as well as complex partial seizures.

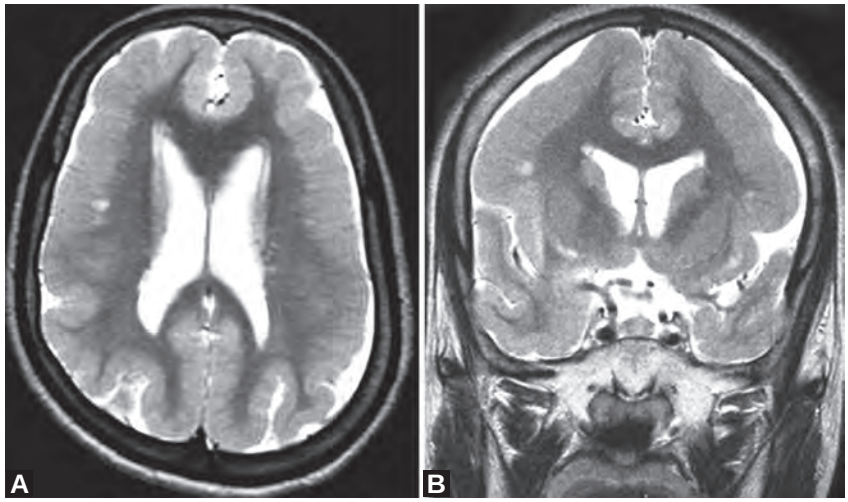
Pachygyria

Pachygyria (Figs 5A to C) is a milder variant of lissencephaly characterised by broad gyri and a thick cortex with an abnormal cytoarchitecture, although histologically the pachygyric cortex may have a more organised cortical structure than in lissencephaly. It is also clear that in many cases lissencephaly and pachygyria coexist in the same patient. Pachygyria is seen in metabolic CNS disorders, such as the Zellweger syndrome (ZS), neonatal adrenoleukodystrophy (NALD) and glutaric aciduria IIA.

On MRI, the cortex appears thicker and the typical figure 8-shaped image seen in lissencephaly is not present in pachygyria. The clinical presentation includes developmental delay and seizures, and half of the patients have microcephaly.



Figs 5A to C: Pachygyria with polymicrogyria



Figs 6A and B: Agyria pachygyria. T2-weighted image showing shallow sulci with thickened cortex and irregular grey-white junction

Polymicrogyria

The term "polymicrogyria" (Figs 5A to C) refers to an abnormal macroscopic appearance of the brain gyration that is characterised by too many small, abnormal gyri. In some cases, the gyri are shallow, small and are separated by shallow sulci, whereas in other cases the gyri are wider.

Histologically, the cortex consists of the molecular and wide neuronal layer (in some cases, there are three poorly defined neuronal layers). These layers are irregularly over-folded and fused, eliminating the sulci and there is evidence of midcortical ischemic laminar necrosis in layer 5. Superficial to this cortical band, the cortex consists of normal layers 4, 3 and 2.

Polymicrogyria can be diffuse or focal, bilateral or unilateral, symmetric or asymmetric. It is diverse in its aetiology and pathogenesis. Although most of the experimental and human foetal pathology data suggest that polymicrogyria may be the result of a post-migratory ischaemic mechanism, others have postulated a premigratory mechanism for some cases of polymicrogyria. Some forms of polymicrogyria are associated with mutations of PAX6, TBR2 and other genes. Bilateral peri-Sylvian polymicrogyria due to mutations of SRPX2, a form of bilateral frontoparietal polymicrogyria, resembles cobblestone lissencephaly. Other forms of polymicrogyria are acquired and are caused by disruptions. Polymicrogyria often occurs with foetal cytomegalovirus infection and prenatal hypoxic-ischemic encephalopathy, including vascular problems related to twinning.

Clinically, patients with polymicrogyria have an extremely variable presentation, depending on the location, extent and whether there is involvement of the contralateral hemisphere. Diffuse polymicrogyria may present with severe developmental delay, microcephaly and hypotonia. Polymicrogyria can be localised to one hemisphere and may also be one of the histologic changes in patients with hemimegalencephaly. MRI findings demonstrate a thick cortex that can be interpreted as pachygyria. However, cortical thickness is less than that observed in pachygyria. The sulci are shallow and the underlying white matter may show an abnormal T2 signal (Figs 6A and B).

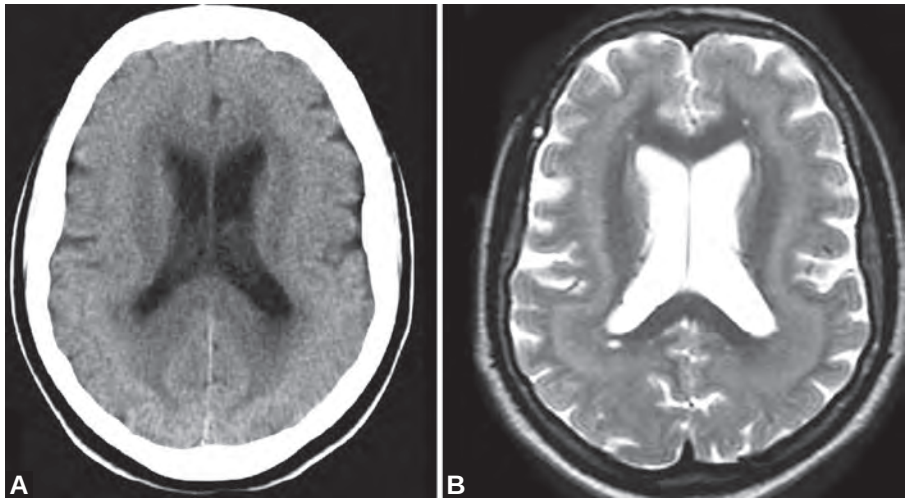
HETEROTOPIAS

Heterotopias are a collection of nerve cells in abnormal locations due to an arrest in the migration process. It can be an isolated disorder or may occur in association with other structural anomalies. Hetrotopias can be of the following types:

(a) Band heterotopia
(b) Subependymal heterotopia
(c) Focal heterotopia.

Band Heterotopia or Double Cortex Syndrome

This syndrome is prevalent in females. Patients have mild to moderate developmental delay, pyramidal signs and, in some cases, there may be associated dysarthria. Full scale IQs ranging from severely low to normal have been reported. EEG investigations usually demonstrate generalised spike-and-wave discharges or multifocal EEG abnormalities. Classic MRI findings demonstrate a band of subcortical grey matter heterotopia underlying the cortical mantle and separated from it by a thin rim of white matter (Figs 7A and B). This is usually more obvious over the fronto-central-parietal region.[61,62] Pathologic specimens have demonstrated normal lamination in cortical layers 1 through 4. Layers 5 and 6 cannot be seen, and layer 6 is merged with the U-fibres of the white matter. Functional MRI studies in double cortex have shown that these regions may play a role in normal brain functioning.[65] Periventricular heterotopias may be seen in tuberous sclerosis, but there the lesions are usually calcified and have a heterogeneous intensity on MRI scanning.[44]



Figs 7A and B: Band heterotopia

Subependymal Heterotopias

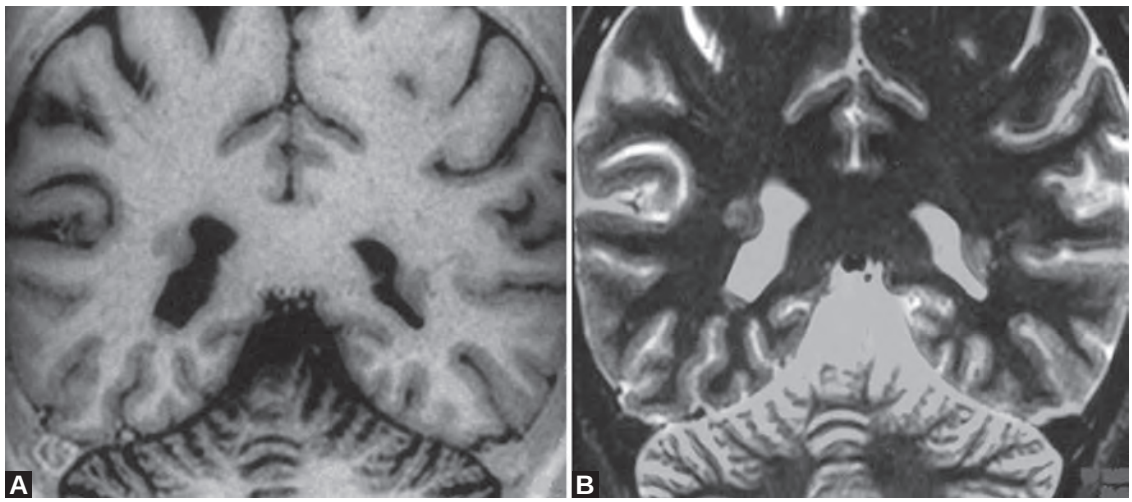
Heterotopias are defined as nodular grey matter masses that can be diffuse, bilateral or unilateral. Subependymal heterotopias comprise one of the most common forms of developmental disorders. These can range from a few nodular clusters of neurons to diffuse lining of the ependymal regions. Clinically, patients with subependymal heterotopias have normal neurologic development, unlike most other neuronal migration disorders.[14]

Most patients with periventricular nodular heterotopia (Figs 8A and B) present with epilepsy (80%). Seizures may be generalised or may appear localisation related, suggesting mesial temporal, neocortical temporal or parieto-occipital origin.[47] Interestingly, those who developed seizures did so in the second decade of life, relatively later than in other MCDs. Onset of epilepsy in the second decade of life, normal developmental milestones and intelligence, and overwhelming female preponderance differentiates subependymal heterotopia from other cortical dysgeneses.[75] The typical MRI features consist of multiple smooth nodules of cortical grey matter in all sequences, protruding slightly into the ventricular lumen, resulting in an irregular ventricular outline and no enhancement on contrast. Subependymal nodules seen in patients with tuberous sclerosis may be mistaken for that seen in heterotopia.

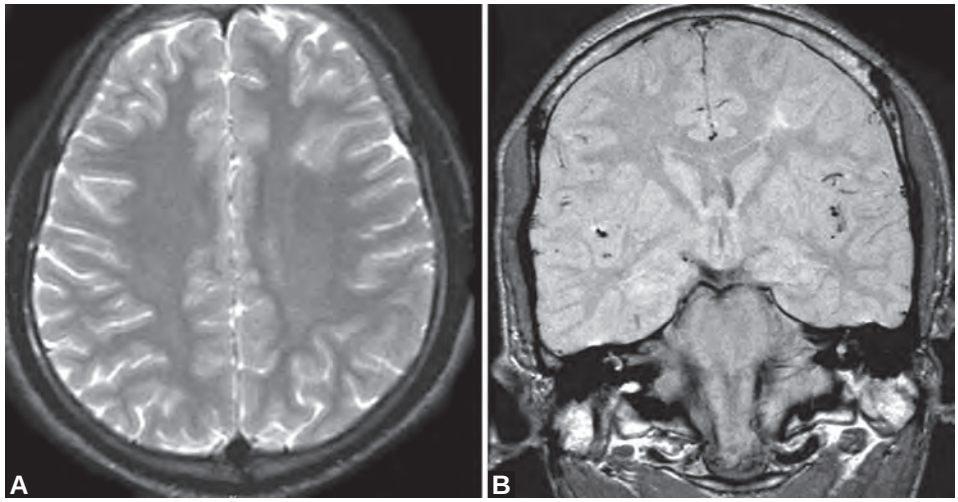
Several syndromes occur in conjunction with heterotopia. The best defined syndrome is bilateral diffuse heterotopia or periventricular nodular ectopia secondary to the mutation of chromosome Xq28.[80] Filamin 1 is the gene defect. Since this disorder is X-linked, it is observed primarily in women, but Dobyns and his colleagues[25] have reported three unrelated boys with bilateral periventricular nodular heterotopias, cerebellar hypoplasia, severe mental retardation, epilepsy and syndactyly. Other reported congenital abnormalities are short gut syndrome, congenital nephrosis and frontal dysplasia.[39]

Focal Cortical Dysplasia

Focal cortical dysplasia (FCD) (Figs 9A and B) is probably the most common form of focal developmental disorder diagnosed in patients referred for intractable epilepsy. Pathologic characteristics are disruption of



Figs 8A and B: Periventricular nodular heterotopia. T1 and T2 coronal images showing periventricular lesions with signal intensity of grey matter suggestive of periventricular nodular heterotopia



Figs 9A and B: Focal cortical dysplasia

cortical lamination with giant neurons and large astrocytes. These changes range from mild cortical disruption without apparent giant neurons to the most severe forms in which cortical dyslamination, large bizarre cells and astrocytosis are present. The most prominent histologic feature is the presence of a large number of abnormal cells with total loss of histologic architecture. Since the original description by Taylor in 1971, FCD has now been recognised to encompass a spectrum of changes, which range from mild cortical disruption without apparent giant neurons to the most severe forms, in which cortical dyslamination, large bizarre cells and astrocytosis are present.[42]

FCD can be classified into two types based on the presence of balloon cells. Type I is without balloon cells and type II is with balloon cells. Type II is more severe and is characterised by the presence of increased cellularity, giant cells and cortical chaos. In a study by Mackay et al.,[50] it was found that pathological findings in FCD and tuberous sclerosis were characterised by the presence of balloon cells.

The clinical manifestations of those with cortical dysplasia are variable. Seizures begin in the first decade of life, usually after the age of 2 or 3 years, but sometimes shortly after birth. In some patients, seizures present in the second decade. The seizures may be partial motor, partial complex or secondary generalised. The location of the lesion corresponds to the clinical presentation. The majority of patients tend to have extratemporal cortical dysplasias. The frontal lobes and, in particular, the precentral and post-central gyri appear to be more involved than other regions in the brain. In a study, correlating pathology and MRI findings in children with intractable partial seizures, cortical dysplastic lesions were present in 23% of patients.[46] Among those with these lesions, the central cortex was involved in almost half. The reasons for this involvement stem from the propensity of the precentral and postcentral gyri to ischaemic injury, as observed in other developmental disorders such as polymicrogyria and schizencephaly.

The presence of FCD in temporal lobes of patients undergoing resection ranges from 6 to 20% in different studies. Porter et al.[66] found cortical dysplasia in 21 out of 33 (64%) paediatric patients with refractory temporal lobe epilepsy. Temporal lobe developmental malformations with cortical dysplasia and balloon cells may coexist with mesial temporal sclerosis (dual pathology).

There is a correlation between the degree of histologic changes and the MRI findings, indicating that only in the most severe cases the abnormality could be detected by MRI. It is likely that high resolution MRI may increase the sensitivity for the detection of these lesions. The most obvious MRI finding of FCD is abnormal signal intensity in the white matter, resulting in a poor grey-white differentiation. The presence of a radiated abnormal signal extending from the ependymal surface of the ventricle to the overlying cortex, termed "transcortical malformation" of cortical development, helps to distinguish FCD from neoplasms.[11] However, this feature is not only recognised in patients with FCD but also in those with tuberous sclerosis. Immunocytochemical staining for tuberin, which is defective in tuberous sclerosis, is effective for differentiation of the two conditions.[57]

Though FCD is a major cause of medically intractable epilepsy, the cellular mechanisms underlying the epileptogenicity of FCD remain largely unknown. Recent work supports the role of developmental alterations of the balance between excitation and inhibition in the pathogenesis of epileptic focal discharges in paediatric patients. Aronica et al.[4] found that there is high expression of metabotropic glutamate receptors (mGluRs), especially mGluR1α and mGluR5, in the dysplastic neurons, suggesting a possible contribution of these glutamate receptors in the intrinsic and high epileptogenicity of dysplastic cortical regions.

MANAGEMENT

The management of patients with congenital malformations includes establishing the cause of the malformation with genetic studies and establishing the foci of epilepsy.

Once such information is gathered, the management includes physical rehabilitation, pharmacotherapy to control seizures and spasticity, genetic counselling, and appropriate surgical treatment.

Best results are obtained when complete or major excision of both the MRI-visible lesion and the cortical areas displaying ictal electrographic activity can be performed. This is more likely when the degree of histological abnormality is mild to moderate or when the lesion is in the temporal lobe. In the case series, reported by Fish et al.[33] from the Montreal Neurological Institute, the results of resection of cortical dysplasia were disappointing. More severe histopathologic abnormalities and central insular or multilobar lesions usually lead to less favourable results; either the major excision of the visualised lesion is impractical or the lesion is microscopically more extensive than shown by the MRI. Rougier et al.[77] reported the results of 100 cortical resections for medically refractory epilepsy and found surgery to be an effective treatment for more than 50% of long-lasting medically intractable seizures. Silbergeld et al.[78,79] reported the benefit of resective surgery in four patients with medically refractory epilepsy due to schizencephaly after proper and extensive pre-surgical evaluation.

Multilobar resection or hemispherectomy for patients with infantile spasms associated with cortical dysplastic lesions and for patients with hemimegalencephaly are often associated with dramatic improvement in seizure control. Callosotomy can be performed in selected patients with diffuse cortical dysplasia who have intractable drop attacks. Bernasconi et al.[9] analysed the results of surgical treatment of intractable epilepsy in patients with subcortical band heterotopia or double cortex syndrome. Their results did not support focal surgical removal of epileptogenic tissue in patients with double cortex syndrome, even in the presence of a relatively localised epileptogenic area.

PROGNOSIS

The prognosis of patients with malformations of cortical development and epilepsy depends on a number of factors. Kobayashi et al.[45] reported that patients with cortical malformations and age of onset less than 3 months (early-onset) had a poorer prognosis when compared to patients with age of onset more than 3 months (late-onset). Patients with early-onset seizures often had FCD while those with late-onset had polymicrogyria. In all seizure free patients epilepsy began after 3 months of age. Patients with mental retardation, bilateral cortical involvement and diffuse EEG abnormalities are thought to have a poor prognosis.[61,62] In most of the studies, patients with MCDs were found to have intractable epilepsy and progressive mental and motor decline and this may be due to selection bias. Ambrosetto[3] reported a small case series of patients with unilateral opercular neuronal migration disorder. All patients had normal intellectual function, normal EEG (except one) and good seizure outcome. Patients with heterotopias and schizencephaly, especially focal and unilateral ones, are found to have a good outcome. Those with lissencephaly and hemimegalencephaly often have intractable epilepsy and are associated with mental retardation. Patients with FCDs tend to have a worse outcome as compared to those with other types of focal lesions.[56] Lesions outside the temporal and frontal lobes were correlated with poor surgical outcome, as were generalised interictal EEG abnormalities, which may reflect extensive or multiple lesions.

16 Encephalocoeles

Ashok Kumar Mahapatra

DEFINITION AND HISTORICAL ASPECTS ON ENCEPHALOCOELES

Encephalocoeles are a group of conditions in which there is protrusion of the brain or both meninges out of the cranial cavity through a skull defect. Depending on the content or herniation, it may be a cranial meningocoele or meningoencephalocoele. When herniated brain contains part of the ventricle, the condition is named as hydroencephaly. Thus, encephalocoele is a general term used for all the above abnormalities.

According to Emery and Kalhan,[28] the first medical report on encephalocoele appeared in 16th century. However, deformities like encephalocoeles were first illustrated in Medieval art and archaic sculpture. In 1813, Ritcher et al. first described a case of nasal encephalocoele (Fenger[31]). Heinecke, in 1882, classified encephalocoeles (Fenger[31]) depending on the hernial tract. Stadfeldt, in 1903, first coined the term fronto-ethmoid encephalocoele (Bumenfeld and Skolnik[12]). Browder and de Veer,[10] in 1934, termed nasal encephalocoeles as "Rhinoencephalocoeles".[9] Tandon,[98] in 1970, reported a comprehensive classification of all encephalocoeles and provided the first large series of these lesions from India. Suwanwela and Suwanwela,[95] in 1972, proposed a morphological classification of sincipital encephalocoeles. Tessier,[100] in 1976, described different facial clefts and correlated them with the congenital deformities.

INCIDENCE OF ENCEPHALOCOELES

Encephalocoeles occur less commonly than spinal dysraphism. The incidence of encephalocoeles is reported to be 1 per 3,000–10,000 live births.[15,41,52,59,90] Overall, occipital encephalocoeles are more frequent than anterior encephalocoeles (75% vs 15%). In general, encephalocoeles are occipital in 75%, frontoethmoidal in 13–15% and parietal in 1–12% cases. Basal encephalocoeles, such as transethmoid and trans-sphenoid encephalocoeles are rare.[40,55,58,60,67,89] The author has encountered eight cases of intranasal encephalocoeles in a series of 102 cases.[67] Trans-sphenoidal encephalocoeles are rare and less than 50 cases have been reported in the literature. In the Western Hemisphere, occipital encephalocoeles constitute 80–90% of all encephalocoeles.[71,79,90] A higher incidence of anterior encephalocoele is reported from Thailand, Indonesia, India, Papua New Guinea and Africa.[7,25,50,63,64,79,93,95,107] The incidence of anterior encephalocoele reported from the West is 1 per 35,000–40,000 live births.[23,93,103]

EMBRYOLOGY

There is no clear-cut explanation for maldevelopment of the neural tube at the cephalic end, leading to encephalocoele. Normally, in embryogenesis, the neural tube closes between the 27th day and 28th day of gestation. However, the anterior and posterior ends of the neural tube close at different times. The anterior neuropore, which lies at the level of the foramen caecum, closes around the 24th day. The development of various neural tube defects has been attributed to either primary failure of closure of the neural tube, or rupture of the neural tube due to some unknown reasons after it has closed around the 27–28th day of gestation.[9] Severe forms, like anencephalus and cranioschisis, may point to an earlier defect, may be in the early neurulation stage. The unfused cephalic end of the neural fold or defective closure of the anterior neuropore may communicate with the amniotic cavity, when skin, cranium and dura fail to cover neural tissue. However, the above hypothesis does not explain the occurrence of occipital or sincipital encephalocoeles with healthy skin cover and the absence of cranial dysraphism.[27,28] Gardner's[35] hydrodynamic theory does not quite explain the pathogenesis. However, rupture of a well-formed neural tube at a later date could explain the well-formed skin cover and lack of cranial dysraphism, as is usually the case with encephalocoeles. The neuroschisis theory proposes the formation of a bleb over the neural tube, which, on healing, gets adherent to cutaneous ectoderm and that can explain the formation of an encephalocoele.

Despite the generally unsatisfactory explanations of defective embryogenesis, there are several aetiological factors which may be responsible for the formation of encephalocoeles.[16,47,48,53,70,75,82,103] Williamson et al.[103] postulated that a viral antigen due to viral infection during early pregnancy may lead to neural tube defects. Hyperthermia, irradiation, hypervitaminosis, hypoxia and salicylates have been reported to cause encephalocoeles both in experimental animals as well as in human beings.[16,55,71] Moerman[75] et al. in 1992, postulated that

an amniotic band and adhesions result in the formation of encephalocoeles. Leong and Saw[58] described displacement of the hindbrain in patients with occipital encephalocoele, which corresponds to the area of the anterior neuropore.

Anterior encephalocoeles are due to failure of the anterior neuropore, which lies in front of the foramen caecum in the floor of the anterior cranial fossa just ahead of the crista galli, which marks the junction of the frontal bone with the ethmoid bone. Failure of the anterior neuropore in early embryonic life leads to herniation of neuroectodermal tissue, interposed between the mesodermal elements, which later are supposed to form the frontal and ethmoid bones. The exact aetiology of anterior encephalocoeles is not known. Geoffery and Hilliance (quoted by Gisselson[37]) suggested the adhesive theory. Wiese et al.[104] suggested the theory of primary mesodermal failure leading to defective bone formation.

CLASSIFICATION OF ENCEPHALOCOELES

A large number of classifications of encephalocoeles (Table 1) are available depending on several aspects, such as site of cranial defect, whether or not the encephalocoele is seen from outside and the size of the encephalocoele.[4,5,22,42,65,66,91] Encephalocoeles are classified as occipital, parietal, frontal, nasal and nasopharyngeal type.[88,107] Suwanwela and Suwanwela[95] have put forward the morphological classification of sincipital encephalocoeles.

A large number of authors have classified anterior encephalocoeles (Table 2). Heinecke, in 1882, classified them as: (a) spheno-pharyngeal, (b) spheno-orbital and spheno-maxillary types (quoted by Fenger[31]), depending on the hernial tract. Mesterton, in 1885, classified anterior encephalocoeles as: (a) naso-frontal; (b) naso-ethmoidal and (c) naso-orbital types. Bumenfeld and Skolink,[12] in 1965, named these encephalocoeles as: (a) trans-ethmoidal; (b) trans-sphenoidal; (c) spheno-ethmoidal and (d) spheno-maxillary. Suwanwela and Suwanwela[95] proposed the classification of sincipital encephalocoeles on a morphological basis. The inner and outer defects in the skull are enumerated in Table 3.

ASSOCIATED PATHOLOGY

A large number of systemic abnormalities have been reported along with encephalocoeles (Table 4).[2,8,35,41,69,75,87,91,102] The musculoskeletal system is widely involved. Rarely, the retina and vitreous can be abnormal.[29,76,87] Morika et al.[76] had described progressive hormonal and visual disturbance, which has been described as "morning glory syndrome". Knobloch and Layer described Knobloch syndrome in 1971,[87] which included a skin defect and visual problems. Associated anomalies can include many genetic syndromes, such as Meckel-Gruber, Von Voss, Chemke, Roberts and Knobloch syndrome.[7,92] Other non-genetic anomalies may include cryptophthalmos, amniotic band, spina bifida, agenesis of corpus callosum

Table 1: Classification of encephalocoeles

A. Congenital:
   Acquired—post-traumatic, post-operative, post-irradiation
B. According to the locations:
   1. Anterior encephalocoeles (frontoethmoidal or sincipital)
   2. Occipital or sub-occipital encephalocoele
   3. Basal:
      - Trans-sphenoidal
      - Transethmoidal
      - Intranasal
      - Spheno-oribital
      - Transtemporal
   4. Cranial vault:
      - Frontal
      - Parietal
      - Temporal
      - Through anterior or posterior fontanel
C. According to the size:
   - Small encephalocoele
   - Giant encephalocoele
D. According to the content:
   - Cephalocoele
   - Encephalocoele
   - Meningoencephalocoele
   - Cranial meningocoele
   - Hydroencephalomeningocoele
E. Encephalocoele as a part of complex syndrome such as:
   - Chiari III—Malformation
   - Knobloch syndrome
   - Morning glory syndrome
   - Walker-Warburg-Syndrome (WWS)
F. Overt:
   Occult
   - Intranasal
   - Intraorbital
   - Intratemporal
   - Intradiploic

Type of encephalocoele	*At skull base*	*In the face*
A. Nasofrontal (Glabellar)	Between frontal and ethmoid bone in front of crista Galli	At the junction of frontal and nasal bone
B. Nasoethmoidal (Anterior Nasal)	do	At the junction of nasal bone and nasal cartilage
C. Naso-orbital (Nasolacrimal)	do	Between frontal process of maxilla and lacrimal bone
D. Transethmoidal (Naso-pharyngeal)	do	No outer defect, encephalocoele in nasopharynx or in nasal cavity
E. Trans-sphenoidal (Intrasphenoidal)	Through the body of sphenoid or sphenoid sinus	No outer defect
F. Interfrontal	—	Through metopic suture or anterior fontanel

Table 4: Systemic abnormalities associated with encephalocoeles

– Cleft lip cleft palate	– Visual disturbances
– Micrognathia	– Vitreoretinal degeneration
– Microcephaly	– Retinal detachment, myopia
– Scalp defects	– Dextrocardia
– Hair Collar sign	– Septal defects
– Klipple–Feil deformities	– Patent ductus arteriosus
– Vertebral abnormalities	– Pulmonary hypoplasia
– Polydactyly	– Renal hypoplasia
– Spina–Bifida	– Renal agenesis
– Diastematomyelia	

and Dandy-Walker syndrome. The most common chromosomal abnormality is Trisomy.[18]

CLINICAL PRESENTATION

Classically, patients with encephalocoeles are born with a swelling at birth. The size and content of the encephalocoeles are variable. In occipital encephalocoele, a globular swelling is noticed over the occipital bone in the midline. Encephalocoeles could be pedunculated or sessile.[53,60] The size of the encephalocoele is hardly ever indicative of its content. Most encephalocoeles are brilliantly transilluminant on examination. However, when a large amount of gliosed brain is present inside the sac, there may be variability in the degree of transillumination.

Usually the head size is small.[32,74] The larger the brain herniation, the smaller is the head size. Sometimes the encephalocoeles may be very large and are called giant encephalocoeles.[2,74,86] The head may be smaller than the size of the encephalocoele. Over the years, the author has encountered four patients with giant encephalocoeles, three in the occipital (Figs 1A to D) and one in the frontal area. The diameter of the head in the patient with a frontal encephalocoele was 11 cm as compared to the diameter of the encephalocoele which was 14 cm. In one patient with a lobulated occipital encephalocoele, the lobules were 14 × 18 × 17 cm in diameter, respectively as compared to the diameter of the head which was only 12 cm. These giant encephalocoeles do contain a large amount of brain and pose a considerable problem during closure. The author has operated upon 22 giant encephalocoeles of which 16 were occipital[2,86] (Table 5).

The site of the encephalocoeles is frequently occipital or suboccipital.[15,52,53,59,79] Around 10% of the encephalocoeles could be anteriorly located.[32,79,95] Rarely, encephalocoeles could be temporal[13,19,53,55,78,102] or parietal[71] in location. They could also be rarely intranasal[6,26,61,84] transethmoidal[40,55,58,73,89,107] or orbital[18,57] in location (Table 6). Very rarely the encephalocoele can be located at the anterior or posterior fontanel.[68] The author has operated on two each of these types.

Patients with frontoethmoid encephalocoele (Fig. 2) present with a swelling over the root or the bridge of the nose at birth[51,63,65,93,95,107] (Fig. 3). Patients with nasopharyngeal, sphenoethmoidal and trans-sphenoidal encephalocoeles do not have an obvious external swelling and may present with nasal obstruction or CSF rhinorrhoea.[3,64,65,67,89] These patients may also present with recurrent attacks of meningitis.[21,54,63,65] Frequently, patients with intranasal encephalocoele may present

to the otolaryngologist and be diagnosed as having a polyp. It is only after biopsy or following surgery, when a patient develops CSF rhinorrhoea, an encephalocoele may be suspected[3,20,48,63,65] Rarely, encephalocoeles may present in the mouth through a cleft palate[58] (trans-sphenoidal transpalatal encephalocoele).[59,83,89,102]

Orbital encephalocoeles usually present with proptosis. It could be a part of a naso-orbital type of encephalocoele[18,23,30,44,63,93,94] where there is proptosis along with hypertelorism (Fig. 4). However, orbital encephalocoeles can present with proptosis without hypertelorism.[18] Orbital encelphalocoeles could also be a part of neurofibromatosis, when there is congenital absence of the wing of the sphenoid bone.[30] The proptosis disappears on assuming the supine position.

ANTERIOR ENCEPHALOCOELES

Nasofrontal Type

This type is also called frontonasal or glabellar encephalocoele. The internal bone defect is round or oval shaped and present in front of the crista galli.[38] The crista galli projects into the defect and forms the posterior margin. The anterior cranial fossa is deep. The facial bone defect is at the junction between the frontal and the nasal bones. Hypertelorism may or may not be present. However, the maxilla, nasal bone and nasal process of the maxilla are normal (Fig. 3). This type is relatively rare.[64,67,93,95]

Fig. 3: Clinical photograph of an 8-month-old child with a frontonasal encephalocoele without hypertelorism

Nasoethmoid Type

This is the commonest type of sincipital encephalocoele and constitutes 85% of anterior encephalocoeles[23,25,51,64,67,81,90,97] (Fig. 2). This type is called long nose encephalocoele. The cranial defect lies in front of the crista galli in the floor of the anterior cranial fossa. The outer or facial defect lies at the junction of the nasal bone and nasal cartilage.[7,95,107] The neck of the encephalocoele is very long. The nasal bone and frontal process of the maxilla form the antero-superior part of the sac. The nasal cartilage and nasal septum form the postero-inferior wall. The lateral part of the sac extends into the orbit and presents at the inner canthi. Thus, the encephalocoele pushes the orbit and the eyeball laterally and downwards, and produces a marked degree of hypertelorism (Fig. 5). The swelling widens the bridge of the nose and pushes the tip of the nose downwards, thus elongating the nose considerably.[7,25,65,67]

Naso-orbital Type

This is a rare form of fronto-ethmoidal encephalocoele.[64,65,93,95,99] Among 118 cases of anterior encephalocoeles, the author found 8 such cases (Table 6). The inner skull defect lies in front of the crista galli and the outer defect is present between the frontal process of the maxilla and the lacrimal bone. The frontal process of the maxilla forms the anteromedial boundary, whereas the lacrimal bone forms the posterior-lateral part of the sac. The outer swelling appears at the inner canthus of the eye and may be unilateral or bilateral. The eyeball and the inner canthus are pushed laterally and downwards (Fig. 6). Thus, in all these patients, some degree of hypertelorism is invariably present (Fig. 7). The nose and nasal bones are normal.

Trans-sphenoid Encephalocoeles

This is the rarest form of encephalocoele reported in the literature.[1,56,59,74,104] Pollack et al.[83] reviewed 8 cases of trans-sphenoid and transethmoid encephalocoeles. Abiko et al.[18] in 1988, reported a single case. The bony defect is present over the roof of the sphenoid sinus. Thus, the encephalocoele may come through the sella or through the planum sphenoidale and enter into the sphenoid sinus and nasopharynx. The patient may have a history of CSF rhinorrhoea. A history of endocrine disturbances is also reported in these patients.[1,45,81,102] Rarely, they may have visual problems.

Fig. 5: Clinical photograph of a 5-year-old child with left sided naso-orbital type encephalocoele pushing the eyeball laterally. There is mild hypertelorism

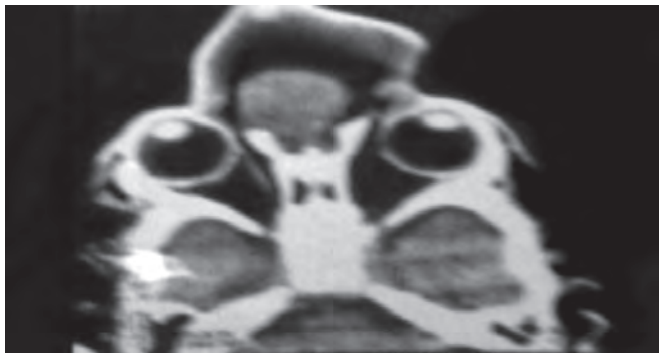

Fig. 6: CT scan axial cut of a child with nasoethmoid encephalocoele with gross hypertelorism

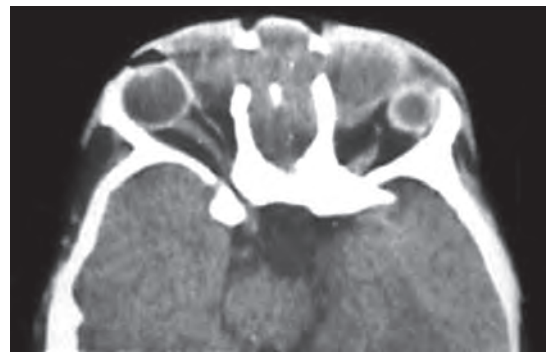

Fig. 7: CT scan of a child with bilateral naso-orbital encephalocoele showing hypertelorism

RARE CLINICAL FEATURES

Hypertelorism is a common finding in anterior encephalocoeles (Table 7).[22,44,52,65,93,94,100,105]

Mahapatra et al.[65] and Mahapatra[66] had reported a much higher incidence of hypertelorism. Rarely, maxillary and zygomatic bone abnormalities are also seen. Neurofibromatosis and 13-15 trisomy[21] syndrome have been reported in patients with encephalocoeles.

Mental retardation is reported depending upon the degree of brain damage. Suwanwela[95] and Suwanwela et al.[93] reported a much higher incidence of mental retardation in patients with anterior encephalocoele. However, the series presented by us reported a lower incidence of mental retardation.[64,66] Children with occipital encephalocoeles with cerebellum and brainstem herniating into the sac may present with poor cry and suckling.[53,82] Increased tone in the limbs and defective temperature regulation indicate a poor prognosis.

The problems of smell and vision are rarely discussed. It is logical to think that smell abnormalities will occur in patients with fronto-ethmoidal or sphenoethmoidal encephalocoeles. In unilateral naso-orbital encephalocoeles with a paramedian anterior fossa defect, smell is likely to be preserved on one side.[66] Visual abnormalities are due to a variety of reasons and may be due to herniation of the occipital lobes into an occipital encephalocoele, chiasmal abnormality in trans-sphenoid encephalocoele or due to orbital encephalocoele[18,29] pressing on the optic nerve. Visual deterioration can also be due to associated hydrocephalus.[48] Rarely, visual deterioration may be due to associated vitreoretinal degeneration.[87]

Few rare syndromes are associated with encephalocoeles. "Knobloch syndrome"[87] was described by Knobloch and Layer in 1971. This syndrome is transmitted by an autosomal recessive gene and characterised by vitreoretinal degeneration with retinal detachment, high myopia and encephalocoele. "Morning glory syndrome"[76] is a condition characterised by nasal encephalocoeles associated with progressive hormonal and visual problems. The basal encephalocoeles are either the trans-sphenoidal or sphenoethmoidal type. Due to pituitary involvement, patients present with dwarfism, polyurea and polydipsia. There is deficiency of growth hormone and ADH.

"Von Voss-Cherstvoy syndrome"[62] is another clinical entity first described by Von Voss et al. in 1979. The syndrome is characterised by an occipital encephalocoele along with phocomelia and cerebellar anomalies and is transmitted by an autosomal recessive gene.[33] The limb abnormality is more often due to a defect in the radius. The other anomalies associated involve the face, heart, lungs, urogenital system, gastrointestinal system and thrombocytopenia. Lubinnsky et al.,[62] in 1994, reported four cases and reviewed the literature on the subject. Walker-Warburg syndrome (WWS) is a lethal, complex syndrome involving the CNS and the eyes, and is genetically transmitted by an autosomal recessive gene. Martinez et al.[69] reported nine children with WWS out of whom eight had occipital encephalocoeles.

Prenatal diagnosis is possible by ultrasound scanning.[11,19] The earliest reported diagnosis is by 13 weeks of gestation. The ultrasound appearance of an encephalocoele is variable in the 1st trimester. Once an encephalocoele is diagnosed, a search for an associated anomaly can be made. Chromosomal abnormalities have been recorded in 15–40% and, therefore, karyotyping should be done in the mother.[17] Maternal serum alpha-fetoprotein levels are elevated in only 3% in the mother, because most encephalocoeles are

Table 7: Clinical presentation in patients with anterior encephalocoeles at AIIMS in 118 patients

covered with skin. In the 2nd trimester, ultrasound scanning is the mainstay of foetal imaging. Although, ultrasound scanning is traditionally used as the mainstay in foetal imaging, the resolution and details of findings in the brain are limited by the mother's body characteristics and the surrounding amniotic fluid. Hence, foetal MRI is the investigation of choice. MRI is also far better in resolving posterior fossa anatomy. The fluid and CSF filled cavities are best demonstrated in MRI scan. The contents of the encephalocoele are well-depicted on MR scan. MRI scanning helps in visualising associated intracranial anomalies such as chiari malformation, Dandy-Walker Syndrome, agenesis of corpus callosum and porencephalic cyst (Fig. 8). More experience will enhance the role of foetal MRI in prenatal evaluation of the brain.

Investigations

Diagnosis of encephalocoele is not difficult. However, a large number of factors influence the treatment and ultimate outcome.[23,32,60,62,72,76,80,107] These include the presence of hydrocephalus, associated CNS anomalies, facial deformity and associated systemic abnormalities. Assessment of all the above factors needs proper investigation which may include the radiological, genetic and hormonal assessment.

The radiological investigations have changed over the years due to advances in imaging modalities. Plain X-ray shows a soft tissue mass and a circular smooth bone defect in the sub-occipital area, the skull vault or at the skull base depending on the site of the encephalocoele. It may show a nasopharyngeal soft tissue mass or displacement of the nasopharyngeal air shadow in sphenoidal or nasopharyngeal encephalocoele.[56,59,74] In sincipital encephalocoeles, X-ray skull will show a deformity of the orbits and increased interorbital distance in cases of hypertelorism.[15,19,45,55] Plain X-ray skull will show an enlarged orbit in case of intraorbital encephalocoeles.[18,30,45,57] Plain X-ray may show hypoplasia of the anterior or middle fossa,[53] skull deformity, craniostenosis, etc.

Carotid angiograms and pneumoencephalograms have been used as investigations in the past.[32,36,96] Suwanwela et al., in 1973,[96] reported the value of ventriculography in patients with anterior encephalocoeles, which helped in assessing the communication between CSF pathways and the encephalocoele sac. Cerebral angiography delineates the intracranial vasculature including the sagittal and transverse sinus. In a large number of cases, there may be abnormality of dural venous sinuses.[14] Though angiography remains the criteria for depicting vascular anomalies, it is rarely used in evaluation of encephalocoeles. MRA and MRV also help in assessment of vascular anomalies, including venous anatomy.

Recently, CT and MRI scans are commonly used modalities in the diagnosis of craniocerebral anomalies including encephalocoeles[1,39,44,47,52,64,65] There are only a few reports on MRI findings.[14,39] CT scan helps in evaluation of the ventricular system. The contents of the encephalocoele can be made out and the bony defect in the skull base can be delineated with bone window settings.[7,14,34,39,66,83] Hydrocephalus is commonly associated with posterior encephalocoeles. However, in anterior encephalocoeles, associated hydrocephalus is reported in 10–15% of cases.[23,32,44,52,64] CT scan can also detect associated anomalies like agenesis of the corpus callosum,[1,47,102] porencephalic cyst (Fig. 8), Dandy-Walker malformation, etc. In transethmoidal or trans-sphenoidal encephalocoeles, CT shows the soft tissue density in the sinuses and the bone defect in the skull base[47,59,61,88,93,105] (Fig. 9). In orbital encephalocoele, its relationship to the eyeball and optic nerve can be evaluated by high resolution CT. The bone cut may show a sphenoid wing defect

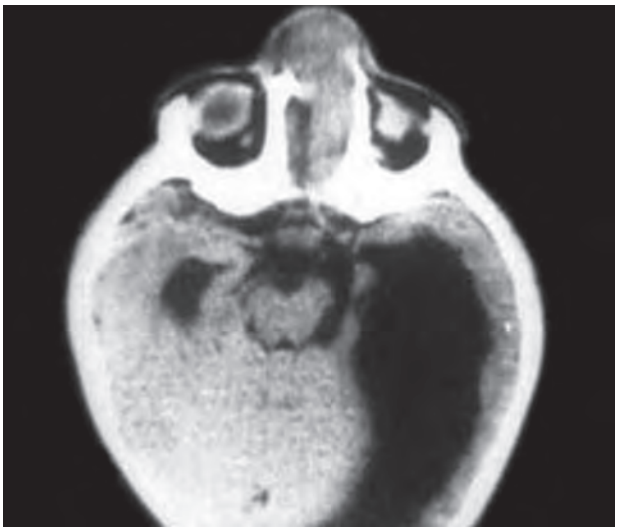

Fig. 8: CT scan head of a child with nasoethmoid encephalocoele which also reveals a porencephalic cyst

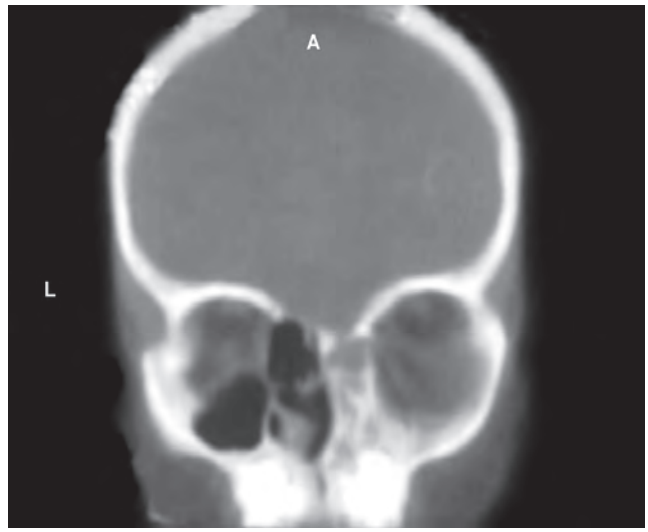

Fig. 9: Coronal CT scan of child with transethmoid nasopharyngeal encephalocoele showing soft tissue opacity in nasopharynx and nose

(as shown in Fig. 4). Metrizamide CT cisternography is useful in cases of occult encephalocoele.[20] Three dimensional CT scans are also used for the evaluation of basal defects.[39] MRI helps in soft tissue delineation. It also helps in diagnosis of Chiari malformation, syringomyelia and associated cortical dysplasia.[14,39]

Isotope studies are sometimes useful in the diagnosis of encephalocoele.[3,96,106] Yoshimoto et al[106] reported a transethmoid encephalocoele in a 2-year-old child who had bacterial meningitis. Isotope cisternography confirmed the presence of CSF rhinorrhoea. Anand et al[3] suggested pre-operative and intra-operative isotope imaging which may help in selection of the appropriate surgical approach.

Recently, visual evoked potentials have been used to assess occipital lobe and anterior visual pathway function.[29] Surprisingly, not much literature is available on visual evoked potentials. When VEPs are recordable from the sac, it indicates the presence of occipital cortex within the sac. Absence of visual evoked potentials may suggest a defect in the visual cortex or dysplasia of optic pathways.[15,53] The limitation of VEP must be emphasised in neonates or infants, in whom the delay could be physiological. The author had performed VEP in three patients with occipital encephalocoeles which showed grossly abnormal waves in two and absent response in one patient.

MANAGEMENT

The principle behind the management of encephalocoeles is to excise the encephalocoele and to repair the dural defect after putting back the herniated brain inside the cranial cavity, if possible. Sometimes, it may not be possible to push the brain into the cranial cavity. Then, the choice is to either excise a part of the brain or to give support to the brain in an extracranial space. Except for the situation with CSF leak, probably there is no indication for emergency surgery.[64,65,67,86] Sometimes, in a patient with a leaking encephalocoele associated with hydrocephalus, shunt surgery may stop the CSF leak and allow the skin to heal. A large number of children with occipital encephalocoele require CSF shunting.[32,42,67,69] According to Tandon (1970),[98] nearly 50% of occipital encephalocoeles have associated hydrocephalus and some may develop after repair.

Fortunately, most of the encephalocoeles have a good skin cover hence, emergency surgery is not required. The surgery can be delayed for weeks and months depending on the condition of the neonate. Surgery is simple when an encephalocoele is small, has a narrow neck, a small cranial defect and very little or no brain inside the sac. An occipital encephalocoele without brain herniation can be operated easily.[43] However, when the sac contains cerebrum, cerebellum and brainstem, surgery may be harmful and it is better to avoid an operation.[29,36,41,55,60,67] Many authors have reported a poor outcome in patients with microcephaly with a large volume of neural tissue within the sac.[41,44] Some authors have treated occipital encephalocoeles in special ways.[34,42,49] Gallo[34] discusses the management of a giant occipital encephalocoele. The technique he described comprised of an extracranial compartment created by utilising a fine tantalum mesh to enclose the herniated brain for protection.

Generally, patients with occipital encephalocoeles are operated upon in the prone position, with controlled ventilation and closed temperature monitoring. Aspiration of CSF prior to incision in patients with a large encephalocoele helps in dissecting out the sac (Figs 10A and B). For a circular encephalocoele with a small occipital bone defect, a transverse incision is ideal. The sac is separated from the skin flap (Figs 10C to E). Patients in whom the encephalocoele extends above and below the posterior fossa, a vertical incision is preferable. Sometimes the brainstem and occipital lobe are present in the sac. Care must be taken to identify the contents of the sac. Rarely, the sagittal sinus, torcula and transverse sinus are in the vicinity of the sac (Fig. 1B). It is always preferable to preserve the neural tissue. The dural defect can be repaired by using pericranium as a graft. In neonates and infants, no attempt should be made to cover the bone defect by a bone graft.[46,53,68,86] In older children with a large cranial defect, autogenous bone graft or acrylic plate may be used for closure of the defect.

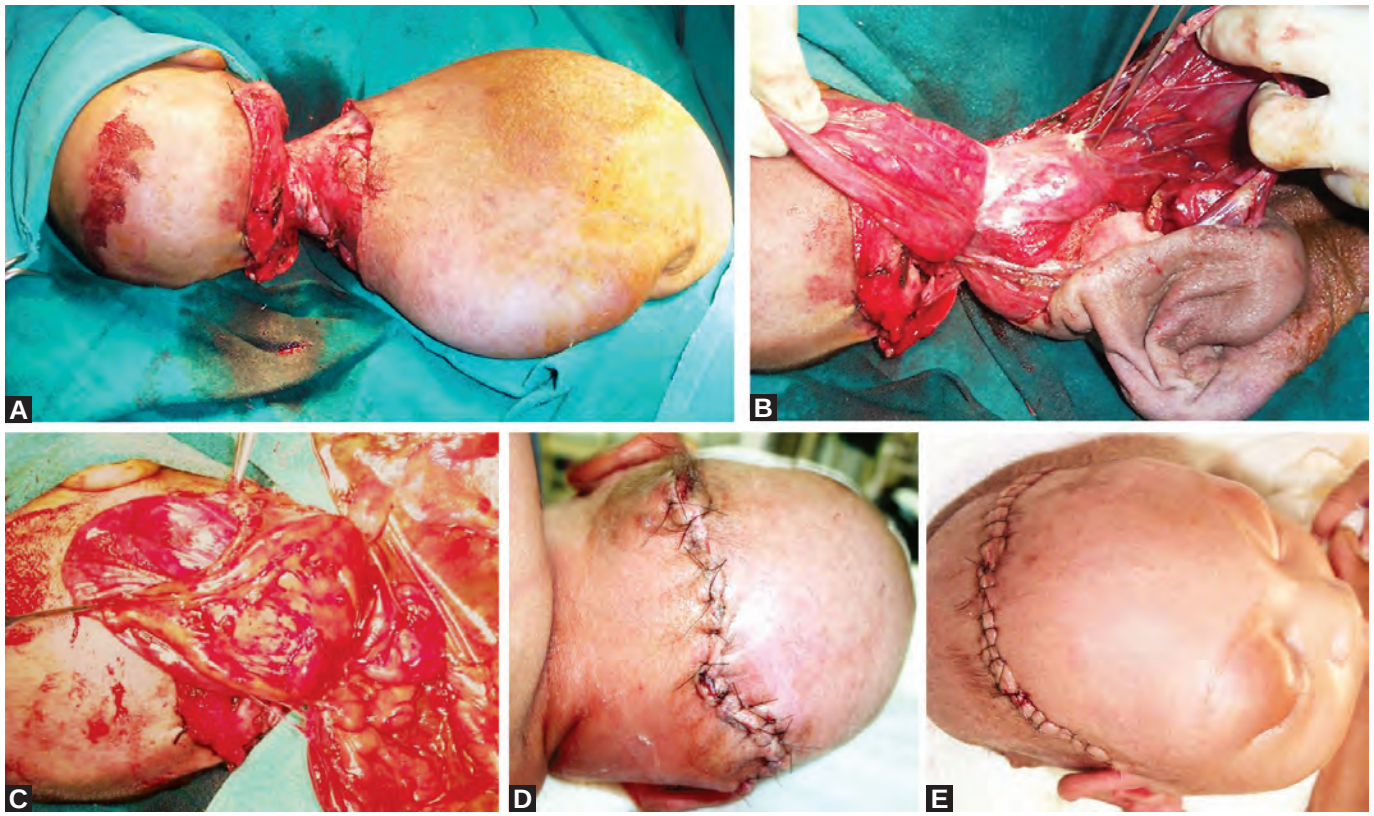
Post-operatively, there may be a CSF leak or acute hydrocephalus may develop. Patients in whom shunt is not performed prior to encephalocoele repair may need ventriculoperitoneal shunt subsequently. Patients may present initially with CSF leak and meningitis.[53] External ventricular drainage is the only alternative in patients with meningitis. Once the meningitis is adequately controlled, a VP shunt can be performed.

Prognosis in Patients with Occipital Encephalocoeles

A large number of factors influence the outcome in patients with occipital encephalocoele. These include site, size of the encephalocoele, amount of brain herniated into the sac, the presence of brainstem, occipital lobe with or without dural sinuses and the presence of hydrocephalus.[15,21,34,48] One of the most important prognostic factors is the presence of associated brain and systemic anomalies.[34,48,58,62,72,82,91] Overall, the outcome in occipital encephalocoele is not very good. In giant encephalocoeles, the mortality and morbidity rates are high. Amongst 14 children with occipital encephalocoele in our series, two died of hypothermia and the third succumbed to meningititis.

Encephalocoeles through the Cranial Vault

Encephalocoeles through the cranial vault are rare. It may be through the frontal, parietal or temporal bones. Encephalocoeles can occur through the anterior or posterior fontanel. Parietal or interparietal encephalocoeles are probably the most common encephalocoeles of the



Figs 10A to E: Intra-operative photograph of a child with occipital encephalocoele showing surgical steps

cranial vault.[71,72] Interparietal encephalocoeles are difficult to treat and do have a poor prognosis.[32,35] Only 15% of these patients have normal mental development, while the rest have mental and physical abnormalities.[71,72] Treatment in patients with small parietal encephalocoeles is not difficult. Patients with large skull defects need cranioplasty. On several occasions, when there is a large cranial defect, the author has used split autogenous outer table grafts.

Temporal and Parietal Encephalocoeles

These are uncommon encephalocoeles.[32,78] They constitute 1% of all cases of encephalocoeles. Rarely, a temporal encephalocoele may develop following radiation[55] and present with CSF otorrhoea. Clyde and Stechison[19] reported a case of temporal encephalocoele presenting with CSF rhinorrhoea. The surgical procedure is similar to that of occipital encephalocoeles.

TREATMENT

Treatment of Trans-sphenoid Encephalocoele

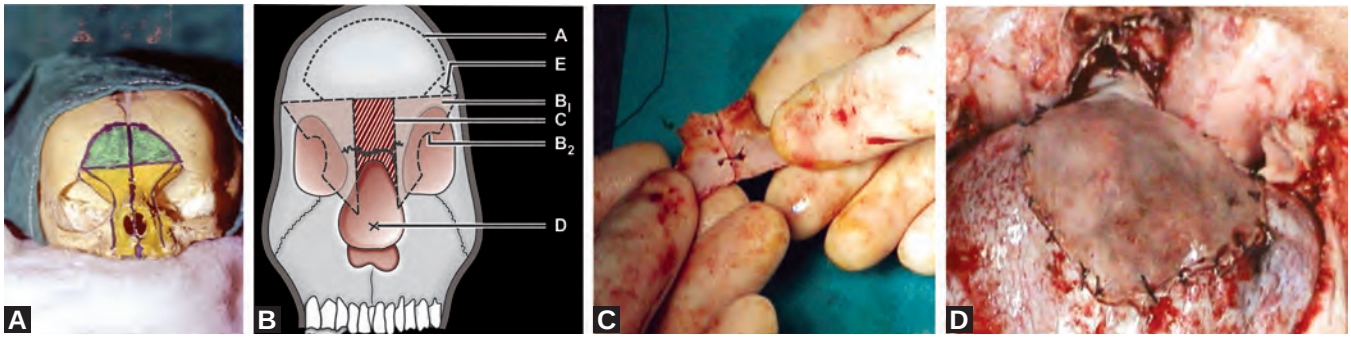
It is rare and only less than 50 cases are reported in the world literature.[40,45,56,59,83,89] Small children with a cleft palate may present with respiratory obstruction or recurrent chest infection. Management is difficult and they need early surgery. The surgical approach can be transpalatal or transcranial.[31,59,83] Some authors have preferred the transcranial approach to the transpalatal one. They repair the temporosphenoidal encephalocoele with a vascularised split calvarial graft. In the author's experience transpalatal surgery is easier and less traumatic. Among our three patients, two had transpalatal repair, however, the third patient had transcranial surgery.

Treatment of Anterior Encephalocoeles

The principle behind the management of anterior encephalocoeles is to repair the dural defect and to correct the bony deformities. Unfortunately, a large number of patients have facial abnormality due to associated hypertelorism,[23,25,51] and an elongated nose. Sometimes, the malformations are complex. Hence, the facial deformity plays an important role in corrective surgery. The cosmetic outcome depends upon the experience of the surgeon, age of the patient, degree of deformity and the teamwork between the neurosurgeon and the plastic or craniofacial surgeon (Figs 11A to D).

One stage repair of encephalocoeles along with the correction of the facio-orbital deformity is a long procedure and requires on an average 6–8 hours of surgery (Fig. 12).[23,25,65,99,104] Hence, the timing must be such that the child is able to withstand a long procedure. In our centre, we prefer to do the surgery when the child is older than 8–10 months.[25,64,65] Early surgical repair is ideal, as the bones are thin and moulding of the bones is easy. Early surgery also prevents CSF leak and the risk of meningitis.

A ventriculoperitoneal shunt prior to corrective surgery prevents post-operative CSF leak in patients with hydrocephalus. One stage correction of the craniofacial



Figs 11A to D: Diagrams showing the bone prior to and after the correction, with bone cuts and amount of bone need to be excised, it also shows dural repair

deformity is ideal.[23–25,44,52,65,77,84,93,100] The factors which influence the surgery are the type of encephalocoele, degree of hypertelorism, degree of nasal deformity and associated CSF leak or meningitis. It was Tessier who popularised the concept of one stage repair.[100] Sometimes, in a small child leaking CSF, a two-stage procedure may have to be carried out.[64,65] Recently, a large number of authors have reported good results with one stage craniofacial correction.[22,23,25,51,65,85] One-stage correction involves bifrontal craniotomy, fronto-orbital osteotomies and medial advancement of the orbit, after excising the extra-bone in the midline to correct the hypertelorism (Figs 11B and C). The initial part of the surgery deals with delineation of the neck of the encephalocoele, followed by excision of the herniated gliosed brain. The dural defect is closed by a dural graft (Fig. 11D). The type of correction of hypertelorism depends upon the degree of hypertelorism (Figs 4, 6, 13A and B). In case of mild hypertelorism, excision of soft tissue in the medial canthus and fixing the medial canthi to the nasal bone may suffice[64,65] (Fig. 5). Sometimes, nibbling of bone at the medial canthi followed by reconstitution of the medial canthus by canthal stitch corrects the hypertelorism.[25,64] Overcorrection of hypertelorism is important, as a significant amount of soft tissue may still be left in the medial canthus at the end of the operation. The aim is to achieve an inner canthal distance of 25 mm. Sometimes, a classical Tessier's operation may not be necessary. Recently, Mahapatra[64-67] had reported advancement of the medial half of the orbit medially and placing a supraorbital bone graft on either side (Fig. 12). By using the above procedure, operating time can be reduced on an average by 90–100 minutes.

Reconstruction of the nose is an important step in correction of anterior encephalocoeles.[23,25,42,85,100] The nasal deformity is maximal in patients with a nasoethmoid type of anterior encephalocoele. Extra skin over the encephalocoele has to be excised. The bridge of the nose is reconstructed by using either a rib or split calvarial graft.[25,65,85,99] Overall cosmetic correction is satisfactory in my experience (Figs 14A and B). Sometimes, to achieve a cosmetically excellent result, several small plastic surgical procedures may be necessary depending on the need of an individual patient, to correct nasal deformity or to excise extra skin or soft tissue at the medial canthi. This is basically because cosmetic acceptance depends upon the socio-economic status and age of the patient. In girls, the need for a better cosmetic result is more. An important post-operative problem following anterior encephalocoele repair is CSF leak leading to meningitis (Table 8). A large number of children do develop transient CSF rhinorrhoea which stops within few days. A small number of patients need lumboperitoneal shunt when CSF leak persists. In our series of 103 patients, there were three post-operative mortalities.[64] One patient died of aspiration pneumonitis, and two due to fulminant meningitis.

Prognosis in Patients with Anterior Encephalocoeles

Generally, the prognosis in children with anterior encephalocoele is better than occipital encephalocoele.[67,72,79,85,101] On the contrary, occipital encephalocoele with hydrocephalus carries a much poorer prognosis.[67] In the author's experience the intellectual function is good in patients with anterior encephalocoele.[64,67] Except for cosmetic problems, which can be corrected with appropriate craniofacial surgery, patients are normal. In the absence of hydrocephalus or meningitis, a large number of children are likely to have normal intellectual development.[22,65,67,72,79] Thus, the overall outcome in children with anterior encephalocoeles is more favourable[64,67] as compared to occipital encephalocoeles.

17 Intracranial Arachnoid Cysts

Chidambaram Balasubramaniam, Vani Santosh

INTRODUCTION

Bright is given the credit of first describing arachnoid cysts (ACs).[8,83] He described these as, "serous cysts forming in connection with the arachnoid and apparently lying between its layers". The brain is completely impressed by them so that when the fluid is let out, a permanent cavity remains, and even the bone of the skull is moulded to their form". Describing another case, he says, "On sawing through the skull cap, a sudden gush of limpid fluid attracted attention and this had been contained in a cyst formed by splitting of the arachnoid membrane...".[83] His description, more than one and one half centuries old, is accurate even today and has practically encompassed all the relevant clinical aspects.

ACs are "intra-arachnoidal" collections of cerebrospinal fluid (CSF). These cysts are found within the arachnoid as isolated collections of CSF. AC may be found anywhere along the CSF axis; the intracranial cysts are all intradural while those located in the spinal canal may be extradural or intradural.[43] Over the years, a variety of names have been given to these lesions, for example, meningitis serosa circumscripta, cerebral pseudotumour, brain cyst, chronic arachnoiditis, chronic cystic arachnoiditis, leptomeningeal cyst, pseudo-porencephalies or closed porencephalies, temporal lobe agenesis syndrome, extracerebral cysts of middle cranial fossa, AC of middle fossa and, of course, AC.[17,40,83,98,100]

Most of the ACs are discovered in the first two decades of life, 60–80% being discovered by 16 years of age. Their occurrence in adults has also been well documented. Some may be discovered when investigations are performed for an unrelated malady and yet others only at autopsy. It has also been documented in foetuses and non-human population.[10,15,45,46,89] Improved diagnostic methods have resulted in more of these cysts being discovered.

"Congenital ACs" which are true or "primary ACs" are not the same as "secondary ACs" which are merely trapped collections of CSF. Thus, the latter variety cannot be included in the category of "True AC" but should be included under the category of leptomeningeal cysts. Although most of these cysts are usually congenital, they may follow trauma or infection of the central nervous system (CNS). The congenital variety accounts for 1% of all intracranial space occupying lesions.

These cysts may be associated with other developmental anomalies of the brain and, by indenting and exerting pressure on the subjacent brain, they may cause secondary local atrophy and gliosis.

Of the many theories proposed to explain their origin, abnormal splitting of the arachnoid during embryogenesis is widely accepted. Their association with the CSF cisterns lends support to this theory. Their clinical features, radiologic features and pathology have been well elucidated, but their management is still shrouded in controversy. "The surgical treatment is as variable as the location of the cyst."[40] In addition, their natural history too has not been well defined since they are well known to be small or large at the time of presentation, and may increase in size or resolve over time.[66,81,82,106]

Currently, there is a resurgence of interest in the origin, pathogenesis and structure of ACs. A better understanding of these factors will directly influence the clinical management of patients with these cysts, since there is a persistent debate as to the choice of the type of surgical treatment.

EMBRYOLOGY AND ANATOMY

A loose and sparsely cellular area lies between the developing neural tube and the notochord at 35–38 days of gestation. This mesodermal derivative is the meninx primitiva. At 48–53 days, this region cavitates. The loose mesenchymal tissue surrounding the developing neural tube forms a compact outer layer and a loose inner layer. This outer part corresponds to the dura; the loose layer which lies deeper gives rise to the pia and the arachnoid. A cavity forms between the outer compact layer and the portion of the inner layer which forms the arachnoid. This cavitation results in the formation of the subarachnoid space.[74,112] This cavity is not a uniform space, but resembles a "meshwork". When the rhombic roof ruptures, the CSF secreted by the choroid plexus finds its way into this "primitive" subarachnoid space and flows through this mesh-like space, the outer wall of the space being formed by the arachnoid and the inner wall by the pia. The CSF is propelled through by this meshwork of tissues by the "pump-like action of the choroid plexuses of the cerebral ventricles".[54] This meshwork probably persists since numerous trabeculae within the subarachnoid space have been observed during microneurosurgery. In addition, "the arachnoid

partitions the subarachnoid space into relatively discrete chambers".[112]

Two theories have been proposed to explain the formation of AC. One holds that sequestration of the CSF resulting from an aberration of the flow of the CSF results in the formation of AC.[86] The other postulates that an abnormal splitting of the primordial arachnoid and the subsequent aberration in the formation of the CSF spaces leads to the formation of the AC.[8,38,100] In the initial stages when the cysts are very small, they probably are completely enveloped by CSF. But as the cyst increases in size, its walls fuse with the arachnoid, thereby trapping the vessels which traverse this space.[100]

If the rhombic roof does not perforate fully, the CSF may find its way into the rhombic roof forming an AC within the cisterna magna.[74]

Suprasellar AC is considered to be an outpouching of the membrane of Liliequist.[74] If this membrane remains imperforated, it prevents the flow of CSF from the infratentorial to the supratentorial compartment. This results in the formation of a diverticulum and, over a period of time, the continued dilatation results in the formation of a suprasellar AC.[36]

ACs are thus congenital malformations, which are wholly intra-arachnoidal, lying between the layers of the arachnoid,[100] the outer and inner layers being formed by the barrier cell layer and basal cell layer, respectively.[8] These are "not simply a dilation of the subarachnoid space walled off by adhesions".[100] ACs are thus isolated from the rest of the subarachnoid space, although CSF can gain entrance into the cyst. The veins which lie in the vicinity of these cysts—during cyst formation—can become "incorporated" into these cysts. These are seen lying within the cysts, unsupported.

The causative factors of these cysts are quite varied. By and large, the most common variety is the congenital form. The other causes include trauma and inflammation. Some experts do not consider the cysts which follow trauma and inflammation as the true AC.[86] This is so because the cysts which follow trauma and infection are not true AC, but merely localised collections of CSF surrounded by scarred arachnoid.[48] Nevertheless, these collections of CSF continue to be called ACs. In addition, not all cysts which are initially diagnosed as congenital AC (based on clinical, imaging or operative findings) are true AC. Some of them may be glioependymal cysts, ependymal cysts or simple cysts lined by atrophic brain.[8]

Some of these cysts may be small and be discovered only at autopsy while others may manifest even in the neonatal period; and yet others have been seen to increase in size over a period of time or be discovered only at autopsy. The exact mechanisms or the factors which lead to the expansion of the cyst are unknown. A variety of factors may come into play in the expansion of these lesions.

Agenesis of the temporal lobe was proposed as a causative factor for middle cranial fossa AC by Robinson in 1964.[8] However, subsequent work has proven that this is not the case. Macroscopic and microscopic observations have shown that the temporal lobe in these patients is normal. Robinson subsequently corrected his earlier conjecture of temporal lobe agenesis.[8,94] An autopsy study has shown that there is "no significant difference in the weight or volume of the cerebral hemispheres to suggest any evidence of agenesis or hypoplasia involving the affected hemispheres".[94] Other studies have also shown that there is no "agenesis" of the temporal lobe, and the surrounding brain is structurally normal. The re-expansion of the temporal lobe following treatment also proves that the temporal lobe is not dysgenetic.[17,44,94]

True AC may be the result of an inflammation occurring in the 6–8th week of embryonic life.[38] Several examples have been attributed to a previous episode of leptomeningitis, most often in early life or even in utero and, occasionally, a previous event of this nature has been clinically documented. Other examples include traumatic injuries, including birth trauma.

Okumora et al. have suggested that ACs are secondary to primary cerebral hemispheric maldevelopment and, therefore, they constitute a form of external hydrocephalus.[77] In any event, congenital ACs must be differentiated from those that follow structural destructive lesions, like porencephaly, that form part of a pre-natal or post-natal encephalopathy.

A minor subarachnoid bleed may result in the formation of a small cyst which subsequently increases in size.[20,40] ACs which follow inflammation, unlike true AC, have inflammatory cells and haemosiderin deposits in the wall.[74,84] These, in addition, may increase in size over a period of time.[88] ACs have also been reported to following craniotomy.[63,105] True ACs are in no way related to porencephalic cysts.

True ACs are congenital and the evidence to support this is strong and may be summarised as follows:

- They occur predominantly in the paediatric age group—as much as 60–80% being discovered by the 16th year of life.[8]
- Most required treatment in the paediatric age group.
- Associated expansion or bulging of the calvarium at the site of the cyst.
- An acquired cause cannot explain the gross and microscopic pathology.
- The subarachnoid cisterns and spaces are not one continuous sea of CSF. Careful dissection and observation during microsurgery clearly reveals the presence of numerous trabeculations and strands in the subarachnoid spaces. In addition, the cisterns are divided into discrete compartments which communicate with one another. These indicate that these cysts result from an abnormal splitting and loculation of CSF as a consequence of an embryologic error.
- The walls of the AC are continuous with the arachnoid; the cyst thus is an "island" in an "ocean" of CSF.
- All cysts are related to a subarachnoid cistern.
- Presence of other congenital brain anomalies.

- Normal structure of the brain as seen during surgery and the re-expansion following surgery.[104]

PATHOGENESIS OF CYST EXPANSION

The expansion of the cysts over time has been attributed to a variety of causes. These include flow of CSF into the cyst by a ball-valve action, secretion of CSF by the cyst wall, secretion by a choroid-like structure in the wall or osmotic gradient.[39] The exact cause has not been determined yet. Direct observational evidence exists only for accumulation of CSF by ball-valve action. A slit valve mechanism was observed in a child with a suprasellar AC during endoscopic surgery. The valve, formed by an arachnoid membrane, was seen to open and close with pulsations.[92] The slit valve mechanism has not only been observed intra-operatively but also pre-operatively using cine mode MRI.[90] Vascular pulsation is the force which propels the CSF into the cyst. The fluid may gain entrance into the cyst during the various phases of the cardiac cycle.[18,75,91] Intra-operative observations during endoscopic surgery have elegantly demonstrated the ingress of CSF during the various phases of the cardiac cycle. The wall of the cyst was seen to pulsate corresponding to the cardiac activity. The wall of the cyst "detaches from the solid surfaces, brain parenchyma, skull base or a major intracranial artery".[91] Inspection of the arachnoid at this time has revealed minute perforations in the wall and the pulsations of the brain are transmitted to the CSF spaces which in turn forces CSF into the cyst. These minute perforations in the cyst wall are not apparent all the time, but only during certain phases of the cardiac cycle. As mentioned earlier, a slit valve mechanism has also been observed.[91,92] Some of these fenestrations have been shown by using the microscope.[39] Communication with the surrounding CSF has also been shown during pneumoencephalography and also cisternography using water-soluble contrast media.

Secretion of CSF by the cyst wall has been postulated to be a mechanism by which these cysts expand. Go et al. in their study have shown microvilli which have features that are observed in fluid-secreting or fluid-absorbing tissues. Also, the ultracytochemical evidence of Na^+–K^+–ATPase and alkaline phosphatase in the plasma membranes of the lining cells suggest a capacity for fluid secretion.[39] Although these indicate possible secretory activity, no direct evidence for secretion exists. Until this is observed directly or definite proof for this is available, this has to be accepted only as a hypothesis.

The protein content of the CSF in the cyst, ventricles and lumbar subarachnoid spaces are not the same.[74] As a result of a haemorrhage from the veins traversing the cyst, the protein content in the cyst can increase, thus setting up an osmotic gradient.[17,29] But, since the fluid within these cysts is almost identical to CSF, the reason for expansion of the cyst by flow of fluid due to an osmotic gradient is difficult to accept as a general rule.

Secretion from choroid-like structures present in the cyst wall has also been postulated to be a cause for the increase in the size of the cyst.

PATHOLOGY

Macroscopic Appearances

Rengachary and Watanabe have compared the structure of normal arachnoid with that of the wall of an AC and have noted similarities and differences.[84] This has provided an insight into the pathogenesis of this lesion. The most striking histological finding in the AC is the splitting of the arachnoid membrane to enclose the cyst, while the pia-mater remains as a separate intact membrane. The normal arachnoid membrane seems to blend with the outer layer of the cyst wall at the margin of the cyst. The cyst is, therefore, intra-arachnoid with an inner and outer wall formed by the arachnoid membrane. Grossly, the cyst consists of a thin transparent wall. Its outer part is distinct from the inner layer of the dura. On its inner aspect, it shows a plane of cleavage from the underlying pia-mater. The cyst is usually filled with clear, colourless fluid. The watery content of an AC is readily seen through its delicate translucent wall. When the wall is punctured, the contents spill to expose the flattened gyri of the adjacent brain. Thereafter, the delicate membrane may be hard to find, its thin substance being almost inapparent. Occasionally, the cyst fluid may be xanthochromic and rich in protein and can be mistaken for a subdural hygroma.[67] Urich et al. have observed that subdural hygroma may also be a secondary complication in children with ACs.[103]

Vessels lie unsupported in the cyst and may rupture easily leading to intracystic haemorrhage (Fig. 1).

ACs of the cerebellopontine angle and parietal lobe have been respectively shown in Figures 2 and 3.

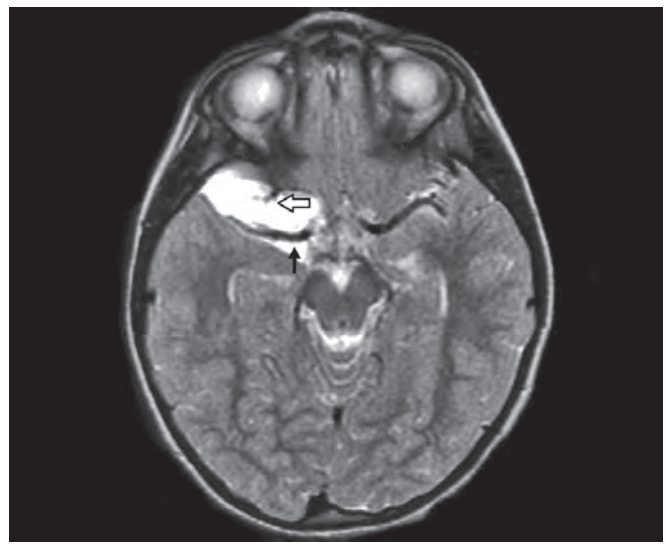

Fig. 1: MR showing unsupported vessels in a Sylvian arachnoid cyst. (Vertical solid arrow: middle cerebral artery. Horizontal open arrow: unsupported vein)

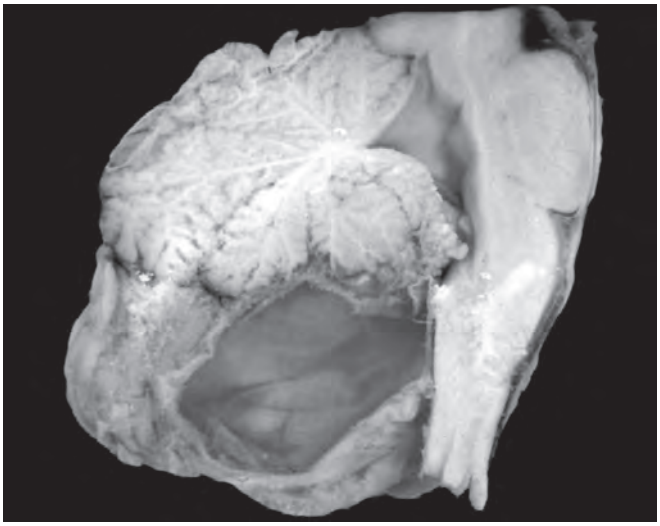

Fig. 2: Cerebellopontine angle arachnoid cyst

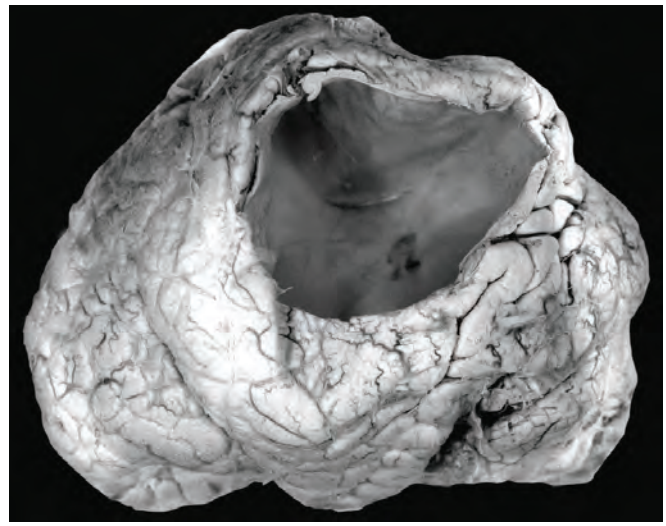

Fig. 3: Parietal lobe arachnoid cyst

Microscopic Appearances

The light microscopic and ultrastructural features of ACs are comparable to the normal arachnoid mater with a few differences.

Normal Arachnoid Mater

Light Microscopic Features

The arachnoid mater consists of a subdural cell layer, a trabecular connective tissue layer and an inner surface cell layer. The arachnoid cells in the subdural layer are flat, having elongated nuclei and dark tapering cytoplasm. The cells are stacked at random. The thickness of this layer varies in the different parts of the CNS. In the very thick area, the cells are plump and clumped irregularly as meningothelial nests.[84] Here, cytoplasmic whorls, psammoma bodies and calcified small vessels are seen. The second layer or trabecular connective tissue layer is a well developed distinct layer in adults. From this layer, traversing trabeculae arise which are attached to the pia mater. There are few cells within this connective tissue. Occasionally, sparse plump arachnoid cells are present. The inner surface cell layer covers the subarachnoid space. The cells in this layer do not tier. Small blood vessels are encountered in this layer, which are also surrounded by a single layer of arachnoid cells. Occasional macrophages are often found in the subarachnoid space.[84]

Transmission Electron Microscopic Features

The subdural arachnoid cells are flat, electron dense and stacked either in a few or several layers in the thin and thick zones of the membrane, respectively. They are connected by frequent gap junctions and desmosomes. They often form onion and skein like concentric whorls made of branching, fine cytoplasmic processes of arachnoid cells. The nuclei of these cells are usually located at the periphery of whorls. An incomplete basal lamina is noted between the arachnoid cell of the innermost tier and the trabecular connective tissue. This tissue separates the subdural arachnoid cells from the subarachnoid space. The trabecular connective tissue contains only a few cells. The thin inner surface arachnoid cells that line the subarachnoid space are similar in structure to the subdural arachnoid cells.

Arachnoid Cyst

Light Microscopic Features

The majority of cases exhibit features suggestive of splitting of the arachnoid membrane. The cyst wall consists of a vascular collagenous membrane. The collagen bundles in the adjacent normal arachnoid membrane and in the superficial layers of the dome of the cyst are compact, while the collagen fibres in the deeper layers of the dome and in the inner wall of the cyst are more loosely arranged. The inner wall of the cyst and pia mater are in direct contact with each other. Here, the subarachnoid space is obliterated.

The dense collagenous tissue in the dome of the cyst is covered by thick layers of subdural arachnoid cells. Two types of cells are seen. The outer tiers are composed of dark cells which are similar to normal arachnoid mater. The inner tiers are composed of lighter cells with large, round nuclei and abundant cytoplasm. The light arachnoid cells are frequently seen lining the subarachnoid space and these cells are also sparsely scattered in the connective tissue. In addition, there are also a few haematogenous cells within the trabecular connective tissue. Blood vessels are scarce in the cyst wall. There are no traversing trabeculae in the cyst lumen.

Transmission Electron Microscopic Features

The superficial dark arachnoid cells which form the outer tiers within the dome of the cyst have condensed nuclei and cytoplasm. The cytoplasm contains abundant filaments and a fair number of rough endoplasmic reticulum, free ribosomes, mitochondria and Golgi complexes.

The inner surface of the AC wall is lined by clear arachnoid cells. These are hyperplastic, larger and appear as evenly hydrated cells, and resemble foetal arachnoid cells. The cells in both layers are closely stacked and connected by frequent desmosomes and gap junctions. The clear arachnoid cells of the inner layer are bordered by incomplete basal lamina. Such cells are also found in the trabecular connective tissue. In contrast to the normal, arachnoid mater where trabecular clear arachnoid cells are widely separated by connective tissue, the clear arachnoid cells in the cyst wall are frequently clustered, with closely opposing plasmalemmas connected by gap junctions and desmosomes.

Immunohistochemical Findings of Arachnoid Cysts

The epithelial nature of the lining cells can be established by immunoreactivity for epithelial membrane antigen. As expected, the cysts are negative for markers found in other intracranial and intraspinal cysts such as GFAP, carcinoembryonic antigen and transthyretin.[65]

NATURAL HISTORY

The natural history and behaviour of these cysts are quite variable and uncertain. Little is known about the natural history of these lesions.[2] Some make their presence felt very early in life, while others are discovered only at autopsy. Even large cysts have been noted at autopsy.[52,94] These cysts are well known to expand over a period of time and manifest as space-occupying lesions or haematomas often following a trivial trauma, with features of increased intracranial pressure.[19] They are also known to disappear after a head injury or undergo spontaneous rupture.[71,82] As discussed above, in addition to disappearing they are also known to grow or fluctuate in size.[7,11]

INTRACRANIAL CYSTS

Clinical Features

Incidence and Distribution

These congenital lesions account for about 1% of all intracranial mass lesions and in 0.5% of autopsies they are seen as incidental findings. Most of the cysts are in the Sylvian fissure region. Males are affected more than females and the cysts occur more often on the left side.[74] While left sided cysts in the Sylvian fissure region are more common in males, the distribution of cysts in other locations is equal in both the sexes.[108,109] About 60–90% of patients are in the paediatric age group and the majority manifest within the first 6 months of life.[44] In 25% of the cases, it is diagnosed at birth. Associated brain malformations may be seen in a significant number of these patients. The cyst is single in 87.5% of patients.

While nearly 50% of the cysts are in the region of the Sylvian fissure, the next common site is the posterior fossa—which accounts for about 20% cases; 10% are in the supracollicular area while 9% are found in the sellar and suprasellar areas. The distribution in the other areas is as follows: interhemispheric fissure 5%; cerebral convexity 4% and clival area 3%. Bilateral, multiple, intraventricular, interpeduncular, intradiploic, craniovertebral junction and clival area cysts are very rare.[4,38,51,73,80,84,102] Rarely, a cyst may extend to more than one compartment.[5]

ACs occurring in siblings, at different sites in the same patient and symmetrically are also rare as are familial cysts.[74,79]

Manifestations—General

Although the cysts in the various locations have specific clinical features, some of the manifestations which have overlapping features can be considered first. Some features are fairly specific for certain cysts that a diagnosis can be made easily. These depend on the location of the cyst, i.e. Sylvian fissure cysts usually cause fits, haemiplegia and headache; suprasellar cysts result in hydrocephalus, endocrine problems and bobble-head doll syndrome; posterior fossa cysts lead to ataxia, hydrocephalus and features of posterior fossa neoplasm. Symptoms can fluctuate in intensity leading to an error in the diagnosis. It has to be emphasised here that these cysts may remain asymptomatic even when large and may be discovered only at the time of autopsy. The aetiology of the symptoms can be classified into "fluid related symptoms", "epilepsy" and "deficiency syndromes".[38]

Headache is a fairly common feature, both in children and adults. The headaches are just a manifestation of the raised intracranial pressure. Up to 70% of patients experience chronic headaches.[74] Enlargement of head size, tense or full anterior fontanelle and wide open sutures are often seen in children.[5]

In children, a diagnosis of congenital hydrocephalus may be made since their proximity to the CSF cisterns causes hydrocephalus by obstruction to the flow of CSF.[29] The incidence of hydrocephalus varies from 30–100% depending on the location of the cyst. Hydrocephalus is common in posterior cranial fossa cysts, but it is seen in almost all midline cysts.[38]

Seizures are common and form an important clinical feature in as many as half the number of patients.[74] These are so, especially in Sylvian fissure cysts. The seizure focus is adjacent to the AC in about a quarter of the patients only. This has led to questioning the validity of postulating the AC as the primary cause of seizures.[6]

Middle cranial fossa or Sylvian fissure cysts may cause "global impairment of brain function by interfering with the blood supply." This has been demonstrated by single photon emission computed tomography studies.[93] Left temporal ACs have also been shown to cause problems in cognition. These improve after surgery.[110] Although endocrine symptoms are commonest in suprasellar cysts, they are not unknown in other cysts.[69]

Peripherally located cysts, usually, are diagnosed later than centrally located cysts since the latter, by causing hydrocephalus, make their presence felt earlier.[38]

In older patients, cysts, when discovered, are usually asymptomatic and occur as incidental findings.[38]

Following rupture, these may present as subdural hygromas or haematomas.[28,33]

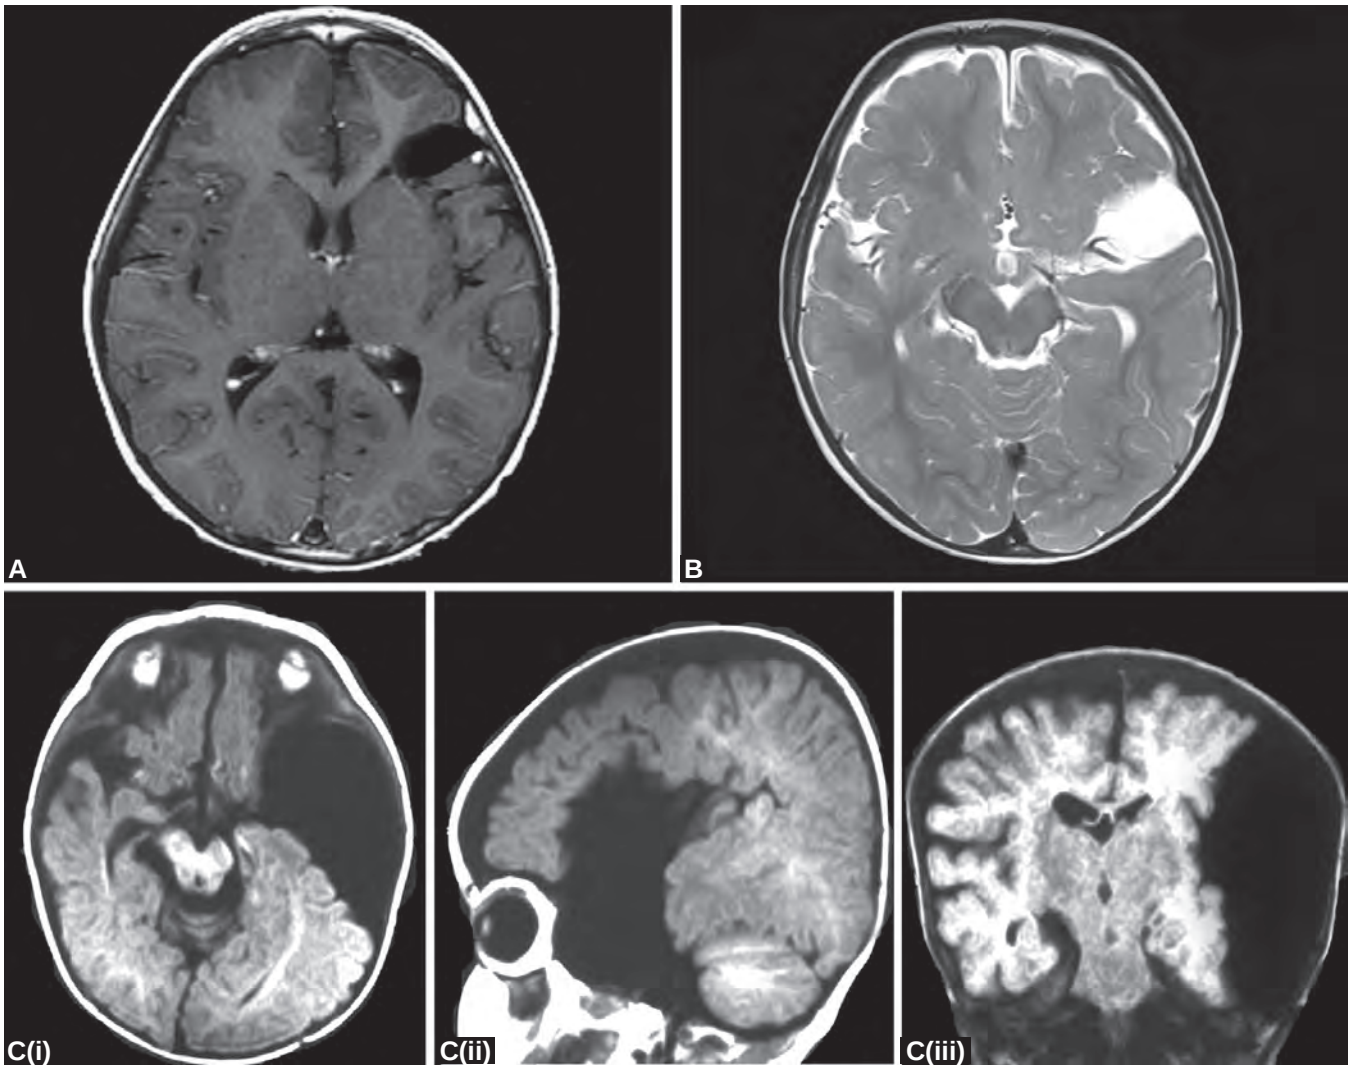
Manifestations—Specific

Sylvian Fissure Cysts

Included in this group are temporal cysts and cysts in the middle cranial fossa. This is the commonest site of occurrence of AC (Figs 4A to C). The incidence ranges from 49% to as much as 68% in some series.[38,84] Headache and seizures are the commonest presentation of AC in this location. Headache reflects the raised intracranial pressure and may not point to the pathology or have localising value. In infants and children, the calvarium may exhibit a bulge and this can be observed clinically and on imaging studies. If the cyst is longstanding or large, there may even be an asymmetrical enlargement of the head. In addition, these may cause changes in the sphenoid wing. The cranial deformity and the midline shift, which are often present, result from the mass effect of the cyst. Since these are located primarily within the Sylvian fissure or are closely related to it, the Sylvian fissure is spread out resulting in a "foreshortening" of the temporal lobe.[5] The Sylvian vessels are pushed posteromedially and lie deep to the cyst. In addition, anomalies of the venous system may be present.[74] These cysts are highly susceptible to trauma and bleeding.[104] Among all groups of cysts, these are most often associated with intracystic haemorrhage.[74] The haemorrhage may not be associated with any definite history of trauma or, if a history of trauma is present, the injury may be trivial. The veins snap easily because they do not have any support and are just bathed by CSF. Such a haemorrhage inside the cyst may present as a subdural haematoma, and be diagnosed as such.[19,33,104] Their presentation as subdural hygromas is also known.[28]

These cysts have been classified into three types based on their size, appearance and CT cisternographic findings by Galassi et al. as follows:

Type I: These are small biconvex cysts which are located in the anterior part of the Sylvian fissure. They do not exert any mass effect or cause cranial deformity.



Figs 4A to C: (A) Type I Sylvian fissure arachnoid cyst. (B) Sylvian fissure arachnoid cyst (Type II cyst). (C) MR images of Sylvian fissure arachnoid cyst: (i) axial; (ii) sagittal and (iii) coronal views. This is a Type III cyst

CT cisternography discloses free communication with the subarachnoid space.

Type II: The cysts are medium sized and quadrangular or triangular in shape. They occupy the anterior and the middle part of the Sylvian fissure. The insula (which corresponds to the medial straight border of the cyst) is exposed and the temporal lobe is "shortened". The frontal lobe may be displaced anteriorly. Bony changes, if any, are minimal. Early pooling of the contrast and partial communication with the subarachnoid space are found on cisternography.

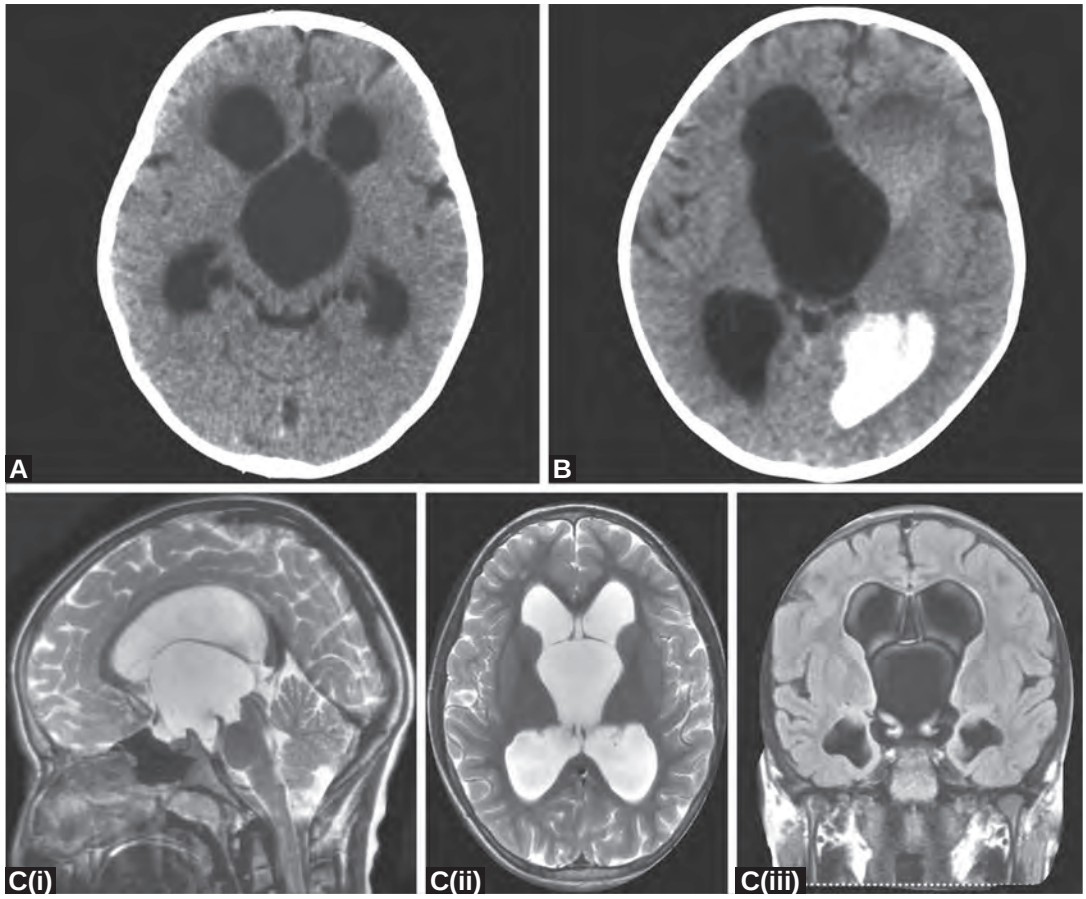
Type III: These cysts are large and oval or round in shape and involve the whole of the Sylvian fissure. They exert considerable mass effect on the brain with severe compression of the brain and midline shift. Deformity of the cranium is marked. Communication with the subarachnoid spaces is not apparent on cisternographic studies, but some contrast may pool around the cyst.[34,86]

The evolution of Type III cysts is unclear (at the present time) as to whether they evolve from Type I or II cysts or they arise *de novo*. If Type I or II cysts progress onto Type III cysts, they need treatment as soon as the diagnosis is made. This is a subject for future studies. Following treatment, re-expansion of the brain is seen in Type I and Type II cysts unlike in Type III cysts where the re-expansion is not full. A Type I cyst is usually discovered incidentally and often needs no treatment unlike Type III cysts, which always are symptomatic. The management of Type II cyst depends on the overall case scenario.

Suprasellar Cysts

These cysts (Figs 5A to C) account for 9–15% of all intracranial ACs depending on the nature of the series and the study.[36] As mentioned earlier, these are considered to be an outpouching of the membrane of Liliequist. Two varieties of suprasellar AC have been described the communicating and the non-communicating variety.[37] Communicating cysts communicate with the pontine cistern and non-communicating cysts are pinched off during development and are thus true cysts.[36] As they grow, these tend to invaginate the third ventricle and in addition exert pressure on the pituitary stalk. They may also bulge out through the Foramen of Monro.[74]

Many of these cysts may have only minimal symptoms and a few signs of localising value but, at times, they have features which are virtually diagnostic. A common presenting feature is hydrocephalus and the resulting features of raised intracranial pressure like headache and vomiting may also be present. Hydrocephalus is actually a very common presenting feature. These cysts may then be mistaken for congenital hydrocephalus, particularly if the attendant features of raised intracranial



Figs 5A to C: Suprasellar AC. (A) Axial CT: note the resemblance to bunny's head. (B) Ventriculography with water-soluble contrast shows the cyst to a non-communicating type of cyst. (C) MR: (i) sagittal; (ii) axial and (iii) coronal

pressure are present.[38] "Bobble-head doll syndrome" is considered diagnostic of suprasellar AC. This syndrome is characterised by a rhythmic 2–3 per second antero-posterior oscillation of the head and trunk. The clinical features are due to the hydrocephalus or compression of the adjacent structures. Suprasellar AC can be mistaken for a dilated third ventricle but it can be differentiated from the latter by its shape, configuration of the frontal horns of the lateral ventricles and also the adjacent structures. In addition, enhancement of the adjacent brain may be seen in AC.[38] These cysts may invaginate into the sella turcica and cause a bitemporal field defect in addition to behaving as an intrasellar mass. They can lead to a variety of endocrine dysfunctions like deficiency of growth hormone and thyrotropin or, by stimulating the hypothalamo-pituitary-gonadal axis, lead to a tall statured and overweight individual.[1] Precocious puberty, panhypopituitarism and diabetes insipidus have also been reported.[42,70] The list of differential diagnoses include craniopharyngioma, Rathke's cleft cyst, colloid cyst of III ventricle, epidermoid cyst, lipoma, ependymal cyst, parasitic cyst and dilated III ventricle in hydrocephalus.[36] AC do not show calcification on CT and present with fewer endocrine symptoms in comparison to craniopharyngioma or Rathke's cleft cyst.[97]

Posterior Cranial Fossa Cysts

The common presenting features are those of a posterior cranial fossa mass lesion namely headache, vomiting and cerebellar signs. Infants may be referred for evaluation of an enlarged head which results from the mass in the posterior cranial fossa. Some of the clinical features apart from hydrocephalus and features of raised intracranial pressure may be very subtle. These cysts can be in the midline or laterally placed as in the cerebellopontine angle (Figs 6A and B). In the latter instance, all the features of a mass in the cerebellopontine angle may be present, viz. sensorineural hearing loss, facial weakness, corneal anaesthesia, etc. Variations of this theme may also be present.

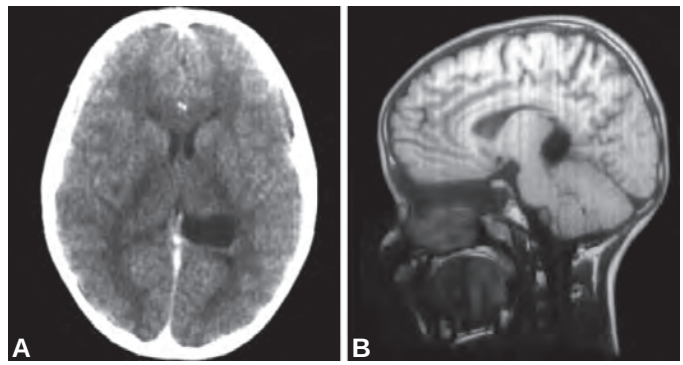
Parasagittal and Interhemispheric Cysts

These two types of cysts are seen more or less in the same region and one may be mistaken for the other, but there are important differences between the two. Parasagittal cysts are seen off the midline while interhemispheric cysts straddle the midline. An important differentiating feature is that the latter are associated with agenesis of the corpus callosum. In addition, parasagittal cysts are unilateral and hence may cause the midline to be shifted to the contralateral side. Being unilateral, parasagittal cysts cause hemicranial enlargement.[85] Parasagittal cysts are elongated while interhemispheric cysts take on a butterfly shape. Compression of the adjacent cerebral tissue is often a feature of parasagittal cysts.[5,85]

Pineal and Quadrigeminal Cistern Region Cysts

AC in relation to the pineal gland and its environs are not common, but are not unknown (Figs 7A and B). The commonest presenting symptom is hydrocephalus. AC here mimics pineal tumours but unlike pineal tumours, Parinaud's syndrome may not be seen.[40,86]

Incisural region cysts also invariably cause hydrocephalus and cortical enhancement may be seen around the cyst.[38]



Figs 7A and B: AC in the region of the incisura. (A) Axial CT. (B) Parasagittal MR

Convexity Cysts

Convexity cysts, even when large, may not manifest many localising signs apart from a local bulge. In infants, these may be mistaken for a subdural hygroma, but ACs do not have an enhancing membrane.[86]

Intraventricular and Intradiploic Cysts

ACs are very rare in these locations. Intraventricular cysts may arise within the ventricles or they may be manifestations of extraventricular cysts which have invaginated into the ventricles. Intradiploic cysts present as erosions of the skull commonly seen in middle-aged patients.[86]

Radiology

ACs present with certain characteristic features on imaging studies. Although a radiologic diagnosis can be made with certainty on many occasions, at times the differentiation from other lesions (for example, suprasellar AC versus suprasellar epidermoid/craniopharyngioma) can pose difficulties.

Plain Skiagrams

Plain skiagrams are no longer in vogue for the diagnosis of AC since other imaging modalities have proven to be more effective. But, nevertheless, at times that may be the first investigation done in the workup of a patient with AC or in a trauma victim who has an undiagnosed AC.

The radiographic features are a reflection of the location of the cyst. Only certain cysts present characteristic features, like those in the Sylvian fissure. Sylvian fissure cysts cause an asymmetry of the vault, as parasagittal and convexity cysts. In addition, Sylvian fissure cysts may elevate the sphenoid and cause the floor of the middle fossa to be bowed downwards. If there is significant mass effect, the groove for the sagittal sinus may also be displaced.[5] In cysts of the Sylvian fissure region, the lesser wing of sphenoid may be displaced forwards. Convexity and parasagittal cysts cause a localised bulge in the calvarium or, if large, an asymmetry of the vault.

Sonography

Sonography is usually done as a screening procedure when a neonate or infant presents with a bulging fontanelle or increasing head size. Sonography reveals ACs to be anechoic fluid-filled mass lesions with sharp margins. Mass effect may also be seen as well as other brain anomalies.[30,76] The findings on sonography must be correlated with other imaging studies.[13]

Computerised Tomography Scan

CT scan features of AC are fairly characteristic and the diagnosis is straightforward in almost all the cases. The basic appearance of these lesions is a hypodense cystic lesion without any calcification, but with well defined non-enhancing, smooth and round borders. Unless there has been a haemorrhage in the cyst, the contents have the attenuation value of CSF. If the cyst is adjacent to the calvarium, a bulge or asymmetry of the cranium may be seen. The cyst itself may have straight biconvex or biconcave borders. A straight medial border is often a characteristic finding in AC of the Sylvian region. The cyst may be biconvex or round in shape. Sharp margins and a cystic appearance are the bases for diagnosis.[107] The inner margin is straight, where it is attached to the leptomeninges.[64] Although the foregoing are the fundamental characteristics of AC, variations of the theme may be encountered every now and then.

Convexity cysts are biconvex or semicircular and may have a straight inner margin which represents their attachment to the rest of the arachnoid.[9] Cortical enhancement may be seen around the cyst.[38] Intracystic haemorrhage will change the attenuation value of the CSF within the cyst.

Although differentiation from other cystic lesions, like cystic gliomas, Dandy-Walker malformation, porencephaly, dilated third ventricle, craniopharyngiomas, Rathke's cleft cysts, lipomas and epidermoids, may be difficult on CT, it is possible in most instances.[44] Neoplasms exhibit enhancing borders and the presence of a mural nodule is a give-away sign for these. The cerebellar vermis is absent or attenuated in Dandy-Walker malformation unlike in AC of the posterior fossa.

The problems of differentiating suprasellar AC from other lesions in this area can be obviated by a study of the CT anatomy of the suprasellar area. The normal suprasellar region resembles a six-pointed star, which is referred to as the "suprasellar star". The anterior limb of the star is formed by the interhemispheric fissure, the two anterolateral limbs are formed by the Sylvian fissure, the two posterolateral limbs are formed by the peri-mesencephalic cisterns while the interpeduncular cisterns go to form the posterior limb. The shape of the suprasellar cistern is altered by pathologies located here. In addition, the normal slit-like shape of the third ventricle should also be taken into account when the CT images are interpreted. Like the shape of the suprasellar cistern, the change in the shape of the third ventricle helps in diagnosing the nature of the lesions present here. The commonest difficulty encountered is differentiating suprasellar AC from the dilated third ventricle seen in hydrocephalus. The five-pointed or six-pointed star configuration of the suprasellar cistern becomes oval or rounded in suprasellar cysts. The change in shape is "primarily the result of notching and lateral displacement of the mesial temporal lobe and flattening and posterior displacement of the brainstem".[36] The dilatation of the basal cisterns helps in differentiating suprasellar cysts from a dilated third ventricle and ependymal cysts of the third ventricle. The suprapineal recess of the third ventricle is more dilated in hydrocephalus than in AC.[36] Calcification is characteristic of epidermoids and craniopharyngiomas. In addition, the borders may

be irregular and enhancement may be seen. A negative attenuation value is seen in lipomas. Suprasellar AC may pose difficulties in the diagnosis. Suprasellar cysts are well demarcated round cystic masses which do not enhance with intravenous contrast. No areas of calcification or fat are present. These allow differentiation from neoplasms, dermoids/epidermoids and lipomas.[36] On axial imaging studies, the suprasellar cyst has been described as resembling a bunny's head.[86] Suprasellar cysts are seen as low density cystic areas in front of the cerebral peduncles and may go laterally up to the Sylvian fissure. Cortical enhancement may be seen around the cyst.[38] The definitive way to differentiate a dilated third ventricle from suprasellar AC is to do contrast cisternography. The contrast does not pool in the AC when it reaches the intracranial compartment unlike in the third ventricle. Communication between the cyst and the subarachnoid space can be demonstrated by air, metrizamide and isotope studies.[43,84,85] Water-soluble contrast studies have disclosed the following three kinds of cysts:

1. Those that communicate freely with the CSF space.
2. Those that communicate slowly.
3. Those that do not communicate.

The smaller cysts communicate freely with the subarachnoid spaces while the larger are of the non-communicating variety.[74] This has a practical significance in that it may be possible to manage the rapidly communicating cysts without surgery,[74] but eventually the contrast enters all the cysts albeit at varying rates. This has led some to question the division into communicating and non-communicating varieties.[24] The preferred term should be slowly communicating and rapidly communicating cysts. The slowly communicating cysts (which are often the large ones) cause neurologic problems and have features of expansile lesions.[24] During cisternography immediately after injection of the contrast, it does not enter the cyst, but the contrast is seen only in the subarachnoid space and this helps in delineating the cyst wall.[87] The contrast enters the cyst in about 6 hours and by 24–48 hours, all cysts are free of contrast even though the contrast clearance occurs at the normal rate from the subarachnoid spaces.[24] The rapidly communicating cysts may just be an arachnoid diverticulum, while the slowly communicating ones may represent a true cyst.[112]

Magnetic Resonance Imaging

MRI adds information to our study and understanding of these lesions. Information which may not always be available on CT may be obtained through MR imaging, even though the diagnosis may be apparent on CT. The basic appearance of these lesions on MR is the same as CT, namely well demarcated non-enhancing CSF containing cystic lesions without any calcification, but MR shows additional features which cannot be seen on CT.

MR shows indirect evidence of bony changes, namely a bulge in the bone and erosion of bone if present. Since cortical bone does not give any appreciable signal on MR, it is seen as a dark curvilinear shadow adjacent to the brain or the lesion.[107] The marrow, however, is seen as an area of increased signal adjacent to the shadow of the inner table. Changes in the calvarium will be seen as an alteration in the normal configuration of the inner table and the marrow. Bone erosion is seen as "decreased thickness" of the marrow signal, or "an interruption in the continuity of the marrow signal".[57] The latter finding has to be interpreted with caution since the marrow signal may not be continuous in all the areas.[107] The excellent soft tissue contrast afforded by the MRI reveals the anatomy in exquisite detail. Like the CT, in the MR images, the cyst is seen as a sharply demarcated hypodense (on T1 study) non-enhancing lesion. The "low signal of cyst fluid on T1 images gives good contrast with adjacent brain and is useful for initial diagnosis and definition".[107] MR, to sum up, is invaluable in evaluating the soft tissue abnormalities, haemorrhages and in delineating the anatomy of the adjacent brain.

Care has to be exercised in interpreting the images if the cyst contents do not appear identical to CSF. There may be several reasons for this. A difference in signal value may be seen between the intraventricular and the extraventricular CSF because of a difference in protein value. Ventricular CSF protein is 15 mg% and it increases to 30 mg% in the basal cisterns. Signal intensity from the ACs is the same as extraventricular CSF.[15] These differences in signal may be subtle and may be overlooked unless a special effort is taken to assess the signal changes. Signal from the cyst on spin echo is higher than ventricular CSF and similar to cisternal CSF.[74] The signal variations may represent minor haemorrhages or may represent some other complication.

The multiplanar imaging capabilities result in advantages which cannot be conferred by CT. The mass effect is best seen in coronal views.[107]

The CT appearance, in the presence of intracystic haemorrhage, varies depending on the "age" of the blood in the cyst. Even if the CT does not reveal haemorrhage and the cyst contents appear isodense on CT, MR may show the haemorrhage.[50] However, the increased signal from the cyst has to be interpreted with caution and correlated with the clinical picture and other investigations since the cyst may contain an increased amount of protein due to other reasons or the pathology may be something else, for instance a neoplasm.

Since the signal from the cyst is the same as CSF, signals from the cyst contents, which are not the same as CSF, should be interpreted with caution since these may be due to a neoplasm. If the signal intensity is the same as CSF in T1 and T2 weighted images, then it is almost pathognomonic of AC. Even if the features are the same as CSF, the presence of enhancement of the cyst walls or mural nodule favours neoplasm.[107]

In an uncomplicated AC, the surrounding brain is normal.[107] Hence, if no abnormal signals are seen from the surrounding brain, differentiation from post-operative, post-traumatic or post-infective/inflammatory cysts

is easy. In all these latter instances, the surrounding brain is abnormal.

MR is also very useful in differentiating AC from other lesions. Steady-state precession (PSIF) MR sequence with cine gating helps in differentiating cysts from enlarged CSF spaces and increases the certainty of establishing cyst communication with CSF spaces.[49] The other lesions which cause interpretive difficulties on CT can be diagnosed with greater certainty on MR using different imaging protocols, since the signal characteristics are different for different lesions. In diffusion weighted images, abscesses, epidermoids and cholesteatoma are hyperintense while ACs are hypointense.[12,61]

Management

Of all the controversies concerning AC, the management of these lesions alone has not been laid to rest. The best operative intervention for children with ACs remains the subject of controversy.[53] The surgical treatment is as variable as the location of the cyst.[40] There are proponents and opponents for every method of managing these lesions. Extremes of views have been presented. On the one hand, the mere presence of these cysts has been considered an indication for surgery since they may rupture or may lead to intracranial haemorrhage.[2] The "middle of the road" policy of not treating asymptomatic or accidentally discovered cysts has also been advocated. At the other end is the proposal to follow a "wait and watch" policy even for large cysts until a causal relationship with the symptoms is proven.[99]
The management of these lesions can be divided into the following groups:

- Conservative approach for all cysts
- Surgery for all lesions (even for asymptomatic lesions)
- Craniotomy and fenestration
- Shunt procedures
- Endoscopic surgery
- Other methods of management

Surgery is indicated in large cysts, which exert a mass effect, or when there is hydrocephalus, fits, features of raised intracranial pressure, a neurologic deficit caused by the cyst or the presence of other symptoms like endocrine, visual/ophthalmic deficits (as may be seen in suprasellar cysts).

Craniotomy and Fenestration

Craniotomy and fenestration of the cyst into the ventricle or adjacent subarachnoid cistern has been proposed as the definitive or curative treatment for these lesions. Recent reports stress that craniotomy for cyst fenestration is associated with a low incidence of morbidity and mortality and may leave the child shunt-independent.[53] The most important step in the operation is the fenestration of the cyst into the adjacent subarachnoid cistern or ventricle. Mere excision of the outer wall may result in a failure. The successful outcome of the surgery hinges on the principle of restoring normalcy to CSF circulation. This can be accomplished only by establishing a communication with the adjacent subarachnoid cistern. Primary treatment is, therefore, resection of the cyst wall and opening of the cyst into adjacent cisterns.[79]

Although the surgical steps vary a bit for cysts in the various locations, the fundamental steps and techniques are the same for all. Suitably placed scalp and bone flaps are reflected. Care has to be exercised during the elevation of the bone flap since the bone may be thinned out or eroded by the cyst. The dura is often times thinned and stretched over the cyst and appears bluish over the cyst region because of the underlying lake of CSF. The dura has to be opened carefully. Usually, the dura separates well from cyst, but adherence at one or two places is not uncommon. In the areas where the dura is adherent, dissection has to be done carefully for two reasons: (1) to prevent inadvertent rupture of the cyst and (2) to prevent rupture of the vessels which are either draped over the dome of the cyst or those which course inside the cyst. After the dura is opened, the cyst is seen. The cyst wall is usually transparent, but may be translucent in a few places. A few vessels may be seen coursing over the cyst wall. These vessels may be coagulated and divided. The outer wall of the cyst is then opened widely. Inside the cyst, veins are seen coursing towards the surface. These veins are coagulated and divided. Care has to be exercised in opening the cyst since these unsupported veins may rupture leading to troublesome bleeding. The brain surrounding the cyst appears normal with a normal sulcal and gyral pattern. However, the brain is compressed and, depending on the location of the cyst, the displacement varies. Once the cyst has been opened, the CSF has to be drained very slowly. Rapid suctioning of the CSF will lead to serious brain shift and cause a haemorrhage away from the site of surgery. This may not be apparent until there is a post-operative problem or post-operative imaging is done. Since the CSF is clear, even a few drops of blood can make progress difficult for the field will become "clouded" by the blood tinged CSF. In this instance, CSF is aspirated slowly with the suction set at low power or through a cotton ball or pattie. The bleeder is identified and coagulated. Unless there has been haemorrhage resulting in adhesions, the cyst is unilocular. "Arachnoidoplasty" has been recommended as an alternative to wide excision of the outer wall of the cyst. Here, instead of wide excision of the outer wall, a linear incision is made in the outer wall of the cyst. After the fenestration of the inner wall, the incision in the outer wall is closed. This technique reduces the chances of the post-operative CSF leak.[95]

After opening the cyst, fenestrating the inner wall may be more physiologic and may obviate the need for a shunt.[95] Mere excision of the outer wall leads to failure because this just creates a communication with the subdural space and not the subarachnoid space.[29] This procedure may lead to the formation of a subdural collection with mass effect.

The findings after opening the cyst depend on the location of the cyst. In Sylvian region cysts, the middle cerebral and internal carotid arteries and their branches are seen without any difficulty. When the microscope is angled to look slightly deeper and posteriorly, the third cranial nerve and the tentorial edge come into view. In addition, the optic nerve is also seen. On opening the arachnoid along the medial surface, the basilar artery and the other structures in the region of the basal cisterns are readily apparent. The medial wall of the cyst is opened widely into the chiasmatic and basal cisterns.

Suprasellar cysts can be approached through a transcallosal, transventricular or subfrontal approach. If the transcallosal route is chosen, once the corpus callosum is incised and the third ventricle opened, the cyst wall is seen. The cyst is then opened widely into the ventricle. The approach involves opening the cisterns in relation to the corpus callosum. Hence, communication with the CSF cistern is established. But to create a wide fenestration, an extensive splitting of the corpus callosum may be needed and this may not be advisable. In suprasellar cysts, effective decompression is not obtained if the cyst is drained only into the subarachnoid cistern. Hence, the cyst should also be drained into the ventricle. For suprasellar cysts, resection leads to good results and even the endocrine symptoms improve.[52]

Upon opening a midline posterior cranial fossa cyst, the floor of the fourth ventricle is seen in addition to the cervicomedullary junction. In laterally placed cysts (i.e. at the cerebellopontine angle), all the structures located there are clearly visible without any retraction. The posterior fossa cysts are widely fenestrated into the adjacent CSF cisterns; in the case of midline cysts into the fourth ventricle and cisterna magna and in the case of the cerebellopontine angle cysts into the CP angle cistern and, if possible, into the cisterna magna.

Once the cyst is widely fenestrated, the dead space may be filled with irrigating fluid to prevent pneumocephalus and also to allow a gradual re-expansion of the brain. Post-operative haemorrhage may result because of the sudden re-expansion of the brain. The dura is closed watertight and the bone flap is anchored and wound closed in the usual manner.

The complications specific to this procedure include haemorrhage in the operated site because of the dead space or snapping of the unsupported veins, failure of the brain to re-expand, aseptic meningitis, subdural collections and a neurologic deficit resulting from brain shift due to rapid decompression.

The success rate, i.e. relief of symptoms and radiologic improvement is 60–96%.[8,86] The reasons for failure of the procedure are due to reformation of cyst walls, incomplete or inadequate fenestration, closure of fenestration, deficiency of flow from the cyst into the ventricle or cistern. Failure to treat the attendant hydrocephalus might also militate against a successful result. For posterior fossa cysts, craniotomy gives better results than shunts.[31]

Shunting

Shunting has been advocated as a treatment modality for intracranial AC. The fundamental idea is to divert the CSF to the peritoneum—as one would in hydrocephalus—where it will get absorbed.

The standard techniques used to perform a ventriculoperitoneal shunt are used. The proximal end of the shunt is placed in the cyst cavity while the distal end is in the peritoneum. There are no hard and fast rules regarding the choice of shunt opening pressure. This is based only on the surgeon's experience and judgement. The proximal end is placed in the cyst cavity through a suitably placed burr hole. The burr hole has to be placed in such a way that it will not be a problem should a craniotomy become necessary as an emergency or as a planned surgical procedure. The proximal end is connected to the reservoir and the distal catheter.

A straightforward ventriculoperitoneal shunt has been proposed as a first line of treatment if contrast cisternography shows good communication of the cyst with the CSF pathways. If the communication is not good, cysto-peritoneal shunt may be needed.[112] The results of shunting are best for middle cranial fossa cysts.[23]

The complications of shunting as a treatment modality for AC are the same as shunting for hydrocephalus. The common problems are shunt failure and infection. In addition, "Slit cyst syndrome" which is similar to the slit ventricle syndrome has also been described.[86] Here, the patient manifests with features of raised intracranial pressure even though the imaging studies show a slit-like cyst. The shunt does not always result in a cure, since the shunts do malfunction at a rate higher than shunts for hydrocephalus.

Endoscopic Surgery

Endoscopic surgery may, in the future, become the standard way to treat intracranial AC. The technique may appear to be simple to the unwary. The investment in technology and instrumentation is high and the learning curve is "steep and long", but this confers the advantage of being minimally invasive. The basic principle here is the same as in craniotomy, viz. establishing a communication between the cyst and the normal CSF pathways.[21]

The endoscope is introduced into the cyst through a suitably placed burr hole. The possible need for converting the procedure into a craniotomy as an emergency or elective procedure at a later date has to be borne in mind when planning this procedure. Once the scope is introduced into the cyst, the anatomy has to be thoroughly studied and the cyst contents inspected. Care has to be taken to avoid the veins which course unsupported through the cyst. The inner wall of the cyst is approached and it is fenestrated. The instruments used to fenestrate depend on the surgeon's choice and experience. The grasping forceps, diathermy (unipolar/bipolar) or laser may be employed. Several holes are made

and these are enlarged with a balloon catheter such as Fogarty catheter. Performing the procedure under constant irrigation keeps the field clear and also clears the tissue debris. Meticulous haemostasis is mandatory. If the cyst is in close relation to the ventricle, in addition to cysto-cisternostomy, cysto-ventriculostomy can also be performed for added benefit. In other words, ventriculo-cysto-cisternostomy is better than ventriculo-cystostomy.[27] This may particularly be useful in suprasellar cysts where the failure rate of surgery is high for any surgical procedure. Endoscopic marsupialisation of the roof of a suprasellar cyst alone has given good results.[16] Endoscopy may be the treatment of choice in the future for AC, especially for deep seated cysts.[22,26,47,56] Further, endoscopy is a good alternative for failed craniotomy or shunt.

Several adjuncts have made endoscopic management easier and more precise. Frameless stereotaxis has proved useful for endoscopic surgery of deep seated cysts but it may not be needed for large lesions,[3,41] or the surgery can be started with the endoscope and then can be converted to a microsurgical technique with endoscope assistance.[35] Endoscopic surgery for AC has been divided into various groups as "endoscopic neurosurgery (EN), endoscope-assisted microneurosurgery (EAM) and endoscope-controlled microneurosurgery (ECM)".[49] These techniques have resulted in an overall success rate of 70%. The best success rates were achieved in patients with intraventricular cysts (89%) and posterior fossa AC (78%). Symptomatic improvement was best achieved in patients with hydrocephalus or focal neurological deficits (81%).[49] It appears that endoscopic management has the advantages of craniotomy combined with the less invasive nature of shunts. Intraventricular cysts and suprasellar AC are easily approached using EN, whereas posterior fossa and Sylvian AC may be more effectively treated using a combined technique (EAM or ECM).[49]

Other methods have also been described to manage AC. It has to be emphasised here that they have not withstood the test of time. Some are only anecdotal and only a limited number of patients have been treated using that modality.

For intrasellar AC, trans-sphenoidal approach and excision has been reported to give good results. This can be done for small intrasellar AC but larger ones or those with suprasellar extension will need a craniotomy for effective management.[68]

Stereotactic intracavitary irradiation, using colloidal Phosphorus-32, has been administered leading to good results.[58,101] Cyst aspiration as a treatment for AC has also been advocated,[29] but simple aspiration through a burr hole and cyst drainage leads to recurrence of the cyst. Cysto-subdural shunt has also been reported to give good results.[108] Cysto-ventriculostomy using stereotactic guidance has been done and the reported results have been good.[25]

SPINAL CYSTS

Introduction

Many congenital and developmental cysts are seen in the spinal canal, namely, ACs, neurenteric cysts, epithelial cysts and inclusion cysts. Spinal ACs are not as common as their intracranial cousins. A variety of names have been used to describe these lesions: "subdural ACs, arachnoid diverticula, leptomeningeal cysts and meningeal hydrops".[77] Unlike their intracranial counterparts, these may be intradural or extradural, with the intradural variety being the commonest.[77]

Embryology

The embryology of these lesions (unlike the intracranial cysts) has not fully been elucidated. The origin of these is more often than not congenital, although these "cysts" may follow inflammation, haemorrhage, myelography or trauma, just like they do intracranially[32,60,62] (refer to the discussion in intracranial AC). Extradural cysts originate as small arachnoid diverticula through defects in the dura.[14] Intradural cysts are thought to arise from the septum posticum which lies on the dorsal aspect of the cord.[14] An alternate theory suggests that the variations in intraspinal CSF pressure leads to the dilatation of the low resistance areas, resulting in the formation of the cyst.[77] An alternate hypothesis envisages that all these "arachnoid diverticula result from hypertrophy, proliferation and dilatation of arachnoid granulations".[77]

Clinical Features

These are the commonest among cystic lesions occurring in the spinal canal.[77,78] The commonest location of these lesions is the mid-thoracic level on the dorsal aspect. Their occurrence on the ventral aspect of the spinal cord is rare,[55,62] Although these occur in other regions too, the incidence is lower.

The common presenting feature is slowly evolving paraparesis. On clinical grounds, it is impossible to attribute the cause of compression to AC. The motor deficit is worse than the sensory or autonomic deficits.[111] In addition, the patients may have root pains and kyphosis. The cause of the latter is unclear.[14] An important differential diagnosis is multiple sclerosis since the symptoms may fluctuate.[14,77] In addition, the symptoms in communicating AC may vary with posture. Spinal meningeal cysts have been classified into three types:[72]

Type I: Extradural meningeal cysts without involvement of spinal nerve root fibres.

Type IA: Extradural meningeal cyst ("extradural arachnoid cyst").

Type IB: Sacral meningocoele ("occult sacral meningocoele").

Type II: Extradural meningeal cysts with involvement of spinal nerve root fibres

(Tarlov's perineural cyst, spinal nerve root diverticulum).

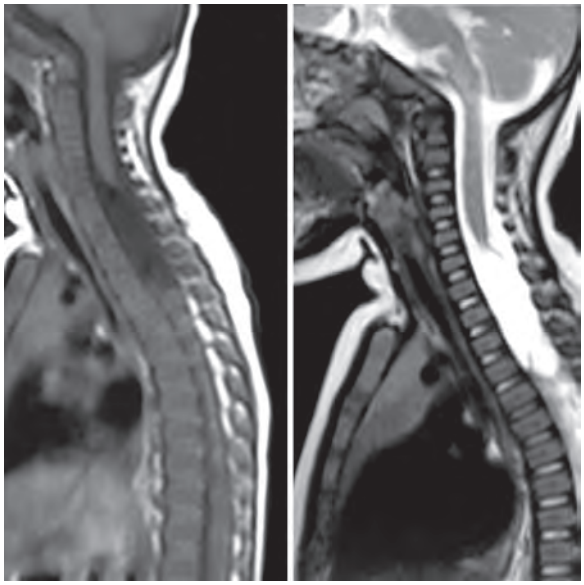


Fig. 8: Spinal arachnoid cyst in the thoracic region (Sagittal MR images)

Type III: Spinal intradural meningeal cysts ("intradural arachnoid cyst").

Radiology

Plain films show erosion of the pedicles at the level of the lesion. Myelography shows, in addition to a filling defect, pooling of the contrast medium inside the cyst if it is of the communicating variety. MRI, however, is the investigation of choice (Fig. 8). This shows a non-enhancing cystic lesion with signals similar to CSF.[77] Cine MRI can demonstrate abnormal fluid flow and spinal cord compression caused by a spinal intradural AC."[96]

Treatment

Like the intracranial cousins, these lesions have to be managed surgically. The outer wall is widely excised. If by doing this, a communication with the CSF space cannot be established a fenestration has to be done. The results of surgery are often very good,[55,62] particularly if surgery is done early.[59,62,77] Shunting may be useful in recurrent lesions.

18 Craniofacial Deformities (Craniostenosis)

Uday Andar, Nitin Mokal

HISTORY/INTRODUCTION

Surgery for craniofacial deformities has evolved over the years just as all other branches of surgery, the most significant factor being the better understanding of the growth of the craniofacial skeleton, and the various driving forces that promote and demote its growth. Though the problem was identified very early in the history of medicine, evident because of the deformed face and the abnormal dentition, its significant contribution in retarding intelligence, increasing intracranial pressure and causing severe airway and visual disturbance has been understood only recently.

Many would consider Prof. Paul Tessier as the father of modern craniofacial surgery. His single minded dedication to this specialty and imaginative surgical procedures has brought a great change in the way craniofacial surgery is looked upon today. The involvement of more than ten specialists in the care and management of these children, only emphasises the modern day understanding of this complex problem and the need to have a dedicated specialty department. Historically, the first operation in India for craniofacial deformity secondary to frontonasal encephalocele—a modified Tessier operation was carried out at AIIMS.[3,4] This was later applied to other craniofacial anomalies.

NORMAL CALVARIAL GROWTH

Craniofacial growth is influenced immensely by the rate of growth of the structures that it protects. Hence, at birth, the cranium is larger than the face because the brain is more developed than the relatively smaller facial skeleton including the teeth. Later on, the cranial growth slows down, and the facial skeleton comparatively grows faster.

The processes involved in normal growth of the craniofacial skeleton are as follows:[1]

Endochondral Ossification

Its growth mainly occurs in long bone endochondral cartilage and, therefore, may contribute very little in the cranium. It occurs mainly at the synchondroses at the skull base.

Intramembranous Ossification and Sutural Growth

Most of the skull bones are membranous bones and their growth is spurred on by the osteoblastic activity in the surrounding periosteum externally and the outer dura internally. This active bone formation may be maximum at the sutural interfaces. These sutural interfaces are under stress due to the growing brain, growing facial musculature and the orbits and the teeth. This continuous stress stimulates bone deposition at these junctions and craniosynostosis interferes with this process and prevents growth.

Remodelling

It is the process by which deposition and resorption of bone occurs in different areas of the skull vault and it is most simply demonstrated by the changes in curvature that occur in the calvarial bone as the skull vault enlarges in the early years of life.

Displacement

It occurs when the bone gets deposited over the suture lines and the enlarging brain displaces the calvarial bones outwards and away to remodel. This type of growth is seen in the mandible where anterior displacement of the body occurs by growth of the condylar neck.

INCIDENCE, AETIOLOGY AND PATHOGENESIS OF PREMATURE CRANIOSYNOSTOSIS

Craniosynostosis occurs due to the premature fusion of a single suture or multiple sutures. The overall prevalence of craniosynostosis is around 1 in 2,500 live births, with ranges of 1 in 709 to 1 in 3,225 of births.[2] The wide variation seen is due to differences in the various criteria under which one labels craniosynostosis.

The last decade of intensive research has linked many of the multiple suture "syndromic synostosis" to a series of mutations in the fibroblast growth factor receptor (FGFR) genes 1–3. Human FGFR mutations follow non-random themes. Specific FGFR3 mutations generate craniofacial dysostosis, some without skeletal abnormalities.[9,13,14]

Common syndromic craniosynostosis, like Apert and Crouzon, have a prevalence of about 1 in 65,000, each, forming about 4–6% of all craniosynostosis. There is evidence of FGFR2 mutation in Apert syndrome, FGFR3 in Crouzon syndrome and FGFR1 in Pfeiffer syndrome. Almost all Apert's and about 50% of Crouzon's arises de novo and there is a correlation with increase in paternal age. The prevalence of Pfeiffer syndrome is lower than others, but there is no definite percentage data.

Apart from this, there are rarer types of single gene syndromes associated with other malformations, metabolic storage disorders and learning disabilities. There are chromosomal aberrations of which craniosynostosis may be a feature. There are teratogenic causes associated with anticonvulsants (valproate, hydantoin), cytotoxic agents (methotrexate, cyclophosphamide, cytarabine), abortifacients and other drugs (chlorpheniramine, nitrofurantoin, chlordiazepoxide and fluconazole).

Isolated craniosynostosis is far more common than multiple syndromic synostosis. Sagittal synostosis seems to be the commonest, followed by coronal and metopic synostosis. True lambdoid synostosis is rare and is difficult to distinguish from deformational posterior asymmetry, which is considered to be positional moulding of the cranium.

Sagittal synostosis accounts for almost 55% of all craniosynostosis.[8,15] It is sporadic, commoner in twins and, though there may be a family history, the inheritance pattern is low. It is three times more common in males than the females.

Coronal suture involvement accounts for about 20% of all craniosynostosis.[11,17] It is almost twice as common in females, and the unicoronal type is twice as common as the bicoronal type. This type is associated with family history, increased paternal age and FGFR3 mutation, especially when it is bicoronal.

Isolated metopic craniosynostosis has a wide reported range varying from 14% by Lajeunie et al.[12] and 3% by Singer,[17] (1999) to 50% by Shuper et al.[16] It is twice as common in males. It can be associated with learning disability, without evidence of high intracranial pressure (ICP). There can be associated chromosomal aberrations. foetal valproate exposure is increasingly recognised as a cause of metopic synostosis with or without learning disability, behavioural disturbances, limb and nail defects and neural tube defects.

Isolated lambdoid craniosynostosis is in the majority of cases deformational. Contributing factors include intrauterine constraint, prematurity, complicated delivery and laying the baby excessively on one side while sleeping. This type is mostly managed conservatively.

CLASSIFICATION AND TERMINOLOGY

Over the years, the nomenclature for various craniofacial deformities has remained constant, but with the entry of molecular genetics, there have been additional terms given to the complex multisutural synostosis. However, in simple terms, these deformities can be classified into three different varieties:

1. Secondary
2. Simple
3. Complex

1. Secondary craniosynostosis can occur as a result of twinning, amniotic bands or uterine abnormalities, and is seen in preterm babies. It can also occur in newborns with hyperthyroidism or maternal hyperthyroidism during pregnancy.[5,7] Pan sutural synostosis is seen in children with microcephaly, where the brain is small and underdeveloped.
2. Simple anomalies include single suture or two suture involvement and are named as:
   - *Sagittal Synostosis or Scaphocephaly or Dolichocephaly*: it is so called when the sagittal suture is singularly prematurely fused and the head attains a long antero-posterior length with or without frontal bossing.[10]
   - *Unicoronal synostosis*: it is also called plagiocephaly, when there is flattening of one side of the forehead and a mild facial scoliosis, due to premature fusion of one coronal suture.
   - *Metopic synostosis or Trigonocephaly*: this occurs when there is premature fusion of the metopic suture, and the forehead assumes a triangular shape like the keel of a boat.
   - *Lambdoid synostosis*: it is also called posterior plagiocephaly when a single lambdoid suture fuses to produce asymmetric occipital flattening.
   - *Bicoronal synostosis or Brachycephaly*: this is a condition where both coronal sutures fuse prematurely and the skull assumes a spherical shape.
   - *Acrocephaly or Turricephaly or Oxycephaly*: a condition where both coronals and anterior sagittal sutures fuse and the skull assumes a pointed tower like shape.
3. Complex craniofacial deformities are mainly associated with syndromes and FGFR mutations and they are named as follows:
   - Crouzon syndrome: this syndrome was described by Crouzon in 1912. Apart from craniosynostosis, this condition manifests maxillary hypoplasia, exorbitism with hyperteleorism and type III malocclusion. There are no obvious skeletal anomalies. There may be associated FGFR3 mutation and phenotypic variability between generations is a common observation.
   - Apert syndrome: this was described by Apert in 1906. It is characterised by bicoronal and anterior sagittal synostosis, midface retrusion and hypertelorism with orbital proptosis and complex syndactyly of hands and feet. They can also have sporadic visceral malformations and skin abnormalities.

- Saethre-Chotzen syndrome: this syndrome is so named after the two people who described their findings in different families around 1931–32. The features here include bicoronal synostosis with variable involvement of the metopic, sagittal and lambdoid sutures. There is associated proptosis, low set frontal hairline, parrot beaked nose, strabismus and brachydactyly.
- Pfeiffer syndrome: this syndrome has features of bicoronal synostosis to pan sutural synostosis and clover leaf deformity of the skull. It was described by Pfeiffer in 1964, and it includes limb anomalies like thick broad thumb and toe, fusion between thumb phalanges and soft tissue syndactyly of thumbs and fingers.
- Clover leaf or Kleeblattschadel deformity: this is an uncommon and severe form of craniosynostosis resulting from the fusion of both coronal and a combination of metopic, lambdoid and sagittal sutures. The midface is retruded with ocular ectopia and dental malposition. The posterior fossa is small and there is cerebellar tonsillar herniation. There may be severe airway obstruction and the clinical prognosis is often poor, unless improved by some very aggressive surgical management.
- Carpenter syndrome: this is a rare syndrome where the cranial deformity mainly involves the sagittal and lambdoid sutures asymmetrically and severely. The affected person is usually short, obese and neurodevelopmentally slow.
- Antley-Bixler syndrome: this is also a rare type of synostosis where there is involvement of coronal and lambdoid sutures, with dysplastic ears, radiohumeral synostosis, long tapering fingers and upper airway abnormalities.
- Jackson Weiss syndrome: this syndrome was reported in the Amish population in 1976. There is craniosynostosis with midfacial hypoplasia and foot abnormalities.
- Muenke syndrome: this syndrome is so described due to its molecular abnormality, which was described in 1977 by Muenke. Here too, there is a coronal synostosis associated with FGFR3 mutation.

RADIOLOGY

Any unusual shape of the head at birth usually sets off a series of investigations which include CT scan of the head, MRI and X-rays of the skull, hands, feet and the cervical spine.

Plain X-ray of the skull is the most commonly used modality and is a good investigation to assess the primary condition and to confirm that there is no other contributory factor like dysplasia or just positional change in shape.

Skull X-ray AP and AP Towne's with lateral view is capable of showing sutural absence, parasutural sclerosis, sutural narrowing and heaping or enostosis and also to confirm whether the entire suture or only part of it is involved.

Computed tomography scan of the head and brain, with 3-D reconstruction, gives an even better picture of the skull bones and sutural fusion, along with the deformity of the sphenoid plate and base of skull asymmetry.

MRI scan is helpful in children with syndromic anomalies to define the airways, cranio-vertebral junction anomalies, hydrocephalus, venous sinus anatomy and any other cerebral or cerebellar anomalies as also the upper laryngo-pharyngeal airway.

Hydrocephalus may occasionally be associated with syndromic synostosis, like Apert, Crouzon or Clover-leaf syndrome, and can be picked up during the course of investigations. If decompression is carried out early, then hydrocephalus may regress, and if not, may require shunt surgery. The mechanism of hydrocephalus may be aqueductal stenosis or venous drainage obstruction in a crowded posterior fossa.

Many experienced units around the world have given up routine X-rays and repeated CT scans of the head in obvious cases of scaphocephalies, and unicoronal synostosis, proceeding for surgical reconstruction.

TREATMENT OF CRANIOSYNOSTOSIS

The treatment of children with this deformity is a challenging surgical task. As mentioned earlier, it requires close co-ordination with specialists in neurosurgery, plastic surgery, maxillofacial surgery, orthodontics, ophthalmologists, ENT specialists and, of course, medical specialists including psychologists, speech therapists, geneticist and trained nursing and paramedical staff. The outcome of recent research has further helped to device various ways for managing some of the more complicated of these anomalies, which are dynamic and continue to worsen with growth.

It is, therefore, prudent to identify the correct timing of surgery in order to achieve an optimum cosmetic effect. The earliest times that surgery can be considered in the various regions of the craniofacial skeleton are when that region completes its full growth potential and this is approximately as follows:

Cranium:	1 year (6 months for sagittal)
Orbits:	5 years and above
Upper maxilla:	9–12 years
Lower maxilla:	17 years and above
Mandible:	17 years and above.

The reasoning behind this careful timing is to minimise relapse of the deformity and repeat surgeries in many cases. It means that the final stage of facial correction can effectively be undertaken at the age of 17–18 years, whereas the unisutural purely cranial deformities can be done between 6 months and 24 months of life.

Apart from this, other factors which need to be considered and influence the timing of reconstructive surgery are: raised intracranial pressure, airway obstruction,

feeding difficulties, ophthalmic problems, cognitive and behavioural problems, disorders of dental occlusion and psychological problems.

In day to day practice, however, the majority of Apert's, Crouzon's, Pfieffer's and other pan sutural synostosis will require some kind of early intervention to release high ICP or respiratory obstruction or exorbitism and the risk of loosing vision.[6] Following this, they will require a definitive cosmetic reconstructive surgery later in life as a final touch.

SURGICAL INCISIONS AND PROCEDURES

The site and size of incisions is mainly dependant on the amount of exposure of the surgical area required. In almost all cranial exposures, a bicoronal incision extending from three fingers above the mastoid and behind the ear, going all the way across to a similar location via the vertex, is by far the best and gives the best exposure anteriorly, posteriorly and in both temporal regions and the best post-operative healed scar with minimally visible hair loss. For facial and midfacial exposures, there are subconjunctival, infraorbital and subciliary incisions as per the preference of the maxillofacial/plastic surgeon.

In sagittal synostosis, where the shape of head is long with a bit of frontal bossing and temporal hollowing, the attempt is to give it a rounded shape as far as possible. This surgery is ideally carried out in the first 6 months of life for the best results. Any corrective surgery for scaphocephaly after the age of one year becomes extensive and potentially more risky. The craniectomy performed is as shown in the Figures 1A to D.

In anterior unilateral plagiocephaly, a plan for surgical repair can either be a standard bifrontal craniofacial advancement or many do believe in repairing the affected side only. The aim is to achieve an overcorrection to make up for any future regression or relapse as far as possible. This is illustrated in Figures 2A to C.

In trigonocephaly, brachycephaly and anterior plagiocephaly, the aim is to remodel the fronto-orbital region by flattening the forehead and at the same time pulling it in front. Thus, a bifrontal bone flap is raised in one block and the supraorbital bar is taken separately, which includes the root of the nose, part of the orbital roof and some part of the lateral orbital wall. We have found it useful to artificially create a long root for the nose, to give a better post-operative result (Fig. 3).

In some pan sutural synostosis, where the ICP is very high, with evidence of papilloedema, but it is too early for frontal remodelling, a posterior vault decompression may be performed. This provides expansion of the cranium and adequate release of ICP. It also gives time for the surgeon to wait for further facial growth before any definitive craniofacial remodelling (Fig. 4).

In the syndromic varieties, where there is need for repositioning of the maxilla, a Le Fort III or Le Fort I corrective osteotomy is necessary.

The monobloc frontofacial osteotomy combines a transcranial frontal advance and extracranial Le Fort III midfacial advance into a single procedure, making use of external distraction frames. This procedure addresses raised ICP, exorbitism, respiratory passage compromise, maxillary hypoplasia and dental malocclusion, all

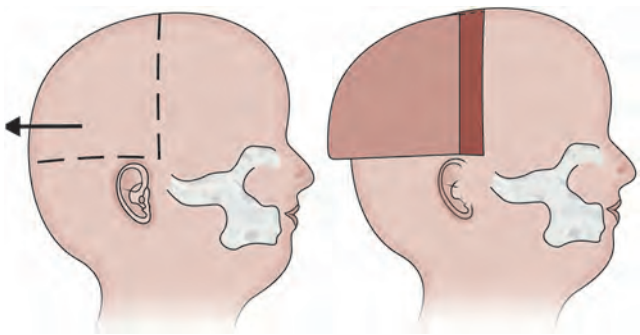

Fig. 4: Posterior vault expansion

together. This cannot be undertaken at very young ages, though there are reports of 3- and 4-year-old who have undergone this procedure, with considerable risk and morbidity (Fig. 5).

COMPLICATIONS OF SURGICAL TREATMENT

The complications of surgical treatment are divided into intra-operative, early post-operative and late post-operative stages.

Intra-Operative Stage

- Injury to the venous sinuses, severe bleeding and haemorrhagic shock
- Injury to the cerebral cortex
- Injury to the eyeball
- Acute brain swelling due to venous drainage compromise, either due to the position or discontinuation of a major emissary vein.

Early Post-Operative Stage

- Airway compromise due to local oedema
- Extra- and intra-parenchymal haematomas
- Fluid and electrolyte imbalance
- Visual compromise or ocular palsies
- CSF leak from the wound or rhinorrhoea, ottorrhoea
- Infection
- Failure of bony fixation.

Late Post-Operative Stage

- Exposure of miniplates and screws used for fixation
- Damage to roots of the teeth and devascularisation
- Soft tissue absorption and hollowing of temporalis muscle area
- Relapse of the bony fusion.

Discussing each of these complications is beyond the scope of this Chapter; it is recommended to refer to the textbook on craniosynostosis mentioned in the references. The dictum is to be extra careful in the pre-operative evaluation and anticipate intra-operative problems, so that, one is prepared for it already (Figs 6A to D).

19 Spinal Dysraphic States

Venkatramana NK

INTRODUCTION

Spina bifida literally means "spine in two parts" or "open spine".[46] Spinal dysraphism involves a spectrum of congenital anomalies resulting in a defective neural arch through which meninges and/or neural elements herniate leading to a variety of clinical manifestations.[31,46] They are divided into aperta (visible lesion) and occulta (with no external lesion).[31,46] Meningocele, myelomeningocele (Fig. 1), lipomeningomyelocele, myeloschisis and rachischisis are the usual names associated depending on the pathological findings. Meningocele (Fig. 2) by definition involves only the meninges with no neural involvement. The other lesions will have a variable extent of neurological involvement. Spina bifida aperta is usually associated with a skin defect with an impending risk of cerebrospinal fluid (CSF) leak constituting "open defects", whereas the occult forms will have full skin cover thickness. Both forms demand different approaches in their management.

PREVALENCE

The estimated incidence of spinal dysraphism is about 1–3/1,000 live births.[31,33] The prevalence of spinal dysraphism has been on the decline world over in the last few decades due to better nutrition for women, folic acid supplementation, improved antenatal care and high resolution ultrasound for prenatal screening and biochemical markers.

EMBRYOLOGY

The embryogenesis of the first 2 months of gestation can be divided into 23 stages. The neural plate is formed at stage 8 around the 18th day followed by neural folds and its fusion. The expansion of the neural tube and subsequent closure will be completed by 28th day. Open defects occur when the caudal neuropore fails to close. The secondary neurulation sets up the spinal cord formation. Defects at this stage will result in occult dysraphism, connecting the epidermis and the mesenchymal tissues leading to a variety of anomalies and tethered cord.[10,31,78,79]

Failure of primary neurulation leads to open dysraphism posing the risks of CSF leakage and exposure of the neural placode. The extent and severity of neurological deficit depends on the degree of malformation of the neural placode and also the level of the defect. The higher the level usually the worse is the prognosis. A spectrum of neurological abnormalities, like hydrocephalus, Chiari malformation, syrinx, gyral malformations,

Fig. 1: Myelomeningocele

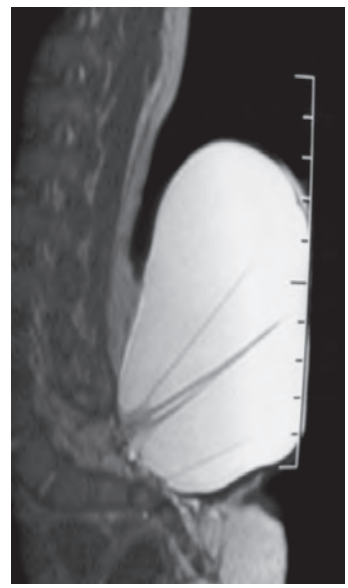

Fig. 2: Meningocele

skeletal malformations and urovesical defects, can be associated. In occult dysraphism, the overlying skin is intact but the spinal cord will be anchored to various tissues starting either from skin, subcutaneous tissue, adipose tissues or cartilage.

AETIOLOGY

The cause of spina bifida is multifactorial with both genetic and environmental factors playing a part. Recent information has stressed on the importance of maternal nutrition and folic acid supplementation, which have contributed to a major reduction in incidence.[79,87]

SYMPTOMATOLOGY

Open dysraphism presents with a swelling over the back which is noticed at birth. Symptoms are primarily referred to CSF leak or the exposed spinal cord. Since the skin over the swelling is poorly developed, it usually gives way during labour resulting in CSF leak, contamination and meningitis. Defects predominantly involve the thoracolumbar, lumbosacral, lumbar, thoracic, sacral and cervical in the order of occurrence. Incidence of high-cervical lesions is about 3.9%.[110] Neurological deficits include motor, sensory and sphincter dysfunction depending upon the severity and level of defect. In severe cases, hypotonic are flexic limbs, sphincter atonia with rectal prolapse may be seen. Chiari malformation presents with lower brainstem and lower cranial nerve dysfunction. The presence of a large head usually indicates hydrocephalus. The associated skeletal abnormalities are kyphosis, scoliosis and deformities of the long bones and feet, hemivertebrae, defective ribs, etc.

ASSESSMENT

The initial assessment of the newborn is extremely important preferably done by both a paediatrician and a neurosurgeon. Examination of the head and neck involves the assessment of head size, shape, skull bones and openness of fontanellae, lacunar skull defects and the size of the posterior fossa. Examination of the back needs assessment of the neural placode, level of the lesion, condition of the skin, extent of skin defect and associated deformities. Examination of the lower limbs for detection of the deformities of the foot and abnormalities of long bones is important. A detailed neurological examination is necessary to assess the level of motor weakness, sensory level and sphincter dysfunction.

PRENATAL DIAGNOSIS

Prenatal screening for neurological abnormalities is based on ultrasound performed routinely or oriented by maternal alpha fetoprotein (AFP) screening. It should be performed around 12, 22 and 32 weeks. Maternal serum screen can detect up to 80% of spina bifida and 90% of anencephaly.[11,17] Sonography may identify up to 90% of myelomeningoceles. Over the last few decades, the diffusion of routine ultrasound has changed the spectrum of the neonatal neurological malformations. Gross lethal abnormalities nearly always result in termination of pregnancy depending on the regional legal system. A growing number of more subtle abnormalities including midline or posterior fossa abnormalities are being discovered. But their postnatal outcome cannot always be predicted accurately, despite the use of foetal magnetic resonance imaging (MRI). Maternal serum screening for chromosomal abnormalities is also increasingly being used. Only in selected situations amniocentesis is contributory.[4,12,21,27,72,95,117]

RADIOLOGICAL ASSESSMENT

Radiological assessment should be done at the earliest depending on the clinical condition. Plain X-rays will reveal skull defects, spine deformities and bony anomalies. MRI is the investigation of choice to study the neural tissue abnormalities and also to assess the severity of hydrocephalus and Chiari malformation (Figs 3A to D). However, ultrasonography can be used to obtain quick information regarding hydrocephalus.[16,42,45]

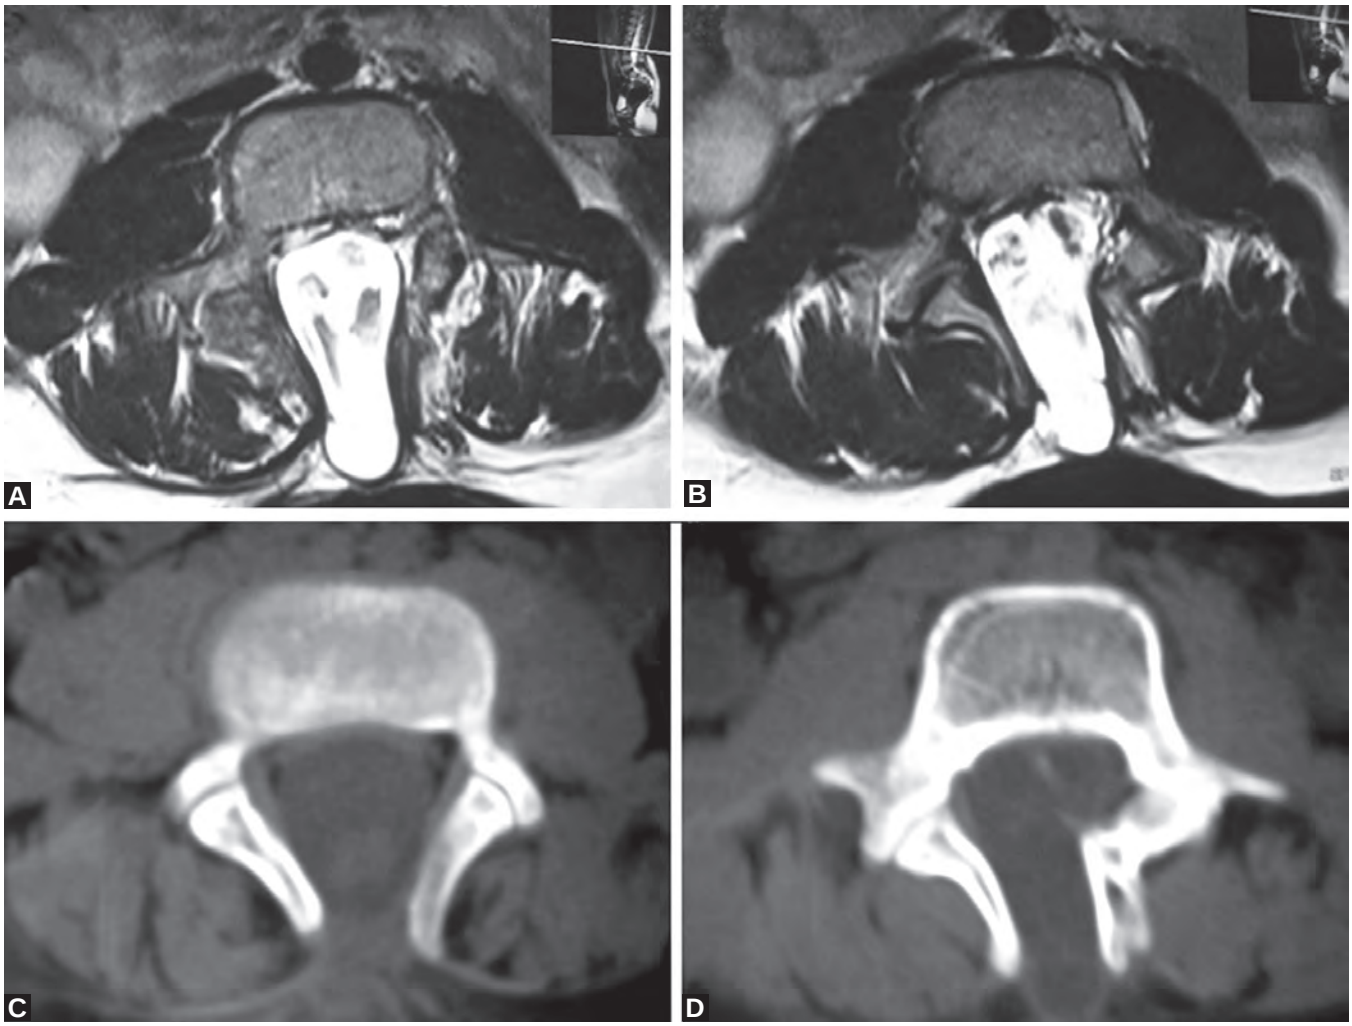
MANAGEMENT

Management of these children needs multidisciplinary approaches. Complete clinical evaluation and appropriate investigations are necessary. Parents need to be counselled and informed regarding the immediate as well as long-term management strategy.[24,25]

The management of a pure meningocele involves a simple repair, while that of a myelomeningocele or myelocele is prolonged, complicated and costly. The treatment does not begin or end with the surgical correction of the local defect, but begins from the moment of birth and continues till such time as maximum possible rehabilitation has been achieved. The total care of such a child requires collaboration between the neurosurgeon, orthopaedic surgeon, plastic surgeon and the urologist. The help of a team of physiotherapists and rehabilitation experts will also be necessary to give the child the best chance for self-sufficiency. Special educational facilities will be required as the child grows up.

SURGICAL TREATMENT

The aim of surgery is to free the placode from the surrounding abnormal skin and to reposition it into the spinal canal with reconstruction of the dura and coverings to prevent CSF leak and infection. The surgical technique depends on the size and the level of the lesion. The help of paediatric, orthopaedic and plastic surgeons may be necessary. Several attempts for maternal foetal surgeries to improve their outcomes were made. The role of foetal surgery for myelomeningocele is yet to be proved.[52,53]



Figs 3A to D: Spina bifida

PATIENT SELECTION

There is considerable controversy regarding selection of patients with myelomeningocele for surgery, i.e. who should be offered surgery and who should not. In the 1960s with the advent of aseptic techniques and antibiotics there was an initial period of enthusiasm when all patients were recommended emergency surgery within 48 hours.[108] Disillusionment followed with Lorber[70] and Ramamurthi[99] suggesting that patients with extensive paralysis, severe hydrocephalus, kyphosis and major associated congenital anomalies in other systems be left unoperated.

But as mortality figures reduced,[14,77] the mood has again changed with more and more surgeons in favour of early surgery.[101] Matson,[73] recognising the variable expression of this malformation, emphasised the importance of considering every child individually. His approach was to identify those who could live rather than identifying children who should be left to die. Though there is no definite method of prognosticating outcome, certain guidelines do exist. Major associated congenital defects of other systems, megalencephaly at birth, severe orthopaedic problems with gibbus at the site of dysraphism, dislocated hips[69] and poor general condition of the child are associated with a poor outcome. Total paralysis with incontinence does not appear to improve with time. It is worth remembering that severe cord lesions higher than the tenth dorsal level are not suitable for orthopaedic rehabilitation.[44] In some patients, one may operate to make nursing care easier or to lessen the social stigma.[2]

Socioeconomic circumstances play an important part in the decision regarding treatment, especially in the developing countries. These patients need repeated hospitalisation for treatment under various specialities. It may be kinder to the child and the family who cannot afford it, to deny operative correction of the myelocele in the first place.[99]

Timing of intervention primarily depends on the clinical condition of the child, and the impending risks. Surgery need not be done as a compelling emergency but should be undertaken as soon as it is practical.[94] In case of suspected meningitis, CSF infection or colonisation of the wound, prophylactic antibiotics and anticonvulsants will form the initial treatment. The child is nursed in an incubator and routine blood counts and serum electrolytes have to be monitored. Blood

grouping and cross matching is done for possible transfusion. Careful assessment of body weight is essential for intra-operative management. The newborn child with myelomeningocele should have saline dressings.[49] It is essential not to use corrosive agents, spirit or antiseptics indiscriminately over the open defects to avoid damage to the underlying exposed neurological tissue.

SURGICAL TECHNIQUE

To obtain successful repair, it is essential to study the surface anatomy and its relationships to the surrounding structures. At the apex of the myelomeningocele usually the flat neural placode is located and from its edge the remnants of the arachnoid membrane gets attached at the nerve root entry zone. From this junction the nerve roots emerge and exit through neural foramina located ventrally. They are seen through the transparent arachnoid membrane which is fused with the skin at the lateral edges of the lesion. The dura mater which is defective posteriorly is loosely adherent to the underlying soft tissue of the back and densely adherent to the bony structures underneath. Rostrally, the dura forms a tube and the neural placode continues into it, which leads to functional spinal cord.

The child is operated upon under general anaesthesia with endotracheal intubation in the prone position with the head and neck placed comfortably. The first step is to isolate the neural placode, while salvaging the nerve roots as much as possible irrespective of their functional status. It is essential that no skin element becomes buried in the repair to prevent the possibility of an implantation dermoid. A vertical midline incision is preferable. In a circumferential fashion, the arachnoid is lifted and the nerve roots are identified. This technique is continued all-round till the neural placode is completely free. The neural placode can then be inverted and sutured. The dura is dissected from the underlying soft tissue. The dural closure needs to be made watertight with a graft, if necessary. The overlying skin is dissected from the underlying fascia and musculature, mobilised and approximated. If necessary, relaxing incisions or flaps may be used to close larger defects. Kyphotic deformity or gibbus can pose special problems. Reigel[100] and Sharrad[107] et al.[109] had advocated resection of the kyphus with primary spinal fusion at the time of surgical repair.[100,109] When the dysplastic skin (Fig. 4) is large causing larger skin defects, balloon tissue expanders can be used to enlarge the normal skin area and reflected subsequently to cover the defect (for detailed operative technique, please check Textbook of Operative Neurosurgery).

Post-operative care is equally important. The child is nursed in the prone position, and the wound is protected from faecal and urinary contamination. Symptomatic hydrocephalus or ACM needs to be treated simultaneously. Supportive nutrition and antibiotics are required. Adequate urological treatment can prevent future complications of the upper urinary tract.[1,8,9] Early management maintaining a low intravesical pressure and intermittent catheterisation with or without pharmacotherapy is beneficial, but urological management should ideally be based on and modified by the urodynamic studies.[1,8,9,18,40,41,56,71,80]

TETHERED CORD SYNDROME

Tethered cord syndrome has been defined as progressive neurological deficits from the restraint of spinal cord movement and traction due to either anatomical or physiological reasons. The advent of MRI and the present understanding of embryogenesis have led to the recognition of this syndrome more often in paediatric neurosurgical practice. The neurological deficits are insidious and progressive and may be motor, sensory, urorectal, pain and/or scoliosis.[11,29,53,118,121]

Embryogenesis

A diagnosis of tethered cord is made when the tip of the conus is below the level of the lower border of the L1 vertebral body. The ascent of the cord, which occurs throughout the embryonic, foetal and postnatal period requires a well-formed cord and a smooth meningeal covering. During neurulation, the ectoderm on either side of the neural plate comes close together as the neural tube closes. When neural tube fusion is complete, the ectoderm detaches on either side in an event called dysjunction and fuses. If, however, the dysfunction occurs before the neural tube closure is complete, or if the closure is faulty, mesenchymal cells gain access to the central canal of the neural tube. The mesenchymal cells then differentiate into fatty tissue to form a lipomyelomeningocele[90] which is essentially a mass of fat extending from the conus medullaris to the subcutaneous plane underlying an intact skin. All the manifestations of lipomyelomeningocele can be explained by this mechanism of embryogenesis.

The solitary thickened filum terminale, however, needs another explanation. If one recollects the complex embryogenesis of the filum terminale, with the very high possibility of a developmental error occurring, it is not difficult to explain the non-resilient, thickened filum terminale. An error in the canalisation of the caudal cell mass may be another explanation for the origin of a lipomyelomeningocele.

According to Marin-Padilla,[93] dural schisis is the basic defect resulting in the various forms of tethering, with a short thick filum terminale occurring as a secondary event. This is not supported by the occasional intra-operative observation of the cut ends of the filum terminale springing back on being divided, as well as the clinical improvement which occurs when the filum terminale alone is divided. Occult spinal dysraphism with tethered cord may be associated with anorectal malformations.[14,30]

Pathogenesis

It is the cord which is tethered, with the nerve roots lying lax and even loosely on either side. The effects of the tethering is maximum close to the site of tethering and when the tethering lesion extends over a distance the maximum effect is on the cord adjacent to the caudal end of the lesion, where the maximum stress lies. Here, it is physically elongated and functionally the most affected.

Tethered cord can result from a variety of conditions. This can broadly be classified into the following points:

- *Anatomical*: In anatomical condition, the conus is placed at a lower level than normal.
- *Physiological*: This is due to tight or thick filum. In this variety, the conus may be at the normal level but the movement of spinal cord is restrained resulting in neurological deficits and vesicle dysfunction called "non-neurogenic bladder".
- *Developmental*: This could be secondary to a variety of conditions like congenital anomalies, terminal lipoma, intra-spinal lipoma,[65,67] lipomyelomeningocele,[32] split cord malformations, sacral agenesis and other occult dysraphic states.
- *Post-operative*: Post-operative tethering that occurs after surgery for myelomeningocele or dermoid or recurrent adhesions from previous surgery often termed retethering.[119,120]

Clinical Features

The name tethered cord implies that the spinal cord is attached tightly to a congenitally abnormal structure in the lumbosacral area, as well as at the cranio-vertebral junction. With growth, the spinal cord is stretched between these two points, resulting in insidious and progressive neurological deterioration. The popular belief that the deterioration occurs mostly during the phases of rapid growth is not confirmed. During embryonic life, the spinal cord lies way down at the sacral segments and gradually the conus ascends and reaches the adult level to L1, as confirmed by ultrasonographic studies. In this pathological situation, the spinal cord is tethered to anatomical structures lower down, preventing the ascent of the conus in parallel to the vertebral growth. On the other hand, there is disproportionate growth between the spine and the spinal cord resulting in progressive traction. Normally, when a child bends forwards, there is an ascent of the spinal cord by one to two segments. The filum can be short and thick with a variable quantity of fibrous tissue making it tight and preventing such movement.

Several theories have been proposed to explain the neurological deterioration in tethered cord syndrome. With the ongoing stretching central fibres are subjected to traction injury, resulting in structural damage. Yamada et al. have shown that the mechanical stretching of the cord during physical activity leads to changes in intracellular respiration, reduction in cytochrome oxidase and shift in redox curves.[121] A third possible mechanism is by ischaemic injury. Traction and elongation of the spinal cord can compress the radial perforating vessels resulting in ischaemic damage. Once the neurological deficit occurs it is rarely reversible, therefore, it is important to treat them prophylactically.[88–90,92,104,121]

Symptoms

The predominant symptoms can be motor in the form of insidiously progressive distal weakness and spasticity, and sensory ones like sensory loss, paraesthesias and trophic ulcers. Neurovesical dysfunction is one of the commonest presentations, ranging from a minor bladder disturbance to frank urinary incontinence, occasionally associated with bowel movement dysfunction. At times, pain can be the major symptom. It may be radicular or funicular, low back or calf muscle pain. The scoliosis due to tethering is a much debated issue, but there is enough evidence to suggest that it is due to the tethering.

Neurological Examination

A detailed neurological assessment is mandatory. Neurocutaneous markers, like tuft of hair, nevus, dysplastic skin, angiomatous patches, lipoma, dermal sinus, presence of human tail and absence of gluteal folds are strong indicators.[18,20] Neurovesical dysfunction, leg pain, scoliosis, motor or sensory deficits, should prompt the clinician to look for possible tethering even in the absence of cutaneous markers (Figs 5A to D).

Tethering being a congenital phenomenon, these children often present to their paediatricians, with vague leg pains; to orthopaedicians with gait disturbance and deformities; to urologists with bladder symptoms, frequent or persistent bed wetting and finally to neurosurgeons when the neurological deficits become overt. Hence, awareness about this syndrome among the medical fraternity is necessary.

Figs 5A to D: (A) Lipoma with tuft of hair. (B) Tail. (C) Tuft of hair. (D) Dysplastic skin

The diagnosis should be based on a high index of clinical suspicion, a detailed neurological examination and investigation for confirmation. MRI is the choice of investigation to identify the anatomical location of the conus and associated abnormalities (Fig. 6). The classical dorsal displacement of the conus with a large, ventral CSF space is often suggestive. Early appearance of lumbar potentials in SSEP has been found valuable, though often difficult to record in children.[13,55]

Indication for Treatment

Any child with progressive neurological deterioration of motor, sensory or urinary function should be treated.

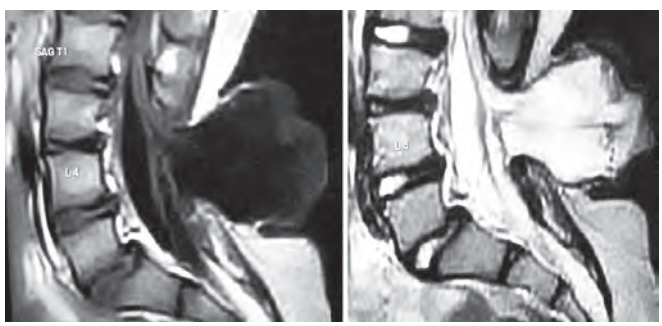

Fig. 6: Imaging of tethering

Pain, spasticity, gait abnormality, persistent or progressive scoliosis are the other indications. Knowing the mechanisms of neurological deterioration prophylactic surgery is logical. If the neurological deficit has already occurred, surgery should be done as soon as the diagnosis is established.

The Principles of Surgery

- Complete untethering of the spinal cord.
- Proper dural reconstruction with adequate CSF space around the spinal cord to prevent retethering.

Retethering

A theoretical risk of retethering exists after the treatment of any tethered cord (Fig. 7) or some of these complex anomalies. Every known precaution should be adopted to prevent such a possibility. This includes complete untethering of all the contributory structures, proper concealing of rough and possible adhesive surfaces by pial sutures, laminectomy to accommodate the thickened cord and to facilitate upwards movement, duraplasty to create a reservoir of CSF around the repaired structures and epidural fat grafts to prevent fibrosis. Some studies reported the advantage of nursing the child in the prone position post-operatively. Subtle neurological worsening

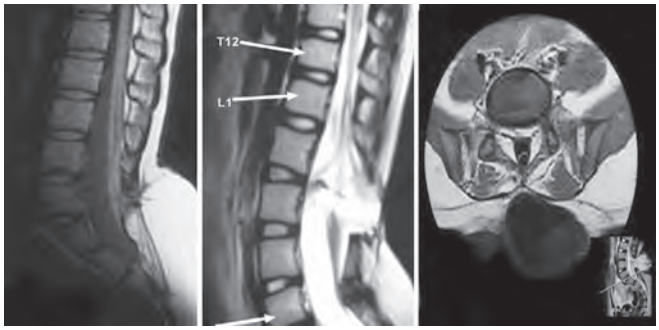

Fig. 7: MRI of tethered cord

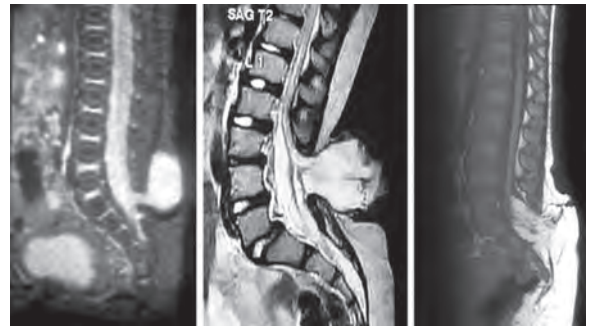

Fig. 9: Lipomyelomeningoceles

or progression of deformities should be looked for during follow-up. MRI should be repeated at the earliest suspicion. At present, there is no foolproof investigation to demonstrate retethering. MRI in the prone position to demonstrate CSF dorsal to the conus has been suggested. Serial electrophysiological and urodynamic studies seem to be indicative. Till such time, clinical diagnosis remains the gold standard. All symptomatic children suspected to have retethering (Fig. 8) should be re-operated to prevent further deterioration. But surgery on purely radiological suspicion for retethering is controversial.

Lipomyelomeningocele

Lumbosacral lipomyelomeningocele (Fig. 9) is a subcutaneous fibro-fatty mass that traverses the lumbodorsal fascia causing a spinal laminar defect, penetrating the dura and tethering the spinal cord. Lipomas are one of the important causes of spinal cord tethering almost all of them have a low lying conus. The term lipomyelomeningocele is used despite the overlying skin being normal. They arise from a disorder of embryogenesis. They usually consist of a single cell type but may have fibrous tissue, muscle cells, neural tissue and a variety of other cell types that arise from all the embryonic layers. The incidence is approximately one in 4,000 births in the USA with a slight female preponderance. True incidence of terminal lipomas is not known. MR studies have shown that 13–26% of lesions account for tethering.[5,15] Symptoms and signs are mainly related to the traction on the lower spinal cord, leading to motor deficits, sensory disturbances, spasticity, urodynamic, urorectal dysfunctions and skeletal deformities.[36] The pathogenesis and natural history of these complex anomalies are not clearly understood. But it is certain that almost all deteriorate in their neurological status over course of time. Proper treatment at the appropriate time will prevent neurological deterioration. Surgical treatment is complex as they pose several challenges and there is a risk of neurological deterioration. A variety of factors can influence the outcome. Anatomical features like size of the lipoma, location (midline or paramedian), wide bony defect, defective muscles and fascia and poor cleavage at the neurolipomatus junction. Physiological factors like degree of traction and the ability to withstand the effects of traction. Pathological factors like vascularity of the fibrolipomatous structures and associated anomalies.[64,66,115]

Lumbosacral lipomyelomeningoceles have been classified by Chapman[23] as dorsal, transitional and terminal types and by Aris as of five types: dorsal, caudal, combined, filar and lipomeningomyelocele.[6]

In Dorsal variety, the lipoma (Fig. 10) enters into the segment of spinal cord dorsally through a fibrofatty pedicle below which normal cord and dura exists. Transitional variety is essentially a dorsal type which covers the entire conus and extends up to the filum. Distally no normal cord exists, whereas in the terminal variety (Fig. 11), normal looking conus ends in the lipoma through a dural defect and all the sacral roots will be cranial to the lipoma.

Diagnosis in 90% of children is made by the presence of a visible lipomatous mass in the midline on the

Fig. 8: Retethering

Fig. 10: Lipoma

Fig. 11: Terminal lipoma

back or a cutaneous marker. Associated hydrocephalus or cranial anomalies are extremely low though the other spinal anomalies can be associated. MRI (craniospinal screening) is the choice of investigation for a comprehensive assessment. The surgical treatment is aimed at complete untethering and prevention of retethering of the cord. Based on the progressive irreversible worsening, prophylactic surgery has been recommended by many authors.[28] There is no controversy regarding lipomas of the filum terminale. Reports from Paris group with 18.7% delayed deterioration on 10 year follow-up of asymptomatic conus lipomas and from the Osaka group stating 88% of their children operated upon prophylactically deteriorated with time, has created further debate on this issue.[5,28,62,74,96,113]

Surgical Technique

Broad principles include vertical skin incision, dissection of subcutaneous lipoma up to the fascia, excision of extraspinal component of lipoma, identification of upper and lower intact laminae and performing laminectomy, identification of normal dura above and below and separation of dural tube from the thoracolumbar fascia all round. Then dural opening (circumferential) around the fibro-fatty stalk, removal of intradural lipoma, gentle dissection of the fibro-fatty pedicle up to the neural structures over the dorsal surface of cord and removal of fibrous tissue up to the neurofibrolipomatous junction, removal of other fibrous bands and finally detachment of the filum. The spinal cord should eventually be made free from five structures: skin, subcutaneous tissue, thoracolumbar fascia, dura and filum terminale to achieve complete untethering.

All known precautions to prevent retethering, like pial, closure to cover the raw dorsal surface of the cord and duraplasty to enlarge the subarachnoid spaces and to facilitate free CSF circulation around the repaired surface of the cord are to be adopted. Replacement of free fat over the dura will fill the dead space, protect the soft tissue, prevent CSF leak and prevent skin edge necrosis.

Surgery for terminal lipomas is relatively easy. One needs to separate the dura from the lipoma and disconnect the neural tissue at the neurolipomatous junction which is often clearly evident.[47,63,76,85,86,93,111,115,116]

Myelocystocele

It is an occult form of spinal dysraphism with a localised, cystic dilatation of the central canal of the spinal cord herniated through a posterior spina bifida. Terminal myelocystocele truly is an anomaly of the caudal cell mass associated with anomalies of the anorectal system, lower genito-urinary system and vertebrae such as anal atresia, cloacal extrophy, lordosis, scoliosis and variable degree of sacral agenesis. They constitute 4–8% of occult dysraphism and rarely occur in the lower thoracic region. The lesion consists of skin covered lumbosacral spina bifida, arachnoid lined meningocele directly continuous with the subarachnoid space and a low lying hydromyelic spinal cord that traverses the meningocele and forms a distal sac which does not communicate with the subarachnoid space. The MR appearance is distinctive and is characterised by trumpet like flaring of the distal cord central canal into an ependyma lined terminal cyst. Surgical correction cannot only release tethering but also prevent the complications.[31,75,94]

SPLIT CORD MALFORMATIONS

Split cord malformations (SCMs) (Fig. 12) are increasingly being recognised as one of the causes of tethered cord syndrome. They are defined as a form of occult spinal dysraphism, in which any part or entire spinal cord, cauda equina and filum terminale are divided into two lateral parts by a dorsal/ventral spur.[3] Renaming them as SCMs have reduced the conflict in terminology, though the pathogenesis of these complex anomalies still remains controversial. The diagnosis has become easy and certain with the advent of MRI. It is necessary to screen the entire spine in order to recognise all the associated anomalies and to plan the management strategies.

Split cord malformations are rare and complex conditions. In the recent years, MRI has renewed the interest in diagnosis, basic understanding and management of these anomalies.[3] Several terminologies were in vogue in literature like "diastematomyelia" (Olivier) and "diplomyelia" (Bruce) with a poor distinction. Pang et al. have proposed a unified theory and named them "Split cord malformations".[22,88,90] The most widely accepted theory about embryogenesis of this complex malformation was originally proposed by Bremer[14] and subsequently modified by Pang et al.[14,88] as "Unified theory of embryogenesis". The basic error appears to be development and persistence of accessory neurenteric canal (ANC). In the early weeks of gestation, the primitive neurenteric canal temporarily connects the yolk sac (endoderm) with the amniotic cavity (ectoderm). Simultaneously, an ANC appears and its persistence will result in a variety of malformations.[14,88] The persistence of the anterior end of

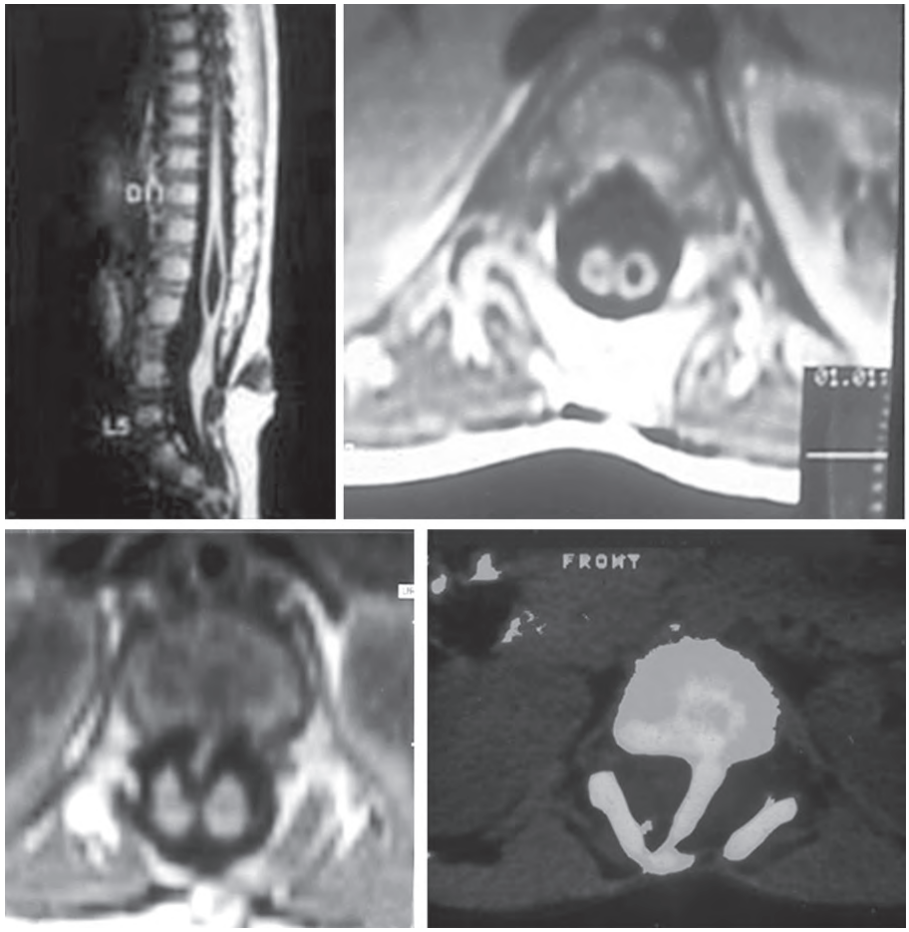

Fig. 12: Split cord malformations

this canal will result in intestinal malformations and of the posterior end in cutaneous malformations like angiomas, hypertrichosis, dermal sinus or dermoid, whereas the persistence of the intermediate part causes a split in the notocord and the neural placode. The division of the notocord then leads to formation of hemiverterbrae, bifid, hypertrophic, hyperplastic vertebrae or fusion of vertebral bodies or posterior elements. The division of the placode later on leads to the formation of two hemicords. If the mesenchyme surrounding the ANC contains precursor meningeal cells, it will result in the formation of dural and bony spurs within, leading to SCM type I. If meningeal cells are not incorporated then it is not involved in the formation of the dural sac and once the ANC disappears it will be transformed into an intradural fibrous band situated between the two hemicords, thus leading to SCM type II. The persistence of the ANC could occasionally interfere with the neurulation process leading to the formation of a meningocele or meningomyelocele, compounding these malformations further.[14]

The original description diastematomyelia denotes splitting of the cord with a bony spur extradurally. Spinal roots arise from the lateral aspect of the hemicords with no medial roots. Diplomyelia is supposed to represent true hemicords and, therefore, harboured in a single dural tube, with medial roots from each hemicord. While others believe that diplomyelia is an extremely rare condition, associated with split of the ventral and dorsal horns. Pang introduced the term "*split cord malformation*". SCM type I constitutes 40–50% of SCM.[88,90,91] Widening of interpedicular distances and hyperplastic laminae are usually associated.[38] The dural sac is always double with division of the spinal canal and cords by an extradural bony or cartilaginous spur. The spur can be anteroposterior, usually attached to the posterior surface of the vertebral body. Rarely, it can have a dorsal attachment to the spine. The spur can divide the canal into two symmetrical halves or can be slanting in the axial plane dividing the canal asymmetrically. In such situations, one of the hemicords can be hypoplastic. Harwood-Nash et al.[46] have reported such asymmetry in 50%. In the majority, the spur is located in the lumbar region and less frequent in lower thoracic, cervical and upper thoracic regions, respectively. Double level spurs have also been reported occasionally. The separation of the cords can extend over several segments before they reunite caudally and the spur is located in the crouch. SCM type II accounts for 50–60% of SCMs. In this anomaly, the dural sac is single with one spinal canal and two almost equal and symmetrical hemicords between which an anteroposterior fibrous band tethering the cords to the dura. Recently, the importance of these fibrous bands as the cause of symptomatic tethering has been highlighted by several authors.[3,35,37,89]

Surgical Technique

The child is positioned prone with underlying supports. A midline skin incision is made extending above and below the level of the lesion. Subcutaneous tissue and the paraspinal muscles are carefully separated. Usually, the widened interpedicular distance or thick posterior elements will assist as a landmark to locate the spinal segments involved. It is preferable to expose the normal laminae one level above and below. The laminae can be hyperplastic or fused. Laminectomy is started at the normal level and continued on both sides close to the pedicles in an encircling fashion, protecting the dura and preserving the facet joints. The central bony spur with its attachment to the lamina is isolated. The two dural tubes are identified and protected. The bony spur is gradually nibbled till its attachment after careful and adequate separation from dura. The dura is then opened in the midline at the normal level extending down elliptically on either side of the sleeve of the spur joining in the midline caudally. The arachnoid is also opened. The dural sleeve over the spur is then completely excised. The cords are inspected anteriorly and posteriorly and all the surrounding arachnoidal and fibrous bands are removed. After securing haemostasis, the dura is closed posteriorly in the midline converting it into a single dural tube. The anterior defect of dura need not be closed. In type II malformations, posterior bony elements almost look normal and hence a marker will be necessary. After laminectomy or laminotomy of the required levels, the dura is opened in the midline. The hemicords are inspected under magnification for the fibrous bands. The fibrous band is usually located ventrally between the hemicords. The band is released from its dural attachment. Other fibrous bands, if present, should be released. The filum is untethered and the dura is closed in the midline. In complex malformations, the other associated anomalies are also dealt with appropriately.[3,98,102,103,109,112]

COMPOUND OR COMPOSITE SPLIT CORD MALFORMATION

Usually these are associated with open dysraphic states. Various forms of split cord can frequently coexist in children with dysraphism, the so-called composite lesions. It could be type I or II or may be a combination at the same or at different levels. Occasionally, the division of the cord is not so clear but there may be a double central canal and duplicated dorsal or ventral horns. Diffuse structural disorganisation and dysgenesis is also known. Occasionally, the two hemicords are partially bridged known as Horse-shoe cord. Composite lesions are associated with other forms of occult dysraphism such as lipoma, dermoid or epidermoid, sinus tract or a teratoma.[48,50] The overall outcome is good in isolated SCMs in comparison to complex varieties. One should carefully evaluate these children to exclude polymalformation syndrome. Several bony and visceral anomalies are known to coexist.[51] Although the majority are diagnosed in infancy, symptoms can manifest at any age and become symptomatic by the second decade. The neurological symptoms can vary from pain, bowel and bladder dysfunction, motor or sensory deficits. Spinal deformity, asymmetry of the limbs, gait disturbance and trophic ulcers are the other associates. In older children pain (lumbago or lumbosciatic) and paraesthesias are more common.[58,68,82] One should search for an anomaly of spinal alignment, midline cutaneous anomaly, enlargement of the spinal canal and an echoic mass in the spinal canal (spur) in prenatal ultrasound examination.[83] Plain X-ray, CT scan, CT myelography and MRI are the imaging modalities used. The radiological abnormalities have vividly been explained by Neuhauser et al.[84] Although some can be recognised on plain X-ray, high-resolution CT scan is sometimes necessary in identifying the spur. MRI is the procedure of choice to demonstrate the spinal cord, the dural sac, the spur, the location of the filum terminale and other associated abnormalities. The filum terminale may be short and thick in 40%. The spinal cord at times is completely split into two separate filums. Hydrosyringomyelia, dermal sinus, dermoid, epidermoid or lipoma can be associated. The CT and MRI can be complementary in increasing the diagnostic accuracy. Urodynamics also forms an important aspect of evaluation to assess the bladder function.[3,7,8,46,58]

DERMAL SINUS

Congenital dermal sinuses (Fig. 13) are a unique form of occult dysraphism presenting with meningitis, tethering or neurological compression with an incidence of one in 1,500 births. The dermal sinus tracts are lined by squamous epithelium and may present anywhere in the midline from the lumbosacral region to the occiput or nasion. Despite an innocuous external appearance the tract may extend over several spinal levels before entering the dura and getting attached to the filum or the spinal cord. Dermoid and epidermoid nodules are frequently associated with these tracts. The small sinus osteum is

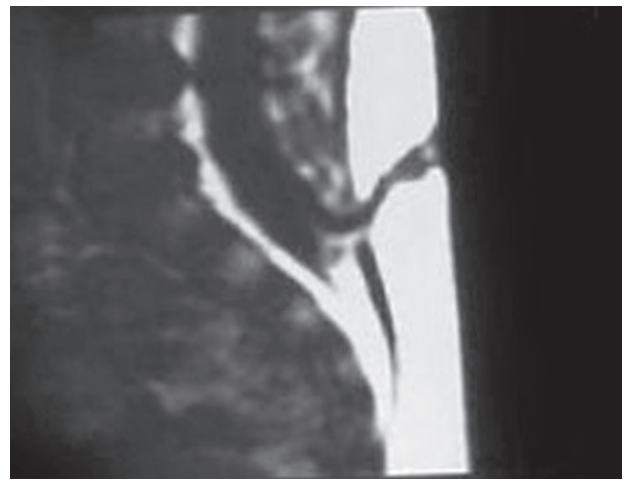

Fig. 13: Dermal sinus

quite often overlooked unless a discharge is noted by the parents. The neurological examination is nearly always intact. The MRI is diagnostic. Embryologically, the formation of the dermal sinuses may reflect incomplete dysjunction. Focal, incomplete separation of the cutaneous ectoderm from the neural ectoderm during the 4th week of foetal development retains the adherence of these layers. Altered dysjunction can lead to dermal sinus terminating in the subcutaneous tissues or may extend to an intramedullary location. The most common location is the lumbosacral area. Thoracic and cervical dermal sinuses are present in 10%. These are usually in the midline providing a portal for infection leading to meningitis or intraspinal abscesses. The most common organisms are *Staphylococcus aureus* and *Escherichia coli* followed by *Proteus* species and anaerobes. Multiple organisms may be cultured. Recurrent meningitis is one of the classical presentations. Neurological examination is normal except in situations where the dermoid or epidermoids leading to cord compression. The treatment includes antibiotics and complete surgical excision of the sinus tract and the associated lesions. Incomplete removal is the usual cause for recurrences.[26,39,54,66,81,97,114]

SYNDROMES OF THE TETHERED CORD

Tethered cord syndrome may occur with the conus in normal position with or without associated neurocutaneous markers. These children usually present with hyper-reflexic neurogenic bladder which was earlier referred to as non-neurogenic bladder. Urodynamic studies often reveal detrusor hyper-reflexia. There is growing evidence that sectioning of the filum improves the bladder function in 96% of patients.[59,60]

TETHERED CORD SYNDROME IN ADULTS

Though unusual, but has a well established entity. The later onset of presentation may be related to the cumulative effects of repeated microtrauma. Distinct precipitating events preceding the symptoms like heavy weight lifting, trauma and lithotomy position have been described in 60%. In many respects it is similar to the paediatric population except that the incidence of low back pain and leg pain is significantly high in adults. MRI is diagnostic though indications for surgery are still controversial and not clear. The majority improve with proper surgical sectioning of the filum.[19,43,59,71,89]

NEUROGENIC BLADDER WITH CONUS AT NORMAL POSITION

These children usually present to the urologists with urinary incontinence and/or associated complications. Tethered cord syndrome has been postulated as a cause of neurogenic hyper-reflexic bladder even in the presence of a conus medullaris at a normal position. These conditions were earlier coined by different names like non-neurogenic–neurogenic bladder. It usually presents in children less than 10 years. They do not have associated regional, neurological or vertebral anomalies. Urodynamics are highly suggestive. Release of filum terminale has shown significant improvement in their bladder control and also the urodynamic abnormalities. Selcuki et al. described 96% improved bladder function.[34,57,61,105,106]

20 Hydrocephalus

Venkatramana NK

INTRODUCTION

Hydrocephalus is a condition wherein excess of cerebral spinal fluid (CSF) accumulates within the ventricular system of the brain, leading to increased intracranial pressure (ICP). This condition apparently can result from various conditions that can affect a foetus, infant, child and adult.[50] Numerous definitions of hydrocephalus have been proposed, the summary of which indicates an underlying imbalance between the production of CSF and its absorption.[60] Although over production of CSF as a cause of hydrocephalus is well recognised in association with choroid plexus papillomas, these are rare tumours in clinical practice.

HISTORY[14,59]

Hydrocephalus has been recognised for centuries. Accumulation of fluid in various intracranial compartments was recognised by Hippocrates (BC460–377) and Claudius Galen (130–200AD).[24] The cerebral ventricles have interested and fascinated physicians for a long time. They were thought to be the seat of the human spirit "pnuema animolis". The large head was attributable to "water on the brain". The first description of internal or ventricular hydrocephalus was made by Rhazes (850–923 AD). However, the first morphological description of hydrocephalus with anatomical enlargement of the ventricles leading to damage of the brain parenchyma was by Andreas Vesalius (1514–64). Jean Louis Petit (1664–1750) gave more complete descriptions and Giovanni Morgani (1680–1771) described the clinical features of a bulging fontanelle and sutural widening in paediatric hydrocephalus. The studies of Thomas Willis (1621–75) facilitated the understanding of the ventricular system and CSF pathways. For the first time he proposed the choroid plexus as the site of CSF production and also introduced the concept of absorption into the venous system via the meningeal "glandules" presumed to be the arachnoid granulations. Franciscus Sylvius (1614–72), Alexander Monroe (1733–1817) and Francois Magendie (1783–1855) have made important anatomical contributions. Finally, Key and Redzaus (1876) established the modern concept of CSF circulation. At this stage, the diagnosis and management was not clear leading to high mortality. Dandy and Blackfan (1913) further contributed by developing experimental models of hydrocephalus and created a means of classification, differentiating between the non-communicating (obstructive) and communicating forms with distinct possible treatment strategies. The treatment options were extirpation of the choroid plexus, removing obstructive pathologies or creation of conduits to drain CSF from the intracranial compartment. The history of the treatment of hydrocephalus has been dealt with in detail by John Scarff in 1963. Dandy in 1922 proposed third ventriculostomy for obstructive hydrocephalus. CSF diversion included planting the ureter into the spinal theca following nephrectomy, thus draining CSF to the bladder. Other surgical procedures include Torkildsen's procedure of draining the lateral ventricle into the cisterna magna and ventriculocisternostomy in aqueductal obstruction. A flood of operative techniques for the diversion of CSF came into use since 1939. In the 1950s, synthetic, biologically tolerated polymers, particularly silicone elastomer became available and thus heralded the shunt era of treatment of hydrocephalus. Meanwhile, advancement in optics and endoscopes popularised endoscopic third ventriculostomy, as originally described by Mixter.

EMBRYOLOGY

The ventricular system develops from the corresponding vesicles of the developing neural tube. The cavity of each telencephalic vesicle becomes the lateral ventricle and that of the diencephalic becomes the third ventricle. The cavity of the rhombencephalon forms the fourth ventricle. Its continuation into the spinal cord is the central canal. During development, each lateral ventricle is a spherical space within the telencephalic vesicle and with the forward and backward growth the ventricle gets elongated antero-posteriorly. The posterior end of the telencephalic vesicle now grows downwards and forwards to form the temporal lobes, making the ventricles "C" shaped. Finally, the occipital horns grow backwards. The approximation of the two growing telencephalic vesicles makes the medial walls of the lateral ventricles appose each other. The floor of this group becomes the roof of the third ventricle and its lateral invagination forms the choroidal fissure. A fold of pia mater extends into this fissure, forming the telachoroidea. A bunch of capillaries develop within this fold leading to the formation of the choroid plexus.[27,29,50]

CEREBROSPINAL FLUID PRODUCTION AND ABSORPTION

The majority of CSF production is by the choroid plexus, contributing 70–80% of the daily volume. A small proportion of CSF may be produced from the ependyma and brain parenchyma. CSF production occurs by a combination of filtration across the endothelium and active secretion of sodium by the choroidal epithelia. Although the cerebral perfusion pressure and ICP do appear to have some effect on CSF production, it is largely independent of these pressures under physiological conditions. CSF which is largely formed in the lateral ventricles passes through the foramen of Monroe into the third ventricle and reaches the fourth ventricle through the aqueduct of Sylvius and then presumably exits through median foramen of Magendi and the lateral foramina of Luschka. According to Weed[68] the formation of CSF creates dissection of the intercellular space of the meninx primitiva to form the subarachnoid space. From the subarachnoid space CSF reaches the parasagittal arachnoid granulations and part of it goes down the spinal subarachnoid space.[68]

Cerebrospinal fluid is produced at the rate of 0.33 ml/min, approximately 500 ml/day. The total volume of CSF varies with age and in adults is 100–150 ml of which 15–25 ml is contained within the ventricles. The mechanism of absorption of CSF has been extensively investigated. Direct absorption from the brain parenchyma, choroid plexus and by the lymphatic channels in the region of the cribriform plate has been postulated. The arachnoidal villi and granulations contribute to the maximum absorption. They are the herniations of arachnoidal tissue into the dural venous sinuses. Two mechanisms have been proposed. The "closed" mechanism, where the villi are blindly diverticulated and absorption occurred by a process of seepage across the endothelial covering. The open mechanism indicates the presence of channels across the villi, opening and closing in a valve like manner permitting unidirectional flow of CSF. Tripathi and Tripathi have proposed a transmembrane transport mechanism, consisting of vacuoles carrying CSF across the endothelial layer. Recently, the role of CNS microcirculation in the absorption of CSF is contributing to the understanding of the pathogenesis of hydrocephalus. As these mechanisms are not still clear, we are forced to follow our understanding and classification based on traditional concepts of CSF circulation.[50,62]

AETIOLOGY AND PATHOPHYSIOLOGY OF HYDROCEPHALUS

The incidence of congenital hydrocephalus is about 0.2–0.5/1,000 live births. A higher incidence has been reported in elderly primiparus mothers. It can be associated with variety of physiological and pathological conditions.[11,12,60] An obstruction at any point in the CSF pathway may result in hydrocephalus. Traditionally, obstruction within the ventricular system is called noncommunicating hydrocephalus and when the impairment is in the circulation through the subarachnoid space or absorption to the venous system, it is called communicating hydrocephalus. Wherever the aetiology is known, it is further divided into congenital and acquired forms. The aetiology of congenital hydrocephalus remains obscure. An inheritable form of aqueductal stenosis has been described in males (X-linked hydrocephalus). The other mechanism of hydrocephalus is over production, seen in papilloma of the choroid plexus.

Rekate has classified hydrocephalus based on CSF flow obstruction. Impaired absorption is another mechanism where venous sinus occlusions, vein of Galen malformations and developmental anomalies like craniostenosis with malformations of the skull base can lead to the development of hydrocephalus. Absence or disease of the arachnoidal villi, resulting in disturbance of absorption can also result in hydrocephalus.[67]

CLASSIFICATION

Based on the results of their neutral phenosulphonaphthalein tests, Dandy and Blackfan subdivided hydrocephalus into two groups.[10] If the chemical injected into the lateral ventricle was recovered within 20 minutes from the spinal subarachnoid space, the hydrocephalus was termed "communicating", implying a patent communication between the ventricles and the subarachnoid space. If there was no recovery, the hydrocephalus was termed "non-communicating" or obstructive. With present day radiological, computerised tomography (CT) and magnetic resonance imaging (MRI) techniques, it is possible to localise with accuracy the exact site of blockage to the flow of CSF. Hence, a more helpful classification is as follows:

1. The hydrocephalus may be due to:
   A. Over production of CSF (a rare entity)
   B. Obstructive: wherein there is obstruction to the flow of CSF in the
      - Lateral ventricles
      - Foramen of Monroe
      - Third ventricle
      - Aqueduct of Sylvius
      - Fourth ventricle
      - Subarachnoid spaces
   C. Absorption defect
2. Based on the site of blockage to the CSF flow the hydrocephalus may be:
   A. Monoventricular or unilateral
   B. Biventricular (both lateral ventricles)
   C. Triventricular (third and both lateral ventricles)
   D. Panventricular (fourth, third and both lateral ventricles)

Depending on the exact aetiology, a secondary classification could be added under the following headings:[35]

1. Congenital
2. Traumatic
3. Inflammatory
4. Neoplastic
5. Degenerative

Fig. 1: Setting sun sign

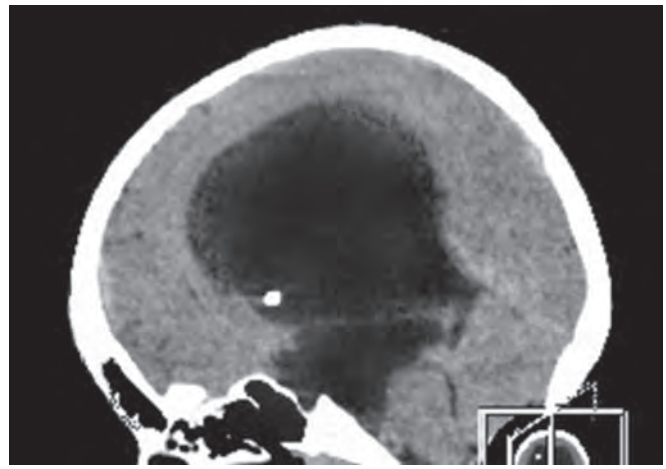

Fig. 2: Sagittal reconstruction CT scan of the brain in a patient with aqueductal stenosis

CLINICAL FEATURES

The presentation of hydrocephalus differs in the case of the neonate and infant compared to the older child or adult. Prior to closure of the cranial sutures and obliteration of the fontanelle, hydrocephalus results in disproportionate head growth. Thus, over the first 2–3 years of life, measurement of the occipito-frontal circumference and plotting this on a centile chart provides a simple and sensitive test. Wherever possible, sequential measurements (corrected for gestational age) should be obtained in order that the trend of head growth in relation to the centile lines can be demonstrated. Clinical symptoms are often subtle and include general irritability, poor feeding and slow attainment of milestones. In addition to head size, clinical signs include bulging of the fontanelle, separation of the cranial sutures, prominent scalp veins and sun-setting appearance of the eyes (Fig. 1). This latter clinical sign is attributed to pressure on the mid-brain tectum by CSF in the supra-pineal recess. Papilloedema can be difficult to diagnose in the infant and indeed is not uncommonly absent in infantile hydrocephalus and so is an unreliable sign in this context.

In older children and adults, the classical symptom complex of raised ICP, headache, vomiting and drowsiness is more likely to herald an underlying diagnosis of hydrocephalus. Where hydrocephalus has developed insidiously, cognitive impairment, poor concentration and behavioural changes occur. Visual obscurations and papilloedema are more common than in the younger age group. In both groups of patients, the presence of bradycardia, hypertension and irregularities in breathing pattern imply critical elevation of ICP and should be treated promptly.

INVESTIGATIONS

In the neonate, the supratentorial ventricular system can be reliably evaluated using ultrasound. This is the imaging modality of choice in the investigation and monitoring of the infant with an open fontanelle. Hematomas or other ventricular masses responsible for hydrocephalus can also be identified. Ultrasound provides a non-invasive and readily available tool for both diagnostic purposes and, by means of sequential studies, a way of charting changes in ventricular size.

Plain X-rays of skull may give an indication. A large skull with different shapes of the vault, sutural separation, cranio lacunae, flat anterior cranial fossa and thinning of vault bones may be seen. Sellar changes and beaten silver appearance may be seen as a sign of raised ICP. A small posterior fossa is often associated with aqueductal stenosis and a large one might suggest Dandy Walker cyst. Multiple calcifications may be an indication of infectious aetiology. Ventriculography was the gold standard during yester years and can demonstrate the size of the ventricles and also the site of the obstruction. It is still valuable in evaluating CSF dynamics. Cerebral angiography is not a usual investigation except in vein of Galen malformations and major venous anomalies. However, hyperplasia, occlusion and elongation of cerebral arteries are usually seen. The venous angle seen in the venous phase is an indicator of the degree of hydrocephalus.[3,48]

Computerised Tomography and Magnetic Resonance Imaging

In order to more fully evaluate the entire ventricular system and investigate the underlying aetiology of hydrocephalus, CT or MRI scanning is required (Figs 2 to 11). Clearly, there is a range of normal ventricular size and, indeed, ventricular size changes with age, rendering absolute measurements of ventricular dimensions of little use. No single radiological parameter can be relied upon to distinguish hydrocephalus from the other causes of ventricular enlargement mentioned above. Some features, however, are strongly suggestive, particularly when occurring in combination. Enlargement of the temporal horns of the lateral ventricles and enlargement of the third ventricle, commensurate with the enlargement

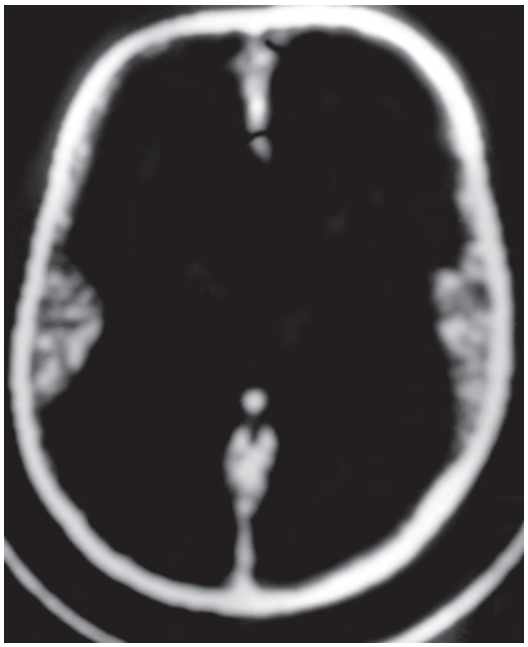

Fig. 11: CT scan of the brain showing gross hydrocephalus

of the rest of the ventricular system, are findings in favour of hydrocephalus. Obliteration of the basal cisterns and effacement of the cortical sulci further support a diagnosis of hydrocephalus. When the ventricles are under pressure, there may be transependymal flux of CSF into the periventricular parenchyma, particularly at the tips of the frontal, occipital and temporal horns. This appears as a low density on CT scan or a rim of high signal intensity on the T2-weighted MRI scans.

Volumetric Measurements

Several methods have been used to calculate ventricular volumes right from the days of pneumoencephalography. Linear measurements, planimetric methods, direct calculation of volume and CT planimetry were used in the past.[6,43,44,53,56] These are not of much clinical use.

Electrophysiology

Electroencephalography (EEG) and evoked potentials, although not of diagnostic value, have been studied usefully in evaluating clinical outcomes in hydrocephalus. The electrical activity has been correlated to the functional integrity of the cortical mantle. The EEG abnormalities could be focal or diffuse and are useful in detecting seizure discharges. The incidence of seizures in hydrocephalus can vary from 18.2-65% (Inees and Markendy). The other abnormalities include focal slowing, focal attenuation, multifocal paroxysmal discharges and generalised discharges.[9,52] Because of the close anatomical relationship of the posterior visual pathway, enlarged ventricles might contribute to visually evoked potential (VEP) abnormalities.[64] Similar abnormalities were reported in brainstem evoked potentials (Figs 12 and 13). These could be due to increased ICP, decreased cerebral blood flow, herniation of the upper brainstem or congenital anomalies, affecting the auditory or visual system and technically due to alteration of the medium, through which the electrical signals are conducted.[65,66] Brainstem auditory evoked potentials, when serially performed, help in identifying the structural abnormalities of the brainstem and can also be an early indicator of shunt malfunction.[13,45,63,65]

Natural History

Laurence suggested that the outlook hydrocephalus was not without hope and survival into adult life was between 20% and 30%. Among the survivors 73% were educable.[7,19]

TREATMENT

Treatment of hydrocephalus is indicated wherever the hydrocephalus is progressive and is associated with increased ICP.[41] A variety of treatments have been tried for hydrocephalus.

Medical Management

Medical measures may be appropriate under certain circumstances. Osmotic diuretics and acetazolamide

Fig. 12: Pre-operative brainstem auditory evoked response in congenital hydrocephalus

(inhibitor of carbonic anhydrase) may be useful, Carbonic anhydrase is present in the choroid plexus and is necessary for the formation of CSF. However, the effects are not sustained and, hence, it is useful only in benign intracranial hypertension or as a temporary measure in post-haemorrhagic hydrocephalus. Historically, compression bandage of the head has been advocated in neonatal hydrocephalus.[24,25] However, it has no place in the modern era.

Bypassing the site of obstruction to CSF flow by diverting the CSF, from the ventricular cavity to a site where it is readily absorbed, is the basic principle underlying the treatment of hydrocephalus. Based on this, shunt procedures have become the mainstay of surgical treatment even in severe hydrocephalus. Shunts can alter the process dramatically in infantile hydrocephalus. Neuroendoscopic third ventriculostomy is an important alternative in select situations. Numerous shunt systems have been devised and marketed.[16,17]

The list of procedures are mentioned here for the sake of historical importance (John E. Scarff)[10]

Therapy based on physiological principles
- a. Choroid plexectomy—Dandy 1918
- b. Third ventriculostomy—Dandy 1922.

Intracranial shunts using tubes
- a. Ventriculocisternostomy—Torkildsen 1939
- b. Ventriculo-transcallosal shunt anterior—Lazorthes
- c. Ventriculo-transcallosal posterior—Kleizer and Geuma
- d. III to IV ventricular shunt—Leksel 1949
- e. Ventriculo-ambiens shunts—Kluzer
- f. Ventriculo-chiasmatic—Feld
- g. Ventriculo-subdural—Forrest
- h. Ventriculo-mastoid—Nosik

Extracranial shunts
- a. Ventriculoatrial—Nusen, Spitz 1952
- b. Ventriculoperitoneal—Scot, Wyan 1958
- c. Ventriculopleural—Heile

Shunts into epithelialised ducts
- a. Ventriculocholecystostomy—Snuth et al.
- b. Ventriculosalpingostomy—Harsh
- c. Ventriculoileostomy—Narmann
- d. Ventricle to thoracic duct
- e. Ventricle to Stensen's duct—Parkinson
- f. Ventriculoureteral shunt—Matson

Lumbar SA to lumbar epidural—Hakim et al.
Theco-peritoneal shunt—Jackson, Snodgrass 1955
Miscellaneous
- To vertebral body—Radvon Teimn
- To Retroperitoneal space—Aboylker.

The shunt assembly comprises a proximal catheter located in the cerebral ventricle and a distal catheter draining into the selected site of CSF absorption, connected by a valve and reservoir incorporated into the shunt system. Numerous shunt systems are available in the market, although all of them have their shortcomings and are prone to similar complications. The proximal catheter has a blind ended tube with multiple side holes to facilitate CSF drainage. A number of devices are available like stylet, endoscope and navigation assistance to facilitate the placement of the catheter into the ventricle. The valve designs are based on differential pressures, fixed and programmable or flow control types. Four types of differential pressure valves are commonly

available: slit valves; midtre valves; ball and spring and diaphragm walls. The fixed valves have low, medium or high pressure alternatives. The setting defines the opening or, more commonly, the closing pressure of the valve. In order to overcome the limitations of the fixed-resistance valves, programmable valves have been developed whose operating pressure can be varied. An externally applied magnetic field is used to alter the position of an internal rotor and thus vary the pressure setting. The pressure gradient across the valve is the difference between the intraventricular pressure and the intra-abdominal pressure in the supine position. In addition, posture, gravity and the added hydrostatic pressure can alter the differential pressures. Anti-siphon device is a siphon controlled device and can be incorporated with the valves. This device houses a mobile membrane which moves in response to the pressure change. When the intrashunt pressure falls, the membrane will occlude the shunt lumen, thereby preventing over drainage. The peritoneal cavity is the most common site of placement of the distal catheter.[23] The alternate sites are the right atrium, pleural cavity and the gall bladder.

Indian Shunt Systems

The cost of most internationally available shunt systems are relatively high for people in most developing countries. To make matters worse, periodic revisions of shunt systems and associate infections adds to the cost. To overcome this problem, many innovative shunt systems have been designed in India. These include: Upadhyaya shunt system; Chhabra shunt system and Sri Chitra shunt system. Chhabra shunt systems include "Slit N Spring", "Z" Flow, Low Pressure, Medium Pressure and High Pressure. These valves were evaluated and compared with the Western systems and found to be equally effective. Low cost of these shunts is of major advantage.

Endoscopic Treatment

With the improvement in the optics and advent of modern neuroendoscopes, variety of treatments are now possible through endoscopic techniques. Popular among them is the endoscopic third ventriculostomy for aqueductal stenosis. In addition, septostomy, extirpation of choroid plexus, removal of paracytic cysts, removal of migrated shunts and arachnoid cysts can be treated effectively through neuroendoscopy (Figs 14 and 15).

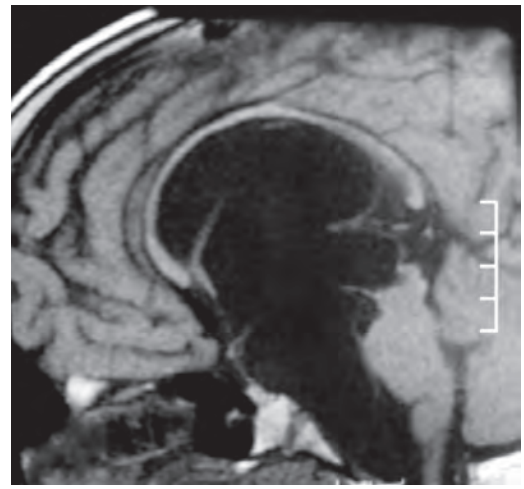

Fig. 15: MRI of the brain sagittal T1W image following endoscopic ventriculo cysto cisternostomy

Complications of Shunts

An extensive range of complications ascribable to shunt surgery have been reported in the literature. They could be classified as mechanical like shunt blockage, disconnection, migration and shortening of length. The flow related complications are CSF over drainage leading to subdural haematoma (Fig. 16), subdural collections, extradural haemorrhage (Fig. 17), low pressure headaches, secondary craniostenosis and cranial deformity and asymmetrical drainage can lead to trapping or isolation of a part of a ventricular system. The slit ventricular syndrome can also occur (Fig. 18). Complications related to absorption are intra-abdominal fluid collections, loculations and hydrocoele and perforation of the stomach,

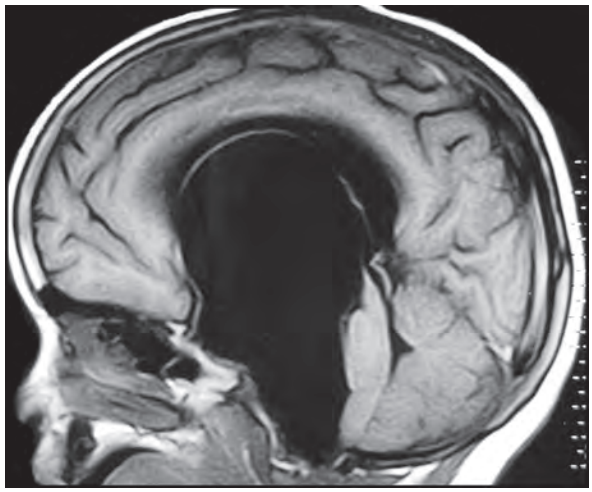

Fig. 14: MRI of the brain sagittal T1W image showing arachnoid cyst with hydrocephalus

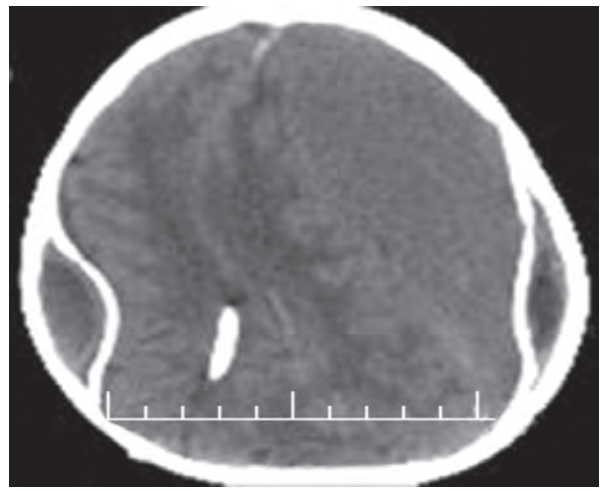

Fig. 16: CT scan of the brain showing bilateral subdural haematoma following ventriculoperitoneal shunt

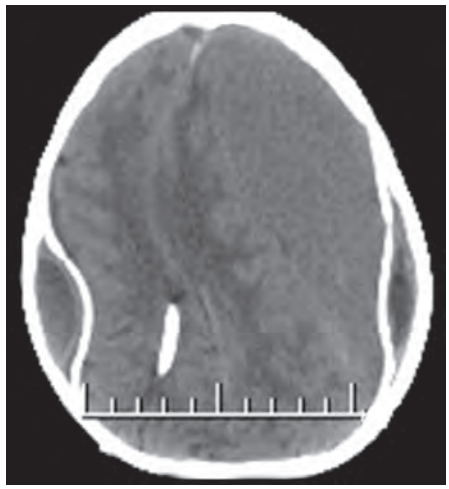

Fig. 17: CT scan of the brain showing bilateral extradural haemorrhage and contralateral subdural haematoma following ventriculoperitoneal shunt

large and small bowel, gall bladder and vagina have been described.[18,28,57]

Shunt infection is one of the most common causes accounting for significant morbidity and mortality. The reported series show the incidence to range from 5-15%. Some centres have reported an incidence as low as 1%. Although many factors appear to contribute to shunt infection, primarily it is assumed to be due to contamination of the shunt system at the time of surgery. Approximately 70% of shunt infections will present within 2 months and the remaining by 6 months of the surgical procedure and rarely beyond 6 months.[5,8] A high index of suspicion is maintained for symptoms like pyrexia, meningismus, irritability and lack of well being. CSF examination is needed to confirm the diagnosis and it may be obtained by the aspiration of the reservoir or from the ventricle. Appropriate antimicrobial therapy and management of the shunt system is necessary for a good outcome. The most common source

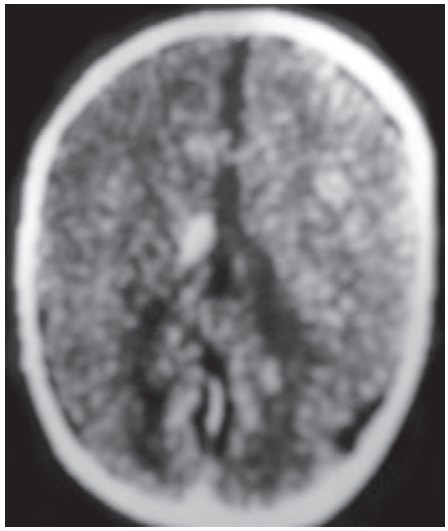

Fig. 18: CT scan showing slit ventricles following ventriculoperitoneal shunt

of infection is coagulase negative *Staphylococci* particularly *S. epidermidis*. *S. aureus* is also well recognised. *Enterococci micrococci* and *coryneforms* account for a significant proportion.[2] Controversy exists as to the need for immediate removal of the shunt system. The most common strategy is to remove the shunt and insert an external ventricular drain for the duration of antibiotic coverage and a fresh shunt inserted once the CSF is sterile. There are several reports indicating that antibiotics given at the time of surgery would reduce the incidence of infection. The role of prophylactic antibiotics, its type, duration and route of administration is still controversial. The more recent technique of antibiotic delivery has been to incorporate antibiotics into the silicon tubing which gradually leaks out and provides protection in the early post-operative period. Antibiotic impregnated shunts are now available; however, the long-term results need to be evaluated.[1,21,26,30,36,46]

Miscellaneous complications: seizures, metastasis, haemorrhage related to catheters and silicone allergy.[4,31,32]

INTELLECTUAL OUTCOME[15,22,37,40,49,51,54,55,58,61,64]

The determinants of intelligence levels and the pattern of intelligence in hydrocephalic children are not fully understood. Many studies have been published concerning the intelligence in both treated and untreated groups, but the criteria for the diagnostic studies, time of intervention and IQ assessment methodologies were different. Hagberg and Sgogrin defined an IQ of 90 as normal. But Lorber and Zachary used IQ greater than 70 as normal.[37] Foltz and Shurtlef described children as "functional", in whom the IQ is more than 75. The age, at which the shunt is placed, the type of hydrocephalus, status of shunt function, associated anomalies and consequent complications, have been incriminated as the responsible factors for a poor IQ. In addition, genetic, social, educational and economic backgrounds also seem to influence the intellectual outcome. However, reviews suggest that there is a decline in mortality and 50–70% incidence of normal IQ with an effective functional shunt. Nulscen and Rekate have correlated IQ with the width of the frontal cortical mantle and concluded that patients with a mantle of less than 2 cm are educable and the IQ was found to be normal in patients with a cortical mantle of more than 3 cm.[51,54,55] The type of hydrocephalus, degree of ventricular dilatation and number of revisions does not seem to affect IQ, as suggested by Dennis and Raimondi. Children with myelomeningocoele have additional problems due to the added physical disability. Untreated children have a mortality of over 80%. Gilllian, Soare and Raimondi reported an IQ of above 80 in 63% of their children with meningomyelocoele and hydrocephalus. IQ seems to have an inverse relationship between the location of the sac and sensory level, as reported by Lorber. The perceptual motor deficit in children with myelomeningocoele could be part of the

Table 1: Measurements of cortical mantle

Group	*Frontal in mm*				*Parietal in mm*			
	Right		Left		Right		Left	
	Pre-op	Post-op	Pre-op	Post-op	Pre-op	Post-op	Pre-op	Post-op
Mean	6.71	19.73	6.51	18.51	15.29	28.99	14.71	28.18
SD	9.27	11.84	8.30	10.21	10.86	12.04	11.13	12.72

disease entity or related to decreased stimulation due to disability or due to a combination.[58,61] Upadhyaya, in his Indian series, did not find any correlation between age at operation or nature of hydrocephalus, but the severity of hydrocephalus seems to correlate with the decline in the IQ. The prognostic factors reported are:

- Clinical—aetiology, degree of motor and sensory deficits, level of meningocoele, severity of hydrocephalus, seizures, ventriculitis and sex of the child
- Radiological—nature of the hydrocephalus, degree of ventricular dilatation and topography of the cerebral vasculature
- Peri-operative—age at the time of surgery, continuing shunt function and complications

Gessel's developmental schedules or Baley scales of infant development are the usual scales used for intellectual assessment in these children. Venkataramana et al.[64] conducted a prospective study on neuropsychological development in 40 children with hydrocephalus. Fifteen of them had associated myelomeningocoele. Only six of them had age appropriate neuropsychological development before surgery. Following shunt surgery, improvement in neuropsychological function was observed in all children. However, the extent of improvement in relation to mental age was significantly higher when CSF diversion was done prior to 6 months of age. Recovery of neuropsychological function seems to have a particular pattern and suggests some form of hemispheric functional lateralisation. It was observed that social and adoptive functions improvement correlated with increase in the right frontal cortical mantle and language development was related to increase in the left frontal and parietal cortical mantle. The motor development was related to both cortical mantles. Reconstitution of cortical mantle results from diminution of white matter oedema and due to reactive astrocytosis. Improvement in the functional status and neurological recovery is reversible only up to a stage. Children with head circumference of more than 50 cm and shunt intervention done beyond the age of 18 months have a higher incidence of subdural haematomas and their intellectual outcomes were uniformly poor , suggesting that beyond a stage the cortical mantle loses its ability to reconstitute, thereby leading to poorer outcomes.[15,22,40,49,64]

Table 1 demonstrates the increase in the cortical mantle thickness following shunt in the frontal as well as parietal cortices on both sides. This clearly demonstrates early shunt treatment reduces the ventricular volume with a corresponding reconstitution of cortical mantle.

Table 2 shows commonly used indices and its correlation with the psychological development assessed in the form of motor, language, adoptive and social functions. Of them post-operative improvement in the cella media index seems to be consistently correlating the motor improvement and to certain extent language and adoptive functions. On the contrary, the improvement in the anterior horn index has a high correlation with the improvement in adoptive functions, whereas the absolute third ventricular diameter seems to be correlating with language and social development.

The mean values of cortical mantle thickness in the frontal and parietal areas on both sides were correlated with the psychological development (Table 3). The results shows that the improvement in social and adoptive functions correlates with the increase in the right frontal cortex, language with the left frontal cortical thickness and the motor development with bilateral increase in the frontal cortices.

SPECIAL TYPES OF HYDROCEPHALUS

Post-Haemorrhagic

During embryonic development, the germinal matrix is the site of intense cellular proliferation. The germinal matrix is a large structure. It begins to involute by the end of 2nd trimester which is completed by 34 weeks. The blood vessels of the germinal matrix have immature connective tissue and lack auto-regulatory capacity. Due to these factors, premature infants born before 34 weeks have a high incidence of intracranial haemorrhage.

Table 2: Correlative values of ventricular indices with psychological development

	Psychological Development			
Index	Motor	Languages	Adaptive	Social
Cella Media Index	0.047	0.216	0.04	0.097
Ant. Horn index	0.139	0.182	0.211	0.512
Absolute III Ventricular diameter	0.096	0.143	0.201	0.4522

Table 3: Correlative values of cortical mantle thickness with psychological development

Cortical Mantle Thickness		*Psychological Development*			
		Motor	Languages	Adaptive	Social
Frontal	Right	0.483	0.277	0.451	0.468
	Left	0.454	0.403	0.019	0.295
Parietal	Right	0.257	0.180	0.261	0.422
	Left	0.355	0.352	0.317	0.337

Haemorrhage is reported in 40–45% of immature infants whose birth weight is less than 500 g and 20% of infants who suffer intraventricular haemorrhage will develop hydrocephalus requiring a shunt. The majority occurs within the first few days of birth and the clinical symptoms can be misleading due to prematurity. Serial ultrasound examinations are helpful, especially when the head circumference is increasing. A ventricular catheter with a subcutaneous reservoir is much safer in avoiding repeated cerebral punctures. Intraventricular fibrinolytic therapy instituted soon after the haemorrhage is detected may prevent chemical arachnoiditis and reduce shunt dependency.[33,34,38,42,69]

Meningomyelocoele

Hydrocephalus complicates open spina bifida in 85–90% of patients. It may manifest after closure of the meningomyelocoele, as the sac acts as a CSF sump. This is usually associated with Chiari malformation; it is preferable to treat hydrocephalus simultaneously to facilitate wound healing after myelomeningocoele repair.[39]

Aqueduct Stenosis

The growth of the tectum and tegmentum makes the lumen of the neural tube narrow in the region of the mesencephalon, leading to narrowing of the aqueduct of Sylvius. Aqueductal stenosis occurs in approximately 10% of children. Several theories exist regarding primary versus secondary forms of aqueductal stenosis. Communicating hydrocephalus with external pressure on the mesencephalon has been proposed as a cause for obliteration of the aqueduct secondarily. Scaring, and gliosis following infection or haemorrhage can cause acquired stenosis. Tumours from the surrounding structures may block the aqueduct. Imaging is confirmatory in such situations.[70]

Dandy Walker Syndrome

This syndrome comprises of agenesis of the cerebellar vermis with cystic dilation of the fourth ventricle, enlargement of the posterior fossa and hydrocephalus. The hydrocephalus manifests in the post-natal period. Additional brain malformations leading to neural developmental delay is reported in 70% of cases. Treatment with placement of a proximal catheter in the lateral ventricle, fourth ventricle and both the ventricles with a wide connecter, have been described. The ideal is to treat the fourth ventricular hydrocephalus and subsequently the supratentorial hydrocephalus, by shunt or endoscopic method.

Post-Meningitic

Hydrocephalus can occur following a range of infectious or inflammatory diseases. Organisation of the inflammatory exudate with scaring or gliosis can produce obstruction to CSF flow, both in the ventricular system and in the basal cisterns, cortical subarachnoid space and may also lead to occlusion of the arachnoidal villi, leading to either obstructive or communicating hydrocephalus (Figs 19 and 20). Bacterial, parasitic and granulomatous infections like tuberculosis and fungal infections can lead to hydrocephalus. It is far more frequently observed in association with the last two conditions. Hydatidosis and toxocara and viral infections are rare causes (Fig. 21). Hydrocephalus in the presence of infection poses several management challenges. Hydrocephalus can be

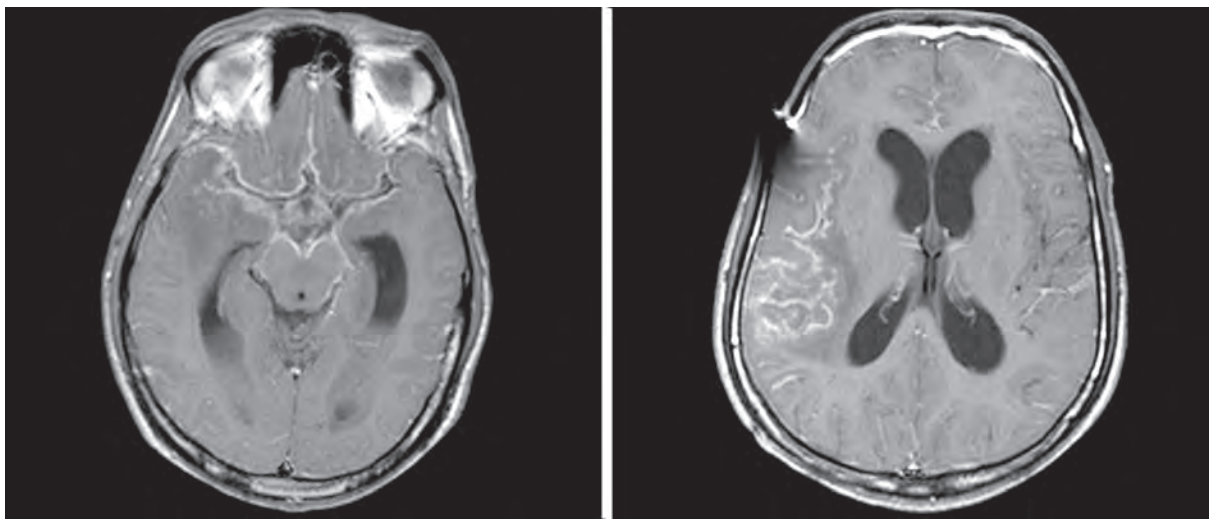

Fig. 19: MRI of the brain showing meningitis with hydrocephalus

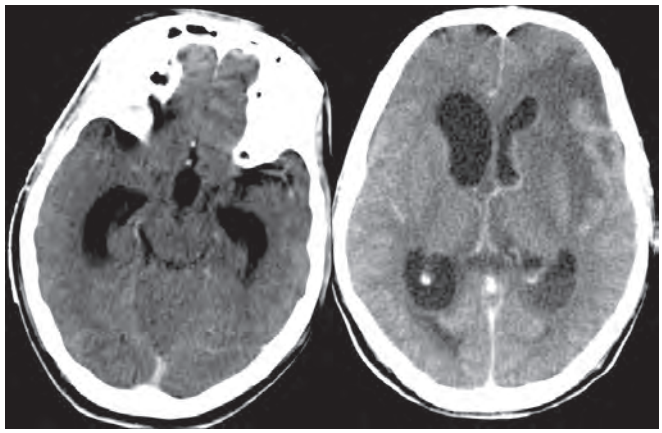

Fig. 20: CT scan of the brain showing meningitis with ventriculitis

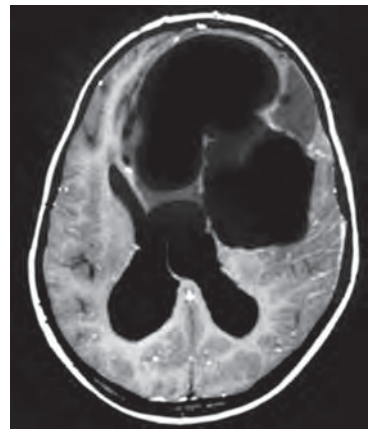

Fig. 21: MRI of the brain showing hydatid cyst with hydrocephalus

acute, causing severe rise in the ICP and rapid deterioration of the clinical condition. The goals of treatment are early diagnosis, effective relief of raised ICP, CSF diversion and treatment of the primary infection. Clinical evaluation, radiological imaging (Tables 4 and 5) and CSF examination including cultures are essential for establishing the diagnosis. In granulomatous infections, at times, it is very difficult to differentiate the type of infection warranting tissue diagnosis or stereotactic biopsy. The outcome depends on effective management of infection, hydrocephalus and the associated complications. External ventricular drainage may be used as a temporary measure till the infection is resolved, before implanting a shunt or doing third ventriculostomy. The incidence of shunt infection or malfunction is very high. Endoscopic third ventriculostomy is gaining popularity with 50–60% success rates in select cases.

Subarachnoid Haemorrhage

Hydrocephalus can occur in 10–15% of patients with subarachnoid haemorrhage. The incidence increases with intraventricular haemorrhage. The mechanism in impaired absorption due to blockage at multiple sites.

Normal Pressure Hydrocephalus

Usually seen in adulthood, it is characterised by gait deterioration, dementia and urinary incontinence. Imaging usually shows enlarged ventricles. In some cases, it may be secondary to infection or haemorrhage in the past. The ICP related symptoms may not be evident. A number of investigations have been advocated in selection of patients for shunt therapy, like isotope cisternography, infusion tests to detect increased CSF resistance in flow, ICP monitoring and therapeutic lumbar drainage. CSF diversion, in carefully selected patients, leads to favourable clinical outcomes.[20]

Hydrocephalus and Venous Hypertension

The role of raised venous pressure as a cause of hydrocephalus has been described long ago as otitic-hydrocephalus. Similar clinical situations have also been described in anchondroplasia and syndromic craniostenosis. The deformed skull base resulting in narrowing of the jugular foramen leading to impaired intracranial venous drainage has been attributed. The raised pressure within the cranial venous sinuses reduces the pressure gradient across the arachnoid villi, leading to impaired absorption. Hydrocephalus also accompanies vein of Galen aneurysms.[47,48]

Arrested Hydrocephalus

Hydrocephalus may evolve into a chronic state in which persistent ventricular enlargement with normal CSF pressures exists. Although it is a controversial entity, it appears to be a compensated hydrocephalus. Treatment strategies should be weighed between the benefit versus complications in individual situations. The exact criteria on which arrested hydrocephalus is based is not clear. However, they need to be monitored for clinical and intellectual development. Disproportionate head

Table 4: Imaging characteristics in infections

Cysticercosis	Free	?	Increased	Decreased	Pyruvate
Abscess	Restricted	Hypoperfused centre Hyperperfused wall	Increased	Decreased only in the wall	Serine and other amino acids

growth, progression of ventricular size and intellectual decline are indications for intervention.

Multiloculated Hydrocephalus

Multiloculated hydrocephalus is still a challenge to treat. It usually occurs after an initial episode of neonatal meningitis or a germinal matrix haemorrhage. CT scan or MRI is usually diagnostic. CT ventriculography has been advocated to delineate the communication between the cysts. This condition needs to be differentiated from cysts associated with hydrocephalus, including dorsal cyst malformations. Among the various treatment options available, placement of multiple shunts, single shunt with multiple fenestrations of all the loculations, craniotomy with lysis of intraventricular septations, stereotactic cyst aspiration or endoscopic cysts fenestration with shunt insertion have been described. The endoscopic option appears the most ideal and can be performed through a single burr hole with the aid of a steerable endoscope. Large fenestrations are usually recommended to prevent recurrent cyst formation. Identifying the loculated cysts is usually a problem, as most often the differentiation between normal parenchyma and the septum is difficult, as well as it is easier to get disoriented during the endoscopy. Intra-operative ultrasound or navigational systems can be of considerable help. After the perforations are made, the multiple cavities are communicated with each other and a single shunt can be placed into one of the major cavities. Repeat procedures are also advised in case the initial one fails to relieve the symptoms. However, the intellectual outcome in these children's has been poor. Only 20% of them can reach normal expected levels of IQ with the best possible treatment. The number, extent of loculations, degree of parenchymal damage, aetiology and effectiveness of treatment seems to influence the ultimate outcome. If the loculations are unilateral, they can be communicated to the opposite ventricle through a septum pellucidotomy.

Hydrocephalus Ex-vacuo

This condition generally indicates enlargement of the ventricles secondary to cerebral parenchymal damage. The ex-vacuo of cerebral atrophy can be associated with ageing, head trauma, severe infection, hypoxia or ischaemic insults. Following radiotherapy and chemotherapy, ventricular enlargement can occur. They are usually associated with white matter loss and concomitant enlargement of the cortical sub-arachnoid spaces and basal cisterns. Peri-ventricular lucency is absent. A number of structural abnormalities of the brain, such as calpocephaly, holoprosencephaly and agenesis of the corpus callosum may also be associated with ventricular enlargement and do not necessarily require any intervention.

21 Endoscopic Management of Hydrocephalus

Aaron Mohanty

INTRODUCTION

With the rapid technical advancement in the recent past, there has been an upsurge in the number and variety of endoscopic procedures performed in various surgical disciplines. Similarly, with the advent of better quality endoscopes and improvement in diagnostic modalities, neuroendoscopic procedures for obstructive hydrocephalus have gained wide acceptance. Endoscopic approaches for obstructive hydrocephalus and certain intraventricular lesions with gross hydrocephalus are being routinely performed as the dilated ventricles provide easy access for endoscopic navigation. However, with the advent of thinner endoscopes and frameless guidance devices, endoscopic approaches to lesions with mild or moderately dilated ventricles are becoming feasible.

NORMAL ENDOSCOPIC ANATOMY

It is important that the neurosurgeon be well versed with the endoscopic ventricular anatomy as the limited field of vision obtained during a neuroendoscopic procedure can cause considerable difficulty in orientation. Important neural and vascular structures adjacent to the neuroendoscope, but outside the field of vision, are at risk of being injured during the endoscopic procedure. The loss of stereoscopic vision and absence of depth perception are also certainly disadvantageous and warrant a clear knowledge of the ventricular anatomy.

APPROACH

The majority of the neuroendoscopic procedures are performed in the lateral and the third ventricles. The standard approach is a precoronal burr hole at Kocher's point (3 cm from the midline, just anterior to the coronal suture on the right side). This point is ideal for reaching the foramen of Monro and the third ventricle. However, in certain circumstances where a more posterior visualisation is required, a parietal burr hole may be placed. For approaching a lesion in the temporal horn, a burr hole in the temporal region may be considered. Alternatively, the temporal horn can be approached through the dilated atrium of the ipsilateral ventricle.

After the burr hole is made, the dura is coagulated and incised. The trocar with the cannula is subsequently introduced into the ventricle. In patients with small ventricles, stereotactic guidance may be used for cannulating the ventricles. The trocar is removed and the endoscope is introduced into the ventricles through the cannula. Orientation to the ventricular structures is achieved initially by adjusting the camera to make necessary alterations so that the operative view matches the position of the patient.

Lateral Ventricles

Often the initial and most important landmark is the foramen of Monro. In cases with developmental anomalies, the location of the foramen of Monro can be identified by locating the choroid plexus and the formation of the internal cerebral veins. The choroid plexus is located at the floor of the lateral ventricles traversing from the lateral to the medial side and enters the foramen of Monro (Fig. 1). Also seen are the thalamostriate and the septal veins which traverse from the lateral and medial sides, respectively and join at the foramen of Monro to form the internal cerebral vein. The medial and anterior border of the foramen of Monro is formed by the fornices. In cases, where the septum is absent, the fornices can be seen as two distinct bundles. The central part of the lateral ventricle up to the ventricular trigone can often be visualised by angling the endoscope posteriorly. Visualisation of the temporal horn requires a flexible scope.

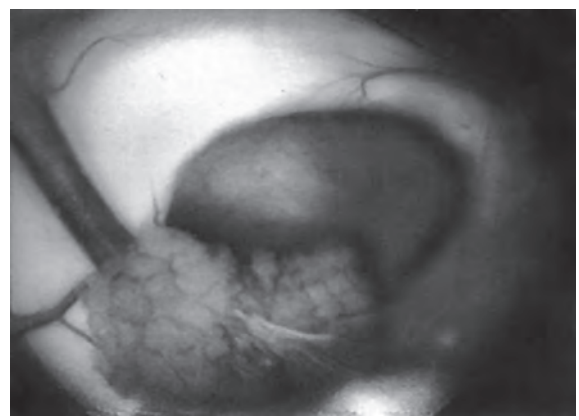

Fig. 1: Endoscopic view of the foramen of Monro: Note the dilated foramen of Monro. The choroid plexus is entering into the foramen at 7 o'clock position. The septal vein is seen just above that. The third ventricular cavity can be seen through the dilated foramen

Third Ventricle

Through the foramen of Monro, the floor of the third ventricle can be visualised (Fig. 2). Subsequently, the endoscope may be navigated through the foramen of Monro. It is pertinent to note that in cases where the foramen is not dilated a smaller diameter endoscope should be used. In the floor of the third ventricle, the paired mammillary bodies can be visualised. The thin membrane anterior to it is called the tuber cinereum, which is often thinned out and translucent in chronic hydrocephalus. The basilar artery pulsations can often be seen through the thinned out membrane. Anterior to it is the infundibular recess (Fig. 2) and the optic chiasma.

The aqueductal inlet is located posterior to the mammillary bodies and often requires a 30° angled scope. The posterior commissures and the pineal recess can be identified just superior to it. Visualisation of the aqueduct for procedures, like aqueductoplasty, often requires a fibreoptic endoscope. Often interthalamic adhesions of various degrees are visualised and large adhesions may hinder the navigation of the instrument.

Aqueduct and Fourth Ventricle

The fibreoptic endoscope can be navigated into the aqueduct in cases where an adequate aqueductal opening permits cannulation. In obstructive hydrocephalus, the aqueduct may be obstructed by a thin septum or a gliosis or may be thinned out. The fourth ventricle and the choroid plexus are identified and the structures in the fourth ventricle can be visualised. The fibreoptic scope can be navigated through the outlet foramina, and the basal cisterns, foramen magnum region and upper cervical region can be inspected.

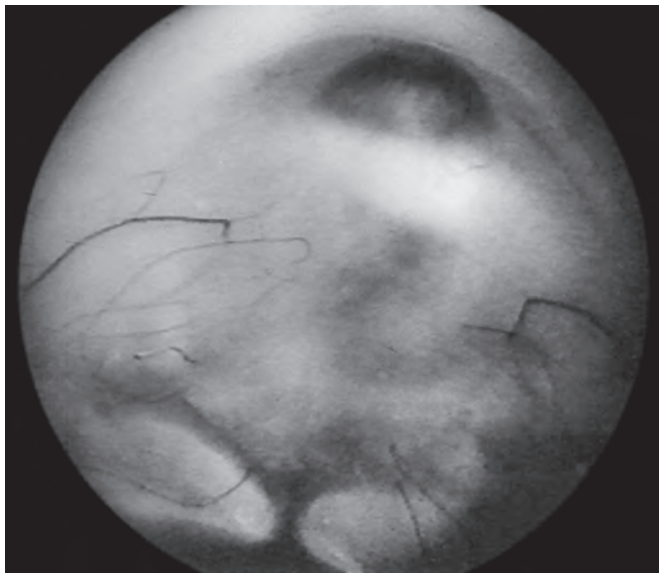

Fig. 2: Third ventricular floor: the mammillary bodies can be identified at 6 o'clock position. The thinned out floor (Tuber cinereum) is visualised anterior to it. The white band seen in the anterior part of the floor is the dorsum sella which is prominent due to the thinned out floor. The dark area at 12 o'clock position is the infundibular recess (the red spot—as it appears pinkish red during the normal endoscopic procedure due to presence of large number of blood vessels)

INSTRUMENTATION

Three prototypes of neuroendoscopes are currently in use: the rigid Hopkins Lens scope; flexible fibreoptic scope and the rigid fiberscope.

Rigid Endoscope

Conventional rigid endoscopes have solid rod lenses and fibreoptic illumination. The recent endoscopes have an outer diameter ranging from 2.6 mm to 6 mm. The larger diameter endoscopes allow for larger working channels and hence a variety of accessory instruments can be used. Rigid endoscopes can have a viewing angle from 0° to 120°. The 0° telescope is the most useful in routine practice; however, the rest are required to inspect the inaccessible areas or to "look around the corner". Rigid endoscopes have the advantage of better vision, better surgical orientation and are easy to use. There are more operating channels available for a rigid endoscope than a fibreoptic endoscope. They are also sturdier and have a longer life than fibreoptic scopes.

Fibreoptic Endoscopes

Significant technical advancements have resulted in the availability of thinner fibreoptic scopes with diameters as small as 0.7 mm. However, the quality of viewing of these thinner endoscopes is poor. Fibreoptic endoscopes are advantageous in their flexibility and ability to explore the areas where a conventional rigid endoscope cannot be navigated. Thin instruments can be passed through the endoscope for obtaining a biopsy. A poor picture quality, difficult orientation and a high maintenance cost are the disadvantages of a fibreoptic endoscope.

Rigid Fibrescope

In this third prototype, fibreoptic bundles are compactly arranged in a rigid frame structure. This architecture adds the advantage of easier orientation and smooth passage of reasonably sized instruments while maintaining the thinner diameter of the flexible scope.

Though several arguments continue regarding the advantages of the rigid and flexible systems, they are considered to be complimentary to each other and for an ideal situation the availability of both during a neuroendoscopic procedure is desirable. The flexible endoscopes can be used through the working channel of the rigid endoscope thus, limiting the problems in orientation (mother-daughter approach).

STABILISATION AND GUIDING DEVICES

The endoscopes with camera attachments are heavy and hence devices are essential to provide the necessary stabilisation during the operative procedure which

frees the endoscopist from holding the instrument. The Gaab's rigid endoscope can be attached to the conventional Leyla retractor by fixators or special holding devices may be used.

Stereotactic Guidance

Stereotactic guidance has been considered to be helpful in patients with small ventricles with difficult cannulation with a plan to reach deep seated targets which may be difficult to identify under normal circumstances. The endoscope can be attached to the stereotactic guiding device. Neuronavigation has especially been useful in planning the trajectory, maintaining the trajectory during the procedure and avoiding injury to adjacent structures. Image guidance is helpful in patients with anomalies of the ventricular system and in patients with multiloculated hydrocephalus. Other adjuncts which often have been used include ultrasound[47] and robotic assisted endoscopic third ventriculostomy (ETV).[51,53]

Additional/Supplementary Instrument

A variety of micro-instruments which are currently available for use along with the neuroendoscope are: grasping forceps for the biopsy; balloon catheters for ventriculostomy; aspiration needles; micro-scissors; bipolar or monopolar RF (saline torch); Nd YAG laser and KTP laser. Intraluminal ultrasound has also been used.

An ultra-light microchip camera transmits the images to a video unit for the purposes of display and recording. A sterile operative field is thus maintained as the surgeon performs the procedure while observing the monitor. However, eye-hand coordination is often difficult and the loss of image quality during the transmission has to be accepted.

The complexity of the operative procedure demands a highly specialised neuroendoscopic team which includes a neurosurgeon, neuroendoscopic anaesthetist, instrument nurse and an assistant.

ENDOSCOPIC PROCEDURES FOR OBSTRUCTIVE HYDROCEPHALUS

The various procedures currently performed for obstructive hydrocephalus are summarised in Table 1.

Third Ventriculostomy

Endoscopic third ventriculostomy has been considered as an acceptable alternative in the treatment of obstructive hydrocephalus in adults and children. Though it was performed as early as 1923 by Mixter, the procedure did not gain widespread acceptance due to inadequate instrumentation. However, availability of better endoscopes with illumination and a growing dissatisfaction with the existing shunt systems lead to renewed interest in endoscopic ventriculostomy.

Table 1: Endoscopic procedures for obstructive hydrocephalus

Pathological condition	*Endoscopic procedures performed*
Aqueductal stenosis	• Third ventriculostomy • Aqueductoplasty (Aqueductal reconstruction) • Aqueductal stenting
Posterior fossa tumour with hydrocephalus	• Third ventriculostomy
Fourth ventricular outlet obstruction	• Third ventriculostomy
Unilateral hydrocephalus	• Septostomy • Foraminoplasty
Multiloculated hydrocephalus	• Membrane fenestrations with endoscopic ventriculoperitoneal shunt insertion
Trapped fourth ventricle	• Endoscopic third ventriculostomy with aqueductal stenting
Miscellaneous	• Endoscopic shunt placement • Removal of adherent ventricular catheter • Removal of migrated ventricular catheter • Choroid plexus coagulation

Patient Selection

As will be discussed later, patients with acquired aqueductal stenosis are considered to be the ideal candidates for third ventriculostomy.[5,12] Aqueductal obstruction due to posterior fossa tumours are also benefited by a third ventriculostomy.[38] The role of third ventriculostomy in hydrocephalic children with myelomeningocoele has been controversial, though a few studies have found it useful.[14,48] Patients with communicating hydrocephalus theoretically would not benefit from the procedure although evidence in this regard has been lacking.

The technical feasibility for performing a third ventriculostomy requires an adequate sized third ventricle so that the endoscope can be navigated with ease without damaging the adjacent hypothalamus and thalamus. The floor of the third ventricle should be examined regarding its thickness by pre-operative magnetic resonance imaging (MRI) as a thin third ventricular floor is easier to perforate than a thicker one. An ectatic basilar artery, if identified pre-operatively, may contraindicate a third ventriculostomy due to risk of injury to the vessel (Fig. 3).

Operative Procedure

A precoronal burr hole is placed just anterior to the coronal suture 2–3 cm away from the midline. The placement of the burr hole is important, as a direct view to the foramen of Monro can be obtained from a properly placed burr hole thus, enabling the usage of only a rigid endoscope. The trocar and cannula are reintroduced into

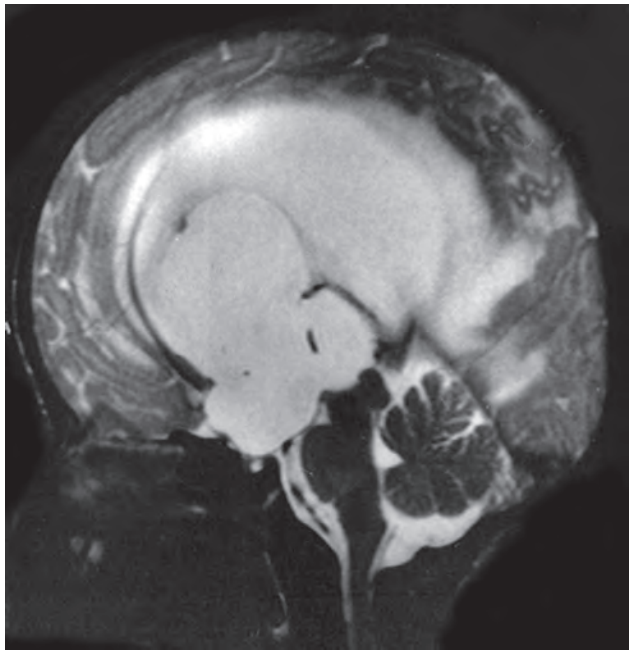

Fig. 3: Sagittal T2-weighted MRI scan of a child with obstructive hydrocephalus showing a long segment aqueductal stenosis. Note the bifurcation of the basilar artery which is placed anteriorly considerably diminishing the space for an endoscopic third ventriculostomy to be performed

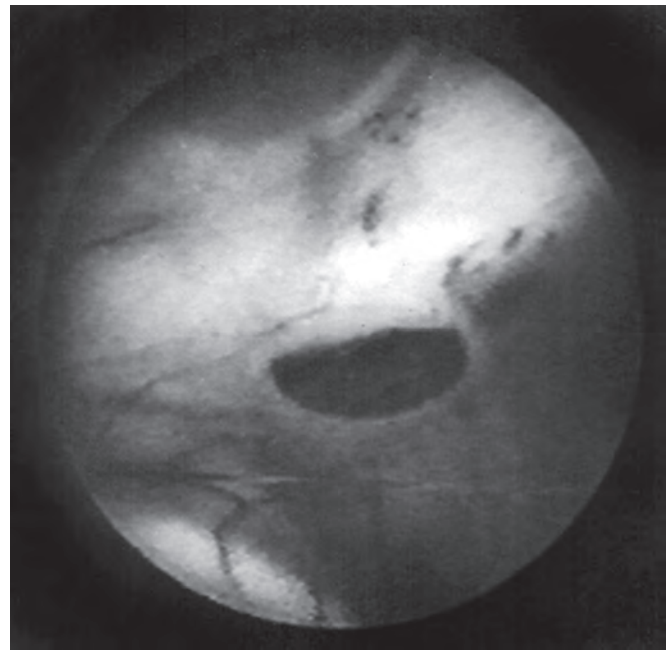

Fig. 4: Initial fenestration performed between the basilar artery and the dorsum sella

the ventricular system after a preliminary ventricular tap is done to assess the exact depth before the insertion. The trocar is then removed and the 0° endoscope is introduced into the lateral ventricle. The foramen of Monro is identified using the standard landmarks as described earlier and the endoscope is navigated into the third ventricle. The mammillary bodies are identified and the thinned out floor of the third ventricle just anterior to it is visualised (Fig. 2). The basilar artery pulsations are often seen through the thinned out floor and the perforators sometimes can be identified. Using a fibreoptic scope or a 30° angled scope the inlet of the stenosed aqueduct can be visualised. A site is chosen in the midline between the basilar artery and the clivus (Fig. 4). Sometimes, the space is very narrow (due to an ectatic basilar artery) and a perforation may be made as close to the clivus as possible. The perforation is made either with the scope itself, with a specially devised forceps,[6] by monopolar or bipolar coagulation or assisted by laser.[50] This is the most critical step of the surgery and a properly performed fenestration is essential in avoiding injury to the basilar artery, which is the most dangerous complication of the procedure. Though all the above techniques have been used, the author prefers fenestration with a 4F Fogarty's catheter with the stylet in place. Presence of the stylet inside the catheter renders adequate firmness to the tip to fenestrate the floor in a single attempt, thus, preventing multiple attempts which can injure the hypothalamic nuclei. Though the ideal fenestration is considered to be in the midline, it is not uncommon to see that the fenestration wavers slightly to the side opposite the burr hole (i.e. to the left side in the right burr hole approach) due to the trajectory. Visualisation and identifying the basilar bifurcation and its branches is highly essential and is the key to prevent an intra-operative catastrophe of injuring the vessels. In patients with thickened or deformed floor (e.g. patients with previous ependymitis, myelomeningocoele), it is difficult to identify the vessels and the proper site for fenestration. Several adjuncts have been used: stereotactic guidance, ultrasound guidance[33] and pulse waved microvascular Doppler probe.[39] After the initial fenestration is made, it is dilated to an adequate size. Several techniques have been proposed by various authors. The most common technique is dilatation with a 4F Fogarty's catheter (Fig. 5). The author usually dilates the balloon to its maximum to achieve the maximum size fenestration. Alternatively, passage of the endoscope itself has been used to achieve the required dilation. Electrocoagulation and cutting probes have also been used for enlargement which, however, potentially can damage the adjacent hypothalamic nuclei by thermal injury.

There is often another thin membrane below the floor which is described as the "second membrane" or the "Liliequist's membrane". Perforation of the membrane is essential for a functioning third ventriculostomy. The scope is then gently advanced to visualise the basilar artery. Continuous irrigation of the ventricular cavity is carried out with Ringer's lactate solution at body temperature to clear the minor bleeding, which might occur during the procedure.

Complications

A transient arrhythmia often occurs during the perforation, which usually settles by itself. In case the

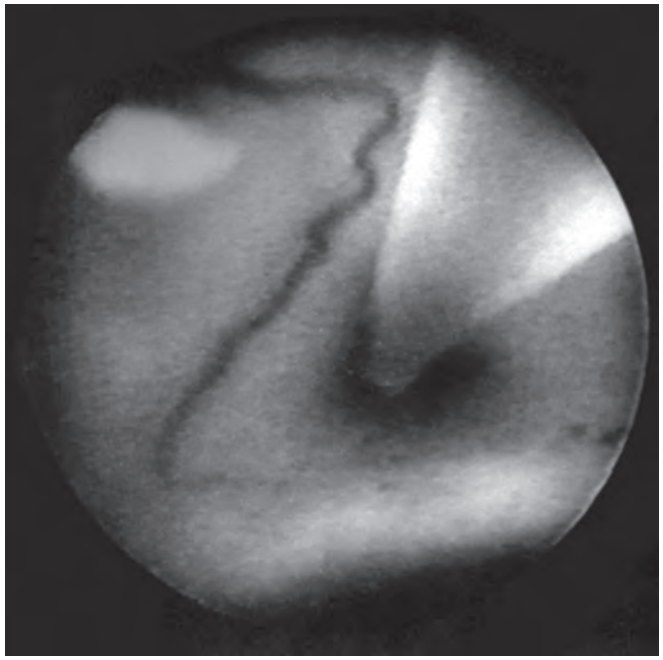

Fig. 5: Aqueductoplasty being performed with the help of a 4F Fogarty's catheter

Fig. 6: T2 sagittal MRI scan of a patient with aqueductal stenosis demonstrating a good flow void (represented by the dark area in front of the basilar artery) in the region of the third ventricular floor

perforation is performed away from the midline hypothalamic damage may result leading to water and electrolyte imbalance which, however, usually is transient. Transient pareses of the III and VI cranial nerves have also been observed.[50] Bleeding from the edges of the perforation is usually self-limiting. However, damage to the basilar artery may occur and may be fatal during the procedure or lead to formation of a pseudoaneurysm.[22] Hence, every attempt should be made to identify the basilar artery through the thinned out floor and avoiding the site of perforation too close to it. Subdural effusions and subdural haematoma can occur due to sudden release of cerebrospinal fluid (CSF).[25]

In a series of 193 endoscopic third ventriculostomies, a mortality of 1%, permanent morbidity of 1.6% and a transient morbidity of 7.8% was reported.[41] The authors, while noting a steep learning curve, ascertained that ETV performed correctly is a safe, simple and effective treatment option for various forms of non-communicating hydrocephalus.

Assessment of Effectiveness

After a functioning third ventriculostomy, the ventricle size often remains large for a prolonged period, though a significant decrease in size is sometimes noted. In a previous study, an average of 35% decrease in third ventricular size and 33% reduction in lateral ventricular volume was noted in patients following a successful third ventriculostomy.[44] Improvement in the pre-operative downwards bulging of the third ventricular floor has also been noticed in the post-operative MRI scans. Additionally, the periventricular lucencies resolve, symptoms resolve and the head size enlargement arrests. The CSF cisterns become prominent suggesting a patent third ventriculostomy.

Radiological studies can demonstrate patency of the fenestration. Though contrast ventriculograms were initially performed with the advent of MRI, flow void through the floor can often be visualised (Fig. 6). T2-weighted fast spin echo images or 2D phase contrast images have been used to assess the flow through the third ventricular floor and have been found to be equally effective in assessing the patency.[9] However, routine assessment of the patency of the third ventriculostomy site is probably not warranted and should be reserved only for cases of clinical failure.[2]

Success Rates

Unfortunately, till now, there has been no reliable predictor for a successful outcome in third ventriculostomy for obstructive hydrocephalus. In a series of 100 consecutive patients, an overall success rate of 76% was reported.[15] The success rates of the procedure depend on the primary aetiology for the hydrocephalus, age of the patient and other associated conditions.

Age and Outcome

Age has been found to be the single most predictive factor in assessing the prognosis of ETV. In large series, success rates of 70–81% in patients older than 2 years and between 45% and 50% in children below 2 years of age is reported.[15,16,48] In a recent multicentre study of 368 patients, age was the most significant determining factor in both the univariate and the multivariate

analysis. A progressive increase in the success rate with increasing age was demonstrated.[8] The 5-year-success rate in patients younger than 1 month was 28% while it was 68% in children older than 10 years. Others have reported similar results.[3,17] Though the reason for the lower success rates in young infants is unclear, inadequate absorption of the CSF by the neonatal and infantile brain has been considered to be the possible cause.

Aetiology and Outcome

The aetiology of hydrocephalus has also been found to be a significant factor in determining the success rates. Reduction in the absorption mechanism of the CSF at the arachnoid granulations as in post-infectious and post-haemorrhagic hydrocephalus has been associated with a lower success rate in this population. Additionally, inflammation at the third ventricular floor can obscure the landmarks and be associated with technical failures. The success rate has varied from 23% to 65% with the lower rates associated with coexistence of haemorrhage and infection.[27,46] The degree of scarring in the basal cisterns has been found to be directly related to the overall outcome in several recent studies.[4,27] ETV has also been found to be successful in the management of hydrocephalus associated with the chronic stages of tubercular meningitis.[4]

Myelomeningocoele with Hydrocephalus

ETV is often considered difficult in patients with spina bifida due to associated anomalies in the third ventricular floor and in the region of the upper brainstem. The success rate of ETV in patients with myelomeningocoele depends on the age of onset of hydrocephalus and any previous shunt insertions. The success rate has varied from 27% in patients who had ETV as their initial procedure to 77% in patients where a previous shunt has been inserted, and the ETV was performed as a subsequent procedure.[14] An overall success rate of 72% was reported in a series of 69 patients who had ETV performed for hydrocephalus associated with myelomeningocoele, though the success rate improved to 80% in patients who were either over 6 months of age or had a previous shunt inserted.[49] Poor absorptive capacity in the initial neonatal period was considered to be the deciding factor for the lower success rate in the early infantile period.

Chiari Malformation and Hydrocephalus

Several reports have demonstrated the efficacy of ETV in managing the hydrocephalus associated with Chiari malformation. In patients with Chiari malformation, the obstruction to the CSF flow occurs in the region of the foramen magnum and the outlet of the fourth ventricle and the success of the ETV relates to diverting the fluid away from the obstruction site into the basal cisterns. Shrinkage of the associated syrinx has also been well demonstrated.[7,29]

Fourth Ventricular Outlet Obstruction

Obstruction to the fourth ventricular outlet results in obstructive hydrocephalus. Commonly due to an inflammatory process, this can be due to either infectious or post-haemorrhagic aetiology. ETV has been found useful in 65% of patients who had outlet obstruction resulting in obstructive hydrocephalus.[27]

Obstructive Hydrocephalus Due to Tumours

Endoscopic procedures have been found to be useful in three areas in patients with intraventricular or paraventricular tumours with hydrocephalus. Associated obstructive hydrocephalus caused by tumours located at or distal to the posterior third ventricle can be treated with ETV. Third ventriculostomy has been found to be effective in posterior third ventricular and tectal plate tumours as an alternative to ventriculoperitoneal (VP) shunt placement.[35] It has also been used as a CSF diversion procedure in fourth ventricular tumours. Secondly, it can be used to biopsy the lesions during the same sitting while performing the third ventriculostomy. This allows obtaining a histological diagnosis prior to attempting definitive tumour removal. In patients with highly radiosensitive tumours (germinoma), a subsequent second procedure can thus be avoided. Thirdly, in selected intraventricular tumours complete tumour excision can be performed endoscopically.[34]

The efficacy of ETV in tumour-related hydrocephalus has been demonstrated in several series. Sainte-Rose et al.[38] in a study of 206 patients found that ETV performed prior to the posterior fossa surgery significantly reduced the incidence of post-operative hydrocephalus and requirement for a VP shunt.[38] In another study, an initial success rate of 95% of ETV in pre-operative hydrocephalus in posterior fossa tumours was noticed though 16% of patients developed a post-operative hydrocephalus requiring a VP shunt.[36] In pineal region tumours, a success rate as high as 91% has been demonstrated.[35] Tectal plate tumours have similarly been managed with ETV and biopsy.[31]

Dandy-Walker Malformation

Endoscopic third ventriculostomy has been extended to the treatment of obstructive hydrocephalus associated with Dandy-Walker malformation. In patients with Dandy-Walker malformation with an open aqueduct, a third ventriculostomy should suffice in diverting the CSF from the site of obstruction. As in other patients with obstructive hydrocephalus, the success rate depends on the age of the patient. An overall success rate of 76% has recently been reported.[26] In the uncommon association of Dandy-Walker malformation with aqueductal obstruction, third ventriculostomy has often to be combined with an aqueductal stent placement.[23]

Considering the above, it is apparent that adult patients with obstructive triventricular hydrocephalus, due to aqueductal stenosis, tectal plate tumours and posterior

Table 2: Classification of aqueductal stenosis

• Long segment aqueductal stenosis (stenosis > 5 mm)
• Short segment aqueductal stenosis (stenosis < 5 mm)
• Aqueductal web

fossa tumours, are excellent candidates for the procedure. Though the success rate of ETV in premature infants drops down to 32%,[3] the comparatively lower success rate in children should not deter the surgeon from performing a third ventriculostomy as a 50% chance of shunt independency often can be achieved. Even in patients with implanted ventricular shunts, third ventriculostomy may be effective and should be considered upon shunt failure.[52]

Aqueductal Reconstruction

Aqueductoplasty and aqueductal stenting have emerged as exciting options for a selected group of patients with obstructive hydrocephalus. The increased usage of MRI in cases of obstructive hydrocephalus has identified a subgroup of patients who could benefit from an aqueductal reconstruction procedure. Aqueductal stenosis, from a neurosurgeon's perspective, is classified as long segment stenosis, short segment stenosis and aqueductal web (Table 2). A long segment aqueductal stenosis with the length of the stenosis exceeding 5 mm (Fig. 7) is not suitable for an aqueductal reconstruction procedure as attempting a reconstruction would lead to periaqueductal region damage. On the other hand, fenestrating the thin web that often blocks the aqueduct (aqueductal web, Fig. 8) or dilating or stenting a segment of stenosis less than 5 mm in length (short segment stenosis,

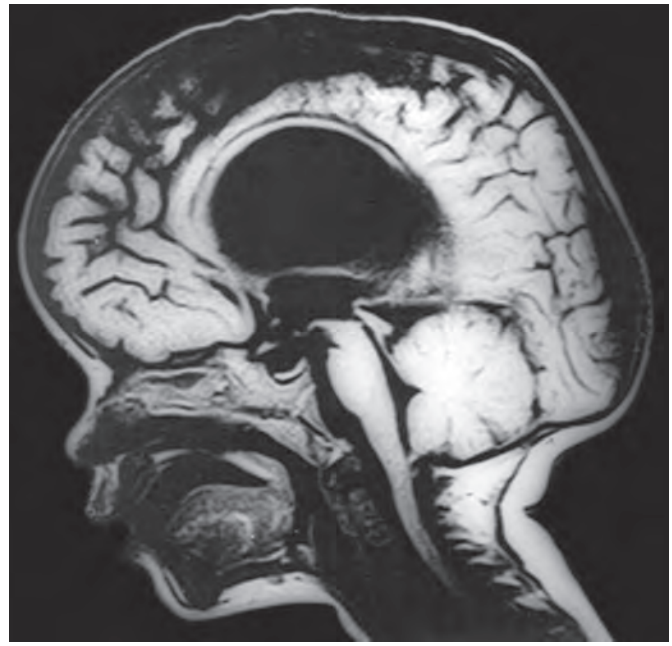

Fig. 8: Aqueductal web: Note the aqueductal web in the proximal aqueduct causing an obstructive hydrocephalus

Fig. 9) is often not difficult. Such cases are ideal candidates for aqueductoplasty or aqueductal stenting. Aqueductal stenting in conjunction with ETV or VP shunt has also been considered for the management of an isolated fourth ventricle.[24,37,43,45]

Technique

A pre-operative MRI study is essential before considering an aqueductal reconstruction procedure. The length of stenosis, angulation of the aqueduct and the size

Fig. 7: Long segment aqueductal stenosis: T1 sagittal image MRI of a child with obstructive hydrocephalus demonstrating a long segment aqueductal stenosis. Aqueductal reconstruction procedures are contraindicated in such a situation as it can lead to injury to the mesencephalon and the periaqueductal grey

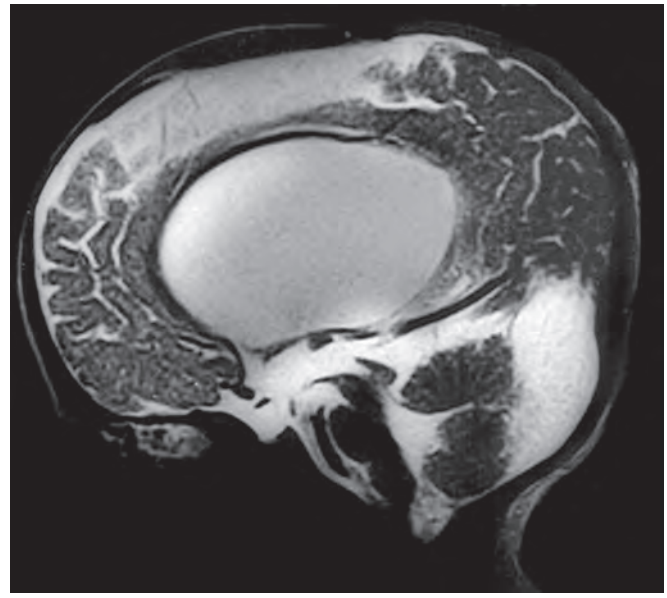

Fig. 9: Short segment aqueductal stenosis: There is short segment aqueductal stenosis causing obstructive hydrocephalus. Aqueductal web (Fig. 8) and short segment aqueductal stenosis is amenable for aqueductal reconstruction

of the fourth ventricle are all important observations, which guide the neurosurgeon and reduce the risk of operative damage to the aqueduct. As mentioned earlier, observation of a long segment aqueductal stenosis is a contraindication for an aqueductal reconstruction procedure. The pre-operative sagittal MRI also guides the neurosurgeon regarding the optimal trajectory of placement of the burr hole, which should be more anterior than the conventional burr hole used for ETV.

After placement of the burr hole, the rigid endoscope is introduced into the lateral ventricle and subsequently is navigated into the third ventricle. After entry into the third ventricle, the endoscope is gently angled posteriorly, care being taken not to injure the rim of the foramen of Monro. The stenosed aqueduct can be identified behind the mammillary bodies (Fig. 10). Subsequently, a soft tipped 3F Fogarty's catheter is used to fenestrate the obstructing element and gently dilate the stenosed aqueduct. The author uses one of the following two as the stent: (a) modified 4 cm ventricular sleeved catheter (aqueductal stent) (Fig. 11) or (b) a long ventricular catheter with an attached reservoir at the burr hole site. In the first option, the free standing stent is prevented from migrating downwards by the sleeve which rests in the aqueductal inlet. To avoid a distal migration, an enthusiastic dilatation of the stenosed aqueduct is not performed. In the second option, the stent is fixed into position by its attachment with the reservoir at the burr hole site. These stents traverse from the frontal region to the fourth ventricle through the foramen of Monro, third ventricle and aqueductal inlet and have a reduced incidence of migration. However, these stents often can fall short with growth and development of the child.

Complications

Aqueductal reconstruction procedures are relatively safe if adequate care is taken not to injure the adjacent periaqueductal region. It is important that the procedure is performed under direct vision and the surgeon should be prepared to abandon the procedure for favour of third ventriculostomy or a VP shunt, if required. Injury to the cranial nerve nuclei in the region of the upper brainstem can cause dysconjugate eye movements and upwards gaze paresis.[10,42] Transient loss of consciousness has also been reported due to injury to the periaqueductal grey.

Success Rates

The success rate of a technically successful aqueductoplasty and aqueductal reconstruction procedure is almost equivalent to the ETV procedures.[10,11,40] In a well documented series, aqueductoplasty was reported to be successful in 82% of cases with short segment aqueductal stenosis and aqueductal web.[42] However, a 25% reclosure rate was noted during extended follow-up requiring resurgery. Placement of an aqueductal stent, though obviates the reclosure seen with aqueductoplasty, has been associated with stent migration.

Choroid Plexus Coagulation

Initially attempted by L'Espinase and Dandy, endoscopic choroid plexus coagulation was subsequently practiced by Griffith.[13,32] An occipital approach appears suitable for ablation of the majority of the choroid plexus of the lateral ventricles. Using bipolar or monopolar coagulation or Nd YaG laser, the plexus can be coagulated. It is often advised to maintain a CSF drain for the first few days. A 52% success rate with no mortality in children with communicating hydrocephalus has been reported.[13]

Multiloculated Hydrocephalus

Multiloculated hydrocephalus usually occurs after an initial episode of neonatal meningitis or a germinal matrix haemorrhage. Requiring drainage of all the cavities by a CSF drainage procedure, the management of this unfortunate event is one of the challenges for any paediatric neurosurgeon. Among the various treatment options available are placement of multiple shunts, single shunt with multiple perforations traversing all the loculations

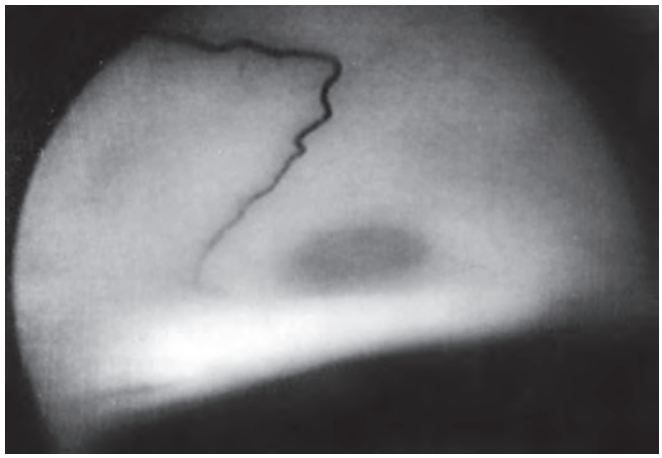

Fig. 10: Endoscopic view of the stenosed aqueduct

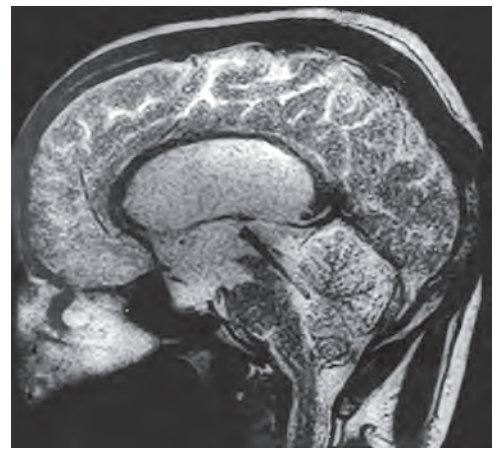

Fig. 11: T2-weighted sagittal image of a patient with placement of aqueductal stent. Note: The wider shoulder of the stent preventing distal migration of the stent

or craniotomy with lysis of intraventricular septations.[30] Stereotactic cyst aspiration or endoscopic cyst fenestrations with shunt insertion have been described. The endoscopic option appears the most ideal and can be performed through a single burr hole with the aid of a steerable endoscope. A large fenestration is usually performed to prevent recurrent cyst formation.[20] Identifying the loculated cysts is usually a problem as most often the difference between the normal parenchyma and the septum cannot be made. Intra-operative ultrasound or navigational systems can be of considerable help in identifying the loculations. After the perforations are made, the multiple cavities are communicated with each other and a single shunt can be placed into one of the major cavities with endoscopic guidance. Alternatively, third ventriculostomy can be performed. However, identifying the normal landmarks poses considerable difficulty due to adhesions and scarring. Repeat procedures are also advised in case the initial one fails to relieve the symptoms. In a series of 34 cases of loculated hydrocephalus, a considerable reduction in the shunt revision rate was achieved during a mean follow-up of 26 months.[20]

Septum Pellucidotomy

In unilateral hydrocephalus due to tumours or adhesions at the foramen of Monro, the septum pellucidum[18] can be perforated endoscopically. Also in cases of triventricular hydrocephalus due to cysts and tumours at the foramen of Monro the septum can be perforated and a lateral ventricular shunt may be avoided.[1] Successful endoscopic fenestration of congenitally occluded foramen of Monro has been described.[28]

Intraventricular Shunt Catheter Placement and Removal of Dislocated Shunt

In cases of multiple shunt malfunctions due to repeated blockage of the ventricular catheter by choroid plexus the proximal ventricular catheter can be placed properly ahead of the choroid plexus in the frontal horn. Though a previous study had demonstrated the decrease in shunt revision rate from 67-49% within 1 year,[21] a recent prospective, randomised, multicentre trial did not find any reduction in revision rates between endoscopically placed shunts and non-endoscopic groups.[19] Endoscopes have also been used for the removal of dislocated and migrated shunt tubes.

22 Normal Pressure Hydrocephalus

Sanjay Behari, Das NK, Vimal Kumar V

INTRODUCTION

Normal pressure hydrocephalus (NPH) is a clinical syndrome characterised by a triad of altered mentation, gait difficulties and sphincter disturbances, together with ventriculomegaly and normal cerebrospinal fluid (CSF) pressure.

The term "*normal pressure hydrocephalus*" was introduced by Hakim in his thesis paper in 1964.[44] In the English literature, the concept of NPH was introduced by Adams et al. (in which Hakim was a co-author). It was published in the New England Journal of Medicine in 1965.[1] Before 1965, several papers had shown the apparent paradox of progressive hydrocephalus without overt signs of intracranial hypertension, but the disease was not established as a separate entity.[127] In 1936, Riddoch had described the syndrome closely resembling the one described by Adams and Hakim.[93] This syndrome had also been described by McHugh[78] and by Messsert and Baker.[80] In the latter paper, there had been relief of symptoms after CSF shunting. Penfield[86] had also described some exceptional cases where CSF spaces were closed and the ventricles progressively enlarged without the measured ventricular pressure rising above 150–200 mm H_2O.

NPH has been classified into two groups. The first group is secondary NPH with a known cause, which includes patients with a past medical history of meningeal irritation (e.g. trauma, meningitis, subarachnoid haemorrhage and subdural haematoma).[104] The second group is idiopathic normal pressure hydrocephalus (iNPH), which includes patients in whom no apparent cause is detectable.

Thousands of elderly people with the classical features of gait difficulty, incontinence and dementia may have the potentially treatable iNPH. The entity may either be confused with other diseases that bear a close resemblance to NPH like dementia associated with Alzheimer's disease or the movement disorders associated with Parkinson's disease, or NPH may co-exist with these diseases. Furthermore, this elderly population may have several comorbid conditions compounding their management problems. With increased health care and improved longevity of life, the number of patients with this entity is likely to increase. In the developed countries, this entity has a very high prevalence with a study quoting that about 5% of the total population of the USA may be suffering from NPH.[73] The ataxia, dementia and incontinence associated with the more advanced stages of iNPH become less responsive to treatment as the duration of the disease increases. Thus, patients with symptoms of less than 2 years duration are more responsive to drainage procedures than those in whom these symptoms have persisted for a longer time. Hence, early detection and management of this disease is extremely vital.

INCIDENCE

Clarfield[20] analysed 32 studies with 2889 patients who presented with the symptom of dementia. The iNPH was diagnosed in 1.6% of these patients. Dauch et al.[24] reported its maximum incidence in the seventh decade, but 25% of the patients in their series were below 50 years of age. In adults, NPH may occur at any age. Some authors have reported the presence of NPH in children, but whether this disease actually exists in children is still controversial. The children may manifest poor scholastic performance, walking retardation in infants or repeated falling spells in older children and delayed bladder control. The sex distribution reported in the literature has a male predominance in nearly every series with the male-female ratio being approximately 2:1.

AETIOLOGY

The aetiopathogenetic factors responsible for iNPH are still not known and various theories have been proposed to account for the progressive ventricular dilatation associated with near-normal CSF pressures as well as the regional cerebrovascular changes.[43,82,119] These include:

Increased Venous Resistance

According to one theory in iNPH, decreased CSF resorption occurs at the level of the arachnoidal villi and granulations (probably due to leptomeningeal fibrosis) as well as the brain parenchyma (i.e. transcapillary and transvenular increased vascular resistance). Decreased CSF absorption increases the transmantle pressure (i.e. the pressure difference between the ventricles and the subarachnoid space) causing ventricular enlargement.[18,21] Thus, often, the ventricles may be dilated out of proportion to any sulcal enlargement, which distinguishes it from cortical atrophy.[52]

Bateman[4,5] has suggested that increased transvenular resistance in the territory of the superior sagittal sinus leads to ventricular enlargement and decreased blood supply in the same territory. He proposed a test for diagnosing NPH based on the quantitative measurement of inflowing carotid or basilar arteries and the outflowing superior sagittal or straight sinus. The net systolic pulse volume and the temporal difference in the arterial and venous peaks may diagnose NPH.

Tissue Distortion

Distortion and stretching of the periventricular tissues including blood vessels increase cerebrovascular resistance and cause ischaemia. In the early stages, the mechanical strain of the brain parenchyma and the interstitial pressure are more pronounced in the periventricular region. Later, the periventricular tissue yields the brain parenchyma shrinks, and CSF pressure returns to normal creating the NPH state.[61,82] Once this state is reached, the gradient of stress distribution is more pronounced at the periphery of the brain causing cerebral blood flow (CBF) to be reduced at the periphery of the cerebral mantle or evenly throughout the cerebral mantle and its white matter.[21,61,82]

Interstitial Fluid Pressure Increase

Suffusion of CSF into the periventricular tissues and the reversal of interstitial fluid flow compress local vessels. The interstitial tissue pressure is too low to actually compress the capillaries. However, the failure of autoregulation and accumulation of toxic/vasoactive substances causes border-zone ischaemia and tissue damage of white matter even with modest systemic hypotension or rises of intracranial pressure (ICP), e.g. even during the rapid eye movement phase of sleep.[18]

Watershed Ischaemia

Watershed ischaemia within the corona radiata may occur in the boundary zone between the middle cerebral artery perforators and the medullary branches from the pial arteries. This may be compounded by a disturbance of cerebrovascular autoregulation within the white matter.[22] This is because the corona radiata is vulnerable to reductions in the cerebral perfusion pressure even within the conventionally defined autoregulatory range when accompanied by impairment of CBF pressure autoregulation. There is also reduced cerebrovascular responsiveness to acetazolamide or CO_2 compared with normal controls.[56]

Vasoactive Metabolites

In iNPH, CSF suffuses from the ventricles into the parenchyma and the flow of interstitial fluid is reduced. This causes interstitial/extracellular oedema predominantly in the periventricular tissue and leads to accumulation of inappropriate vasoactive metabolites in this oedema. These metabolites may interfere with intrinsic mechanisms (e.g. nitric oxide) subserving cerebrovascular reactivity. The accumulation of amyloid protein may also damage tissues including vessels. These lead to failure of autoregulation in iNPH.

Vascular Disease

Bradley[14-17] has proposed that the venous resistance may increase in elderly patients due to deep white matter ischaemia. In NPH patients, there is a high incidence of periventricular white matter hyperintensities representative of small vessel ischaemic changes. In some iNPH cases, cerebral small vessel disease perhaps occurs due to hypertension and may cause multiple, small, deep cerebral infarctions in the periventricular white matter and basal ganglia. These multiple areas of infarction reduce the elasticity of the periventricular tissue leading to enlargement of the ventricles provoked by intraventricular CSF pressure pulsations, which are also increased in the case of systemic hypertension. This causes maximum dilatation of arteries, resulting in the loss of autoregulation and lack of response to acetazolamide. When arterioles occlude, the draining venules also close. The CSF normally drained by these veins becomes obstructed causing transient elevations of intraventricular pressure and ICP, resulting in ventricular enlargement.

CRITERIA FOR DIAGNOSIS

The guidelines for the diagnosis and management of iNPH published in the supplement of "*Neurosurgery*" in 2005 have suggested that "*PROBABLE iNPH*" may be diagnosed based on the following criteria:[92] The onset should be insidious, usually in a patient above the age of 40 years, with a minimum duration of at least 3–6 months and be slowly progressive over time. There should not be evidence of an antecedent event, like head trauma, intracerebral haemorrhage, meningitis or any known causes of secondary hydrocephalus, nor any other neurological, psychiatric or general medical conditions that may explain the syndrome. The clinical features must be in the form of gait/balance disturbance with at least one other area of impairment in cognition, urinary symptoms or both.[55,73]

With respect to gait/balance, at least two of the following should be present that are not entirely attributable to other conditions. These include decreased step, height and length; decreased speed and increased trunk swaying during walking; widened standing base with toes turned outwards during walking; spontaneous or provoked retropulsion; en bloc turning or impaired walking balance.

Cognition impairment may be in the form of increased response latency, decreased fine motor speed and accuracy, difficulty in maintaining attention, and impaired recent recall, impaired insight, abstraction, multi-step procedures, working memory and behavioural or personality changes.

Urinary incontinence in the absence of any primary urological disorders may be episodic or persistent urinary urgency (frequent perception of a pressing need to void), frequency (>6 voiding episodes in an average 12 hours period despite normal intake) and/or nocturia (need to urinate >2 times in an average night).

The computed tomography (CT)/MRI must show ventricular enlargement that is not entirely due to cerebral atrophy or congenital enlargement (Evan's index >0.3); no macroscopic obstruction to CSF flow; a callosal angle of > 40 degrees on coronal magnetic resonance imaging (MRI); a decrease in the diameter of the corpus callosum on sagittal MRI as the dorsal surface of the ventricle domes upwards and evidence of periventricular lucency (that is not due to ischaemia or demyelination as distinguished by fluid attenuated inversion recovery sequences).[41] An MRI may also show an aqueductal or fourth ventricular flow void arising from a signal artifact created by hyperdynamic CSF flow through the cerebral aqueduct. Supportive evidence may be in the form of serial brain imaging showing progressive enlargement; a radionuclide cisternogram showing delayed clearance of radiotracer over the cerebral convexity over 48–72 hours; a cine MRI study showing increased ventricular flow rate and a single photon emission computed tomography (SPECT)-acetazolamide challenge showing decreased periventricular perfusion that is not altered by acetazolamide.

On lumbar puncture (LP), the CSF opening pressure should be in the range of 5–18 mmHg (or 70–245 mm H_2O).

If patients do not meet all of the above criteria, but are still suspected of having iNPH, certain exceptions are permissible for a designation of "POSSIBLE". The clinical presentation and history may include any of the following six exceptions:

1. Symptoms have a subacute or indeterminant mode of onset.
2. Symptoms begin at any age following childhood.
3. Symptoms have less than a 3 months or indeterminant duration.
4. Symptoms remotely follow events, such as mild head trauma, intracerebral haemorrhage, childhood and adolescent meningitis or other conditions, that the clinician judges unlikely to be immediately causally related.
5. Symptoms coexist with other neurologic, psychiatric or general medical disorders that the clinician judges not to be entirely attributable to these conditions.
6. Symptoms are non-progressive or not clearly progressive; if either incontinence and/or cognitive impairment is present in the absence of gait or balance disturbance or if gait disturbance or dementia occur alone.

On brain imaging, the ventricular enlargement is associated with cerebral atrophy that may explain the ventricular size or there are structural lesions that may influence the ventricular size. The opening pressure measurement outside the range required for iNPH which also places the patient in this category.[79]

The condition is unlikely to be iNPH, if there is no evidence of ventriculomegaly. There are signs of increased ICP, e.g. papilloedema; no symptom in the clinical triad of NPH is present and/or the symptoms may be explained by other causes.

CLINICAL FEATURES OF IDIOPATHIC NORMAL PRESSURE HYDROCEPHALUS

Idiopathic normal pressure hydrocephalus occurs due to insufficient CSF absorption. It may lead to symptoms due to vascular ischaemic effects, elevated transmantal pressure, axonal stretching of the periventricular white matter and deformation of the brain parenchyma. It has been suggested that ventricular enlargement leads to vascular stretching, decreased compliance and high pulse pressure leading to local barotrauma or tangential shear stress.[12,42]

Gait Abnormality

Gait impairment is the commonest and, often, the first symptom in patients with NPH.[29] The spectrum of gait disturbance ranges from a non-specific imbalance to complete inability to walk and a magnetic retropulsive stance. Initially, there may be slowing with difficulty in turning and a mild instability, which may not be distinguishable from the senile gait or very early Parkinsonism gait.[29,102,120] On progression of the disease, stride length shortens and gait speed slows and there is decreased floor clearance and difficulty in turning. In late phases of the disease, the gait becomes a "*magnetic gait*", and the patients appear to have forgotten how to take a step or even to stand.[10,105]

An analysis of gait of iNPH patients shows decreased cadence, decreased step height, diminished stride length and reduced counter rotation of the shoulders relative to the pelvis during walking.

The posture in these patients is known as "*hydrocephalic astasia-abasia*" and is forwards leaning with a wider sway and imbalance accentuated by eye closure.

Other movement disorders commonly seen are limb and trunk apraxias, inability to climb into one's own bed, difficulty in turning and shifting position and various akinetic, tremulous, hypertonic and hyperkinetic movements.

The features that distinguish iNPH from Parkinson's disease are the absence of significant resting tremor or drooling, and failure to improve when levodopa is administered.[102,106] In the former condition, cogwheel rigidity, if present, is mild compared to the degree of gait difficulty. In cerebellar diseases, ataxia, dysarthria, gaze-evoked nystagmus and appendicular dysmetria may be present, while these are not a feature of chronic hydrocephalus.

When gait disturbance is the predominant symptom of NPH, it implies an improved chance of responsiveness

to CSF shunting; the absence of gait ataxia, on the other hand, predicts poor responsiveness to shunting.[103] It is also true that after CSF diversion, gait abnormality is the most likely component of the symptom triad to improve.[58,103,120] The ventricular size on radiology may not reliably predict the degree of gait abnormality or its improvement after surgical intervention.

In iNPH, gait disturbances may arise due to compression of upper motor neuron fibres passing through the medial portion of the corona radiata as a consequence of ventricular dilatation. Electromyography suggests contraction of the antagonistic muscle groups and increased activity in the antigravity muscles acting on the hip and knee joints. This disorder of phased activation of muscle groups points towards subcortical motor control indicative of premotor pathway involvement. With progression of the disease, and extensive subcortical white matter changes, the pyramidal tracts also become involved manifesting with extensor plantar response. Subcortical dopaminergic nigrostriatal pathway impairment may also contribute to gait and movement disturbances by leading to a disturbance in motor planning. Impaired input from the sensorimotor cortex, the superior frontal cortex, and the anterior cingulate gyrus to the reticular formation in the tegmentum of the brainstem may also contribute to the gait and stance disorder.[103,120]

Cognitive Deficits

NPH is the cause of less than 1% of all dementias. Initially, there is slowing of mental processing, reduced organisational and problem-solving skills and a reduction in prior interests. Patients may become more taciturn, less spontaneous in conversations, withdrawn and apathetic. This abulia reflects bifrontal lobe dysfunction and leads to changes in personality, memory loss and a reduced ability to perform mechanical activities or to think three-dimensionally.[121] As the dementia progresses, patients may have difficulty in finding words. Aphasia, however, is not prominent in the dementia of NPH. By the time significant memory deficits appear, motor slowing and some degree of gait apraxia are typically evident. When the dementia is moderate to advanced, it may overlap clinically with Alzheimer's dementia, Lewy-body dementia or subcortical dementias. A distinction can be made by the presence of a wide-based "*magnetic*" gait in NPH, which is not a feature of Alzheimer's dementia.[122] Vascular dementia can be distinguished by magnetic resonance (MR) imaging of the brain that may show scattered or extensive ischaemic changes in the latter disease. Cognitive impairment is the least likely component of the clinical triad to recover. If the dementia is severe, CSF shunting may result in little or no improvement.[36,89,111,114,120] Various psychometric tests have documented that NPH does not fit the criteria of degenerative (Alzheimer type) or atherosclerotic dementia.[122] Patients with NPH exhibit subcortical type of mental deficits including forgetfulness, decreased attention, inertia and mental slowness with a pattern of memory impairment that differs from the cortical dementias as seen in Alzheimer's disease. NPH is also not associated with "*aphasia-apraxia-agnosia syndrome*", which characteristically occurs in cortical dementias.[106] When significant intellectual loss occurs in the clinical presentation, other diagnosis should be considered and shunt surgery should be avoided even in the presence of ventricular dilatation. Significant hippocampal atrophy on MRI studies is an important neuroimaging criterion for the diagnosis of Alzheimer's disease.[47]

Various psychiatric disorders in association with iNPH are depression, mania, aggression, obsessive compulsive disorder, psychosis and disturbance of impulse control.

Urinary Incontinence

Disturbances of bladder control range from urinary frequency to incontinence. Urinary incontinence may be present in about half of the patients diagnosed with NPH. Incontinence typically signifies a late stage of NPH, although some degree of urgency is often present even in the early stages.[121] Bladder symptoms may not improve or resolve with CSF diversion.[2] Patients with more advanced iNPH may show indifference to the episodes of incontinence due to an associated frontal lobe syndrome. The gait disturbance, apraxia and bradykinaesia may also physically prevent the patient from performing successful toileting. The problems in urinary function may initially be due to the involvement of sacral fibres of the corticospinal tract and later may be a feature of dementia.[120]

Urinary frequency, urgency and incontinence may also result from a variety of common disorders, including benign prostatic hyperplasia, cystitis and other causes of a flaccid or spastic neurogenic bladder. The evidence of hyperactivity of urinary bladder with strong contractions elicited by infusions of small volumes of fluid into the bladder may help in distinguishing iNPH from other conditions. Incontinence is not specific for NPH and appears to be a poor independent predictor of the response to treatment.

Other reported symptoms of NPH are syncopal episodes, changes of sleep pattern, oculomotor abnormalities and endocrinal disturbances. The clinical features that are not expected with iNPH are papilloedema, seizures and headaches.

On the basis of the clinical presentation alone, Black[9] reported that the most favourable response to shunting was in patients with the complete triad who achieved a 61.2% rate of improvement and a 35.4% complication rate.

Differential Diagnosis of Normal Pressure Hydrocephalus

This includes a number of conditions that are common in the elderly age group and have been elucidated by Azeddine et al.[6,66] and by the iNPH guidelines. These

include neurodegenerative disorders, like Alzheimer's disease, Parkinson's disease, Huntington's disease, frontotemporal dementia, progressive supranuclear palsy, amyotropic lateral sclerosis and multisystem atrophy; vascular dementias including cerebrovascular disease, stroke, multi-infarct state, Binswanger's disease, leukoencephalopathy and vertebrobasilar insufficiency; hydrocephalic disorders, like aqueductal stenosis, arrested hydrocephalus, long-standing overt ventriculomegaly syndrome and non-communicating hydrocephalus; infectious diseases, like Lyme, HIV and syphilis and urological disorders, like urinary tract infections, bladder or prostate cancer and benign prostatic enlargement. Many miscellaneous disorders may simulate features of NPH in the elderly age group. These include B_{12} deficiency, collagen vascular disorders, epilepsy, depression, traumatic brain injury, spinal stenosis, Chiari I malformation, post-subarachnoid haemorrhage hydrocephalus, spinal cord tumours and carcinomatous meningitis among several other causes.

Diagnosis

Since first described by Adams, Fisher and Hakim in 1965, NPH has mainly been diagnosed clinically.[1,7] Due to the clinical features of NPH overlapping with other types of dementia, imaging has been used to strengthen the diagnosis in uncertain cases. Different imaging modalities have also been used to help in providing any potentially useful prognostic information.[119]

There is no consensus about which tests work and how reliable they are. The various modalities used for diagnosing iNPH and for prognosticating the outcome of treatment are discussed here. Imaging evaluations, such as pneumoencephalography and angiography, are not discussed because they are no longer in use.[54]

Computed Tomography

The CT scan shows the presence and extent of hydrocephalus as well as the degree of existing cortical atrophy. The CT diagnosis of NPH (Fig. 1) relies on enlargement of the lateral and third ventricles, enlargement of the temporal horns, prominent basilar cisterns, enlarged suprasellar cistern, non-visualisation of the high cerebral convexity sulci, and possible enlargement of the fourth ventricle.[40] The temporal horn dilatation is thought to be more specific for the diagnosis of NPH and correlates with positive findings on radionuclide cisternography.

The Evans index (or frontal horn ratio) is the most commonly used parameter for the evaluation of ventricular dilatation. It is the ratio of the maximum width of the frontal horns to the maximum width of the inner table of the cranium. Ratios greater than 0.32 are consistent with the diagnosis of NPH. However, it cannot differentiate NPH from cortical atrophy or obstructive hydrocephalus as the ratio may increase in all three entities. Furthermore, higher pre-operative Evans ratio (Fig. 2) (e.g. > 0.40) does not correlate with clinical improvement.[121]

Primary cortical atrophy may cause ex-vacuo ventricular dilatation. On CT scan, the cortical sulci and basal cisterns may become prominent. However, 50–60% of patients with cortical atrophy and classical signs of iNPH may still respond to shunting.[90,95,109] The presence of periventricular lucencies around the ventricular system may correlate with clinical improvement. However, they may also be found in non-NPH dementia.[100]

Nuclear or Computed Tomography Cisternography

Cisternography, originally described with radionuclides, has also been performed with iodinated contrast agents.[46,85] In both techniques, the CSF kinetics are similar. Radionuclide cisternography is performed by injecting an isotope iodine[131] labelled serum albumin or indium[111] via a LP. A two-dimensional gamma imaging is done intermittently over 24–48 hours. In hydrocephalic patients, both the ventricular reflux and delayed ascent and prolonged activity of the tracer over the cerebral convexity are evaluated. Nuclear or CT cisternography may show ventricular reflux with a slow cortical uptake. There is also persistence of ventricular reflux for more than 24 hours, a feature that helps in discriminating NPH from cerebral atrophy and in determining the shunt responsive patients.[50]

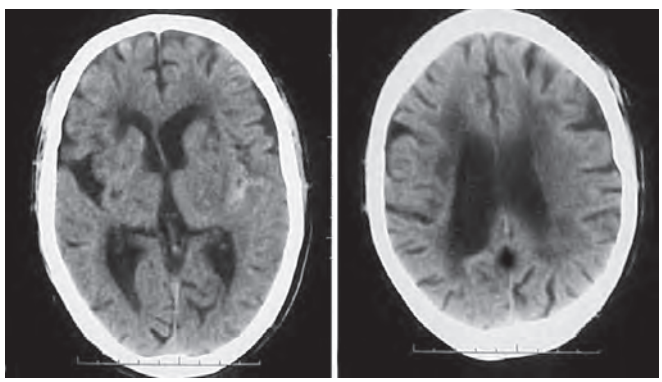

Fig. 1: CT diagnosis of a case of normal pressure hydrocephalus

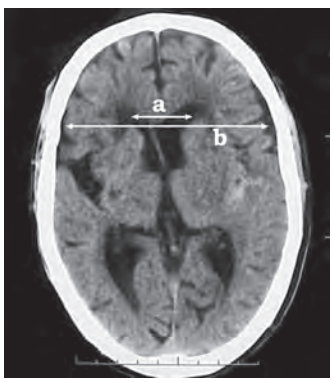

Fig. 2: Calculation of Evans ratio

The advantages of the CT technique include direct visualisation of intrathecal injection under fluoroscopy and improved spatial resolution, possibly for quantitative analysis. However, this poorly evaluates flow at the cerebral convexities, which is more easily seen with the radionuclide technique. CT is also more susceptible to motion artifact, which is common with demented patients. Overall, there is no greater advantage of CT cisternography over the radionuclide technique. The recent recommendation is that cisternography is not very helpful in identifying patients with iNPH and should not be included as an option. It may reveal disordered CSF absorption at the level of the arachnoidal villi, but is insensitive to resistance at the level of the veins. In patients who have an associated cortical atrophy, it cannot predict the response to shunting.[116]

A xenon-CT performed simultaneously with an intrathecal infusion test under pressure-volume stress may show disturbances in CBF autoregulation. A reduction of the regional CBF is usually associated with cortical atrophy.[65,69,71,108]

Magnetic Resonance Imaging

The assessment of NPH using MR imaging includes a study of the same parameters assessed on CT scans. In addition, a detailed study of the periventricular white matter is also possible because of its improved visualisation.[32,62] The presence of these changes is considered as a negative prognostic indicator. However, patients with even severe white matter changes on MR imaging may be benefited from surgical shunting and may have excellent clinical outcomes. The periventricular white matter has been studied in patients having NPH using an MR imaging technique called magnetisation transfer (MT). This technique measures the interaction between the pool of unbound water protons in tissues and the pool of water protons bound to macromolecules such as proteins and membranes. White matter changes with a high rate of MT are considered abnormal. These are detected much earlier on MT sequences than on routine T2 weighted imaging.[28,51,114]

Using three-dimensional (3D) MR imaging, Tsunoda et al.[112,113] compared the total intracranial and ventricular CSF volumes in patients with NPH with those of normal, age-matched controls and patients with cerebrovascular disease, and found increased total intracranial CSF volumes in the former. Thus, patients with NPH had ventricular volume to total intracranial volume ratio higher than those of both comparison groups. In fact, ratio values greater than 30% are seen only in patients with NPH indicating a very high specificity.[125]

According to Holodny et al.,[47] patients with Alzheimer's disease have significantly decreased hippocampal volumes along with increased size of perihippocampal fissures compared with both NPH patients and normal age-matched controls.

MR has also been used to study the pathophysiology of NPH by evaluating the presence of decreased vascular compliance in the superior sagittal sinus and straight sinus in NPH patients.[53] Bateman[5] demonstrated that the vascular compliance in NPH patients was decreased compared to control patients with or without cerebral atrophy. Interestingly, vascular compliance in NPH patients studied after removal of CSF approximated values seen in the control groups.

Magnetic Resonance Cerebrospinal Fluid Flow Studies

The use of MR imaging to evaluate the dynamics of CSF flow includes both qualitative as well as quantitative evaluation. Quantitative measurements include assessment of flow velocity and the flow volume through the cerebral aqueduct.[14–17,34,35,75,76,113]

On MR imaging, a signal void (Jet sign) is seen in the region of the cerebral aqueduct. This is because the velocity of fluid motion increases when larger volumes move through passages with decreasing cross-sectional areas.[48] The velocity of moving CSF is also related to viscosity, cerebral compliance, heart rate, cardiac output, blood pressure and cerebral autoregulation.[3] Patients with iNPH have a pathological cerebral compliance and a majority of them suffer from hypertension. Some of them also have impaired CBF autoregulation. These patients may have a hyperdynamic CSF motion that appears as CSF flow void[34,35,59] This is recognised as a signal loss within the ventricular system on T2 weighted MR scans and may be due to dephasing of protons that move along a gradient that is perpendicular to the imaging plane.[25] Although aqueductal flow void may be seen in normal persons, its extension to the adjacent third and fourth ventricles is more marked in the iNPH group than in normal persons. The signal void observed in patients with hydrocephalus is often more pronounced than in patients with normal ventricles. This is due to the presence of higher volume, turbulent CSF flow in these patients. This finding has been used to triage patients to CSF shunting based on the appearance and extent of the flow void.[87,118] In 1991, Bradley et al.[15] suggested that patients with an increased flow void on MR imaging were more likely to have a good or excellent response to shunting. In 1993, Mascalchi et al.[28,76] prospectively demonstrated the possible utility of this finding in predicting shunt-responsiveness using a qualitative, gradient-echo cine technique. However, other papers including a study by Krauss et al.[59] in 1997 disputed this finding. In the latter study, the degree and extension of the CSF flow void were not found to have significant predictive value in determining the outcome of shunting. The volume of CSF pulsating back and forth through the aqueduct during systole or diastole (the aqueductal CSF stroke volume) as well as its velocity have also been measured using phase contrast MR

imaging.[53,68,84] However, the cut-off point of CSF flow volume at which a diagnosis of iNPH may be made and the response to shunting determined with certainity have still not been decided.

Cerebral Perfusion

Cerebral perfusion studies showed decreased CBF in iNPH. However, as CBF is also decreased in patients with cerebral atrophy, it may be difficult to distinguish between the two conditions using this technique.[63,123] Alzheimer-type dementia may be differentiated as a regional decrease in CBF of the temporoparietal area may be present. Normalisation or near normalisation of CBF after LP in patients having iNPH has prognostic importance as this subset of patients may improve after shunting.[64] The acetazolamide challenge test (i.e. a vasomotor response to carbonic anhydrase inhibitors) or inhaled CO_2, which normally increases CBF, often fails to do so in iNPH patients, particularly in the periventricular white matter.[81] This is possibly due to the existence of already maximally dilated arterioles as a result of local ischaemia. The acetazolamide challenge test may also be used to select patients for shunting, since the patients with a good response to ventriculoperitoneal (VP) shunting usually have a pre-operative CBF above 20 ml/100 g/min.[3] In support of this, a haemodynamic test conducted by Mori[83] in a multi-institutional study in Japan on patients with iNPH consisted of (apart from the other tests) identification of arterial hypertension as a risk factor and of determining whether or not CBF was greater than 20 ml/100 g/min with impaired vascular response to acetazolamide in the periventricular area.

Cerebral Metabolism

^{18}F-fluoro-deoxy-glucose positron emission tomographic (PET) scans of the brain have demonstrated globally decreased brain metabolism and CBF in patients with iNPH when compared with controls.[49] Momjian et al.[82] found a more pronounced CBF reduction adjacent to the ventricles on PET scans and a logarithmic normalisation with distance from the ventricles. Thus, there is an enlargement of the area of the region of subcortical periventricular low CBF.[82] This area also shows a greater restoration of CBF after shunting than the cortex, which correlates with clinical improvement. However, individual patients have heterogeneous CBF defects and no characteristic and consistent pattern has been found in most of the studies.

Enlargement of the subcortical low cerebral flow region taken from slices through the midbrain or basal ganglia as demonstrated on SPECT using either ^{99}mTc hexamethylpropyleneamine or ^{123}I-isopropylamphetamine may also be useful in identifying candidates for shunt surgery.[107]

Transcranial Doppler Ultrasonography

Transcranial Doppler (TCD) ultrasonography has been used to study the pre-operative and post-operative cerebral haemodynamics in iNPH.[27,97] One study conducted pre-operatively claimed that patients who showed normal or near normal CO_2 reactivity of the brain before surgery, showed the greatest clinical improvement after treatment. Other studies comparing the pre-operative and post-operative imaging showed that patients who responded positively to shunting had a statistically significant increase in CO_2 reactivity in the anterior cerebral arteries, middle cerebral arteries, or both after surgery.[67] Measurement of the pre-operative end diastolic velocities also has prognostic significance. When CBF velocity is maximum at the diastolic phase of the cardiac cycle, it indicates that the patient may be benefited by CSF shunting. TCD has not been used to diagnose or plan treatment of patients with iNPH routinely and is currently only being performed in a few institutions for research of CBF patterns in iNPH.[31]

Tap Test

The tap test is one of the commonly used tests to determine the clinical response to installation of a shunt in iNPH. It is easy to perform and is inexpensive. It has been documented that if after CSF (40–50 cc) drainage through an LP the patient improves clinically, it indicates that he/she may be shunt responsive.[94,103] The sensitivity and specificity of the test increases when more fluid is tapped. A positive predictive value of more than 70% has been reported. If, however, the patients are selected for a shunt procedure based only on a positive tap test, a considerable number of shunt-responsive NPH patients would be missed. Thus, NPH patients should not be excluded for shunt surgery based on a negative spinal tap test since a CSF tap test has a good positive predicitive value but a low specificity.[23,118,128] When combined with SPECT measurements of CBF before and after the tap test, higher predictive rates of shunt responsiveness are obtained. An increase of more than 80% in CBF after CSF removal was predictive of response to shunt surgery with an accuracy of 77%.[38,45,128]

Measurement of Cerebrospinal Fluid Opening Pressure

Manometric measurement of CSF opening pressure on LP is also used for determining shunt responsiveness in patients with iNPH. LP is performed in the left lateral decubitus position with the zero point of the manometer being positioned at approximately the height of the atrium of the heart. Before a pressure reading is made, the patient should fully be relaxed, preferably with legs extended, for a period of 5 minutes after the LP needle is introduced. CSF pulsations should synchronise with cardiac pulsations. This ensures that the tip of the needle is adequately in the subarachnoid space when the

measurement is made. In normal volunteers, the CSF opening pressure averages 122 ± 34 mm H_2O (8.8 ± 0.9 mmHg). In patients with iNPH, the CSF opening pressure averages 11 ± 3.3 mmHg (150 ± 45 mm H_2O) but may fall between 4.4 mmHg and 17.6 mmHg (60–240 mm H_2O). Thus, in iNPH, the mean CSF opening pressure is slightly higher than normal but is still within the normal range. In iNPH, there may be transient high pressure waves (B waves) during prolonged intraventricular pressure monitoring, but these waves are not sustained. CSF opening pressures in the range of 105–190 mm H_2O may indicate probable iNPH. At the extremes of the expected range (60–104 mm H_2O or 191–240 mm H_2O), iNPH may be possible. Pressures outside this range would make the diagnosis of iNPH unlikely. Thus, iNPH may be distinguished from secondary forms of hydrocephalus where the CSF pressure is usually high (usually above 18 mmHg; 245 mm H_2O) and the increased CSF pressures are sustained.[51,83,109]

Continuous Intracranial Pressure Monitoring

Continuous ICP recording over 24 hours has been correlated with the outcome following installation of a shunt. A normal or slightly elevated ICP (> 15 mmHg) and an increased frequency of B waves (occupying more than 50% of the monitoring period) may be indicative of a lower compliance. However, there is a lack of normal age-matched control data in the literature.[57] It has been proposed that the amplitude and duration rather than the frequency of B or A waves are important. However, both A and B waves often poorly predict which patients will respond to shunt surgery.[98,118]

Controlled Continuous Lumbar Drainage

Controlled continuous lumbar drainage consists of draining 10 cc of CSF per hour for a period of 72 hours. In Haan's[41] study, all patients with a positive test improved after shunting. However, the potential risks and disadvantages (hospitalisation and costs) prevent this test from being routinely used in clinical practise.[124] Reported complication rates with ELD are 5–20% and may be in the form of severe nerve root irritation and infections.[19]

Impedence of Flow Offered by Cerebrospinal Fluid Absorption Pathways

This resistance offered by CSF absorption pathways may be measured by several methods. In the Katzman[99] test, a pump introduces artificial CSF or saline into the lumbar subarachnoid space at a known constant rate. The resistance is the difference in the final steady-state pressure reached and the initial pressure divided by the infused flow rate. In the bolus method, about 4 ml is injected into the lumbar subarachnoid space at the rate of 1 ml/sec. This method measures both the resistance offered by the CSF absorption pathways as well as the brain compliance (defined by the pressure-volume index). A third method calculates the resistance and compliance during ascending pressure curves in response to a known infusion rate.[96] Thus, it is not essential to reach the steady state using this method. A constant pressure and ventriculocisternal method has also been described. In a study conducted by Kahlon et al.[51] the lumbar infusion test was performed with two needles inserted in the lower lumbar subarachnoid space, one of which was connected to a pressure recording device. The initial steady state CSF pressure was recorded before starting a constant rate infusion of Ringer solution through the needle. The CSF pressure was continuously recorded for at least 45 minutes through the other needle via the pressure monitoring device attached to the needle to establish a steady state pressure plateau representing the pressure level at which absorption balanced infusion. The steady state plateau pressure exceeding 22 mmHg was used as a criterion for shunt surgery.[79]

A problem with measuring impedence of CSF flow is that it increases with age even in normal individuals. Headache and meningismus may occur following fluid infusion. This test may help in increasing the accuracy for identifying iNPH when tap test results are negative.

The predictors of good surgical candidates for shunting in iNPH are summarised in Table 1.

SURGICAL MANAGEMENT OF IDIOPATHIC NORMAL PRESSURE HYDROCEPHALUS

Patient Selection

The pathophysiology of iNPH is not well established and it is not possible to ascertain when the point of "*irreversibility*" of brain injury is reached.[8] Patients with severe cerebrovascular disease do not respond as well

Table 1: Predictors of good surgical candidates for shunting in iNPH

Evaluation parameters	*Positive predictor*
Clinical examination	Presence of classic triad, especially gait disturbance as the primary symptom
Lumbar puncture	Opening pressure > 100 mm water
Cisternogram	Typical NPH pattern, especially persistent ventricular activity at 48 hours
Continuous CSF monitoring	CSF recording pressure >180 mm water; frequent beta waves
Cranial CT scan	Enlarged ventricles; periventricular hypodensities; flattened cortical sulci; small or absent perihippocampal fissures
MRI	All of the above, specially small or absent perihippocampal fissures
Transcranial Doppler studies with carbon dioxide reactivity	Reactivity above 25% with pathologic readings on pressure recordings

to shunting but may still derive some benefit from the procedure.[39,119] The neurological decline in spite of shunt placement in iNPH may be related to the progression of comorbid conditions rather than as sequelae of iNPH. Malm et al.[70] reported that the number of patients with improvement following shunt surgery declined from 64% at 3 months to 26% at 3 years. These findings suggest that shunt may not always arrest the progression of iNPH or its associated comorbid conditions.[37] However, even a temporary improvement ranging 1–3 years in such patients in an advanced age makes a substantial difference to their quality of life. The CSF shunt improves the symptomatology of patients with iNPH due to its dual action, i.e. the diversion of a greater proportion of CSF as well as the provision of additional capacitance. The latter is because, with modulation of pulse pressure, the interstitial oedema and pressure also decrease, improving perfusion and decreasing ischaemia This may be the reason why third ventriculostomy is also effective in some patients of iNPH.[32] As small vessel atherosclerosis is a slowly progressive disease, at some point, CSF diversion is not enough to improve perfusion.[123] Thus, patients with severe white matter disease or those with very low CBF may not respond to shunting, since irreversible atrophy has already taken place in these individuals.[56,60,107] The damage may be more diffuse than that seen on the T2 weighted MR image. This is because the MT ratio is often decreased (indicating loss of myelin protein) and the apparent diffusion coefficient is often increased (indicating increased interstitial oedema) in these patients who seem to be having normal appearing white matter on T2 weighted images.

Surgical diversion of CSF is recommended for iNPH patients in whom there is a favourable risk-to-benefit ratio.[117,120] Factors, such as coagulation status, immune incompetence, comorbidity, functional status and advanced age, should be taken into account while considering surgical intervention.[8] In general, patients exhibiting negligible symptoms may not be suitable candidates for surgical management, given the known risks and complications associated with shunting in iNPH.

The medical treatment of NPH consists of acetazolamide and repeated LPs, which have occasionally yielded prolonged clinical improvement.[81]

Current Recommendations of the iNPH Guidelines for iNPH Diagnosis and Use of Supplemental Prognostic iNPH Tests for Identifying Shunt Responsive Patients

On the basis of clinical examination and neuroimaging (CT/MR), the patient may be categorised as "*probable*", "*possible*" or "unlikely".

Improvement following shunt placement for "*possible*" or "*probable*" iNPH ranges from approximately 61% to slightly less than 50%. Thus, if the classical triad is present and no other illness accounts for the clinical presentation, then one may proceed directly to CSF diversion without supplemental tests.[55,72,112] In the unlikely NPH category, a shunt placement is usually deferred.[98]

Supplemental testing may be in the form of CSF tap test, resistance to flow of CSF determination and/or external lumbar drainage. This may be done in order to increase the certainty of positive shunt response beyond 50 to 61%.[23]

A favourable clinical response to a 40–50 ml CSF tap test indicates that the patient is likely to be benefited from CSF diversion surgery.[19,23,45,94,128] This may be performed for three consecutive days and clinical assessment made. If the tap test does not elicit a favourable clinical response, however, it cannot be used as an exclusionary test due to its low sensitivity (26–61%). Thus, if a negative tap test is obtained, supplemental tests should be performed. If the opening pressure during tap test exceeds 18 mmHg, a diagnostic work up for secondary causes of hydrocephalus should be initiated.[94]

Determination of resistance to CSF flow may be performed on an outpatient basis, like the tap test, and carries a higher sensitivity (57–100%) than the tap test.

Prolonged external lumbar drainage in excess of 300 ml has a high sensitivity (50–100%) and is the most effective supplemental test for identifying surgery responsive iNPH.[74] However, it requires hospital admission and may be associated with complications like severe headache, subdural hygroma/haematoma and meningismus.

Type of Shunt

Various shunt diversion procedures have been described for the treatment of iNPH that have included the VP and ventriculoatrial (VA) shunts, the lumboperitoneal shunt and the ventriculopleural shunt.[7,8] The most commonly used CSF diversion procedures in iNPH are the VP and lumboperitoneal shunts. However, patients who have a history of peritonitis or multiple abdominal operations may not have adequate CSF drainage due to decreased absorptive capacity of the peritoneal cavity. In these patients, a VA shunt may be preferred.

Endoscopic third vetriculostomy has also been advocated as a therapeutic option in selected patients. ETV reduces the intraventricular pressure (with a consequent increase of the CBF and also restores the normal CSF dynamics. Thus, ETV showed a 72% response rate in NPH in the series by Gangemi et al.[33] which is comparable to the improvement seen in various shunting procedures.

Valve Selection

The shunt valve selection may have a bearing on the outcome of iNPH since it maintains a balance between an efficient CSF drainage and prevention of overdrainage related complications.[13,126,129] The valve designs may be of different types:

- Differential pressure valves (e.g. Chhabra shunt): A spring loaded ball check valve or the opposed leaves

of a slit valve will open, if the pressure differential across the valve mechanism exceeds a set value. They may be categorised into low pressure (approximately 20–40 mm H_2O); medium pressure (approximately 50–90 mm H_2O) and high pressure (approximately 100–140 mm H_2O). One of the problems with these valves is that, in an upright position of the patient, the increased hydrostatic column of CSF builds up a high pressure differential across the valve. This may permit a propensity to over drainage (siphoning) of CSF. To counteract this gravity dependent drainage, antisiphon devices may be added in series immediately distal to a differential pressure valve.[26] However, in patients with iNPH in whom the CSF pressure is truly normal (including lack of frequent B waves), placing an antisiphon device may be ineffective.

- Flow limiting valves: These may either (i) have a differential pressure valve that in conditions of normal CSF flow limits CSF flow rate by narrowing the aperture of the valve mechanism and in conditions of high ICP, switches to a high flow rate (e.g. NMT Orbis-Sigma and Phoenix shunts); or (ii) incorporate a high flow resistance tube without a differential pressure mechanism in series to an adjustable differential pressure valve that prevents gravity dependent overdrainage by selectively reducing high CSF flow rates when the patient is in an upright position (e.g. Codman FloGuard valve); or (iii) incorporate a dual stage differential pressure valve (containing tantalum spheres that move within the valves in response to gravity) which has a low pressure in the supine position and a high pressure in the upright position (e.g. Miethke dual switch valve).[126]
- Programmable valves (e.g. Sophy and Codman-Medos valves): These permit the opening pressures of the differential pressure valve mechanisms to be changed non-invasively.[52] The valve adjustments may be made depending upon whether or not overdrainage, underdrainage or a subdural fluid accumulation is occurring.[9,88,129]

The use of an adjustable valve may be beneficial in the management of iNPH due to the increased capability of non-invasively managing both overdrainage and underdrainage. In the study of McConnell et al.[77] a careful volumetric analysis has revealed that changes in ventricular volume correlated with adjustments in valve pressure settings for those patients who improved clinically after shunting. Various retrospective series comparing the non-programmable with programmable shunt systems, however, have so far not yielded any statistically significant benefit in using any specific valve type or configuration.

Clinical Scales for Assessing Outcome

The various scales used for assessing clinical outcome at follow-up after shunt placement have included the Stein and Langfitt scale, the Black scale, the modified Rankins' scale and Boon's Dutch NPH scale.[11] Assessment of cognitive functions may objectively be done using the Mini-mental state examination (Table 2).

Management of Patients Who Fail to Improve or Those Who Deteriorate Clinically Following Shunt Placement

Subdural Fluid Collection Following Cerebrospinal Fluid Diversion

In case a subdural haematoma/hygroma with significant symptoms and mass effect develops, it should surgically be evacuated. In case it is small or asymptomatic then it may be followed using repeated CT scans. In case there is recurrence, persistence or increase in the size

Table 2: Clinical scales for objective assessment of iNPH patients

A. Stein and Langfitt scale[101]	
0:	No neurological deficit, able to work
I:	Minimal deficit, able to function independently at home
II:	Some supervision required at home
III:	Custodial care required despite considerable independent function
IV:	No practical capacity for independent function

Source: Stein SC, Langfitt TW. Normal pressure hydrocephalus: predicting the results of cerebrospinal fluid shunting. J Neurosurg. 1974;41:463–70.

B. Black scale[9]	
Excellent:	Resumed pre-illness activity without deficit
Good:	Resumed pre-illness activity with deficit, improved in two or more categories
Fair:	Improved but did not return to previous work, improved in one category
Transient:	Temporary major improvement
Poor:	No change or worsening
Dead:	Died within 6 weeks of surgery or as a result of surgery

Source: Black PM. Idiopathic normal pressure hydrocephalus: results of shunting in 62 patients. J Neurosurg. 1980;52:371–7.

C. Grading scale for NPH established by the reseach committee on intractable hydrocephalus, Ministry of Health and Family Welfare of Japan, 1996

Grade	Definition
Gait disturbance	
0	Normal
1	Unstable but independent gait
2	Walking with one cane
3	Walking with two canes or a walker frame
4	Walking not possible
Dementia	
0	Within normal range
1	No apparent dementia but apathetic
2	Socially dependent but independent at home
3	Partially dependent at home
4	Totally dependent
Urinary incontinence	
0	Absent
1	Absent but with polyuria or urinary urgency
2	Sometimes only at night
3	Sometimes even during the day
4	Frequent
Total grade:	0 to 12

Source: Mori K. Management of idiopathic normal pressure hydrocephalus: a multi-institutional study conducted in Japan. J Neurosurg. 2001;95:970–3.

D. Modified Rankin scale[91,115]

Grade	Description
0	No symptoms
1	No significant disability despite symptoms: able to carry out all usual duties and activities
2	Slight disability: unable to carry out all previous activities, but able to look after own affairs without assistance
3	Moderate disability: requiring some help, but able to walk without assistance
4	Moderately severe disability: unable to walk without assistance, and unable to attend own bodily needs without assistance
5	Severe disability: bedridden, incontinent and requiring constant nursing care and attention

2. Rankin J. Cerebral vascular accidents in patients over the age of 60. II. Prognosis. Scott Med J. 1957;2:200–15.

E. Folstein mini-mental status examination[30]

Score	Task instructions
5	Date orientation: 1 point each for year, month, day of week, season and date.
5	Place orientation: 1 point each for state, country, town, building and floor or room.
3	Register objects: Name three objects slowly and clearly. Ask patient to repeat them. 1 point each for each item correctly repeated
5	Serial sevens: Ask patient to count backwards from 100 by 7. Stop after five answers. 1 point for each correct answer
3	Recall objects: Ask patient to recall the objects mentioned above. 1 point for each item correctly remembered
2	Naming: Ask patient to name watch and pencil. 1 point each for each correct answer
1	Repetition: Ask patient to repeat the phrase: "No ifs, ands or buts". 1 point for correct answer
3	Comprehension: Ask patient to: (1) Take paper in left hand. (2) Fold it in half. (3) Put it on the floor. 1 point for each correct movement

Contd...

Contd...

1	Reading: Ask the patient to read the statement "Close your eyes" and follow instructions. 1 point if the patient's eyes close
1	Writing: Ask the patient to write a sentence. 1 point, if the sentence has a subject, a verb and makes sense
1	Drawing: Ask patient to copy a pair of intersecting pentagons onto a piece of paper. 1 point if the Figure has 10 corners and 2 intersecting lines

A score of ≥ 24 is considered normal.

F. Dutch NPH scale[10]

Scale

1. Gait scale: It evaluates 10 features of gait and measures number of steps and seconds required for a 10 m walk. Range: 2–40.

$$\text{Outcome measure: } \frac{\text{preop score} - \text{last or mean F/U score}}{\text{preop score}} \times 100$$

2. Dementia scale: This scale composed of the 10 words, digit span forwards and backwards, trial making, and finger tapping tests. Range: 4–40.

$$\text{Outcome measure: } \frac{\text{preop score} - \text{last or mean F/U score}}{\text{preop score}} \times 100$$

3. NPH scale: It composed of the sum of gait scale and dementia sale. Range: 6–80.

$$\text{Outcome measure: } \frac{\text{preop score} - \text{last or mean F/U score}}{\text{preop score}} \times 100$$

4. Modified Rankin scale: This disability score was extended to a 7 point scale by including a grade 4 (defined as moderate disability, partially independent, and needing assistance for less than 50% of the day. Range: 0–6.
   Outcome measure: preop grade—last or mean follow-up grade
5. Modified mini-mental state examination:[110] This evaluates disturbance of cognition. Range: 0–100.
   Outcome measure: preop score—6 or 12 months score

Level of improvement: Improvement in NPH scale score

	Improvement in modified (%)	Rankin score
None	<15	< 1 grade
Moderate	15–29	1 grade
Marked	30–44	2 grades
Excellent	≥ 45	≥ 3 grades

of the haematoma/hygroma then consideration for valve adjustment may be done.[18] The settings of the adjustable valves should be increased. In case of fixed valves, replacement with an adjustable valve, the addition of an antisiphon device or revision with a higher pressure valve may be carried out.

Unchanged or Increased Ventricular Size

In case of adjustable valves, the valve settings may be lowered. If the patient does not improve even at the lowest settings and the CT still shows no change in the ventricular size, then shunt patency should be

evaluated using X-ray or radionuclide evaluation or by an LP, ventricular tap or shunt chamber tap. If initially a fixed valve had been placed, then one directly proceeds for evaluation of shunt patency. If the shunt is working, a lower pressure valve is placed, the antisiphon device is removed or the distal slit valves may be removed. In case the shunt is not working, it is replaced.

Whenever there is lack of improvement, other comorbid conditions (like ischaemic cerebrovascular diseases and extensive white matter diseases) and social influences must also be evaluated.

23 Bony Anomalies of the Craniovertebral Junction

Sanjay Behari, Rabi N Sahu, Vijendra Kumar Jain

INTRODUCTION

The term craniovertebral junction (CVJ) refers to the occipital bone that encircles the foramen magnum, the atlas and the axis cervical vertebrae. The medulla oblongata, cervicomedullay junction and upper cervical spinal cord pass through the bony canal formed by these structures. The CVJ has a predilection for a variety of congenital anomalies due to its complex embryological development. Any bony abnormalities that affect this complex can result in neural compression along the entire circumference, vascular compromise and abnormal cerebrospinal fluid (CSF) dynamics.[25] In order to treat the patients with CVJ anomalies, a detailed knowledge of the embryology, anatomy as well as CVJ biomechanics is essential.

EMBRYOLOGICAL ANATOMY OF CRANIOVERTEBRAL JUNCTION

The bony cranial base is formed by the process of endochondral ossification in which a cartilaginous framework first develops, followed by bony osteogenesis; remodeled by distorting forces of brain and eye morphogenesis. During the 4th week of gestation,[42] somites are formed, of which four occipital somites and the upper two cervical somites are involved in the development of CVJ.[28] The first two occipital sclerotomes ultimately form the basiocciput. The third sclerotome is responsible for the exoccipital centre and forms the jugular tubercle. The fourth occipital sclerotome is called the proatlas and has three divisions: (1) hypocentrum that forms the anterior tubercle of the clivus; (2) centrum that forms the apical ligament and the apex of the dens and (3) third division, which is the neural arch of the proatlas that has further two subdivisions, the ventral rostral part and the dorsal caudal part. The ventral rostral part forms the occipital condyles, the anterior portion of the foramen magnum and the alar and cruciate ligaments, whereas the dorsal caudal portion forms the posterior arch of atlas and its lateral masses. The hypocentrum of the first cervical (C1) sclerotome forms the anterior arch of atlas, the centrum forms the dens and the neural arch of C1 forms the posterior-inferior arch of atlas. The 2nd cervical spinal segment has three similar divisions: (1) hypocentrum, which disappears; (2) centrum, which forms the body of the axis and (3) neural arch, which forms the facets and posterior arch of axis. The odontoid process fuses with the base of the axis by the age of 8 years. On the other hand, the tip of the dens is not ossified at birth and is represented as a separate ossification centre that usually appears at age 3 and fuses with the remainder of the dens by the age of 12.[50]

Wide varieties of congenital anomalies are possible because of this complex developmental sequence. More often, multiple abnormalities are present in a single individual, which may involve both osseous and neural structures. This maldevelopment usually occurs between the fourth and the seventh months of intrauterine life. CVJ anomalies can be classified into the following types:

- Failure of segmentation
- Failure of fusion of different bony components
- Hypoplasia
- Ankylosis

Various genetic associations have been found with CVJ anomalies. A study shows a high association of methylenetetrahydrofolate reductase (MTHFR) gene 677C to T polymorphism and higher T allele frequency (which encodes enzymes of the folate pathway implicated in the causation of neural tube defects) with atlantoaxial dislocations, especially the irreducible variety.[35] Homeotic transformation due to mutation or disturbed expression of the *Hox* gene has been postulated as a possible mechanism responsible for assimilation of the atlas into the occiput. The *PAX* regulatory genes control segmentation of the somites and sclerotomes to establish vertebral boundaries. During chondrification of the vertebrae, the *PAX* gene is strongly expressed in the developing vertebrae and, therefore, its expression may underlie vertebral fusion and may be responsible for the Klippel-Feil anomaly (bony fusion of adjacent vertebrae). There is increased incidence of occipitocervical instability and CVJ abnormalities associated with Down's syndrome.[36,47]

CLASSIFICATION

The congenital CVJ anomalies may be divided into the following:

1. Malformations of occipital bone
   a. Manifestations of occipital vertebrae, i.e. clivus segmentations, remnants around foramen magnum, proatlas remnants
   b. Basilar invagination
   c. Condylar hypoplasia
   d. Assimilation of atlas

2. Malformations of atlas
   a. Atlas assimilation
   b. Atlantoaxial fusion
   c. Hypoplasia of atlas arches
3. Malformations of axis
   a. Segmentation defects of C1-C2 or C2-C3 vertebrae
   b. Dens dysplasia
      i. Hypoplasia of the dens
      ii. Ossiculum terminale
      iii. Os odontoideum
   c. Irregular odontoid segmentation
4. Syndromic atlantoaxial instability
   a. Inborn errors of metabolism (Morquio syndrome)
   b. Down's syndrome
   c. Grisel's syndrome

Malformations of the Occipital Bone

As mentioned earlier, the four occipital somites and upper two cervical somites are involved in the development of CVJ. The malformations of the occipital somites may take many forms often with varied symmetry. There may be clivus segmentation, remnants around foramen magnum or proatlas remnants. Sometimes, a condylar canal may traverse through the clivus representing the primitive neural canal. These anomalous developments are collectively termed as "manifestations of occipital vertebrae". Some of the minor anomalies may go undetected throughout life. Some may cause various neural compressive myelopathies. There may be neck pain with assorted rotatory neck deformities like "cocked robin" appearance due to asymmetric maldevelopment around the foramen magnum.[33]

Basilar Invagination and Platybasia

Basilar invagination (BI) is a congenital form of occipital hypoplasia, which manifests by prolapse of the spinal column into the skull base (Fig. 1).[25,26,50] Platybasia is often used synchronously with BI; it is an anthropological term used to describe an abnormal excessive obtuse angulation of the basal angle between the anterior skull base and the clivus. This angle is normally 132 degrees, but when platybasia is present it exceeds 142 degrees. Basilar impression refers to cranial base flattening, platybasia or BI developing as a result of some bone softening due to acquired conditions like osteogenesis imperfecta, Paget's disease or hyperparathyroidism.[15,41,48] Two types of BI have been described: (1) anterior or vertebral invagination which is characterised by shortening of the occipital base and the clivus with concomitant platybasia and shallow posterior fossa and (2) paramedian invagination resulting from hypoplasia of the occipital bones. In this case, the clivus develops normally, but is displaced posteriorly. In this type of BI, condylar hypoplasia is also frequently found. Apart from these two extreme types of BI, some overlapping varieties of BI may also occur.[1,4] Other anomalies associated with platybasia are Klippel-Feil syndrome and occipitalisation of the atlas. BI has also been associated with Down's syndrome and skeletal dysplasia.[20,25,50]

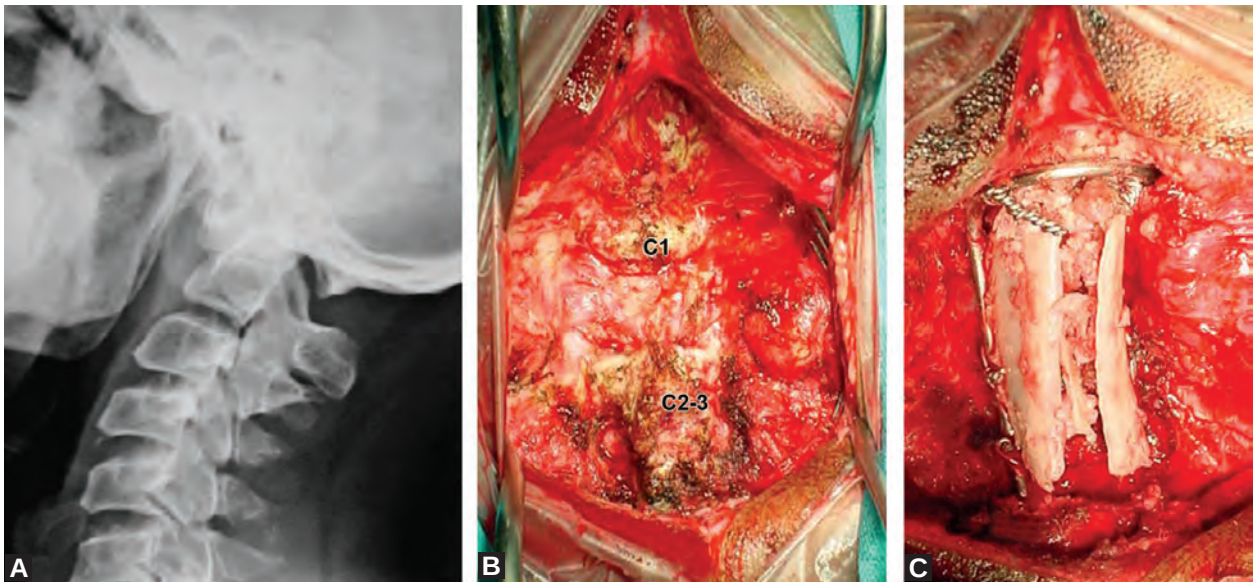
Fig. 1: Sagittal T2-weighted MR image showing BI with central dislocation of the odontoid into the foramen magnum causing cervicomedullary compression

Symptoms of BI are related to compression of the cervicomedullary junction, which develop when the midsagittal diameter of the foramen magnum is less than 19 mm. The most common presenting symptom in BI is neck pain. This symptom is present in 80–85% of patients and frequently originates in the suboccipital area and radiates to the vertex.[13,50] The most frequent neurological sign elicited relates to myelopathy. BI is also often associated with atlantoaxial dislocations and Chiari I malformations. The treatment of BI should start with skull traction to attempt reduction of the ventral compression and to change the curvature of the posteriorly directed odontoid to a more vertical one. Reduction in general is better in children than in adults. The treatment following traction is relatively straight forward. In the reducible variety of atlantoaxial dislocation associated with BI, an occipitocervical fusion is required with or without posterior fossa or upper canal decompression. On the other hand, in patients with the irreducible variety of atlantoaxial dislocation, or a pure BI that is causing neural deficits and canal compromise, a transoral decompression is required to remove ventral compression. This extensive osteoligamentous removal is frequently followed by instability requiring dorsal occipitocervical fusion with or without posterior decompression.

Malformations of Atlas

Atlas Assimilation

Atlas assimilation, also called occipitalisation of atlas, is one of the most common anomalies of the CVJ affecting 0.14–2.7% of individuals.[21] To qualify as atlas assimilation, there must be bony continuity between the atlas and skull base, not merely radiological evidence of lack of movements (Figs 2A to C).[27] Assimilation of atlas may involve the anterior arches, the lateral masses or the posterior arch.[30] When the condyles are fused to the lateral masses, the deformity is usually asymmetric. The most common cause of symptoms related to atlas assimilation



Figs 2A to C: (A) A lateral radiograph of the cervical spine showing atlantoaxial dislocation with occipitalisation of the atlas with C2-C3 fusion. (B and C) An intra-operative photograph of the same patient where occipitalisation of the posterior arch of atlas and C2-C3 fusion is seen. A contoured rod fusion was performed for the coexisting C1-C2 instability

is its association with atlantoaxial dislocation.[5,27] The other associations with atlas assimilation are Klippel-Feil syndrome (fusion of cervical vertebrae), BI and Chiari malformation.[5,16,28] The neurological deficits may range from neck pain to subtle myelopathy to severe quadriparesis. Symptoms of intracranial hypertension may be found secondary to obstruction of CSF outflow owing to the crowded posterior fossa and associated Chiari malformation.[27] Sometimes, an asymptomatic person may develop weakness secondary to trauma or sudden neck flexion and extension.[25] Asymptomatic atlas assimilation does not require treatment. However, surgical decompression with or without stabilisation may be needed in those patients with symptoms due to foramen magnum stenosis, associated irreducible or reducible atlantoaxial dislocation, BI or Chiari malformation. Due to the non-availability of a well developed posterior arch of atlas, an occipitocervical rather than a C1-C2 fusion is required for posterior stabilisation.

Occipitalisation of atlas is often associated with Klippel-Feil syndrome with the classical triad of low hairline, a short neck and a webbed neck with restriction of neck movements. Deafness, cleft face, high arched palate, facial palsies; cardiovascular disorders such as mitral valve disease, ventricular septal defect, coarctation of aorta and patent ductus arteriosus; genitourinary tact disorders such as unilateral, horse-shoe or ectopic kidney; bicornuate uterus; or thoracic dysplasias, ectopic lung, or rib fusions may be associated.

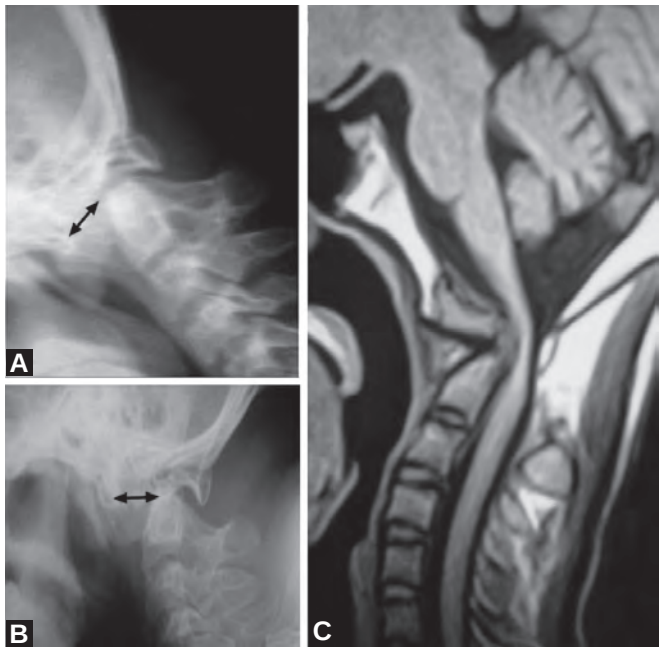
Aplasia and Hypoplasia of the Anterior and Posterior Arches of Atlas

Congenital anomalies of the atlas are frequently manifested as aplasia or hypoplasia of the atlas arches.[25,26] The lateral masses and part of the posterior arch of C1 develop from the proatlas. Anomalies of the ring of C1 can take many shapes, with clefts within the ring of the atlas being more common than complete aplasia.[52] Defects in the anterior arch ring are quite rare, being observed in less than 0.1% of adult spines; however, defects within the post ring are much more common, occurring in anywhere from 0.5 to 5% of anatomical specimens.[31] Ninety-seven per cent of posterior clefts cases are noted in the midline, with only 3% of posterior clefts located in a lateral position near the sulcus of the vertebral arteries.[43] Defects within the ring of C1 are frequently associated with Klippel-Feil syndrome and spina-bifida of the axis.[18] In addition, a prominent tubercle of the neural arch of C2 has also been observed in several cases. It has been proposed that it represents a posterior tubercle of the atlas which has become fused to the axis. An assimilated posterior arch is often associated with asymmetrical lateral occipito-C1-C2 joint synostosis.

Radiographic evaluation with plain films can be misleading, with clefts frequently simulating Jefferson fractures.[9,43] Congenital anomalies of the C1 arches may also produce lateral defects on AP open mouth views.[9,19] This finding may be responsible for causing confusion between the diagnosis of arch hypoplasia and the Jefferson fractures in cases of cervical trauma. The overriding in congenital anomalies is only of a 1–2 mm magnitude, whereas Jefferson fractures usually produce an offset of 7.3 mm.[19]

Congenital Anomalies of Atlantoaxial Joint

The most complex articulation in the cervical spine is between the atlas and the axis. Three joints link the atlas and the axis, the two facet joints on the lateral aspect and the third one which is the most important between the odontoid and the anterior arch of atlas. The



Figs 3A to C: (A) A lateral radiograph in flexion showing an atlantoaxial dislocation. (B) The dislocation is irreducible in extension. (C) T2-weighted sagittal MRI showing the atlantoaxial dislocation causing significant thecal compression

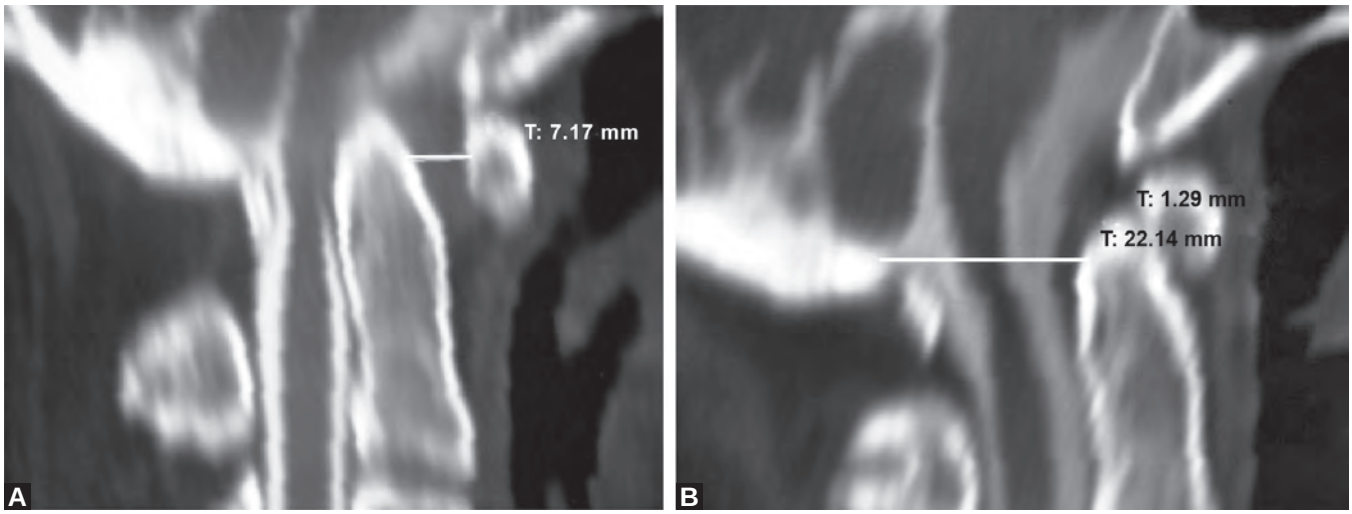
stability of the atlantoaxial joints is dependent primarily on the integrity of the transverse axial ligament (TAL) that limits excessive anterior translation of the axis while allowing rotation of the atlas on the axis through an arc of 90 degrees. In case of an incompetent TAL, the atlantoaxial joint becomes unstable and is dislocated posteriorly resulting in atlantoaxial dislocation (AAD). The congenital disorders involving the atlanto-odontoid articulation include hypoplasia or absence of the odontoid as well as incompetence or absence of the TAL.[4,41] Depending on the reducibility of the dislocation, the AAD may be irreducible (Figs 3A to C) or reducible (Figs 4A and B). In a few patients with a dysplastic or a hypoplastic odontoid, a "*hypermobile*" AAD exists, that causes cervicomedullary compression both in flexion (that displaces the odontoid tip posteriorly relative to the C1 arch) and extension (that displaces the C1 arch posteriorly relative to the axis) movements of the neck. This subtype requires special care during intubation, positioning and stabilisation with the patient being maintained in a strictly neutral position.[4,39]

Atlantoaxial Rotatory Fixation

Atlantoaxial rotatory fixation is a rare disorder in which the atlas gets fixed in a position normally achieved during rotation. Patients present with painful torticollis and a typical '*cocked robin*' position of the head: rotation, slight flexion and with the head tilting contralateral to the direction of rotation. During childhood, laxity of the ligamentous apparatus and joint cups allows a wider range of motion and rotation within these joints. The largest rotation of the cervical spine occurs at the atlantoaxial joints. When the rotation exceeds 40 degrees, an interlocking of the lateral inferior facet of the atlas occurs over the superior articular facet of the axis vertebra. If the TAL is deficient, the anterior arch will sublux forward producing a dislocation with an interlock at much less than 40 degrees. Further rotation more than 30–35 degrees produces an angulation of the ipsilateral vertebral artery. This phenomenon has an implication in certain sports activity like football injuries and wrestling, as well as with children under general anaesthesia or those who undergo chiropractic manipulations.[11,32,34]

Os Odontoideum

Os odontoideum is an uncommon CVJ abnormality that exists as a separate ossicle apart from a hypoplastic dens (Fig. 5). It usually moves with the clivus (dystopic) or with the atlas and the axis vertebrae (orthotopic). Its genesis and natural history have been debated, and its proper treatment remains uncertain.[12] Sometimes,



Figs 4A and B: (A) Sagittal reconstructions of intrathecal contrast CT scan in flexed position of the neck showing an atlantoaxial dislocation with occipitalised atlas. (B) In extended position showing reduction of the C1-C2 dislocation

Fig. 5: An intrathecal contrast CT scan showing an atlantoaxial dislocation with os odontoideum

os odontoideum is associated with early childhood trauma and is postulated to be an acquired phenomenon. At other times, it is proposed to be a congenital sclerotomal segmentation defect. The latter hypothesis states that os odontoideum results from the failure of fusion and the hypertrophy of the proatlas.[40,42,51] The presence of abnormal motion dynamics necessitates surgical intervention, as do associated neurological deficits. Asymptomatic patients in whom os odontoideum is incidentally discovered and in whom no abnormal motion dynamics are demonstrated should be followed closely.

Os odontoideum may be distinguished from an acute fracture of the dens by the presence of a smooth cortical margin of the os as well as of the odontoid surface in close proximity to it; an associated hypertrophic rounded and prominent anterior arch of atlas; and other associated congenital anomalies like occipitalised atlas or Klippel-Feil anomaly.

Ossiculum Terminale

This is a dystopic ossiculum of the dens that could be classified as an ossiculum terminale persistens or as os odontoideum.[46] When the terminal ossification part of the odontoid process remains separated beyond the age of usual fusion (i.e. up to 13 years) and survives as a separate ossicle cranial to the tip of the dens, it is called ossiculum terminale. The clinical presentations and management issues are similar to that of os odontoideum. It is also called the terminal ossicle (of Bergmann).

Syndromic Abnormalities of Craniovertebral Junction

Mucopolysaccharidoses

Mucopolysaccharidoses (MPS) are primary metabolic abnormalities of carbohydrate metabolism. These diseases are inheritable storage disorders manifested by mental retardation, macrocephaly, corneal clouding, small stature, dwarfism and skeletal dysplasia. Generalised ligamentous laxity causes the development of atlantoaxial dislocation. In some patients, radiographic evidence of hypoplasia, absence of odontoid process or even os odontoideum has been found. Death is common in Morquio syndrome (Mucopolysaccharidosis type IV) by the age of 7 years.[38] Other described syndromes with similar manifestations are type VI mucopolysaccharidosis (Maroteaux-Lamy syndrome), mucopolysaccharidosis (MPS) Type VII (Sly disease) and Hurler's syndrome.[49] Bone marrow transplantation has been found successful in certain patients with these disorders. Spinal cord compression due to atlantoaxial subluxation[14] at the CVJ is a major cause of disability and death in these patients. Once cervical myelopathy appears, early posterior occipitocervical fusion has been advocated in order to arrest the progression of neurological disability and is successful in most cases.[2]

Down's Syndrome

This is the most commonly occurring chromosomal anomaly described in humans occurring in about 1.4/1000 live births. Atlantoaxial instability due to ligamentous laxity occurs in 15–20% of Down's syndrome patients.[10,17,29] Other bony abnormalities, like os odontoideum, hypoplastic odontoid process and rotatory atlantoaxial subluxation, have also been found. The most common clinical complaints include neck pain and torticollis. Cervicomedullary compression associated with hyper-reflexia, ataxia and progressive weakness are also documented in a majority of patients. Atlantoaxial fusion is required in the symptomatic group with instability limited to the atlas and axis.[31]

Grisel's Syndrome

This is a unilateral or bilateral atlantoaxial subluxation occurring as a result of parapharyngeal infections. The pathophysiology involves metastasic inflammation causing ligamentous stretching and subluxation, muscle spasm and regional hyperaemia with decalcification of ligamentous structures. The management of such lesions requires precise visualisation of the area by means of MRI. Elimination of the source of infection is the mainstay of treatment. The CVJ region must be stabilised with a Halo brace during the phase of active treatment. Most cases do well with conservative measures.[54,55]

Clinical Symptomatology

The symptoms and signs of craniovertebral anomalies[24] are diverse owing to compression of the medulla, spinal cord, cranial nerves, spinal roots as well as vascular compromise secondary to various bony malformations. The signs of myelopathy are variable both in severity and in symmetry. Similarly, the sensory disturbances are also diverse and may include posterior column as well as bladder symptoms. Various brainstem signs are common when there is compression of the cervicomedullary region which include horizontal and down beat nystagmus, dysmetria, vertigo, internuclear ophthalmoplegia and sleep apnoea. Cranial nerve dysfunctions of trigeminal, vestibulocochlear, glossopharyngeal, vagus, accessory and hypoglossal nerves have also been reported.

Rarely, deficits, like hemiparesis, visual field defects and sleep attacks simulating narcolepsy, have been reported in these disorders.[36]

Symptoms related to vascular compromise are rare, but include syncope, vertigo, episodic hemiparesis, altered consciousness and transient impairment of vision. Usually these symptoms occur as a result of chronic or repetitive vascular compression due to abnormal mobility of the sub-occipital spine.

The stigmata specific to CVJ anomalies include a small stature, short and webbed neck, low hairline, facial asymmetry, mirror movements of the hands and high arched palate.

The neurological symptoms are slowly progressive in most cases, but rapid progression of symptoms does occur with trauma or other catastrophes. Some of the symptoms may become static after sometime.

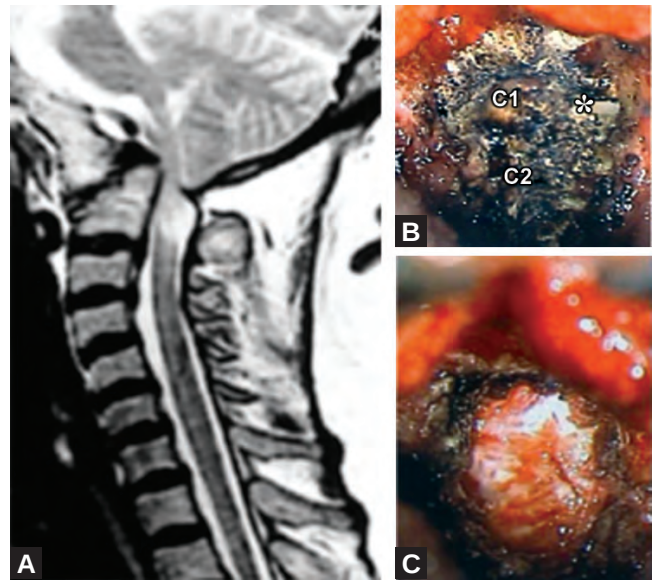
Investigations

The radiological investigations of CVJ anomalies must start with a good quality X-ray of the CVJ with active flexion, extension and transoral views. Numerous craniometrical reference lines were used to describe the atlantoaxial instability before the advent of CT and MRI scan. These measurements are meant to analyse the degree of medullary cord compression and other skull deformities associated with these bony anomalies. The basal angle is the angle formed by the line joining the nasion to the tuberculum sellae and the line joining the tuberculum sellae to the anterior lip of the foramen magnum. Normally, this angle should be about 132 degrees. When it exceeds 142 degrees, platybasia is present. McRae's line measures the sagittal diameter of the foramen magnum from the opisthion (the posterior lip of the foramen magnum) to basion (the anterior lip of the foramen magnum).[22,23] If the tip of the odontoid is above this line, BI is present. Chamberlain's line is drawn from the hard palate to the posterior margin of the foramen magnum, and the presence of more than a third of the length of the odontoid process above Chamberlain's line signifies the presence of BI. Wackenheim's clivus canal line is drawn tangentially to the posterior surface of the clivus; when BI is present the odontoid process intersects this line. Fishgold's digastric line, measured on frontal X-ray projections, connects the digastric grooves lying just medial to the mastoid processes. This line normally lies 11 ± 4 mm above the atlanto-occipital junction.[23] The normal atlantodental distance should be limited to 4.5 mm in children due to the relative resilience of the TAL, and in adults, its upper limit is about 3 mm. When the atlantodental distance exceeds the above-defined limits, AAD is said to be present. Another important measurement is the space available for the cord (SAC), which is the posterior dental distance between the posterior surface of the odontoid process and the posterior lip of the foramen magnum through which the neural structures pass. Normally, it should be more than 19 mm, otherwise cord compression is likely to occur.

Other important investigations include CT scan and MRI of the CVJ. The CT scan gives two- and three-dimensional projections of the CVJ, whereas the MRI scan is important to note abnormalities in the soft tissue as well as cord abnormalities in and around the cervicomedullary segment of the spinal cord.

Surgical Management

The surgical treatment of symptomatic CVJ anomalies requires a precise identification of the underlying pathophysiological conditions. The operative treatments include the anterior, posterior as well as the combination of both these approaches. Symptomatic patients with CVJ anomalies are divided into two groups: (1) with reducible deformity; and (2) with irreducible deformity. Some of the irreducible variety may be reducible with application of skeletal traction, especially under cover of muscle relaxants and general anaesthesia and in such situations these patients are grouped under the reducible variety. The principle of surgery in the reducible group is to fix the deformity in a perfectly reduced position by a posterior construct and bone grafts (Fig. 2C). In the irreducible group, the aim should be to attain a neural decompression if necessary with resections of misaligned fixed bony tissue using the anterior transoral approach (Figs 6A to C), and to stabilise the CVJ that is rendered unstable by the extensive osteoligamentous excision.[32] There are various procedures available for stabilisation of the CVJ like stabilisation with custom countered rods, various bone grafting techniques with plates and screws



Figs 6A to C: (A) A T2-weighted sagittal MR scan showing irreducible AAD with occipitalised atlas and C2-C3 fusion causing marked thecal compression. as well as wires or cables (for more details, please check Textbook of Operative Neurosurgery).

CONCLUSION

The CVJ represents the mobile segment of the spine. It is developmentally also the most active region and is associated with numerous bony and soft tissue anomalies. Management of the myriad clinical manifestations and occasional catastrophic consequences due to CVJ anomalies represents one of the foremost technical challenges of neurosurgery. Future innovations in instrumentation and improvements in knowledge of its genetic associations may help in overcoming these challenges.

Note: There are many studies done by the Indian neurosurgeons which are now of historical importance.[3,6-8,16,33,37,44,45,53]

24 Syringomyelia

Suresh Nair, Girish Menon, BRM Rao

INTRODUCTION

Syringomyelia is not a specific disease but rather a manifestation of various different pathologic processes with an estimated prevalence rate of 8.4 cases in 100,000 people.[6] The pathophysiologic and therapeutic modalities available in hindbrain related syringomyelia have been intensively analysed in recent times. Although several different hypotheses have been proposed for the mechanism of syringomyelia, the aetiology, pathogenesis and pathophysiology remain unclear and a subject of controversy. Over the years, attempts have been made to classify syringomyelic conditions in an effort to improve our understanding and management of this disease complex. Syringomyelia may be associated with different pathological conditions, both developmental and acquired. Because the natural history of the illness remains poorly understood, the true benefits of surgical intervention over what may be the natural course of the condition is also unclear. Patient prognosis and long-term response to surgery also remain highly variable. A thorough understanding of the pathologic process and treatment options are imperative for the neurosurgeon to determine appropriate treatment.

TERMINOLOGY AND CLASSIFICATION

Syringomyelia is defined as "tubular cavitations" (i.e. cyst) of the spinal cord extending over many segments. Many issues are controversial, especially the distinction between (a) hydromyelia and syringomyelia and (b) the terms communicating and non-communicating syringomyelia. Simon[59] introduced the term "hydromyelia" in 1857 to describe a spinal intramedullary cavity lined by ependymal cells and containing fluid identical to CSF, thus representing a dilatation of the spinal canal. This was distinguished from "classic syringomyelia" which was defined as being lined by glial tissue. The distinction between these two may be difficult to establish, even after histological examination. Although pure forms of hydromyelia may exist, hydrosyringomyelia is probably a more accurate term to describe the pathological findings of asymmetrical cavitations within the spinal cord lined by both ependymal and glial tissues.

Equally controversial is the terminology communicating and non-communicating syringomyelia. Although Barnett et al.[6] introduced the term communicating syringomyelia, with the assumption that in syringomyelia associated with Chiari malformation a communication between the fourth ventricle and spinal cord lesion, either exists or had existed at some time and then got blocked off, no such continuity of CSF flow between the fourth ventricle and syrinx could be demonstrated, even with high quality magnetic resonance imaging (MRI). This led Milhorat[36] to classify syringomyelia into three types: (a) communicating syrinx occurring with hydrocephalus and anatomically continuous with the fourth ventricle; (b) non-communicating syrinx which is separated from the fourth ventricle by a syrinx free segment of spinal cord and occurring with Chiari malformation, extramedullary compressive lesions, spinal cord trauma, intramedullary tumours, infections, etc. and (c) atrophic syrinx occurring with myelomalacia. This classification is quite different from what Barnett et al. described in their monograph on the subject, where communicating syringomyelia is the one occurring with developmental anomalies of the posterior fossa and non-communicating was equivalent of primary spinal syringomyelia due to tumour, trauma and infection. Syringomyelia associated with abnormal downward displacement of the tonsils has certain features which are distinct from cystic cavities occurring at lower spinal cord levels as a sequel to trauma or inflammation. But conditions that result in constriction of the subarachnoid space at the craniovertebral junction, i.e. impaction of the cerebellar tonsils, bony abnormalities at the foramen magnum or extrinsic compression by a extramedullary tumour all have some features in common. Hence, the classification put forward by Batzdorf[8] seems most simple: (a) syringomyelia related to anomalies at the craniovertebral junction (CV) and (b) syringomyelia related to abnormalities at the spinal level. Abnormalities at the CV junction that can result in the development of syringomyelia are those conditions that produce at least a partial block of the subarachnoid space at that level of the neuraxis.

AETIOPATHOGENESIS

Syringomyelia is associated with many different pathologic conditions.[13] The numerous causes of syringomyelia are listed in Table 1. The majority of cases are due to hindbrain descent of the Chiari malformation and the syrinx is usually in the cervical spinal cord

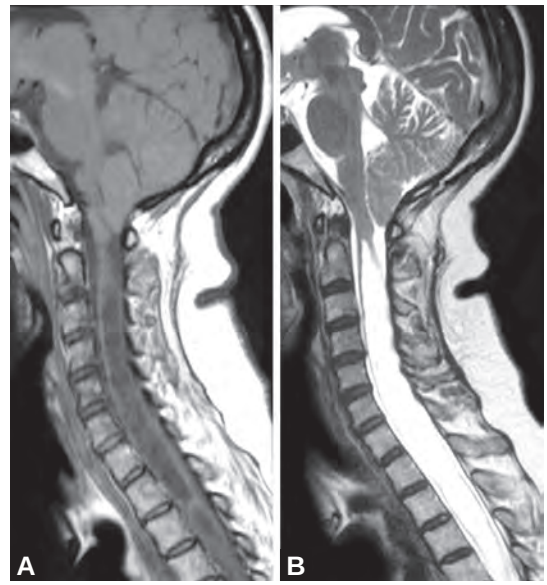
(Figs 1A and B). In the author's series of 206 operated cases of syringomyelia, an associated Chiari malformation was seen in 61% of patients.[47] Traumatic syrinx usually develops in the vicinity of the spinal injury and is most frequently located in the thoracic spine. Syrinx associated with occult spinal dysraphism usually occurs just rostral to the lipoma and is located in the lower thoracic and lumbar levels (Figs 2A to C). Myelomenigocoeles are associated with Chiari type II malformations and the syrinx is mostly in the cervical and thoracic levels. Although neoplasms, trauma, inflammation and displaced cerebellar tonsils are the most common causes of cyst formation within the spinal cord, most intramedullary tumour associated cysts are an entirely different condition, in which protein rich cyst fluid is generated by the neoplasm itself. Such tumour associated cysts are not discussed in this chapter, as their treatment is that of the neoplasm itself.

Mechanism of Syrinx Formation

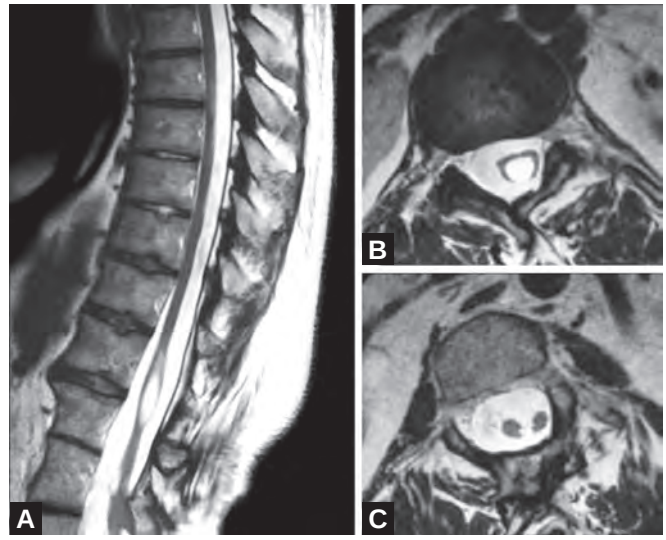
Syringomyelia Associated with CV Junction Anomaly

The most common CV junction anomaly associated with syringomyelia is Chiari malformation. In the author's published series of Chiari malformation more than 50% of patients had associated syringomyelia.[40,42,45,46] Chiari malformation represents a hind brain herniation from the posterior fossa into the cervical spinal canal. Even though four types of Chiari malformations are generally



Figs 1A and B: (A) MRI sagittal T1. (B) T2 showing cervicodorsal syrinx in a patient with Arnold Chiari Malformation

described, the fourth type merely represents agenesis of the cerebellum and thus doesn't represent true Chiari malformation. Type III is a rare variation, which is actually an encephalocoele in the occipital cervical junction. Type I Chiari malformation consists of herniation of the cerebellar tonsils into the upper cervical spinal canal. The medulla is essentially normal. The herniation may extend below the C2 lamina. The remainder of the brain is quite normal without any associated anomalies. Only in 10% of cases there is hydrocephalus. In Chiari type II malformation, in addition to the herniation of the tonsils and vermis, there may be buckling of the medulla because of the caudal herniation of the brainstem as well. There are associated anomalies in the brain, such as beaking of the tectum, presence of large



Figs 2A to C: MRI of a patient with diastematomyelia with syrinx. (A) MRI sagittal T2 showing syrinx at D12-L1. (B) T2 axial at D12-L1 showing the syrinx. (C) T2 axial at L1 showing the split cord malformation

massa intermedia, etc. Chiari II malformations are associated with a meningocoele and the majority of them have hydrocephalus as well as 88% of these patients have syringomyelia.

The exact mechanism of entry of the cyst fluid in most cases of syringomyelia is not known. Chiari[12] believed that the fluid was present in the cord due to the persistence of an embryonal state (hydromyelia) associated with hydrocephalus; the syrinx in his model would be of the communicating variety. Gardner[20] proposed the hydrodynamic theory to explain the association of hydrosyringomyelia with Chiari malformation. He postulated that arterial pulsations of the choroid plexus induced pulse waves of cerebrospinal fluid (CSF) that forced open and progressively distended the central canal, because of impaired outflow from the fourth ventricle. Normally, the foramina of Magendie and Luschka open during the 5th month of foetal life, allowing the pulse wave to be transmitted to the subarachnoid space. In Chiari malformations, the caudally displaced tonsils obstruct the foramen of Magendie and continue to direct the pulse wave into the central canal. Although this mechanism may have a role in the foetal development of hydrosyringomyelia, the arterial pulse wave is not likely to continue later in life. Williams[70] proposed a modification of the hydrodynamic theory, in which venous pressure changes were responsible for the formation of hydrosyringomyelia. During coughing or Valsalva manoeuvre, venous engorgement of epidural veins forces CSF into the spine rostrally. The herniated contents of the posterior fossa then act as a ball valve to trap the fluid intracranially. After the intracranial pressure dissipates, there is a craniospinal pressure dissociation that tends to suck the CSF caudally through the patent central canal. Likewise, the increased intraspinal pressure could force the intracavitary fluid within the syringomyelic cavity to dissect upward, extending the cavity and creating syringobulbia. These theories suggested that the syrinx developed and progressed from expansion of the central canal of the spinal cord, by CSF pulse pressure waves or craniospinal pressure differentials transmitted from the fourth ventricle to the syrinx. Surgical treatments were devised to reduce pressure transmission through the central canal of the spinal cord to the syrinx. Although treatments based on these theories met with moderate success, autopsy and radiographic studies rarely demonstrated a patent spinal canal in adult patients with syringomyelia and thus it became clear that development of syringomyelia must occur through some other mechanism. A relative obstruction at the foramen magnum has been supported by the clinical work of Tachibana[64] who showed that elevated intracranial pressure induced by a compressed jugular vein is not transmitted into the spinal canal of patients with Chiari malformation during neck flexion. Pre-operative MRI studies of these patients with syrinx done with cine mode MRI in cardiac gated phase contrast scanning have shown a significant reduction in CSF flow at the foramen magnum, anterior to the medulla, as well as rostrally into the fourth ventricle and even posteriorly over the cerebellar tonsils and the cisterna magna. Because expulsion of CSF into the cervical subarachnoid space is the normal compensatory mechanism in response to brain expansion during cardiac systole, brain expansion forces the cerebellar tonsils into the partially enclosed spinal subarachnoid space. Because the partially enclosed spinal subarachnoid space has low compliance to abrupt changes in volume, tonsillar descent results in enlarged cervical subarachnoid pulse pressure waves that compress the surface of the spinal cord. This causes progression of syringomyelia by abruptly compressing the cord and propelling the fluid in the syrinx longitudinally with each pulse. According to this widely accepted concept of Oldfield,[50] these pulsatile pressure waves, by forcing the CSF into the cord through the perivascular and interstitial spaces, are responsible for the origin and maintenance of syrinx. This movement of the syrinx fluid inferiorly during systole and superiorly during diastole can be demonstrated by cine MR imaging. This theory differs from that of Williams because it proposes that the CSF movement into the spinal cord is propelled by the systolic pressure wave and not by the increased venous pressure from the Valsalva manoeuvres. Stoodely et al.[63] using horse radish peroxidase as a tracer in sheep, demonstrated that reducing arterial pulsations would decrease the flow into the central canal. Their findings supported the hypothesis that there was a unidirectional flow of fluid from the perivascular spaces, across the interstitial space and into the central canal, driven by arterial pulsations. Under normal circumstances, presumably, the fluid would travel through the central canal to the fourth ventricle and into the subarachnoid space. This model helps to explain the accumulation of fluid in non-communicating syrinx, where there are isolated spinal segments due to scaring and other causes. Stoodely et al. proposed two distinct mechanisms for the normal migration of fluid through the perivascular spaces: (a) systolic expansion of the arteries in the perivascular space may force fluid through the surrounding basement membranes, while in diastole, fluid may enter the perivascular spaces from the subarachnoid space and (b) pulsation in the subarachnoid space transmitted through perivascular spaces acts as an impetus for flow.[62] Milhorat et al.[37] proposed that CSF was continually produced by the ependymal cells lining the central canal and the expansion of the central canal occurred in segments isolated by occlusion or stenosis at each end, such as occurs with viral ependymitis. A non-pathogenetic ageing mechanism may also lead to obliteration of the central canal in many people. Ball and Dayan[5] proposed that the subarachnoid fluid dissects into the spinal cord parenchyma along the Virchow Robin space, when tonsillar impaction prevented the upward escape of CSF. The intramedullary fluid in this theory would gradually enter the central canal. Aboulker[2] proposed a

similar theory with fluid entering along the dorsal nerve roots.

Why some patients with significant tonsillar herniation remain asymptomatic, whereas others have symptoms that frequently appear in adulthood is poorly understood. It has been suggested that gradual development of arachnoid adhesions near the foramen magnum, possibly secondary to mild yet repeated trauma caused by tonsillar motion with Valsalva manoeuvres, plays an important role. Such adhesions and arachnoid scarring, frequently observed during surgery, are thought to lead to progressive deterioration of the CSF space, altered CSF dynamics and increased compression of the spinal cord. Moreover, altered CSF dynamics, which plays a central role in several theories on the pathogenesis of syringohydromyelia, could explain its subsequent development. The relative importance of these factors remains poorly understood. Non-invasive methods for their detection and consideration in clinical decision making are currently inadequate. Neither arachnoid adhesions nor altered CSF dynamics are directly visualised on conventional CT or MRI. No specific risk factors for the development of syringomyelia in Chiari malformation had been known until 1992, when Stevens et al.[61] reported that syringomyelia is apparently more frequent in those with Chiari malformation who have a moderate degree of cerebellar herniation (9–14 mm) and less frequently with mild or severe herniation. This study further confused our understanding of the pathogenesis and pathophysiology of syringomyelia associated with Chiari malformation, by demonstrating that the completely tight compression in the advanced stage of cerebellar tissue herniation is not the condition that leads to the fluid circulatory change, which creates a syrinx in the cord. The development of syringomyelia is absolutely not the result of concentrated mechanical forces in the spinal cord, but obviously the product of disturbed fluid dynamics. It may be speculated that a threshold point exists for the central canal along with some degree of narrowing of the subarachnoid spaces, to balance patency of the obex at and around the foramen magnum. Stevens suggested that syringohydromyelia might occur less frequently with extreme degrees of herniation, where the obex lies below the level of the obstructing tonsils. This presupposes a communicating form of syringomyelia that is not universally accepted; however, it is not clear whether a low obex is present at all times.

Syringomyelia Related to Primary Spinal Abnormalities

The mechanism proposed for the development of post-traumatic syringomyelia is that the necrotic tissue and the haematoma within the injured spinal cord are resorbed and replaced by a cystic cavity,[69] but this theory is challenged by findings that a syrinx may occur after minor trauma. A proposed mechanism related to scar formation is the "spinal-spinal pressure dissociation" model, where subarachnoid scarring after trauma, in a fashion similar to that in hindbrain descent, impedes rapid pressure equilibrium in the subarachnoid space proximal and distal to the scar, which causes the CSF to move into the lower pressure environment of the central canal region of the spinal cord.[30] It is not known exactly why the fluid enters and accumulates within the spinal cord, but a common feature of the associated conditions is a focal or diffuse obstruction of the subarachnoid space, preventing the normally near instantaneous pressure equilibrium under various physiologic conditions, such as coughing or straining.

Spinal syringomyelic cavities may develop and fluctuate during the course of demyelinating diseases, like multiple sclerosis as a consequence of CSF dynamics imbalance.[60] Multiple sclerosis plaques are frequently found in areas adjacent to CSF pathways. These plaques can undergo degenerative change with resultant syrinx formation, involving areas of plaque and spinal cord rostral and caudal to the plaque.[14] Alternatively, a syrinx like lesion can develop, following atrophy of the swollen spinal cord which has undergone demyelination.[18,27] The predilection of inflammatory lesions of the spinal cord to produce secondary necrosis and subsequently syrinx may be a consequence of the tight investment of the cord by pia.[52]

Mechanism of Syrinx Propagation

There are various theories explaining the expansion of the fluid cavities. Gardner proposed that the high pressure waves from the fourth ventricle passing through the opening at the rostral end of the central canal produced progressive enlargement of the fluid collection. Ball and Dayan[5] and Aboulker[2] proposed that the fluid entering the spinal cord parenchyma, driven by the arterial pulsations, would coalesce and rupture into and therefore enlarge the central canal. Williams[70] proposed that the pressure differentials initiated by epidural venous distension after normal physiologic events, such as coughing and straining caused to and fro fluid dissection within the spinal cord referred to as slosh. Oldfield[50] proposed that the systolic pressure wave of the subarachnoid CSF applied against the surface of the spinal cord forces the syrinx fluid to move caudally within the cyst.

SYMPTOMATOLOGY

Most patients with hind brain related syringomyelia become symptomatic in young adulthood. Rarely, syringomyelia may develop in childhood or late adulthood. In a series by Thrush and Foster[65] of 100 patients with syringomyelia, the mean age at onset of symptoms was thirty one years. In the author's series the majority of the patients were in the third decade.[6] Syringomyelia is generally more common in males and has been the same at our institute. Even though familial cases have been described, occurrence in different races is unknown. Syringomyelia usually progresses slowly and the course may extend over many years. The condition may have

a more acute course, especially when the brainstem is affected. Syringomyelia usually involves the cervical area. Symptomatic presentation depends primarily on the location of the lesion within the neuraxis. The majority of cases of syringomyelia are associated with Chiari malformation. Therefore, it is essential to differentiate symptoms predominantly due to central spinal cord cavitations from those due to hindbrain descent.

Symptoms Predominantly Due to Central Spinal Cord Cavitation

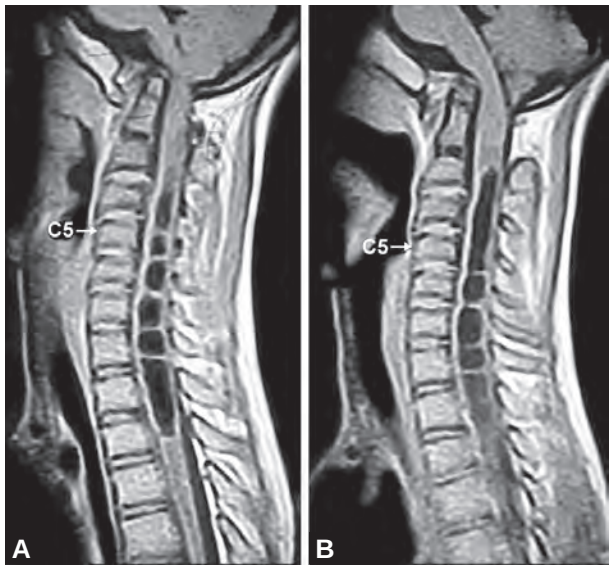
The classic symptoms of a syrinx[13] within the spinal cord include dissociated sensory loss, amyotrophy and spastic paraparesis (upper motor neuron symptoms in the lower extremities and lower motor neuron symptoms in the upper extremities). In later stages, with a larger syrinx, the symptoms may become bilateral. The dissociated sensory deficit is due to damage of the spinothalamic fibres (conveying pain and temperature sensation) in the anterior commissure. The ascending sensory fibres involved with light touch and proprioception are usually spared. The anterior commissure is damaged at the levels of the syrinx but remains intact rostrally and caudally. The resulting sensory deficit has been described as "cape like" or as a "suspended sensory level of cuirasse" because it typically involves the breast-plate distribution. If the syrinx extends laterally to involve the spinothalamic tracts, there will be analgesia in the lower limbs. When the cavity enlarges to involve the posterior columns, position and vibration sense in the feet are lost and astereognosis may be noted in the hands. Amyotrophy of the muscles is due to damage of the anterior horn cells. It usually begins in the hands and extends into the proximal upper extremities. Damage to the nerve bodies innervating the lumbricals may cause a claw hand deformity. Lower extremity motor symptoms are due to destruction or compression of the corticospinal tracts in the lateral columns. Typically, this results in asymmetric spastic paraparesis with absent superficial reflexes, increased deep tendon reflexes and extensor plantar responses. Respiratory insufficiency, which usually is related to changes in posture, may occur. Sphincter disturbance may occur as a late finding. Sexual dysfunction occurs in some. When sympathetic neurons in the intermediolateral cell column get involved, Horner's syndrome occurs. Scoliosis may develop and is due to damage to the dorsomedial and ventrolateral spinal nuclei. The site of the convexity of the scoliosis appears to correspond with the laterality of the syrinx as seen on MRI. Patients with syringomyelia frequently suffer from deep aching pain, usually in the neck and shoulders that may be due to dural distension or a central mechanism. Finally, neurogenic arthropathy (Charcot's joints) develops in 25% of patients with syrinx.[8] They form in areas of analgesia, usually involve the humeral head and result in gross deformity of the shoulder, elbow, hand and wrist. Charcot joints are also associated with tabes dorsalis, syphilis and diabetes, but in these conditions usually the joints in the lower extremities are involved. Syringomyelic patients can develop complex regional pain syndrome (CRPS), formerly known as reflex sympathetic dystrophy. CRPS is a pain syndrome that develops after an irritating noxious event. Typically, evidence of oedema, changes in skin blood flow, abnormal pseudomotor activity in the region of the pain, and allodynia or hyperalgesia is observed. The site is usually the distal aspect of an affected extremity.[14] Of the wide variety of precipitating factors that can cause injury to peripheral or central neural tissue, syringomyelia is a central nervous system cause of CRPS. Due to syrinx formation, the intermediolateral column of the spinal cord is stimulated rather than inhibited by branches of second order sensory neurons. The hyper-responsive sympathetic vasoconstrictor motor fibres severely restrict blood flow to the affected area, resulting in cyanosis, mottling and hypothermia.

If the syrinx extends into the medulla, syringobulbia develops, with symmetric limb weakness, palatal weakness, wasting of the tongue, dissociated trigeminal sensory loss and nystagmus. Lower cranial nerve signs and symptoms are seen particularly with basilar invagination. Rarely, the syrinx cavity can extend beyond the medulla in the brainstem into the centrum semiovale (syringocephalus).

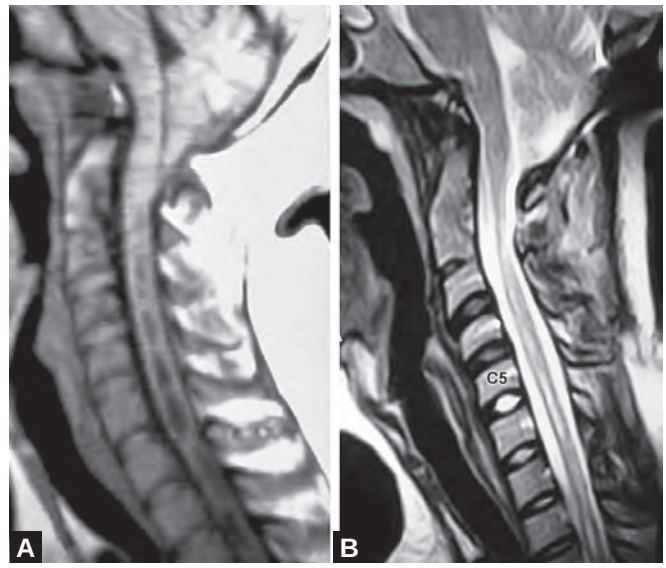
Clinical symptoms associated with Chiari malformation include headache, neck pain, cerebellar dysfunction, nystagmus, spasticity, ataxia, diplopia and bulbar palsies (dysphagia). These symptoms tend to develop in adolescence and early adulthood. The most common symptoms are occipital headache and pain in the distribution of the occipital nerve that may be exacerbated by coughing or sneezing and relieved by lying supine. Pain was the presenting symptom in 50% of patients with syringomyelia seen by the author. Fifteen percent of our patients did not have any sensory loss.[47] While evidence of motor dysfunction was noted only in 70% of the patients with syringomyelia with Chiari malformation, it was noted in as high as 91% of patients without associated Chiari malformation.[40,41,45] We also could identify various clinical syndromes as described by Saez et al.[55] when we analysed the presenting clinical picture of 252 patients of Chiari malformation. One hundred and eighty two patients in this group had syringomyelia. While a foramen magnum compression syndrome was seen in 36% of patients, it was central cord dysfunction in 55%. Approximately 4% of patients who presented with incordination, ataxia and nystagmus were categorised as cerebellar syndrome group. A small percentage (3%) presented with spasticity only and the remaining 2% had miscellaneous presentation.[40,41] Many authors have recognised the prognostic value of certain clinical variables, including the above mentioned clinical syndromes.

IMAGING

Magnetic resonance imaging is the best imaging modality for syringomyelia. It is able to demonstrate the extent of syrinx along with associated soft tissue abnormalities



Figs 3A and B: (A) MRI sagittal T1. (B) T2 showing cervicodorsal syrinx in a patient with CV junction anomaly



Figs 4A and B: MRI sagittal T1 showing cervicodorsal syrinx in another patient with CV junction anomaly

of the craniovertebral junction [Figs (3A and B) and (4A and B)], neoplasms (Figs 5A to C), stenosis and arachnoid scarring. Imaging of the entire rostrocaudal extension of the cyst or cysts is important. It also helps to see the flow and septations inside the syrinx. Gadolinium enhanced images are indicated if a tumour is suspected. Magnetic resonance angiography may be helpful in cases of syringomyelia associated with vascular lesions. Myelography with delayed CT performed after 4–12 hours may be used in patients who are unable to tolerate MRI and may demonstrate contrast accumulation in the cyst. Batzdorf[17,42] has successfully used this technique in the evaluation of patients with posttraumatic syringomyelia where associated scar tissue obliterated the local anatomical details on the MRI and in cases where the level of subarachnoid scarring and obstruction was not well delineated. More recently, cardiac gated cine mode T2 weighted MRI has been used to demonstrate CSF flow patterns and it has been proposed that less pulsatile flow within the syrinx is associated with a decreased likelihood of benefit from surgery.[50] This modality may also be useful in distinguishing patients with asymptomatic tonsillar descent from those with abnormal flow dynamics who are more likely to benefit from surgery.[3] Since the development of MRI, real-time ultrasonography is rarely used for imaging syringomyelia. It is technically more feasible in young children or in thin patients. Routine radiographs may demonstrate a widened cervical canal, bony abnormalities of the skull and CV junction, platybasia, midline keel and assimilation of the atlas. Twenty percent of our patients had associated basilar invagination.[40,41]

NATURAL HISTORY

The natural history of syringomyelia varies from spontaneous and complete regression to progressive devastating neurologic deficits. There are no large series delineating the natural history of untreated syringomyelia. Boman and Livanainen[10] reported the natural history of 55 un-operated patients with a diagnosis of syringomyelia, seen at the University of Helsinki from 1920 to 1965. It is not clear how many had an associated Chiari malformation. They reported relatively slow progression in all cases. Only 3 had a disability, preventing them from working within 5 years of onset. Twenty-eight had slow progression with worsening. Twenty-seven had a stationary period without progression for more than 10 years. Clearly, although the disease was often progressive, it was also often intermittent in its development with long periods of stability. In spite of this lack of information on the disease's course, it is usually viewed, as Lord Brain[11] described it, "relentlessly progressive". Although there have been case reports, it appears that spontaneous resolution is the exception. The unpredictable clinical course of syringomyelia causes difficulties and controversies regarding management. The possibility that a syrinx may spontaneously disappear may warrant a more conservative approach in certain instances. It was noted that patients with a nearly normal sized spinal cord were more likely to have a benign clinical course and if significant spinal cord dilation was seen, the symptoms tended to progress. These findings suggested that it might be reasonable to consider surgical intervention in those patients, noted to have clear radiological progression of their syringomyelia, even in the absence of significant progression of symptoms.

MANAGEMENT

There is no currently clear consensus about the optimal therapy and differing opinions are found in the literature. Syringomyelia is caused by many different conditions and thus may require different treatments. Another problem, encountered in interpreting the available information, is that a fairly long follow-up is needed because syrinx progression may occur slowly over time.

SELECTION OF PATIENTS FOR SURGERY

Operative management of syringomyelia should be considered when there are progressive neurological deficits by clinical criteria or when sequential imaging techniques show progressive enlargement of syringomyelia.[9] With the availability of high resolution MR images more and more non-distended intramedullary cavities are detected. We have no idea at present whether all such cavities ultimately enlarge or whether cerebellar tonsillar impaction is progressive in all patients. All the available data in literature predates the availability of high resolution MR and, therefore, does not provide an accurate picture of the spinal cord cysts. So, until the question of inevitability of progression can be answered with more certainty, patients with little or no neurologic impairment and non distended syrinx cavities should be followed-up with serial neurological examination and imaging before surgery is recommended. Size of the syrinx cavity alone should not be used as an indicator for surgery, as shown by Nair[49] and Grant,[22] where no correlation existed between cyst size and neurological deficit. As there is no evidence at present that a cyst can continue to enlarge without producing new deficits, surgical therapy should be considered for all distended cysts.

Nair et al.[48,49] have devised a simple clinical and radiological grading system for assessing the severity of the illness and to establish a uniformity in the clinical and radiological evaluation. Our clinical grading system takes into account the subjective, as well as the objective status of the patient with the clinical score ranging from 0–15 with a score of 0 for an asymptomatic individual and 15 for a severely disabled patient (Table 2). The patients were then graded into four clinical grades, depending upon the score (Table 3). Based upon the post-operative clinical score, the percentage clinical improvement (CI) can be calculated from the formula:

Table 2: Clinical scoring system

Clinical Feature		*Score*
Pain	Absent	0
	Mild-Moderate	1
	Incapacitating	2
Sensory	Asymptomatic	0
	Symptoms + No deficit	1
	+/–Symptoms + < 50% deficit	2
	+/–Symptoms + > 50% deficit	3
Cranial Nerve	Asymptomatic	0
	Symptoms + No deficit	1
	+/–Symptoms + Unilateral deficit	2
	+/–Symptoms + Bilateral deficit	3
Cerebellar	Asymptomatic	0
	Symptoms + No deficit	1
	+/–Symptoms + Unilateral deficit	2
	+/–Symptoms + Bilateral deficit	3
Motor	Asymptomatic	0
	Proximal/Distal only	
	Grade IV	1
	Grade III	2
	Grade II/I	3
	Proximal and Distal both	
	Grade IV	2
	Grade III	3
	Grade II/I	4

Table 3: Clinical grades

Grade 0	Asymptomatic	Score 0
Grade I	Mild	Score 1–5
Grade II	Moderate	Score 6–10
Grade III	Severe	Score 11–15

%CI = preoperative score - postoperative score/ preoperative score x 100

Our study proved that patients in mild clinical grade (grade I) had a much better chance of good to excellent outcome than grade II patients.

Radiologically syrinx size was assessed by cyst:cord and cord:canal ratios and a radiological grading system was devised with a score range of 0 to 8. (Tables 4 and 5). These radiological scores are based on the maximum anteroposterior dimensions of the syrinx, cord and canal at the same level. Percentage radiological improvement (RI) can be calculated by the formula:

%RI = Preoperative score - postoperative score/ preoperative score x 100

Our study[48,49] revealed lack of correlation between the clinical and radiological grades pre- as well as post-operatively. A radiological reduction in the syrinx size far outweighed the clinical improvement. On the basis of pre-operative clinical grade, one can predict the clinical outcome after surgery, whereas radiological grade fails to prognosticate the clinical outcome.

The likelihood of improvement of a symptom or symptoms following surgery should influence the decision to recommend surgery. It is known that not all the clinical manifestations of syrinx, which occur, with abnormalities of the CV junction respond equally to surgery. The main goal of surgery is to arrest progression of neurological deficits. Many authors[16,41] have recognised the prognostic value of certain clinical variables including clinical syndromes. Suboccipital headache caused by tonsillar impaction responds well to adequate decompressive therapy. Pyramidal tract manifestations and spinothalamic sensory loss improve, as the pressure of the cysts on these pathways is reduced. Weakness and atrophy of the hands show little improvement because of destruction of corresponding anterior horn cells.

Table 4: Radiological scoring system

		Score
Cyst:Cord	0.76–1	4
	0.51–0.75	3
	0.26–0.50	2
	0.01–0.25	1
	0.0	0
Cord:Canal	0.91–1	4
	0.81–0.9	3
	0.71–0.8	2
	0.61–0.7	1
	< 0.6	0

Table 5: Radiological grades

Grade 0	No cyst	Score 0
Grade I	Mild	Score 1–4
Grade II	Severe	Score 5–8

Similarly, dysaesthetic pain, which is a form of denervation dysaesthesia due to destruction of ascending spinal pathways with a thalamic projection, responds poorly to decompressive therapy. Each patient must be judged individually, keeping in mind that progression of symptoms can sometimes occur rather abruptly. Because some of the neurologic deficits tend to become fixed once they develop, most patients with Chiari malformation and a distended syrinx must be candidates for surgery. Chiari malformation presenting with lower cranial nerve involvement or symptoms of direct brainstem compression must also be candidates for surgery.[40,41]

Surgical Management of Syringomyelia Associated with Craniovertebral Junction Anomalies

Management of Chiari malformation with associated syringomyelia continues to pose a great challenge to physicians. Treatment of symptomatic patients is strictly surgical. Meadows et al.[35] and Nair et al.[43,44] in recent reviews had published the pros and cons of various surgical options. The management strategy follows a "top down" rule.[39,54] Treatment always begins by addressing hydrocephalus, if it is present. A VP shunt placed in patients with hydrocephalus may relieve both cerebellar ectopia and dilatation of the central canal as well. Early surgical techniques attempted to address syrinx and Chiari malformation separately with a decompressive procedure directed at the foramen magnum for Chiari and a myelotomy or shunting procedure directed at the syrinx. However, after the elucidation of the relationship between the syrinx and the pathology at the foramen magnum, surgeons now prefer to reserve shunting for patients who fail to respond to initial posterior fossa decompression. Most patients with Chiari malformation and syringomyelia are treated with a sub-occipital decompressive craniectomy, as well as cervical laminectomy to the distal tips of the cerebellar tonsils. The goal of the surgery is to relieve cord compression and to re-establish adequate CSF flow. The specific surgical steps in this operation continue to undergo modification, as surgeons attempt to identify the optimum treatment. This is usually dictated by patient characteristics and the surgeon's experience. The occipital bone may be considerably flattened and can have a rostral tilt at the foramen magnum. The dorsal ring of the atlas may be incomplete or thin. Most of the time, a markedly thick dural band is found at the foramen magnum that may conceal or contain aberrant veins. The dura is usually incised in a standard Y pattern, although some authors[26,38] have stressed that dural opening may be unnecessary. They contend that simple bony decompression without intradural exploration alone relieves the ball valve effect of Chiari malformation. There is controversy regarding the extent of decompression required to alleviate symptoms. Dural bands and arachnoid adhesions maybe freed, although several surgeons have stressed the importance of avoiding undue manipulation of the

subarachnoid space. Manipulation of the tonsil has also become a matter of considerable debate. Whereas several authors have suggested some form of manipulation ranging from simple retraction to bipolar coagulation or resection, only one study[23] has shown any additional benefit to such methods. In comparison to adults where the cerebellar tonsils may be necrotic secondary to chronic compression, there is rarely a need to excise the cerebellar tonsils in children. Occasionally, a thin membrane is found to occlude the foramen of Magendie, in which case the membrane is excised to establish communication with the fourth ventricle. If the tonsils cannot be mobilised, a tube or silastic wick is placed to maintain the patency of the fourth ventricle outlet in the midline. In the presence of dense arachnoid adhesions, some surgeons keep a shunt tube between the fourth ventricle and the intact subarachnoid space around the spinal cord. Gardner[19] had suggested the practise of plugging the obex with a small strip of muscle to prevent communication with the fourth ventricle. A number of authors have reported encouraging early results with this practise. This technique went into disrepute as several studies have shown the long-term results to be less encouraging with late neurological deterioration reported in many cases.[43] Intractable vomiting and respiratory embarrassment were also reported after plugging of the obex. The opened dura is later reconstructed in a capacious manner using a graft. In a review of patients who underwent decompression with and without duraplasty, Matsumoto and Symon[44] noted no difference in the reduction of hydromyelia. However, regarding improvement of symptoms, patients without duroplasty had a significantly worse outcome compared to those with duraplasty. Even though surgeons differ on the usefulness and safety of additional procedures like duraplasty, excision of tonsils and obex plugging, there is general consensus on the importance of CV junction decompression in the treatment of Chiari malformation with syringomyelia. In patients in whom there is no neurological improvement without radiological collapse of the syrinx cavity, 3–6 months after foramen magnum decompression, a syringoperitoneal shunt is inserted.

Management of Syringomyelia Related to Primary Spinal Abnormalities

The indications for surgery in patients with primary spinal syringomyelia are debatable. The natural history of these lesions is not known. As a rule, relatively rapid loss of neurological function facilitates the decision for surgery. The various management options for primary syringomyelia include syringostomy, shunting to the subarachnoid, pleural or peritoneal spaces and endoscopic release of septations. Syringostomy is the oldest and simplest surgical method. It involves a laminectomy at the appropriate level and a dorsal longitudinal incision through the thinned out spinal cord into the syrinx cavity. Incisions are usually made in the midline or just posterior to the dorsal root entry zone. Intra-operative real-time ultrasonography is useful in locating the largest section of the syrinx and where it is most superficial and in guiding the drainage/shunt catheter into the optimal position.[15] Problems with syringostomy include locating the optimal myelotomy site, minimising the risk of tissue damage and keeping the stoma patent. A technical variation was recently introduced by Ventureyra et al.[66] to solve the problem of stoma closure by scarring or gliosis. They proposed introducing a myringostomy tube through a small 3 mm midline myelotomy at the level of the maximum syrinx enlargement, to maintain the syringosubarachnoid communication. Shannon et al.[58] reported on a series of syringostomies and noted that patients whose main symptom was pain all improved, while patients whose predominant symptom was sensory loss did not. In their review of world literature from 1971 to 1991 including 1,301 operative cases, Aschoff and Kunze[4] found 176 syringostomies reported by eight different authors; the results were 41% improvement, 25% stabilisation and 34% deterioration.

Shunting procedure may achieve syrinx drainage into the pleural, peritoneal or subarachnoid spaces. The technique involves exposing the spinal cord by laminectomy or hemilaminectomy over the area where the syrinx has the largest diameter. A small myelotomy is performed, either in the midline or at the dorsal root entry zone.[53] A variety of valveless silastic catheters have been used. The catheter may be inserted cephalad or caudal, depending on the neurosurgeon's preference. The distal end of the catheter may then be placed in the subarachnoid space or tunnelled into the pleural or peritoneal space. The success rates of various shunting procedures are very different among the series and this has led to shunt advocates and shunt detractors.[31,57] Another procedure which was tried in the past is terminal ventriculostomy. The terminal ventricle is the dilated portion of the central canal that extends below the tip of the conus medullaris into the filum terminale. A laminectomy is performed over the caudal limit of the fluid sac and the filum is opened. This procedure is suitable only in patients with symptoms of syrinx without Chiari malformation. It is inappropriate in cases in which the hydromyelic cavity does not extend into the lumbar portion of the spinal cord or into the filum terminale.

Another surgical option is to attempt to recreate the normal CSF flow pattern and thus remove the impetus for syrinx formation. At the spinal level it involves open or endoscopic dissection of subarachnoid adhesions and the enlargement of the local subarachnoid space by expansile duroplasty or creation of a pseudomeningocoele. To increase the local CSF flow area, Wiart et al.[68] suggested tacking the dura open to create a pseudomeningocoele. Levi and Sonntag[32] suggested using an expansile duroplasty with a synthetic patch to help prevent a CSF leak. A final procedure used to recreate a more normal spinal CSF flow is spinal cord transection in complete paraplegia with an ascending syrinx.[57] As microsurgical skills progress lysis of local adhesions may prove to be an excellent treatment option

for syringomyelia that can prevent the need for implantation of a foreign body.[13] More minimally invasive treatments for syringomyelia have been evolving. Because many of the syrinx are septated, a shunt may not communicate with all of the fluid containing chamber, which can be seen with an intra-operative real-time ultrasound imaging and treated accordingly. Huewel et al.[25] used the endoscope to divide the septations and create a continuous pathway. Goldstein et al.[21] described CT guided percutaneous drainage of syringomyelia. Further studies will help to determine the value of these minimally invasive techniques.

Given a patient with syringomyelia, how are we to decide which is the optimal management for that patient. On the basis of MRI characteristics, Abe et al.[1] have classified syringomyelia into five types and have suggested the most appropriate treatment for each type. Type I has associated Chiari malformation and MRI, shows wedge shaped herniated tonsils to be occupying the cisterna magna with the rostral end of the syrinx looking conical and there is no obliteration of the caudal part of the fourth ventricle. As these findings suggest the herniated tonsils to be compressing the brainstem and spinal cord and mechanically obstructing the CSF flow at the foramen magnum, a foramen magnum decompression with or without duraplasty alone is required. Type II patients have basal arachnoiditis, usually with a history of difficult labour. MRI of these patients reveals the cisterna magna to be narrowed by scar tissue or by herniated tonsils. However, the tip of the tonsils is rounded and a cavity resembling the subarachnoid space may be seen in the region of the cisterna magna. In addition, the upper end of the syrinx is rounded and the lower part of the fourth ventricle will be well visualised. These MRI findings suggest that the foramen magnum is not mechanically obstructed by herniated tonsils but rather by arachnoid scarring due to arachnoiditis. As treatment, the authors have suggested foramen magnum decompression followed by placement of a shunt tube from the fourth ventricle to the ventral cervical subarachnoid space to prevent reobstruction of the foramen of Magendie. In patients with type III syringomyelia, MRI reveals a direct communication of the syrinx with the fourth ventricle via a patent central canal and is associated with hydrocephalus. The treatment suggested is foramen magnum decompression followed by opening of the membrane obstructing the foramen of Magendie, which will equalise the pressure between the ventricular system and the subarachnoid space. In addition, to prevent refilling of the syrinx, Abe et al.[1] have suggested plugging of the obex with a Dacron fabric. Type IV patients of syringomyelia have obliteration of the subarachnoid space around the spinal cord due to arachnoid scarring with a normal craniovertebral junction. There is extension of the syrinx both rostrally and caudally from the site of scarring. When scarring is localised, a syringosubarachnoid shunt rostrally from the site of scarring is advised. When the scarring is not localised a syringoperitoneal shunt is the treatment recommended. For type V patients in whom no associated lesions could be found on MRI or with cine MRI, either a syringosubarachnoid shunt or a lumboperitoneal shunt is suggested as the most effective treatment.

Results of Surgery

The results of surgery for syringomyelia associated with Chiari are variable and some signs and symptoms show a characteristic response to surgery. In the review by Levy et al.[33] patients presenting with exertional headache, as the dominant feature, showed the best results with 60% showing improvement. While 47% of patient presenting with mixed signs of cerebellar and lower brainstem and cervical cord involvement showed improvement, only 30% of patients with symptoms attributable to intrinsic cord lesions had any improvement. Dyste and coworkers[16] found that pain improved in 81.5%, worsened in 7.4% with 11.1% having no change. Motor strength improved in 70%, became normal in 21%, worsened in 6% and remained unchanged in 3%. Sensation by contrast improved in only 6%, remained unchanged in 61%, became normal in 29% and deteriorated in 4%. Analysis of the long-term results at our institute[29] with a mean follow-up of 58 months and a minimum of 12 months showed overall improvement in 60% of patients. While symptoms remained static in 24%, these deteriorated in 16%. Suboccipital pain improved in 72% of cases. While spinothalamic pain and motor symptoms improved in 57.6% and 47.6% of patients, cerebellar symptoms and cranial nerve deficits improved in 60% and 72%, respectively. The five most common clinical manifestations in Batzdorf's series[9] of syringomyelic patients were sensory deficit, motor weakness, sub-occipital pain, dysaesthetic pain and spasticity. Of these, headache and spinal pain responded best to surgery, presumably because pressure and distension of the dura were relieved. Weakness of lower limbs and spasticity improved in two thirds of patients but weakness with atrophy of hands often failed to improve. Relieving pressure on the corticospinal tracts relieves symptoms in the lower extremities, whereas destruction of anterior horn cells rarely improves. Dysaesthesia and sensory deficits improved in only 20% of patients. Mild scoliosis (less than 35) may improve or stabilise, but severe deformities progressed. Out of the 93 patients of syrinx with Chiari malformation treated over a ten year period at the All India Institute of Medical Sciences, New Delhi,[51] 76% of the patients who underwent modified William's procedure demonstrated clinical improvement, as opposed to the improvement seen in 55% of patients who underwent Gardner's procedure and 53% who underwent just foramen magnum decompression with or without duraplasty.

In 1996, Vernet et al.[67] compared syringopleural to syringosubarachnoid shunting in 31 children with five years follow-up. Of the 19 patients treated with syringopleural shunts, 11 improved and 8 remained stable. Of the 13 patients treated with syringosubarachnoid shunts, only one improved, eight remained stable and three deteriorated. They concluded that it was best to shunt the

syrinx fluid outside of the subarachnoid space. Klekamp et al.[28] in 1997 reviewed 107 patients who had syringomyelia associated with subarachnoid scarring due to arachnoiditis or trauma. Twenty nine patients remained stable and thus required no treatment. The 78 patients with progressive neurologic deterioration underwent 121 procedures with a follow-up of 32 months; all had arachnoid scarring near the syrinx, 52 from trauma and 69 from inflammation. Patients treated with shunting fared poorly. Those with focal scarring had recurrence of the syrinx in 92% and those with extensive scarring had recurrence in 100%. Microdissection of the scar and decompression of the subarachnoid space with fascia lata graft produced stabilisation in 83% with focal scarring, but in only 17% with extensive scarring. In this series, with associated scarring, the syringopleural and syringoperitoneal shunts fared better than the syringosubarachnoid shunts. The authors concluded that scar resections were the best treatment option if a focal area is involved and that no procedure is effective if diffuse scarring exists.

CAUSES OF SURGICAL FAILURE AND THEIR PREVENTION

Patient prognosis and long-term response to surgery remain highly variable, which proves the wide divergence in clinical presentation and surgical management.[35] Many patients who initially improve with surgery frequently return to their pre-surgical state or sometimes even become worse and continue to deteriorate. Whether this denotes the natural course of the condition in a subset of this patient population is not known. Because the natural history of this condition is poorly understood, the true benefits of surgery over what may be the natural history of this condition are poorly understood. Progressive neurological deficits after the initial operation should lead one to suspect post-operative cerebellar ptosis with tethering and scarring of the cervical spinal cord and recurrent syringomyelia.[24] Rarely, deterioration is due to instability at the craniovertebral junction, or even in some cases due to regeneration of the foramen magnum. Patients develop cerebellar ptosis when the craniectomy is too large for the specific patient. The herniated tonsils and vermis become adherent to the duroplasty, leading again to obstruction of CSF flow and reappearance of syringomyelia. These patients present with new onset of severe headache located in the frontal and vertex region which is not associated with Valsalva manoeuvres. This pain is due to stretching of an inadequately supported duramater of the posterior fossa, which is innervated by nociceptive fibres, which has contribution from the trigeminal nerve. This pain is different from the one attributed to attachment of nuchal muscles to the duramater of the posterior fossa, which occurs with neck movement. What is the optimal size of the craniectomy to prevent cerebellar ptosis? Samii et al.[56] have advised that the size of the craniectomy should be limited to the width of the spinal canal and not to extend further upward than 2 cm from the rim of the foramen magnum. The importance of performing a small craniectomy is magnified in patients with Chairi malformation, because a significant proportion of these patients have small posterior fossa volume. Apart from an oversized craniectomy, there are other possible causes for scar formation between the dural graft and the cord. Post-operative arachnoid scarring can be caused by insufficient haemostasis, obex plugging with muscle or autologous graft material or a large pseudomeningocoele. Blood and its breakdown products or muscle proteins may cause severe arachnoiditis. This may be provoked by William's technique of leaving the dura open after decompression. Plugging the obex with muscle may also create severe arachnoid scarring, particularly at the foramen of Magendie. Autologous graft may receive pial vascularisation, leading to dense adhesions of such grafts to the cerebellar cortex. Pseudomeningocoele or epidural CSF collection due to insufficient dural closure can create epidural pressure high enough to press the graft against the underlying cord and cerebellar cortex leading to scar formation. Apart from reducing the size of the craniectomy, this post-operative tethering can be prevented by suturing the duroplasty with running sutures to prevent any large CSF collection. A devitalised or artificial graft material should be used rather than autologous graft, such as fascia lata or galea which shows greater tendency for scarring. Other than utilising measures to prevent post-operative tethering, how and in what circumstances should a post-operative tethering at the foramen magnum be treated? Treatment of post-operative tethering at the level of the foramen magnum is possible, but can be extremely dangerous and can lead to life-threatening complications. It is recommended under certain circumstances. Post-operative adhesions of artificial graft material to underlying structures and adhesions related to pseudomeningocoele can be released by sharp dissection. But patients with a history of meningitis or with dense adhesions of autologous grafts are poor candidates for re-operation. Dissection of severe and extensive adhesions anywhere along the spinal canal is dangerous and, even if successful, the overwhelming majority of patients will only have a short life as scarring is likely to reappear. In cases of cerebellar ptosis due to an oversized craniectomy, Holly and Batzdorf[34] have suggested partial suboccipital cranioplasty to alleviate the stretching of the duramater.

Shunting procedures for syringomyelia are associated with potential complications. The tube may become kinked or displaced. It may be blocked internally by arachnoid scar, proteinaceous fluid or tissue debris. Over drainage of CSF may induce hindbrain herniation and in cases with pre-existing Chiari malformation, may lead to cardiorespiratory arrest. CSF leaks and fatal infection may develop. Batzdorf et al.[7] in 1998 reported on a follow-up analysis of 42 patients shunted for syringomyelia, with a 50% recurrence of cyst expansion representing shunt failure. There

were 18 patients with shunt obstruction and three patients with functioning shunts that had deterioration related to tethering of the spinal cord. Long-term follow-up is needed to determine the future adverse effects of a tethered catheter in a mobile spinal cord.

25 Epidemiology of Head Injury

Rajkumar, Samir Kumar Kalra, Ashok Kumar Mahapatra

INTRODUCTION

Head injury is one of the most important public health problems today. The incidence of head injuries is steadily increasing all over the world and our country has the dubious distinction of having the highest incidence in the world of head injuries due to road traffic accidents per 1,000 vehicles or deaths per 1,000 accidents. The care of head-injured patients forms an important part of neurosurgical management in all countries. The modernisation of industries as well as modes of transport have increased the incidence and the severity of injuries. The management of severe head injury is a major challenge to neurosurgeons and basic neuroscientists, as the consequent mortality and morbidity is depressingly high. There is a need for an extensive multidimensional effort to improve the prognosis of head-injured patients and provide them a better quality of life. To achieve these aims, the epidemiology of head injury needs to be known especially the incidence and its burden on society.[17]

The literature review reflects that the epidemiology has been an oft-neglected area of study with very few epidemiological studies pertaining to head injuries.[4,5,8,10-12,25] The majority of the injuries reported in India are from the cities, which reflects not just their higher incidence in these areas but also the lack of reporting from rural areas. Another facet to such reporting is that most of the reports are based on medicolegal reports and hence may not be indicative of the true incidence. So, it can be appreciated that the majority of head injuries go unreported and the reported incidence may just be the tip of a huge iceberg[3,6,23,26] (Table 1).

Table 1: Incidence of brain injury, selected reports

Authors	*Year*	*Study from*	*Rate per 100,000*
Jennett and MacMillan	1981	UK	270
Klauber et al.	1981	San Diego, USA	294
Selecki et al.	1981	New South Wales, Australia	377
Kraus et al.	1984	San Diego, USA	180
Edna and Cappelen	1984	Norway	200
Fife et al.	1986	Rhode Island, USA	152
Razzak and Luby	1994	Pakistan	185
Wang et al.	1996	China	56

The incidence of head injury is mentioned as per 100,000 persons per year and has a wide range from 56 to 430.[4,5,8,11,12,22,25] The incidence is related to the characteristics of geography, climate, social activity of people, the sense of traffic safety, the basic traffic construction and management. The incidence varies widely in the urban and the rural populations. The incidence also relates to the adequacy of the reporting and is better in the developed countries vis-à-vis the developing countries. The highest incidence has been reported from the study by Field who reported an incidence as high as 430/100,000 persons in 1976.[5] The recent data suggests a decline in incidence per 100,000 persons with Fife et al. 1986[11] reporting the lowest incidence of 152/100,000 persons. The overall incidence in the US is around 200 per 100,000 vehicles per year[10] and nearly 1.6 million people per year suffered from head injury in the US.[7,20,30] In Spain, the incidence of head injury was 91/100,000 persons as reported in 1988. However, a report from China recorded the lowest incidence of 56 per 100,000 persons in 1986.[33]

The extensive studies even from small areas, like San Diego and Wales, have contributed enormously to the existing epidemiological data set for head injuries.[4,5,12] The epidemiological studies may be hospital based or based on traffic police records.[14,21,23] Both have their own advantages as well as pitfalls and formulating data based on both sources may not be practical most of the times.

The incidence of accidents and the deaths related to them have steadily been increasing over the years. Over the last 3–4 years, the incidence has, however, shown a decline in some parts of the country as is reflected in the incidence in Delhi (Table 2). Even in the US, there has been a 50% fall in head injury admissions in 2002 as compared to 1980.

The urbanisation and increased vehicular load has contributed significantly to the tremendous rise in the incidence of head injury in India.[14,23] Nearly 70% of the road traffic accident patients have head injury and amongst the deaths in road accidents, 70% are due to head injury[21] and most of these deaths occur during the first 2–3 days of sustaining injury.

In the New York Times, the fatality rate in India for 10,000 vehicles was reported as 55 in 1987, which was the highest in the world at that time.[19] Currently,

Table 2: Road accidents and fatal accidents in Delhi

Year	*Number of non-fatal accidents*	*Number of deaths*
1991	6,414	1,651
1993	6,815	1,686
1995	7,216	2,003
1997	10,548	2,176
2001	8,113	1,778
2003	6,700	1,645
2005	6,450	1,575

annual road accidents in India are over 600,000 and every minute there is an accident and every 8th minute there is a death. India has the highest accident rate in the world with a 6% reported incidence in 1991.[3] This is despite the fact that the total numbers of vehicles in India are only 1% of the world's total vehicles.

In 1986, Baker et al.[1] reported that over 8% of total deaths in the US were related to injury. Overall the annual numbers of deaths per year in the US are nearly 50,000.[29,31]

The development of roads has not kept pace with the number of vehicles that are plying on the roads. This has been the hallmark of the urbanisation of our country and especially of our metros. The number of accidents is directly proportional to the number of vehicles on the road. At the time of independence, the total vehicles in India were 300,000 and, in 1995, the number had increased to nearly 27,000,000. In Delhi alone, the vehicles have increased tremendously whereas the expansion of roads and the construction of flyovers have lagged behind. The motor vehicle registration in Delhi is the highest in India with nearly 500 registrations per day, and the number of vehicles reached almost 3 million in 1997 as compared to 0.5 million in 1980 (The Times of India, 27th December, 1997). This represents the exponential growth of vehicular load and reflects on the increased accidents and deaths.

Even though the overall incidence of deaths due to vehicular injuries has increased, the number per 1,000 vehicles has decreased to 14.7 in 1990 as compared to 80 in 1970. This incidence, however, is still very high compared to other countries.[21] The figures from Table 3 show that the number of accidents per 1,000 vehicles in India was nearly 2.5 times more compared to the US. However, in comparison, the numbers of deaths were 10 times more. This data is based on a report published in "Indian Auto", December 1991.[26]

Table 3: Indian statistics

Parameters	*1970*	*1980*	*1990*	*2000*
		(Numbers in thousand)		
Number of accidents	114	153	282	340
Number of injured	70	109	224	290
Number of deaths	14	24	54	70
Number of accidents per 1,000 vehicles	80.3	33.8	14.7	14.0
Total number of vehicles	1,401	4,514	19,177	29,180

Table 4: Number of accidents and deaths per 1,000 vehicles in different countries

Country	*Accidents per 1,000 vehicles*	*Deaths per 1,000 vehicles*
Australia	3.1	0.39
Brazil	1.3	0.34
France	8.7	0.40
Japan	9.8	0.20
UK	14.0	0.52
USA	12.2	0.25
India	31.8	2.5

TYPE OF INJURY AND DISABILITY

The majority (75–80%) of head injuries are minor or moderate[4,6,10] and, fortunately, only a minority are severe injuries. The incidence of severe head injury increases with age and about 5–10% of total injuries are fatal (Tables 3 and 4). In 1980, Besse[2] reported that 90% of head injuries in children were minor. There is a marked variation in the relative incidence of the types of head injury and this is primarily due to the protocols and criteria of hospital admission at various centres. This occurs especially in cases of mild injuries and thus the hospital data can be fallacious due to this. This is reflected by the following data: National Hospital Discharged Survey (NHDS) of the US in 1985 showed 50% of all head-injured patients discharged from the hospital had concussion. The data from the US reported an overall mortality of 20–30 per 100,000 persons. Several studies from the US (e.g. San Diego, Minnesota and Chicago) reported that 63–86% of head injuries were mild.[10,11] An incidence of 30 deaths per 100,000 persons has been reported. In India, over 60,000 people die due to road accidents every year.

Head injury has become a major health hazard in India and presently most of the cities in India report a rising trend.[14,19,21,23,26] An enormous loss of productivity occurs due to the mortality and morbidity associated with such injuries, and one of the major challenges that confronts a healthy society is its prevention. Kalyanaraman (1971)[9] reported head injury death to be the fourth most common cause of death in Madras General Hospital, next to malignancies, tuberculosis and myocardial infarction. Sano[28] reported head injury to be the seventh most common cause of death in Japan.

It was estimated by Lewin[13] in England and Wales that every year 1,200 new head-injured patients were added to the group of moderately disabled who could not return to their jobs. These figures are difficult to estimate in the developing countries due to various factors but the incidence is likely to be much higher. In the US, Walker[32] estimated that one person in every 200 would require medical care for head injury each year, which would result in 1% of the working population being disabled on any given day. It has increasingly been realised

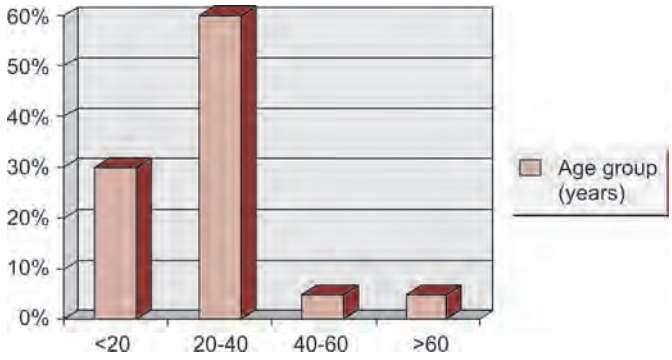

Fig. 1: Group affected by head injuries in terms of years

that minor injuries may result in functional disabilities way out of proportion to the severity of the trauma.

AETIOLOGY OF HEAD INJURY AND AGE DISTRIBUTION

The most common group affected by head injuries are the young people between 20 years and 40 years (Fig. 1) and the incidence is lowest at extremes of age, i.e. below 5 years and above 60 years.[10] From the total percentage of patients with head injury, this age group forms about 60–70% by itself. This may have multifactorial linkage and is primarily related to the social, cultural and demographic practises of this age group. In India, 40% of the total population belongs to the paediatric age group and around 25–27% of all head-injured patients are children under 16 years of age.[15,27] Studies from other countries, like the USA, also show a peak incidence of head injury in the third decade and the head injury rate ranged 300–600 per 100,000 persons.[10]

The most common cause of head injury is road accidents contributing to about 60% of injuries.[10-14,21,26] Injuries due to falls constitute the most frequent cause in children and they contribute to nearly 25–30% of total injuries.[24] Birth trauma is the most frequent cause in the neonatal age group.[27] There is a considerable variation in the aetiology of head injury in the paediatric age group.[24,27] Among the children, most injuries range 3–10 years of age.[24] A frequent cause is bicycle injury which occurs in older children and contributes around 10% of all head injuries in children.[24]

There are certain types of head injuries peculiar to the different regions of the country like the fall of a coconut on the head in Kerala and the Kolhu injury during the sugarcane crushing season in Punjab. Gunshots as a cause of injury are also prevalent in some parts of India and so are the injuries due to *Lathi* and *Gandasa*.

GENDER AND HEAD INJURY

The number of accidents is directly proportional to the type and number of driving and outdoor activities. Understandably so, the incidence is more in males as compared to females and most of the studies quote an incidence of 3:2 in favour of males.[10,24] This incidence reverses in infants and elderly patients above 65 years of age and this is also the age group where females are least cared for in comparison. The peak incidence for males is in the age group of 15–25 years with an incidence reaching 600–700/100,000 persons.[10] In comparison to the females, even though this is the most frequent affected age group, the incidence is about 40% (500–700 in males vs 150–250 in females/100,000 persons). In the paediatric age group, the incidence is again higher in males overall with a ratio of 1:1.6–1.9 in favour of boys.[24]

REASONS FOR ROAD ACCIDENTS IN INDIA

A variety of causes contribute to road accidents and the common causes in the Indian set up are presented in Table 5. The recent trend has, however, shown a decline in the relative incidence of accidents, especially in the developed countries. This has largely been due to thorough understanding of epidemiology of head injuries related to road accidents. Improved highway engineering leading to well-designed roads and improvement in safety measures in motor vehicles has led to such a decline. Public awareness of prevention of accidents has also played an important role and, amongst them, the use of helmets, seat belts, knowledge of traffic rules and understanding the long-term implications of severe accidents have been the most contributory. India has lagged behind primarily due to the poor understanding and implication of all such factors. The reluctance on the part of the people and the authorities has also contributed; however, the recent declining trends have been heartening and one does indeed see a silver lining.[3,19,23]

Only 1% of the total 43,000 km of National Highways in India meets international standards. The safest highways in the world are considered to be in the US, and there is an incidence of 1 death per 160 million kilometres driven in the US. Whereas, in India, comparably there

Table 5: Reasons for increasing number of accidents in India

Road related problems
• Poor road design
• Inadequate lighting
• Improper maintenance
• Lack of adequate road breadth and area
• Lack of bilane system
Vehicle related problems
• Poor vehicular standard
• Improper brake system
• Lack of seat belt
• Continued usage of old vehicles with inadequate safety devices
• Running of other non-motorised vehicles like bicycle, cycle-rickshaw, bullock cart, camel cart, etc. coupled with stray animals on roads
Driving related problems
• Inadequate training
• Easy availability of driving license
• Flexible and oft-broken traffic rules
• Poor visual acuity of drivers
• Consumption of drugs and alcohol

are 6 deaths per every 1 million kilometres driven. Thus, the number of deaths in India is about 960 times more frequent than in the US. The primary factors responsible for such an incidence are poor road design, improper maintenance, poorly maintained vehicles with no safety facilities, apathetic attitude of authorities and, above all, poorly trained and reckless drivers. The procurement of driving license in India is not very difficult even for the untrained drivers and these add on to the onus of vehicular accidents. Moreover, poor vision, old age and intoxicated drivers also cause vehicular accidents in India. A multidirectional approach, considering all the above factors, can reduce the number of accidents in India.

FINANCIAL IMPLICATION OF HEAD INJURY

Most people sustaining head injuries are young people in the productive part of their life and the loss of life and rehabilitation of these victims costs a lot of money and incurs a significant economic burden to the country. One of the WHO reports mentioned that out of 3.5 million injuries related deaths all over the world in a year, 700,000 were due to road accidents and nearly 1.5 million injured people required medical care. In 1993, Nakajima[18,21] reported 5,000 billion US dollars being the cost of medical bills and rehabilitation costs.

The loss of life or the associated morbidity not only reflects on the patient but also on the concerned family or rather society as a whole. They contribute to a significant financial burden as well. Ramamurthi[21] stated that a 350 crore rupees financial loss per year occurred due to accidents a few years back and the present estimate is nearly double that of the quoted figure.

Currently, the number of deaths due to road accidents alone in India is over 60,000. There are many other causes of head injuries apart from road accidents and a rough figure of around 100,000 is mentioned presently. A significant number of cases still go unreported and if included would inflate this figure even further.

CONCLUSION

A thorough understanding of epidemiology of head injury is central to their prevention. There has been a progressive increase in the total incidence of deaths related to head injuries over the years and across the globe. The relative incidence has, however, shown a decline in the recent years. India has been a major contributor to the overall global incidence of road traffic accidents as well as the related deaths.[16]

The majority of head injuries occur in the 2–4 decade and children constitute 25–30% of all head injury victims. Mortality and morbidity due to head injury are very high and associated with a significant financial burden all over the world. Prevention of head injury is a highly desirable aim and this can be achieved by improving road conditions, educating the public and conforming to safety measures.

ACKNOWLEDGEMENT

The authors are extremely grateful to Mr AP Dhar Dwivedi, Department of Neurosurgery, SGPGIMS, Lucknow, for secretarial assistance for this manuscript.

26 Biomechanics of Head Injury

Deepak Agrawal, Ashok Kumar Mahapatra

INTRODUCTION

Head injuries are very common and, apart from treatment, a very important area to which attention must be given is prevention. Prevention has three stages: (i) to stop the accident from occurring; (ii) to reduce the injuries on impact and (iii) to minimise the risk of subsequent complications. Understanding the biomechanics can go a long way in planning better prevention strategies for all the above three stages. In this chapter, we will review the current understanding of the biomechanics of head injuries and the application of this knowledge towards decreasing the incidence of head injuries.

TYPES OF MECHANICAL FORCES

Mechanical forces leading to head injury can be categorised as static or dynamic[9] (Fig. 1).

Dynamic Loading

Dynamic loading is more commonly seen and is defined as input force applied to the cranium over a very short period of time (usually less than 50 ms). Dynamic loading may further be subclassified as "impact loading" and "impulsive loading".

Impact Loading

Impact loading, which is the more common type, is a combination of contact and inertial forces. A sudden impact causes the head to accelerate, resulting in inertial forces coming into play, increasing the severity of injury. The inertial effects may be minimised if the head is immobilised at the time of the impact. Head rests in cars can play an important role in minimising the inertial forces during an impact in car accidents.

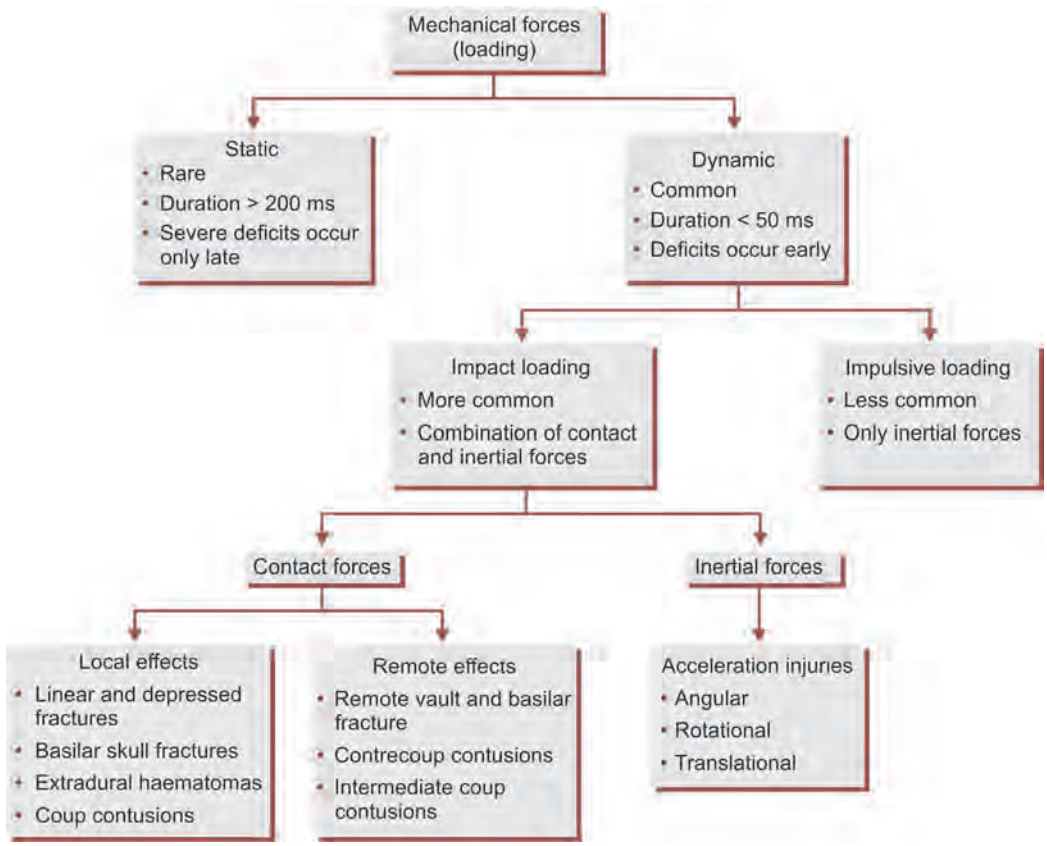

Fig. 1: Types of mechanical forces involved in head injury

Contact injuries: Contact injuries result from forces that occur during direct impact.[11,12] The impact results in complex mechanical events that occur both near and distant from the point of contact (contact phenomenon). Contact injuries typically cause focal injuries, but they do not cause diffuse brain injury. Neural brain damage by this mechanism is typically superficial and localised to the immediate vicinity of the skull injury. Since most impacts set the head into motion, these injuries are associated with acceleration injuries which may result in remote effects.

Local effects of contact injuries: These include depressed fractures, linear fractures, basilar skull fractures, extradural haematomas and coup contusions.[13] Depressed skull fractures are a result of a concentrated force immediately beneath the impacting object. The surface area of the hitting object should be small enough to cause concentration of stress and strain. The momentum of the object is borne by the localised area of the skull and not the remaining skull as in linear fractures. When local skull bending at the site of impact exceeds the strain limit for the bone, it results in the bone bending inwards like a cone. The apex of the bone which is formed by the inner table breaks first and results in a linear fracture.[19] The fracture tends to follow the path of least resistance and is complete when the energy in the impact process is dissipated completely.[11] In children, sutural diastasis may occur. Direct impact to the face, mastoid or occiput, therefore, results in basilar skull fractures.[14] Local bending of bone also results in tearing of dural vessels, leading to epidural haematomas. When the in bent skull recoils back to its position, negative pressure is created which results in tensile strain on the underlying pial vessels and brain resulting in a focal contusion[13] (Table 1).

Remote effects of contact injuries: These are due to skull distortion and stress waves. If the impacting object is broad and the impact occurs over a thick portion of the skull, a remotely placed thinner portion of the skull, with its decreased tensile strength, may fracture. Stress waves may also account for the remote contact effects such as basilar fractures, potential haemorrhages and intracerebral haematomas.[1,13]

Table 1: Clinical classification of head injuries[1]

Skull fractures	*Focal brain injuries*	*Diffuse brain injuries*
Vault	Contusion	Concussion
Linear	Coup	Mild
Depressed	Contrecoup	Classic
	Intermediate	
Basilar injury	*Haemorrhagic*	*Diffuse axonal*
	Extradural	
	Subdural	
	Intracerebral	
	Petechial	
		Other

Inertial injuries: These are commonly called acceleration and deceleration injuries. Acceleration injury of the head causes either a functional or a structural failure of neural and vascular structures, where the severity and extent of disruption are linked to the magnitude, rate, duration and type of inertial loading.[1,9]

Three types of acceleration may occur in inertial injuries:

1. Translational acceleration occurs when the brain moves in a straight line at its centre of gravity, i.e. pineal gland.
2. Rotational acceleration occurs when brain tissue moves around its static centre of gravity.
3. Angular acceleration occurs when there is movement of the centre of gravity in an angular manner. Angular acceleration is a combination of both translational and rotational acceleration.

Angular acceleration is most commonly encountered clinically and the centre of angulation is usually the mid-cervical and lower-cervical regions. The higher the centre of angulation, the greater is the rotational component. As the centre of gravity shifts inferiorly in the cervical spine, the translational component increases.

Three zones of the brain (e.g. surface, intermediate and deep) can be affected differentially as the duration of acceleration increases. At short acceleration duration, the brain experiences very little strain resulting in only surface zone injury. However, at longer acceleration durations, the inertial effects increase and the resulting strains penetrate deeper into the brain tissue. Hence, structural damage to superficial vascular tissue (bridging veins and pial vessels) occurs in short acceleration duration with a large acceleration magnitude, whereas deeper brain tissue injury occurs in longer duration acceleration with lesser acceleration magnitude.[13]

Impulsive Loading

Impulsive loading occurs when the head is put into motion or when the motion of a moving head is suddenly arrested without the head itself being struck or impacted. As there is no direct impact on the head, no contact forces are involved and injury is caused purely by inertial forces. A blow to the thorax or face can set the head into violent motion without direct impact of the skull. Other examples include fall from a height or being thrown off a moving vehicle.

Static Loading

Static loading is uncommon and is defined as input force applied to the load relatively slowly (over 200 ms). Typical examples of static loading are injuries from slowly moving vehicles or earthquakes that trap the head against rigid structures resulting in slow crushing of the skull. Static loading causes multiple comminuted fractures of the vault or base of skull. Severe neurological deficits, although uncommon, may be present if the brain is also distorted and compressed directly due to static loading. Duhaime et al.[8] reported a series of seven

children with head injuries caused due to static loading. Patient ages ranged from 15 months to 6 years. In four cases, the child's head was run over by a motor vehicle backing up in a driveway or parking lot. In the other three patients, the static loading occurred when the child climbed or pulled on a heavy object, which then fell over with the child and landed on the child's head. One child with cervicomedullary disruption died shortly after his arrival at the hospital. The others showed varying degrees of soft tissue injury to the face and scalp, with Glasgow Coma Scale scores ranging from 7 to 15. Computed tomograms (CTs) and magnetic resonance images (MRIs) showed multiple and often extensive comminuted calvarial fractures, as well as subarachnoid and parenchymal haemorrhages. All patients had basilar cranial fractures. There was one cervical spine injury but no major vascular injuries. One child had pituitary transection, four had cranial nerve palsies and another developed a delayed cerebrospinal fluid rhinorrhoea 18 months after injury. All children made good cognitive recoveries, with some having relatively mild fixed focal deficits.

MECHANISM OF SPECIFIC INJURIES

Concussion and Sports Injuries

Concussion, or mild traumatic brain injury (TBI), occurs in many activities, mostly as a result of the head being accelerated.[5] Angular or rotational head motions cause transient electrophysiologic dysfunction of the reticular activating system in the upper midbrain, caused by rotation of the cerebral hemispheres on a relatively fixed brainstem. In this type of injury, most of the strain is insufficient to cause structural damage, but results in biochemical and ultrastructural changes such as mitochondrial ATP depletion.[13] However, the physiological basis of amnesia remains unclear. Recent sophisticated laboratory research has better elucidated injury biomechanics associated with concussion in professional football players. This data has led to changes in helmet design and new helmet technology, which appears to have beneficial effects in reducing the incidence of cerebral concussion in high school football players. In a prospective study on 2,141 athletes, Collin et al.[6] showed that improved helmet design resulted in a 31% decreased relative risk and 2.3% decreased absolute risk for sustaining a concussion, as compared to standard helmets.[6]

Contrecoup Contusions

The predominant mechanism for contrecoup contusions is head acceleration (inertial effects). The term is a misnomer, as actual impact is not necessary.[7,16] In situations where the head undergoes impulsive loading, contrecoup lesions occur solely due to acceleration effects.[11,12]

Subdural Haematoma

Acute subdural haematoma is due to disruption of surface vessels, usually bridging veins. Disruption of bridging veins mostly occurs from inertial force and not from contact force. The acceleration is of short duration with a high strain ratio loading. Hence, acute subdural haematomas are usually associated with diffuse axonal injury (DAI) and cerebral contusion.[9]

Diffuse Axonal Injury

Diffuse axonal injury is considered as an extreme form of concussional injury and may be caused by long duration rotational or angular acceleration.[2,3,10] The extent of axonal damage depends upon the magnitude, duration and rate of angular acceleration. Neuronal damage occurs in a centripetal fashion, from the cortex inwards to the brainstem, as the force of injury increases. The direction of acceleration is important in the production of DAI. Pure sagittal acceleration may result in a milder DAI, whereas angular acceleration in the coronal plane is associated with a higher incidence of severe DAI.

Shaken Baby Syndrome

Shaken baby syndrome (SBS) is characterised by a constellation of clinical findings, including subdural bleeds, retinal haemorrhages and fractures of the extremities and ribs, with no external evidence of cranial trauma. Interestingly, attempts to reproduce this injury using biomechanical models have not yet succeeded.[15,18] Bandak[4] carried out injury biomechanics analysis of the reported SBS levels of rotational velocity and acceleration of the head for their injury effects on the infant head-neck. Resulting forces were compared with experimental data on the structural failure limits of the cervical spine in several animal models as well as human neonate cadaver models. Their study clearly showed that cervical cord and brainstem damage would occur prior to and, more importantly, at lower levels of rotational velocity and acceleration then purported in SBS. The very basis of SBS therefore remains controversial.

FUTURE RESEARCH

Presently, the controlled cortical impact model is used to study focal TBI. Although the impact variables can be well defined, little is known about the biomechanical trauma as delivered to different brain regions as well as the response of neurons to mechanical trauma. This knowledge, however, could be valuable for interpretation of experiments (e.g. immunohistochemistry, etc.), especially regarding the comparison of the regional biomechanical severity level to the regional magnitude of the trauma sequel under investigation. Finite element (FE) analysis,[20] using high resolution T2-weighted MRI images of rat brain, to simulate displacement, mean stress and shear stress of brain during impact has recently been used as a tool for biomechanical simulation and holds considerable promise, especially if complemented with the use of MR elastography.

Also, at the cellular level, plasma membrane disruption may be the earliest cellular outcome from a mechanical trauma. The increase in membrane permeability due to such disruptions may therefore play an important role in the initiation of deleterious cascades following brain injury.[17] Researchers have used novel devices capable of applying stress at high rates to neuronal cells cultured on a microelectrode array to simulate TBI. Spontaneous electrophysiological activity of injured cultures can then be monitored to get an insight into the neuronal effects of TBI.[17] The outcome from such ongoing research may help in our knowledge of the pathophysiology and biomechanics of head injury leading to improvement in preventive measures.

CONCLUSION

The mechanical forces causing head injury can be classified into dynamic and static in nature. Dynamic loading is further subclassified into impact and impulsive loading. Direct injuries are a type of impact loading which may result in linear fractures, extradural haematomas and coup contusions. Both impact and impulsive loading can lead to acceleration injuries which can be angular, translational and rotational. Cerebral concussion, contrecoup contusions, DAI and subdural haematoma are typical examples of acceleration injuries.

Although much insight has been gained into the biomechaincs of head injury, a lot remains to be done. FE analysis and neuron tissue culture are the thrust areas of ongoing research in biomechanics of head injury.

27 Pathology

Sankar SK, Anita Mahadevan

INTRODUCTION

Socio-technological and economic progress in the developed and developing countries have brought about a significant change in the health related problems in their communities. Due to massive international and national commitment there has been a significant decline in infectious and communicable diseases. According to recent reports by The World Bank, WHO and Harvard School of Public Health, morbidity and mortality related to injuries has been recognised as the third major public health problem across the globe in the new millennium.[131,194] Traumatic brain injury (TBI) is a major condition affecting all aspects of human life, contributing to mortality, morbidity, disability and the resultant socio-economic impact on the family and society. The epidemiology of TBIs provides insight into the magnitude of the problem, population-ethnic characteristics, risk factors, mode, pattern and nature of injuries, the survival and the outcome, and the long term sequelae.[78,76,136,150] This type of information is crucial in designing, implementing and evaluating intervention programmes in terms of feasibility, affordability, sustainability and cost effectiveness, and evolve policy strategies beneficial to both the citizen and society.[75,77] A comprehensive epidemiological study of head injury from a South Indian city, Bangalore, indicated that the incidence and mortality rates were 160 and 20 per 100,000 population, respectively per year.[26,78] The extent of neurotrauma registration in Indian hospitals constituted approximately 25% of all registrations at casualty emergency services. Severe, moderate and mild injuries were seen in 69%, 15% and 16% of patients, respectively and the case fatality rate is 9.6%.[26]

It is estimated that, in India, of the 1,440,000 TBIs per year, nearly 180,000 succumb. Road traffic accidents and falls are the major cause of traumatic injuries in 62% and 22% respectively, followed by violence in 10% of cases. People in their prime and in the productive age group of 20–30 years are affected maximally, men being at greater risk.[26,75] Alcohol has been a major risk factor for traffic injuries, falls, violence, work related accidents and others (Table 1). Alcohol consumption also poses a significant influence on the evolution of the pathology, diagnosis and management as well. A point of major concern is that, in the majority of developing countries, the vulnerable road users are the pedestrians, motorised two wheeler users, and bicyclists, unlike car occupants in the Western countries. Among falls that cause brain injuries, the large majority (70%) are domestic falls, followed by others in schools, agricultural land and construction sites. Emergence of communal and political violence has become a matter of great concern for policy makers, and has resulted in bizarre forms of injury complicating the mechanics of brain injury.

Table 1: Factors modulating primary brain injury

a.	Precise type, location, extent (size) of injury		
b.	Type	→	Moving vehicle
		→	Missile—gun shot, stone throw
		→	Fall or assault (blunt/sharp/size of impact)
	Blunt Injury	→	Wide damage, long-term psychological impairment, poor recovery
c.	Biological factors in victim	–	Pre-existing disease
		–	Psychological status
		–	Nutritional status prior to injury
		–	Consumption of sedative, alcohol, psychoactive drugs

In India, unlike the Western countries, neurotrauma due to violence is inflicted by piercing and blunt objects than by firearms, constituting 2–23% of TBI across studies. Neurotrauma due to sports and recreational activities is found to vary from 4–10% and due to fall or hit by objects about 4% (cricket ball, cement, brick, ceiling fan, heavy utensils, coconut, etc.). We have no realistic estimate of TBI related to natural disasters, though it is a common feature year after year. In India, it is estimated that nearly 1% of the population is disabled and nearly 30–40% of these disabilities are due to TBI. Only 10% of the disabled receive adequate rehabilitation. Till date the study of head injury was confined to neurosurgeons, orthopaedic surgeons and forensic pathologists to meet the treatment requirement and medico legal aspects related to it. The Indian literature had a major limitation in that the problem of head injuries was studied in individual centres on issues of specific interest to the researchers.[13,15,96,154,155,158,177] Information is available only on motor vehicle injuries, thus it is a gross underestimate of the problem. The cultural and socio-economic aspects of society and genetic polymorphism also influence the biology of head

injury. It is essential to have an understanding of the evolution of pathology and pathophysiology, for timely and effective management of cases of TBI.

CAUSES OF BRAIN DAMAGE—TRAUMATIC BRAIN INJURY

The different causes of TBI are listed in Table 2.

Focal Brain Injury

Brain damage in non-missile head injury is classified as "focal" or "diffuse". The focal damage includes contusion and lacerations on the surface of the brain and intracranial haematoma and raised ICP as a secondary phenomenon. Focal injuries result from localised damage, found in nearly 58% of patients with severe head injuries and 66% of deaths associated with head injury.[71]

Contusions

In 1930, Spatz[171] characterised contusion and described the gross and microscopic features. Lindenberg and Freytag[105] carefully delineated the various topographic patterns and tissue responses in blunt trauma of the head and defined contusion as a bruise of the surface of the brain, which is covered by intact dura. Contusions are caused by blunt contact of the brain with various bony surfaces of the skull. According to Graham,[67] the pia arachnoid is intact over a contusion, but is torn in a laceration.

Table 2: Causes of brain damage—traumatic brain injury

A. Focal lesions:
- Fracture of the skull
- Scalp laceration
- Surface contusions/Lacerations of the brain
- Intracranial haemorrhage
  - Extradural
  - Subdural
  - Subarachnoid
  - Intracerebral
- Damage secondary to raised intracranial pressure (ICP).
- Damage to vessels due to trauma → dissection → thrombosis → large territory infarction

B. Diffuse lesions:
- Diffuse axonal injury (DAI) (secondary to stretching/rupture of axons)
- Diffuse brain swelling (Secondary to vasomotor paralysis → vasodilatation → vasogenic oedema)
- Diffuse small vessel injury—(Secondary to acceleration/deceleration → rupture of small vessels)

C. Sequelae of head injury:

DAI + hypoxic brain damage → Severe disability, vegetative state.

(Traumatic injury to the scalp and skull are not dealt with in this chapter)

Fig. 1: Severe contusion of the orbital surface of the frontal lobe more on one side, indicating angular impact against the anterior cranial fossa

Editors' comment: The pathological clinical and prognostic significance of cerebral contusion was a subject of a comprehensive study reported by Kristiansen and Tandon in 1960.[104]

Recent contusions are haemorrhagic (Figs 1 and 2) and, when superficial, are characteristically restricted to the crests of the gyri, but often extend into the sulci and the underlying white matter (Figs 3A and B). When located deep in the Sylvian fissure, they are visible on slicing the brain (Fig. 4). They develop rapidly by rupture of pial vessels soon after impact. With time, they are seen as shrunken brownish areas on the crest of gyri.

Healed contusions are commonly found in chronic epileptics, with repeated history of falls and are of medico legal importance. Unlike in all other age groups, the contusion in infancy (battered baby syndrome) results in tears in the sub-cortical white matter and inner layers of the cortex, particularly in the frontal and temporal lobes and the cortex above and below the Sylvian fissures. The most common sites of contusion in closed head injuries are the under surface, and polar regions of the frontal

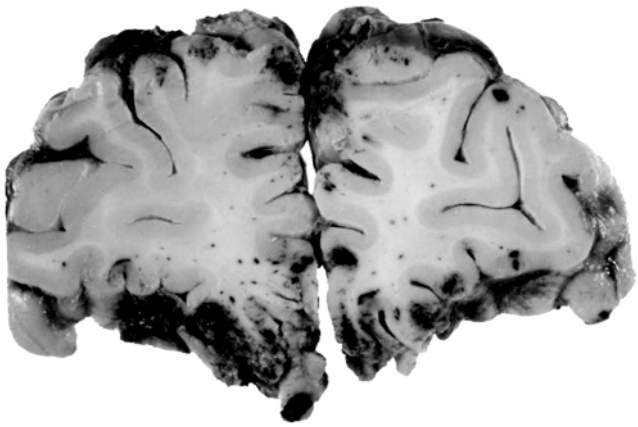

Fig. 2: Contusions along the orbital surface of the frontal lobe and adjacent white matter and also on the surface of the superior frontal gyrus and along the medial surface — gliding contusion

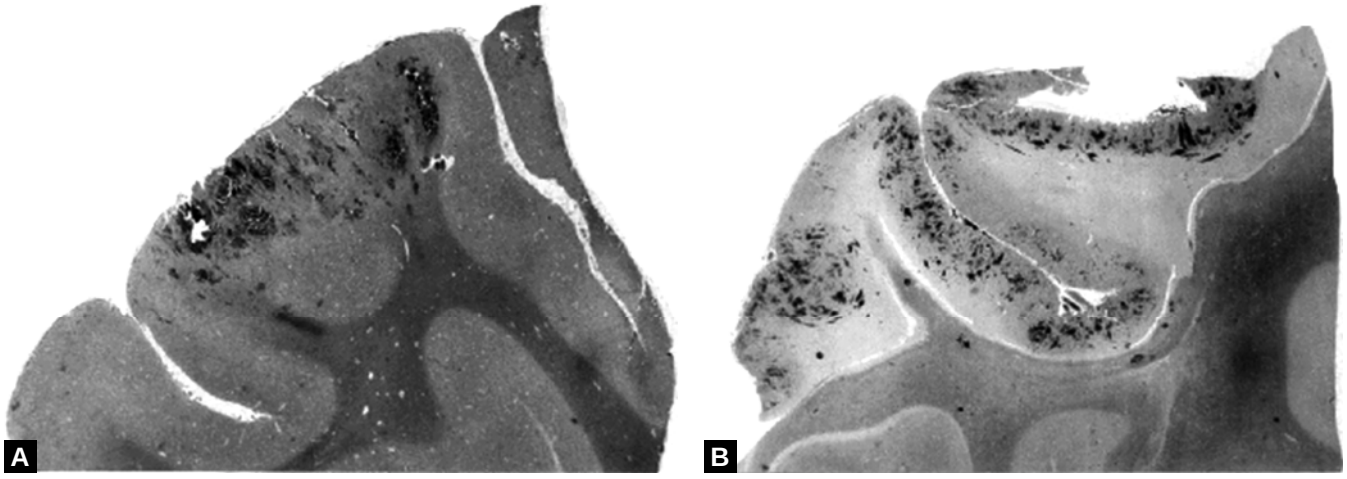

Figs 3A and B: (A) Recent contusion, haemorrhagic and confined to the crest of a gyrus. (B) Contusion involving the crest of gyri and extending into the depth of sulci, usually visible after 48 hours

and temporal lobes followed by their lateral surfaces. Contusion of the parietal and occipital lobes and cerebellum are rare and usually associated with local fracture. The surrounding brain shows focal reactionary oedema. Various forms of contusions provide clues about their evolution:

Fracture contusion: It is related to the site of fracture, common in the frontal lobe.

Herniation contusion: Parahippocampal gyrus and cerebellar tonsils impacting against the tentorium and foramen magnum, respectively, follow blunt impact on the vortex.

Gliding contusions: Adjacent to the superior sagittal sinus, (Parasagittal contusions) haemorrhages in the superficial cortex and white matter, caused by anteroposterior gliding movement of the brain with respect to the dura and falx cerebri. The parasagittal bridging veins entering the sinus may be torn with haemorrhage. They are usually bilateral and asymmetric, and associated with diffuse brain damage and DAI.

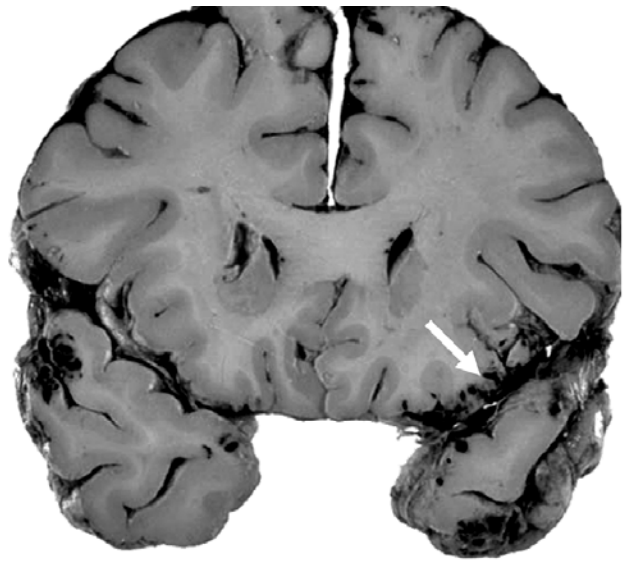

Fig. 4: Contusions along the Sylvian fissure due to impact against the sphenoid wing and temporal poles

Coup contusion: It occurs at the site of impact in the absence of fracture. The extent depends on the size of contact between the skull and the striking object and the accelerating force transmitted to the underlying brain.

Contre coup contusion: It occurs in the brain away from the site of impact, usually in a diagonally opposite anatomical area, caused by deceleration of the moving head against bone. Because of the complex nature of head motion in any accident and the anatomical irregularities of the inner surface of the skull, contre coup contusions may not be exactly opposite the point of impact. Hence, a contre coup contusion can be defined as a contusion not below the site of impact, irrespective of its exact location. Contusions are more severe in patients who have fracture of the skull in comparison to those who do not; contusions are more severe in patients who do not experience a lucid interval than those who do; contusions are less severe in patients with DAI than those without.[4,110]

Contusion index: For an objective evaluation of the extent of contusion and for clinical correlation, Adams et al. developed a quantitative approach. The index is the product of the extent and depth of contusional damage.[4] The extent includes both haemorrhagic and non-haemorrhagic necrosis, evident only on histology. The clinical usefulness of this contusion index is doubtful.[122]

Intracranial Haemorrhage

It is a common complication of severe forms of blunt head injury where the patient deteriorates after a period of lucid interval.

Editors' note: The classical lucid interval is not a consistent feature even in extradural haematomas (EDHs) and is an exception than a rule in acute subdural and intracerebral haematomas.

It has been noted in 55% of cases in the Glasgow database. The majority of patients who develop a haematoma have a skull fracture. Though, clinically, the haematoma may not be apparent until it causes mass effect and raised ICP, imaging techniques can detect them before they become apparent clinically. In traumatic intracranial haemorrhage there may be bleeding into the extradural, subdural or subarachnoid space, into the brain parenchyma and into the ventricles.

Extradural haematoma: EDH occurs in approximately 2% of all forms of head injury[91] and in 5–15% of fatal head injuries.[51,115] In the majority, there is associated skull fracture and usually follow a fall or road accident, but, in children, it can occur in the absence of a fracture. The haemorrhages originate from the ruptured meningeal vessels and enlarge by stripping the endosteum and dura from the skull and indenting the brain. Nearly 50% of EDHs occur in the region of the squamous part of the temporal bone, which is thin and easily fractured by blunt impact, tearing the middle meningeal artery.[126] In 20–80% of cases, it can occur in the frontal and parietal areas. Posterior fossa EDH can also occur and follows injury to the middle meningeal vein, diploic vein, dural sinuses or tear of the carotid artery before it enters the intracranial dura along the base of the skull.[31] Contrary to the generally held view, EDH is usually associated with contusions, influencing the clinical course.[177]

The size of the EDH can increase by up to 50% till the end of the 2nd week following the injury, after which it starts shrinking by organisation and may be resolved completely by 6–8 weeks after injury. However, most patients with significant EDH deteriorate rapidly and require early surgical intervention.

Following fire accidents at home/industrial zones or arson, fissure fracture of the skull and extradural heat haematomas may occur. The haematomas have a pink spongy appearance like "cooked meat", indicative of thermal injury, unlike the usual dark colour. For it to develop the victim needs to be alive and the EDH follows the pattern of external charring. A combination of EDH and fracture of the skull in fire victims may pose difficulty in interpretation, with medico legal implications. EDH can occur without fracture, following contact related skull deformation alone and vessel tear.

Subdural haematoma: Subdural haematoma (SDH) is caused by rupture of bridging veins, connecting the superior surface of the brain to the sagittal sinus. These types of lesions are common in adults and the elderly following even trivial trauma or whiplash movement of the head. Some SDHs are of arterial origin. It may occur in combination with intracerebral haemorrhage, and the two can communicate with each other, when it is referred to as "burst lobe".[177] Unlike EDH, SDH tends to spread diffusely to cover the entire hemisphere. In young adults they are common following falls, assaults and vehicular accidents. Occasionally, interhemispheric SDH may occur after minor injury in association with anticogulant therapy. Acute SDHs are found in approximately 10–30% of all patients with head injuries.[8,151,156,176,179]

Fig. 5: Subdural haematoma encapsulated by a membrane. Note the brownish discoloration of the underlying leptomeninges due to haemolysis. The brain is irregularly compressed (2 weeks after injury)

The SDH is defined as being acute, subacute or chronic based on histological features, but the classification is found to be unsatisfactory. Subdural haematoma is considered acute by the clinicians when composed of clotted blood and subacute when it is symptomatic within 3 days of injury and is usually composed of clotted blood. It is classified as chronic when it is already encapsulated which takes more than 3 weeks after injury. Most chronic SDH consist of fluid blood. On gross examination in case of a chronic SDH, a subdural membrane forms around 3 weeks after the injury (Fig. 5). It must be emphasised that acute and chronic SDH are distinct entities on the basis of their aetiopathogenesis, clinical picture and treatment (see individual chapters). The SDH causes compression of the brain to leave a smooth indentation, more often in old age, due to slow progression (Fig. 6). During the acute phase it may stain the

Fig. 6: Extradural haematoma causing flattening of the underlying brain. Note the absence of damage to the brain

adjacent arachnoid by haemolysis and release of haeme pigments. Most SDHs resolve spontaneously and do not progress to chronic SDH. Occasionally, an SDH may get encapsulated between the dura externally and subdural membrane internally and grow slowly due to repeated leak from the newly formed vessels during the healing phase, following vigorous movement of the head or trivial trauma. Following absorption, sometimes, a thin translucent membrane may be left adherent to the leptomeninges over a wide area, causing impedance to cerebrospinal fluid (CSF) flow. Histologically the subdural membrane resembles a flat membrane of granulation tissue with haemosiderin containing histiocytes or extra cellular clumps of haemosiderin. In nearly 15–20% of cases a variable eosinophilic leukocyte infiltration may be seen admixed with other chronic inflammatory cells and mast cells. The relationship of the eosinophilic reaction, either to evolution or chronicity, is not clear.

In aged individuals with cerebral atrophy, the haematoma expands slowly, and the period of spatial compensation may take so long that the cerebral hemispheres may be markedly distorted, but without significant increase in ICP. Death is usually due to secondary events, and not the initial impact, that results in brainstem distortion and compression.

Occasionally, clear or xanthochromic fluid may accumulate in the subarachnoid space resulting in hygroma and compression of the underlying brain (Fig. 7). This is considered to be due to a valve like arachnoid tear causing unidirectional flow of CSF into the subdural space that mixes with liquefied blood.[166] These subdural hygromas are reported in 7–12% of all intracranial mass lesions.[8,172] Kudesia et al.[105] reported subdural haematomas in 25.8% of cases. In this series, there was associated cerebral contusions in 94% of cases and skull fracture in 53%. Nearly 25% of cases with SDH had associated DAI. Adams et al.[8] reported SDH in 11% of cases with DAI.

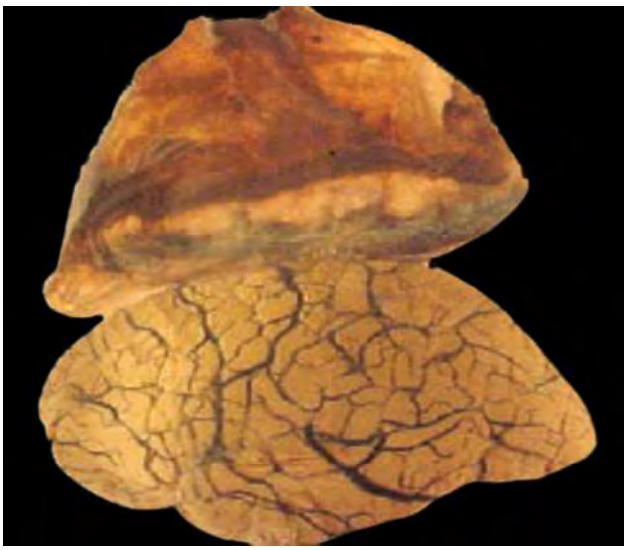

Fig. 7: Subdural membrane, covering the brain with almost total resorption of the blood clot (10 weeks after injury). The anterior part of the brain is compressed on both sides

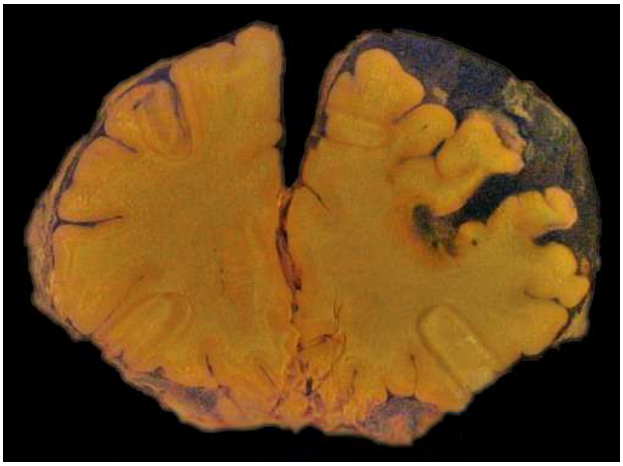

Fig. 8: Severe degree of subarachnoid haemorrhage mimicking subdural haematoma. Note the extension of haemorrhage into the sulcus indicating its plane in the subarachnoid space

Some amount of subarachnoid haemorrhage (SAH) is present almost invariably in any acute head injury in which there are cerebral contusions (Fig. 8). Intracerebral haematomas are present in 15–20% of all patients of traumatic injury in the Glasgow database.

Intracerebral haemorrhages: They are often multiple and most frequent in the white matter of the frontal and temporal lobes and, occasionally, the cerebellum. Intracerebral haematomas need to be distinguished from tissue tear haemorrhages noted in the severe form of DAI.[66] The latter are usually multiple, linear, small, parasagittal in location and caused by tensile tear of both vessels and axons in the white matter.

Post-traumatic deep intracerebral haemorrhage in the region of the basal ganglia (Fig. 9) is recognised to occur more frequently than thought of previously, with the advent of superior imaging techniques. However, the commonest sites of intracerebral haematoma are temporal, followed by the frontal lobe, the same sites

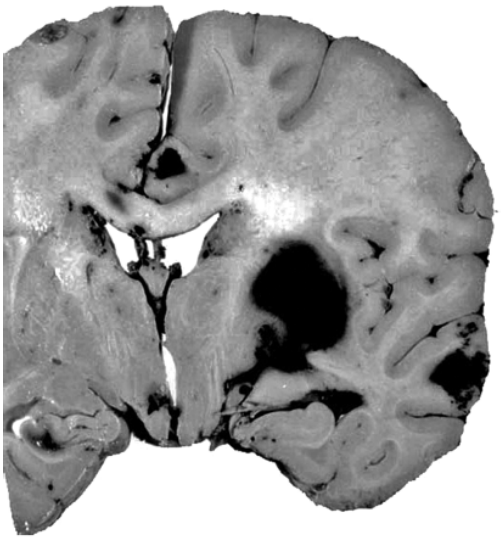

Fig. 9: Basal ganglion haematoma. A small haematoma in the cingulate gyrus with mild transfalcine herniation and another in the middle temporal gyrus, due to direct impact

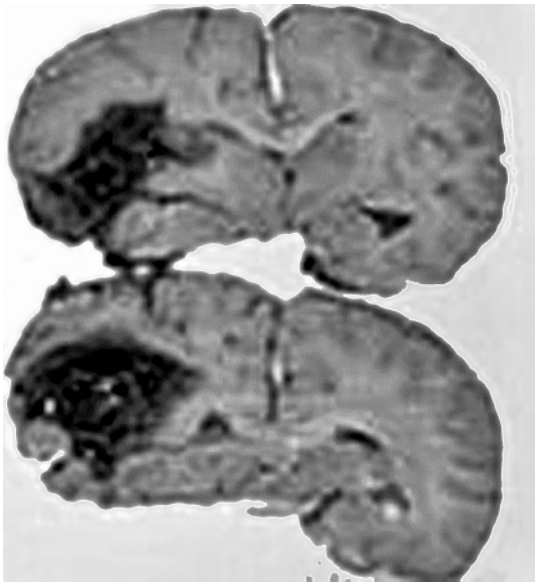

Fig. 10: Burst lobe. The haematoma in the left temporal lobe has ruptured into the subarachnoid space

Fig. 11: Periaqueductal, subependymal haemorrhages in addition to primary and secondary pontine haemorrhages

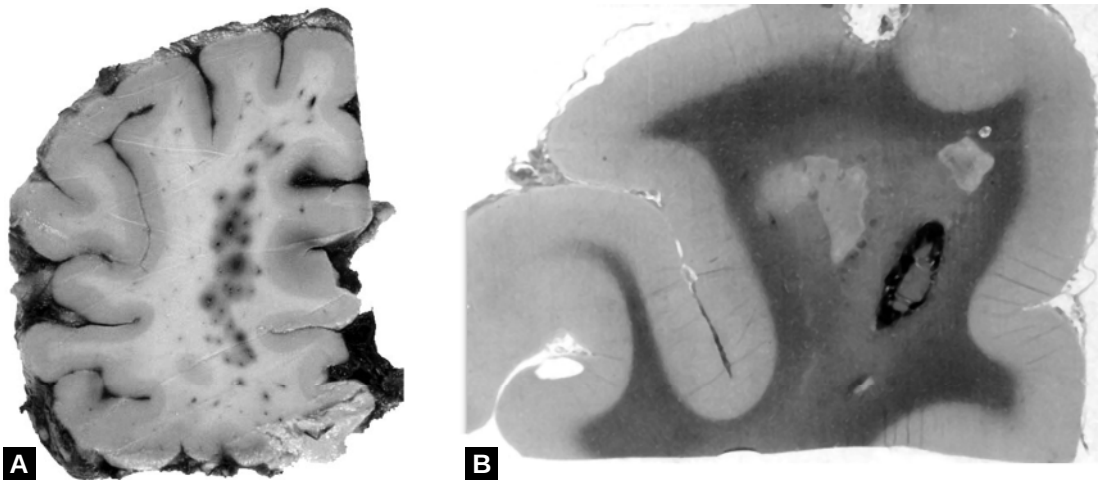
where contusions occur most frequently. Macpherson et al.[113] reported that computed tomography (CT) scans demonstrated basal ganglionic haematoma in 61 out of 2,000 head injury patients. Patients with basal ganglionic haematoma form a subgroup within head injury patients, because of their association with diffuse brain injury, surface contusions, gliding contusions and DAI. Adams et al.[5] reported the incidence of patients with deep intracerebral (basal ganglionic) haematoma to be 63 out of 635 cases of head injury. Lee and Wang[107] in a retrospective study of 52 cases of closed head injury, found the haematoma to be located in the putamen in 74.9%, caudate in 77% and thalamus in 17.4%. Kudesia et al. from India,[105] reported intracerebral haematoma in 24.4% and it was located in the basal ganglia in 11.4% of cases of head trauma. When an intracerebral haematoma destroys the parenchyma and communicates with the overlying subarachnoid and subdural haematoma, it is referred to as "burst lobe" (Fig. 10).

Histological examination of the brains with basal ganglionic haemorrhage (BGH) resembles those noted following DAI, although both these pathological entities can coexist. Vascular damage and microhaemorrhages predominate, the area bordered by zones of axonal pathology. These suggest that the haematomas in the deep cerebral parenchyma are caused by rupture of cerebral blood vessels at the time of impact. The frequent coexistence of DAI and BGH suggests that the biomechanics of the evolution of the two lesions is essentially similar, requiring angular acceleration of the head as in the case of a road traffic accident than in a free fall. Experimental studies on primates[10,59] have revealed that the blood vessels are likely to be affected only by injuries of greater severity than that involved in shearing of axons in the white matter. The anatomical location of the haemorrhages and haematoma following trauma are to an extent similar to areas manifesting hypertensive haematomas due to rupture of thin, long end arteries and also highlighting the vulnerability of these vessels to sudden alteration of pressure gradients and shearing forces. Hence, discriminating an intracerebral haemorrhage due to a hypertensive episode or ruptured saccular aneurysm and fall from an accidental injury with haemorrhage may not be possible and a definite opinion cannot be offered. This has medico legal implications.

Intraventricular haemorrhages: Intraventricular haemorrhages (IVH) are also usually associated with DAI.[10,32] Kudesia et al. from India,[105] in a study of 30 patients with severe head injury, noted IVH in nearly 50% of cases with radiological evidence of DAI. In these cases, subependymal haemorrhages due to rupture of veins with a breach of the ependyma (Fig. 11) and corpus callosal haemorrhages related to DAI extending to the fornix and septum and rupturing into the ventricle were common. In cases of IVH, the axonal bulbs are particularly observed in the subependymal area.

Diffuse (Multifocal) Brain Damage

Diffuse brain damage, following TBI, becomes evident by instantaneous loss of cerebral function and long lasting disturbances of consciousness with residual sequelae in patients rendered unconscious at the time of impact.[183] This diffuse pathology is the cardinal mechanism for prolonged unconsciousness in nearly 50% of patients with no expanding intracranial mass.[7] These diffuse lesions are seen in nearly one third of all head injury deaths.[58] Further, some patients who sustained minor injury may have diffuse damage in the brain that manifests later when subjected to mild cerebral ischaemia.[47] Among the four types of diffuse cerebral injury that follow trauma: (1) diffuse vascular injury, which is most serious and is found in patients who succumb soon after head injury.[183] The other three forms which manifest in



Figs 12A and B: (A) Multiple small haemorrhages in the parietal white matter. Survival 1 hour. (B) Histological preparation showing white matter haemorrhage and two ischaemic pale lesions. Survival 24 hours

those who survive longer and seek hospitalisation are: (2) DAI; (3) diffuse ischaemic brain damage and (4) diffuse brain swelling.

Diffuse Vascular Injury

Multiple small haemorrhages are frequently seen in the brains of patients who succumb very soon after a head injury, especially those who die instantaneously after impact. These haemorrhages, although considered a manifestation of severe degree of DAI,[8] are likely to be mechanical in origin caused by mechanical stretching and shearing of small blood vessels.[138] As they are usually seen in the brainstem, Tomlinson[183] suggested that they are indicative of brain damage that is incompatible with life. However, there is a spectrum of lesions that can result and can be compatible with life if located in the cortical white matter. They are usually conspicuous in the white matter of the anterior frontal (Figs 12A and B) and temporal lobes, periventricular white matter, thalamus and brainstem. In the brainstem they are numerous in the periaqueductal and fourth ventricular subependymal area (Fig. 11) and rarely seen in the caudal pons and medulla oblongata. Though some considered them to be primary brainstem haemorrhages, they essentially represent diffuse brain damage of vascular origin, in view of their widespread nature. When located in the corpus callosum and dorsolateral quadrant of the brainstem, they can be mistaken for DAI, but they are not restricted to these sites when present.

Many of these haemorrhages can be observed grossly, but many more, like perivascular haemorrhages, become evident on microscopic examination. These microscopic haemorrhages are, especially, present around small arterioles and venules with disruption of the vessel wall (Figs 13A to C). Kudesia et al.[105] reported these haemorrhages in more significant numbers in patients with gross evidence of DAI (42%) than in those without DAI (7%), suggesting a close association between these haemorrhages and DAI. The perivascular distribution of

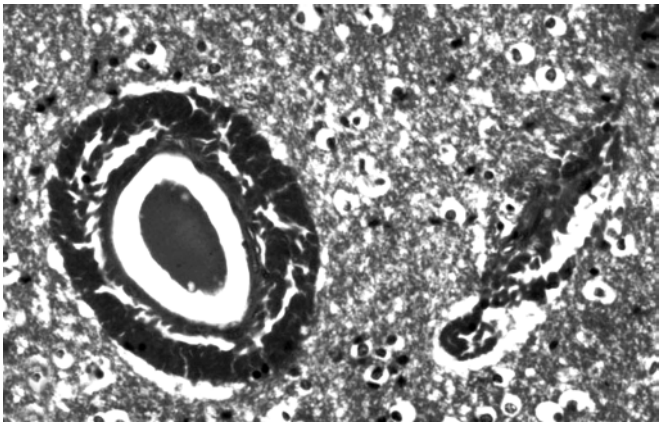


Fig. 13A: Perivascular acute haemorrhage due to tear of the vessel wall. Survival 30 minutes (HE × 160)

axonal retraction bulbs (Fig. 13C) in these cases suggests shearing and stretching of the axons by the mechanical forces, though vessels themselves were not torn, because of the differential threshold of reaction to acceleration deceleration impulses.[11,105] These observations provide evidence that shearing strains, especially rotational, as seen in road traffic accidents, are likely to disrupt the

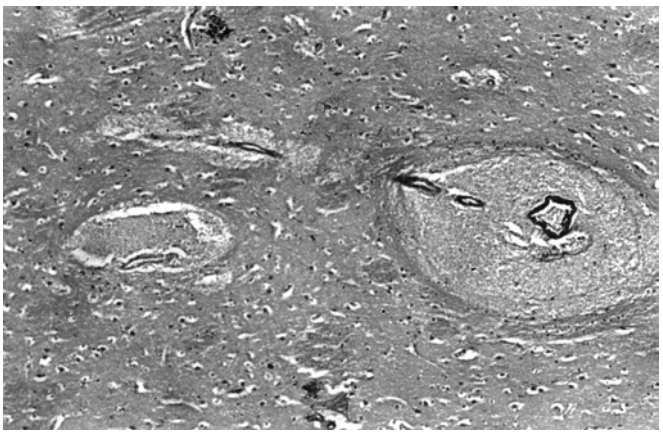

Fig. 13B: Perivascular haemorrhage around a vein. Survival 30 minutes. Note absence of white matter lesion due to acute nature of evolution (HE × 80)

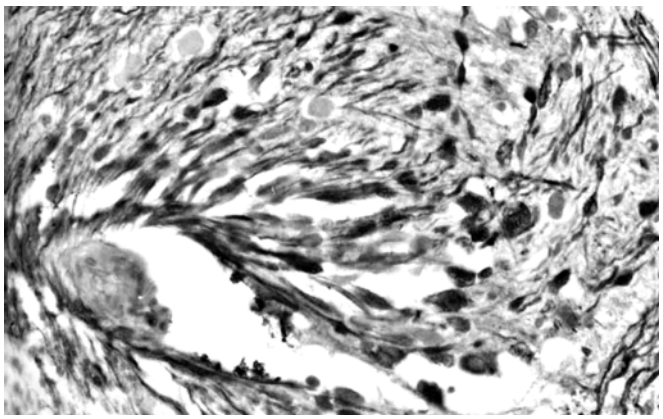

Fig. 13C: Wind blown appearance of perivascular axonal retraction bulbs, suggesting shearing and stretching of axons by the mechanical forces (Immunoperoxidase—NF × 200)

vessels and axons. Due to differential mobility of structures during acute displacement of the head, the blood vessels with firm collagenous walls lag behind.[163]

In conclusion, our study supports the hypothesis that TBI is characterised by frontomedian dysfunctions, which may be responsible for clinical deficits in the long-term and which might be modified by rehabilitative strategies in the future.[156,161]

Damage to blood vessels following injury: In addition to small vessel rupture due to mechanical avulsion, ischaemic damage as an accompaniment of DAI following trauma, medium sized and large vessels also can be damaged. The main vessels that show evidence of tear are the vertebral and the internal carotid arteries. The internal carotid artery can get traumatised in the sigmoid portion as it traverses the bony canal in the base of the skull following a fracture (Figs 14A and B). It can manifest as a pseudo aneurysm, the blood accumulating between the media and the adventitial sheath or dissecting the media, into two layers. Carotico-cavernous fistula is another rare sequel of head injury. The vertebral artery can get damaged in the canal in the first cervical vertebra, even without fracture of the transverse process or in the space between the transverse process of the axis and atlas as it emerges from the canal and penetrates the spinal dura below the foramen magnum. Occasionally, the vertebral artery can be traumatised in the subarachnoid space as it courses through the foramen magnum. More than real traumatic tear of the vessel, of great clinical importance is the not so well recognised vascular spasm and new imaging studies will assist the clinician in recognising them.

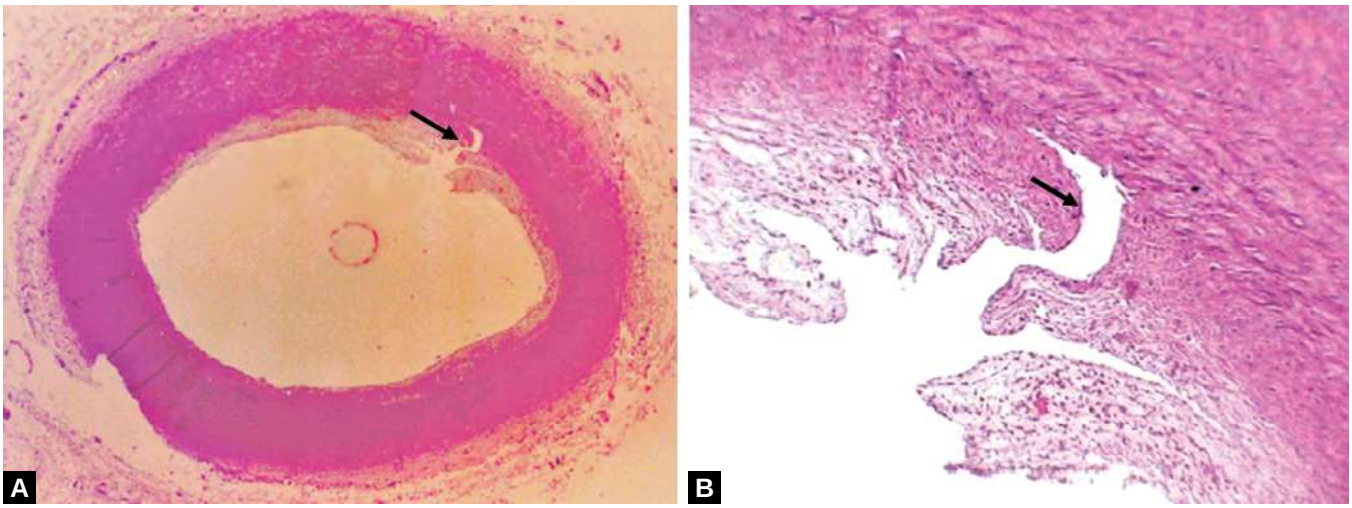
Features of Raised Intracranial Pressure and Brain Swelling

Following TBI, three types of brain swelling are observed:

1. Swelling adjacent to a contusion and intracerebral haemorrhage
2. Diffuse swelling of the unilateral cerebral hemisphere
3. Bilateral diffuse brain swelling.

The essential mechanism for all the types appears to be vasogenic, due to deranged vasotonicity or vasoparalysis, mediated by neurotransmitters, ionic imbalance and physical injury.

Consequent to contusion and haemorrhage, the breakdown in the blood brain barrier (BBB) causes localised vasogenic oedema.[41] Diffuse swelling of one side of the hemisphere is usually seen in relation to an ipsilateral acute subdural haematoma.[9] When the haematoma is evacuated, the adjacent brain swells to fill the void and may herniate through the craniotomy wound. This also appears to be vasogenic in pathogenesis and contributes to rapid clinical deterioration. An epileptic seizure alone or a large supratentorial tumour pre-existing alters the BBB further, aggravating the oedema and herniation. These events have medicolegal implications.



Figs 14A and B: (A) Road traffic accident, with injury to internal carotid artery without fracture. An intimal tear is seen due to impact. Following vasospasm the patient had ACA, MCA territory infarct on the side of impact and injury to the internal carotid artery. Survival 3 days (HE × 10); (B) Higher magnification showing the intimal tear. Note the sub-intimal thickening and proliferation of medial muscle cells (HE × 200)

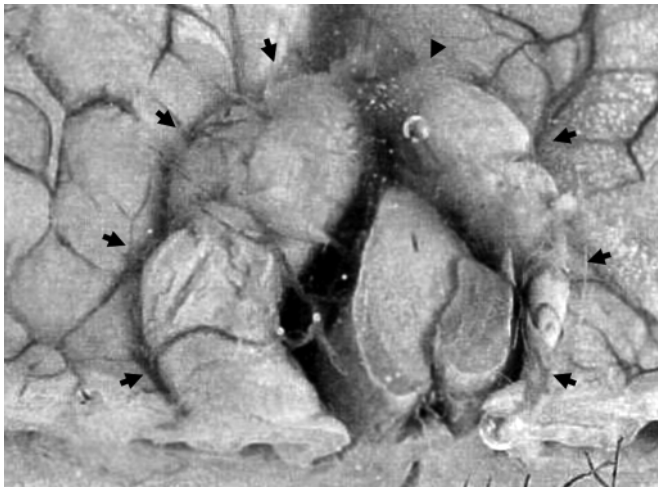


Fig. 15: Bilateral parahippocampal gyrus herniation through the tentorial hiatus forming a ring (arrow heads) and compressing the mid brain

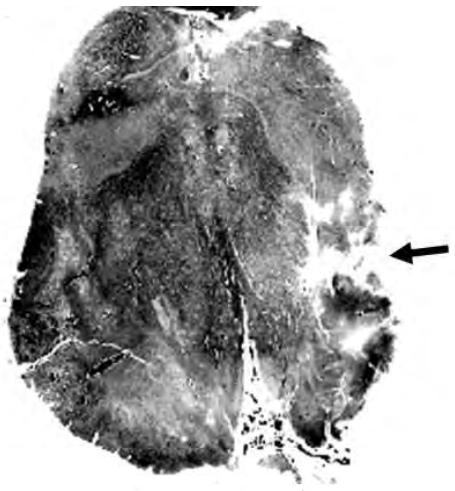

Fig. 16: Kernohan's notch — tear of contralateral aspect of crus cerebri against sharp tentorium (arrow) due to oedema. Ischaemic and demyelinating lesions seen (LFB × 4)

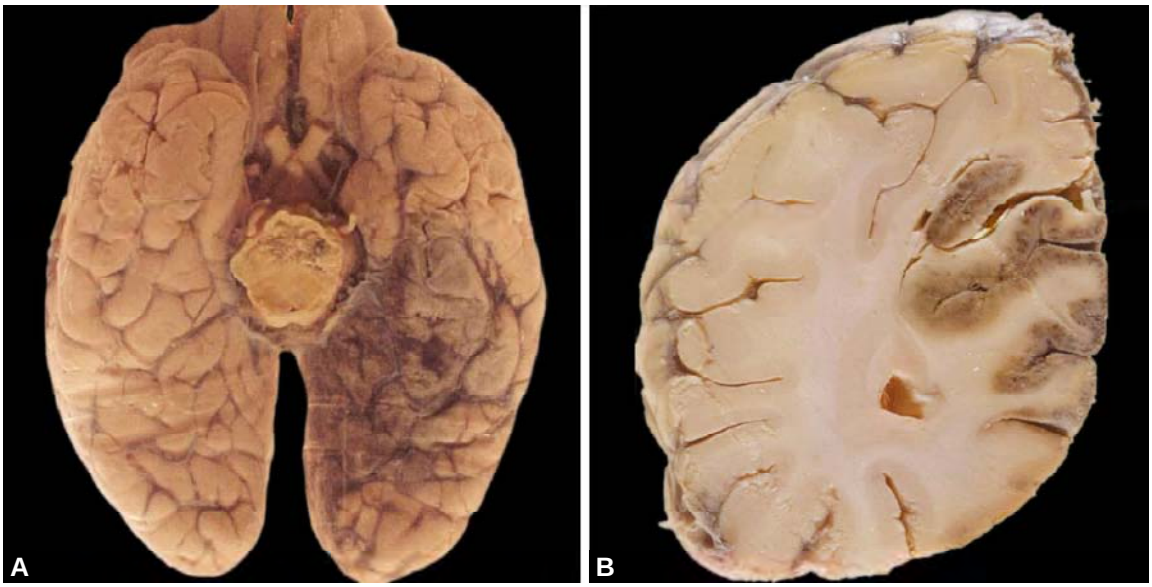
The supratentorial-expanding lesion, with raised ICP, causes downwards displacement of the brain, the parahippocampal gyrus (Fig. 15) and uncus herniating down with pressure necrosis. The pressure necrosis is evident only when the raised ICP is of some hours' duration. If the ICP rises rapidly and death supervenes soon, the parahippocampal herniation may not be seen. Furthermore, when the ICP is due to an expanding lesion infratentorially, no pressure necrosis of the hippocampi may be found but, on the other hand, there is upwards herniation of the vermis, the tentorial margin producing a groove. The other neuropathological features of raised ICP include supracallosal transfalcine cingulate gyrus herniation, contralateral grooving of the cerebral peduncle (Kernohan's notch), (Fig. 16) due to compression against the sharp tentorial margin, infarction in the territories of the anterior and posterior cerebral arteries (Figs 17A and B), anterior choroidal artery and superior cerebellar arteries. Some of the lesions can be haemorrhagic due to pressure on the veins around the brainstem, resembling a venous infarct. Rapid downwards displacement of the cerebellum and brainstem manifests as cerebellar tonsillar herniation (Fig. 18), compression of the medulla and death. An atrophic brain in old age may not manifest the features of herniation, despite raised ICP following trauma, due to available intracranial space for expansion. Kotapka et al.[103] in an analysis of 112 fatal cases of non-missile head injuries recorded hippocampal damage in 84% of cases. Kudesia et al.[105] in a study of 356 brains of TBI from India, noted features of raised ICP in 292 brains (82%). They observed pressure necrosis of the parahippocampal gyri in 88%, subfalcine herniation in 10.6%, calcarine infarction in 7.5% and Kernohan's notch in 2% of cases. All the cases showed



Figs 17A and B: (A) Right side posterior cerebral artery territory haemorrhagic infarct due to downward herniation and compression of PCA against the tentorium. Note ischaemic softening of tectum of mid brain. (B) Haemorrhagic infarction of calcarine cortex and adjacent gryi due to reperfusion following compression of PCA

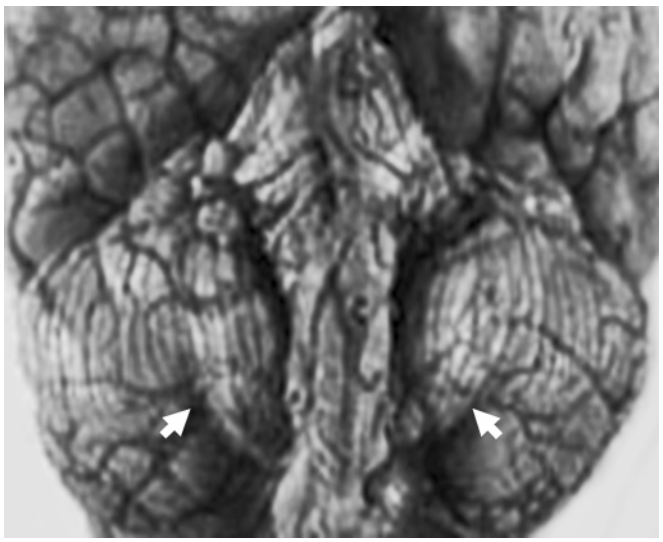


Fig. 18: Bilateral cerebellar tonsillar herniation (arrow heads) into the foramen magnum compressing the medulla oblongata

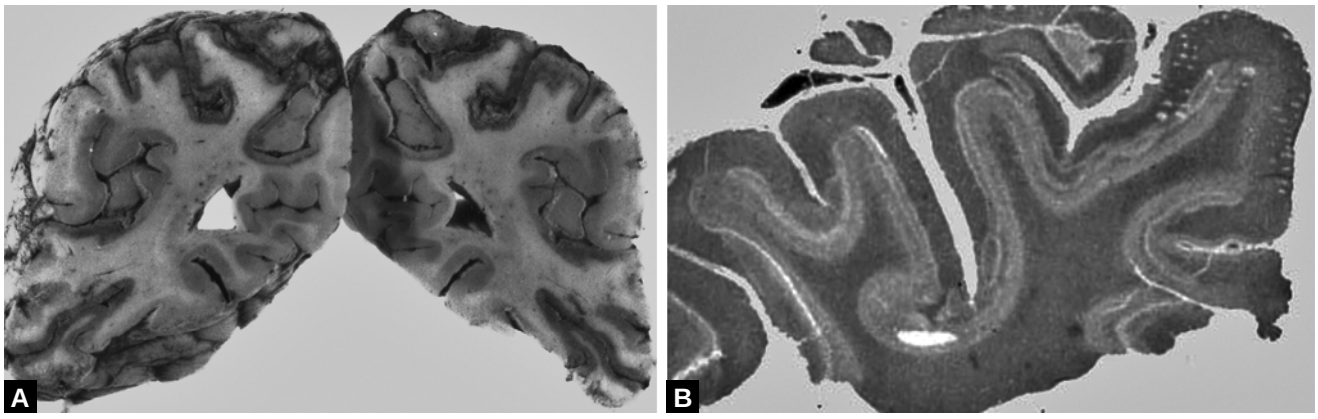
features of infratentorial herniation. A close association between DAI and ICP was observed (89% cases), suggesting a causal relation and synergistic effect in determining a poor prognosis.

Ischaemic Brain Damage

Ischaemic damage to the brain is common in fatal head injuries. The lesions are more common in the hippocampus and basal ganglia than in the cerebral cortex and cerebellum. Episodes of hypoxaemia, raised ICP, transient failure of cerebral perfusion pressure due to fall in cerebral blood flow (CBF), associated cardiac arrest and status epilepticus at the time of injury contribute to the ischaemic insult and form an important cause for mortality and morbidity. The hippocampus is selectively vulnerable to a variety of hypoxic events like cardiac arrest, status epilepticus and hypoglycaemia and is involved in nearly 84% of cases.[103] A post-traumatic electrical storm, flood of excitatory neurotransmitters-like glutamate and vascular leak are some of the events contributing to the ischaemia.[49] Regional or global reduction in CBF following trauma, usually occurring within 8 hours, has an important effect on brain viability and neurological consequences.[117] Following TBI, the brain may be at risk to even minor alterations in CBF, increase in ICP and apnoea. The ionic fluxes, like raised extracellular K+ results in increase in glycolysis and accumulation of lactic acid and acidosis.[197] During these periods of relative ischaemia, intracellular Ca++ increases. By 6 hours post-injury, the brain undergoes metabolic depression with reduction in CBF, glucose and oxidative metabolism, in experimental conditions.[88] In patients who make a good recovery, the CBF recovers sooner and to a greater extent. Using transcranial Doppler ultrasonography, vasospasm has been demonstrated in severely head injured patients, which contributes to post-traumatic hypotension.[24,25] These events of hypotension, and reduced CBF cause ischaemic lesions in the cerebral arterial territories, especially at the watershed zones of the anterior cerebral artery (ACA), middle cerebral artery (MCA) and posterior cerebral artery (PCA) territories (Figs 19A and B). Gross examination of the brain may look normal, but histological examination reveals laminar necrosis (Fig. 19B). These patients have relatively normal CT features, but the recovery is poor and they may become vegetative.

Diffuse Axonal Injury

This diffuse form of white matter damage, leading to post-traumatic dementia, was initially called "diffuse degeneration of cerebral white matter" by Strich.[173] Adam et al.[10] recognised this diffuse lesion in the white matter of patients who survived with vegetative or severely disabled state more than 4 weeks after injury due to impact and shearing forces. Initially, the clinical syndrome of primary brainstem injury was considered to be an expression of DAI, but now the two are recognised as distinct entities, though they can coexist or occur concurrently during the mechanics of impact. As the axonal damage can be identified on postmortem, by



Figs 19A and B: (A) Ischaemic softening with discoloration involving the cortical ribbon, on both sides due to prolonged hypotension and attempts at reperfusion (Survival 76 hours). (B) Histological preparation showing continuous laminar necrosis of the lower layers of cortex due to hypotension and hypoxic injury (Survival 8 days)

Fig. 20: Early diffuse axonal injury involving corpus callosum focally, but affecting the septum and formix more (Survival 28 hours)

microscopy, the term DAI is better used as a histological entity as defined by Adams et al.,[3] reserving the term, diffuse brain injury (DBI) to connote the clinical state. Sahuquillo et al.[157] also advocated the use of the term DBI to describe patients rendered immediately unconscious on impact and do not show any mass lesion on the admission CT scan. DAI is now defined as the occurrence of diffuse damage to the axons in the cerebral hemispheres, in the corpus callosum, in the brainstem and, occasionally, in the cerebellum resulting from head injury. Three distinct structural abnormalities are recognised in the pathology of DAI:

1. Focal lesions in the corpus callosum (Figs 20 to 25).
2. Focal lesions in one or both dorsolateral quadrants of the rostral brainstem adjacent to the superior cerebellar peduncle (Figs 23 and 24).
3. Diffuse damage to axons, especially in the corona radiata and other long fibre tracts (Fig. 21).

Fig. 21: Contusions and diffuse axonal injury involving the corpus callosum and frontal white matter (Survival 48 hours)

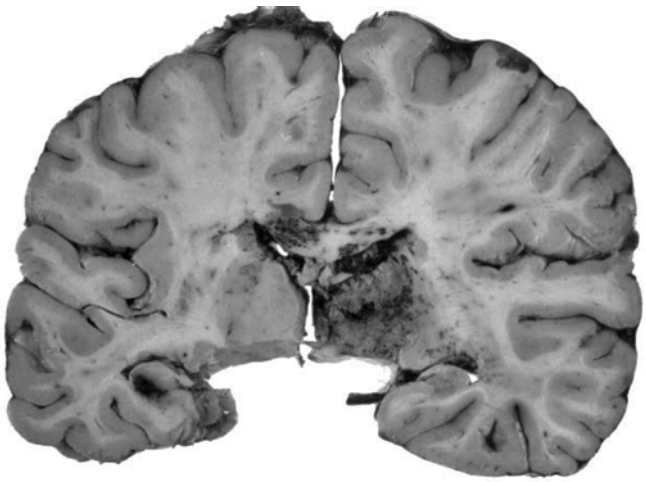


Fig. 22: Acute haemorrhagic lesion in the left half of corpus callosum. The right thalamus and left hippocampus have haemorrhagic lesions due to asymmetric venous compression along the base due to down ward displacement of brain (Survival 4 days)

It is conceivable that DAI encompasses a spectrum of pathological changes, correlating with severity of injury, beginning with the concussive syndrome leading to minor cerebral injury to severe forms of brain impairment, which include immediate coma with decerebrate posturing, prolonged coma and incomplete recovery. This assumption is further supported by the identification of axonal damage in humans with minor head injury and concussion, as well as in experimental minor head injury produced in animals by percussion.[137] These observations have led to grading of DAI for clinical correlation (Tables 3 and 4).[3]

In the initial stages after injury, the focal lesions in the corpus callosum and dorsal brainstem are haemorrhagic, usually unilateral and asymmetric when bilateral. From the corpus callosum they may extend down to involve the septum and fornix (Fig. 20). With progression of time, the lesions become brown leading to gliotic scars and tiny pale infarcts. On histological

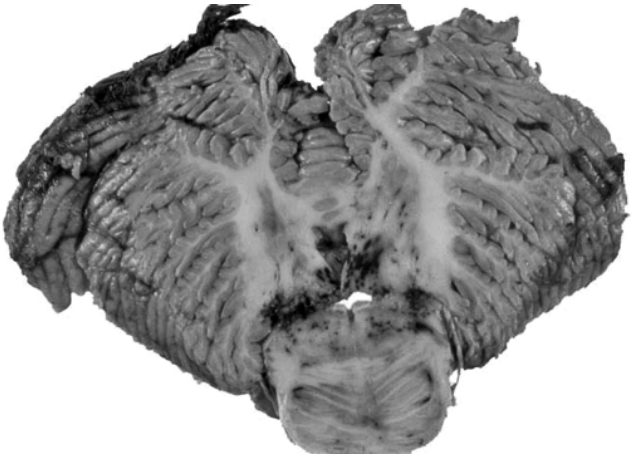

Fig. 23: Diffuse axonal injury-haemorrhagic lesion in the rostral pons, involving the tectum, middle cerebellar peduncle and cerebral vermis (Survival 24 hours)

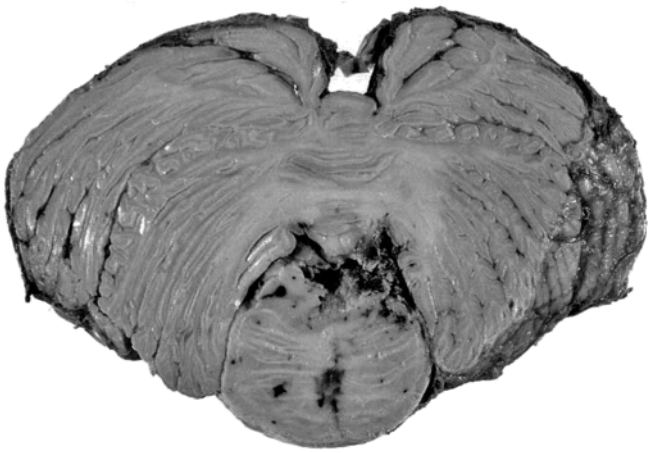

Fig. 24: Diffuse axonal injury lesions in the rostral pons involving the tectal area. Note multiple Duret haemorrhages in the midline involving paramedian vessels and lateral tectal zone due to rupture of long circumferential vessels

Table 3: Grading of diffuse axonal injury[3,59]

Grade I	Only histological evidence of axonal damage in white matter without focal lesions in corpus callosum, brainstem.
	Complete or partial lucid interval.
Grade II	Widely distributed axonal injury along with focal lesions in corpus callosum.
	Partial lucid interval
Grade III	Diffuse axonal damage with focal lesions in corpus callosum and brainstem.
	Did not talk—No lucid interval.
Identification:	Survival for 18–20 hours: visible axonal pathology—Silver stain (30%).
	Survival for 2–3 hours: visible axonal pathology by antibody to beta β-APP (92% cases).
Pathogenesis:	Primary axotomy—shearing of axolemma and resealing in 60 minutes after acceleration/deceleration injury at Node of Ranvier
	Secondary axotomy—Multiple foci of axonal injury
	→ At Node of Ranvier form Nodal bulbs
	→ At Internodes form axonal swelling 15 minutes after injury.

Table 4: Diffuse axonal injury

Evolution:	Early—Haemorrhagic
	3 days—Pale, rarefied
	Weeks-Months—Residual haemosiderin.
Axonal injury:	Disruption of axolemma (in the absence of infarcts and axonal swelling other lesions)
Survival days:	Multiple axonal swellings and oval/round bulbs at the end.
Survival weeks:	Clusters of microglial cells in white matter
Survival months:	In vegetative state—Wallerian degeneration in white matter

- Lower incidence of lucid interval
- Skull fracture, surface contusions, basal ganglia haematomas: common

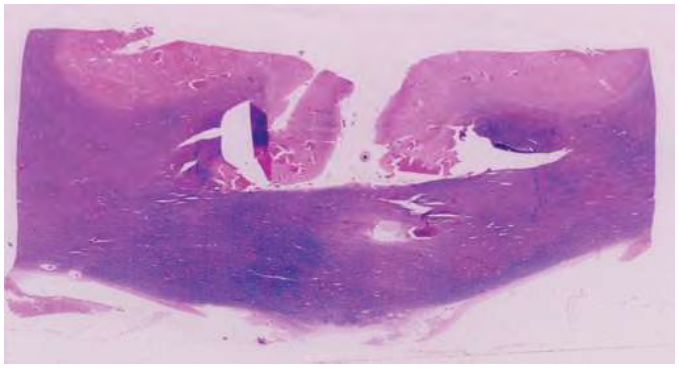

Fig. 25: Healing DAI lesion in the corpus callosum. Note small haemorrhage and adjacent pale ischaemic lesion (Survival 6 days LFB × 2)

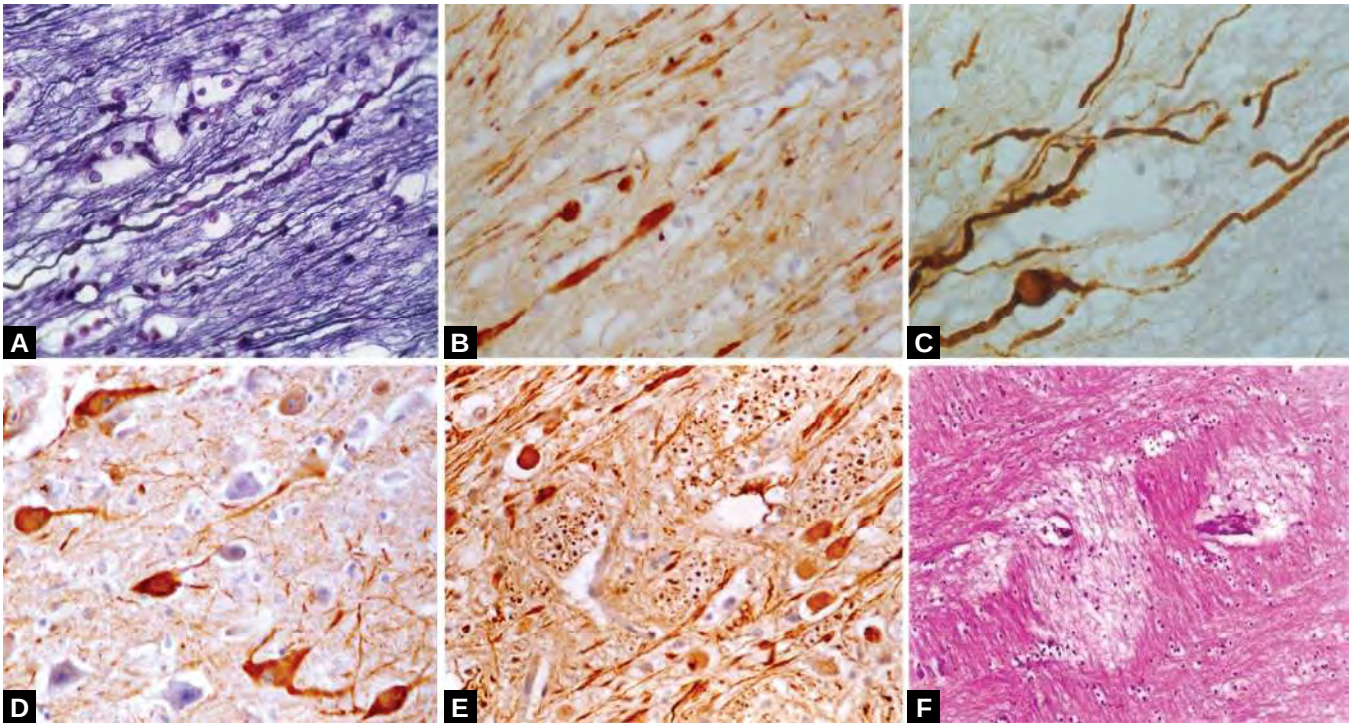
examination the initial haemorrhage is perivascular, later extending to the surrounding tissue. Silver impregnation and immunohistochemical stain using antibody to neurofilament (NF) reveals numerous axonal swellings adjacent to the focal lesion 15–18 hours after injury (Figs 26A to F). Kudesia[105] has shown a spectrum of changes in the axons that correlate with the temporal evolution of the lesions. At 6 hours post-injury, the axons were only swollen and varicose without disconnection while, at 24 hours, they appeared grossly swollen and formed bulbs/spheroids, indicating disruption and interrupted axoplasmic flow. The axonal pathology was evident within 6 hours in 80% of cases with DAI who survived 8 hours or more. The axonal pathology in those surviving less than 8 hours could be identified only by immunohistochemical staining with NF antibodies, but not by silver stains.[65,132] Recent studies highlighted the utility of immuno-histochemistry using antibodies to ubiquitin[162] and beta amyloid precursor protein (β-APP).[125,165] Axonal APP immunoreactivity was present in all patients who survived 3 hours or more, thereby demonstrating that expression of β-APP is upregulated following injury and is useful as an early marker. It is important to realise that accumulation of β-APP is not restricted to head injury patients and can be observed in dystrophic axons of elderly subjects and in association with cerebral infarcts.[62,166] In addition to dystrophic axonal bulbs, Kudesia et al.,[105] also observed NF antibody immunolabelled neurons close to the dystrophic axons, indicating extension of pathology to the respective neurons in a retrograde fashion. In an evaluation of time course events in the axonal pathology, he observed a larger proportion of axonal swellings and varicosities than axonal bulb formation in patients surviving up to 8 hours. Later, by 10–15 hours survival, the axonal swelling increased only slightly, but axonal bulbs with disconnection were identified in most cases. This suggests that, the stage of axonal swelling may be a reversible phase, while disconnection and bulb formation indicates irreversible axotomy. Though more work is needed, it is plausible to think that by timely appropriate therapy at this stage, there is a likelihood of



Figs 26A to F: (A) Diffuse axonal injury focal axonal swelling without disconnection (Bodian × 460); (B) Axonal swelling in corpus callosum 8 hours after injury (× 460); (C) Disruption and globular swelling of axons in fornix. Survival 12 hours (× 460); (D) Dystrophic changes in cortical neurons proximal to damaged axons (× 460); (E) Dilated axonal spheroids in thalamus. Survival 36 hours. (× 240). (B-E: Immunostain with phosphorylated NF Ab); (F) Rarefied lesion in superior cerebellar peduncle. Survival 4 days (H and E × 160)

recovery in many of the traumatised, yet not disconnected axons. With longer survival, the axonal bulbs diminish in number, and can persist up to 3 months following injury. During this phase microglia, macrophages and astrocytes become prominent, indicating scavenging and scar formation at the site of injury.[62] Later, rarefied lesions resembling small ischaemic infarcts can be seen as tell tale evidence of DAI.

Kudesia from India,[105] in a study of 356 brains, noted macroscopic markers of DAI lesions in 57 cases (16%); corpus callosum alone was involved in 18 cases, dorsolateral brainstem in 10 cases and both corpus callosum and brainstem in 29 cases. In 8 cases, only microscopy revealed features of DAI, while on gross examination the brains failed to show any lesions, except for oedema. Similarly, Adams et al.[3] identified 10 cases of histologically recognisable lesions among 122 cases of DAI. In general, DAI can be found in any patient injured accidentally with high inertial loading as in road traffic accidents.[28,60]

Frequent involvement of the brainstem in cases of DAI indicates that this lesion is probably the common structural basis for persistent disability or the vegetative state so often seen in severe DAI. The involvement of the brainstem is almost always accompanied by similar lesions in the corpus callosum and deep cerebral white matter and less frequently related to haemorrhagic areas. Frequent involvement of the fornices, an important hippocampal projection pathway involved in memory mechanism, may underlie some of the persisting memory disturbances in survivors of mild forms of DAI following blunt head injury.[109] Similarly, a more widespread functional derangement of the axonal projections of the reticular activating system may account for transient loss of consciousness in cerebral concussion, a milder form of DAI.[18,109] The medulla oblongata is relatively spared in DAI.[11,35]

The direction in which the head moves following impact plays an important role in the degree and distribution of axonal damage. According to Graham and Generelli,[66] although some degree of axonal damage can occur in any directional movement, the full blown picture of widely distributed axonal damage in cerebral white matter and brainstem can occur due to geometrical change in the strain pattern induced by the falx and tentorium during lateral motions of the head during rotational acceleration. Certain anatomical areas in the midline, like the corpus callosum, basal ganglia, internal capsule and the brainstem, move in the opposite direction to the rest of the structures, thus generating maximum shear and tensile strains. These areas along the midline where the white fibres diverge out show maximal degree of axonal damage consistently. The brain tolerates best, movement in the horizontal or sagittal plane that causes less damage than lateral displacement.

The other pathological hallmark of DAI is diffuse microglial proliferation, at places forming clusters that resemble the early encephalitic process. These aggregates of microglial cells are thought to be a cellular reaction at the sites of minute tissue tears,[11] seen earliest at 15 hours

post-trauma. Cytokines secreted by these cells further aggravate tissue damage through Ca^{++} ion influx. This feature may persist for a few days to assist in scavenging the tissue breakdown products.

Kudesia[105] has shown ultrastructural evidence of DAI, as early as 3 hours following injury. The most characteristic findings on EM study of human DAI were separation of the myelin sheath and detachment of the axolemma from myelin, swelling of axons filled with cytoskeletal components and mitochondria, and extrusion of axonal contents through the tear to the exterior.[195] With progression, in long-term survivors, the swollen axons contain granular material and only a few organelles. The severity of ultrastructural lesions in humans is usually more when compared to experimental material, probably due to technical limitations in specimen collection and processing, and fixation artifacts.

Fat embolism (small haemorrhages): Fat embolism is a well-recognised, though relatively uncommon cause of progressive neurological deterioration without an acute intracranial expanding lesion. Usually one finds multiple petechial haemorrhages in the white matter.[9,97] These need to be differentiated from severe degree of DAI with white matter haemorrhages and vascular congestion in cases of cerebral malaria in tropical countries. Occasionally, the classical petechial haemorrhages may be absent in spite of extensive fat embolism. In patients with multiple injuries with fracture, the brain needs to be scrutinised for fat embolism by staining a frozen section of the suspected area with Oil Red O.[130] The intravascular fat stains bright red. In pregnant women, amniotic fluid embolism needs to be suspected. In addition, multiple haemorrhages may be found due to thrombocytopaenia secondary to drug reaction, sepsis and small vessel diseases.

PATHOLOGY OF TRAUMATIC HEAD INJURY IN CHILDREN

The pattern of intracerebral injury in infancy differs from that described in adults due to:

- increased elasticity and moldability of the infant's skull due to suture patency
- softer consistency of brain due to incomplete myelination
- shallow cranial vault

In children, fracture of the skull is not uncommon as the skull is thin and breaks easily with impact. The finding of a subdural haematoma suggests "shaken baby syndrome"; a form of child abuse, though perinatal trauma needs to be kept in mind.

Subdural haematoma can occur due to rupture of bridging superficial cerebral veins, tentorial laceration with rupture of the straight sinus, transverse sinus, vein of Galen and laceration of falx with rupture of the inferior sagittal sinus. Occipital osteodiastasis due to traumatic separation of the cartilagenous joint between the squamous and lateral aspects of the occipital bone (common with breech delivery) results in posterior fossa subdural haematoma. Other causes of subdural haematoma in children include birth trauma, bleeding diathesis, meningitis (Haemophilus influenzae) and shunt surgery.

Epidural haematomas are infrequent in infants, possibly due to the intradiploic course of the middle meningeal artery until the skull is fully ossified and the fontenelle are closed.[108]

Head trauma in infants is characterised by haemorrhagic tears in the cerebral white matter, unlike in adults who develop surface cortical lesions only following contusion. This is probably due to lack of support to vessels in the immature white matter, which easily rupture following rapid acceleration-deceleration movements of the head. These lesions can be associated with DAI and axonal retraction bulbs.[191] DAI may occur in the absence of skull fracture or grossly visible parenchymal lesions in the brain. Unlike in adults, DAI is not seen in the brainstem of infants.[191]

Sarala Das et al. made similar observations based on the study of 40 brains from cases of traumatic injury in the paediatric age group (unpublished). The impression that contusions of the brain are less common in children following head injury than adults based on CT scans is incorrect, as autopsy studies revealed their presence in 90% of cases.[68] Zimmerman et al.[199] reported fewer incidences of DAI in children than in adults. The incidence of ischaemic brain damage is essentially similar to that noted in adults. Diffuse bilateral cerebral oedema with deep coma is more common in the paediatric age group, especially in infants, than adults following traumatic injury, without overt gross damage.[22]

Epilepsy has long been established as a late consequence of head injury and is related to the severity and type of injury. Depressed skull fracture, cortical laceration and parenchymal haematoma contribute to increased risk of post-traumatic epilepsy. Early epilepsy occurring during the 1st week of injury is more common in children and may progress to status epilepticus resulting in irreversible ischaemic damage if not controlled adequately. The occurrence of early epilepsy also enhances the chance of developing late epilepsy, delayed by a year or more, in children. However, the risk of late epilepsy after head injury is less common in children than adults.

OTHER AREAS

Brainstem[114,175,178,180]

The clinical features of altered sensorium, hypertonicity, decerebrate rigidity, bilateral dilatation of pupils and absence of cold caloric response following traumatic injury indicate the anatomical localisation of damage to the brainstem. Deteriorating state of consciousness, decerebration and depression of vital signs represent significant caudal displacement of the upper brainstem towards the tentorial hiatus. Shearing of the brainstem

is maximal in the region of the aqueduct with the fibres of the medial longitudinal fasciculus being vulnerable resulting in internuclear ophthalmoplegia.[40] Oculomotor nerve palsy is common with brainstem injury due to damage either at its exit from the midbrain or fascicular injury in the midbrain. "Locked in syndrome" due to traumatic basilar artery dissection or direct impact following clival fracture have been reported.[187] In the midbrain, the haemorrhagic lesions are in the dorsolateral part, almost always involving the superior cerebellar peduncle.

The brainstem can be involved by any one of the following mechanisms:

1. Primary brainstem injury—not so rare as considered.
2. As a part of DAI.
3. Secondary brainstem injury—due to downwards herniation, torsion, lateral displacement.

Primary Brainstem Injury

Similar to the spinal cord, the brainstem is a relatively fixed structure tethered by cranial nerves and has restricted movement because of the investing meningeal coverings in close proximity (Figs 27 to 30).

In a series of 988 autopsied cases of road traffic fatalities, Simpson et al.[169] found gross primary damage to the brainstem in 36 (3.6%) cases. Some of these could be under diagnosed as the changes may be attributed to artifactual damage occurring during removal of the brain at autopsy.[48]

Mechanical effects on the brainstem and its surrounding structures due to rotation acceleration of the head along the transverse, vertical and sagittal axis cause primary injuries, without the association of lesions in the supratentorial compartment. During the initial impact, due to its inherent inertia, the brain remains relatively stationary, though the brainstem, because of its long axis oscillates. This results in microscopic and macroscopic haemorrhages in the isthmus cerebri, the cerebral peduncles, cerebellar brachium conjunctivum and tear of the long fibre tracts. The location of the lesions in the brainstem with tears and haemorrhages in the tentorium suggest that the brainstem injury is primary. Improperly used automobile seat belts can result in whiplash injury, with rotational movement of the brainstem alone, leading to severe morbidity or fatality.[42] Hyperextension of the neck with stretching of the brainstem can result in tissue tears and haemorrhages in the dorsal area of the midbrain and pons. If the shearing trauma or anteroposterior brain movement is severe, there can be supratentorial

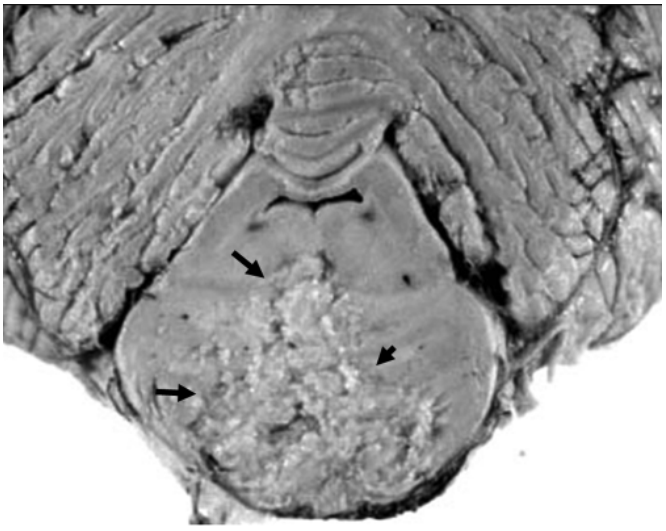

Fig. 29: Large, pale ischaemic infarct of ventral pontomesencephalic junction due to compression and prolonged vasospasm. Survival 4 days, road traffic accident with extensive subarachnoid haemorrhage

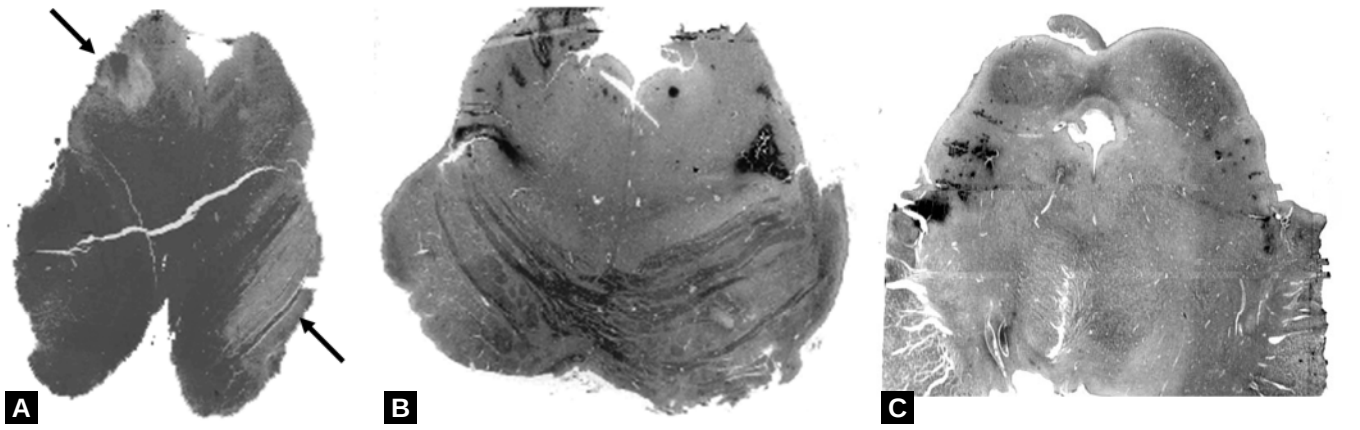

Figs 30A to C: (A) Localised pale infarcts (arrows) involving the right crus cerebri and left tectal area due to compression and prolonged vasospasm. Survival 5 days (LFB × 2); (B and C) Multiple duret haemorrhages involving the long circumferential vessels asymmetrically due to angular momentum and oscillation. Survival 18 hours (HE × 3)

injury, overshadowing the brainstem injury in clinical practice. Rotational forces produce axonal shearing, ischaemic necrosis and microhaemorrhages of the tegmental areas, while a forward thrust results in laceration of the upper brainstem against the sharp edges of the tentorium damaging the long tracts resulting in clinical signs on the opposite side of the body.[16]

The commonest primary brainstem injury is the pontomedullary rent that follows circumferential fracture through the petrous bones, ring fracture around the foramen magnum or fracture dislocation of the cervical vertebra. Similar lesions can be caused as a consequence of angular acceleration of the head as a form of DAI. Pontomedullary rents could be under diagnosed, as a partial rent is compatible with survival.[48] The second distinct form is massive laceration at the ponto-mesencephalic junction, usually found in association with pontomedullary rents in one-third of cases.[21,121] The third variant is direct contusion with focal laceration of the striate pons and is usually associated with clival fracture. The fourth distinct type is traumatic laceration or complete transection of the medulla from the cervical spinal cord. McCormick reported ten cases of spino medullary separation.[121] This is common in "dead at the scene" trauma victims, associated with separation of the atlas from the skull.[189]

In patients who survive for a few days following injury, one can find small ischaemic lesions, microhaemorrhages confined to the tegmentum of the lateral and superior margins of the mesencephalon and rostral pons revealing a spectrum of ages, without features of elevated ICP, thus qualifying them to be called post-traumatic primary brainstem lesions.

In a study of 45 cases of non-missile traumatic cranial injuries at NIMHANS, Bangalore,[168] primary brainstem injuries were observed in 7 cases and secondary brainstem injury in 29 cases. One-third of these cases with secondary brainstem injuries had hypothalamic damage indicating the widespread and dynamic nature of the injury. The patients with midline pontine haemorrhages had shorter survival than those with midbrain lesions,

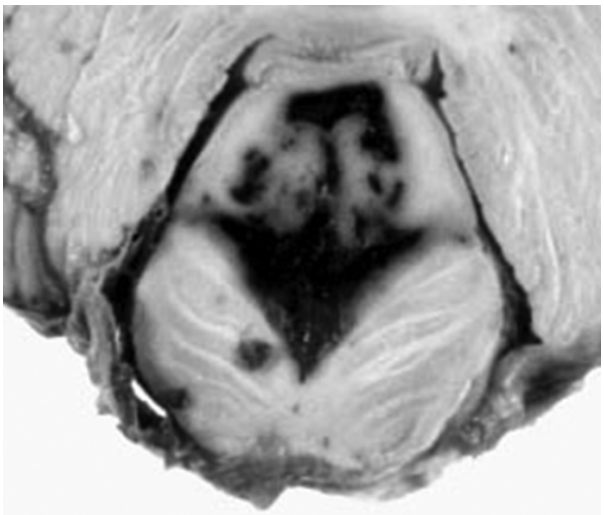

Fig. 31: Fall from a height, survival 16 hours. Large midline haematoma in the pontine tegmentum, reticular formation, medial longitudinal fasiculus, trapezoid body, nuclear areas. Note associated secondary haemorrhages

probably due to involvement of the medial reticular nuclei (Fig. 31).

Secondary Brainstem Injury

This is the commonest form caused by expanding supratentorial oedema or haemorrhage that results in downwards displacement and shearing strain on long fibre tracts and the perforating vessels (Figs 30A to C and 32A and B). Disruption of the perforating arteries entering the rostral brainstem from the basilar artery and posterior cerebral arteries due to sudden caudal displacement at the moment of impact results in multiple haemorrhages. These lesions, commonly referred to as "Duret haemorrhages", result from occlusion/shearing of paramedian short and long circumferential arteries, especially at the pontomesencephalic junction due to sudden and marked elevation of supratentorial pressure. The lesions are overtly haemorrhagic, though localised pale infarcts of the brainstem do occur in

Figs 32A and B: (A) Haemorrhages along the midline due to rupture of paramedian vessels due to sudden downward displacement. (B) Large midline haematoma involving decussation of superior peduncles, medial longitudinal fasciculus and dorsal tegmental nucleus. Survival 18 hours

patients with transtentorial herniation secondary to vasospasm and vascular compression (Fig. 29).[121] Most of the brainstem injuries defy classification due to complex dynamic impact and movement of the internal structures. Occasionally, lateral pressure exerted by the herniating medial temporal lobe on the midbrain can compromise the regional blood flow and cause local infarcts without necessarily being haemorrhagic. Rarely, entrapment of the posterior inferior cerebellar artery can result in medullary infarcts.[80,93]

The brainstem shows features of DAI, as an extension from other areas, following severe degree of injuries. Lateral aspects of the tectum and the superior and middle cerebellar peduncle show linear haemorrhages extending into the cerebellum. However, to establish DAI as the cause of brainstem injury tissue from the parasagittal white matter, corpus callosum and several levels of brainstem need to be studied.[66] Secondary brainstem haemorrhages are found in about 3% of all autopsies. Their frequency comes down with advancing age as a consequence of cerebral atrophy and increased pericerebral capacity. Similarly, brainstem haemorrhages rarely occur in infants and young children who die of head injury due to greater pliability of the calvarium and a wider tentorial hiatus.

Hypothalamus

Hypothalamic dysfunction following head injury may lead to aberrations in homeostatic functions including appetite and satiety mechanism and the thermoregulatory process. Injury to the hypothalamus produces dissociated ACTH-cortisol levels with no response to insulin-induced hypoglycaemia, hypothyroxaemia with preserved TSH response to TRH, low gonadotrophin levels with normal response to gonadotrophin releasing hormone, variable GH levels with paradoxical rise of ADH secretion, disturbed glucose metabolism, loss of thermoregulation, etc. Most severe injuries involving the skull base are sufficient to damage both the hypothalamus and pituitary causing a mixed endocrine picture. Increased ICP can alter the hypothalamic anatomy, releasing vasopressin and contributes to adrenal gland stimulation, a mechanism requiring intact brainstem function. Hypothalamic involvement is commonly associated with pituitary pathology following head trauma as a part of multifocal brain damage.[118,102,185] Post-traumatic long lasting diabetes insipidus indicates damage to the infundibulum or tuberal hypothalamus. In some instances of post-traumatic hypothalamic injury, disruption and haemorrhage in the supraoptic nuclei and optic tract may develop.[37,87] This form of hypothalmo-visual injury is a reflection of the close proximity of these structures and the fact that the lateral group of hypothalamic nuclei tethered to the visual tract may be exposed to the shearing stress and rupture of the thin penetrating vessels in the anterior perforated substance. The ischaemic lesions almost certainly are due to shearing of small perforating vessels at the time of impact. The microhaemorrhages localised to various hypothalamic nuclei bear a remarkable resemblance to lesions found in fatal cases of ruptured cerebral aneurysm. The pathogenesis of the lesions in hypothalamus following ruptured aneurysms and SAH in the chiasmatic cistern is probably due to vasospasm and reperfusion injury than evulsion as in traumatic injuries. Venous engorgement due to raised ICP or downwards displacement of the brain compressing the veins around the tentorial hiatus can also contribute to hypothalamic haemorrhages, especially the posterior group along the midline. Thus, not all the hypothalamic lesions found at autopsy have resulted from injury due to primary impact. It is

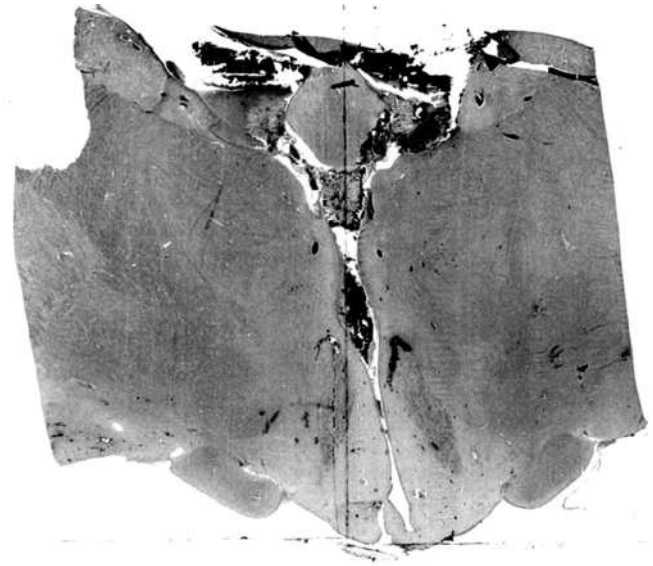

Fig. 33: Fall from height and impact on the vortex in an adult. Whole mount of coronal section of hypothalamus through infundibular area. Note haemorrhages in periventricular hypothalamic nuclei, in addition to involvement of fornix. Survival-3 hours (LFB × 5)

noted that temporo-parietal rather than fronto-occipital blows lead to hypothalamic lesions, suggesting lateral displacing forces shear the hypothalamic vessels, the upper hypothalamus moving more than the lower.[36] Downwards displacement of the brain towards the sella, by an impact on the vortex, can result in damage to the lower hypothalamus, infundibulum and upper half of the pituitary stalk, shearing the perforating vessels of the anterior cerebral arteries (Fig. 33).

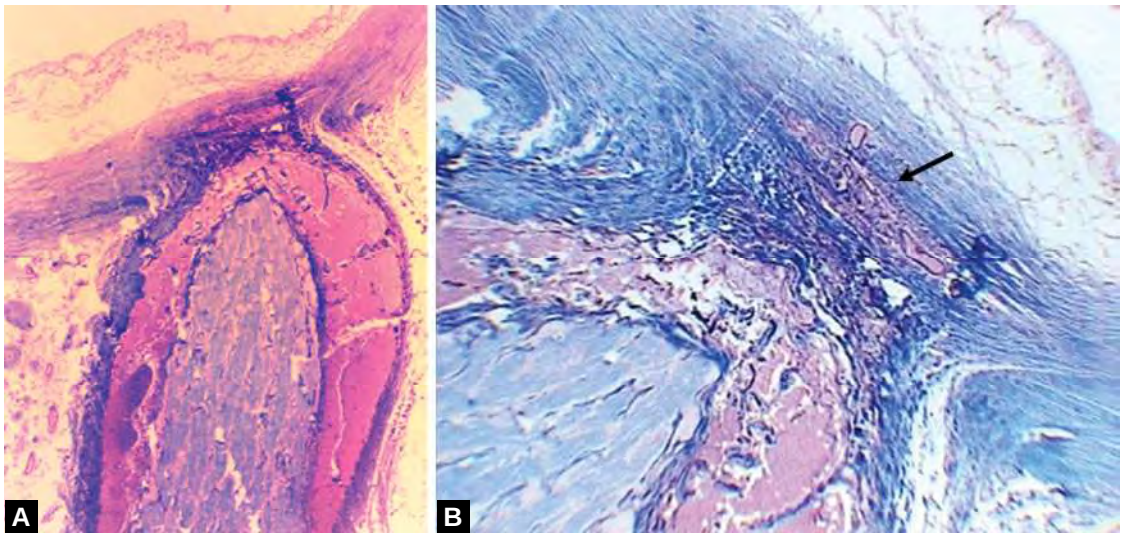
Post-traumatic hypothalamic injuries are more common in the young. In an autopsy study of 106 patients dying soon after closed head injury, Crompton recorded a hypothalamic lesion in 42.5% with it being bilateral in 22.6% of cases.[36] The pathological lesions were microhaemorrhages and ischaemic lesions involving various groups of nuclei. The microhaemorrhages were seen discreetly involving the subependymal paraventricular nuclei, lateral hypothalamic nuclei amongst the fibres of the median forebrain bundle and supra optic, but rarely in the region of the median eminence or infundibulum. Many of these are usually associated with cortical contusions indicating the diffuse and severe nature of injury though, rarely, isolated hypothalamic lesions may be seen.

Pituitary

Although an array of potential neuroendocrine problems can occur after TBI, most of the commonly encountered problems are transient in nature.[1,2] Panhypopituitarism is actually a rare post-traumatic phenomenon, but may be responsible for significant alterations in the level of the patients' consciousness. Direct pituitary trauma as an aetiology of hypopituitarism is less common than hypothalamic injury. Yuan and Wade[198] presented an overview of hypothalamic and pituitary alterations in brain trauma, the incidence of hypothalamic pituitary damage, mechanism of injury and features of hypothalamio-hypophysial defects. While hypothalamic-pituitary lesions have been commonly described at postmortem examination, a limited number of clinical cases of traumatic hypothalamo-pituitary dysfunction have been reported, probably because head injury of sufficient severity to cause hypothalamo-pituitary damage usually leads to early death. Most frequently seen are anterior lobe infarction, posterior lobe haemorrhage and destruction of the pituitary stalk.[81,87] Avulsion of the pituitary stalk with resultant interruption of pituitary blood supply is seen more often than direct injury to the pituitary. Post-traumatic haemorrhage into the neural lobe occurs, but extensive infarction is rare and, thus, post-traumatic diabetes insipidus is transient. Permanent diabetes insipidus indicates damage at a higher level; either at the infundibulum or at the hypothalamus. However, most of the damage to the pituitary is secondary to raised ICP, resultant ischaemic events reflecting multifocal brain damage. In a series of 434 traumatic victims from UK,[121] pituitary lesions, mostly consisting of haemorrhages into the posterior lobe (37%), infarction in the anterior lobe (17%), and a small number with capsular and anterior lobe haemorrhage and stalk laceration were observed. In McCormick's series of 110 cases of closed head injury, various types of pituitary lesions were seen in a large number (85% of cases).[121,122] From New Delhi, Prasad et al.[146] studied pituitary glands collected at postmortem from patients who died of head injury (n = 60) and other systemic injuries (n = 32%). They recorded capsular haemorrhage in 50%, haemorrhage and ischaemic necrosis of the anterior lobe of the pituitary in 25%, posterior pituitary haemorrhages in 20% and combined lesions in the rest. Ischaemic necrosis of the pituitary was also noted in cases with non-cranial injuries secondary to hypovolaemia, sepsis, diabetes mellitus and other systemic causes. Traumatic skull fracture was found to be associated with higher incidence of all types of pituitary haemorrhage and necrosis, though no distinct correlation with the location of the base of the skull fracture was evident.

Cranial Nerves

Trauma to the cranial nerves is not uncommon during TBI. Following gliding contusion of the orbitofrontal area or fracture involving the anterior cranial fossa, loss of olfactory sense is common. The most vulnerable part of the optic nerve is the portion traversing the optic canal. Following traumatic SAH the blood extends into the orbital portion of the optic nerve causing vasospasm. Rarely, the haemorrhage may dissect the scleral collagen and spread inside (Figs 34A and B). Severe trauma to the apex of the orbit or fracture in the middle cranial fossa extending medially can cause injury to the III, IV and VI cranial nerves and, occasionally, the Gasserian ganglion. Injury to the petrous temporal bone by lateral



Figs 34A and B: (A) Fall from height, with diffuse subarachnoid haemorrhage in the base, extending into the orbit along the subarachnoid space around the optic nerve. Note stretched dura externally (× 10); (B) Higher magnification showing haemorrhage separating scleral collagen (arrow), indicating the severe impact on the orbital cone (× 120). Masson's Trichome stain

impact can cause facial and VIII cranial nerve injuries of varying degrees. Damage to the lower cranial nerves is common following gunshot wounds or severe angular injury to the occipital bone and impact against the clivus. The injuries to cranial nerves are relatively ignored, being overshadowed in the attempt to save life.

CELLULAR/MOLECULAR RESPONSE TO BRAIN INJURY

A wide range of pathological insults to the brain, including mechanical injury, ischaemia and seizures induce the immediate early genes (IEGs), *C-fos*, *C-jun* and *jun B*. The members of the *fos* and *jun* families function as transcription factors, mediating long term adoptive responses of neurons to acute stimuli.[129,148] TBI induce changes in electrical properties of cell membranes and cytoskeletal structures that most likely result in aberrant cellular signalling pathways, which may subsequently be translated into an acute genomic response. Since these biochemical, molecular, anatomical and behavioural responses manifest as pathological damage and behavioural deficit, the study of genomic responses will help to understand the pathophysiology and evolution of traumatic injury. Most of the information available is from animal model systems and data on the human system needs to be generated. In the rat lateral fluid percussion model, the immediate early genes, *C-fos*, *C-jun* and *jun-B* were found to be increased bilaterally in the cortex and hippocampus.[141,149] The levels of *C-fos* and *jun-B* and RNA levels return to the control level in 6 hours, but *C-jun* mRNA remains elevated. Inducible heat shock protein (HSP 78, grpa4) can be observed up to 12 hours post-trauma, on the ipsilateral cortex of the impact site—which indicates stress response.[112] This stress protein can be immuno-localised in neurons, glia and endothelial cells.[181] *C-fos* and *C-jun* regulate nerve growth factor, amyloid precursor protein, opioid precursor proteins and modulate synaptic plasticity—and thus the recovery.[39,123,129,147] Further work is needed to extrapolate these observations to human beings.

Inflammation and Cytokines

Recapitulating the acute inflammatory process following acute focal brain injury like contusions, polymorphonuclear leucocytes accumulate in the damaged tissue temporarily coinciding with cerebral oedema[123] (Table 5). These cells find their way into CSF and peripheral blood to cause leucocytosis, leading to erroneous diagnosis of an infectious process. In experimental models, induction of neutropaenia has not shown a beneficial effect on the progression of oedema and tissue damage.[160,188] The macrophages replace the polymorphs to initiate the repair process and scavenging of the necrotic debris.[74] These macrophages also secrete cytokines, like 1L-1β, 1L-6 and TNF-α,[63,196,197] that initiate an excitotoxic neurodegenerative process with upregulation of

Table 5: Pathophysiology of head injury

Early traumatic process (not an event)
Traumatic brain injury → Acute perturbation → Mechanoporation in neurons lasting from minutes to 3–4 hours
Transient separation of cell membrane lipid layer from protein Components—receptors, channel proteins
↓
Sonic influx of K^+ inside and Na^+, Ca^{++}, Cl^- to outside
↓
Closure of defect by Ca^{++} activated lysolecithin patching and membrane fusion
Mild injury: Return to normal after few seconds to a few minutes (mild contusion)
Severe injury: Ca^{++} $\uparrow\uparrow\uparrow$ → severe cell toxicity

their receptors to find their way into the CSF. Thus, CNS derived cytokines may play a role in the pathophysiology of TBI.[128] This is further confirmed by the protective effect of endogenous 1L-1 inhibitors and 1L-1 receptor antagonist during the acute phase of head injury.[159,184] The cytokines, however, also produce a protective effect by induction of growth factors, astrocyte proliferation, inhibition of Ca^{++} currents and promote macrophage migration to the site as a defence mechanism.[153]

Traumatic brain damage being a dynamic process with a temporal evolution, various cellular components are involved with inflammatory damage being one of them.

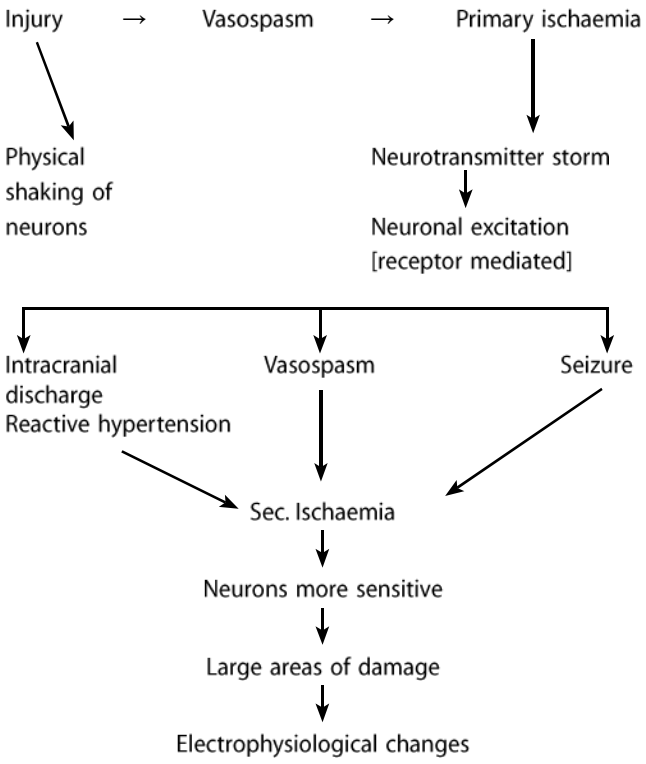
The direct impact mediated transient mechanoporation of the cell membrane and voltage channel dependent electrical activity at all cell membranes cause an influx of extracellular calcium. Similarly, NMDA receptor mediated, inositol-3-phosphate and G-protein coupled activation can cause release of intramitochondrial/intracellular calcium following trauma.[164] This causes activation of phospholipases, free radical generation through arachidonic acid metabolism and activation of deleterious proteases.[124] The protease activation in turn causes damage to the cell membrane and neuronal cytoskeleton, leading to delayed cell death. Sequestration and pumping out of the intracellular calcium may facilitate recovery. The total brain calcium concentration has been found to increase following focal or diffuse injury at the injured site, the high ionic level persisting for 48 hours in the rat model.[88,89] In the first 24 hours following injury, the axonal cytoskeletal elements, the neurofilaments, microtubules and associated proteins, their cross linking/stabilising phosphokinases get affected resulting in axonal swelling, dissolution, reduced axoplasmic flow and finally secondary axotomy. The demonstration of β-amyloid precursor protein in axons as early as 2 hours after brain injury is a reflection of these post-traumatic events.[140,166] Focal brain injury causes primary axotomy. The events of secondary axotomy are dependent on the degree of injury, mechanical distortion caused and the metabolic state of the brain at the time of injury. Though it is advocated that the node of Ranvier with a high density of ion channels is the site of injury due to high sensitivity,[6] it appears that the axons fail at the site of maximal tensile loading—the nodal, paranodal, internodal domains and not at any preordained site. Following trauma, most of the fibres undergoing reactive changes are of large calibre, long tract axons that are most likely subjected to maximal strain at some point along their length. In these fibres, reactive axonal swellings are seen at points where the axons decussate, cross blood vessels or change their intra-axial course, suggesting that sites of maximal tensile loading are prone for failure.[140,145]

Hypersensitivity of Traumatised Brain to Secondary Cerebral Ischaemia

Hypersensitivity of traumatised brain to secondary cerebral ischaemia is illustrated in Tables 6 and 7.

Table 6: Pathobiological changes caused by traumatic brain injury

Post-traumatic brain hypersensitivity to ischaemic and chemical insults



Non-traumatised brain—Tolerates same degree of ischaemia better

- Secondary ischaemia—starts 1 hour post-trauma → Brain hypersensitivty lasts for 24 hours post-trauma
- Secondary ischaemia starts → Beyond 24 hours post-trauma → Brain hyposensitive

Table 7: Neurochemical/neurotransmitter changes

Traumatic brain injury

- Injury induced membrane depolarisation
- Activation of voltage dependant channels
- Acetyl choline ↑↑↑—brain, cerebrospinal fluid
- Reduced binding or low affinity → Cholinergic receptors (muscarinic)
  → In Hippocampus, brainstem, for 2 weeks
- Acetyl choline excitation → Behavioural abnormalities and cognitive deficits
  (R_X: Anticholinergic drugs useful !!!)
- Catecholamine/monoamine—alterations proportional to degree of injury
- Levels and receptor binding
  ↓
  Vasomotor changes
- 5HT levels ↑↑↑↑ — cerebral hemisphere—same side of injury
  ↓
  Glucose internalisation reduced
  ↓
  Anoxic injury
- Dopamine levels (transporter ↑↑↑↑)
  - Down regulation of dopamine receptor (↓↓)

Contd...

Contd...

- Excitatory amino acids ↑↑↑ (hippocampus, neocortex)
  - Immediate lasts for 4–6 days
- Fall in Mg^{++} levels → secondary damage via neurochemical path and influx of Ca^{++}
- Rise in Ca^{++} levels → lasts for 2–4 days

↓

Cytoskeletal damage (within 24 hours)

- Accumulation of amyloid precursor protein (within 24 hours) for repair

Secondary insults like hypertension, hypoxia and global ischaemia worsen the bioenergetic, electrophysiologic and behavioural status of humans or animals subjected to TBI. Mild TBI or transient forebrain ischaemia, by themselves, do not result in appreciable histological changes, but when mildly traumatised brain is subjected to ischaemia, sequentially enhanced selective vulnerability and regionally restricted (like hippocampus) delayed ischaemic neuronal cell death can be noted in the absence of any initial overt pathological changes.[20,90] This exemplifies the phenomenon of brain hypersensitivity to secondary cerebral ischaemia, which is well studied in the fasting cat[92] and rat model.[44]

It is now becoming well established that a mild TBI, not capable of evoking overt structural cell change, can elicit a net phase of neuroexcitation by release of multiple neurotransmitters. These neurotransmitters in turn lead to receptor mediated calcium channel gating and calcium influx, disturbed neuronal ionic homeostasis, yet not enough in magnitude and duration to result in lethal injury.[44] Paralleling these traumatically induced changes, it is now well established that during ischaemia, extensive ionic shifts occur, including calcium homeostasis. This is related to energy failure, inactivating energy dependent ion membrane pumps, fall in cellular membrane potential and calcium influx via the voltage gated calcium channel (NMDA). This is further aggravated by post-ischaemia excitatory neurotransmitter release (similar to traumatic injury) and calcium influx as mentioned earlier.[30] When these compounding events occur in tandem, they result in significant tissue damage. But, when they manifest in sequence, the deranged calcium homeostasis can cause delayed and diffuse neuronal damage. This sequence of events can be reduced or abrogated in animal models by use of drugs competitive to muscarinic acetylcholine receptors (scopolamine) and the noncompeting NMDA antagonist, phencyclidine.[92] These cellular events can manifest, especially in some neuronal populations like the hippocampus, with long lasting changes in excitability thresholds and abnormal neuronal function as a consequence of aberrant stimulation of key regulatory calcium response elements. This trauma induced calcium influx mediated hypersensitivity to secondary ischaemia appears to persist for at least up to 24 hours post-injury. Interestingly, if more than 24 hours elapse between the traumatic and ischaemic insults, the brain becomes hyposensitive.[144] Though many of these observations are made in animal models, they have significant clinical relevance. In traumatically brain injured patients, ischaemic events can be precipitated by vasospasm and secondary intracranial hypertension. If the injured patient was fasting, was hypoglycaemic due to diabetes or in shock the resulting ischaemia during the window period may significantly and adversely alter the clinical course. Whether pharmacokinetic alteration of receptor mediated ionic imbalance during the critical period will be of use needs evaluation.

Ionic Events and Role of Excitatory Amino Acids in Traumatic Brain Injury

TBI, during the evolution, depending on the site, diffuse or focal and the severity, pass through different stages of physiological progression. The knowledge has been accrued through different experimental models. The ischaemic changes in the hippocampus, noted at postmortem following TBI, need not be caused by actual hypoxic or anoxic insults. Following a focal injury, either in clinical TBI or in the experimental setting, the adjacent brain shows decrease in CBF. A global decrease in blood flow with ischaemic changes rarely manifest, unless ICP rises uncontrollably.[186] One major event that occurs at the moment of impact in neuronal cells is the sudden and massive ionic influxes across the cell membrane of Na^+, Ca^{++} and Cl^1 and efflux of K^{+134}. In close impact injury, proportional to the degree of impact the shear, tensile or compressive strains generated, the ionic fluxes could be over wide brain areas.[98,99]

Following sudden efflux of K^+ $[(K^+)_e]$ a sequence of events are observed immediately in animal models, that probably occur in clinical practice as well.

1. As the magnitude of trauma crosses a threshold, an abrupt efflux of K^+ occurs from a baseline of 3–6 mM to a maximum of 60 m with membrane electrical changes and traumatic depolarisation (TD). As long as a large strain is generated, the K^+ efflux occurs over a wide area of the brain simultaneously. This can be observed bilaterally in the cortex, hippocampus and brainstem, especially following a blunt injury causing oscillation of the brain. In a restricted injury, this sequence of events could remain unilateral.[45] The recovery from the increase in K^+ to the baseline level takes a variable period of time, from 3–8 minutes.
2. Localised mechanical or K^+ ionic membrane stimulation induces other ionic events called spreading depression (SD), a pattern identical to $[K^+]_e$ with a threshold. The SD causes sudden disruption of other ionic homeostasis. The SD is usually localised, spreads slowly to adjacent areas and recovers soon unlike TD.[133]
3. Following injury, energy failure and anoxia, abrupt and rapid ionic fluxes occur with a short latent period of a minute, called anoxic depolarisation (AD).[79]

The three events TD, SD and AD, either in tandem or in various combinations, can disrupt the powerful mechanisms maintaining ionic homeostasis.

During traumatic brain and ischaemic injury, concomitant with a large increase in K^+ efflux, excitatory amino acids are released as a result of depolarisation at nerve terminals.[98,99] Denervation of the glutaminergic afferents have been shown to delay ionic changes in the hippocampus during ischaemia.[14] Receptor ligand gated ion channels opened by sudden indiscriminate release of EAA causes sudden influx of calcium, further enhanced by TD, SD and AD, thus a malignant cycle ensues. The massive ionic fluxes lead to cytotoxic oedema.[190] During this period the energy metabolism of the brain increases to activate energy-dependent ion pumps and ATP hydrolysis to restore the ionic homeostasis. This energy dependent ion pump activation and glycolysis, in TBI, causes accumulation of lactate and free fatty acids within minutes after injury.[46] This TBI is severe in states of low energy stores like hypoglycaemia, starvation, cold temperature and diabetic state. With the occurrence of TD following injury, in addition to the neurons, the astrocytes and microglia also get activated in an hour and start proliferating.[99] The activated astrocytes mop up extracellular K^+, convert excitatory glutamate to glutamine and try to envelop the neurons to guard against the ionic flood. The microglial cells, the macrophages of the brain are sensitive to depolarising events and become activated, releasing cytokines.[100] These cytokines can further damage the already injured neurons. The microglial activation can be prevented by antagonists to receptors of excitatory aminoacids.[99]

Role of Apolipoprotein E in the Outcome of Head Injury

Apolipoprotein E (ApoE) is a key component of the system involved in lipid transport in the nervous system. It transports cholesterol and phospholipids to the injured neurons and helps in repair of the cell membrane, neurite growth, dendritic remodelling and synaptogenesis.[142] Following injury there is a coordinated increase in the expression of ApoE by astrocytes and LDL receptors by neurons, facilitating the transport. Transient global ischaemia is found to dramatically increase ApoE immunoreactivity of neurons within a few hours after injury in the rodent model.[86] In man, there are three common alleles of ApoE gene located on chromosome 19, designated E_2, E_3 and E_4. The association between ApoE-E_4 and Alzheimer's disease has been confirmed worldwide. A tenfold increase in the risk of Alzheimer's disease was associated with ApoE-E_4 and history of traumatic injury. Head injury in the absence of ApoE-E_4 allele did not increase the risk. Given the similarities between Alzheimer's disease and dementia pugilistica, recent studies suggest that possession of ApoE-E_4 allele is associated with increase in the severity of chronic neurologic deficit in high exposure boxers.[95] Deposits of amyloid β protein (A beta) are found not only in cases of dementia pugilistica but in nearly 30% of patients with a single episode of severe head injury.[69] However, one study from Rotterdam, the Netherlands did not find trauma to be a major risk factor for dementia or AD in the elderly and ApoE genotype may not be associated with the clinical outcome.[127] This could be related to ethnic variability and needs further evaluation.

Polymorphism of ApoE gene appears to influence the neuropathological findings in a patient who dies of head injuries. More people who die from head injuries compared with non-head injured controls have deposits of amyloid beta-protein in the cerebral cortex, the amyloid β-protein deposits being present predominantly in patients with the ApoE-E_4 allele.[182] This shows a significant genetic association of ApoE polymorphism with outcome after TBI. Patients with ApoE-E_4 are more than twice likely to have adverse outcome 6 months after head injury than those with other genetic alleles. These observations have provided the first evidence for a link between a genetic susceptibility (ApoE-E_4) and an environmental trigger (head injury) to the development of Alzheimer type pathology[70] and also a genetic susceptibility to the outcome of brain injury.[52] Experimental studies have shown that following subdural haematoma, a rapid cellular redistribution of ApoE occurs and precedes a significant elevation in the levels of ApoE. These alterations in ApoE may occur initially as a part of the brain protective response to injury.[84]

Recent animal model studies using ApoE-deficient (knock out) mice revealed that these mice have memory deficits and neurochemical derangement and poor recovery following closed head injury than control mice.[85] This response appears to be due to reduced ability of ApoE deficient mice to counter antioxidative damage and further confirms the protective role of apolipoprotein in traumatic injury to the brain.[111]

Recently, a higher frequency of ApoE-E_4 was reported in patients who did not recover from post-traumatic coma than in those who recover consciousness soon.[170]

Ethanol Potentiation of Central Nervous System Trauma

Alcohol consumption has been a major risk factor in occurrence of neurotrauma. A study from Bangalore has noted that 16% of TBIs were related to the effect of alcohol consumption and the mortality was two times higher in this group.[26,27] A series of counter measures like education and legislation enforcement have yielded results in reducing alcohol related TBI to a variable degree.[75] A growing body of evidence indicates that moderate ethanol intake, even in the presence of adequate nutrition, may result in cell injury and cell death in the myocardium, liver and nervous system. Ethanol and its principal metabolite acetaldehyde, because of their lipophilic nature, get intercalated into the cell membrane, altering the biochemical and biophysical properties. In addition, the free radicals generated damage the cell membrane and other structures like mitochondria, depleting the

energy system.[23] To understand the pathology further, Flamm et al.[50] studied a cat model where the spinal cord and brain were subjected to impact injury in animals infused with alcohol. At the time of impact the blood alcohol was 450 mg% and after 24 hours, alcohol was not detectable. The animals which received the impact injury after alcohol infusion, showed disappearance of evoked potentials immediately after injury, and haemorrhages and oedema involving both grey and white matter 5–24 hours after injury. Nearly 80% of animals remained paraplegic, while a few regained the evoked potentials and recovered partially. The control animals, which had not received alcohol, had normal evoked potentials immediately following the injury. The spinal cord, 5–24 hours after impact, was essentially normal or had small haemorrhages. After 5 days the animals were mobile and 6–9 weeks after injury, they exhibited difficulty in walking. With minor injury to the brain, the control and alcohol infused animals were essentially normal. With greater impact, the alcohol infused animals had three to four times more extensive oedema and haemorrhages when compared to non-alcohol infused control animals. Altered platelet function, acetaldehyde induced mitochondrial damage and deranged adrenergic vasotonic activity following alcohol administration could be responsible for haemorrhagic lesions and oedema.[34,192] Free radical induced inhibition of Na+/K+—ATPase activity in the membrane could contribute to depressed evoked potentials. Synergistic action of alcohol and trauma produce the effect in neural conduction and late deleterious sequelae, which either of them individually could not produce. These features observed in the canine model appear to have significant relevance to human TBIs following alcohol consumption.

USE OF MRI IN ASSESSING THE TRAUMATIC BRAIN INJURY

MRI and related magnetic resonance techniques are more sensitive than CT in detecting and defining the focal and diffuse brain injury following trauma. Prediction of the outcome by imaging is dominated by a few variables like intracranial haemorrhages, brain swelling and DAI. CT may show petechial haemorrhages, but these punctuate lesions may resolve quickly and less than 20% of DAI is macroscopically haemorrhagic.[56] Small lesions and non-haemorrhagic lesions in the lobar white matter, corpus callosum and brainstem are detected in the MRI due to its excellent resolution. In adults, continued restlessness and agitation 2 months following TBI is associated with delayed T1 and T2 weighted signal abnormalities in the frontotemporal area and poorer outcome beyond 6 months after injury and some remain in persistent vegetative state.[17] Similarly, in a large study of children following TBI, the presence of large volume lesions in the frontal lobe correlated with defect in learning and memory function.[43] It appears that atrophy and compensatory hydrocephalus may be associated with bad outcome and long-term sequelae[82] detected on MRI, especially the frontal horn and III ventricle. During the acute phase, MRI image hypodensities noted in the deep dorsal brainstem indicate a poorer prognosis than those in the ventral and superficial brainstem, correlating with the pathological changes described.[167] Essentially, the late imaging correlates better with prognosis than the early MRI findings. Gadolinium enhancement of MRI in the acute phase highlights the injury to the BBB and the evolution of the lesion following injury.[174]

The features like small haemorrhages not detectable on T1 or T2 weighted imaging become evident in the gradient spin echo sequence. In children, especially, the abnormalities detected in gradient spin echo sequences at 3 months after injury correlate with both the severity of initial injury and also the outcome at 1 year.[64] In adults also, abnormalities may be noted in the gradient echo sequence within 5 days, but may not correlate with the outcome.[83] Diffusion weighted imaging sensitive to random movement of water molecules shows initially restricted diffusion (representing cytotoxic oedema) followed by unrestricted diffusion (vasogenic oedema) highlighting the evolution of dynamic events in the acute phase. The features are essentially similar to the evolution of clinical stroke. In a study of five severely injured patients in the first few days following TBI, restricted diffusion was noted in the brain surrounding focal lesions, which had normal signal intensity on T2 weighted imaging.[94] Lagares et al. found the anatomical substrate of TBI depicted by MRI to be a useful prognostic tool in patients with moderate and severe head injury. Patients with a score of 4 or less on the motor subscale of the GCS scale were those who benefited most from the prognostic information provided by MRI.[106] In paediatric TBI, assessment of DWI and ADC values is useful in evaluation, especially in those areas of brain that appear normal on conventional imaging. Early identification of children at high risk for poor outcome may assist in aggressive clinical management of paediatric TBI patients.[53]

Perfusion weighted imaging shows regional reduction in CBF and is sensitive to microscopic tissue level blood volume changes. Recent studies by perfusion weighted imaging have revealed reduced cerebral perfusion, both in the regions of contusion and also apparently normal surrounding brain, bringing to light the widespread nature of damage, which has a bearing on outcome.[55]

Bosnell et al.[19] studied the application of diffusion tensor imaging in recovery from TBI and summarised its uses as below:

- Monitoring pathological change
- Predicting recovery
- Identifying individual targets of therapy
- Providing outcome measures
- Providing measures of potentially compensatory structural changes
- Understanding of normal brain anatomy to aid in interpretation of the consequences of localised damage

Proton magnetic resonance spectroscopy (MRS) in clinical studies revealed reduction in N-acetyl aspartate in the white matter, reflecting DAI and poorer clinical outcome.[12,54] The occurrence of choline and myoinositol peaks reflect the reactive astrocytosis accompanying the DAI, neuronal damage and oedema.[54] Lactate is seen in severely injured adults within the first few hours in the contused brain. In children, visible levels of lactate indicate a poorer prognosis.[12] One recent phosphorous MRS study in severely injured patients during the acute phase revealed increase in phosphocreatine: inorganic phosphate ratio and alkaline pH in the regions of normal appearing brain, reflecting the depleted energy state of neurons and reactive astrocytosis.[57]

Single photon emission computed tomography may be the only examination to reveal perfusion abnormalities which are related to symptoms in the absence of other objective findings, such as post-traumatic amnesia, vertigo or personality change.[101]

Functional MRI, sensitive to the oxidative state of haemoglobin, reflecting oxygen extraction and regional activation, has not been widely used to study TBI. In one study of a patient with mild TBI, within 1 month, the regions of activation for memory were found to be similar to control subjects, but an altered degree of activation was noted with increasing processing load for memory, especially in the frontal lobes.[120]

Mamere et al. used a set of quantitative MR imaging techniques which could non-invasively demonstrate the neuronal and axonal damage in the normal appearing white matter and corpus callosum of human brains, secondary to moderate or severe TBI. The quantitative techniques used by them included: bicaudate and bifrontal ventricle-to-brain ratios, T2 relaxometry, magnetisation transfer ratio, apparent diffusion coefficient and proton spectroscopy by using an NAA/creatine ratio.[116]

Neuropathology of Post-Traumatic Sequelae

Severe disability after head injury is usually associated with abnormalities in the rostral brainstem, intracranial haematoma (SDH and intracerebral), cerebral oedema, circulatory and respiratory disturbance—thus, indicating the role of secondary events in the evolution during the first 1 month. These secondary events persist and are seen more frequently in patients who were vegetative for more than 1 month, especially with DAI and ischaemic damage. In patients with persistent vegetative state, widespread bilateral neocortical and white matter lesions are seen, some of them are cavitatory.

Late traumatic epilepsy is by far the most frequent complication of blunt head injury, the risk being higher in patients with intracerebral haematoma or compound depressed skull fracture and surface contusion. In adults, early epilepsy (occurring during the 1st week after head injury) is rare unless it is associated with depressed fracture, dural penetration, cortical laceration, intracerebral haematoma, retained foreign body and post-traumatic amnesia. Early epilepsy is common in children. This suggests a close association between focal brain damage and traumatic epilepsy. The epileptogenesis results from a combination of glial scar,[139] ischaemic lesions and disordered neuroglial function.[143] Willmore[193] postulated that the presence of blood in the neuropil is a critical aetiological factor. Iron liberated from haemoglobin and transferrin may be important in epileptogenesis based on the experimental evidence in cats and rats that had focal epileptiform seizures following injection of ferrous chloride into the sensorimotor cortex.

Temporal lobectomy specimens from cases of post-traumatic epilepsy, unlike idiopathic TLE, show less of Ammon's horn neuronal loss and gliosis and the outcome is better with temporal lobectomy.[119]

Neurologic diseases with possible connection with head injury include Alzheimer's disease,[33,135] Parkinson's disease[73] and motor neuron disease. Association with the occurrence of Creutzfeldt Jakob disease has also been suggested. A large number of concussive or subconcussive blows, as common in boxers, induce the development of progressive dementia.[29,61] In a detailed study of brains from ex-boxers, the pathological features noted were cavum septum pellucidum, fenestration of the septum, thinning of the fornix and corpus callosum, neuronal loss in the cerebellum and loss of pigmented neurons in the substantia nigra.[38] Numerous neurofibrillary tangles distributed diffusely in the cerebral cortex and in the brainstem and conspicuous scarcity or absence of neuritic plaques classical of Alzheimer's disease is observed. The brains of boxers[29] and those subjected to prolonged domestic violence[152] have numerous non-neuritic diffuse plaques not identifiable by congo-red or silver stains, but labelled by antibody to β amyloid protein. This is probably mediated by upregulation of glial cytokines and β amyloid precursor protein as a protective stress response.[72] Post-traumatic SAH may cause impedance to CSF circulation and can lead to communicating or obstructive hydrocephalus. Reduction in brain volume due to multiple ischaemic lesions and diffuse DAI may contribute to further normal pressure hydrocephalus manifesting with dementia.

Pathology and Pathogenesis of Spinal Cord Injury

INTRODUCTION

Injury to the spinal cord is not just an acute disease. Long after the initial injury, the chronic long-term effects on the body are staggering because, although the pathology that occurred in the cord itself may have become fixed or static, the other organ systems including sensorimotor, respiratory, gastrointestinal, urinary and reproductive systems in the body undergo progressive changes that adversely affect function.

Initial research in spinal cord injuries (SCIs) was focused on detailing those pathological events responsible for the irreversible cord damage following injury. Now, renewed interest in the field has followed spectacular progress in inducing central nervous system (CNS) repair and regeneration that may make a "cure" for spinal paralysis a reality in the near future. But, for these discoveries to be applied to human SCIs, an in-depth knowledge of the pathology and pathophysiology is essential. In order to fully appreciate the pathological sequence of structural alterations in SCIs, it is also essential to keep in mind that the response of living tissues to injury undergoes continual changes with time. The key to the development of treatment strategies is dependant on the elucidation of the various sequential steps involved at the molecular level so that the process can be arrested or reversed before the onset of irreversible damage.

The annual incidence of SCI in various countries ranges from 15 cases to 40 cases per million population.[55] In civilian life, the most common causes are road traffic accidents, sports and recreational activities, accidents at work, falls and violence. SCI is the price we pay for modernisation and advent of industrialisation.

CLASSIFICATION OF SPINAL CORD INJURIES

SCI can be classified as "open" and "closed" injuries depending on the dynamics of the force, the separation into the respective categories being dependant on the integrity of the dura. In general, open injuries result from sharp or penetrating injuries while blunt force causes indirect or closed injuries by transmission of the mechanical impact to the cord without injury to the spine. A combination of the two may also occur as in fracture dislocation resulting from blunt force, wherein the dislocated bony spicules can cause penetrating injury and tear of arachnoid/dura.

Mechanisms of Closed Injuries

The mechanisms and classification of injuries of the spinal column have been a controversial issue with many differing views, as the forces generated produce not only displacement but also a combination of three-dimensional linear and rotational forces. Roaf[45] proposed that the mechanism of injury and the anatomical lesion that results is best described by indicating the direction of the resultant vector and the axis of rotation. Unlike the moveable head, the spinal cord is rarely submitted to acceleration injury. Accordingly, SCI are most often classified into four groups according to the most predominant factor at the time of injury as: (1) flexion and deflexion injuries; (2) vertical compression; (3) rotational injuries and (4) those with a combination of forces. All these mechanisms, except vertical compression, are associated with crushing of the cord. Vertical compression injuries often produce incomplete cord lesions.

Flexion and Deflexion Injuries

Ventroflexion and dorsiflexion forces produce deformities of the spine with or without accompanying cord injury. In this form of trauma, three types of forces come into play: (1) transverse shear; (2) longitudinal shear and (3) torsion. Among these, transverse shear is the most important. Flexion and deflexion injury is the most common mechanism of neck injuries (e.g. whiplash injuries) and results in anterior and posterior longitudinal ligament tears. The cord gets stretched diagonally upwards resulting in a transverse tear if there is a fracture dislocation or protrusion of the disc just above the fulcrum in both types of injury.

Flexion (anteroflexion/hyperflexion) injuries: Minor degrees of anteroflexion forces produce only dislocation or deformities of the spine without any cord lesion unless the cervical spine is pathologically stiff, but extreme hyperflexion injuries result in severe spine deformities leading to fracture, fracture dislocation of vertebral bodies, prolapse of discs, dislocation of articular processes, and is associated with severe local damage to the cord causing central necrosis and haemorrhage.

Acute anterohyperflexion of the neck in infants causes fatal central cerebral haemorrhage or haemorrhagic necrosis of the medulla or upper cervical cord.

Hyperextension injuries: The term "hyperextension injuries" encompasses retroflexion or dorsiflexion forces, and fracture dislocations caused by facial or frontal injuries. Roaf[45] was of the opinion that this term is inaccurate as extension would literally mean longitudinal distraction. Such forms of pure extension injuries are rare and happen with excessive skull traction[25], which causes fractures of the neural arches and, rarely, cord damage. But the majority of injuries to the cervical cord result from facial or frontal trauma as in a blow to the forehead or diving into shallow water and, in this form of injury there is retrohyperflexion of the head and neck

with or without rotation. As the mechanism involved is not pure longitudinal distraction, it forces the articular processes of the mid cervical vertebra backwards to cause separation of the body from the intervertebral disc or fracture dislocation with compression of the articular processes. Further separation will lead to tear of the anterior longitudinal ligament. The posterior longitudinal ligament buckles up, squeezing the cord backwards over the lower vertebra causing partial or complete transection of the spinal cord. The correct biomechanical term proposed for this form of injury is "deflexion"[45] or "retro-deflexion"[11] as disruption of the ligaments can only be produced if there is rotational force in addition to flexion and hyperextension.

In elderly persons with cervical spondylosis, dorsiflexion causes significant cord damage by tearing of the intervertebral disc and angulation of the cord already narrowed by ankylosing spondylitis.

Retroflexion of the head and neck causes central cord injury which can take the following forms:

- Small intramedullary haemorrhages with oedema (focal haematomyelia, representing butterfly-like central haemorrhage or haemorrhagic necrosis in the grey matter)
- Direct contusion of the cord (ischaemic malacia caused by squeezing of the cord)
- Central concussion with surrounding oedema and central ischaemic infarct due to vascular insufficiency caused by compression of the vertebral arteries.

Compression Injuries

The vertebral body absorbs compression injuries caused by vertical impact and cause vertebral fractures while the ligaments are intact. Such injuries follow a fall on the head or neck, car accidents, etc. resulting in flattening of the vertebral body, fracture of end plates and rupture of the nucleus pulposus.

Such injuries affect the thoracolumbar junction (most moveable part of the thoracolumbar spine) or lower cervical spine. Protrusion of the fractured vertebral body (posteriorly more often than anteriorly) or the intervertebral disc (acute retropulsion) in the transverse plane causes compression of the spinal cord.

Rotation Injuries

This can affect any part of the vertebral body, its articulations and the ligamentous complex to cause fracture dislocations (unilateral/bilateral, stable/unstable) and displacement of the intervertebral discs. This most often involves the thoracolumbar junction and the upper lumbar spine. Compression leads to cord injury and this type of injury is also associated with lesions in the cord and roots in the region of the cauda equina.

Combined Mechanisms

Pure extension or flexion injuries do not produce ligamentous rupture, disc destruction or fracture dislocations and requires coexisting rotational forces. Dislocations are the most common in the cervical spine due to its marked mobility, followed by the lower thoracic and thoracolumbar spine.

Flexion-rotation injuries produce unstable fracture dislocations that are associated with rupture of the posterior longitudinal ligaments, separation of spinous processes and unilateral or bilateral facet dislocations. Bilateral dislocations are more often associated with compression or crush injury of the cord.

In hyperextension (retroflexion) injuries of the neck, the anterior longitudinal ligament ruptures with posterior dislocation of the vertebral body that compresses the cord. In patients with cervical spondylosis, even minor injuries can cause subluxation without rupture of the anterior longitudinal ligament.

In the so-called "whiplash injuries", there is ventro/dorsiflexion of the cervical spine with rotation, compression and anteroposterior angular acceleration. This causes excessive distortion with soft tissue damage, in addition to damage to both anterior and posterior ligaments, the nerve roots and disc with or without cord injury.

Types of Cord Lesions in Closed Injury

For the pathologist, a classification based on the nature of the lesion is more meaningful rather than one based on the mechanics of trauma and is similar to that used for craniocerebral injuries:

- Primary traumatic lesions—which are the immediate result of direct trauma on the cord
- Secondary traumatic lesions—that develop from non-traumatic secondary sequelae resulting from the circulatory alterations, oedema, etc.
- Late sequelae of both primary and secondary traumatic effects that include repair, regeneration and secondary tract degeneration. Late complications and delayed progression (myelopathies) that occur at various intervals.

Primary Traumatic Lesions

This includes all local lesions at or adjacent to the site of impact caused by direct trauma as in laceration of the cord coverings, extradural, intradural and subarachnoid haemorrhages. The damage to the cord ranges from petechial haemorrhage and oedema to central necrosis, and damage to the vasculature or nerve roots.

Extramedullary haemorrhages: Traumatic epidural, subdural and subarachnoid haemorrhages are uncommon in adults and, also, rarely severe enough to cause cord compression. Subarachnoid and extradural haematomas are more common following birth injury and perinatal distress. Spinal subdural haematomas, similarly, are rare in adults except if there is associated bleeding tendency and more common in neonates following obstetric trauma. This is an important cause of perinatal paraplegia.

Concussion of the cord: Concussion is by definition a functional disorder, which is reversible and is produced by blunt direct injury without anatomically discernible damage to the cord. Like its cranial counterpart, it is associated with transitory changes in the nerve cells (neuronal chromatolysis and necrosis), fibre tracts, focal myelin and axonal breakdown, small haemorrhages, oedema and microscopic foci of ischaemic necrosis. The pathological events in concussion of the cord is focused in the grey matter, and results in haemorrhagic necrosis. Hypoperfusion of the grey matter, which is the initiating factor along with increase in intracellular calcium and reperfusion injury, plays a key role in cellular injury. The extent of necrosis depends not only on the amount of initial force of trauma but also the concomitant compression, perfusion pressures and blood flow, and administration of pharmacological agents. Preventing these mechanisms in the initial stages will limit the cascading effects.[50]

Compression: This may result from fracture dislocation of the vertebra, prolapsed disc, exostosis and spondylitic changes and, rarely, from extensive extramedullary haemorrhage. Compressive effects are more often encountered in the cervical region than the thoracolumbar, which has greater degree of space within the spinal canal.

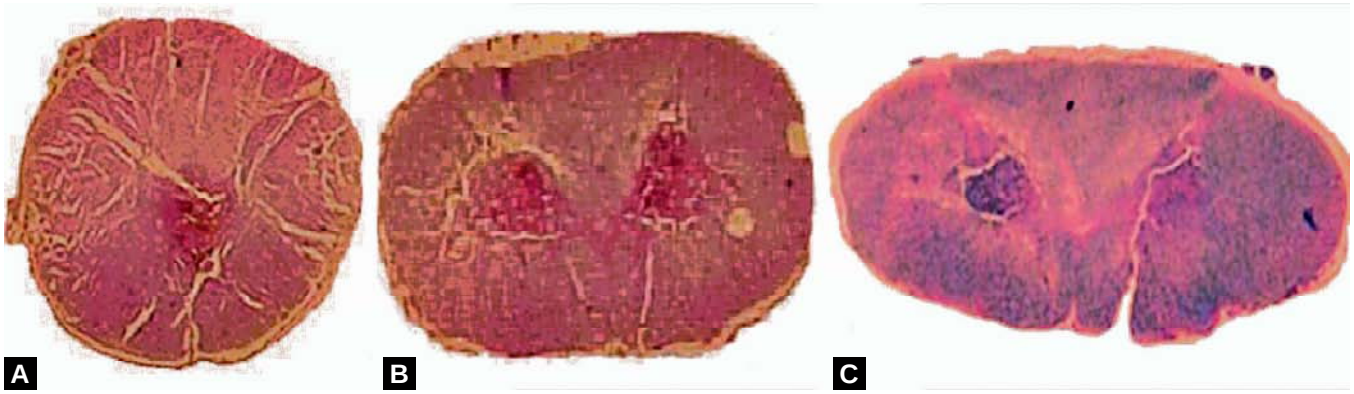
The pathological changes caused by compression include necrosis with or without haemorrhage or non-necrotic changes depending on the duration. The effect of short duration compression on the cord and its vasculature is almost the same as that found in concussion, while compression of greater intensity and duration produces marked oedematous swelling both above and below, and complete transverse necrosis at the level of compression. On sectioning there is central haemorrhage and softening occupying the central grey matter with variable spread into the white matter. The central necrotic tissue can extend in either direction in the posterior columns. These can later be transformed into cystic cavities. Ischaemic infarcts can occur rarely in the segments remote to the site of impact due to compression of radicular or anterior spinal arteries. In compression injuries, wherein the patient survives for longer duration, the acute phase subsides and is gradually replaced by a reparative process that causes demyelination and cavitation of the central grey matter, which is eventually replaced by a glial or collagenous scar. In cases surviving for months or years, the level of impact is marked by a dense scar that is adherent to the meninges obliterating the arachnoid space. The cord itself becomes thinned out and sclerotic or is converted into a fibrous or gliotic band. Apart from gliosis and demyelination as described above, axonal loss is also observed. This occurs in the white matter, whereas grey matter structures are relatively preserved. Critical compression of the cord will result in collapse of the venous side of the microvasculature, resulting in vasogenic oedema, which in turn may lead to rapid progression of dysfunction.[36]

Contusion of the cord: The term connotes all primary injuries to the spinal cord and its coverings caused by indirect blunt violence transmitted to the cord. It includes all non-disruptive injuries without evidence of continuing compression. It ranges from small petechial haemorrhages and oedema to extensive crush injuries wherein the cord tissue is pulped, but complete tears are rare. The pathology, similar to cerebral contusions, evolves over three consecutive stages:

1. An early phase of haemorrhage and necrosis
2. An intermediate stage wherein the process of resorption and organisation begins
3. The final stage of scarring or syringomyelia.

Acute stage: The immediate changes that follow acute injury are oedema and intramedullary haemorrhage, tissue disruption, inflammation, vascular alterations and effects on the preserved axons and myelin. Initially the most obvious abnormality is tissue disruption, which is followed by oedema, which appears within minutes and takes an hour or two to develop fully. Grossly visible bleeding may not always be present. At the site of impact, the cord is flattened and grooved transversely (Fig. 35) or swollen and bluish-red, but intact. On cross-section, the cord shows haemorrhage within the central grey matter, which can either be confined to only the central part or extend into one or both posterior horns or assume the typical H-shaped configuration of butterfly haemorrhages (Figs 36A and B).

Fig. 35: Road traffic injury with upper cervical cord injury (arrow). Survival up to 5 days



Figs 36A to C: Cervicomedullary. (A) Upper cervical segments. (B) Showing haemorrhagic necrosis of grey matter (HE × 10). Myelin stain. (C) Showing widespread demyelinating ischaemic lesions (LFB × 10)

Microscopically, petechial haemorrhages are the first to appear within the central grey matter caused by extravasation of erythrocytes from thin-walled vessels. Haemorrhages occur initially around the ventral part of the posterior horn and around the central canal. Differential vulnerability of the central grey matter of the cord is attributed to the grey matter being softer and more easily expandable as well as the differential vascularisation of the grey over white matter.

The initial leakage of RBCs is followed by engorgement of the capillaries and veins, which is seen as early as 2 hours post-trauma leading to rupture with leakage of plasma into the tissues. In crushed areas, there is fibrinoid necrosis or occlusion, and thrombosis of the intramedullary veins with compression of arteries and meningeal vessels within 24 hours of injury.[59] In addition to haemorrhages within the central grey area, there is also a zone of mechanically disrupted tissues causing rupture of cell membranes and liquefaction necrosis caused by dissolution and disintegration. The neurons in the adjacent grey matter show chromatolysis and progressive ischaemic cell death attributed to a disorder of the microcirculation as the endothelium of the intact capillaries swell reducing perfusion through the injured segment causing local tissue hypoxia.[57]

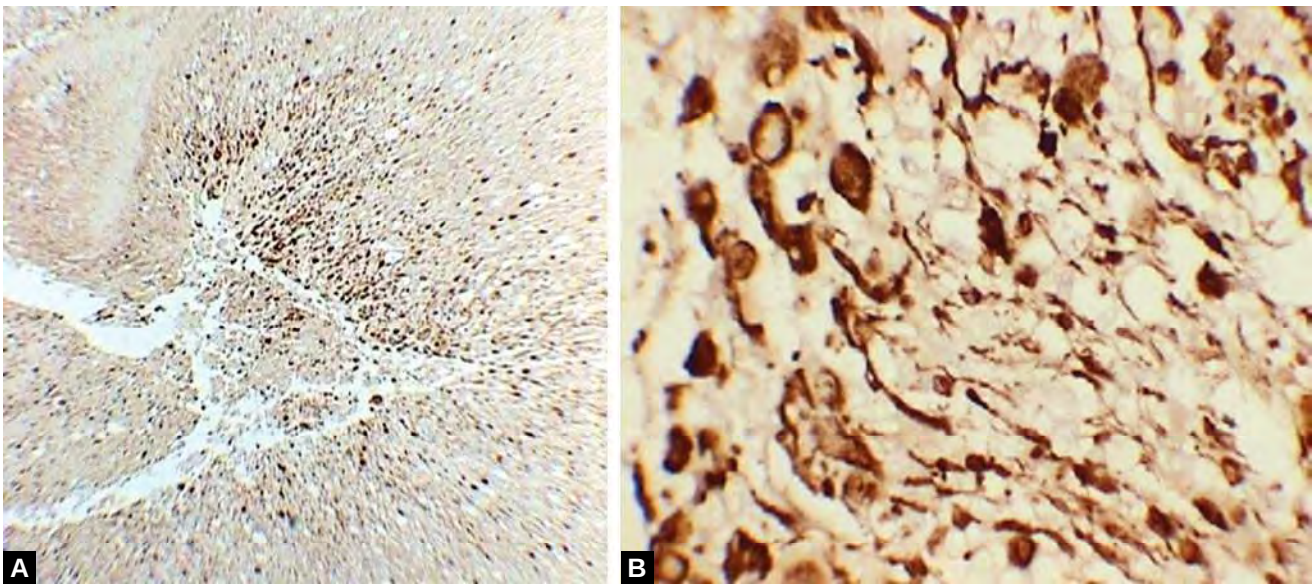
The haemorrhagic necrosis is accompanied by oedema that expands and loosens the neuropil, and distends the white matter causing separation of the fibre tracts giving it a honeycomb appearance. Both haemorrhage and oedema show a centrifugal pattern of spread from the central grey matter to the adjacent posterior and posterolateral columns of white matter to eventually involve the entire transection of the cord, which becomes round and tense within the covering meninges obliterating the subarachnoid and the subdural spaces. These then tend to spread longitudinally upwards and downwards rather than in a transverse direction and are responsible for deterioration following injury. The tendency to spread in the longitudinal axis is explained by the looser texture and greater vascularity of the grey matter enclosed by linear compact fibre tracts. The resultant centrally located, but elongated solid clot extending over several segments is termed "haematomyelia".

Apart from the haemorrhage and oedema, exudation of polymorphs followed by monocytes begins from the vessel walls into the damaged parenchyma within 24–48 hours. These are brought in by the cytokines released from injured and reactive astrocytes and microglial cells.[47,48,57] The granulocytes are soon replaced by lymphocytes and macrophages that induce the resorptive changes by scavenging the damaged tissue components.

The acute lesion is also characterised by traumatic changes of demyelination and Wallerian degeneration of the axis cylinders, which have escaped total disruption. Immediately following injury, there is complete disruption of a proportion of nerve fibres and partial injury to others. In the former the damage is permanent, while, in the latter, it is still reversible. Axonal damage can be detected within hours of injury by immunohistochemical methods using antibodies to the βA4 moiety of the amyloid precursor protein. This highlights two types of axonal damage:

1. Irregular varicosities appear within 30 minutes of injury and indicate a failure of the rapid anterograde axonal transport.
2. The axonal spheroids ("retraction bulbs") become apparent within 24 hours of injury suggesting that varicosities may progress to total axotomy and spheroid formation (Figs 37A and B).

It is interesting to speculate whether some of the varicosities recover and not progress. Spheroids are the equivalent of embryonal growth cones and so is the source of regeneration although abortive. These lesions are identical to the diffuse axonal injury occurring in the brain in the supratentorial compartment and evolve early on in the evolution of traumatic injury. Curiously, the term "diffuse axonal injury" however, is not applied when the lesions appear in the spinal cord. The changes in the cord involve only a few segments in proximity, unlike in the brain, where the changes are diffuse. Traumatic demyelination follows within a few hours of injury (Fig. 36C). Kakulas et al. observed that remyelination



Figs 37A and B: (A) Immunostain for neurofilament showing axonal bulbs along the periphery of ischaemic haemorrhagic lesion in the cord. Note the centrifugal nature of axonal damage with sphenoid formation due to disruption of axons (× 20). (B) Higher magnification showing axonal disruption and spheroids (× 400)

found in long-term survivors was not of the central oligodendrocytic type, but of peripheral myelin produced by Schwann cells.[29] This form of remyelination was found in 16 out of 27 patients who survived 6 months or more.

Intermediate "repair" phase: Within 24–48 hours post-trauma, the transverse progression of acute haemorrhagic necrosis, extravasation of RBCs and local blockage of blood flow begins to subside, but the oedema reaches a peak within 3–6 days after the injury. Within 2–3 days following the contusion, the haemorrhagic necrosis is gradually resorbed and a reparative process begins. The early polymorphs are replaced by lymphocytes and macrophages, which invade the margins of the necrotic area. Within the first 2 weeks after injury, the oedema subsides and the smaller foci of haemorrhages are resorbed leaving behind only a few haemosiderin laden macrophages while the lipid filled histiocytes in the necrotic area tend to surround the small vessels in an attempt to release the debris into the vascular channels. The next stage is heralded by the appearance of astrocytic gliosis, which depends on the degree of damage, such as with mild injury, reactive gliosis begins within 24–36 hours, but when there is severe damage, astroglia also disintegrate along with the nervous tissue. Therefore, in these areas, the mesenchymal elements, which originate from the blood vessels and leptomeninges aid in the process of repair. The central necrotic area progressively undergoes cystic dissolution. Along the margins, vessels proliferate and the resolving central necrotic area is soon surrounded by a zone of highly vascularised granulation tissue ("proliferation zone"). This gradually replaces the defect in a centripetal direction progressing from the preserved peripheral areas to the central necrotic foci. The central area of haemorrhagic necrosis is eventually replaced by a multilocular cyst traversed by gliovascular bundles. The surviving axons bordering the lesion are swollen, but simultaneously, secondary degeneration of the spinal nerve roots and the long fibre tracts begins. The anterior nerve roots are more affected than the posterior.

The vascular changes that occur in this stage include thrombosis of the pial and intramedullary vessels with subsequent organisation and recanalisation.[28] These can cause secondary ischaemic damage to the cord at sites remote from the original injury.

Late stage: Months to years after the injury, damaged parts of the cord are totally replaced by connective tissue. The zones above and below develop dense isomorphic gliosis, which replaces the lost neurons and nerve fibres. At the level of the lesion, all that remains is a dense fibrous scar that is formed by fusion of the periosteum and dura mater. The leptomeninges are thickened, discoloured from sequelae of haemorrhage and adherent, obliterating the subarachnoid space while the cord tissue is converted into a narrow fibrous band. On transverse sectioning, the cord tissue is found to be reduced to a thin rim that surrounds small gliotic islands of cord tissue that are separated by strands of highly vascularised connective tissue and dense collagenous bands. Cavitation involves the central grey matter and the posterior funiculi, the inner walls of the cavity being lined by gliomesenchymal cicatrised tissue with macrophages and occasional deposits of calcium and iron. With time, the iron and haemosiderin deposits disappear. Features of regeneration may be seen. The spinal roots appear thin and demyelinated and are also surrounded by fibrous scars. Above and below the lesion, patchy areas of gliosis and demyelination or scarred areas with dense gliosis and small cystic cavities with necrotic contents

and gliomesenchymal walls maybe found. Wallerian degeneration of tracts also progresses with subsequent gliosis. Changes in the vasculature of the cord in the late stages include organisation and recanalisation of occluded intramedullary and pial vessels, an obliterative vasculopathy.

Late sequelae (Post-traumatic syringomyelia): A nidus of traumatic haematomyelia or myelomalacia followed by liquefaction and cavitation, instead of solid scar formation is the initiating lesion. Further, a communication between the syringomyelic cavity and the subarachnoid space can act as a valve-like promoter, once the original cavity has been established. Histologically, post-traumatic syrinx is not any different from an idiopathic syrinx.

Sharply circumscribed areas of necrosis resembling infarcts are more readily identifiable in the chronic phase. These occur at considerable distances from the injury site and may conform to the distribution of anterior sulcal arteries,[33–35] while others may be of venous origin. The pathophysiology of these lesions is not definite, but is of clinical importance as they can explain some of the clinical deficits that are remote from the lesion site.

A less common type termed "microcystic myelomalacia" (marshy cord syndrome) described by MacDonald and his co-workers[37] is post-traumatic central degeneration without frank syringomyelia. Arachnoiditis has been seen with this condition. This may play a role in the progression of both post-traumatic syringomyelia and cystic myelomalacia.

In the absence of a dural tear, intramedullary scarring is usually minimal as is the astrocytosis or gliosis.[55] Due to Wallerian degeneration involving both rostral and caudal axons, the cord in the chronic stage is atrophic at the injury site as well as rostrally and caudally.

A range of regenerative changes have been described with in growth of Schwann cells and peripheral myelin with axons from the ventral and dorsal nerve roots. The proliferation may be extensive enough to produce intramedullary neuromas.[27]

PATHOPHYSIOLOGY OF ACUTE SPINAL CORD INJURIES

A fundamental observation in both clinical as well as experimental SCI is that the pathological appearance of the lesion changes dramatically over the first few days after injury. Experimental models have been developed that can simulate almost all forms of human SCI.[21,55] From the observation that myelotomy and removal of the central haemorrhagic necrotic material results in improvement in neurological function, Allen[5,6] proposed the concept of a secondary mechanism of injury. He believed that a noxious agent present in the necrotic material was responsible for further damage to the cord. Numerous processes that contribute to the pathophysiology of SCI have now been identified that are similar to head injuries, cerebral ischaemia and subarachnoid haemorrhage.

The secondary mechanisms involved in the pathophysiology of SCI include both local effects on the components of the cord itself such as neurons, astrocytes, microglia and blood vessels and systemic effects that include shock, hypoxia or other complications.

Systemic Effects

Neurogenic Shock

Spinal cord injury is one of the common causes for neurogenic shock, which results from a combination of decreased sympathetic tone, unopposed vagotonia and possible secondary changes in the heart.[24,31] The magnitude of the shock is directly related to the level (more common in complete cervical injuries) and the severity of the injury. The peripheral resistance and cardiac output can remain depressed for long periods of time following the injury.

Local Effects

Damage to the Microcirculation

A common feature of SCI is the development of central haematomyelia. This is attributed to the mechanical disruption of the capillaries, arterioles and venules due to the mechanical force of injury and distortion by impact, compression or laceration.[18]

Biochemical Changes

Of the biochemical derangements that occur in acute SCI, the key event is damage caused by the excitatory neurotransmitter glutamate that mediates injury through elevation of intracellular calcium. Increased levels of intracellular calcium sets into motion a chain of events, all of which acting via different pathways cause cell death and tissue necrosis. These processes include activation of proteases that degrade neurofilament proteins; lipases that cause dissolution of cell membranes, and release of free radicals that cause lipid peroxidation. Lipases also cause release of prostaglandins and eicosanoids from damaged neuronal membranes that can, in turn, induce vasospasm.

Inhibitors of these pathways appear to be a logical way to arrest damage caused by these secondary mechanisms. Experimental studies have attempted to examine this issue. For instance, blockage of the NMDA receptor through which glutamate acts using MK-801 (a receptor antagonist), has been shown to have a protective effect.[19] Similarly, methylprednisolone probably exerts its cytoprotective effect by inhibition of lipid peroxidation and reducing the release of free radicals.[26]

Electrolyte Shifts

The most important is increase in intracellular calcium that plays an important role in pathogenesis in acute SCI similar to ischaemic injuries and head trauma. Calcium enters either through disrupted cell membranes or through voltage gated calcium channels following

depolarisation or via receptors activated by glutamate. Increase in calcium within the vascular smooth muscle can result in tetanic contraction or vasospasm causing ischaemic damage.

STRATEGIES FOR TREATMENT OF SPINAL CORD INJURY

SCI is one of the most physically, psychologically, as well as, socially devastating afflictions. With remarkable advancements in critical care and rehabilitation, many patients who sustain SCI are surviving and have extended life spans up to 40 years post-injury.[8,55] But as there are currently no regimens to successfully enhance recovery of function, these individuals remain severely disabled. It's therefore imperative to discover ways to achieve both functional restoration and repair. This would have a powerful effect not only in the quality of life of the afflicted but also their families and health care costs.

The approaches vary from:

- Arresting the immediate effects of injury so that secondary damage to the cord is prevented or arrested
- Induce axonal regeneration to re-establish pathways so that functional restoration is possible
- Reconstruct the injured segment by transplantation or grafting.

Initial interest was focused on developing pharmacological regimens that can protect the cord at the time of the acute injury. These operate by suppressing some of the secondary processes that are activated following the trauma. For instance, methyl prednisolone[26,61] and the ganglioside GM-1[22], inhibit the inflammatory reaction and generation of free radicals. Use of antioxidants for countering the free radical damage has also been proposed. Antisera to nitric oxide synthase have been shown to have a protective effect.[48] The GABA inhibitors, such as Riluzole or Gabapentin, may be useful in limiting the damage caused by excitotoxicity.[52,53] The benefits of this form of approach are, however, limited and no functional improvement has been recorded in the chronic stages of SCI.

Following traumatic injury in the spinal cord, as in other organs, tissue repair begins, the difference being that in the spinal cord and brain it is not a regenerative process but a fibroproliferative event that progresses into a glial scar that "patches", but does not restore the damaged tissue. In the CNS, this can have potentially devastating functional consequences.

In the CNS, wound healing follows a very precise sequence of events that are grouped in order of progression as: inflammation, tissue formation and remodelling in which there is glial scar formation, and deposition of extracellular molecules.[14]

The glial scar that results, however, thwarts axonal regeneration acting as a physical barrier. Additionally, recent work suggests that orderly regrowth may also be adversely influenced by molecules within the glial scar that in some way signal neurons to stop growing (axonal outgrowth) or alter their direction of growth.[16] The molecules most strongly implicated in directing axonal growth are found in the extracellular matrix of the glial scar.[51] Most often upregulated are Tenascin C[12] and Chondroitin sulphate,[38] closely associated with Laminin. Laminin is permissive to growing axons and, *in vitro*, stimulates neurite growth. Tenascin C is inhibitory, but its effects vary depending on the microenvironment. Therefore, with proper molecular tools it maybe possible to manipulate the extracellular matrix so that a supportive environment for sprouting and regeneration is created.

Regeneration of the CNS axons is the prime target for treatment of end stage lesions. Much interest in regeneration followed the experimental study, which showed that a piece of sciatic nerve when inserted into the lesion site formed a conduit for the elongation of axons in the adult rat.[3,15,44] This was the first demonstration that CNS axons did have the capacity to regenerate if they were provided a permissive milieu in which to grow.

Following closely on the heels of this discovery, numerous methods of achieving the primary goal of promoting regeneration by transplantation have been tried out. Peripheral nerve grafts were developed by Aguayo et al.[1,2] Other techniques involve grafting of embryonic tissues or Schwann cells,[39,42,58] olfactory ensheathing cells,[30,43] and cells genetically engineered to produce neurotrophins[23] and even inert substances, like polyethylene glycol,[49] have produced exciting results with remyelination.

Anderson and his colleagues[7] assessed the feasibility of grafting foetal neural tissues taken from the foetal spinal cord (embryonic days 2–24), foetal brainstem (E21–38), foetal neocortex (E38) and a mixture of foetal spinal cord and brainstem into adult cat spinal cord. Chronic lesions that resemble human SCI (i.e. single/multicystic cavity surrounded by a peripheral rim of spared white matter) were produced by using static loading forces. They demonstrated that transplantation of foetal CNS tissue into these chronic compressive injuries did survive, integrate and show connectivity with host tissue. In addition, under appropriate conditions, these were capable of enhancing the recovery of locomotor function. Additionally, the capacity for homotypic transplants to promote recovery of function is greater than heterotypic transplants. The functional capacity of the graft depended on the time interval between injury and transplantation, and if the lesion cavity was debrided prior to grafting.

Falci et al.[20] went one step further and introduced human foetal spinal cord into the post-traumatic cysts with the intention of preventing development of post-traumatic syringomyelia rather than inducing regeneration, with some success.

Whether foetal tissue transplant will ever be applicable to human SCI is debatable given the ethical and procedural problems that arise with procurement of

foetal tissue, non-invasive monitoring of the graft site, assessment of outcome, etc., but this is an important stepping stone in the treatment of chronic SCI.

Neural stem cells have been the focus of intense research in recent times aimed at developing transplantation strategies to promote neural recovery in the injured nervous system. Neural stem cells have the capacity of self-renewal to generate progeny that are capable of differentiating into both neurons and glia. Transplantation of human neural stem cells obtained from embryonic tissue has shown both neuronal and astrocytic differentiation.[13,41,54] Remyelination and recovery of impulse conduction has also been demonstrated following transplantation into demyelinated rat spinal cords.[4] But relative inaccessibility of these cells for autologous therapy, the ethical and practical problems in obtaining embryonic tissues with their inherent problems of host incompatibility, and rigorous testing for viral screens make this an unpopular choice of therapy, forcing investigators to look further for alternate sources of neural precursors.

Recent work by Bjornson and his colleagues[9] demonstrated that neural stem cells could generate a variety of haematopoietic cells *in vivo* including myeloid and lymphoid cell lineages. This revealed the startling fact that the neural precursor cells are not restricted to purely neural lineage. The reverse was soon demonstrated when bone marrow stromal cells were shown to differentiate into astrocytes when injected into the lateral ventricle of mice[32] and into neurons both in *in vitro* culture systems[60] and in x-irradiated mice.[10,40] This raised the intriguing possibility of using bone marrow stromal cells as an alternative source of neural cells in traumatic and neurodegenerative diseases of the CNS for repair strategies. Bone marrow is easily accessible and more importantly will allow autologous transplantation obviating host incompatibility, and need to screen for viral and foreign antigens. Sasaki and his co-workers successfully demonstrated that transplantation of bone marrow cell fraction into demyelinated spinal cord caused extensive remyelination, albeit of peripheral Schwann cell myelin type.[46] Notwithstanding exciting results of a variety of transplantation techniques in the rodent model of SCI and some recent experimental attempts in humans so far the restoration of useful function has not been achieved.

Although many encouraging experimental models have been developed, all modalities of therapy tried so far address only axonal regrowth and not restoration of physiological function. As the neurological disability in SCI is a combination of motor (pyramidal and extrapyramidal), sensory and autonomic dysfunction, each of these must be corrected in order to achieve a complete cure. This contrasts with the simplistic view that all that is required for a cure is independent ambulation. The autonomic dysfunction that affects bowel, bladder, reproductive and cardiovascular systems is much more distressing than dysfunction of the motor system, which has received the maximum attention till date. "Restorative Neurology" is a clinical specialty that seeks to improve residual neurological function unlike conventional "rehabilitation" that focuses on enhancing the function of uninjured parts in order to make up for lost function. Dimitrijevic[17] was the first to make pioneering efforts in this important specialty. Approaches towards improvement of residual function include physical, pharmacological, electrical or neurophysiological methods (epidural stimulation, functional electric stimulation, computer modelling, etc.).

There is also the problem of CNS plasticity to be considered, because of which, isolated segments of the cord get subjected to abnormal inputs causing physiological aberrations and derangements, which means that simple reconnection of the transected segment by regeneration may not restore normal function. A better appreciation of the neurophysiology will be an important factor in restoring functions once central regeneration is achieved by whatever means.

28 Concussion Brain

Sandeep Vaishya, Khan Z

INTRODUCTION

Concussion, derived from the Latin concutera ("to shake violently")[38] or the Latin concusses ("action of striking together")[6] is the most common type of traumatic brain injury. The term "concussion" has been used for centuries and is still most commonly used in sports medicine,[2] while the term mild traumatic brain injury (MTBI) is preferentially used in general medical contexts. Concussion is frequently defined as a head injury with a transient loss of brain function and is known to cause a variety of physical, cognitive and emotional symptoms.

The most widely accepted definition is the one proffered by The Committee on Head Injury Nomenclature of Neurological Surgeons in 1966 and defines it as "a clinical syndrome characterized by immediate and transient post-traumatic impairment of neural function such as alteration of consciousness, disturbance of vision or equilibrium, etc. due to brainstem dysfunction".[13,55] The more recent description, as given by The American Academy of Neurology, states that "concussion is the trauma induced alteration in mental status that may or may not include loss of consciousness".[26] The recent modification stems from the understanding that the injury is not restricted to the brainstem only.

MECHANISM

The brain is anatomically designed to prevent damage from light trauma, as the surrounding cerebrospinal fluid acts as a cushion for absorbing the impact while it is ill suited to bear more severe impacts or the forces associated with rapid acceleration. Concussion may be caused by impact forces, in which the head strikes or is struck by something or impulsive forces, in which the head moves without itself being subject to blunt trauma (for example, when the chest hits something and the head snaps forward).[50]

Forces may cause linear, rotational or angular movement of the brain or a combination of these types of motion.[50] In rotational movement, the head turns around its centre of gravity and in angular movement it turns on an axis not through its centre of gravity. Amongst all these forces, the amount of rotational force is considered the major type of force to cause concussion and the largest component in its severity.[42] Studies with athletes have shown that the amount of force and the location of the impact are not necessarily correlated to the severity of the concussion or its symptoms and have called into question the threshold for concussion previously thought to exist at around 70–75g.[19,21,48]

Rotational forces primarily affect the midbrain and diencephalon and the subsequent injury is thought to disrupt the normal cellular activities in the reticular activating system located in these areas, which eventually produces the loss of consciousness often seen in concussion.[38,46] Other areas of the brain that may be affected include the upper part of the brainstem, the fornix, the corpus callosum, the temporal lobe and the frontal lobe.[3]

PATHOGENESIS AND PROPOSED THEORIES

Most of the theories proposed to explain the genesis of concussion rely on the understanding of the post-traumatic responses of the various parts of the brain, towards different types of force employed for causing the injury. Some of the authors have also dwelled upon the consequent metabolic changes occurring in the brain's milieu. Below is a summation of the various theories along with the proposed reasons which are generally based upon the aforementioned explanations.

Ricker, as early as in 1919, suggested that concussion could be due to extreme vascular dilatation followed by constriction,[44] while Duret, in 1921, proposed that it could be due to the forces of CSF impinging on the floor of the fourth ventricle and sudden compression of the cerebral hemispheres. Trotter, in 1932, as quoted by Symonds,[51] suggested that it could be the result of a momentary cerebral anaemia, due to compression or indentation of the skull. Subsequently, in the year 1940, Scott[49] suggested that temporary rise of intracranial pressure above the systolic pressure with sudden cerebral anaemia could be one of the causes.

Denny Brown and Russell[14] in the year 1941 suggested acceleration to be responsible for "concussion". It was observed that in experimental studies on cats and monkeys, the sudden acceleration produced changes in brainstem function. This was categorically defined as acceleration concussion. It was further reported that since this injury is dependent on the rate of increasing velocity, anything which dampens the blow will prevent it. This remains the principle underlying the use of crash helmets.

Walker et al.[54] in the year 1944, proposed that the underlying reason for concussion could be the presence of pressure waves which cause primary intense neuronal stimulation followed by a temporary paralytic phase. Bronstien[5] in 1946 was perhaps the first researcher to suggest the role of acetyl choline, which is normally absent in CSF and was present in large quantities in experimental and clinical head injuries. Acetyl choline in high quantities can block synaptic transmission by depolarisation of the post-synaptic membrane.[53] This remains the basis of the hypothesis regarding changes in the reticular system during concussion. Foltz and Schmidt[17] proposed, in 1956, that concussion was due to reversible blocking of the functional integrity of the brainstem reticular system. In the year 1960, Dott[15] suggested that stretching of perforators causes vasospasm, resulting in brainstem anoxaemia. Symonds, in the same year, proposed that the instantaneous loss of cerebral function was the result of sudden direct damage, either by stretching or by compression of the nerve cells or fibres in the brain. Rowbotham[47] (1964) believed that less force might cause temporary derangement of fibre conduction or synaptic transmission, without actual anatomical disruption of fibres. The experimental concussion study conducted by Ommaya and colleagues[37] in the year 1964, found slowing of circulation and disruption of blood brain barrier as perhaps the primary cause of concussion. Kaplan[25] (1966) divided the entity into two subdivisions, as physiological concussion with reversible changes and pathological concussion with irreversible changes and permanent neuronal cell damage. Kristiansen and Tandon[27] (1960) considered the latter to represent a transitional stage between concussion and contusion.

PATHOPHYSIOLOGY

Most of the clinical studies proposed that concussion is caused by acceleration and deceleration forces.[18,36] It may be considered as the mild end of the traumatic brain injury continuum with loss of consciousness and post-traumatic amnesia being brief in duration and with minimal axonal stretch. Limited stretch of axons leads to initiation of a pathophysiological process that leads to very limited cell death, depending upon the morphology of the cell. The majority of these changes are a reversible series of metabolic events.

As per Giza and Hovda,[20] the primary mechanism includes ionic shifts, abnormal energy metabolism, diminished cerebral blood flow and impaired neurotransmission. Stretching of axons often invariably results in an indiscriminate release of neurotransmitters and uncontrolled ionic fluxes. With changed ionic gradients, the cell responds by activating ion pumps to restore the normal membrane potential. Pump activation increases the glucose consumption, leading to increase in local cerebral metabolic rate of glucose in tandem with decrease in cerebral blood flow, causing disparity in supply and demand of glucose. There also appears to be impaired oxidative metabolism and decreased mitochondrial function. This leads to over utilisation of the anaerobic energy pathway and elevated lactate levels as a by product. As is well known, magnesium is necessary for ATP generation, protein synthesis and maintenance of cellular membrane potential. The intracellular magnesium level decreases in such a state and remains low for some days, leading to derangement of these functions. The sustained calcium influx results in metabolic dysfunction and energy failure. High levels of intracellular calcium combined with stretch injury can lead to an irreversible process of destruction of microtubules within the axons.[20,24]

CLINICAL PICTURE

Concussion is a short lasting event and a neurosurgeon rarely sees the patient during the period of concussion. Immediately after the injury, the patient may experience brief loss of consciousness. The muscles become hypotonic and the respiration is slowed with an imperceptible pulse and fall of blood pressure which starts returning to normal within a few seconds or a minute. The stage of confusion may last for a few minutes and the patient often complains of severe headache.

Amnesia is emerging as perhaps the most important sign for careful assessment after concussion. It may present as retrograde amnesia or anterograde amnesia. The presence and duration of amnesia, disorientation or mental disturbance has been associated with an immediate good outcome or slower recovery. The period of amnesia shrinks over time with recovery.[12,31,34]

The most common symptom associated with concussion is headache or dizziness which may last for three hours to seven days. Most frequently, it presents as concussion headache, which is a feeling of constant localised or generalised pressure in the skull. The patient may also complain of blurring of vision and increased fatigue or feeling sluggish.[1,12,22]

There may be cognitive changes with problems of attention, concentration, short-term memory, learning and multitasking. Another commonly reported symptom is that of emotional changes which may present as irritability, sadness/depression, nervousness/anxiety or silliness and euphoria. These symptoms may be brief or may last for long, in case of more significant injury.

STRUCTURAL AND FUNCTIONAL IMAGING

Concussion presents itself largely as a metabolic event and not a structural injury, therefore limiting the role of conventional neuro-imaging techniques, like CT and MRI which are almost always unremarkable following simple concussion.

Recently, functional MRI and Blood Oxygen Level Dependent (BOLD) activity have been used to study the functional changes after concussion injury. They showed decreased activity in the mid dorsolateral prefrontal

Table 1: Comparison of concussion grading scales

	Grade I	*Grade II*	*Grade III*
Cantu guidelines	Post-traumatic amnesia <30 minutes, no loss of consciousness	Loss of consciousness <5 minutes or amnesia lasting 30 minutes–24 hours	Loss of consciousness >5 minutes or amnesia >24 hours
Colorado Medical Society guidelines	Confusion, no loss of consciousness	Confusion, post-traumatic amnesia, no loss of consciousness	Any loss of consciousness
American Academy of Neurology guidelines	Confusion, symptoms last <15 minutes, no loss of consciousness	Symptoms last >15 minutes, no loss of consciousness	Loss of consciousness (IIIa, coma lasts seconds, IIIb for minutes)

cortex. Increased activity was seen in the temporal and parietal lobes after concussion, as compared to controls.[10] PET/SPECT studies done in concussed patients showed a pattern of frontal hypoactivity.[45]

Electroencephalography done in post concussion patients revealed amplitude reduction in all standard frequency bands, especially during standing.[52] N2/P3 or P300 responses have been used in cognitive event related potentials for evaluation of patients with concussion.[16,28,41,43] Auditory P3 paradigm showed mixed results with decreased P3 amplitudes.

CUMULATIVE EFFECTS

The cumulative effects of concussion are poorly understood. The severity of concussion and its symptoms may worsen with successive injuries, even if a subsequent injury occurs months or years after an initial one.[23] Symptoms may be more severe and changes in neurophysiology can occur with the third and subsequent concussions.[35] Studies have had conflicting findings on whether athletes have longer recovery times after repeat concussions and whether cumulative effects such as impairment in cognition and memory occur.[40]

Cumulative effects may include psychiatric disorders and loss of long-term memory. For example, the risk of developing clinical depression has been found to be significantly greater for retired football players with a history of three or more concussions than for those with no concussion history. Three or more concussions is also associated with a fivefold greater chance of developing Alzheimer's disease earlier and a three-fold greater chance of developing memory deficits.[7]

SECOND IMPACT SYNDROME

Second impact syndrome is related to an extraordinarily rare cascade of events in which a patient experiences a catastrophic brain injury, following a seemingly mild concussion. Sustaining a second brain injury during a period of recovery from first concussion has been linked to second impact syndrome. The pathophysiological basis of this syndrome is cerebrovascular congestion or loss of cerebral auto-regulation, leading to brain swelling and oedema.[9,11] If a second injury is inflicted within 24 hours, there is a marked breakdown of the blood brain barrier which may be the possible mechanism for the rapid swelling and oedema.[29]

RECOVERY TIME

Single concussion typically resolves in less than two weeks.[4,30-33,39]

GRADING SCALES

Three grading systems are followed most widely: One was developed by Robert Cantu, one by the Colorado Medical Society and a third by the American Academy of Neurology.[26] Each divides concussion into three grades, as summarised in the Table 1.[8]

TREATMENT

Pure concussion, being a self limiting and an extremely short lived phenomenon, does not need any treatment. When concussion merges with traumatic unconsciousness, which is a phenomenon of longer duration, investigation with CT is necessary and the appropriate treatment may be given. All patients must be kept under observation. Post-concussion syndromes like giddiness, light-headedness or difficulty in concentration may require symptomatic treatment and reassurance. The preventive measures need emphasis.

29 Cerebral Contusions

Ravi Ramamurthi, Nigel Peter Symss

INTRODUCTION

Cerebral contusion (in Latin *contusio cerebri*) is a bruise of the brain parenchyma. Localised contusion, laceration or intracerebral haematoma may occur after a head injury in any part of the brain, either singly or in combination. These may be due to coup/direct or contrecoup injury, and may be caused by the brain striking or being squeezed against dural partitions. When occurring in non-vital areas, even a large contusion may not be troublesome, while a small contusion in a vital area, like the hypothalamus, pons or medulla, may be fatal.[10] In closed head injuries, the accelerating and decelerating forces make the brain move within the cranial cavity under shearing strains. The cortex gets bruised or contused at the site directly under the force of trauma, at the opposite end (contrecoup) or in remote areas. Dural partitions play an important role in causing localised contusions.

CONTUSION

Cerebral contusion is the most frequently encountered lesion following head injury, occurring in 20–30% of severe head injuries.[28,47] Contusions are wedge shaped, with the apex pointing towards the white matter.[1,38,43] In a contusion, the pia is intact and, if the pia is torn, it becomes a laceration. Contusions can occur without laceration, but a laceration is always associated with contusion.

Based on the mechanism of injury, McCormick[43] divided contusions into various types:

- Coup
- Contrecoup
- Intermediate coup
- Gliding
- Herniation
- Fracture contusion.

Coup contusion occurs beneath the area of impact. *Contrecoup*[25] contusion occurs in remote areas, particularly in the area diagonally opposite to the site of impact (Fig. 1). *Intermediate coup* occurs within the brain and is located between coup and contrecoup contusions (Fig. 2).[36,37] Gliding contusions occur on the vertex due to the rostrocaudal movement of the brain. These contusions involve the deeper layers of the cortex more than the surface gyrus, with extension into the convolutional white matter.[44] Herniation contusions occur at the site of subfalcine, tentorial or tonsillar herniations. Medial temporal and hippocampal contusions are commonly associated with tentorial herniation. Fracture contusions

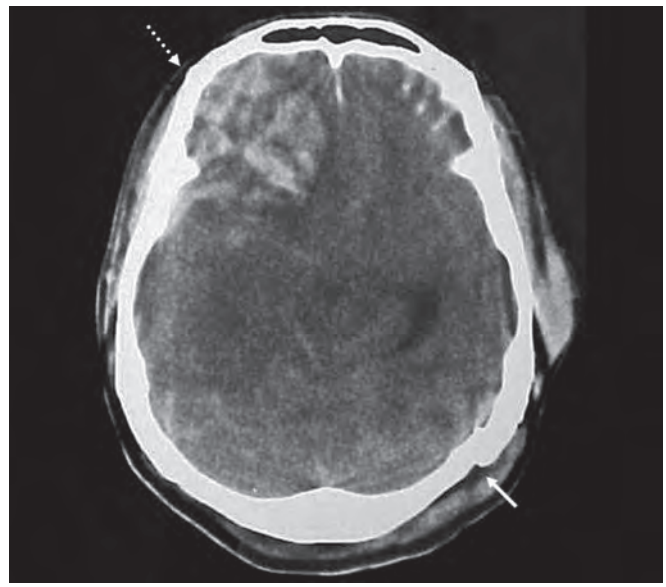

Fig. 1: Contrecoup contusion: The site of injury is shown by solid arrow. Haemorrhagic contusion is diagonally seen opposite to the site of injury—dashed arrow

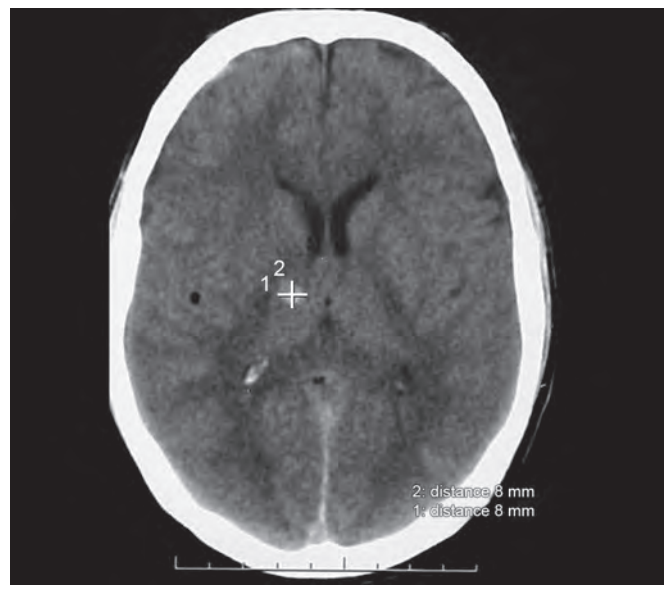

Fig. 2: CT scan showing intermediate contusions

are coup contusions that lie under the fracture line. Extensive contusion associated with subdural haematoma is called burst lobe. A burst frontal or temporal lobe is associated with high mortality and morbidity.[17]

Pathology

The gross appearance of a contusion is an area of haemorrhage beneath the pia extending, usually through the cortex, into the convolutional white matter. Severe brain contusion is often associated with non-haemorrhagic mass effect that rapidly progresses within 12–48 hours after the trauma. The pathogenesis underlying such a rapid progression of mass effect cannot be fully explained by vasogenic and cytotoxic brain oedema. Kawamata and Katayama[65] proposed that the high osmolality within the contused brain tissue generates an osmotic potential across the central and peripheral areas, causing the brain to accumulate a large amount of water. To determine the role of tissue osmolality in contusion oedema, they studied changes in tissue osmolality, specific gravity and ion concentration in contused brain in both experimental and clinical settings. They found the total ionic concentration $[Na^+] + [K^+] + [Cl^-]$ did not significantly alter at any given time. They concluded that inorganic ions do not primarily contribute to the rise in osmolality, suggesting that the increase in colloid osmotic pressure through the metabolic production of osmoles or the release of idiogenic osmoles could be the main cause of contusion oedema.[67] Hypoxia and hypotension still cause a substantial proportion of secondary injuries and many reports associate secondary brain injury with neuroinflammatory responses. Chemokines have been found in the cerebrospinal fluid but not in the brain tissue of patients following head injuries. Stefini et al., in their study, analysed if chemokines were expressed in pericontusional brain tissue in patients with moderate or severe head injury undergoing surgical evacuation of their contused brain. They found CCL2, a monocyte chemo-attractant produced by activated astrocytes, was the most strongly expressed chemokine, followed by CXCL8, CCL3 and CCL4. The chemokines CXCL10 and CCL5 were expressed at very low levels, and XCL1 was not detected. They concluded that chemokine activation occurs early following moderate or severe head injury and is present for several days after the trauma, and may contribute to neuroinflammatory exacerbation of post-traumatic brain damage in the pericontusional brain tissue.[63]

Just as in subcutaneous bruises, in brain contusion also, breakdown of erythrocytes takes place and haemosiderin pigments are released. Phagocytosis of the haemosiderin granules occurs. Macrophage activity is intense, as also the activity of compound granular corpuscles. Reactive gliosis occurs at the edges. Thus, over a period of 48 hours to several months, healing takes place in a graded manner and the contused area begins to look almost like normal tissue, yet some scarring and gliosis remain. Secondary degenerative changes following cerebral trauma include axonal disruptions, reorganisation of neuronal circuits and new growth of viable connections. Such changes may not be discernible in computed tomography (CT) scans, but may prove to be important in determining the clinical course.

Li et al. studied the effects of ginsenoside Rg1 on the expression of insulin-like growth factor-1 (IGF-1) in the brain of rats after experimental brain contusion, and concluded ginsenoside Rg1 enhances the recovery of the contused brain through increasing the expression of IGF-1.[35]

Chieregato et al. evaluated the response to an acute elevation of cerebral perfusion pressure (CPP) of the regional cerebral blood flow (rCBF) measured in the oedematous area of traumatic contusions. Their findings suggest that CPP elevation induced by norepinephrine is effective in improving contusional rCBF only in selected cases, which are represented by a subset of contusions with critical perfusion, which can be identified by rCBF measurements. Conversely, in contusions with rCBF higher than critical low values, the CPP elevation could probably induce a temporary breakdown of the blood-brain barrier, and norepinephrine leads to a vasoconstriction with a worsening of regional perfusion.[8]

LACERATION

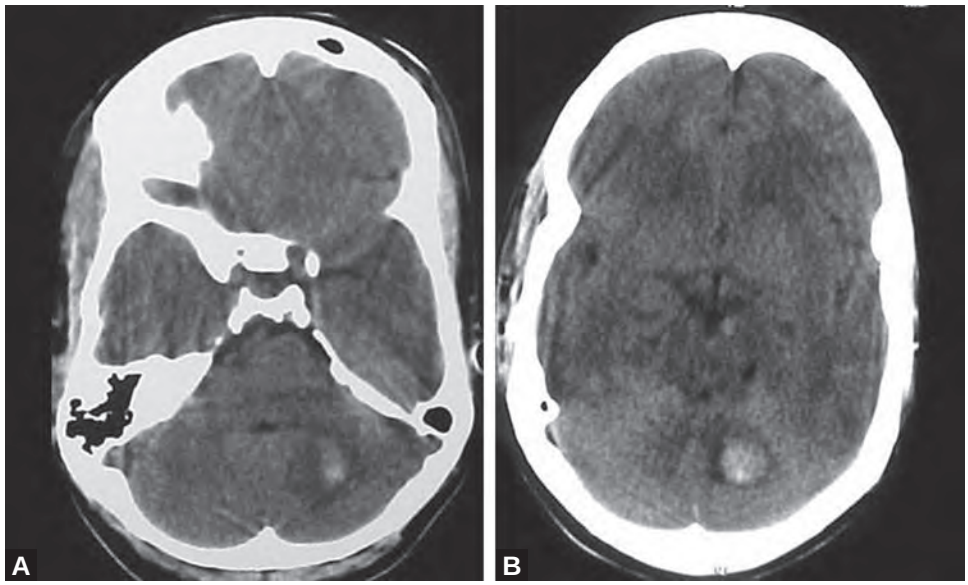
Laceration of the brain may accompany a contusion. It could be cortical-subcortical. In tangential craniocerebral wounds and in depressed fractures, bone fragments tear the dura and the subjacent brain is lacerated. The laceration varies in depth and is associated with perifocal oedema. A penetrating type of laceration is produced by high velocity missiles, the laceration taking a tubular pattern with its diameter increasing towards the exit wound. An extensive shock wave results in damage extending radially around the tubular laceration. This may involve the ventricles which may also be penetrated directly and the CSF escapes along with brain matter through the wound.[49]

Indirect injury causes lacerations due to translational impacts inside the cranial cavity. Thus, following an occipital impact, lacerations may occur in the frontal, orbital and temporal poles.

In the lacerated area, there is extensive damage to tissues. Extravasation of blood adds further damage. Degenerating brain tissue and products of blood degradation release many substances which can produce vasospasm, damage to the blood-brain barrier and cerebral oedema. The devitalised area is susceptible to infection and may result in a brain abscess, unless early antibiotic therapy is started. Contiguous areas of contusion may coalesce and form a localised intracerebral haematoma.

Clinical Features

Contusion can present with limb weakness, lack of motor co-ordination, numbness, aphasia, and memory



Figs 3A and B: Cerebellar contusion

and cognitive problems, depending on the contusion's location in the brain.[30] When the injury is moderately severe and the level of consciousness is good, a localised contusion can often be suspected from the clinical picture produced. It must, however, be emphasised that there is no consistent diagnostic feature of a contusion. It may produce no clinical deficit, depending upon its size, location, extent of associated oedema and haemorrhage and it may result in a rapidly deteriorating clinical course indistinguishable from an expanding intracranial haematoma.[16] Contusions are often multiple and frequently associated with other lesions, and hence their clinical picture is quite confusing. Large or multiple contusions involving the frontal and temporal lobes may produce raised intracranial pressure (ICP), midline shift and associated coma. Also, when the level of consciousness is depressed, the clinician has to rule out an expanding intracranial haematoma. Intracerebral haematomas are often associated with loss of consciousness due to the severity of the injury.

The CT scan and magnetic resonance imaging have made a tremendous difference to the diagnosis and subsequent management of all aspects of head injuries. Still it is essential for the neurosurgeon to recognise the clinical picture of localised damage to different parts of the nervous system, to be able to make correct judgments as to therapy and to assess progress. Hence, the clinical syndromes are discussed in detail.

Contusions of the frontal lobe, temporal lobe, sensorimotor cortex, cerebellar hemisphere and hypothalamus can clinically be made out as characteristic syndromes.

Frontal Lobe Injury

Prolonged post-traumatic confusion or a state of delirium in the earlier stages and a Korsakoff-like state in the later stages may result from contusions and laceration of the frontal lobe.[34] The patient may be disoriented and may have a memory disturbance and confabulation. Persistent nocturnal and occasional diurnal incontinence, as well as euphoria and disinhibition may closely resemble the clinical picture seen in frontal tumours. Focal motor or adversive fits with or without generalisation may occur. Often the seizures appear generalised from the onset.

Sensorimotor Contusion

Some form of pyramidal deficit is a common accompaniment of moderately severe head injuries. Upper motor neuron type of facial weakness, fall of the outstretched hand, weakness of handgrip, dragging of the foot while walking and an extensor plantar response may often be seen on one side.

Sometimes the hemiparesis is more marked and requires exclusion of an intracranial haematoma or middle cerebral or carotid artery occlusion. A detailed neurological examination may reveal varying degrees and types of cortical sensory loss. Special tests may be required to bring out associated parietal lobe dysfunction.

Cerebellar Injury

Contusions of the cerebellum or of the cerebellar peduncles are not common (Figs 3A and B). Occasionally, following a blow to the back of the head and in association with an occipital fracture, obvious unilateral cerebellar signs, like hypotonia, nystagmus and inco-ordination, are observed. When these signs occur without any impairment of consciousness or evidence of increased ICP, a space occupying posterior fossa haematoma is unlikely. Cerebellar dysarthria and an ataxic broad-based gait may also be seen. Recovery is spontaneous, early and generally almost complete.

Hypothalamic Injury

Hyperpnoea and excessive pulmonary secretions indicate associated hypothalamic damage. Unexplained severe and irreversible shock may indicate primary hypothalamic damage, but is very rare. Persistent hypothermia has been noted following widespread damage to the periventricular grey matter around the third ventricle.[68] Diabetes insipidus may follow bilateral infarction of the supraoptic nuclei and hypernatraemia may result from bilateral damage to the ventromedial nuclei.[68] Treatment of these manifestations is purely symptomatic until spontaneous recovery occurs, but severe hypothalamic damage almost always leads to a fatal outcome.

Usually contusions, lacerations and small haematomas can be treated conservatively with the patient under close observation for signs of increasing ICP. If a large intracerebral haematoma develops it needs evacuation.

Radiology

CT scanning is the imaging modality of choice for traumatic brain injury[69] because of its widespread availability, the rapid imaging time, the low associated costs and its safety. To standardise the imaging procedure, 5-mm slices should be obtained from the foramen magnum to the sella and 10-mm slices should be obtained above the sella, parallel to the orbitomeatal line.

Cerebral contusion is the commonest traumatic lesion visualised on CT scans. Dublin et al.[14] reported a 40% incidence while Zimmerman et al.[68,74] reported 21%.

The CT scan appearance in cerebral contusion depends on the presence of oedema and haemorrhages in the contused region and hence, presents a variable appearance depending on the predominance of either factor. Thus, there is a combination of high attenuation and low attenuation areas, described as 'salt and pepper appearance' by French and Dublin.[15] There is enhancement with contrast in an area of contusion due to vascular disruption. The high attenuation areas due to haemorrhage are short lasting while the low attenuation due to oedema may persist for a long time. In large contusions, ventricular displacement or compression may be seen. Chesnut et al. found the following early CT scan findings to correlate with outcome: (a) status of the basal cisterns; (b) midline shift and (c) subarachnoid haemorrhage in the basal cisterns.[7] Perfusion CT (PCT) has been found to be better in the evaluation of tissue viability than non-contrast CT, suggesting that PCT could be implemented for the early assessment of patients with traumatic brain injury.[61]

In the MR, there is a combination of different signal intensities. In non-haemorrhagic contusions, hypointense signals on T1 and hyperintense signals on T2 are observed. Haemorrhagic contusions show marked variability in signals depending on the age of the contusion.

Management

The management of patients with cerebral contusion depends on the location and extent of the contusion, and the neurological status of the patient. Patients with small or deep seated contusions can be managed without surgery, and can be followed with frequent assessment of their neurologic status. The ICP should be monitored and, if raised, should be treated accordingly. However, ICP monitoring is not mandatory in all cases.

The development of raised ICP from larger contusions may result in secondary brain injury, placing the patient at risk of further neurological deterioration, tentorial herniation and death. Rehman et al. recommend using ICP monitoring or blood flow measurements to trend patients with bifrontal intraparenchymal contusions and Glasgow Coma Scale (GCS) greater than eight to prevent clinically undetected deterioration from transtentorial/central herniation (Fig. 4).[54]

Since contusions tend to evolve, the timing of surgery with respect to the occurrence of neurological deterioration clearly affects the outcome.[42] Becker et al.[3] advocated early evacuation of traumatic intracranial haematomas and contusions for the purpose of avoiding secondary complications. Patients with GCS scores 6–8 with frontal or temporal contusions greater than 20 cm^3 in volume with midline shift of at least 5 mm and/or cisternal compression on CT scan, and patients with any lesion greater than 50 cm^3 in volume should be treated surgically, as an emergency.[55] Based on their CT classification, Marshall et al.[41] defined a mass lesion as a lesion of volume greater than 25 cm^3. They showed differential outcome between patients with evacuated and non-evacuated mass lesions (23% vs 11% favourable outcome, respectively) in their series of severe TBI patients, after resuscitation (GCS 8 or less). In contrast, Servadei et al. in their paper from the European Brain Injury

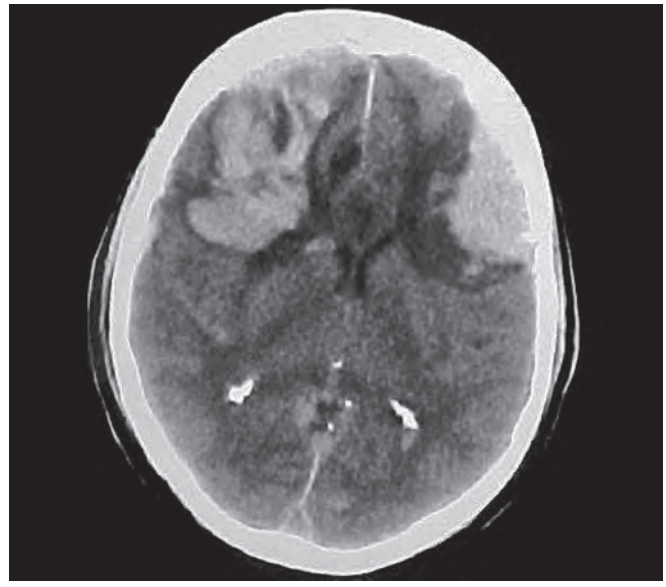


Fig. 4: CT scan of a patient with bilateral frontal contusions

Consortium[59] evaluating a series of 724 TBI patients with a GCS of 3–12 showed a 45% rate of favourable results in evacuated mass lesions versus 42% in non-evacuated mass lesions using the same classification system.

There is reluctance in operating on contusions involving a dominant lobe, and medical therapy along with frequent assessment of the neurological status can be tried in an attempt to tide the patient over the period of maximum oedema.[66] Large decompressive craniectomy with opening of the dura mater without resecting the contused brain has been performed as a treatment for cerebral contusion.[19,40] Decompressive procedures, including subtemporal decompression, and temporal lobectomy are other surgical options for patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation.

Lee et al.[32] reviewing 29 patients undergoing operation for a combination of acute subdural haematoma and severe contusion and swelling of the temporal lobe with uncal herniation reported a significant improvement in outcome with the combination of temporal lobectomy, subtemporal decompression and debridement of contused brain. Mortality decreased from 56% to 8%, with a concomitant increase in average GOS from 2.2 to 4.0.

Kawamata et al.[68] analysed the results of surgical excision of necrotic brain tissue in 182 patients with cerebral contusion registered with the Japan Neurotrauma Data Bank. Of these, 121 patients (66%; Group I) were treated conservatively, and 61 (34%; Group II) were treated surgically. Most Group II cases (90%) underwent complete excision of necrotic brain tissue and evacuation of clots. They found Group I demonstrated higher mortality at 6 months post-trauma when compared to Group II (48% vs 23%; p = 0.0001; n = 182). The results of their study do not directly confirm the superiority of surgical therapy for cerebral contusion, but shows that patients who underwent conservative therapy had a poorer outcome. They concluded that this also supports their hypothesis that early massive oedema is caused by cerebral contusion accompanied by necrotic brain tissue, indicating that surgical excision of necrotic brain tissue provides satisfactory control of progressive elevation in ICP and clinical deterioration.[68]

Prognostic Factors

These include age,[24,46,48,60] admission or post-resuscitation GCS,[18,20,46,48,53,60] presence of pupillary response/brainstem reflexes,[6,46] respiratory insufficiency,[9] raised ICP[5,6,20,46,63] and the status of the basal cisterns or third ventricle[42,68] on CT scan. Other variables significantly correlate with outcome. These include location of the lesion,[51,60] ICH volume,[9,68] GCS at time of follow-up CT,[68] lowest recorded GCS,[6] severity of surrounding oedema,[5] timing of surgery,[42,53,56] occurrence of pre-operative neurological deterioration,[42] and presence of acute hemispheric swelling or concomitant subdural haematoma.[6]

Outcome

The mortality from cerebral contusion has been reported to be from 25 to 60%.[57] Patients who are comatose at the time of surgery generally have a poorer outcome.[68]

Temporal Lobe Contusion

On account of its vulnerable situation, contusion of the temporal lobe is frequent in head injuries. Courville[11] found contusion of the temporal lobe in 70% of fatal head injuries. The pulped necrotic brain in temporal lobe contusion swells and is capable of producing a fatal increase in ICP.[4] Focal oedema and contusion of the temporal lobe may also be so severe as to compress the blood vessels in the middle fossa and lead to extensive secondary ischaemia.[34] The majority of temporal lobe injuries are associated with injuries to the frontobasal region, brainstem and other parts of the brain. However, in a few cases the injury to the temporal lobe is the major component and produces a characteristic clinical picture, justifying its description as a separate syndrome.[2,13,21,27,45,62] Temporal lobe contusion may mimic the clinical picture of an extracerebral haematoma and may present acutely or subacutely. It is frequently associated with a varying degree of subdural haemorrhage. Kristiansen and Tandon[29] pointed out that, from a pathological standpoint it is difficult to draw a clear-cut line between a lesion which could be called cerebral contusion with haemorrhage and a real intracerebral haematoma. This explains the variety of names given to these lesions like traumatic intracerebral haemorrhage,[11] pulped temporal lobe,[4] intradural haematomas,[52] exploded temporal lobe,[23] traumatic encephalomalacia[33] or simply temporal lobe lesions in head injury.[64]

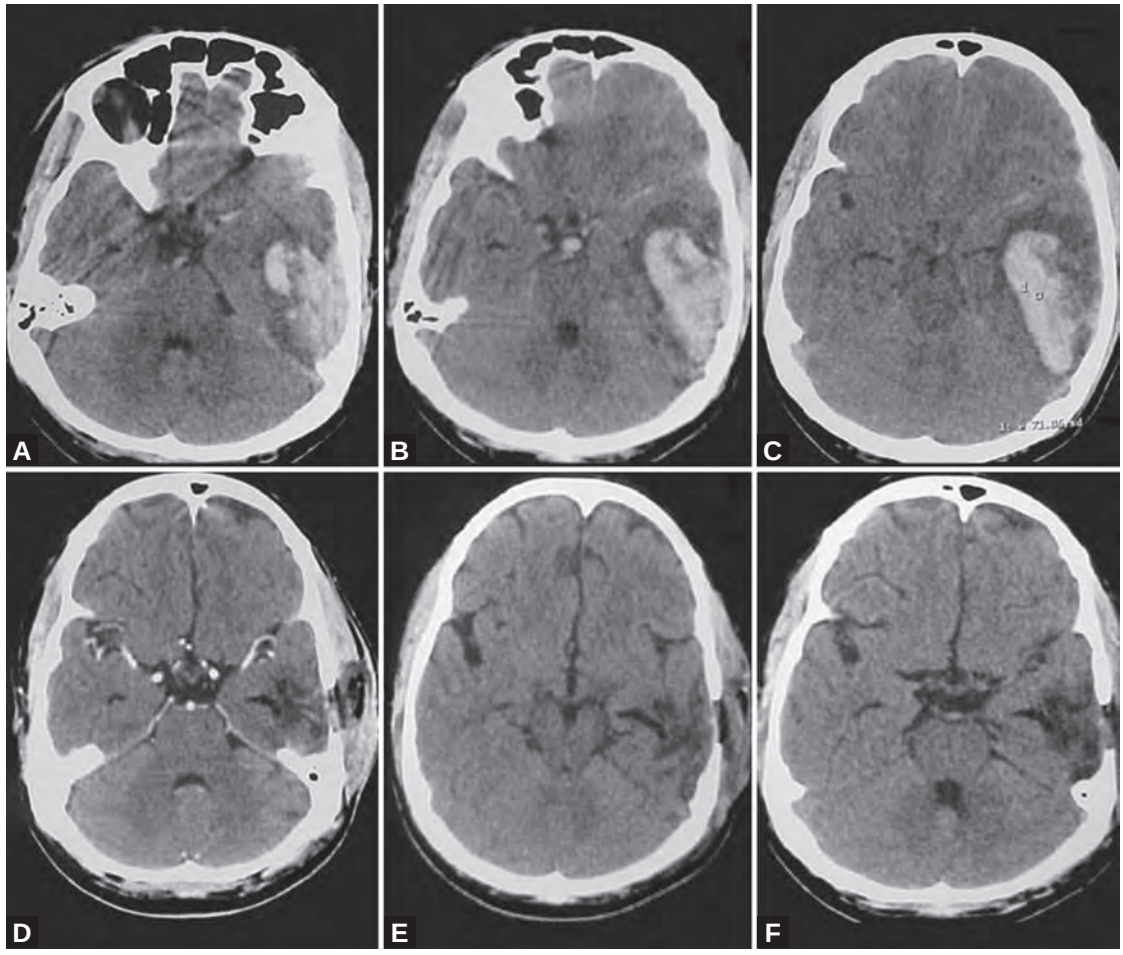
A detailed analysis by Tandon[65] of 236 surgically treated cases of post-traumatic temporal lobe lesions revealed the following important features. The lesion commonly affected persons between the ages of 20 years and 50 years (72.9%); 11.9% were below 20 years and 15.7% were above 50 years. Two-thirds of the patients were unconscious from the moment of injury till operation or death, while 17.7% had a lucid interval. Nearly two-thirds (64.2%) had hemiparesis: contralateral in 122 and ipsilateral in 30 cases. About one-half of the patients had pupillary abnormality, one pupil dilated and fixed in 28.3% and both in 19.5%.

In subacute and chronic cases, the clinical manifestations are slow in evolving. There is usually a history of a blow to the side or back of the head. The patient shows rapid improvement from the initial unconsciousness but does not progress to complete recovery. He may continue to be mildly restless, but co-operative. Often he is mute or just able to say a few words and obey simple commands. The level of consciousness may remain stationary at this stage for several days or may deteriorate following any respiratory complication or after the administration of excessive fluids.[34]

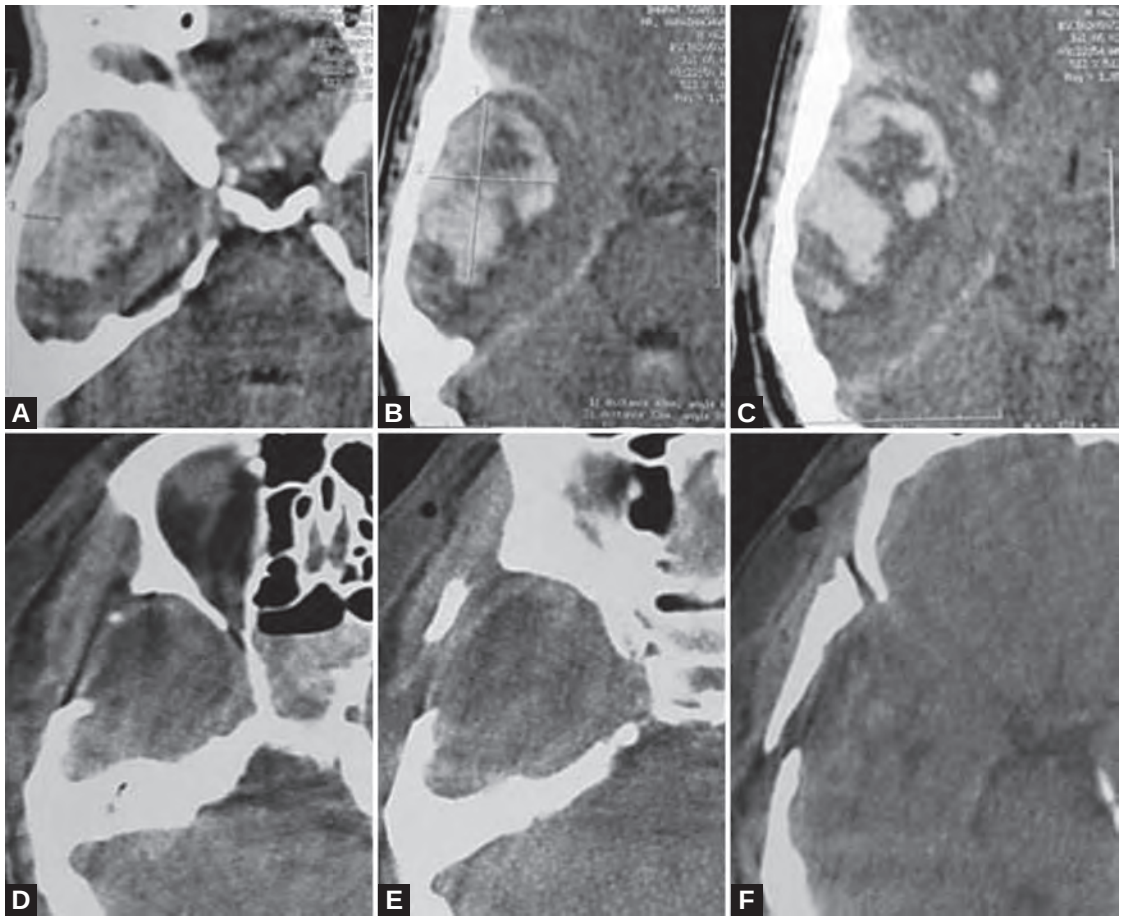
In the initial stages, the pupils are equal and reacting but later there may be a little transient dilatation and sluggish reaction on one side, or alternatively on both sides. A mild hemiparesis, with central weakness of the face, may become slowly evident. Dysphasia may be present if the dominant hemisphere has been affected. These findings suggest a mass lesion in the cranium. CT scan helps to exclude extracerebral haematomas and confirm haemorrhagic contusion with local oedema. Frank intratemporal lobe haematomas are also common. CT reveals the age and extent of the contusion, the presence of necrosis and oedema and any shift of the midline structures.

In mild cases of contusion, when the clinical condition is satisfactory, one is justified in using anti-oedema measures and keeping the patient under observation. These measures are not useful in laceration with oedema or with an intracerebral haematoma. In such cases, if the neurological condition worsens and if the CT shows a large lesion, craniotomy is indicated to decompress the temporal lobe or to remove any associated haematoma (Figs 5A to F and 6A to F). It should be stressed that temporal lobe haematomas and contusions are potentially dangerous due to the possibility of rapid herniation into the tentorial hiatus. If parts of the temporal lobe, usually the pole and anterior part, are lacerated, necrotic and non-viable, the necrotic portions are removed. If the swelling is marked and the affected side is non-dominant, sometimes one may be justified in doing partial anterior temporal lobectomy, as a method of internal decompression.[45] Patients with sizeable and acute progressive lesions requiring surgery (excluding those with small contusions seen on CT) carry a risk of mortality of 41–57%.[26,50,58,65] Those requiring surgery within 24 hours of injury also have a high mortality, prompting de Vet,[12] Vigouroux and Guillermain,[42,68] Lanksch et al.[31] and Papo et al.[50] to consider surgery within 24 hours to be futile. However, Seeling et al.[58] reported that early surgery, especially within 4 hours after injury, reduced the mortality to 30%. Tandon[65] observed that younger age, history of lucid interval and absence of pupillary abnormality are favourable prognostic factors.

The use of lobectomy in the management of severe closed head trauma[22] has been stressed by Litostky et al.[39] who found this useful, especially in younger patients with a relatively high initial GCS score who subsequently deteriorated or developed increased ICP. Basauri et al.[2] found that old age and alcoholism influenced the ultimate recovery adversely. Recovery is quite slow. Profound disturbance of recent memory is seen out



Figs 5A to F: (A to C) Pre-operative CT scan of the brain showing haemorrhagic contusion in the temporal lobe causing mass effect and midline shift. (D to F) Post-operative CT scan of the brain showing complete resolution of the contusion



Figs 6A to F: (A to C) Pre-operative CT scan of the brain showing haemorrhagic contusion in the temporal lobe. (D to F) Post-operative CT scan of the brain showing complete resolution of the contusion

of proportion to other mental changes. Dysphasia may recover only partly.

30 Diffuse Axonal Injury

Rajkumar, Vivek Kumar Vaid, Ashok Kumar Mahapatra

INTRODUCTION

Diffuse brain injury is defined as the pathology of head-injured patients who are unconscious from the moment of impact without any evidence of space occupying intracranial lesions on computed tomography (CT) scan or magnetic resonance imaging (MRI).

Diffuse brain injury can exist in four principle forms, viz.

1. Diffuse axonal brain injury
2. Diffuse hypoxic/anoxic/ischaemic injury
3. Diffuse swelling
4. Diffuse vascular injury

Of these four forms, diffuse axonal injury (DAI) is the one that is gaining the most attention particularly because of its relationship in its less severe forms to the sequelae of subtle brain injury.

Traumatic TDAI was first described by Strich[38] as "diffuse degeneration of white matter following severe head injury". This was a study on patients having severe dementia following head injury and the term DAI was not used by her. In a later publication she described shearing of nerve fibres as a cause of brain damage due to head injury.[39] This was based on the observation of retraction bulbs on microscopic examination of autopsy material. Two decades later, Adams et al.[1] in a paper entitled "Diffuse axonal injury due to non-missile head injury in humans: an analysis of 45 cases" described the pathological hallmarks of this condition. They went ahead to study the condition in subhuman primates and compared the lesions to those observed in humans.[2] Since then, a number of terms have been used to describe (TDAI) and include "shearing injury", "diffuse white matter shearing injury" and "inner cerebral trauma". The current definition includes severely head-injured patients with normal scans, tissue tear haemorrhages, traumatic subarachnoid and intraventricular haemorrhages, diffuse brain swelling and unilateral swelling with midline shifts.

PATHOPHYSIOLOGY

It is caused by angular or rotational acceleration and deceleration inertial effects and not by contact phenomena.[47] The severity of axonal damage is related to the magnitude, duration and onset rate of the angular acceleration.

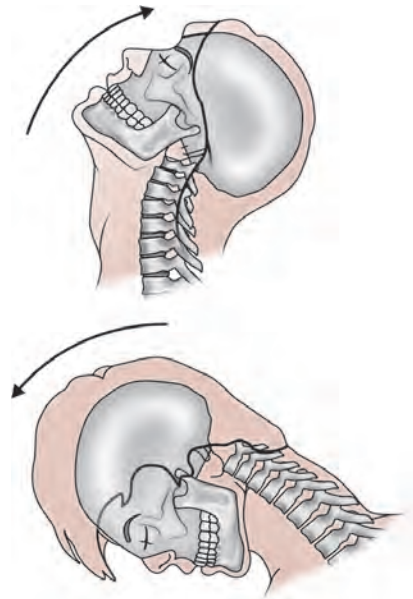

Fig. 1: Sudden acceleration-deceleration impact can produce rotational forces that lead to diffuse axonal injury

The pathophysiology of DAI was first described by Holbourn in 1943,[21] using two-dimensional gelatin moulds. His work led to the understanding that shear injury is not induced by linear or translational forces but rather by rotational forces.[14,47] Sudden acceleration-deceleration impact can produce rotational forces that affect the brain (Fig. 1). The injury to tissue is the greatest in those areas where the density difference is the greatest. For this reason, approximately two-thirds of DAI lesions occur at the grey-white matter junction (Fig. 2).

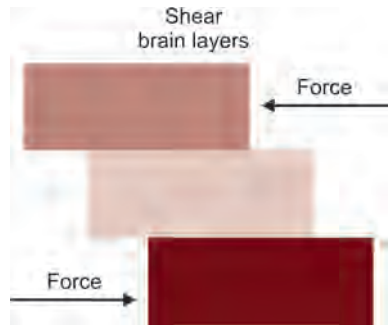

Fig. 2: Shear injury greatest in areas where the density difference is the greatest such as the grey-white matter junction

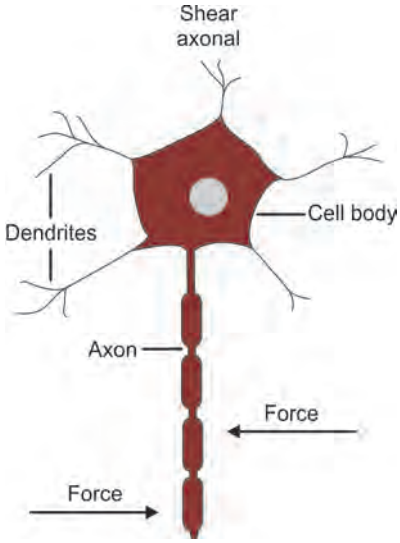

Fig. 3: Shear injury causing primary injury (axotomy) to the neuron

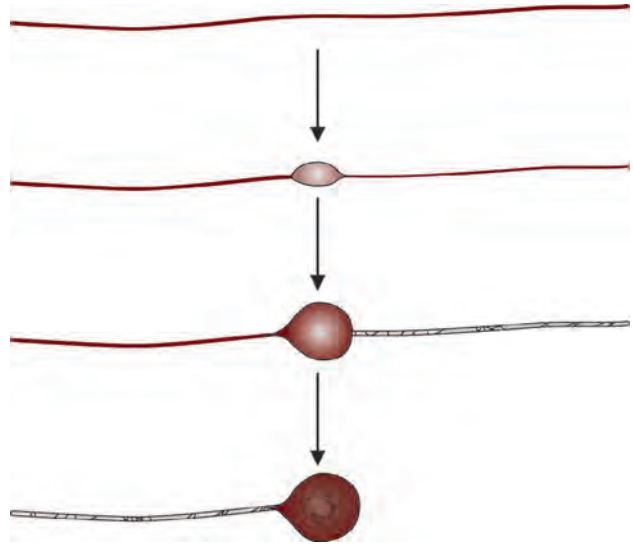

Fig. 4: Shear injury causing focal alteration of the axoplasmic membrane, leading to impaired axonal transport, axoplasmic swelling, with the axon subsequently splitting into two pieces and formation of a retraction ball

When shearing forces occur in areas of greater density differential, the axons suffer trauma (Fig. 3); this results in oedema and in axoplasmic leakage (which is most severe during the first 2 weeks following injury). The exact location of the shear-strain injury depends on the plane of rotation and is independent of the distance from the centre of rotation. Conversely, the magnitude of injury depends on the following three factors:

1. The distance from the centre of rotation.
2. The arc of rotation.
3. The duration and intensity of the force.

The true extent of axonal injury typically is worse than that visualised using current imaging techniques. On the microscopic level, the axon may not completely be torn by the initial force, but the trauma still can produce focal alteration of the axoplasmic membrane, resulting in impairment of axoplasmic transport. This would lead to axoplasmic swelling, with the axon subsequently splitting into two pieces and forming a retraction ball—a pathologic hallmark of shearing injury.[25,36-38,40-43] The axon would then undergo Wallerian degeneration (Fig. 4). Dendritic restructuring might occur, with some regeneration possible in mild-to-moderate injury.

Within the basal ganglia, the effect of DAI produces parenchymal atrophy brought on by shrinkage of astrocytes in the lateral and ventral nuclei, with sparing of the anterior and dorsomedial nuclei, the pulvinar, the centromedian nuclei and the lateral geniculate bodies. Cholinergic neurons have been found to be slightly more susceptible to trauma than are neurons belonging to other neurotransmitters. Peripheral lesions usually are smaller than central lesions. The lesions typically are ovoid or elliptical, with the long axis parallel to the direction of the involved axonal tracts. A high association is seen between thalamic injury and DAI.

Remaining surviving axons may be vulnerable due to secondary events leading to hypoxia, ischaemia and subsequent release of excitatory amino acids and free radicals. The ultimate event in neuronal death appears to be the influx of calcium ions.[40] Büki et al.[10,11] had demonstrated calpain-mediated spedin proteolysis in the pathogenesis of traumatically induced axonal injury. In another study they reported Cytochrome C release and caspase activation in TDAI.

Both silver staining and beta-amyloid precursor protein immunohistochemical staining have proven useful in the pathologic identification of DAI lesions.[9-11,19,20,29]

Diffuse axonal injury was classically believed to represent a primary injury (occurring at the instant that the trauma occurred). It has become apparent, however, that the axoplasmic membrane alteration, transport impairment and retraction ball formation may represent secondary (or delayed axotomy) components of the disease process. Accumulation of the precursor protein of amyloid[9,20] within 2 or 3 hours of injury indicates the beginning of delayed axotomy. The process may continue for 24 hours or more. The exact mechanisms causing secondary injury are not yet known, but it is postulated that there may be increased permeability to Ca^{2+} in the region of Ranvier's node or, alternatively, within the internal cytoskeleton itself.[40] This leads to disorganisation of microtubules and neurofilaments, hence a block in axonal transport resulting in axonal focal swelling. Later on, the classical axonal bulb appears (Figs 5A and B). Any measure which prevents or minimises secondary axotomy can improve clinical outcome.

PATHOLOGY OF TRAUMATIC DIFFUSED AXONAL INJURY

McCormick[27] described three "classic" lesions which characterise severe TDAI. These were earlier described as characteristic pathological lesions in TDAI in 1981 by Adams et al.[1]

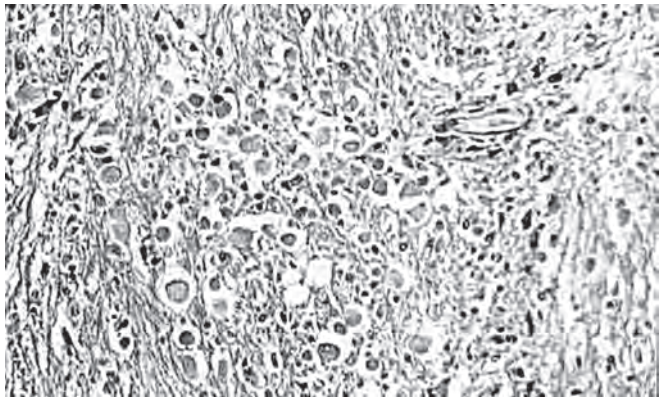

Fig. 5A: Shear injury leading to focal alteration of the axoplasmic membrane, leading to impaired axonal transport, axoplasmic swelling and subsequent formation of retraction balls as visible under the microscope (20x)

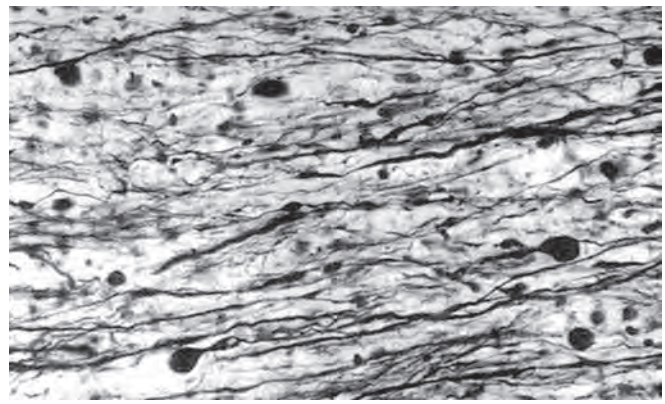

Fig. 5B: Shear injury leading to focal alteration of the axoplasmic membrane, leading to impaired axonal transport, axoplasmic swelling and subsequent formation of retraction balls as visible under the microscope (40x)

- Reactive axonal "retraction" balls.
- Haemorrhagic necrosis in the dorsolateral quadrant of the rostral brainstem.
- Haemorrhagic necrosis in the corpus callosum.

The axonal swellings are the microscopic hallmark of TDAI. They become apparent within hours after injury and may persist for a year or more. Typically, the process is diffuse and bilateral, involving the lobar white matter at the grey-white matter interface. The most commonly involved area is the frontal and temporal white matter. Microglial stars develop in these damaged sites and may eventually replace the swollen axon. Degeneration of long tracts will evolve and ventricular dilatation will follow.[25,27,36,37]

The lesion in the dorsolateral quadrant of the rostral brainstem is usually haemorrhagic and involves the dorsolateral/lateral part of the midbrain and the rostral pons, almost always involving the superior cerebellar peduncle.

The lesion in the corpus callosum usually lies lateral to the midline and affects the inferior and posterior part of the corpus callosum. These lesions may extend over several centimetres. The callosal injury may be focal, segmental or may extend from the genu to the splenium.

Other sites of involvement are the caudate nuclei, thalamus, tegmentum and internal capsule. Internal capsule lesions are associated more frequently with haemorrhage than are with other lesions and are secondary to the proximity of the lenticulostriate vessels.

Adams et al.[3] described the stages of involvement according to the anatomic location of the lesions:

- Stage I—This involves the parasagittal regions of the frontal lobes, the periventricular temporal lobes, and, less likely, the parietal and occipital lobes, internal and external capsules, and cerebellum.
- Stage II—This involves the corpus callosum in addition to the white-matter areas of stage I. Stage II is observed in approximately 20% of patients. Most commonly, the posterior body and splenium are involved; however, the process is believed to advance anteriorly with increasing severity of disease. Both sides of the corpus callosum may be involved; however, involvement is more frequently unilateral and may be haemorrhagic. The involvement of the corpus callosum carries a poorer prognosis.
- Stage III—This involves the areas associated with stage II, with the addition of brainstem involvement. A predilection exists for the superior cerebellar peduncles, medial lemnisci and corticospinal tracts.

INCIDENCE OF TRAUMATIC DIFFUSED AXONAL INJURY

The incidence of TDAI will be higher at autopsy than would be obvious on radiographic (e.g. CT and MRI) examination.[25,36-38,40-43] Adams et al.[3] found TDAI in 28% of non-missile head injuries histologically at autopsy. In 20% of these cases, the diagnosis of TDAI could not have been made without microscopic examination. The CT incidence of TDAI in various series varies from 2.4% to 15.5%.

Diffuse axonal injury represents approximately one-half of all intra-axial traumatic lesions.[14,15,18,25,33,43] No racial or sex predilection exists. DAI can occur at any age. Some studies suggest that DAI may occur *in utero*, if a pregnant woman is subjected to sufficient force.[49]

CLINICAL PRESENTATION

Patients with severe TDAI present in an unconscious state from the onset of trauma, with the majority of severely injured patients showing a combination of generalised extensor posture or flexion. About one-third of TDAI patients may recover sufficiently from the initial head injury to talk before lapsing into coma.

Classically, DAI has been considered a primary-type injury, with damage occurring at the time of the accident. Research has shown that another component of the injury comprises the secondary factors (or delayed component), since the axons are injured, secondary swelling occurs, and retraction bulbs form.[25,36-38,40,42,43] Of patients

with DAI, 80% demonstrate multiple areas of injury on CT scans.

The degree of microscopic injury is usually considered to be greater than that seen on diagnostic imaging and the clinical findings reflect this point. DAI is suggested in any patient who demonstrates clinical symptoms disproportionate to his or her CT scan findings. DAI results in instantaneous loss of consciousness and most patients (> 90%) remain in a persistent vegetative state, since brainstem function typically remains unaffected. DAI rarely causes death.

Compared with patients who have an epidural haematoma, patients with DAI are less likely to have a lucid interval. There is little association between DAI and the presence of skull fractures; in addition, the existence of DAI has no bearing on whether a subarachnoid or subdural haemorrhage is present.

The chance that a patient will remain in a persistent vegetative state is greater when lesions are observed in the supratentorial white matter, corpus callosum and corona radiata. The prognosis also worsens as the number of lesions increases. For the almost 10% of patients who experience a return to any form of normal function, this improvement will be seen within the 1st year. DAI lesions can result in deficits in information transfer between the two hemispheres through the corpus callosum, commonly resulting in auditory deficits.

DIAGNOSTIC STUDIES

Magnetic resonance imaging is the preferred examination for diagnosis of DAI (particularly with gradient-echo sequences), although CT scanning may demonstrate findings suggestive of DAI and is more practical and available.[13,16,17,30,32,34,50] Studies have indicated that MRI can play a role in predicting the length of coma in DAI patients.

Conventional Radiography

No specific findings related to DAI can be made using conventional radiography; however, other signs of head trauma can be appreciated, such as facial bone fractures or fluid levels within the paranasal sinuses. The degree of confidence is low, since conventional radiography cannot demonstrate subtle soft-tissue changes. While radiographs can clearly demonstrate skull fracture, this is not helpful in DAI, since DAI is rarely associated with skull fracture.

Computed Tomography Scan

Among patients eventually proven to have DAI, 50–80% have a normal CT scan upon presentation. Delayed CT scanning may be helpful in demonstrating oedema or atrophy, which occurs later. Small petechial haemorrhages, located at the grey-white matter junction, as well as in the corpus callosum and brainstem, are characteristic of CT scan findings in the acute setting (Fig. 6).

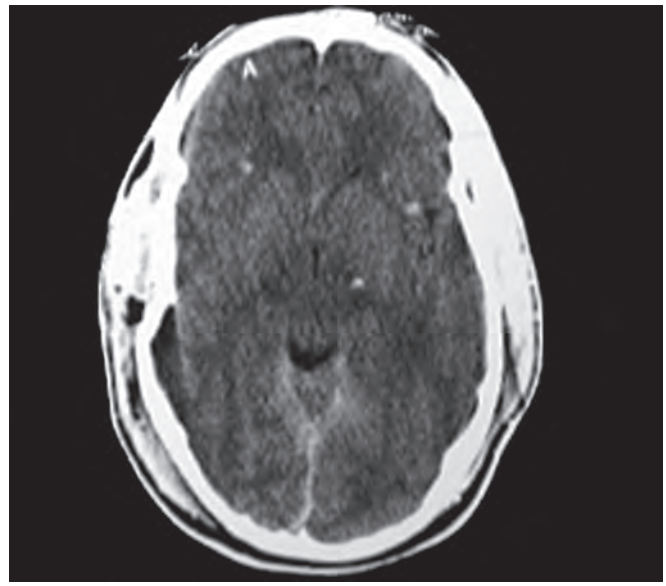

Fig. 6: Non-contrast CT scan of a trauma patient demonstrates multiple petechial haemorrhages consistent with DAI, characteristically located at the grey-white matter interface

The following CT scan criteria have been suggested by Wang et al.[43]

- One or more small intraparenchymal haemorrhages less than 2 cm in diameter, located in the cerebral hemispheres
- Intraventricular haemorrhage
- Haemorrhage in the corpus callosum
- Small focal areas of haemorrhage less than 2 cm in diameter, adjacent to the third ventricle
- Brainstem haemorrhage.

One may also observe small focal areas of low density on CT scans; these correspond to areas of oedema occurring where shearing injury took place.

MRI is more sensitive in the detection of subtle soft-tissue abnormalities; however, CT scanning is more available and practical in the current medical environment and is, therefore, the "mainstay of acute investigation of head injury" according to Teasdale.[41]

The degree of confidence in CT scanning is moderate, since the only finding may be petechial haemorrhage, and fewer than 20% of patients with DAI demonstrate this finding on CT scanning alone. When petechial haemorrhages are observed with the appropriate clinical findings, the sensitivity of CT scanning in the detection of DAI is high.

Magnetic Resonance Imaging

Recommended sequences include T1-weighted, T2-weighted, T2-gradient-echo, proton density-weighted and diffusion-weighted images.[5,6,12,30,35,46,50]

- T1-weighted images are helpful for anatomic localisation; however, non-haemorrhagic lesions may be isointense to surrounding tissue. Haemorrhagic lesions appear hyperintense on T1-weighted images. Non-haemorrhagic lesions appear hyperintense

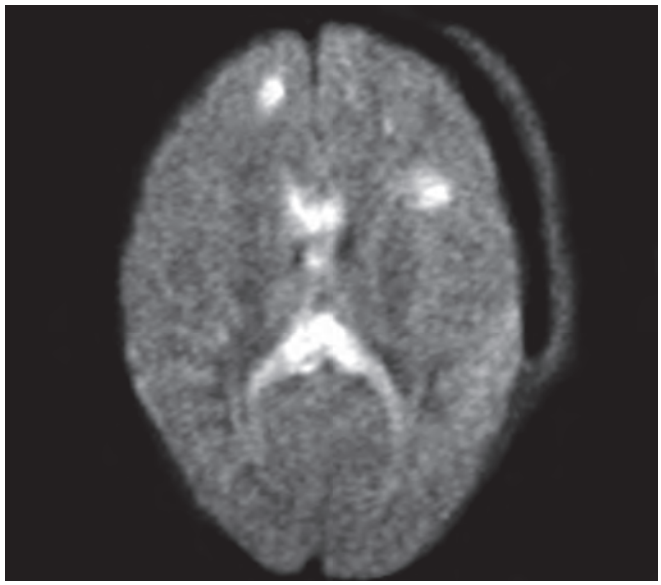

Fig. 7A: MRI diffusion sequence demonstrating multiple foci of abnormal increased signal at the grey-white matter junction and within the corpus callosum in a patient with DAI

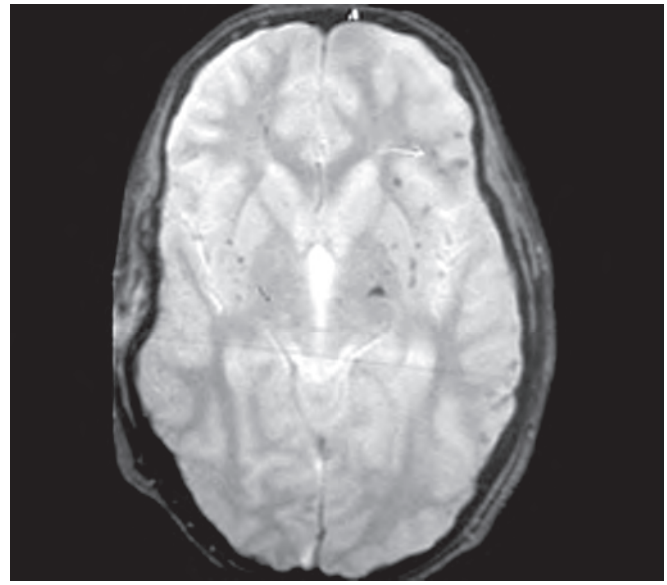

Fig. 7B: Gradient-echo axial MRI demonstrating numerous small foci of diminished signal consistent with the paramagnetic effect of the haemoglobin content of many acute haemorrhages

on T2-weighted sequences. Diffusion-weighted sequences can reveal hyperintensities in areas of axonal injury (Fig. 7A).

- Gradient-echo sequences are particularly useful in demonstrating the paramagnetic effects of petechial haemorrhages. Gradient-echo imaging can often demonstrate signal abnormality in areas that appear normal in T1-weighted and T2-weighted spin-echo sequences (Fig. 7B). For this reason, gradient-echo imaging has become the mainstay of MRI examination for patients with suspected shearing-type injuries. The abnormal signal on gradient-echo images can persist for many years after the injury.
- The most common MRI finding is the presence of multi-focal areas of abnormal signal (bright on T2-weighted images) in the white matter in the temporal or parietal corticomedullary junction or in the splenium of the corpus callosum.
- Other areas that are frequently abnormal include the dorsolateral rostral midbrain and the corona radiata. Eventually, non-specific atrophic changes are observed.

One area of research has been magnetisation transfer imaging. Studies have reported that the magnetic transfer ratio has shown promise in identifying areas of injury not visible on the above MRI pulse sequences. This may allow the radiologist to appreciate a truer representation of the degree of microscopic injury. Studies have indicated that MRI can play a role in predicting the length of coma in DAI patients. The volume of white-matter lesions has been correlated to the degree of injury, as measured by MRI. MRI has also been used to quantify cerebral blood flow in damaged areas of the brain, thus predicting injury severity. The degree of confidence is high, since abnormal signals in the characteristic locations discovered in the clinical setting of recent trauma, leaves little doubt about the diagnosis of DAI.

A novel MRI technique, diffusion tensor imaging (DTI),[4,7,8,22,24,26,28,31,45,48] permits the examination of white matter integrity *in vivo* through observing the amount of water diffusion within biological tissues.[11,30] A direct comparison between DTI-detected white matter integrity changes and histological findings in an animal model of axonal injury[26] suggests that DTI may become a valuable imaging tool for detecting DAI.

Two diffusion parameters[8] are used for characterising white matter integrity, namely fractional anisotropy (FA), a ratio from 0–1 that represents the degree of alignment of the underlying fibres[31] in a voxel, and mean diffusivity that represents the presence of overall restrictions to water diffusion (Fig. 8).

Nuclear medicine currently has no role in the routine diagnostic workup of patients with possible DAI; however, studies have suggested that iodine-123 single-photon emission CT (SPECT) imaging[23] demonstrates areas of hypoperfusion in regions of known injury and reveals additional areas of injury not visualised with MRI.

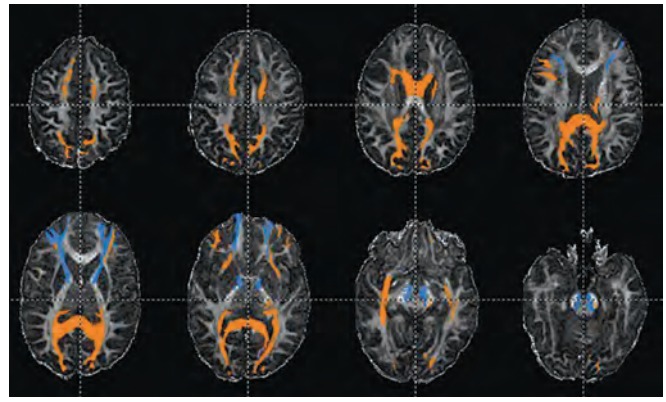

Fig. 8: Diffusion tensor imaging "a newer concept" in radiological assessment of diffuse axonal injury

DIFFERENTIAL DIAGNOSIS

One must consider the following in the differential diagnosis of TDAI:

- Cavernous angioma of the brain
- Embolic and/or haemorrhagic stroke
- Multiple sclerosis.

MANAGEMENT OF TRAUMATIC DIFFUSE AXONAL INJURY

The following basic principles are applicable for managing patients with DAIs:

- Immediate establishment of ventilation and circulation at the site of accident
- Aggressive monitoring and control of intracranial pressure (ICP)
- Intensive care to achieve neuronal recovery.

The patency of the respiratory tract must be maintained or established and restoration of adequate ventilation should have top priority. Endotracheal intubation is often necessary to protect the airway and maintain ventilation.

Cerebral perfusion pressure (CPP) is defined as mean arterial pressure (MAP) minus ICP. CPP = MAP - ICP. The initial approach to maintain MAP (hence CPP) is the establishment and maintenance of circulatory volume by administering an adequate volume of crystalloids, colloids or blood products, as appropriate.

It is important to identify the patients who are at risk of developing increased ICP. Risk factors which can predict intracranial hypertension are:

- Subarachnoid haemorrhage
- Midline shift
- Abnormal mesencephalic cistern

Patients with subarachnoid haemorrhage are twice as likely to develop increased ICP. Detection of an abnormal mesencephalic cistern in the CT scan indicates that patients are thrice as likely to develop increased ICP. The more the midline shift more is the chance of developing raised ICP.

Severe head-injured patients with a normal CT scan have a 10–15% chance of developing intracranial hypertension after 72 hours, hence serial follow-up CT scans are necessary. Most investigators report improved outcome with treatment at 15–20 mmHg levels. ICP may be measured from intraventricular, intraparenchymal, subdural and extradural sites (Fig. 9).

Various medical methods for controlling increased ICP are:

- Position of the patient's head
- Osmotherapy and diuretics
- Hyperventilation
- Barbiturates
- Cerebrospinal fluid drainage.

PROGNOSIS

In TDAI, little can be done about the primary axonal injury. Measures to reduce ICP and measures to prevent or reverse the secondary insults (such as oedema, ischaemia and secondary neuronal death) should be taken aggressively as it may improve the mortality and morbidity in TDAI.

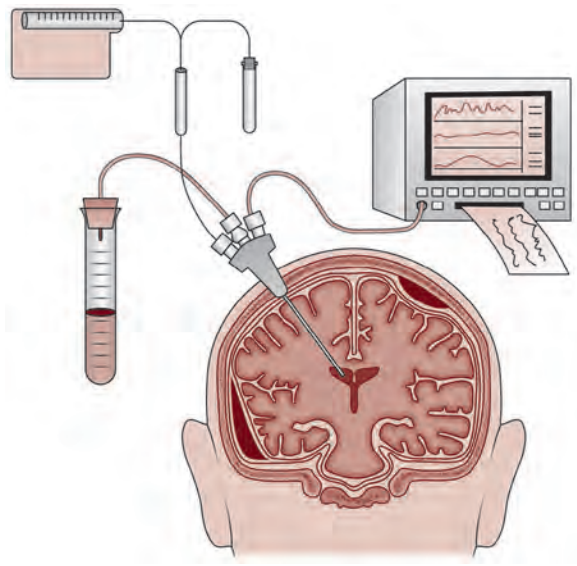

Fig. 9: Mechanism for intracranial pressure monitoring; also helpful to drain cerebrospinal fluid so as to lower intracranial pressure

Wilberger et al.[44] found a correlation between the admission GCS score and the eventual outcomes of patients with DAI.

In severe head injury, 42% of the patients died or were severely disabled or vegetative at discharge. Mild-and-moderate head injuries did well; no patient was severely disabled or vegetative at discharge, and no patient died. In patients with brainstem or corpus callosum tissue tear haemorrhages, the outcome was especially poor. Paterakis at al.[35] in 2000 had reported the outcome in patients with TDAI and highlighted the prognostic role of MRI.

CONCLUSION

Traumatic diffuse axonal injury is characterised by reactive axonal "retraction" balls, haemorrhagic necrosis in the dorsolateral quadrant of the brainstem and haemorrhagic necrosis in the corpus callosum. DAI is caused by angular acceleration or rotational acceleration and the extent of axonal damage depends upon the magnitude, duration and rate of angular acceleration. Classically, these patients become unconscious immediately upon impact, and the CT scan shows focal punctuate haemorrhages in the cerebral white matter, basal ganglia, corpus callosum or dorsal part of the brainstem. MRI is superior to CT scan in demonstrating non-haemorrhagic contusions. Maintenance of cerebral perfusion and aggressive monitoring and control of ICP is the mainstay of medical management.

31 Fat Embolism

Krishna Reddy A

INTRODUCTION

Fat embolism is a pathological entity characterised by occlusion of multiple blood vessels with fat globules, which presents clinically with manifestations of diffuse pulmonary insufficiency causing hypoxia, neurological dysfunction, pyrexia, tachycardia, tachypnoea and petechiae occurring 12–48 hours after trauma. The incidence of fat embolism presenting clinically varies between 0.5% and 2% of patients with long bone fractures and 5–10% of patients with multiple fractures. Subclinically it is present in almost all cases of long bone fractures. Drummond and his co-workers reported an incidence of 0.5% in 1800 children with pelvic and long bone fractures.[6]

Zenker,[28] in 1862, was the first to report the presence of fat in the lungs of a trauma victim. In 1865, Wagner, who produced fractures in dogs, was the first to recognise that the fat actually originated from the bone marrow. Von Bergmann,[4] first recognised the entity clinically in 1873. Lehman and Moore[17] suggested a metabolic origin of this complication in 1927. Sevitt,[26] a British pathologist, proposed a distinction between pulmonary and systemic fat embolism and emphasised the more serious clinical consequences of the latter. Peltier,[23] an American surgeon, suggested that the morbidity from fat embolism is in large part a result of hydrolysis of neutral fat to highly toxic fatty acids and that the inflammation produced by these substances is the primary cause of the clinical manifestations.

AETIOLOGY

The causes of fat embolism syndrome (FES) are as follows:

Traumatic Factors

- Fractures
  - Long bone
  - Pelvis
- Burns and subcutaneous adipose tissue injuries
- Surgery
  - IM nailing
  - Total hip and knee arthroplasty

Non-Traumatic Factors

- Procedures
  - Cardiopulmonary resuscitation (CPR)
  - Cryosurgery of bone
  - Intraosseous fluid and drug
  - Administration
  - Liposuction
  - Intra-operative autotransfusion
  - Lymphangiography
  - Hysterosalpingography

Diseases

- Sickle cell anaemia
- Acute pancreatitis
- Fatty liver
- Diabetes
- Immunosuppression.

Drugs

- Lipid emulsions
- Intra-arterial cisplatin
- Long-term steroid administration.

PATHOPHYSIOLOGY

Two theories have been proposed to explain the pathophysiological basis of the FES:

1. Mechanical theory of Guass
2. Biochemical theory of Lehman and Moore.

According to the mechanical theory, FES results because of physical obstruction of the pulmonary and systemic vasculature by the embolised fat which is liberated into the circulation from the bone marrow at the site of the fracture. This theory basically explains the FES of traumatic origin. The presence of cardiac septal defects will increase the incidence of systemic embolism.

According to the biochemical theory, which explains the non-traumatic origin of FES, fat globules in the pulmonary or systemic circulation originate from the lipids normally present in the blood. Physiochemical alterations of these compounds can lead to FES by two mechanisms: toxic and obstructive. Circulating free fatty acids (FFAs) are directly toxic to the pneumocytes and the capillary endothelium. However, controversy exists with regards

to the origin of the FFAs.[13] Peltier[23] proposed that they are produced by the action of the pulmonary lipase on the circulating neutral fat. Others have postulated that the offending FFAs originate from the body fat. FFAs are usually cleared by the liver and in the presence of shock and associated hypovolaemia and sepsis, the blood flow to the liver is reduced, which leads to the exacerbation of the toxic effects of the FFAs.

The obstructive mechanism attributes the development of FES to the coalescence of chylomicrons into fat globules, which is triggered by the mediators released at the site of fracture.

Neither the mechanical nor the biochemical theory alone can provide an entirely satisfactory explanation for the genesis of FES and it is therefore proposed by Peltier that shortly (hours) after an initial obstructive process, a second phase begins during which FFAs exert their toxic effect on the organs where neutral fat had embolised initially. Currently, this seems to be the most widely accepted view.

Additional mechanisms appear to contribute to the pathophysiology of FES. These include activation of the platelets, coagulative and fibrinolytic cascades.

Pathological examination revealed alveolar oedema and haemorrhage with multiple fat droplet depositions and fibrin thrombi. Fat droplets were also found in the arterioles and/or capillaries in the lung, kidney and brain. Immunohistochemical staining identified inducible nitric oxide synthase (iNOS) in alveolar macrophages.[14]

CLINICAL FEATURES OF FAT EMBOLISM SYNDROME

There are several puzzles in this otherwise distinctive clinical syndrome. It strikes the young and healthy, whereas older patients do not seem to carry any risk. It usually occurs after lower limb and pelvic fractures and not with upper limb fractures. It is more frequent with closed fracture and after multiple fractures. Although FES usually presents as a multisystem disorder, the most seriously affected organs are the lung, brain, cardiovascular system and skin.[24]

Fat embolism syndrome is a serious manifestation of fat embolism that involves a cascade of clinical signs, such as petechial haemorrhages, deteriorating mental status and progressive respiratory insufficiency, usually occurring within 24 hours of injury.[1]

Clinically, FES consists of a triad of hypoxia, confusion and petechiae appearing in a patient with fracture, 1–2 days after the trauma.[10] Sixty percent of all cases of FES are seen in first 24 hours after trauma and 90% of all cases appear within 72 hours. The various clinical forms of FES are summarised in Table 1.

NEUROLOGICAL ABNORMALITIES

Neurological impairment occurs in about 85% of cases who die of FES. The incidence in survivors is quite variable. It begins as an acute confusional state and then progresses to stupor and coma. Seizures have been

Table 1: Various forms of fat embolism syndrome

Clinical form	*Occurrence after injury (%)*	*Onset after injury*	*Clinical presentation*	*Mortality rate (%)*
Subclinical	60	12–72 hours	Non-specific or absent symptoms Moderate hypoxaemia (PaO_2 < 80 mmHg on room air) Moderate elevation of $AaDO_2$ (> 20 mmHg on room air) Moderate hypocapnia ($PaCO_2$ < 30 mmHg during spontaneous breathing) Moderate decrease of platelet count (<2 lakhs/μL)	0
Non-fulminant subacute (classic form)	Single fracture (1–5) Multiple fractures (5–10)	12–96 hours	Dyspnoea, fever, tachycardia, petechiae, cerebral signs, hypoxaemia (PaO_2 < 60 mmHg on room air), anaemia, thrombocytopenia and coagulation abnormalities, lung opacities on chest X-ray	0-5
Fulminant	< 0.2	Few hours	Acute cor pulmonale, frank pulmonary oedema, moderate to severe hypotension, cerebral signs, severe hypoxaemia, acidosis	> 50

Reproduced with kind permission from Levon MC. Chapter on fat embolism in Anesthesiology clinics of North America 1993.

reported. Focal neurological deficits can be identified, including anisocoria, hemiplegia, scotomata, apraxia, aphasia and conjugate eye deviation. In spite of the severe initial neurological impairment, clinical recovery usually occurs and permanent deficits are infrequent. Focal neurological findings typically follow the encephalopathy. Focal lesions, such as pontine haemorrhage have been described. Cerebral oedema and decorticate posturing have been reported in severe cases and are reversible, suggesting that in certain cases, intracranial pressure monitoring may be beneficial. Focal neurological findings should be investigated to rule out lesions caused by associated head injury. Persistent alteration of consciousness or seizures are bad prognostic signs.[16]

Pathologically, diffuse petechial haemorrhages are present, predominantly in the white matter of the cerebral cortex. Ischaemic lesions are present and fat globules are demonstrated in the micro-vessels. A less frequent lesion is a non-haemorrhagic ischaemic micro-infarct that is randomly distributed and not regularly associated with intravascular fat globules.

DIAGNOSIS

Diagnosis of this syndrome is mainly a clinical one, that requires accumulation of clinical and laboratory findings and exclusion of other diagnostic possibilities. Several diagnostic criteria have been reported in the literature, of which two have found wide acceptance:

Gurd and Wilson's Criteria[12]

- Major clinical features: petechial rash, respiratory insufficiency and cerebral involvement.
- Minor clinical features: pyrexia, tachycardia, retinal changes, jaundice and renal changes.
- Fat macroglobulaemia.

Presence of one major clinical feature, four minor clinical features and fat macroglobulaemia, gives a positive diagnosis.

Lindeque et al. Criteria[18]

- PaO_2 < 60 mmHg in room air
- $PaCO_2$ > 55 mmHg or pHa < 7.3
- Spontaneous respiratory rate > 35 breaths/min (even after adequate sedation)
- Clinical signs of increased work of breathing (dyspnoea, accessory muscle use) and tachycardia.

The presence of at least one of these findings in a patient with long bone fracture(s) establishes the diagnosis of FES.[5]

Laboratory Tests

Cytological examination of urine, blood and sputum after Sudan or Oil Red O staining may permit detection of fat globules, either free or in macrophages, within 2–3 hours after collection of the specimen. Lipiduria, although it indicates a significant degree of fat embolism, cannot reliably identify patients with FES. Examination of the blood for fat globules by cryostat test helps in the diagnosis when it is performed on the blood obtained from the pulmonary vasculature, where a large amount of fat globules are trapped.

Quantification of the cells containing fat droplets in broncho-alveolar lavage material was helpful in diagnosing clinical fat embolism. At least 63% of the captured cells contained fat globules in patients with proven FES, whereas lipid was present in less than 2% of lavage cells in those without the clinical syndrome. The lavage is to be done with the help of a fibreoptic bronchoscope that is wedged in a sub-segmental bronchus, preferably in the one with maximal infiltrates on the chest radiograph.[9] Other laboratory tests like measurement of blood lipids, activated complement levels and coagulation parameters will not help in the diagnosis of the FES.

Chest radiograph abnormalities are non-specific, lag 12–24 hours behind clinical symptoms and occur in only 30–50% of affected individuals. Diffuse, evenly distributed fleck like shadows and increased interstitial and alveolar densities are the typical findings and give the radiograph a snow-storm appearance. Ventilation/perfusion scans show sub-segmental perfusion defects, a finding highly suggestive of FES. The typical mottled appearance of these scans may be present even in the absence of the radiographic signs. Most patients presenting with a normal initial radiograph develop radiographically evident abnormalities within 72 hours of injury and most cases showed radiographic resolution within 2 weeks of hospitalisation, although chest imaging plays little role in the clinical management of fat embolism.[20,25]

CT scan of the brain in cases of cerebral fat embolism may demonstrate diffuse oedema and low density areas with haemorrhages. Focal abnormalities on the scan may correlate with focal neurological signs. Despite encephalopathy and focal abnormalities, CT scan may be normal in some cases.

MRI is indicated in any patient with orthopaedic injuries who manifests an unexplained acute alteration in mental status, despite a normal head CT[14] MRI of the brain may show hypointense signals on T1-weighted images and hyperintense signals on T2-weighted images. On the diffusion-weighted scans, areas of fat embolism were revealed as bright spots on a dark background ("starfield" pattern). High-intensity lesions in the brain on diffusion-weighted images may serve as an early-appearing and more sensitive indicator of the diagnosis of fat embolism, in the clinical context of long bone injury without head trauma.[15,21,27] MRI with T2 and diffusion-weighted images revealed multiple, reversible brain lesions, suggesting vasogenic oedema and is consistent with this entity. At present, MRI is the most sensitive technique to evaluate cerebral fat embolism.[7] The diagnosis of cerebral fat embolism is shown here to demonstrate infarcts, secondary to fat emboli more intensely than T2 weighted sequences 24 hours after

the onset of symptoms. Embolic foci are hypointense on apparent diffusion coefficient mapping, consistent with cytotoxic oedema associated with cell death and restricted water diffusion. This technique increases the sensitivity for detecting cerebral fat embolism and offers a potentially important tool for its diagnosis.[19]

Single photon emission computed tomography may demonstrate hypoperfusion in areas of fat embolism.[5,8] Transcranial Doppler was found to be useful for monitoring of the microemboli moving in the cerebral vessels. Embolus monitoring may thus serve as a diagnostic tool in evaluation of cerebral fat embolism after long bone fractures. In addition, intra-operative monitoring with transcranial Doppler may identify the emboligenic surgical manoeuvres during the surgical procedures of cardiopulmonary bypass and carotid endarterectomy.[2]

DIFFERENTIAL DIAGNOSIS

Several of the cardiac, respiratory, neurological and haematological conditions need to be differentiated clinically from the FES. Careful review of the symptomatology, laboratory and radiological findings and monitoring of the haemodynamics and oxygenation status will help in the diagnosis of fat embolism. However, pulmonary abnormalities are difficult to differentiate. Pulmonary infiltrates appearing within hours of injury were caused by contusion and/or aspiration of gastric contents, those between the 1st and 2nd post injury day were primarily due to FES and/or ARDS and a delay of more than 2 days in the appearance of infiltrates indicated an infectious aetiology.[5]

MANAGEMENT

Prevention

Most authors recommend early fixation of all fractures after stabilisation of the systemic complications, although this approach has neither decreased nor worsened the incidence of FES in these patients. In a patient who had a concomitant head injury—some studies suggest that early definitive stabilisation is safe, while others have indicated that it is deleterious. Surgery can best be carried out after the patient has been fully resuscitated. There are theoretical concerns regarding occurrence of cerebral fat embolism during fixation of fractures. Most cerebral fat embolism, however, appears to occur at the time of fracture and is not necessarily produced during its stabilisation.

Treatment of Established Fat Embolism Syndrome

Treatment is largely symptomatic with therapy for respiratory failure similar to that used in the management of acute respiratory distress syndrome. Corticosteroids have not been found to be of significant benefit.[11]

The mainstay of treatment of FES is supportive. Administration of adequate humidified oxygen (titrated against the patient's needs by monitoring the arterial blood gas levels), together with fluid replacement and physiotherapy to the chest to minimise the risk of secondary infection, are instituted when FES is suspected. Mechanical ventilation is advocated wherever there is an indication. The hypoxaemia is addressed by manipulating the concentration of inspired oxygen and using positive end expiratory pressures. Antibiotics may be required for secondary infection and tracheostomy and nutritional support may be needed if prolonged ventilation is necessary.

Specific methods of treatment like administration of heparin, dextran and anticytokines have been tried with some encouraging results, but none of these interventions has been widely adopted, because each has a substantial risk of harmful and occasionally catastrophic side-effects.

Corticosteroids most likely decrease the incidence of FES by limiting the endothelial damage caused by the FAAs, but they are associated with significant risk of complications of infection and gastrointestinal bleeding, as many of the patients have multiple injuries. Clinical trials in which steroids were effective used a dose of 30 mg/kg body mass of methyl prednisolone administered on admission and repeated once at 4 hours or 1 gm on admission and two more doses at 8 hour intervals. However, FES is primarily a disease of the respiratory system and current treatment is therefore mainly with oxygen and meticulous mechanical ventilation.[22] Evidence suggests that corticosteroids may be beneficial in preventing FES and hypoxia but not mortality in patients with long-bone fractures. The risk of infection is not increased with the use of corticosteroids. However, methodological limitations of these trials necessitate a large confirmatory randomised trial.[3]

PROGNOSIS

Mortality from FES is usually between 5% and 15%, but it may be as high as 36% in patients who require mechanical ventilation. Patients with FES may have persistent neurological deficits, although spontaneous recovery may occur gradually over many months. Approximately 25% of patients experience permanent neurological deficits. Restoration of normal arterial oxygen levels commonly provides little relief from the CNS signs and symptoms, which usually resolve only 24–48 hours after pulmonary manifestations. Severe hepatic and renal involvement may result in permanent impairment in function of these organs.

ACKNOWLEDGEMENTS

Author is thankful to Dr K Jagan Mohan Reddy (MCh, Neurosurgery) for his help in preparing the manuscript, to Smt Susheela Devi for her secretarial help.

32 Paediatric Head Injuries

Chidambaram Balasubramaniam, Ramachandran B

INTRODUCTION

"A neonate is not a small child; neither is a child a small adult."

Trauma has become a leading cause of mortality and morbidity the world over. Although children and adults are affected by traumatic injuries the problems are worse in the paediatric age group due to the long-term implications of the mortality and morbidity. In our country, we are winning the war against infections and malnutrition as in most countries. This means trauma will soon become a serious public health problem—just as infections and malnutrition were several years ago.[83] Not only is the spectrum of injuries in children different from those encountered in adults, the overall spectrum of injuries varies from region to region around the world too, to cite an example, child abuse, —mercifully, —is not as prevalent in India as it is in the West, but falls from a height seem to be more common in our country.

Central nervous system (CNS) injuries are the most common among the various system injuries and, among the various system injuries these are the leading cause of mortality. Measurable deficits occur even after mild to moderate head injury but are markedly greater after severe injury.[35,103] In addition, the presence of an intracranial injury contributes significantly to the mortality resulting from polytrauma.[20,98]

In the United States, 52% of the total mortality in children is due to trauma, making it the leading cause of death in children.[83] More than half the patients who come to the emergency department for the management of head injuries are children.[29] Duhaime and his colleagues have reported that non-accidental injuries account for nearly 25% of all head-injured children under the age of 2 years.[27] The problem seems to be no less in our country,—in the year 1990, in Rajasthan alone, 10,456 accidents were reported.[83] Around 50,000 deaths occur every year as a result of traffic accidents. "The death rate per 10,000 vehicles in India is 45 while it is only 3 in developed countries".[78] The number of traffic accidents in our country is increasing. From 55,478 in 1960 it had increased to 220,000 in 1990.[79]

In a retrospective study spanning three years, 23.6% of all admissions to the paediatric surgical ward were for the management of trauma. In this analysis 2,100 children who were 13 years or younger admitted for the management of trauma, the commonest injury was cranial injury which constituted 84.3% of all cases (78.9% had isolated cranial injury while cranial with extracranial injuries formed 5.4%). This was followed by abdominal injury and skeletal injury. In this study not only was head injury the commonest nature of injury, it was also the leading cause of mortality. Around 161 out of these 2,100 (7.7%) children died, the cause in 145 of these 161 being head injury.[83]

In a study of 100 children admitted consecutively for the management of head injury, 50% were in the age group of 1–4 years while 33% were in the group 4–10 years.[95] Some significant and interesting facts have emerged from this study. A sizable percentage of the injuries were clustered around the weekend (15% on Friday, 18% on Saturday and 24% on Sunday) and half the injuries occurred between 4 PM and midnight. Around 73% of the injured children hailed from nuclear families; this may be a reflection on the breakup of the joint family system which has been the norm in our country for centuries. The spectrum of injuries in our country is different from that seen in other countries. While traffic accidents are more common in the Western countries, falls are more common here.[83,95] Fall from a height,—which was the leading cause of the head injury,—was seen in 68 out of the 100 children studied and falls from balconies were seen in 31 of this group of 68 children. Traffic accidents were the cause of the head injury in only 28%. In an analysis of 22,215 cases of head injuries seen over a period of a quarter of a century, 2,666 (12%) were in the age group 0–15 years with a male-female distribution almost equal. The distribution was as follows: Falls 1,173 (44%); Road accidents 988 (37%); Birth injuries 112 (4.2%); Coconut injuries (i.e. coconut falling on the head) 60 (2.2%); Miscellaneous injuries 335 (12.5%).[78] In an analysis of 297 children (0–10 years) admitted to a neurosurgical unit, the incidence of head injuries was found to be 22%. But the male to female ratio was found to be 2.5:1. 67% were due to falls while 24.4% were due to traffic accidents.[9] "...given the human and economic importance of head injury, there is an urgent need to acquire more epidemiological information on the management and outcome of head injury of all grades of severity."[22,91]

From the foregoing it is apparent that the incidence of traumatic injuries of the brain are on the increase in our country and may soon be the leading cause of mortality and morbidity.

GROWTH AND DEVELOPMENT

The child, and in particular the brain, undergoes constant and dynamic changes from birth to adulthood. These changes have serious implications when the brain suffers a traumatic injury. The changes are seen in body weight, head size, blood volume, tracheal size, etc. These have direct implications on the management of the child who has sustained a polytrauma or head injury.

First is the fact that the child's brain has just commenced the process of "growth" and any insult at this stage may leave lasting deficits. "In the adult, the insult takes place in a developed organ system, whereas a child's injury affects the brain and also the subsequent maturation process",[30] but this process is not without its own advantages. It is comparatively easier for the uninjured parts of the brain to "take over" the functions of the injured portions. Neuronal plasticity which, in simple terms, is the process by which the CNS develops and recovers from an insult is active till growth is complete. In spite of neuronal plasticity coming into play in the recovery process, the outcome depends on the age at the time of injury, severity and the location of the injury.[30] The two other important factors which have a direct influence on the outcome are the increased water content in the child's brain and the process of myelination which continues past the second year.

The other, which is equally important, concerns the changes which take place in the growing child,—for instance the size of the head in relation to the size of the body. These changes are to be factored into the equation when dealing with a child who has sustained an isolated head injury or polytrauma. A consideration of these will help in understanding the implications of the trauma as it concerns the child as a whole and in particular with reference to the brain and the response of the child to the trauma.

The physiologic differences between a child and an adult and the changes which take place as the child grows can be considered with reference to the whole body, i.e. airway, breathing, etc. and the CNS. A consideration of the former is of fundamental importance in the management of the injured child since the requirements change as the child grows.

The child's airway shows many differences as compared to the adult airway. The airway is small not only because children are smaller, but also because of anatomical factors. The tonsils and adenoids are large and contribute in no small measure to narrowing the airway, particularly if they are enlarged. In addition, the nasal passages are smaller as is the mouth and the supraglottic area. The practical implications of these are the need for the availability of different sizes of endotracheal tubes at the time of intubation.[20] The larynx, in addition to being soft, is also more anteriorly placed; this makes it more susceptible to narrowing when the neck is flexed or extended. Since the head is large compared to the body size in a child, the laryngeal dimensions are not at their maximum when the child lies supine. Distally, the anatomy of the trachea, too, has similar implications. The trachea is narrow at the level of the cricoid and the soft vocal cords are highly prone to damage at the time of intubation. A trauma victim with loss of the airway dies in 3–4 minutes. However, if the airway is patent and the patient is unable to breathe, death ensues in 5–7 minutes, whereas untreated hypovolaemic shock leads to death in 10 minutes. The impact of these on the day to day management are as follows: (a) the presence even of a small amount of food, blood or mucus can compromise an already small airway; (b) the neck needs to be only slightly flexed,—if needed at all,—so that the head is in the sniffing position for intubation. The presence of spinal cord injury without radiologic abnormality (SCIWORA) has to be borne in mind when intubating.

The consumption rate of oxygen in children is twice that of adults. The infant heart can increase the output, in a state of shock, only by increasing the heart rate and not the stroke volume. So, in situations of hypoxia/hypovolaemia the blood pressure and perfusion are maintained only by an increase in the heart rate.[11,20] Hence, the child may go into irreversible hypovolaemic shock without manifesting hypotension. Overt clinical features of shock are seen when around 25% of the circulating volume is lost and a loss of 50% results in death.

The relative surface area of children is greater than adults. So, hypothermia is a real danger when the clothes are removed to evaluate the injuries in a child who has sustained polytrauma.

The changes in the CNS parallel the changes seen in the rest of the body. The head and the brain of infants and children are larger and heavier with respect to the body compared to adults. This, combined with soft cervical vertebrae and a supple neck, leads to an increased susceptibility to injuries of the upper cervical spine. These also explain why shearing injuries are more common in children. Although the cerebral blood flow (CBF) and cerebral metabolic rate of oxygen ($CMRO_2$) are lower than the adult rate, in infants these increase to more than 50% the adult values by the age of 3–4 years. These reach the adult values by the mid teens.[11]

From the above discussion it will be apparent there are differences between the CNS of children and that of adults. These exist not only at the anatomic level but also at the physiologic level.

CLINICAL ASPECTS

Evaluation and Management of the Injured Child

Under this section, the author will discuss the basics of clinical evaluation of the injured child—particularly the head-injured child. The important physiologic aspects have already been discussed and the specific entities will be covered subsequently.

The care of the head-injured child follows the basic principles of polytrauma care. The child with a head

injury may have also suffered damage to other systems that can be life threatening and will affect the outcome. Immediate management consists of the Primary Survey and Initial Resuscitation. The purpose of the Primary Survey is to rapidly identify and treat the life threatening injuries. In the absence of signs of cerebral herniation or progressive neurological deterioration, no specific steps are recommended for the treatment of intracranial hypertension at this stage.[12] The steps in assessing and evaluating a child who has suffered a traumatic injury are as follows: (a) airway, (b) breathing, (c) circulation, (d) disability (neurologic) evaluation, (e) exposing and evaluating all injuries and (f) fluid therapy for resuscitation. Hypoxia and hypotension have been shown to be associated with increased morbidity and mortality and should, therefore, be treated aggressively.[51]

Airway management takes priority over all others. The specific aspects of the paediatric airway have been discussed earlier. If an oral airway has to be passed, occlusion by the tongue is avoided by passing the airway sideways along the tongue and then rotating it by 90°. The head is maintained in a position of slight flexion to avoid compression of the larynx. If there is any doubt about securing the airway the child is intubated immediately. A seriously head-injured child is assumed to have cervical spine injury as well, and it may be impossible to rule this out immediately. Care should be taken, while clearing the airway and during further manoeuvres, not to flex or hyperextend the spine. The airway should be cleared by a "jaw thrust" technique, rather than a "head tilt–chin lift" manoeuvre.[7] A hard cervical collar of the appropriate size should be applied and, whenever this is removed, the cervical spine must be stabilised manually by an assistant. The child's neck should not be hyperextended for intubation nor is it necessary. The neck is slightly flexed— "sniffing position"— prior to intubation. Gentle pressure on the cricoid not only facilitates intubation it also prevents distention of the stomach by the air entering the stomach during preoxygenation and also aspiration of the stomach contents. A non-cuffed endotracheal tube is preferred because the narrow cricoid acts as a natural cuff and also to prevent pressure necrosis by the cuff. There is no quick way or short cut to intubation; all precautions are to be taken. Hundred per cent oxygen is administered immediately after clearing the airway. Bag-valve-mask ventilation should be avoided unless there are signs of impending herniation. The following guidelines can be used to decide which patients should receive assisted ventilation with an endotracheal tube[5,31] (Table 1).

In suspected anterior skull base or facial fractures an orogastric rather than a nasogastric tube is passed lest the latter enter the intracranial cavity through the fracture site. The patient is assumed to have a full stomach and therefore is at risk of vomiting and aspiration.

Table 1: Guidelines for intubation

- A GCS of 8 or less
- A decrease in the GCS >2, irrespective of the initial GCS
- Anisocoria >1 mm
- Cervical spine injury compromising ventilation
- Apnoea
- Loss of the cough and/or gag reflexes
- Inability to clear upper airway secretions
- Uncontrollable seizures

In addition, since cervical injury cannot be ruled out (even if the child has a normal cervical spine X-ray) adequate precautions must be taken during intubation to maintain spinal immobilisation.[66] This is best done by having an assistant perform in-line manual stabilisation. The preferred technique of intubation is rapid sequence orotracheal intubation under direct vision by an experienced person. The size of the endotracheal tube can be determined using the formula "(age in years + 16) ÷ 4". Endotracheal intubation is a noxious stimulus that results in increased intracranial pressure (ICP). Unless the patient is in a state of cardiopulmonary arrest, he should always be prepared with adequate pre-oxygenation, sedation and neuromuscular blockade. The drugs used should be chosen after considering the haemodynamic stability of the patient, since some will cause or exacerbate hypotension. These have been elaborated in Table 2. If the patient has signs of increased ICP, and is haemodynamically stable, a combination of fentanyl, lidocaine, vecuronium and thiopentone sodium may be used. Thiopentone sodium causes dose dependent hypotension and should be used with caution if the blood pressure is already low. Lidocaine is used because it blunts the rise in ICP during intubation.[41] Succinyl choline is contraindicated since it can increase the ICP. Similar to the adult patient, avoidance of hypotension and hypoxia are the key to decreasing mortality.

Table 2: Drugs for intubation of the head-injured child

• Haemodynamically unstable	Fentanyl 2–4 mcg/kg
	Lidocaine 1 mg/kg
	Vecuronium 0.2–0.3 mg/kg
• Haemodynamically stable	Fentanyl 2–4 mcg/kg
	Lidocaine 1 mg/kg
	Midazolam 0.1–0.2 mg/kg
	Vecuronium 0.2–0.3 mg/kg
• Raised ICP	Fentanyl 2–4 mcg/kg
	Lidocaine 1 mg/kg
	Thiopentone sodium 4 mg/kg
	Vecuronium 0.2–0.3 mg/kg

Once the patient has been intubated, the child should be ventilated with 100% oxygen and maintained

normocapnic, unless there is evidence of intracranial hypertension. The patient should be sedated adequately with short-acting agents, such as midazolam. Neuromuscular paralysis should generally be avoided, unless it is required to provide safe transport or resuscitation.

Breathing is best evaluated by observing the chest movement. The two common factors which compromise breathing in children are: (1) soft chest wall which makes them more susceptible to chest visceral injuries and (2) gastric distension resulting from aerophagy. The cardiovascular system should be rapidly assessed by examination of the heart rate, blood pressure, quality of the peripheral and central pulses, peripheral perfusion and cerebral perfusion.[7] Patients with isolated head injuries seldom are in shock except in certain special situations. Therefore, if a child with head injury is in shock, other sources of blood loss, such as intra-abdominal injuries, should be sought. The primary objective in the patient with shock is to restore the intravascular volume as quickly as possible. Fluids should not be withheld in the patient in shock due to concerns of worsening cerebral oedema. If intravenous (IV) access cannot be established quickly, an intraosseous needle has to be inserted to administer fluids. As soon as IV access is established, a bolus of an isotonic crystalloid (normal saline or lactated Ringer's solution), 20 ml/kg, should be given rapidly. Dextrose containing fluids should not be used for boluses since they will lead to hyperglycaemia, which is associated with a poor outcome. If the patient does not respond after two 20 ml/kg boluses of crystalloid, a colloid or blood can be administered. Patients can also be in shock due to cardiac contusion or spinal cord injury, which may require inotropic therapy. There is strong evidence, in both adults and children, to suggest that even brief periods of hypotension are associated with a poor outcome. Therefore, hypotension must be treated aggressively, initially with fluids and then with inotropic support if required. The following table (Table 3) gives the 5th percentile of systolic blood pressure at different ages—these are the minimum acceptable.

As discussed earlier, the cardiac response to a fall in the circulating volume is different in children and adults. Further, the non-atherosclerotic vessels of children respond well to pressor agents resulting in a normotensive response rather than the hypertensive response seen in adults. In cases of polytrauma or severe head injury, as soon as IV access is established, blood is drawn for basic investigations. The neurologic evaluation is done next (the details of neurologic evaluation will be discussed subsequently). In a child with a Glasgow Coma Score (GCS) of 8 or below, intubation is carried out in the emergency room and good IV access is established. At times the child may be brought to the emergency department with signs of raised ICP. Clinical signs of increased ICP, such as unilateral or bilateral pupillary dilatation, asymmetric pupillary reaction, posturing or other evidence of neurological deterioration, should be treated aggressively. The patient should be hyperventilated acutely and, if the intravascular volume has been replaced adequately, mannitol administered intravenously (up to 1 gm/kg). Anti-oedema measures are commenced if clinically indicated even before a CT scan is obtained. Urinary catheter is placed to assess the urine output even if anti-oedema measures are not instituted in the emergency room. The clothes are then removed and the child is evaluated as a whole. A good look at the spine, posterior chest and abdominal walls can be obtained by logrolling the child keeping in mind the possibility of spinal injury. It is important to avoid hypothermia when doing this since hypothermia is tolerated poorly. The relatively large surface area in children predisposes not only to hypothermia but also to increased insensible water loss. In addition, under conditions of increased stress hypothermia results in acidosis and a worsening of the metabolic status. After resuscitation, basic investigations should be done, including electrolytes, glucose, haematocrit and blood gases. After the initial resuscitation the patient is transported to the nearest available CT scanner. If sedation is required, a short-acting agent should be employed. Paralysis is used only if sedation alone prevents safe transport to the scanner. Paralysis should never be used alone since it has no sedative effect.

Even under the best of conditions the neurologic evaluation of a child is not as easy as that of an adult. A good history should be obtained after the child has been stabilised. The mechanism of injury should be noted. In addition the behaviour immediately after the injury is important. If the child had been unconscious from the time of injury it indicates a serious injury like diffuse axonal injury. This is only more difficult in a child, as the parents and the doctor are under stress when dealing with a child who has sustained an injury. The ubiquitous GCS and the AVPU scoring systems have been evolved to make objective assessment easier. The GCS is a more comprehensive scoring system although AVPU may be easier to use. The AVPU scoring is as follows: A—Alert; V—Responds to verbal commands; P—Responds to pain and U—Unresponsive.[7] The GCS is more popular and more comprehensive. The adult scoring system has been modified for use in children. In this scoring system the best response in three categories [Eye opening (E), Motor response (M) and Verbal response (V)] is noted and a score is given to each of the responses and the individual scores are totalled. The highest score is 15/15 and the lowest 3/15. A score of 8 or below indicates a state of coma and 3/15 "death". The adult and the paediatric score are as indicated in Table 4.[58]

Table 3: Systolic blood pressure at different ages

Age	*Systolic BP*
0–1 month	60 mmHg
>1 month to 1 year	70 mmHg
>1 year	70 + (2 x age in years) mmHg

Table 4: Glasgow coma score in adults and children

Score	*Adults*	*Children*
Eye opening:		
4	Spontaneous	Spontaneous
3	To command	To sound/speech
2	To pain	To pain
1	None	None
Motor response:		
6	Obeys spontaneous	Spontaneous/ obeys
5	Localises	Localises
4	Withdraws	Withdraws
3	Abnormal flexion	Abnormal flexion
2	Abnormal extension	Abnormal extension
1	None	None
Verbal response:		
5	Oriented	Appropriate for age
4	Confused	Crying but consolable
3	Inappropriate words	Irritable/Restless
2	Incomprehensible sounds	Lethargic
1	None	None

It has to be emphasised here that children cannot be expected to respond in the same way adults do. This is so because the motor and verbal skills are age dependant.[74] A child who is "normal" may not have a score of 15/15. Based on a 14 point GCS scoring system the best response which can be expected in the various ages has been enumerated. This has been given in Table 5.[74] The GCS, it will be apparent, is not as reliable in children as it is in adults. It is "not accurate for children less than 5 years of age and is even more limited in children less than 3 years".[74] But the GCS scores have been shown to be inversely related to the number of positive findings on CT, i.e. patients with low GCS have more abnormal CT findings than those with higher GCS.[45] In children, absence of physical signs does not exclude an intracranial injury.[38] It has also been found that there may be a disparity between the clinical and the CT findings. No single clinical feature can predict what abnormality the CT may disclose in children. In addition, it is difficult to correlate the clinical findings with the CT findings.[25,70,73] These go to show the difficulty in evaluating an acutely head-injured child as opposed to adults where evaluation is easier. This brings to the fore that CT should be done even if there is a suspicion of abnormality and the neurosurgeon should be "liberal" in ordering a CT.[85] Assessment is more difficult in infants and the clinical signs may not reflect an intracranial injury. Only a CT scan will demonstrate an intracranial injury in a substantial number of infants.[36] Castellani et al. have evaluated the importance of Serum S-100B level as a serum marker of head injury and found that values below the cut-off safely rule out intracranial lesions. By using this serum marker, unnecessary CT scans may be decreased.[13]

Table 5: Best scores in various ages

Age	*Best motor*	*Best verbal*	*Best overall*
0–6 months	2 or 3	2	9
6–12 months	4	3	11
12–24 months	4	4	12
2–5 years	4 or 5	4	13
>5 years	5	5	14

To simplify the scoring in children younger than 2 years "a score of 5 is given if the there is any vocalisation at all and 1 if no crying is elicited". In children younger than 1 year of age, a stereotypic eye opening may be seen. This is not a normal response.[11] A severely head-injured infant can exhibit certain stereotyped movements which on initial evaluation appear to be purposeful but, in reality, these are reflex movements.[10]

Additional points to be noted in the examination are palpation of the fontanelles and sutures. The former may be bulging or tense in the presence of raised ICP while the latter may be splayed. These are applicable only to young children. Examination of the ocular fundi may not be possible in all children, particularly so if the child is crying.

Vomiting is very common after head injuries in children. Although vomiting is a hallmark of raised ICP in adults who have sustained a head injury, it may follow even trivial injuries in children. It, often, is a source of concern particularly for the anxious parents. Vomiting may be limited to one or two episodes or may be protracted. In addition, the vomiting may start a day or so after the injury. Although a CT should be done to rule out an intracranial mass lesion it often is normal. Intravenous antiemetics are given if the vomiting is protracted or oral antiemetics fail. Once the vicious cycle is broken, the vomiting stops. Insertion of a nasogastric tube in this situation only serves to increase the discomfort.

Seizures too are common in the head-injured child and like vomiting may follow even trivial injuries. These may be limited to a single episode of generalised seizures, a brief spell of tonic seizure or a vacant stare. Many a time these are self limiting and need no specific therapy. A CT should be done to rule out a focal injury or a mass lesion, but very often it is normal. No specific therapy is needed, nor are long-term anticonvulsants indicated. If, however, these are prolonged, focal or occur several hours or days after an injury it is usually indicative of a serious injury. These children may need long-term anticonvulsants. Anti-seizure prophylaxis is beneficial only for early post-traumatic seizure prophylaxis, i.e. seizures occurring within the first week after injury.[12] The following group of children are at increased risk for post-traumatic seizures: "those with diffuse cerebral oedema, acute subdural haematoma,

compound depressed skull fracture with parenchymal damage, or severe head injury (GCS ≤8)".[39] Children less than 3 years old and those suffering prolonged unconsciousness (>12 hours) are also at increased risk.[19,72] The routine use of anti-seizure prophylaxis for late post-traumatic epilepsy has not been advocated.[12]

Acute deterioration may follow moderate to severe head injuries and this may be due to seizures, brain oedema or intracranial haemorrhage.[11] Intracranial haemorrhage is not the commonest cause of hypotension or hypovolaemic shock in a trauma victim. It is usually the result of bleeding elsewhere—long bone fractures or visceral injury. The blood loss resulting from scalp injury can be severe enough in children to precipitate hypovolaemic shock. Even subgaleal haematomas can be large enough to cause significant blood loss. There are two instances where an intracranial haemorrhage can cause hypovolaemia. The first is the situation where an epidural haematoma "decompresses" itself through a wide linear fracture resulting in a large scalp haematoma. The second instance is in a child with hydrocephalus. Here the cerebrospinal fluid (CSF) is "pushed" out through the shunt by the expanding clot resulting in hypotension and anaemia from the blood loss. These may be the only manifesting symptoms.[11]

There are a few factors which make evaluation of children difficult in the emergency room or casualty. These are:

- *Pain and anxiety*: The child who has suffered an injury is oftentimes anxious and inconsolable. These are made worse when there is also an associated painful injury like a fracture of a long bone.
- *Separation anxiety*: Examination is easy if one of the parents is allowed to be by the side of the child. This will not be possible if the child is being resuscitated or the child is being evaluated for polytrauma. If possible the child must be allowed to sit on the parent's lap. The presence of too many well meaning relatives results in an anxious doctor.
- *Hostile environment*: The injured child perceives everyone in the busy emergency department to be "enemies" and hence the child must be made to feel comfortable before the examination can be carried out if the injury is not too serious.
- *Assessment of the higher functions*: This is made difficult by the fact that the motor and language skills are constantly changing with age and due allowance has to be given for this.

Injuries in the Various Age Groups

No age group is exempt from head injuries. The pattern of head injuries and the spectrum vary in the various ages but a certain degree of overlap is often present. For instance, depressed fractures are seen in almost all the ages from the newborn to well into adulthood (Figs 1 and 2). In the first few years of life, however, falls are common. These may take place when the child is learning to walk or when the child is engaged in play.

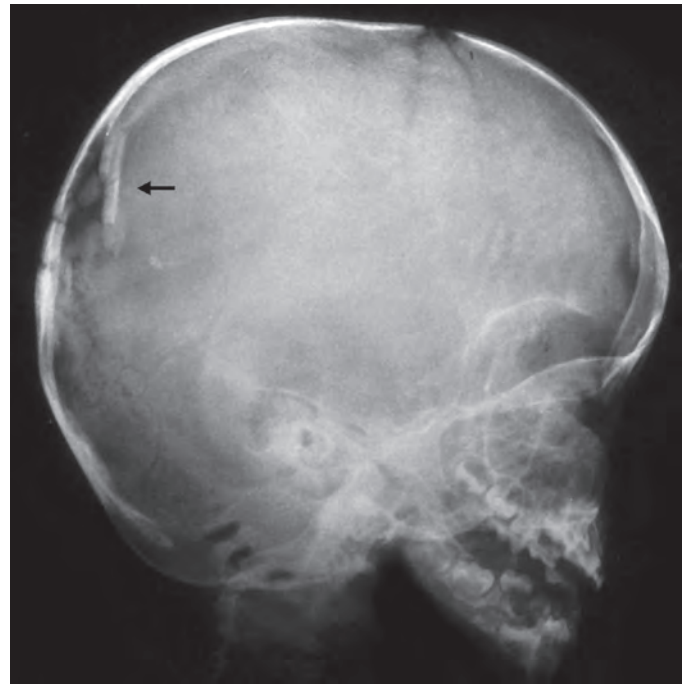

Fig. 1: Depressed fracture X-ray

The older child is more prone to injuries sustained as a result of a traffic accident on the way to or from school. Falls from balconies, too, are seen more often in this age group.

Injuries in neonates are due to two factors: (1) those caused by the natural forces of labour and (2) those produced by obstetric intervention.[11] There is some overlap between the two groups. The injuries involve the scalp, skull and the intracranial compartment. Major intracranial injuries in neonates are uncommon. These constitute 1–3% of trauma cases in busy paediatric neurosurgical units and are associated with 10% mortality and 30% morbidity.[11] Although open scalp injuries are uncommon, scalp haematoma may be present. These are self

Fig. 2: Depressed fracture CT

Fig. 3: Pond fracture clinical

limiting and resolve in a few days. Closed depressed fractures referred to as "ping pong" or "pond" fractures are seen in the parietal region usually at the parietal eminence (Fig. 3). These fractures may result from the soft cranium being pressed against the sacral promontory or ischial tuberosity of the mother. This injury may also be seen when forceps have been applied. The scalp is intact and a small amount of scalp haematoma may be associated with it. Clinical examination reveals the extent of the injury. Although plain skiagrams reveal the amount of depression, a CT scan is needed to evaluate the degree of underlying brain damage (Fig. 4).

Parenchymal injuries or bleeds are uncommon in neonates. Epidural, subdural and subarachnoid haemorrhages again are not very common. Intraventricular haemorrhage from germinal matrix haemorrhage is seen in premature infants but not in term infants. The other cause for intracranial bleeds is clotting disorders. Most of these bleeds are not very big and may be treated conservatively. The common manifestations of intracranial

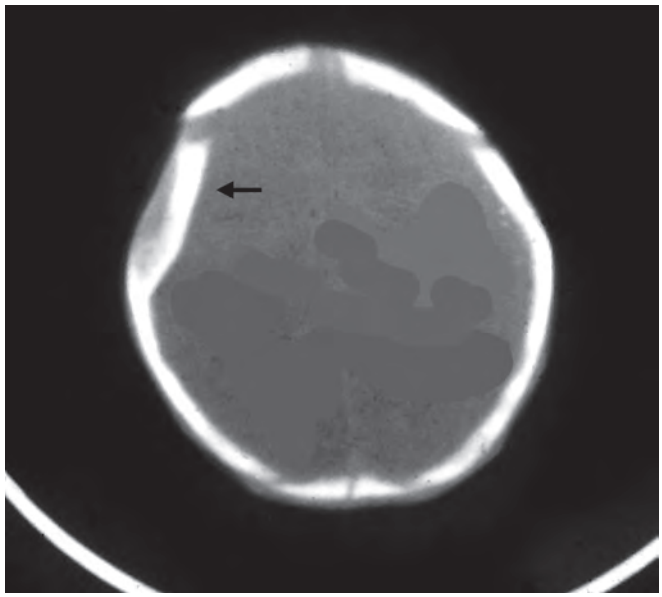

Fig. 4: Pond fracture CT

haemorrhage in neonates are seizures, low APGAR, bradycardia, poor cry and poor respiratory efforts.[20] Extreme care has to be exercised if surgery is to be carried out and only the minimum required is done. As mentioned earlier, these children should be cared for only in neonatal units by a dedicated team. Even though the procedures as such may appear simple, these surgical operations should be undertaken with caution. The margin for error is very small. Even a small volume blood loss may be large in terms of percentage of blood volume and can prove disastrous. The team (neurosurgeon and anaesthetist) must be trained or experienced in the care of neonates, and post-operatively these infants must be cared for in the neonatal unit.

Posterior fossa haemorrhage can occur in neonates as a result of birth trauma. During the process of labour the skull is compressed in the anteroposterior direction. This results in stretching of the falx and also compression of the cerebellum. The result is rupture at the falcotentorial junction and consequent bleeding from the venous sinuses and bridging veins. In addition, parenchymal cerebellar haematomas may occur. A constellation of clinical features is seen ranging from lethargy to features of raised ICP, brainstem dysfunction and seizures. The decision to operate is a difficult one to take and during surgery the team must be prepared for profuse bleeding.

Injuries in infants resulting in diffuse axonal injury are unusual. Shaken baby syndrome refers to the infants with acute subdural haematoma and subarachnoid haemorrhage, retinal haemorrhages and periosteal new bone formation at epiphyseal regions of long bones resulting from to and fro shaking of a child's body producing a whiplash motion of the child's head on the neck. Head-injured infants are likely to have undergone shaking followed by sudden inertial injury from impact. The most important finding was that the predominant neurohistological abnormality in cases of non-accidental injury in infants is due to hypoxia and not diffuse axonal injury.[35]

Injuries in toddlers result from a variety of causes. This is the age when children are learning to walk and explore their surroundings. Fall from a cot and stumbling and falling when learning to walk are the commonest causes. Many of these falls are a cause for concern to the anxious "new" parents and grandparents. Often, many of these falls are not witnessed. The common symptoms which prompt the parents to seek medical attention are vomiting, seizures and the appearance of subgaleal haematoma a few days after the fall. Sometimes, the parents may recall the history of fall or it may be so trivial that they may not recall it at all. The subgaleal haematoma often enlarges in size over a day or two and becomes softer as it liquefies. The parents have to be reassured that the haematoma will clear in about two weeks. The indications for aspiration are persistent fever, suspicion of infection or large size. In the latter instance, coagulopathy has to be excluded, for instance haemophilia in boys. Vomiting may also occur several hours after

the fall. Antiemetics given intravenously usually suffice. Anticonvulsants are indicated only for short-term prophylaxis.

Falls, minor or major (like from the first floor balcony), may not cause significant intracranial problems,[11] but a skull fracture may be seen in many instances. These fractures may be extensive and may extend bilaterally.

Epidural haematomas may occur in this age group without any skull fracture or only an insignificant fracture. This is because the skull, being soft, may bend in and out without fracturing. In this process it may injure the meningeal vessels or, if the skull fractures, the bleeding may be from the skull itself since the child's skull is very vascular.

Rotational acceleration in children due to blunt trauma to the ear may result in "tin ear syndrome" which comprises of unilateral ear bruising, radiographic evidence of ipisilateral cerebral oedema with obliteration of the basilar cisterns, and haemorrhagic retinopathy. Similar trauma may also result in shear stress and tearing of the subdural veins, loss of cortical vasomotor tone, cerebral hyperaemia, herniation and death.[42]

Subdural haematomas (SDH) usually follow a severe injury like falls from the first or second floor, traffic accidents, etc. The presentation is more acute and these children deteriorate faster. In children, the subarachnoid spaces are prominent particularly in the frontal and parietal regions. A small or minor bleed may occur in these regions following even a trivial injury. These do not require any specific treatment.

Injuries in older children and teenagers are usually the result of falls from balconies, injuries sustained when playing and traffic accidents on the way to and from school. The major cause of serious injuries in this age group is acceleration-deceleration injury. Hence, diffuse injuries are commonest in this age group among children.[11]

Head Injuries in Haemophiliacs

Bleeding is the most frequent cause of death in children with congenital coagulation disorders, and intracranial haemorrhage accounts for the majority of mortality in all age groups.[24] Haemophilia A and B are the most common inherited bleeding disorders. Even a minor head trauma may produce significant intracranial pathology. Immediate diagnosis and rapid medical management are mandatory if morbidity and mortality are to be minimised.[24] Among all haemophiliacs approximately 3.5–4.0% had intracranial haemorrhage during the neonatal period which is considerably (40–80 times) higher than expected in the normal population.[99] In haemophiliacs who have suffered from intracerebral haemorrhage, more than 40% had it within 1 week of birth. Birth trauma was identified as an important risk factor for intracerebral haemorrhage in patients with haemophilia.[50] Haemophilia in the newborn can be a challenge in terms of both diagnosis and management. In the presence of a family history of haemophilia, safe outcome of these patients is achieved by mutual cooperation and optimal management by obstetricians, haematologists and neonatologists. When a family history is absent, haemophilia in the neonate may not be suspected. Diagnostic difficulties may then arise due to failure to recognise the presence of abnormal bleeding, which is often different from that typically observed in older children with haemophilia. In addition, diagnostic investigations are complicated by physiological differences in the neonatal haemostatic system.[14] Intracranial haemorrhages in older children are rare, and a better outcome may be expected.[50]

The most important aspect of intracerebral haemorrhage management is early replacement therapy in haemophilic patients. This prompt treatment will increase the chances of a better prognosis. Administration of the deficient coagulation factor after every head trauma, even when considered minor is advocated by a few authors. Recombinant factor VIIa can enhance haemostasis in patients with FVII deficiency and other coagulopathic conditions.[8,22,75]

SPECIFIC INJURIES AND PROBLEMS

Even though there is an overlap between the problems in adults and children, the latter present certain features which are unique. Not only is the pathologic process different, even the clinical features and management are different too. Similarly, the problems encountered in neonates are different from those seen in older children.

Scalp injuries are seen commonly in all age groups and are a part of almost all traumatic injuries involving the head and neck. A certain amount of scalp haematoma is seen even at the time of birth—caput succedaneum—which resolves over a few days. The blood loss can be very profuse from scalp lacerations since the scalp is very vascular. If the laceration is large the child can exsanguinate. Even subgaleal haematomas associated with simple linear fractures of the skull may be associated with a significant blood loss. Palpation of the edge of the haematoma gives the feeling of palpating the edge of a depressed fracture, but often times this is not the case.

Fractures are seen in all paediatric age groups. They are present in up to 20% of children admitted for the management of head injuries.[80] Despite this high prevalence many of the fractures do not need any treatment. The fracture is a good indicator of an underlying parenchymal injury. To detect these injuries a plain X-ray of the skull is enough in most of the instances. However, parenchymal injuries cannot be seen on the plain X-rays at all. Hence, CT is the preferred mode of investigation. It has to be emphasised that fractures, not detected on the CT, hardly influence the outcome or management.[80] The point worthy of note is in children, as in adults with acute head injury, the presence of a skull fracture increases the probability of developing an intracranial haematoma significantly.[60,88]

In adolescents, the presence of a skull fracture is the only significant risk factor for predicting an ICH.[16] In

a child who has a simple linear fracture and a normal clinical and CT examination the chances of developing an intracranial haematoma or a complication later on is next to nothing.[56,59,86] Also if a child is seen a day or later after the injury and a linear fracture is discovered, if the child has no neurologic symptoms the chances of the child harbouring an intracranial haematoma becomes very low. Hence, a CT may not be indicated.

Linear fractures are the commonest variety of skull fractures in children. Certain unique features are seen with respect to such fractures in children. Linear fractures can cross suture lines and some of the fractures may extend bilaterally (at times even across the sagittal suture). Since the frontal sinus does not develop till the end of the first decade, a fracture involving the frontal region may extend into the roof of the orbit or even up to the clinoid process because the force of the impact (which is transmitted to the base of the skull) extends for quite some distance (Figs 5 to 7). The unpneumatised sinus does confer an advantage in that post-traumatic CSF leaks are uncommon in children. Growing fractures, a rare complication of fractures, are also peculiar to the paediatric age group. These are also referred to as enlarging/expanding skull fractures, leptomeningeal cysts and post-traumatic meningocoeles.[59] Usually a wide linear fracture is seen at the time of injury as the first manifestation. A dural laceration beneath the fracture is mandatory for this to occur. The dural laceration and the fracture result in the "amplification of the ICP pulse wave", which in turn results in herniation of the arachnoid and brain. Over a period of time, due to the transmitted pulsations of the brain, the edges of the fracture separate and the fracture "grows". These manifest clinically as a pulsatile swelling at the site of injury a few months after the injury. In addition, hemiparesis and seizures may be present. Since this entity is associated with a severe injury, a meningocerebral cicatrix

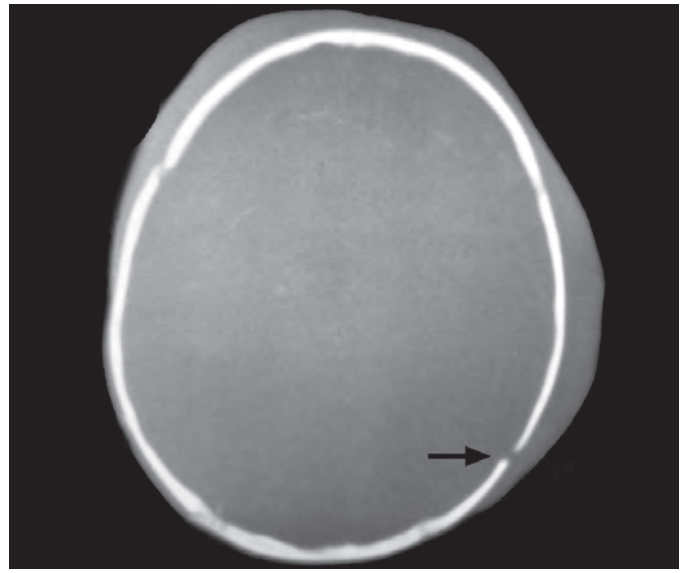

Fig. 6: Linear fracture CT

is usually also seen at the site of injury. The treatment is surgical. The fracture margins are exposed and the dura and arachnoid are exposed. These are separated from the site of incarceration. Watertight dural repair is mandatory to prevent further incarceration and growth of the fracture.[92] The calvarium is then reconstructed preferably using autogenous bone grafts.

Depressed fractures in the paediatric age group are usually green stick fractures unlike those in adults. This is because the skull of children is softer than the skull of adults. Being soft, the calvarium of the child can undergo distortion without fracturing. When the calvarium is distorted or deformed as a result of an injury the dura can be stripped away or the middle meningeal vessels injured, resulting in the formation of an extradural haematoma or, at times, because of the bending, the inner table may fracture without the

Fig. 5: Linear fracture X-ray
arrow head diastatic arrow

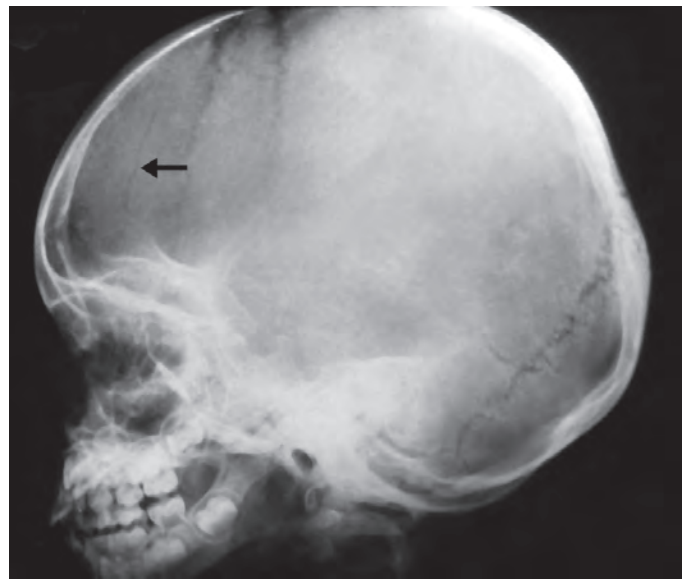

Fig. 7: Linear fracture X-ray

outer table exhibiting any sign of fracture. In neonates the skull is "soft" and membranous, hence it does not fracture so easily. A linear fracture is uncommon and is usually the result of pressure or battering against the maternal pelvis. A depressed fracture results from pressure against the sacral promontory, ischial tuberosity or forceps application. A scalp haematoma may mask the underlying fracture. The investigation of choice is a CT scan. Small fractures do not need any specific treatment since the growing brain "pushes" the depressed segment out. The indications for surgical elevation are similar to those for other closed depressed fractures, namely large diameter of the depression (>3–4 cm), significant depression, pressure on or deformation of subjacent brain, focal deficit, seizures or cosmetic disfigurement. Surgery, if it is to be performed, is best done within the first week. This will make elevation easier since the depressed segments would not have fused. The technique of elevation is simple. Through an incision placed close to the margin of the depression a small burr-hole is made. A periosteal elevator is gently introduced epidurally under the fractured bone up to or just beyond the point of maximum depression. The depressed bone is gently elevated by levering the periosteal elevator over the surgeon's finger. This manoeuvre will avoid pressure on the edge of the bone by the periosteal elevator which can deform or fracture the underlying bone. A vacuum device (i.e. obstetric vacuum extractor) has also been used to elevate these fractures.[59,80]

In a child who has an acute severe head injury and also a depressed fracture, the former takes precedence over the latter. This rule can be applied even if the fracture is compound. Here the skin can be closed to provide a cover for the fracture, and the dura and the fracture can be addressed electively. Basal fractures and those involving the frontal air sinuses are commoner in adults. If there are clinical indicators of basal fractures or fractures involving the frontal air sinus (like raccoon eyes or Battle's sign), the presence of these fractures must be assumed to be present until proved otherwise and all precautions must be taken during management. To cite an example, an orogastric rather than a nasogastric tube must be placed if an anterior skull base fracture is suspected lest the tube enter the intracranial compartment through the fracture. Controversy surrounds the issue of antibiotic prophylaxis in the management of skull base fractures. Since there are recommendations for and against the use of prophylactic antibiotics, the decision to use (or not to use) should be based on the clinical scenario and the neurosurgeon's judgement. The need for admitting all children with an uncomplicated skull fracture has been questioned, if the family are dependable and the child can be brought to the hospital quickly, admission may not be needed in all.[96]

Contusions of the brain in children as in adults may be a cause for delayed deterioration. Small contusions are known to enlarge after resuscitation. Those that exert a mass effect, especially those in areas which can easily lead to herniation, may need to be treated surgically even prophylactically.[59] The incidence of seizures in a child with a contusion is not greater than in the child who has developed an extradural hematoma (EDH) or one who has a normal CT after a head injury.[39]

Concussion, which is basically a transient loss of consciousness followed by normal function, can manifest in a wide variety of ways in children. At one end is the mildest form where the child recovers without any deficit whatsoever, while at the other end is the child who is neurologically devastated from diffuse axonal injury. Concussion is considered to be a mild form of diffuse injury of the brain and diffuse axonal injury as the extreme form with a whole range of severity lying in between.[58] Not only can these follow a trivial injury, they can also be disproportionate to the severity of injury.[20] The clinical picture of concussion does not always follow a severe head injury. This condition often follows injuries sustained at play, or even minor falls. Often the imaging studies may not disclose any abnormality unless the patient manifests serious symptoms. The basic pattern and clinical manifestations are the same as in adults, but some of the features not seen in adults are encountered. In the most benign form the child may be stunned soon after a head injury only to "regain consciousness" soon and act normally. After recovery the child may be irritable, have headaches or have difficulty concentrating for a few weeks if the concussion had been severe.[59]

Cortical blindness is an entity peculiar to children. Immediately, or soon after a fall, the child complains of loss of vision.[69] The pupils will be reacting normally to light. The blindness recovers without any treatment. Associated features are headache, nausea, vomiting and irritability.[77] The aetiology has been attributed to concussion of the occipital lobe and transient "kinking" of the posterior cerebral arteries. Vasospasm has also been proposed as a cause.[15] This condition has to be differentiated from post-traumatic optic neuropathy where the blindness is unilateral and recovery is poor. The following have been associated with a benign outcome "mild head trauma, brief or no LOC, onset of blindness occurring within hours of the head injury, absent optokinetic nystagmus, duration of blindness less than 24 hours, agitation and restlessness, absence of skull fracture or visible cerebral injury on CT scan, absence of other neurological deficits, and EEG findings that initially show posterior slowing with subsequent normalisation". An increased awareness will result in more cases of this kind being diagnosed.[101]

Paediatric concussion syndrome is a dramatic event but with a good outcome. A child who had been well after a minor head injury becomes somnolent and irritable. A few hours after the event, pallor, cyanosis and vomiting develop. A hypotensive episode may also be present. Imaging studies are normal and the child regains normalcy in a few days. The aetiopathogenesis is poorly understood. Other conditions, like expanding intracranial haematoma, fits, brain oedema and

electrolyte imbalance (sodium in particular) have to be ruled out. The diagnosis of this condition is by a process of exclusion.[59] Children who do not show the expected recovery or who recover slowly may have post-traumatic subarachnoid haemorrhage or even a mild form of diffuse axonal injury.[59]

Diffuse brain swelling is a condition seen in children, but not commonly in adults.[58] It is 2–5 times commoner in children.[102] This may be seen after a mild head injury. Following a lucid interval the level of consciousness rapidly deteriorates with an associated increase in the ICP. Even though the child may be clinically normal, the initial CT may show changes like compression of the perimesencephalic cisterns, absent third ventricle and diffuse cerebral swelling.[10,52,58] The treatment has to be initiated on a high index of suspicion. Aggressive and early initiation of therapy results in a good outcome. The aetiology of this condition is supposed to be a post-traumatic vasoreactive phenomenon resulting in a significant rise in ICP.[58] There is increased cerebral blood volume resulting from hyperaemia and engorgement which in turn results in raised ICP. These have been shown by blood flow studies.[52] Since children have a wide range of CBF this hypothesis has been questioned.[102] The exact aetiology is unknown till date. This clinical entity has been described in adults too but the outcome is better in children.[52]

Diffuse axonal injury, which is an injury resulting essentially from angular acceleration/deceleration forces, is uncommon in infants while in older children it is the result of a fall or traffic accident where the child is knocked down by a vehicle. The child is rendered unconscious from the time of the accident. A variable motor response ranging from abnormal flexion/extension to a withdrawal response is encountered. In addition abnormalities in pupillary size and response and other brainstem signs including posturing and abnormalities of eye movement may be encountered, but these responses "do not reflect a significant trend".[59] The CT may be "disproportionately" normal compared to the clinical severity of injury. The CT may at times show petechial haemorrhages in the deep white matter, haemorrhages in the region of the splenium, thin SDH, subarachnoid haemorrhage, intraventricular haemorrhage and small contusions. The management of this condition is along the lines of management of the severely head-injured patient.

Post-traumatic intracranial haematomas are seen from as low as less than 0.1% to as high as 35% of patients with head injury.[74] The three varieties of post-traumatic haematomas EDH, SDH and intracerebral haematomas (ICH) have different aetiologies depending on the age of the child. In neonates it is trauma related to birth, while in toddlers and older children it falls, and in adolescents it is related to traffic accidents in addition to accidents sustained during play and falls. The manifestation, too, varies with age. Neonates present with anaemia, bradycardia, irritability, tense fontanelle, focal deficits and altered consciousness. The older children, however, have other features of raised ICP like headache, vomiting, alteration in level of consciousness and focal deficits.[74] The location of the intracranial haematomas depends to some extent on the age of the child (Table 6, Fig. 8).[67]

Table 6: Location of the intracranial haematomas

Neonates	*Infants*	*Toddlers*	*Adolescents*
Posterior fossa Supratentorial	SDH (Acute/ chronic)	EDH	ICH SDH (Acute EDH

Extradural haematomas in infants are venous in origin unlike those in older children in whom it is arterial. The other sources of bleeding are the fractured edge of the bone and from venous sinuses (Fig. 9). The latter is often the source in posterior fossa haematomas. In older children the aetiology is as in adults, bleeding from the middle meningeal artery. In infants needle aspiration of these haematomas has been recommended as a treatment modality.[74] Conservative management of EDH in children has been described. Criteria have been described for conservative treatment and also termination of conservative treatment.[65,74] For nonsurgical treatment the indications are children with no neurologic deficit but with headache, nausea, vomiting and lateral rectus palsy in supratentorial clots. Conservative treatment is terminated if the patient develops a focal deficit, the level of consciousness deteriorates, pupillary changes develop, headache, or vomiting persists or rebleeding occurs. Delayed epidural haematoma is usually seen following a severe head injury. The diagnosis is made on a high index of suspicion in the absence of neurologic deficit. The outcome is good if timely intervention is carried out, even in delayed EDH.[33,67] The source of bleeding in a posterior fossa EDH is usually venous—from a venous sinus. An associated fracture is seen in a significant number of children. At times the clot can extend to the supratentorial compartment as well. Rapid deterioration is a hall mark of this condition.

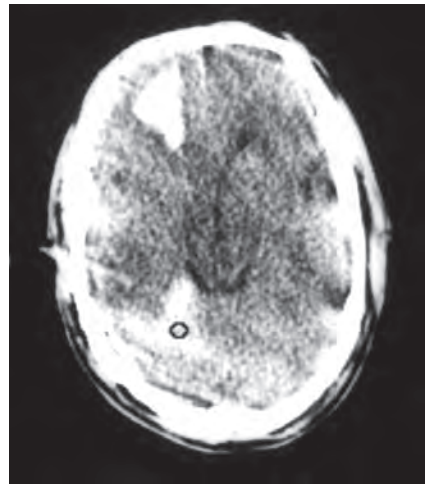

Fig. 8: Post-traumatic ICH

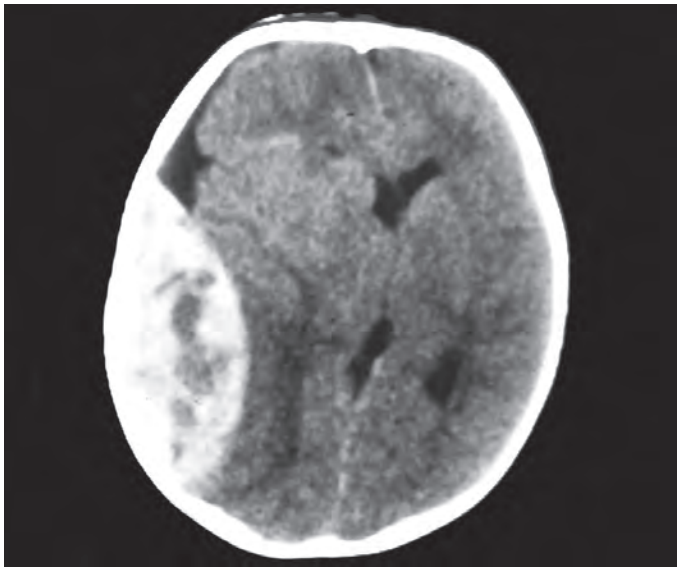

Fig. 9: EDH

SDH in older children generally present as they do in adults—as an acute event following trauma. In neonates, due to enlarged subarachnoid spaces, the bridging veins snap easily and may lead to a subdural collection. Small haematomas may occur even after a trivial injury. This is because the subarachnoid/subdural spaces are wide in this age group and the bridging veins are relatively unsupported, but a significant haematoma never results from a trivial injury unless there is an associated medical problem like coagulopathy. These are often accompanied by other injuries in the intracranial compartment. In managing these lesions, due to the frequent association of other traumatic lesions, treatment should also be directed at raised ICP. The posterior fossa is a common site of SDH in neonates. These are usually due to tears of the tentorium or rupture of the bridging veins. Chronic SDH are known to occur in children, but the classical picture seen in adults is absent. These are usually the result of over drainage following a shunt or bleeding into a subdural collection. Careful radiologic evaluation will aid in differentiating SDH from other subdural collections.

ICH occurring in childhood has certain features which are not encountered in adults. Since the aetiopathogenesis, clinical features and management of germinal matrix haemorrhage are completely different, they will not be considered here. In a child who presents with an intracerebral haemorrhage even with a history of trauma an underlying cause for the bleed other than trauma has to be kept in mind if dictated so by the clinical picture. These include bleeding as a result of coagulopathies, vascular malformation or tumour (Table 7).[67] In such instances, the size and location may not correspond to the severity of the injury; screening for coagulopathy and appropriate radiologic studies will help in differentiating these conditions from post-traumatic haematomas. These lesions can be large and can be differentiated from haemorrhagic contusions by not being cortical in location and having a more or less uniform density on the initial CT. The management of these lesions is along the same lines as in adults. However, even if there is a suspicion of viability of the brain, it is better not to remove the affected area since children recover better than adults, and the "damaged" area may recover its functions well.

Table 7: Spontaneous intracranial haemorrhage: causes

Structural causes:
• Bleed into a tumour or an infarction
• Vascular malformations: AVM; aneurysms; cavernomas
• Vasculopathies: Inflammatory; moyamoya syndrome
• Dural sinus thrombosis
• Venous infarcts
Non-structural causes:
• Coagulopathies: Haemophilia; vitamin K deficiency
• Liver disorders
• Anticoagulation therapy
• Disseminated intravascular coagulation: Due to any cause
• Platelet disorders
• Fulminant sepsis
• Unknown aetiology: Germinal matrix haemorrhage

CRITICAL CARE

The critical care of children has evolved into a distinct specialty. The problems in children and the needs of children are entirely different from those of adults; hence children requiring intensive care have to be cared for in special dedicated units. Nowhere is this more apparent than in neurologic and cardiac care. It has been estimated that children with head injuries account for 10% of all ICU admissions and 10% of all ICU days.[28]

Indications for Admission to the ICU

Not every child who has sustained a head injury needs be admitted to the ICU. Guidelines have been proposed for admission criteria to the ICU.[6] The reason for admission to the ICU may be for the management of a neurosurgical problem or the treatment of other problems. In simple terms, the following groups will need to be admitted to the ICU for care or, at least, observation.

Neurosurgical Indications

- Post-operative patients
- Seriously head-injured children—even if the child in neurologically intact, i.e. child with multiple contusions
- Children with impending neurologic deterioration
- Children with proved or suspected raised ICP
- Children with more than one episode of seizure even if the seizures are mild.

Non-neurosurgical Indications

- Intubated children—intubated for any reason whatsoever

- Polytrauma victims
- Children with compromised cardiopulmonary status.

Care in the ICU

The question of who is in charge of the child in the ICU may come up. Intensive care management of children should be a combined effort between the neurosurgeon and the paediatric intensivist. Anything else will result in a poor outcome.

There are two aspects to the care of the child in the ICU: (1) Monitoring and (2) Managing.

Monitoring in ICU

There are two parameters which are routinely monitored in the ICU. The non-neurologic monitoring, i.e. haemodynamic and other parameters like fluid and electrolyte therapy. The other is the neurologic part which consists of clinical examination and ICP monitoring.

Haemodynamic: In addition to routine PICU monitoring (heart rate, respiration, pulse oximetry and non-invasive blood pressure), all patients with serious head injuries should have invasive monitoring of the central venous and arterial blood pressures. This is especially true if they are receiving mannitol therapy or other therapies to reduce raised ICP. Arterial BP monitoring allows changes or falls in BP to be noted in real time (which may occur if the child is receiving diuretics or barbiturates) so that appropriate measures, like fluid boluses or pressor support, can be instituted. In addition, in ventilated patients, drawing blood samples, particularly for blood gases, is rendered easy. A central venous line is very useful to titrate fluid balances, especially in children who have the syndrome of inappropriate ADH secretion (SIADH) or cerebral salt wasting syndrome (CSW). In certain situations a child may be adequately hydrated, but may still be hypotensive—as in a child receiving barbiturates. In such situations the need for inotropic support will be dictated by the CVP and arterial pressure.

In ventilated patients, end tidal carbon dioxide ($ETCO_2$) monitoring is invaluable. This allows non-invasive breath-by-breath measurement of the exhaled CO_2 and detects large swings in the CO_2 tension immediately. It also allows less frequent measurement of arterial blood gases and thus reduces the overall cost of therapy.

Fluids and electrolytes: The aim of fluid therapy should be to maintain euvolaemia. If for some reason crystalloids are to be withheld, colloids can be administered to maintain euvolaemia (euvolaemic dehydration). Traditionally, head-injured patients have been fluid restricted due to the risk of cerebral oedema and SIADH. However, the administration of large volumes of isotonic fluids does not result in cerebral oedema.[5] It is important to maintain an adequate preload so that the cardiac output and blood pressure are sufficient to maintain optimal cerebral perfusion. A central venous pressure monitor is invaluable in guiding therapy and should be inserted in all seriously ill patients, especially those receiving mannitol or other diuretic therapy. Large volumes of hypotonic fluids should not be administered. Additional dextrose should not be administered since the head-injured patient is often hyperglycaemic to begin with, and hyperglycaemia has been linked with poor outcome in head injury.[18] Our current practice is to give the patient normal maintenance requirement of fluids as normal saline with potassium or lactated Ringer's solution and monitor the serum glucose frequently. Dextrose is added only if the patient develops hypoglycaemia. Additional fluid administration is guided by CVP, blood pressure, heart rate and perfusion, and is administered as boluses of either isotonic crystalloid (normal saline or lactated Ringer's solution), or colloid. In a child who is critically ill, a child who is being ventilated or receiving anti-oedema measures, serum electrolytes are to be checked at least twice a day and, if mannitol is being given, serum osmolarity should be checked, ideally, before every dose of mannitol.

Patients with head injury are at risk of developing the SIADH. This manifests as a decreased urine output, despite adequate filling pressures and hyponatraemia, and is managed by fluid restriction. An important differential diagnosis for hyponatraemia in head injury is the CSW, which is caused by an excess of atrial natriuretic peptide and results in massive urinary losses of sodium and water, resulting in severe hyponatraemia and volume depletion.[26] It is vital to differentiate between the two conditions since the therapy is different (Table 8).

Hypertonic saline has been used in the management of head-injured patients, with various reports claiming that ICP is decreased; patients have shorter ICU stays and fewer complications.[49,84] However, there are still no well performed prospective randomised controlled trials which show that this modality is superior to conventional treatment. Therefore, the routine use of hypertonic saline is not recommended at this time. It may, however, be used in individual circumstances at the physician's discretion.

Nutrition: Early nutritional support is extremely important. Head-injured patients, like all trauma victims, have a hypermetabolic state with increased nitrogen excretion that can last for several weeks. Undernutrition in head injury has been linked to increased mortality.[71] When the management of nutrition in a brain-injured child is

Table 8: Differential diagnosis of SIADH and CSW

Parameter	*SIADH*	*CSW*
Volume depletion	No	Yes
Plasma volume	Isovolumeic or ↑	↓
Serum sodium	↓	↓
Serum osmolarity	↓	Normal or ↑
Serum uric acid	↓	Normal
Serum ADH	↑	↓
Urine sodium	↑	↑
Sodium loss	Normal	Very high
Urine output	Low	Very high

Table 9: Equation for predicting BMR from body weight (W = body weight in kg)

Age (Years)	*Males (Kcal/day)*	*Females (Kcal/day)*
0–3	60.9 W–54	61.0 W–51
3–10	22.7 W + 495	22.5 W + 499
10–18	17.5 W + 651	12.2 W + 746

(From: WHO: Energy and Protein Requirements. Report of a Joint FAO/WHO/UNU Expert Consultation Technical Report Series 724. Geneva, WHO; 1985)

being planned, the requirements of a normal child in that age group and the additional allowances needed by a child who has sustained an injury need to be assessed and then plans are made to ensure the total requirement is met.[99]

Current adult recommendations are to provide 140% of the resting metabolic expenditure in non-paralysed patients and 100% of the resting metabolic expenditure in paralysed patients, with at least 15% of the calories as nitrogen, by the seventh day following head injury. Although it may be difficult to measure the resting metabolic expenditure routinely, the basal metabolic rate (BMR) can easily be calculated and used as a guide (Table 9).

Enteral nutrition has significant advantages and is much cheaper than parenteral. If the patient does not tolerate orogastric or nasogastric tube feedings, the tube can be advanced into the jejunum with the aid of prokinetics or under fluoroscopy and continuous drip feeds administered. Several paediatric enteral nutrition formulas, including a semi-elemental formula, are available. Parenteral nutrition is started only if the patient does not tolerate enteral feeds or if there are injuries which preclude enteral feeding. Although studies comparing enteral and parenteral nutritional support have not been conducted in children they both have certain limitations and advantages. The principles of tube feeding may be summarised as follows:[99]

- Allow 2–5 days to meet full nutritional requirements
- Use isotonic feeds initially
- Careful adjustments to be made in children who are chronically/critically ill and also in malnourished children
- If intolerance develops to feeds the last tolerated formulation is restarted and changes are made slowly
- Continuous feeds are stated at 1–2 ml/kg/hr and increased slowly till full requirements are met
- If the child is also receiving parenteral fluids, fluid overload may occur.

ICP monitoring has come to stay in the management of a head-injured patient, but the use of ICP monitoring in adults has only been recommended as a guideline.[12] There are insufficient data concerning ICP monitoring in children and this has not been considered as a part of standard care in children.[2] Monitoring of ICP is one of the more controversial issues in the management of head-injured patients. This therapy is not used universally and there is evidence both for and against monitoring. The issue has not been studied in a properly conducted prospective randomised clinical trial. Nevertheless, it has become standard practice in most large head injury centres.

Rationale: All therapies used in the treatment of severe head injuries are potentially harmful and can adversely affect the outcome. In order to scientifically apply the therapies and thus minimise adverse effects, it is necessary to monitor ICP. High ICP correlates with poor outcome in severe head injury. Lowering the ICP reduces the risk of herniation, helps optimise cerebral perfusion and oxygenation and may thus improve outcome. When the ICP is monitored using a ventricular catheter, CSF can be drained through the catheter to reduce ICP. In addition, ICP data correlate strongly with outcome—patients with normal ICP have the best outcome, those with elevated but controllable ICP do less well and those with uncontrollable ICP have the worst outcome. Therefore, the data can be very useful in counselling families.

Indications for ICP monitoring: There are no specific recommendations for children, but the adult guidelines are to monitor the ICP in all patients with severe head injury and an abnormal head CT scan on admission.[12] ICP monitoring is also recommended for patients with severe head injury and a normal head CT scan if they have hypotension or unilateral or bilateral motor posturing. Severe head injury is defined as a GCS of 3–8 after cardiopulmonary resuscitation. An abnormal head CT is one that shows a haematoma, oedema, contusion or compressed basal cisterns.

Using ICP to guide therapy: Normal ICP in adults is 0–10 mmHg. In the absence of good data for children, these adult baselines are often used. However, more important than the actual ICP is the blood flow to the brain. This is reflected by the cerebral perfusion pressure (CPP), which is the difference between the mean arterial pressure and the ICP (CPP = MAP – ICP). Therefore, even if the ICP is elevated, it may be possible to maintain adequate blood supply by increasing the MAP. It must be borne in mind that these numbers apply to the entire brain and do not reflect what is happening in individual areas. Although the exact level at which one should intervene is being debated, most centres intervene when the ICP is greater than 15–20 mmHg. A strategy of targeting the CPP is more physiological, rather than treating the actual ICP. A CPP target of 70 mmHg is often used in adults. Good guidelines are not available for children, but a CPP target of 40–50 mmHg in infants and toddlers and 50–60 mmHg in older children are recommended.[31] If the ICP is high, it may be necessary to use inotropic support to elevate the blood pressure in order to meet these CPP goals.

Techniques of ICP monitoring: A ventricular catheter connected to a standard pressure transducer is the gold

standard. In addition to measuring ICP, it allows CSF drainage for reducing the ICP. This can be placed at the bedside in the ICU. However, ventricular drains can sometimes be difficult to insert in patients with cerebral oedema in whom the ventricles are compressed. The catheter should be connected to a closed drainage system and the transducer must be maintained at a fixed level with respect to the patient (generally at the level of the external auditory meatus). The risks associated with a ventricular catheter are misplacement, haemorrhage, obstruction, migration of the catheter and infection. The risk of infection increases significantly after the fifth day and, therefore, the catheter should be changed after every 5–7 days.

The other devices used commonly are fibre optic catheters with a pressure transducer at the tip. These can be placed in the parenchyma and are thus easy to insert, especially if the ventricle size is small. They are also significantly more expensive. Subarachnoid, subdural and epidural devices are not accurate and should not be used.

Monitoring cerebral metabolism: Various techniques, including jugular venous saturation, near-infrared spectroscopy, cerebral parenchymal pO_2 monitoring, cerebral microdialysis and positron emission tomography have been used to monitor the cerebral metabolism.

Of these, jugular venous saturation has been used extensively. A special catheter is inserted in a retrograde manner through the neck into the jugular vein and threaded up to the jugular bulb. Venous saturations are monitored via a probe at the catheter tip. The amount of oxygen remaining in the blood after supply to the brain reflects oxygen utilisation by the brain and is indicative of the state of the cerebral metabolism. The minimum value is taken as 50% and values lower than this have been reported to be associated with increased mortality in adults.[34] The arteriojugular venous difference in oxygen content can also be calculated from the information provided by this technique. This information can be used to titrate therapies such as barbiturate coma. One limitation of this technique is that it measures only global oxygen utilisation, which may not be representative of the state of the injured areas.

Monitoring cerebral blood flow: Cerebral blood flow can be measured by techniques such as: (1) stable Xenon-enhanced CT; (2) radioactive ^{133}Xenon scanning; (3) transcranial Doppler and (4) cerebral thermal perfusion.

Of the three, stable Xenon-enhanced CT is the simplest and can be performed using almost any of the recently introduced CT scanners with slight modifications. It provides important information about the regional blood flow and may be coupled to interventions such as altering the arterial blood pressure or $PaCO_2$ level to see the effect of such physiological manipulation on blood flow.

Radioactive ^{133}Xenon scans can be performed at the bedside and gives information about regional blood flow. It can also be performed before and after physiological manipulation, as described above. Transcranial Doppler is sometimes used in adults, but has very limited application in children.

A cerebral thermal perfusion probe consisting of two thermistors is placed intracerebrally via a burr hole in the vascular area of interest in the brain. The probe is connected to a probe monitor that continuously displays the perfusion data. This provides the details of CBF.[90]

Managing in the ICU

As in monitoring, there are two broad divisions: (1) raised ICP and (2) associated problems (like seizures) and each one influences the overall outcome.

Therapy for raised ICP is one of the basic management problems in the ICU. Raised ICP contributes to a poor outcome in more than half of all the severe head injuries.[2] As in any situation in neurosurgery, the cause is an increase in the volume of the brain, CSF, blood or a mass lesion. Increase in CSF volume and a mass lesion are best treated by surgical measures and the techniques will not be elaborated here. Increase in blood volume (as in hyperaemia) has been discussed earlier. Raised ICP has to be carefully managed. A variety of methods is available to manage the raised ICP. A single method very seldom suffices. The raised ICP might have to be managed using various combinations of the several techniques available. The combination of therapies to be adopted will be dictated by the clinical scenario, experience of the team and the facilities available.

The strategies may be divided as follows:

- General
  - Head positioning; haemodynamic (regulating CPP); sedation and paralysis
- Barbiturate
- Diuretic
- Ventilatory
- Surgical
  - CSF drainage; removal of mass lesions; decompressive craniectomy.

General

Head position plays a role in reducing the ICP. Elevation of the head to 30° lowers the ICP. In addition the head has to be kept in the neutral position lest turning the head result in kinking and compression of the jugular veins.

Cerebral perfusion pressure (CPP which is the Mean Arterial Pressure—ICP, i.e. CPP = MAP – ICP) and ischaemia are intertwined and, since the latter has a significant influence on the outcome, it is important to ensure CPP is adequate in a head-injured patient.[2,12] Following a traumatic injury to the brain there is a global fall in the CBF and in areas adjoining contusions it is even lower than the global fall in CBF.[12] The ideal values of MAP and CPP have not been defined in children. Since the normal ICP of 20 mmHg in adults is high for the paediatric population, a "working value"

of 15 and 17–18 mmHg is taken for infants and children respectively.[2] A corollary of the foregoing is the values are only very general and each child has to be treated on a case-by-case basis. This is because the blood pressure of a child varies with age and in some a normotensive status will suffice while another may need mild hypertension.[2] If there is loss of autoregulation it will only serve to worsen the cerebral hyperaemia and raise the ICP further. The extension of the above discussion is hypotension should be avoided and, if present, should be treated with fluid boluses of crystalloids/colloids and the possible addition of pressor agents.

Sedation and paralysis are employed primarily in children who are being ventilated. Agitation and muscular activity result in an increase in the ICP and should be controlled. All patients who are being mechanically ventilated should be sedated adequately. The ideal sedating agent should be a short acting one since frequent neurological assessment is mandatory. An infusion of midazolam, 0.1–0.3 mg/kg/hr can be used safely. Fentanyl, 1–4 mcg/kg/hr, can also be added. Opiates cause miosis and this should be kept in mind during the neurologic assessment.

Routine paralysis has been linked to longer ICU stay and a higher incidence of pneumonia.[44] Neuromuscular blockade should only be used when excessive muscular activity cannot be controlled with sedation alone. Once pharmacologically paralysed, the neurological examination is limited to checking the pupillary size and reaction. In addition, the occurrence of seizures will be masked. If deemed necessary, infusions of vecuronium (0.1–0.2 mg/kg/hr) may be used. The dose should be titrated using a peripheral nerve stimulator to maintain 1–2 twitches on train of four stimulations. If this is not available, the infusion can be stopped every morning to allow the patient to recover from paralysis and then restarted, if necessary. The longer acting drug pancuronium can also be used, but it causes tachycardia. The initial dose of pancuronium is 0.1–0.15 mg/kg IV followed by an infusion at 0.02–0.04 mg/kg/hr, if needed.

Sometimes, children who are not intubated and ventilated may be irritable or agitated. However, they should not be sedated unless absolutely necessary since this will affect the neurological examination and can mask a deteriorating neurological status. If such a clinical situation warrants sedation, a CT has to be done to make sure there is no pathology which can explain the irritable state. It has to be emphasised here that trials have been conducted comparing intermittent versus continuous paralysis and sedation. No single regimen has proved superior. There are advantages and disadvantages in both regimens. The best regimen is probably what the doctors caring for the child are used to or comfortable with.

Barbiturates

Barbiturates are effective in lowering raised ICP by their effect on altering the vascular tone, lowering cerebral metabolism and inhibition of free radical peroxidation. Their primary effects may be by reducing the cerebral metabolic demands, thereby reducing the blood flow, which in turn results in a reduction in cerebral blood volume and perfusion.[12] They may be useful in hemodynamically stable children with refractory raised ICP. Since barbiturates have potent cardiovascular side effects, CVP and arterial pressure monitoring are mandatory and hypotension should be treated aggressively with additional volume and inotropic support, if required. Most patients with barbiturate-induced hypotension will respond to dopamine infusion after adequate volume replenishment. All patients should ideally have continuous EEG monitoring and the dose titrated to achieve burst suppression. Although pentobarbital is the commonly used drug, thiopentone sodium is used in our country since the former is not available. It has to be added here that the use of thiopentone has also been advocated.[31] Thiopentone sodium can be given as a loading dose of 3–5 mg/kg. Then a maintenance infusion of 1–2 mg/kg/hr may be continued. An intermittent dose of 5 mg/kg 4–6 hourly has also been advocated to achieve the same end point.[2] The end point of barbiturate is to achieve a burst suppression pattern on EEG. Their use prophylactically has not been proven to be useful. The use of barbiturates is usually a "last resort" therapy.

Diuretic

Both loop and osmotic diuretics have been used in the management of head injury.

Mannitol is useful to control raised ICP after severe head injury. The exact mechanism of action of mannitol is still unclear, but it probably has two separate actions:

1. Through its rheological properties, it reduces blood viscosity and produces an increase in the CBF and also oxygen delivery to the brain. The increase in plasma volume after the administration of mannitol may raise the blood pressure and increase the CPP.
2. Its osmotic effect occurs in about 15–30 minutes after administration. Mannitol creates an osmotic gradient across the blood-brain barrier, which results in dehydration of the brain and thus reduces the ICP.

Mannitol is excreted entirely through the kidneys and causes a pronounced osmotic diuresis. A Foley catheter is necessary when mannitol is used. There is a risk of acute renal failure due to acute tubular necrosis, especially when used in large doses or the serum osmolality is allowed to exceed 320 mOsm/L. Mannitol should not be used when there is pre-existing renal failure.

In the absence of ICP monitoring, mannitol can be given when there are signs of transtentorial herniation or progressive neurological deterioration. The initial dose is usually 0.5–1 g/kg body weight given intravenously. The child is then given mannitol at a dose of 0.25–1g/kg. Intermittent bolus doses (administered 4–6 hourly) are thought to be safer and more effective than a continuous infusion.

Care should be taken to maintain euvolaemia since the brisk diuresis can quickly cause dehydration. Serum sodium and osmolality should be checked one hour before each dose and the dose omitted if the sodium exceeds 150 mEq/L or the osmolality exceeds 320 mOsm/L (serum osmolality is best measured with an osmometer, and not calculated). Mannitol has been advocated as a "small volume resuscitation fluid" to be used in the initial fluid resuscitation of patients with head injury and hypovolaemia.

Loop diuretics can be used in combination with mannitol. The drug of choice is furosemide. In addition to causing diuresis, furosemide has been shown to decrease CSF production. The recommended dose is 1 mg/kg/day. Furosemide can be used in addition to mannitol. No matter which diuretic is used, it is important to maintain euvolaemia since hypovolaemia and even brief episodes of hypotension are associated with poor outcome. These two drugs may have a synergestic action if used in combination. If used in combination with mannitol severe dehydration and electrolyte imbalances may result. So, very careful monitoring is essential in such situations.

Ventilatory Support

The concept of hyperventilation was built on the foundation of the response of the cerebral vasculature to CO_2. The logical extension of this was the use of hyperventilation to reduce ICP. Since raised ICP and brain swelling occur in up to 40% of patients with severe traumatic brain injury it was assumed hyperventilation would benefit all with raised ICP.[12] Hyperventilation, however, is a double edged sword. It reduces the ICP by vasoconstriction but this vasoconstriction also worsens the already existing cerebral ischaemia which is almost an inevitable occurrence of severe head injury. So the use of hyperventilation is limited to brief periods when there is an acute deterioration or "for longer periods if there is intracranial hypertension refractory to sedation, paralysis, CSF drainage and osmotic diuretics".[12] The use of chronic prolonged or prophylactic hyperventilation should be avoided.[12]

Modes: No single mode of ventilation has been shown to be superior to another in the care of head-injured patients. However, it is prudent to use the lowest mean airway pressures possible, since this will minimise the intrathoracic pressure and thus prevent further increases in the ICP. Either a pressure controlled or volume controlled mode of ventilation can be used. If pressure control is chosen, just enough pressure to move the chest adequately should be used. Care should be taken to avoid large tidal volumes as this will increase the incidence of barotrauma and volutrauma to the lungs, and will increase the intrathoracic pressure. Generally, a tidal volume of 7–10 ml/kg should be sufficient. Similarly, inspiratory times should be age appropriate and generally ranging from 0.6 seconds in the newborn to 1 second in older children and adults.

High levels of positive end expiratory pressure (PEEP) should also be avoided because it will raise the intrathoracic pressure and may impede venous return, thus affecting the ICP. In the uninjured lung, a PEEP of 2–4 cm H_2O is used. Using no PEEP can be detrimental since it may lead to lung collapse at the end of expiration. However, if there is lung damage and oxygenation is impaired, as much PEEP should be used as is necessary to maintain optimal oxygenation.

Routine nursing procedures, such as endotracheal suctioning, cause an increase in the ICP. Therefore, the patient should be disturbed as little as possible. IV lidocaine (1 mg/kg) has been advocated prior to suctioning in order to blunt the centrally mediated increased ICP.[41] However, this has been questioned recently and, if used, it should not be administered more often than every 4 hours to avoid over dosage.[76] If intermittent paralysis is used, the suctioning can be timed to immediately follow the dose of paralysing agent to abolish the cough response.

Surgical Measures

Surgical measures include CSF drainage, removal of mass lesions and decompressive craniectomy.

CSF drainage: Although the indications and guidelines for ICP monitoring in children are still being worked out, ICP monitoring has almost become a standard of care in adults. Monitoring through an indwelling ventriculostomy catheter is probably the best. If such a device is available it can be used to monitor the ICP and also vent CSF whenever the ICP rises. The volume of CSF to be drained will depend on the clinical scenario and the protocol followed by the team in charge of the child. The CSF can be removed manually every time the pressure rises beyond a set level or the drainage chamber can be positioned in such a way that the CSF drains automatically when the pressure goes above the set level.

CSF drainage through the lumbar route has its advocates too and it has been successfully employed. This has been tried not only in those with subarachnoid haemorrhage, but also in those with "refractory intracranial hypertension".[63] In a study of adult patients who had refractory intracranial hypertension, even after conventional therapies had failed, lumbar CSF drainage was instituted if the basal cisterns were seen on CT. The conclusions of the study were, "Controlled lumbar cerebrospinal fluid drainage significantly reduces refractory intracranial hypertension. The danger of transtentorial or tonsillar herniation is minimised by considering lumbar drainage in the presence of discernible basilar cisterns only". Similar work has also been done in children and the results have been good.[54]

Removal of mass lesions, if they are responsible for raised ICP, should be done promptly. The management issue of these has been addressed in the appropriate chapters.

Decompressive craniectomy, which was initially described by Cushing, is now staging a resurgence, but it is mired in debate and controversy. It is used in cases of refractory intracranial hypertension where conventional therapies have failed. The technique involves removal of a large bone flap and opening the dura. The dura may be left open as it is or a patch may used to "enlarge" the volume of the dural compartment. Once the period of intracranial hypertension has settled and the patient has improved, cranioplasty is done. There are proponents and opponents to this method of managing "malignant" raised ICP. The decompression may be bifrontal or temperoparietal.

Bifrontal decompressive craniectomy has been shown to reduce the ICP and also the amplitude of the ICP waves.[100] In children, unilateral decompressive or bilateral craniectomy has been shown to be associated with a good outcome.[43,87] This has been shown to be useful even in the presence of associated intracranial lesions and the recommendations are to perform it sooner rather than later.[23] The experience of one and all has not been so gratifying. The observations have shown "there was a significant decrease in midline shift after craniectomy, but this did not translate into decompressive craniectomy demonstrating a beneficial effect on patient outcome".[62] Observations have also shown that there is "a significant decrease in expected mortality, but severe morbidity in the survivors".[94] Correlation of the clinical and experimental findings also does not show that this procedure confers an excellent benefit on the outcome.[21]

What has to be borne in mind is that this procedure does not always translate into a good outcome for those with refractory raised ICP. Until randomised studies are done this has to be considered a last ditch effort to salvage a limited group of patients who have failed all other therapies to control the raised ICP. The results in terms of improved mortality and particularly morbidity remain unproven at the present time.

Corticosteroids have been utilised as a standard form of treatment in the management of head injury until recently. There is a large volume of literature regarding their use in head-injured patients, both adults and children. However, none have shown conclusively that the administration of steroids is beneficial or has any adverse effects.[4] Therefore, steroids are not recommended in the treatment of head injuries at this time.[12]

Therapy for associated problems too cannot be taken lightly. These may appear simple at first glance, but often have far reaching consequences.

Hypo/Hyperthermia

Hypothermia as a therapeutic measure to combat raised ICP was proposed initially in the 1950s.[2] Mild to moderate hypothermia (32–34°C) has been advocated in the management of severe head injury. Several studies in the past have shown beneficial effects, such as lower incidence of seizures, decreased ICP and an improved neurological outcome. Its beneficial effect in children was reported, but due to "lack of scientific methodology" this did not gain widespread acceptance. Even in adults this has not proved useful.[2] A review has concluded that there is no evidence that hypothermia is beneficial in the treatment of head injury.[32]

In contrast, hyperthermia (even 1–2°C for brief durations) has marked deleterious effects on neuronal recovery and blood-brain barrier integrity and should be controlled immediately.[31] Fever is a serious problem in the ICU. The cause may be neurogenic, i.e. related primarily to the injury, or it may be the result of polytrauma or sepsis. The cause for the fever should be established and treated vigorously. Every degree centigrade rise in temperature increases the $CMRO_2$ by 9%. So it is clear why fever is deleterious in the head-injured child.

Seizures

Between 6.5% and 10% of children with head injury develop post-traumatic seizures. Post-traumatic seizures are further divided into early onset (occurring within one week after injury) and late onset (occurring later than one week after injury). Children are more prone than adults to develop early onset seizures. Seizure activity has multiple adverse effects in head injury. They can affect ventilation and oxygenation, thus leading to secondary damage and increased ICP. In addition, they also increase the metabolic demands of the already injured brain. Therefore, seizures must be treated aggressively.

Immediate control of seizures can be achieved with either lorazepam or midazolam, 0.1 mg/kg IV. The dose may be repeated if needed. In addition, the patient should also be started on a longer acting drug, such as phenytoin (loading dose of 15–20 mg/kg followed by a maintenance dose of 5–8 mg/kg). Phenobarbital, although effective, is not recommended because it depresses the sensorium and can mask a deteriorating neurological status. For uncontrolled seizures or status epilepticus the child may require thiopentone sodium.

Certain patients are more at risk of developing early onset seizures. These include those with a GCS less than 10, EDH or SDH, penetrating head injuries, intracerebral haematomas and depressed skull fractures. Such patients may also be given anticonvulsants prophylactically. However, although prophylactic administration of anticonvulsants is effective in preventing early onset seizures, this does not prevent late onset seizures nor does it have any effect on the incidence of death or neurological disability.[81] Therefore, prophylactic anticonvulsants are recommended only during the first week in patients at risk of developing seizures.[12]

Complications

Disseminated intravascular coagulation (DIC): Brain tissue is a rich source of tissue thromboplastin. Following a severe traumatic brain injury there may be a significant

outpouring of thromboplastin from the injured brain. The released thromboplastin initiates the coagulation cascade which results in the scenario of a "runaway" consumptive coagulopathy or DIC. In one study, one-third of paediatric patients with head injury had evidence of DIC.[61] This can occur as early as one to two hours following the injury and the patient can have profuse bleeding that is difficult to control. Therefore, all patients with severe head injury should have their coagulation status monitored at admission and also as indicated clinically, regularly, and any bleeding tendency must be treated aggressively with fresh frozen plasma and cryoprecipitate, as appropriate.

Neurogenic pulmonary oedema (NPE) generally occurs 2–12 hours after injury, although its onset can be delayed further. It manifests as hypoxia, hyperventilation and hypercarbia, with bilateral fluffy infiltrates on the chest X-ray. This oedema is non-cardiogenic and is due to increased pulmonary permeability. Medullary ischaemia causes a sudden massive surge in sympathetic activity, which leads to increased pulmonary vascular pressures and shifts blood from the systemic into the pulmonary circulation. There is increased permeability in the lungs, which allows the transudation of fluid into the alveoli.

NPE generally resolves spontaneously if the patient survives. However, it may complicate patient management because the hypoxia can lead to secondary injury. In order to overcome the oedema, high levels of PEEP may need to be applied. This, in turn, can interfere with cerebral venous drainage and thus increase ICP. The presence of NPE in any head injured or polytrauma victim results in a poor prognosis.

SUMMARY

The management of a child in the ICU is a dynamic process, in the sense that no one rule or therapy can be strictly adhered to in a given child since the clinical scenario may change frequently. The management has to be changed as per the dictates of the clinical situation. The management in the ICU has been stratified into three tiers which serve as a foundation for guiding the treatment.[55] It should be emphasised that there is no "water tight" division between the various levels and there is a considerable degree of overlap between the various tiers. It is worthy of note here that a lot of the management strategies have evolved from the studies of head-injured adults (since the incidence of head injuries is more in adults, various modalities can be evaluated by clinical trials) and the child admitted to the ICU for various other causes. What should also be borne in mind is, if the child is treated merely as a small adult it would amount to courting disaster.

Treatment has been divided into basic, escalated and intensive tires (Table 10). Two rules are to be observed in following these guidelines before "escalating therapy to any higher level":

Table 10: Different treatment therapies

Treatments	*Monitoring*
Basic level therapy:	
• Elevation of head end of bed	• Systemic BP and oxygenation
• Keep head in neutral position	• Intracranial pressure
• Sedation ± Paralysis	• PaO_2; $PaCO_2$; pH
• Mechanical ventilation to keep $PaCO_2$ between 35 and 40 mmHg	• Intake/output; pulse; pulse pressure; weight
• Maintain euvolaemia to slight hypervolaemia	• Haemogram; serum electrolytes; blood glucose and blood urea nitrogen
• Maintain normal fluid and electrolyte status; No fluid restriction; avoid anaemia and hyperglycaemia	• Monitor for sepsis/fever and if present treat aggressively
• Temperature: maintain euthermia; treat hyperthermia	• CT scan
Escalated therapy:	
• Ventricular CSF drainage	• Ventricular catheter
• Mannitol	• Central venous pressure
• Maintain $PaCO_2$ between 30–35 mmHg	• Serum osmolality
Intensive therapy (for refractory raised ICP):	
• High dose barbiturate therapy	• Continuous EEG, serum level of barbiturates
• Lumbar CSF drainage	• Jugular venous O_2 saturation, CBF
• (? Decompressive craniectomy)	
• Hyperventilation for acute rise in ICP	

(Source: Modified from Leurssen[55])

- "one must confirm that the current therapy is being correctly applied"
- "prior to any escalation of therapy, escalation of systemic and neurologic monitoring must occur."[55]

OUTCOME

Head injuries have been divided into two broad categories: (1) primary and (2) secondary. The former occurs at the time of the injury while the latter occurs later on as a result of a compromise in A, B, C, D, E and F which have been discussed earlier. A compromise in any of these ultimately results in neuronal hypoxia, leading to injury or death of the neurons and this is the reason for the poor outcome. Nothing can be done about primary injury apart from prevention and prophylaxis, while preventing the latter is very much in our hands and every effort has to be taken to minimise it, if not prevent it all together.

Using the GCS scoring system about 80% of head injuries in children are mild (GCS 13–15), while 10% are moderate (GCS 9–13) and 10% are severe (GCS 3–8).[58] Using the above criteria, the incidence of severe injuries in children is half that of adults.[58] Severe brain injury is commoner in the "older" population than it is in children. It has also been observed that the outcome in children is better than it is in adults.[3,57,58]

Factors associated with a poor outcome include low GCS and prolonged impairment of consciousness.[58] These were seen not only at the time of discharge but also at 6 months post injury and several years after the injury.[58] The GCS alone is a good predictor of outcome in children. Hyperglycaemia, and especially its persistence over time, appears to be an important negative prognostic factor in children with head injury.[19] The factors which result in a poor outcome include presence of hypoxia on admission and CT scan features of subarachnoid haemorrhage, diffuse axonal injury and brain swelling.[64] In those with a minor head injury, no clinical sign is absolutely indicative of an ominous outcome. We have to depend on imaging studies to identify those children with mild head injury who are at risk.[48] The morbidity and mortality are higher in infants and young children than in older children.[2,58]

The data generated by the Traumatic Coma Data Bank have shown very important and interesting features. About 103 children (0–15 years of age at the time of injury) treated at four centres were evaluated at 6 months (92 children) and 1 year (82 children) post injury. The Glasgow Outcome Scale was used to assess these children. Children 0–4 years fared the worst (62% mortality at 1 year) whereas children 5–10 years fared the best (2/3 good recovery at 1 year), the others were in between these two groups. A low GCS score concomitant with non-reactive pupils was particularly predictive of poor outcome. Bilateral brain swelling with or without midline shift and the presence of a mass lesion seen on CT were also predictors of a poor outcome. The Kings Outcome Scale for Childhood Head Injury (KOSCHI) is a specific paediatric adaptation by Crouchman et al. of the original adult GOS. The GOS category of "persistent vegetative state" was replaced by vegetative. "Good recovery" was allocated two categories, keeping in mind the relatively minor sequelae in a developing child. They have also elaborated in detail the definition of each category for easy adaptation in children.[93]

In short, the outcome after a severe head injury depends on age, neurologic state and CT findings as have been discussed above.[53] Not only the mortality is less in children compared to adults, the outcome in survivors is better too. In a series of 330 patients, the mortality in children was 24% as opposed to 44% in adults. One year post injury, 55% of children and 21% of adults had a good outcome.[2] Even though the overall outcome in children is better than adults, children do not always emerge "unscathed" after a severe head injury. A variety of anxiety symptoms have been recorded in children 1 year following severe head injury.[93]

CONCLUSION

Most of the literature suggests children fare better than adults after a head injury. "The significant influence of age on outcome is not explained by the increased frequency of systemic complications or ICH with age."[12] Children do not react or respond to an injury, whatever be the nature of the injury, the way adults do. The fundamentals may be same in all age groups, but the problems in children are unique; even clinical assessment is fraught with difficulties. As has been mentioned earlier, infants may manifest few clinical features in spite of harbouring an intracranial pathology.[69] A CT should be done in all symptomatic children although this may not be true for their adult counterparts.

In the light of the rising cost of medical care, the routine scanning and admission of all children who have sustained a head injury has been brought under scrutiny.[1,37,82] A prospective study has shown the need for CT even in children with mild alterations in mental status (GCS 13–14).[97] More studies are mandatory to come to a firm conclusion and, if done prospectively, firm conclusions/guidelines can be proposed.

In an analysis of a large series of head-injured children, two factors which determine the presence of an intracranial complication have been identified and these can be identified by the primary care taker, these are impaired consciousness and skull fracture.[17] An increased awareness should be created to prompt early referral for a better outcome.

Children present problems that are unique and completely different from those of adults. The aetiology of injury, the difference in physiologic parameters, possible interference with growth and development, and the requirement of different set of facilities in terms of personnel and equipment present facets and cannot be compared to the larger adult population.[46] The question of who should care for children with a head injury has been the subject of many a debate. The data show children who have suffered a blunt trauma have a better outcome when treated at a paediatric trauma centre.[40] This better outcome has been shown not only with respect to trauma in general but also head injuries in particular. Children brought to a paediatric trauma centre have had a better outcome than those who have been referred to another hospital and then transported to a paediatric centre.[47] The improved outcome in head injuries has contributed significantly to the overall better outcome.[68]

A poor outcome in severe head injury is not unknown or it, probably, is only to be expected. But the incidence of disability after a mild head injury in young people and adults seems to have been underestimated.[91] So much so the very concept of mild head injury seems to have been questioned. Whether this can be extended to children needs to be evaluated.[89]

The development of a treatment strategy for a severely head-injured child involves a synthesis of the known clinical and radiographic classification of the

injury with the nature of mitigating systemic injuries and complications. It also involves the continuous reassessment of the evolution of the injury, both expected and unexpected, and the responses to each therapy. Selecting a therapy is still a matter of experience.[58]

33 Clinical Assessment of a Head Injured Patient

Rajkumar, Samir Kumar Kalra, Ashok Kumar Mahapatra

INTRODUCTION

The successful management of patients sustaining head injury requires careful assessment of the details and diligent anticipation of forthcoming sequelae. A comprehensive neurological evaluation of the head-injured patient remains the single-most efficient factor in their diagnostic evaluation. A correct assessment not only helps in better management but also enables us to do a judicious triage of such patients.[8,9] The clinical evaluation provides an index of local and generalised dysfunction of the nervous system and repeated assessment indicates the ongoing neurological state and the response to treatment. The clinical assessment thus is central in the initial evaluation and subsequent management of all head-injured patients.[10,11]

Such an assessment requires a careful general examination to look for associated injuries and other sources of bleeding helping in prioritising the treatment and carrying out requisite investigations. The patients may present in a conscious state or with altered consciousness, and the major goals of assessment[12] are:

- To determine the presence of an intracranial mass lesion requiring operative removal.
- To have a baseline evaluation of clinical parameters for future comparison.
- To define an abnormal intracranial mass lesion for institution of appropriate operative or non-operative therapy.
- To diagnose associated injuries.
- To carry out necessary investigations.
- To prognosticate patients and apprise them or relatives of the possible course of illness.
- To allow statistical analysis and comparative studies.

However, before any clinical evaluation, it is important to assess and ensure the patency of the airways, and ascertain the systemic circulatory status by recording the blood pressure and pulse.

CONSCIOUS LEVEL

The initial evaluation should be as thorough as possible whether the patient presents in a conscious or an unconscious state. The anatomical, as well as physiological parameters are assessed on examination. The anatomical parameters are assessed by the abbreviated injury scale and the injury severity score. The Glasgow Coma Scale (GCS) and the Revised Trauma Score (RTS) are commonly used to measure the physiological derangements. The internationally accepted standard scale to quantify the neurological state after head injury is the GCS and the numerical scores used for assessment in this score have demonstrated their practicability and validity in prognosticating patients of head injury over the years.[16] The RTS provides an assessment of the physiological state by including respiratory rate, systolic blood pressure and GCS. The trauma score and injury severity score and a severity characterisation of trauma are the recent introductions to the scoring assessment scales. The GCS still remains the most widely used and has stood the test of time over the years.[10,12,16] The most important fact in respect to consciousness is not the findings of the initial observation but its dynamic changes virtually from the moment of injury and especially in the early post-traumatic period.

GENERAL EXAMINATION

The first concern of the physician after having assessed the level of consciousness is to assess the respiration and ensure a clear airway and oxygenation. The establishment of adequate alveolar ventilation assumes top priority. All accumulated secretions, blood or vomitus should be sucked away and associated jaw, tongue, throat or chest injuries should be looked for as all of these impede respiration.[9,12,17] The respiratory abnormalities should be attended to expeditiously to prevent further injury to the already insulted brain. Endotracheal intubation is often necessary to protect the airway and maintain the ventilation. As a rule, intubation requires ventilation.[2,12,17]

The vital parameters including the pulse rate, blood pressure and respiration should be assessed. Head injuries associated with raised ICP may manifest Cushing's response of raised blood pressure and bradycardia.

Editorial note: In clinical practise, this is extremely rare and not a helpful feature for assessment or management of acute head injury.

The patients who present with shock usually have associated visceral injuries or fractures of long bones as the cause of their blood loss and they manifest with hypotension associated with tachycardia.[7,9,12] The presence of shock, however, is observed in the initial period

following head trauma and it generally recovers spontaneously. An association of hypotension with bradycardia is suggestive of cervical injury.[5,10,12] It is important to recognise that in infants and young children even a small amount of blood loss, as in a scalp haematoma, could result in hypotension.

CLINICAL HISTORY

The history is the next step in evaluation after having stabilised the respiratory and vascular status of the patient. A complete history can be given by a conscious patient and should be obtained. Information regarding the precise time of injury and mechanism of injury should be elicited. The feedback from the attendants, relatives, police or any eye witness who brought the patient should also be obtained regarding the scene of the accident and the course of events following injury.[2,8,12] Their account of the accident becomes absolutely important in patients who are in an unconscious state. A report from the referring hospital, if any, should actively be sought. The information regarding drug or alcohol intake and the past medical history is also valuable. The history of bleeding from the ear, nose or throat should be sought. The duration and timing of loss of consciousness has to be asked for. The associated co-morbid conditions and any significant concurrent or past illness (e.g. diabetes, hypertension, ischaemic heart disease, etc.) should be enquired for and taken note of. They are important in management and prognosis. The history regarding leak of cerebrospinal fluid (CSF) from the nose or ear must be asked for.[3,5,12]

Post-traumatic amnesia is an index of the severity of injury and should be asked for. It is also a significant risk factor for the occurrence of post-traumatic seizures.[18] In conscious patients, memory regarding the accident and recent events should be tested. The duration of retrograde and post-traumatic amnesia should also be recorded. Post-traumatic amnesia is a useful index of severity of the injury and a good guide to the period of rehabilitation necessary before return to full work. In children this assessment, however, becomes difficult.[9,12] Brachial plexus or peripheral nerve injuries are also sometimes associated and should be ruled out historically.

A history of seizures should be enquired into and recorded. The seizures occurring following trauma may be of three types:

1. Immediate seizures; occurring within 24 hours.
2. Early seizures; occurring within 7 days.
3. Late seizures; occurring later than 7 days.

The diagnosis of head injury is usually straightforward and stabilisation of the patient assumes highest priority. Due to these factors, a detailed history is not taken in these patients and is mostly missed. This tendency should be condemned and one must be aware of the importance of a detailed history in these patients. All such information is valuable not only for diagnosis and management but also may be required for medico-legal purposes.[10,12]

GENERAL PHYSICAL EXAMINATION

The patient should systematically be examined after appropriate resuscitative measures and detailed history have been obtained. The examination should be comprehensive and must include the general physical condition as well as neurological status. The vital parameters should be recorded and, importantly, for temperature recording, the rectal temperature should be obtained. This is reflective of the central body temperature and not affected by external factors. The chest, abdomen, pelvis, spine and long bones should also be assessed for associated injuries and an effort should be made to have a comprehensive whole-body examination. All scalp wounds, lacerations and avulsions should be inspected. The forehead should be palpated for signs of a depressed fracture or frontal sinus injury. Associated CSF rhinorrhoea or otorrhoea are usually secondary to basal skull fractures and should be sought. Bilateral periorbital haematomas (raccoon eyes) result from fractures of the orbital roof. Associated bleeding beneath the pericranium over the mastoid (Battle's sign) usually appears after 2–3 days.[10,12] Dental occlusion should be checked to rule out a mandibular fracture. A high index of suspicion should be kept for an associated cervical injury. The auscultation of carotid arteries and the eyes should be done to rule out an associated carotid dissection and traumatic carotid cavernous fistula, respectively. A careful examination of the chest and abdomen is mandatory.

NEUROLOGICAL ASSESSMENT

The single most important parameter of neurological examination is the state of consciousness. This should be recorded meticulously as per the GCS as already discussed. The score was first introduced in 1974 and then revised in 1977 by the addition of another motor response.[5,10,12,16] The score includes eye opening, best motor response and best verbal response (Table 1).

Table 1: Glasgow coma scale

Eye opening:
1. No eye opening
2. Opens eyes to pain
3. Opens eyes to verbal commands
4. Spontaneous eye opening
Best motor response:
1. No movement
2. Extensor response
3. Flexor response
4. Withdraws to pain
5. Localises to pain
6. Obeys commands
Best verbal response:
1. No sounds
2. Incomprehensible sounds
3. Inappropriate words
4. Confused conversation
5. Well oriented speech

The patient is examined vis-à-vis the above list and each patient is given a score after adding the three parameters. A fully conscious patient has a score of 15 and a deeply comatose and areflexic patient would have a score of 3. A GCS of 8 or less is consistent with coma. The GCS has been adopted by neurosurgical units all over the world to evaluate head-injured patients. The score also helps to classify the types of head injury into three categories namely:

1. Mild head injury; GCS 13–15.
2. Moderate head injury; GCS 9–12.
3. Severe head injury; GCS 8 or less.

The score, however, has a few pitfalls despite its wide acceptance. They are:

- Eye movements and other brainstem reflexes are not taken into account.
- Patients with dysphasia or with bilateral ecchymosis have inaccurate recording.
- GCS does not take into account the pupillary status and vital parameters.
- Facial fractures or lip and tongue injuries may impede patients from talking.
- The usefulness in children is limited and a modified scale called the "children coma scale" is used for them.

The children coma scale has the same three parameters used in the GCS and only the verbal response is different from the GCS. This is best used in children below 4 years of age. The verbal response is as follows (Table 2):

Pupillary Status and Optic Nerve Function

The pupillary status constitutes an important part of the neurological examination and the size, shape, position, reaction to light and the pupillary reflexes should be recorded in all cases. An attempt to see the fundus is also made at this time along with the observation of the iris margins and evidence of local injury to the eye.[10,12,15] The pupillary examination provides important clues to the diagnosis and treatment and is a sensitive indicator of a developing intracranial mass.

The pupillary size depends upon a balance of tonic forces constituted by pupilloconstrictor parasympathetic and pupillodilator sympathetic controls. The pupillary status and their changes are related to the brainstem and both II and III nerve activity. In an unconscious patient, the direct and consensual reflexes are most important aids to assess optic nerve function.[15] In patients having hemianopias, the signs are elicited from the blind side of the visual field. The direct and consensual reflexes should both be elicited as they help to distinguish between II and III nerve injuries. A unilateral dilated and non-reactive pupil with absent consensual reflex points towards an underlying optic nerve injury. The interruption of oculo-sympathetic neurons may result in Horner's syndrome.[9,12,15] This syndrome is characterised by unilateral miosis, facial anhidrosis, ptosis, pseudo-enophthalmos and loss of ciliospinal reflex.

Bilaterally dilated pupils are indicators of a poor prognosis and are early harbingers of brain death.[6,15,19] There are certain conditions like bilateral glaucoma with blindness, drugs like atropine, datura and glutethimide poisoning which can lead to bilateral pupillary dilatation and such entities should be kept in mind when one sees a patient with bilaterally dilated and non-reactive pupils.

The patients with accidental or post-surgical aphakia may have irregular pupils. Colobomas of the iris may lead to irregular pupils as well. Opiate and barbiturate poisoning lead to small-sized pupils. All such abnormalities of the pupil should also be borne in mind during the pupillary examination.

Table 2: Verbal response

Points	*Best verbal response*	
5	Smiles, oriented to sound, follows objects and interacts	
	Crying	*Interaction*
4	Consolable	Inappropriate
3	Inconsistently consolable	Moaning
2	Inconsolable	Restless
1	No sound	No sound

Eye Movements

The eye movements are commonly affected after structural lesions and can easily be tested in conscious and cooperative patients. For unconscious patients, the "Doll's head ocular movement" and oculovestibular reflex (caloric response) can be elicited. These are amongst the most important signs for assessment of brainstem function.[4,11] Sinha et al.[13] were the first to study this systematically in a large series of unconscious patients. Its value was later confirmed in an autopsy study.[14]

The "Doll's head ocular movement" is performed in the supine position and rotating the head horizontally or vertically to 30° from the neutral position. The eyes normally maintain their position in space by moving to the side opposite to the direction of movement of the head and absent movement indicates brainstem insult. The test is not performed in cases with suspected cervical spine injuries.

The "oculovestibular reflex" is elicited by caloric stimulation of the labyrinth. The patient is supine with head flexion of 30° so that the horizontal semicircular canal lies in the vertical plane, with the ampullae at the highest point. The ears are irrigated with water, first at 30°C and then at 44°C for 40 seconds. In comatose patients, irrigation of the external auditory meatus is done with at least 20 ml of ice cold saline. The presence of nystagmus in the same direction as the warm saline and in the opposite direction to the cold saline (well-known mnemonic: COWS) is indicative of the integrity of the brainstem. It also helps to evaluate abnormalities of the ocular nerves or gaze paresis.[4,11] It also helps to

predict the prognosis and in case the reflex is not elicited, brainstem injury can be inferred.

Patients with head injury can also have upward or downward gaze palsies. The upward gaze palsies occur in compressive or destructive lesions involving the pretectal area of the midbrain, posterior commissure and dorsal midbrain tegmentum.

Lesions in the pons involving the pontine paramedian reticular formation (PPRF) produce conjugate deviation of the eyes towards the opposite side. Internuclear ophthalmoplegia is due to a lesion in the medial longitudinal fasciculus (MLF) of the midbrain. In this condition, there is impaired adduction of the ipsilateral eye with nystagmus of the abducting opposite eye during attempted lateral gaze to the opposite side. The so-called "one and a half syndrome" is due to a lesion involving both the PPRF and the MLF on the same side and is associated with ipsilateral gaze paresis with impaired adduction of the ipsilateral eye and nystagmus on abduction of the opposite side. It is possible to ascertain these deficits by using the cold-caloric (vestibulo-ocular reflex) test in unconscious patients.

Skew deviation in which one eye is directed upwards and the other eye is directed downwards may also be noted. They are indicative of lesions of the brachium pontis or dorsolateral medulla and point towards a grave prognosis.

Other Cranial Nerves

It is impossible to examine the olfactory nerve in unconscious patients. Fractures of the anterior cranial fossa may be associated with loss of smell and, so, the sense of smell should be examined in all conscious patients.[10,12]

The V cranial nerve may be injured in fractures of the middle cranial fossa. The corneal reflex tests the integrity of the V and VII cranial nerves and is done with a moist light cotton wisp. The VII and VIII cranial nerves may also be affected in fractures of the petrous pyramid. The more common longitudinal fracture of the petrous bone is due to a lateral blow to the head and may result in facial nerve injury and CSF leak. The less common transverse fracture results from occipital blows and is associated with a higher incidence of facial nerve injury and other complications.[12] There may be associated CSF otorrhoea, deafness or vertigo. Patients may also have vertigo on account of micro-haemorrhages in the vestibular system. It is impossible to test the auditory component of the VIII nerve directly in the unconscious patient (except by evoked potential using audiometric inputs). The vestibular component is tested using the caloric test.

Posterior fossa fractures involve the lower cranial nerves. A haematoma below the mastoid is seen as a skin discolouration. The assessment of vocal cord function, gag and swallowing evaluates glossopharyngeal and vagus nerve functions. The endotracheal tube in an unconscious patient can be manipulated to elicit these responses.

Motor Examination and Reflexes

In conscious and alert patients, muscle tone can be evaluated by passive range of movement and muscle power by assessing voluntary movement. The Medical Research Council Grading is used to grade muscle function:

Grade 0: Complete paralysis
Grade 1: Flicker of contraction
Grade 2: Muscle contracts, but cannot overcome gravity
Grade 3: Muscle contraction against force of gravity only
Grade 4: Some degree of weakness can be overcome with resistance
Grade 5: Normal power

The assessment of motor power in an unconscious or unco-operative patient is done by observing the characteristics and strength of response to painful stimuli. The painful stimulus used is pressure applied with the thumb in the supraorbital groove thereby pressing on the supraorbital nerve. The responses of the two sides are compared.

Mass effect on one side produces pupillary dilatation on the same side with hemiplegia of the opposite side.[2,15] This is the usual situation and is due to the involvement of the III nerve, and the pyramidal tracts in the cerebral peduncle. There are exceptions to this axiom and the dilated and non-reactive pupil may be associated with ipsilateral hemiplegia due to the indentation of the contralateral cerebral peduncle by the edge of the tentorium cerebelli (Kernohan's notch). The "decorticate posture" indicates severe supratentorial damage. This is represented by patients in abnormal flexion with adduction and internal rotation of the shoulders, slow flexion of elbow, wrist and fingers with flexion or extension of the lower limbs. The "decerebrate posture" indicates a lesion in the midbrain between the superior and the inferior colliculi. There is extensor motor response with the head extended backwards and extension of all limbs and internal rotation of the arms and opisthotonus position.

Deep tendon and superficial reflexes should be examined. The common tendon reflexes include biceps, supinator, triceps, knee and ankle jerks. The abnormal reflexes may be exaggerated, diminished or absent. The superficial reflexes include the plantar reflex and the superficial abdominal reflex. Patients with corticospinal tract involvement have an extensor plantar response. In patients with suspected spinal cord injury, anal wink and bulbocavernous reflexes are also checked. The tests for co-ordination, involuntary movements and gait should be included as a part of the examination whenever feasible. They may also give an important insight to the prognosis of head-injured patients.

SENSORY AND LOCAL EXAMINATION

The sensory examination should include tests for pain, touch, temperature, vibration and sense of position.

This part of the examination should not be neglected. The local examination should include looking for any external swelling, laceration or avulsion. It should be detailed and comprehensive as well, looking for the sites of fractures and scalp haematomas. A simple depressed fracture can often be seen and palpated, except when covered by a scalp haematoma. Local deformity and tenderness should be sought. The examination of the neck for tenderness and stiffness should be performed as a routine and there should be a high index of suspicion of an associated cervical injury in all cases of head injury.

BRAIN DEATH

The crucial point in determining brain death is the cessation of all brainstem functions. The aim of neurological examination is to prove death of the whole brainstem and to detect any evidence of persisting function. The causes of brainstem death can be either related to primary damage of the brainstem itself or secondary damage resulting from increased intracranial pressure with compromised blood supply.[1,12] A better understanding of brainstem death has clearly increased the number of patients in whom mechanical ventilation has electively been stopped, avoiding both an excessively long and tragic waiting period for the family and the enormous costs of intensive care. The concept of brain death became a legal issue and, in India, it was defined in 1995 in "The Transplantation of Human Organ Act, 1995". There are various criteria used differently all around the world to define brain death. Each brain dead patient is a potential donor for organs and all neurosurgeons must be well aware of the rules, regulations and the essential criteria required for such a diagnosis.

SUMMARY

Head injury is a significant public health problem today. It is a dynamic phenomenon and the initial assessment of a head-injured patient is highly dependant on a thorough clinical assessment. Despite a few drawbacks, the GCS has widely been accepted as an index of evaluation of these patients. The scheme of examination follows a strict protocol and has to be tailored according to the neurological status of the patient. Following systematic guidelines helps in examining unconscious and uncooperative patients and a wealth of information can be derived. Most of the cranial nerves can also be and should be assessed in these patients. A comprehensive sensorimotor examination follows assessment of cranial nerves. Detailed neurological evaluation helps in prognosticating and prioritising the treatment and helps in deciding further investigations. Better management can be accorded in case such a schema is followed.

34 Fluid and Electrolyte Balance in Head Injury

Sharma RR

INTRODUCTION

In the setting of head injury, the incidence of significant fluid and electrolyte imbalance increases with the severity of injury. Though it is very rare in minor head injury (1–2%) and infrequent in moderate head injury (5–8%), it is very frequent in severely head injured patients (8–25%). Principally, polytrauma patients with severe head injury, especially central neuraxis damage and hypothalamic insult, usually develop fluid and electrolyte disturbances. Fluid and electrolyte imbalances have major implications for the management of these patients as the severity of the disturbance also increases proportionally to the severity of head injury. Minor fluid and electrolyte disturbances are self correctable, moderate disturbances get corrected with routine therapy, whereas the management of severe disturbances may be extremely challenging even in neuro-intensive care units (NICUs). Interestingly, unresponsiveness to treatment also increases with the severity of injury. Before one gets entangled in the vicious circle of intractability and clinical irreversibility, appropriate steps in the management may help in salvaging the patient.

Currently, the overall outcome of primary brain injuries is improving with the use of a structured management plan including active resuscitative measures (ABCDE), use of GCS for initial and subsequent clinical evaluations, controlled ventilation, computerised tomography (CT) scan to study the intracranial status on a periodic basis, emergency neurosurgical intervention, NICU and intracranial pressure (ICP) and cerebral perfusion pressure (CPP) monitoring for physiologic management. Prevention of secondary brain damage is one of the main goals of modern management. Therefore, the management of arterial blood gases, coagulation profile and fluid and electrolyte balance are of paramount importance in these patients to prevent secondary brain injuries, intrahospital morbidity and mortality. Clinical manifestations of fluid and electrolyte disturbances may resemble those due to raised ICP with or without a space occupying lesion such as an intracranial haematoma/contusion. Therefore, periodic CT brain scans and laboratory investigations are utilised to ascertain the appropriate cause and to sort out its management.

GENERAL CONSIDERATIONS

Head Injury Patients

In head injury patients, maintenance of precise fluid balance is of paramount importance in preventing hypovolaemia, electrolyte imbalance and intravascular coagulation. Inadequate fluid therapy results in hypotension and underperfusion of the vital organs, whereas excessive fluid therapy results in cerebral, pulmonary and peripheral oedema. The body's mechanisms are usually adequate for correction/compensation of fluid imbalance of minor and moderate severity, but in the severely or critically ill patients, the mechanisms are usually compromised. These latter cases need intensive care management.

Normal Homeostatic Mechanisms

Normal homeostatic mechanisms maintain intracellular fluid (ICF) and extracellular fluid (ECF) volume, tonicity and composition in healthy individuals (Table 1). However, in patients with acute head injury, alterations in fluid volume, tonicity and composition occur due to an emergent neuroendocrine surge [antidiuretic

Table 1: Composition of ECF and ICF compartments (mmol/l)

Sr. No. Cations	*Ions*	*ECF (plasma)*	*ECF (ISS)*	*ICF*
1.	Na^+	135–145	135–140	5–10
2.	K^+	4.5–5.5	4.5–5.5	156–160
3.	Others	2–3	2–3	14
Anions

	Total	292	302	368

hormone (ADH) to retain water, Renin-Angiotensinogen II-Aldosterone to retain sodium, and catecholamines to support the vascular system], which is mainly aimed at maintaining an effective intravascular volume for adequate cerebral blood flow at the expense of ICF and ECF fluid tonicity and composition [Na^+, K^+, HCO_3^- and H^+].[1,5,28,29] Disturbances of ICF/ECF tonicity and composition are often associated with a worsening neurological status. Excessive capillary leakage in the brain is well recognised as a cause of acute cerebral swelling and its association with high morbidity and mortality. Inappropriate fluid therapy is, therefore, potentially harmful in such patients with acute cerebral trauma. The maintenance of a stable ionic concentration in the body fluids is necessary for normal cellular functions and metabolism.[43,45] Many of the potentially serious complications due to improper fluid and electrolyte therapy are largely preventable and, therefore, should be recognised early in the clinical course and treated in time.

BASIC PHYSIOPATHOLOGICAL FACTS

Fluid and electrolyte imbalance in patients with severe head injury more often present with a diagnostic dilemma and, therefore, precise diagnosis is established by periodic laboratory investigations and neuroimaging studies.

Water Distribution in the Body

A 70 kg person has 42 litres of body water; 28 litres (66%) in the intracellular space (ICF) and 14 litres in the extracellular space (ECF): 10.5 litres in interstitial space and 3.5 litres in plasma. Water is obtained from the diet (1.5–2.1 litres/day) and oxidative metabolism (400 ml/day) and is lost (2–2.5 litres/day) through the kidneys (sensible loss of 1.5 litres/day), lungs, gut and skin (sum total insensible loss of 1 litre/day). Its distribution in ICF and ECF is determined by the osmolalities of these compartments. Osmolality is the sum of the total solute particles in the solution and is expressed as the molal concentration of all solutes in water (mOsm/kg). The normal serum osmolality ranges from 280 mOsm/kg to 295 mOsm/kg. Normally, ICF and ECF are isotonic. Any change in osmolality of a compartment results in the net to and fro movement of water between the ECF and the ICF to restore isotonicity. The minimum volume of urine necessary for normal excretion of metabolic waste products is about 500 ml/day (20 ml/hr), and minimum daily dietary water intake is about 1100 ml.

Free-water deficit = (0.6 × body weight in kgs) × current serum sodium/1.40–1.

Sodium Distribution in the Body

The majority of exchangeable sodium is extracellular: the normal ECF sodium concentration is 135–145 mmol/l while that of the ICF is only 4–10 mmol/l. Most cell membranes are permeable to sodium and the gradient is maintained by active pumping of sodium from ICF to ECF by Na^+/K^+-ATPase pump. The normal daily intake of sodium is about 100–200 mmols, but the daily obligatory loss is less than 10 mmols. Sodium balance is maintained by regulation of its renal excretion; 70% of glomerular filtrate is absorbed in the proximal convoluted tubules, 25% in the loop of Henle and nearly 5% in the distal convoluted tubules and collecting ducts (Renin-Angiotensinogen II-Aldosterone mechanism).[1,5,28,29,43]

Na^+ requirement is usually calculated by the following equation:

0.6 × body weight × serum Na^+ deficit = mmol of sodium × 0.05 = gm of salt required.

1 gm of NaCl gives 44 mmol of Na^+.

Na^+ deficit in mmols × 2 = ml of 3% saline.

1 ml of 3% saline provides 0.5 mmol of Na^+.

Osmolarity of the ECF

The osmolarity of the ECF is normally maintained in the range 280–295 mmol/l of water. Increase in ECF osmolarity in comparison to ICF osmolarity causes three main effects:[4,28,29,43,45]

i. Stimulation of the hypothalamic thirst centre promoting dietary water intake.
ii. Movement of water from ICF to ECF in order to maintain isotonicity, and
iii. Stimulation of hypothalamic osmoreceptors causing the release of ADH for effective renal water reabsorption and minimising urinary water output and, therefore, resulting in a concentrated (low water-high solute) urine.

Osmoreceptors

Osmoreceptors are highly sensitive to the increased ECF osmolarity even by 1% more than the ICF osmolarity and, therefore, stimulation of these osmoreceptors results in immediate release of ADH in the circulation.[4,12,23,29,43,45] They are located outside the blood-brain barrier in the anteroventral region of the third ventricle of the hypothalamus. If the ECF osmolarity falls, then there is no sensation of thirst; ADH secretion is inhibited (and a dilute urine is produced) allowing increase in renal water loss to restore ECF osmolarity (by raising it) to a normal level. If an increase in ECF osmolarity occurs as a result of a solute, such as urea, which readily diffuses across cell membranes, the ICF osmolarity is also increased. In such cases, the ECF and the ICF remain isotonic and, therefore, osmoreceptors are not stimulated.

Hypovolaemia

Significant hypovolaemia (10%) is a powerful stimulus (via angiotensinogen, arterial and venous baroreceptors and volume receptors) to ADH release to restore effective ECF volume even though there is a decrease in osmolarity.[4,8,12,23,29,43,45] Maintenance of volume takes precedence over the maintenance of serum osmolarity. ADH is synthesised in the supraoptic nuclei of the

hypothalamus and passes down the nerve axons into the posterior pituitary from where it is released into the circulation.[1,28,29,43]

Antidiuretic Hormone

Antidiuretic hormone is essential for life as it maintains serum osmolarity by enhancing renal water reabsorption as it increases the permeability of the renal collecting tubules to water in response to increase in ECF osmolarity (above 285 mmol/kg). However, if ECF osmolarity is below 285 mmol/kg ADH secretion is strongly inhibited.[15,28,29,31,35,43]

Mechanism of action of ADH on renal tubules is interesting[27,31] ADH attaches to a specific vasopressin receptor on the contraluminal side of the renal medullary tubular cell. This attachment activates renal (medullary tubular) cellular adenyl cyclase. The latter stimulates production of cyclic AMP. Abundant cellular cyclic AMP then activates a protein kinase on the luminal side of the cell causing phosphorylation of membrane protein leading to an increased permeability of the tubular cell to water, facilitating its transport into the renal medullary circulation and then back into the general circulation. Steroid replacement therapy lowers plasma ADH to normal and inhibits the secretory activity of the supraoptic neurons, and therefore has some role in the syndrome of inappropriate ADH (SIADH) secretion.

ADH plays a vital role in the control of the tonicity of the ECF[8,12,15,23,27,31,35] and indirectly of the ICF and, therefore, overall control of water balance in the body. Excessive ADH secretion results in dilutional hyponatraemia (SIADH) with a risk of water intoxication while decreased ADH secretion results in excessive renal water loss (diabetes insipidus—DI) causing hypernatraemia with a risk of severe dehydration (Table 2).

In the setting of head injury: Minor head injury patients rarely, moderate head injury patients infrequently and severe head injury patients very frequently develop fluid and electrolyte disturbances. In general, patients with brain damage with preservation of the hypothalamo-pituitary axis develop SIADH, whereas DI is due to hypothalamo-pituitary axis disturbance/damage.[1,4,11,22,28,29,43,45] Damage to the posterior pituitary gland may also cause temporary failure of ADH secretion/release.

In head injury patients, ADH is released in response to the clinical status (raised ECF osmolarity, raised ICP, hypovolaemia, nociceptive stimuli, emotional stress), drug therapy (barbiturates, morphine, carbamazepine, chlorpropamide, angiotensin, thyroxin, glucocorticoids, cholinergic and beta-adrenergic stimulations) and mechanical ventilation (positive airway pressure), whereas ADH is suppressed by phenytoin, ethanol, anticholinergics, atropine, alpha adrenergic stimulation, reserpine, chlorpromazine, besides increased plasma volume (hypervolaemia) and reduced plasma osmolarity.[8,12,23,28,29,31,43] Steroid replacement therapy lowers plasma ADH to normal and permits the normal diuretic response to hydration by inhibiting the secretory activity of the supraoptic neurons (a weak response).[28,29,43] Antinatriuretics (catecholamines, Renin-AngiotensinogenII-Aldosterone, cortisol) help in volume restitution or expansion following trauma.

Atrial Natriuretic Peptide (ANP) and Brain Natriuretic Peptide (BNP)

Brain natriuretic peptide (largely of cardiac ventricular origin) has biological effects on the control of blood volume, blood pressure and electrolyte composition. ANP/BNP induce natriuresis through direct tubular effects or by inhibition of the Rennin-Angiotensinogen II-Aldosterone mechanism.[2,22,42]

Hypervolaemia is also kept under check as there is no appreciable ADH secretion in such circumstances and the excess of water is therefore lost from the kidneys. It is routinely measured by central venous pressure monitoring. Moreover, natriuretic peptide hormone (ANP, a 28-amino acid peptide) is produced by the cardiac atria when hypervolaemia exerts excessive stretch on the sensitive atrial stretch receptors. It antagonises the Renin-AngiotensinogenII-Aldosterone mechanism which leads to natriuresis and hypovolaemia.[14,25,42]

Table 2: Clinical manifestations of Na^+ imbalance

Sr. No.	*Organic systems/ clinical state*	*Hyponatraemia*	*Hypernatraemia*
1.	Neurological	Cerebral oedema, disorientation, lethargy, apathy, impairment of consciousness, seizures, coma, Cheyne-Stokes respiration, hypothermia	Cerebral dehydration, restlessness, irritability, disorientation, ataxia, seizures, coma, intracranial haemorrhage
2.	Muscular	Cramps, hypotonic weakness, depressed reflexes, rhabdomyolysis.	Increased muscle tone, hyperreflexia
3.	Renal	Oliguria, concentrated urine or hypertonic urine	Polyuria, diluted urine or hypotonic urine
4.	Gastrointestinal	Loss of appetite, nausea, vomiting	Thirst

Serum Osmolality and Osmolarity

In clinical practise, serum osmolality and osmolarity are routinely measured using the following equations:

Osmolality (mOsm/kg) = 2 x [Na^+] + Glucose/18 + BUN/2.8.

Osmolality is a measure of solute concentrate per kilogram of solvent.

Osmolarity (mmol/l) = 2 x [Na^+] + [urea] + [Glucose]

Osmolarity is a measure of solute concentrate per litre of solution.[29]

ECF osmolarity, ICF osmolarity and the difference between these two are powerful stimuli for osmoreceptors to modulate ADH secretion for the maintenance of effective intravascular volume. In clinical practise, the difference between osmolality and osmolarity is negligible (Table 3).

In head injury patients, abnormalities of serum sodium (<125 or >150 mEq/l or <150 or >300 mmol/l) and serum osmolality (<260 or >320 mOsm/kg) should be avoided. Over hydration *per se* will not cause brain oedema if the serum sodium value is normal (135–145 mEq/l); however, it can cause brain oedema at brain injury sites only when it is combined with hyponatraemia (<130 mEq/l) because ECF water shifts to the ICF compartment in an attempt to maintain ECF/ICF isotonicity.

Loss of Fluid and Electrolytes

Loss of fluid and electrolytes without protein loss will raise the haematocrit and plasma protein concentration.[1,5,8,15,23,28,29,31,35,43,45] These two parameters provide a good guide to ECF losses. For example, an initial value of albumin (Pr1), if later, rose to Pr2 following loss of fluid (dehydration) then the percentage fall in ECF volume can be calculated as follows:

% fall in ECF volume = [1 - Pr1/Pr2] 100.

A fall in plasma volume can be more precisely calculated with the initial (Hct1) and subsequent (Hct2) haematocrit readings:

% fall in plasma volume = 100 [1-(Hct1/100-Hct2 x 100-Hct2/Hct2)] = [1-Hct1/Hct2] 100.

Haematocrit and plasma protein (albumin) are therefore more useful in the assessment of plasma volume and ECF fluid losses as compared to the Na^+ measurements where, although the Na^+ is being lost, it does not change in its serum concentration or in cerebral salt wasting syndrome (CSWS).[1,25,27]

By invasive haemodynamic monitoring, a low pulmonary capillary wedge pressure (<18 mmHg) or low CVP (<6 mmHg) implies volume depletion. Clinical evidence of dehydration, weight loss, orthostatic hypotension, CVP <6 mmHg and negative water balance are noted in CSWS. Moreover, elevation of haematocrit, the serum creatinine and serum protein concentration point to dehydration in CSWS. Increased natriuresis and elevated serum K^+ also suggest CSWS.[2,7,11,22,42]

Isotope-dilution techniques show features suggestive of CSWS, such as a decreased plasma volume (<35 ml/kg) and a decreased total blood volume (<60 ml/kg).

In the water loading test, increased free-water reabsorption in the renal tubules suggests increased ADH secretion.[2,27,38] Appropriate or inappropriate ADH secretion can be differentiated from one another by examining the urine volume, creatinine clearance, osmotic clearance and fractional water excretion.[2] If the overall clinicopathological results suggest dehydration, then increased free-water reabsorption in the renal tubules points to appropriate ADH secretion. On the other hand, increased free-water reabsorption in the absence of dehydration suggests inappropriate ADH secretion as in SIADH. Normal or reduced free-water reabsorption in the presence of dehydration (reduced creatinine clearance, polyuria and high fractional or osmotic diuresis) and inappropriate natriuresis (sodium excretion of >0.001 mmol/hour, which is inappropriate in the presence of severe hyponatraemia) are central features of CSWS. Disproportionate fractional water clearance relative to the free-water clearance suggests an osmotic

diuresis. In DI, there is disproportionate free-water clearance.[2,7,11,15,18,31,32,35,37]

It is essential that appropriate fluid and electrolyte studies be done early in the course of management of the head-injured patient. Therapy is directed primarily towards the underlying cause of the fluid and electrolyte abnormality. In the potentially salvageable patients, optimal correction may occur spontaneously or may require cautious use of medical therapy to achieve a good outcome (Table 4).

MAIN CLINICOPATHOLOGICAL CATEGORIES

There are two main types of clinicopathological categories:

I. Hyponatraemia
II. Hypernatraemia

HYPONATRAEMIA

Maintenance of Volume in Hyponatraemic States

Hyponatraemia (a low serum sodium concentration) is a common finding in the intensive care unit due to disturbance of the hypothalamo-hypophysial axis, a metabolic response to trauma or a sick cell syndrome requiring principally management of the underlying cause.[1,5,6,11,17,18,22,27-29,32,35,43,45] It is commonly due to water excess than to sodium loss. The severity of hyponatraemia is divided into three categories: mild (Na^+ <135 to 125 mEq/l); moderate (Na^+ 120–124 mEq/l) and severe (Na^+ <120 mEq/l).

Aetiopathogenesis

The risk of developing significant hyponatraemia increases in cases of moderate and severe head injuries, fracture base of skull and subdural haematoma.[6,17,35,38]

Following acute injury, the body retains water and sodium as a consequence of an acute neuroendocrine surge in an attempt to maintain an effective extracellular volume and thereby intravascular volume. The water content of ECF increases as compared to its solute concentration, which results in dilutional hyponatraemia. Hyponatraemia lowers the seizure threshold, exacerbates cerebral oedema and causes impairment of the level of consciousness.[29,35,37] However, the degree of cerebral disturbances usually depends upon the rapidity of the development of hyponatraemia; a serum sodium level of 115 mmol/l may be asymptomatic if it develops slowly over a long period of time, whereas a rapidly developing serum sodium level of 120–130 mmol/l may have severe neurological consequences.

In the setting of hypervolaemia with hyponatraemia, initially the brain cells (e.g. glia and neurons) swell due to the increase in cellular volume following the movement of ECF water to the ICF compartment. The water movement from ECF to ICF compartment results due to the low ECF osmolarity as compared to the ICF osmolarity. Later, a gradually adaptive but down regulatory volume reduction is achieved mainly by the loss of intracellular ions, such as K^+, Cl^-, taurine, phosphocreatine and amino acids including excitatory neurotransmitters (e.g. glutamine and glutamate). This consequently causes neurologic impairment.[1,5,28,29,43,45] Hyponatraemia ultimately leads to cerebral oedema and raised ICP with deleterious consequences.

Water retention (not natriuresis) is a marked feature of ADH excess, whereas natriuresis (not water retention) is a prominent feature of ANP excess. Clinically, the intravascular volume expansion due to ADH excess is an important feature of SIADH. The intravascular volume depletion with natriuresis due to ANP and BNP excess

is a marked feature of CSWS. Interestingly, ANP can suppress ADH secretion while ADH may itself stimulate ANP secretion.

In SIADH, water retention (hyponatraemic hypervolaemia) inhibits aldosterone secretion and, therefore, relative natriuresis continues. CSWS causes high natriuresis due to high ANP/BNP and low aldosterone activity.[2,7,13,17,18,21,22,27,32,34,35,38,42]

Differential Diagnosis

Various hyponatraemic syndromes in head-injured patients may be differentiated primarily on clinical and laboratory grounds.[1,4,6,11,15-17,27-29,35,37,43,45] Sodium depletion is seldom due to inadequate input (nutritional restriction), but more often due to excessive renal loss of sodium (CSWS due to high ANP levels, or urinary sodium loss in diuretic therapy). The clinical features of sodium depletion are primarily as a result of decreased ECF volume. The plasma sodium will be normal if fluid is lost isotonically as in traumatic haemorrhage/bleeding, and increased if it is lost hypotonically (excessive sweating in hyperpyrexia, mechanical ventilation or gastrointestinal hyperkinesia). Thus, the plasma sodium concentration in various clinical conditions of sodium depletion may be variable (low, normal or high). Sodium loss never occurs alone but is always accompanied by some loss of water. The fluid lost may be isotonic or hypotonic with respect to the plasma.

Hyperosmotic Hyponatraemia

Head injury patients with hyperglycaemia, uraemia and prolonged mannitol therapy are more prone to develop hyponatraemia. When plasma solute concentrations (e.g. glucose, mannitol, urea, etc.) are increased, a shift of water from the ICF to the ECF causes cellular dehydration and intravascular volume expansion with dilutional hyponatraemia. Because of water shift from ICF to ECF, it is also called translocational hyponatraemia. In addition, increased serum osmolarity causes direct stimulation of osmoreceptors and ADH release. This leads to renal water retention and further worsens the dilutional hyponatraemia. Moreover, such an increase in ECF volume inhibits volume receptors, thereby decreasing aldosterone secretion. This, in turn, leads to renal loss of sodium (natriuresis). Mannitol is an osmotic diuretic which increases ECF volume and reduces ICF volume to treat cerebral oedema. Following mannitol infusion in high dose with low renal output, hyponatraemia may occur via the aforementioned mechanisms and may lead to pulmonary oedema due to rapid volume expansion, metabolic acidosis and hyperkalaemia. In hyperglycaemic hyponatraemia with high renal output, patients may have gastrointestinal symptoms such as dryness of mouth, nausea, vomiting and abdominal pains besides dry skin and low jugular venous pressure. Intensive management of hyperglycaemia is therefore of paramount importance in such clinical settings.

Isosmotic Hyponatraemia

Pseudohyponatraemia may result due to decreased fractional water content of the plasma in cases of hyperproteinaemia (two times the normal values) and hyperlipidaemia. An increase in positively charged paraproteins or a decrease in negatively charged albumin concentrations in plasma can displace Na^+ from the plasma or ECF to the ICF compartment causing hyponatraemia. Fractitious hyponatraemia with normal serum osmolality therefore requires special attention to correct the conditions responsible.

Hypotonic fluid therapy with dextrose saline, half strength saline or 5% dextrose in head injury patients may result in isosmotic dilutional hyponatraemia, which may in turn cause cerebral oedema. These patients may develop nausea, disorientation, confusion, convulsions and gastrointestinal disturbances. These solutions are better avoided; however, if needed, they should be used judiciously in head trauma patients.

Hyposmotic Hyponatraemia

Excessive water intake and/or water retention are responsible for hyposmotic (dilutional) hyponatraemia. This condition must be assessed and treated differently in different clinical settings.

In low dietary intake, depletion of both ICF and ECF solutes can lead to hyponatraemia. In true sodium depletion due to nutritional neglect, hyponatraemia is accompanied by evidence of a contracted blood volume (low blood pressure, decreased skin turgor and elevated haematocrit). Here correction is achieved slowly with careful dietary manipulations.

In dilutional hyponatraemia due to excessive hypotonic fluid infusion, peripheral oedema is a prominent feature and, in addition, there may be evidence of cerebral oedema, congestive heart failure or hepatic disease. Urinary sodium concentration will be less than 10 mmol/l in both the aforementioned conditions: chronic dietary salt depletion and dilutional hyponatraemia due to excessive hypotonic fluid therapy using dextrose saline, half strength saline or 5% dextrose.

The persistence of dilutional hyponatraemia implies either SIADH or renal impairment (acute tubular necrosis). Dilutional hyponatraemia with low serum proteins and low serum urea indicates SIADH. In normal subjects, osmolarity of the maximally dilute urine is about 50 mmols/l. In SIADH, osmolarity of urine is more than 50 mmols/l, and peripheral oedema is not a prominent feature, whereas dilutional hyponatraemia with a dilute urine with peripheral oedema indicates renal impairment. Hyponatraemia is common after infusion of hypotonic fluids (5% dextrose or dextrose saline), when the ability of the body to excrete water is depressed.

Common Hyponatraemic States in Head Injury Patients

Initially, CSWS was recognised in the early 1950s and later, the syndrome of inappropriate (excess) antidiuretic

hormone (SIADH) in 1957 by Schwartz.[10,24,36,43] The majority of head injury patients with hyponatraemia present with SIADH or CSWS. In a few cases, both conditions may coexist. CSWS and SIADH are characterised by hyponatraemia, hyperosmolar urine and hypernatriuresis in patients with normal renal, suprarenal and thyroid functions. The major distinction between these two conditions is the volume status of the patient. In CSWS, the ECF volume is contracted and the patient appears dehydrated; whereas in SIADH, the ECF volume is expanded and a clinical picture of fluid overload is often seen. Patients with CSWS respond to fluid and sodium administration while those with SIADH respond to fluid restriction. In neurosurgical patients, CSWS is more common than SIADH.

Syndrome of Inappropriate ADH Secretion

Syndrome of inappropriate ADH (SIADH) secretion[5,11,15,27,32,35,36] usually begins in the first or second week following head injury and with appropriate therapy lasts no more than one to two weeks. In SIADH, there is a continuous secretion of ADH even in the presence of conditions such as hyponatraemia, hypo-osmolar serum and hypervolaemia which normally inhibits ADH secretion.

The typical clinical features of SIADH are hyponatraemia, with concomitant hypervolaemic hyposmolar ECF, relative hypernatriuresis with hyperosmolar urine and absence of clinical evidence of volume depletion (normal skin turgor and blood pressure). The clinical symptoms include anorexia, nausea, vomiting, irritability, personality changes and neurological manifestations including seizures (bulbar or pseudobulbar palsy, stupor, muscular weakness, loss of reflexes, positive Babinski sign and convulsions).

Cerebral Salt Wasting Syndrome

Cerebral salt wasting syndrome (CSWS)[2,5,10,14,21,22,24,38,42,43] is due to an inappropriate/unregulated release of atrial natriuretic peptide. It presents with hyponatraemia, hypovolaemic hypo-osmolar ECF, hypernatriuresis with hyperosmolar urine and volume depletion (contracted intravascular volume). Persistence of high salt loss in the urine despite fluid restriction differentiates this condition from SIADH where salt loss depends on a liberal fluid intake. The estimation of intravascular volume (by CVP) and urinary sodium usually differentiates salt retaining state (SIADH) from salt losing state (CSWS). Initially, Peters et al.[24] and Cort[10] described CSWS as a condition with hyponatraemia with natriuresis and believed that the CNS normally influences the ability of the kidneys to reabsorb sodium in the proximal tubule and that a defect in this regulatory function can lead to natriuresis. Many workers have reported a reduction in the red cell mass in patients with CSWS. Vingerhoets and de Tribolet[41] distinguished between two clinical syndromes of hyponatraemia and natriuresis, which differed in the interval between the neurological insult and the emergence of hyponatraemia: the acute syndrome (<3 days) and the delayed syndrome (>1 week). They found elevated serum ADH levels in patients with the acute syndrome and depressed or normal levels in the chronic syndrome. SIADH is commonly seen in the acute and CSWS in the chronic syndrome.

The main diagnostic criteria of SIADH and CSWS are outlined in Table 4.

Management[2,5,12,19,20,27,33,35,41]

Hyponatraemia is basically treated according to the underlying disease process, serum osmolarity/osmolality and clinical estimates of total body sodium. The cornerstone of therapy in SIADH is fluid restriction, whereas in CSWS volume replacement and correction of the haematocrit.

SIADH[19,20,33,41]

Patients with SIADH are basically treated with fluid restriction usually below one litre/day until serum Na^+ returns to normal levels with some salt supplement or replacements. The free-water restriction should be sufficient to decrease total body water by 0.5–1.0 litre/day. The resultant reduction in glomerular filtration rate enhances proximal tubular absorption of salt and water as well as stimulates aldosterone secretion.

Mild cases (Na^+ >125 mEq/l) are best treated with fluid restriction, whereas moderate cases (Na^+ <125 mEq/l to 120 mEq/l) with water restriction to 600–800 ml 5% dextrose in 0.45% saline per 24 hours, with or without normal saline; diuresis usually occurs in 36–48 hours. Patients with severe hyponatraemia (Na^+ <120 mEq/l) or in coma or with seizures may require hypertonic saline, with furosemide; 20–40 mg.[14] Diuretic therapy is used with utmost caution and monitoring to promote water loss. When hypertonic saline therapy is considered, it should be given only to restore Na^+ concentration to levels that no longer represent a hazardous state. The endpoint of hypertonic saline therapy is generally a serum Na^+ level of 120 mEq/l or absence of overt symptoms. Initially, plasma Na+ may be increased by 1–2 mEq/l/hr. Care should be taken to avoid hypernatraemia by cautious correction so that the plasma Na^+ should not be increased more than 12 mEq/l in 24 hours or 25 mEq/l in 48 hours, or to a concentration greater than 130 mEq/l.[2,9,29] Demeclocycline (anti-ADH synthetic hormone) antagonises the action of ADH on the renal collecting ducts and, therefore, may be used (600–1200 mg/day) to induce nephrogenic resistance to ADH.[2,20] Phenytoin is used as an antiepileptic drug with an added benefit as an anti-ADH agent.[19] Fluorocortisone (0.3–3 mg/day) is mainly used to inhibit action of ADH on the aldosterone mechanism, and to help in raising serum Na^+ levels.[26]

Cerebral Salt Wasting Syndrome[2,3,5,10,21,24,25,27,36,42,45]

The principles of managing hyponatraemia associated with CSWS consist of the treatment of an underlying cause, restriction of intravascular volume, isotonic fluid (e.g. normal saline, plasma and blood) infusion and fludrocortisone.[2,3,11,22,26,27,35,40,44] These measures are effective without jeopardising ICP control in most cases. CSWS is best managed with salt containing fluid orally, enterally or intravenously to maintain CVP around 10–12 mmHg. The patient's haemoglobin and haematocrit levels are measured daily and, if needed, packed cells with isotonic fluid or whole blood are given as per requirements.

Rapid correction of chronic hyponatraemia[9,12,27,35,40] using hypertonic saline has been associated with fatal central pontine and extrapontine myelinolysis; on the other hand, severe acute hyponatraemia can cause fatal cerebral oedema (tentorial herniation) and status epilepticus. Despite such concerns, the management of hyponatraemia with diuretic therapy (furosemide) and supervised saline infusion (isotonic/hypertonic) is safe.

HYPERNATRAEMIA

Common Hypernatraemic States

Clinically significant hypernatraemia (a high serum sodium concentration) is much less frequent in head-injured patients than hyponatraemia. It is either caused by the loss of water or an excess intake of sodium.

Aetiopathogenesis[2,4-6,11,15,17,22,27,30,35,37,39]

In hypernatraemic states, especially in head injured patients, water depletion mainly occurs due to an increased water loss as in DI (lack of ADH), renal DI (ADH insensitivity), mannitol therapy (osmotic diuresis), glycosuria (osmotic diuresis), prolonged hyperpyrexia (increased sweating), hyperventilation (increased insensible loss) and antibiotics related diarrhoea and, less commonly due to reduced intake of dietary water. The neurological causes of hypernatraemia include cerebral trauma, cerebral tumours (craniopharyngioma, pituitary tumours,), vascular disorders (Sheehan's syndrome, SAH-cerebral aneurysm), meningoencephalitis, surgery in the sellar-suprasellar-third ventricular region and an idiopathic variety. Despite the frequent pathological demonstration of pituitary and hypothalamic damage in head injury, the incidence of DI is relatively less common. However, DI is a mortal sign in patients with massive brain injuries and uncontrollable intracranial hypertension.

In clinical practise, excessive water loss without much sodium loss is unusual except in clinical DI. Pure water loss is borne by the total body water and not just the ECF, and therefore signs of a reduced ECF volume are not usually present. Severe water depletion causes cerebral dehydration that stimulates intracellular mechanisms for brain cells to synthesise osmotically active compounds and acute cerebral oedema may then follow rapid fluid replacement with deleterious consequences. Severe water depletion is therefore corrected in a cautious manner by 5% dextrose or hypotonic saline (2/3 deficits in the first 24 hours and 1/3 in next 24 hours).

Differential Diagnosis[5,7,11-13,15,27,30,35,39,42]

Serum hyperosmolarity, polydipsia (thirst leading to increased intake) and polyuria following hypothalamo-hypophysial trauma are the hallmarks of DI.

The differential diagnosis includes other conditions causing polyuria and polydipsia, i.e. renal DI, diabetes mellitus, chronic renal failure, hypercalcaemia, hypokalaemia and psychogenic polydipsia. Simple biochemical tests will easily eliminate many of these possibilities. Solute diuresis in hyperglycaemia, uraemia, osmotic or loop diuretics is diagnostic. Aldosterone deficiency presents with normal or slightly decreased serum sodium with only an occasional change in thirst mechanism. The urine specific gravity remains between 1.009 and 1.035 and urine osmolality between 250 and 320 mOsmol/kg, whereas water diuresis (DI) presents with normal or increased serum sodium levels and intense thirst and polyuria. The urine specific gravity remains between 50 and 150 mOsm/kg, whereas a normal (water deprived) individual will concentrate his urine with urine output of 0.5 ml/min and urine osmolality of greater than 750 mOsm/kg.

In DI, decreased ADH secretion results in uncontrolled renal water loss (dilute urine) with dehydrational hypernatraemia. Renal DI is due to renal insensitivity to ADH despite increased ADH levels in serum and urine, and psychogenic polydipsia-polyuria is due to a compulsive desire to drink. These conditions are differentiated with the help of either water deprivation tests or serum and urine ADH assays. Diabetes mellitus (hyperglycaemia), hypercalcaemia, chronic renal failure and hypokalaemia may also cause polyuria and polydipsia but are easily differentiated from central DI by routine biochemical tests. If it is due to the use of Demeclocycline (anti-ADH agent) then this drug should be discontinued. If random urine osmolality is greater than 750 mOsm/kg, DI is basically excluded.

Diabetes Insipidus[5,7,11-13,22,30,35,39,42]

Diabetes insipidus (DI) is a common condition after craniofacial trauma, skull base fractures and hypothalamo-pituitary injuries. It can be permanent or transient disappearing in a few days to a few weeks. Polytrauma, cerebral hypoxia, cerebral ischemia in haemorrhagic shock, neurosurgery in the suprasellar region, fat embolism, drug overdose, etc. may cause DI. Hypothalamo-hypophyseal injury poses a particular risk of developing transient or permanent DI. It is transient in the majority of patients lasting for 3–5 days; however, in one-fourth to one-third of cases, it may be permanent. Some patients show a triphasic response manifested by early transient DI, followed by

return of normal urinary functions for 1–3 weeks and then relapse leading to permanent DI.

Clinical Manifestations

Clinical manifestations of DI:[12,13,28,29,30,39,43] Polyuria, (>2–3 litres/day), polydipsia, hypernatraemia with hypovolaemia, high serum osmolality (320–330 mOsm/kg), low urine osmolality and a dilute urine (specific gravity less than 1005), and a urine to serum osmolality ratio of less than one, implying a negative water balance are characteristic features of DI.

Diagnostic Tests[1,5,28,29,30,35,39]

Serum and urine ADH assays and/or a water deprivation test are performed. A normal person on water deprivation for 8 hours will have urine output 0.5 ml/mt and will concentrate urine to preserve water. Urine osmolality will rise and become greater than 500 mOsm/kg. Patients with DI fail to concentrate their urine and the water loss continues as dilute urine.

During the water deprivation test, in patients with DI, the urine does not become concentrated and the serum osmolarity rises during the 8-hour test period. However, a normal person will maintain serum osmolarity below 295 mmol/l during this 8-hour period. Serum osmolarity above 285 mmol/l is a strong stimulus for ADH release to maintain serum osmolarity in the normal range by retaining more water. On administration of desmopressin in patients suspected of DI, if the urine becomes concentrated and the serum osmolarity falls then the diagnosis of DI will be confirmed.

Measurement of ADH levels in urine and serum in relation to plasma osmolarity is far more desirable than the water deprivation test in acute head injury patients as the latter may be highly inappropriate in many of these patients. If the ADH assays are not available then a therapeutic trial with desmopressin is highly indicated to resolve the diagnostic dilemma.

Management[1,2,5,7,11,12-14,22,25,30,39,42]

Daily measurements of body weight, fluid intake/output, haemoglobin, haematocrit, renal function tests (e.g. serum creatinine, BUN, electrolytes, etc.), serum sugar, serum osmolarity, urine specific gravity and urine osmolarity are performed.

Treatment of hypernatraemia basically consists of water and electrolyte replacement. Hypernatraemia is corrected slowly because of the risk of neurologic sequelae such as seizures and cerebral oedema. The water deficit is corrected over 24–48 hours and plasma Na^+ is gradually reduced by 1–2 mEq/l/hr.

The aim of the fluid therapy is to replace hourly urine output along with the usual estimate for the insensible loss, with hypotonic fluids. The volume depletion may lead to reduction in the mean systemic arterial pressure and subsequently a reduction in the CPP and, therefore, needs cautious correction.

Regardless of its cause, hypernatraemia should initially be treated by administration of hypotonic fluids such as water (orally) or 5% dextrose (parenterally). Urine output in DI may exceed 10 l/day, although less than this is more usual. Adequate fluid replacement, desmopressin [Desmopressin (1-desamino-D-arginine vasopressin) is a synthetic analogue of ADH] for severe cases and chlorpropamide (oral hypoglycemic agent) 50–200 mg/day or carbamazepine (antiepileptic agent 600 mg/day) for mild cases of DI may be used.

Desmopressin is indicated if urine output exceeds 6–7 l/day, or urinary output remains more than 250 ml/hr for consecutive 2–4 hours or the patient is unable to maintain fluid balance and the normal intravascular volume. Treatment with vasopressin should not be withheld in verified cases of DI. There are many preparations of vasopressin which are highly effective:

- Aqueous vasopressin (5–10 IU IM/IV, 4–6 hourly)
- Vasopressin tannate-in-oil (5 IU IM/daily as initial therapy once in 2–3 days)
- Lysine vasopressin nasal spray (2 IU/spray, 6–8 hourly)
- DDAVP (l-deamino-8-D-arginine vasopressin): 10–20 mg intranasally on OD or BD basis.

Care must be exercised during the active treatment of DI/hypernatraemia to prevent water intoxication (lethargy, confusion, seizures and coma) due to excessive administration of desmopressin, hypoglycaemia due to chlorpropamide therapy, and significant hypovolaemia following diuretic therapy (by further contracting ECF volume). While controlling post-traumatic seizures, carbamazepine stimulates ADH release in patients with DI. In patients with dangerously high serum sodium, the use of one of the methods such as peritoneal dialysis/haemodialysis/haemofiltration is strongly considered to remove excess of serum sodium. The patient does not respond to any treatment in terminal hypernatraemia, which has the worst prognosis. Haemofiltration employs a filter containing a membrane having characteristics similar to those of capillary endothelial cells. Water and smaller molecules (with a molecular weight ≤20,000) can pass freely across the membrane. The filter is connected to arterial and venous lines and the hydrostatic pressure drives a solution similar to the ECF across the cell membrane. Haemofiltration in NICU has advantages over conventional haemodialysis in fine control of fluid and electrolyte balance and removal of water soluble waste products and drugs.

CONCLUSION

A majority of the patients with mild and moderate head injury show no appreciable fluid and electrolyte abnormalities (normovolemic and normonatraemia); however, a subset of moderate and severe head injury patients suffer from fluid and electrolyte disturbances (commonly hyponatraemia and less often hypernatraemia).

The more severe the head injury, the higher the chances of serious fluid and electrolyte disturbances with more chances of unresponsiveness to the treatment. Therefore, recognition of common disturbances such, as hyponatraemia (SIADH and CSWS) and hypernatraemia (DI) is of paramount importance because of their different clinical presentations, disparate nature of appropriate treatment strategies and responsiveness to the protocol-based treatment in the early stages of occurrence.

Higher incidences of fluid and electrolyte disturbances occur especially in patients with injury to larger areas of the cerebral hemispheres, central neuraxis including the brainstem and hypothalamo-hypophyseal system and, therefore, these patients need intensive care. Neurological recovery in responsive patients occurs rapidly if appropriate fluid and electrolyte therapy is instituted in time. To institute appropriate therapy, a proper understanding of the aetiopathological mechanisms, their diagnostic parameters and treatment protocols is necessary. Inappropriate management worsens existing brain injury and results in otherwise avoidable morbidity and mortality with poor overall outcome. Therefore, clinicians must be aware of the fluid and electrolyte disturbances in head injury patients so as to recognise them early enough in time to treat appropriately.

35 Scalp Injuries

Krishna Reddy A

INTRODUCTION

The skin is the largest organ of the body and the scalp is the thickest component of the skin. The scalp plays its role in generalised functions like protecting the underlying calvarium and the brain, and specialised functions like regulation of body temperature, nourishment of the outer cortex of the skull and defining aesthetic characteristics of the patient's facial image.[18]

The scalp is in a vulnerable, exposed portion of the body and hence is prone to injury. Scalp laceration is the most common head injury requiring operative care.[18] Usually, primary healing occurs with infrequent complications. However, significant therapeutic problems can occur with avulsion, thermal, electrical injuries and post-malignancy and post-radiation defects.

Historical Aspects

3000 BC: Egyptians studied the natural history of extensive scalp injuries.[30]

2180 BC: Skulls dating back to this age have shown changes consistent with post-mortem scalping.

320 BC to 100 BC: Inflicting scalp wounds was a widely prevalent procedure among ancient dynasties as a method of marking slaves, a mode of punishment inflicting chronic suffering and slow death;[18] and war trophies.

17th century AD: Celsus first mentioned trephination of the exposed skull to allow formation of granulation tissue.[18,30,37]

1654: Augustine Belloste first performed 'Celsus' technique.[12,18]

1871: Netilitsky performed the first skin graft to resurface a scalp defect.[12]

1908: Concept of vascularity of pericranium recognised by Robinson.[45]

1911: Davis published a review of his management techniques of scalp trauma.

1918: Harvey Cushing studied over 250 cases of scalp injuries during World War I and established surgical treatment principles.[7]

1924: Mc Williams discussed four types of skin grafting with an improved method of treating total avulsion of the scalp.[37]

1944: Harold Gillies described the use of tubed pedicles, local flaps and the handling of scalp tissue in injuries.[14]

1946: Kazanjian and Webster described methods for reconstruction of extensive scalp loss.[26]

1953: Kazanjian described repair of partial scalp loss.[27]

1960: Jacobson and Suarez described microsurgery in anastomosis of small vessels, (about 1 mm in diameter) with more than 80% patency (13-SS). This has revolutionised the management of scalp avulsion.[21]

1969: Lu reported successful results with direct suturing of the avulsed scalp.[31]

1972: Mc Lean and Buncke performed the first successful covering of scalp with omental free tissue.[36]

1976: Miller reported the first successful replantation of avulsed scalp with microanastomosis.[38]

1982: Alpert et al. described the principles of surgery for scalp avulsion.[1]

1983: Argenta et al. described the use of tissue expansion in reconstructive scalp surgery.[2]

ANATOMY

The scalp extends from the supraorbital ridges anteriorly to the inferior nuchal line posteriorly and to the auriculocephalic angle laterally. Apart from the forehead, the scalp is completely covered with hair in most individuals. The thickness of the scalp varies from 3–8 mm, being thick over the occipital region and thinner over the frontal and temporal areas. The skin is the first layer and is 3–8 mm thick. The septa of the superficial fascia lie in the connective tissue layer. Numerous blood vessels and nerves course through this layer. The galea aponeurotica, the next layer, is characterised by a flat central tendon, attached between the frontalis and occipitalis muscles. The galea offers tensile strength to the scalp, failure of closure of which leads to contracture of attached muscles and a depressed appearance of a scalp wound. The subepicranium, containing loose areolar tissue and small vessels, provides scalp mobility. It is the usual plane of scalp avulsion, haematoma or infection. The pericranium is adherent to the skull, contains many small capillaries that pass through the underlying bone and has an outer layer of fibrous connective tissue and an inner layer of elastic fibres.[51]

DESCRIPTION OF SCALP INJURIES

Caput Succedaenum

It is due to scalp oedema which occurs in the newborn following trauma during prolonged engagement of the head at the pelvic outlet.[25] It presents as a boggy swelling seen at birth and usually subsides spontaneously within 2–3 days.[25]

Cephal-Haematoma

It is a subperiosteal haematoma occurring almost exclusively as a result of birth trauma. Since the pericranium meets the endocranium at the suture lines, this haematoma takes the shape of the underlying bone. It is seen usually following forceps delivery. It usually gets absorbed within a period of 2 weeks, failing which it may need aspiration. It may occasionally calcify and may require surgical excision.[25]

Abrasion

It is a destruction of the skin, usually involving the superficial layers of the epidermis only. It is caused by a lateral rubbing action by a blow, a fall on a rough surface, by being dragged in a vehicular accident, by fingernails, thorns or teeth bite. Pressure and movement by an agent on the surface of the skin is essential to cause this injury. The spectrum of injury may range from flattening of epidermal cells and elongation of nuclei to partial or complete removal of the epithelium and damage of the superficial layer of dermis. Many abrasions have some deeper areas of sub-epidermal damage, which may result in superficial scarring. Sometimes, full thickness of the skin may be damaged in places, but usually in an interrupted, irregular manner, and intact epidermis remains within the area of the abrasion. The rougher the surface, and the more rapid the movement of the skin over it, the deeper is the injury. The exposed raw surface is covered by exudation of lymph and blood which produces a protective covering known as a scab or crust. Abrasions vary in size, depending on the extent of the body surface exposed to the abrading force. They are simple injuries, bleed slightly, heal rapidly and scar is not formed. Large abrasions can cause severe pain and bleeding.

The main types of abrasions are:

Scratches: They are caused by a sharp or pointed object passing across the skin, such as fingernails, pin or thorn. The surface layers of the skin are collected in front of the object, which leaves a clean area at the start and tags at the end.

Grazes (Sliding, Scraping or Grinding Abrasion): The most common type occurs when there is movement between the skin and some rough surface in contact with it. They show uneven, longitudinal parallel lines (grooves or furrows) with the epithelium heaped up at the ends of these lines, which indicate the direction in which the force was applied.

Pressure Abrasions (Crushing or Friction Abrasions): They are caused by crushing of the superficial layers of the epidermis and are associated with a bruise of the surrounding area. It occurs if the movement of the instrument is around 90° to the skin.

Impact Abrasions (Contact or Imprint Abrasions): They are caused by impact with a rough object, when the force is applied at or near a right angle to the skin surface. The abrasion is slightly depressed below the surface, unless there is bulging due to underlying contusion or local oedema.

Impact abrasions and pressure abrasions reproduce the pattern of the object causing it and are called patterned abrasions.

Age of the Abrasion

The exact age cannot be determined, but a fair estimate may be done.

Fresh: Bright red

12–24 hours: Lymph and blood dries up leaving a bright scab

2–3 days: Reddish brown scab

4–7 days: Epithelium grows and covers defect under the scab

After 7 days: Scab dries, shrinks and falls off.

Contusion (Bruise)

A contusion is an effusion of blood into the tissues due to the rupture of blood vessels (venules and arterioles) caused by blunt trauma. The extravasated blood is diffusely distributed through the tissue spaces and the margins are blurred.

Age of the Contusion

Immediately:	Red
Few hours to 3 days:	Blue
4th day:	Bluish-black to brown (haemosiderin)
5–6 days:	Greenish (haematoidin)
7–12 days:	Yellow (bilirubin)
2 weeks:	Normal.

Laceration

Lacerations are tears or splits of the skin. These are usually caused by sharp objects. In a laceration caused by a blunt object, localised portions of tissue are displaced by the impact of the blunt force, which sets up traction forces and results in tearing of the tissues.

Split Lacerations

Splitting occurs by crushing of the skin between two hard objects. Scalp lacerations occur due to the tissues being crushed between the skull and some hard object, such as the ground or a blunt instrument.

Stretch Lacerations

Overstretching of the skin, if it is fixed, will cause a laceration. There is localised pressure with pull which

increases until tearing occurs and produces a flap of skin, which is peeled off the underlying bone or deep fascia. This is seen in the running over by a motor vehicle and the flap may indicate the direction of the vehicle.

Scalp lacerations are primarily troublesome because of bleeding. Infection is extremely rare because of the rich blood supply. One-layer closure with continuous monofilament suture and locking of alternating sutures to prevent edge inversion usually is adequate. Sutures are left in place for 10–14 days, to allow maximal wound tensile strength to develop in order to prevent spreading of the scar, since a wide, hairless scar is more visible than any potential suture marks except in a bald scalp. The tissue adhesive hair apposition technique also is effective in repairing scalp lacerations. The sting of local anaesthesia injections can be lessened by using smaller gauge needles, administering the injection slowly and warming or buffering the solution.[11]

Avulsion

An avulsion is a laceration produced by sufficient force (shearing force) delivered at an acute angle to detach (tear off) a portion of a traumatised scalp from its attachments along the path of least resistance, which is the loose areolar tissue layer. Scalp avulsion requires a strong tearing or shearing force. If the force is extensive enough, the scalping will progress to the boundaries of the galea at the supraorbital ridges and the zygomatic, mastoid and occipital nuchal line. Scalp avulsion is a threatening blood loss injury. Rapid cessation of bleeding, wound compression and aggressive fluid resuscitation are important. With adequate resuscitation, careful evaluation and replantation as soon as possible the outcome is usually good.[20,39,46]

Thermal Injury

Thermal injury may be caused by dry heat (burns), hot liquids (scalds) and steam. The depth of injury is directly proportional to the burning temperature and the time of exposure, and inversely proportional to the depth of the skin. In the scalp, deep injuries are less common due to thick skin and rich circulation. As the hair follicles are in the subcutaneous space, re-epithelialization of deep second-degree injuries also is rapid; provided there is no infection. Hence, conservative treatment is indicated where the injury is superficial or depth is questionable.[43]

Electrical Burns

Luce and Hoopes showed that the non-infected burnt skull can act as an *in situ* bone graft and regenerate, if covered by tissue of good vascularity.[32] The therapy for electrical burns therefore should consist of excision of the burnt scalp and pericranium, once the margins of the burn are established and before infection occurs (1–3 days) and immediate coverage with vascularised flaps, either local or distant. The burnt skull should be left intact, unless it is infected or underlying damage to the dura or brain is suspected.[53]

Grading of Electrical Burns

1. First degree	Superficial redness
2. Second degree	Partial thickness Blistering Regenerate spontaneously
3. Third degree	Full thickness Leathery skin Does not heal spontaneously Requires excision and grafting.

Chemical Burns

Injury by chemical agents can be accidental (more common, especially in children), homicidal (due to an assault) and suicidal (rare). Alkali burns are more common than acid burns. The damage caused to the scalp is determined by the duration of contact, the concentration, penetrance, quantity and the mechanism of action of the chemical compound. Copious irrigation of the injured part with sterile water helps in minimising the duration of contact. Neutralisation is the next step and is done by dilute acetic acid for alkali burns and with dilute sodium bicarbonate for acid wounds.[7] Extensive debridiment should be avoided, particularly when the depth is difficult to determine and a conservative approach is practised in such cases.

Radiation Injury

Ionising radiation may cause radiodermatitis or radionecrotic ulcer by microvascular damage and reduced cell turnover. Wound healing is also significantly affected in such scalps. The radionecrotic ulcer may further worsen the matter by undergoing malignant transformation. Treatment includes excision followed by grafting with fresh, uninvolved, vascularised tissue. Free flaps have the greatest success rate in the long run.[18]

MANAGEMENT

Resuscitation

When a scalp injury has occurred, the emergency facility receiving the patient should stabilise the patient's vital signs, determine the patient's tetanus prophylaxis status, do the necessary diagnostic procedures, and administer a broad-spectrum antibiotic and analgesics. Preparation for blood transfusion should also be made. The exposed cranium should be covered with saline moistened gauze. In case of scalp avulsion, the amputated scalp should be placed in a plastic bag and the bag placed in ice chips, awaiting replantation.[10,12,13,21,31,38]

Initial Evaluation of Scalp Injury

- Detailed history
- Detailed physical examination
- Assessment of mechanism of injury
- Evaluation of intracranial injury
- Evaluation of cervical spine injury, if any

- Appropriate neuro-imaging
- Additional history—male pattern baldness, Previous scalp trauma, Radiation injury.

Aims of Management of Scalp Injury

- Rapid and safe coverage of underlying structures
- Minimising the risk of infection
- Transforming a dirty wound into a clean wound
- Transforming an open wound into a closed wound
- Providing a durable tissue cover
- Restoring normal contour and function
- Achieving acceptable aesthetic result.

Assessment

Assessment of the Scalp Injury Includes the Following

- Duration since injury
- Environment of injury
- Wound characteristics:
  - Size
  - Shape
  - Depth
  - Margins
  - Presence of haematoma
  - Presence of foreign body
  - Necrosis
- Vascularity of local tissue:
  - Abundant
  - Poor
- Nature of the defect in the bed:
  - Pericranium
  - Cortical bone
- Character and abundance of the local tissue
- Potential for simple camouflage.

Duration since injury is an important determinant of wound viability and the outcome after surgical repair. It is now accepted that a wound exposed to the exterior for more than 6 hours has a four-fold increased risk of infection, compared to the one exposed for a lesser duration.[8,9,34] "The scientific basis of this time gap lies in the fact that doubling time of commonly found wound pathogens is an average of 30 minutes and 10,000 bacteria per gram of tissue is the microbiological representation of clinical infection." Hence, a primary closure of a scalp injury is ideally done within 6 hours. However, this time gap can be safely extended in the case of a clean wound and also to some extent in a wound with minimally devitalised edges.

An environment containing sand, mud, gravel, wood and metal particles significantly increases the risk of infection of the wound by the direct contact of exposed tissues to these substances.[6] Healing is thus naturally delayed in such cases, either by conservative treatment or surgical manipulation.

A scalp wound with a size more than 3 sqcm with a complex shape, irregular outline, charred, burnt or necrosed margins and those having an underlying haematoma or foreign body have a higher risk of infection and poorer healing.[8] Measurement of size should be done before excision of scalp injuries, with the slack in the edges taken up by gentle pulling. The real defect may be much smaller than is at first apparent, because the edges of the wound retract.[30] It has to be borne in mind that even minimal trauma must be evaluated and managed accordingly.[7,34] Cases of large subgaleal haematomas following trivial trauma like pulling of hair and bumping the head are rare, but significant enough to take note of and exercise caution.[40]

The choice of reconstruction and the wound healing depends upon the "vascularity" of the graft and wound, respectively. If the supply in the area of the defect is adequate, free grafting may suffice. If local supply is inadequate, either because of scarring, radiation effects or exposed bone, the graft must carry its own circulation for a successful take.

The nature of the bed of the wound relates both to the circulation available for the graft and to the need for protecting the underlying structures. Exposed diploic bone will easily support a simple skin graft, as will the dura; however, a skin graft on the dura would hardly suffice for long-term protection of the brain and hence calvarial reconstruction plays an important role.

The easiest reconstruction usually is accomplished with local tissue, and this has to be the first choice. The most efficient closure is accomplished if tissue can be mobilised by flap techniques to achieve a primary closure of the donor site.

The need for complex flap closure may be obviated if the defect can be covered by a simple change of hairstyle or by a hairpiece or a hat. Hence, the potential for simple camouflage plays a prominent role.[37]

Surgical Principles in Treating Scalp Injuries

- Large subgaleal haematomas should be evacuated early.[40]
- Meticulous haemostasis and approximation of wound margins is essential.[7–9,30]
- Local debridement to be done wherever necessary, to remove non-viable tissue and re-orient the wound.[8,34]
- Galea has to be closed with absorbable sutures for protection and retention of skin edges.[9,14,34]
- The flap should be taken from the scalp wherever feasible ("replace like with like").[6,9,14,30,34]
- Take the scalp flap from areas of relative excess (lateral and posterior), and place in areas of relative deficiency (anterior and medial).[9,30,34,41]
- Axial scalp flaps permit significant increase in length-base ratio, compared to the conventional random flaps.[18,26,30]
- During scalp replantation anastamosis should be done between two normal vessels.[4,21,38]
- The scalp can survive on one superficial temporal artery. But anastamosis of, as many arteries or veins as possible, has to be done during scalp replantation.[26,30]

- Veins should be anastamosed first during scalp replantation, unless there is significant ischaemia in which case anastamosis of arteries first is a priority.[13,21,31,38]
- Leeches have long been used to supplement venous drainage post-operatively for grafts,[30] but recently machines which perform controlled low suction of blood ("artificial leech") have undergone clinical trials successfully in the USA.
- In the presence of viable pericranium, split thickness grafts are used and free tissue transfer is indicated when viable pericranium is lost.[5,30,34]

Surgical Planning and Execution

Reconstructive Ladder: Options for Covering the Scalp Defect

- Primary closure
- Delayed primary closure
- Secondary intention healing
- Local transposition flaps – random axial
- Distant flaps – split thickness skin graft island pedicle flaps (trapezium, latissimus dorsi, temporalis)
- Free autogenous tissue transplantation (skin, muscle, omentum).

The reconstructive techniques for scalp defects are mentioned as follows, in general order of decreasing indications. These are:

1. *Split thickness grafts*: These are partial thickness of skin containing epidermis and variable thickness of dermis.
2. *Full-thickness skin grafts*: These consist of a complete thickness of skin with epidermis and dermis but without subcutaneous fat.
3. *Local attached flaps*: These flaps contain skin and subcutaneous tissue and carry their own circulation during transfer.
4. *Distant detached flaps*: Skin and subcutaneous tissue from a non-contiguous area is used that carries its own circulation during the transfer process until circulation is established in the recipient area.
5. *Distant re-attached flaps*: Tissue is harvested from a distant donor site with its vascular supply included and revascularised by microsurgical anastomosis at the recipient site.[12,21,47] Such flaps include skin and subcutaneous tissue, musculocutaneous flaps, muscle flaps with skin grafts and omentum with an overlying skin graft.[36]
6. *Scalp expansion*: Gradual expansion of adjacent scalp with subsequent advancement into the defect.[29,35]

Free Skin Grafts

These represent the first line of reconstruction of scalp defects. Two general principles govern their selection: (1) the thicker the graft, the lower the percentage of take and (2) the more dermis that is included, the less the contraction.[12] In large defects, such as in a granulating burn wound, initial closure may be done best by covering the wound with a thin, meshed graft even though reconstruction with flaps may be planned at a later date. The thickness of dermis in the graft determines the eventual contracture of the recipient bed. A thin split graft may contract 60–70% in area over the period of a year, gradually pulling in the edges of the wound to a degree that would be impossible to achieve at the time of initial closure because of suture necrosis.[12]

Free grafts can be harvested from any site. Grafts retain the characteristics of the donor site, therefore colour match and texture can sometimes be pre-selected.[48]

Free grafts in scalp reconstruction:

- Scalp
- Temporalis fascia
- Latissimus dorsi
- Parascapular
- Omentum
- Scapula
- Rectus abdominis
- Internal oblique
- Groin
- Radial aspect of the forearm.

Use of the superficial temporal artery and vein for scalp and face reconstruction is reliable and safe. The superficial temporal artery and vein should be considered as primary recipient vessels in microsurgical reconstruction of the upper two-thirds of the face and/or scalp.[16]

Compared to the omentum flap, the latissimus dorsi offers more tissue and has less donor site morbidity, and secondary surgery, such as cranial bone reconstruction, is possible. The preferred donor vessels are the maxillary artery and the external jugular vein and to avoid any vascular compression, a myo-cutaneous flap is used.[19]

Split Skin Graft

A split graft can be taken by any standard method, i.e. free-hand knife or one of the various dermatomes. Failure of the graft is due to interposition of pus, clot or serum between the graft and the bed and this must be prevented. Pressure on the graft is most easily achieved with a tied-over stent dressing, using enough bulk so that the resulting force is downward.[37]

The full-thickness graft is cut by standard scalpel excision and is clearly limited in size to those donor sites where primary suture closure is possible. These include the retro-auricular area where the maximal graft size permissible is 3 × 5 cm; the hairless supra-clavicular area and the groin crease. Application of acellular human dermis (AlloDerm) and split-thickness skin graft can be performed in a single phase. This shortens the treatment period and produces an excellent outcome.[23]

Techniques of Flap Transfer

Flap Theory

In the scalp the circulation is primarily axial, with the intervening areas between large known vessels being of random circulation. Large flaps are therefore successful, as long as the circulatory system between the galea

and the skin is not violated, either by poor flap design or by obstruction of venous return by tight closure or by the accumulation of fluid between the galea and the pericranium.[12,37]

Local Flaps

The basic concept of local flap transfer is to move available tissue with its circulation intact from an area of excess to an area of deficiency.[9,27] In the scalp, the only areas of excess are laterally and posteriorly, since the movement of tissue from the anterior scalp causes distortion of the forehead and hairline.[22,30,34]

Local Scalp Flaps with Galeal Scoring

Small Defects (<6 cm): The use of local (Fig. 1) flaps based on the major nutrient blood supply is the best method to close these wounds. The non-stretchable scalp can be made to cover a larger area by scoring the galea perpendicular to the direction of tension.[30] The galea can be cross-hatched to relieve tension.

Medium-Sized Defects (6–8 cm)

The best choice is usually a large scalp flap with skin grafting of the donor pericranium. In some cases, use of multiple axial flaps is helpful. This concept was initially described by Orticochea[42] as a four-flap technique, utilising the entire remaining scalp to close the defect. Orticochea[41] later modified this to a three-flap technique in which two smaller flaps adjacent to the defect are used to provide primary wound closure and a third larger flap, consisting of the entire remaining scalp, covers the donor defect, following rotation of the two smaller flaps. These flaps are based on known vascular territories and can be used to cover defects up to one-third of the scalp surface area.

Orticochea Flap Techniques

The width of the two smaller flaps should be at least one-half the width of the primary defect so that, when mobilised and juxtaposed, they automatically cover the raw surface.[34,41,42] The larger flap should cover the rest of the scalp (Fig. 2). If the defect is lateral to the midline, the base of the pedicle of the large scalp flap should be on the contralateral side of the defect. These flaps are elevated in the loose areolar plane, and will require extensive undermining of the remaining scalp, forehead and nape of the neck.[42]

Large Defects (8–10 cm)

When the defect is large, anterior and off to one side, a subtotal scalp flap can be raised based on the superficial temporal and posterior auricular arteries.[8,9,30] The remaining scalp can be transposed with a large donor deficit that must be grafted.

Pericranial Flaps and Overlying Skin Grafts or Local Flaps

Pericranial flaps are endowed with a rich vascular network that allows them to be used as pedicled flaps to cover denuded bone and act as a bed for skin grafting. They should be designed larger than the recipient site because of their elastic properties.[17,24,30]

Muscular Flaps

The latissimus dorsi muscle, which can be transferred as a myocutaneous unit or as a free muscle only and covered with a split-thickness skin graft, was first used in 1978 to cover a scalp defect. The muscle is large enough to cover the entire scalp and is reliable in its anatomy. In addition, the thoracodorsal artery and vein provide a long pedicle that aids in the utility of this flap.[8,18] The

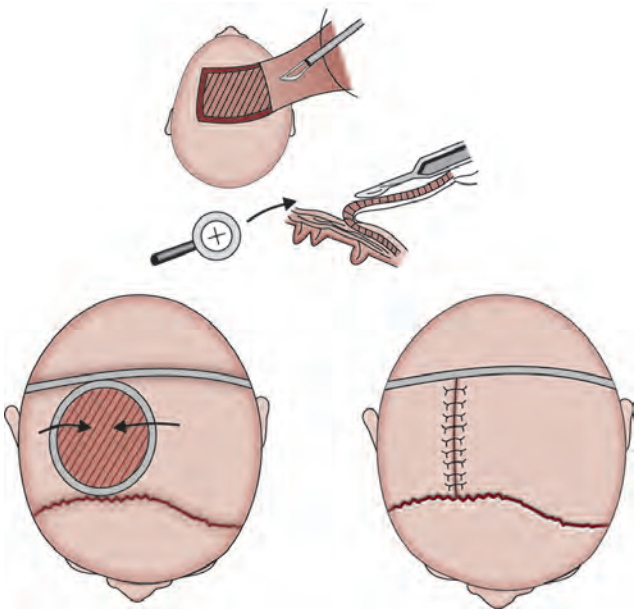

Fig. 1: Local flap with galeal scoring method

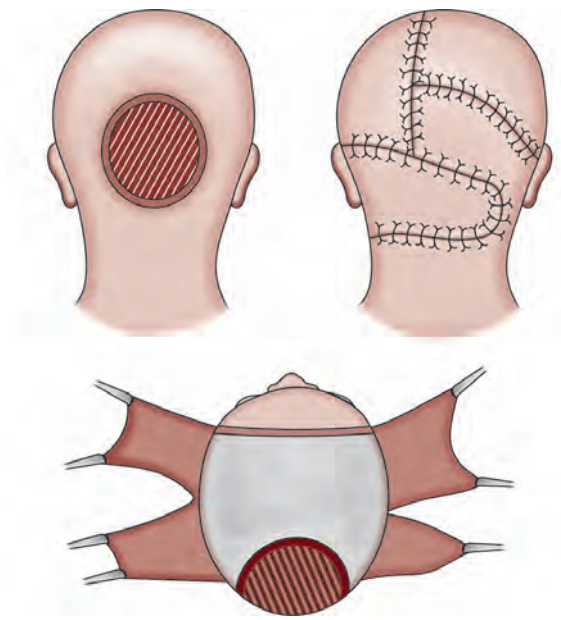

Fig. 2: Four flap method

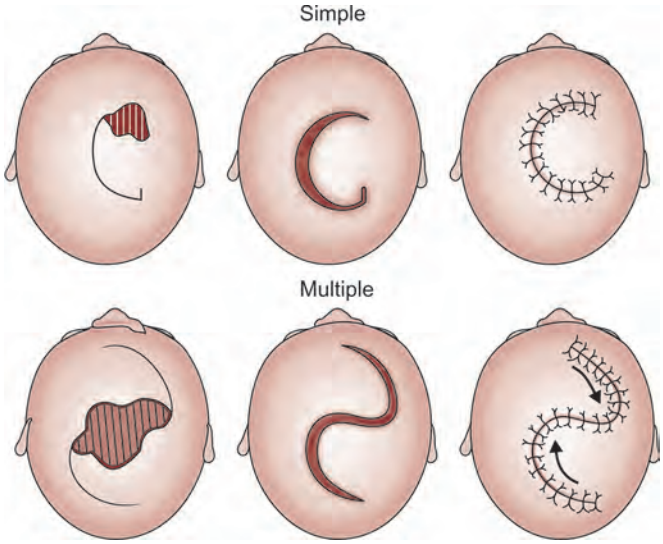

Fig. 3: Rotation flaps

parascapular flap is more bulky than the latissimus dorsi flap but does not sacrifice a functional muscle.[8,18] It cannot cover the entire scalp. These flaps are unsatisfactory from an aesthetic standpoint and do not restore hair-bearing tissue to the scalp.

Rotation Flaps

Planning a rotation flap (Fig 3) requires an understanding of a simple geometric concept. "Tissue is added to the defect subtracting from the flap donor area and this is achieved by changing the defect shape from non closable to closable."[30] For example, if the defect is a square 2 inches on a side, the area is 4 sq in, movement of a flap to fill a 4 sq in defect creates a 4 sq in donor defect. Primary closure will be impossible because of suture tension necrosis.

Now, consider making a 10 inch semicircular incision; which will result in the flap rotating into the defect, leaving an elliptical defect 10 inches long still having a total area of 4 sq in. Due to the change in shape of the donor defect, primary closure is then possible, since maximum width of the defect would be 0.5 inch or less.[30]

Calvarial Reconstruction

Calvarial reconstruction is undertaken to provide adequate protective coverage of intracranial contents and to restore calvarial contour. Defects of the frontal region warrant cranioplasty for both cosmetic and protective reasons. Autogenous bone is the material of choice in the growing craniofacial skeleton. Manson et al.[33] reported no statistical difference in the incidence of infection between the use of autogenous bone and mesh-acrylic in reconstructions involving the frontal region. If a frontal defect extends into the frontal sinus, autogenous bone should be used to decrease the risk of infection. Defects in the parietal or occipital region most often require cranioplasty for protective reasons. Defects in the temporal region need cranioplasty less often, because of some protection offered by the overlying temporalis muscle.

Materials Used for Calvarial Reconstruction

Autogenous material	***Alloplastic material:***
Split rib grafts	Acrylic[18]
Calvarial bone grafts	Hydroxyapatite cement
Bone paste	Vitallium
	Stainless steel
	Tantalum
	Titanium

Calvarial reconstruction can be done, beyond controversy, in the acute situation;[50] the only exception being the presence of local infection and devitalised tissue; in which case, soft tissue cover has to be done in the acute setting and bony reconstruction has to be postponed by one year.[50]

Dural Closure and Intradural Repair

Primary closure of a dural tear is mandatory in any scalp injury. When there is an associated loss of dura, a duroplasty is done with temporalis fascia, if the latter is viable and is not needed for scalp defect closure. Otherwise, fascia lata serves the purpose well.[30,48]

Tissue Expansion

In 1978, Radovan[44] and, in 1982, Austad and Ross[3] published reports on the first clinically successful techniques of tissue expansion (Fig. 4) and demonstrated the prototypes of expanders clinically useful today. "This method is based on the simple principle that the skin is capable of significant expansion, sometimes enormously" (one need not over-emphasise the enormous stretching of abdominal skin in pregnancy and extreme obesity). Up to 50% of the scalp can be resurfaced with expanded skin without changing the hair growth pattern or creating new donor defects.[28,29,52] The expander is a silicone bag with a self-sealing fill valve that is placed beneath the tissue to be expanded.[44] Expansion is then done percutaneously with incremental saline injections into the valve.[44]

"It has to be understood that the expansion is planned in the normal scalp adjacent to the defect and not under the graft or at the site within the area of intended primary closure". The prosthesis is placed beneath the galea and expanded over a few months at 6–80 days

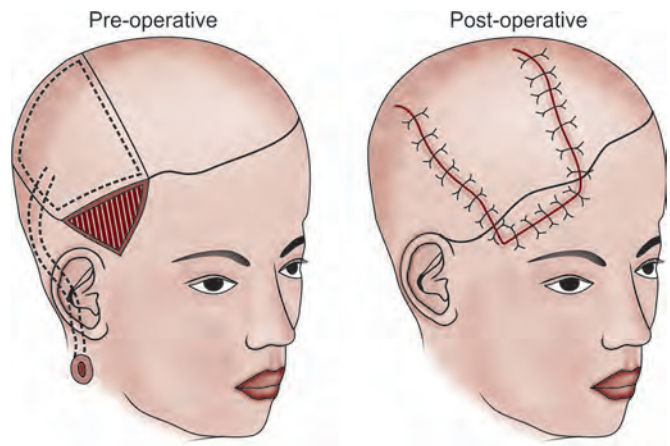

Fig. 4: Expansion flaps

intervals.[44] Following the desired expansion, the hairless scar is excised and primary closure accomplished by advancing the expanded scalp into the defect.[2] Intraoperative filling of the expander reduces the need for drains, by preventing haematoma and seroma formation. A good estimation of flap length is twice the height of the expander above the skin surface. Over-expansion by 30–50% makes the procedure more reliable.[44]

Replantation

Miller and associates were the first to report successful total scalp replantation by microvascular anastomoses.[38] The superficial temporal artery has the most reliable inflow and replantation of the entire scalp can be based on a single arterial and venous anastomosis,[32] showing that the midline of the scalp is not an absolute barrier for segmental blood supply. However, most reports of successful scalp replantation are based on multiple arterial and venous anastomoses.[14,38] As a rule vein grafts are used to avoid using arteries within the zone of injury.[31] There is no strict time frame for replantation of avulsed scalp, but successful replantation has been accomplished up to 18 hours after injury.[32]

Ideally, two operating teams should be available for the replantation surgery. One team identifies and tags the vessels on the avulsed scalp and the other team works on the patient's head identifying vessels and debriding the wound.

Locating the vessels on an avulsed scalp can be time consuming and should be done with the aid of magnification. The paired vessels that should be investigated are the supraorbital, temporal, postauricular and occipital. The diameters of the vessels in adults will range from 0.5 mm to 1.5 mm. A normal vessel has to be anastamosed to another normal vessel and to be sure, operative microscopic evaluation of the intima is mandatory.[14,38] Anastamoses should be performed outside the zone of injury and should be multiple, whenever possible.[14,38] The scalp is tacked exactly into place and drains are placed before suturing. The dressing should be light and non-compressive.

Most authorities recommend post-operative anticoagulation,[27] either in the form of heparin followed later by aspirin or low molecular weight heparin. Gregory Dostall et al. have recommended usage of low molecular weight dextran in a dose of 20 cc/hour for 3–5 days post-operatively.[15]

Post-operative assessment of replanted scalp:

1. Clinical examinationColour
   Capillary refill
   Temperature
   Capillary bleeding
2. Doppler[49]
3. Thermocouples
4. Fluorescein staining
5. Transcutaneous oxygen measurements
6. Impedance techniques.

Omental Transfer

McClean and Bunke described the free vascularised omental transfer (Fig. 5) for scalp coverage.[26] The

Fig. 5: Partial scalp avulsion, omental transfer for scalp avulsion

omentum was moulded to the scalp defect and then covered with a split-thickness skin graft. The necessity of laparotomy and the availability of less morbid flaps are limitations of this procedure.[26]

Complications of Scalp Injuries

- Infection
- Wound necrosis
- Calvarial, dural and brain injury
- Graft rejection
- Wound contracture
- Poor cosmetic result.

FUTURE PERSPECTIVES

Scalp Transplantation

The potential for scalp transplantation is tremendous in the years to come. Buncke et al. already have reported a case of scalp transplantation involving twins in whom one had suffered an avulsion injury, which was managed with the aid of a free flap harvested from her sister's scalp.[4] This case illustration goes a long way in proving that once the immunological barriers are resolved, allografts and even xenografts may be employed in scalp injury management.

Foetal Tissue Healing

Tremendous amount of time and dedication is being expended in research on foetal wound healing. As the results of the research on this apparently regenerative process unravel, they may be applied to scalp injuries.

ACKNOWLEDGEMENTS

Author is thankful to Dr T Sanjay (MCh, Neurosurgery) for his help in preparing the manuscript and drawings, to Smt Susheela Devi for her secretarial help.

36 Acute Subdural Haematomas

Sanjay Behari, Anuj Chaitley, Manish Singh Sharma, Ashok Kumar Mahapatra

INTRODUCTION

Acute subdural haematomas (SDHs) are haematomas accumulating within the subdural space of the brain to become clinically symptomatic within 24–72 hours of injury. They are extracerebral, hyperdense, crescentic collections between the dura and the brain parenchyma and regarded as "acute" when diagnosed within 14 days of traumatic brain injury.[10] They are usually located over the cerebral convexities conforming to the convex brain surface. When extending along the tentorium or falx cerebri, their extent is contained by dural reflections.[15,20] There is a wide variation in the incidence of acute SDH (5–29%) as the primary lesion in patients admitted with head injury. Acute SDH often occurs in the fifth and sixth decades (mean age 31–47 years) and, therefore, the mean age of patients with acute SDH is older than with other types of head injury. Men are twice to four times more likely to be affected than women.[10,15]

AETIOPATHOGENESIS

Acute SDH is frequently due to falls, assaults or vehicular accidents. When the head lands on or strikes against a hard surface or when there is an assault to the head with a hard object, there may be avulsion of the bridging veins. The mechanism for this injury is often rapid deceleration of the cranium with a relatively low magnitude of the shear force applied. Rotational acceleration of the head, as occurs in boxing, may also produce these injuries.[20] Avulsion of parasagittal and Sylvian bridging veins is often accompanied by a degree of diffuse axonal injury and polar contusion. The low pressure venous bleeding accumulates to form a haematoma of sufficient size to compress the brain by two mechanisms. Episodes of coughing, straining or vomiting may cause sufficient bleeding to prevent progressive tamponade by the brain. The avulsion of veins directly attached to the sagittal sinus may be held open because of the high venous sinus pressure rather than be compressed by the haematoma. Cortical contusion with haemorrhage from a small cortical artery rupture is also a common cause of acute SDH. This results in a characteristic "burst lobe" injury with SDH, polar contusion, cerebral haematoma and hemispheric swelling. Occasionally, coalescence and rupture of parenchymal small vessel bleeding from a contusion may also cause an acute SDH. This may occur especially when consumption coagulopathy develops or in patients on anticoagulant therapy. Such a SDH is often associated with sizable intraparenchymal clots.[9,10] Maxeiner and Wolff[12] performed a post-operative analysis of size, space-occupying effect and form of the SDH in patients who had died due to acute SDH resulting from one of the three common causes namely: (1) cerebral contusions; (2) rupture of bridging veins and (3) rupture of small cortical arteries. They termed the bleeding from torn bridging veins, and rupture of small cortical arteries as "pure SDHs" as they occurred without any gross (focal or diffuse) damage to the brain itself. They found that the volumes of arterial and venous acute SDH and their relative areas in the horizontal planes were similar irrespective of the causal mechanism. The haematoma thickness and midline shift were higher in arterial SDH. On the other hand, in venous SDH, the difference between the midline shift and the haematoma thickness was lower than in arterial SDH (i.e. in venous SDH, a smaller acute SDH was associated with a greater midline shift) indicating a tendency towards more pronounced midline shift in venous, rather than arterial SDH of similar volumes. They also found that venous SDH due to bridging vein ruptures were generally located in the central frontoparietal, parasagittal region and had a comparatively smaller length and thickness than the arterial SDH which were more often located in the temporoparietal region.

Poor outcome following acute SDH may also be related to the ischaemic damage occurring in the hemisphere underlying the haematoma due to raised intracranial pressure producing impaired cerebral perfusion. Removal of an acute SDH often results in reversal of global ischaemia.[2,13,14] However, hemispheric oedema below the acute SDH may occur even when the haematoma is thin and may be related to an excitotoxic mechanism due to the massive release of excitatory glutamate and aspartate neurotransmitters. Excessive activation of excitatory neurotransmitter receptors, especially glutamatergic N-methyl-D-aspartate receptor, can cause neuronal damage closely resembling ischaemic necrosis.[20]

Howard et al.[5] found that 56% of acute SDH in the younger group (18–40 years) were caused by motor vehicular accidents and only 12% were caused by falls. Whereas, in the older groups (> 65 years), 22% and 56%, respectively, of acute SDH occurred due to the two conditions. In comatose patients, motor vehicular

accidents are responsible for acute SDH in 53–75% patients because these are often high-velocity accidents with associated diffuse axonal injury.

Associated intracranial injuries occur in more than 50% of patients with acute SDH and have a significant prognostic implication.[9,19] Associated lesions occur in 47–57% of patients presenting with Glasgow Coma Score (GCS) scores between 13 and 15, and in 65–82% of patients with GCS scores less than 10. In patients with acute SDH, contusion and fractures are the most frequent injuries encountered; associated subarachnoid haemorrhage has been seen in 14–25% of patients with SDH and epidural haematomas in 14–25% of patients. Extracranial injuries are seen in 18–51% of patients including facial fractures, limb fractures, thoracic and abdominal trauma. Around 70% of patients with other associated lesions have a contrecoup injury. Bilateral acute SDH occurs in 8–33%.

CLINICAL SPECTRUM

The clinical presentation is non-specific and occurs due to mass effect produced by the acute SDH as well as associated parenchymatous injury. It depends upon the severity of the primary injury, the associated parenchymal injuries and the rapidity of accumulation of the acute SDH. According to Jameison et al.[6] and Obana and Pitts,[10] the patients may remain unconscious throughout or may vary in sensorium from being totally unconscious to being lucid to unconscious, or may remain lucid throughout. About 40–50% of patients are unconscious at the time of their primary injury and remain comatose for prolonged periods. Stone et al.[18] showed that 53% of their patients with lucid interval neurologically deteriorated. Pupillary asymmetry ipsilateral to the side of haematoma with contralateral hemiparesis may be due to transtentorial herniation. However, false localising pupillary dilatation contralateral to the lesion may occur due to direct optic nerve, oculomotor nerve or brainstem injury on that side. Ipsilateral hemiparesis may be due to associated brain injury or due to Kernohan's notching produced by compression of the contralateral cerebral peduncle against the tentorial edge. The incidence of associated seizures has varied from 6 to 22%.[10,15]

Posterior fossa acute SDH is rare and occurs in 2.3–3% of patients who underwent surgery within 72 hours of injury. Occipital trauma and associated occipital fractures may be responsible. Posterior fossa acute SDH occurs due to tearing of bridging veins, laceration of the tentorium, contusion of the cerebellum or injury to venous sinuses. Cerebellar signs, neck stiffness and pain or symptoms of raised intracranial pressure due to the size of the lesion or the development of hydrocephalus may be the presenting features. Despite urgent surgical evacuation, the mortality ranges from 5 to 75%.[1,4,10]

IMAGING FEATURES

On CT scans, an acute SDH appears as crescentric, hyperdense collections that lie between the arachnoid and the inner meningeal layer of the dura that conform to and often exert a mass effect on the surface of the brain (Figs 1 to 3). It extends across sutural lines, but does not cross the falx or the tentorium (Fig. 4). In contrast to this, an extradural haematoma is biconvex, less likely to cross sutural lines and may cross the falx or tentorium. An acute SDH may occasionally be biconvex due to adhesions between the brain and the dura mater, or when it is thick. The exact thickness of the crescentric SDH should be measured by taking the CT images with a wide window to distinguish the hyperdense clot from bone.[20] According to Servadei et al., early CT scan (within 3 hours from injury) underestimates the size of the associated parenchymal contusions and the consequent oedema. Patients who show subarachnoid haemorrhage on early CT are those at highest risk for evolving contusions. The worst outcomes previously associated with acute SDH may, in many cases, be due to the concomitant presence of contusions in multiple areas of the brain and consequent development of oedema. Thus, the use of sequential CT scan should be included in the routine management of head-injured patients.[16,17] In the younger population, an associated swollen hypointense, ipsilateral hemisphere indicates a very poor prognosis.[20] In patients with acute anaemia and haemodilution (during resuscitation from multiple injuries), the acute SDH may appear as isodense to hypodense on CT.[3] A subacute SDH may also be isodense to the brain.

Magnetic resonance (MR) scan is a sensitive investigation for diagnosing an acute SDH (Figs 36.5A to D). The image acquisition time of an MR scan is more (30–60 minutes) than the CT scan and, therefore, a restless and irritable patient with a head injury may cause several imaging artifacts. Patients with ferromagnetic foreign bodies or electronic implants need to be excluded. Thus, MR is less preferred in the clinical setting in patients

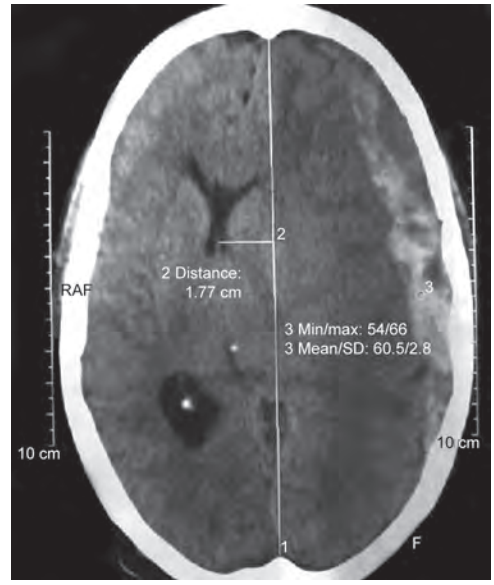

Fig. 1: Non-contrast axial CT scan showing a crescentric acute subdural haematoma causing midline shift

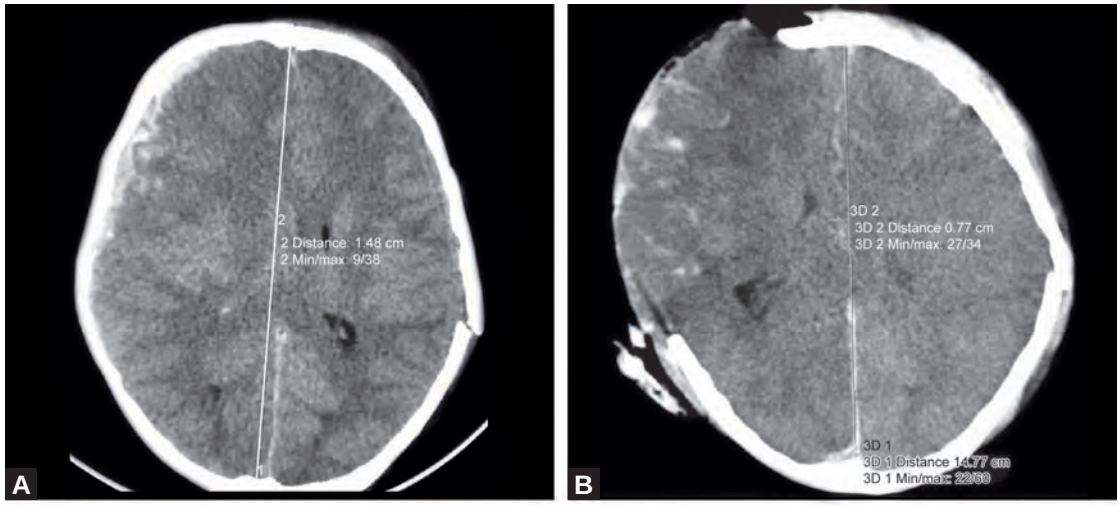

Figs 2A to C: (A) Axial CT scan showing a thin rim of subdural haematoma, with disproportionate midline shift and effacement of sulci and ventricular system. There is a parietal skull fracture contralateral to the side of the acute subdural haematoma. (B) Axial CT showing that following a large frontoparietal craniectomy, the oedematous brain herniates through the craniectomy defect. (C) Intracranial pressure monitoring. The lower-most wave is the characteristic waveform obtained on intracranial pressure monitoring. The systolic, diastolic and mean (in brackets) intracranial pressures are seen

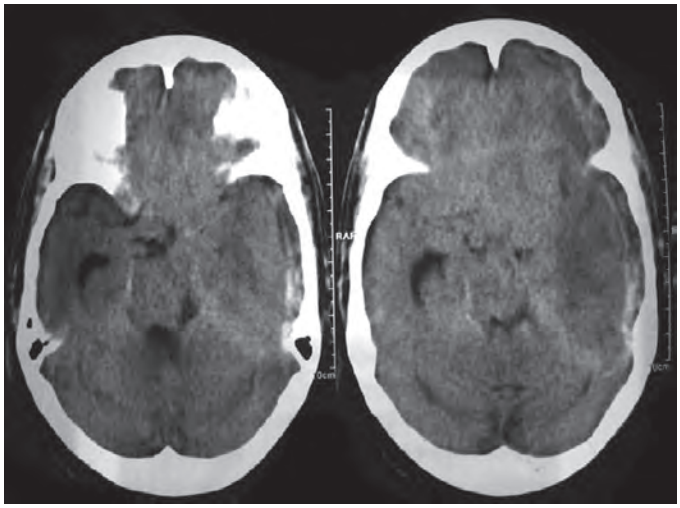

Fig. 3: Axial CT scan showing a tentorial subdural haematoma

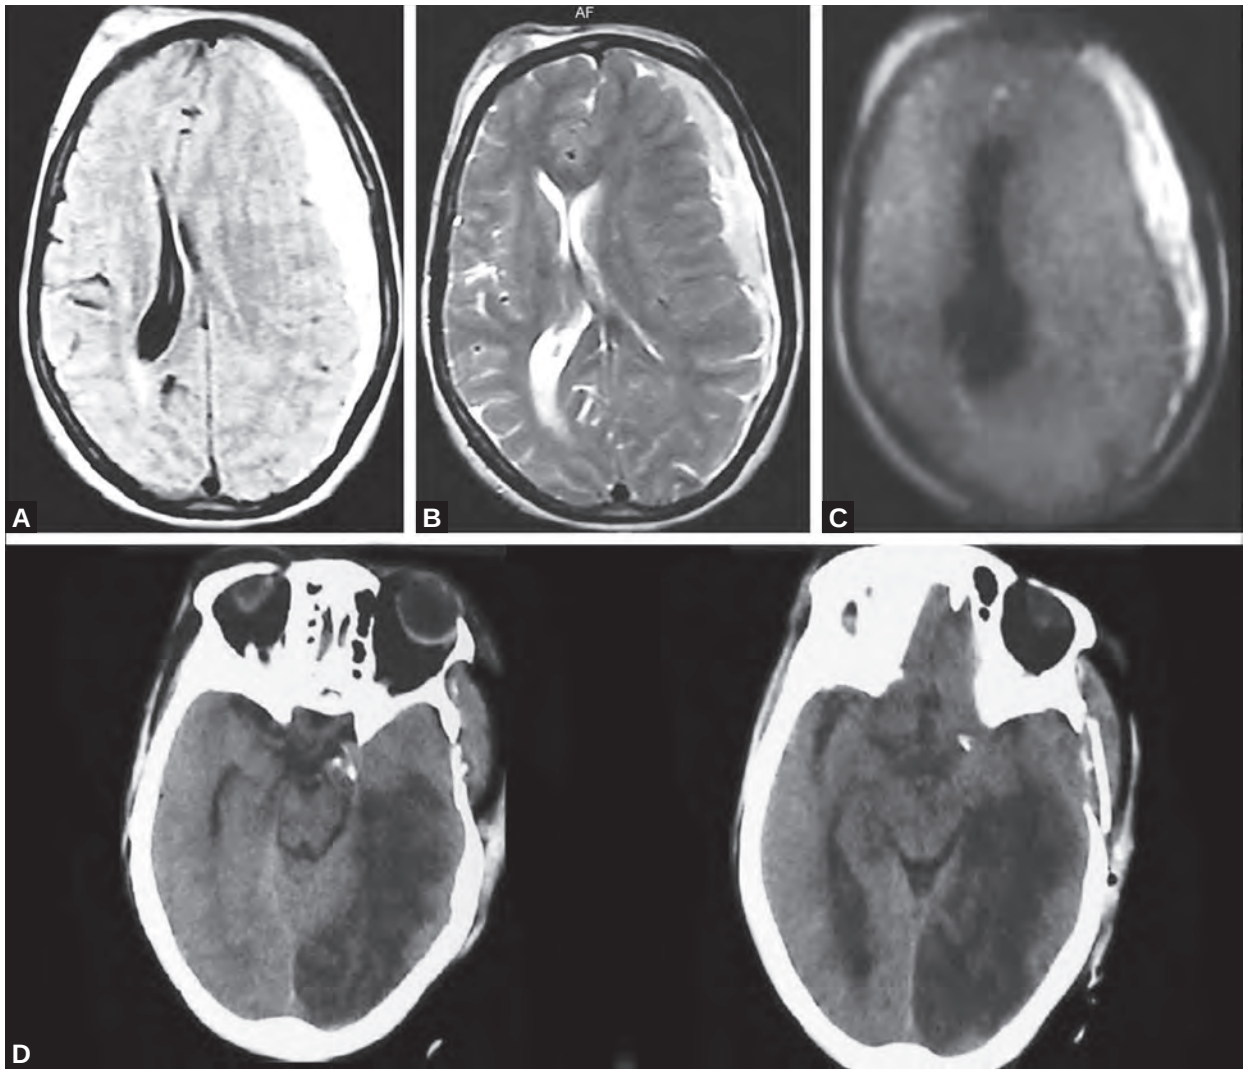
Fig. 4: Axial CT scan showing a thin rim of subdural haematoma causing uncal herniation and effacement of basal cisterns



Figs 5A to D: (A) Axial T1-weighted MR image showing a subacute SDH haematoma that is hyperintense and causing significant midline shift. (B) Axial T2-weighted image showing that the subacute SDH is still hyperintense. (C) Diffusion-weighted MR image showing the characteristic hyperintensity indicating the clot is solid in nature. (D) Follow-up CT scan after 20 days of haematoma evacuation. The patient did not improve following surgery due to the development of posterior cerebral artery infarct as a result of transtentorial herniation despite the subsidence of midline shift and opening up of the basal cisterns

with head injury as compared to a CT scan. The conventional long TR spin echo provides T2-weighted, and short TR spin echo or inversion recovery section demonstrates T1-weighted contrast differences. Gradient echo T2-weighted sequences highlight magnetic susceptibility changes making them sensitive to haemorrhage but at the cost of reduced definition close to the paranasal sinuses and other brain-air interfaces where there is an artifactual loss of signal due to diamagnetic susceptibility gradient effects. Ultrafast echoplanar imaging and other newer MR sequences have been developed that increase the speed of image acquisition. Cerebral diffusion, perfusion and functional studies at higher anatomical resolution show the presence of associated ischaemia.[20]

Bone generates a low signal on MR and, therefore, enables identification of even a small acute SDH associated with moderate to severe contusions. On MR imaging, the acute SDH ages in a similar way to intracerebral haemorrhage but its appearance in acute and subacute stages may be modified by decreased resorption of serum and liquefaction of the haematoma. Thus, in the hyperacute stage, lasting from minutes to a few hours, due to the oxyhaemoglobin content, the haematoma is dark on T1-weighted images and bright on T2-weighted images. In the acute stage, lasting for the next 1–12 hours, the presence of deoxyhaemoglobin causes the haematoma to be isointense on T1-weighted images and dark on T2-weighted images. The subacute stage that starts as early as 3 days and is established from a week may be divided into the early and late stages. In the early subacute stage, the methaemoglobin appears bright on T1-weighted and dark on T2-weighted images. In the late subacute stage, signals are bright on T1-weighted and T2-weighted images (Figs 5A and B). As the SDH become chronic (21–30 days) these signals become hypointense on T1-weighted and T2-weighted

images.[20] Fresh haemorrhage within a subacute SDH may give rise to the layering effect of the high and low attenuation clot. Occasionally, the presence of bilateral acute SDH may cause no midline shift despite the mass effect. The effacement of frontal horns, obliteration of sulci and gyri and compression of third ventricles points towards mass effect in these cases. An MR may also be more sensitive than a CT scan in picking up small gliding contusions, contrecoup injury or brainstem injury associated with the acute SDH. An extradural haematoma may be distinguished from an acute SDH by the sharply delineated, low intensity dura between the haematoma and the displaced brain in the former. Acute SDH is often associated with displaced cortical pial veins demarcated by flow voids. MR coronal imaging will also distinguish between the two entities.[20]

Radionuclide tracers, such as ^{99m}Tc hexamethyl propylene amine oxime (^{99m}Tc-HMPAO) and xenon-enhanced CT cerebral blood flow studies, may also give an idea about the regional cerebral blood flow and hypoperfusion below an acute SDH. Loss of autoregulation may cause the hypoperfused area in the subacute phase to appear hyperperfused. Severe continued hypoperfusion below an acute SDH eventually leads to tissue loss in that area.[14]

SURGICAL MANAGEMENT

The aim of surgery is to evacuate the haematoma and any associated underlying lesions in order to relieve the mass effect and improve the focal neurological deficits.[7] However, if the patient has no brainstem reflexes and is hypotonic with no motor response, surgery may not be useful. The size of the haematoma that should definitely be removed has not been ascertained. Removal of a very thin acute SDH may not be indicated as the clinical deterioration is usually due to associated lesions in this case and is not likely to improve with acute SDH evacuation. Although the current consensus is to have an acute SDH promptly evacuated through a craniotomy in 90–97% patients, conservative treatment of a small acute SDH in patients (approximately 3%) with contraindications for surgery have been reported. Some of these patients make a good recovery while some others require subsequent surgical evacuation of the haematoma. Non-operative therapy should only be considered in patients who are fully conscious, when the extra-axial mass is the single dominant lesion, that is, there are no multiple contusions or potentially significant contralateral mass lesions (which may be preventing midline shift), and when there are no features of mass effect such as a midline shift greater than 3 mm, or basal cisternal effacement. In such cases and, especially if the lesion is less than 10 mm at its thickest point, conservative therapy may be successful in most instances. The SDH will usually resorb within 1 month, although there are occasional instances of chronic SDH formation. Similarly, a deep-seated interhemispheric or tentorial SDH in a stable conscious patient may not need surgical evacuation.[7]

The guidelines for selecting patients for conservative management of the SDH proposed by Mathew et al.[11] include: (1) GCS score greater than or equal to 13 since injury; (2) absence of other intracranial haematomas or oedema on CT scan; (3) midline shift of less than 10 mm; and (4) absence of basal cisternal effacement. However, Wong[23] could not find the level of SDH volume, thickness or the associated midline shift beyond which failure of conservative treatment could be predicted. According to the recommendations of the Total Brain Injury Author Consortium[1] for the surgical management of acute SDH published in 2006, an acute SDH with a thickness greater than 10 mm or a midline shift greater than 5 mm on CT scan should surgically be evacuated, regardless of the patient's GCS score. All patients with acute SDH in coma (GCS score less than 9) should undergo intracranial pressure monitoring. A comatose patient (GCS score less than 9) with an SDH less than 10 mm thick and a midline shift less than 5 mm should undergo surgical evacuation of the lesion if the GCS score decreased between the time of injury and hospital admission by 2 or more points on the GCS and/or the patient presents with asymmetric or fixed and dilated pupils and/or the intracranial pressure exceeds 20 mmHg. An increase in haematoma size on CT scan with increasing intracranial pressure and decline in neurological status is also an indication for surgical removal of the lesion. Regarding the timing of surgery, it is recommended that in patients with acute SDH and with indications for surgery, surgical evacuation should be performed as early as possible. If surgical evacuation of an acute SDH is indicated in a comatose patient (GCS < 9), it should be performed using a craniotomy with or without bone flap removal and a duraplasty.

Since an acute SDH is composed of solid clots, a large craniotomy centred over the haematoma is the recommended technique for its evacuation.[7,19,21] If the haematoma is frontotemporal, a craniectomy centred over a temporal burr hole may be performed. The dura is opened and all accessible clot should be removed. Obana and Pitts[10] recommend a "95% operation" in which all easily accessible dark, clotted blood (usually under pressure) should be removed, but clots near dural venous sinuses or out of safe reach should not be pursued. Removal of the last bit of clot offers no added advantage and unnecessarily subjects the patient to the risk of catastrophic bleeding. It may sometimes be preferable to make several slits in the dura without joining them together as this will minimise herniation of the brain through the site of dural opening, which can be dramatic and may even prevent closure of the scalp. An attempt should be made to identify the parasagittal venous bleeder, if no cortical source of bleeding is evident. Parasagittal irrigation with depression of the medial cortex and raising the venous pressure by the anaesthetists are manoeuvres to identify the bleeding point. The latter may be controlled with bipolar coagulation or liga clips. If it is direct and profuse from the

sagittal sinus, then a muscle patch may be required for tamponade. Failure to identify and control the parasagittal bleeding source may cause recurrence of acute SDH. Removal of contused brain or even a frontal or temporal lobectomy may be considered when cortical damage and the mass effect are severe. A duraplasty using temporalis fascia, pericranium, fascia lata or dural substitutes such as lyophilised dura or woven collagen may be performed. If possible, the bone flap should be replaced and secured and scalp layer closed meticulously.[7] Intraoperative brain swelling is commonly seen with acute SDH. This may be the result of pre-existing multiple small gliding contusions and diffuse axonal injury. The potentially remediable causes of brain swelling after evacuation of an acute SDH include impaired ventilation (due to pneumothorax, endotracheal tube dislodgement or occlusion) requiring hyperventilation and change of airway; an intracerebral haematoma developing beyond the craniotomy margins or contralateral haematomas requiring evacuation and dehydrants; or, acute hydrocephalus developing due to coexisting intraventricular haemorrhage or due to midline shift causing contralateral foramen of Monro block that requires a ventricular drainage procedure. If intracranial pressure control is not achieved with maximum dehydrant therapy then consideration must be given to the removal of contused and swollen brain. The frontal and/or temporal lobectomy must be aimed at removing only the damaged brain and at avoiding eloquent areas. The drawback of a lobectomy is that removal of the brain tissue frequently does not control intracranial pressure.[7]

A wide decompressive haemicraniectomy/craniotomy with duraplasty (Figs 2A and B) may be useful in obtunded patients with intact brainstem function who subsequently deteriorate due to increased hemispheric oedema or the SDH. An intracranial pressure monitoring device and adjuvant medical management of raised intracranial pressure is useful in such cases.[7,13,21] The Medical College of Virginia criteria for performing this procedure is when intracranial pressure control is not achieved with maximum therapy using mannitol, ventricular drainage, pressors, moderate hyperventilation ($PaCO_2$ = 32 ± 2 mmHg) and moderate hypothermia (32 ± 2°C); pupils not fixed and dilated; and preserved brainstem responses and central conduction time on evoked potential testing.[7]

Burr-hole drainage of an acute SDH is usually unsuccessful because the underlying clot is solid. It may, however, be used to localise the site of clot in case imaging facilities are not available, following which the burr hole may be enlarged to a craniectomy.[7]

OUTCOME

The mortality from an acute SDH in all patients shows a wide range (42–90%); in all age groups with GCS between 3 and 15 requiring surgery ranges between 40% and 60%; and in comatose patients requiring subsequent surgical evacuation is between 57% and 68%. Residual or recurrent haematoma requiring evacuation has been seen in approximately 14% of patients.[10] Occasionally, removal of the mass effect caused by the acute SDH may increase the underlying intracerebral haematoma or contralateral acute or chronic SDH. Post-operative haematomas should be suspected and a post-operative CT obtained in patients who fail to improve or those who deteriorate and in whom the intracranial pressure monitoring shows persistently high intracranial pressures. The post-operative complications following evacuation of an acute SDH may include osteomyelitis, wound infection, meningitis, subdural empyema and ventriculitis.[1,10]

The factors determining outcome include:

1. The neurological status: This forms the most significant factor in determining outcome. In patients with acute SDH and GCS of 3–5, the mortality was 76% and good to moderate outcome occurred in 14% patients; those with GCS of 6–8 had a mortality of 36% and a moderate to good outcome in 40% of patients.[10] Pupillary asymmetry correlates with a poorer outcome. In bilateral pupillary abnormalities, the mortality is over 80%; in unilaterally dilated but reactive pupils, the mortality reported is approximately 50% and, in unilaterally dilated non-reactive pupils, the mortality reported is approximately 58%.[10,18] Decerebrate posturing, flaccid patients (mortality 77–95%), and patients with hemiparesis and hemiplegia (mortality 35–48%) also have a poorer prognosis as compared to intact patients.[10]
2. Age: Younger patients have a better outcome than older patients due to less comorbid conditions in the former. A number of authors have not found any significant correlation between age and mortality, but a significant association between age and functional recovery.
3. CT parameters: CT parameters such as clot thickness, haematoma volume, midline shift and patency of the basal cisterns: Howard et al.,[5] following surgery for acute SDH, found a significant correlation between poor outcome and the volume of SDH and the midline shift.[5] Servadei et al.[16,17] also found a correlation between outcome and clot thickness and the status of the basal cisterns. Kotwaca and Brezezinski[8] also found a significant relationship between midline shift and outcome in patients with GCS scores lower than 10, who were undergoing surgery for SDH. However, van den Brink et al.[22] found no difference in haematoma volume, midline shift and patency of the basal cisterns in surgical patients with favourable versus unfavourable outcome. Zumkeller et al.[24] revealed a 10% mortality rate in patients with a clot thickness of less than 10 mm and a 90% mortality for patients with clot thickness greater than 30 mm. Thus, these parameters do seem to influence outcome, but the specific threshold values need to be determined.
4. Timing of surgery: Usually conservative treatment is adopted and surgery deferred in patients with

less severe acute SDH and in better neurological status. Thus, mortality is less whenever timing from injury to surgery increases in most of the published series. In comatose patients, however, there was a significant decrease in mortality and increase in functional recovery in patients who underwent surgery within 4 hours of injury as compared to those in whom surgery was delayed beyond 4 hours of injury. The mechanism of secondary brain damage is direct compression of the underlying cortex and brain shift that causes local zones of ischaemia. If the elevated intracranial pressure is unrelieved, leading to reduced cerebral perfusion pressure, then global ischaemic brain damage may occur.[10]

5. Intracranial pressure: Persistently elevated (> 20 mm Hg) post-operative intracranial pressure is associated with a poorer prognosis.[1,10]
6. Associated lesions: An associated intracerebral haematoma or contusion did not influence mortality but the functional outcome was significantly better in patients without contusions. Associated diffuse axonal injury significantly influences outcome.[19] Jamieson and Yelland[6] classified acute SDH based on their associated lesions into: simple acute SDH without brain injury (mortality: 22%); acute SDH with contusion (mortality: 30%) and complicated acute SDH (with parenchymal laceration, intracerebral haemorrhage or burst temporal lobes; mortality: 53%).
7. Comorbid conditions: Lung infections, septicaemia, meningitis, shock, cardiac arrhythmias, upper gastrointestinal haemorrhage or cirrhosis may all influence outcome.[1,10]

According to the Traumatic Brain Injury Author group, the key issues for further investigation in cases of acute SDH include the influence of craniotomy versus decompressive craniectomy on the outcome; the impact of the timing of surgery, the pre-operative hypotension and hypoxia on outcome; identification of subgroups that do not benefit from surgery such as older patients with low GCS scores, pupillary abnormalities and associated intracerebral lesions; and investigating whether operating on all comatose patients regardless of their clot thickness would lead to a better outcome.[1]

In 2001, Tandon,[19] in a review article concluded that isolated acute SDH, acting as a compressive lesion, is an uncommon clinicopathological entity with the majority of patients having associated focal (contusion/laceration/intracerebral haematoma) or global (diffuse axonal injury, subarachnoid haemorrhage) involvement or both. Ischaemia underlying an acute SDH and hemispheric brain swelling may be superadded and self-perpetuating and may lead to uncontrollable elevations of intracranial pressure with consequent herniation, brainstem compression and haemorrhage. The molecular cascade initiated by the injury may lead to secondary brain damage. Thus, even with successful and early evacuation of the clot and aggressive intensive care management, mortality still remains high and functional status is often compromised. The future reduction in morbidity and mortality will depend upon the effective prevention, arrest or reversal of the molecular events that are responsible for the secondary ischaemia and cytotoxic oedema. Acute SDH should therefore be subclassified as SDH with or without associated parenchymal pathology in order to shift the focus from the haematoma to the brain injuries as that would lead to a more expeditious addressal of the entire coexisting pathology and the secondary changes. This would permit better comparison of different therapeutic modalities and better prognostication.

37 Extradural Haematomas

Ashok Kumar Mahapatra, Vivek Kumar Vaid, Rajkumar

INTRODUCTION

Extradural haematoma (EDH) is a collection of blood between the potential space that exists between the inner table of the skull and the dura (periosteal layer). Extension of the haematoma usually is limited by suture lines owing to the tight attachment of the dura at these locations (continuation of periosteal layer of the dura with the pericranium at the sutures).

EPIDEMIOLOGY

Extradural haematoma occurs in approximately 2% of all patients with head injuries and 5–15% of patients with fatal head injuries. EDH is considered to be one of the most serious complications of head injury, requiring immediate diagnosis and surgical intervention. EDH may be acute (58%), subacute (31%) or chronic (11%). It usually occurs in young adults and is rare in children below 2 years of age[1,13,34] (due to the plasticity of the immature calvarium) or after age 60 (because the dura is adherent to the overlying bone). The incidence of delayed extradural haematoma (DEDH) following an initially negative CT scan is reported in 10–30%.[16]

PATHOPHYSIOLOGY

Extradural haematoma usually results from a brief linear contact force to the calvarium that causes separation of the periosteal dura from bone and disruption of interposed vessels due to shearing stress. Skull fractures are found in 85–95% of adult cases. Arterial or venous structures may be compromised, causing rapid expansion of the haematoma. However, chronic or delayed manifestations may occur when venous sources are involved. The haematoma arises from injury to the middle meningeal artery in over one half of the patients, from the middle meningeal vein in one third and from diploic veins or a torn dural venous sinus in the remainder.[44]

The temporoparietal region and the middle meningeal artery are most commonly involved (66%),[12,21,36,37,40,44–46,48] although the anterior ethmoidal artery may be involved in frontal injuries, the transverse or sigmoid sinus in occipital injuries and the superior sagittal sinus in trauma to the vertex. Bilateral EDHs account for 2–10%[19] of all acute epidural haematomas in adults but are exceedingly rare in children. Posterior fossa EDHs occur in 5% of all cases of EDH.[17,25,28,30,35,42,43,54] Associated intracranial injury occurs in a minority of patients thus implying a better prognosis for these patients, if managed emergently. The risk factors for DEDH include lowering of intracranial pressure (ICP) medically and/or surgically, thus reducing the tamponading effect, rapid correction of haemodynamic shock and coagulopathies.[19]

CLINICAL PRESENTATION

This classification was first described by Kristiansen and Tandon in 1960.[39] Patients with EDH may have the following five clinical presentations:[3,5–13,20,45,46,48,49,51]

- Conscious throughout (8–24%)
- Unconscious throughout (23–24%)
- Initially conscious and subsequently unconscious (20–28%)
- Initially unconscious and subsequently lucid (14–21%)
- The "Textbook" presentation consisting of brief post-traumatic loss of consciousness (LOC), followed by a "lucid interval" for several hours and then obtundation, contralateral hemiparesis and ipsilateral pupillary dilatation occurs in less than 10–27% of the patients.

A lucid interval is not pathognomonic for EDH; other post-traumatic mass lesions can also present in a similar manner. There are no definite symptoms of EDHs. The triad of head injury with lucid interval, mydriasis on the side of the haematoma and contralateral hemiparesis occurs in only 18% of the cases and mainly when the EDH is localised to the temporoparietal region.

The dilated and non-reactive pupil can be associated with ipsilateral hemiplegia. This is due to indentation of the contralateral cerebral peduncle by the edge of the tentorium cerebelli (Kernohan's notch). Initially, the pupil on the side of EDH contracts due to irritation of the oculomotor nerve and the opposite pupil will be normal in size. In the next stage, the ipsilateral pupil dilates due to paralysis of the oculomotor nerve. Finally, the pupils of both the sides become dilated and fixed (Hutchinson's pupil).

Editorial note: So called Hutchinson's pupils is neither characteristic nor follows the sequence originally reported. For good outcome the diagnosis and treatment of EDH should be carried out prior to the pupil becoming dilated and fixed.

Paralysis of extraocular muscles supplied by the oculomotor nerve occurs a little after pupillary changes as the pupillary fibres are more sensitive to pressure due to their peripheral arrangement in the oculomotor nerve.

Patients may also present with minimal complaints such as headache, nausea and vomiting. The variable appearance and progression of symptoms depend on the location, speed and growth of the haematoma. A post-traumatic disorder (a form of vagal syncope), described by Denny-Brown, consisting of "lucid interval" followed by bradycardia, brief episodes of restlessness and vomiting, without intracranial hypertension or mass, must be considered in the differential diagnosis.

DIAGNOSIS

The diagnosis of EDH must be considered when the plain skull X-rays show a fracture[1,3,5–11,13,34] and it must obviously be clinically correlated. A fracture is not identifiable in approximately 40% of the cases. If the clinical condition of the patient permits and a non-contrast computed tomogram (CT) scan is possible, it must be done urgently. The "Classic" CT appearance is seen in 84% of the cases and consists of a hyperdense, biconvex (lenticular) mass adjacent to the skull[4,13,32,52] (Fig. 1). Fracture lines will further be evident and mass effect appreciated. Generally the EDH is confined (restricted) within sutures, but this may not be the case every time. Occasionally, air may be visualised within the haematoma due to an associated internal or external compound fracture of the skull.[15,24] Magnetic resonance imaging (MRI) can also be done, but is time consuming and in no way superior to CT. Another diagnostic modality now under development is near infrared spectroscopy which can be used with reasonable sensitivity and specificity for detection of intracranial lesions in a short time[26,27] and could be informative when the patient is herniating, and urgent surgical intervention is required. Cervical spine evaluation usually is necessary because of the risk of neck injury associated with EDH.

MANAGEMENT

Laboratory investigations which are routine for traumatic brain injury patients are also done. These are as follows:

- *Complete blood count (CBC) with platelets:* To monitor for infection and assess haematocrit and platelets for further haemorrhagic risk.
- *Prothrombin time (PT)/activated partial thromboplastin time (aPTT):* To identify bleeding diathesis.
- *Serum chemistry, including electrolytes, blood urea nitrogen (BUN), creatinine, and glucose:* To characterise metabolic derangements that may complicate the clinical course.
- *Toxicology screen and serum alcohol level:* To identify associated causes of head trauma and establish the need for surveillance with regard to withdrawal symptoms.
- *Type and hold an appropriate amount of blood:* To prepare for necessary transfusion needed due to blood loss or anaemia.

In 1990, Pickard and co-workers[47] showed that surgical management of post-traumatic EDH is one of the most "cost effective" of all surgical procedures in terms of quality of life and work years preserved.[48] Management of EDH most of the time is surgical,[1,3,5–13,34,53] but, in a few selected patients, non-surgical management[13,14,32,38,48,49] may be attempted (Figs 2A and B). These are:

- Small EDH (≤1 cm maximal thickness)
- Subacute or chronic EDH
- Minimal neurological signs and symptoms.

These select few patients must be closely observed and surgery undertaken, if the patient fails to show progressive improvement. In 50% of the cases, there is a transient increase in size between days 5–16, and it is during this time period that most of the non-surgically managed patients need special attention.[16] Surgery should be done for most posterior fossa EDHs.

In a rapidly deteriorating patient with suspected EDH, a CT scan is inappropriate. The clinical triad of altered mental status, unilateral pupillary dilatation with loss of light reflex and contralateral hemiparesis is most often due to upper brainstem compression by

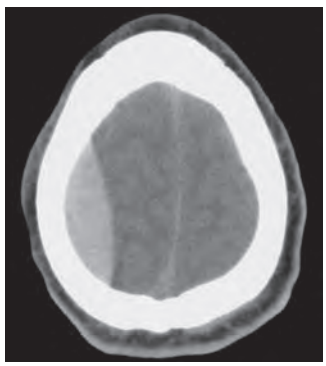

Fig. 1: Right frontotemporal EDH with mass effect managed by surgical intervention

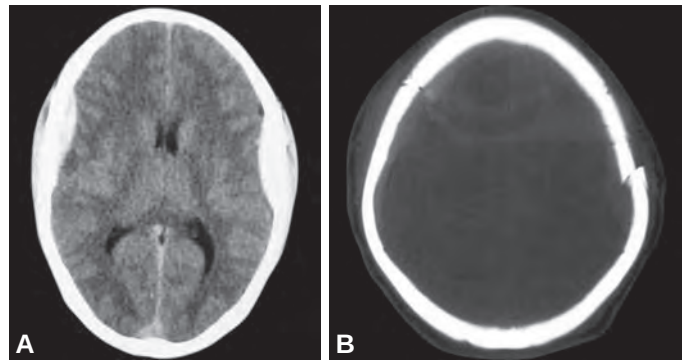

Figs 2A and B: CT scan of the brain. (A) With bone windows. (B) Showing bilateral EDH with fracture calvarium managed conservatively

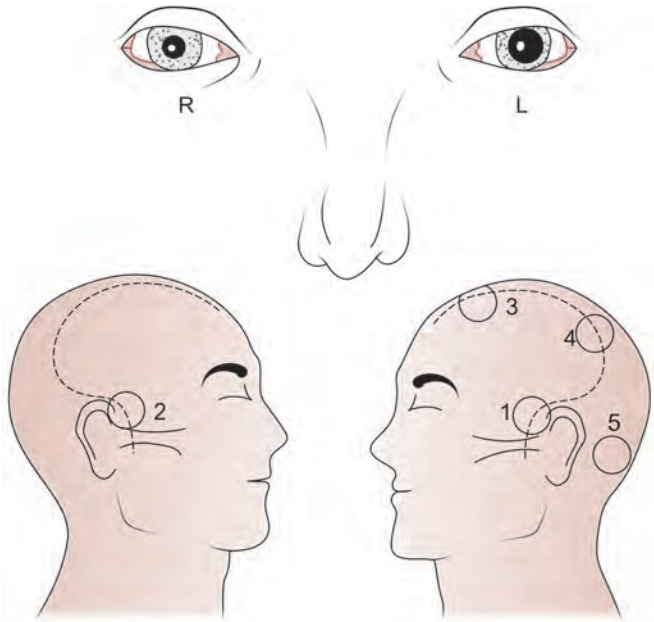

Fig. 3: Order of placement of exploratory burr holes: (1) temporal burr hole on the side of initial dilatation of pupil; (2) temporal burr hole on the opposite side; (3) frontal burr hole on the side of initial dilatation of pupil; (4) parietal burr hole on the side of initial dilatation of pupil and (5) occipital burr hole on the side of initial dilatation of pupil

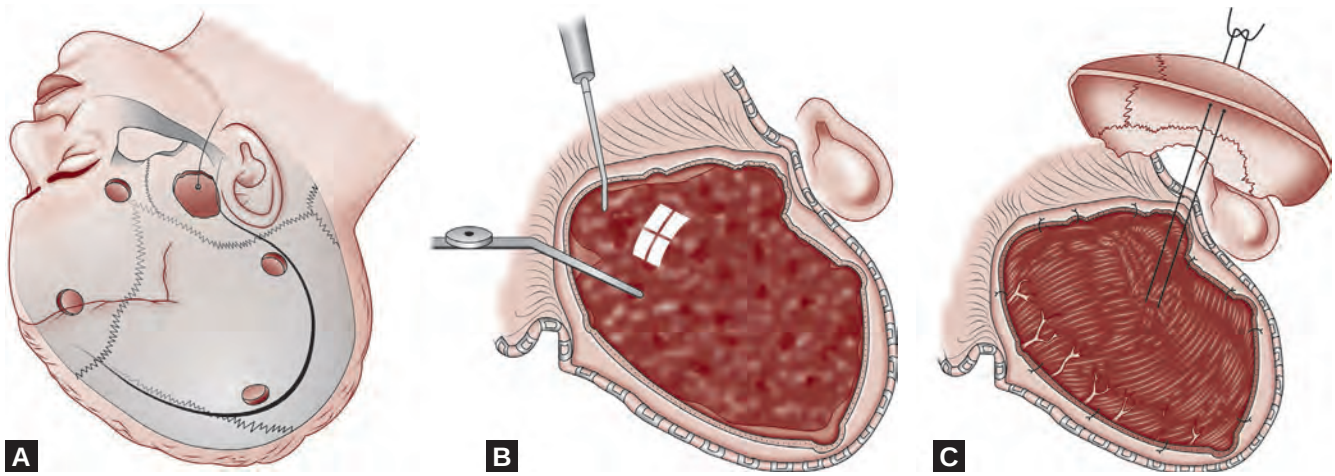
uncal herniation which, in the majority of trauma cases, is due to EDH. In such patients exploratory burr holes are indicated.[18,26,27,41,48–51,53] The choice of the site for initial burr hole placement are (Fig. 3) as follows:

- Start with temporal burr hole on the side
  - Ipsilateral to the dilated pupil (will be correct side in >85% of EDHs and other intra-axial mass lesions.
  - If both the pupils are dilated, use the side of the first dilating pupil (if known).
  - If the pupils are equal, or it is not known which side dilated first, place on side of obvious external trauma. For example, bruising and/or scalp haematoma.
  - If there are no localising clues, place holes on left side (to evaluate and decompress the dominant hemisphere).
- If no epidural haematoma is found, the dura is opened if it has bluish discolouration (suggests subdural haematoma), or if there is a strong suspicion of a mass lesion on that side.
- If completely negative, usually perform temporal burr holes on the contralateral side.
- If negative, further burr holes should be undertaken if CT scan can still not be done.
- Proceed to ipsilateral frontal burr hole.
- Subsequent burr holes may be placed at the parietal region and lastly in the posterior fossa.

If the burr hole is positive, then a modest bony decompression is performed around the burr hole and then the definitive craniotomy undertaken incorporating the burr hole(s).

Patients who are neurologically stable and can undergo CT scan should have this investigation done at the earliest. This avoids time consuming and often misleading diagnostic burr holes. If EDH is detected, then the indications for surgical management are given as follows:

- Any symptomatic EDH.
- An acute asymptomatic EDH >1 cm (containing more than 40 ml of blood) in its thickest measurement.
- EDH in paediatric patients (low threshold for sudden deterioration as there is less room for the clot to accumulate).
- Failure of non-surgical (conservative) management. There are mainly three surgical objectives (Figs 4A to C). These are as follows:
- To remove the clot, thus reducing the ICP and eliminating the focal mass effect.
- Achieve absolute haemostasis.
- Prevent reaccumulation by placing dural hitch sutures (tack-up sutures). A central tack-up suture (Poppen's suture) in the middle of the craniotomy flap is always advisable.



Figs 4A to C: (A) Skin incision for trauma flap with subtemporal craniectomy for initial rapid decompression of the haematoma. (B) Gentle evacuation of the EDH with irrigation and suction. (C) Adequate haemostasis with placement of dural hitch sutures at the margins of the craniotomy with a central hitch suture fixing the dura to the raised bone flap

POSTERIOR FOSSA EDH (PFEDH)

Among the posterior fossa post-traumatic haematomas, EDH is the most common lesion that requires surgery, followed by SDH and ICH, respectively. Infratentorial EDH is most often due to lateral sinus injury, but injury to sinuses deep to the skull base may be more frequent than is commonly realised.[2,17,22,25,28–30,43] Occipital fractures extend into the petrous bones in more than one third of the cases, resulting in significant hearing loss (mostly sensorineural) in 20% of cases and facial nerve injury in 9% of cases.

Clinically, deterioration may be rapid, with respiratory depression occurring without any pupillary change or motor signs. Headache, nausea, vomiting and neck stiffness are the most common signs. The patient may present with a classic lucid interval, but in acute cases, patients more commonly present with signs of brainstem compression of rapid onset.

Patients with posterior fossa EDH should intensively be managed with a low threshold for surgical intervention.[2,17,22,25,28–30,35,42,43,54] The principles and objectives of surgery remain the same as for supratentorial EDH, i.e. evacuation of EDH and reduction of ICP and mass effect, adequate haemostasis and placement of dural tacking sutures (Figs 5A to C). In view of obstructive hydrocephalus placement of a right frontal ventriculostomy is mandatory before surgery. Bone removal should include the rim of the foramen magnum inferiorly and go up to the edge of the transverse sinus superiorly, to allow identification and control of bleeding from the sinus. A rapidly performed craniotomy using a high speed drill and a craniotome is possible in place of the usually performed craniectomy, as the dura is already stripped from the overlying bone by the haematoma and there is minimal chance of dural injury.

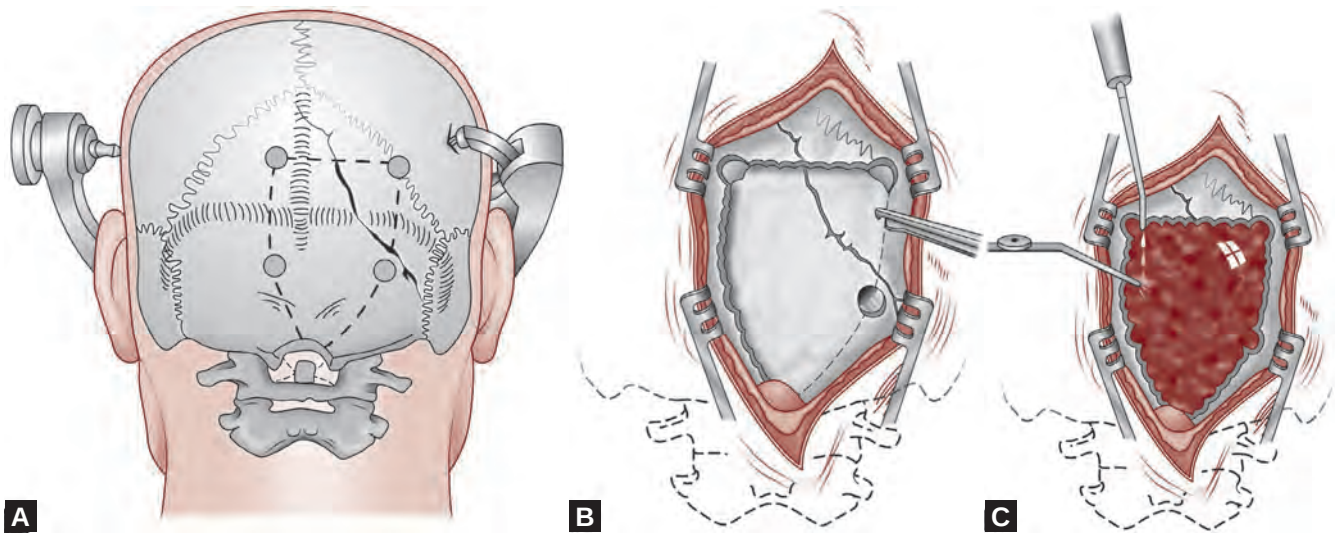
After emergent neurosurgical evacuation of the haematoma, the patient is transferred to the intensive care unit (ICU) for further care. Subsequent care generally includes the following:

- Serial neurological examinations
- Management of elevated ICP
- Avoidance of hypotension or hypertension [i.e. maintain mean arterial pressure (MAP) between 70–130 mmHg]
- Use of isotonic solutions, such as normal saline, to minimise cerebral oedema
- Avoidance of hyperthermia
- Treatment or prevention of post-traumatic seizures
- Observation and potential repair of CSF leaks
- Prevention and, when necessary, treatment of urinary tract infection
- Prevention of venous thrombosis
- Prophylaxis for gastric ulcers
- Physical, occupational and speech therapy as required
- Repeat CT scan for clinical deterioration.

MORBIDITY AND MORTALITY

Delay in diagnosis and treatment is the most common preventable cause of morbidity and mortality. Recurrent or residual haematoma may result from failure to gain full access to the haematoma and to the lacerated meningeal vessels or multiple small bleeders on the dura where it has been stripped off the inner table of the skull.

Mortality following treatment of EDH varies from 5 to 43%. Mortality is particularly low in children (5–10%) and increases sharply in those over age 40 (35–50%). Associated intracranial lesions, such as subdural haematoma (SDH), intracerebral haematoma (ICH) and cerebral contusion, carry a poor outcome and results in mortality rate four times greater when compared to those patients without such lesions. Older age, poor preoperative neurological condition, large haematoma volume, delay in operative evacuation, large midline shift and post-operative elevation in ICP are all associated with poor prognosis.[12,18,20,21,23,31,33,36,37,40,45,46,48,50,51,53]



Figs 5A to C: (A) Skin incision for evacuation of posterior fossa extradural haematoma (EDH). (B) Craniotomy done with underlying EDH being visualised. (C) Gentle evacuation of the EDH with irrigation and suction

In the present environment of consumer protection and awareness the medical/legal pitfalls to be considered are given below:

- Failure to consider diagnosis, especially in a conscious patient with normal pupils
- Failure to diagnose EDH in a patient with altered mental status (instead naming alcohol or another intoxicant as the cause)
- Failure to closely observe traumatic brain injury patients with frequent neurologic evaluations
- Failure to transfer expeditiously to a trauma centre with a neurosurgeon (delayed transfer and triage may be the principal determinant of death)
- Failure to consider EDH in all patients who have experienced head injury
- Failure to promptly evacuate the haematoma when surgically indicated.

CONCLUSION

EDH occurs in approximately 2% of patients with head injuries. EDH is considered to be the most serious complication of head injury, requiring immediate diagnosis and surgical intervention. It usually occurs in young adults, and is rare in children below 2 years or after the age of 60 years. The temporoparietal region and the middle meningeal artery are involved most commonly. EDH occurs due to vascular tear and dural stripping following trauma. EDH should be suspected in patients with progressive deterioration in level of consciousness and patients with a lucid interval. CT scan is the investigation of choice and shows a biconvex lenticular hyperdense lesion on plain CT. Early diagnosis and quick surgical evacuation is the key to good results. The outcome depends upon on the level of consciousness at the time of operation, and associated brain and systemic injuries. Quick diagnosis and early surgical evacuation lead to excellent results.

38 Traumatic Intracerebral Haematomas

Ravi Ramamurthi, Nigel Peter Symss

Patients with head injury who sustain sublethal intracranial damage normally tend to recover unless certain secondary complications set in. These are often referred to as "epiphenomena" or "the second accident".[19] These "epiphenomena" signify the onset and perpetuation of post-traumatic intracranial hypertension. A common and treatable cause of post-traumatic intracranial hypertension is an expanding intracerebral haematoma. The survival rate of the victims sustaining a sublethal intracranial injury depends to a large extent on the early recognition and treatment of intracranial haemorrhage.

CLASSIFICATION

Traumatic intracranial haemorrhage may be classified on the basis of the anatomical location of the bleed as subarachnoid, extradural, subdural or intracerebral; and on the basis of the time factor as acute, subacute and chronic. The latter classification is arbitrary, but useful for diagnosis and prognosis.

Intracerebral haemorrhage can be either in the form of a haematoma or a contusion. Intracerebral haematomas are more common, occurring as the primary lesion in 10% of severe closed head injuries in the Traumatic Coma Bank (TCB) data study series.[10] It is difficult to distinguish between intracerebral haematomas occurring primarily and those associated with a contusion. Haemorrhagic contusions were present as the primary lesion in 3% of severe closed head injuries in the TCB data study.[10]

INCIDENCE

The incidence of intracranial haemorrhage in acute head injury is difficult to assess. There can be no reliable data available regarding those cases who die immediately after the accident and those that do not reach the hospital.

In India, the pattern of incidence of complications has shown an interesting variation. Three decades ago, acute subdural and extradural haemorrhages were less frequent as traffic accidents were mostly slow-speed injuries.[25] This picture has now changed with the increasing number of automobiles and motorized traffic in the cities. The high speed attained by vehicles on the highways of the West is not seen in India and the developing countries because of the type of roads and the type of traffic.[29,30] This is bound to change with the advent of world-class roadways in India such as the Golden Quadrilateral and similar roads. The existence of ambulances and the availability of first aid on these highways are but a small step in the right direction.

INTRACEREBRAL HAEMORRHAGE

Most severe head injuries have some degree of intracerebral haemorrhage which may be conveniently classified as follows:

1. Immediate
   a. Cortical and subcortical haemorrhage (local or diffuse) in association with brain laceration and contusion.
   b. Petechial haemorrhages – small, medium or widespread in the brain substance.
   c. Massive intracerebral haemorrhage.
2. Delayed intracerebral haemorrhage.

Immediate Intracerebral Haemorrhages

Cortical and Subcortical Haemorrhage

All lacerations or contusions of the brain, either due to direct injury as in a depressed fracture and penetrating injury or in a closed head injury due to an acceleration-deceleration type of trauma are associated with some amount of subpial and subcortical extravasation of blood. In the closed type of trauma, such lacerations are most marked in the frontal, temporal and occipital poles and their undersurfaces. These areas of the brain are more vulnerable as they strike the irregular inner surface of the skull and also because they impinge over the sphenoidal and petrous ridges of the base of the skull. The damaged capillaries in the surrounding area give rise to a number of small haemorrhages and the area of laceration is surrounded by an area of oedema. When extensive, this oedema may result in raised intracranial pressure (ICP). Traumatic basal ganglia haematomas are due to acceleration and deceleration injuries. A contusion index has been developed that grades contusions based on the depth of injury (1-superficial cortex, 2-full thickness of cortex, 3-cortex white matter junction) and extent of contusion (1-localised, 2-moderately extensive, 3-extensive).[13]

Petechial Haemorrhages

In many cases of acute brain injury where epiphenomena have not occurred, autopsy studies reveal small or moderate foci of haemorrhage in the white matter, basal ganglia, brainstem, corpus callosum and the cerebellum. Impairment of respiratory function due to any cause following a head injury leads to anoxia of the brain, which also results in petechiae. These are not unlike those found in cases of asphyxia and strangulation. These haemorrhages are also caused by distortion of the brain occurring at the time of the accident with consequent damage to the capillaries. The intracranial vessels are fixed either at the base of the skull or at the dural sinuses, while the substance of the brain is soft and floating in the cerebrospinal fluid (CSF). The shearing strain of the injury causes friction between the fixed vessel and the deformed brain substance – "neurovascular friction" of Shimizu et al.[27]

Small haemorrhages of this type attain clinical significance in critical areas like the pons or the midbrain.[30] When occurring around the aqueduct, they may lead to obstruction to the flow of CSF. Contusions in the brain with capillary haemorrhages may coalesce and form small haematomas. These are often multiple. Schneider et al.[26] found that 36% of contusion haematomas were multiple and 64% were solitary. These are often associated with other injuries to the brain like extradural or subdural haematomas and fractures. These small haematomas rarely require operative removal. After absorption some of them may coalesce and form cavities resulting ultimately in post-traumatic porencephalic cysts, which may or may not communicate with the ventricular system or the subarachnoid space.

Massive Traumatic Intracerebral Haematoma

Traumatic intracerebral haematoma as an isolated lesion is not common. However, those associated with contusion and laceration and acting as a significant mass lesion constitute one of the most common lesions requiring surgical relief.[28] More frequent in the older age group, they are situated mainly in the temporal and frontal lobes, due to the brain impacting against the rigid skull. Parietal and occipital lobe haematomas are much less common and are usually due to direct impact, as seen in assaults.[14] They rarely occur in the cerebellum (Figs 1 and 2). The source of haemorrhage is the rupture of an artery or vein. Multiple haematomas involving the brainstem and basal ganglia may occur.[2,23,30] Most intracerebral haematomas are visualised as hyperdense mass lesions and can be detected by computed tomography (CT) immediately after the trauma. It may be noted that in many, if not most cases of traumatic intracerebral hemorrhage (ICH), there is an accompanying, usually inconsequential, layer of subdural blood.
