Interference with MR imaging	Use of titanium instead of stainless steel implants

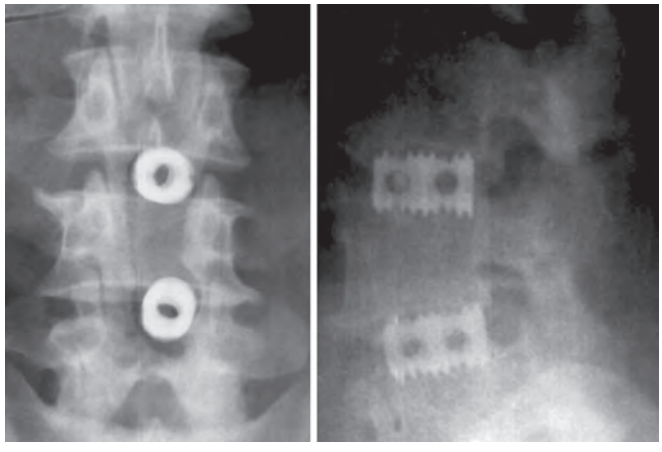

Fig. 17: Cages for lumbar fusion implanted through posterior approach (AP and lateral radiographs)

fitness is stressed repeatedly. Psychosocial issues must be sorted out before surgery. Poor general health, severe osteoporosis and extensive multilevel spondylotic disease contraindicate surgery.

Uninstrumented fusion: Intertransverse fusion using 'H' shaped grafts and posterolateral (facetotransverse) *in situ* bone fusion (PLF) using slivers of autografts were the standard techniques in the past. For the fusion to take well, adequate clearance of muscle and periosteum from the fusion surface was needed. This called for a paraspinous transmuscular (Wiltse) approach through a single midline or a horizontal incision (through which an iliac graft also could be harvested) or two paired paraspinous incisions. These procedures also entailed prolonged immobilisation, strict use of orthosis and restriction of activities. Our practice in the past was to

Table 7: Disadvantages of the conventional midline approach and advantages of the paraspinous transmuscular approach to open lumbar pedicle screw placement (Adapted with permission from *Progress in Clinical Neurosciences Vol. 23*)[14]

Disadvantages of the conventional midline approach	*Advantages of the bilateral paraspinous transmuscular approach*
Erector spinae muscle damage	Reduced muscle damage
Prolonged retraction	No prolonged retraction
Ischaemic damage	No ischaemia
Physical trauma	No physical injury
Bulk of muscle	No bulk of muscle
Prevents lateral starting of screw track	To prevent lateral starting of screw track
Convergence of screws difficult	Convergence of screws easy
Medial pedicle breach, risk to nerve root	Least possibility of breaching medial pedicle wall or damaging root
Poorer purchase, especially in osteoporotic bone	Good purchase even in osteoporotic bone
Needs cross-connector to prevent toggling	Cross-connector not needed for 1 level
Comes in the way of taps and wrenches	Does not interfere with taps and wrenches
Anatomical landmarks obscured, especially when facets are hypertrophic	Anatomical landmarks not obscured
Longer incision, skin necrosis from retraction	Shorter incision, no skin necrosis
Longer duration of surgery	Shorter time of surgery
Blood loss, need for drain	Minimal blood loss, no need for drain
Longer recovery time, pain	Shorter recovery time, less pain, analgesic need

do uninstrumented PLIF using iliac bone block autografts. When this procedure is done under the operating microscope through adequate laminofacetectomies, the risk to the nerve root is minimised. The bone grafts have a wider area of contact and are placed in compression between the bodies allowing early ambulation and ensuring adequate union.[49] PLIF also allows restoration of disc height. We should not forget that procedures like PLF and PLIF have a long history and have given good results in the hands of experts. An example is Yamamoto's series of 67 patients of DSO who had PLIF, nearly 2/3rd of them without pedicle screw augmentation.[67] The ultimate fusion rate was 94% (including delayed fusion and collapsed fusion) and 89% were reported to be in the excellent or good category. This is to be compared with the 64–80% good results reported by most series for initial decompression alone.[15]

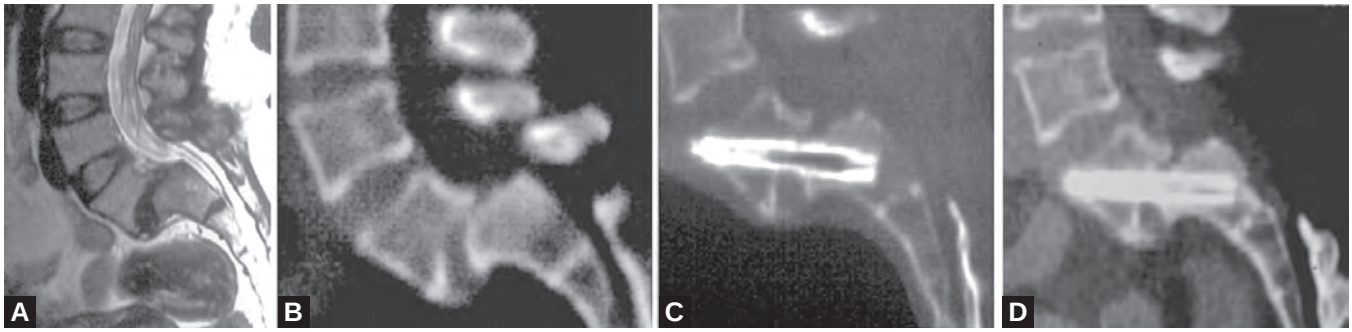
Anterior lumbar interbody fusion (ALIF) which used to be done through the transperitoneal approach was a major surgical undertaking.[26] We now, prefer the open mini-extraperitoneal anterior or anterolateral approach.[4] The results with ALIF have been demonstrated in 33 patients (including 13 with spondylolisthesis) with failed back surgery syndrome, in whom the back pain, leg pain and functional status improved significantly to 76%, 80% and 67% respectively. The complications related to the approach were iliac vein injury and ileus.[12] In cases of pathological spondylolisthesis where there is considerable destruction of the bodies, we prefer to do anterior debridement and fusion along with posterior pedicle screw instrumented PLF in a single session or as a two-stage procedure. Pyogenic spondylodiscitis, tuberculosis and tumours are common examples.

Instrumented fusion: Our standard procedure consists of pedicle screw instrumented posterior lumbar interbody fusion using bone chips derived from the laminofacetectomy. Since we encountered several disadvantages with the conventional midline approach (Table 7), we have switched to the bilateral paraspinous transmuscular approach in the last 5 years. This approach is akin to the Wiltse approach originally described for PLF.[63] Our technique of bilateral paraspinous transmuscular approach is described in an article in *Progress in Clinical Neurosciences*.[14] The advantages of the bilateral paraspinous transmuscular approach are listed in Table 7. This approach is ideal for patients with a midline scar from previous surgery. In patients with high-grade L5-S1 olisthesis, we have used trans-sacral fibular strut grafting, which can give a stable fusion without the need for pedicle screws.[55] Figures 18A to D show an example of such a procedure done through the posterior route.

Post-operatively, the patient is ambulated as early as possible, generally by day 2 or 3 and discharged by day 4 or 5. Back exercises are taught and activity gradually increased in the second week after the sutures are removed. Most patients resume low levels of activity in the 3rd to 4th week and unrestricted activity after 3 months. Corsets are not used routinely. Follow-up standing radiographs in flexion and extension are done at 3 months and at 1 year.

CONCLUSION

The key to success in managing lumbar spondylolisthesis is to know in whom, when and how to intervene. The best results are obtained in a symptomatic patient in good general health who does not have psychological overlay. The surgical team performing spondylolisthesis surgery must be conversant with more than one method of doing surgery but need not necessarily be capable of doing every conceivable procedure in the book. The



Figs 18A to D: High-grade dysplastic spondylolisthesis treated by posterior to anterior trans-sacral fibular strut graft fusion. (A) MRI. (B) CT (prior to surgery). (C) Immediate. (D) 1 year follow-up CT after fusion

wise surgeon would desist from trying out every new spinal implant introduced by a commercially motivated industry. Results improve when the team does the same procedure again and again over the years.

117 Skeletal Fluorosis

Raja Reddy D, Srikanth R Deme

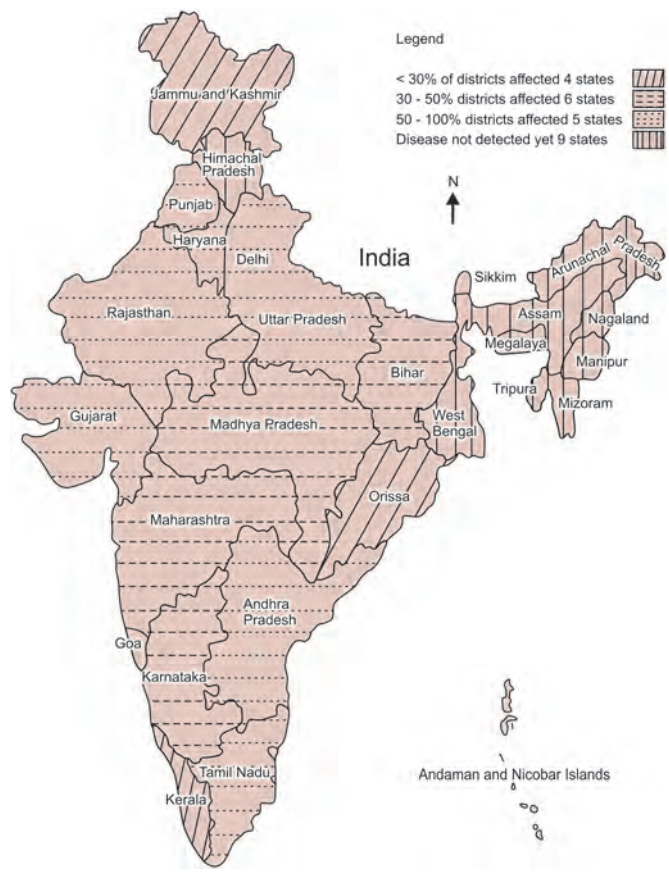
INTRODUCTION

Fluorine, a gaseous element, is a halogen which being electronegative and reactive of all elements does not occur in free form in nature. This element was isolated in 1886 by Nobel laureate Henri Moissan and it combines directly with most elements and indirectly with a few to form fluorides. Fluorides are ubiquitous in nature and are present in rocks, soil, water, plants, foods and even air.

The relationship between fluoride and dental caries was first noted in the early part of the 20th century when it was observed that residents of certain areas of USA developed brown stains on their teeth. These stained teeth, although unsightly, were highly resistant to dental decay and caries.[5] In 1930s, it was discovered that the prevalence and severity of this type of mottled enamel was directly related to the amount of fluoride in the water.[93] Subsequently, it was recognised that fluoride consumption in optimal amounts in the water supply imparted protection against the development of dental caries without staining the teeth.[13] Another benefit of fluorides is that the incidence of osteoporosis seems to occur less frequently in regions with high fluoride content in water than in those in which the inhabitants consumed little fluoride. Although, the importance of this element to normal mineralisation of hard tissues and formation of caries resistant enamel has been recognised, there has been as yet no conclusive evidence proving that it is an essential element for human health.[45] Indeed, a fluoride deficiency syndrome is yet to be described. This may be due to the fact that human body requirement of this micronutrient must be small which is met with naturally through food and water. Excessive ingestion of fluoride through water, food or dust causes acute toxicity or a debilitating disease called 'fluorosis', a term coined and first used by Cristiani and Gautier in 1925.[11] Acute fluoride intoxication is rarely seen and results most frequently from accidental ingestion of large amounts of fluoride compounds. The acute lethal dose of fluoride for a 70 kg man is 2.5–5.0 gm. Chronic fluoride poisoning is more common and can affect animals as well as humans. Excessive intake during the pre-eruptive stage of teeth leads to dental fluorosis and further continued ingestion over years and decades causes bony or skeletal fluorosis. Lastly, crippling disease produces neurological manifestations.

Feil first mentioned fluorosis in humans as an occupational disease in 1930.[16] This was substantiated when the occurrence of skeletal fluorosis in cryolite miners was reported in Denmark.[48] Skeletal fluorosis was next reported as a disease endemic to an area in India.[83] Their study led to the publication of first reports of neurological manifestations of fluorosis in the late stages. Subsequently cases of endemic and industrial fluorosis have been reported from various parts of the world.[61]

High incidence of endemic fluorosis in India is due to the fact that large areas of the country contain water supplies having high levels of fluoride. All states of India except the Northeast and Himachal Pradesh reported cases of fluorosis and 25–30 million people are exposed to high fluoride intake and half a million suffer from skeletal fluorosis (Map 1). In China, 300 million people are living in endemic areas of fluorosis out of which 40



Map 1: Incidence of fluorosis in different states of India

million have dental fluorosis and 3 million suffer from skeletal changes.[41]

METABOLISM OF FLUORIDE

Biological effects of fluoride intoxication are related to the total amount of fluoride ingested whatever the source, be it food, water or air.

Sources of Fluoride

Foods

Nearly all foods contain small quantities of fluoride and the total daily intake through any average human diet is small except in endemic regions. In certain endemic regions of India, the fluoride content of vegetables and food may be very high.[7] The contribution of food to the total daily intake of fluoride varies from region to region. Staple diets rich in Sorghum, *Ragia* or *Bajra* containing high silicon besides fluoride seem to aggravate fluoride toxicity in some endemic areas of India.[3,57]

Water and Beverages

In case of natural waters, the variation in the fluoride content from region-to-region is dependent upon such factors as the source of water, type of geological formation and the amount of rainfall. Surface waters generally have low fluoride while ground water may have high concentrations of fluoride as has been found in many parts of the world. The fluoride content of water in different parts of India is shown in Table 1. The highest fluoride concentration of 28.9 PPM was reported from India.[7] The fluoride content of seawater varies from 0.8 to 1.4 PPM, which explains why the fluoride content of diet rises when sea food is consumed. Among beverages, tea has an exceptionally high fluoride content which varies in different brands from 122 to 260 PPM or more. Each cup of tea may supply 0.3–0.5 mg of fluoride. Bottled beverages, which are increasingly being consumed around the world, have a variable content of fluoride and should be considered as additional sources of fluoride.

The fluoride intake dependent upon consumption of drinking water and beverages is determined by such factors as body size, physical activity, food habits and variations in atmospheric temperature and humidity.[22] That is why in tropical countries, like India, the daily fluoride intake is very high. Farm labourers drink a lot of water from wells and naturally have high fluoride intake and are at risk of developing fluorosis.

Table 1: Incidence of fluoride in water resources of India

States	*No. villages having maximum F > 2.0 mg/L*	*Fluoride level mg/L*
Andhra Pradesh	1245	28.9
Bihar	100	4.4
Gujarat	250	5.0
Haryana	360	11.0
Karnataka	300	8.0
Madhya Pradesh	150	7.0
Maharashtra	250	3.8
Orissa	200	4.0
Punjab	80	12.0
Rajasthan	450	28.0
Tamil Nadu	315	8.0
Uttar Pradesh	300	4.5

Optimum fluoride level in drinking water for a tropical country like India is < 0.5 PPM or 0.5 mg/L

Air

The atmosphere has very low fluoride content, and in 97% of non-urban areas fluoride is hardly detectable. The fluoride content of the atmosphere rises wherever there is volcanic action or industrial activity. Volcanic fumarole vapours have high concentration of fluoride, and industrial emissions from mining or manufacture of fluoride containing minerals may be hazardous. Low-grade coal has high levels of fluoride and smoke may be a source of fluoride pollution.

Total Daily Fluoride Intake

The fluoride contents from all the sources determine the human intake of fluoride. In the majority of endemic areas around the world, the main contribution is from water, and only in a few areas of India and China significant amounts come from food and, rarely, polluted air is the culprit. The estimated range of safe and adequate intake of fluorides for adults is 1.5–4.0 mg/day and it is less for children and those with renal disease. The daily intake of fluoride in endemic regions varies from 10 to 35 mg and can be even higher in summer months.

ABSORPTION OF FLUORIDES

Soluble inorganic fluorides ingested through water and food is almost completely absorbed and also those inhaled from the respiratory tract. Absorption of less soluble inorganic and organic fluorides varies from 60 to 80%.[10] Fluorides are absorbed from the gastrointestinal tract by a process of simple diffusion without any mechanism of active transport being involved. Various dietary components apparently influence the absorption of fluoride from the gut. It has been noticed that salts of calcium, magnesium and aluminium, when added to the diet, reduce the quantum of fluoride absorption on account of the formation of their less soluble compounds. This is the reason why waters with high calcium and magnesium content check the incidence of fluorosis, as indicated by epidemiological studies.[31] Therefore, it is to be expected that all other factors being equal, the incidence of skeletal fluorosis would be less where the calcium and magnesium content of drinking water is high.[62] It is noteworthy that administration of magnesium salts (serpentine and magnesium hydroxide) to patients

suffering from fluorosis and experimental animals has increased the faecal and urinary excretion of fluorides. Similarly, increased absorption of fluoride from the gastrointestinal tract ensues from the addition of substances, like phosphates, sulphates and molybdenum, to the diet and these can increase fluoride toxicity.[14]

DISTRIBUTION OF FLUORIDES

About 96–99% of the fluoride retained in the body combines with mineralised bones, since fluoride is the most exclusive bone-seeking element on account of its affinity for calcium phosphate.[4] But it has been noticed that there is no significant retention of it in the body, if very small quantities of fluorides are ingested.[46] In fact, there was no discernible retention of fluoride when up to 4–5 mg was ingested daily. But when more than 5 mg were ingested about half of it appeared to have been retained by the skeleton and rest excreted through urine. Observations show that after absorption from the gut fluoride enters the circulation, with plasma fluoride accounting for three fourths of the total amount of fluoride found in whole blood and the rest is in the cells. Fluoride in plasma exists in free ionic and bound forms, the latter bound to serum albumin forming about 85% of the total amount of fluoride in plasma.[98] Plasma fluoride in normal individuals in non-fluoridated areas ranges from 0.14 to 0.19 PPM and is higher in fluorotic patients.[88] Newer methods, which only measure the ionic component of plasma fluoride levels, show lower values which range between 0.004 PPM and 0.008 PPM when drinking water contained traces of fluoride and varied from 0.1 to 0.2 when water was fluoridated. Plasma fluoride concentrations tend to increase slowly over the years. It is seen that plasma levels of fluoride do not fluctuate widely despite a wide variation of fluoride levels in drinking water presumably due to the action of some regulatory mechanisms, which have not yet clearly been identified.[86] The sequestration of fluoride into the skeleton, urinary excretion and loss sustained through sweat helps in regulation of plasma fluoride. The levels of fluoride in most soft tissues of the body are lower than 1 PPM but are higher than those of plasma. The fluoride content of the brain is 0.4–0.68 PPM and the concentration in cerebrospinal fluid (CSF) is 0.1 PPM which is lower than that of plasma.[25]

The uptake of fluoride by the skeleton is very rapid and depends upon the vascularity and the rate of its growth. The fluoride uptake of young bones is faster than that of mature bones. The fluoride is incorporated more readily in the active, growing and cancellous areas than in the compact regions. It has been observed that skeletal fluoride concentration increases almost proportionately to the amount of fluoride ingested and the duration of its ingestion.[95] The amount of fluoride present in various bones of the same skeleton differs from bone-to-bone with the pelvis and vertebrae registering higher fluoride content than limb bones. Even in the limb bones, the amount of fluoride deposited in them depends upon the activity of muscles attached to them. In caged monkeys, the fluoride content of the upper limb bones is more than that in the lower limb bones. It is this increase in the fluoride content of the skeleton that provides the most reliable clue to excessive fluoride intake. The other indicators, such as urine and soft tissue levels which manifest wide fluctuations, cannot be relied upon. Once incorporated into the hard tissues, the fluoride is retrievable, although with difficulty, and entails an extremely slow process of osteoclastic resorption spread over many years.

EXCRETION OF FLUORIDES

Faeces

Fluoride present in faeces comes from two sources: (1) the ingested fluoride that is not absorbed and (2) the absorbed fluoride that is excreted into the gastrointestinal tract. About 10–25% of the daily intake of fluoride is excreted in the faeces.

Urinary

The elimination of absorbed fluoride occurs almost exclusively via the kidneys. Urinary fluoride in normal individuals fluctuates widely between 0 PPM and 1.2 PPM with an average of about 0.4 PPM when the fluoride content of drinking water is 0.3 PPM.[102] Urinary levels of fluoride are higher in individuals exposed to higher intake of fluoride. The renal clearance of fluoride is directly related to urinary pH and, under some conditions, to urinary flow rate. In alkaline urine, the fluoride is present in ionic form and hence its renal clearance is rapid. In acidic urine, on the other hand, fluoride is present in non-ionic form (HF) and hence it is rapidly reabsorbed by the renal tubules. The excretion of fluoride is much less if the person concerned is suffering from chronic kidney disease resulting in renal failure, which inevitably leads to high concentrations of fluoride in serum as well as bone.[111] In experiments on rats with renal insufficiency, increased intake of fluoride caused decreased glomerular filtration rate and increased blood urea nitrogen along with increase in serum and bone concentrations of fluoride. Since disturbed renal function predisposes to excessive retention of fluoride, individuals suffering from chronic renal failure may, therefore, develop skeletal fluorosis even at a considerably low level of 1 PPM of fluoride in drinking water.[52,68,106]

Sweat

Some fluoride is also lost from the body through sweat, and so, appreciable amounts may be lost in situations marked by excessive sweating. Sweat fluoride concentrations are similar to plasma.

Other Routes

The amount of fluoride in breast milk is low and the same is true of saliva.

CLINICAL FEATURES

Fluoride intoxication presents an extraordinary degree of uniformity in its clinical manifestations. It occurs in humans as dental and skeletal fluorosis. They are separated by a prolonged, relatively symptom-free interval during which the skeleton does not stop accumulating fluoride. In its advanced stages, skeletal fluorosis causes crippling deformities and neurological complications.

The effects of fluoride intoxication are related to the total amount of fluoride ingested, although earlier, only water was taken into account presumably because the supply of fluoride by food was deemed negligible. The safest minimum daily intake of fluoride is not known.[15] Earlier reports suggested that any daily ingestion of over 28 mg of fluoride would be harmful.[6] Subsequent studies cited 20 mg as the maximum safe limit,[26] but in endemic areas where the presence of local factors, like nutritional status and prolonged exposure, tend to aggravate the fluoride toxicity, the safe level of fluoride intake may be even lower. In India, balance studies of the cases of endemic skeletal fluorosis revealed an average fluoride intake of 9.88 mg and it is held that any intake of more than 8 mg would be harmful.[29] Kreptogorsky[37] suggested 3.2 mg as the highest level of fluoride intake, which could be deemed safe. It is true that in persons with normal functioning kidneys there is a wide margin of safety.

Dental Fluorosis

Dental fluorosis mainly involves enamel but severe intoxication may affect the dentine as well as the pulp. Enamel fluorosis occurs when fluoride concentrations in or in the vicinity of the forming enamel are excessive during its pre-eruptive development. Mottling of teeth is one of the earliest and most easily recognisable features noticed in the first decade of life (Fig. 1). Both sexes are equally affected. The permanent teeth are affected and they lose their normal creamy white translucent colour and become rough, opaque and chalky white. Pitting and chipping are other marks of fluorosis. Brown or black pigment gets deposited on the defective enamel and, once established, tends to remain there permanently. Incidence of dental fluorosis in endemic areas exhibits a linear relationship to the fluoride content of water, but it may also vary with other factors.[30] Dental fluorosis does not obviously occur when there has been no exposure to fluoride in the first decade of life.

Pre-Skeletal Stage

The duration of this stage may vary with the amount of fluoride ingested daily. Reportedly, it ranges from 10 to 30 years or even longer in endemic areas and from 10 to 15 years or longer in cases of industrial fluorosis.[19,89] In the early stages in endemic regions, generally, signs or symptoms do not appear. The persons concerned may occasionally complain of pain in the small joints of the limbs and back, which are often mistaken for rheumatoid arthritis or ankylosing spondylitis. However, various reports from Europe and America suggest that there would be symptoms corresponding to gastrointestinal, musculoskeletal, respiratory and visceral systems during this stage.[58,79,104] The majority of these visceral symptoms may be due to allergy to fluoride in susceptible individuals or the effect of fluoride on the various target organs, and these are non-specific.

Fig. 1: Characteristic mottling of teeth with pigmentation

Skeletal Fluorosis

Early in the development of fluorotic changes in the skeleton, the patients often complain of a vague discomfort and paraesthesiae in the limbs and the trunk. Pain and stiffness in the back appear next, especially in the lumbar region, followed by the dorsal and cervical regions. Restriction of spine movements is the earliest clinical sign of fluorosis. The stiffness increases steadily until the entire spine becomes one continuous column of bone, manifesting as a condition referred to as 'poker back' (Fig. 2). In man, the spine is most likely to be affected first and severely due to its being required to sustain the erect posture.[49] When the condition becomes severe and chronic, various ligaments of the spine are involved and it soon spreads to various joints in the limbs owing to the involvement of the joint capsules, the related ligaments, tendinous attachments to the bones and interosseous membranes. The involvement of the ribs gradually reduces the movement of the chest during breathing, which finally becomes mainly abdominal. When that happens, the chest assumes a barrel shape. With the increasing immobilisation of the joints due to contractures, flexion deformities may develop at the hips, knees and other joints, which make the patient bedridden. Bony exostoses may also appear over the limb bones, especially around the knee, the elbow and on the surface of the tibia and ulna. Despite the fact that the entire bone structure has become affected, the mental faculties remain unimpaired till the last stages are reached.

Fig. 2: Marked rigidity of spine with restricted movements

Fig. 4: Genu valgum deformities of the lower limbs

The stage at which skeletal fluorosis becomes crippling usually occurs between 30 years and 50 years of age in the endemic regions (Fig. 3). Newcomers to a hyperendemic region may sometimes develop symptoms of skeletal involvement within 4 years of their arrival.[83] Men suffer more than women from severe affects of the disease, presumably because their work is usually more strenuous than that of women.[30,83] The factors which govern the development of skeletal fluorosis are: (a) high levels of fluoride intake; (b) continual exposure to fluoride; (c) strenuous manual labour; (d) poor nutrition and (e) impaired renal function due to disease.[12,57,62] In regions with very high fluoride content, the disease may affect younger age groups including children. The longer the exposure to fluoride the higher will be its incidence. In tropical countries, skeletal fluorosis occurs even while drinking low levels of fluoride. It is the farm labourers who are prone to develop fluorosis rather than those engaged in sedentary occupations. Epidemiological observations revealed that nutritional status might influence chronic fluoride toxicity. Trace elements do play a role in fluoride toxicity. Aluminium, arsenic, selenium and strontium are known to aggravate fluoride toxicity, whereas calcium and magnesium have a beneficial role. Some of these elements are found in abnormal concentrations in drinking water supplies of endemic areas.[63] They may be responsible for the severe nature of fluoride intoxication in these regions.

Fig. 3: Crippling stage of skeletal fluorosis with deformities of limbs

Endemic Genu Valgum

Deformities occur most notably in weight-bearing lower limbs in children poorly nourished with a low calcium intake[38] in endemic areas (Fig. 4). There is increased calcium turnover in cases of endemic skeletal fluorosis. Diets poor in calcium provoke secondary hyperparathyroidism.[99] This in turn leads to osteoporosis and deformities of weight-bearing lower limb bones.

NEUROLOGICAL MANIFESTATIONS OF SKELETAL FLUOROSIS

The neurological sequelae in skeletal fluorosis manifesting usually as radiculomyelopathy arise principally due to the mechanical compression of the spinal cord and nerve roots brought about by osteophytosis and sclerosis of the vertebral column.[87] However, it is only in the later stages, owing to pressure on the radicular vessels in the intervertebral foraminae that vascular complications may supervene. Neural toxicity attributable to fluorides is yet to be established.

Neurological complications arise at a late stage of the disease in about a tenth of the patients with skeletal

Map 2: High endemic regions of fluorosis in India

fluorosis.[33] In 1937, Shortt and his colleagues from India reported on ten chronic cases with a history of 30–40 years intake of water containing 2–10 PPM of fluoride.[83]

Later there were similar reports from other parts of India.[9,33,50,67] The largest number of cases with neurological manifestations was reported from two endemic belts (Map 2): Punjab, Haryana, Rajasthan and adjacent Uttar Pradesh in North India and from Andhra Pradesh in South India. There have been few reports of fluorosis with neurological complications from countries other than India.[61]

The patients suffering from neurological manifestations varied in age from 20 to 70 years and the mean age of 74 cases reported by Jolly and his colleagues was 56 years. In the case of younger age groups, these complications may be traced to higher levels of daily fluoride ingestion. It was noticed that fluorosis occurred less frequently in areas having low levels of water fluoride, the lowest ranging from 1.2 to 1.35 PPM.[84] Men were reported to have been affected more frequently than women who formed only 6% of the cases reported by Jolly et al.[31] and who numbered 18 out of 70 cases described by Siddiqui.[85] Similar findings were reported by other investigators from India,[69] except for one lone report from Rajasthan where females slightly predominated over males and also developed fluorosis earlier than men.[97]

It is the cervical cord rather than the dorsal cord that is commonly affected by fluorosis. In the Punjab series, 70% of the cases had cervical spine involvement. Although the lumbar spine is usually the first to exhibit skeletal changes caused by fluorosis, compression of the cauda equina rarely occurs because its roots are so easily accommodated that by the time they are pressed upon, other parts of the spinal cord would have been affected. Although the disease develops slowly but relentlessly, the neurological deficits may sometimes be precipitated by a minor trauma.[43,77] Such cases present a wide spectrum of neurological deficits, which may be found manifesting as either lower motor neuron or upper motor neuron defects or both, which is more common. These may be found along with those caused by skeletal fluorosis resulting in restriction of spine movements. It is to be noted that in fluorosis higher cerebral function defects or cranial nerve palsies are rarely encountered.

Myelopathy

Patients suffering from fluorosis usually experience difficulty in walking due to the progressive weakness in the lower limbs. With the spreading of this weakness to the upper limbs, neurological disabilities occur that makes the patient bedridden. These disabilities are due to motor and sensory deficits, which are followed by sphincter disturbances. In such a condition, motor disabilities predominate over the others and sensory defects affecting touch, vibration, position and joint sense tend to be bizarre and widespread. When this happens, acroparaesthesiae may occur and a sensory level is hardly ever seen. What is striking is that due to the coexistence of crippling deformities at the hips, knee and other joints it becomes difficult to decide whether the disabilities are caused by neurological lesions or by skeletal deformities. Flexor spasms appear only at the late stage of the illness.

Radiculopathy

Nerve root compression leads to atrophy of various muscle groups in both the upper and the lower limbs. With the onset of fasciculations motor neuron disease may be mimicked. The upper limbs appear to be affected more than the lower limbs which may be traced to the commoner involvement of the cervical region or even the anatomical features of the cervical spine.[73] Sensory changes may not be as striking as disabilities of motor function and root pains do not usually occur. In advanced cases, marked cachexia develops on account of disuse atrophy of limb and trunk muscles.

Cranial Nerve Lesions

The skull is not much affected in fluorosis and basal cranial nerve foraminae are not encroached upon except in the advanced stages of the disease.[91] Of the cranial nerves, the most frequently affected, in a quarter of the cases investigated, has been the eighth nerve. In all cases calvarial changes caused by fluorosis are discernible. A progressive high frequency perceptive deafness is observed. Moreover, bone conduction is affected more

than air conduction. Nevertheless, total deafness rarely occurs. It is perhaps the compression of the nerve in the sclerosed and narrowed auditory canal that accounts for the deafness in fluorosis.[64]

Optic neuritis, however, is hardly ever seen in patients with endemic fluorosis, although administration of sodium fluoride in large doses as a therapeutic measure in osteoporotic patients was reported to have had a damaging effect on the optic nerve.[23] A higher incidence of myopia and optic pallor in a small proportion of cases of endemic fluorosis has been by seen us, which could be incidental.

Peripheral Neuropathies

Exostoses, which mainly develop around the knee, elbow and ankle, may press upon the median, ulnar or lateral popliteal nerves. Pain and paraesthesiae followed by weakness in the limbs may be caused by such bony growths. Even meralgia paraesthetica has been reported to occur in fluorosis.[9] Fluorotic patients may also manifest entrapment syndromes involving other peripheral nerves. Degenerative disc disease is very uncommon in fluorotic patients.

Cerebral Ischaemia

Involvement of the vertebrobasilar circulation caused by compression of the vertebral artery by cervical osteophytes may occasionally occur.[89] Increased calcifications of major vessels and disturbance of lipid metabolism that has been reported in fluorosis may lead to cerebrovascular accidents.

The occurrence of certain other neurological features, like headache, tetaniform convulsions, mental depression and electroencephalographic disturbances, have also been reported.[105] Several other complaints have been related to fluoride intoxication without adducing irrefutable ground for such conclusions.[81]

LABORATORY INVESTIGATIONS

General

A mild degree of anaemia and a decrease in erythropoietic activity of bone marrow are found in fluorosis, which may be due to associated nutritional factors or secondary to osteosclerosis and encroachment of medullary cavities. CSF analysis in cases of fluorotic spinal compression reveals a moderate rise of protein and the other constituents are normal. Balance studies have revealed the retention of phosphorus, magnesium, nitrogen and calcium, of which the latter has been markedly positive.[94] Evidence of impaired renal function was reported in a certain proportion of fluorotic patients.[83] The abnormalities included impaired urea clearance, decreased glomerular filtration rate and increased blood urea nitrogen. Singh et al.[91] found a generalised aminoaciduria in patients suffering from fluorosis, especially excessive tyrosine excretion, but investigations made by Srikantia and Siddiqui[96] did not bring out any abnormalities of amino acid excretion in urine. Alkaline phosphatase is often found elevated in fluorosis, which may be due to increased turnover rather than any specific effect of fluoride on the enzyme.[80] Fluorides are known to activate and inhibit enzyme systems. At low serum levels, fluorides are known to stabilise and activate several enzymes and, at higher levels, fluoride inhibits enzymes such as adenyl cyclase, pyrophosphatase, etc. In endemic regions, people with poor nutrition, especially those on low intake of calcium in their diets, develop secondary hyperparathyroidism.

Electrophysiological Studies

Neurophysiological experiments have revealed that sodium fluoride has anticholinesterase and anticurare like effects on muscle and nerve, although it has no effect on normal muscle membrane potentials even in the endplate region.[36] There are very few electrophysiological studies of muscle and nerve in endemic skeletal fluorosis.[73] Peripheral nerve conduction velocities in such cases are normal and compound action potentials are usually within normal range. These findings suggest that the nerve lesion in fluorosis is located either in the nerve roots or anterior horn cells in the spinal cord. Study of late responses, F wave and H reflex in cases of endemic fluorosis proved unequivocally that the nerve lesion is located in the root, which is responsible for the muscle involvement in fluorosis.[51] The nerve conduction velocities are found to be reduced to 30–35 m/sec in peripheral nerve entrapment on account of the pressure of exostoses or ligaments around the joints. In these cases both motor and sensory conduction velocities are affected, motor more than sensory.

Electromyographic studies in cases of endemic skeletal fluorosis have given unequivocal evidence of neurogenic atrophy, but no evidence of myopathy has been seen. The recognisable features which may be found singly or jointly in all such cases are the presence of fibrillation potentials, reduced interference pattern, increase in mean action potential amplitude and duration of surviving units. Some have shown polyphasia, which are of giant size. Other features noted in EMG studies are the upper limb muscle groups are more involved than the lower limbs and that the proximal muscle groups are more affected than the distal musculature. These changes are perhaps peculiar to the cases that were studied. In general, EMG findings endorsed those of clinical neurological examination, but muscle changes might sometimes be detected earlier through EMG studies than by clinical examination.

Fluoride Estimations

Diagnosis of fluorosis depends upon the estimation of fluoride levels of urine, serum and bone. Many methods are available for the determination of fluoride and the most widely used involve colorimetry or the fluoride

Table 2: Urinary fluoride levels in endemic fluorotic patients

		Urinary fluoride levels in PPM or mg/litre				
Name	*No. of days*	*Minimum fluoride level*	*Maximum fluoride level*	*Average*	*Variance*	*SD*
Yelliah	12	0.5	3.1	1.5183	0.5496	0.7413

Laxmidevamma	24	4.48	10.01	6.095	2.492	1.5787

specific ion electrode. The latter is more popular than other methods because it is faster. Frant and Ross[20] introduced the selective electrode which gives an electrochemical response that is proportional to the fluoride ion activity in the sample.

Urine Fluoride Estimation

Urinary fluoride levels are the best indicators of fluoride intake. Since fluoride excretion is not constant throughout the day, 24-hour samples of urine are more reliable than random or morning samples for the estimation of fluoride content. In normal individuals urinary fluorides fluctuate widely between 0.1 PPM and 2.0 PPM with an average of about 0.4 PPM when the fluoride content of drinking water is 0.3 PPM. In general, urinary fluoride rises in relation to fluoride intake and it fluctuates widely from day-to-day and ranges from 0.5 to 4.48 PPM minimum and from 1.5 to 13.0 PPM maximum in cases of skeletal fluorosis (Table 2, Fig. 5). Urinary fluoride levels vary greatly in fluorotic patients unlike those of experimental animals, which are given a uniform diet.[74] In some highly endemic areas, urinary content of fluoride could be as high as 26 PPM or more.[91] A study on the excretion pattern of urinary fluoride in fertiliser workers showed an average of 4.2 PPM with a range of 1.5–7.5 PPM.[24] Urinary fluoride levels could be low in cases with renal disease. Fluorotic patients on a low fluoride regimen eliminate more fluoride than their intake.

Serum Fluoride Estimation

When chemical methods of estimating fluoride levels in serum and blood came to be employed by different research workers, wide divergence was noticed in their findings, but when fluoride ion electrode was used for

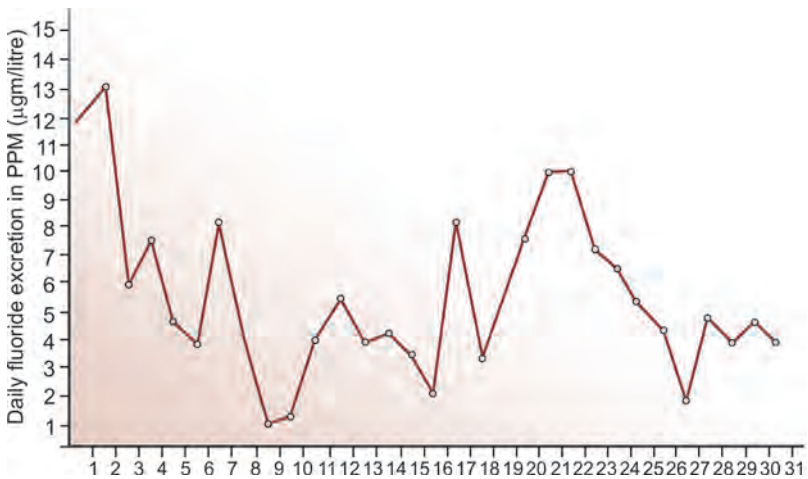

Fig. 5: Daily urinary fluoride level in a patient with skeletal fluorosis. Urinary fluoride excretion fluctuates widely, which makes it difficult to assess the effect of drugs

investigation, the fluoride levels in serum were found to be considerably lower: 0.4–0.9 PPM in fluorotic patients and 0.19–0.4 PPM in normal subjects. Normal values for blood in non-endemic regions varied between 0.002 mg/100 ml and 0.008 mg/100 ml. In endemic regions blood fluoride levels ranged between 0.02 mg/100 ml and 0.15 mg/100 ml whereas, in patients with skeletal fluorosis, they were 0.02–0.19 mg/100 ml.[91] Serum fluoride levels in 500 normal healthy adults ranged between 0.03 PPM and 0.13 PPM with a mean of 0.08 PPM and they were 0.04 and 0.28 PPM with a mean of 0.16 PPM in 17 fluorotic patients in our laboratory. The urinary levels of fluorides of these 17 fluorotic patients varied between 0.68 PPM and 7.80 PPM with a mean of 3.28 PPM.

Bone Fluoride Estimation

Measurement of bone fluoride content allows the determination of the extent of bone fluoride retention and is a useful complement to bone histology for the diagnosis of skeletal fluorosis and could be used for the management of fluoride treatment of osteoporosis. Bone samples are collected and prepared for subsequent analysis using the fluoride selective electrode. Roholm's study of industrial fluorosis revealed that bone fluoride content varied from 6000 to 8400 PPM in bone ash, whereas normal bones had a concentration ranging 500–1000 PPM,[79] but observations of fluoride content of bones in endemic areas are at variance with those mentioned above. For instance, the fluoride levels at which osteosclerosis was detected ranged 700–7000 PPM of fat-free dry bone in cases from Punjab[32] and from 1800 to 6280 PPM of fluoride in endemic areas of Sahara.[59] While reporting their findings, these authors commented upon the lack of correlation between the fluoride content of bones and the degree of osteosclerosis seen in radiographs. Weatherell et al.[109] hold the view that the rate of intake of fluoride is much more important than the amount of fluoride in the bones for the development of skeletal fluorosis. When the daily intake of fluoride is low, the skeleton may be accumulating enormous amounts of fluoride over a prolonged period without manifesting any alteration in its structure or function. When the rate of fluoride ingestion is high, as in endemic areas, the incidence of fluorosis is usually high. Weatherell and his colleagues suggested that, with high intake, a local increase in concentration of fluoride occurs at the site of active mineralisation along with high biological activity, which cause the changes that lead to fluorosis. Bone scintigraphic studies done by us in endemic fluorosis cases have shown a super scan appearance suggesting a very high metabolic activity in the bones. Electron probe microanalysis has confirmed that the newly laid bone has a higher content of fluoride than the bone existing before fluoride ingestion.[80]

Bone Biopsy

Histopathological changes of bone in fluorosis show that the haversian system is poorly formed and there

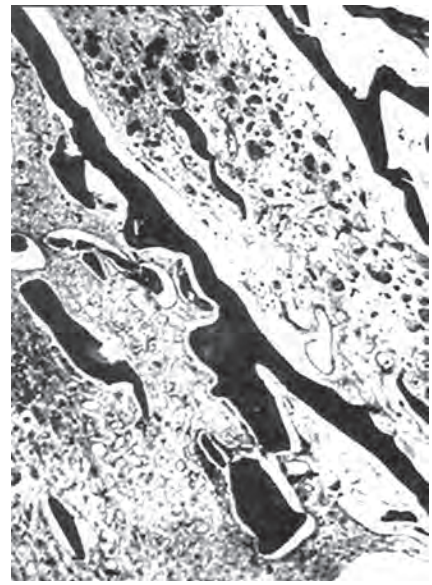

Fig. 6: Poorly formed haversian system and disordered lamellar orientation in the compact bone

is disordered lamellar orientation in the compact bone (Fig. 6). Osteoid tissue is found in the spongy bone and some of these irregular deposits of osteoid tissue extend into the attached muscles. In some of these cases, the osteoid tissue showed calcified muscular attachments. Ligaments show calcification and ossification. Crystals of fluoride material, which are described in cases of industrial fluorosis, were not seen in cases of endemic fluorosis.[69] Skeletal fluorosis involves mainly the spine, pelvis and long bones and it rarely affects the small bones of the hands and feet.

Pulmonary Function Tests

In fluorosis there is involvement of the rib cage, which causes restrictive lung disease. Vital capacity is reduced and the FEV1/FVC ratio is above 85% and the respiratory curve of flow-volume loop is flattened when the lungs are abnormally stiff in the late stages due to a restrictive ventilatory defect.

Scintigraphic Studies

Radionuclide bone scans using technetium labelled methylene diphophonate (99mTc-MDP) in fluorosis shows mostly a superscan appearance and in some cases joint abnormalities. Increased tracer activity between the forearm bones and the diffuse linear tracer activity along the ligamentous attachments were seen. Concentration of tracer may be noted in the joints such as sacroiliac and the anterior iliac spine where the inguinal ligament is attached. Hence, the bone radionuclide scan reveals the functional display of skeletal metabolism in fluorosis.

Radiology of Fluorosis

In fluorosis the radiological findings closely parallel those of gross pathological changes, but there is no

clear correlation between the degree of musculoskeletal changes and the osseous fluoride content. The mechanism of skeletal fluorosis has not been clearly demonstrated. It is difficult to assert that the density of bone is a result of reactive new bone and osteoid formation as a response to fluoride intoxication. All that can be said is that the density may be quantitative rather than qualitative owing to the increase in the matrix unaccompanied by any increase in mineralisation. Bone continues to be formed, but the thickened trabeculae with uncalcified borders are resistant to resorption and so they thicken.

In infancy and childhood, generally no definite radiological findings are demonstrable except in cases with malnutrition, especially calcium deficiency. Radiological changes usually manifest at puberty and in adulthood. However, in some young adolescents, osteopenia of a generalised nature may be seen along with sclerotic areas at the metaphyseal ends of long bones simulating renal rickets. In such cases, the epiphyses are also dense. The vertebral bodies may be prone to sclerosis of the endplates. Fluorotic poisoning does not materially affect growth, but the marks of fluorosis are discernable as growth lines at the metaphyses of long bones. In adults, the radiological findings could be set forth in three stages, each overlapping the preceding one.[8,76,79]

1. The findings are mainly confined to the axial skeleton. The primary trabeculae appear slightly rough due to sclerosis. This is clearly revealed in the iliac wings and the thoracolumbar vertebral bodies. In the secondary trabeculae, however, these are not prominent. The bones assume a ground glass appearance, an early manifestation.
2. In the next stage, the thick primary trabeculae merge with the secondary trabeculae to make the bone homogeneously dense (Fig. 7). The bone contours become uneven due to subperiosteal new bone apposition, which is prominently present in the ribs, pelvis and vertebral column. The skull demonstrates minimal changes in the base. The appendicular skeleton, however, is less affected, but the long bones of the limbs may show encroachment of the medullary cavities with endosteal new bone. The spongiosa bone manifests trabecular prominence and sclerosis. It may be noted that ligamentous calcification begins most frequently in the paraspinous, sacrospinous and sacrotuberous ligaments.
3. In the final stage, the bones of the axial skeleton demonstrate characteristic radiological features. The bones appear chalk like with an ill-defined trabecular pattern. With the loss of cortical and trabecular definition, the bone appears woolly (Fig. 8). The cortices of long bones are dense and thick due to amorphous subperiosteal new bone formation. The medullary cavities are encroached upon by endosteal new bone. In such cases, calcification in the para-articular ligaments is pronounced. Calcification is marked at the insertion of tendons and muscles and is seen in the interosseous membrane (Figs 9 and 10).

Fig. 7: Lateral view of dorsal spine showing uniformly dense vertebral bodies

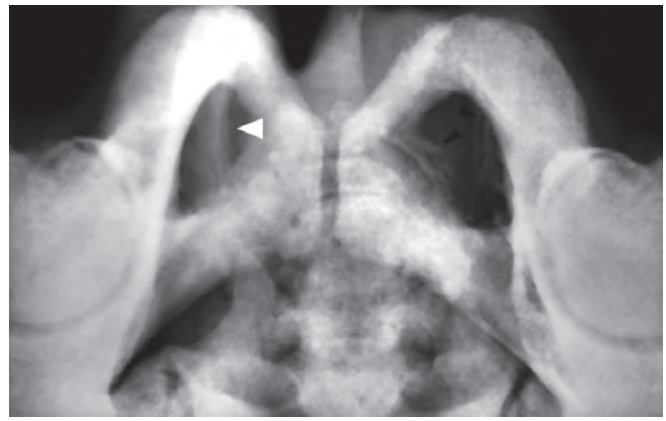

Fig. 8: Irregular calcification of sacrotuberous and sacrospinous ligaments and diffuse increase in the density of pubic bones

The articular ends of bones are less affected, but, in advanced cases, the condyles of long bones are prominent with irregularity of cortical bones. Osteophyte formation in the vertebral column is frequent (Figs 11 and 12). These osteophytes may encroach upon the intervertebral

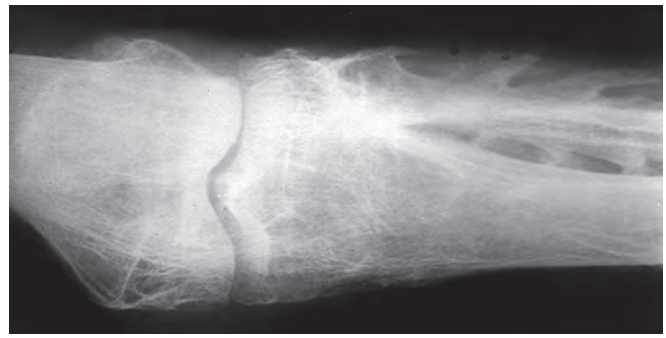

Fig. 9: Marked osteophytosis, extensive interosseous membrane calcification, ligamentous calcifications and degenerative changes in the knee joint

Fig. 10: The forearm bones are dense with calcification of a portion of the interosseous membrane

Fig. 12: Vertebral bodies are dense with haziness of the trabeculae and extensive osteophytes are seen

foramina, spinal canal and foramen magnum. The ribs are slightly enlarged with needle-like projections, which point to the advance of calcification into the intercostal muscles and membranes. There is extensive calcification of the costal cartilages. Subperiosteal resorption of bone and osteomalacia are found in some cases. The skull shows minimal changes in the calvarial bones. Sclerosis of bone at the sutural lines is one of the minor manifestations. However, the bones at the base show marked thickening. The petroclinoid ligaments show dense calcification. The occipital protuberance is very prominent and exostoses may occasionally be noted. Small osteophytes may encroach upon the foramina

Fig. 11: Lateral view of cervical spine skiagram showing anterior osteophytes, syndesmophytes and calcified posterior longitudinal ligament

and produce cranial nerve palsies, as for instance the 8th nerve. A tendency towards calcification may be noted in the falx cerebri. Hypercementosis of the roots of the teeth is also encountered in some cases. Bony excrescences are present at the iliac crest, ischial tuberosities, condyles of long bones and other protuberances of bones. In such cases, there is a possibility of large calcareous spurs developing and the bones of the hands and feet show cortical thickening. Calcification of interspinous and intervertebral ligaments is noteworthy. In the differential diagnosis of radiological findings of fluorosis, several 'entities' should be taken into consideration. Paget's disease, which prevails in certain geographical areas and races, may produce diffuse sclerosis of bones and may closely mimic fluorosis. However, the enlargement of affected bones and the lack of calcification at the musculotendinous insertion and interosseous membranes and para-articular ligaments provide a clue, which should enable one to differentiate it from fluorosis.

Diffuse osteosclerotic lesions, such as myelofibrosis, osteoblastic metastases, myeloma, hypoparathyroidism and renal osteodystrophy, may pose a similar problem. However, a skeletal survey should help in differentiating them from fluorosis. Osteopetrosis, melorheostosis and similar congenital forms of diffuse sclerotic bone lesions should be identified and distinguished from skeletal fluorosis. Differentiation is also called for in the case of a high degree of metal intoxication such as phosphorus, vitamin D and radium. However, in most of these cases, the clinical history would be of great help in arriving at a proper diagnosis. Mastocytosis, tuberose sclerosis and, occasionally, syphilis, yaws and other infective lesions have to be differentiated from one another. To this long list may be added unusual lesions of Gaucher's disease, sickle cell anaemia and idiopathic osteosclerosis as well as other esoteric lesions caused by familial

hypophosphataemia, vitamin D resistant osteomalacia, Wilson syndrome, etc.

Osteosclerosis is a well-known effect of chronic fluoride intoxication, which can also cause osteoporosis and osteomalacia. It was Roholm[79] who, describing bone changes in industrial fluorosis, suggested that in certain cases osteoporosis could occur. Soriano,[94] while giving an account of 'wine fluorosis', made a mention of the development of osteoporotic and osteomalacic changes in the skeleton of individuals concerned. He pointed out that smaller doses of fluoride stimulated osteogenesis and new bone formation, while severe intoxication led to increased bone resorption and defective matrix formation. A significant observation in this regard has been that at high levels of fluoride intake there is reduced collagen synthesis in humans.[54]

Osteoporotic changes occurring in the bones of the legs in endemic skeletal fluorosis have been reported as Kenhardt bone disease from South Africa.[27] This usually affects children whose limb bones revealed demineralisation accompanied by thinning of the cortex and widening of the medullary cavities. The adult population of the area showed classical osteosclerotic changes of the skeleton. Cases similar to those in Africa were reported from various endemic regions of India and China. These changes in the appendicular skeleton of young individuals seem to be due to poor nutrition, especially low in calcium.[39,107] Liad and Wu,[42] describing the radiological features of endemic skeletal fluorosis from China, concluded that osteoporosis towards the ends of long bones is an early radiographic sign in individuals under the age of 40 years even among those with a good nutritional status. In high endemic regions with a very high intake of fluoride and diets being deficient in calcium there is a secondary hyperparathyroidism, which also adds to the radiological changes. Hence, a variety of radiological changes are seen in endemic regions with poor nutrition.

Computed Tomography

Computed tomography is the best imaging modality for visualisation of bony pathology and it provides more details than plain skiagrams. Besides proper appreciation of the morphological anatomy and density of the various parts of the vertebra, it shows the exact location and direction of the osteophytes compressing the various neural elements and thus helps in proper surgical planning (Figs 13 and 14). Spinal canal and root canal stenosis is also better appreciated with CT scan. The calcified ligaments are visualised earlier and with much more clarity than by plain roentgenology, so are the indentations of the epidural space and the alterations in the spinal canal. By reconstruction, CT provides exact dimensions of the ossified intraspinal ligaments such as the posterior longitudinal ligament and yellow ligaments (Fig. 15). The anterior osteophytes are seen to be most prominent in the thoracolumbar region. The facetal joints occasionally show significant hypertrophy. In delineation of ossification of the forearm interosseous membrane and ligaments of the pelvis in early cases of fluorosis CT is extremely sensitive.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI), being non-invasive, obviates the difficulties in performing myelography and, on the other hand, delineates the anatomy of the soft tissue structures and the spinal cord changes. It also demonstrates associated abnormalities, like psuedomeningocoele and cord changes, due to prolonged compression and secondary vascular compromise. It is useful to image the entire spine, which may

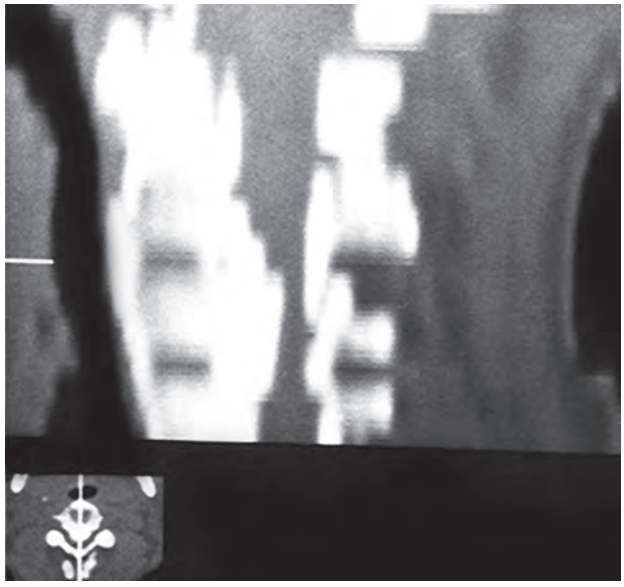

Fig. 13: Sagittal CT showing OPLL and calcified ligamentum causing severe compression of the cord

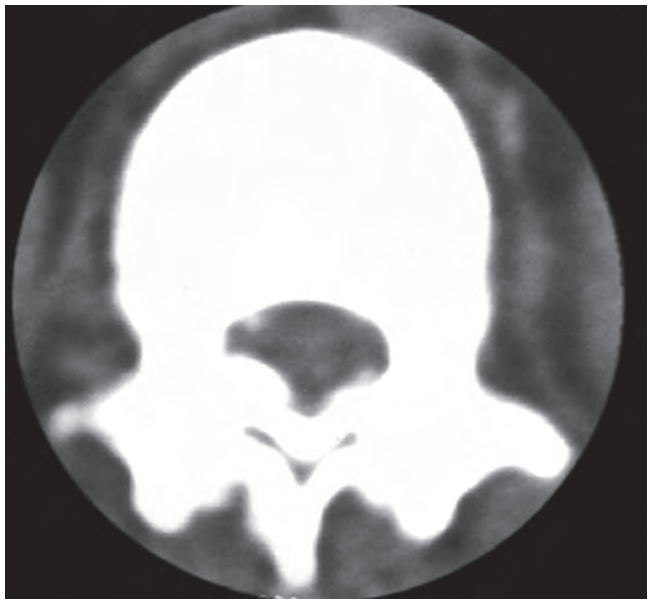

Fig. 15: Axial CT scan of dorsal spine showing bilateral dense flaval ligamentous ossification and increased density of bones

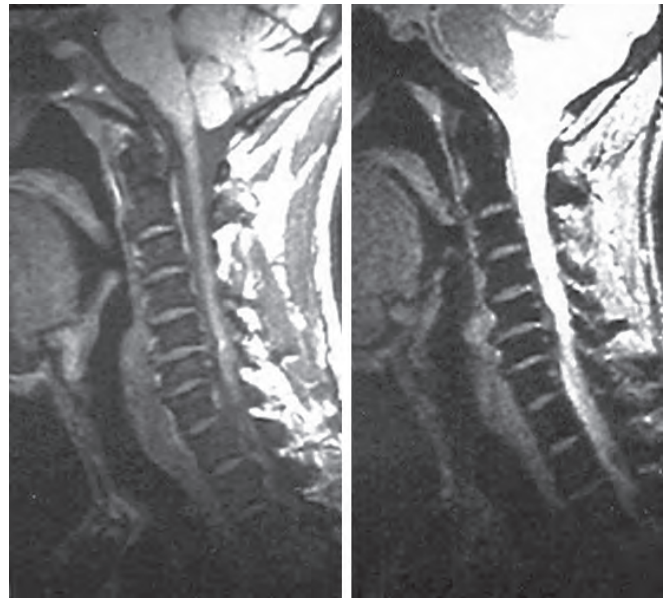

Fig. 17: MRI scan of the cervical spine in fluorosis. Note pronounced low intensity of bone marrow both on T1- and T2-weighted images, calcification of posterior longitudinal ligament and myelomalacia opposite C5

demonstrate incidental and interesting pathological lesions peculiar to fluorosis (Fig. 16). Fluorotic vertebrae are seen to be hypointense in both T1- and T2-weighted images (Fig. 17).[76] The localised areas of hypertrophy and ossification of ligaments are visualised clearly and these give a clue to the surgical approach. However, the differential diagnosis of cervical disc herniation, spondylosis and segmental OPLL is often difficult and plain radiography, tomography or CT can be complementary in this regard. MRI is superior to CT in the evaluation of the cervical and upper dorsal area due to shoulder girdle artefact on CT image, but in demonstration of minute ossification of ligaments and spinal canal stenosis, CT is more useful. As for spinal cord morphology, there is no better imaging modality than MRI. Evidence of chronic cord compression producing pathological changes, like myelomalacia, cavitation and necrosis, is seen as a high intensity signal in the spinal cord in T2-weighted images. This is frequent in cases of continuous OPLL since this type of ossification causes severe cord compression. Apart from these chronic changes, pathology of acute cord injury and its sequelae are visualised with clarity.

Fig. 16: MRI scan of dorsal spine, T2 sagittal showing low intensity marrow, ossified anterior longitudinal ligament and multiple levels of calcified flaval ligaments

Myelography

At advanced stages of skeletal fluorosis, lumbar and even cisternal punctures become difficult for obvious reasons, hindering the undertaking of myelographic studies. What is observable in the early stages is the localised epidural type of block, which is extensively found in the later stages (Fig. 18). For finer details, water-soluble contrast myelography coupled with computed tomography is far superior. However, following the advent of non-invasive MRI imaging, myelography is now seldom performed.

PATHOLOGY OF FLUOROSIS

Gross Changes in the Skeleton

Skeletal changes involving overall increase in bone mass, 2–3 times the normal is a characteristic feature of fluorosis.[69,90,108] The changes will be first noticed in the vertebral column and pelvis and, thereafter, in the rib cage and limb bones. The bones become whitish and, occasionally, mottled like the teeth. A clear indication of chronic fluorosis is the calcification and ossification of ligaments and interosseous fasciae occurring along

Fig. 18: Lumbar myelogram showing patchy epidural type of block

with periosteal new bone formation and development of exostoses on long bones and osteophytes in the spine (Fig. 19). It is in the muscular attachments and tendinous insertions that new bone formation occurs, as a result of which there is a thickening of the cortex and narrowing of the medullary cavity (Fig. 20). The effect on the vertebral column is seen in roughening of pedicles, laminae, and spinous and transverse processes. The osteophytes projecting into the spinal canal and intervertebral foraminae may press upon the cord and spinal roots and thus account for the radiculomyelopathic features in chronic fluorosis (Fig. 21). The spine is converted into a single rigid bone as a result of ossification of spinal ligaments and fusion of the adjacent bony structures (Figs 22A and B). The bones of the pelvis exhibit changes essentially similar to those found in the spine. The skull

Fig. 19: Photograph of macerated upper limb bones showing ossification of interosseous membrane and prominent landmarks of muscular attachments

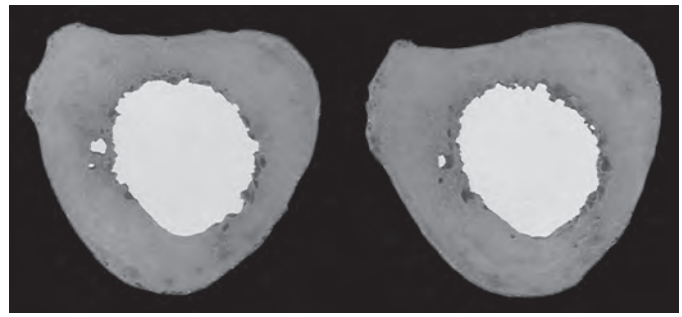

Fig. 20: Cross-section of mid-shaft of femur in fluorosis exhibiting dense cortex

is rarely involved, although there may be thickening of the calvaria and a roughening of the outlines of the foramen magnum. Other foraminae at the base of the skull are rarely affected, which is the reason why cranial nerve defects do not appear in fluorosis.

Histopathology of Bones

There have been few reports on the pathology of fluorotic bones and they present a confusing picture. These reports are unhelpful in that they are silent about the histogenesis and the mechanisms that bring about changes in bones. The work of Johnson et al.[28] on osteofluorosis is indeed outstanding because it spells out the mechanisms underlying the development of skeletal changes caused by fluorosis in animals and man. It was they who set forth three successive stages of development of fluorosis in bones, viz. fluoridation, mottling and abnormality. Bone fluoridation or chemical fluorosis is indicated if the fluoride content is less than 2500–5000 PPM. When this condition is reached, gross inspection and radiological examination will not reveal any abnormality but, when subjected to microscopic study, changes are seen such as mottled osteone. The mottled osteone is signified

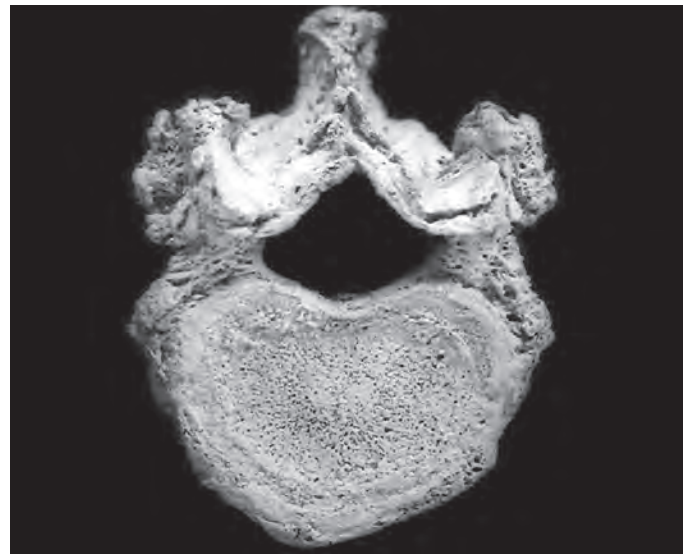

Fig. 21: Showing lumbar vertebral thickening and irregularity of its surfaces

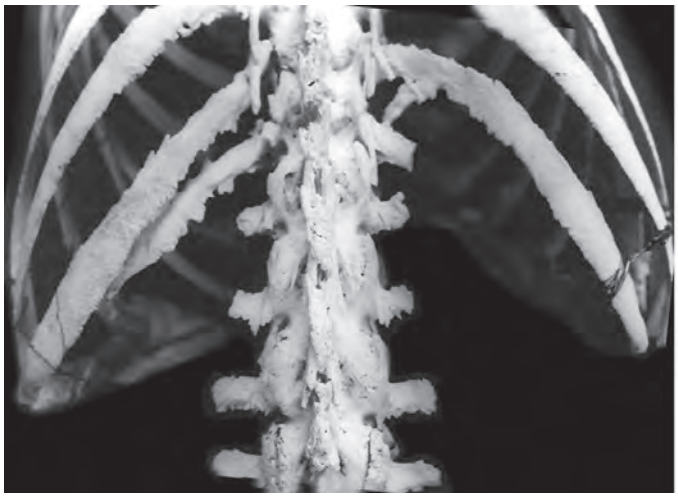

Fig. 22A: A segment of the vertebral column and the ribs showing typical changes of fluorosis (dorsal view)

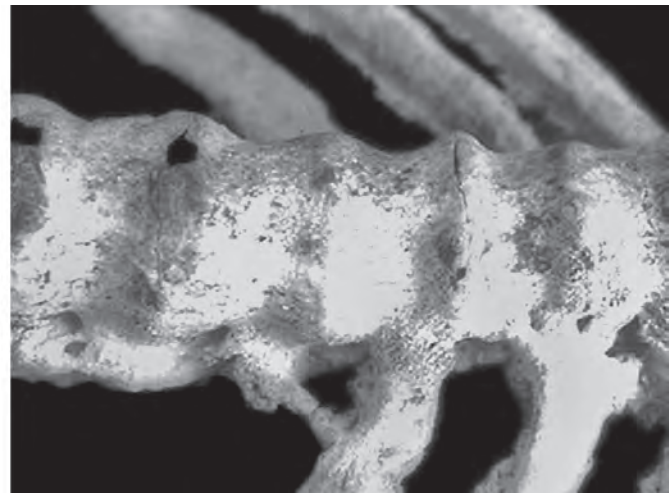

Fig. 22B: Anterior view of spine in fluorosis

by brownish discolouration and increase in the number of osteocytes found in a tangled mass on its periphery synchronising with a reduction of osteocytes in the rest of the osteone. What is further noticeable is the failure of these abnormal osteones to calcify although, in the other parts, abnormality is marked by calcification and in the formation of collagen matrix. Similar changes are also observable in the periosteal new bone. Indeed, mottling may be said to result from the action of fluoride on osteoblasts. The final stage is reached when the fluoride levels exceed 5000–6000 PPM, a stage at which even the naked eye could detect abnormality in the formation of the bone. These changes cause impairment of mechanical properties of bones.

Muscle Pathology

Neurological manifestations in skeletal fluorosis are secondary to compressive myelopathy. Franke[18] suggested that there could a direct toxic effect of fluoride on the spinal cord as well as on muscle based on a lone report of a study in a patient with industrial fluorosis who died due to glioblastoma multiforme. Similar myopathic changes were also reported in experimental studies by Kaul and Susheela.[34,35] Similar cardiac muscle changes have been reported in experimental animals and these might have been caused by the administration of very large doses of fluorides to these animals.[56,100] Our own detailed histochemical and histological studies on muscle in 22 patients suffering from endemic skeletal fluorosis have not revealed any muscle involvement due to toxic affect, but muscle changes were characteristic of denervating muscle pathology (Figs 23A and B).[78,82]

Nerve Pathology

Sural nerve biopsies were performed in 13 patients suffering from endemic skeletal fluorosis and processed for the study of: (a) myelinated fibre densities and diameter frequency distribution; (b) internodal lengths and diameter on teased fibre preparations and (c) histological changes.[78] Myelinated fibre densities were reduced indicating a dropout, probably due to axonal degeneration or demyelination, or both. It is, however, unusual that there was relative sparing of larger fibres, which is not the case in compression neuropathies. The data suggests that there is a selective damage to small myelinated fibres or their neurons with intact larger and fast conducting fibres (Figs 24 to 26). Hence, there was no significant reduction in conduction velocities in electrophysiological studies in fluorosis.

Spinal Cord Studies

There has been no report of spinal cord examination having been made in cases of fluorotic spinal compression. In a few cases in which autopsy was performed, the bones were macerated for studying the changes in

the vertebral column, but no attention was paid to the spinal cord and spinal nerves. Franke[18] reported anterior horn cell damage in the spinal cord without there being compression of the cord or nerves and it was attributed to the direct action of fluoride on these tissues. We studied spinal cord changes in fluorotic dogs from endemic regions without myelographic evidence of compression. The spinal cords revealed no abnormality histologically to suggest anterior horn cell disease.[7,75]

DIFFERENTIAL DIAGNOSIS

In areas of known endemicity, the diagnosis of dental and skeletal fluorosis does not present any problem. In

industries, where fluoride intoxication is a known hazard, skeletal fluorosis marked by restriction of spine movements can easily be diagnosed. In the early stages of skeletal fluorosis patients complain of arthritic symptoms, which have to be differentiated from those caused by such diseases as rheumatoid arthritis and ankylosing spondylitis. This is all the more important in the case of children residing in endemic regions in whom these symptoms need to be differentiated from those of rheumatic arthritis.[101] Diseases that are known to produce osteosclerosis in skiagrams should be taken into account while undertaking a diagnosis. In children and young adults genu valgum deformities have to be distinguished from those brought about by rickets and sometimes by osteodystrophies. When sclerosis of the vertebral column is not marked, calcification of the interosseous membrane in the forearm bones clearly indicates the incidence of fluorosis, which indeed is a very suggestive radiographic sign.[92]

Preskeletal stage of fluoride intoxication poses problems for diagnosis. In these cases, radiographs of the skeleton do not show sclerosis or calcification of the ligaments, nor will urinary levels of fluoride be found significantly elevated. Moreover, the symptoms that are manifested are so varied that they may be identifiable with those of various other system diseases.

Freitag and colleagues[21] state that for early diagnosis of skeletal fluorosis, microradiographic techniques are more helpful than conventional skiagrams. In doubtful cases, a bone biopsy and estimation of its fluoride content may have to be undertaken.[17] Mild trauma producing major neurological deficit is a known complication of skeletal fluorosis and in such situations in non-endemic regions one might overlook the diagnosis of fluorosis. MRI scans of the spine showing hypodensity of vertebrae in both T1- and T2-weighted images suggest that the underlying pathology is one caused by fluoride intoxication.[77]

TREATMENT OF FLUOROSIS

Prevention

In all cases of skeletal fluorosis, prevention is the aim, since no cure is possible through medical or surgical therapy, especially if it is allowed to develop to the stage when it becomes a crippling disease.

Prevention of Endemic Fluorosis

In India, which is highly endemic for fluorosis, over 50% of groundwater sources have excess of fluoride for a tropical country and it affects more than 150,000 villages. The supply of water with permissible levels of fluoride, although desirable, cannot obviously be made available to the vast number of people nor can they be shifted. That is why water purifying or defluoridation plants should be pressed into service in those areas. The plane of nutrition appears to play a crucial role in the incidence and severity of fluorosis and, hence, a balanced diet having adequate calcium and vitamins reduces the toxicity of fluoride.

Prevention of Industrial Fluorosis

Workers in industries and mining exposed to fluorides should be monitored and it should be ensured that their fluoride content of urine is below 5 PPM. It is said that skeletal fluorosis would not develop in well-nourished individuals, unless fluoride content of bones exceeds 5000 PPM.[47]

Medical Therapy

It is noteworthy that patients suffering from skeletal fluorosis, when kept off fluoride intake, register a negative fluoride balance while continuing to excrete large amounts of fluorides for years.[6,29,84] It should be obvious that excretion of fluorides mobilised from the skeleton through urine and faeces is a very slow and prolonged process lasting for many months or even years.[95] Attempts have been made to study the effect of various drugs on the binding of fluoride in *in vivo* studies and excretion of fluoride in *in vivo* experiments performed in animals and human beings. *In vitro* studies revealed that bone meal, serpentine, *dowex*, magnesium compounds, etc. could be effective in the reduction of the fluoride levels of water having a high fluoride content.[65,101] *In vivo* experiments with animals showed that salts of calcium, magnesium and aluminium acted as a check on fluoride absorption and also increased its excretion from the body.[2,103] The use of serpentine resorted to in recent times for increasing the excretion of fluoride in human fluorosis cases has been successful for clear reasons.[66] This naturally occurring mineral, which is chemically a magnesium metasilicate, seems to have an enormous capacity for absorbing fluoride at a wide range of pH and that is why it seems to hasten the excretion of fluoride from the body by mobilising it from bones. It has been observed during the administration of serpentine that the urine becomes markedly alkaline, which probably has the effect of increasing fluoride excretion from the body. An observation which tallies with the findings of physiological experiments of Whitford et al.[112] and which suggests that fluoride renal clearance is a pH dependent event. Since serpentine is impure and represents a group of minerals which comprise of chrysotile, antigorite, lizardite and a number of subgroups such as orthochrysotile, etc. having traces of many elements including fluorine, the use of active ingredients of serpentine, namely magnesium oxide and magnesium hydroxide, has been tried and found effective in animal fluorosis as well as in humans.[70,72] Magnesium hydroxide has been more effective than serpentine in both in-vivo and in-vitro studies of both animals and human beings,[60,70] but long-term studies have to be undertaken for gauging the effectiveness of these drugs in humans. Experiments conducted by Marier[44]

and Odell et al.[55] found a similarity between magnesium deficiency symptoms and those of fluoride intoxication which made them suggest that higher intakes of magnesium might prove beneficial to endemic fluorosis cases. Our own clinical and experimental studies confirm their observations and lend support to the view that, physiologically magnesium ion has a peculiar affinity for fluoride.

Surgical Management of Skeletal Fluorosis with Neurological Manifestations

Neurological manifestations of fluorosis are mainly mechanical in nature although, at advanced stages, secondary vascular changes may supervene. Surgery can obviously be of little help to the alleviation of neurological deficits in view of the extensive prevalence of the disease. Surgical decompression is only possible in such of those early cases in which the compression is confined to a small segment of the vertebral column. But management of even these cases bristles with problems due to the marked fixity of the spine and rigidity of the thoracic cage. Moreover, the markedly reduced expansion of the chest and the vital capacity of the lungs tend to create post-operative chest complications. Furthermore, intubation of the trachea during anaesthesia becomes problematic due to the rigidity of the cervical spine and positioning of the patient for surgery becomes difficult. That is why laminectomy, which has to be extensive in view of the disease being widespread, becomes difficult and burrs have to be used for removing the laminae.[1,40,53,71,110] However, the results of surgical decompression of the spine undertaken in a select group of cases were found to be encouraging in the cervical region, but discouraging in the dorsal region,[71] which might be attributed to the peculiarities of the anatomical features of these regions. Lumbar compression rarely necessitates surgical decompression as the roots get accommodated easily and by the time they are pressed upon, other parts of the spine become affected precluding surgery. It is on account of all these reasons that the attitudes towards the use of surgery in the case of spinal compression vary from those of cautious optimism to those of pessimism. In recent years, with accurate localisation of the compression in its extent in both vertical and axial planes by the MRI, fibre optic intubation and rigid fixation, better illumination and instrumentation during surgery for drilling and removal hard fluorotic bone and post-operative ventilatory support has made surgery safer and effective in alleviation of mechanical compression in fluorosis.

In recent years, the surgical approach to certain types of lesions of the cervical spine in fluorosis has changed. Fluorotic compression in the cervical region is due to: (a) cervical canal stenosis (Fig. 27); (b) localised calcified ligamentum flavum; (c) osteophytes causing compression anteriorly and lastly (d) ossification of the posterior longitudinal ligament or a combination of these lesions (Fig. 28). OPLL is very common in fluorosis and was found in 37 of 80 people over the age of 40 years in whom

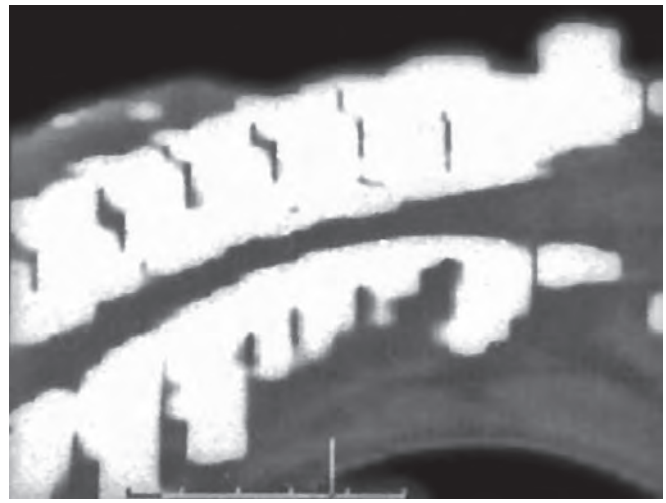

Fig. 27: Severe stenosis of the spinal canal in fluorosis. Note the markedly thickened laminae, spinous process and the osteophytes

cervical spine skiagrams were taken in an endemic village. The posterior approach is indicated in cases of canal stenosis and in lesions of the ligamentum flavum. Such of those cases in whom minor trauma causes major cervical myelopathy would also benefit from decompressive laminectomy. Ossification of the posterior longitudinal ligament, which could be continuous or segmental, is tackled through the anterior approach with better results than in the past when the posterior approach was used. Even when the posterior approach is undertaken in such cases, newer methods are followed such as canal expansive laminoplasty which obviates the complication of the anterior approach that immobilises the spine and destabilising problems following extensive laminectomy. Dorsal cord compression in fluorosis is of three types: (1) diffuse, extensive where surgery is not beneficial (Fig. 29); (2) localised posterior osteophytic or ossified ligamentous compression, wherein results are excellent (Figs 30A and B) and lastly (3) localised posterior osteophytes which are spread over many vertebral levels, although technically feasible to excise them, the

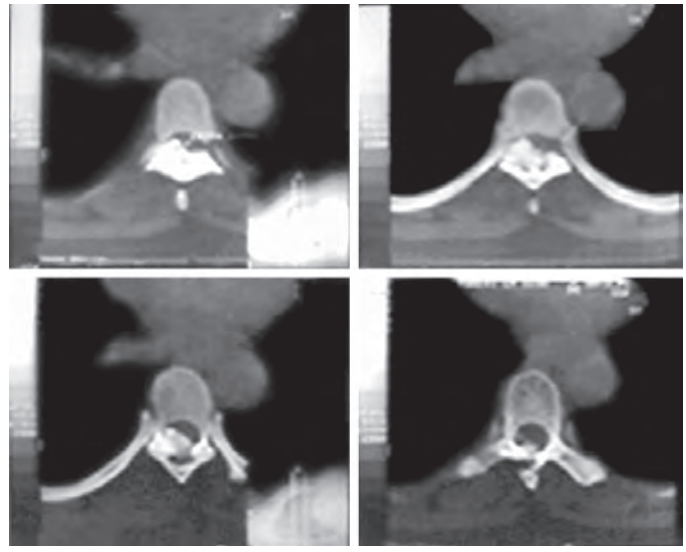

Fig. 31: Severe dorsal laminar and ligamentous compression of the cord extending over many vertebral levels

results obviously are not all rewarding (Fig. 31). It is also not known what happens to all those patients after surgery, when they go back to their endemic areas and again start to ingest high fluoride containing water and food.

118 Osteoporosis

Ramakrishna Easwaran, S Sundarrajan

INTRODUCTION

Osteoporosis is the commonest metabolic bone disorder. An estimated 61 million people have osteoporosis in India.[39] The aging of the population and changes in lifestyle or food habits are contributing to the increasing prevalence of osteoporosis. For a disorder that is so common, it is grossly under recognised. Vertebral compression fracture, which presents to the neurosurgeon is only the tip of the iceberg of the problem of osteoporosis in the community.

DEFINITION

Osteoporosis is defined as "a disease characterised by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk".[15] In addition to loss of bone mass or bone mineral density (BMD), other factors contribute to the loss of bone strength in osteoporosis (Table 1).

AETIOLOGY

Normal bone consists of organic (30%) and inorganic (70%) components. The organic osteoid component is mostly made up of type 1 collagen. The inorganic component is mostly made up of hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, a macrocrystalline mineral.[42] Bone is a dynamic tissue that keeps on remodelling during a person's lifetime. Osteogenetic and osteoclastic activities are continuous and are decided by local stresses, nutrition and hormonal factors. The peak bone mass which is a function of gender, race, genetic or familial factors, nutrition and exercise in adolescence is attained at 30–35 years.[10,62,72,74,84] Loss of bone mass begins after the age of 35 in normal men and women at the rate of 0.3% per year. At menopause, the rate of trabecular bone loss dramatically increases to 3% per annum for 10–15 years.[26] This postmenopausal (previously called 'type 1') osteoporosis appears to be mainly due to increased osteoclastic activity rather than insufficient osteogenetic activity.[42] Beyond the age of 70, the loss is slower and the rate of loss is the same in men and women. The age associated bone loss equally affects the trabecular and cortical bone. This age related bone loss (previously called 'type 2') osteoporosis appears to be mainly due to insufficient osteogenetic activity. Several factors, such as decreased absorption of calcium, reduced activation of vitamin D, a decline in the lifespan and function of osteoblasts and decreased concentrations of sex hormones, contribute to age associated osteoporosis.[48,78]

The reduction in bone mass and BMD is called osteopaenia when it is subclinical. When it is severe enough to produce symptoms or increase the fracture risk it is called osteoporosis. The World Health Organization (WHO) criteria (Table 2) based on the BMD give a quantitative definition of osteopaenia and osteoporosis.[86]

The fracture risk approximately doubles with fall in the BMD by each standard deviation below the normal as defined in the criteria.[51] The criteria based on BMD are only convenient clinical signposts. As is evident from Table 1, BMD must not be construed to be the *only* determinant of bone strength.

A new, yet-to-be-established, hypothesis proposes that the stress placed on the haematopoietic system due to menstrual blood loss influences the osteogenetic-osteoclastic system leading to osteoporosis in women.[29] Excessive mast cell activity has also been held responsible for osteoporosis.[12] Amylin, a peptide product of the pancreatic beta cells is similar to calcitonin and may be a factor in the osteoporosis of type 1 diabetes.[8] In a mouse model of osteoporosis, decreased spatial memory and hippocampal neuron number has been demonstrated,

Table 1: Factors weakening the bone in osteoporosis

Loss of bone mass and reduced mineralisation (reduced BMD)[86]
Reduced capacity to heal microfractures[57,81]
Altered bone turnover[69]
Alteration in bone microarchitecture[11]
Alteration in bone geometry[7]

Table 2: Criteria for osteopaenia and osteoporosis[86]

Category	*Criteria based on mean bone mineral density (BMD) of young adult reference population-t score*
1. Normal	Mean ± 1 standard deviation (SD)
2. Osteopaenia	1–2.5 SD below mean
3. Osteoporosis	< 2.5 SD below mean
4. Severe osteoporosis	< 2.5 SD below mean + any insufficiency fracture

Table 3: Aetiology of osteoporosis

Primary	*BF*	*BL*
Postmenopausal		↑
Age associated osteoporosis (OP)	↓	
Rare: Idiopathic juvenile OP, Transient hip OP, Regional migratory OP[81]		
Secondary		
Endocrine		
Excess of cortisol (Cushing), thyrotoxicosis, hyperprolactinaemia		↑
Deficiency of growth hormone, parathormone, gonadal hormones, insulin	↓	
Dietary		
Calcium/vitamin D deficiency, malabsorption, alcohol, scurvy	↓	
Systemic disease		
Inflammatory bowel disease, liver disease	↓	
Haemolytic anaemia, myeloma, leukaemia, mastocytosis		↑
Rheumatoid arthritis, chronic obstructive pulmonary disease	↓	
Drugs		
Glucocorticoids, antiepileptic drugs, anticoagulants, antiandrogen therapy	↓	↑
Genetic		
Osteogenesis imperfecta, Marfan syndrome, Ehlers-Danlos syndrome	↓	
Others		
Prolonged immobility, sedentary life style, smoking, HIV infection	↓	↑

Note: BF, Bone formation; BL, Bone loss; ↓, Decreased; ↑, Increased.

but one wonders if the common link is accelerated senescence.[49]

Several secondary causes of osteoporosis are seen in practice, especially among males with osteoporosis (Table 3). Neurosurgeons are likely to see osteoporosis due to glucocorticoid or antiepileptic therapy, Cushing syndrome, hypopituitarism and prolonged immobility.

CLINICAL FEATURES

Osteoporosis is essentially asymptomatic until a fracture occurs. Many patients, who are ultimately shown to have osteoporosis, complain of pain, especially over the low back or lower extremities. While this may be due to microfractures, the pain syndrome overlaps with the pain caused by degenerative lumbar spondylosis and osteoarthritis, which are common comorbidities. Fatigue and pain may also be worsened by the associated depression.[38]

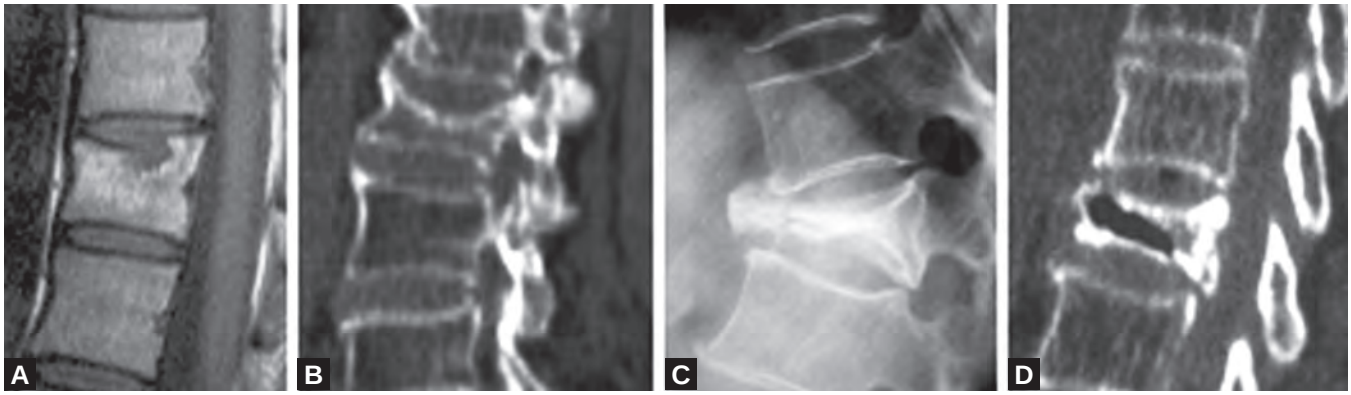
Vertebrae (50%), proximal femur (20%) and distal radius (15%) are the common sites of insufficiency fractures in osteoporosis.[53] The vertebral fracture may occur after being jolted during travel in vehicles or just with a minor fall. The elderly are more prone to fall because of visual impairment, dizziness or loss of co-ordination. The impact is of low energy. There may be no remembered fall, although many patients recall a pain of acute onset. The pain is localised to the site of the vertebral fracture and there is often a girdle pain. Patients with T12 or L1 fracture may complain of pain over the L5-S1 area. Radicular leg pain is rare and should suggest spondylosis or metastasis. The pain is worsened by sitting, spinal movement or coughing. Neurological deficits of spinal cord or cauda equina function are also not common except when there is a break in the posterior cortex of the vertebral body.[41] Painless deformity of the spine may occur due to one or more vertebral compression fractures. Often, the vertebral fracture is asymptomatic and is incidentally detected by X-ray, such as a routine chest radiograph. Reduction of body height of more than 2 cm should prompt a search for vertebral compression fracture.[76] Progressive kyphosis (Dowager's hump) is a consequence of multiple compression fractures.

History of fractures caused by minimal trauma (fragility fracture) elsewhere in the body is often elicited. Women with insufficiency fractures may recall their mothers being similarly afflicted. Intracapsular femoral neck fractures are mainly seen in postmenopausal osteoporosis while the intertrochanteric fracture is common in age-associated osteoporosis. The mortality and morbidity of osteoporotic hip fractures is higher than that of vertebral fractures. This is more so for men with osteoporotic fracture than women.[16] In patients with one vertebral fracture, the risk for a subsequent vertebral fracture is 33-fold higher in men and 11-fold higher in women.[54]

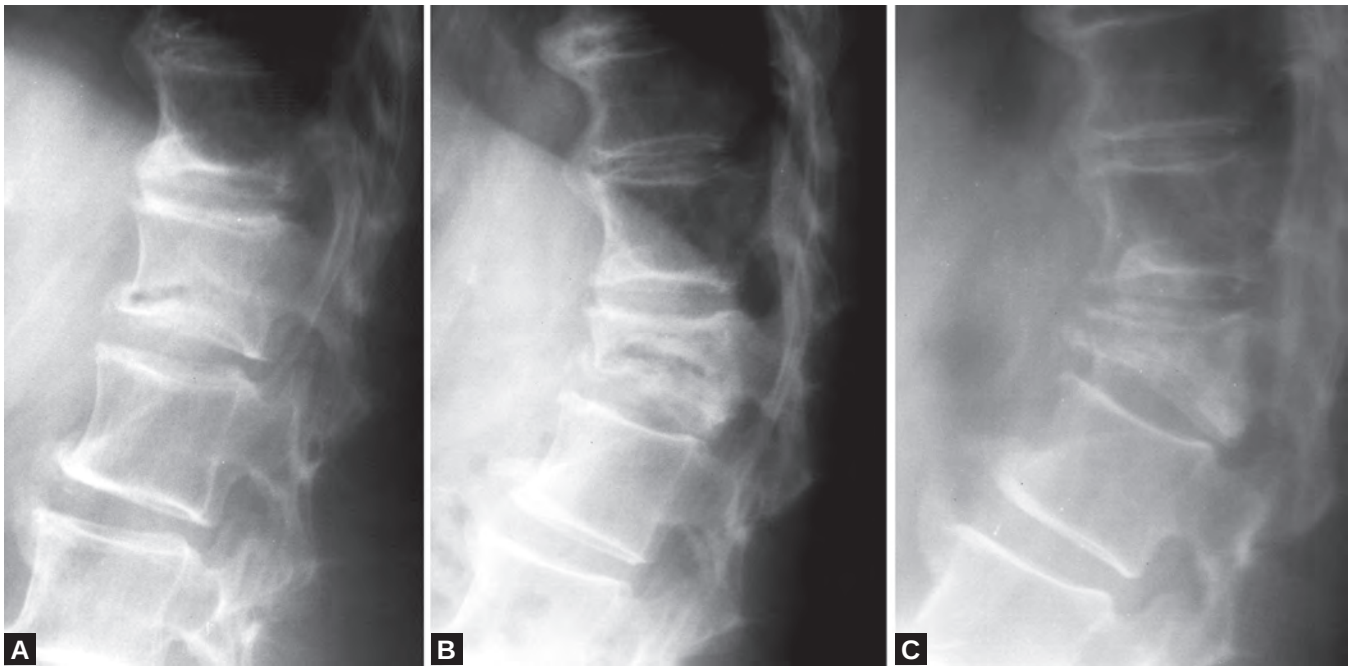
INVESTIGATIONS

Plain Radiography

Osteoporosis becomes evident on standard radiographs only when the bone mass diminishes to nearly 50% and, therefore, it is a poor and unreliable tool for assessing



Figs 1A to D: Various patterns of vertebral compression fractures. (A) MRI of superior endplate fracture. (B) Sagittal reformatted CT of "fish vertebra". (C) Lateral radiograph of vertebra that appears radiodense due to compaction of the bone in an anterior wedge compression fracture. (D) Sagittal reformatted CT of axial compression fracture with intravertebral cleft

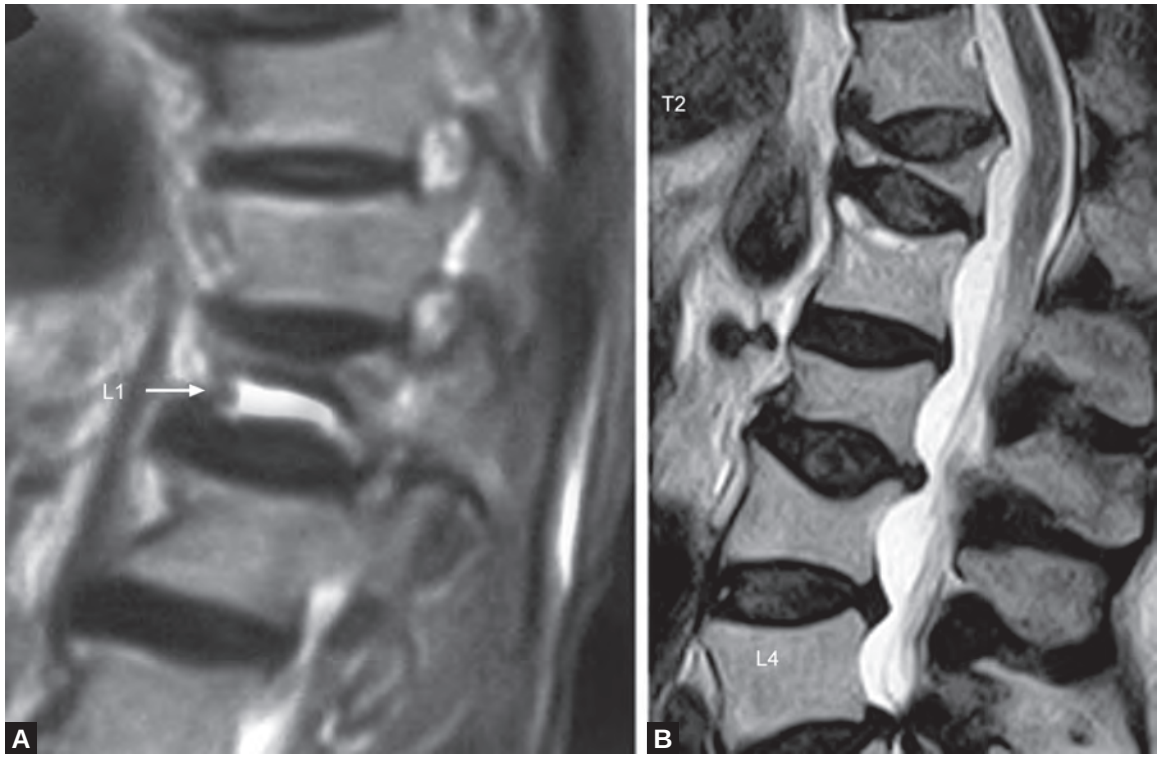


Figs 2A to C: Progression of osteoporotic wedge compression of L1 vertebral body in an 85-year-old man. (A) Note the cleft in the anteroinferior part of the body in the initial radiograph. (B) The cavity is bigger in the radiograph taken 2 months later and the vertebra has become wedged. (C) The kyphosis has worsened due to increasing anterior wedging in the radiograph taken after 3 more months. The cleft is less obvious due to collapse. The endplates and disc spaces are preserved in all films

osteoporosis. Prominent Schmorl's nodes may be seen. Breaks in the vertebral endplates are also seen (Fig. 1A). In the advanced stages, ballooning of the discs into the weak vertebral body may cause the end plates to appear biconcave (fish vertebra) (Fig. 1B).

Silent multiple vertebral compression fractures are the hallmark of osteoporosis. Therefore, it is mandatory to screen the entire vertebral column by imaging. A difference in height of the vertebra of greater than 4 mm between the anterior and the posterior borders should be taken as evidence of a compression fracture. The compression may involve the anterior and the posterior borders equally, sometimes to the extent of causing a vertebra plana. The compaction of trabeculae due to compression fracture may give a paradoxical radiodense appearance to the vertebra (Fig. 1C). It is usually not possible to assess the age of the fracture on radiographs. Although CT (Fig. 1D) or MRI may show the intravertebral cleft better, it is often seen on standard radiographs (Fig. 2A). Comparison with previous X-rays shows the progression of osteoporotic clefts and loss of vertebral height (Figs 2A to C).

Anterior wedging, preserved disc spaces and absence of vertebral displacement or paraspinous shadows are classical findings of the osteoporotic compression fracture. Fractures are generally in the thoracolumbar junction and usually not above T6 level. Posterior wedging and the 'wink sign' on anteroposterior radiographs due to loss of pedicle suggest metastasis or myeloma. A cavity in the vertebral body is seen, but the walls are



Figs 3A and B: MRI of osteoporotic compression fracture of vertebra. (A) Sagittal T2-weighted MR image of the same patient as in Figure 2. The absence of T2 hyperintense signal in the parenchyma of the bone in the chronic stage and the presence of hyperintensity in the cleft, the preservation of the posterior cortex with anterior wedging are characteristic. (B) Sagittal T2-weighted MR image of an 80-year-old woman with previous fracture (fish vertebra) at T12 level and a new superior endplate fracture at L1 level manifested by the T2 hyperintense signal. Note the ballooned discs

sclerotic rather than lytic, unlike those seen with metastasis (Figs 1D and 2A). The presence of a vertebral body cleft is a predictor of delayed collapse and subsequent neurological deficit.[37] Sacrum is a rare, but increasingly recognised, site for insufficiency fracture.[45] While the diagnosis of an insufficiency fracture can be made by plain radiography, further investigations may be needed to rule out metastasis or myeloma.

Computerised Tomography Scan

CT scan is mainly required to look for retropulsed fragments in the spinal canal and to demonstrate the intravertebral cavity (fluid content) or cleft (gas or vacuum) that can be targeted for vertebroplasty (Figs 1D and 3A). The reconstructed sagittal and coronal CT can detect subtle compression fractures missed by conventional radiography. The presence of callus may indicate an old fracture. CT is very useful to study the pedicle width and the integrity of the posterior cortex for vertebroplasty. Primary vertebral lesions, such as haemangioma, show up well on CT. *Micro CT* employs highly collimated beams from a Synchrotron to produce microarchitecture maps on micron thick sections of bone.[11]. This technique can at present be done only on *ex vivo* bone samples and is a research tool.

Magnetic Resonance Imaging

The presence of hyperintense oedema in the bone on T2-weighted images indicates a recent fracture. Hence MR is useful for picking up the recent fracture for treatment in a patient with multiple wedge compression fractures (Fig. 3B). The subtle infiltrates caused by tumours or infections are seen earliest with MRI. In the absence of a cavity, contrast enhanced MR has been found to show an area of non-enhancement that corresponds to the cleft which can be filled up during vertebroplasty.[64] Study of microarchitectural changes can be done with the help of thin section MRI.[11]

Radionuclide Imaging

The advantage of radiotechnetium imaging is the ability to look at the whole skeleton simultaneously. This is helpful for metastasis screening. Recent osteoporotic fractures appear as hot spots while the clefts may show up as cold spots. It is also a useful technique for imaging patients with pacemakers, who cannot undergo MRI.

Quantitative Assessment of Bone Mineral Density

Single photon or dual photon absorptiometry utilising radionuclides are now out of vogue. Since its introduction

in 1987, dual energy X-ray absorptiometry (DXA or DEXA) has become a rapid, reliable and cost-effective method of measuring BMD.[3] Low BMD predicts fracture better than elevated cholesterol levels predict coronary artery disease.[86] The lumbar spine and proximal femur are usually studied. The presence of osteophytes, compression fracture, deformities and presence of implants or aortic calcification may vitiate the results in the lumbar spine.[47] The *t* score is the number of standard deviations below the average BMD of a young adult of the same race and sex, while the *z* score is a similar measurement with reference to an age and sex matched control. Osteoporosis is defined as *t* score being at least –2.5 (Table 1).[86] Low *z* scores indicate a secondary cause for osteoporosis. About half of the fragility fractures occur in the group diagnosed to have merely osteopaenia by the WHO criteria.[75] Measurement of forearm BMD is recommended for hyperparathyroidism associated osteoporosis.[5]

BMD measurement in the hip may not necessarily predict fracture risk in the spine.[56] Spinal BMD measurements may particularly be important in younger postmenopausal women, since they may show osteoporotic values earlier than the hip,[68] while the hip measurements are more suited to the older men and women.[56] The normative data are different for each brand of DXA machine. BMD values in Indian population are approximately 15% lower than those in Caucasian women.[65] BMD measurement by DXA results in less radiation exposure than a chest radiograph (10 mrem as compared to 50 mrem).[68]

Quantitative Computerised Tomography

Quantitative computerised tomography (QCT) gives excellent three-dimensional (voxel) information on specific parts of the lumbar spine. The technique is more accurate, but it is expensive and carries a greater radiation exposure than DXA. The *t* and *z* scores for QCT are different from those determined by hip DXA because only trabecular BMD is measured by QCT.[44]

Quantitative Ultrasonography

Quantitative ultrasonography (QUS) is performed on the calcaneum. The technique measures either ultrasound transmission velocity or broadband ultrasound attenuation, but these parameters are affected not only by BMD but also by other factors such as bone architecture. The reproducibility of the results is low and the correlation between the BMD at the calcaneum and the osteoporotic fracture risk in the hip or vertebra is debatable. Therefore, QUS can at best be considered a screening tool. The low cost and portability of QUS are advantages for mass screening.

The indications for performing bone densitometric studies are given in Table 4 and are in keeping with the guidelines by the US National Osteoporosis Foundation.[60] Osteoporotic fractures occur 10–20 years earlier in Indians as compared to Caucasians and hence the age criteria have to be lower for the Indian population.[39]

Table 4: Indications for osteoporosis screening (BMD measurement)

All women > 65 years, (? All men > 75 years)
Postmenopausal women < 65 years with 1 additional risk factor
Premenopausal women or men with 2 risk factors
Risk factors: 1. Personal history of fracture (fragility or traumatic)
2. Family history of fragility fracture
3. Low body weight (< 57 kg), recent loss of > 5% body weight [22]
4. Amenorrhoeic women, early menopause, delayed menarche
5. Presence of any secondary cause for osteoporosis listed in Table 2, especially steroid/antiepileptic therapy, rheumatoid arthritis and inflammatory bowel disease
6. Smoking, alcoholism, sedentary lifestyle
7. Increased risk for falls
Monitoring osteoporosis therapy (usually 2 years after starting therapy)

Assessment of Bone Turnover

The markers of bone formation (bone specific alkaline phosphatase, osteocalcin) and bone resorption (deoxypyridinoline, collagen telopeptides) have been measured but are clinically not commonly done. They have been more accurate in the assessment of perimenopausal rather than postmenopausal women.[36] They may be measured in a serial manner for monitoring therapy.[69]

TREATMENT

Medical Treatment

The two medical strategies for treating or preventing osteoporosis are to reduce bone resorption and to increase bone formation. Table 5 summarises the drugs currently in use for treatment of osteoporosis. Only sodium fluoride (no longer in use) and synthetic fragment of parathyroid hormone (teriparatide) work by enhancing bone formation. All the other drugs in Table 5 act predominantly by preventing excessive osteoclastic activity. Strontium ranelate has a dual mode of action.

Bisphosphonates constitute the first line therapy in those who can tolerate the drug.[70] Bisphosphonates provide 7% increase in hip and spine BMD and 60% decrease in markers of bone resorption. Bisphosphonates also reduce the incidence of new vertebral fractures by 50%.[24] The fracture protection effect is seen even before the BMD starts improving and is always greater than the degree of rise in BMD.[18] These findings suggest that bisphosphonates may improve bone strength by means apart from improving bone mineralisation.[21,73] Oesophageal ulceration caused by bisphosphonates can

Table 5: Drug therapy for osteoporosis

Drug	*Dosage and route*	*Adverse effect*	*Proven efficacy in risk reduction*	*Recommended for*
Bisphosphonates				Prevention and treatment
Alendronate	5 mg daily or 35 mg weekly, oral, for prevention. Twice this dose for treatment	Esophagitis, myalgia	Vertebral, non-vertebral and hip fracture	
Risedronate	5 mg daily or 35 mg weekly, oral	Esophagitis incidence same as alendronate	Vertebral, non-vertebral and hip fracture	
Ibandronate	2.5 mg daily or 150 mg monthly, oral	Joint pain, fever with first dose of 150 mg	Vertebral fracture	
Strontium ranelate	1-2 gm daily at night, oral	Diarrhoea, venous thromboembolism	Vertebral and non-vertebral fracture	Prevention and treatment
HRT				
Low-dose oestrogen	Conjugated equine oestrogens 0.625 mg daily, oral	Venous thromboembolism, stroke, myocardial infarct, breast cancer	Vertebral, non-vertebral and hip fracture	Prevention and treatment
SERM				
Raloxifene	60 mg daily, oral	Hot flushes, leg cramps	Vertebral fracture only	Prevention and treatment
Calcitonin	100-200 IU, daily, subcutaneous or nasal		Vertebral fracture only	Treatment only
Teriparatide	20 µg/day	Hypercalcaemia	Vertebral, non-vertebral and hip fracture	Treatment (presently for 2 years)

be prevented by taking the dose on an empty stomach in the morning with 200 ml of water. The patient must be instructed to strictly avoid lying down or taking any diet for 30 minutes. Etidronate, a first generation bisphosphonate, was associated with necrosis of the jaw and is no longer used. Pamidronate is an intravenous alternative that can be used for those who cannot tolerate oral bisphosphonate therapy.

In a randomised controlled trial, alendronate was better than risedronate and was just as well tolerated.[71] The maximisation of bone mass takes 7 years and hence bisphosphonate therapy is always long term, possibly lifelong. There is no rapid fall in BMD after cessation of bisphosphonate therapy,[23] unlike that which occurs on withdrawing hormone replacement therapy.[28] Bisphosphonates offer protection against hip, spine and other fractures, unlike synthetic oestrogen receptor modulators (SERM, e.g. raloxifene) which mainly act on the vertebral trabecular bone.[25] Strontium ranelate therapy reduces the risk of vertebral fracture by 40% and is less effective for preventing other fractures.[55,63]

Hormone replacement (HRT) with either low dose oestrogen or a combination of oestrogen and progestin is no doubt an effective way to combat postmenopausal osteoporosis. The vertebral fracture incidence came down by 50% and hip fracture by 33% in two large studies.[72,85] However, the increased incidence of myocardial ischaemia, stroke, venous thromboembolism and breast carcinoma have led to the abandonment of HRT as the primary treatment for postmenopausal osteoporosis.[80]

Recombinant human parathyroid hormone (1–34) (teriparatide) stimulates bone remodelling by increasing bone formation. It afforded 50% risk reduction of all fractures in a randomised trial.[61] The combination of bisphosphonates and teriparatide in a concurrent, cyclical or sequential manner appears logical, but there is no evidence of a superior efficacy of such combinations in reducing fracture risk.[43] Salmon calcitonin is not used for prevention but is mainly useful for managing severe pain in patients with osteoporotic fractures.

Once a patient has a fragility fracture, drug therapy is naturally indicated. Preventive drug therapy is indicated in patients with *t* score of –2.5 or less. It is also indicated in patients with *t* score of –2 to –2.5 along with one additional risk factor listed in Table 4.[79]

General Measures

The importance of maintaining calcium and vitamin D intake throughout life cannot be overemphasised.[6] The recommended daily intake is summarised in Table 6. Calcium and vitamin D supplements are indicated when the diet alone cannot provide the recommended daily intake and when the patient is on bisphosphonate therapy.[74] Supplemental calcium must be given in 2–3 split doses. High oxalate containing vegetarian diets may prevent absorption of dietary calcium. For those without renal disease, alfacalcidol does not offer a significant advantage over cholecalciferol. Maintenance of body weight, regular weight bearing activity and physical exercise are also essential. Preventing falls is desirable. Hip protectors can be used selectively.

Conservative Management of Vertebral Compression Fracture

The pain of the recent vertebral compression fracture responds to bed rest and simple analgesic therapy. Prolonged bed rest is poorly tolerated by the elderly and hence the patients are mobilised early, usually within a week or two. Anterior spinal bracing may be used in the first 6–8 weeks after the fracture. Calcitonin helps the pain when other analgesics fail. All fractures that remain painful after 3 weeks, selected early fractures and chronic non-healing fractures greater than 6 weeks old are considered for percutaneous augmentation.

Percutaneous Intervention for Osteoporotic Vertebral Compression Fracture

Indications

Percutaneous injection of polymethylmethacrylate (PMMA) bone cement was first done in France for haemangioma of the vertebra in 1984.[19] Over the last 15 years, it has widely been applied to relieving the pain of osteoporotic vertebral compression fractures. The other indications include osteolytic metastasis and myeloma with or without pathological fracture,[31] vertebral histiocytosis and the painful fractures of osteonecrosis (Kummell's disease). The prophylactic augmentation of the osteoporotic vertebra before it gets fractured is a recent but debated indication.[2] Since 1999, correction of kyphosis by a balloon inserted percutaneously has been available as an adjunct to vertebroplasty. Kyphoplasty opens up the wedged vertebra by means of an inflatable bone tamp prior to injection of bone cement. This should ideally restore the vertebral height and correct the kyphosis. Even when the kyphosis correction is minimal, the compaction of the trabeculae that occurs during kyphoplasty allows a greater volume of cement to be injected under lower pressure, thus minimising the risk of cement leakage.[58]

Table 6: Recommended daily intake

Age (Years)	*Calcium (mg)*	*Vitamin D (IU)*
3–8	800	200
9–17	1300	200
18–50	1000	400
51–70	1200	400

Mechanism of Pain Relief

Vertebroplasty has been proved by *in vitro* biomechanical studies to stiffen the vertebra.[52] Stabilisation of the microfractures is one mechanism of pain relief after vertebroplasty. The heat produced by the exothermic polymerisation of methylmethacrylate may damage the nociceptive nerve endings in bone. The unpolymerised monomer may directly damage the cells secreting pain mediators.

Contraindications

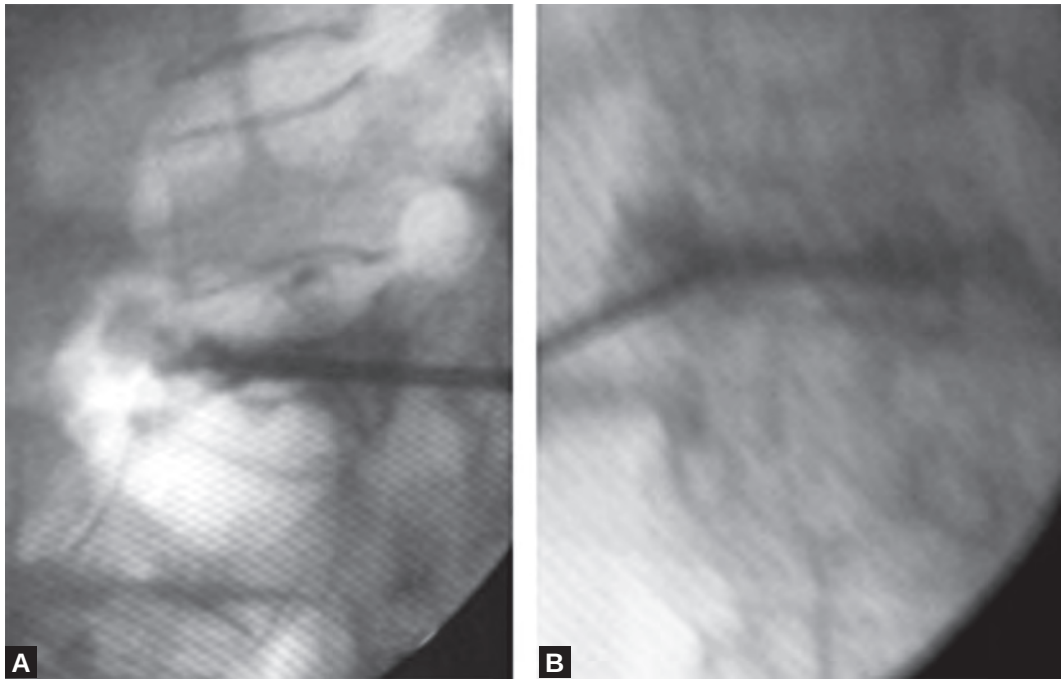
Systemic or local infection, bleeding diathesis and neurological deficits due to spinal canal compromise may contraindicate vertebroplasty and kyphoplasty. Disruption of the posterior vertebral cortex increases the chance of intraspinal cement leakage. The procedure may be rendered difficult by a totally (> 90%) collapsed vertebra but may still be done. The patient shown in Figure 1C underwent vertebroplasty with good relief of pain. In view of its minimally invasive nature, even patients who are not medically fit for major open surgical stabilisation procedures can be candidates for percutaneous vertebral augmentation.

Technique

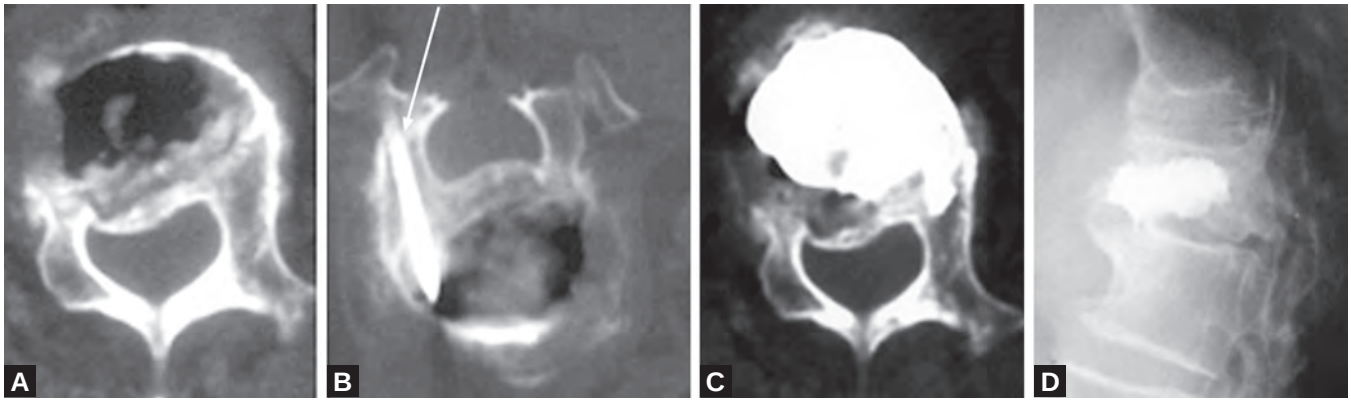
Vertebroplasty is done under local infiltration analgesia. Conscious sedation is useful. General anaesthesia is reserved for those who need to undergo multiple level augmentations in one session or when kyphoplasty is planned, but the patient must be medically fit. The patient is positioned prone for thoracic or lumbar fractures, on bolsters, with the spine in some extension to allow postural reduction.[13] The procedure is done on a radiolucent table with C-arm image intensifier screening. Rotating a single plane C-arm image intensifier to obtain anteroposterior and lateral projections is sufficient (Figs 4A and B) but a biplane image intensifier saves time. CT guided needle placement is used when the vertebrae or pedicle landmarks are difficult to visualise on radiography, when simultaneous lesional biopsy is planned and for procedures on the cervical vertebrae. We have used routine CT guided placement of the needle for the transpedicular approach (Figs 5A and B). Peri-operative systemic antibiotic may be supplemented by addition of tobramycin to the cement preparation.

Approach

Transpedicular approach is the classical route. The advantages are that the pedicle is a well-recognised radiographic landmark and that the long intraosseous path prevents nerve root injury minimising cement leakage



Figs 4A and B: Vertebroplasty. Needle position for C-arm image intensifier guided vertebroplasty by the transpedicular approach. (A) Lateral projection. (B) AP projection



Figs 5A to D: CT guided vertebroplasty. (A) Axial CT scan of osteoporotic wedge compression of L1 vertebral body (same patient as in Figure 2) Note the cavity in the body and the intact pedicles. (B) Percutaneous transpedicular needle placement was done. (C) Methylmethacrylate vertebroplasty was done. Note the bilateral filling in the post-procedure CT after unipedicular injection. The patient had excellent pain relief. (D) Follow-up lateral radiograph one year after vertebroplasty. Note the partial height restoration and reduction of kyphosis as compared to Figure 2C

into the soft tissues. In this approach, although the needle lies in one half of the vertebra, the entire vertebra often gets filled (Fig. 5C). In some cases, bipedicular injection may be needed to fill both halves of the vertebral body. In small pedicles, such as those seen in the upper thoracic region, the parapedicular approach may be chosen. For kyphoplasty, the inflatable balloon tamp needs to be placed in the middle of the vertebral body and hence the parapedicular approach may be preferred. Through a paraspinous stab incision, a 11G needle is placed in the vertebral body. The pedicle may be viewed either in a straight anteroposterior projection or may be seen 'end-on' by rotating and angling the image intensifier. Biopsy is obtained if needed. Injection of iodinated contrast confirms the correct placement and outlines the venous pattern but is not mandatory.[83] Despite venography, bone cement might enter the venous system.

Cement Injection

Chilling the bone cement components before the procedure extends the time for the cement to set. Since commercial preparations vary in their barium content and some may not sufficiently be radio-opaque, sterile barium sulphate is added to obtain 1:3 barium:PMMA mixture. Injection of bone cement in a thick soupy consistency is done with 1 ml syringes using hand pressure. Injection when the mixture is too thin encourages venous embolisation and must be avoided. The injection is done under lateral image intensifier screening to look for entry of cement into the spinal canal. The body opacifies with

cement in the anterior to posterior direction. The volume needed per level might be 2–6 cc. Cement injection is stopped when the posterior quarter of the body is filled or when it leaks beyond the vertebra. The patient must lie prone for 15–20 minutes until the cement hardens. The patient can be ambulated within hours. Pain relief is usually seen within a day and is lasting. The radiographical correction of kyphosis is also lasting (Fig. 5D), but loss of correction has been seen in some cases. Pain relief has been reported in up to 90% of patients undergoing vertebroplasty in various series done for different indications. Calcium phosphate cement has recently been tried for vertebroplasty.[59] Bioactive glass-ceramic reinforced material has also been introduced as an alternative to PMMA.

Technique of Kyphoplasty

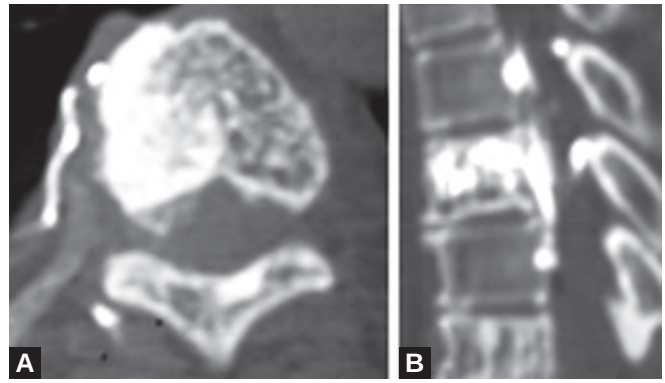
The initial steps are similar to vertebroplasty. The needle, placed in a similar manner, is exchanged for a cannula and introducer system over a guide pin. Through this the balloon tamp is introduced and inflated till the kyphotic deformity is corrected or the balloon reaches the cortical margin. The balloon is then deflated and bone cement is injected. More viscous cement can be injected under lower pressure into the cavity created. Kyphoplasty is generally done with bilateral approaches but unipedicular kyphoplasty has been reported.[34]

Results

A prospective but non-randomised study has shown that vertebroplasty for *acute* vertebral compression fracture can reduce the pain, disablement, hospital stay and improve quality of life as compared to medical management.[20] Small numbers of patients studied in the long term have shown efficacy of vertebroplasty to last 4 or 5 years.[66] Kyphoplasty has also shown similar efficacy in improving pain score and disability index in a prospective study.[17] An average of 68% restoration of anterior height of the vertebra was observed at 1 year in a study of balloon kyphoplasty, but there were also patients in whom there was no height restoration at all.[46] In another study, 58% of the fractures were partially reducible with kyphoplasty and mean Cobb angle correction was 14 degrees.[67]

Complications

Placement of the needle may engender root injury and might fracture the pedicle or rib. Cement leakage may be seen in 60% of patients[33] and is usually asymptomatic, especially when it occurs into the anterior or lateral paravertebral spaces, disc or the perivertebral veins (Fig. 6A). Small intraspinal leaks may also be asymptomatic (Fig. 6B). Symptomatic cement leakage may result in either radiculopathy or myelopathy, and occurs in only 1%.[33] The frequency of leakage is the same in those with or without the intravertebral cleft, but epidural leaks are more common in patients without a cleft.[40] Pain and minor deficits might improve with steroids and expectant therapy, while the serious deficits call for surgical decompression.[19] Pulmonary cement embolism is rare. Bleeding at the puncture site, transitory worsening of pain and fever in the hours following injection due to the heat generated during polymerisation and bone infection have been reported.[27] Complications are more common in patients with tumours undergoing vertebroplasty.



Figs 6A and B: (A) Asymptomatic entry and persistence of bone cement in the intercostal vein one year after vertebroplasty for haemangioma of T3 vertebral body. (B) Asymptomatic intraspinal leak of bone cement in a patient undergoing vertebroplasty for haemangioma

Concerns

The toxicity of PMMA to the personnel and the patient is an issue that needs to be clarified. Vertebroplasty and kyphoplasty have not yet been evaluated against best medical therapy or between themselves in prospective randomised, controlled trials. Cementing one vertebra in a very osteoporotic spine may promote fractures at the adjacent levels.[82]

Surgery for Osteoporotic Compression Fractures

The widespread availability of vertebroplasty has lessened the need for surgical intervention for osteoporotic vertebral compression fractures. Patients with demonstrable instability and significant neurological deficits may need surgery in the acute stage. Delayed neurological progression after initial fracture healing also calls for surgery. The techniques of stabilising and fusing the spine are similar to those used in non-osteoporotic vertebrae. The problems of instrumentation and fusion of the osteoporotic bone are dealt with in the next sections. Apart from these are the complications caused by the age and poor medical fitness of osteoporotic patients.

Instrumentation in Osteoporotic Spine

Instrumentation of the osteoporotic spine (Table 7) is rendered difficult by poor purchase of screws leading to screw pullout, wires cutting through the bone, greater tendency for settling of cages and proneness for iatrogenic fracture.[1,32] The weakest link in osteoporotic bone is the bone-metal interface. The less stiff segments adjacent to the rigid instrumented segment may fail.[82] These problems can be solved to an extent by: (1) increasing the points of

Table 7: Recommendations on the methods for internal fixation of the osteoporotic spine

Level	*Method of choice*	*Comments*
Odontoid fracture type 2	1. Anterior screw fixation[4] 2. Posterior transarticular screw fixation	Chance of wire cut through high in Gallie or Brooks wiring
Subaxial cervical spine	1. Anterior constrained plate-screw construct 2. Unconstrained plate with bicortical screw purchase (Caspar) 3. Rectangular cages sit on the peripheral thick cortical shell and are better than porotic autografts	Lateral mass fixation is prone to fail Interspinous wires may cut through
Thoracic spine	1. Multiple segmental fixation using pedicle screw or sublaminar wire construct, 2–3 levels above and below the injured level, supplemented by laminar hooks 2. Bicortical purchase and placement of screws as safely as possible near the end plates for anterior fixation 3. Claw or staple washers prevent the screw head from sinking into the soft vertebral body	Spinous process wire cut through, pedicle screw pullout, pedicle break after sublaminar wiring and hook failure due to break in pars-pedicle junction are likely[9,14]
Lumbar spine	1. Multiple segmental fixation using pedicle screw construct 2. Under-tapping or no tapping,[30] injecting carbonated apatite cement under pressure,[50] convergent screw paths, large diameter screws, expanding tip screws help achieve good pedicle screw placement 3. Placement of a good interbody construct (bone or cages) lessens the strain on the pedicle screw system	Lower the BMD, greater the chance of pedicle screw pullout. Pedicle screws cannot be used in spines with BMD < 0.3–0.4 gm/sq cm.[77] Placing bone graft in a stripped screw hole does not prevent screw pullout in osteoporotic bone

fixation to evenly spread out the stresses over many levels; (2) adding supplementary fixation as for example using laminar hooks, wires or transverse connectors along with pedicle screws; (3) using PMMA bone cement to augment fixation;[35] (4) using "escape" methods like larger screws to thwart loosening; (5) using larger cylindrical or rectangular cages which maximise the surface area of contact; (6) using implants which are less stiff and nearer to bone in elasticity; (7) using appropriate orthoses for longer periods and (8) by careful selection of the method of fixation in individual cases (see recommendations in Table 7).

Interbody Fusion in Osteoporotic Spine

Notwithstanding the generally poor autogenous donor bone quality, tricortical iliac crest autograft is still the best for fusing the osteoporotic spine. Cylindrical threaded cages, rectangular cages and femoral ring allografts are available. Cages made of steel, titanium, PEEK ceramic and carbon fibre are available. Material that is similar to bone in stiffness will give a better result, as subsidence of a hard interbody spacer is a real problem in osteoporotic bone. Cylindrical cages do not conform to the apposing surfaces in the disc space and rectangular cages seem to be better. The central portions of the vertebrae are softer than the peripheral cortical shells that are denser dorsally and ventrally. Rectangular cages or bone grafts supported by these rims are less likely to fail, especially in osteoporotic bones. End plate integrity must be maintained to prevent settling of cages or strut grafts. Bone morphogenic protein improves bone fusion but is very expensive.

SUMMARY

Osteoporosis epidemic is on the rise. Neurosurgeons should have osteoporosis in their minds when they see patients on long-term glucocorticoid or antiepileptic therapy. Simple supplementation of calcium and vitamin D, early diagnosis by BMD measurement, antiresorptive therapy and early pain relief with percutaneous augmentation will help to reduce the morbidity due to osteoporotic vertebral compression fracture.

119 Classification of Tumours of the Nervous System

Vani Santhosh

CLASSIFICATION

The earliest classification of central nervous system (CNS) tumours was that of Bailey and Cushing in 1926.[1] These authors studied the embryogenesis of the various cellular components of the CNS and then attempted to classify tumours based on cytogenesis after enumerating about 20 cell types in the nervous system. The next well accepted classification was that of the World Health Organization (WHO)[73] in 1979, termed 'International Classification of Central Nervous System Tumours'. This represents the initial consensus of opinion put forth by several independent groups. Essentially, it was derived from Bailey and Cushing's classification and, despite widely differing view points, has maintained uniformity on most of the commonly recognised tumour entities and their frequent variants.[72]

This classification was revised and, in 1993, the WHO proposed a new classification of tumours of the nervous system (2nd edition). This was based on the premise that a particular type of tumour occurs as a result of abnormal proliferation of a particular cell type. Since the behaviour of the tumour is determined by the basic cell type, it was clear that tumour classification dictates the choice of therapy and predicts prognosis.[29,36]

The 1993 classification reflects the progress and changes made since the publication of the first edition of nervous system tumour classification in 1979. Several new tumour entities were included, for example, pleomorphic xanthoastrocytoma (PXA), central neurocytoma, desmoplastic infantile ganglioglioma/astrocytoma (DIG/DAI) and dysembryoplastic neuroepithelial tumour (DNET). Histological variants of some of the tumour entities were included. More importantly, with the introduction of immunohistochemical techniques for assisting histological diagnosis, and with increasing morphological and molecular data on glioma progression, it was realised that glioblastoma (GBM) is synonymous with malignant astrocytoma Grade IV and was thus grouped with astrocytic neoplasms. The classification of embryonal tumours was largely retained and the term primitive neuroectodermal tumour (PNET) was used as a generic term for medulloblastomas and other neoplasms that are histologically indistinguishable from medulloblastoma and located at sites in the CNS other than the cerebellum.

The 3rd edition[31] of WHO classification of tumours of the nervous system was published in the year 2000. The format of this classification is different from the earlier two editions in that each tumour entity has been discussed comprehensively, which included the clinical, epidemiological and radiological aspects along with gross and histological morphology, molecular genetic features and predictive/prognostic factors for that tumour. This classification has been made to suit clinicians, pathologists, geneticists and clinical oncologists. The tumours also bear the International Classification of Disease for Oncology (ICD-O) codes, which can facilitate epidemiological analysis of neoplasms of the nervous system.

Some of the new tumour entities included in this classification are: chordoid glioma of third ventricle, cerebellar liponeurocytoma, atypical teratoid/rhabdoid tumour and perineurioma. Some of the histological variants of known tumour entities include; tanycytic ependymoma, large cell medulloblastoma, rhabdoid meningioma and teratoma with malignant transformation. The entity polar spongioblastoma has been deleted from the classification in this edition. In addition, the classification has extensively been revised for meningiomas. Further, this classification emphasises various genetic profiles of tumours and the role of the molecular diagnostic approach to tumour classification, which is considered to have a bearing on the prognosis and therapy, for example, the distinct subtypes of GBM, the clinically useful 1p 19q markers in oligodendrogliomas and 22q/1N11 for atypical teratoid/rhabdoid tumours. In short, the WHO 2000 classification of nervous system tumours was proposed to be used by the neuro-oncologist and the medical research community worldwide.

The 4th edition of the WHO Classification of the Nervous System (2007) is the latest published classification. The changes incorporated in this classification reflect the recognition of new tumour entities and additionally offers a better understanding of tumour behaviour. This classification lists several new entities like angiocentric glioma, papillary glioneuronal tumour, rossette forming glioneuronal tumour of the fourth ventricle, papillary tumour of the pineal region, pituicytoma and spindle cell oncocytoma. Some of the histological variants added are, pilomyxoid astrocytoma, anaplastic medulloblastoma and medulloblastoma with extensive nodularity (MBEN). The WHO grading scheme and the sections on

genetic profiles of CNS tumours have been updated. In the section of familial tumour syndromes, the entity of 'rhabdoid predisposition syndrome' has been included. On similar lines as the WHO 2000 (3rd edition), the classification is accompanied by comprehensive information with the clinicopathological and biological characteristics of each tumour.[5,38,39] Table 1 represents the current WHO classification of CNS tumours.

GRADING OF CENTRAL NERVOUS SYSTEM TUMOURS

The goal of any grading system is that tumour grade should predict the biological behaviour of a neoplasm. It should be sufficiently objective, so as to minimise interobserver variability and maximise reproducibility. Tumour grade is the key factor that influences and guides adjuvant therapy.

WHO has included a grading scheme in its classification and this has largely replaced previously published grading schemes. Most CNS neoplasms are included in the grading scheme except for some newer entities, since additional data and long-term follow-up of these neoplasms are required.[29,31,39]

Significance of Grading

In the CNS, tumours are graded from I to IV. Grade I tumours are those with low proliferative potential and could possibly be cured by surgical resection alone. Grade II tumours are usually infiltrative, have a lower proliferative potential, but often progress to higher grade malignancy and recur, for example, diffuse astrocytoma (DA) (Grade II) which can progress to anaplastic astrocytoma (Grade III) and GBM (Grade IV). Grade III tumours are malignant and these patients have to receive appropriate radiotherapy and/or chemotherapy. Grade IV tumours are cytologically malignant, with brisk mitosis, often associated with necrosis. These patients have a poor prognosis and a fatal outcome. Examples for Grade IV tumours are GBM and most of the embryonal tumours.

Predictive Value of Tumour Grades

WHO grades definitely predict response to therapy and outcome.[39] However, several studies have shown that, apart from tumour grading, other clinical parameters particularly age of the patient, Kernofsky performance status, location of the tumour, radiological characteristics, especially the contrast enhancement pattern, extent of surgical resection, tumour proliferation indices and genetic alterations are the factors that govern the biological behaviour of brain tumours and the prognosis of patients, particularly in gliomas. Despite all these variables, studies have shown that patients with WHO Grades II tumours survive for more than 5 years and those with Grade III tumours survive for 2–3 years. In Grade IV tumours, the prognosis largely depends upon the degree of response to effective treatment regimens. The prognosis for GBM patients is very poor with the mean survival period not exceeding 9–12 months.[33] However, in patients with medulloblastoma and germ cell neoplasms (Grade IV tumours) who have received adequate adjuvant therapy, the 5-year survival rate exceeds 67% and 80%, respectively.[39]

Grading of Astrocytomas

Astrocytomas are the most heterogeneous neoplasms varying in their grades of malignancy within the same neoplasm. Several grading schemes have been applied to this group of tumours, notably that of Ringertz,[56] St. Anne/Mayo[8] and the published WHO schemes.[39] Currently, the objective criteria taken into account for grading astrocytomas are: nuclear atypia, mitotic activity, microvascular proliferation and/or necrosis. Tumours with nuclear atypia alone are graded as II, those with nuclear atypia and mitosis are graded as III and tumours additionally showing microvascular proliferation and/or necrosis are graded as WHO Grade IV neoplasms. This grading scheme is comparable to the St. Anne/Mayo grading system with one major difference, i.e. Grade I astrocytoma. According to WHO, this term refers to pilocytic astrocytoma, which is a circumscribed tumour. However, according to the St. Anne/Mayo grading system, Grade I is designated to a rare DA without nuclear atypia. Currently, the WHO grading system is the one mostly used for ease and uniformity.

Nuclear atypia refers to variation in nuclear size or shape, multinucleation and hyperchromasia. Mitosis should be unequivocal but there is no importance given to their number and morphology. Sometimes it is difficult to differentiate a Grade II from a Grade III astrocytoma, when there is a solitary mitosis in a large tumour. Several authors advocate that MIB-1 labelling indices be used to distinguish accurately a Grade II from a Grade III astrocytoma.[23,48] The term 'endothelial proliferation' or 'microvascular proliferation' refers to 'heaping up' of endothelial cells rather than simple hypervascularity or glomeruloid vasculature. Necrosis can be either of the 'field' type or 'wreath' type with perinecrotic pallisading of tumour cells. It is important to know that these four objective criteria (e.g. nuclear atypia, mitosis in tumour cells, endothelial proliferation and/or necrosis) appear in a predictable sequence as the tumour grade increases.[39] Table 1 represents the current WHO grading of CNS tumours.

ASTROCYTIC TUMOURS

Among CNS neoplasms, astrocytomas are the commonest, comprising more than 60% of the primary tumours. They represent a wide range of neoplasms that differ in their location within the CNS, age and gender distribution, morphological features, growth potential, extent of invasiveness, tendency to progression and clinical course. Astrocytomas are divided into two distinct

Metastatic Tumours	

categories—circumscribed astrocytic tumours and diffusely infiltrating astrocytic tumours.[55]

Circumscribed Astrocytic Tumours

The circumscribed astrocytomas clearly exhibit distinct clinicopathological features. Tumours in this group include: (a) Pilocytic astrocytoma (WHO Grade I) and its variant Pilomyxoid astrocytoma; (b) PXA (WHO Grade II); (c) Subependymal giant cell astrocytoma (SEGA) (WHO Grade I). These tumours are relatively circumscribed and generally tend to have a more favourable prognosis which is due to a reduced capacity for invasive spread and limited potential for growth and anaplastic progression. Therefore, clear recognition of these entities is important.

Pilocytic Astrocytoma (WHO Grade I)

Pilocytic astrocytomas typically arise in children and young adults are more often circumscribed, slowly growing and indolent neoplasms corresponding to

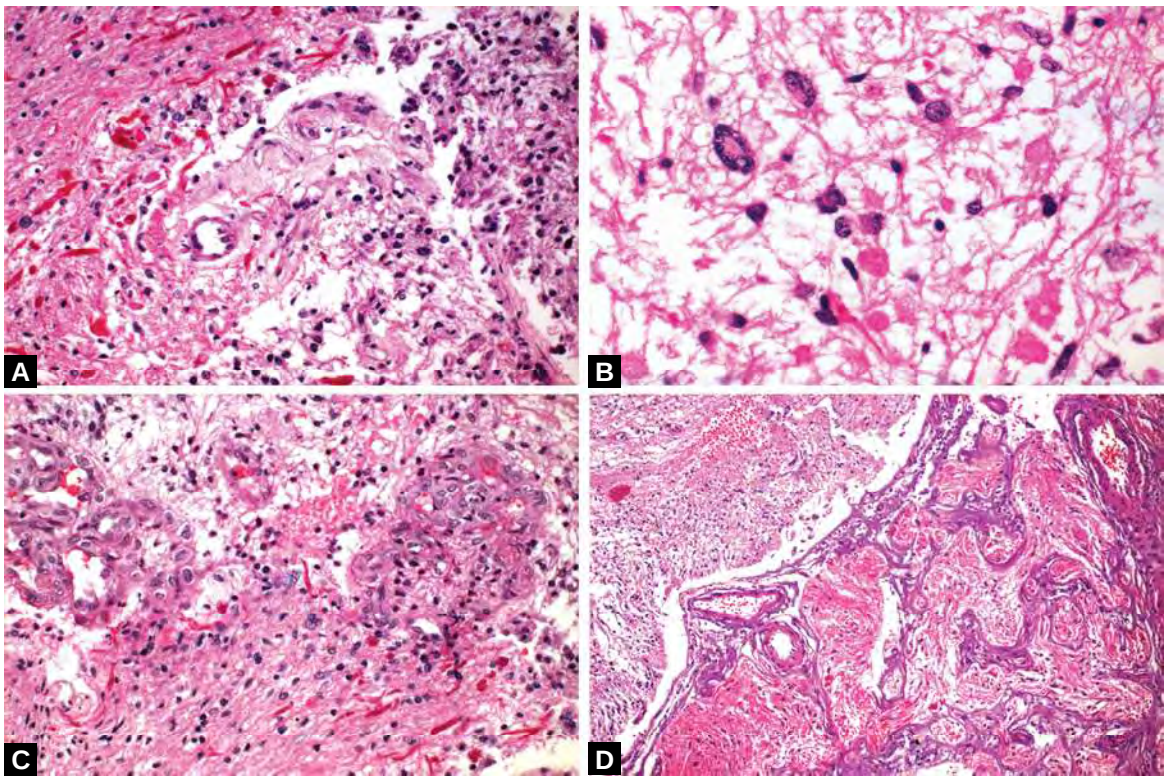
WHO Grade I. Unlike DAs, they have very little tendency for anaplastic progression.

Incidence and localisation: They comprise 3–6% of all intracranial neoplasms and 5–6% of all gliomas.[39] In children, pilocytic astrocytoma is the commonest glial neoplasm[18,33] with a predilection for the cerebellum,[20] optic pathway and the hypothalamic-third ventricular regions[59] and, hence, the synonyms: 'cerebellar astrocytoma', 'optic glioma', etc. Other regions in the neuraxis, like the brainstem, cerebral hemispheres, thalamus and basal ganglia, and spinal cord, can also be involved. In large hypothalamic and brainstem gliomas, when they occupy the ventricular cavity, it becomes difficult to determine their exact site of origin.

Clinical features: The clinical presentation of a pilocytic astrocytoma is that of a slowly growing lesion. Cerebellar tumours present in the first two decades clinically with clumsiness of movements and features of raised intracranial pressure. Brainstem tumours are usually of the dorsal exophytic type[60] and cause hydrocephalus or brainstem dysfunction. Optic pathway tumours present with visual loss and hypothalamic/pituitary dysfunction as is seen in patients with large hypothalamic tumours.[59] Tumours in the cerebral hemispheres produce focal neurological deficits or non-localising signs and in the spinal cord, present as an expanding mass.

Neuroimaging: By CT and MRI, these tumours are relatively circumscribed and the majority have a heterogeneously enhancing cyst with a mural nodule (Fig. 1A). The nodule is not hyperdense. These characteristics distinguish them from DA (WHO Grade II). Exceptionally, the tumour can be a solid lesion and calcification is seen in 5–25% of cases.[15]

Histopathology: Classically, pilocytic astrocytoma demonstrates a biphasic pattern of growth, consisting of compact portions composed of elongated, bipolar or 'piloid' astrocytes associated with Rosenthal fibres and microcystic zones being made up of multipolar cells, eosinophilic granular bodies (EGB) and hyaline droplets (Figs 1B and C). Several times, pilocytic astrocytomas show extensive degenerative nuclear atypia with pleomorphic and hyperchromatic nuclei (Fig. 1D). However, mitotic activity is not evident or a rare mitotic figure may be seen. Glomeruloid vascular proliferation is frequently observed in cerebellar and hypothalamic pilocytic astrocytomas. This is responsible for the contrast enhancement seen on MRI and can occasionally cause diagnostic confusion with high grade astrocytomas, particularly in small biopsies. However, endothelial hyperplasia, a feature of high grade diffuse astrocytic tumours, is not evident in pilocytic astrocytoma.[20] In pilocytic astrocytomas, vascular proliferation, mitotic activity and necrotic



Figs 1A to D: Histological features of pilocytic astrocytoma. (A) Compacted piloid cells with Rosenthal fibres and loose textured cells with microcysts (HE X 320). (B) Marked nuclear atypia in the absence of mitosis and presence of several eosinophil granular bodies (HE X 320). (C) Prominent glomeruloid vascular proliferation in the tumour (HE X 320). (D) Subarachnoid spread of the tumour (HE X 320)

foci, even when present, do not have the same ominous prognostic significance as in DAs.

Since pilocytic astrocytomas are slowly growing, indolent neoplasms, they can histologically show several regressive changes. One such feature is markedly hyalinised ectatic vessels which can at times resemble a cavernous angioma with piloid gliosis. Along with this, there can be haemosiderin-laden macrophages reflecting an old bleed. Other regressive changes include calcification, infarct-like necrosis and tumour infiltrating lymphocytes[39] and, occasionally, hyperchromatic large nuclei resembling a malignant cell.

Sometimes pilocytic astrocytomas (particularly those arising in the cerebellum and optic nerve) infiltrate the leptomeninges and impart a distinct lobular pattern to the tumour. This is not indicative of aggressiveness and malignant transformation, nor does it portend subarachnoid dissemination. In contrast, it is a characteristic and diagnostically helpful feature. Other histological features seen at times include oligodendroglioma-like cells seen particularly in cerebellar tumours and pallisading arrangement of cells that resemble what was termed as 'primitive polar spongioblastoma'.

Pilocytic astrocytomas are very indolent tumours with a low proliferative index. The MIB-1 labelling indices range from 0 to 3.9% (mean 1.1%) (Fig. 1C). Very rarely pilocytic astrocytomas undergo malignant transformation with high mitotic activity, endothelial proliferation and pallisading necrosis and have been termed anaplastic (malignant) pilocytic astrocytoma. It is presumed that such tumours occur as a result of radiotherapy given to a previous pilocytic astrocytoma.[10]

Histogenesis: It is presumed that pilocytic astrocytomas arise from radial glia which are present in the hypothalamus, cerebellum and the spinal cord during development, and the glial cells of the pineal gland. These astrocytes presumably have the capacity to form Rosenthal fibres and the hair-like 'piloid fibres'.

Prognostic and predictive factors: Pilocytic astrocytomas are very slowly growing tumours which stabilise during their course of evolution. Recurrence is rare and most often is a reflection of cyst reformation. Supratentorial neoplasms and delay in radiotherapy, when required, are associated with shorter survival.[28] Recurrent hypothalamic and brainstem tumours are known to have increased morbidity and mortality.[59] Pilocytic astrocytomas associated with neurofibromatosis-1 (NF-1) tend to be less aggressive and sometimes spontaneously regress.[61] The prognosis of these tumours labelled as 'atypical' or 'malignant' is not very clear.[39]

Pilomyxoid Astrocytoma (WHO Grade II)

Pilomyxoid astrocytoma is a recently recognised variant of pilocytic astrocytoma. These tumours manifest in very young children, below the age of 4 years (median 10 months), most often in the hypothalamus or 3rd ventricular region, but can occur at other sites common to pilocytic astrocytoma.[69] Distinct histopathological features include a monomorphic bipolar population of neoplastic pilocytes in a prominent myxoid background in an angiocentric arrangement (Fig. 2). Rosenthal fibres and EGBs are absent, mitotic activity is slightly higher and the MIB-1 labelling index ranges from 2 to 20%. Immunostaining demonstrates strong diffuse reactivity to GFAP, S-100 protein and vimentin. Some tumours are positive for synaptophysin.[39]

Histogenesis: The cell of origin is not known but some state that the tumour arises from radial glia in the proximity of the optic tract.

Prognostic and predictive factors: These tumours are more aggressive than pilocytic astrocytomas.[69] Local recurrence and craniospinal seeding have been observed.

Pleomorphic Xanthoastrocytoma (WHO Grade II)

This is another circumscribed variant of astrocytoma with a favourable prognosis, typically occurring in young adults and children, in the superficial cerebral hemispheres, in close association with the leptomeninges and often as a cystic neoplasm with a mural nodule.

Incidence and localisation: PXA accounts for less than 1% of all intracranial neoplasms. Typically, the tumour is located in the superficial cerebral cortex often involving the leptomeninges (therefore also called meningocerebral glioma). The tumour is most often located in the temporal cortex followed by the parietal and frontal cortex.[17]

Clinical features and neuroimaging: Most patients have long standing seizures given the superficial location of the tumour. By CT and MRI, these tumours are well circumscribed or cystic masses with an enhancing mural nodule. Peritumoural oedema is not pronounced owing to the slow growth of the tumour and calcification is uncommon.

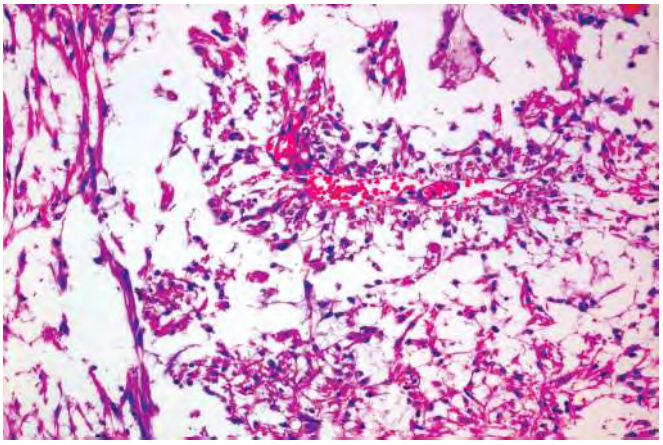


Fig. 2: Pilomyxoid astrocytoma: the tumour shows a monomorphic population of piloid cells in a homogeneously myxoid background. Angiocentric arrangement of tumour cells is also seen (HE X 320)

Histopathology: The tumour is circumscribed (Fig. 3A) and composed of closely packed, highly pleomorphic giant and lipidised cells. Variable xanthomatous change is seen in the cytoplasm because of intracellular accumulation of lipids. The astrocytic nature of the tumour cells is demonstrated by GFAP immunopositivity. Prominent EGB is a constant finding. A dense intracellular reticulin network and lymphocytic infiltrates are typical microscopic features. Necrosis and mitosis are usually absent. Another histological hallmark of PXA is the presence of intratumoural reticulin fibres, best seen using silver impregnation (Fig. 3B). By immunohistochemistry, the tumour cells are constantly positive for GFAP and S-100 protein. However, variable expression of neuronal markers has been reported.[25] The behaviour of PXA is generally that of an indolent tumour and most tumours have a MIB-1 labelling index of less than 1%. However, a small percentage of PXAs can recur and undergo malignant transformation. These tumours show higher mitotic activity (5 or more mitosis in 10 HPF) and are termed as 'PXA with anaplastic transformation'. On recurrence, the tumour might show histological features similar to the original tumour or increasing anaplasia.[39]

Histogenesis: It has been proposed that PXA arises from subpial astrocytes.[27] Ultrastructural studies have shown that both the subpial astrocytes and the tumour cells of PXA have a prominent basal lamina, which accounts for the rich reticulin network within the neoplasm. Some authors, however, state that PXA has a more complex histogenesis in view of the expression of neuronal and other markers by the tumour cells.[24]

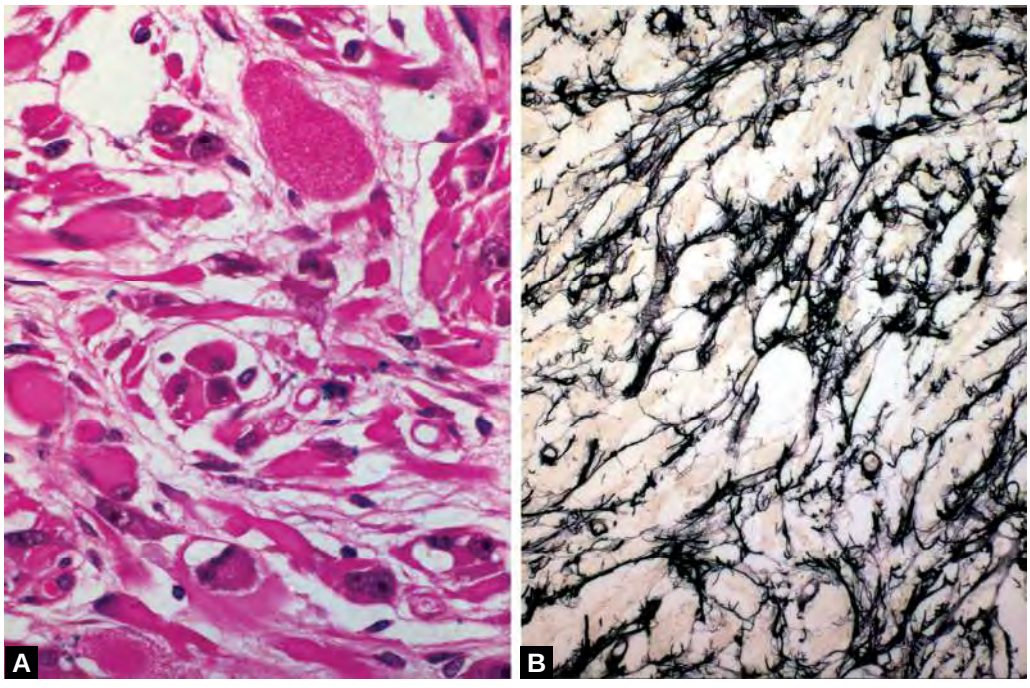
Prognosis and predictive factors: Despite its pleomorphic histomorphology, the prognosis of patients with PXA is favourable. Extent of tumour resection and a low proliferative index are definite prognostic factors. In one large series,[17] recurrence-free survival of 72% at 5 years and 61% at 10 years has been observed.

Subependymal Giant Cell Astrocytoma (WHO Grade I)

This is a benign, slowly growing tumour composed of large cells resembling gemistocytes and ganglion cells (ganglioid astrocytes), typically arising from the walls of the lateral ventricle.

Incidence and clinical features: SEGA is the most common CNS tumour in patients with tuberous sclerosis complex (TSC). Its incidence ranges from 6 to 14% in patients with confirmed TSC and it is one of the major criteria for the diagnosis of TSC.[58] The tumour manifests mostly in children and young adults and the patients often present with worsening of seizures or symptoms of raised intracranial pressure.[57]

Histopathology: SEGAs show a wide phenotypic spectrum of astrocytes ranging from polygonal and spindle shaped astrocytes to large polygonal cells resembling gemistocytic astrocytes with abundant glassy cytoplasm. In addition, characteristic giant pyramidal cells with a ganglionic appearance and nuclei with prominent nucleoli are also seen (Fig. 4). Occasional nuclear pleomorphism and multinucleated giant cells can be seen in SEGA. However, mitosis is absent or very rare and the proliferative index is generally low (mean 1.5–7.4%).The tumours are extremely vascular with numerous dilated vessels resembling cavernous spaces and this results in massive spontaneous haemorrhage in the tumour. Calcification is a common feature. By



Figs 3A and B: Pleomorphic xanthoastrocytoma. (A) Tumour shows highly pleomorphic astrocytes and eosinophil granular bodies. There is no mitosis (HE X 320). (B) Reticulin stain highlights the extensive intra-tumoural reticulin fibres (HE X 320)

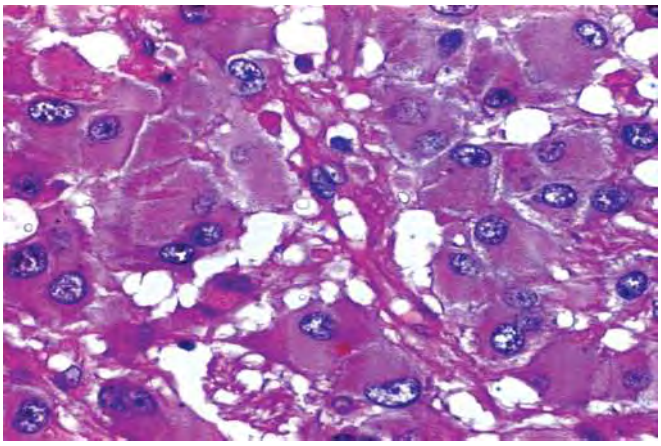


Fig. 4: Subependymal giant cell astrocytoma (SEGA) showing characteristic 'Ganglioid astrocytes' (HE X 320)

immunohistochemistry, the tumour cells express mixed glioneuronal markers. There is variable expression of GFAP and S-100 protein and some cells also express neurofilament protein and other neuronal markers including several neuropeptides. These findings suggest that SEGA contains cells with a capacity for divergent phenotypic differentiation including glial, neuronal and neuroendocrinal forms.[39]

Diffusely Infiltrating Astrocytic Tumours

This group encompasses at least 75% of the astrocytic tumours and termed as 'diffusely infiltrating astrocytomas'. This is further subdivided into: (a) DA/WHO Grade II; (b) Anaplastic astrocytoma (WHO Grade III) and (c) Glioblastoma (GBM-WHO Grade IV) and its variants such as giant cell GBM and gliosarcoma are currently also included in this group.[39] This category inevitably has a more ominous prognosis due to significant tendency for these tumours to undergo malignant transformation, infiltrate the surrounding brain and to invade the leptomeninges.

Diffuse Astrocytoma (WHO Grade II)

This is a diffusely infiltrating astrocytoma which is considerably differentiated, usually manifesting in young adults and most often supratentorial in location. It has an intrinsic tendency for malignant transformation, progressing to anaplastic astrocytoma and finally to GBM.[39]

Incidence and localisation: DA comprises 10–15% of all astrocytic neoplasms.[9] The peak incidence is in young adults between 30 years and 40 years of age. The tumour may be located anywhere in the CNS, but is mostly encountered in the cerebral hemispheres. Other common sites include the brainstem and spinal cord.

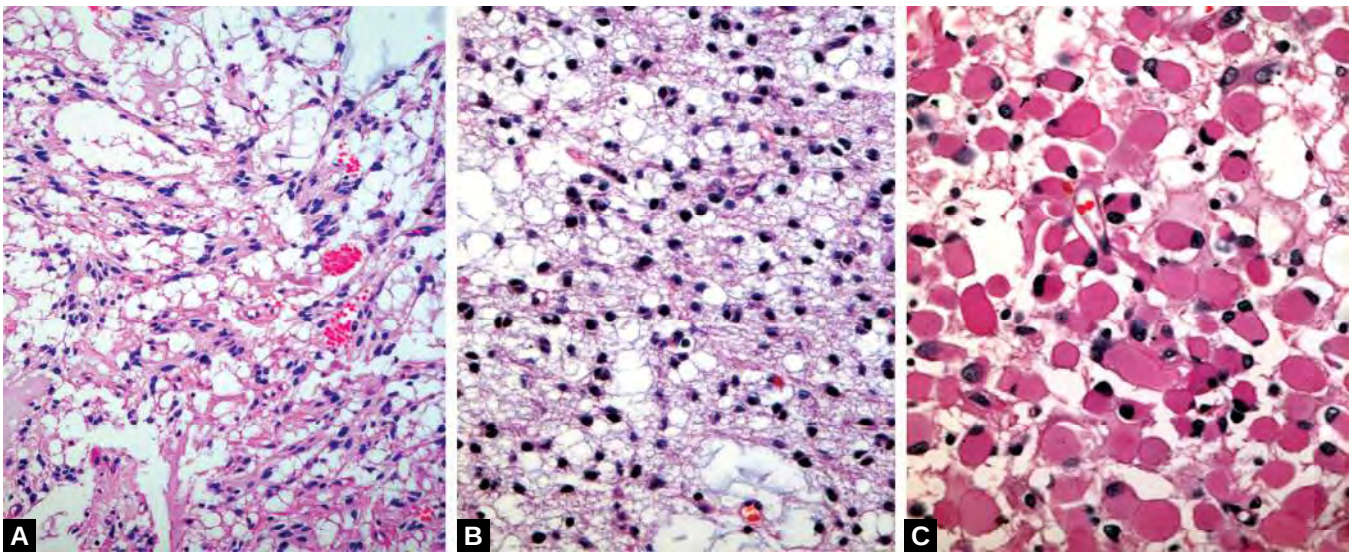
Clinical features and neuroimaging: Seizures are the most common presenting symptom. Others are subtle and include features of raised intracranial pressure, motor deficits, speech and cognitive dysfunction.[67] In contrast to pilocytic astrocytomas, on CT and MRI, these tumours are ill-defined, homogeneous masses of low density without contrast enhancement.[64]

Histopathology: DAs may be subdivided into fibrillary, gemistocytic and protoplasmic types based on the resemblance to the morphology of normal and reactive astrocytes (Figs 5A to C). In practice, most are fibrillary but mixed neoplasms, especially gemistocytic elements are common. These are mildly hypercellular tumours exhibiting a moderate degree of nuclear atypia. The cells are embedded in a loosely fibrillated, microcystic matrix. Mitosis is absent and infiltration of the cortex is seen. An occasional mitosis which can be seen at times does not allow the diagnosis of anaplastic astrocytoma.[39] The fibrillary variant is the most frequent type and is a mildly hypercellular neoplasm composed of well differentiated spindle to stellate cells with mild to moderate nuclear atypia, separated by a loosely fibrillated and sometimes microcystic matrix. Mitotic figures are absent or very rare. Some show prominent infiltration of the cortex. Protoplasmic forms are composed of small tumour cells with round nuclei and limited number of delicate cytoplasmic processes. Gemistocytic variants contain usually more than 20% of gemistocytes. These cells are plump, with glassy, abundant cytoplasm. Some studies indicate that gemistocytic astrocytomas are prone to undergo malignant progression to a higher grade more rapidly than ordinary DAs and accordingly warrant more aggressive therapy.[64] Perivascular tumour infiltrating lymphocytes are commonly seen. The MIB-1 labelling index is less than 4% in these tumours and this is an important tool which can be used to differentiate DAs from anaplastic astrocytomas.[62]

Prognostic and predictive factors: These tumours are known to progress to anaplastic astrocytomas within a mean period of 4–5 years. Malignant progression is determined by clinical and biological factors.[49,66] Some of the recognised clinical parameters that are associated with a favourable prognosis include age of the patient, seizures as the single presenting symptom and gross total resection of tumour. Among histopathological factors, tumours with a significant proportion of gemistocytes tend to progress more rapidly to anaplastic astrocytoma.[32] Some studies have shown that presence of tumour infiltrating lymphocytes and microcystic degeneration in the tumour are associated with a slightly better prognosis.[53] A MIB-1 labelling index of greater than 5% has been found to constitute a threshold value for early progression. The presence of p53 mutations has not been found to be useful in prognostication in these tumours.[37,39]

Anaplastic Astrocytoma (WHO Grade III)

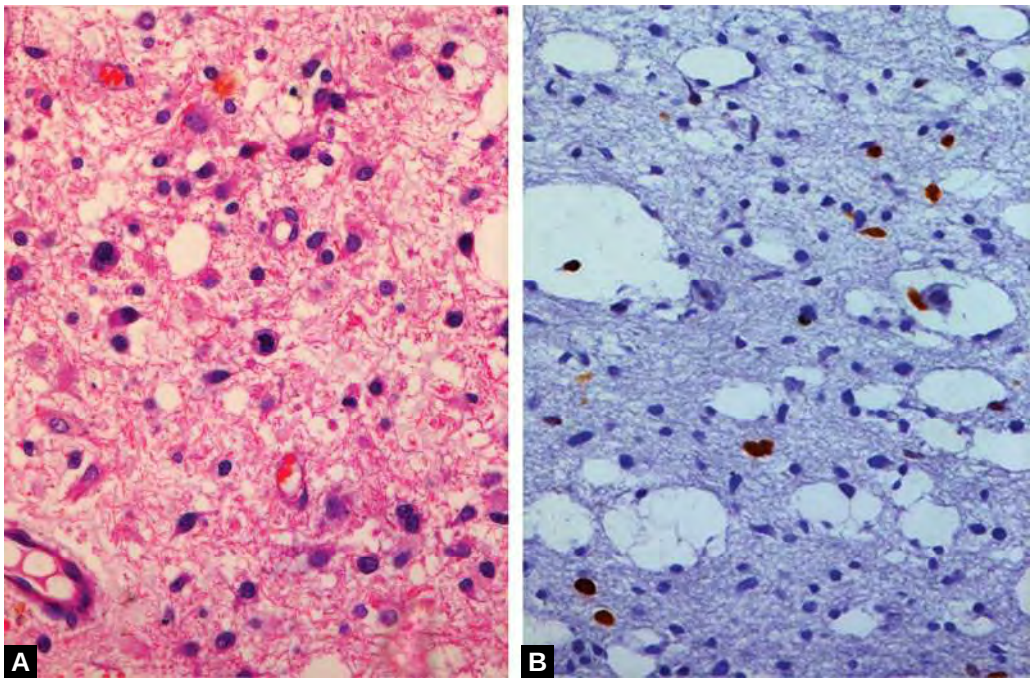
This is a more cellular, diffusely infiltrating tumour arising in the cerebral hemispheres and, apart from significant nuclear atypia in the tumour cells, show prominent mitotic activity. These tumours may arise from a pre-existing DA or *de novo*.



Figs 5A to C: Diffuse astrocytoma grade II. The tumour can be composed of fibrillary astrocytes. (A) Protoplasmic astrocytes. (B) Gemistocytic astrocytes. (C) Note the prominent microcystic stroma in A and B (HE, AX160: BX160: CX320)

Incidence, localisation and clinical features: The mean age at which the tumour is detected is 45 years.[51] Tumours are most often located in the cerebral hemispheres. Symptoms are similar to those of DA and in some patients, where the tumour arises from a pre-existing DA, the symptoms are of longer duration. Radiologically they show variable contrast enhancement and significant perilesional oedema.

Histopathology: Histologically these tumours resemble DAs. However, in addition to nuclear atypia, they exhibit increased mitosis (Figs 6A and B). Since anaplastic features may be focal, the prognostic value attached to grading minute fragments obtained by stereotactic biopsies depends on the representative sampling of the neoplasm. In such samples, presence of a single mitosis is significant and indicative of malignancy. However, if the sample is ample as obtained from open surgery, the presence of a single mitosis is not sufficient to grade the tumour as anaplastic. In such cases, MIB-1 labelling would definitely improve diagnostic accuracy.[23] The MIB-1 labelling index in anaplastic astrocytomas ranges from 5 to 10%.[39]



Figs 6A and B: Anaplastic astrocytoma-grade III. (A) The tumour is hypercellular and exhibits mitotic activity (HE X 320). (B) Nuclei of several cells show immunoreactivity for the proliferation marker MIB-1 (HE X 320)

Prognostic and predictive factors: These tumours are known to progress to GBM in a mean time interval of approximately 2 years. The clinical prognostic factors are similar to those in DAs.[39]

Glioblastoma (WHO Grade IV)

This is the most common and most malignant glioma arising in adults and despite advances in therapeutic strategies, these patients have a dismal prognosis.

Incidence and localisation: GBMs are the most frequent brain tumours accounting for about 12–15% of all intracranial neoplasms and more than 60% of all astrocytic tumours.[51] The peak incidence is between 45 years and 75 years.[39,51] The tumour occurs mostly in the cerebral hemispheres, affecting the subcortical white matter and spreading to the superficial grey matter. The tumour is known to spread across the corpus callosum to the contra lateral hemisphere and such tumours are referred to as 'butterfly gliomas' (Fig. 7A). The deep nuclear masses, particularly the thalamus and basal ganglia are also sites for GBM, especially in children.[39] Brainstem GBMs often affect children.[11] The cerebellum and spinal cord are rare sites for this neoplasm.

Clinical features and neuroimaging: Most patients present with features of raised intracranial pressure and focal neurological deficits. Extensive haemorrhage may occur within the tumour and produce stroke-like symptoms clinically. The duration of symptoms is short (less than 3 months) in the majority of patients, and these tumours are *de novo* or primary GBMs. In others, the tumour occurs as a result of progression from a lower grade astrocytoma and such patients have a longer duration of symptoms. Such tumours are referred to as secondary GBM.[52]

Imaging features: On imaging, GBMs often have a low density centre which is mainly due to variegated necrosis, and an enhancing rim due to enhanced neovascularity and a hypercellular, fleshy neoplasm. There is also a corona of oedema around the tumour (low density, hypointense on T1-weighted image and hyperintense on T2-weighted image). This is attributed to 'oedematous' white matter and areas of neoplastic infiltration.

Histopathology: The cellular morphology is highly variable and hence the term 'GBM multiforme'. The tumour usually contains highly pleomorphic cells with fibrillary astrocytes that are admixed with gemistocytic, lipdised and multinucleated giant cells and clusters of small undifferentiated cells. Occasionally, within the tumours large granular cells with PAS positive cytoplasmic granules can be present in small groups. Nuclear atypia is significant and mitosis is brisk with several bizarre mitotic figures. Some of these tumours, however, are composed of sheets of undifferentiated small cells that should be differentiated from de-differentiated anaplastic oligodendrogliomas or even lymphomas and primitive neuroectodermal tumours. Such tumours form a subset called 'small cell GBM'. Sometimes, there can be foci of large epithelial-like cells within GBMs with reduced expression of GFAP. These tumours are referred to as 'adenoid GBM' and are mostly seen in recurrent samples of GBM. A mucinous stroma and a 'mesenchymal' component (gliosarcoma) can also be present. Rarely GBMs may contain an oligodendroglial component and these tumours are currently being described as 'GBM with oligodendroglial component' and these tumours have been found to have a marginally better survival rate.[39]

Glioblastoma is a highly vascularised neoplasm. The tumour always shows extensive neovascularisation (sprouting angiogenesis). In addition, several large feeder vessels show marked sclerotic changes, abnormal branching and thrombosis.[39] One of the histological hallmarks of GBM is the presence of microvascular proliferation, which is characterised by heaping up of proliferating endothelial cells along with pericytes and vascular smooth muscle cells. These are called "glomeruloid tufts". These endothelial cells are mitotically active. Another fundamental feature of GBM is necrosis. Two types of necrosis can be distinguished, large ischaemic necrotic zones called 'field' necrosis and multiple irregularly shaped serpigenous pseudopallisading necrosis called 'wreath' necrosis. Compared to adjacent tumour cells, pseudopallisading cells show higher apoptotic and lower proliferative rates (Figs 7B to H).

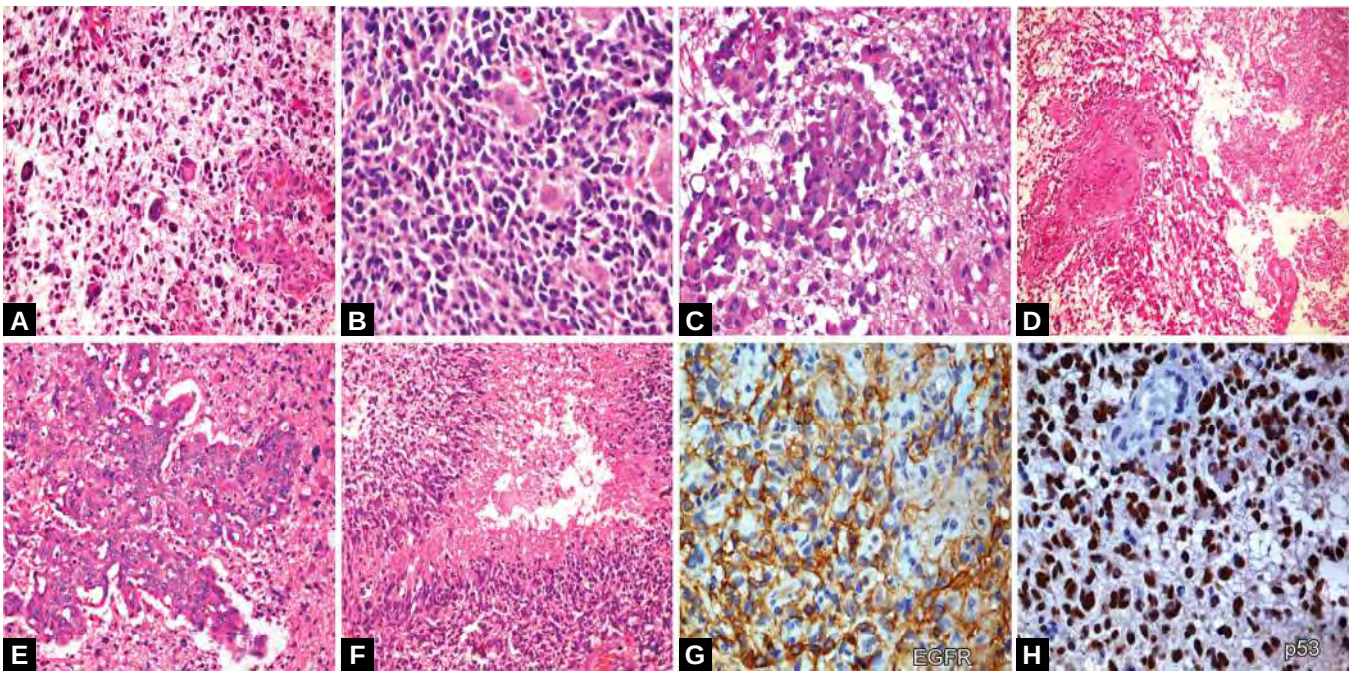
Glioblastomas are known to have extensive invasive capacity. They arise and spread in the white matter and diffusely infiltrate the grey matter. The pattern of spread is perineuronal (called 'satellitosis'), perivascular, subependymal and subpial, and spread along myelinated tracts is also seen. Such morphological patterns of spread are referred to as 'secondary structures'. They are highly diagnostic of diffusely infiltrative tumours such as GBM, oligodendroglioma and gliomatosis cerebri.[39]

Biology/Molecular Genetics/Predictive and Prognostic Factors

Molecular Genetics

Two interrelated concepts of molecular oncogenesis have been developed over the past three decades and it is now proposed that initiation and progression of astrocytomas, similar to several other neoplasms, are under the influence of tumour promoting oncogenes and tumour suppressor genes. Accordingly, two pathways have been defined in the development of classical GBM resulting in the formation of primary and secondary GBM.[63]

Primary GBM occurs in elderly individuals, presenting with a short clinical history and no clinical or histological evidence of progression from a lower grade astrocytic glioma as precursor. Molecular genetic studies have shown that the majority of these tumours have amplified oncogenes like the epidermal growth factor receptor (EGFR) gene on chromosome 7. They also possess deletion in the cell-cycle-related INK4a-ARF genes, $p16^{INK4a}$ and $p19/p14^{ARF}$. Mutations of the *p53* gene



Figs 7A to H: Glioblastoma grade IV. (A) The tumour is composed of pleomorphic astrocytes with increased mitosis. Note the microvascular proliferation (HE X 320). (B) Small cell variant of glioblastoma shows sheets of undifferentiated astrocytes (HE X 320). (C) Adenoid variant of glioblastoma with groups of cells having epithelial morphology (HEX160). (D) Large areas of ischaemic necrosis in the tumour. Also note sclerosed and thrombosed vessels adjacent to zones of necrosis (HE X 160). (E) Microvascular proliferation with formation of 'glomeruloid tuft' (HE X 160). (F) Characteristic pseudopalisading necrosis (HE X 160). (G) Cytoplasmic membrane labelling of EGFR, seen often in primary glioblastoma (Immunoperoxidase x 320). (H) Nuclear accumulation of *p53* in tumour cells and not endothelial cells, seen often in secondary glioblastoma (immunoperoxidase x 320)

(tumour suppressor gene on chromosome 17p13.1) are infrequent and noted in less than 10% of cases. However, the other tumour suppressor gene that is often mutated is the phosphate and tensin homology (PTEN) gene located on chromosome 10. On the other hand, secondary GBMs evolve from a lower Grade II or Grade III DA. They occur in younger individuals and show predominantly p53 mutations along with other genetic alterations such as amplification of CDK-4 or loss of Rb involved in cell cycle regulation. Tumours in this younger group of patients also tend to express a different signal transduction alteration-amplification or over expression of platelet derived growth factor (PDGF). It is not clear whether these two variants of GBM (primary and secondary) are different prognostically. However, understanding the pathways underlying their development would help in future to design novel therapeutic strategies.[30]

Epidermal growth factor receptor: The oncogene encoding EGFR is located on chromosome 7. EGFR is a transmembrane receptor that can sense extracellular ligands, like EGF and TGF-α, and subsequently transduce the proliferation signal. EGFR gene amplification is seen most often in primary GBM (in about 40% of cases), always associated with protein over expression. EGFR amplification is often associated with structural alterations of the gene forming truncated variants, like EGFR VIII,[2] leading to uncontrolled cell proliferation via the PI3-kinase, RAS and mitogen-activated protein kinase signalling pathways. In view of this, EGFR VIII is a promising target for therapy.[7]

The other forms of GBM include giant cell GBM and gliosarcoma. In contrast to classical GBM, these variants always develop *de novo*, and have a distinctly different molecular pathway compared to classical GBMs.

Phosphate and tensin homology: This gene is located on chromosome 10q 23.3 and plays a major role in the PI3K/EGFR/AKT pathway. In this pathway, EGFR, when activated after binding to its ligands, recruits PI3K (phosphatidylinositol 3-Kinase) to the cell membrane. PI3K converts PIP2 (phosphatidylinositol-4,5-bisphosphate) to PIP3 which in turn activates its downstream molecules such as AKT and mammalian target of Rapamycin (mTOR). This in turn leads to uncontrolled cell proliferation and survival. Normally PTEN inhibits the PIP3 signal and inhibits proliferation. It gets mutated in about 15–40% of GBMs, mostly primary GBMs.[70]

The p53 tumour suppressor gene that is located on chromosome 17p 13.1 encodes for a 53 kDa nuclear phosphoprotein which plays an important role in regulation of the cell cycle, and in cell response to DNA damage and other vital cellular functions.[4] This gene is mutated in several human neoplasms and notably in astrocytic glioma.[41] The wild type protein is not detected by

immunohistochemistry due to its short half-life and it is the mutated, thus highly stable protein that is detected.[7] p53 mutations are seen in more than 65% of secondary GBMs and are generally evident in lower grade astrocytoma.[30] Mutations occur less frequently (about 25%) in primary GBMs also. Another gene, the MDM2 (located on chromosome 12q 14.3), inhibits the actions of wild type p53. Interestingly, the transcription of MDM2 is induced by wild type p53.[3] In normal cells, this autoregulatory feedback regulates the activity of these two genes. MDM2-mediated degradation of wild type p53 is further regulated by $p14^{ARF}$ which binds to MDM2. Therefore, loss of function of the tumour suppressor gene p53 can occur when there are alterations of either the p53 gene itself or of MDM2 and/or $p14^{ARF}$ amplification. Over expression of MDM2 occurs in greater than 50% of primary GBMs and loss of function of $p14^{ARF}$ occurs both in primary and secondary GBMs.[52] Cell cycle control is also regulated by the $p16^{INK4a}$/CDK4/RB1 signalling pathway. Alteration of this pathway can also lead to neoplastic transformation. This pathway is disrupted in a variable proportion of primary and secondary GBMs. Loss of heterozygosity (LOH) of chromosome 10 occurs frequently in GBMs.[52] LOH of 1p and 19q are also noted in GBMs in varying proportions.[39]

Parameters of Invasiveness

DAs have the inherent property to invade brain parenchyma, which is largely independent of the histological grade. GBMs, however, have the highest invasive capability. These properties may be related to the capability of tumour cells to modify the various extracellular matrices (ECM) in the CNS which in turn facilitates invasion. Studies on several adhesion molecules, which play an important role in modifying ECM components, have begun to yield data which ultimately may be useful in diagnosis and prognostication.

Recent gene expression profiling studies have revealed subsets of GBMs with increased expression of ECM components and intracellular proteins that are associated with cell motility. Several molecular determinants of invasion have been described including activation of TGF-β and AKT pathways.[71] Since invasion due to protease activity is rather a late effect in tumourigenesis, it provides an attractive target for therapeutic intervention in established tumours. Several protease inhibitors are currently being tested in clinical trials.

Tumour Angiogenesis

Astrocytoma development and progression is always accompanied by the formation of new blood vessels. GBM is the most vascularised of all human neoplasms. The classical angiogenesis is the sprouting angiogenesis, in which there is recruitment of endothelial cells by neoplastic astrocytic cells, endothelial cell proliferation, migration and vasculogenesis.[12] Angiogenesis in gliomas is regulated by several factors. Hypoxia is the important underlying factor and this leads to accumulation of hypoxia-inducible factor 1-α (HIF-1α) which in turn leads to transcriptional activation of several genes that regulate angiogenesis, cellular metabolism, cell proliferation/apoptosis and migration.[12] An important downstream target of HIF-1α is vascular endothelial growth factor (VEGF). VEGF is mainly produced by the perinecrotic pallisading neoplastic cells in GBMs. Current evidence suggests that VEGF, which binds to VEGF receptors 1 and 2, is the most important regulator of vascular functions in glioma induced angiogenesis.[40] This is upregulated not only in all high grade astrocytomas, but also in a sub-set of low grade DAs which can progress to a malignant phenotype, suggesting that malignant transformation in low grade astrocytomas is at least partly based on their inherent angiogenic potential. This could form a basis in future for providing a rationale for therapeutic strategies directed at inhibiting the angiogenic process and, thus, tumour progression in patients with astrocytomas.

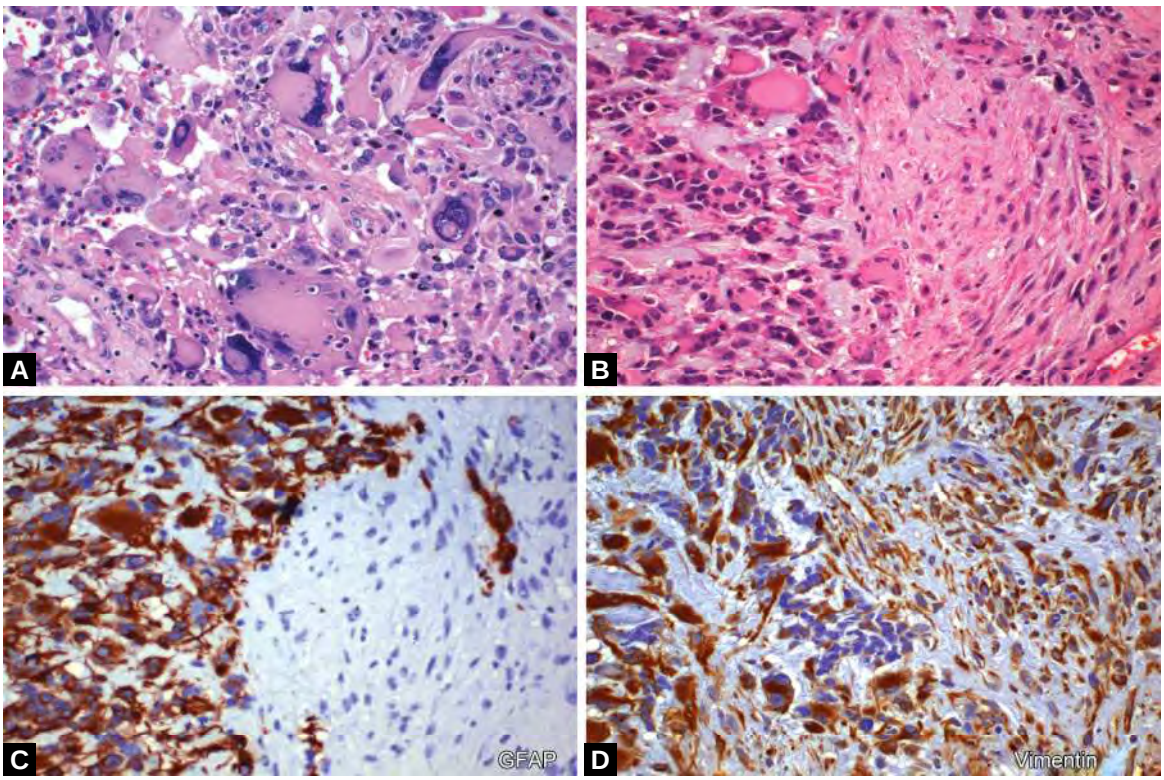
Gene Expression Profiles in Glioblastomas

Microarray expression profiling of GBM allows simultaneous analysis of thousands of genes and is likely to identify molecular markers associated with tumour subtype, progression and patient survival.[34] Through cDNA microarray experiments, several distinct gene categories of transcripts differentially expressed in different sets of GBMs have been currently identified.[68]

Prognostic and Predictive Factors

The prognosis of patients with GBM is dismal, with a mean survival of 10–12 months. Currently available treatment options are multimodal, which include surgery, radiotherapy and chemotherapy, but these have shown to improve survival only marginally in these patients.[33] Most multivariate studies have shown that age and Kernofsky performance score are strong predictors of outcome in patients with GBM. Younger patients are known to have a better prognosis in most studies.[6] On histology, the extent of necrosis correlated with poor prognosis in some studies.[21] There has been no consistent correlation between p53 mutations, EGFR amplification and patient survival.[50]

Temazolamide is one of the important alkylating agents currently used in the treatment of GBMs. It causes tumour cell death by forming cross-links between adjacent strands of DNA by alkylation of O^6 position of guanine.[47] O^6-methylguanine-DNA methyl transferase (MGMT) is the repair enzyme that removes the O^6 position in DNA and in turn protects cells from the effect of alkylating agents.[44] Hypermethylation of the promoter, CpG islands of the gene results in loss of MGMT expression thus enhancing susceptability to the alkylating agent. MGMT promoter hypermethylation in



Figs 8A to D: Giant cell glioblastoma and gliosarcoma. (A) Several bizarre tumour giant cells in giant cell glioblasoma (HE X 320). (B) Gliosarcoma with biphasic gliomatous (left) and sarcomatous components (HE X 320). (C) The gliomatous component shows strong GFAP immunoreactivity (Immunoperoxidase X 320). (D) Vimentin staining is seen in both the gliomatous and the sarcomatous components (Immunoperoxidase X 320)

GBM is seen in some patients and is associated with longer survival.[19]

A few biomarkers have currently been identified in the serum of GBM patients.[39] YKL-40 is one such marker. It is known to be over-expressed in GBM tissues and is a secretory protein. Its detection in the serum has been used to monitor GBM patients for early tumour recurrence.[22]

Giant Cell Glioblastoma

These tumours are characterised by the presence of numerous bizarre multinucleated giant cells (Figs 8A to D) which are sometimes lipidised, with an abundant reticulin network and, thus, can be mistaken for PXAs. They show high frequency of p53 mutations. It accounts for nearly 5% of all GBMs. They have a relative circumscription and are firm tumours. On imaging they can be mistaken for a metastatic deposit. Microvascular proliferation is exceptional. The cells are variably positive for GFAP, but constantly show reactivity to S-100 protein, vimentin, β-tubulin, p53 and EGFR. In view of their less infiltrative nature, patients with this tumour are reported to have a better prognosis than in classical diffusely infiltrating GBM.[43]

Gliosarcoma

This tumour is characterised by a dual population of glial and mesenchymal cells. It accounts for 2% of all GBMs.[39] In tumours with a predominant mesenchymal component, the tumour appears as a well demarcated hyperdense mass with homogeneous contrast enhancement mimicking a meningioma.[42] The demonstration of a distinct malignant mesenchymal component which is GFAP negative is necessary to distinguish gliosarcoma from desmoplastic response in a GBM with meningeal infiltration. Currently there is cytogenetic and molecular evidence of a monoclonal origin for both glial and mesenchymal elements of this malignant tumour.[45] Some studies have shown these tumours to have a better prognosis than classical GBM,[46] although not supported by other series.

Gliomatosis Cerebri

This tumour is defined as a diffuse glioma, usually astrocytic, showing extensive infiltration of the cerebral hemispheres, involving at least three cerebral lobes, usually with bilateral and/or deep grey matter involvement, and with frequent extension to infratentorial structures.[39] It corresponds to WHO Grade III. By CT and MRI, there is diffuse enlargement of cerebral structures without tissue destruction or focal tumour mass or 'epicentre'. T2 weighted or FLAIR MR sequences reveal the full extent of the tumour with significant signal hyperintensity. This spreading neoplasm produces minimal mass effect. Histologically, the tumour cells are most often astrocytic, but cases with oligodendroglial cells or

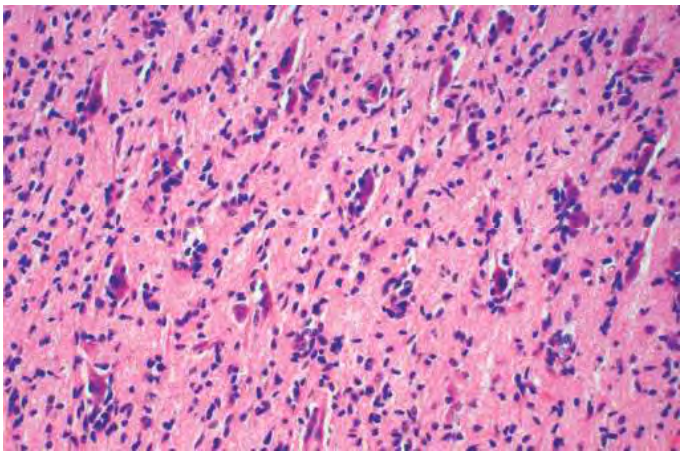


Fig. 9: Gliomatosis cerebri: there is a diffuse infiltration of the cortical grey matter by undifferentiated fibrillary astrocytes with preservation of neurons (HE X 80)

mixed oligoastrocytic cells are known.[65] Despite diffuse infiltration of the white and grey matter by the tumour cells, the anatomical structures are relatively preserved (Fig. 9). Two hypotheses regarding histogenesis of this tumour have been put forth. Some authors believe that gliomatosis cerebri represents a subset of diffusely infiltrating glioma with an extensive capacity to spread,[16] while others consider that it results from simultaneous neoplastic transformation in an extensive tissue field in the cerebral hemisphere termed as 'field transformation'.

Oligodendroglioma

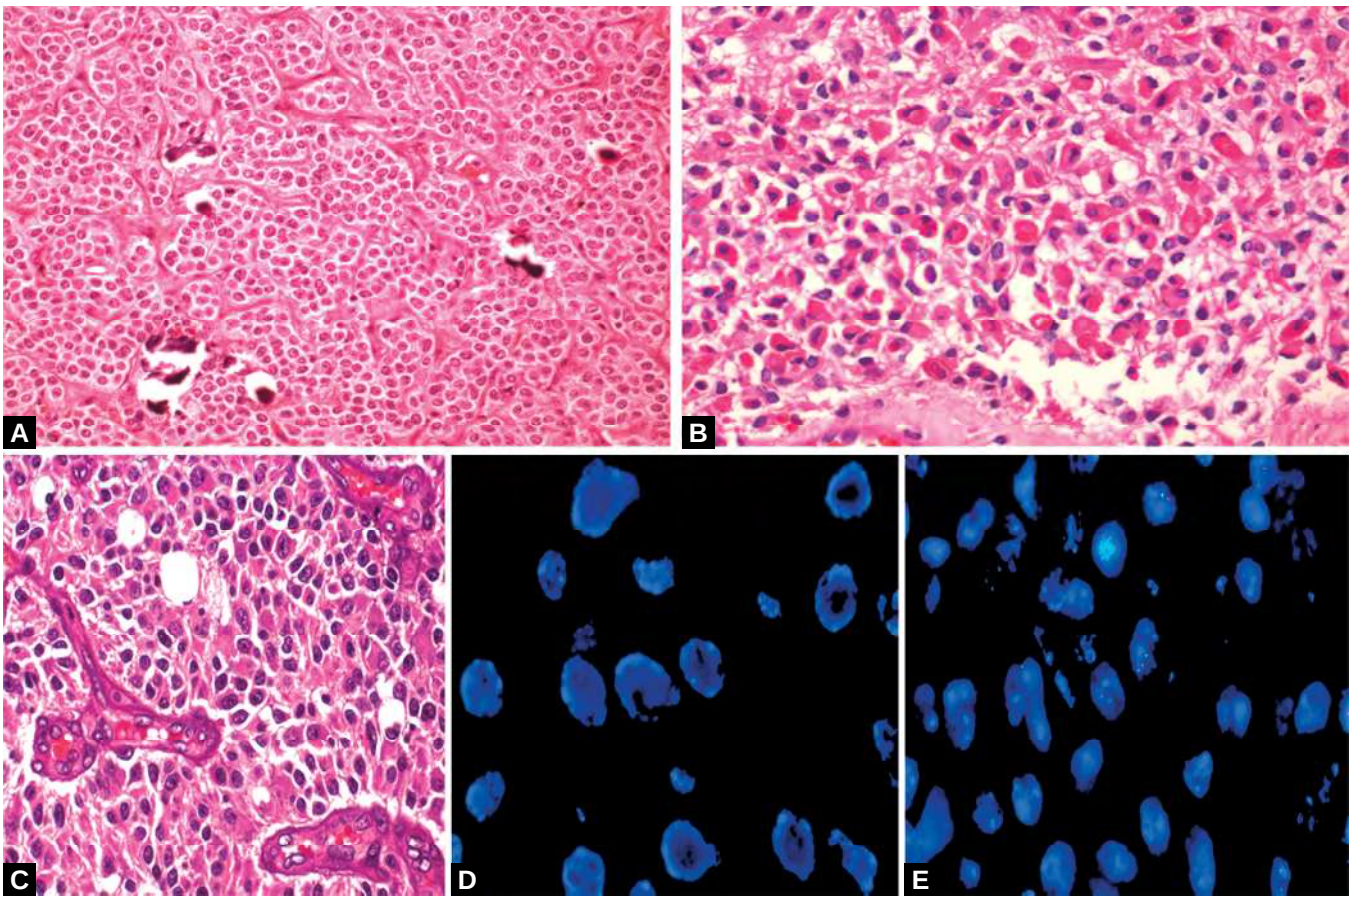
According to the World Health Organisation (WHO 2007) classification, oligodendrogliomas are well-differentiated, diffusely infiltrating tumours of adults, typically located in the cerebral hemispheres and composed predominantly of cells morphologically resembling oligodendrocytes. They constitute about 5% of all gliomas and the incidence varies from 5 to 18% in different series. Oligodendrogliomas are divided into two grades; oligodendroglioma (Grade II) and anaplastic oligodendroglioma (Grade III).

Incidence and localisation: They are predominantly tumours of middle age (range 35–55 years). Grade II are more common in individuals less than 40 years and Grade III neoplasm is seen after the age of 40 years. Six per cent of the oligodendrogliomas occur in children. The most common sites are the cerebral hemispheres involving the frontal, temporal, parietal and occipital lobes, respectively. Rare sites are cerebellar hemispheres, brainstem and spinal cord.

Clinical features and neuroimaging: The most common symptoms are seizures and headache. On CT scan, the tumours appear as hypodense or isodense lesions. Calcification is often seen. On MRI, a well demarcated hypointense lesion on T1-weighted images becoming hyperintense on T2-weighted images will be seen. Perilesional oedema is moderate and tumours can show haemorrhage and cystic change. Correlation of the status of 1p/19q with the pattern on imaging has shown that tumours exhibiting co-deletion of 1p/19q chromosomal deletion have mixed signal intensity on T1-weighted and T2-weighted images.[25]

Histopathology: Oligodendrogliomas show a patternless growth characterised by sheets of cells with round nuclei and swollen clear cytoplasm (honeycomb appearance or fried egg appearance). Microcysts filled with mucoid material, arcuate vascular pattern (chicken wire capillary pattern), focal areas of dystrophic calcification, loss of demarcation between grey and white matter, perineuronal satellitosis and subpial spread are the salient features (Figs 10A and B). Occasional mitosis can be present. In addition, some oligodendrogliomas contain cells referred to as "minigemistocytes" and "gliofibrillary oligodendrocytes". The minigemistocytes are smaller than the conventional gemistocytes and lack process formation (Fig. 10C). They have oligodendrocytic nuclei and plump hyaline cell bodies with abundant eosinophilic cytoplasm. The gliofibrillary oligodendrocytes also possess a moderate quantity of cytoplasm with well-defined cell borders, but their fibrillarity is less obvious and processes are sparse. Both these cell types are positive for GFAP, Hence, the term "transitional cell" has been used to refer to these cell types, because they form a cytological and ontological bridge between typical astrocytes and oligodendrocytes. Increased cellularity, pleomorphism, presence of necrosis, increased mitosis and vascular proliferation are the features of anaplastic (Grade III) oligodendrogliomas (Fig. 10D). Tumours with MIB-1 labelling index of greater than 5 are likely to be anaplastic and indicate an unfavourable outcome. There are no specific markers for oligodendroglioma and hence the diagnosis continues to rest on histological criteria. The cells of a well-differentiated oligodendroglioma are immunonegative for GFAP, but the transitional cells can be GFAP positive. Proteins such as myelin basic protein (MBP), myelin associated glycoprotein (MAG) and galactocerebroside (GaLC), which are specific proteins of mature and developing oligodendrocytes, are only inconsistently expressed in oligodendroglial tumour cells. Recently, two markers Olig-1 and Olig-2 encoding transcription factors expressed in early developmental and mature stages of oligodendrocytes have been seen in oligodendrogliomas.[35] However, other studies have shown their expression in astrocytic tumours also.

Molecular genetics: Deletions on chromosomes 1p and 19q identify anaplastic oligodendroglial neoplasms that are likely to respond well to some chemotherapeutic regimens and are associated with prolonged patient survival. Deletion of these chromosomal alterations is becoming increasingly important in evaluating these glial tumours. Interphase fluorescence *in situ* hybridisation (FISH) is one of the methods used for screening these tumours.



Figs 10A to E: Oligodendroglioma. (A) The tumour shows typical 'Honey comb' arrangement of oligodendrocytes. There are areas of microcalcification (HE X 160). (B) Sheets of minigemistocytes in the tumour (HE X 160). (C) Anaplastic oligodendroglioma with microvascular proliferation, nuclear atypia and mitosis (HE X 320). (D) FISH preparation showing 1-p deletion in anaplastic oligodendroglioma. Four cells clearly show one red signal as seen for 1p 36 test probe and two green signals are seen for the 1q 25 reference probe, indicating loss of one copy of 1p36 (X 800). (E) FISH preparation showing 19q deletion in the same tumour. Several cells show one or no red signal for the 19q13 test probe and two green signals for the 19p13 reference probe, indicating loss of one copy of 19q13 (X 800)

(Fig. 10E) These chromosomal alterations are found in 70–90% of oligodendrogliomas in different series.[26]

The frequent loss of heterozygosity (LOH) on 1p and 19q in oligodendrogliomas and oligoastrocytomas indicates that these chromosome arms harbour as yet unknown tumour suppressor genes, which are of paramount importance in their tumourigenesis. However, the oligodendroglioma-associated tumour suppressor genes on 1p and 19q are as yet to be characterised.

Allelic losses on 1p and 19q are linked to a favourable response to chemotherapy and longer survival in anaplastic oligodendroglioma patients treated with Procarbazine, Lomustine and Vincristine (PCV). In a recent study by Reifenberger et al.[54] combined LOH on 1p and 19q chromosomal loci was associated with late progression, longer overall survival, and a higher 5-year survival rate. Depending on the presence or absence of combined LOH on 1p and 19q, patients with anaplastic oligodendroglial tumours treated with adjuvant radiotherapy and/or chemotherapy showed a median time to progression of 86 months versus 39 months, a median overall survival of 91 months versus 46 months, and a 5-year survival rate of 80% versus 36%, respectively. Similarly, LOH on 1p and 19q was associated with longer survival in patients with low-grade oligodendroglial tumours (TTP: 57 months versus 47 months; OS: 172 months versus 105 months; 5-year survival rate: 92% versus 70%). Several other independent studies have confirmed these observations. Although all these studies are based on a retrospective analysis of relatively small numbers of patients, their results suggest 1p and 19q deletions as a genetic marker important in diagnostic and prognostic assessment of oligodendroglial tumours.

Oligoastrocytoma

Oligoastrocytomas are "tumours composed of a conspicuous mixture of two distinct neoplastic cell types morphologically resembling the tumour cells in oligodendroglioma and DA". They are subclassified into Grade II oligoastrocytoma and anaplastic Grade III oligoastrocytomas.

There is a high degree of variability in the morphological criteria used for the diagnosis of oligoastrocytomas. The diagnosis of oligoastrocytomas "requires the recognition of two different glial components both of which must be unequivocally neoplastic". However, the percentage of each component minimally required for diagnosis has not been specified in the WHO classification system. Oligoastrocytomas may be a biphasic compact variant or an intermingled diffuse variant. In the biphasic variant, the two areas are juxtaposed, (Figs 11A to D), while in the intermingled variant they are intimately admixed. No mitosis or necrosis is seen in Grade II tumours. Anaplastic Grade III oligoastrocytomas are characterised by nuclear pleomorphism, high mitotic activity, microvascular proliferation and necrosis. About 30–50% of oligoastrocytomas are characterised by loss of 1p and 19q in both the components, strongly suggesting a monoclonal origin of the two cellular components. Another 30%, however, carry genetic aberrations typically found in astrocytic gliomas, i.e. mutations of p53. Thus, oligoastrocytomas are genetically heterogeneous with one subset related to oligodendrogliomas and another to DAs.[41] From a clinical viewpoint, it has become increasingly important to differentiate between oligoastrocytomas and pure astrocytic tumours because a subset of oligoastrocytomas, like oligodendroglial tumours, appears to respond favourably to chemotherapy with PCV regime.

EPENDYMAL TUMOURS

These include Ependymoma (WHO Grade II), Anaplastic ependymoma (WHO Grade III), Subependymoma (WHO Grade I) and Myxopapillary ependymoma (WHO Grade I).

Ependymoma (WHO Grade II)

This is a slowly growing tumour arising from the ventricular walls and composed of neoplastic ependymal cells.

Incidence and Localisation

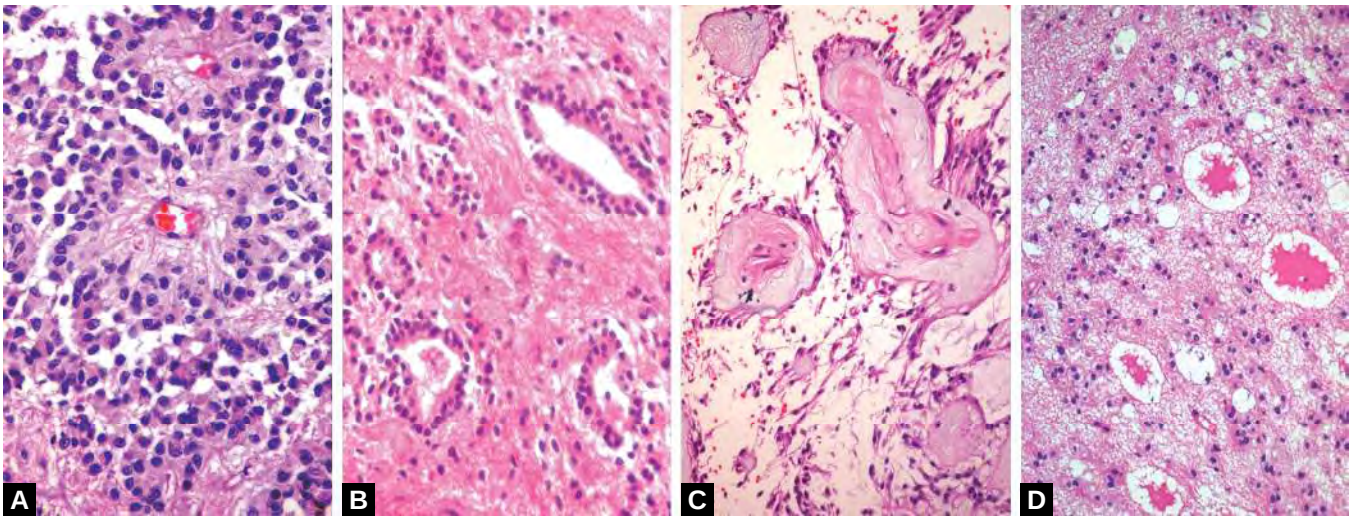
These tumours comprise about 2–9% of all intracranial neoplasms. Infratentorial ependymomas occur most often in children, while supratentorial tumours occur in children and adults. In the spinal cord, in adults, this tumour accounts for 50–60% of glial neoplasms.[39] Ependymomas occur most commonly in the spinal cord, fourth ventricle, lateral ventricle and third ventricle in that order of frequency.

Clinical Features and Neuroimaging

These depend on the neuroanatomical site of the neoplasm. Most fourth ventricular examples present with features of obstructive hydrocephalus and raised intracranial pressure. Tumours of the spinal cord present with motor and sensory deficits. On CT and MRI they are seen as well circumscribed tumours with a varying degree of contrast enhancement, focal cystic component, areas of haemorrhage and calcification.

Histopathology

Ependymomas are moderately cellular neoplasms composed of clusters of cellular zones containing cells with a monomorphic nuclear morphology ('salt and pepper' speckling of the nuclear chromatin), alternating with a cellular fibrillated glial stroma. Other histological features include perivascular pseudorosettes and ependymal rosettes. Perivascular rosettes comprise of cells arranged around vessels with long glial processes resting on the vessel walls. True ependymal rosettes and ependymal canals are composed of columnar cells arranged around



Figs 11A to D: Ependymoma. (A) Classical ependymoma with perivascular rosettes. (B) Ependymal canals (HE, A X 320; B X 160). (C) Myxopapillary ependymoma shows myxoid degeneration of the core of papillae that are bordered by ependymal cells (HE X 320). (D) Subependymoma shows clustered nuclei, fibrillary stroma and microcystic change (HE X 160)

a distinct central lumen. Calcification, cyst formation, fresh and old bleed can be seen. Usually, mitosis is absent or rarely present. Immunohistochemically, most of the ependymomas including papillary variants are immunoreactive for GFAP, which is predominant in the pseudorosettes. These tumours are also positive for S-100 protein and vimentin (Cytokeratin protein) is focally positive. A high percentage of ependymomas also express EMA. Synaptophysin is not expressed by the tumour cells.

Histological Variants

Cellular ependymoma: This is a variant with increased cellularity and absence of pseudo or true ependymal rosettes. Since other features of anaplasia are not evident and mitosis is rare or absent, this tumour belongs to WHO Grade II.

Papillary and myxopapillary ependymoma: This tumour is composed of well-formed papillae with round to oval monomorphic tumour cells around the blood vessels. Other histological features of ependymoma, such as pseudorosettes, ependymal rosettes and ependymal canal, could also be seen. Usually, mitosis is absent or rarely present. The papillary structures of ependymoma, a lack basement membrane, are in sharp contrast to the papillae of choroid plexus tumours. Myxopapillary ependymomas occur in the filum terminale region. Here the papillary core shows myxoid change.

Clear cell ependymoma: This variant contains clear cells resembling oligodendroglial cells. They occur most often in the supratentorial compartment. Recent data shows that this variant has a more aggressive behaviour than classical ependymoma.[14]

Tanycytic ependymoma: These tumours are often found in the paraventricular region of the infundibulum, fourth ventricle and spinal cord, where the brain-CSF barrier is not strong. They are composed of long spindly bipolar cells that poorly intertwine. These cells are presumed to be tanycytes or ependymoglial cells (paraventricular) with long processes recapitulating their development.[13] Perivascular rosettes are rare and ill-defined, and ependymal rosettes are not seen. They can be mistaken for astrocytic tumours but they have ultrastructural features of cells in ependymoma like intracellular cilia.

Predictive and Prognostic Factors

Children, particularly with posterior fossa tumours, have a far worse prognosis than adults (particularly with spinal tumours). The site of the tumour is an important prognostic factor. Posterior fossa tumours fare much worse than supratentorial tumours. Spinal tumours have a better survival. Extent of resection determines further progression and frank anaplastic change in the tumour is a known factor for poorer survival.[64]

Anaplastic Ependymoma (WHO Grade III)

This tumour is a malignant variant of ependymoma characterised by high mitotic activity, necrosis and microvascular proliferation. The tumour shows an aggressive growth pattern and is associated with a poor prognosis, particularly in children.

Subependymoma (WHO Grade I)

This tumour is characterised by clusters of isomorphic nuclei dispersed over fine glial stroma and with prominent microcystic change. They have a very low mitotic activity or none. Sometimes, these tumours can coexist with a classical or cellular ependymoma and such tumours are graded according to the ependymal component.[39]

120 Pathogenesis of Tumours of the Nervous System

Radhakrishnan VV

Neurosurgical and radiotherapeutic management of human malignant intracranial tumours would greatly be facilitated by an understanding of the pathogenetic mechanisms which are responsible for the initiation and progression of the intracranial tumours as well as for their biological behaviour. Since the first classification of brain tumours by Virchow, who coined the term 'glioma', enormous efforts have been made in basic neurosciences towards an understanding of the morphology, behaviour, immunology and molecular genetics of central nervous system (CNS) tumours. Despite the exciting findings in these fields and the development of newer therapeutic approaches, the existing knowledge of the aetiopathogenetic mechanisms of spontaneously occurring human CNS malignant tumours still remains ill defined.

An overview of pathogenetic mechanisms that appear to be involved in the development of human CNS tumours is given, some of which are potentially significant, but not yet well characterised. The pathogenetic mechanisms in CNS tumours are discussed under the following heads: (1) Molecular pathogenesis (oncogenes and tumour suppressor genes); (2) Hereditary factors; (3) Oncogenic viruses; (4) Radiation; (5) Chemical carcinogens; (6) Immunosuppression; (7) Hormones and (8) Trauma.

MOLECULAR PATHOGENESIS OF GLIOMAS

The term 'glioma' refers to primary tumours of the brain originating from the major components of glial tissue, i.e. astrocytes, oligodendrocytes and ependymal cells. The first morphological consequence of anaplasia may be cell atypia, which, however, is not a hallmark. With anaplasia, the growth fraction increases and it is very likely that an oncogene activation or tumour suppressor gene deletion is involved in the passage of cells from the non-proliferating to the proliferating pool. The increase in cell density, enhanced mitotic response and nuclear pleomorphism are direct consequences of anaplasia, whereas other histological signs, such as nuclear pleomorphism, necrosis and endothelial proliferation, usually regarded as indicative of malignancy, represent indirect consequences only. Based on these four morphological characteristics, Daumas-Duport et al. published in 1988 a simple method of grading of gliomas.[18] Tumours are grade I if none of these criteria are met, grade II with one criterion, grade III when two are met and grade IV if three or four criteria are present in the sections. In fact, the World Health Organization (WHO) system is a three-tiered grading system, assigning grade II to astrocytoma (fibrillary, protoplasmic and gemistocytic), grade III to anaplastic astrocytoma and grade IV to glioblastoma multiforme.[37] Grade I tumours form a distinct category with tumours such as pilocytic astrocytomas and sub-ependymal giant cell astrocytomas. The described histopathological grading systems are not perfect since they often fail to provide essential information regarding invasiveness, malignant character and patient survival. In other words, detailed neuropathological analyses of biopsy specimens have not revealed morphological parameters that reliably predict the malignant progression of astrocytic neoplasms. Molecular genetic studies may hold promise for this vexing problem. Demonstrating the genes involved in the malignant progression of astrocytomas might identify subgroups in their well-known histopathological grades.

The initiation and progression of sporadically occurring human malignant tumours are a result of genetic alterations, mutation, deletion or rearrangement in one or more genes. Gross chromosomal aberrations in the form of both numerical and structural alterations are often demonstrated. Extra copies of the genetic material that encode an oncogene could increase the expression of the oncogene protein and tilt the balance towards uncontrolled DNA synthesis. The loss of genetic material that encodes a tumour suppressor gene could again favour uncontrolled DNA synthesis. Thus at least two types of genes have been implicated in the tumourigenic process of malignant tumours of the CNS: (1) Proto-oncogenes that promote cell growth and (2) Tumour suppressor genes (TSG), which negatively regulates cell growth.

Tumour Oncogenes

In 1976, DNA sequences almost identical to viral oncogenes were discovered in the genomes of all vertebrate and invertebrate cells.[78] These genes, named proto-oncogenes, encode growth factors, growth factor receptors and components of signal transduction mechanisms that mediate the cell cycle. In neoplastic cells, such genes are frequently found to be mutated or over expressed and

are, therefore, referred to as oncogenes. Earlier, it was believed that at least two oncogenes have to be active for malignant transformation of gliomas. Since then more than one hundred oncogenes are known to be involved in glial tumourigenesis. Two main groups of oncogenes will be discussed: one involved in growth factor pathways and the other in cell cycle control.

Growth Factors

Epidermal Growth Factor (EGF)

Several growth factors or their receptors have been found to be over expressed in gliomas. In particular, there is evidence for the amplification of the EGF gene and epidermal growth factor receptor (EGFR) gene.[43,47,89,92,94] The EGF, which is the protein encoded by the EGF gene, is a small polypeptide and has about 50% amino-acid homology with transforming growth factor-alpha (TGF-α).[69] The EGFR is a multifunctional allosteric transmembrane protein with an extracellular binding site for EGF, a single transmembrane region and an intracellular domain that exhibits tyrosine kinase (TK) activity.[75] Activation of this EGFR associated TK results in a number of cellular activities, including mitogenesis and migration of the cell. The EGFR gene has been localised on the short arm of chromosome 7, within 7p11-12. Amplification as well as over expression of the EGFR gene has been demonstrated in many histological types of brain tumours. Rearrangements at different places in the EGFR gene corresponding to the extracellular binding to EGF or to the cytoplasmic domains have also been recorded. The EGFR gene has been found to be amplified and over expressed in 1% of low grade astrocytomas, in a cumulative incidence of around 10% in anaplastic astrocytomas and in about 30–40% of glioblastoma (GBM) and is, therefore, considered to be a hallmark of malignant transformation in patients with gliomas.[20,31] When examining DNA on a cell-by-cell basis using the FISH method, it becomes clear that the percentage of amplification/over expression in GBM is even higher and reaches 60%.[74] Most individuals, whose gliomas carry an EGFR mutation or amplification, have a poor prognosis, even when the tumour is classified as a grade II astrocytoma.[20] An aberrant form of EGFR gene is present on the surface of the neoplastic cells and represents a tumour specific epitope that does not exist on the normal cell. Recently, the role of EGFR as a determinant by which GBM invades normal brain tissue has been demonstrated *in vitro*.[63] Invasion into the adjacent brain parenchyma could successfully be inhibited at much lower concentrations of TK inhibitors. Therefore, inhibition of these TK inhibitors might prove to be more successful than targeting their ligands or the extracellular domain of EGFR gene.

Vascular Endothelial Growth Factor (VEGF)

VEGF, a 46-kDa protein, is a dimeric growth factor. VEGF has two principal biological activities: (a) to promote microvascular permeability and (b) the ability to function as an endothelial cell mitogen and potentially stimulate angiogenesis. The ability to increase vascular permeability is independent of other inflammatory mediators such as cytokines. The effect of VEGF on endothelial cells is dependent on the activation of the receptor protein tyrosine kinase (RPTK).[60] There is strong evidence that VEGF plays a dominant role in the development of angiogenesis that accompanies the anaplastic progression of astrocytic tumours.[91] There is almost no expression of VEGF in the normal adult brain. There are also some indications of VEGF production when human malignant astrocytoma cell lines are stimulated with EGF and PDGF.[29] The current role of angiogenesis in malignant astrocytoma and the potential effects of VEGF on endothelial cells make this growth factor system an ideal candidate for therapeutic manipulation. Attempts have been made to abrogate angiogenesis and tumour growth, utilising specific antibodies directed against both N and C terminals of the VEGF molecule, and thus block both vascular permeability and endothelial mitogenic activity. It has been shown that a monoclonal antibody against VEGF significantly reduces tumour growth of a human glioblastoma multiforme cell line when transplanted into male mice. The growth inhibition was up to 80% and was associated with a marked reduction in tumour vessel density.[41]

Tumour Angiogenesis Factor (TAF)

This is another growth factor found to be present in high levels in glial tumours. It may play a role in the proliferation and possible subsequent transformation of vascular and perivascular mesenchymal elements to the development of an angiosarcoma. The mitogenetic properties of this factor have been determined *in vivo* and *in vitro* assays. The latter have included cultures of endothelial cells grown in the media conditioned by tumour cell lines of neuroepithelial origin such as C6 rat glioma, the C1300 mouse neuroblastoma and human neuroblastoma cell lines.[79] The other growth factors with potential mitogenetic activities include erythropoietin, found to be active in capillary haemangioblastoma; progesterone receptors in meningiomas and insulin-like growth factor receptors in glioblastoma.[72]

Other Growth Factors in Gliomas

Certain glioblastomas may also over express the transforming growth factor-alpha (TGF-α) gene, the protein product of which resembles EGF and binds to the EGFR stimulating TK activity.[56] Several studies demonstrated over expression of platelet derived growth factor (PDGF) and PDGF receptor in glioblastoma.[70] The oncogene encoding PDGF is located on chromosome 22. The basic fibroblast growth factor (bFGF) gene is known to exert a trophic effect upon a variety of cells of neural origin and is prevalent in the neural tissue. Human glioma cell lines binding the receptor proliferate in response to exogenously applied bFGF. It has also been suggested

that bFGF may promote glial tumour growth by the stimulation of angiogenesis or neovascularisation.[55]

The 12q Amplicon Including CDK4 and MDM2

Besides the growth factors, another important cell cycle regulator mechanism consists of the cyclin dependant kinases (CDKs) and their inhibitors. They regulate a number of target molecules by phosphorylation. Activation of these CDKs will lead ultimately to DNA replication and mitosis. The CDKs are activated by cyclins and inhibited by a still growing number of proteins that include factors named after their apparent molecular weights: p15, p16, p21 and p27, encoded by their respective TSG. The expression and interactions between these three types of molecules, CDKs, cyclins and CDK inhibitors account to a great extent for cell cycle control. The interaction between these molecules gives rise to different pathways, where many proto-oncogenes and TSG will have their own place. One such pathway involves cyclin D1, CDK4 and p16 as the inhibitor of retinoblastoma protein pRb1. pRb1 inhibits the progression from G1 to the S phase of the cell cycle, while CDK4 inhibits its function by phosphorylation. Over expression of CDK4, therefore, will indirectly stimulate cell growth (by controlling pRb1) and eventually lead to uncontrolled mitosis. Amplification of the CDK4 gene occurs in 30% of patients with anaplastic astrocytomas.[68]

Gene amplification in human tumour cells often involves large regions of genomic DNA, which can be several megabases in length. Such a large amplicon can be found in gliomas where a region on chromosome 12q13-14 [including CDK4 gene as well as the murine double minute (MDM2) gene] is often amplified. Reifenberger et al. analysed the MDM2 gene located on the same amplicon as the CDK4 gene in anaplastic astrocytomas and glioblastoma and found it to be present in 8–10% of patients.[68] The MDM2 gene product was shown to be a cellular regulator of *p53* activity. One copy of the p53 gene is frequently lost and the remaining copy is mutated in gliomas. An alternative mechanism for the loss of function of the p53 protein, if present, would be the over expression of genes coding for proteins known to bind to p53 and inhibit its function.

Besides the CDK4 and MDM2 genes, the 12q13-14 amplicon also harbours the genes SAS, GADD153, GLI and A2MR. The gene GLI, first found in a glioma, located on chromosome[12] (12q, 12-q14.3) has been found to be highly expressed and amplified in a human malignant glioma cell line. It is related to the oncogene of the 12q amplicon. However, it has so far not been shown to possess any transforming property and its precise role in tumourigenesis still remains unclear.

Tumour Suppressor Genes (TSG)

A second class of genes related to anaplasia is TSG. Indications for the existence of TSG came from observations made during the study of retinoblastoma, occurring both in sporadic and familial form.[39] The association of loss of genetic material with the development of cancer is consistent with the idea that the normal allele protecting against the formation of retinoblastoma must be dominant and, therefore, must be inactivated or deleted before the mutant, recessive retinoblastoma allele will give rise to the tumour. In the familial form, one mutation (first hit) is already present due to inheritance. The second hit (mutation or the loss of the other allele of a TSG) occurs somatically in the target tissue (retina). A high penetrance in the familial form that affects both eyes in very young children reflects the high probability of the second hit in these patients. In the sporadic form, two somatic events usually occur. Since the somatic mutation rate is low, only one eye is affected and the children are older before they develop retinoblastoma. This led to the two hit theory of Knudson[25] where inactivation due to loss of functional inhibition of both copies of specific allele on two homologous chromosomes may lead to tumourigenesis. In most instances of TSG inactivation, one allele carries a point mutation while the other is inactivated by a major structural alteration such as chromosomal deletion, inversion or translocation.

Retinoblastoma (Rb) Gene

The Rb gene is localised on chromosome 13q14 and has been isolated for the first time in 1986.[27] The Rb gene, which is the product of pRb1 protein, is involved in the transition of the cell from G0 or G1 to the S phase in the cell cycle. Inactivation of the Rb gene has been reported in about 20% of anaplastic astrocytomas and GBM, and it is concluded that the phosphorylated pRb1 is involved in the malignant progression of gliomas.[24] It was demonstrated later that 85% of a series of GBM had one or the other defect, thereby highlighting that the cell cycle growth control system determining their progression from G1 to the S phase by the phosphorylation of pRb1 is defective.

p53

Several intracranial tumours including gliomas with loss of chromosome 17 show partial chromosomal deletion with the common region of allelic loss involving *17p13*.[11,14] This region is known to encompass a candidate tumour suppressor gene encoding a 53-kilo Dalton nuclear protein known as p53.[6] The *p53* protein, which is the product of the p53 wild-type gene, is involved in cell cycle control. At least two stages in the cell cycle are regulated in response to DNA damage—the G1-S and the G2-M transitions. These transitions serve as checkpoints at which the cell cycle progress can be delayed to allow the repair of damage before entering either S phase or M phase. *p53* encodes a nuclear protein that suppresses this cell transformation. *p53* mediates this effect on cellular growth either by inducing apoptosis (programmed cell death) or through a transient cellular arrest at the G1 phase. Adenovirus mediated *p53* transfer

was reported to produce rapid and generalised death of human glioma cells via apoptosis.[30] The effect of *p53* on the transient cellular arrest at the G1 phase is mediated through the activation of the WAF-1 gene (also termed CDKN1), which results in the production of p21 protein, which in turn inhibits CDK4 and CDK6. The function of the *p53* protein is inhibited by the protein product of the MDM2 oncogene, which binds with *p53* protein. Thus, amplification of the MDM2 oncogene may result in excessive *p53* protein binding which in fact may have the same effect as mutation of *p53*. The mutant *p53* proteins analysed so far have a much longer half-life than that of the wild-type resulting in large amounts of the mutant protein which can transform cells to tumours.[34] Certain *p53* mutations result in the loss of the cell cycle control function and increase the transformation potential of cells. The description that *p53* is also involved in the angiogenesis of glioblastoma raises the interesting possibility that the lack of the wild-type *p53* may have a crucial and tumour cell-extrinsic impact on tumourigenesis.[84]

Somatic mutations of the *p53* gene have been reported to occur frequently in most of the human tumours including gliomas. Over 200 naturally occurring mutations have been described in different human tumours without identification of any brain specific mutations. p53 mutations are associated with 17p allele loss in low-grade astrocytomas as well as in glioblastoma multiforme.[85] Mutations of *p53* gene have been reported in all grades of gliomas, indicating that these mutations represent an early molecular event in the pathogenesis of gliomas. Until now, no grade-specific *p53* mutations are identified. Gliomas are observed with increased prevalence in association with Li-Fraumeni Syndrome (LFS of breast cancer, sarcomas, autosomal dominant patterns of inheritance), NF-1, NF-2, tuberose sclerosis and Turcot's syndrome. Gliomas occur in more than 10% of patients with LFS. Germ line *p53* mutations have been reported in a subset of LFS families as well as in non-LFS patients with gliomas.[52] The prevalence of inherited p53 mutations, a phenomenon that will render the individual more likely to develop the tumour (two hit theory of Knudson), has been estimated at 1% in the general population and at 20% in patients with a personal or family history of malignancy.[26] All these persons have a higher chance of developing gliomas. GBM in four siblings has recently been described without any *p53* mutations, indicating that a genetic event other than *p53* alteration can be responsible for the tumourigenesis of GBM in these patients.[21] The frequency of *p53* mutations was 64% in tumours with only one 17p allele, whereas it was 37% in patients with both *p53* alleles.[25] These mutations are often associated with a corresponding loss of the second copy of chromosome 17, thus meeting the classical paradigm of recessive tumour suppressor gene inactivation as described by Knudson et al.[39]

Sidransky et al.[76] analysed the *p53* gene in 10 primary brain tumour pairs, i.e. samples of tumours of the same patient but at different time points, to define the genetic events during tumour progression. The histological progression of brain tumours was associated with a clonal expansion of cells that have previously acquired a mutation in *p53* gene endowing them with a selective growth advantage. This data supports the clonal evolution model of tumour progression. It was found that the mutations of *p53* gene could be a reliable predictor for malignant transformation in a subset of gliomas.[26] On the contrary, recurrent astrocytomas have been investigated where progression of malignancy apparently occurs independent of *p53* mutation indicating that other genetic events promoting progression of glioma do occur. For glial tumours, *p53* is involved in the initiation as well as progression. *p53* alteration occurring in about 60% of low-grade astrocytomas might be important in the tumourigenesis of most, but not all gliomas.

p16

Until now, only p53 on chromosome 17p and Rb gene on chromosome 13q have been identified as major TSG that play a role in glial tumourigenesis, both these genes having a pivotal role in the cell cycle control mechanism. Another gene involved in the cell cycle progression located on the CDKN2 (MTSI, p16) gene on chromosome 9p is involved in the formation and progression of glial tumours.[61] Deletions involving chromosomal region 9p21 appear to be the most common molecular abnormality observed in grade III astrocytoma as well as in glioblastoma multiforme, where they have been reported to occur in 82% of glioma cell lines.[82] CDKN2 gene encodes p16, a cell cycle regulatory protein. p16 inhibits CDK4 and CDK6, thereby potentiating pRb1 as a cell cycle regulator. Inactivation of pRb1 may also occur through other mechanisms. Amplification of CDK4 gene inactivates pRb1 by phosphorylation. In total, about 85% cases of glioblastoma multiforme had one or the other defects demonstrating that cell cycle growth control systems determining progression from G1 to S phase by the phosphorylation of pRb1 is defective.[81]

LOH-10

Since the loss of alleles is in chromosome 10 in almost 80% of cases of glioblastoma multiforme, it is presumed that inactivation of a tumour suppressor gene on this chromosome is a critical step in the transition of astrocytoma grade III to glioblastoma multiforme. Despite considerable efforts, the common deletion region on chromosome 10 at molecular level remains poorly defined. For the present, this common deletion region is mapped at 10q25.[67] Others reported two independent suppressive regions on chromosome 10(10pter-q11 and 10q24-q26) that are involved in the progression of glioma.[77] A strong correlation between EGFR amplification and genetic loss of loci at chromosome 10 has been demonstrated, suggesting that co-operative mechanisms within such loci may underlie a subset of glioblastoma multiforme.

LOH-22q and 19q, 13.2-13.3

Allelic loss of 22q is detected in about 20% of gliomas regardless of their histopathological grades. There is also evidence to suggest that two or more than two TSG may reside on chromosome 19, one on 19p, important in the development of grade II astrocytoma and another on 19q, 13.2-13.3, important in the development of anaplastic astrocytoma.[69]

Genetic instability

Genetic instability has been suggested as a possible mechanism in the development of cancer. Initially this phenomenon was observed in hereditary non-polyposis colon carcinoma as well as in sporadic colorectal tumours. The genomic instability can be observed as a change in the length of microsatellite sequences in the tumour DNA as compared to constitutional DNA. The genomic instability is the result of replication errors. In hereditary non-polyposis colonic carcinoma, the observed replication errors are caused by mutations of the hMSH2 gene, which is located on 2p or by a mutation of the hMLH1 gene on chromosome 3p. Microsatellite instability has been found in many tumours including gliomas. It is present in low-grade astrocytomas, but more frequently in glioblastoma, and appears as a hallmark of a more generalised genomic instability.[83]

von Deimling et al.[86] suggested the existence of two different subsets of glioblastoma: one subset that has lost parts of chromosome 10 and 17p and another that might have arisen secondarily from a low-grade precursor, i.e. astrocytoma grade II and grade III. These patients are relatively younger and had a previous history of a low-grade astrocytoma (Type I). Another subset in which glioblastoma seems to arise *de novo*, may be characterised by the loss of parts of chromosome 10 and the amplification of the EFGR gene, without loss of heterozygosity for 17p (Type II). Patients with type II glioblastoma had no previous history of a low-grade astrocytoma and were significantly older than the patients with type I glioblastoma. These two subsets accounted for approximately two thirds of all investigated cases in their study.

HEREDITARY SYNDROMES

Familial clustering does not seem to account for a majority of brain tumours. However, a high incidence of brain tumours has been observed in up to 9% of families with at least one affected member with brain tumour, suggesting that tumour susceptibility may be inherited in these cases.[93] An analysis of tumour distribution among the relatives of 243 childhood brain tumours suggested that 4% might be attributed to hereditary factors.[7]

A number of hereditary syndromes, such as phakomatosis or familial cancer syndrome, are also associated with an increased risk for brain tumours. The phakomatoses (e.g. neurofibromatosis, tuberose sclerosis, von-Hippel-Lindau disease) are neurocutaneous disorders, characterised by tumours of ectodermal and mesenchymal origin, with vascular malformations of the skin, eyes and the CNS. Neurofibromatosis type I (NF-1) is characterised by café-au-lait spots, hamartomas of the iris (Lisch nodules) and multiple cutaneous and plexiform neurofibromas. Other neoplasms associated with NF-1 include schwannoma, phaeochromocytoma, rhabdomyosarcoma, optic glioma and astrocytoma. The NF-1 gene has been identified and mapped to chromosome 17q11.[57] It encodes the protein 'neurofibromin', which stimulates a ras-associated GTPase and may, therefore, exhibit its physiological role as a transducer for growth factor mediated signals. The NF-2 gene located on chromosome 22q11 encodes the proteins merlin/schwannomin, a cytochrome-associated protein.[80] The clinical triad of tuberose sclerosis (TSC) consists of adenoma sebaceum, seizures and mental retardation. The most frequently observed tumours are subependymal giant-cell astrocytoma and ganglioglioma.[42] Two genetic loci have been identified for this disorder, TSC1a on chromosome 9q34 and TSC2 on chromosome 16p. The disease-causing gene product has been identified only for TSC2, called 'tuberin' and it encodes a GTPase activating protein that may act in a similar fashion as the NF-1 protein.[71] Patients with Turcot's syndrome develop gliomas and adenomatous polyposis coli, which regularly progresses to colorectal carcinoma. The adenomatous polyposis coli (APC) gene has been cloned and mapped to chromosome 5. However, a recent survey of sporadic and Turcot's syndrome associated brain tumours failed to detect somatic mutation of the APC gene in the brain tumour tissue suggesting that other genetic alterations are responsible for the phenotype.[36] Li-Fraumeni's syndrome is caused by an inherited mutation of the p53 tumour suppressor gene. Affected patients display a variety of tumours, most commonly carcinoma of breast, sarcoma, leukaemia and brain tumours.[48]

Hereditary syndromes, such as the phakomatoses, provide phenotypically defined pedigrees for the diseases of interest that allows the identification of the relevant altered genes using molecular genetic approaches. If cytogenetic evidence implicates a specific chromosomal region, an investigative approach may be justified by screening candidate genes for mutations. In most cases, however, a detective approach is more effective, which employs the genome-wide screening of pedigrees for genetic markers. Linkage analysis then allows regional alignment of the disease causing locus to a minimal chromosomal region. Finally, the gene responsible for the phenotypes can be identified. Once the disease-causing gene has been identified, it can further be characterised as to its physiological and pathophysiological functions towards the development of rational treatment. In addition, genetic testing will help to identify individuals at risk, allowing early diagnosis and intervention. Thus an understanding of the genetic basis of hereditary disorders may also provide an insight to common pathogenetic mechanisms underlying the more frequent

sporadic brain tumours. Despite the great progress that has been accomplished towards the characterisation of genes underlying a hereditary tumour syndrome, no genetic risk factors predisposing to the development of sporadic brain tumours have been identified to date.

ONCOGENIC VIRUSES

Most available information regarding the role of oncogenic viruses in the causation of brain tumours are based on experimental and epidemiological studies. Several oncogenic viruses are known to induce a high incidence of brain tumours in rodents following intracerebral injection. Transgenic mice were used to identify the transforming viral genes responsible for the induction of brain tumours.[1] The type of brain tumour induced depends upon the transforming gene or the regulatory DNA sequence and the genetic background of the experimental model. Viral oncogenes have also been used in a grafting model in which retroviral vectors are used to transfect foetal rat brain cell line *in vitro*, which is subsequently injected into the caudoputamen of adult rats.[90]

A large number of oncogenic viruses have been implicated in the pathogenesis of human brain tumours and these include: simian virus, JC virus, Rous sarcoma virus, adenovirus, polyoma virus and papilloma virus. Among these, two to three oncogenic viruses are relevant to the pathogenesis of human brain tumours.

Simian Virus-40 (SV-40)

Experimental studies suggested that several oncogenic viruses are capable of inducing neuroepithelial and embryonal tumours in rodents. Primitive neuroepithelial tumours induced by 'simian virus-40 (SV-40) large T-antigen' are morphologically indistinguishable from that of human medulloblastoma. SV-40 large T-antigen binds and inactivates several tumour suppressive genes including p53 and Rb gene and is capable of transforming human cells *in vitro*.[8,9]

Historical Evidence

SV-40 virus was iatrogenically introduced on a large scale into the human population in North America and Europe between 1955–1962 through SV-40 virus contaminated polio vaccine.[9] SV-40 viral sequences have been identified in a variety of human neoplasms, raising the question of a possible aetiological role.[8] In brain tumours, SV-40 sequences have been detected at an overall frequency of approximately 35%[8] while the surrounding normal brain rarely contained SV-40 viral genetic material.[50] In another study, 25–50% of brain tumours of Swiss patients contained SV-40 sequence, which was not detected in a similar series of brain tumours from Finland, a country where SV-40 contaminated polio vaccine was not used.[58] This suggests an association between SV-40 viral infection and origin of human brain tumours. These observations also indicate that SV-40 is able to spread vertically in human populations to be present even today, 44 years after the cessation of the use of SV-40 contaminated polio vaccine. Because of the large population involved, the aetiological role of SV-40 in human brain tumours needs to be carefully assessed. Instead its presence may reflect a bystander infection due to an intra-tumoural microenvironment that favours viral replication in humans with a latent SV-40 infection.

JC Virus

JC virus has an extensive nucleotide sequence homology with SV-40 and also overlapping antigenicity, but the host range is definitely different. While SV-40 rarely infects human cells, latent JC viral infection is very common with a seroprevalance of 40–60% in most developed countries particularly in immunocompromised patients. In the brain, JC virus infection may cause progressive multifocal leucoencephalopathy. Most of the information regarding brain tumours due to JC virus infection is based on experimental evidence. Following intracerebral injection into newborn hamsters, JC virus causes brain tumours, mostly embryonal in nature, i.e. medulloblastoma and primitive neuroectodermal tumour.[87] Matsuda et al.[51] using *in situ* hybridisation, demonstrated that JC virus primarily infects cells of the external granular layer of the developing cerebellum, which then migrate to the internal granular layer where medulloblastomas are detected as early as 30 days following the inoculation. Following intracerebral inoculation of newborn rats with JC virus Tokyo-1, a strain isolated from the brain of a patient with progressive multifocal leucoencephalopathy, more than 70% animals developed brain tumours in the forebrain and cerebellum as seen in hamsters. Histologically, these tumours were undifferentiated neuroectodermal neoplasms probably originating from the subependymal matrix zones.[59] Two Colombian owl monkeys inoculated with JC polyoma virus derived from human PML cases developed brain tumours that closely resembled human astrocytomas.[44]

Adenovirus 12

Human adenovirus 12 has been shown to induce neuroblastoma and retinoblastoma in rodent models following intracerebral and intraorbital inoculation. Kolke et al.[40] established transgenic mice expressing the human adenovirus type 12 EIA and EIB genes under the control of the mouse mammary tumour virus long terminal repeat (LTR) and all the 12 homozygous mice developed neuroblastoma of the olfactory nerve between the ages of 6 and 9 months.

EFFECT OF RADIATION

Radiation has been implicated in the induction of human intracranial neoplasms for over thirty years. However, the exact incidence of intracranial tumour development following irradiation is still unknown. Meningiomas have

been reported to develop following radiation therapy for pituitary and glial tumours. Mann et al.[49] first reported the occurrence of malignant meningioma just six years after radiation to treat an optic nerve glioma. Lacono et al.[33] who reviewed 40 cases, noted that the latent period for the occurrence of meningioma in patients receiving less than 800 Rads was 31.3 years, while in the high dose-irradiated group (more than 2,300 Rads), the average latent period of development of tumour was 20.8 years. This data suggests that the higher the dose of irradiation, the shorter the latent period for the development of tumour. The most convincing evidence that radiation was associated with an increased incidence of meningioma was published by Modden et al.[54] They reviewed 11,000 children with *Tinea capitis*, who received radiation therapy to the scalp on an average 350–400 rad to each of the five scalp fields with a calculated brain dose of 140 Rads. Compared with a well matched control group, a four-fold increase in the incidence of meningiomas occurred in the irradiated group. A latent period of 16 years elapsed before tumour discovery in most of these children. From this data, it seems logical that these meningiomas were in some way related to the low-dose radiation, but conclusive proof is still lacking.

Fibrosarcomas are the next common type of tumours to develop after radiation therapy. Waltz et al.[88] reported two cases of fibrosarcoma developing after radiation therapy for pituitary adenomas. They also reviewed 13 previously reported cases. All these patients cited in the review received 3,500 Rads. The latent period was generally between 5 and 12 years.

Approximately 16 glial tumours have been reported following radiation. Chung et al.[12] reviewed these cases and emphasised that from the relatively few reported cases it is impossible to make a definite statement on the role of radiation in the development of glial tumours. However, the following criteria should be defined in order to incriminate radiation therapy in the development of intracranial tumours: (a) the tumour occurs within the anatomical territory of radiation; (b) an adequate latent period exists following radiation, commensurate with the dose of radiation given; (c) no factors predisposing to tumour development exists such as neurofibromatosis or multiple endocrine neoplasia syndrome; (d) the tumour would rarely occur spontaneously in a control group of non-irradiated patients.

Radio Frequency (RF) Radiation

In recent years, there is a rapid increase in the use of cellular phones. The question whether or not RF exposure following long-term usage of cellular phones causes brain tumours is not established. Data so far gathered is too limited to implicate the biological effects of radio exposure for the occurrence of brain tumour. However, exposure to higher frequency radio frequency fields is known to increase local tissue heat and vascularity and these may be expected to affect the blood-brain barrier.[2]

CHEMICAL CARCINOGENS

Several studies have been undertaken to test the assumption that N-nitroso compounds play a role in the evolution of human brain tumours, since some of these agents are potent neurocarcinogens in rodents, particularly when administered perinatally. Nitroso compounds have been detected in nitrite-preserved food and in beer, but they can also be formed in the stomach after the intake of their chemical precursor, nitrate/nitrite and secondary amines. The results of one multicentre analytical study suggest that the risk of developing a primary brain tumour may be higher in people with a high intake of meat, particularly cooked ham, processed pork and bacon.[5] Dietary habits during pregnancy are also suggestive of an adverse effect of food and are a likely source of nitroso compounds.[73] In some studies, an inverse association was noted with the intake of fruit and vegetables and vitamin C, which is known to block the endogenous formation of nitrosamines.[64]

Experimental data in animals provides evidence that chemical carcinogens, such as nitroso compounds and polycyclic hydrocarbons, can be used to induce brain tumours. Druckrey et al.[22] demonstrated that N-methyl-N-nitrosourea (MNU) selectively induced CNS tumours. Malignant gliomas developed in 90–100% animals within eight months after regular intravenous administration of MNU. Anaplastic and mixed gliomas along with oligodendroglioma are the commonest MNU induced CNS tumours. They occur preferentially in the subcortical white matter, hippocampus and periventricular regions. Ethyl nitrosourea (ENU) is another commonly used alkylating agent. Ivankovic et al.[35] found that a single ENU dose of 20 mg/kg body weight given to rats in the third trimester of pregnancy induced neural tumours in 100% of the offspring. Administration of ENU on the 15th day of gestation results essentially in CNS tumours, while exposure to ENU on the 21st day of gestation leads primarily to spinal cord and nerve sheath tumours. ENU has the advantage that a single dose of intravenous administration results in about 100% tumour formation, with low systemic toxicity and the morphological characteristics of the tumour are very similar to human oligodendrogliomas. The metabolism and mitogenesis of nitrosourea has been well studied. After intravenous administration, the nitroso compounds are widely distributed in the body and they cross the blood-brain barrier. They are rapidly hydrolysed and generally have a half-life of less than 10 minutes. According to Kleihues and Rajewsky,[38] the alkylating agents cause the formation of O-alkylated bases, especially O-alkylguanine. This molecular alteration results in mispairing of DNA bases, which can initiate the neoplastic transformation in the brain.

Despite sufficient experimental data suggesting that chemical carcinogens may have a role in animal models, so far no firm evidence of the carcinogenic effects of these elements in humans has been established. A link

between occupational exposure to nitroso compounds, polycyclic aromatic hydrocarbons, polyvinyl chlorides, synthetic rubber, acrylonitrile and other chemical compounds is still controversial.[4] This is likely due to the presence of several chemicals at any work place. Further, the number of patients studied is often too small for a given tumour entity to demonstrate a causal relationship between exposure to chemical carcinogens and development of brain tumours in the human.

IMMUNODEFICIENCY STATUS

Among all intracranial malignant tumours, association of congenital or acquired immunodeficiency disorders with primary central nervous system lymphoma (PCNSL) has been established. During the past two decades, the incidence of PCNSL has tripled.[46] The reason for this increased incidence of PCNSL in part is accounted for by the growing number of immunosuppressed individuals who have a well-known proclivity to develop these tumours. This susceptible cohort includes those with iatrogenic immunosuppression such as organ allograft recipients[53] and acquired immunodeficiency syndrome. Overall PCNSL occurs in as many as 6% of AIDS patients and may be seen in conjunction with other neurological complications such as cytomegalovirus or toxoplasmosis infection, or progressive multifocal leucoencephalopathy.[62] About 4% of the malignancies that occur in individuals with congenital immunodeficiency syndromes are PCNSL.[28] In particular, children with Wiskott Aldrich syndrome appear to develop these tumours.[32] The association of immunodeficiency disorder and PCNSL is further substantiated by the fact that these neoplasms occur much more at a younger age (mean group 31y) when compared to the occurrence of PCNSL in immunocompetent individuals.[23] The Epstein-Barr virus (EBV) is frequently found in lymphomas and in immunodeficient patients. This is thought to play a role in the pathogenesis. The EBV sequence has also been consistently found in AIDS-related PCNSL.[13] Regardless of its role in oncogenesis, the detection of EBV may occasionally be of diagnostic utility. Specifically, the presence of clonal viral sequences as detected by Southern blot hybridisation studies can be taken as evidence of neoplastic cell proliferation.[15] In addition, use of highly sensitive PCR to detect EBV genome in the CSF of AIDS patients may be diagnostic of PCNSL, providing a simple and non-invasive alternative to stereotactic biopsy.[19]

HORMONAL FACTORS

There is some evidence to suggest a role of hormonal factors in the development of meningioma and possibly acoustic schwannoma and pituitary adenomas. Steroid hormones can cross the blood-brain barrier and progesterone is thought to affect the growth of some intracranial tumours, especially meningiomas, gliomas and vascular tumours.[10] The female preponderance of meningioma and pituitary tumours has been well established in clinical and population studies,[16,17,45,66] an effect that was stronger in younger than older women.[16] Discrepancies between populations and clinical studies suggest that either some referral or health care bias may be overestimating female cases in clinical studies or that females are systematically under reported in population based incidences studies. This underscores the importance of having accurate incidence data on which to base hypotheses.

TRAUMA

An association between trauma and meningioma/glioma development has been proposed frequently. Based on their observations, Cushing and colleagues[17] suggested that one-third of meningiomas were related to previous trauma. More recent case reports of brain tumours associated with previous trauma sites were explained by the introduction of carcinogenic compounds into open wounds or by the activation of dormant tumourigenic cells during repair-related proliferation.[65] While repeated case reports keep the intriguing relationship in mind, sufficient data is not there to support an aetiologic role of trauma for primary brain tumours. Review of larger series did not detect a significant correlation between trauma and brain tumours.[3]

Precise pathogenetic mechanisms in the development of human malignant cerebral neoplasms are still not well defined. However, advances in basic neurosciences during the past two decades, especially in cellular and molecular genetics, biology and immunology, have produced a wealth of information on the pathogenesis of human brain tumours. Understanding of the processes such as cell-cycle control, programmed cell death and angiogenesis, together with the discovery of oncogenes and TSG have provided insight into the mechanisms of initiation, proliferation and progression of the tumour. Tumourigenesis is a multistep process caused by genetic changes that are either inherited or acquired. The identification of the genes responsible for hereditary syndromes associated with tumours such as p53, Rb and NF genes and the elucidation of their functional role have been extended to understanding the pathogenetic mechanisms underlying sporadically occurring brain tumours. In addition, analysis of genetic changes, such as gene amplification or loss of heterozygosity, allow the identification of markers that can be used as more accurate tools for diagnosis and the assessment of tumour prognosis. Finally, understanding of cellular and molecular processes involved in tumourigenesis may lead to more rational therapeutic approaches including the inhibition of angiogenesis, the replacement of tumour suppression genes with either gene transfer or the enhancement of specific immune responses. Many questions are still waiting to be answered. Therefore, the primary goal of the neuro-oncologist over the next decade will be to identify the many remaining TSG. The significance of recently identified epiphenomena, such

as telomere activation in tumours, DNA methylation and genetic instability in tumourigenesis, await further investigation, but may offer new therapeutic targets in the treatment of brain tumours.

ACKNOWLEDGEMENTS

The author thanks the Director of the institute for his kind permission to publish this material. The author is indebted to Ms Sumi, Senior Research Fellow, in the preparation of the manuscript.

121 Germ Cell Tumours of the Central Nervous System

Vani Santhosh

Primary central nervous system (CNS) germ cell tumours are known to have a higher incidence in Far East Asia than in the West. In series from Japan, Taiwan and Korea, the reported incidence is about 8–15% of all primary CNS tumours in the paediatric age group[4] as against 3–4% in the Western series.[8] The majority of patients are below the age of 25 years and the peak incidence is 10–14 years. A distinct male preponderance has been observed.

They are classified as follows:

- Germinoma
- Teratoma—mature teratoma, immature teratoma, teratoma with malignant transformation
- Yolk sac tumour
- Embryonal carcinoma
- Choriocarcinoma

CLINICAL FEATURES AND LOCALISATION

These tumours preferentially affect midline structures. The majority of tumours arise from structures around the third ventricle-pineal region followed by the suprasellar compartment.[7] Other sites include: intraventricular; basal ganglionic; diencephalic; intramedullary and intrasellar. Germinomas have a predilection to arise from the suprasellar region while other non-germinomatous tumours arise from the other sites mentioned above.

Clinical symptoms depend on the anatomical site of the neoplasm. Those in the pineal region present with features of obstructive hydrocephalus and neuro-ophthalmic paralysis or Parinaud's syndrome due to infiltration of the tectal plate. They can also present with features of raised intracranial pressure. Tumours in the suprasellar region produce visual compressive symptoms. They disrupt the hypothalamo-pituitary axis and may produce diabetes insipidus and features of pituitary failure, which include retarded growth and sexual maturation. Some tumours that secrete human chorionic gonadotrophin (HCG) can cause precocious puberty. In general, the symptoms are more protracted in germinomas than in other germ cell tumours.

IMAGING FEATURES

On CT and MRI scans, except teratomas, all others are solid masses that are isointense to hyperintense relative to grey matter and show prominent contrast enhancement. Intratumoural cysts, areas of calcification and areas of low signal attenuation characteristic of fat are seen in teratomas.

PATHOLOGY

Germinoma

These are composed of large neoplastic cells that resemble primordial germ cells. The cells are round with a vesicular, centrally placed nucleus with a prominent nucleolus and abundant glycogen filled cytoplasm. Mitosis is frequent but necrosis is rare. The cells are disposed in sheets and lobules separated by a desmoplastic stroma. Infiltration of the tumour by a variable number of mature lymphocytes (T cells) is a characteristic feature (Fig. 1). Some tumours can have florid lymphocytic or lymphoplasmacytic infiltrates along with epithelioid granulomas and giant cells. In such tumours, it is important to identify primordial germ cell elements to avoid a misdiagnosis of a granulomatous lesion. Immunohistochemical markers for the germ cell component include cell membrane staining for placental alkaline phosphatase (PLAP), ckit and nuclear labelling for OCT4.[3]

Teratoma

These tumours contain ectodermal, endodermal and mesodermal elements.

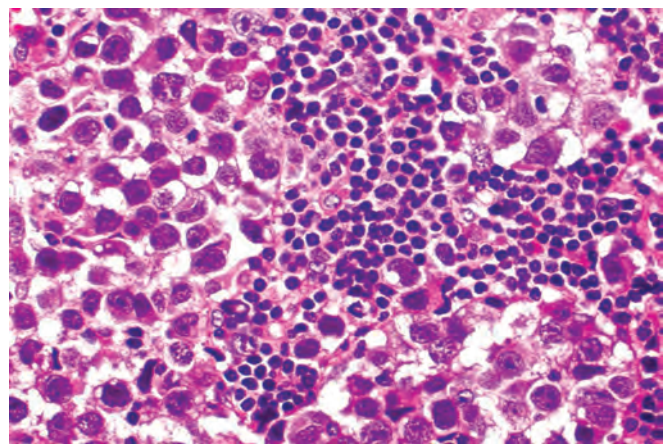

Fig. 1: Germinoma showing characteristic malignant germ cells admixed with mature lymphocytes (HEX320)

Mature Teratoma

These are composed of fully mature 'adult type' tissue elements. The common ectodermal elements include skin and neuroepithelial tissues. Mesodermal elements are represented by cartilage, fat, muscle and bone and the endodermal elements include respiratory or intestinal type of epithelium.

Immature Teratoma

This variant contains incompletely differentiated components resembling foetal tissues either as a minor portion of the tumour which is otherwise composed of mature elements or it can predominate in the tumour. The component that is often immature is the mesenchymal or neuroectodermal elements and these cells are mitotically active (Fig. 2).

Teratoma with Malignant Transformation

These are rare tumours exhibiting malignant transformation of one of the somatic elements. Commonly seen are undifferentiated sarcomas, or regions of squamous cells or adenocarcinomas within the tumour.

Yolk Sac Tumour

This tumour is composed of a loose myxoid matrix within which are primitive appearing epithelial cells (representing yolk sac endoderm). The cells can be in solid sheets, trabeculae or line delicate fibrovascular projections to form distinctive papillae known as Schiller-Duval bodies. They can also show a reticular or sinusoidal growth pattern. The diagnostic feature, although not always present, is the presence of PAS positive, diastase resistant hyaline globules located intracytoplasmic or freely in the myxoid stroma. The tumour cells exhibit high mitosis and cytoplasmic labelling of alpha fetoprotein (AFP) and this is characteristic. The hyaline globules are also AFP positive.

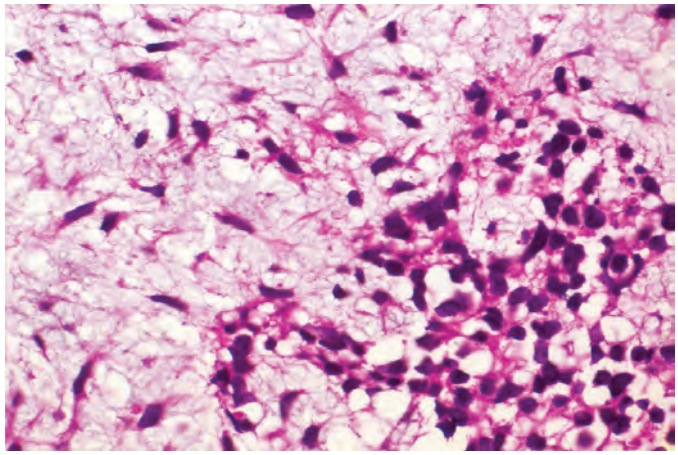

Fig. 2: Immature teratoma with embryonic mesenchyme like stroma and primitive neuroepithelial cells (HEX320)

Choriocarcinoma

These tumours contain cytotrophoblastic and syncitiotrophoblastic elements. Ectatic stromal vascular channels and large areas of fresh haemorrhage characterise this tumour. Cytoplasmic immunoreactivity for βHCG and human placental lactogen is diagnostic.

Embryonal Carcinoma

This rare tumour is composed of large cells arranged in abortive papillae, gland-like structures and can replicate an early embryo forming the 'embryoid bodies'. The tumour cells show cytokeratin immunoreactivity along with PLAP and OCT[4] labelling.

Often CNS germ cell tumours are encountered as mixed histological forms. In fact, only germinomas and teratomas are generally encountered as isolated tumour types.[1]

HISTOGENESIS

One of the hypothesis for the origin of CNS germ cell tumours is the neoplastic transformation of germ cells that either migrate in an aberrant fashion or 'home' to the embryonic CNS. However, immunohistochemical studies on foetal pineal gland for germ cell markers including PLAP expression have never shown this gland to harbour primordial germ cells.[2] An alternate hypothesis postulates an origin for CNS germ cell tumours in a variety of displaced embryonic tissues that can be sometimes incorporated in the developing neural tube.[6] Another speculation is the involvement of totipotent or pleuripotent stem cells in the origin of these tumours.[9]

PROGNOSTIC AND PREDICTIVE FACTORS

Prognosis depends on the histological sub-type of the tumour. Mature teratomas are curable by complete resection of the tumour. Germinomas are extremely radiosensitive and 10 year survival has been recorded after craniospinal irradiation.[7] The tumours most resistant to treatment are yolk sac tumours, embryonal carcinoma and choriocarcinomas. Immature teratomas and mixed germ cell tumours with predominant teratoma and germinoma components and containing non-germinomatous components occupy an intermediate position in terms of aggressiveness.[5]

122 Embryonal Tumours of the Central Nervous System

Chitra Sarkar, Sharma MC

Embryonal Tumours of the CNS are highly malignant tumours (WHO grade IV) occurring predominantly in children. The following tumours are included in this group according to the WHO classification (2007):

1. Medulloblastomas (MBs)
2. CNS primitive neuroectodermal tumours (PNETs):
   - CNS/Supratentorial PNETs (SPNETs)
   - Medulloepithelioma
   - Ependymoblastoma
3. Atypical Teratoid/Rhabdoid tumours (AT/RTs).

MEDULLOBLASTOMAS

These are the most common malignant brain tumours of childhood accounting for approximately 12–25% of all CNS tumours in children. They correspond histologically to WHO grade IV and are subdivided into the following histological subtypes (WHO 2007):[48]

- Classic MB
- Desmoplastic/Nodular MB
- MB with extensive nodularity (MBEN)
- Anaplastic MB
- Large cell MB
- MB with melanotic differentiation (Melanocytic)
- MB with myogenic differentiation (medullomyoblastoma).

Clinical Features

The overall mean and median ages at diagnosis are 13 years and 9 years respectively with a peak age of occurrence around 7 years. Among the adult patients, 80% are in late adolescence or early adulthood (median 25 years).[48] MBEN typically occur in infants less than 3 years of age. The desmoplastic variant, however, shows almost equal distribution between children and adults. There is a marked male preponderance with approximately two-third of patients being males.[12,48]

MBs are tumours of the cerebellum with 75% of them arising in the cerebellar vermis. A hemispheric or lateral location is more common among adolescents and adults. The most common subtypes of MB in a hemispheric location are desmoplastic/nodular types.[12,48]

The presenting clinical features commonly include gait disturbances and truncal ataxia. These are often associated with features of raised intracranial pressure secondary to obstructive hydrocephalus. In the later stages, clinical manifestations may be related to the spread of tumour through the CSF pathways.

Imaging

Imaging (both CT and MRI) reveal most MBs as solid masses with intense enhancement on contrast injection. Striking "grape like" pattern on MRI is characteristic of MBEN.[12,48]

Histopathology

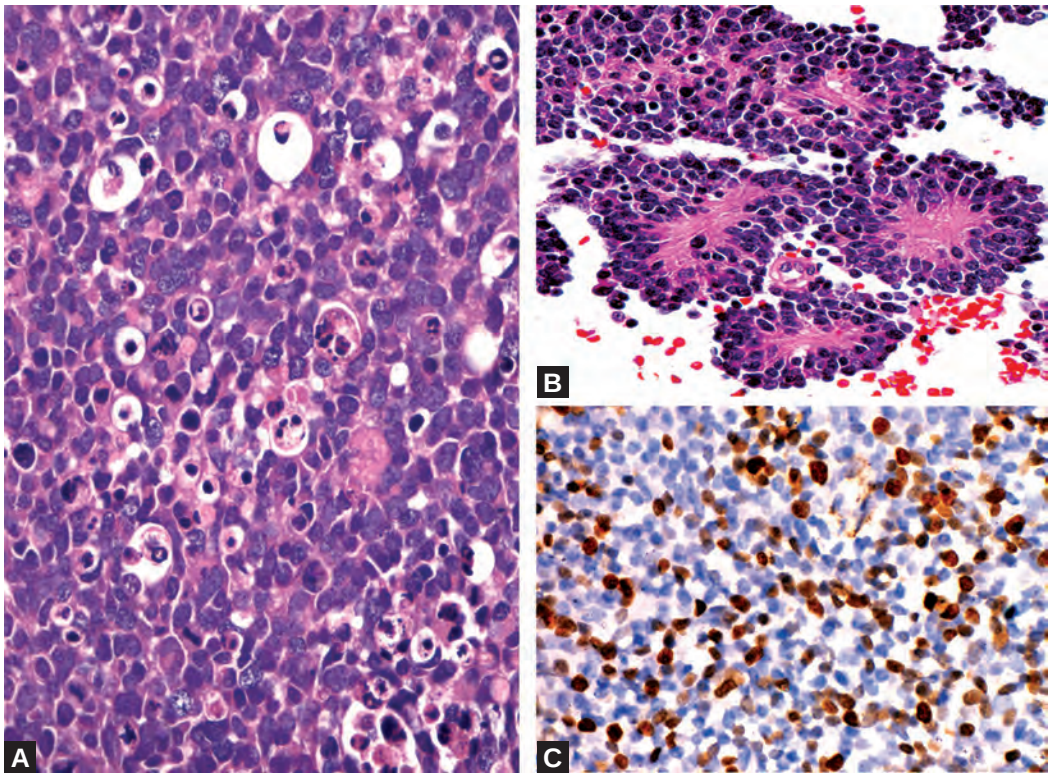
The majority of MBs arise in the vermis and appear as pink or grey masses that can project and fill the fourth ventricle. Foci of necrosis are generally small and extensive necrosis is uncommon.

Classic Medulloblastomas

Classic MBs are characterised by sheets of densely packed cells with hyperchromatic round to oval or carrot shaped nuclei, scant cytoplasm, numerous mitosis and conspicuous apoptosis (Fig. 1A). Homer-Wright rosettes are observed in less than 40% of cases (Fig. 1B). These rosettes are characterised by arrangement of tumour cells around a fibrillary centre. Varying degrees of neuronal and glial differentiation can be seen in these tumours. Areas of necrosis and vascular hyperplasia are uncommon. The tumour shows high mitotic activity (Fig. 1C).

Desmoplastic/Nodular Medulloblastomas

Desmoplastic/nodular MBs show a distinctive nodular architecture with reticulin free pale islands alternating with reticulin rich internodular regions (Figs 2A and B). The cells within the nodules have round uniform nuclei, with evidence of neuronal differentiation (synaptophysin +ve) and show low mitotic rate (low MIB-1 labelling index) but high apoptosis. In contrast, the cells in the internodular regions have hyperchromatic irregular nuclei, show evidence of glial differentiation (GFAP +ve) and have a high mitotic rate, but a low apoptotic rate. This characteristic pattern may be present either diffusely or focally throughout the tumour. It is important to emphasise that MBs showing only increased amounts of reticulin fibres and/or collagen, but lacking the nodular pattern, are not classified as desmoplastic/nodular

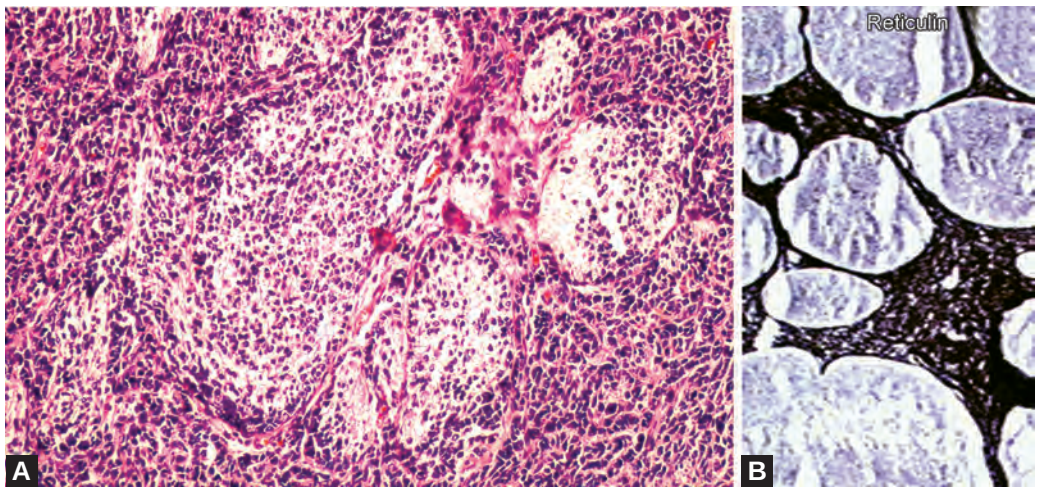


Figs 1A to C: (A) Classical medulloblastoma made up of sheets of undifferentiated cells with elongated, hyperchromatic nuclei interspersed with apoptotic bodies and cells in mitosis. (B) Focal areas show characteristic Homer Wright rosettes with central fibrillary neuropil representing neuronal differentiation. (C) MIB-1 immunostaining highlights high mitotic response [A:HE x 240; B:HE x 120; C:Immunoperoxidase x 120]

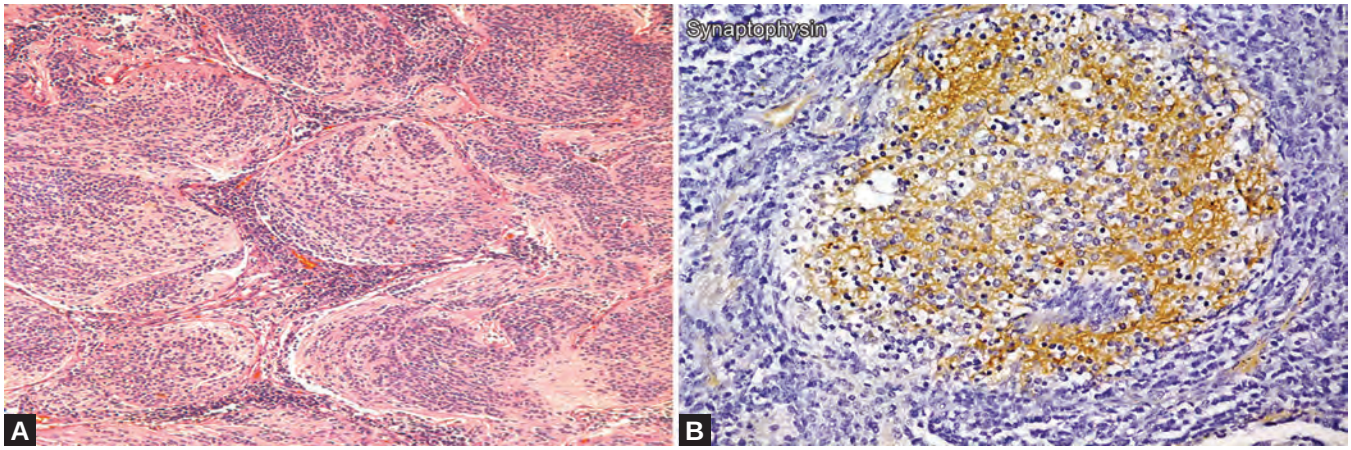
variant. The high reticulin/collagen content could be a secondary event to leptomeningeal invasion.

Medulloblastomas with Extensive Nodularity

MBEN comprise of nodules having round cells with uniform nuclei arranged in a laminar/streaming pattern with a fine fibrillary neuropil like matrix (cells resemble those of central neurocytoma) (Fig. 3A). These cells express synaptophysin (Fig. 3B) while the surrounding undifferentiated cells are negative. They possibly represent the most differentiated form of desmoplastic MBs comprising of well-delineated nodules with little or no internodular cellular component unlike desmoplastic MBs.



Figs 2A and B: (A) Desmoplastic medulloblastoma with pale nodular areas surrounded by islands of undifferentiated cells. (B) Nodular arrangement is highlighted by dense reticulin framework encircling the central reticulin free pale zones [A:HE x 100; B:Retculin silver x 60]



Figs 3A and B: Medulloblastoma with extensive nodularity (MBEN) shows characteristic pale neurocytic zones. (A) that strongly express synaptophysin. (B) in contrast to the surrounding undifferentiated cells [A:HE x 80; B:Immunoperoxidase x 120]

Anaplastic Medulloblastomas

Anaplastic MBs are characterised by marked nuclear pleomorphism, nuclear moulding, cell-to-cell wrapping, high mitotic activity (including abnormal forms) and high apoptotic rate (Figs 4A and B). The above changes have to be pronounced and widespread within a tumour to label it as an anaplastic MB. If these features are present only focally, then a tumour cannot be labelled anaplastic MB. Several studies have documented histological progression from non-anaplastic to anaplastic MB (similar to malignant progression in gliomas).

Large Cell Medulloblastomas

Large cell MBs comprise of monomorphic cells with large round vesicular nuclei, prominent nucleoli and variable amounts of eosinophilic cytoplasm with abundant mitosis and apoptosis. Large cell and anaplastic MBs show considerable histological overlap and, hence, in several studies, a combined large cell/anaplastic category (LC/A MBs) has been proposed.

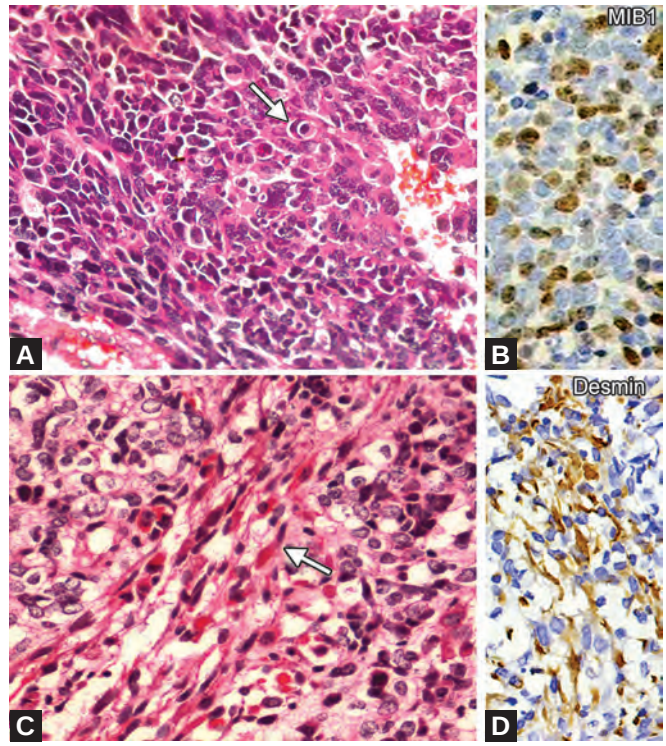
Melanocytic Medulloblastomas

Melanocytic MBs are characterised by the presence of melanin in scattered tumour cells.

Medullomyoblastomas

Medullomyoblastomas comprise of areas of classic MBs admixed with cells that show rhabdomyoblastic differentiation (spindle or strap cells with cross-striations of skeletal muscle and immunopositivity for desmin) (Figs 4C and D).

Most MBs are immunopositive for nestin and vimentin. Synaptophysin is also by and large positive, although its expression may take several forms (from completely negative to patchy positivity to diffuse positivity). The other markers that can be demonstrated, at least focally in many MBs, include class III beta tubulin, MAP-2, neuron specific enolase and neurofilament. Expression of all the above neuronal antigens indicates varying degrees of differentiation of MB along the neuronal lineage. The significance of immunopositivity for GFAP in MBs remains controversial. Most tumours contain GFAP positive reactive astrocytes but there are tumours in



Figs 4A to D: Large cell/anaplastic medulloblastomas showing. (A) Large pleomorphic cells with (B) High mitotic activity and at places showing characteristic cell-to-cell wrapping (A, arrow). High mitotic response is evident on MIB-1 immunostaining. Medullomyoblastoma. (C) Showing rhabdomyoblastic differentiation with elongated strap cells with bright red cytoplasm (arrow) admixed with undifferentiated medulloblastomas cells. (D) These cells are strongly positive for desmin. [A:HE x 240; B:MIB-1 x 280; C:HE x 240; D:Desmin x 240]

which unequivocal GFAP positivity is noted within the neoplastic cells. Varying degrees of photoreceptor differentiation (immunopositivity for retinal S antigen and rhodopsin) are also noted in some MBs.[12,48]

Tissue from the undifferentiated areas does not show any specific ultrastructural features. In the areas of neuroblastic differentiation (rosettes), the cells show neurite like cytoplasmic processes filled with microtubules. Dense core vesicles and synapse-like structures may also be seen. In areas of glial differentiation, abundant intermediate filaments are noted.

The histogenesis of MBs has remained controversial for over 80 years, since Bailey and Cushing first recognised it as a distinct clinicopathological entity in 1925. There are two main hypotheses. One view suggests that MBs arise from the cells of the external granular layer of the cerebellum. The second hypothesis states that MBs are derived from subependymal matrix cells, which reside throughout the embryonal CNS, including the fourth ventricle, which give rise to neuronal and glial cells.[11]

Perhaps, most likely, is a combined theory proposing that MBs arise from more than one cell type. Based on this theory it is suggested that classic MBs are derived from the periventricular primitive zone while nodular MBs arise from EGL cells. New candidate cells of origin continue to be proposed and one such recent hypothesis is the origin from CD133+ve stem cells found predominantly in the white matter of the postnatal cerebellum.

Molecular Genetics

Molecular and genetic alterations in MBs have been worked out extensively using various techniques. These have been divided into three main groups namely: (i) non-random chromosomal abnormalities; (ii) abnormalities in signal transduction pathways and (iii) altered expression of neural transcription factors.

Non-random Chromosomal Abnormalities

Chromosome 17: Partial or complete deletion of the short arm of chromosome 17 (17p) is noted in 30–50% of MBs and is the most frequent non-random chromosomal abnormality. The most common mechanism for 17p loss in MBs is isochromosome 17q. Interestingly, the well-known tumour suppressor gene (TSG) p53, although located on chromosome 17p, is rarely mutated in MBs (only in 5–10% cases).[1,58] This suggests that inactivation of other TSGs on 17p must be important in MB tumourigenesis, of which an important one is now believed to be hypermethylated DNA in cancer-1 (HIC-1) gene.

Other chromosomes: Loss of genetic material from chromosome 1q and 10q are demonstrated in approximately 20–40% of MBs. Other non-random chromosomal abnormalities detected in MBs include isolated examples of deletions of 3q, 6q, 9q, 10q, 11p, 11q and 16q and gains of 4p, 5p, 5q, 7q, 8q and 9p.[9,61]

Gene amplification: C-myc gene amplification occurs in 4–17% of MBs, followed by N-myc.[3,4,19] Large cell/anaplastic MBs, in particular, appear to have a high incidence of C-myc and N-myc amplification. Recently, Fan et al. noted amplification of the human telomerase catalytic protein subunit gene (hTERT) locus at chromosome 5p15 in 42% of MBs and other embryonal tumours.[26]

Abnormalities in Signal Transduction Pathways

Sonic Hedgehog SHH-PTCH signalling pathway: Sonic Hedgehog (SHH) is a family of ligands secreted by the Purkinje cells of the cerebellum, which promote the replication of granule cells, while PTCH is a TSG located on chromosome 9q.[74] SHH and PTCH function as part of a signalling pathway controlling normal CNS development.

Abnormalities in the SHH/PTCH signalling pathway was first suggested following the observation that 1–2% of patients developing MB have Gorlin's syndrome or Naevoid Basal Cell Carcinoma Syndrome (NBCCS) which are caused by mutations of the PTCH gene.[25] Subsequently, molecular studies on sporadic MB cases have shown alterations of the SHH/PTCH pathway in about 25% of cases, with a potential but not exclusive relation with the desmoplastic phenotype.[23,24,56]

'Wingless' (WNT/WG) signalling pathway: This is another signalling pathway that regulates cell proliferation and is essential for normal CNS development. Involvement of this pathway in MB was first suggested because of the association of some MB cases with type 2 Turcot's syndrome, a familial cancer syndrome, in which patients have adenomatous colonic polyps, predisposing to colonic carcinoma, in association with germ-line mutations of the APC gene (Adenomatous Polyposis Coli).[14] Disruptions in this WNT/WG signalling pathway have been found in about 13% of sporadic MBs.[23,24]

Neurotrophin signalling pathway: The neurotrophin signalling pathway comprises of the neurotrophin family along with the tyrosine receptor kinase family of receptors (Trk receptors A, B and C) and plays a major role in cerebellar development. Increased expression of Trk receptors, especially TrkC, has been noted in MBs, especially desmoplastic MBs.[7,54,71]

ErbB receptor signalling pathway: ErbB receptor signalling pathway is important in both cerebellar development and MB tumourigenesis. The ErbB2 receptor especially appears to play a central role in MB. In a study of more than 100 paediatric MBs, Gilbertson et al. reported ErbB2 protein expression in approximately 80% of MBs and co-expression of ErbB4 in 54%.[29,30]

Notch signalling pathway: Notch is a pathway that plays a critical role in regulation of neural stem cells. In the cerebellum, Notch 2 has been shown to promote proliferation of EGL progenitor cells. In MBs, elevated levels of Notch signalling have been found in about 15% of cases and this was caused by amplification of Notch 2 gene.

Altered Neural Transcription Factors

Many transcription factors involved in the development of CNS are deregulated in MBs, e.g. PAX5 and PAX6 mRNA (paired box containing gene transcription factors active in neural development) have been detected in 70% and 78% of MBs by *in situ* hybridisation. Other neural transcription factors found to be over expressed in MBs include ZIC (granule cell marker), NEUROD family of transcription factors, SOX transcription factors and REST (repressor of neuronal differentiation).

Molecular Differences between the Different Medulloblastoma Variants

Molecular genetic analysis studies reveal that large cell and anaplastic (LC/A) variants are particularly associated with myc oncogene (C-myc and/or N-myc) amplification and raised C-myc mRNA levels.[11] A recent study suggested that 17p loss/isochromosome 17q is also more frequent in LC/A MBs than in classic MBs. Abnormalities of chromosome 17 have been found more frequently in non-desmoplastic MBs than in the desmoplastic type.

Gajjar et al. reported ErbB2 expression most frequently in LC/A MBs. Further, increased aneuploidy in LC/A MBs was detected by several groups, suggesting that additional genetic changes are yet to be discovered.[27]

Deletions of chromosome 9q, PTCH gene mutations and mutations of other genes in the SHH signalling pathway occur preferentially, and in a significant proportion (30–40%) of desmoplastic MBs.[56] Eberhart et al. noted TrkA and TrkC in a high percentage of desmoplastic MBs, predominantly within their nodules.[21]

Treatment and Prognosis

Before 1970, the overall 5-year survival rate for patients with MBs was only 2–30%. Since then, with the advancements in diagnosis, imaging and management (both surgical and radio-chemotherapeutic) the 5-year survival has markedly improved to 60–70%.[18]

MBs spread via the CSF pathways with subarachnoid seeding occurring in up to one-third of patients at the time of diagnosis.[47] Recurrence, generally local, is unfortunately very common and mostly occurs within the first 2 years after initial treatment; however, late recurrences can occur sometimes 10–19 years after diagnosis. Systemic/extraneural metastasis is also described, the most common site being bone, followed by lymph nodes. They may manifest up to several years after initial treatment, within a median time of 12–32 months. The development of recurrence or metastasis carries a poorer prognosis with lowered 5-year survival rates. Patients with MB also have an increased risk for the development of second malignancies that is particularly attributable to the longer survival times as well as the use of RT and CT.[20,47]

Risk Stratification in Medulloblastomas (Prognostic Factors)

Clinical Factors

MBs have been stratified on the basis of age, extent of resection and Chang et al. metastasis staging into the following two risk groups:[15,75]

1. *Average risk:* Patients older than 3 years of age with non-metastatic disease and total or near total resection (<1.5 cm of residual tumour on post-operative imaging).
2. *High risk:* Patients less than 3 years, with incomplete surgical resection (>1.5 cm residual tumour) or with metastatic disease at presentation (Chang stages M1-4).

The major limitation of this stratification is that it does not differentiate high and low-risk patients within the same clinical stage. This is true, since there is wide discordance of clinical outcomes due to biological differences within a tumour. Therefore, the considerable shortcomings of the current clinical staging system are its inability to identify 20–30% of average risk patients with resistant disease or overtreated average risk patients.

These concerns have induced the search for stratification of MBs based on multiple parameters; this includes histology and new molecular markers. This will help in enhancement of the utilisation of existing therapies for MBs and minimise the hazards of suboptimal treatment and devastating side effects.

Histopathological Factors

The most important histopathological factors with a demonstrable role in prognosis of MBs are histopathological subtype, extent of nodularity and grade, and extent of anaplasia.

Histopathological subtypes: The best prognostic outcome is seen with MBEN[69] while large cell/anaplastic MBs have the worst outcome with high local recurrence, CSF and systemic metastasis and death within 1–2 years of diagnosis.[50] Prognosis of the desmoplastic variant still remains debatable. They have been inconsistently correlated with better outcome, worse prognosis or no relation with survival time. Other variants with poor outcome are melanotic MBs and medullomyoblastoma, with survival of 2 months to 2.5 years in the former, to less than 1 year in the latter.[22,33,34,44,46]

Anaplasia: It has been proposed as the criteria associated with aggressive behaviour and poor outcome.[11]

Differentiation: MBs have been shown to differentiate along glial or neuronal cell types. Different studies have shown variable prognostic significance for GFAP positivity ranging from better to poor to equivocal.[35,43]

Proliferation index and apoptotic index: Sarkar et al. have shown higher proliferation index and lower apoptotic indices in childhood as compared to adult MBs.[64] The overall significance of cell proliferation and apoptotic

index as prognostic markers is still debatable.[38] Ito et al.[42] have shown that MBs with a labelling index greater than 20% behave aggressively, while Schiffer et al.[66] showed no correlation of proliferation index in adult and childhood MBs.

Ploidy: Aneuploid tumours have been shown to respond favourably to treatment as compared to diploid tumours.[60]

Molecular, Cytogenetic Factors and Signalling Pathway Markers

It has been shown that combined analysis of molecular and clinical factors gives better risk stratification than clinical factors alone.

Loss of 17p/Isochromosome 17q

Poor outcomes, shortened survival and metastasis have been demonstrated with 17p deletions and/or isochromosome 17q. C-myc alterations in association with 17p alteration further promote their aggressive behaviour.[5,65]

C-myc and N-myc Amplification

Tumours with myc gene amplification have a significantly worse clinical outcome, shorter survival[57] and resistance to therapy. Therefore, it is important to identify myc gene amplification or myc RNA overexpression, since these parameters can act as independent prognostic criteria.

Gene Profiling

Gene expression profiling of MBs have been studied using oligonucleotide microarrays. Genes attributed to cerebellar differentiation and genes encoding extracellular matrix proteins have been correlated with a better prognosis. However, concomitant expression of genes related to cell proliferation and multidrug resistance are associated with poor outcomes.[57] Platelet derived growth factor receptor (PDGFR) and Ras/mitogen-activated protein (MAP) kinase signal transduction pathway show upregulation in metastatic disease.

TrkC Expression

TrkC is the single most important predictor of favourable outcome in MBs. Segal et al.[67] reported a high 5-year survival of 89% in MBs with high TrkC as compared to 46% for those with low TrkC. Also a 4.8-fold greater risk of death was reported in children with low TrkC mRNA expression.[37] Moreover, 100% progression-free survival was reported in PNET/MBs with combined low C-myc and high TrkC mRNA expression.[36]

ErbB2 Expression

Increased ErbB2 expression is associated with poor prognosis. Maintaining the cut-off of 50% for ErbB2 labelling of tumour cells, two different series have reported 10-year survival of 48% and 10% and 25-year survival of 46% and 17% respectively.[31,32]

Wingless (WNT/WG) Pathway

Nuclear accumulation of beta-catenin, a marker of activation in the WNT pathway, has been found to be an independent marker of good outcome.

The mainstay of treatment of MBs has been maximal surgical resection, whole neuraxis radiation and chemotherapy. However, only 60% of children with MBs are cured using the aggressive regimen and most of them suffer long-term side effects in the form of neuropsychological sequelae and neurocognitive decline.[39,53] Hence, new modalities of treatment aimed at lowering the dose of craniospinal axis irradiation (CSA-RT) combined with adjuvant chemotherapy (CT) are being tried. New treatment modalities being investigated include new techniques of three-dimensional conformal RT and intensity modulated radiation therapy (IMRT) which precisely direct RT to the desired site and minimise the neurotoxicity of conventional RT.[49,63]

New biological and molecular factors are also being targeted for novel therapeutic approaches. One of these is cyclopamine, a plant-derivative teratogen that inhibits the SHH/PTCH1 pathway by binding to and altering the conformation of SMO gene product. The recent finding that cyclopamine can reverse the effect of oncogenic SMO and PTCH mutations in murine cells *in vitro* suggest that this pathway may prove to be a future novel therapeutic target.[70]

A second class of potential molecular therapeutic agents for MBs is small molecule inhibitors of receptor tyrosine kinases like ErbB2 and PDGFR. Very recently, Erlotinib (TM), a dual specific ErbB1/ErbB2 inhibitor, was shown to selectively inhibit ErbB2 signalling, cell invasion and ErbB2-dependent prometastatic gene expression in MB cells *in vitro* and *in vivo*.[40] Further, the recent success of anti-ErbB2 monoclonal antibody Herceptin (TM) in the treatment of patients with advanced ErbB2 overexpressing breast cancer provides precedence for using such a strategy as a valuable target for novel therapy for MB.[16] A novel immunotherapeutic approach in the form of adoptive immunity by the T cells grafted with a HER2-specific chimeric antigen receptor has shown to induce sustained regression of established MBs in an orthotopic, xenogenic severe combined immunodeficiency model.[2]

Neural stem cells, retrovirally transduced with cytosine deaminase gene (CD-NSCs) treatment, followed by 5-fluorocytosine administration have shown to prolong survival periods significantly in experimental animals.[68]

The future of molecular therapies in MBs will, however, greatly depend on the continued co-operation between clinical and basic science disciplines.

ATYPICAL TERATOID/RHABDOID TUMOUR

This is a highly malignant CNS tumour in children, histologically corresponding to WHO grade IV.[45] It comprises about 1–2% of paediatric brain tumours and about 10% of CNS tumours in infants.

Clinical Features

AT/RTs most often present in children less than 3 years of age (mean age 2 years). They are rare in children older than 6 years and even rarer in adults. Male preponderance is noted.[41] AT/RTs occur both in the supratentorial and infratentorial locations (ratio of 1.3:1). Infratentorial tumours are commonly located in the cerebellar hemispheres, cerebellopontine angle and brainstem.[10] Supratentorial tumours are more often located in the cerebral hemispheres and less frequently located in the ventricular system, suprasellar or pineal region. About 2% of AT/RTs arise in the spinal cord. Variable clinical presentation is noted depending upon the age of the patient, location and size of the tumour.

Imaging

AT/RTs are isointense to slightly hyperintense with a variable degree of contrast enhancement, similar to MBs.

Histopathology

AT/RTs (Figs 5A to F) are soft pinkish and red bulky tumours with foci of haemorrhage and necrosis. Some regions of tumour may appear firm and grey-white.

AT/RTs are histologically heterogeneous lesions. The most conspicuous feature is the presence of rhabdoid cells with eccentrically placed vesicular nuclei, prominent eosinophilic nucleoli and abundant eosinophilic cytoplasm containing globular intracytoplasmic eosinophilic inclusions. In addition to these rhabdoid cells, most tumours contain variable components of primitive neuroectodermal, mesenchymal and epithelial cells (Figs 5A and B). Mitotic figures are abundant and necrosis is common.

AT/RTs show a wide range of immunoreactivity. Rhabdoid cells are consistently positive for vimentin (Fig. 5D) and epithelial membrane antigen (Fig. 5E). Expression of glial fibrillary acid protein, neurofilament protein, synaptophysin, smooth muscle actin (Fig. 5F) and cytokeratin are variably observed. Germ cell tumour markers are never expressed in these tumours.

Histogenesis and Molecular Genetics

The histogenesis of AT/RTs is not known. Various hypotheses suggested include origin from pluripotent foetal cells, neural crest cells, meningeal cells and germ cells.[10]

The genetic hallmark of AT/RTs is mutation or loss of the INI1 (hSNF5/SMARCB1) gene locus at 22q11.2 chromosome.[59] Consequent to the mutation, there is loss of INI1 protein expression in almost all AT/RTs. In normal tissue and in most tumours, INI1 is expressed as a nuclear protein; however, in AT/RTs there is loss of nuclear expression of INI1 in tumour cells. Immunohistochemical staining for expression of INI1 protein appears to be a sensitive and specific marker for diagnosis (Fig. 5C) of AT/RTs.[8,73]

Treatment and Prognosis

The overall prognosis of AT/RTs is very poor, mean survival being 11 months and median survival 17 months.[13] The majority of patients develop local recurrence and/or neuraxis dissemination, and die within a year of diagnosis.

CENTRAL NERVOUS SYSTEM PRIMITIVE NEUROECTODERMAL TUMOURS

This is a heterogeneous group of malignant tumours occurring predominantly in children and adolescents and which correspond histologically to WHO grade IV. The term CNS-PNET has been introduced in the new (2007) WHO classification and refers to all undifferentiated or poorly differentiated embryonal tumours that occur at any extra-cerebellar site in the CNS.[51] The following tumours are included in this category:

- Supratentorial PNET (sPNET)
- CNS neuroblastoma
- CNS ganglioneuroblastoma
- Medulloepithelioma
- Ependymoblastoma

Supratentorial Primitive Neuroectodermal Tumour

This is an embryonal tumour occurring in the supratentorial location, composed of undifferentiated or poorly differentiated neuroepithelial cells with the capacity for divergent differentiation along neuronal, astrocytic, muscular or melanocytic lines. Tumours of CNS/supratentorial PNETs with only neuronal differentiation are termed cerebral neuroblastoma while those with neuronal differentiation with ganglion cells are termed ganglioneuroblastoma. Since these are rare tumours, their precise incidence is difficult to determine.

Clinical Features

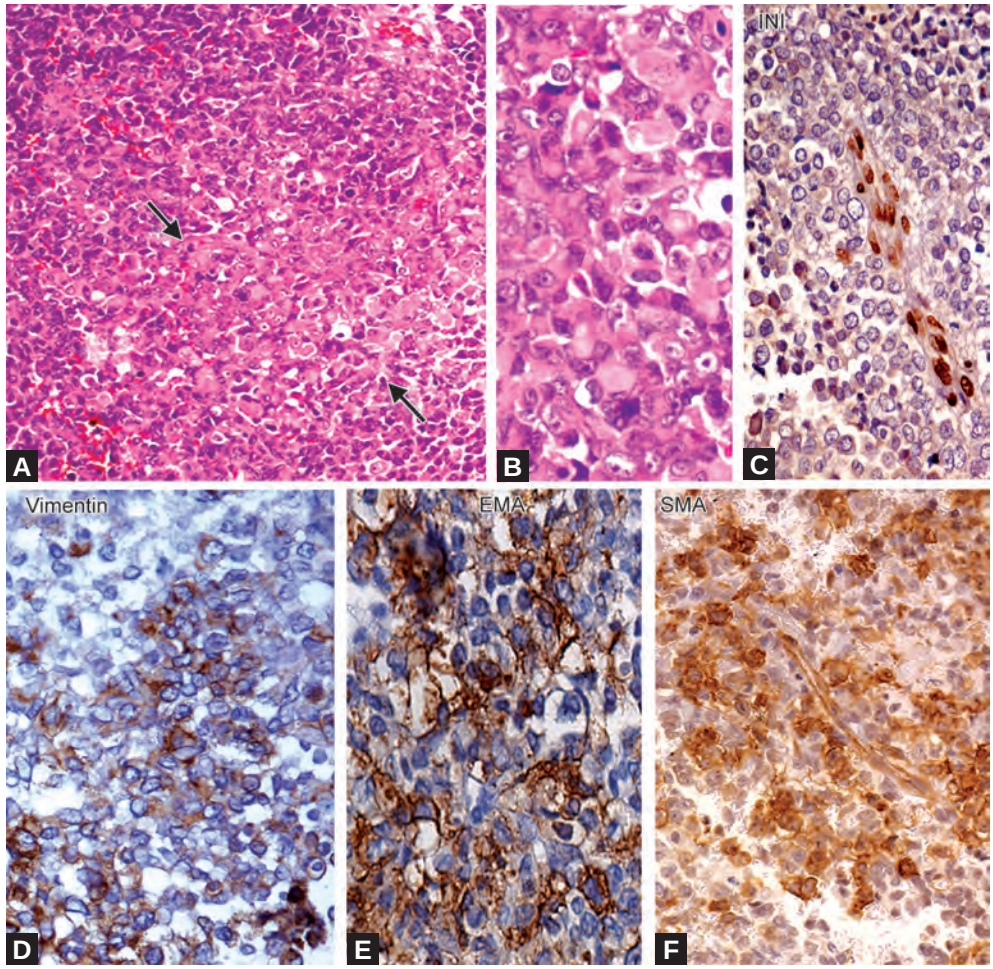
The mean age is 5.5 years with a range of 4 weeks to 20 years. Male preponderance is noted. These tumours are found most commonly in the cerebral hemispheres. Rarely, they have been reported from spinal cord and suprasellar regions. Clinical presentation is related to the site of origin of tumour.

Imaging

They are isointense to hyperintense and show enhancement on injection of contrast material.

Histopathology

These tumours appear as pink-red soft tumours with or without cysts and haemorrhage. These sPNETs are histologically similar to MBs, being composed of poorly differentiated round to oval cells with high nuclear cytoplasmic ratio and brisk mitosis. Fibrillary background may be seen in these tumours and Homer Wright rosettes can also be present. Calcification is a relatively



Figs 5A to F: Atypical rhabdoid/teratoid tumour showing conspicuous rhabdoid cells with vesicular nuclei, prominent nucleoli and eosinophilic globular cytoplasmic inclusions (arrows, A and B) admixed with undifferentiated cells. The tumour cells are negative for INI1 (C) and strongly positive for vimentin (D), epithelial membrane antigen (E) and smooth muscle actin (F) [A:HE x 160; B:HE x 300; C:INI1 x 160; D, E and F: x 240]

common feature within degenerated areas. Neuronal and glial cells, ependymal canals, striated muscle or melanin bearing cells, indicating divergent differentiation of tumours may be seen. These sPNETs express many of the neuronal markers, namely synaptophysin, class III beta tubulin and neurofilament protein. Variable degree of GFAP expression may also be seen.

Histogenesis and Genetics

Histogenesis of sPNETs is controversial. They possibly arise from primitive neuroepithelial cells. The genetic abnormalities in sPNETs are different from MBs. Although they are histologically similar to MBs, they lack many of the molecular genetic alterations characteristic of MBs. Thus, losses of 17p and isochromosome 17q abnormality are rarely seen in sPNETs.[13] In contrast, other genetic abnormalities seen in sPNETs are expression of neuroD family of basic helix-loop-helix transcription factors and RASSF1a promoter methylation. sPNETs also express Achaete-Scute, which is another neurogenic transcription factor with homology to neuroD genes.[62] Recent microarray studies have also revealed that MBs and sPNETs can be separated based on their specific pattern of gene expression.

Outcome and Prognosis

Children with sPNETs have a worse overall 5-year survival rate compared to children with MB. Infants less than 2 years of age have a poorer prognosis than older children.[28] CSF dissemination can be found in nearly one-third of patients. Extraneural metastasis to bone, liver and cervical lymph nodes have also been reported.[72]

Medulloepithelioma

These are very rare embryonal tumours, most examples being single case reports.

Clinical Features

They generally occur in neonates, infants and very young children aged less than 5 years (age range less than 1 month to 23 years with a mean of 45 months).

Medulloepitheliomas develop in both the supratentorial and infratentorial compartments.[52] The majority are located in the periventricular region and the remaining in the cerebral hemispheres. Isolated examples have been described in the cauda equina, presacral areas, posterior fossa and pons. Outside the CNS, these tumours occur intraorbitally.[55]

Most patients present with symptoms of raised intracranial pressure because the tumour is often large at the time of presentation. On imaging, they are similar to other embryonal tumours.

Histopathology

They are greyish-pink tumours with areas of haemorrhage and necrosis. Medulloepitheliomas have a cytoarchitecture closely resembling that of the embryonic or primitive neural tube. They are characterised by papillary, tubular and trabecular arrangements of the neoplastic pseudostratified neuroepithelium, having a PAS-positive external limiting membrane with the cells resting on a delicate reticulin framework. Mitoses are abundant and tend to be located more on the non-ciliated, reticulin-free luminal surface. Sometimes, multiple lines of differentiation, viz. neuronal, glial and mesenchymal elements can also be identified.

These tumour cells reveal extensive immunoreactivity for nestin, vimentin and microtubule associated protein type 5, similar to cells of the primitive neural tube. Other markers, like NF, CK and EMA, may be found in some cases. Positivity for GFAP and synaptophysin, if present, reflects the cell lineage of differentiation.

Genetics

Molecular genetics of medulloepitheliomas has not been well-characterised. In two cases, hTERT gene amplification has been reported, similar to that seen in MBs.[6]

Outcome and Prognosis

These are rapidly growing tumours and most children die within a year of diagnosis often with CNS dissemination, but rarely with systemic metastasis. Intraorbital medulloepitheliomas, which are different from their CNS counterparts in that they rarely metastasise, are effectively treated by enucleation and generally carry a favourable prognosis.[52]

Ependymoblastoma

These are rare embryonal tumours.

Clinical Features

They generally occur in neonates, infants and very young children aged less than 5 years. Males and females appear to be equally affected.

Ependymoblastomas are predominantly supratentorial and many appear entirely intraparenchymal without any obvious relationship to the ventricular lining, which is in marked contrast to typical ependymomas.

The most common presentation is with features of raised intracranial pressure and hydrocephalus. CT and MRI reveal contrast enhancing large tumours with extensive surrounding oedema.

Histopathology

They are generally well-circumscribed, grey-white tumours. The diagnostic features of ependymoblastomas are dense cellularity with distinctive multi-layered ependymoblastic rosettes or tubules. Unlike typical ependymal rosettes, these are formed by multiple layers of tumour cells, the inner ones often in mitosis. The outer layer of cells of the rosettes merges with the background of undifferentiated neuroectodermal cells. Immunohistochemistry (IHC) reveals positivity for vimentin and sometimes S-100 protein. Scanty GFAP positivity and absence of luminal EMA reactivity differentiate it from typical ependymomas. Unlike other embryonal tumours, ependymoblastomas do not show IHC evidence of neuronal differentiation.

Histogenesis

These tumours are presumed to arise from periventricular neuroepithelial cells.

Prognosis

These tumours grow rapidly with craniospinal dissemination and fatal outcome usually within 6 months to 1 year of diagnosis.[17]

ACKNOWLEDGEMENT

The authors wish to acknowledge the help of Dr Arvind Rishi, Senior Resident, Department of Pathology, AIIMS, in the preparation of the manuscript.

123 Tumours of Meninges

Sundaram C, Shantveer G Uppin

MENINGIOMA

Meningiomas are generally slow growing benign tumours accounting for 13–26% of primary intracranial tumours. The tumours arise from the arachnoid cap cells.[41] Classification of the tumours arising from the meninges is given in Table 1.[40]

Primary Melanocytic Lesions

Diffuse melanocytosis, melanocytoma, malignant melanoma, meningeal melanomatosis.

Other Neoplasms Related to the Meninges

Haemangioblastoma.

Age and Gender

Meningiomas are tumours of adults with a peak incidence between 50 years and 60 years. They also occur in children and the elderly. They are twice as common in women as in men.

Site

Meningiomas occur in intracranial, spinal, orbital and ectopic locations (Figs 1A to F). The common intracranial locations include parasagittal, falx, cerebral convexity, olfactory groove, tuberculum sellae, sphenoid ridge, cerebellopontine angle, optic nerve, parasellar region and within the ventricles. Spinal meningiomas are more common in the thoracic region.[36,57]

Clinical Features and Associations

Meningiomas may present as space occupying lesions, with raised intracranial pressure, focal deficits or seizures. They may be incidental and asymptomatic. They can occur in association with neurofibromatosis 2 and may be multiple.

Radiological Features

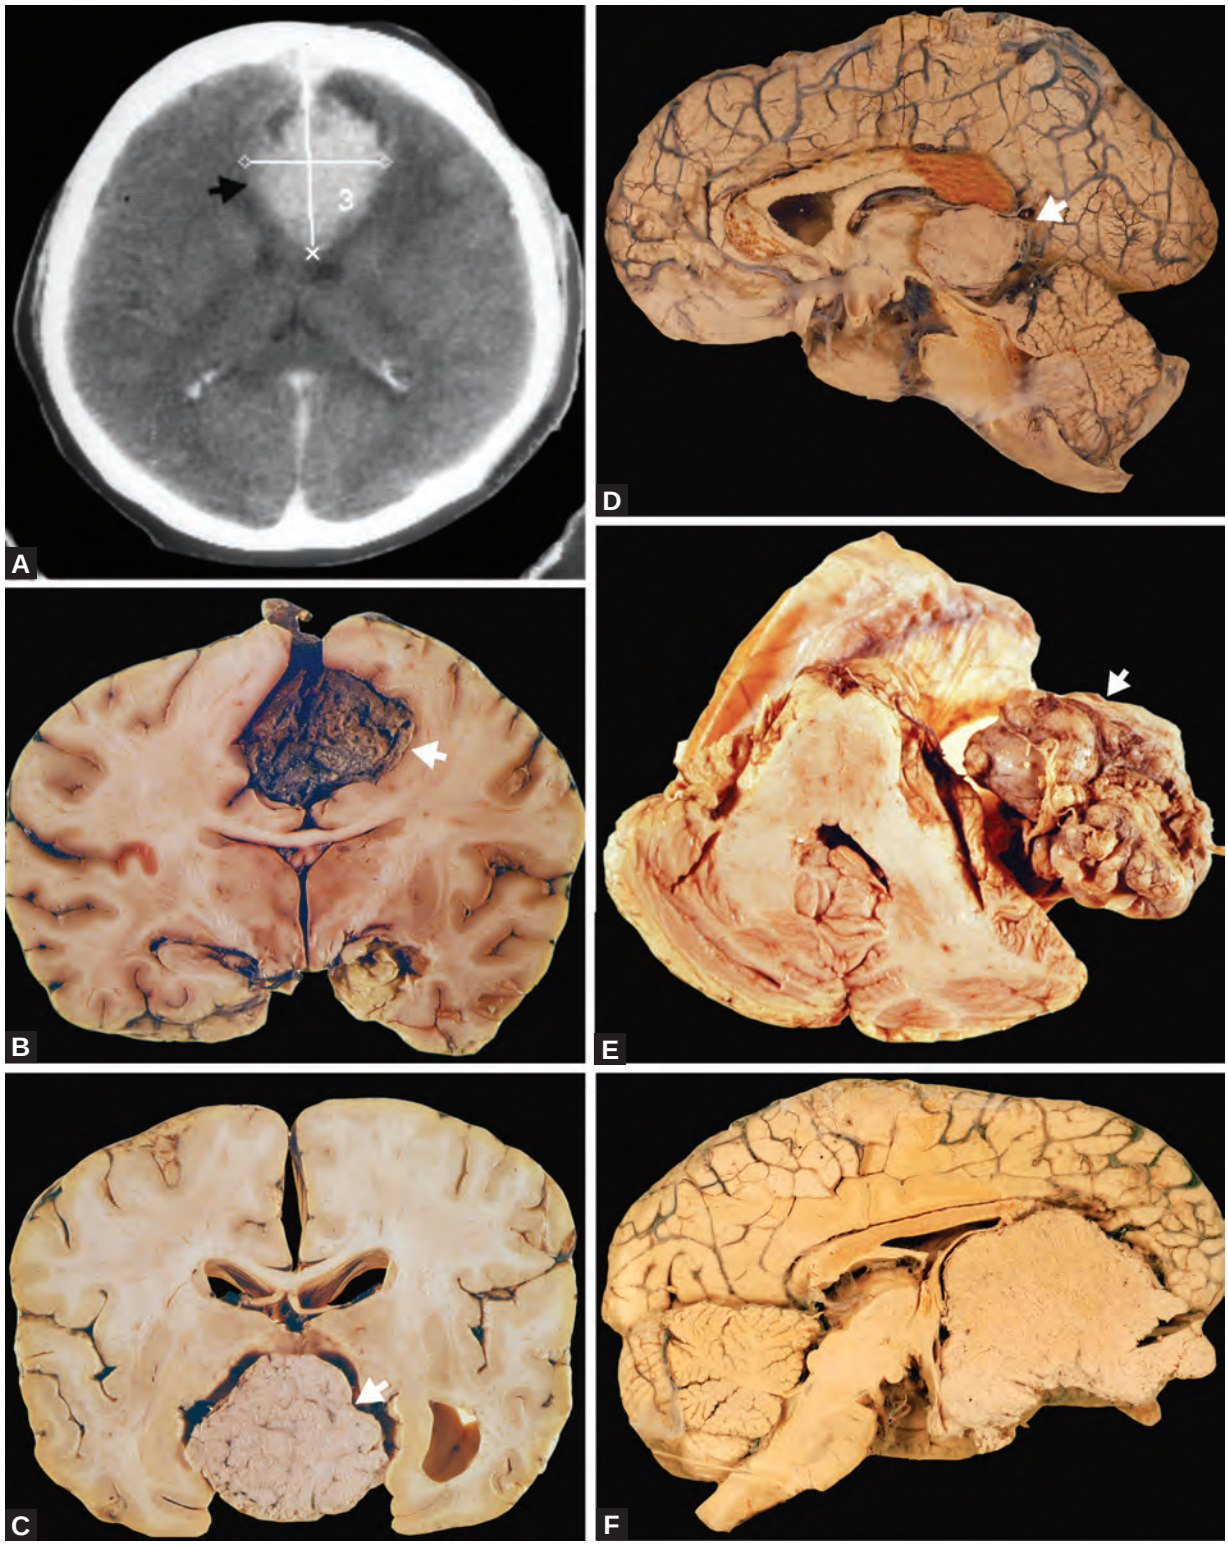
Meningiomas are isointense or hyperintense on the T2-weighted image and enhance with contrast. A short tapered peritumoural extension of contrast material along the inner surface of the tumour due to its attachment to the dura is called dural tail and is a helpful diagnostic feature of meningioma.

Gross Pathology

Meningiomas are lobulated, well demarcated tumours attached to the dura (which may not be obvious in all tumours) (Figs 1A to F). Some tumours are flattened and are called the enplaque variety. The tumours compress the adjacent brain parenchyma and may produce oedema. The peritumoural oedema is related to the size of the tumour, proliferative activity and histological subtype.[43] The overlying bone may show hyperostosis due to the presence of tumour cells in the diploic space. The tumour may infiltrate the dura, sinuses, bone, muscle, orbit, soft tissues and the brain. This infiltration is responsible for local recurrence even after complete resection.

Table 1: Tumours of the meninges (WHO 2007)[2]

Tumours of the meningothelial cells	
Meningioma (Figs 1 to 3)	
Meningothelial	*Metaplastic*
Fibroblastic	Chordoid
Transitional	Clear cell
Psammomatous	Atypical
Angiomatous	Papillary
Microcystic	Rhabdoid
Secretory	Anaplastic (malignant)
Lymphoplasmocytic-rich	
Mesenchymal tumours (Figs 4A and B)	
Lipoma	Chondroma
Angiolipoma	Chondrosarcoma
Hibernoma	Osteoma
Liposarcoma (intracranial)	Osteosarcoma
Solitary fibrous tumour	Osteochondroma
Fibrosarcoma	Haemangioma
Malignant fibrous histiocytoma	Epithelioid haemangioendothelioma
Leiomyoma	Haemangiopericytoma
	Anaplastic haemangiopericytoma
Leiomyosarcoma	Angiosarcoma
Rhabdomyoma	Kaposi's sarcoma
Rhabdomyosarcoma	Ewing's Sarcoma—PNET



Figs 1A to F: (A) Cranial CT scan showing a large uniformly enhancing lesion in anterior falcine region (arrow) with perilesional oedema. (B) Coronal slice of brain shows a large anterior falcine meningioma occupying the interhemispheric fissure compressing the cingulate gyrus and lateral ventricles corresponding to CT scan. (C) Large lobulated meningioma below the third ventricle, distending the ipsilateral temporal horn of lateral ventricle. (D) Sagittal view of brain showing a large meningioma in the pineal region, compressing the pulvinar of thalamus. (E) A large meningioma in the cerebellopontine angle (arrow) arising from free edge of tentorium compressing the pons and cerebellum and distorting the fourth ventricle. (F) A meningioma in the orbitofrontal area arising from the anterior cranial fossa. Patient presented with long standing dementia

Microscopy

Meningiomas exhibit a wide variety of histological diversity. The common histological varieties include meningothelial, fibroblastic and transitional forms. Psammomatous meningioma is more common in the spinal canal. However, they are benign and belong to WHO grade I (Figs 2 and 3).

Meningothelial Meningioma

This is composed of lobules of meningothelial cells with indistinct cytoplasmic margins and intranuclear pseudoinclusions. Cellular whorls and psammoma bodies are uncommon (Fig. 2A).

Fibroblastic Meningioma

This is composed of spindle cells in a fascicular architecture with intercellular collagen. Intranuclear inclusions and psammoma bodies are uncommon but calcification of the stroma is frequent (Fig. 2B).

Transitional Meningioma

This is characterised by cellular whorls usually around a central thin vessel and is intermediate between meningothelial and fibroblastic meningiomas. Psammoma bodies may be seen (Fig. 2C).

Psammomatous Meningioma

This type of meningioma shows extensive whorl formation and calcification along the concentric cellular whorls or central vessel forming numerous calcific psammoma bodies (Fig. 2D). These meningiomas are common in the spinal canal and olfactory groove.

Angiomatous Meningioma

Meningiomas rich in small vascular channels, some densely hyalinised, are called angiomatous meningiomas and they have no prognostic significance (Fig. 2E).

Microcystic Meningioma

This tumour arises from the arachnoidal trabecular cell.[24] The tumours are associated with peritumoural oedema, and large para and intratumoural cysts. Microscopically, there is accumulation of extracellular fluid with interconnecting cell processes. Whorl formation and psammoma bodies are infrequent.

Secretory Meningioma

This meningioma, in addition to a meningothelial and transitional pattern, demonstrates intracytoplasmic single or multiple brightly eosinophilic, periodic acid Schiff (PAS) positive globules which are called 'pseudopsammoma bodies'. Immunohistochemically, these globules are positive for epithelial membrane antigen (EMA), cytokeratin and carcinoembryonic antigen (CEA).[63] Serum or cerebrospinal fluid levels of CEA may also be elevated (Fig. 2F).

Lymphoplasmacyte Rich Meningioma

This type of meningioma is characterised by a dense infiltrate of lymphocytes and plasma cells, sometimes forming lymphoid follicles with germinal centres. This is associated with polyclonal hypergammaglobulinaemia. This lymphoplasmacytic response remits with tumour removal and reappears with recurrence.

Metaplastic Meningioma

These are meningiomas in which bone, cartilage, fat, myxoid tissue or xanthoma cells may be seen.

According to WHO 2007,[41] meningiomas are graded based on certain histological features (Table 2).

Certain histological types, like chordoid, clear cell, papillary and rhabdoid, and a few other histological features are associated with aggressive behaviour.

Clear Cell Meningioma (WHO Grade II)

These tumours have patternless sheets of polygonal cells with clear cytoplasm due to glycogen accumulation labelled by PAS stain (Fig. 2G). The vessels and stroma are hyalinised. Immunohistochemistry shows weak EMA positivity. These tumours, in spite of gross total removal, have aggressive behaviour with multiple recurrences, local spread and spinal metastases.[65]

Atypical Meningioma (WHO Grade II)

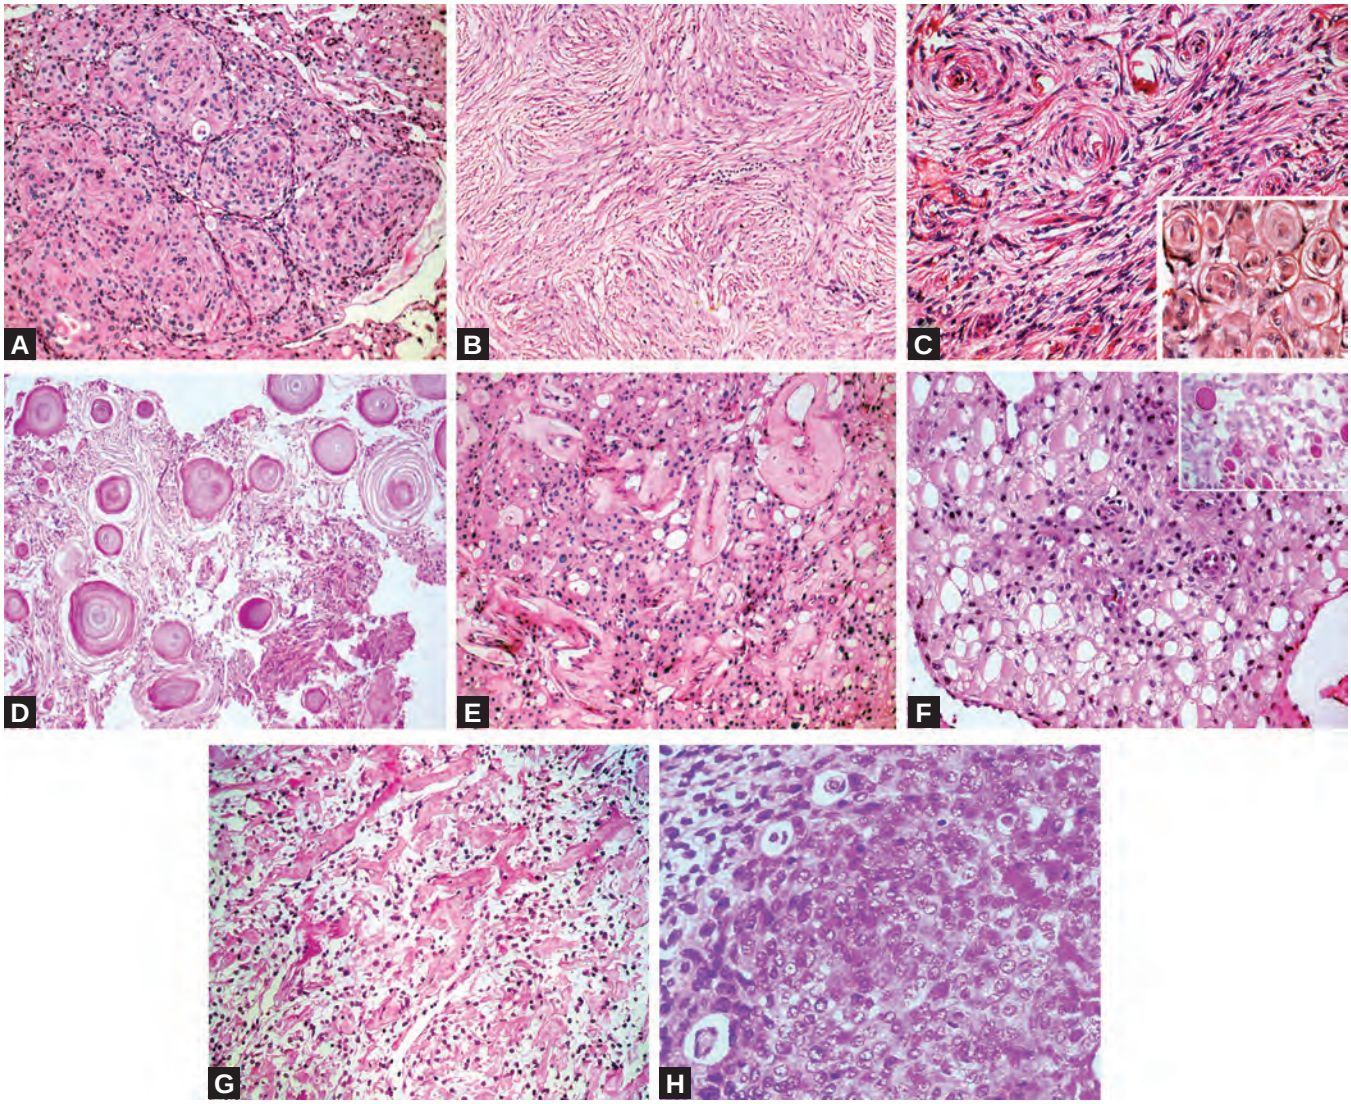
Any histological subtype of meningioma, which fulfils the criteria of WHO Grade II 2007 (Table 3), is associated with a greater chance of recurrence (Fig. 2H). Five-year recurrence rate may be as high as 50%.[43] MIB-1 labelling index is moderately high.

Chordoid Meningioma (WHO Grade II)

These tumours contain trabeculae of vacuolated or eosinophilic cells in a bluish matrix mimicking a chordoma (Fig. 3A). Meningothelial or transitional features may be seen in focal areas. Lymphoplasmacytic infiltrates are common.

Table 2: Histological grading of meningioma (WHO)[1]

Grade	*Criteria*
Grade II (Atypical meningioma)	Mitosis 4 or more/10 high power field or Three of the following five features: 1. high cellularity 2. loss of architectural pattern 3. small cells with high nuclear/cytoplasmic ratio 4. prominent nucleoli 5. necrosis
Grade III (Anaplastic meningioma)	Mitosis more than 20/10 high power field or Features of malignancy of a frank carcinoma or sarcoma or melanoma



Figs 2A to H: (A) Meningothelial meningioma showing lobules of meningothelial cells separated by thin compressed vascular septa (HE x 120). (B) Fibroblastic meningioma with fascicular pattern of spindle-shaped meningothelial cells arranged in interlacing bundles (HE x 120). (C) Transitional meningioma with areas showing fibroblastic morphology with spindled meningothelial cells and transitional zones with whorls. Inset: characteristic meningothelial whorl formation (HE x 200, Inset: HE x 300). (D) Psammomatous meningioma with numerous meningothelial whorls and calcified psammoma bodies (HE x 120). (E) Angiomatous meningioma with large vascular spaces separated by strands of meningothelial cells. Note prominent vascular hyalinisation (HE x 160). (F) Secretory meningioma with sheets of meningothelial cells dispersed in variably vacuolated stroma. Note the scattered eosinophillic hyaline bodies in stroma. Inset: highlights PAS positivity of secretory bodies (HE x 160, Inset: PAS x 200). (G) Clear cell meningioma with meningothelial cells having clear cytoplasm separated by hyalinised vascular channels (WHO Grade II) (HE x 160). (H) Atypical meningioma showing meningothelial cells in patternless sheets. Note cellular pleomorphism, nucleolar prominence and mitotic activity (WHO Grade II) (HE x 320)

Table 3: Aggressive meningiomas: grade, behaviour and histological type[2,4]

Grade	*Behaviour*	*Histological sub-type*
WHO grade II	Greater chance of recurrence	Atypical
WHO grade II (Brain invasive)	Greater chance of recurrence	Chordoid
		Clear cell
		Benign/Atypical
WHO grade III	i. Greater chance of recurrence	Anaplastic
	ii. Locally infiltrating growth	Papillary
	iii. Dissemination to systemic sites	Rhabdoid

Immunohistochemistry shows scant positivity for EMA and S100. These are rarely associated with Castleman's disease and other haematological conditions like iron refractory anaemia and polyclonal gammopathy.[30] Recurrence is nearly 100% after subtotal resection.[13]

Papillary Meningioma (WHO Grade III)

These are rare and tend to occur in children and young adults. They have a perivascular pseudopapillary pattern (Fig. 3B). The tumours exhibit an identifiable meningioma component and a variable papillary component. These tumours invade locally and into the brain parenchyma in 75%, tend to recur in 55% and metastasise in 20% of cases.[49]

Rhabdoid Meningioma (WHO Grade III)

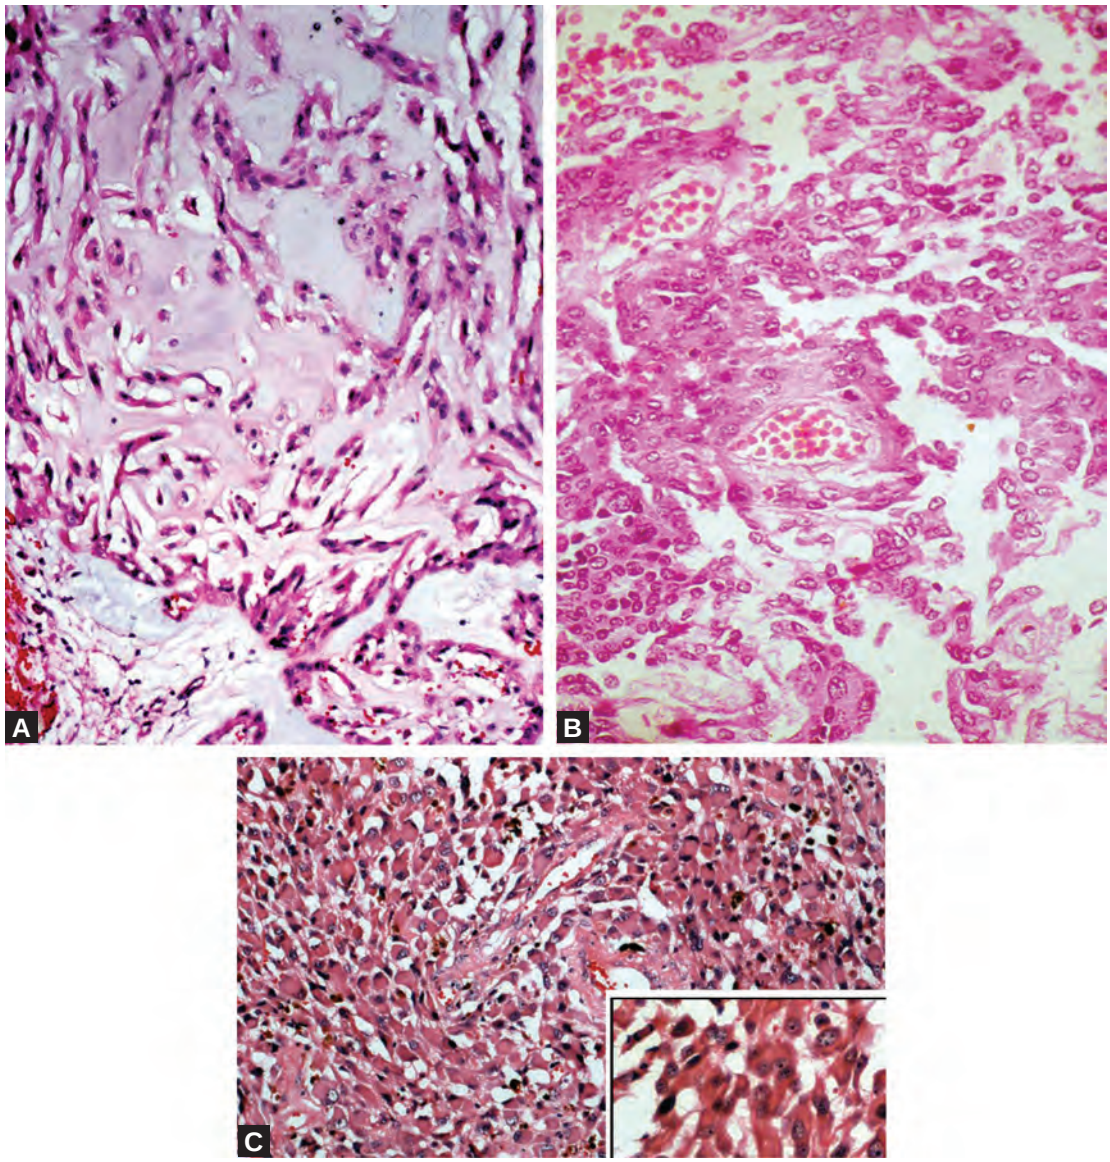
These tumours exhibit characteristic rhabdoid cells in diffuse sheets or focally (Fig. 3C). These rhabdoid cells have eosinophilic cytoplasm with eccentric nuclei and prominent nucleoli. The rhabdoid cells may be absent in the primary tumour and appear in recurrent tumours. MIB-1 index is high and recurrence is frequent.

Anaplastic Meningioma (WHO Grade III)

Meningiomas fulfilling the criteria of WHO 2000 of anaplastic features are usually fatal with a median survival of less than 2 years.[52]

Immunohistochemistry

The majority of meningiomas stain for EMA, but in atypical and anaplastic meningiomas, it is less consistent.



Figs 3A to C: (A) Chordoid meningioma with cords of meningothelial cells in a mucin-rich matrix resembling a chordoma (WHO Grade II) (HE x 200). (B) Papillary meningioma with meningothelial cells lining thick vessels resembling papillary structures (WHO grade III) (HE x 240). (C) Rhabdoid meningioma showing sheets of large tumour cells with characteristic eccentrically placed nuclei and deep eosinophilic cytoplasm as seen in inset (WHO grade III) (H&E x 2400; Inset: HE x 320)

All meningiomas show vimentin positivity. The S-100 protein is variably expressed. Secretory meningiomas are positive for CEA in pseudopsammoma bodies and for cytokeratins in the cells surrounding the pseudopsammoma bodies.[40]

Molecular Genetics

Chromosomal abnormalities have been described associated with the evolution of meningioma by Giemsa staining, fluorescent *in situ* hybridisation (FISH), comparative genomic hybridisation (CGH) and spectral karyotypic techniques.[56] The majority of sporadic and familial meningiomas are associated with abnormalities in chromosome 22. The Neurofibromatosis 2 (NF2) gene, on chromosome 22q12.2, a tumour suppressor gene, is believed to play a central role in the formation of meningiomas, in addition to schwannomas in cases of NF2 (Table 4). Meningioma sub-types show polymorphism in their rates of NF2 gene mutations, i.e. fibroblastic and transitional forms show 70–80% and meningothelial meningiomas 25% mutations.[62] Atypical and anaplastic meningiomas also show NF2 gene mutations in 70%, suggesting that NF2 gene mutations are probably involved with oncogenesis but not tumour progression.[37] The NF2 associated meningiomas are very few compared to sporadic meningiomas and the frequency of loss of heterozygosity (LOH) of chromosome 22 exceeds that of NF2 gene abnormalities. This led to the hypothesis that additional tumour suppressor genes on chromosome 22 are probably important in tumourigenesis in meningiomas. Search for other tumour suppressor genes resulted in the recognition of genes, BAM 22, LARGE, MN1 and INI1 as possible candidates.[38,39] LARGE gene mutations are implicated in recurrence and MN1 in multiple meningiomas.[38,54] Chromosome 1p abnormalities have been implicated in progression of meningiomas to higher grade and recurrence.[31,56] The other cytogenetic abnormalities that are noted in meningiomas include 6q, 7, 9p, 10, 14q, 18q, 19 or 20 chromosomes, but how these abnormalities aid in tumour progression is unknown.[3,4]

Production of vascular endothelial growth factor (VEGF) is associated with peritumoural oedema. Higher grade tumours are associated with a decrease in progesterone receptor staining and an increase in MIB-1 nuclear labelling.[56] Complex cytogenetic and molecular abnormalities including CDKN2A, CDKN2B, CDKN2C and PTEN gene mutations are identified in higher grade meningiomas.[27] Microsatellite instability is also described in meningioma.[55] Multiple meningiomas are clonal in origin and 50% exhibit NF2 gene mutations. Paediatric meningiomas, although rare, show NF2, 1p and 14q deletions and exhibit aggressive behaviour.[50]

Table 4: Genetic mutations, growth factors and association with meningioma tumourigenesis and progression

NF2 gene mutations	Tumour genesis
1p gene mutations	Tumour progression to high grade, recurrence
LARGE gene mutations	Tumour recurrence
MN1 gene mutations	Multiple meningiomas
Production of VEGF	Peritumoural oedema

Note: NF2: neurofibromatosis type 2, VEGF: vascular endothelial growth factor

Proliferation

Meningiomas exhibit increase in proliferative activity from benign to atypical to anaplastic varieties. This can be assessed by mitotic activity. The mean mitotic counts vary widely. The other markers of cell proliferation include nucleolar organiser regions (AgNORs), bromodeoxyuridine (BrdU) incorporation and MIB-1/Ki-67. Labelling indices are most commonly used and they show a highly significant graded increase correlating with progression from benign to atypical to anaplastic tumours.[14] The proliferation markers also show an increase in recurrent tumours. Table 5 depicts the increase in labelling index of different proliferation markers in meningiomas. Diploidy is more common in meningiomas, but the proportion of aneuploidy is higher in atypical and malignant meningiomas than in benign meningiomas. The proliferation index is high in aneuploidy than in diploidy.[47]

Recurrent Meningiomas

Although the majority of meningiomas are benign, recurrence after gross total resection still remains a problem. Risk stratification based on histological features alone has limitations. Various studies showed several parameters associated with recurrence. Extent of surgical resection, grade and sub-type of tumour, MIB-1/Ki-67 labelling index and loss of short arm of chromosome 1 (1p-) by *in situ* hybridisation are important parameters singly or in combination in predicting recurrence.[1,32] According to Maes et al.,[42] human telomerase catalytic subunit (hTERT) expression is a better predictor of recurrence in meningiomas than Ki67 labelling index.

Hormone Receptors

Meningiomas exhibit enhanced growth rate during reproductive life correlating with elevated sex hormone levels. There is an association with carcinoma of the breast also. Nearly 84% of meningiomas express progesterone receptors and it is influenced by histological grade, type and site.[9] Progesterone receptor levels are low in convexity, fibrous and atypical meningiomas and also associated with peritumoural swelling.[6,8] Lack of progesterone receptors is associated with large tumour size, atypia and anaplasia.[32] Androgen receptors reside in the nuclei suggesting a role for activating gene expression.[11]

Treatment and Prognosis

Surgery is the primary therapy. The extent of surgery affects the recurrence. Tumours in the cerebral

Table 5: Factors associated with recurrence of meningioma

I.	Extent of surgical resection:	
	a. Skull base	
	b. Parasagittal	
II.	Histological subtype	Chordoid, Clear cell, Papillary, Rhabdoid meningiomas
III.	Grade of tumour	Atypical, Anaplastic meningiomas
IV.	Invasion into adjacent structures	Muscle, dura, bone, brain
V.	Others	MIB-1 LI, ↓progesterone receptors, loss of expression of alkaline phosphatase receptors, loss of 1p gene, LARGE gene mutations

convexity and spinal canal can completely be resected, but tumours of the skull base, orbit and enplaque variety pose problems and hence recurrences are common. Five-year recurrence rate after gross total resection of benign meningiomas is 7–20%, for atypical meningiomas it is 29–40% and for anaplastic meningiomas it is 50–78%.[52,53] Factors associated with lung metastases include prior craniotomy, venous sinus invasion, local recurrences, histological malignancy and papillary morphlogy.[2]

HAEMANGIOPERICYTOMA

Definition and Grading

Haemangiopericytoma (HPC) of the central nervous system is a highly cellular and richly vascular neoplasm, histologically indistinguishable from its soft tissue counterpart. They correspond histologically to WHO Grade II, the anaplastic variant corresponding to Grade III neoplasms. However, the histological criteria for grading are not clearly established.

Incidence

These represent about 0.4% of primary brain tumours.[25] The ratio of meningeal HPC to other forms of meningiomas reported in the literature has ranged from 1:40 to 1:60.[21]

Age and Gender

Meningeal HPC are tumours of adults (mean age 43 years) and are more common in males (M:F = 1.4:1).[21]

Location

The majority are dural based and supratentorial with only occasional reports of an intraparenchymal location.[21,26] Multifocality has not been reported. Clinical and neuroimaging features that help in differentiating HPC from meningiomas are presented in Table 6.

Gross and Microscopic Features

Grossly these are lobulated, firm, well demarcated tumours with a fleshy, greyish to red brown cut surface. Microscopically, these are highly cellular tumours comprised of spindle shaped cells arranged around thin walled vascular spaces (Fig. 4). These vascular spaces have characteristic "staghorn" configuration (Fig. 4A). The degree of mitosis is variable.[46] These tumours lack cellular whorls, nuclear pseudoinclusions and psammoma bodies unlike those noted in meningiomas. These tumours are reticulin rich and have reticulin fibres enveloping individual cells (Fig. 4B).

Immunohistochemistry

The tumours are diffusely positive for vimentin, negative for EMA and express CD34 (Fig. 4A, Inset) in one third of the cases.[51]

Genetic Susceptibility, Cytogenetics and Molecular Genetics

There is no evidence of familial clustering in HPCs. Chromosomal rearrangements of 12q13 (common in HPCs), 19q13, 6p21 and 7p15 have been reported in HPCs.[44] NF2 gene mutations have not been reported in HPC.[29]

Treatment and Prognosis

These tumours are usually treated with surgery followed by local irradiation to the tumour bed. Haemangiopericytomas have a high recurrence rate (65%, 76% and 87% at 5-, 10- and 15-years, respectively). Another unique feature of HPC is their tendency to metastasise to extracranial sites like lung, liver and bone.[21] Histological features predictive of decreased survival include increased mitotic rate (≥ 5/10 HPF), high cellularity, nuclear pleomorphism, haemorrhage and necrosis.[46] These lesions correspond to WHO Grade III.

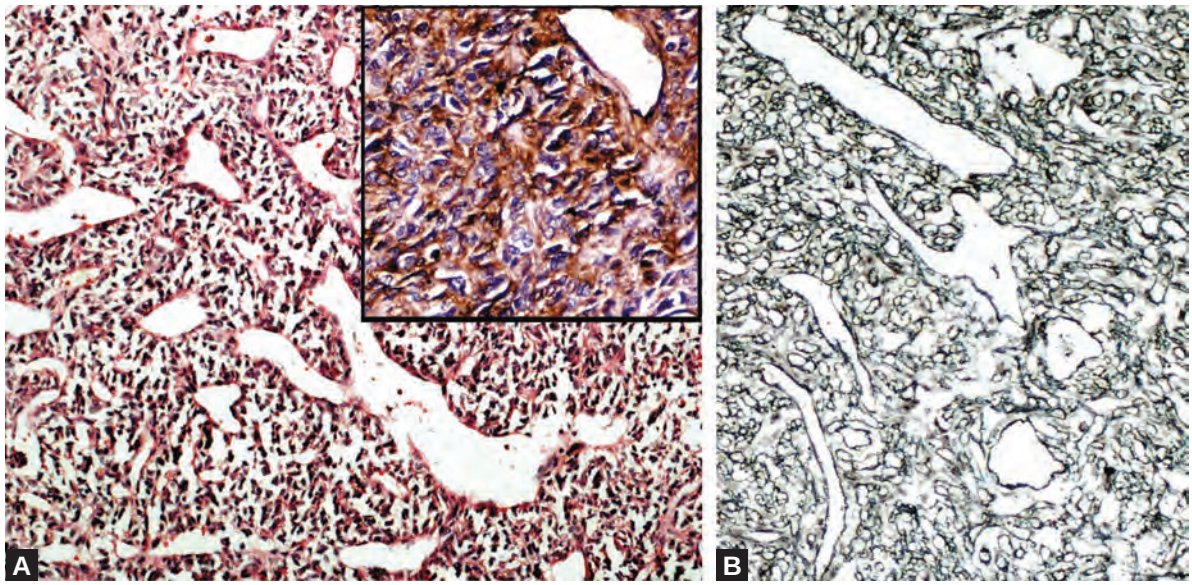
SOLITARY FIBROUS TUMOUR

Solitary fibrous tumour (SFT) is a rare tumour of the meninges, which is pathologically identical to similar tumours occurring in the pleura and other extrapleural sites. These tumours resemble meningiomas in terms of their age of occurrence and female predominance,[10] and can involve both the cranial and spinal meninges. The imaging features resemble those of meningioma.[10]

Grossly, these are firm, grey-white and circumscribed tumours. The size of the tumours ranges from 1 to 7 cm in the reported series.[28] Microscopically, the majority of the tumours show moderate cellularity with spindle cells arranged in fascicles between dense bands of collagen. There may be areas showing increased cellularity and reduced collagen as well as foci with a vascular pattern reminiscent of haemangiopericytoma. These tumours lack whorls, nuclear pseudoinclusions and psammoma

Table 6: Differences between meningioma, haemangiopericytoma and solitary fibrous tumour

	Meningioma	*HPC*	*SFT*
Incidence	13–20% of primary CNS tumours	0–4% of primary CNS tumours	Rare
Age in years	Peak incidence: 60–80 years	43 years (mean age)	57 years (mean age)
Male:Female	1:2	1.4:1	2:5
Location	Cranial-cerebral convexity, especially parasagittal spinal (11–12%)—mostly thoracic Intraventricular——most often lateral ventricle Multifocal tumours—16%	Cranial—most often involves tentorium and subtentorial space; 1/5th in posterior fossa Spinal—8% Multifocal tumours—not recorded	Falx, occipital and spinal dura, tentorium, and cerebellopontine angle Multifocal tumours—not recorded
Clinical features	Signs and symptoms referable to location and compression of adjacent structures	Indistinguishable from meningioma, but relatively shorter duration of symptoms	Indistinguishable from meningioma
Neuroimaging	Well demarcated dural based lesion Broad based dural attachment Dural tail sign adjacent to main mass Hyperostosis of adjacent bone Calcification	May resemble meningioma Narrow based dural attachment—more frequent Dural tail sign—50% Hyperostosis of adjacent bone—absent Calcification—absent Prominent vascular flow voids on MRI Angiography—cork-screw like vessels	May resemble meningiomas Hyperostosis—occasionally
Microscopic features	Wide range of histopathological appearance Fibrous type needs differentiation from HPC and SFT Lacks 'staghorn, vascular pattern of HPC Whorls, psammoma bodies and intranuclear inclusions seen Reticulin—Scarce, segregates tumour into lobules	Characteristic 'staghorn' branching vascular pattern Whorls, psammoma bodies and intranuclear inclusions—absent Reticulin—rich, envelope individual cells	Variable cellularity with intervening collagen bands Staghorn vessels—may be present in some Collagen sheathed vessels Whorls, psammoma bodies and intranuclear inclusions—absent
IHC	Vimentin—positive EMA—positive S-100—positive (80%) CD 34—positive (60%) Factor XIIA—positive (65%)	Vimentin—positive EMA—negative S-100—negative CD 34—positive (33%) Factor XIIA—positive (78%)	Vimentin—positive EMA—negative S-100—negative CD 34—positive (80–90%) Factor XIIA—positive (100%)
Genetic susceptibility, cytogenetics and molecular genetics	Familial clustering—present Association with NF2 NF2 gene mutation—60% of sporadic meningiomas del 22—most consistent abnormality	No evidence of familial clustering Rearrangements of 12q13 (common in HPCs), 19q13, 6p21 and 7p15 NF2 gene mutations—not reported	-
Recurrence and Metastasis	Recurrence rate: Benign meningiomas—7–20% Atypical meningiomas—29–40% Anaplastic meningiomas—50–78% Extracranial metastasis—extremely uncommon	Recurrence rate: 65% at 5 years 76% at 10 years Extracranial metastasis—64–68% at 15 years (bone, lungs and liver)	Recurrence rare



Figs 4A and B: (A) Haemangiopericytoma showing characteristic branching vascular pattern with intervening plump spindle cells (H&E x 120) Inset: Tumours cells showing CD34 positivity (Immunoperoxidase x 320). (B) Reticulin stain highlighting the vascular pattern and showing reticulin fibres enveloping individual tumour cells (Reticulin silver stain x 120)

bodies. Mitoses are sparse. Immunohistochemically these tumours show diffuse positivity for CD34 and are negative for EMA and S-100.[10,28]

HAEMANGIOPERICYTOMA AND SOLITARY FIBROUS TUMOUR—CURRENT CONCEPT

Stout and Murray[59] are credited with the first description of HPC, which they presumed to be a neoplasm comprised of pericytes exhibiting a characteristic well-developed 'staghorn' vascular pattern. Over the years it has been realised that the morphological features of HPC were not specific and can be seen in many benign and malignant soft tissue lesions. The literature review revealed that only about 30% of HPCs showed ultrastructural features and 10–20% immunohistochemical features of pericytic differentiation,[5,15] thus questioning the fundamentals on which this entity came into existence.

On the other hand, SFT was first described as a pleural based lesion of submesothelial origin.[33] Soon it was realised that SFT could also occur in extrapleural sites including soft tissues and visceral organs. Solitary fibrous tumours show a morphological spectrum ranging from fibrous to cellular forms, the latter being virtually indistinguishable from haemangiopericytoma. Hence, it is now suggested that HPC should be recognised as a cellular variant of SFT.[18]

Even in case of meningeal HPC, which is traditionally considered as a distinct entity, there is evidence that it belongs to the spectrum of SFT, representing its cellular variant. Based on their comparative study on fibrous meningioma, HPC and SFT, Perry et al.[51] concluded that in some cases it was impossible to make a distinction between SFT and HPC, morphologically and/or immunohistochemically. Tihan et al.[61] in their comparative study of SFT and conventional HPC of CNS, observed that two lesions which were initially diagnosed as conventional meningeal HPC recurred as SFT-like neoplasm, a finding that further supports the unifying concept. The current concept is that HPCs represent a cellular variant of SFT and not a distinct entity, at least in soft tissue locations and the same may hold true for CNS lesions as well.

In a seven-year study (2000–2006) at Nizam's Institute of Medical Sciences, Hyderabad, 571 meningiomas were diagnosed of which 538 (94.2%) were grade I, 24 (4.2%) were Grade II and 9 (1.6%) were grade III meningeal tumours. Atypical meningiomas were 19 (3.2%), clear cell 2 (0.4%), chordoid 3 (0.5%), rhabdoid 4 (0.7%) and papillary 1 (0.2%). The Ki-67 labelling index (LI) in grade I was 2.58 ± 2.61%, in grade II 9.7 ± 4.59% and in grade III 22.3 ± 9.8%. Brain infiltration was noted in 30 cases and Ki-67 LI was 4.71% in them. There were 22 recurrent meningiomas and Ki-67 LI was 5.04% in them. During the same period 14 haemangiopericytomas were diagnosed, of which 11 were grade II and 3 were grade III. The mean KI-67 LI in grade II tumours was 4% and that for grade III tumours was 8.5%.

HAEMANGIOBLASTOMA

Haemangioblastomas are WHO grade I tumours of uncertain histogenesis. They constitute 1.3% of intracranial neoplasms and 7.3% of posterior fossa neoplasms.[48] They occur both as sporadic tumours and in association with the inherited syndrome of Von Hippel Lindau (VHL) disease. Haemangioblastoma is a cardinal feature of VHL disease and about 30–40% of all cerebellar haemangioblastomas are associated with VHL disease.[52]

Location

Sporadic haemangioblastomas occur predominantly in the cerebellum but VHL associated tumours occur in brainstem and spinal cord. Supratentorial location is rare. They may be single or multiple, the latter often in association with VHL disease.

Age and Gender

The sporadic tumours have a peak incidence between 35 years and 45 years and VHL associated tumours occur earlier (mean age of 29 years).[12] There is no gender predilection.

Clinical Manifestations

Haemangioblastomas are slow growing tumours and present with symptoms of raised intracranial pressure. The tumours produce erythropoietins and hence cause secondary polycythaemia.

Neuroimaging

Magnetic resonance imaging (MRI) is the investigation of choice which has replaced CT and angiography. Various morphological patterns are described on MRI and CT. For example, (i) pure cystic, (ii) cyst with mural module, (iii) cyst with wall enhancement, (iv) solid and cystic areas and (vi) solid.[23]

Pathogenesis

Stromal cells, the neoplastic component of the lesion express high levels of hypoxia inducible transcription factors (HIF)-1 and HIF-2.[17] Normally, HIF-1 and HIF-2 are degraded by several enzymes, transcription factors and proteosomal complexes including VHL protein and pVHL.[34,45] Stromal cells also express receptors for growth factors like epidermal growth factor, transforming growth factor alpha, vascular endothelial growth factor (VEGF) and platelet derived growth factors (PDGF).[17,35] Inactivated pVHL due to a mutated gene or other factors lead to accumulation of HIF-1 and HIF-2 in stromal cells which in turn lead to upregulation of vascular endothelial growth factor and erythropoietin at transcriptional level.[35] This explains the elevated erythrocytosis and also the formation of vascular and cystic components of haemangioblastomas. Inactivation of the VHL tumour suppressor protein and subsequent loss of function in the VHL and Elongin BC Complex results in dysfunction in the ubiquitinisation of HIF which is an important step in the development of haemangioblastoma.[58] The stromal cell protein expression is characteristic and it has been shown that it is similar to the embryonic progenitor cells with haemangioblastic differentiation.[19] These studies suggest that a variety of autocrine loops may be initiated depending on the activation of HIF and the presence of protein in the stromal cells in different topographical regions of the CNS.[19]

Gross Pathology

Haemangioblastoma is a circumscribed mass but unencapsulated (Fig. 5A). It is reddish in colour due to its vascularity and sometimes yellow due to the lipid content in the stromal cells. It may be solid, cystic or partly solid and partly cystic (Fig. 5B).

Microscopy

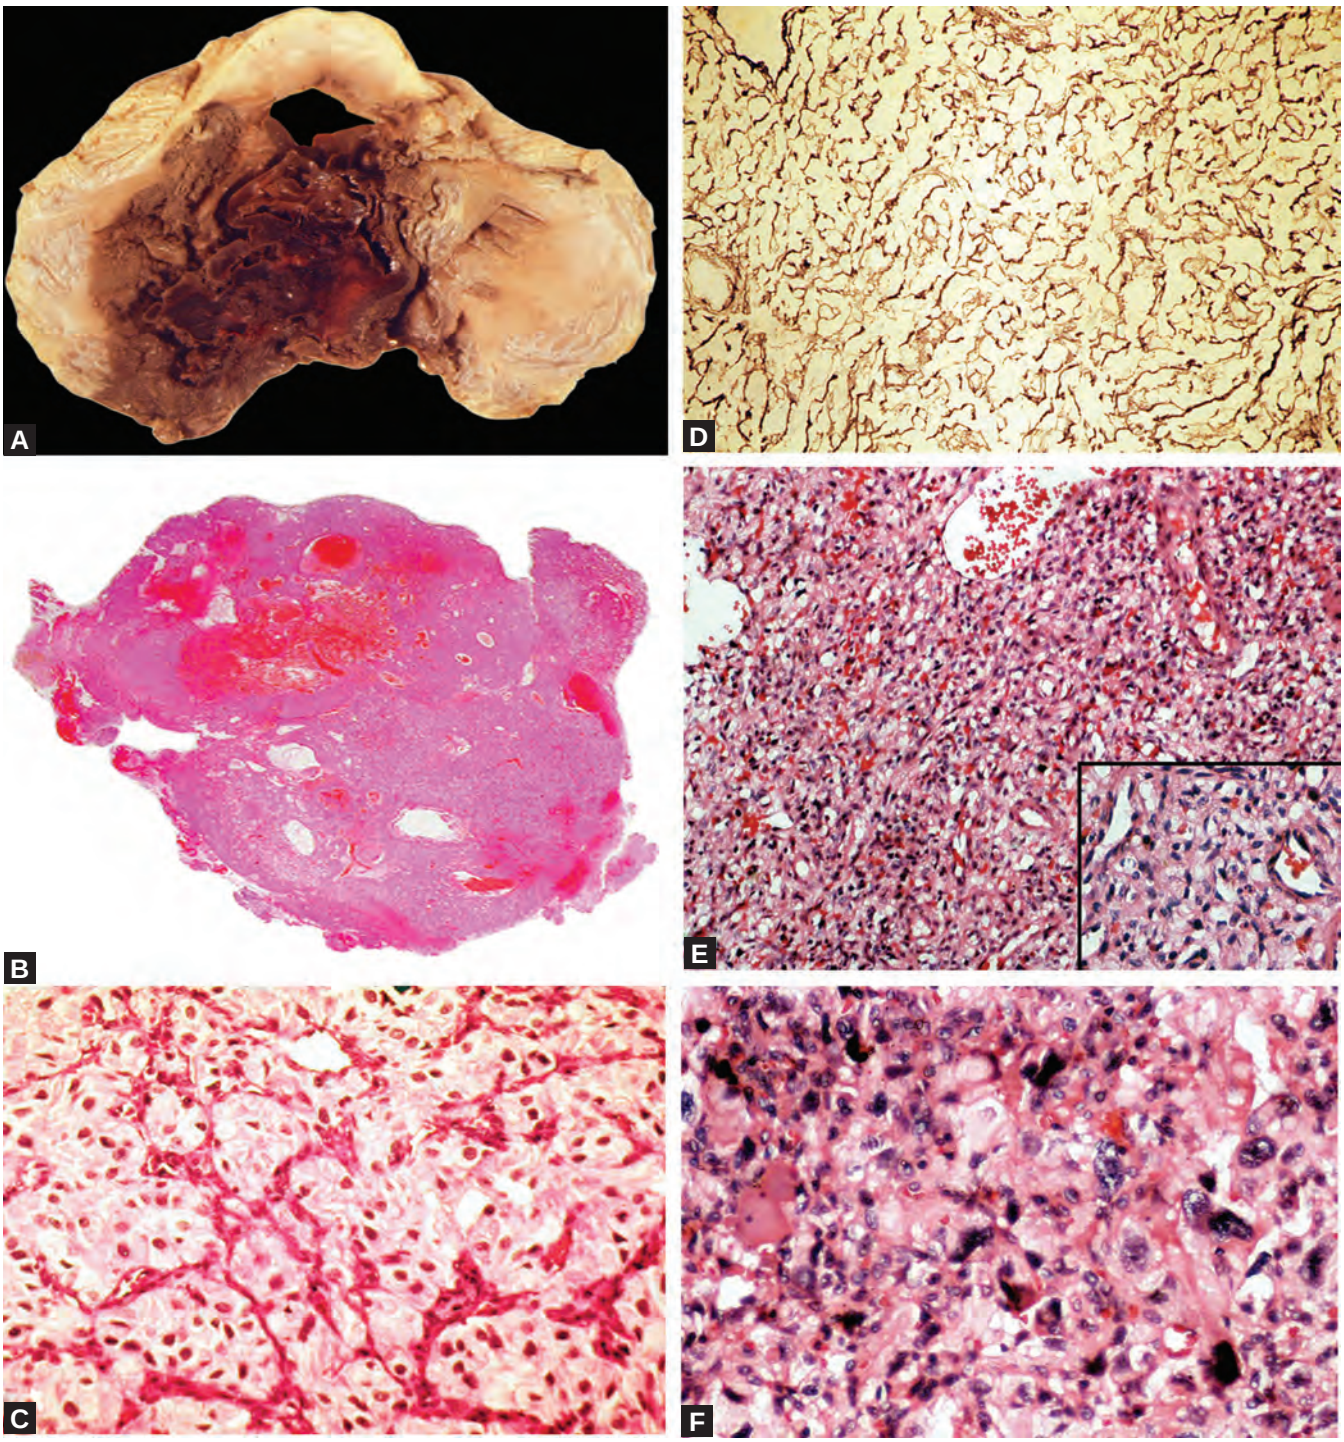
The tumour is composed of two components: The capillary sized blood vessels and the stromal cells. The stromal cells are the neoplastic component (Figs 5B to F). Based on the pattern of arrangement of stromal cells and capillary sized vessels, two patterns in the tumour are described—reticular and cellular patterns. When stromal cells are evenly distributed between capillary blood vessels it is called reticular pattern (Figs 5C and D) and when there are sheets of stromal cells with random vascular changes, it is called cellular pattern (Figs 5E and F).[22] The stromal cells have abundant cytoplasm with variable amounts of lipid and glycogen. The nuclei may show pleomorphism but mitosis is not a feature. The blood vessels are usually thin walled but sometimes thick walled vessels may be seen. Haemorrhages, haemosiderin laden macrophages, hyalinisation and microcyst formation may be seen. Reactive astrocytes with Rosenthal fibres at the periphery of the tumour may be seen. Infiltration into adjacent cerebellar tissue is rarely noted. Necrosis and calcifications are usually absent. Reticulin fibres are seen around blood vessels and groups of stromal cells. Stromal cells stain positive with oil red O reflecting the lipid content. The clear cell appearance of stromal cells may lead to a diagnostic problem mimicking metastatic renal cell carcinoma.

Ultrastructurally, the stromal cells contain electron-lucent cytoplasm containing lipid droplets and bundles of delicate filaments. Electron-dense bodies reminiscent of Weibel-Palade bodies of endothelial cells are also described in the stromal cells in some studies.[64]

Immunohistochemically, the stromal cells lack endothelial cell markers (von Willibrand factor and CD34) and endothelium associated adhesion molecule (CD31). Stromal cells express neuron specific enolase (NSE) and the neural cell adhesion molecule transthyretin. Vimentin is expressed and glial fibrillary acidic protein (GFAP) is not expressed by the stromal cells.[7,64] The stromal cells have no consistent antigen expression profile. The Ki-67 labelling index is less than 1%.

Prognosis

The outcome following surgical resection is favourable for sporadic tumours compared to VHL associated tumours. Mortality is low and permanent neurological deficits are extremely rare with improved microsurgical techniques in sporadic haemangioblastomas. In cases of VHL associated haemangioblastoma, haemorrhage is the most common cause of death. The histological sub-type



Figs 5A to F: (A) Horizontal sections through pons and cerebellum show a large cystic haemorrhagic lesion occupying the cerebellar vermis. The lesion shows sharp circumscription from surrounding parenchyma with brownish discolouration. The fourth ventricle is dilated. (B) Whole mount section through the cerebellar lesion shows a highly vascular lesion with foci of haemorrhage and focal cystic change (HE x 12). (C) High magnification highlights tightly packed stromal cells forming lobules and compressing the thin vascular channels (HE x 360). (D) Reticulin stain highlights rich reticulin framework and high vascularity of the tumour (Reticulin silver x 120). (E) Haemangioblastoma (cellular variant) with densely packed tumour cells and rich capillary network (HE x 120). Inset: Stromal cells showing foamy vacuolated cytoplasm (HE x 300). (F) Haemangioblastoma with stromal cells showing nuclear atypia and hyperchromasia. This feature is not indicative of malignancy (HE x 420)

of cellular variant is associated with more chances of recurrence.[62] Recurrence is common when it occurs in young age, associated with VHL syndrome and in multicentric tumours.[16] Solid tumours with less cystic spaces and tumours with lower proportion of lipid laden cells have higher chances of recurrence.[16,60] Risk of spontaneous haemorrhage is extremely low in haemangioblastoma of size smaller than 1.5 cm.[20] In VHL associated haemangioblastomas, neuroradiologic screening and lifelong follow-up are necessary for identification of new lesions before they become symptomatic.[12]

124 Pituitary Tumours, Sellar and Suprasellar Lesions

Geeta Chacko

INTRODUCTION

The sella turcica in which the pituitary gland is housed is an intricate assembly of anatomical structures representing elements of neural, endocrine, vascular, osseous and meningeal tissues being in close proximity to the cavernous sinus, hypothalamus, and major blood vessels, nerves, bone and connective tissue. Lesions in the sellar region are, therefore, remarkably diverse, originating from varied tissues in the region (Table 1).

PITUITARY ADENOMA[8,55]

Pituitary adenomas are benign tumours that comprise 10% of all intracranial neoplasms and are a preventable cause of blindness. It is the most common neoplasm of the sellar region and may even be detected incidentally as frequently as 5–20%. They are derived from adenohypophyseal cells, are most often confined to the sella turcica, grow slowly, enlarge by expansion and are demarcated from the normal pituitary tissue by a pseudocapsule.[5] Pituitary adenomas can be a part of the multiple endocrine neoplasia syndromes. These tumours are monoclonal proliferations related to defects in oncogenes and tumour suppressor genes.[26]

Clinical features are related to mass effect and include visual symptoms, headache and hypopituitarism. In the case of secretory adenomas, the symptoms are related to the hormone secreted. Growth hormone (GH) excess is associated with acromegaly or gigantism; overproduction of prolactin (PRL) is associated with amenorrhoea, galactorrhoea, infertility, hypogonadism, decreased libido and impotence; increased secretion of adrenocorticotropic hormone (ACTH) causes Cushing's disease; follicle stimulating hormone (FSH) and luteinizing hormone (LH) oversecretion leads to hypogonadism or are clinically silent and hypersecretion of thyrotropin (TSH) leads to hyperthyroidism.

Radiographic Features

One sees a well defined tumour in the adenohypophyseal region (Fig. 1A).

Gross

The tumour is a well circumscribed brown-coloured mass in the sellar-suprasellar region (Fig. 1B).

Microscopic Features

The tumour is composed of sheets of monomorphic cells with uniform round to oval nuclei, evenly dispersed chromatin and moderate amounts of cytoplasm (Fig. 1C). The tinctorial properties of the latter vary from acidophilic to amphophilic or even basophilic. Cells within the same tumour have similar tinctorial properties, unless plurihormonal. A delicate capillary network traverses the tumour. A pseudorosette arrangement is seen if a papillary pattern is present.

Differential Diagnosis

Normal Adenohypophysis

A monomorphous population of cells is seen in adenomas, whereas the normal adenohypophysis has a mixture of cell types with different tinctorial properties (Fig. 1D). The acinar pattern of the normal adenohypophysis is disrupted in adenomas, which is best appreciated on a reticulin stain (Figs 1E and F).

Metastatic Carcinoma

These usually have brisk mitotic activity and show epithelial features with prominence of nucleoli.

Intra-operative diagnosis is rarely requested for the straight forward adenomas. In certain circumstances when the dura appears firm or abnormal, an intra-operative consult is sent to exclude other pathologies. It is imperative that the specimen be sent rapidly and preferably on moistened gelfoam or a smooth surfaced material so as to avoid drying. Gauze is not advised as the tissue tends to get impregnated into it and is difficult to remove.

Pituitary adenomas smear easily and hence, this method, smear or squash preparation of rapid processing, are preferred to frozen sections. Adenomas form cellular smears of uniform monomorphic cells. Differentiation from normal gland requires a reticulin stain and this is not optimal in an intra-operative setting. Hence, in the case of a microadenoma (such as in ACTH secreting tumours when the surgeon wishes to determine whether the entire tumour has been removed) it is preferable that all material be submitted for routine processing, so that, serial sections can be examined with both hematoxylin and eosin, as well as reticulin stains to detect the microadenoma.

Table 1: Lesions of the sella turcica

I. Neoplastic lesions of the sella turcica[1]	
Sellar, suprasellar region:	
Pituitary adenomas	Craniopharyngioma
Germ cell tumours	Spindle cell oncocytoma
Infundibulum and neurohypophysis:	
Granular cell tumour	Pituicytoma
Optic chiasm and hypothalamus:	
Astrocytoma	Ependymoma
Gangliocytoma	Ganglioglioma
Ganglioneuroma	
Bone and connective tissue:	
Post-irradiation sarcoma	Chordoma
Haemangiopericytoma	Chondroma
Chondrosarcoma	Fibroma
Fibrosarcoma	Lipoma
Plasmacytoma	Giant cell tumour of bone
Schwannoma	Paraganglioma
Vascular:	
Haemangioma	Glomangioma
Haemangioblastoma	Haemangiopericytoma
Olfactory groove:	
Meningioma	
Miscellaneous:	
Lymphoma[2]	Langerhan's cell histiocytosis
Leukaemia	Melanoma[3]
Metastatic tumours	
II. Non-neoplastic lesions of the sella turcica	
Sellar, suprasellar region:	
Pituitary hyperplasia	Rathke's pouch cyst
Empty sellar syndrome	Giant cell granuloma
Lymphocytic hypophysitis	Granulomatous hypophysitis
Xanthogranuloma	Rosai-Dorfman disease
Erdheim-Chester disease	Xanthoma disseminatum
Epidermal cyst	Dermoid cyst
Sarcoidosis[4]	Abscess[5, 6]
Tuberculosis[7]	Mucocoele
Infundibulum, neurohypophysis, optic chiasm and hypothalamus:	
Hamartoma	
Bone and connective tissue:	
Fibrous dysplasia	Cholesteatoma
Vascular:	
Aneurysms	
Miscellaneous:	
Malformative tumours and cysts	

ADENOMAS OF SPECIFIC CELL TYPE[21]

It is now generally accepted that light microscopic examination of pituitary adenomas based on staining characteristics of different secretory granules (chromophobe, acidophil and basophil) is inadequate to assess the clinical and endocrine status of the patients. Ultrastructural study of these tumours has led to a better understanding of their nature, but it cannot be fully relied upon particularly with respect to their secretory function. Although the size of the secretory granules gives a good indication of the nature of the hormone in a normal pituitary gland, in neoplastic conditions the size of the granules varies so widely that it has limited diagnostic value. Further, no adenoma including the clinically and biochemically inert null cell adenomas are agranular on ultrastructure.

Localisation of hormones in pituitary adenomas can be done quite accurately with immunohistochemistry and in conjunction with estimation of serum hormones, the functional status of pituitary adenomas can be better assessed. Hence, for a full evaluation of the endocrine status of pituitary adenomas, it is considered necessary to use a combination of currently available techniques such as light microscopy, electron microscopy, immunohistochemistry, and serum hormone analysis. This approach has led to a better understanding of the biological behaviour of pituitary adenomas including their clinicopathological correlation. Further, based on histological, immunohistochemical and ultrastructural studies of a large number of pituitary tumours, a new World Health Organisation (WHO) classification has been introduced. Tables 2 and 3 summarise the current WHO classification of pituitary adenomas along with their clinicopathological, immunohistochemical and ultrastructural features.

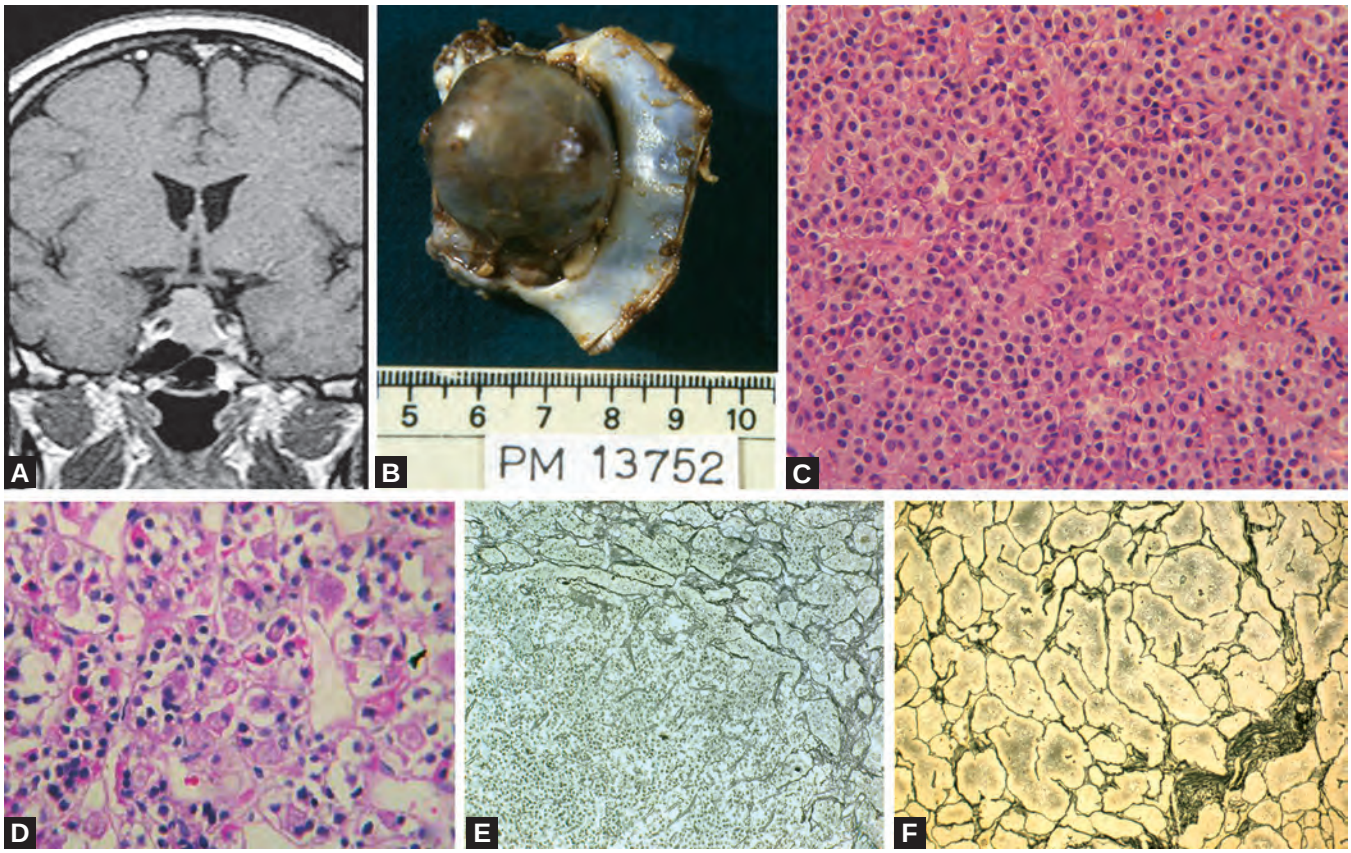
The salient features that are special to the different subtypes are discussed below.

Growth Hormone Cell Adenoma

GH tumours constitute 15–20% of pituitary adenomas. These tumours are often plurihormonal and show secondary immunoreactivity for PRL, alpha-subunit (α-SU), TSH, FSH and LH. Cytokeratin paranuclear dot-like positivity is seen in the sparsely granulated variant and corresponds ultrastructurally to paranuclear intermediate filament known as "fibrous bodies" (Figs 2A and B).[22]

The sparsely granulated variants are clinically aggressive. Growth hormone-releasing hormone (GRH) overexpression correlates with the level of GH as well as the aggressiveness of the tumour.[49]

The GH excess due to adenomas is not restricted to the sparsely and densely granulated variants of GH adenomas, but as described below, is also seen with mixed GH-PRL, mammosomatotrophic and acidophil stem cell adenoma, as well as with plurihormonal adenomas.



Figs 1A to F: (A) Magnetic resonance imaging of pituitary adenoma showing well defined tumour in the sella. (B) Large well circumscribed sellar-suprasellar macroadenoma. (C) Pituitary adenoma: sheets of monomorphic cells with uniform round to oval nuclei, evenly dispersed chromatin and moderate amounts of cytoplasm (H&E X 400). (D) Normal adenohypophysis—cells have varied tinctorial properties (H&E X 400). (E) Disrupted reticulin in the adenoma compared to retained reticulin in adjacent compressed normal pituitary (Gordon Sweet's Reticulin Stain X 90). (F) Normal acinar pattern of adenohypophysis highlighted by reticulin (Gordon Sweet's Reticulin Stain X 200)

Prolactin Cell Adenoma (Prolactinoma)

The frequency with which this tumour is seen by pathologists is on the decline as medical therapy with dopamine agonists is effective in the vast majority of cases obviating the need for surgery.

These tumours are seen in the reproductive age group. There is a female predominance, with females in the reproductive age group presenting with amenorrhoea and galactorrhoea, while they are functionally silent in post-menopausal women and in men.

Other causes of hyperprolactinaemia such as primary hypothyroidism and antipsychotic drug use need to be ruled out. Hyperprolactinaemia due to stalk effect needs to be recognised as distinct from that due to an adenoma. The latter usually results in biochemical values greater than 150 ng/ml.

Psammomatous calcification and amyloid deposition are features that are peculiar to prolactinomas. Immunoreactivity corresponds to the Golgi zone with secondary immunoreactivity for α-SU. Prolactinomas have abundant rough endoplasmic reticulum and the presence of "misplaced exocytosis", which is the presence of secretory granules between neoplastic cells (Fig. 2C). These tumours can be aggressive in both males and females in the post-reproductive age group.

Morphology after medical treatment: The dopamine agonist, bromocriptine, has a dramatic effect on the histology and ultrastructural features of prolactinomas with cells undergoing atrophy. There is significant stromal fibrosis (Fig. 2D). The changes are reversible and cessation of therapy results in regrowth of the adenoma.

Adenomas Producing Growth Hormone and Prolactin[36]

There are three principal subtypes of adenomas producing both GH and PRL

Mixed Growth Hormone Cell-Prolactin Cell Adenoma

These are rare indolent neoplasms that manifest with acromegaly and have serum PRL elevation. The bimorphous nature is evident on ultrastructure (Fig. 2E).

Table 2: WHO classification of pituitary adenomas: clinical and pathological characteristics

WHO classification–adenoma type	*Incidence*	*Clinical features*	*Staining characteristics*	*Hormone (localised by immunohistochemistry in tumour cells)*
Lactotropic adenomas:				
Sparsely granulated	25%	Amenorrhoea and/or galactorrhoea	C	Prolactin (PRL)
Densely granulated	1%	in females/impotence/non-functional Amenorrhoea and/or galactorrhoea in females/impotence	A	PRL
Somatotropic adenomas:				
Sparsely granulated	5%	Acromegaly or gigantism	C/A	Growth hormone (GH)
Densely granulated	5%	Acromegaly or gigantism	A	GH
Adenomas with combined lactotropic and somatotropic features	5%	Acromegaly or gigantism ±	A/C	GH/PRL
Mixed GH cell/PRL cell	3%	Hyperprolactinaemia	A	GH/PRL
Mamosomatotroph	1%	Acromegaly or gigantism ±	C	GH/PRL
Acidophil stem cell		Hyperprolactinaemia		
		Hyperprolactinaemia or "non-functional"; only occasional acromegaly		
Corticotropic adenomas:				
Cushing (densely/sparsely granulated)	10%	Hypercortisolism	B	Adrenocorticotropic hormone (ACTH), β-lipotropic hormone (LPH), endorphins and propiomelanocortin (POMC)
Nelson	2%	Pigmentation; mass symptoms	B/C	ACTH, β-LPH, endorphins and POMC
Crooke cell	<1	Hypercortisolism	B/C	ACTH, β-LPH, endorphins and POMC
Silent corticotropic	3%	Mass symptoms; hypopituitarism	B/C	ACTH, β-LPH, endorphins and POMC
Glycoprotein adenomas:				
Gonadotropic	7–15%	Hypogonadism; functionally silent; mass effects	C/B	Follicle stimulating hormone and luteinizing hormone
Thyrotropic	1%	Hypothyroidism or hyperthyroidism	C/B	thyrotropin (TSH)
Plurihormonal adenomas	10%	Usually acromegaly ± hyperprolactinaemia; glycoprotein hormone production rarely expressed	C/A	Usually GH, PRL and TSH, α – subunit; includes other unusual combinations
Silent sub-type 3	3%	Mass effects; hyperprolactinaemia or GH effects	C/A	No specific hormones
Null cell adenomas	20%	Visual symptoms; hypopituitarism;	C	None ± mild hyperprolactinaemia as a result of pituitary stalk compression
Non-oncocytic	14%	headache		
Oncocytic	6%	Visual symptoms; hypopituitarism; headache	A	None ± mild hyperprolactinaemia as a result of pituitary stalk compression

A—Acidophil, B—Basophil, C—Chromophobe

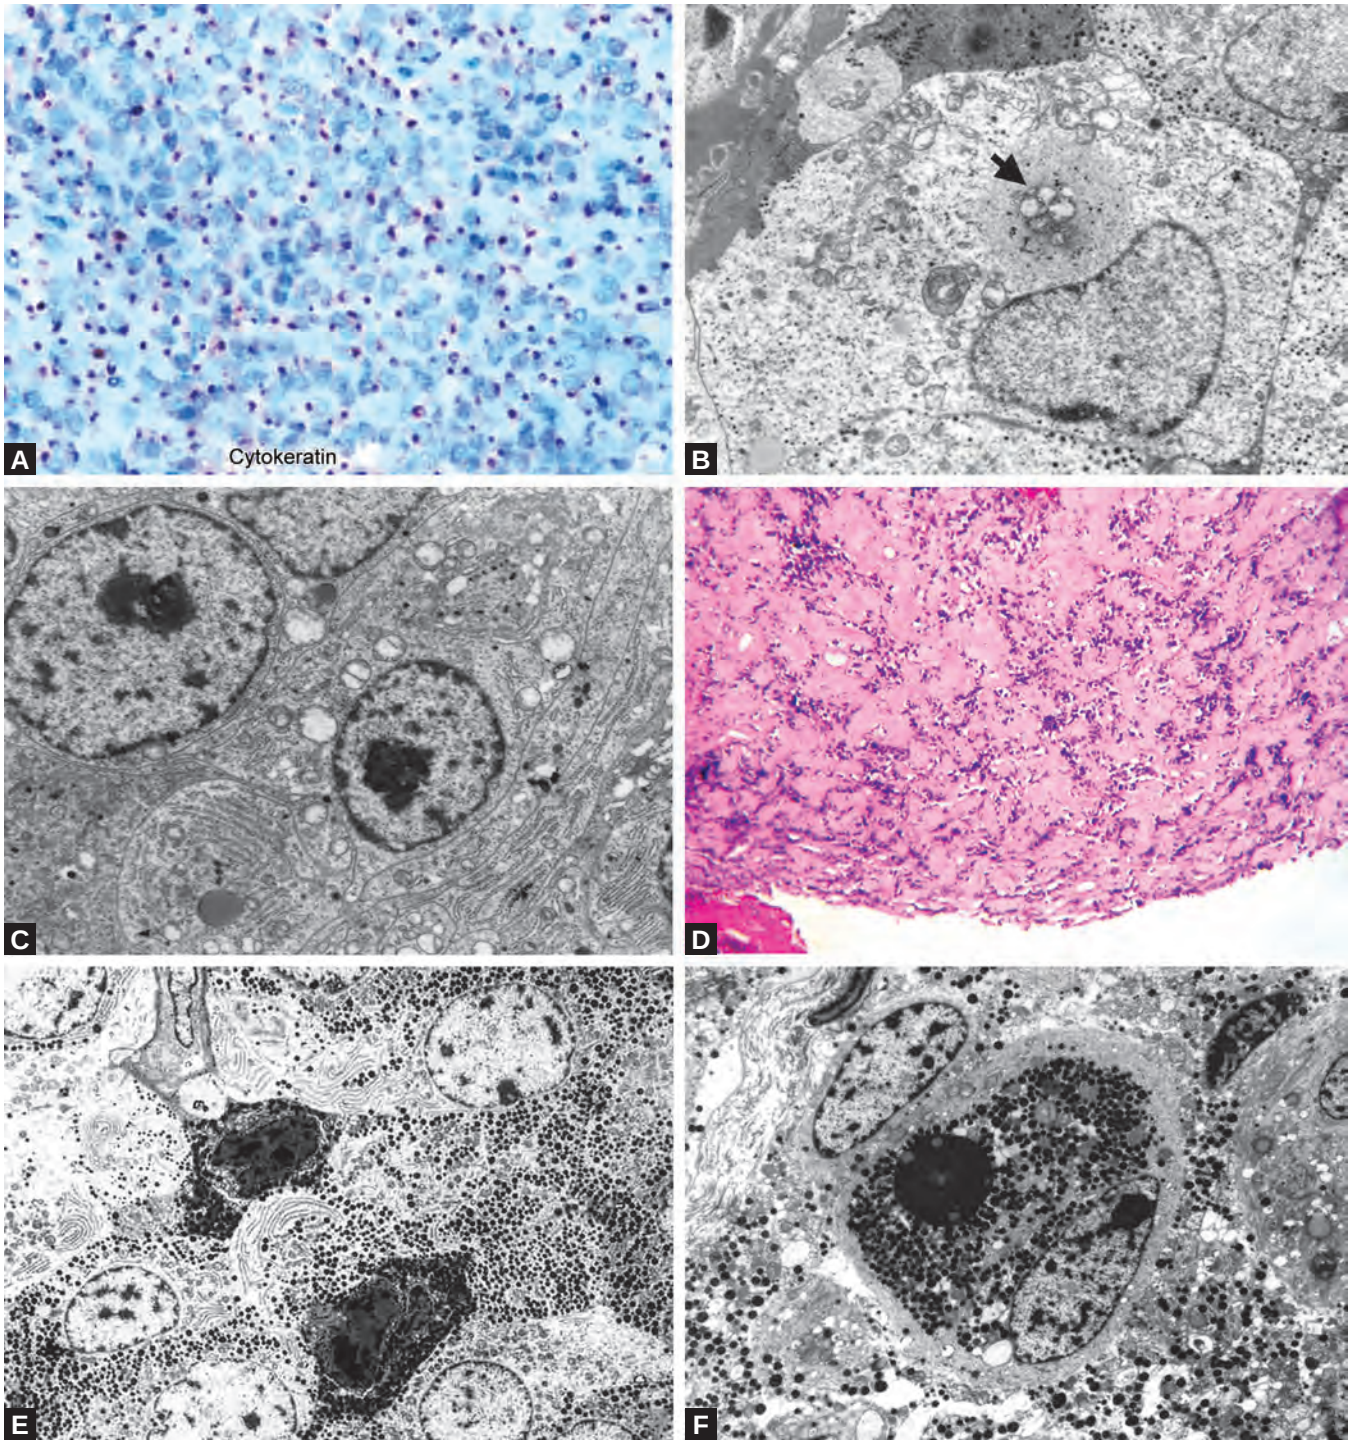
Table 3: Pituitary adenomas: ultrastructural features

Adenoma type	*Ultrastructural features*
Prolactin cell adenoma:	
Densely granulated adenoma	Cells round to oval with eccentric and oval to irregular nuclei. The RER in parallel stacks. Prominent ring shaped Golgi.
Sparsely granulated adenoma	Cells polyhedral with oval to irregular nuclei. The RER in "Nebenkern"(concentric whorl) formation. Golgi abundant, ring shaped or convoluted. Misplaced exocytosis present.
Growth hormone cell adenoma:	
Densely granulated adenoma	Round to oval cells with central, round to oval nuclei and prominent nucleoli. Peripheral parallel arrays of RER. Golgi prominent, spherical and numerous vesicles.
Sparsely granulated adenoma	Pleomorphic cells with single to multiple, eccentric and irregular nuclei. The RER in peripheral parallel rows or scattered. Abundant, ring-shaped Golgi. Paranuclear fibrous bodies may be present.
Adenoma with combined lactotrophic and somatotrophic features:	
Mixed growth hormone cell-prolactin cell adenoma	Variable proportions of sparsely and densely granulated growth hormone and prolactin cells with ultrastructural features as detailed above.
Mamosomatotroph cell adenoma	Polyhedral cells with oval to irregular nuclei. Well developed and prominent RER and Golgi. Two populations of secretory granules within the same cell—150–450 nm and 350–2000 nm size.
Acidophil stem cell adenoma	Elongated cells with irregular nuclei. Poorly to moderately developed RER and Golgi. Few secretory granules.
	Paranuclear fibrous bodies, misplaced exocytosis, abnormal/giant mitochondria and variable oncocytic change may be present.
Corticotroph cell adenoma:	
Densely or sparsely granulated Cushing adenoma	Round, angular, or elongated cells with round to oval nuclei. Abundant RER and prominent Golgi. Perinuclear and cytoplasmic microfilaments present.
Nelson syndrome	As above but with little or no microfilaments.
Crooke cell adenoma	As above but with marked accumulation of macrofilaments.
Silent corticotroph cell adenoma	Resembles densely or sparsely granulated Cushing adenoma.
Silent subtype 1	Small polyhedral cells with centrally placed nuclei. Numerous RER, prominent Golgi.
Silent subtype 2	No perinuclear and cytoplasmic microfilaments.
Glycoprotein adenoma:	
Gonadotroph cell adenoma	Small to medium cells with sparse RER. Golgi moderate, occasionally dilated. Vacuolar ("honeycomb") transformation of Golgi in adenomas of females.
Thyrotroph cell adenoma	Small; angular cells with elongated processes; irregular to oval nuclei. Poorly developed profiles of RER; moderate Golgi.
Plurihormonal adenomas:	
Silent subtype 3	Heterogenous group of adenomas which vary greatly in ultrastructural appearances; some tumours are monomorphous, whereas others consist of two or three distinct cell types.
	Irregular polar cells. Nuclei pleomorphic with spheridia. Moderate RER; prominent Golgi. Abundant SER.
Null cell adenoma:	
Non-oncocytic adenoma	Small polyhedral cells with irregular, indented nuclei. Sparse stacks of RER; moderate Golgi.
Oncocytic adenoma ("pituitary oncocytoma")	Large polyhedral cells with irregular, indented nuclei. Sparse stacks of RER; moderate Golgi. Abundant mitochondria—some dilated and some with inclusions.

RER—Rough endoplasmic reticulum
SER—Smooth endoplasmic reticulum

Mammosomatotroph Cell Adenoma

These tumours present with acromegaly and hyperprolactinaemia. The tumour has a single cell type with reactivity for both hormones. Key features include densely granulated cells resembling somatotrophes, but exhibiting both large granules and misplaced exocytosis, a feature of lactotrophes. By double labelling immunoelectron microscopy both hormones can be localised within the same cell and often within the same granules.



Figs 2A to F: (A) Sparsely granulated variant of growth hormone adenoma—cytokeratin paranuclear dot-like positivity (Avidin peroxidase X 400). (B) Sparsely granulated variant of growth hormone adenoma—paranuclear intermediate filament on ultrastructure, corresponding to the "fibrous body". (C) Prolactinoma: ultrastructure of a prolactin cell adenoma with well-developed rough endoplasmic reticulum and sparse secretory granules, with misplaced exocytosis. (D) Prolactinoma: stromal fibrosis following treatment with bromocriptine (H&E X 90). (E) Prolactinoma: ultrastructural appearance of a mixed GH-PRL adenoma displaying the bimorphous nature of sparsely granulated lactotrophs and densely granulated growth hormone cells. (F) Adrenocorticotropic hormone (ACTH) adenoma: electron dense secretory granules in a densely granulated ACTH adenoma

Acidophil Stem Cell Adenoma[13]

These tumours are rare and are usually non-functional. Hyperprolactinaemia may be present. Immunoreactivity for PRL generally exceeds that for GH. Secondary immunoreactivity is seen for α-SU and TSH. The cells show some features of both GH and PRL producing cells. Oncocytic change is a common feature due to the presence of numerous mitochondria, some of which are giant. The tumours show progressive growth and invasive behaviour.

Adrenocorticotropic Hormone Cell Adenomas

There are three principal subtypes of ACTH-producing adenomas:

Adenomas of Cushing's Disease

These tumours constitute 10% of all pituitary adenomas and are predominantly microadenomas. The male to female ratio is 1:5. The ACTH immunoreactivity is variable. These tumours are densely granulated with electron dense, teardrop secretory granules and perinuclear bundles of intermediate (cytokeratin) filaments (Fig. 2F).

Microadenomas can be difficult to diagnose and hence, samples submitted for histopathology have to be carefully handled with minimal wastage during sectioning. Reticulin and periodic acid-Schiff (PAS) stains are helpful in identifying the adenoma.

Crooke's hyaline change is a conspicuous finding in the non-neoplastic pituitary surrounding an ACTH-producing adenoma. It is seen surrounding the nucleus as a pale zone and consists of perinuclear accumulation of keratin microfilaments within the corticotroph. Rarely, Crooke's hyaline change affects the cells of an ACTH-producing adenoma.

Adenomas of Nelson's Syndrome

Adrenalectomy for undetected microadenomas was performed in the past to treat adrenocortical hyperplasia. This lead to unsuppressed growth of the microadenoma, with progression to invasive macroadenomas.[19] Nelson's adenomas underlie a significant proportion of pituitary carcinomas.

Silent Corticotroph Cell Adenomas

Approximately 5% of corticotroph cell adenomas are unaccompanied by elevations in ACTH or clinical evidence of Cushing's disease.[37] These are usually invasive macroadenomas. There are two subtypes of silent corticotroph cell adenomas:

1. Subtype I
2. Subtype II.

Glycoprotein Adenomas

These tumours produce hormones that have two amino acid chains. The α-SU is common to all these hormones and a beta that has functional specificity. They include gonadotropic (FSH-LH) and TSH adenomas.

Gonadotroph Cell Adenoma

These represent 10% of pituitary adenomas.[56] They are seen primarily in elderly individuals, most often in males. These are macroadenomas with a low invasion rate.

These adenomas show perivascular pseudorosette or ribbon formation (Fig. 3A). Oncocytic change is seen in approximately 50% of adenomas. Staining for FSH and/or LH and the α-SU is highly variable and patchy (Fig. 3B), with secondary immunoreactivity for PRL, GH and ACTH. These tumours have small (200 nm) secretory granules that are peripherally located. A "honeycomb" Golgi complex is seen in female patients.

Thyrotroph Cell Adenoma

These tumours are the least common (1%) of pituitary adenomas.[10] They manifest as hypothyroidism in individuals of all ages. There is an equal gender distribution.

The majority are invasive macroadenomas. TSH positivity and variable staining for α-SU, GH and PRL typify these adenomas. Secretory granules are few, small (200 nm) and peripherally located beneath the plasma membrane.

Plurihormonal Adenomas

Adenomas that produce both amino acid hormones (GH, PRL, ACTH) and/or glycoprotein hormones (LH, FSH, TSH, α-SU) are termed plurihormonal adenomas.[11]

Acromegaly is a common feature with GH, PRL or TSH. Other plurihormonal adenomas that are reported are: PRL-TSH; PRL-FSH/LH and ACTH-LH-α-SU.

Silent Adenoma, Subtype III

These tumours are clinically silent or non-functional and are seen in the second and third decades in females, and at any age in males. Immunoreactivity is seen for any of the pituitary hormones; however, some adenomas are entirely immunonegative.[14] The adenomas are aggressive in behaviour.

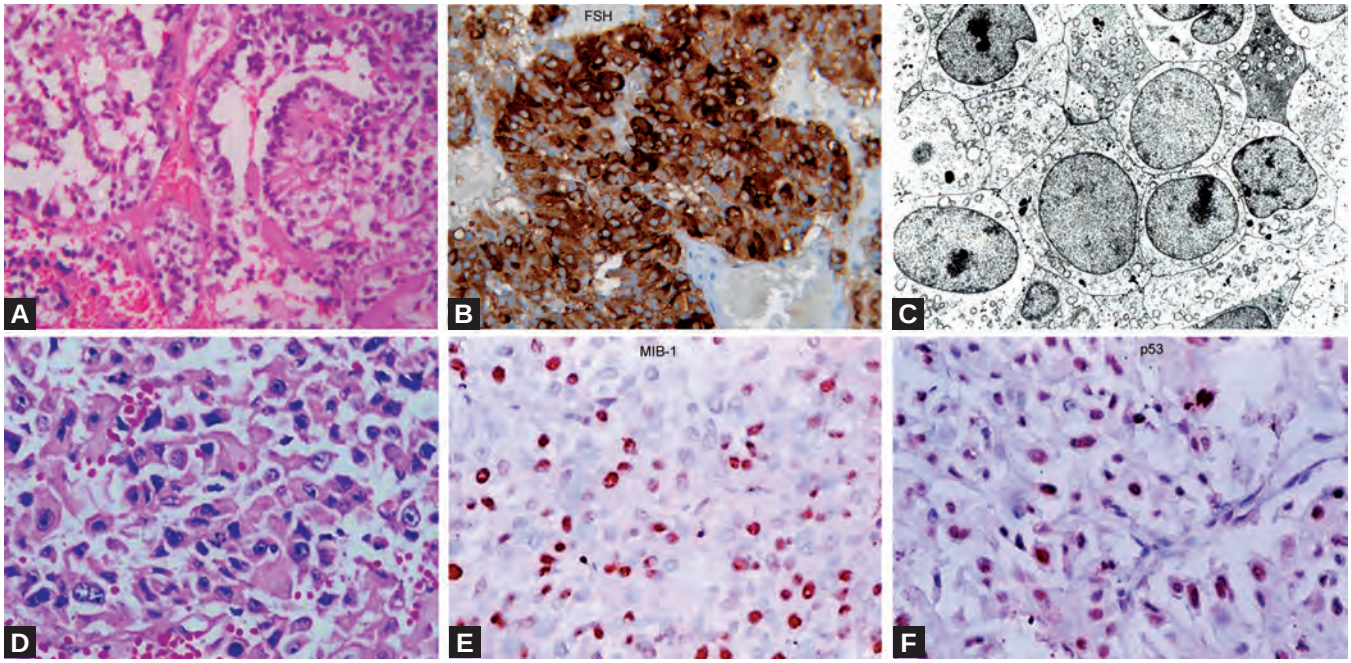
Null Cell Adenomas

These adenomas constitute one-fifth of all pituitary adenomas.[20] These tumours are clinically silent or non-functional and indolent in behaviour. They are macroadenomas with 40% being invasive. The tumours are negative for pituitary hormones, or show scant glycoprotein hormone or α-SU production. There is a paucity of organelles and only few small secretory granules (Fig. 3C) on electronmicroscopy.

INVASION AND MALIGNANCY IN PITUITARY ADENOMAS

Invasive Adenoma

A subset of tumours demonstrates a propensity for infiltrative and destructive growth.[41] Termed invasive adenomas they represent a group between the well-demarcated benign adenomas and the metastasising pituitary carcinomas.[50] Routine histological tests fail to reliably distinguish aggressive and locally invasive pituitary adenomas from those that are biologically indolent. Morphological markers of aggressiveness in most tumour systems, namely nuclear pleomorphism, cytological atypia, high cellularity, necrosis and brisk mitotic activity are of limited usefulness in pituitary



Figs 3A to F: (A) Gonadotroph adenoma with papillary configuration resulting in pseudorosette formation (H&E X 400). (B) Gonadotroph adenoma immunopositive for follicle stimulating hormone (Avidin peroxidase X 400). (C) Ultrastructural appearance of a null cell adenoma with small cells in which the cytoplasmic organelles are poorly delineated. (D to F) Atypical pituitary adenoma with pleomorphism, mitotic activity, a MIB-1 labelling index of greater than 3% and immunoreactivity for p53 (D: H&E X 400; E&F: avidin peroxidase X 400)

neoplasms, particularly in the assessment of their invasive tendency, growth rate, potential for recurrence and general biological behaviour. Several other biological markers have been studied to determine predictors of behaviour in adenomas and these are discussed later in this Chapter.

Atypical Adenoma

Atypical adenomas are adenomas that are in a category intermediate between benign adenomas and the pituitary carcinomas. These adenomas have mitotic activity, a MIB-1 labelling index of greater than 3% and immunoreactivity for p53[21] (Figs 3D to F).

Pituitary Carcinoma

This tumour is defined as one which has either craniospinal spread or metastasis to lymph nodes, liver or bone. These tumours are by and large functional, but may not show overt histological signs of atypia.[21,42]

Pituitary Apoplexy

Surgical specimens from cases of apoplexy can range from haemorrhagic material to infarcted tumour and combinations of these. On occasion there may be old haemorrhage as evidenced by the presence of cholesterol crystals and haemosiderophages. Viable tumour may also be present. In the absence of viable tumour, immunostaining is not advised as ambiguous results may be obtained.[6] The reticulin framework of an adenoma is usually preserved and, hence, a stain to highlight this is helpful in diagnosis.

MARKERS OF BIOLOGICAL BEHAVIOUR OF PITUITARY ADENOMAS

DNA Analysis

The clinical relevance of DNA analysis in pituitary tumours is still to be conclusively established, with variable results on secretors and non-secretors.[27]

Karyotypic studies on pituitary adenomas have shown abnormalities in chromosome 1, 4, 7 and 19 in functional tumours and numerical abnormalities in non-functioning tumours. There are no reported differences in karyotype between functional and non-functional tumours.

Proliferation Markers

It has been shown that pituitary adenomas with histologically proven dural invasion have a statistically significantly higher Ki-67 index compared with non-invasive adenomas.[18,48] In the study by Thapar et al.[48] the mean Ki-67 derived growth fractions for non-invasive adenomas, invasive adenomas and pituitary carcinomas were 1.34%, 4.66% and 11.91%, respectively. Establishing a threshold labelling index of 3% served to distinguish invasive from non-invasive adenomas with 73% sensitivity and 97% specificity. These findings are disparate from those of Gandour-Edwards et al.[9] and Lath et al.[25]

In the study by Lath et al.[25] the mean Ki-67 LI was 0.84% (+/− 2.08) with a range of 0–17.45%. The mean Ki-67 LI was higher in invasive tumours 1.33 +/− 3.232 than in non-invasive tumours. The difference in Ki-67 LI between invasive and non-invasive adenomas was, however, not statistically significant. Gandour-Edwards et al.[9] too failed to confirm the Ki-67 proliferation index as a marker of invasive pituitary adenomas involving the sphenoid sinus.

p53 Tumour Suppressor Gene

In a study by Thapar et al.[50] expression of *p53* gene mutation was present in 100% of pituitary carcinomas, 15.2% of invasive adenomas and none of the non-invasive adenomas. Data from other studies have, however, failed to confirm the validity of the p53 gene as a clinical predictor of the aggressiveness of pituitary adenomas.[3]

Apoptosis

Kulig et al.[23] reported a relatively low level of programmed cell death in a wide range of pituitary tumours. In this study the highest apoptotic index was present in pituitary carcinomas. The B-cell lymphoma-2 was moderately expressed in all groups of tumours and normal pituitary, and was much weaker in pituitary carcinomas. The Bax, Bad and Bcl-X were expressed in most pituitary tissues with less intensive staining in carcinomas, indicating that both pro-apoptotic and anti-apoptotic proteins are expressed concurrently in the same cells.

Angiogenesis

Pituitary adenomas show a lower microvascular density than normal pituitary tissue with the exception of invasive prolactinomas and pituitary carcinomas.[52,54]

Growth Factors

Many growth factors are expressed in normal pituitary and pituitary adenomas.[34] There is, however, no evidence for using the expression of growth factors or their receptors as prognostic markers.

MOLECULAR PATHOLOGY: ONCOGENES AND TUMOUR SUPPRESSOR GENES[29]

Amplification of oncogenes H-ras and c-Myc and inactivation of tumour suppressor genes Rb, p53, nm[23] has been thought to play a role in initiation and adenoma progression. C-erbB-2 staining was reported in 40% of invasive adenomas and 1.2% of the non-invasive tumours.[28] Pituitary oncogenes gsp, Cyclin D1 and PTTG are frequently found in pituitary adenomas.[57] Cyclin D1 is found more frequently in non-functioning and aggressive adenomas.[16,53] Cyclins A, B and E are expressed in all adenomas and are significantly higher in macroadenomas compared to microadenomas.[53] The allelic loss of a RB1 intragenic marker on chromosome 13q loss is more frequent in invasive adenomas.[31,45] The ZAC gene is highly expressed in the adenohypophysis, however, there is a reduction or absence of ZAC mRNA and protein expression reported in non-functioning pituitary adenomas.[30] GADD45 gamma mRNA is another suppressor found in the normal adenohypophysis, but in only a few clinically non-functioning pituitary tumours. Absence of the cyclin-dependent kinase inhibitor 2A/multiple tumour suppressor gene 1 (CDKN2A/MTS//p16) was demonstrated in 78% of non-functioning tumours.[44]

All cases of pituitary adenoma require a hematoxylin and eosin section and preferably reticulin and PAS stains. This together with the clinical and biochemical profile helps in diagnosis of most pituitary adenomas. *Reticulin* stain helps in detection of microadenomas. Immunohistochemistry is imperative in the detection of mixed GH-PRL adenomas, acidophil stem cell adenomas, silent corticotroph adenomas, gonadotrophic adenomas, and null cell adenomas and in confirming PRL production when serum PRL levels are not markedly elevated. Immunohistochemistry for the MIB-1 monoclonal antibody and p53 are helpful in diagnosing atypical adenomas. Electron microscopic examination is useful in the diagnosis of mixed GH-PRL adenomas, acidophil stem cell adenomas, female gonadotroph adenomas, null cell adenomas and silent subtype III adenomas.

Potentially aggressive adenomas are sparsely granulated GH adenomas, acidophil stem cell adenoma, PRL adenomas in the post-reproductive age group, ACTH adenomas associated with Nelson's syndrome and silent subtypes I and II, TSH adenomas and silent subtype III.

CRANIOPHARYNGIOMA[4]

These are epithelial neoplasms which arise in the sellar and/or third ventricle region.[2]

Clinical Features

Craniopharyngiomas manifest with hypothalamo-pituitary dysfunction and visual disturbances.

Histological Subtypes

There are two histological subtypes:
1. Adamantinomatous
2. Papillary

1. Adamantinomatous

The tumours are thought to arise from Rathke's cleft, squamous metaplasia of adenohypophyseal cells of the pituitary stalk or embryonic rests with odontogenic potential. These tumours are seen in the first two decades of life, although they can also be seen in adults.

They are cystic, contrast enhancing, partly calcified masses (Fig. 4A) in the sellar or third ventricular region.

Gross

The tumour is ill circumscribed with a poor interface with adjacent brain. They are partly cystic with calcific material and "machine–oil" fluid rich in cholesterol particles. Chemical meningitis results if the contents spill into the cerebrospinal fluid space.

Microscopic Features

They are similar to odontogenic tumours like adamantinoma of the jaw with anastomosing trabeculae of epithelial cells that exhibit peripheral palisading of columnar epithelial cells and enclose in their central portions loosely arranged epithelium known as "stellate reticulum" (Figs 4B and C). Amorphous masses of keratin (wet keratin) with secondary calcification are seen. The cyst contents incite an inflammatory reaction that is usually xanthomatous. Cholesterol granulomas are also a feature.

Behaviour

Adamantinomatous craniopharyngiomas have a propensity to recur owing to their infiltrative nature and, especially, if they are subtotally excised.

Sometimes biopsy material is scant and consists of the cyst contents or wet keratin without any epithelial elements. In such a case only a presumptive diagnosis of craniopharyngioma can be made.

Adamantinomatous craniopharyngiomas often infiltrate the adjoining parenchyma as nests and incite a rim of piloid gliosis (Fig. 4D). This may rarely be the first sample that reaches the pathologist for a frozen section. A mistaken diagnosis of a pilocytic astrocytoma arising from the optic pathway should be avoided by being aware of the clinico-radiological and intra-operative correlates as well as by the fact that gliosis is usually less cellular and lacks eosinophilic granular bodies and the biphasic appearance of pilocytic astrocytomas.

Differential Diagnosis

Epidermoid cyst: These cysts have lamellated keratin instead of wet-keratin nodules, gradual keratinisation of the epithelium and the presence of keratohyaline granules.

2. Papillary Craniopharyngioma

Papillary craniopharyngiomas are seen primarily in adults in the third ventricle or suprasellar space. The sella may hence, be normal.

Gross

They are solid tumours that have papillary fronds (Fig. 4E).

Microscopic Features

A discrete tumour with simple squamous epithelium covering fibrovascular cores without adamantinomatous features (Fig. 4F) typifies this tumour. "Wet" keratin, machine-oil fluid and calcification are not features of this neoplasm.

Behaviour

Complete excision is possible due to their well circumscribed nature. Reported recurrence rates are low after radical excision, however, more recent reports suggest that these tumours too have a propensity to recur similar to adamantinomatous craniopharyngiomas.

Differential Diagnosis

- Epidermoid cyst
- Adamantinomatous craniopharyngioma.

PITUICYTOMA AND GRANULAR CELL TUMOUR[4,8]

These tumours are seen in adults, usually in the fourth and fifth decades of life.

Their cell of origin is the pituicyte, which is a modified glial cell of the infundibulum, and neurohypophysis. They are well circumscribed contrast enhancing tumours, isointense on T1-weighted and T2-weighted images seen in the sellar/suprasellar region in relation to the neurohypophysis and infundibulum.

Gross

These are firm, tan-coloured masses that can be vascular.

Microscopic Features

Granular Cell Tumour

The tumour is composed of sheets of polygonal cells with granular, eosinophilic PAS-positive, diastase resistant cytoplasm with eccentrically placed round nuclei with uniform nucleoli (Fig. 5A). Perivascular lymphocytic infiltrates are sometimes present.

Pituicytomas

These tumours are composed of fascicles of spindle-shaped cells with an astrocytic morphology and fibrillary cytoplasm, uniform bland nuclei and distinct small nucleoli. Mitotic activity is sparse.

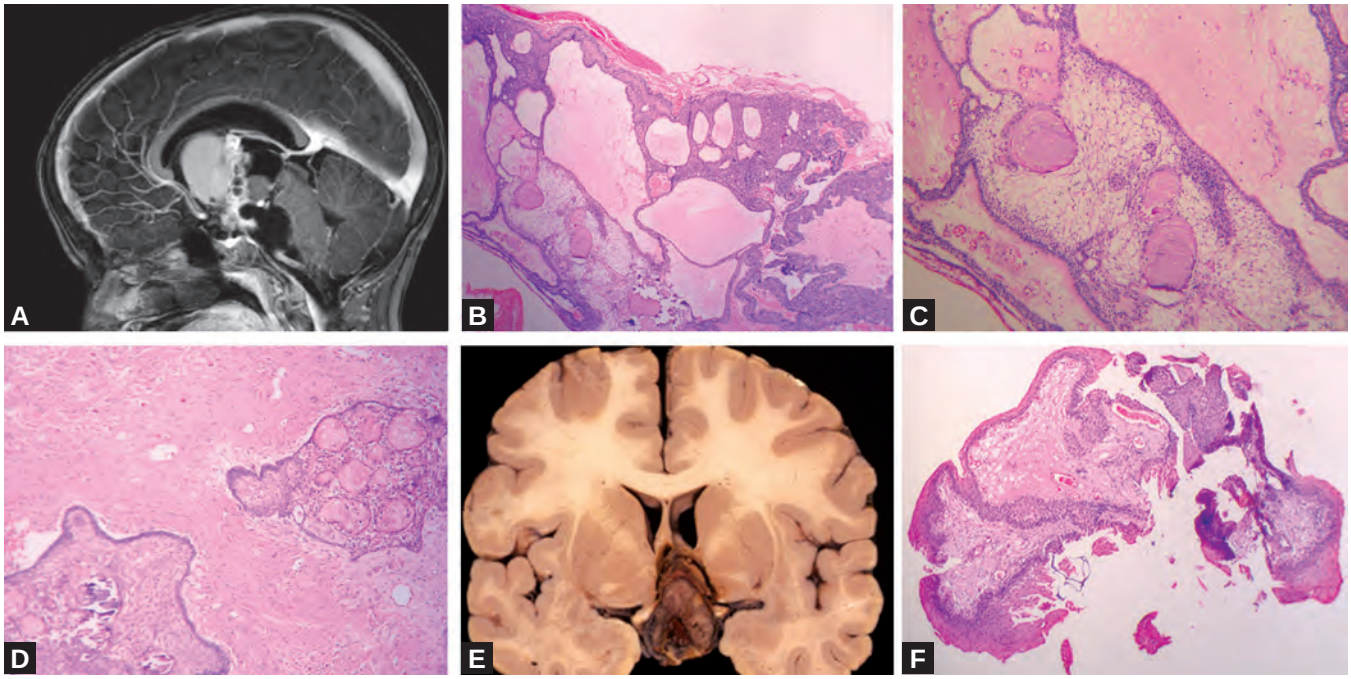
Immunohistochemistry

Granular cell tumours are CD68 positive and rarely S-100 protein and GFAP positive.

Pituicytomas are S-100 protein positive and variably reactive to GFAP.

Ultrastructural Features

Numerous intracytoplasmic lysosomes (Fig. 5B) are seen.



Figs 4A to F: (A) Magnetic resonance imaging of a partly cystic craniopharyngioma. (B and C) Adamantinomatous craniopharyngioma with cystic spaces and anastomosing trabeculae of epithelial cells that exhibit peripheral palisading of columnar epithelial cells and enclose in their central portions loosely arranged epithelium known as "stellate reticulum" (H&E: A X 40; B X 90). (D) Piloid gliosis surrounding islands of adamantinomatous craniopharyngioma (H&E X 90). (E) Papillary craniopharyngioma occupying the third ventricle. (F) Papillary craniopharyngioma: simple squamous epithelium covering fibrovascular cores without adamantinomatous features (H&E A X 40)

Differential Diagnosis

Pilocytic Astrocytoma

These are large tumours seen mainly in childhood with a biphasic histological pattern with rosenthal fibres and eosinophilic granular bodies.

Behaviour

These tumours are reported to have a variable prognosis with recurrences.

SPINDLE CELL ONCOCYTOMA OF THE ADENOHYPOPHYSIS[7]

These tumours arise from folliculostellate cells. They are seen primarily in adults who present with visual field defects and panhypopituitarism. They resemble pituitary adenomas on imaging.

Microscopic Features

These are tumours composed of spindle-shaped cells. Mitotic activity is absent.

Immunoreactivity

These tumours are positive for vimentin, epithelial membrane antigen and S-100 protein and are negative for all the pituitary hormones, synaptophysin, chromogranin and GFAP.

Prognosis

There are no recurrences reported to date.

POST-IRRADIATION SARCOMA[4,8]

These tumours are seen following irradiation to the sellar region after a latent period of about 10 years.

Microscopic Features

The histological features are those of a fibrosarcoma, osteosarcoma or a rhabdomyosarcoma, which is often admixed with a pituitary adenoma.

Behaviour

The tumours are locally aggressive.

NON-NEOPLASTIC LESIONS OF THE SELLA TURCICA[4]

Rathke's Cleft Cyst

They arise from Rathke's cleft rests. These cysts are rarely symptomatic.[47] They are often an incidental finding at autopsy or present as cysts that cause visual symptoms, hyperprolactinaemia, diabetes insipidus, growth retardation or other endocrinal dysfunction. They are intrasellar cysts with suprasellar extension with a high signal on T1-weighted images. Calcification is absent.

Microscopic Features

The cyst is lined by a single to pseudostratified layer of columnar, mucin-producing or ciliated cells with a few goblet cells (Fig. 5C). Squamous metaplasia is seen occasionally. They are rarely associated with adenomas.

Behaviour

Recurrences have been reported.[17]

Empty Sella Syndrome[15,46]

It is of two types, primary or secondary. In the primary form, arachnoid herniates into the sella through an incompletely formed sellar diaphragm resulting in displacement of the infundibulum and compression of the gland. In the secondary form the herniation is secondary to loss of the intrasellar contents, either secondary to surgical resection, apoplexy or necrosis.

Giant Cell Granuloma[4]

Giant cell granuloma is thought to be autoimmune in origin.

Clinical Features

They manifest with pituitary insufficiency and diabetes insipidus, occasionally.

Gross

In the early stages an enlarged gland is seen and later one sees a shrunken gland.

Microscopic Features

Discrete non-caseating granulomata containing several giant cells, with associated fibrosis (Fig. 5D) are seen within the adenohypophysis.

Behaviour

It is a self-limiting condition.

Differential Diagnosis

Tuberculosis, fungal infections and sarcoidosis. Necrotising granulomas are usually of infective aetiology. Sarcoidosis usually involves the neurohypophysis or hypothalamus.[24]

Lymphocytic Hypophysitis[1,4,33,51]

This is secondary to an autoimmune response which is both cellular and humoral, most often directed against pituitary hormones.

Clinical Features

These manifest with pituitary insufficiency and hyperprolactinaemia. There is a female predominance usually in late pregnancy or post-partum.

Radiographic Features

A symmetric enlargement of the pituitary is seen with contrast enhancement (Fig. 5E).

Gross

A firm gland is seen macroscopically.

Microscopic Features

Lymphocytic hypophysitis is characterised by pituitary acini extensively infiltrated by lymphocytes, as well as occasional plasma cells and histiocytes (Fig. 5F). Lymphoid follicles with germinal centres are seen. There is extensive fibrosis. An inflammatory infiltrate may also be seen in other endocrine organs.

Treatment

A biopsy is followed by hormone replacement as this can be fatal if untreated.

Pituitary Hyperplasia[4,12]

Pituitary hyperplasia occurs in response to stimulation by hypothalamic releasing hormones either as a physiological response to end-organ failure or due to a neoplasm.

Microscopic Features

Hyperplasia is either nodular or diffuse in pattern and usually involves one cell type. The reticulin stain plays a pivotal role in the diagnosis of hyperplasia. Nodular hyperplasia is seen as expanded acini. Cell counts are required for the diagnosis of diffuse hyperplasia.

Growth Hormone Cell Hyperplasia

It is seen with GRH-producing tumours, such as carcinoids and pheochromocytomas.[38] These cells are immunoreactive for GH.

Prolactin Cell Hyperplasia

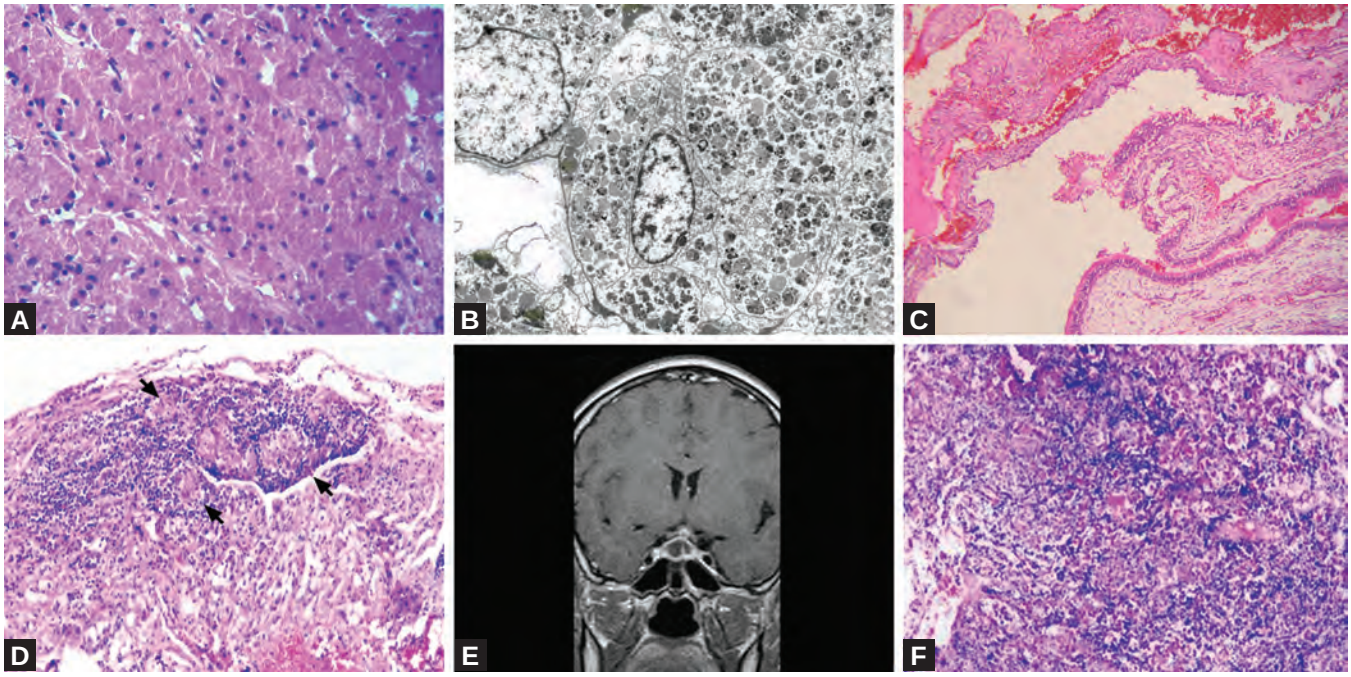
It is seen as a constant feature in association with pregnancy and lactation.[43] It is also seen in long standing cases of primary hypothyroidism, secondary to increase in TSH releasing hormone as well as in Cushing's disease.

Corticotroph Hyperplasia

Corticotroph hyperplasia is seen in the adenohypophysis adjoining a corticotroph adenoma. It is also seen in untreated Addison's disease as well as in association with tumours that produce corticotropin-releasing hormone.[40]

Gonadotroph Hyperplasia

It is seen in early onset primary hypogonadism such as in Klinefelter's or Turner's syndrome.[35]



Figs 5A to F: (A) Granular cell tumour: sheets of polygonal cells with granular, eosinophilic cytoplasm and eccentrically placed round nuclei (H&E X 400). (B) Granular cell tumour: numerous intracytoplasmic lysosomes. (C) Rathke's cleft cyst wall lined by single to pseudostratified layer of columnar epithelium (H&E X 90). (D) Giant cell granuloma: adenohypophysis with discrete non-caseating granulomas (H&E A X 40; B&C X 90; D X 400). (E) Magnetic resonance imaging of a case of lymphocytic hypophysitis: hypointense mass with peripheral enhancement. (F) Lymphocytic hypophysitis: dense infiltrates of lymphocytes and occasional plasma cells interspersed with adenohypohyseal cell clusters (H&E X 90)

Thyrotroph Hyperplasia

It is seen in patients with long-standing primary hypothyroidism.[32,39]

125 Lymphomas and Metastatic Tumours of Nervous System

Sundaram C, T Roshni Paul

LYMPHOMAS OF THE CENTRAL NERVOUS SYSTEM

Non-Hodgkin's lymphomas of the central nervous system (CNS) can be primary or secondary. Systemic lymphomas can spread to the CNS in about 10% cases, usually in advanced or relapsing phase. Certain primary sites, like testis, bone marrow, bone, paranasal sinus, are more likely to seed the CNS. High grade lymphomas spread to the brain more frequently than others, and the involvement is usually leptomeningeal.

Primary central nervous system lymphoma (PCNSL) is a non-Hodgkin's lymphoma that is confined to the brain, leptomeninges, eye or spinal cord without evidence of involvement of other parts of the body.[32,41]

Involvement of the brain is uncommon in Hodgkin's lymphoma and plasma cell dyscrasias. They can, however, present with spinal cord compression.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Epidemiology

Primary central nervous system lymphoma (PCNSL) was considered a rare neoplasm before 1980 and it constituted less than 1% of all intracranial neoplasms.[63] However, there were reports of increasing incidence of PCNSL from the West. There was a tenfold increase in the incidence of PCNSL from 1973 to 1992.[68] This was largely attributed to the epidemic of acquired immunodeficiency syndrome (AIDS)[18] and also to immunosuppressive therapy for patients with organ transplantation and other autoimmune diseases. However, increase in the incidence of PCNSL was observed in immunocompetent individuals also during the same period, for reasons not clear.[4] On the other hand, recent data suggests that the annual incidence of PCNSL may be stabilising or declining slightly.[36,59] There were a few hospital-based series of PCNSL reported from India, which did not show any significant increase in the incidence of PCNSL over the last 24 years.[53,65] Similar observations were made from Canada, Denmark and Scotland[30,33,46,51] suggesting significance of geographical domains for the incidence of PCNSL.

Predisposing Conditions

PCNSL occurs in both immunocompetent and immunosuppressed individuals.

The immunodeficiency states associated with PCNSL may be acquired or congenital. The immunodeficiency states include AIDS and immunosuppressive therapy for organ transplantation (especially cardiac and renal transplantations). The congenital immunodeficiency states include: Wiskott-Aldrich syndrome; severe combined immunodeficiency syndrome; immunoglobulin A deficiency; ataxia-telangiectasia; X-linked lymphoproliferative syndrome and Chediak-Higashi syndrome. PCNSL is diagnosed in at least 2% of human immunodeficiency virus (HIV) infected individuals and is an AIDS defining illness. The relative risk of PCNSL in HIV infected individuals was 3600 fold when compared to the general population before the use of highly active antiretroviral therapy (HAART). It has decreased after the introduction of HAART.[4,50] PCNSL is a late manifestation of the disease in AIDS when $CD4^+$ T cell counts are less than 200/μl.[41,49] In India, the majority of PCNSLs are reported in immunocompetent individuals. Clinical as well as autopsy studies of HIV related neurological diseases in India reported very low incidence of PCNSL.[8,28,45,53] This is probably related to early deaths in AIDS patients due to opportunistic infections.

Age and Gender

PCNSL occurs in all age groups, but age differs significantly depending on the immune status. In immunocompetent individuals, the mean age at diagnosis is 55.2 years while in immunosuppressed individuals, the mean age is 30.8 years.[29,69] The mean age of PCNSL in India varies from 39 years to 44 years in immunocompetent individuals, significantly lower than that reported from the West.[65]

There is a male predominance in both AIDS patients (> 95%) and in immunocompetent patients with PCNSL (2:1).

Clinical Presentation

The clinical features depend on the neuroanatomical location of the lesions. The patients present with focal

neurological deficits, neuropsychiatric symptoms, raised intracranial pressure, seizures or ocular symptoms.[4] The leptomeningeal lesions may be asymptomatic and spinal cord lesions are usually discrete intramedullary nodules.[47]

Pathogenesis

The pathogenesis of PCNSL is unclear as the CNS does not contain any lymphatic system. Three hypotheses have been put forwards but none of them can explain the pathogenesis completely:[37] (i) A systemic B cell lymphoma develops and spreads to all organs, but lymphoma cells are eradicated by an intact immune system in all organs. The CNS being an immunologically privileged site, the cells proliferate and develop neoplasia there. However, there is no evidence of concomitant lymphoma at other immunologically privileged sites like testis. (ii) B cell lymphomas that arise elsewhere in the body develop particular adhesion molecules permitting homing to the CNS, where such cells proliferate and develop into lymphomas in the absence of immune regulation. (iii) An intracerebral inflammatory lesion with polyclonal inflammatory infiltrate may progress to a neoplastic monoclonal B cell proliferation similar to MALT lymphoma evolving from gastritis induced by *Helicobacter pylori*. However, there is paucity of B cells even in inflammatory CNS disorders. Also, to date, no difference in cell surface expression of adhesion molecules have been found between PCNSL and systemic lymphoma.[37,59,60] Smith and colleagues identified a B cell attracting (BCA) chemokine (CXCL-13), which is responsible for homing of B cells to secondary lymphoid organs.[71] Both BCA-1 and its receptor CXCR-5 are expressed by B cells in PCNSL suggesting their possible role in homing of B cells in the CNS.[22] Recent evidence shows that BCA-1 and SDF-1 (both B cell chemokines) are expressed by retinal pigment epithelium in primary intraocular lymphoma.[38,64] Animal models of PCNSL show that lymphoma cells enter the brain preferentially through the choroid plexus and cranial nerves and then disseminate along the optic nerve sheath into eye. Recent studies suggest that the tumour arises in an extraneural environment with subsequent localisation to the CNS, possibly by virtue of a specific neurotropism. It is probably a late germinal centre or a postgerminal centre lymphoid neoplasm.[39]

In the majority of immunosuppressed patients, PCNSL is associated with latent infection of B cells by Epstein Barr virus. Virtually all PCNSLs in AIDS patients contain EBV DNA. Clinical or sub-clinical infection with EBV results in both humoral and cellular immunity and EBV persists despite the immune effector responses and results in latent infection of B cells. The proliferation of B cells is controlled by T cell immunity. In HIV and other immunosuppressed states, due to loss of T cell mediated immunity, there is proliferation of B cells which are latently infected with EBV. There is evidence that EBV infection of tumour clone is associated with CNS tropism[2,43,67,74] (Table 1).

Non-AIDS Related Molecular Pathology

PCNSL and primary intraocular lymphomas express BCL-6 which is a germinal centre cell marker suggesting that the tumour cells are derived from mature B-cells which are exposed to an antigen and undergone T cell dependent maturation in the germinal centre.[26,76] BCL-6 expression is associated with favourable prognosis.

Roychowdary et al. (2003)[6] developed a rat model of EBV related PCNSL which allows preclinical evaluation of antiviral therapy in EBV related PCNSL. Studies applying molecular genetic techniques provide information about molecular markers, which help understand pathogenesis and also predict prognosis.

Gross Pathology

Four forms of involvement have been described in PCNSLs: (i) discrete or diffuse intracranial mass lesions that are solitary or multiple, often in contact

Table 1: Comparison between PCNSL in the immunocompetent and AIDS PCNSL

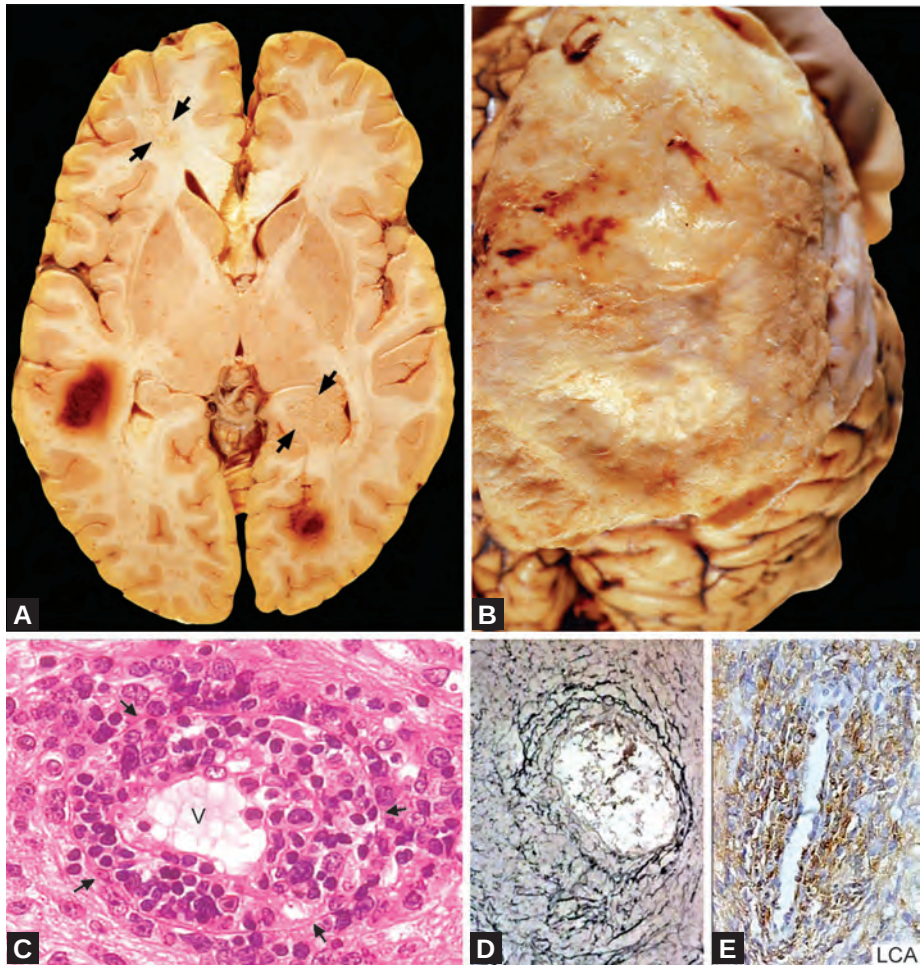
	PCNSL in immunocompetent individuals	*PCNSL in AIDS patients*	*References*
Median age at diagnosis	55.2 years	30.8	16, 17
	India 39–44 years	Indian data not available	7
Gender	M:F = 2:1	> 95% male	16, 17
Multifocality	25%	52%	16
Leptomeningeal involvement	7% at diagnosis, 4% by MRI, CSF cytology, autopsy	More common at diagnosis, almost 100% at autopsy	34
Haemorrhage into tumour	Uncommon	Common after surgery	19
Necrosis	Usually not seen	Extensive	40
Clinical features—change in mental status, seizures	Less common	More common	16
Clinical course	Weeks to months	Days to weeks	41
CD4 counts	Normal	< 200/μl	42
Ebstein Barr virus genome	0–20%	94–100%	40

with ventricular or meningeal surface; (ii) leptomeningeal lesions; (iii) ocular lesions with or without other lesions and rarely (iv) spinal cord lesions.[47] Majority of the intracranial lesions are supratentorial (85%) in the periventricular zone and areas in thalamus, basal ganglia and corpus callosum[4,10] and the lobar lesions in the frontal, parietal, temporal and occipital lobes in the descending order of frequency.[4] Primary leptomeningeal lymphoma, without parenchymal involvement (7%) and primary intraocular lymphoma (6%), are rare forms of PCNSL and spinal cord involvement is very uncommon (less than 1%).[44,62,68] Leptomeningeal involvement is common in PCNSL either in mass lesions or primary leptomeningeal form, but majority are asymptomatic. However, it provides an important aid in diagnosis by CSF cytological examination (Figs 1A and B).

Histology

PCNSL are most often high grade diffuse large B cell Lymphoma (DLBCL) according to REAL and WHO classifications.[3,52] All types of lymphoma including the rare ones with signet ring cell morphology or anaplastic large cell (Ki-1) type have been reported in the brain. The PCNSL in AIDS frequently include immunoblastic and small non-cleaved Burkitt-like cell type. Low grade PCNSL similar to systemic NHL as a subgroup are described recently.[48] The round to oval cells infiltrate the cerebral parenchyma diffusely and aggregate in the Virchow Robin spaces with infiltration of the vessel walls. The tumour cells are angiocentric, pleomorphic, discohesive and infiltrative. There is no associated endothelial proliferation or thrombosis. The cells show high mitotic index. The vessels show perivascular cuffing and the reticulin stain shows splaying of reticulin fibres (Figs 1C and D). The AIDS related PCNSL shows atypical features, areas of necrosis and EBV genome by *in situ* hybridisation, and EBV associated latent membrane protein by immunohistochemistry (Figs 1C to E).

More than 95% of NHL in the brain are of B cell lineage and show CD 20 and CD 79a positivity. A few reactive T cells can be seen in B cell PCNSLs. Other evidence of B cell lineage includes clonal IgH gene rearrangements, frequent alterations of non-coding regions of the BCL 6 gene and BCL-6 protein expression.[62] Primary T



Figs 1A to E: (A) Axial slice of brain shows pale, circumscribed lymphomatous deposits (arrows) in left frontal white matter and hippocampus, and haemorrhagic lesions in left temporal and right parieto-occipital white matter. (B) A large circumscribed pale lymphoma deposit on the dura resembling a meningioma. (C to E) Microphotograph of lymphomatous lesion shows characteristic. (C) Angiocentric distribution of lymphoma cells. (D) Splitting reticulin framework. (E) Immunohistochemistry shows positive labelling of tumour cells for LCA. (C:HE x 320, D:Reticulin silver x 160, E:Immunoperoxidase for LCA x 160)

cell lymphomas including anaplastic large cell variant, constitute a small minority of PCNSL, especially in the cerebellar and leptomeningeal examples.

In a study of PCNSLs at the Nizam's Institute of Medical Sciences, Hyderabad, 56 cases of PCNSLs were diagnosed from 1988 to 2006. The median age of presentation was 42 years, with male predominance. The PCNSLs have remained fairly constant through the years forming 1.07% of intracranial neoplasms. Of the 56 cases, 55 cases were immunocompetent and only one patient was HIV positive. Majority were large B-cell lymphomas and 19/19 cases were negative for E B Virus by *in situ* hybridisation.

Diagnosis

The diagnosis of PCNSL may be suggested by several radiological findings.[69] They are angiographically avascular. On CT scans, they are either isodense or hyperdense in relation to the normal cortex, as opposed to glial tumours and metastasis, which are hypodense. They tend to cause less oedema than gliomas. More than 90% are contrast-enhancing. The radiographical appearance of PCNSL differs significantly between AIDS and non-AIDS setting. In immunocompetent patients, PCNSL appears multifocal in one-third of patients, enhance uniformly with contrast, and lack ring enhancement, whereas in AIDS associated PCNSL, the lesions are multifocal in 30–75%, may be cortical or subcortical and enhance after contrast administration.[49] On MRI, PCNSL is typically hypointense or isointense on T1-weighted images with variable enhancement pattern on Gadolinium, especially ring enhancement.[49] It is difficult to reliably distinguish AIDS associated PCNSL from AIDS related infections, especially Toxoplasmosis on CT or MRI. Diffusion weighted MRI and metabolic imaging hold promise in this direction.

Cerebrospinal Fluid Examination

It should be performed in all patients with suspected PCNSL, unless contraindicated by a large posterior fossa mass lesion, elevated intracranial pressure or coagulopathy. Cytological examination may provide useful information and eliminate the need for surgery.[13,49] CSF shows raised protein, low sugar, may be positive for tumour markers such as β2 microglobulin and LDH. Cytology may be positive in a third of patients and detection rate increases after repeated sampling. Flow cytometry improves sensitivity of detecting occult leptomeningeal disease.[9] Polymerase chain reaction (PCR) for EBV DNA in CSF has a sensitivity of 80–100% and specificity for lymphoma of 93–100%.[42] It is also positive in EBV associated systemic lymphoma in AIDS patients. Combining CSF-EBV analysis with metabolic imaging improves the accuracy of diagnosis of AIDS-PCNSL.[63] In a recent review, Batchelor and Loeffler discussed the unique diagnostic, prognostic and therapeutic issues of PCNSLs in immunocompetent patients.[38]

Role of Stereotactic Brain Biopsy

Stereotactic Brain Biopsy (SBB) is the standard procedure for obtaining tissue for a pathological diagnosis of cerebral lymphoma. The centre of the suspected lesion should be targeted for biopsy. The advantages of SBB over open biopsy include minimal skin incision, option of local anaesthesia, short post-operative recovery period, and low rate of morbidity and mortality. Surgical excision of a parenchymal PCNSL confers no survival benefit. They may be associated with a worse survival along with a risk of seeding the leptomeninges with tumour cells.

The morbidity and mortality of SBB is higher in AIDS patients due to the high frequency of haemorrhagic complications. Stereotactic biopsy is particularly useful to obtain tissue in PCNSLs involving deep structures like thalamus, periventricular area and corpus callosum.[47]

Use of steroid therapy before biopsy can obscure histopathological features due to tumour cell apoptosis to the point that lesional cells disappear completely.[47] As most patients with PCNSLs have relapses if treated with steroids alone and there are difficulties in establishing subsequent diagnosis, corticosteroids should not be administered before biopsy.[39]

Prognostic Markers

Age more than 60 years, performance status more than one; elevated serum LDH, high CSF protein concentration and involvement of deep regions of the brain (periventricular regions, basal ganglia, brainstem and/or cerebellum) were significantly and independently associated with bad prognosis and low survival rate.[35]

PCNSL without treatment has a median survival of 1.8–3.3 months only. Combined modality approach with chemotherapy and whole brain radiotherapy has improved survival, but relapses occur in almost all PCNSL.

Spinal Cord Compression Due to Haematological Malignancies

Spinal cord compression due to haematological neoplasm is a serious complication requiring immediate diagnosis and treatment. It can occur due to involvement of spinal cord, spinal leptomeninges, dura or vertebra. The spinal involvement is common with multiple myeloma (MM),[66] followed by NHL,[7] but rare in Hodgkin's lymphoma,[73] leukemia[5] and extramedullary myeloid cell tumour (EMCT).[34]

Patients with myeloma or lymphoma have a good prognosis even if they present with cord compression, when treated appropriately and promptly.

Non-Hodgkin's Lymphoma

Cord compression has been noted at presentation in 2.2% of cases of NHL. Back pain and weakness are the commonest presenting symptoms.[7] All histological

grades of NHL have been reported. Surgery to provide a tissue diagnosis followed by combined radiotherapy and chemotherapy is indicated for all cases.

Hodgkin's Lymphoma

Hodgkin's lymphoma presenting with spinal cord compression is very rare and occurs in only 0.2% cases of Hodgkin's lymphoma.[73] The thoracic spine is the most commonly involved site. Histopathology of the lesion along with detailed clinical evaluation with history of previous biopsy, lymph nodal status and organomegaly is required to make a definitive diagnosis.

Multiple Myeloma and Solitary Plasmacytomas

Involvement of spinal cord and/or nerve root by myeloma is a serious complication and is secondary to involvement of vertebrae. It occurs in about 10% of patients of multiple myeloma and may be the initial manifestation.[7] Solitary plasmacytomas can also present with spinal cord compression.[20] Recognition of paraspinal mass by CT/MRI is useful in diagnosis and early recognition is important. Histology is diagnostic and immunohistochemistry for kappa and lambda light chains of immunoglobulins can be carried out. Associated amyloidosis carries a poor prognosis. Clinical, imageological and biochemical evaluation including serum and urine immunoelectrophoresis along with bone marrow examination is necessary for instituting therapy.

Myeloma involving skull bones of the vault do not usually produce neurological symptoms but those involving base of the skull can produce cranial nerve involvement. Meningeal involvement in myeloma is rare and intracerebral mass lesions are rarely reported.[75,16]

Solitary plasmacytomas are rare and account for less than 10% of plasma cell tumours and are morphologically indistinguishable from multiple myeloma on immunohistochemistry. Skeletal survey and bone marrow evaluation are necessary to rule out multifocal lesions. Although the prognosis for solitary plasmacytoma is significantly better than that of multiple myeloma, solitary plasmacytoma eventually progresses to multiple myeloma.

METASTATIC TUMOURS OF THE CENTRAL NERVOUS SYSTEM

Metastatic involvement of the brain and spinal cord is one of the most serious complications of systemic malignancy and its incidence seems to be increasing with improvement of therapies for systemic malignancies. It may be the initial manifestation of a systemic malignancy.

Epidemiology

It is difficult to determine the exact incidence of brain metastases. It is estimated that 5–20% of patients dying of systemic cancer will be found to have metastatic disease to brain at autopsy and about half to two thirds of them will have symptoms referable to metastasis.[25,54,72] Advances in neuroimaging and routine staging to assess CNS involvement will offer insight into the actual incidence.[31]

Pathogenesis

Brain metastases exhibit considerable clinical and neuropathological heterogeneity. This cannot be explained only by the pattern of regional blood flow. Tumour cells have marked genetic, biochemical and cytological diversity.

The metastatic tumour cells use specific adhesion molecules to attach to microvessel endothelial cells. They then respond to endothelial cell derived motility factors and invasion factors, like neurotrophins and basement membrane degradative enzymes, which facilitate brain invasion by metastatic cells locally destroying blood-brain barrier.[11]

The tumour cells proliferate in response to local paracrine and autocrine growth factors. Receptors to paracrine growth factor, like transferrin (a glycoprotein), are expressed in greater numbers on the surfaces of cells that are metastatic to brain. Transferrin-like factors are important for invasion, colonisation and growth of metastatic cells in CNS and probably explain why certain tumours, like melanoma, lung carcinoma and breast carcinoma, metastasise to brain.[11,20]

Spread of the Tumours

Systemic tumours spread to brain by three routes: (i) haematogenous; (ii) contiguous and (iii) perineural.[72] Haematogenous spread is the commonest route by which the tumour cells reach the brain and spinal cord. The tumour cells reach nervous system via systemic circulation through pulmonary vasculature or through a patent foramen ovale in the heart rarely. Metastases may occur anywhere in the brain, but in general, the distribution is proportional to the blood supply to specific areas of the brain. Hence, grey matter is more commonly involved than white matter, and metastases occur with equal frequency to both hemispheres. Eighty per cent occur in cerebral hemispheres, 10–15% in cerebellum, 2–3% in brainstem.[24] Multiple metastases are seen in 50% of patients and numerous military metastases are described as military carcinomatosis.[72]

Tumours in CNS that develop by invasion of a primary tumour in the adjacent structures, like paranasal sinuses or bone, are not actually considered as metastases because they remain in continuity with the primary neoplasm. Tumours that spread by contiguous invasion include carcinomas of nasopharynx, paranasal sinuses, skull bone and middle ear.[61] Of these, nasopharyngeal carcinoma is the commonest. Osseous tumours of the skull and vertebrae also spread by contiguous invasion. Metastases to skull bones can occur from primary

tumours-like neuroblastoma in children and tumours of prostate, breast, kidney, thyroid, lung and myeloma in the adult.[72]

Perineural metastases are the least common and this type of spread is supposed to be the mechanism for meningeal carcinomatosis.[14]

Tumours Metastasising to Brain

The incidence of brain metastases and the spectrum of metastasising primary tumours vary with patient's age. In general, brain metastases occur more frequently in adults than in children. In adults, primary tumours metastasising to brain include lung, breast, kidney, gastrointestinal tract and melanoma in descending order.[19,27] Apart from the cerebral hemispheres, cerebellum and brainstem, other intracranial sites of metastases include pituitary, pineal and choroid plexus. The metastases can also involve pre-existing lesions like glioma, meningioma, schwannoma, arteriovenous malformations and infarcts[1,12] (Figs 2A to C).

Metastases affecting the spinal cord may involve the epidural space, leptomeninges or intramedullary spinal cord. Epidural metastases are the commonest and usually present as the initial manifestation of malignancy.[58] They arise by extension from a metastatic deposit in the vertebra. Thoracic spine followed by lumbosacral and cervical spine are involved by the metastases. Lung is the most common primary affecting area followed by breast, prostate and lymphoma.

In children, leukaemia and lymphoma involve the leptomeninges. In children younger than 15 years osteosarcoma and rhabdomyosarcoma produce solid brain metastases, while in older children germ cell tumours produce metastatic deposits.[15,70]

Melanoma, although constitutes only 4% of all cancers, has the highest propensity to result in brain metastases. Genitourinary tumours and sarcomas do not frequently metastasise to brain. On the other hand, any tumour can metastasise to the brain and patients with no known history of cancer may present with brain metastases.[56]

Metastases from melanomas and lung carcinomas tend to be multiple while tumours from breast, colon and kidney tend to be single. Metastases from melanoma and choriocarcinoma are usually haemorrhagic (Fig. 2A).[72] Metastatic choriocarcinoma should be considered in the differential diagnosis of haemorrhagic intracranial masses in women of child bearing age and the surgically resected blood clots should be examined histologically for determining the aetiology.[40] Systemic lymphomas and leukaemias involve leptomeninges and do not involve parenchyma and leptomeningeal carcinomatosis is usually an adenocarcinoma.[72] Primary brain tumours, like germinoma and medulloblastoma, also spread by CSF pathway. Histology of primary tumour also influences the metastasising potential. Small cell carcinoma and adenocarcinoma of lung along with breast carcinoma are found to metastasise to brain twice more frequently than other histological types.[70]

Diagnosis

Following clinical evaluation, the size, location and number of metastases can be assessed by CT and MRI. The approach to evaluation of the lesions is given in the flow chart. High index of clinical suspicion is required to make a diagnosis of leptomeningeal involvement as the neurological manifestations can be protean (Fig. 2D). The diagnosis should be suspected when symptoms and signs suggest involvement of multiple anatomic sites in CNS. These include headache, altered sensorium, cranial nerve palsies, back or radicular pain, lower motor neuron weakness, sphincter incontinence and sensory abnormalities.[21] The cerebrospinal fluid examination has to be repeated two to three times with more volume of CSF (up to 10 ml) when the clinical suspicion is high to get a positive yield (Fig. 2D3) and it has to be supplemented with special stains and immunohistochemical stains. Gadolinium enhanced T1-weighted MRI complements CSF cytology in suspected leptomeningeal metastases.[23] Similarly, the tissue obtained after surgery should be subjected to special stains and immunohistochemical studies in addition to routine haematoxylin and eosin staining. The immunohistochemical panel should include pancytokeratin, leucocyte common antigen and HMB-45 and extended as per requirement.

Approach to evaluation of a patient with brain metastasis is represented in Flow chart 1.

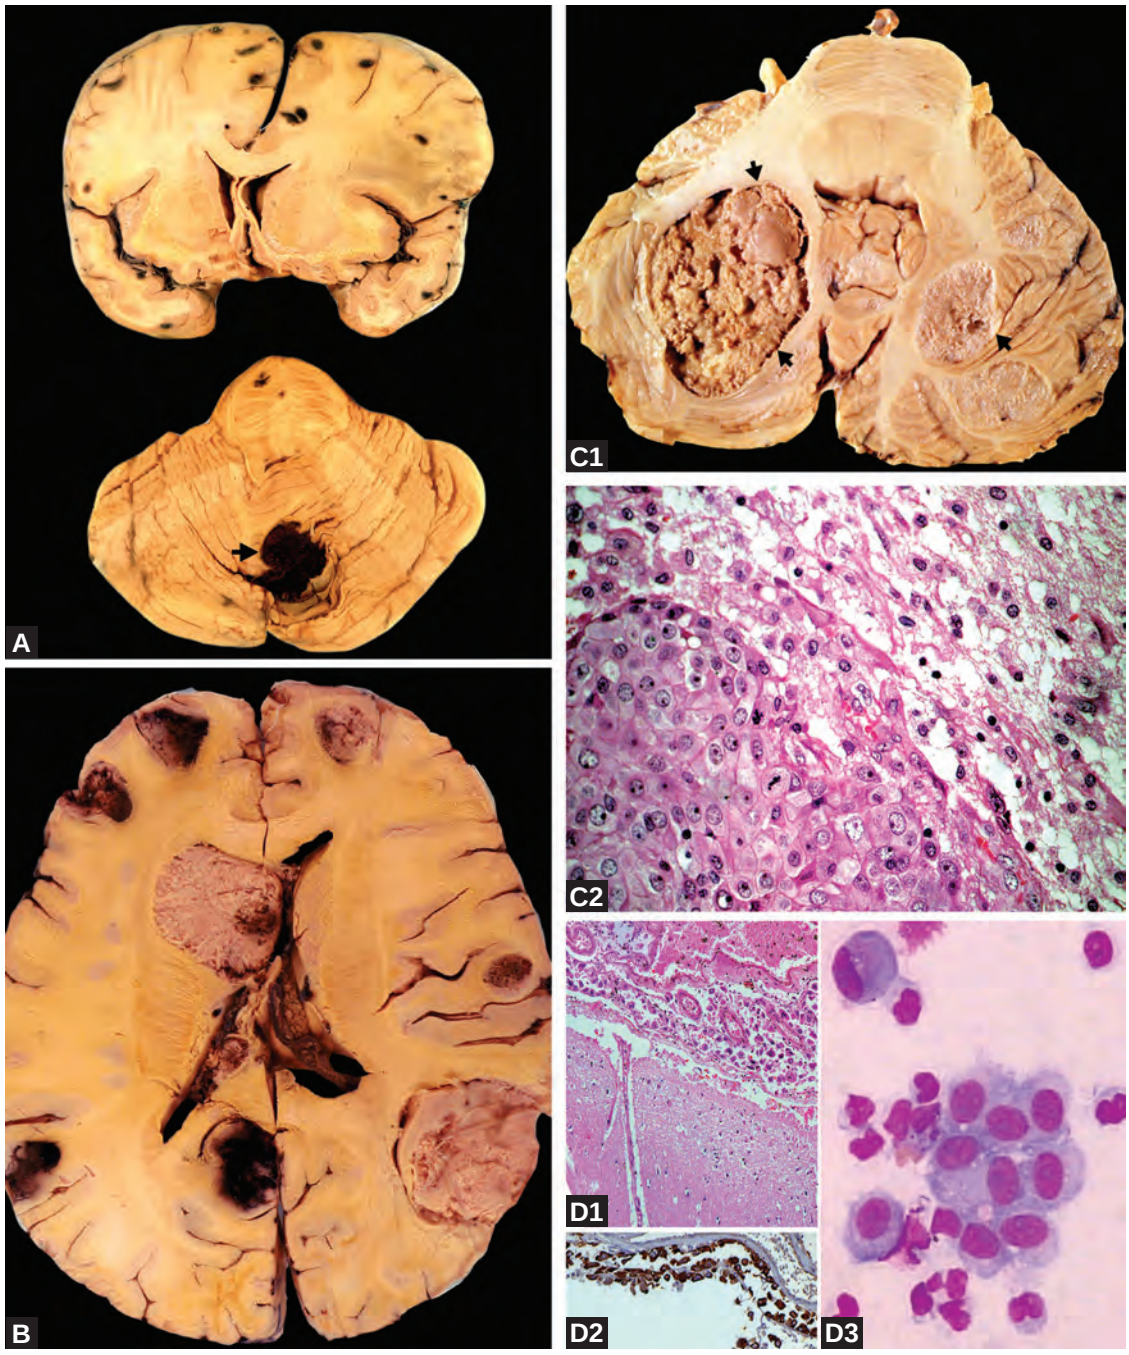
Prognostic Factors

Outcome in patients with metastatic brain disease depends on four parameters that include; age less than 60 years, unknown or controlled primary cancer, Karnofsky performance scale score greater than 70 and metastatic spread limited to the brain. Patients with all the four favourable factors had a predicted 200 day survival of 52% while the patients with none of the favourable factors had a predicted survival time of 54 days.[57] Patients with carcinoma breast, who have CNS involvement, whether occult or symptomatic, have an impaired survival.[55]

The institution of systemic chemotherapy was a positive prognostic factor in patients with subarachnoid lesions detected by neuroimaging or with extra CNS tumour deposits.[10]

Acknowledgement

The authors thank Dr. Megha S. Uppin who helped a lot for the preparation of the manuscript.



Figs 2A to D: (A) Coronal slice of brain showing multiple tiny haemorrhagic lesions in bilateral frontal and temporal lobes at grey-white junction in a case of choriocarcinoma. A large haemorrhagic lesion is also seen in the cerebellar vermis (lower panel) with small haemorrhagic lesions in pontine tegmentum. (B) Axial slice of brain showing multiple circumscribed solid lesions in bilateral frontal and parieto-occipital lobes involving the cortical ribbon and left caudate nucleus compressing ipsilateral lateral ventricle. Some of these lesions show haemorrhages. The patient was found to have bronchogenic carcinoma. (C) Horizontal slice through the brainstem and cerebellum shows large circumscribed lesions in bilateral cerebellar white matter compressing and distorting the dentate nuclei. The lesions appear tan with papillary configuration and tiny foci of cystic change on sectioning (C1). Histology shows metastatic squamous cell carcinoma in white matter (C2) (C2:HE x 320). (D) Subarachnoid space lined by malignant cells (D1) confirmed to be of epithelial origin on immunohistochemistry for cytokeratin (D2). Cytology of cerebrospinal fluid of the same patient showed tightly cohesive clusters of tumour cells with abundant basophilic cytoplasm and eccentric nuclei. Note small vacuoles in cytoplasm and cytoplasmic blebs (D3). The patient was an elderly male who presented with multiple lower cranial nerve palsies (D1:HE x 120, D2:Immunoperoxidase for cytokeratin x 200, D3:MGG x 400)

126 Cerebral Oedema in Relation to Neoplasias of Nervous System

Shankar SK

A variety of mechanical effects and circulatory disturbances can be initiated by expanding lesions of appreciable size in the cranial cavity, which include tumours (primary and secondary), abscesses, large granulomas, massive subdural or intracerebral haemorrhage and also diffuse brain swelling. These circulatory disturbances involving the cerebral vasculature, brain parenchyma and CSF pathway result from inability of the adult cranium to expand under increased intracranial pressure. The disturbances are more proportional to the rapidity of growth of the mass (e.g. intracerebral haematoma, glioblastoma, metastasis) than the size (a large extra-axial meningioma), reflecting the accommodative compliance of the brain to slowly evolving pressure changes. In normal human adults, the intracranial volume includes intracellular (1100–1300 ml), interstitial (100–150 ml), CSF (75–100 ml) and blood (75–100 ml) spaces. Exchanges of fluid amongst these compartments take place in response to osmotic and hydrostatic forces at the interphase between:

a. Intracellular and extracellular compartments (cell membranes);
b. Blood-brain barrier (BBB);
c. CSF and brain (ventricular ependyma and glia limitans at the surface of the brain) and
d. Blood and CSF (choroid plexus and arachnoid granulations).

In addition, nearly 30 ml of water in brain is produced daily from glucose metabolism.[21] As the skull in the adult is rigid, any increase in brain parenchymal volume by tumour or haemorrhages would result in replacement of fluid from the low pressure CSF (approximately 10 mmHg in man) and venous (about 10 mmHg) compartments initially followed by the high pressure arterial compartment (approximately 100 mmHg mean), as enunciated in the Monroe-Kellie doctrine.[38] The volume of cerebrum and cerebellum, the space available in the supratentorial and infratentorial cranial cavity and the ventricular size cause differential pressure gradients by occlusion of the subarachnoid space at the tentorial incisura or between the intracranial cavity and the spinal subarachnoid space following the obliteration of communication at the level of the foramen magnum. This explains why, at times, the lumbar spinal fluid pressure may be within normal limits in patients with raised intracranial pressure. Other modifying factors could be elderly age of the patient with pre-existing cerebral atrophy and infants with pliable cranial fontanelle that provide compensatory capacity for accommodating a space occupying lesion.

The reciprocal relation between the volume of the space occupying lesion and the resultant increase in intracranial pressure is particularly important in causing clinical symptoms. In the later stages of growth of mass lesions, uniform increment of volume causes an exponential increase in intracranial pressure, rendering the patient vulnerable to minor changes in intracranial pressure with serious clinical consequences.[46] These pressure changes are the consequence of distribution of intracellular, interstitial, intravascular and intraventricular fluid volume manifesting as oedema, a subject of extensive clinical and experimental research.

The physiochemical properties of water enable it to act as a solvent for electrolytes and also influence the molecular configuration and hence the function, especially the enzymes and polypeptide chains in biological systems.[21] Association of water with electrolytes determines the osmotic regulation of cell volume and transmembrane ionic gradient essential for excitation and impulse transmission in the nervous system. The normal BBB is relatively permeable to water, but considerably less to ions and principal electrolytes. Brain fluid regulation takes place within the context of systemic fluid volume control, which depends on mutual interaction of osmotic, volume and pressure regulatory receptors in the hypothalamus, heart and kidney, hormones like vasopressin, renin-angiotensin, aldosterone, atriopeptins, immunoreactive substances and their respective sites of action. The concentration of Na^+, K^+ ATPase activity and the presence of Na^+ and K^+ antiporter at the abluminal (external) surface of cerebral capillaries than in other vascular beds in the body suggest that cerebral microvessels play an active role in brain volume regulation and ion homeostasis.[38] The normal brain extracellular space (ECS) amounts to 12–19% of brain volume and is markedly reduced following anoxia, ischaemia, metabolic poisoning and spreading depression of electrical activity. The asymmetric distribution and ionic gradient of Na^+, K^+ and Ca^{++} between the intracellular space (ICS) and the ECS underlie the role of these cations in nerve excitation, conduction and signal transduction.

Under normal conditions, the extracellular compartment within the brain has two fluids—the interstitial fluid and CSF and the ECS extending from the BBB, through a series of 100–150A° wide intricate intercellular spaces, anatomically continuous with CSF spaces. Following hydrocephalus, there is hydrodynamic distension of these collecting channels due to retrograde flooding of the extracellular compartment by the CSF with formation of periventricular oedema.[45]

To understand the pathophysiology of cerebral oedema in various pathological states, it is essential to have some basic insight into the normal structural and physiological elements involved in maintaining fluid homeostasis in the brain.

BLOOD-BRAIN BARRIER

The blood-brain barrier maintains a stable environment for neurons to function effectively. It excludes many toxic substances and protects neurons from circulating neurotransmitters, like norepinephrine and glutamate, following stress response. This exclusion is mediated by specialised anatomic barrier properties of cerebral capillaries. The brain in addition is considered a relatively immunologically privileged site, thereby abrogating the immune mediated and inflammation mediated oedema in contrast to extra CNS sites.[38] Specific examples of immunomodulatory factors include:[15]

a. Transforming growth factor-β (TGF-β) present in CSF, which endows macrophages with a capacity to induce antigen-specific suppression of delayed type hypersensitivity reaction.[23]
b. Low concentration of complement in extracellular fluid of brain reduces the possibility of antibody mediated inflammatory reactions in CNS that can cause oedema.[16]
c. The highly selective membrane at the capillary endothelium has low permeability to hydrophilic compounds and has a selective carrier mediated transport system instead of passive diffusion.
d. Factors produced in this immunologically privileged site on the contrary can distribute widely in the CNS microenvironment without significant diffusional loss into the capillary plasma because of an intact barrier.

In addition, the barrier membrane may control, by selective expression of homing receptors and other mediators of transmembrane passage, the movement of lymphocytes and macrophages in and out of the CNS.[5] Dynamic gradients may be superimposed by neoplasms and inflammatory mass lesions (abscess, granulomas) altering the equilibrium in both halves of the brain by local production of cytokines and immune mediators. Such a mechanism can explain the different immune responses between the normal side and the tumour-bearing side, manifesting with focal oedema or diffuse cerebral oedema even with a small focal lesion.

Anatomy of Blood-Brain Barrier

The structural blood-brain barrier is formed by specialised brain capillary endothelial cells and the astroglial processes that ensheath more than 95% of the abluminal (external) microvessel surface. The endothelial cells in the brain microvessels have tight junctions impervious to hydrophilic compounds (but permeable to lipophilic compounds, like alcohol, addiction forming drugs like morphine and anaesthetics) and relative lack of a pinocytic vesicular transport system.[54] In capillaries of peripheral organs and in sites of brain lacking BBB (circumventricular organs), blood borne polar molecules diffuse passively across vessels through interendothelial fenestrations and by passive fluid phase or receptor mediated endocytosis. The endothelial cells of the BBB are relatively deficient in vesicular transport and the interendothelial zone is not fenestrated but interconnected by a complex array of tight junctions with a resistance of 2000 Ω/cm^2 (normal interendothelial resistance 5–10 Ω/1 cm^2) and exclude even small molecules like K^+ ions.[14] With this barrier, the vessels are impermeable to poorly lipid soluble compounds like mannitol. Anticonvulsants, like phenobarbitone and phenytoin, bind to plasma protein and thus, reduce their delivery to the brain. Glucose, L-DOPA, large neutral amino acids and vinca alkaloids are delivered by non-energy dependent selective endothelial transport and enzyme systems, thus increasing permeability to them. Glucose is transported selectively by a hexose transporter (glucose transporter isotype-1 Glut-1 located on chromosome 1) which is facilitative and saturable and stereospecific glucose is driven across the luminal and abluminal surface of the endothelium, using a higher concentration gradient in the plasma. Glycine, glutamate and neutral amino acids are transported exclusively at the abluminal side of the endothelium by an energy dependent, Na^+ ion dependent carrier system, to limit accumulation of excitatory and inhibitory neurotransmitters in the CNS.[2] Multiple drug resistance (MDR) transporter, a transmembrane protein is found in the microvessels of the BBB, which is involved in delivery of chemotherapeutic drugs like vinca alkaloids, actinomycin D and steroid hormones. MDR genes expressed at the BBB interphase protect the brain from circulating toxins. The external membrane of brain capillary endothelial cells have a high concentration of Na^+ K^+ ATPase that exchanges intracellular Na^+ with extracellular K^+ in an energy dependent manner, thus removing the extracellular K^+ in conjunction with astrocytes following neuronal depolarisation. The catecholamine, vasoactive leukotrienes and glutathione bound products are inactivated by various enzyme systems of the barrier endothelium. These features represent the 'biochemical blood-brain barrier' in addition to the 'physical barrier'. Microvessels in the posterior pituitary, area postrema, subforniceal organ, lamina terminalis, subcommisural organ, pineal gland, median eminence and neurohypophysis lack the BBB.

Interendothelial fenestrations and many pinocytic vesicles account for easy transport across these vessels. The subforniceal organ is a chemoreceptive area that monitors blood angiotensin level to regulate water balance and other homeostatic functions.

During the development of the brain, not all capillaries develop the BBB at the same time, the barrier in the spinal cord forming earlier than in the telencephalon. The evolution of the barrier property is independent of endothelial proliferation.[54] The neural analogue of the brain is vascularised by invagination of proliferating vessels from an extraneural vascular plexus in the leptomeninges. Soon after penetration into neural tissue, the interendothelial fenestrations are lost and they mature into brain capillaries with a BBB. This BBB property is induced in the microcirculation by chemical signals from the brain. These barrier properties will develop in peripheral endothelial cells that invade the brain tissue, but are lost in the brain endothelial cells that invade the peripheral extraneural tissues. Astrocyte foot processes in conjunction with cyclic adenosine monophosphate agonists, specifically increase interendothelial tight junctions and their complexity, but not the neurons and oligodendroglia. This feature has an implication in the evolution of cerebral oedema and contrast enhancement on MRI/CT imaging and consequent clinical implications of respective tumours like oligodendrogliomas and gangliogliomas. Although the capillaries in the centre of the primary tumours (e.g. GBM, oligodendrogliomas) and metastatic tumours lack BBB, those vessels at the border between the proliferating edge of the tumour and the surrounding brain retain their impermeability. To deliver chemotherapeutic agents, the BBB can be opened by hyperosmolar mannitol. This opening of the BBB by mannitol is reversible after about 4 hours, but the major disadvantage is the breach of BBB is random and disseminated,[49] thus neurotoxic drugs cause widespread damage. In view of this, to deliver drugs, local muscle grafts which are richly vascularised and yet lack BBB property in the microvessels are tried. A similar phenomenon occurs following invasion of metastatic tumours and meningiomas into the brain with significant oedema at the interphase.

CEREBROSPINAL FLUID AND HYDROCEPHALUS

The CSF communicates with brain interstitial fluid and acts as a conduit for polypeptide hormones secreted by hypothalamic neurons that act at remote sites in the brain. The pH of CSF affects both pulmonary ventilation and cerebral blood flow. Small solutes diffuse freely between the interstitial fluid and CSF in the perivascular space (Virchow-Robin spaces) and across the ependymal lining of the ventricular system, the pia glial membrane at the surface facilitating movement of metabolites from deep brain parenchyma to the cortical surface and ventricular system. The total CSF volume is approximately 140 ml (lateral and third ventricle—12 ml; spinal subarachnoid space—30 ml, brain subarachnoid space and major basal cisterns containing most of the CSF), as measured by dynamic CT studies. Every day 500 ml of CSF is formed. The choroid plexus, which is structurally similar to the distal collecting tubules of the kidney produces CSF by capillary filtration and an epithelial secretory mechanism, and maintains the chemical stability of the CSF. The capillaries traversing the choroid plexus are freely permeable, but the blood-CSF barrier exists along the apex and sides of the epithelial cells of the choroid plexus. The barrier is responsible for carrier mediated active transport. The secretory capacity of the choroid plexus epithelium is bidirectional, facilitating continuous CSF production into the ventricles and active transport of metabolites out of the CNS into the blood. Under normal conditions, the blood plasma and CSF are in osmotic equilibrium, although CSF is low in K^+, Ca^{++}, bicarbonates and glucose and is more acidic than plasma. The normal pressure of CSF is 65–195 mm water (5–15 mmHg). The formed CSF is drained by a directional movement to the subarachnoid space and into the cerebral venous sinuses by hydrostatic gradient, passing through the arachnoid granulations functioning as unidirectional valves. In view of continuity between the ventricles and the interstitial space, a limited amount is drained into brain capillaries passing through the Virchow-Robin space and to the superolateral subarachnoid space traversing the pia glial membrane. Dynamic disturbances in the formation and drainage of CSF from the ventricles lead to accumulation of the fluid causing hydrocephalus with hydrodynamic sequelae. This hydrocephalus has the following three possible causes:[6]

1. Although rare, enhanced secretion is considered to occur in some functional tumours like choroid plexus papilloma, as resection of the tumour can relieve hydrocephalus. These tumours are usually associated with high CSF protein content, thus impairing the absorption as well.
2. Impaired absorption of CSF may result from conditions that raise intracranial pressure like parasagittal meningioma compressing the veins, thrombosis of cerebral veins and cortical venous sinuses or due to tumour associated hypercoagulable states. Impaired CSF absorption causing communicating hydrocephalus occurs following subarachnoid haemorrhage and bacterial meningitis clogging the channels. Impaired CSF absorption is believed to be the cause of normal pressure hydrocephalus.
3. Obstruction to CSF pathways can result from tumours like septal and medial thalamic gliomas, subependymal giant cell astrocytomas and ependymomas obstructing the foramina of Monro. An anatomical site vulnerable for all the three mechanisms is the narrow aqueduct of Sylvius. Tectal gliomas projecting into the pathway, gliosis due to intrauterine infections and haemorrhage, fourth ventricular ependymomas, choroid plexus papillomas

and medulloblastomas cause obstruction to free flow causing ventricular dilatation proximally.

The accumulated CSF in the hydrocephalic ventricles, due to transient or continuous hydrocephalic attacks with a raised hydrostatic pressure gradient, backtracks into subventricular brain tissue by breaching the ependymal barrier and the subependymal gliotic tissue by bulk flow. The periventricular nuclear zones offer resistance to the spread as also low-grade thalamic gliomas with a glial fibre mesh work.

AQUAPORINS IN THE BRAIN

Regulation of water permeability across the microvessels, between the blood and brain was initially considered to be a simple passive diffusion or by bulk flow across a pressure gradient, lower cerebral blood pressure retarding the formation and spread of cerebral oedema. With the recognition of water channel proteins (aquaporins, AQPs) in Xenopus oocytes for the first time in 1992,[53] the AQP family of at least 11 subtypes has been identified in biological tissue. The AQP family is grouped according to their selectivity characters: water selective channels (AQP 1, 2, 4, 5 and 8), channels transporting glycerol and small solutes (AQP 3, 7, 9 and 10) and channels transporting chloride at low pH (AQP6). Each subtype has its own cellular distribution and distinct regulatory mechanism in its expression.[2,46] AQP1 is expressed in the apical surface of choroid plexus epithelium facilitating CSF formation, capillary endothelial cells throughout the body and a few microvessels in the human brain,[56] in human astrocytoma and metastatic carcinoma. In the spinal cord AQP1 is involved in water recycling and neural signal transduction for pain. AQP4 is the predominant type in the brain, expressed abundantly in perivascular glial processes and ependymal cells, but absent in neurons, oligodendroglia and microglia. AQP4 is expressed also in the abluminal and luminal aspects of microvessel endothelial cells. This protein is anchored by α-syntrophin (an adapter molecule associated with dystrophin) and this interaction is essential for localisation of AQP4 on the foot processes of astrocytes in contact with the vessel for fluid transport. Water transport via AQP4 is essential for normal neural activity. These glial water channels may modulate brain excitability and the initiation and generalisation of seizure activity. In the hypothalamus, the astrocytes express AQP4 and have an osmoregulatory role.[4,48,69]

AQP9 is expressed in the ependymal lining of the ventricle and tanycytes of the mediobasal hypothalamus and less, so in astrocytes and endothelial cells, suggesting a role in extrachoroidal production and resorption of CSF.[18,68]

Upregulation of AQP4 is observed in the oedematous zones of cerebral contusion, bacterial meningitis, glioblastoma and reactive astrocytes around metastatic tumours.[51] Similar enhancement of AQP1 and AQP9 are also noted along the margin of a tumour and decrease in the centre.[3,31,36,37] After focal transient ischaemia, AQP9 expression is increased on AQPs in peri-infarct areas. These observations suggest that AQPs play a role in regulation of post-ischaemic oedema, clearance of lactate from the ischaemic tissue and water transport in tumours.[36] The AQP function in brain microvessels is regulated by the adrenergic innervation of microvessels.[36] It is recently found that AQP1 and AQP4 are also present in brain microvessel endothelial cells. Experimental studies indicate enhanced AQP4 expression following hyponatraemia, around the site of infarcts and after mannitol administration. Similarly, AQP1 expression is increased by dexamethasone in vascular endothelial cells, while testosterone upregulated AQP4 expression.[36,50] AQP4 inhibitors reduce cytotoxic oedema only, if administered early to slow down the entry of oedema fluid into the brain parenchyma but once formed or, at the resolution phase, there is no role. On the other hand AQP4 upregulation facilitates clearance of oedema, providing a low resistance transcellular route for oedema fluid to move out.

CEREBRAL OEDEMA

Cellular and hydrodynamic physiology and hydro-oncotic changes due to electrolyte and protein build-up occurring within the cells and in the ECS leads to obligatory movement of water and water logging, manifesting as oedema.[29,45]

Cytotoxic Oedema

This is the result of deranged cellular metabolism resulting in inadequate functioning of the Na^+ and K^+ pumps in the glial cell membrane. As a consequence, Na^+ and water are retained in the astrocytes. These swollen astrocytes accumulate in grey and white matter, secondarily affecting neuronal and oligodendroglial function and intracellular fluid homeostasis. Cytotoxic oedema is noted with various intoxications (dinitrophenol, triethyltin, hexachlorophene, isoniazide), Reye's syndrome and ischaemia. In this form of cerebral oedema, the BBB is intact still (intact barrier oedema). This needs to be distinguished from focal cytotoxic injuries or abnormal accumulation of metabolic substances (as they cannot be cleared) due to enzyme defects (inborn errors of metabolism).

Hydro-oncotic changes due to electrolyte and protein build-up accruing within the cells and in the ECS leads to obligatory movement of water and water logging. The cellular oedema occurs (cytotoxic brain oedema) through intracellular hyperosmolarity and extracellular hypotonicity and a deranged ATP dependent Na^+/K^+ pump at the cell surface.

Vasogenic Oedema

Disruption of the cerebral capillary barrier (BBB) mechanism by structural and functional alterations of the

cerebral capillary endothelium and astrocyte foot process forms the underlying mechanism for vasogenic oedema. This form of oedema is found in response to trauma, tumours, focal inflammation and the later stages of cerebral ischaemia. The amount of oedema is greater in the white matter than grey matter, with a widened ECS, accumulation of water and Na^+ and decreased K^+ and swollen astrocyte foot processes reflecting initial glial cytotoxicity (closed barrier progressing to open barrier oedema). The interendothelial fenestrations are widened and transendothelial vesicle trafficking is enhanced. Most of the time, combined cytotoxic and vasogenic oedema manifest, one progressing to the other or they can manifest together from the onset, based on pathophysiological events.

Hydrostatic Oedema

Vasogenic oedema has to be differentiated from two other types of brain bulk enlargement like vascular swelling caused by vascular dilatation and venous obstruction. Brain oedema can be the first event in the initial stages of intracranial hypertension. Following acute and transient systemic hypertension beyond 160 mmHg, the 'BBB' and 'blood-CSF' barriers are opened transiently due to hydrostatic pressure and transudation occurs through interendothelial fenestrations and transendothelial fluid trafficking occurs through vesicles. At this stage, initially, there is no significant change in Na^+ and K^+ content of the brain, CSF and muscle with no measurable cerebral oedema, but with progression, the tendency is enhanced. Following venous compression and stasis proximal to the compression, the water with plasma proteins move out as a transudate by hydrostatic pressure through veins and venules which are devoid of a barrier. Later, the extracellular protein accumulation causes an osmotic gradient, drawing the fluid out of the vessels.

Red blood lysis contributes to brain oedema formation after intracerebral haemorrhage. RBC haemolysate (oxyhaemoglobin) has been found to be spasminogen in subarachnoid haemorrhage. Lysed RBCs alter the blood-brain barrier more than packed RBC's in a haematoma. These effects are evident 72 hours after the event.[71]

The cellular mechanisms related to high altitude (mountain sickness) oedema is not clear. Nitric oxide (NO) induced vasodilatation and altered cerebral circulation as a response to hypobaric oxygen status is considered to cause cerebral oedema.[17,71]

Osmotic Oedema

The usually marginally higher osmolality of the CSF and extracellular fluid as compared to plasma is reduced by an abnormal hypo-osmolar oncotic gradient created in the circulation following SIADH, water intoxication and haemodialysis. As a consequence water flows into the ECS causing cerebral oedema. In this form, the BBB is relatively intact. In the dynamics of events this form resembles oedema due to venous stasis.

The extracellular brain oedema (interstitial) appears as a result of build-up of oedema fluid in the ECS and can be due to hydrostatic extracellular brain oedema (through enhanced ultrafiltration and formation of CSF), oncotical (osmotic) extracellular brain oedema (vasogenic oedema) and hydrocephalic extracellular brain oedema. Most of the times, combined brain oedema manifests, one progressing to the other or they can manifest together from the onset based on pathophysiological events.

Hydrocephalic Extracellular Oedema

This form of oedema is essentially paraventricular, following a breach in the ependymal barrier leading to backflow of CSF into the brain parenchyma. Subependymal gliosis and the nuclear areas around the ventricle resist this movement of fluid. The hydrostatic fluid accumulation in the ventricles could be due to the rare enhanced production of CSF by ultrafiltration by choroid plexus, or continuous and longstanding stasis due to defective drainage at different levels. In this form of oedema the BBB is intact till the late stages. The oedema is essentially due to hydrostatic pressure and without a significant oncotic gradient. The precise mechanism underlying such oedema-induced neuronal dysfunction is not clear. It is suggested that interstitial brain oedema impairs oxidative metabolism even at the early stage of hydrocephalus and there is a shift to anaerobic glycolysis in spite of normal cerebral blood flow.[35]

Brain Oedema Following Trauma

Brain oedema leading to expansion of brain volume has a critical impact on morbidity and mortality following traumatic brain injury (TBI). Two major types of traumatic brain oedema exist; vasogenic due to a breach in the blood-brain barrier and fluid accumulation in the interstitial space and, cytotoxic oedema due to sustained intracellular water accumulation. Following TBI, various kinins and mediators of inflammation are released, which enhance vasogenic and cytotoxic oedema. In addition, osmotic brain oedema is caused by extravasation of plasma products and thus, a local imbalance in blood and tissue products and hydrocephalic oedema occur due to obstruction of CSF outflow. Cytotoxic oedema is of decisive pathophysiological importance following TBI as it develops early and persists, while the BBB is gradually restored, reducing vasogenic oedema. Avoiding cerebral anaerobic metabolism and acidosis is beneficial to control lactate and H^+ ion. No definite compound inhibiting the mediators and ion channels showed beneficial results in clinical trials despite successful experimental studies. In therapy, both cytotoxic and vasogenic oedema need to be managed simultaneously in traumatic brain injury. This assumes greater importance when TBI compounds a pre-existing brain tumour/mass lesion in clinical practice.[67]

BRAIN TUMOURS AND OEDEMA

Oedema associated with a brain tumour often exceeds the mass effect induced by the tumour itself resulting in raised intracranial pressure, destruction of tissue homeostasis and neurological disturbances.[66] All aggressive brain tumours, like malignant gliomas, metastatic tumours and many benign tumours, like meningiomas, produce oedema regardless of the cell of origin. The lethal effect of tumour-associated oedema is illustrated by the nearly ten-fold reduction in brain tumour mortality following reduction of oedema by steroid therapy.[32] Vasogenic oedema is the archetypical example with brain tumours, produced by fluid flow into the ECS of the brain parenchyma through an incompetent BBB. All focal lesions, including primary and metastatic tumours, abscesses, encephalitides and radionecrosis produce cerebral oedema. Brain swelling associated with long-term therapy of tumours remains to be an important issue in cases of recurrent tumours and lesions treated by radio/chemotherapy and radiosurgery rather than resection. In contrast to perilesional oedema and reactive astrocytosis associated with meningiomas and metastatic tumours, oedema around high-grade gliomas is characterised by extensive infiltration by tumour cells, thus distinguishable by histological and clinical properties.

a. Metastatic and non-glial tumours produce angiogenic factors, promoting new capillary formation with significant ultra structural abnormalities like more frequent pinocytic vesicles in the endothelial cells, and an irregular basal lamina.

   In human glial tumours, the endothelial junctions are either short or elongated. The endothelial cells display hyperplasia, irregular basal lamina and a large extravascular space.[57]

   In malignant gliomas, the endothelial cells have defective tight junctions, fenestrations, increased pinocytic vesicles and incomplete ensheathment by the basal lamina.

   These structural abnormalities explain a defective or lost barrier function facilitating exudation of plasma into the surrounding brain.

b. The morphologically disrupted tight junctions in the newly formed vessels in malignant gliomas are associated with paucity or lack of occluding[26] claudins[19] and junctional adhesion molecules.[42] These transjunctional proteins, through ZO-1 and ZO-2 bind to cytoskeletal proteins in endothelial cells. The decreased expression or function of these proteins results in opening of interendothelial junctions and initiation of oedema, and this feature is found in high-grade gliomas (Grade III–IV).[39]

c. VEGF, a cytokine, has a mitogenic and chemotactic action on the endothelial cells facilitating angiogenesis and also enhances the permeability of the endothelium, which is more potent than histamine.[12] VEGF exerts its effect on venules and capillaries, but not on smooth muscle cells or fibroblasts of vessels. VEGF impairs the function of occludin and thus opens the tight junctions and enhances fenestration of the endothelium. Upregulation of VEGF is found in gliomas, meningiomas and metastatic tumours.[52] In meningiomas (WHO Grade I) the upregulation of VEGF is mediated by platelet derived growth factor (PDGF), epidermal growth factor (EGF) and oestrogens.[41,43,60] Transitional, meningotheliomatous and secretory meningiomas are associated with oedema.[20] The peritumoural brain oedema in cases of meningiomas is found to be related to pial blood supply following a breach in the arachnoid and adherence to the brain.[10] Secretory meningiomas and anaplastic meningiomas are frequently found to be associated with extensive pial blood supply, while fibrous and psammomatous meningiomas, either in the cranium or spinal canal are rarely fed by pial blood vessels and produce mild oedema. In terms of pathophysiology, small tumours with significant oedema and large tumours with minimal oedema appear to correlate with the amount of pial blood supply from the superficial cortex. This suggests that the cerebral microvasculature on penetration into an extracerebral meningioma looses inherent barrier properties and behaves like the leaky extracerebral vessels. The secretion of VEGF by the meningeal tumour cells could facilitate angiogenesis from the pial microvessels and their entry into the meningioma.[44]

   By serial analysis of gene expression (SAGE) in microvascular endothelial cells derived from human brain tumour specimens Carson-Walter et al.[11] found five unique markers confined to the tumour microvasculature. One of these genes, plasmalemmal vesicle associated protein-1 (PV-1) was identified in the transendothelial channels in the fenestrated endothelium. This protein is selectively induced in high-grade gliomas and in hypoxic conditions like stroke causing disruption of the BBB, but not in the normal brain with an intact BBB. In view of its location on the cell membrane and selective expression in tumour endothelium along with angiogenesis, PV-1 inhibition by molecular targeting (RNAi) is a therapeutic modality that is being explored in the treatment of gliomas.[11]

d. Microglia rich brain tumours, especially gliomas, are associated with peritumoural oedema, via arachidonic acid, prostaglandin E2, lipoxygenase derived biologically active metabolites and cox-2 produced by these activated cells.[7,62] Induction of nitric oxide synthase (NOS) following anoxia and the modulating role of NO in vasodilatation, peritumoural oedema and angiogenesis have been found more commonly with metastatic tumours than primary brain tumours. Serotonin, thromboxanes and platelet activating factors are the other vasogenic substances involved in the pathophysiology of tumour associated oedema, especially with a coexisting cerebral infarct adjacent to a tumour and associated macrophage response.[27,58]

e. The spread of vasogenic oedema fluid by hydrodynamic bulk flow is determined by anatomic barriers like the nuclear areas and long fibre tracts which can be splayed apart. In the white matter, because of low resistance, even a small pressure gradient can result in spread of oedema in finger like projections similar to a phenomenon observed following cortical venous thrombosis and resultant white matter oedema. This formation of oedema and its spread by bulk flow is more common in metastatic tumours, which lack a blood-brain barrier. Diffusion tensor imaging by MRI has provided an insight into this pathophysiology, but also opened a new avenue of convection enhanced (bulk flow of fluid against gradient) drug delivery as a therapeutic modality.[22]

Malignant thalamic gliomas with perilesional oedema use the ventricular surface to drain off the fluid by bulk flow, depending on cell density and intercellular spaces below the ependyma.

As a consequence of hydrocephalus and raised CSF pressure, spontaneous but intermittent cerebrospinal rhinorrhoea is seen in some cases. Spontaneous ventriculostomy-perforation of the ventricular wall at a point where it is thin like the lamina terminalis, median eminence, peripheral white matter, between the fornix and forceps major, is nature's diversion route to reduce ventricular hydrostatic pressure. Cisternography reveals alterations in the flow dynamics of CSF. Now CT and MRI can offer similar information. In normal individuals technetium labelled albumin injected into the lumbar subarachnoid space can be traced by a gamma camera up to the cortical convexities and the CSF may reflux into the ventricles only, if the pressure dynamics are altered.

The volume of cerebral oedema, especially peritumoural, is dependent not only on the rate of production but also the resorption of fluid away from the lesion via the channels in the interstitial space which drain into the ventricles and to a smaller extent into the subarachnoid space. The resorption of extravasated proteins by the reactive astrocytes in the white matter reduces the oncotic pressure and facilitates the resorption of oedema. The local venules and capillaries also participate in resorption of oedema. Dexamethasone has been found to act at the endothelial level by retarding oedema formation than by enhancing resorption.[30] The extracellular oedema distribution volume and capillary permeability rate constant are found to be higher in meningiomas than gliomas and metastatic tumours.[5] Dynamic perfusion weighted MR studies revealed lower regional cerebral blood flow volume and lower blood flow rate in zones of peritumoural oedema, which is modulated by dexamethasone.[8] Another interesting observation on analysing apparent water diffusion (ADC) and directionality of water movement (anisotropy) by Diffusion Tensor (DT) MR imaging is the greater apparent water diffusion and less restriction of anisotropic movement in high-grade gliomas. This suggests destruction of the extracellular matrix by invading tumour cells. Correlative studies between MR imaging and histopathological features have revealed greater concordance between T2 signal abnormality and fractional anisotropy by DT imaging with oedema propagation and tumour infiltration. This understanding of oedema fluid flow dynamics and tumour cell spread is of great interest not only to optimise oedema treatment but also to facilitate drug delivery and brain tumour therapy.[47]

Dexamethasone not only reduces VEGF expression but also interferes with the effect of VEGF on capillary endothelial cells, acting through a glucocorticoid receptor.[24,40] As thrombin, a protein involved in the coagulation cascade is implicated in angiogenesis, cell proliferation and oedema formation, thrombin antagonists, like argatroban, have been found to be useful in reducing oedema and the occurrence of tumour related neurological deficits.[28]

In view of oedema induction by the macrophage system in the brain through the cox-2 pathway, selective cox-2 inhibitor like Rofecoxib have been tried and found to be as effective as dexamethasone in experimental studies. Rofecoxib acts by reducing the production of VEGF.[70] To treat brain tumour related oedema and reduce dependency on corticosteroids, the phytotherapeutic agent, 'Boswellic acid' has been tried in Europe and found effective in inhibiting oedema formation and even growth of malignant gliomas.[61] In a physiological approach to control *in vivo* corticosteroid release, attention has been directed towards corticotropin releasing factors (CRF) and they have been found to be useful in reducing BBB permeability in patients with brain metastasis and in experimental models with gliomas.[64] To control both glioma growth and associated cerebral oedema through the VEGF pathway, the anti-angiogenic drug, Semaxanib (selective inhibitor of tyrosine kinase activity of VEGFR, Flk-1), has been tried and found efficacious in rats with gliosarcoma and nude mice bearing human GBM xenografts.[63] Pan VEGFR inhibitor (via tyrosine kinase inhibitor), AZD2171, has been found to alleviate oedema in patients with GBM.[9] As the oedema fluid clearance in the brain requires passage through aquaporin-4, modulation for enhanced expression provides a novel therapeutic option.[36]

SECONDARY EFFECTS OF CEREBRAL OEDEMA-RAISED INTRACRANIAL PRESSURE

Papilloedema

This is caused by compression of the central retinal vein as it traverses the subarachnoid space of the optic nerve sheath. The compression results in fluid exudation from the engorged veins and capillaries. The fluid accumulation is minimal in the optic nerve as the enhanced venous pressure is countered by the transmitted increased intracranial pressure around the nerve and the fluid accumulation is maximal in the unsupported

disc zone. Reduced blood flow in the region of the disc and lamina cribrosa further contribute to axonal swelling interfering with rapid axonal flow and increasing swelling.[44,65]

Intracranial Herniations

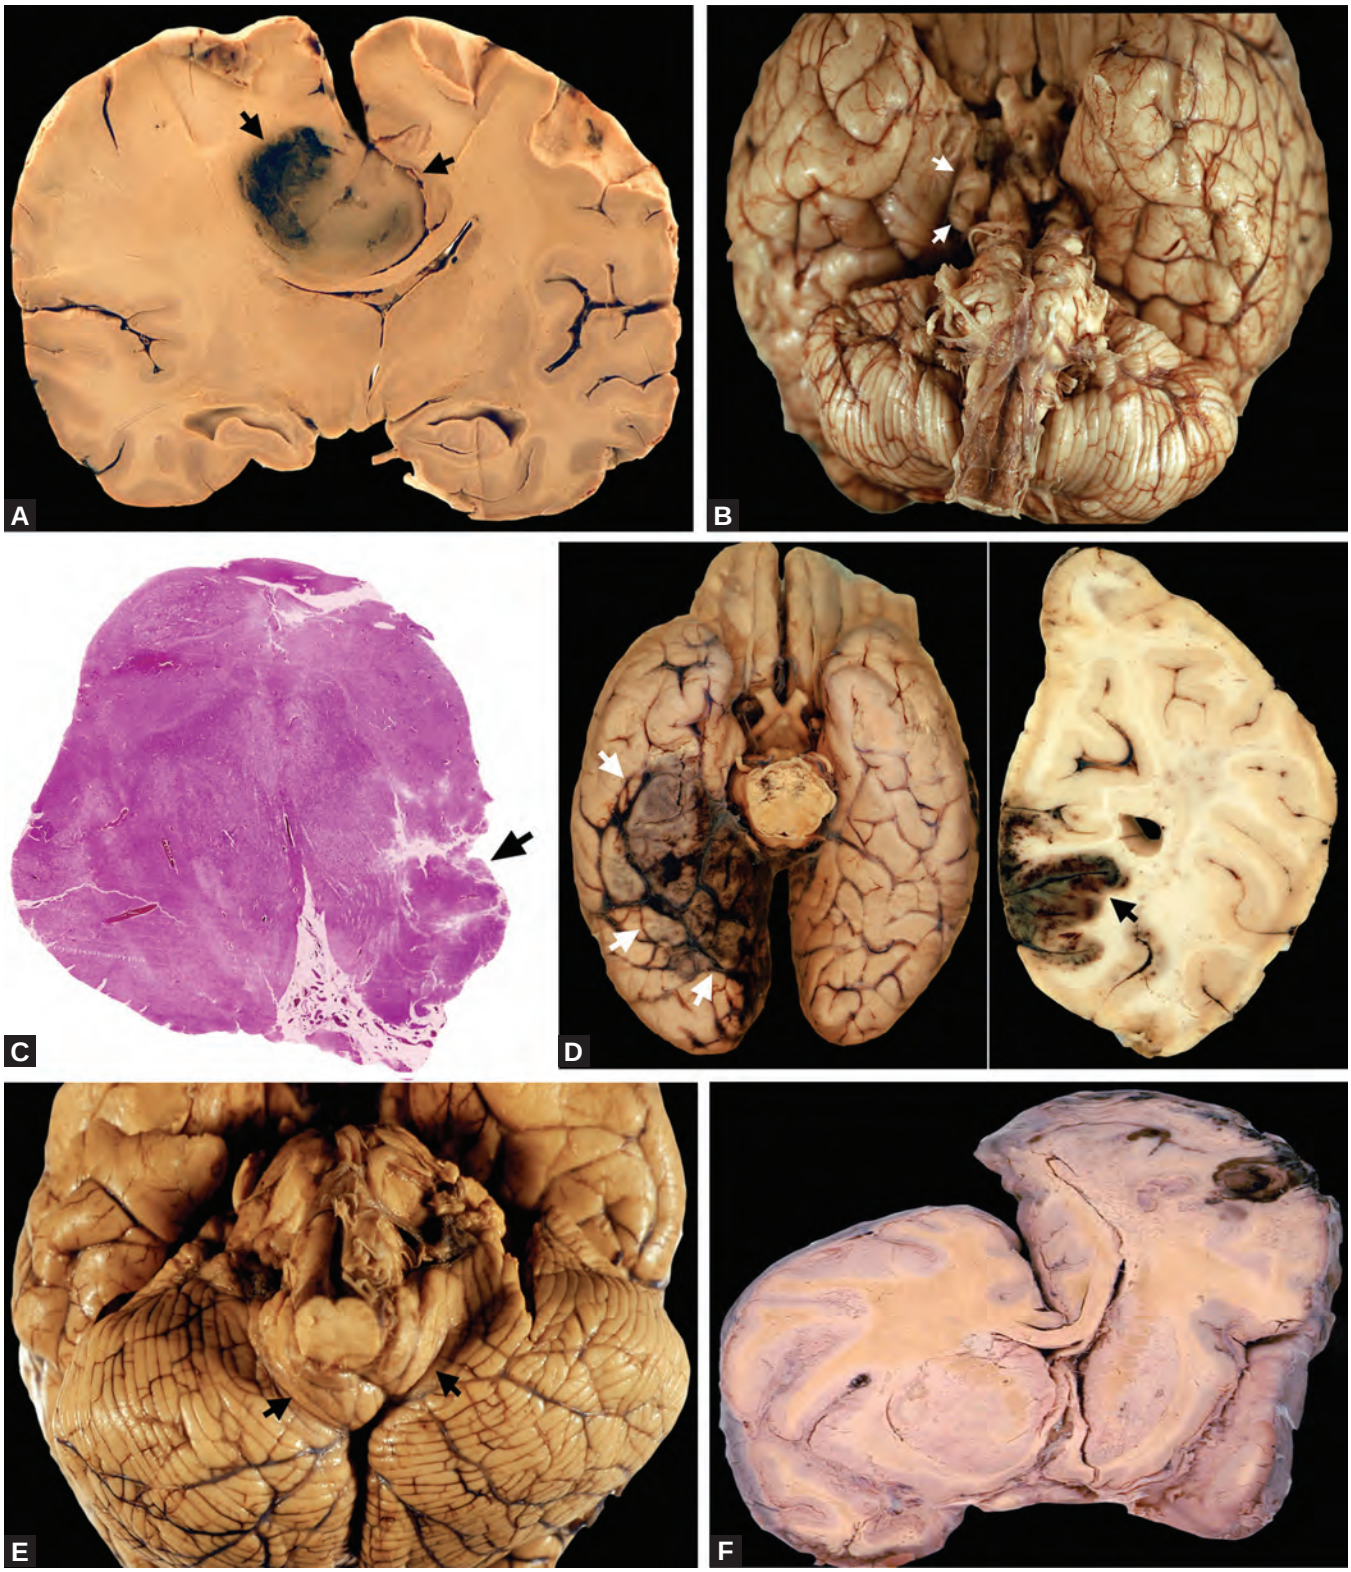
Laterally placed tumours in frontoparietal areas result in depression of the corpus callosum on the same side and herniation of the supracallosal gyrus beneath the free edge of the falx resulting in indentation along the medical surface of the cingulate gyrus (Fig. 1A). It may compress the branches of the anterior cerebral artery resulting in infarction.[59] With downwards displacement of the brain, the lesser wing of the sphenoid causes grooving on the inferior surfaces of the orbitofrontal lobes.

Raised intracranial pressure due to supratentorial tumours either in the midline or laterally placed, causes downwards displacement of the brain, impacting the uncus and parahippocampal gyrus through the tentorial hiatus (Fig. 1B). The characteristic early sign is the wedge shaped pressure necrosis in one or both parahippocampal gyri and in severe cases haemorrhagic necrosis occurs.[1] Rapidly growing temporal gliomas usually result in ipsilateral uncal herniation. More centrally located tumours cause bilateral herniation, compressing and deforming the mid-brain and aqueduct. Lateral displacement of the brain following unilateral herniation pushes the cerebral peduncle against the rigid free edge of the tentorium leaving a groove referred to as Kernohan's notch (Fig. 1C). Rarely, there may be bilateral lesions of this kind on the crura suggesting torsion and swelling of the brainstem. Obliteration of the lumen of the aqueduct by the herniation can result in raised intraventricular pressure supratentorially, but not transmitted to the spinal subarachnoid space, recording a normal spinal pressure paradoxically.[34] Decompression of the supratentorial tumour and lowering the pressure in the cranial cavity may cause caudal displacement of the brainstem either along the midline or laterally, thus stretching the paramedian or long circumferential perforators and causing their rupture or avulsion and pontine tegmental haemorrhages. The tentorial hiatus is of variable size in individuals, the tentorium enveloping the brainstem more tightly in some than in others and thus determining the form and degree of tentorial herniation and the related clinical features.[13] Kinking of the posterior cerebral artery along the tentorial free edge can cause necrosis of the medial occipital cortex, especially the calcarine cortex, with punctate haemorrhages. The venous component is usually associated with it to cause conspicuous congestion (Fig. 1D). Similarly, caudal displacement of the brainstem and kinking of the posterior cerebral artery can cause secondary compression of the ipsilateral oculomotor nerve. Following unilateral hippocampal herniation and concomitant lateral pressure on the tegmental part of the midbrain may cause circulatory disturbances in the third cranial nerve nuclei leading to 'paralysis like loss of upwards movement' of the eyes and pupillary asymmetry.[33] With cerebellar tumours, the roots of the sixth cranial nerve may get compressed against the anterior inferior cerebellar artery, causing sixth nerve paresis. Lateral displacement of the cerebrum may cause circulatory disturbances in the stalk of the pituitary with secondary hormonal disturbances.[33] Similarly, caudal displacement of the brainstem and the drag may cause bruising of the pituitary stalk against the dorsum sellae or avulsion.

Expanding lesions in the posterior fossa may cause upwards herniation of the cerebellar vermis through the tentorial hiatus and cause compression of the superior cerebellar arteries leading to ischaemic infarction. Similarly, a downwards thrust can cause compaction of the cerebellar tonsils into the foramen magnum with grooving and necrosis of the tonsils (Fig. 1E). Severe tonsillar herniation, especially sudden, can cause compaction of the medulla with fatal consequences, while a mild degree of cerebellar tonsillar herniation may not be of any clinical consequence.

The surgical opening in the vault of the skull provides an outlet for the oedematous brain to fungate out with necrosis due to compression of meningeal vessels along the edge of the bone. This is usually seen in herniation of the cerebrum through a burr hole or craniotomy wound in cases of glioblastoma (Fig. 1F). The herniated parenchyma is usually necrotic and haemorrhagic. Persistent intracranial pressure can cause erosion of posterior clinoid processes and enlargement of the sella and thinning along the lesser wing of the sphenoid and orbital plates. Ionising radiation and chemotherapy to brain tumours and haemopoietic malignancies cause damage to the vessel walls. The brain tissue contiguous to the neoplasm is more vulnerable to radiation injury than the normal CNS. The fibrinoid necrosis of the vessel walls and resultant exudation of the protein rich serum into the necrosed brain results in oncotic brain oedema. In addition, enhanced vascular permeability and an impaired blood-brain barrier causes exudation of fibrin into the white matter followed by oedema and demyelination.[55] Primary injury to the brain vasculature with an early effect on cerebrovascular endothelium is an important cause of oedema following radio/chemotherapy and radionecrosis, manifesting with a mass effect. Variable degree of fibrillary gliosis in the white matter in children treated for acute lymphoblastic leukaemia is considered to be secondary to reversible cerebral oedema.[25] In the areas of demyelination following radiation, the BBB is relatively intact in contrast to vasogenic oedema. Although radionecrosis and chemotherapy related necrosis do not elicit significant inflammation during the healing phase, intense microglial response may cause cytokine mediated oedema, which is usually steroid responsive.

Brain tumour oedema and the associated structural changes in the surrounding brain are a complex event and multifactorial. It is the result of imbalance between



Figs 1A to F: (A) Coronal slice of the brain at level of mamillary body showing a transfalcine herniation (arrows) caused by malignant glioma of the cingulate gyrus. (B) Uncal herniation on right side (arrows) caused by a supratentorial mass lesion displacing the brain downwards and laterally. Note the torsion of the brainstem as well. (C) Whole mount preparation of the brainstem of the pontomesencephalic junction showing destruction of the crus due to compression against the tentorial free margin (arrow)—Kernohan's notch. Note linear haemorrhages on the opposite side (LFB x 8). (D) Unilateral large calcarine infarct on the right side (arrows) and infarction of the basis pontis following unilateral downwards displacement of the brain and compression of right posterior cerebral artery against the tentorial free margin. A close-up view of coronal slice shows haemorrhagic infarction of the calcarine cortex extending to the adjacent gyri. (E) Marked bilateral tonsillar herniation with a groove caused by impaction against foramen magnum (arrows) compressing the medulla oblongata. (F) Upwards herniation of the frontal cortex with malignant glioma through craniotomy opening. Note the distortion of the ipsilateral ventricle and the corpus callosum

water moving in and out of the brain. Molecular abnormalities of tumour endothelial tight junctions enhancing blood-brain barrier permeability and identification of water channels, the AQPs and their molecular diversity have enhanced our understanding of pathophysiology. Many dynamic events are yet to be understood in order to optimise the therapeutic approach at the bedside.

127 Tumour Markers in Tumours of Nervous System

Chitra Sarkar, Vaishali Suri, MC Sharma

A tumour marker is defined as "any substance that makes possible either a qualitative diagnosis of neoplasia or a quantitative estimate of tumour burden".[7,39] Hence, a tumour marker is also broadly defined as any cell product related to any event during tumour formation and/or growth such as malignant transformation, proliferation, differentiation/cell lineage and metastasis.[62]

USES OF TUMOUR MARKERS

The following are the uses of tumour markers:[7,39,62]

a. Diagnosis: Improves diagnostic capability
b. Characterisation of tumour in terms of cell lineage/degree of differentiation and maturation
c. Evaluation of treatment response:
   - Success of surgery—complete/incomplete surgical resection of the tumour
   - Effectiveness of chemotherapeutic drug
   - Guide for selection of most effective drug for each case
d. Assessment of aggressiveness of tumour:
   - Helps selection of treatment strategies
   - Helps prediction of prognosis/outcome
e. Detection of primary tumour metastasising to nervous system
f. Detection of recurrence of neoplastic lesion
g. A tool for screening asymptomatic population—for early detection of malignant disease.

CHOICE OF TUMOUR MARKERS

The most important criteria for the selection and use of tumour markers are their high sensitivity and specificity to identify the neoplastic nature, cell of origin and molecular fingerprint of neoplasia.[7,62] Otherwise, given the low prevalence of brain tumours in the general population, the marker would have very little predictive value.

CLASSIFICATION OF TUMOUR MARKERS

- Markers detected in Serum/CSF as a screening modality
- Markers detected in cells/tissues (immunohistochemical markers) to identify tumour cell lineage (Table 1)
- Molecular markers.

Table 1: Immunohistochemical markers for identifying cell lineage in CNS tumours

Glial tumours	• Glial Fibrillary Acidic Protein (GFAP)
	• S-100 protein
Neuronal tumours	• Synaptophysin
	• Neurofilament
	• Beta-tubulin
	• Microtubule associated protein (MAP 2)
	• Neuron specific enolase (NSE)
	• Alpha-internexin
	• Peripherin
	• GFAP +/- (aberrant expression)
Choroid plexus tumours	• Cytokeratin
	• S-100
	• Transthyretin
	• GFAP (20%)
Meningeal tumours	• Epithelial membrane antigen (EMA)
	• Vimentin
	• S-100
	• Cytokeratin
Schwann cell tumours	• S-100
	• Leu 7
Melanocytic tumours	• S-100
	• HMB 45
	• Meland D
Lymphomas	• Leucocyte common antigen (LCA)
	• B and T Cell
	• B (CD-20) and T cell (CD 3)
Germ cell tumours	• Alpha foetoprotein (AFP)
	• Human chorionic gonadotropin (HCG)
	• Placental alkaline phosphatase (PLAP)
	• Human placental lactogen
Tumours of vascular origin	• Factor VIII
	• CD 34 (also stem cell)
	• VEGF
	• Ulex Europeus
Neuroendocrine tumours	• Synpatophysin
	• Chromogranin
	• NSE
Stem cell	• Nestin, CD-133

USE OF TUMOUR MARKERS DETECTED IN SERUM/CSF

Oncofoetal Proteins

The only group of CNS tumours wherein detection of tumour markers in serum/CSF is useful at present is the germ cell tumours[1,7,62] (Table 2). Detection of tumour markers, such as AFP, HCG, PLAP, CEA and HPL, in the serum/CSF is more reliable and sensitive for diagnosis than CSF cytology. Further, in this group of tumours, markers help to monitor response to therapy and to identify early tumour recurrence.

The only drawback is that the absence of tumour markers in serum/CSF does not exclude a diagnosis of germ cell tumours.

TUMOUR MARKERS IN CELLS/TISSUES (IMMUNOHISTOCHEMICAL MARKERS)

Diagnostic neuropathology has benefited immensely in the last two decades with the advent of immunohistochemistry on tissue sections.[14,35,40,61] The development of reagents to identify epitopes associated with cell lineage, cell cycle, cell activation, oncogene and tumour suppressor gene products have helped to clarify the nature of cellular maturation, tissue differentiation, tumour progression and metastasis. All this has resulted not only in improving diagnostic accuracy, but also in clarifying developmental pathways within and between cell lineages involved. It has also lead to revision of tumour classification, prognostication and prediction of clinical outcome.

Use of Oncofoetal Markers[5,8]

The use of oncofoetal markers is chiefly for the diagnosis of intracranial germ cell tumours, both primary and metastatic. The various immunohistochemical markers for the diagnosis of germ cell tumours are enumerated in Table 3.

Types of Tumour Markers in Cells/Tissues[15,16,34,36]

Tumour Markers for Diagnostic Use

1. Cell lineage/differentiation markers:
   a. Structural/cytoskeletal proteins, cytokeratin, glial fibrillary acidic protein (GFAP), neurofilament, desmin, vimentin, nestin, actin, tubulin, microtubule associated proteins (MAPs)
   b. Cell surface antigens: Lymphoid markers—leucocyte common antigen (LCA), T cell markers (CD3), B cell markers (CD20)
   c. Secretory products: hormones, Immunoglobulins
   d. Neuroendocrine markers: Synaptophysin, chromogranin, neuron specific enolase (NSE).
2. Oncofoetal markers
   – Alpha foetoprotein (AFP)
   – Placental alkaline phosphatase (PLAP)
   – Human chorionic gonadotropin (HCG)
   – Carcinoembryonic antigen (CEA)
   – Human placental lactogen (HPL)
3. Miscellaneous
   – S-100, epithelial membrane antigen (EMA)

Tumour Markers Useful for Prognostic Evaluation

1. Cell cycle/proliferation markers
2. Oncogene/tumour suppressor gene proteins
3. Growth factors/receptors
4. Hormones/receptors
5. Adhesion molecules
6. Angiogenic factors

Table 2: Immunoreactivity of some common CNS tumours

Tumour	*GFAP*	*S-100*	*Synaptophysin*	*NFP*	*EMA*	*CK*
Astro/Oligo/Ependymal	+	+	-	-	-	-
Neurocytoma	+/-	-	+	+	-	-
Neuroblastoma/medulloblastoma	+/-	+/-	+	+/-	-	-
Ganglioglioma	+	+	+	+	-	-
Choroid plexus	+/-	+	-	-	+/-	+/-
Meningioma	-	+/-	-	-	+	+/-
Schwannoma	+/-	+	-	-	+/-	-
Metastatic carcinoma	-	+/-	-	-	+	+

Table 3: Immunohistochemical markers of germ cell tumors

Diagnosis	*PLAP*	*AFP*	*β-HCG*	*HPL*	*CK*
Germinoma	+	-	+/-	-	10%
Teratoma	+	+/-	-	-	+/-
Embryonal carcinoma	+	-	-	-	+
Yolk Sac tumor	+/-	+	-	-	+
Choriocarcinoma	+/-	-	+	+	+

Cell Proliferation Markers

Various stages of cell proliferation in neoplastic cells can be detected to get an insight into cell biology and evolve methodologies in cancer therapy (Table 4).

Uses of cell proliferation markers: These are very useful to measure the growth rate of tumours and hence these are markers of prognostic significance.[43,61]

a. Correlate with histological tumour grades and indicate aggressiveness
b. Correlation with prognosis. It is essential to realise that some cells, like vascular endothelial cells, intestinal epithelial cells and germinal cells, have inherent high proliferative activity as a reparative process.

In astrocytic tumours, a positive association between MIB-1 LI (labelling Index) and five year progression free survival (PFS) has been noted in a series of 98 cases of paediatric high grade gliomas by Pollack et al.[43] Thus, in patients with LI of less than 18%, the five year PFS was 33+7% whereas, in those with LI greater than 36%, the five year PFS was 11+6%. Others, however, have not noted any such correlation. In atypical neurocytomas, with MIB-1 LI of greater than 2%, a good correlation with outcome has been described by many authors.

Thus, cell kinetic studies are more accurate and objective methods of assessment of tumour growth rate and biological aggressiveness of tumours lacking definitive histopathological features. Proliferation indices can be used as an important adjunct to histological grading for guiding patient prognosis and management. However, their usefulness in predicting of tumour behaviour in terms of recurrence and survival remain controversial and, hence, they cannot be used as standalone prognostic markers.[27]

Molecular Genetic Markers

The clinical significance of molecular parameters for diagnostic and prognostic assessment of gliomas is just emerging. Some are elaborated below:

Loss of 1p/19q and prognosis: Oligodendrogliomas are the first CNS neoplasms in which a genetic signature, viz. chromosomal segments 1p and 19q deletion has been associated with outcome and response to chemotherapy.[18,19,21,22,31,32,53,58] A 5-year survival rate of 95% has been observed for those with deletions of 1p and 19q versus 65% for those without deletions. Those with deletions also had longer overall survival of 172 months versus 105 months without deletions.[6,19] In a series of 39 patients with anaplastic oligodendroglioma nearly all of the 70% with positive response to PCV chemotherapy (procarbazine, CCNU and vincristine) exhibited loss of heterozygosity (LOH) of 1p/19q. Recently published data indicate a similar and better outcome in patients with LOH 1p/19q treated at the time of diagnosis with both PCV chemotherapy and radiotherapy or only by chemotherapy.[6,30] Other recently published studies also support this positive correlation between LOH 1p/19q and survival.[5,23]

Two recent phase III prospective clinical trials by Radiation Therapy Oncology Group (RTOG) 9402 and European Organization for Research and Treatment of Cancer (EORTC) 26951 have included correlative analyses of 1p and 19q deletions in tumour specimens of anaplastic oligodendroglioma and anaplastic oligoastrocytoma as prognostic markers. The RTOG 9402 study showed that LOH for either 1p or 19q was a significant independent prognostic variable correlating with the outcome ($p = 0.01$). In EORTC 26951, a significant difference in survival was also observed for patients with 1p/19q loss as compared with those without deletions ($p = 0.003$).[9,10,59] Thus, combined loss of 1p and 19q is identified as a favourable prognostic factor in both studies independent of the treatment arms. Thus, irrespective of whether a patient was treated with RT alone or with PCV and RT, the survival was better if the patient had 1p/19q deletions. However, at this time, there is insufficient information to allow therapeutic decisions or assignment of treatment to be made solely on the basis of 1p and 19q deletion status.

This molecular signature of oligodendrogliomas has also become very important in diagnostic assessment of these tumours, e.g. for differential diagnosis of oligodendroglioma from neurocytoma, DNET, etc. The presence of 1p/19q deletion supports a diagnosis of oligodendroglioma.[48]

Table 4: Methods of detection of cell proliferation on tissue sections

Marker	*Technique*	
Mitotic figure	Routine Histology	M phase
AgNOR staining	Silver stain	Nucleolar organising region
[^{3}H] – Thymidine	Autoradiography	S Phase
BrdU/IdU	Immunohistochemistry	S Phase
Ki-67/MIB-1 antibody	Immunohistochemistry	G1, S, G2, M Phase
PCNA antibody	Immunohistochemistry	G1, S, G2, M Phase
Topoisomerase II	Immunohistochemistry	G1, S, G2, M Phase
Fluorescent antibody labelling of cell membrane	Flow cytometry	All phases

p53 mutations and prognosis: TP53 is a tumour suppressor gene and in tumours it is expressed in mutated form. The prognostic significance of mutated TP53 over expression in diffuse astrocytomas is controversial. TP53 mutations were not associated with an overall change in the prognostic outcome in a series of 159 consecutive WHO grade II astrocytomas and oligoastrocytoma patients treated at a single neurosurgical clinic.[11]

In the GBM group also, there is conflicting evidence as to whether or not *p53* alterations independently correlate with patient survival, although they may indirectly impact prognosis in certain patient subgroups.[8,49,55] While some hospital-based studies showed no association between TP53 status and outcome in patients with a glioblastoma,[38,52] one study indicated that the presence of TP53 mutations was a favourable prognostic factor.[49] At the population level, univariate analysis revealed that the presence of TP53 mutations was predictive of longer survival.[38] However, age-adjusted multivariate analysis revealed no difference in survival between patients with or without TP53 mutations.[38]

Thus, the presence of TP53 mutations may simply indicate occurrence of the glioma in a younger age group and slow progression, and does not reflect the survival period and prognosis as commented by some studies.[45] These studies need to be critically evaluated before interpreting for prognostication.

Presence of *p53* mutations are of diagnostic help in a few situations, e.g. for differential diagnosis between grade II and pilocytic astrocytoma. If *p53* mutation is present, it favours a diagnosis of grade II diffuse astrocytoma as *p53* mutations are rarely seen in pilocytic astrocytomas.

EGFR amplification/overexpression and prognosis: The predictive value of epidermal growth factor receptor (EGFR) amplification has been unclear. In earlier hospital-based studies (40 cases), EGFR amplification was associated with poorer survival in patients with a glioblastoma.[28,57] In contrast, a meta-analysis of seven previous studies (a total of 395 glioblastomas) did not reveal a significant predictive value of EGFR amplification.[40] Several studies have suggested that EGFR amplification is predictive for certain age groups of glioblastoma patients.[3,50,52,54] Shinojima et al.[50] reported that EGFR amplification was a significant predictor of poorer overall survival in glioblastoma patients and that the EGFR gene status was a more significant prognostic factor in younger patients (<60 years). Simmons et al.[36] reported that EGFR overexpression was associated with poorer survival of glioblastoma patients younger than the median age, and that EGFR over expression was negatively associated with survival in cases without TP53 mutation. Other studies found EGFR amplification to be a predictor of longer survival only in older glioblastoma patients.[3,54] At the population level, EGFR amplification did not affect survival of glioblastoma patients at any age.[38]

Loss of 10q/PTEN mutations and prognosis: Second only to gains on chromosome 7, losses involving chromosome 10 are quite frequent in astrocytomas, limited mainly to high-grade tumours.[12,41] LOH 10 is the most frequent genetic alteration in glioblastomas and occurs in 60–80% of cases.[29,46]

The available data on PTEN alteration and survival of glioblastoma patients are heterogeneous. In several studies, PTEN mutations were not associated with prognosis of glioblastoma patients[2,49,54,63] and this was confirmed at the population level.[38] Terada et al.[56] identified LOH around PTEN as a predictor of less favourable prognosis in a set of 40 astrocytomas (grades II–IV).

Sano et al.[47] reported that the PTEN mRNA level is an independent prognostic factor for glioblastoma patients. Patients whose tumours had low PTEN transcript levels had significantly shorter survival times than patients with high PTEN mRNA expression.

Smith et al.[54] reported that PTEN mutations were a powerful independent marker for short survival in their group of anaplastic astrocytoma patients. PTEN mutations were detected in 11 of 62 tumours, with the median survival times being 4.4 months versus 34.4 months for cases with and without PTEN mutation, respectively.[54]

C-myc/N-myc amplification, Erb-B 2 overexpression and Trk-C expression in prognosis of medulloblastomas: Chromosomal gains of MYCC and MYCN locus has been identified in medulloblastoma in 4–17% of cases. The MYCC or MYCN amplification is associated with the aggressive large cell tumour variant and a poor clinical outcome. Over expression of ErbB2 receptors has been proposed as an independent indicator of aggressive behaviour, while high TrkC receptor expression indicates a favourable outcome.[33]

Genetic/Molecular Markers for Prediction of Response to Treatment

Temozolamide (TMZ): O6-Alkylguanine-DNA Alkyltransferase (AGT)

Temozolamide (TMZ) is an attractive therapeutic agent for brain tumour management through much work remains to be done to develop biomarkers that can reliably predict response among malignant glioma patients. One clearly important modulator of TMZ response is O6-alkylguanine-DNA alkyltransferase (AGT), a critical DNA repair protein also referred to as O6-methylguanine-DNA-methyltransferase (MGMT). This enzyme removes chloroethylation or methylation damage at the O6 position of DNA guanines, thereby protecting normal cells from exogenous carcinogens, and similarly protecting tumour cells from alkylating and methylating chemotherapeutic agents.[47] AGT levels vary significantly across and within tumour types.[13,51] Methylation of the AGT promoter can diminish AGT transcription and expression.[17] AGT levels can be most readily measured by either immunohistochemistry or by a methylation specific PCR assay.[26,44,60]

Friedman et al. initially implicated AGT in TMZ responsiveness among malignant glioma patients.[58] In

a series of 36 newly diagnosed patients (including 33 with GBM), the response rate to TMZ was 60% among patients with low-level of expression of AGT (detected by immunohistochemistry in 20% of cells) compared with only 9% among patients with high-level of AGT (present in 20% of tumour cells). Similarly, following Carmustine (BCNU) chemotherapy, a radiographically detectable response in 12/19 (64%) patients with malignant glioma was noted with methylated AGT compared to only 1/28 (4%) patients with unmethylated AGT.[20] Two subsequent prospective studies demonstrated that AGT methylation is associated with better survival among malignant glioma patients treated with TMZ.[24,25] Of note in these studies is that the Kaplan-Meier survival curves for patients with methylated and unmethylated AGT become particularly divergent after 12 months of follow-up. Furthermore, these studies suggest that tumour AGT status is an independent predictor of outcome following alkylator-based chemotherapy, because AGT status does not correlate with established clinical prognostic factors.

Therefore, a looming, fundamental question is whether tumour AGT status should ultimately direct treatment of newly diagnosed GBM patients at all. Although results to date suggest that AGT status is an important biomarker for TMZ responsiveness, these findings require further validation in additional prospective analyses.

Microarray Based Expression Profiling for Prognostication of Glial Tumours

In the past, the number of genes that could be evaluated at one time was limited. Because most cancers (including GBM) have very complex patterns of differential gene expression profiles, the study of single genes in individual tissues only provides limited information towards our understanding of the bigger picture of neoplasia. The advent of high throughput complementary DNA (cDNA) and oligonucleotide microarray technology allows comprehensive gene expression analyses and has presented a significant advance in neuro-oncology.[4,37]

Microarray expression profiling of gliomas has identified molecular subtypes as well as genes associated with tumour grade, progression and patient survival.[4,24,25,37,42] Reports that expression profiles predict outcome better than histological classification provide support for the hypothesis that neoplasms defined morphologically as anaplastic astrocytoma and GBM represent a mixture of molecular genetic subtypes.[4,37,42] For example, the study of Phillips et al.[42] on high grade gliomas revealed three subclasses—one high grade glioma subclass displaying neuronal lineage markers associated with longer survival while two other subclasses enriched for immature neural stem cell markers displaying short survival. Poor prognosis subclasses exhibited markers of proliferation or of angiogenesis and mesenchymal differentiation. Upon recurrence, tumours frequently shifted towards the mesenchymal subclass.

Thus, given the possibility that molecularly distinct disease entities may exhibit different clinical responses, a greater understanding of the behaviour of molecularly defined subsets of tumours may aid in better prognostication and development of more effective therapies. At present various tumour markers are utilised by many centres with a hope to improve the prediction of tumour biology and use it in prognosticating the clinical response and survival. For a neurosurgeon of the coming years, it is essential to be aware of the developments in basic science to translate these to bedside patient care and effective treatment.

128 Tumours of Cranial and Peripheral Nerves

Sundaram C, Anita Mahadevan

Before the advent of advanced imaging techniques, tumours of the cranial nerves were detected only by looking at bony changes they produced in the skull base foramina (on plain radiographs) or invasive techniques such as cisternography and angiography. Current imaging techniques and advances in treatment modalities have completely altered the natural history of these tumours making these one of the success stories of modern neurosurgery. Further, new insights into the biology of peripheral nerve tumour growth and development have unfolded newer modes of oncogenesis. These molecular advances are opening up potentially new and exciting avenues targeted therapies.

This group of tumours shows diversity not only in the wide range of histopathological features but also in their anatomical location and clinical behaviour. More frequently than any other class of CNS tumours, they occur in the setting of familial tumour syndromes, in particular, the neurofibromatoses.

One of the long standing difficulties with nerve sheath tumours was the struggle to develop a universally accepted classification. The current WHO classification[16] is provided in Table 1.

Table 1: WHO classification of peripheral nerve sheath tumours

Benign tumours of peripheral nerve
Schwannoma
Conventional
Cellular
Plexiform
Melanotic
Neurofibroma
Cutaneous (diffuse/nodular)
Plexiform
Perineurioma
Intraneural perineurioma
Soft tissue perineurioma
Malignant peripheral nerve sheath tumours (MPNSTs)
Epithelioid
MPNST with divergent mesenchymal and/or epithelial differentiation
Melanotic
Melanotic psammomatous

SCHWANNOMA

Schwannomas are benign, slow growing neoplasms of the central and peripheral nerve sheath that arise anywhere distal to the oligodendroglial-Schwann cell myelination junction. They are defined by WHO as encapsulated benign tumours composed exclusively of Schwann cells. They have been variously referred to in literature as "neuromas", "neurinomas" (Verocay, 1910) and "neurilemmomas" (Stout, 1935).

The majority of schwannomas are solitary, sporadic tumours although syndromic associations are seen particularly when multiple.

Syndromic Associations

- Neurofibromatosis type 2 (NF2) is associated with bilateral vestibular schwannomas and multiple peripheral nerve schwannomas.
- Schwannomatosis, a rare genetically distinct disorder[18] is associated with multiple peripheral schwannomas in the absence of bilateral vestibular schwannomas.
- Carney's complex is associated with psammomatous melanotic schwannomas.

Incidence and Site

As neoplasms of the nerve sheath, they may arise intracranially, intraspinally or in the periphery. They constitute 5–10% of all intracranial tumours. Sensory roots are more often affected than motor or autonomic roots. The peak incidence is in the third to sixth decade although no age is exempt. The intracranial tumours have a female predilection.

Ninety per cent of intracranial schwannomas arise from the vestibular division of the eighth cranial nerve. Other cranial nerves combined account for only 10% of all intracranial schwannomas. Trigeminal schwannomas are the second most frequent and may take origin from the ganglion, root or rarely the divisions of the trigeminal nerve. Glossopharyngeal, vagal and spinal accessory nerve schwannomas are recorded while involvement of other cranial nerves, such as oculomotor, trochlear, abducens and hypoglossal, that are purely motor nerves are extremely rare. Intraparenchymal schwannomas (intracerebral and intramedullary) are extremely rare but have been reported.[4,14]

The clinical and radiographic features vary according to the parent nerve involved. In general, these tumours present as mass lesions, produce neurological dysfunction by distorting the parent nerve and compressing the surrounding cranial nerves, brainstem and cerebellum.

They cause widening of the bony foramina and scalloping or erosion of bone at the skull base that are recognised on plain radiographs. They arise as extra-axial masses in the subdural space and widen the cisterns within which they are located, which is how they are recognisable on cisternography or pneumoencephalography. Angiographically, they are detected to receive their blood supply from branches of the external carotid system. On CT, they appear as isodense to slightly hyperdense, well circumscribed lesions which enhance on contrast administration. On MRI, they remain slightly hypointense on T1W1 and hyperintense on T2W1 and enhance uniformly and intensely on contrast administration. Degenerative change, particularly cystic change, is readily detectable on MR imaging.

Gross Pathology

Schwannomas are typically discrete, solitary and well encapsulated. They tend to displace the parent nerve eccentrically and have a smooth lobulated appearance (Figs 1A to C). The cut surface is glistening and interrupted by bright yellow areas (xanthomatous change), cysts and haemorrhage. In tumours arising from the peripheral nerves, the parent nerve of origin can usually be identified.

Conventional Schwannomas

Microscopically, conventional schwannomas are classically described as being composed of alternating compact zones (Antoni A pattern) and less cellular, loose textured (Antoni B) regions. The Antoni A regions have well ordered arrays of elongated spindle shaped cells with tapering, buckled nuclei and eosinophillic cytoplasm. The nuclei may line up in palisades with intervening nuclei-free zones forming characteristic structures called Verocay bodies (Fig. 1D). The Antoni B regions are poorly organised clusters of large vacuolated cells with small round nuclei (Fig. 1E). Cystic change and xanthomatous change are common in these zones, as are hyalinisation of vessel walls with thrombosis and perivascular haemosiderin deposits (Figs 1F to H). The Antoni B regions, therefore, probably represent degenerative changes. The prominent vascular hyalinisation may be responsible for intense contrast enhancement on imaging. Cystic change in the tumour contributes to hyperintensities on T2W1. The classic histology is more prominent in intraspinal and peripheral tumours, while the intracranial tumours typically lack the prominent palisades and show more prominent Antoni B regions with prominent xanthomatous changes.

Attention has been focused on two microscopic variants—the ancient schwannoma and the cellular schwannoma that demonstrate histological features that could be mistaken for malignant change.

Ancient Schwannomas

This refers to large tumours of long duration that have undergone extensive degenerative changes. They commonly demonstrate bizarre pleomorphic nuclei that represent degenerative atypia and do not connote malignancy (Fig. 1I).

Cellular Schwannomas

These are defined as hypercellular schwannomas composed exclusively of Antoni A areas, and devoid of Verocay bodies (Fig. 1J). Mitotic activity is readily identifiable (not exceeding 4 per 10 high power fields). They are found most often in paravertebral sites in the pelvis, retroperitoneum and mediastinum. Intracranially, they are described in facial and trigeminal nerves.[5] A single report of multiple cellular schwannomas is on record.[26] The clinical presentation does not differ, but the finding of hypercellularity, fascicular growth pattern, nuclear atypia and mitosis may lead to a mistaken diagnosis of malignancy. The Ki-67 labelling index ranges from 5.6% to 6% and p53 staining is found in a significant proportion, although with only few positive cells.

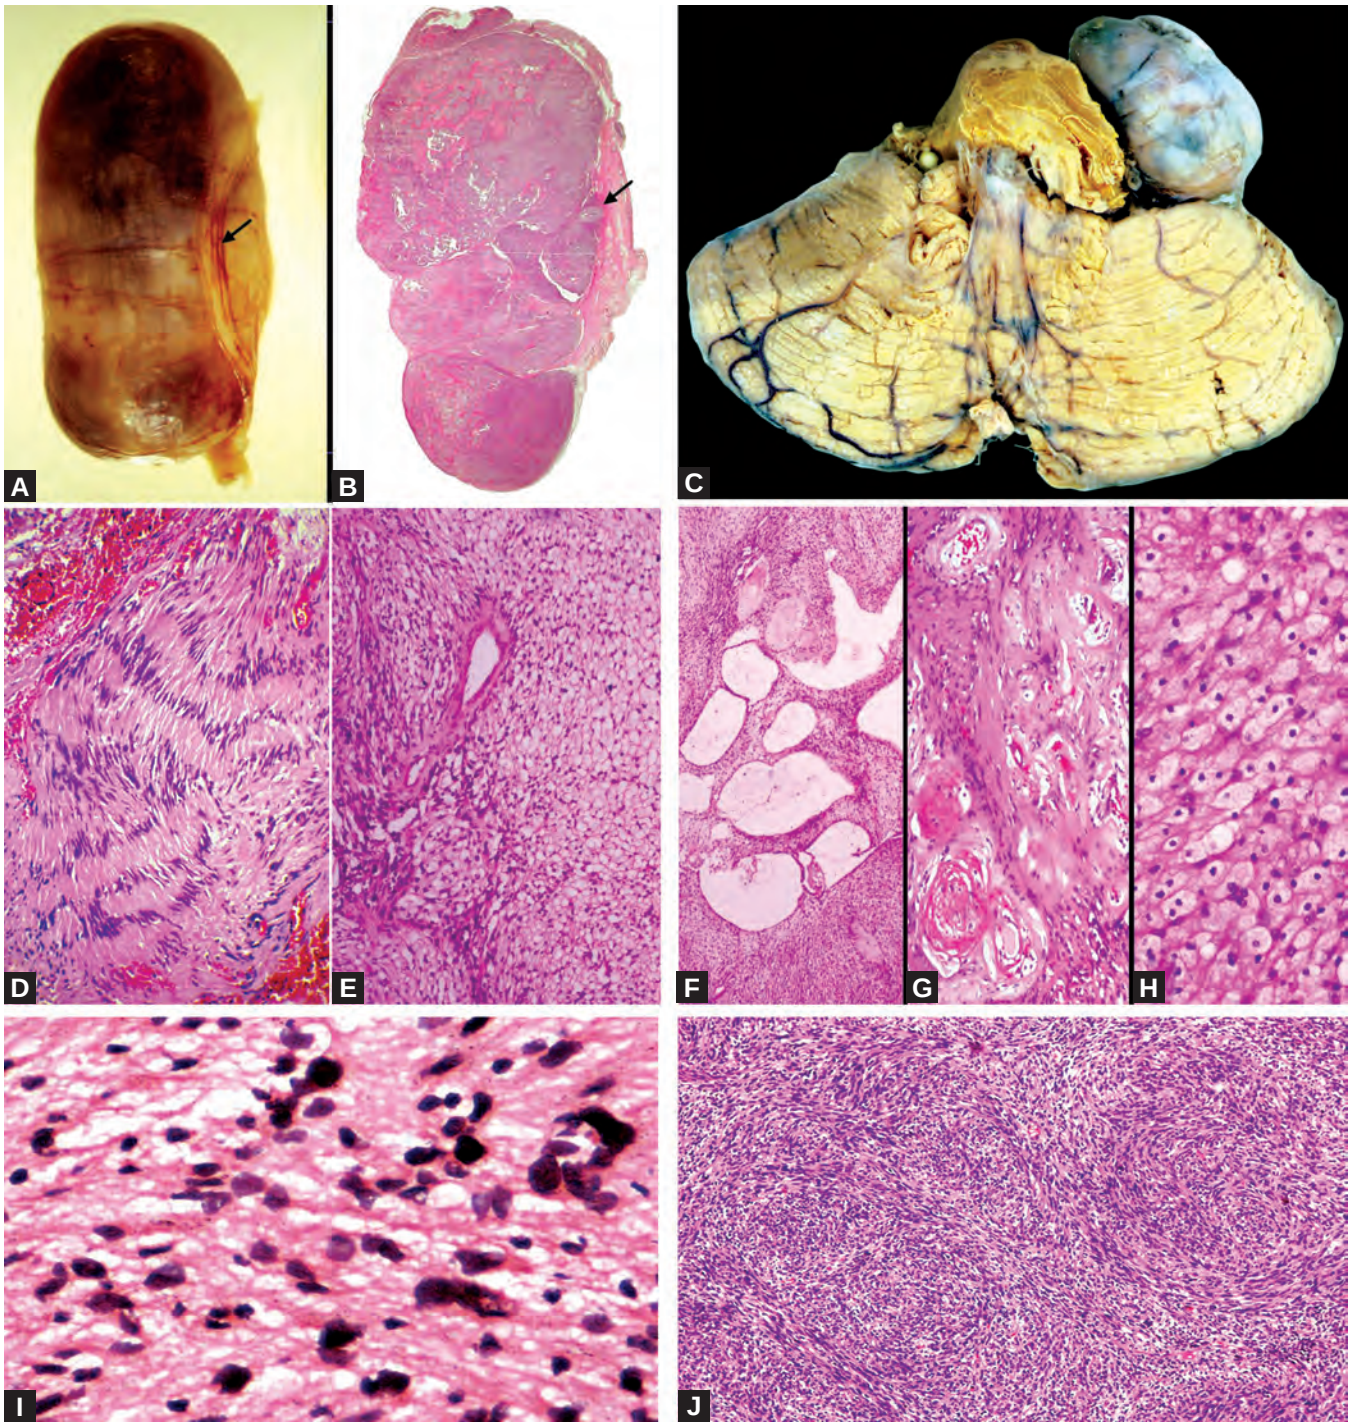
Cellular schwannomas are benign and may tend to recur, particularly the intraspinal examples, but no case has been reported to metastasise or show a malignant transformation.

Melanotic Schwannoma

These are grossly pigmented tumours that have cells that both ultrastructurally and immunophenotypically have schwannian characteristics but contain melanosomes and are reactive for melanoma markers. They are extremely rare and occur a decade earlier than conventional schwannomas. They may be psammomatous[3] or non-psammomatous.[11] The former involve nerves of the intestinal tract or heart and rarely cranial nerves. The majority of non-psammomatous tumours are seen in the spinal nerves. The distinction is of importance as approximately 50% of patients with psammomatous tumours have Carney complex[2] (that includes cardiac myxoma, lentigenous facial pigmentation and endocrine hyperactivity, most commonly Cushing syndrome with multinodular adrenal hyperplasia or acromegaly due to pituitary adenoma). Slightly over 10% of melanotic schwannomas follow a malignant course.

Plexiform Schwannoma

This refers to the growth of the tumour in a plexiform or nodular manner.[27] It is more often seen in the skin or subcutis of an extremity, head and neck or trunk where it arises from a nerve plexus. The cranial and spinal nerves are usually spared and the tumour is associated with NF2 (not NF1) or schwannomatosis.[9]



Figs 1A to J: (A) Gross photograph of an encapsulated schwannoma arising from a nerve (arrow). (B) The whole mount histology section shows encapsulation of the tumour and compressed fibrotic remnants of nerve (arrow) [HE x 5]. (C) Cerebellopontine angle schwannoma arising from vestibulocochlear nerve. The tumour is well encapsulated and compressing the pons. (D) Palisading of Schwann cells with cell free zones forming characteristic Verocay bodies in compact Antoni (type A) zones. (E) Loose textured microcystic Antoni (type B) zones. (F to H) Degenerative changes in a schwannoma with cystic change. (F) Vascular hyalinisation. (G) Xanthomatous change. (H) Marked nuclear atypia (degenerative nature) in an ancient schwannoma. (I) Is not indicative of malignancy. (J) Cellular schwannoma showing compact Antoni A areas with increased cellularity and low mitotic activity [D&E: HE x 120, F&G: HE x 80, H: HE x 240, I: HE x 320, J: HE x 120]

Immunohistochemistry

Tumour cells exhibit strong and diffuse positivity for S100 protein. They may also be positive for myelin-associated glycoprotein (Leu 7) and focally express GFAP. They are usually negative for myelin basic protein and EMA (marker of perineurial cell).

Ultrastructure

Ultrastructural features are diagnostic and demonstrate long entangled cell processes that enclose the intervening stroma analogous to normal axon-Schwann-cell-axon sheathing arrangement (pseudomesaxon). This is in contrast to a neurofibroma in which true axons are found within the tumour surrounded by Schwann cell processes (mesaxons). A well defined continuous basal lamina separates the cell processes from the stroma. The cells are devoid of pinocytotic vesicles and cell-cell junctions are rare.

Syndromic Association

Most schwannomas are sporadic but, when multiple, occur in association with two inherited tumour syndromes—neurofibromatosis 2 (NF2) and schwannomatosis. Bilateral vestibular schwannomas are pathognomonic of NF2 while multiple peripheral schwannomas in the absence of other NF2 features is characteristic of schwannomatosis, a newly recognised syndrome.[18] The gene product of NF2 Merlin/schwannomin is believed to perform a tumour suppressor gene function. Biallelic inactivation of the NF2 gene is identified in most sporadically occurring schwannomas as well as meningiomas.[25] Recent studies suggest that Merlin belongs to the protein 4.1 super family and is closely related to the ERM protein and provides a linkage between membrane-associated proteins and actin cytoskeleton. Being located on the membrane cytoskeleton, Merlin is not likely to directly control the cell cycle machinery. Merlin is probably a novel type of tumour suppressor that co-ordinates the processes of growth-factor receptor signalling and cell adhesion.

Psammomatous melanotic schwannomas are associated with Carney complex. Extensive genetic studies have implicated NF2 gene on chromosome 22 as a tumour suppressor gene integral to the formation of sporadic schwannomas also. Inactivating gene mutations are detected in up to 60% of schwannomas including the cellular variant. Loss of the protein merlin (or schwannomin) that the gene NF2 encodes has been demonstrated by immunochemistry or Western blotting as a universal finding in all Schwannomas.

NEUROFIBROMA

These are defined as well demarcated intraneural or diffusely infiltrative extraneural tumours that are composed of an admixture of neoplastic Schwann cells, perineurial-like cells and fibroblasts. Like Schwannomas they are most often single when sporadic but, when multiple, are associated with neurofibromatosis 1 (NF1).

There is no age or gender predilection. They have three distinct growth patterns: (1) localised; (2) diffuse and (3) plexiform. In the localised form, they present as cutaneous nodules (localised cutaneous neurofibroma) or as a mass arising from a peripheral nerve (localised intraneural neurofibroma). Unlike Schwannomas, they are occasionally seen in the spinal nerves[23] but are virtually unknown in the cranial nerves (Table 2). The diffuse growth pattern is rare and can present with localised involvement of skin and subcutis (diffuse cutaneous neurofibroma) or extensive involvement of soft tissue of an entire limb (elephantiasis neuromatosa). The diffuse form, despite its extensive involvement, never shows malignant transformation. The plexiform variant on the contrary is virtually pathognomonic of NF1 and, although rare (2–3%), is the most frequent form to show malignant transformation. They arise from large nerve trunks or plexuses.

The cutaneous tumours are either circumscribed or diffuse, and appear gelatinous and grey-tan on sectioning. Those confined to nerves are fusiform and well circumscribed while the plexiform variant that arises from nerve trunks or a plexus appears multinodular causing expansion and matting together of involved trunks producing a characteristic "bag of worms" appearance.

Table 2: Differences between neurofibroma and schwannoma

Features	*Neurofibroma*	*Schwannoma*
Cell of origin	Unidentified, mixture of Schwann cell, axons, perineurial-like cell and fibroblast	Schwann cell
Parent nerve	Fusiform enlargement/infiltration	Compressed
Capsulated	No	Yes
Growth pattern	Localised, diffuse, plexiform	Localised, plexiform (rare)
Degenerative changes	Uncommon	Common (cystic change, xanthomatous change, hyalinisation, haemorrhage)
Immunohistochemistry for S100	Focal	Diffuse
Ultrastructure	Mesaxons	Pseudomesaxon
Syndromic association	NF1	NF2 Carney's complex Schwannomatosis
Malignant transformation	2–3% (NF1)	Exceptional

Histological Features

Neurofibromas are characterised by both cellular and stromal components. The former is an admixture of neoplastic Schwann cells, perineurial-like cells and fibroblasts that typically proliferate in a haphazard fashion dispersed in a stroma rich in collagen and mucopolysaccharides (Figs 2A to C). If arising from a medium sized nerve, the tumour remains confined within the epineurium. If arising in small nerves, they spread diffusely into soft tissues. Large diffuse neurofibromas often show tactile differentiation with Wagner-Meissner like corpuscles and pigment containing melanotic cells. In the plexiform variant, the nerve bundles are matted together by tumour (Fig. 2D) and commonly demonstrate residual recognisable nerve fibres at the centre (Fig. 2E) and may infiltrate the dorsal root ganglia (Fig. 2F). Unlike schwannomas, degenerative changes (cystic change and xanthomatous change) as well as vascular hyalinisation are lacking. Immunohistochemically, S100 staining is present but less diffuse than in schwannomas. Variants of neurofibromas have been described.

Atypical Neurofibroma

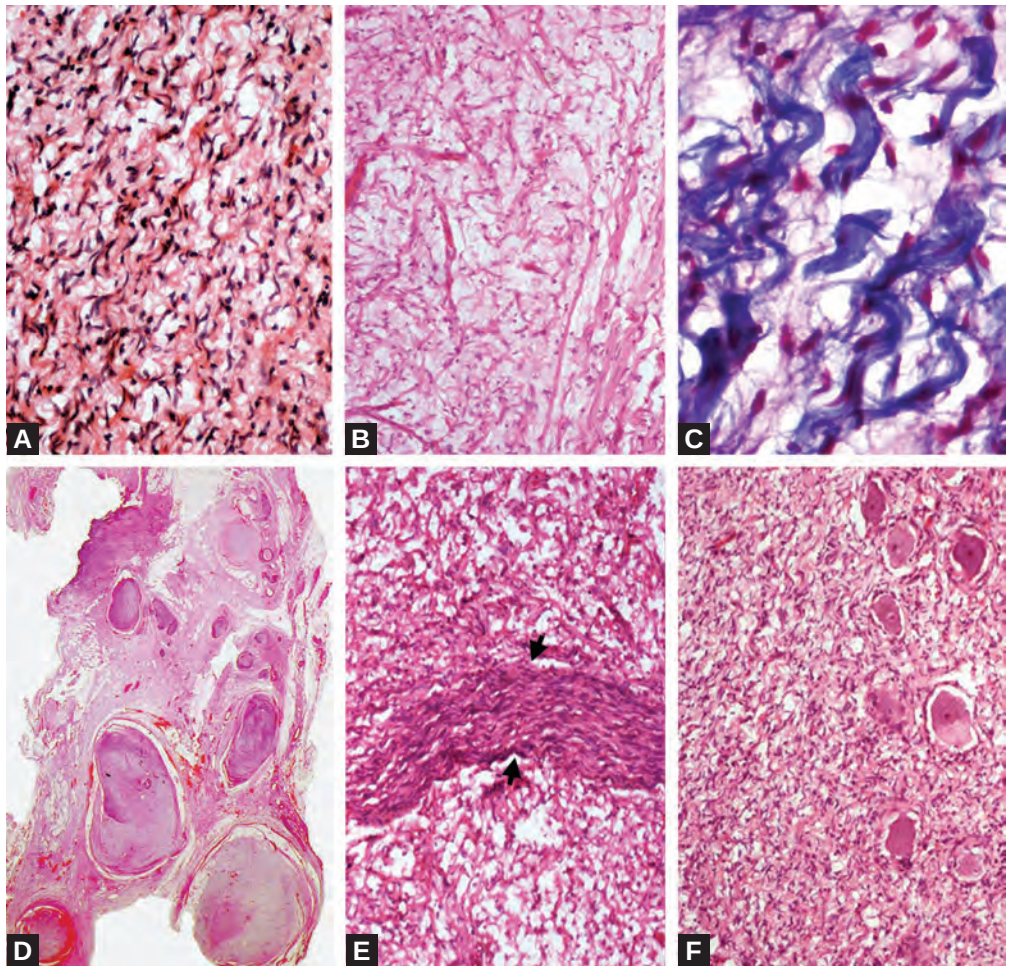
Presence of nuclear atypia (degenerative) in the absence of cellularity and mitotic activity in an otherwise typical neurofibroma is termed atypical neurofibroma. No risk of malignancy is identified in this variant.

Cellular Neurofibroma

Similar to cellular schwannomas, these demonstrate increased cellularity and appreciable mitotic activity, but do not connote malignant transformation. They need to be differentiated from malignant peripheral nerve sheath tumour (MPNST) by their low mitotic activity, lack of necrosis and absence of significant cellular atypia.

Cell Biology

Given the admixture of cell types, there has been a continuous debate as to whether neurofibromas represent a neoplastic or hyperplastic phenomenon. *In vivo* studies have convincingly demonstrated that Schwann cells from neurofibromas in contrast to normal Schwann cells



Figs 2A to F: (A) Neurofibroma showing characteristic wavy spindle cells dispersed haphazardly. (B) Myxoid degeneration with (C) collagen deposition in stroma resembling "shredded carrots" is common [A,B: HE x 120, C: Masson trichrome x 240]. (D) Whole mount view of expanded fascicles of varying sizes in a plexiform neurofibroma [HE x 5]. (E) Plexiform neurofibroma showing remnant of nerve twig in centre. (F) Infiltrating a dorsal root ganglion. (F) [HE x 120]

promote angiogenesis and invade the basement membrane[24] and, when grafted into nude mice, form neurofibroma-like tumours.[19] Recent studies have demonstrated that both NF1 associated tumours and sporadic neurofibromas show inactivation of NF1 gene.[20] The NF1 gene product, neurofibromin is a tumour suppressor and its inactivation in Schwann cells causes neurofibromas. The fibroblasts isolated from neurofibromas, however, demonstrate at least one normal allele and express NF1 protein.

Prognosis

The plexiform neurofibromas and those arising from major nerves are precursor lesions of MPNST. Malignant transformation is rare in the other forms of neurofibroma but, in the plexiform variant, malignant transformation occurs in 2–5%. It is more common in deep seated lesions and in cases where the duration of NF1 exceeds 10 years.

PERINEURIOMA

A benign tumour composed exclusively of neoplastic perineurial cells, they occur as intraneural lesions producing expansion of the involved nerve or as soft tissue lesions with no demonstrable origin from a nerve. They are extremely rare with just over 30 cases reported in literature.[15]

They are unassociated with any syndromes. Monosomy of chromosome 22 has been demonstrated in both types.[7,12] The intraneural perineuriomas most often affect peripheral nerves of the extremities causing nerve thickening, and progressive muscle weakness and atrophy closely mimicking hypertrophic neuropathies.

Intraneural perineuriomas are benign and do not show any tendency to recur or metastasise. Biopsy is sufficient for a diagnosis and resection should be avoided to retain neurological function.

MALIGNANT PERIPHERAL NERVE SHEATH TUMOURS

The term incorporates lesions that arise from specialised cells of the endoneurium and perineurium. It encompasses the previously used terms—malignant schwannomas and neurofibrosarcoma.

To define a tumour as MPNST it must satisfy one of the following criteria:[22]

- Arise from an identifiable peripheral nerve trunk and have histological features consistent with recognised types of MPNST.
- Arise in a patient with NF1 and have a histological type conforming to MPNST.
- Arise from a pre-existing benign nerve sheath tumour (schwannoma, neurofibroma or ganglioneuroma).
- Show histological features corresponding to a recognised type of MPNST with morphological evidence of Schwann cell or perineurial cell differentiation.

These types of MPNST recognised by WHO are depicted in Table 1.

Predisposing Factors

NF1 is the most important risk factor for MPNST and accounts for 50% of all tumours. Risk of a patient with NF1 developing MPNST varies in various series from 2–29%[21] with a lifetime risk of 10%. In general, patients with NF1 develop tumours a decade earlier. Tumours associated with NF1 show a loss of NF1 expression and high levels of Ras, but additional genetic events that inactivate key cell cycle regulators are required for malignant transformation. Radiation is another important risk factor seen in 10% of cases with a long latent period between exposure and tumour development.[6,10]

Incidence and Localisation

These are uncommon neoplasms and almost two thirds arise from neurofibromas, often of the plexiform type in the setting of NF1. Development from a pre-existing schwannoma is extremely rare.

MPNSTs occur most often in adults in the third to sixth decade. Large and medium nerves are more prone to involvement with the most common sites being the brachial plexus in the upper arm and the sciatic nerve in the buttock and thigh. They are large and often demonstrate foci of haemorrhage and necrosis on sectioning. Cranial nerve involvement is extremely rare with the fifth nerve being most frequently involved.[1,17]

Histopathology

MPNSTs grow within a nerve fascicle in fibrosarcoma-like pattern and commonly invade through the epineurium into the soft tissues. Large areas of geographical necrosis and brisk mitotic activity are common. Perivascular accentuation of tumour and haemangiopericytic growth pattern is a common feature. About 15% exhibit unusual histological features such as epitheloid morphology and divergent differentiation.

Epithelioid MPNST does not show any association with NF1 and carry a better prognosis. Divergent differentiation may produce glandular epithelium (Glandular MPNST), while neuroendocrine and squamous differentiation is uncommon. Association with NF1 in glandular MPNST is high as is the mortality.

MPNSTs showing rhabdomyosarcomatous differentiation (Malignant triton tumours) are more common than glandular MPNST and 60% of patients have NF1. Few cases from the cranial nerves are on record.[13,17]

Prognosis

The prognosis is extremely poor with overall 5-year and 10-year survival rates being only 34% and 23%.

Recent studies suggest that positron emission tomography and glucose analogue 18-fluorodeoxyglucose might be useful in presurgical differentiation between benign and malignant nerve sheath tumours.[8]

KEY POINTS

- Benign nerve sheath tumours include schwannoma, neurofibroma and perineurioma.
- Solitary tumours are often sporadic while multiple tumours are associated with familial tumour syndromes particularly neurofibromatosis 1 and 2 and a newly recognised entity, schwannomatosis.
- Schwannomas more commonly involve cranial and spinal nerves while cranial nerve involvement is very uncommon in neurofibromas.
- Sensory nerves are preferentially involved by schwannomas with the vestibular division of the eighth nerve and the trigeminal nerve being most frequent.
- Cellular schwannomas tend to recur with predilection for paravertebral regions (pelvis, retroperitoneum and mediastinum).
- Malignant transformation in schwannomas is exceedingly rare.
- The plexiform variant of neurofibroma has a higher risk of malignant transformation.
- Advances in imaging techniques (positron emission tomography and use of 18-FDG) allow presurgical detection of malignant transformation.
- Newer surgical options are being evolved in treatment particularly stereotactic radiosurgery allowing more precise treatment with retained function of the involved nerve.
- Molecular advances have revealed novel modes of tumourigenesis in producing sporadic tumours and development of neurofibromatosis that may have an implication in developing targeted therapies.

129 Tumours of the Choroid Plexus

Yasha TC

Choroid plexus tumours (CPTs) are intraventricular neoplasms arising from the lining epithelium of the choroid plexus and comprise the following:[36]

Choroid plexus papilloma (CPP)	WHO Grade I
Atypical papilloma (APP)	WHO Grade II
Choroid plexus carcinoma (CPC)	WHO Grade III

INCIDENCE

Tumours of the choroid plexus are rare neoplasms forming 0.36–0.6%[39,43] of all intracranial tumours. They are more frequent in children and account for 2–3.69% in them.[39] Twenty per cent of patients present during the 1st year of life and 50% in the first decade.[43] In infants less than 2 years of age CPT are the third most common CNS tumours following medulloblastoma and ependymoma.[34] Papillomas occur approximately 3–5 fold more often than carcinomas,[28] and the latter are more common in children less than 2 years of age.

SITE

In children, CPT most frequently arise in the lateral ventricle, followed by the fourth and third ventricle,[4,7,43] while in adults the fourth ventricle is the commonest site followed by the lateral ventricle.[43] CPCs occur more often in the lateral ventricles of children less than 2 years of age.[30] CPT also present at the cerebellopontine angle as an extension of the tumour through the foramen of Luschka where they are often benign and rarely bilateral.[22] Diffuse hyperplasia of the choroid plexus[11] associated with communicating hydrocephalus is an entity now categorised as bilateral CPP.[8,12] Rare intra-parenchymal examples with no attachment to the ventricle have also been reported in the cerebral cortex[5] and in the brainstem.[33]

AETIOLOGY

Choroid plexus tumours are usually sporadic. They have been associated with Li-Fraumeni and Aicardi syndromes and a possible association with SV 40 virus has also been suggested.

Association with SV 40 Virus

Human polyoma viruses (e.g. BK and JC viruses) are tumourigenic in animal models and cause ependymomas and choroid plexus neoplasms in them. In humans, the presence of viral DNA signature of a closely related monkey virus, SV40 was noted in 50% of choroids plexus tumours and in almost all ependymomas.[3] Transgenic mice expressing SV40 large T antigen and SV11(+), develop spontaneous tumours of the choroid plexus.[38] The viral T antigen binds to cellular protein targets that favour tumourigenesis.

Role of p53

There is increasing evidence for the role of *p53* involvement in CPT tumourigenesis. CPTs are seen in patients of Li-Fraumeni syndrome (LFS) with *p53* germline mutations.[21] Loss of heterozygosity, other chromosomal alterations and possibly association with SV 40 virus are likely mechanisms of inactivation of wild type *p53*.[27]

Aicardi Syndrome

CPTs also occur in association with Aicardi syndrome, an X-linked dominant disorder with a triad of corpus callosal agenesis, infantile spasms and chorioretinal lacunae.[10,40]

Recurrent chromosomal abnormalities in CPT are gains of chromosome 7 and region 12q.[13] Gains of 9p and loss of 10q have correlated with a more favourable prognosis in CPCs.[37]

CLINICAL FEATURES

Choroid plexus tumours are usually slow growing and cause symptoms by mass effect and obstructive hydrocephalus. Occasionally, communicating hydrocephalus is caused by excessive CSF production by the functional tumour cells particularly in bilateral lateral ventricular CPP. Lesions in infancy may cause enlargement of the head. In children, the median age at presentation is 17 months (1-138) for CPP and 13 months (2-102) for CPCs.[28] Congenital tumours have also been identified on antenatal sonography.

A rare case of temporal lobe epilepsy caused by CPP in the temporal horn in a 27-year-old lady has been reported.[31]

NEUROIMAGING

On MRI, CPP are brilliantly enhancing intraventricular, lobulated masses, isointense on T1W and well-defined, and hyperintense on T2W images (Fig. 1A). CT scans

reveal isodense to hyperdense lesions. MR spectroscopy shows a higher level of myo-inositol in CPP compared to CPCs. On the other hand, markedly elevated levels of choline are noted in malignant tumours of the choroid plexus.[20]

MRI features commonly associated with CPC are a large intraventricular lesion (approximately 4–5 cm), with irregular enhancing margins; heterogeneous signal, oedema (73%), hydrocephalus and the presence of disseminated tumour (45%).[30] The latter is associated with a poor prognosis. Metastatic spread to lung and bone has also been reported.[9]

On occasion, CPP exhibit 'drop' metastases into the thecal sac[15,18] and rarely a more diffuse subarachnoid spread can be seen,[23] even after a long asymptomatic period.[45] Hence, total neuraxis imaging at the time of initial diagnosis as well as periodic follow-up examinations after resection is recommended.[45]

PATHOLOGY

Macroscopy

Papillomas are generally circumscribed, greyish red, soft tumours with a characteristic granular, cauliflower like surface (Fig. 1B), with focal gritty areas due to calcification. On sectioning, the tumour has variably compact and loose grey white areas with haemorrhage and cystic change.

Choroid plexus carcinomas can be infiltrative, less circumscribed and show areas of haemorrhage and necrosis (Fig. 1C).

Microscopy

CPP are benign papillary neoplasms resembling the normal choroid plexus and are composed of delicate papillary fronds with central fibrovascular cores lined by a layer of benign cuboidal to columnar epithelium (Fig. 2A). The vessels are thin walled or variably hyalinised. Histological features of anaplasia are not seen and mitotic activity is very low. Rarely, oncocytic change of the epithelial cells with abundant eosinophilic cytoplasm rich in mitochondria, focal clear cell, mucinous change or melanisation may be observed. These changes do not have any prognostic significance. Rarely, a mucinous adenoma pattern[35] or tubulo-glandular pattern may be noted.

Psammomatous and non-psammomatous calcification, xanthomatous change, lymphocytic infiltrates in the stroma, cystic change and haemorrhage are often present. Extensive psammomatous calcification may be associated with aggressive behaviour and a higher proliferative index.[41] Cartilage, ossified bone (Fig. 2B) and, rarely, adipose tissue may also be seen as a metaplastic change.[6] Occasionally, large angioma-like aggregates of thin walled vessels can be observed in the core. Ultrastructurally apical microvilli, basement membrane, tight junctions and interdigitating cell membranes characterise the tumours.[26]

Atypical CPP

Tumours with one or more atypical features in focal areas, namely loss of papillary pattern, increased cellularity, necrosis and nuclear pleomorphism, but without frank anaplasia fall into this intermediate histological grade. Mitotic activity of greater than or equal to 2 per 10 high power fields is found to be the sole atypical feature associated with recurrence[17] and is the defining criteria for this grade in the WHO 2007 classification.[26]

Choroid Plexus Carcinoma

It is characterised by overt features of malignancy, namely solid growth with loss of papillary architectural

Figs 1A to C: (A) MRI brain: contrast enhanced MRI shows an intensely enhancing lobulated mass lesion within the fourth ventricle extending through the left foramen of Luschka. (B) Forty-year-old woman with an intraventricular choroid plexus papilloma filling the fourth ventricle, lifting up the cerebellum and obstructing the foramen of Magendie. (C) One-year-old child with a large intraventricular tumour filling the right lateral ventricle and causing CSF obstruction and mass effect. Areas of haemorrhage are seen within the tumour. Histology showed choroid plexus carcinoma. Seedings were seen along the ventricular lining in the occipital horn

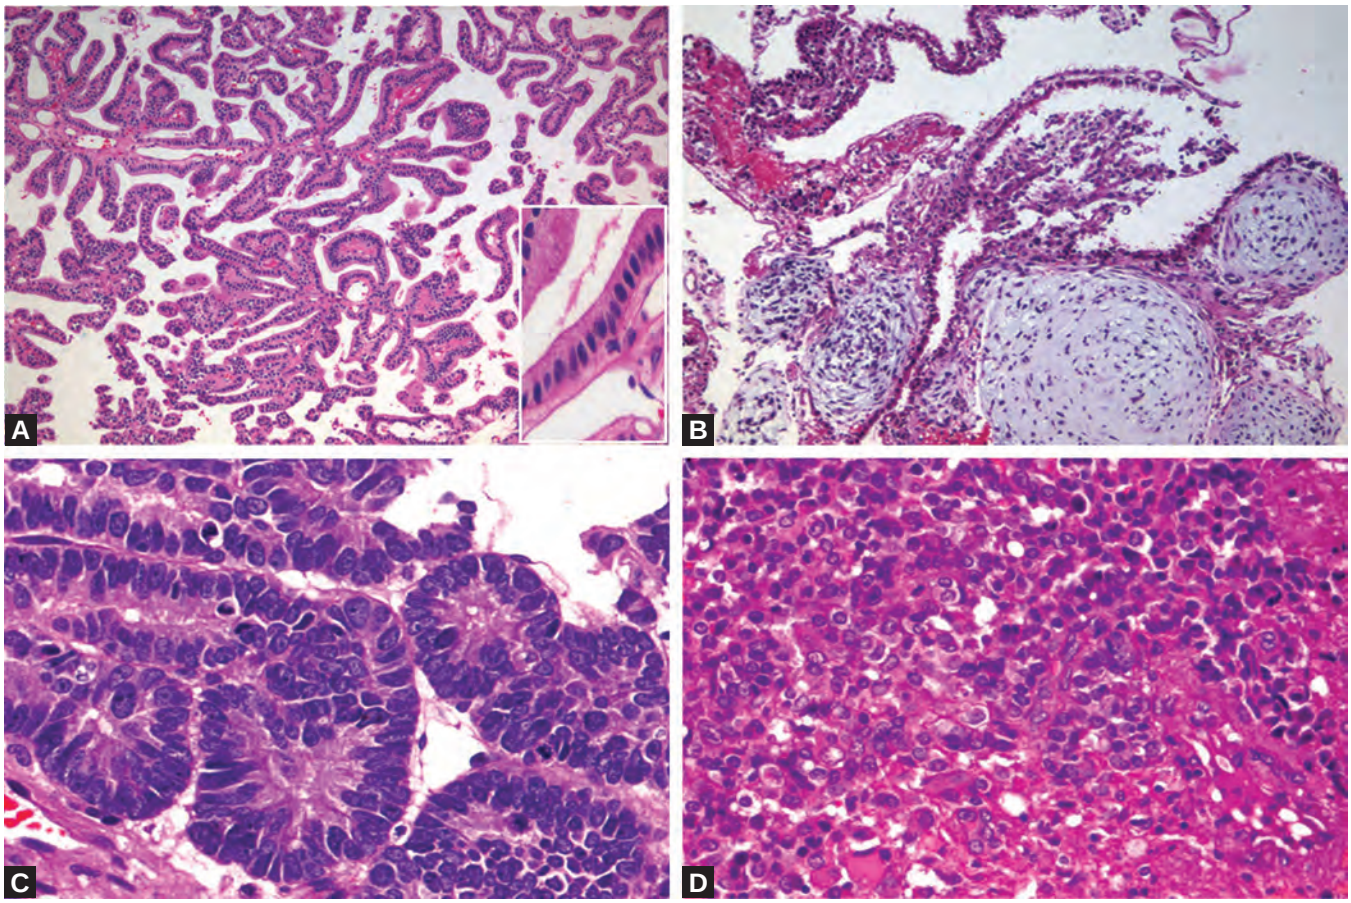
pattern, nuclear anaplasia, high mitotic activity (often more than 5 per 10 high power fields) and parenchymal infiltration (Figs 2C and D). The tumour may show both solid and papillary areas and necrosis is often present. Occasionally, cohesive clusters of tumour cells in otherwise typical choroids plexus papillomas have been noted within the adjacent brain parenchyma and their importance in prognostication is debatable since follow-up studies have not shown an increase in recurrence in them.[24] Infiltration by singly dispersed tumour cells has a more ominous connotation and is seen in CPC.

IMMUNOHISTOCHEMISTRY

Almost all choroid plexus neoplasms, both papillomas and carcinomas, express cytokeratin and vimentin. The majority (80–90%) of CPP and less frequently the malignant form are labelled by antibody to transthyretin (TTR) and S-100. Developmentally, the choroid plexus cells normally express GFAP, a glial marker, which persists in very few cells in adulthood. This is reflected in the plexus tumours, and GFAP is present in a small number of tumour cells in 25–55% of CPP and 20% of CPC.[36] Epithelial membrane antigen is generally absent.[26] Lack of or reduced S-100 staining has been associated with a poorer prognosis in CPC. Inconsistent expression of TTR in CPC and the finding that metastatic carcinomas also express TTR limits its utility as a diagnostic marker of CPC, especially in adults.[1]

A recent study using DNA microarrays and gene expression profiling of normal and neoplastic choroid plexus has identified Kir7.1 (inward rectifier potassium channel) and stanniocalcin-1 protein to be sensitive and specific markers for choroid plexus tumours.[14] Immunostaining for INI-1, a transcription factor expressed in nuclei, is retained[19] unlike atypical teratoid/rhabdoid tumours (AT/RTs) which are associated with INI/hSNF5 mutations and lack of staining. Survivin, a multifunctional molecule that inhibits cell death and is expressed exclusively in cells with high proliferation is localised to the ependyma and choroid plexus in the normal brain. In paediatric ependymomas and choroid plexus tumours, loss of nuclear survivin expression correlates with increasing cytologic atypia.[2]

The normal choroid plexus shows an MIB labelling index of 0.01–0.4%, while in CPP it ranges from 0.2% to



Figs 2A to D: (A) Choroid plexus papilloma with multiple papillary fronds composed of fibrovascular cores lined by cuboidal to columnar epithelial cells (inset: nuclei are oval and bland) [HE x 120, Inset: HE x 320]. (B) Islands of metaplastic hyaline cartilage are present in the stroma of a papilloma [HE x 120]. (C) Choroid plexus carcinoma. The papillae show increased cellularity and are lined by hyperchromatic, anaplastic cells with high mitotic activity [HE x 320]. (D) Choroid plexus carcinoma with solid growth of tumour cells and infiltration of brain parenchyma on the right [HE x 240]

6% (mean of 1.9%). CPC have a high LI of about 14% (range 7.3–60%).[26] Following chemotherapy, some CPC have shown a reduction in MIB-1 labelling index, suggesting that chemotherapy may work in part in reducing the proliferative potential.[4] Adhesion molecules, like CD44, markers for invasive growth and metastasis, are found in atypical CPP and CPC.[42] Altered p53 expression, a tumour suppressor gene, was found in all CPC and in one fourth of papillomas. In half of the positive cases, more than 70% of cells were labelled.[16] Mutations of *p53* gene, however, are present in less than 10% of cases of CPC and are absent in CPP.[26]

Immunolabelling for Aquaporin 1, a water channel protein, is seen in the normal choroid plexus and in CPP. Intense, diffuse staining correlated with a large hydrocephalus and the presence of tumoural cysts. It is negative in CPC.[25]

DIFFERENTIAL DIAGNOSIS

Typical benign CPP does not pose any diagnostic problem. On the other hand, CPC with their loss of architecture may mimic an embryonal AT/RT especially in the infratentorial compartment, metastatic carcinomas and rarely papillary ependymoma. Expression of INI-1 genetic marker is retained in CPC in contrast to its loss in ATRT. Metastatic carcinomas and CPC share many immunohistological features including reactivity for cytokeratin, and TTR, and currently there is no single marker that can reliably differentiate them. Two recently identified molecules, Kir7.1 (inward rectifier potassium channel) and stanniocalcin-1 are potential markers for choroid plexus tumours.[19] Aggressive papillary tumour of the endolymphatic sac or duct of the middle ear (also known as endolymphatic sac tumour, ELST) is histologically identical to CPP and explains the earlier reports of CPP in the temporal bone, close to the internal acoustic meatus. These tumours, unlike CPP, do not express TTR and are often a component of von Hippel Lindau (VHL) disease.[29] Anaplastic papillary ependymomas may mimic CPC. Perivascular pseudorosettes and strong perivascular GFAP fibre positivity serve to identify the former.

PROGNOSIS

For choroid plexus tumours histological features and complete surgical resection are the most important prognostic factors. In CPP, complete resection is more frequently possible (80.4–100%) than in atypical (61.5%) or malignant forms (39%).[28,44] Management is influenced by several factors like resectability, vascularity, presence of craniospinal spread and treatment of associated hydocephalus.[5]

After gross total resection in papillomas recurrences are rare and the functional outcome is excellent in 92%.[7] The median survival for CPP is 75.5 months.[28] In the small proportion of cases where resection of CPP is incomplete a wait-and-watch policy is advocated. In case of plexus carcinomas, gross total resection is possible in about 33% of cases and the median survival is only 6 months (range 1–90 months).[28] For CPCs, adjuvant chemotherapy and craniospinal radiation following surgery should be considered although its uniform efficacy in all cases remains to be established.[28]

The excessive vascularity of the CPT lends itself to peri-operative morbidity and mortality and infants have a higher risk of massive bleeding and coagulation disturbances.[32]

130 Pineal Parenchymal Tumours

Vani Santhosh

Neoplasms occurring in the pineal region are very rare, comprising 0.5–1% of all intracranial neoplasms in adults. Among these, pineal parenchymal tumours are a small group, ranging from 15 to 30% of pineal region tumours. According to the revised WHO 2007 classification of central nervous system tumours, pineal parenchymal tumours (PPTs) are classified as pineocytoma (PC-grade I), pineal parenchymal tumour with intermediate differentiation (PPT-ID grade II/III) and pineoblastoma (PB-grade IV) and papillary tumour of the pineal region.[1] Papillary tumour of the pineal region is now recognised as a distinct entity in this group.

PINEOCYTOMA (WHO GRADE I)

Clinical Features and Localisation

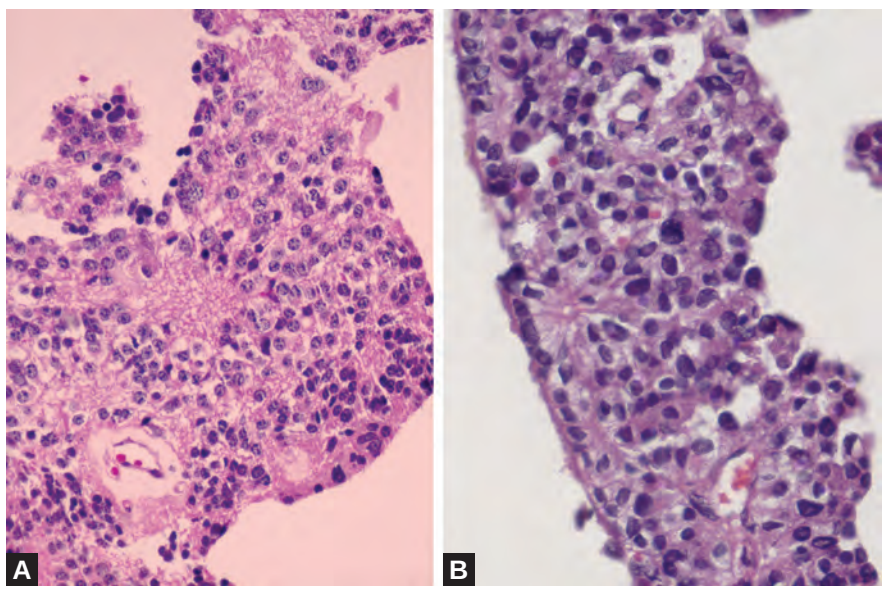
This is a slowly growing, relatively demarcated tumour occurring in the pineal region. Patients often present with neuro-ophthalmic paralysis or Parinaud's syndrome. They can also present with features of raised intracranial pressure.

Imaging Features on Computerised Tomography Scan

The tumour is relatively well demarcated with foci of calcification. It tends to be isointense on T1W images of MRI and hyperintense on T2W images. There is intense homogeneous contrast enhancement. Associated hydrocephalus is always seen.

Pathology

These are well differentiated neoplasms composed of uniform mature cells resembling pineocytes, arranged in sheets or ill-defined lobules (Fig. 1A). Mitotic activity is either absent or very low. Calcification is evident in some cases. Pineocytomatous rosettes are often seen. These are composed of pineocytic cells arranged around a fine meshwork of neuropil-like stroma (Fig. 1B). Occasional tumours exhibit foci of pleomorphic binucleate or multinucleate ganglionic cells and have been termed as pleomorphic variant of pineocytoma with ganglionic differentiation.[5] The tumour cells strongly express neuronal



Figs 1A and B: (A) Pineocytoma showing uniform mature cells amidst which are cell-free neuropil-like zones [HE x 320]. (B) Pineocytic rosette with cell-free space filled with a fine meshwork of cell processes [HE x 320]

markers such as neurofilament protein, synaptophysin, neuron specific enolase and others. They also express retinal s-antigen and rhodopsin indicating a photosensory differentiation of tumour cells.

PINEAL PARENCHYMAL TUMOUR OF INTERMEDIATE DIFFERENTIATION (PPT-ID; WHO GRADE II/III)

Clinical Features and Localisation

This is a pineal parenchymal tumour of intermediate grade malignancy which comprises about 20% of all pineal parenchymal tumours. The tumour occurs at all ages. The clinical features are very similar to that of pineocytoma and distinct imaging features are seen.

Pathology

The tumour exhibits varied histomorphological features. The majority are moderately cellular neoplasms exhibiting a lobular or sheet-like arrangement (Fig. 2). Some of the neoplasms exhibit a neuroendocrine or papillary pattern. There is a moderate degree of nuclear atypia and mitotic activity. There has been some attempt at sub-classifying these tumours according to the extent of mitotic activity.[3] Neuronal differentiation in the form of Homer-Wright rosettes or ganglion cells are seen occasionally. This tumour has a similar immunohistochemical marker profile as pineocytoma.

PINEOBLASTOMA (GRADE IV)

Prognostic and Predictive Factors

This is the most malignant of all pineal parenchymal neoplasms and is a form of primitive neuro-ectodermal tumour. The tumour most often affects children and has a predilection for CSF dissemination in view of its proximity to the CSF cisterns behind the mesencephalon.

Clinical Features and Localisation

The clinical presentation is similar to other pineal parenchymal tumours but the duration of symptoms is shorter than the others.

Imaging Features

On CT scan, pineoblastoma is a lobulated or poorly demarcated, homogeneous mass which is hyperdense after contrast enhancement. The tumour is hypointense to isointense on MRI scan and exhibits significant heterogeneous contrast enhancement. Calcification and extensive cystic change is rare. Infiltration of the surrounding structures and CSF dissemination is commonly seen.[8]

Pathology

Pineoblastomas are poorly differentiated neoplasms with features in common with other central primitive neuroectodermal tumours. They are composed of densely packed small cells with a hyperchromatic nucleus and scanty cytoplasm. Characteristic Homer-Wright and Flexner-Wintersteiner rosettes are seen (Fig. 3). The latter indicates a retinoblastic differentiation. Rarely fleurettes are also seen. All tumours exhibit a very brisk mitotic activity (more than 6 mitoses in 10 high power fields). In addition, apoptosis is also detectable on Hematoxylin and Eosin stained sections. Necrosis is also seen in several tumours. Rarely, a mixed tumour with alternating areas of pineocytoma and pineoblastoma can be noted. Pineoblastomas with mesenchymal or melanotic differentiation are referred to as 'Pineal anlage' tumours. The immunophenotype of pineoblastomas is similar to other pineal parenchymal tumours. The tumour exhibits a high MIB-1 index.[2]

HISTOGENESIS OF PINEAL PARENCHYMAL NEOPLASMS

The pineocyte is a cell with photosensory and neuroendocrine functions in lower animals and is believed to

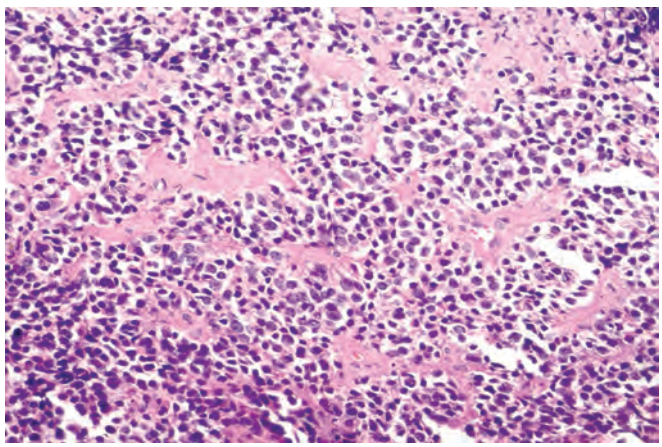


Fig. 2: Pineal parenchymal tumour of intermediate differentiation—the cells are arranged in a lobular manner separated by fibrovascular septa [HE x 160]

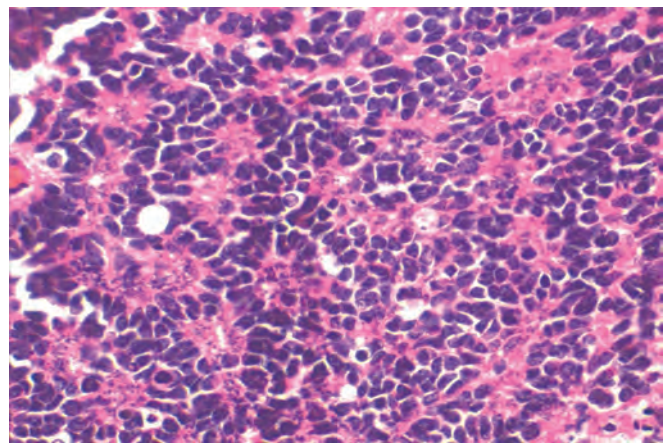

Fig. 3: Pineoblastoma—a highly cellular tumour with Homer-Wright and Flexner rosettes [HE x 320]

be the cell of origin of pineal parenchymal tumours. Ontogenically the pineal gland resembles the phylogeny of the human retina. During the late foetal gestational and early postnatal period, the pineal gland contains primitive cells arranged in small rosettes similar to developing retina. Later, the cells differentiate along neuronal lineage. The pineocyte is a differentiated cell and appears before 1 year age. To a large extent, there is a recapitulation of these developing events in the three groups of pineal parenchymal tumours.[6]

PROGNOSTIC AND PREDICTIVE FACTORS OF PINEAL PARENCHYMAL NEOPLASMS

Prognosis of patients with pineocytoma and PPT-ID after a gross total resection is variable. A 5-year-survival rate is noted in more than 75% of patients with pineocytoma and it ranges from 40 to 75% in patients with PPT-ID.[7] Pineoblastoma patients have a short progression-free survival. In general, some of the factors affecting survival in pineal parenchymal tumours are the morphological sub-type of the tumour, mitotic and MIB-I labelling index, presence of necrosis and neurofilament immunolabelling.[3]

PAPILLARY TUMOUR OF THE PINEAL REGION

This is an uncommon tumour of the pineal region in adults composed of cells with an epithelial morphology arranged as papillary structures. These cells exhibit cytokeratin immunoreactivity and ultrastructurally show features suggesting ependymal differentiation. The tumour grade is variable and may correspond to grade II or III. Only about 38 cases have been reported in literature thus far.[4]

131 Neuronal and Mixed Neuronal Glial Tumours

Sharma MC, Chitra Sarkar

GANGLIOGLIOMA AND GANGLIOCYTOMA

These are well differentiated slow-growing neuroepithelial tumours consisting of neoplastic mature ganglion cells alone (gangliocytoma) or in combination with neoplastic glial cells (ganglioglioma). Both gangliocytoma and ganglioglioma correspond to WHO Grade I (Table 1) but, rarely, the glial component in ganglioglioma can be WHO Grade III.[4] The criteria for Grade II are controversial.[4,29] Ganglion cell tumours are found throughout the neuraxis, but the favoured sites are the cerebral hemispheres, especially the temporal cortex, followed by the cerebellar hemispheres, brainstem, spinal cord, optic chiasm, pituitary and pineal glands. Children and young adults are most commonly affected.[29] The most common presentation is with seizures but, sometimes, these lesions remain subclinical for decades.[6,9,47,71]

Neuroimaging

CT scan shows a well circumscribed mass lesion with a cyst and mural nodule. Calcification in the tumour and scalloping of the overlying bone can also be seen, but features of mass effect are absent. On MRI, this tumour is hypointense on T1WI and hyperintense on T2WI and the mural nodule will enhance.[29] The other brain tumours which show a cyst with mural nodule are pilocytic astrocytoma, pleomorphic xanthoastrocytoma, haemangioblastoma and, sometimes, papillary glioneural tumour (PGNT).

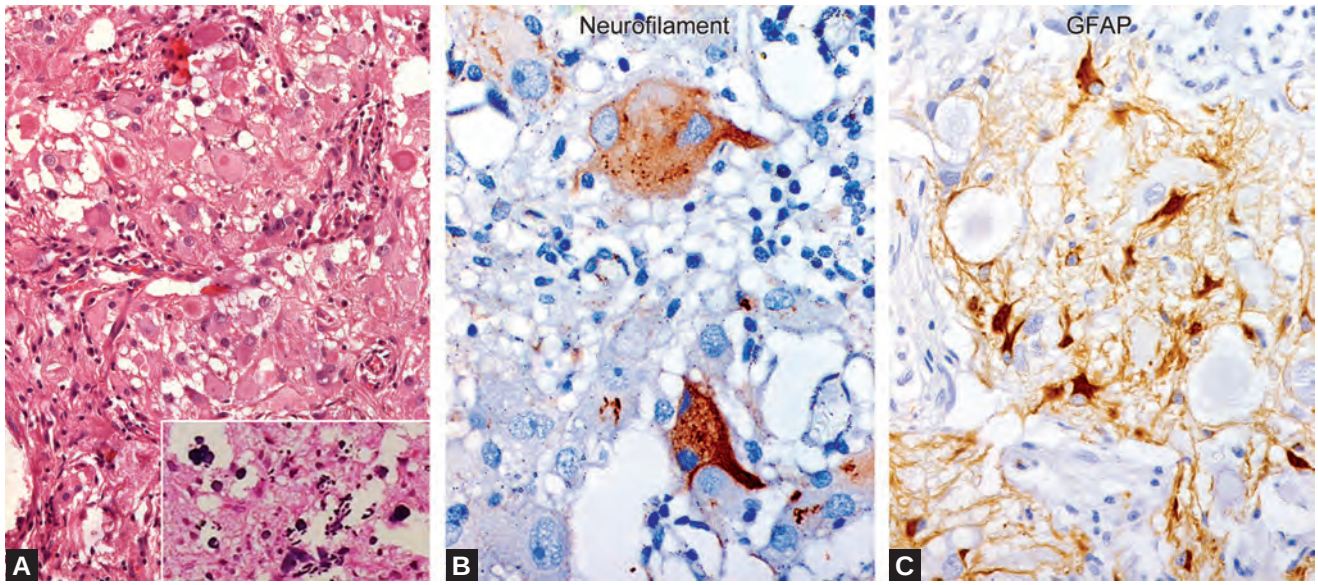
Histopathology

Ganglion cell tumours are typically well circumscribed with expanding margins, and infiltration of the surrounding parenchyma is unusual. Gangliocytoma is composed of nodular aggregates of ganglion cells in a fibrillary background. The individual cell has distinct cellular outlines, eosinophilic cytoplasm and large nucleus with prominent nucleolus. Cytoplasmic vacuolation, irregular distribution of Nissl substance, nuclear pleomorphism and binucleation differentiates a neoplastic cell from a normal neuron in the cortex. Perivascular lymphocytes are common and, sometimes, occur in large numbers to form a lymphoid follicle. Areas of dystrophic calcification are common. Mitosis, necrosis and vascular proliferation are typically absent.[29,47,71]

Gangliogliomas are composed of a dual population of cells consisting of neoplastic ganglion cells admixed with neoplastic astrocytic cells. These two elements may be admixed intimately, or be present separately, any of the two components dominating. The ganglionic component is composed of lobules of large cells with eosinophilc cytoplasm with vacuolation and paucity of Nissl substance (Fig. 1A). Nuclear dysplasia and binucleation favour the neoplastic nature of the cell (Fig. 1B). The glial component comprises of reactive looking astrocytes (Fig. 1C), at times a perfect caricature of pilocytic astrocytoma or oligodendroglioma. Perivascular lymphocytic inflammation and calcification is a frequent finding (Fig. 1A, Inset). Some cases show abundant eosinophilic granular

Table 1: The following tumours are included in the group of neuronal and mixed neuronal-glial tumours as per WHO classification (2007):

S.No.	*Name of the entity*	*WHO grade*
1.	Dysplastic gangliocytoma of cerebellum (Lhermitte-Duclos disease)	Hamartomatous/Grade I if neoplastic
2.	Desmoplastic infantile astrocytoma and ganglioglioma	Grade I
3.	Dysembryoplastic neuroepithelial tumour	Grade I
4.	Gangliocytoma and ganglioglioma	Grade I
5.	Papillary glioneuronal tumour	Grade I
6.	Rosette forming tumour of the fourth ventricle	Grade I
7.	Central neurocytoma and extraventricular neurocytoma	Grade II
8.	Cerebellar liponeurocytoma	Grade II
9.	Spinal paraganglioma	Grade I



Figs 1A to C: (A) Ganglioglioma showing biphasic pattern with lobules of large dysplastic neurons and peripherally placed neoplastic glial component. Note perivascular lymphocytic cuffing and focal calcification (inset). (B) Neurofilament immunostain highlights large binucleate cells with condensation of neurofilament [A:HE x 160, Inset x 100, B: Immunoperoxidase x 300, C: Immunoperoxidase x 240]. (C) GFAP labelled astrocytic component in the midst of ganglion cells

bodies and microcystic change as observed in pilocytic astrocytomas. Necrosis, mitosis or endothelial proliferation is not a common finding. The tumours which show frequent mitoses, necrosis or vascular proliferation in the astrocytic component are designated as anaplastic gangliogliomas of WHO Grade III.[4] The stroma with desmoplasia is commonly seen and this is better appreciated with a special reticulin stain or Masson trichrome stain. This feature is extremely useful in the diagnosis and differentiation from other tumours. Subarachnoid spread is not indicative of aggressiveness of this tumour and is commonly seen in benign CNS tumours.[6,47,71]

The surrounding brain may show areas of dystrophic calcification and neurofibrillary tangles, as seen in Alzheimer's disease. Focal cortical dysplasia (FCD), in the form of loss of laminar architecture or large dysplastic neurons, is seen in some cases.[9]

The ganglionic component is immunopositive for neurofilament proteins (NF), synaptophysin, MAP-2[7,10] and NeuN. CD34 positivity is demonstrated in 70% of the cases, especially in the temporal lobe tumours.[8,19,23,68] The glial component is positive to glial fibrillary acidic protein (GFAP), but is negative to MAP-2 protein. MIB-1 LI is low and sometimes can be spuriously interpreted as high, as infiltrating lymphocytes are also labelled. Grade III gangliogliomas show high MIB-1 LI. Under the electron microscope, the neuronal component shows neurosecretory granules and synapses.

Ganglioglioma needs to be differentiated from a large number of conditions like reactive neurons or glial cells, pilocytic astrocytomas, oligodendrogliomas and low grade diffuse astrocytoma infiltrating the normal brain. Sometimes, it is difficult to discriminate between normal reactive neurons in the cortex and neoplastic ganglion cells. However, loss of polarity, cytoplasm vacuolation, nuclear dysplasia or binucleation and CD34 immunolabelling of the cells favour a neoplasm. Focal clear cell change is seen in ganglioglioma, but diffuse change is likely to favour the diagnosis of oligodendroglioma, and positivity for neuronal markers in the clear cells excludes the diagnosis of oligodendroglioma. The tumours with predominant astrocytic component need to be differentiated from pilocytic astrocytomas and immunopositivity for neuronal markers coupled with negativity for MAP-2 favours the diagnosis of ganglioglioma. MAP-2 positivity is classically seen in true pilocytic astrocytomas but is surprisingly negative in the astrocytic component of ganglioglioma.[39]

Patients with neurofibromatosis-1 (NF-1) and Peutz-Jeghers syndrome are more prone to have ganglioglioma. Genetic abnormalities commonly found in ganglioglioma include gain of chromosome 7 and loss of chromosome 9p.[44]

The histogenesis of ganglioglioma remains unresolved. These tumours probably arise from dysplastic or malformative precursor glioneural lesions with neoplastic transformation of the glial component.[46]

Treatment and Prognosis

Surgical excision is the treatment of choice and curative. Good prognosis is associated with temporal lobe location, long history of epilepsy and complete resection. Seizures may persist in cases associated with cortical dysplasia. Anaplastic transformation is a bad prognostic indicator.[29]

LHERMITTE-DUCLOS DISEASE/DYSPLASTIC GANGLIOCYTOMA OF THE CEREBELLUM

It is a benign cerebellar tumour composed of dysplastic ganglion cells. The exact grade has not been assigned to this lesion in the WHO classification of tumours, as its exact nature is not clear.[4] This lesion was described by Lhermitte and Duclos and by Spiegel in the same year. This entity is also called cerebellar granular cell hypertrophy, diffuse hypertrophy of the cerebellar cortex and gangliomatosis of the cerebellum. Recently, it has been shown that it has a strong association with Cowden disease.

The majority of patients are adults at the time of presentation, although it may present in a range of 3–74 years. Most of the patients present with cerebellar dysfunction and obstruction of the CSF pathway. Mass effect, associated macrocephaly and seizures are common. MRI shows diffuse thickening of the cerebellar foliae.

Histopathology

Under low power magnification the cerebellum looks distorted and enlarged, and still maintains the architecture. The lesion causes diffuse enlargement of the molecular and internal granular layers of the cerebellum which are filled by large pleomorphic ganglionic cells. A layer of abnormally myelinated axon bundles in parallel arrays is observed in the outer molecular layer and extends from the granular layer through the molecular layer, and is better appreciated with myelin stains. Scattered small cells, morphologically consistent with granular neurons, are seen in the subpial region or in the molecular layer. This whole appearance is referred to as inverted cerebellar cortex. Purkinje cells are either absent or markedly reduced in numbers. The associated findings include abnormally ectatic vessels, calcification and vacuoles in the molecular layer or cerebellar white matter.[46]

The neurons are immunopositive for synaptophysin, chromogranin and neurofilament, but are negative for GFAP. Immunohistochemistry also shows loss of PTEN protein and increased expression of phosphorylated-Akt and S6 in the dysplastic neurons. Mitotic response in the cells is low.

This entity is likely to be mistaken for a ganglioglioma if the specimen is fragmented. The geographical confinement to layers of the cerebellum and widened cerebellar folial architecture on MRI are the most helpful in discrimination between the two conditions.

The exact origin of this condition is not known but a hamartomatous origin is favoured. If neoplastic, then it corresponds to WHO Grade I tumour.[46]

DESMOPLASTIC INFANTILE GANGLIOGLIOMA/ASTROCYTOMA

Desmoplastic infantile ganglioglioma (DIG)/astrocytoma (DIA) are large cystic tumours occurring in infants. They involve the superficial cortex, or leptomeninges, are often attached to the dura, show marked desmoplasia and correspond to WHO Grade I. DIG and DIA differ only with respect to the presence of ganglion cells in the former and their absence in the latter. Otherwise they have similar features.[14]

Clinical Features

Desmoplastic astrocytoma was variously described as meningocerebral astrocytoma attached to the dura with desmoplastic reaction or superficial cerebral astrocytoma attached to the dura. Desmoplastic supratentorial neuroepithelial tumours of infancy with divergent differentiation probably belong to the category of DIG.

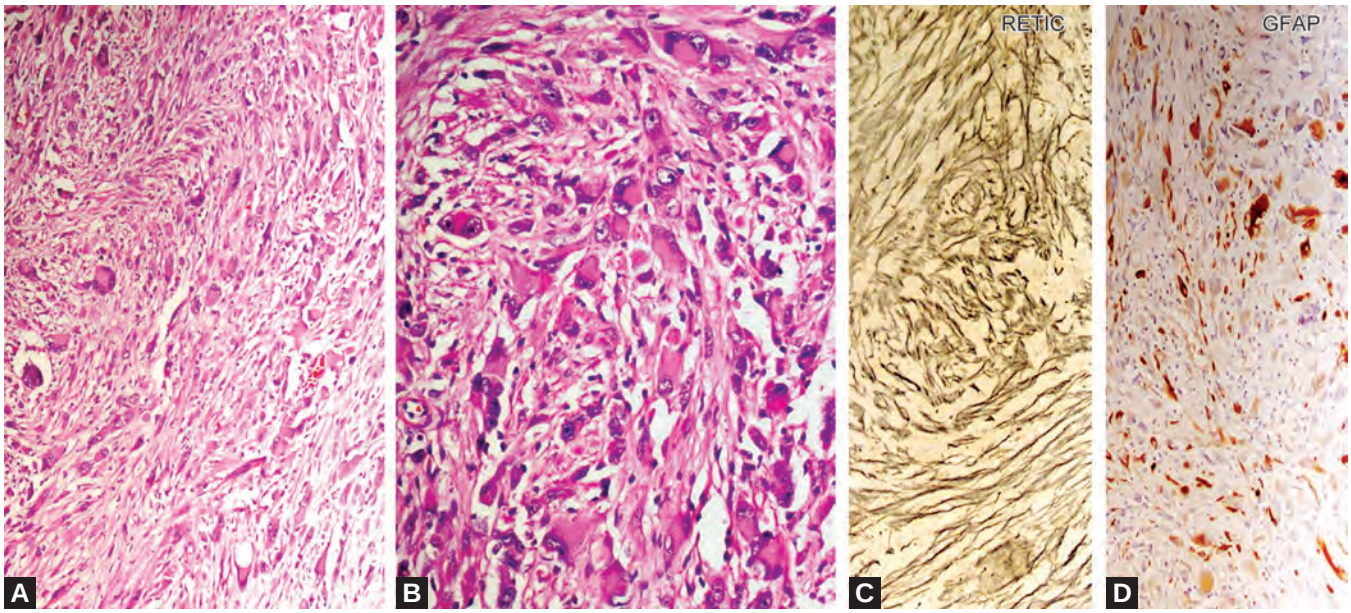
These are rare tumours of childhood, predominantly seen during the 1st year of life. Males are more commonly affected than females, but this male predominance is stronger when they occur between the ages of 5 years and 25 years. Most of the children present with marked enlargement of the head, bulging fontanelles, lethargy and 'setting sun' sign of short duration. Seizures and neurological deficits are uncommon.[14]

Neuroimaging

CT scan shows a large cystic lesion with a solid isodense or hyperdense superficial portion. MRI shows the cystic component to be hypointense on T1WI and hyperintense on T2WI, the superficial solid portion being contrast enhancing. Some authors have described five cardinal diagnostic signs namely: (1) massive size; (2) cystic architecture; (3) superficial position; (4) contrast enhancement and (5) dark desmoplastic component on T2WI, which are helpful in pre-operative diagnosis.

Histopathology

The most important feature of these tumours is desmoplasia (Fig. 2A) which varies in extent from region to region and from tumour to tumour. Some areas may be free of this feature. The lesions have three components: desmoplastic leptomeningeal, poorly differentiated neuroepithelial and cortical components. The leptomeningeal component is composed of fibroblast, like spindle shaped cells and pleomorphic cells, with an eosinophilic cytoplasm arranged in fascicles derived from the glial component (Figs 2A and B). These areas are reticulin rich (Fig. 2C) and mimic mesenchymal tumours. GFAP positive astrocytes are the sole component of DIA (Fig. 2D), but DIG, in addition, contains neuronal components ranging from small neurons to large ganglionic cells. The poorly differentiated neuroepithelial component comprises reticulin poor nodular aggregates of small cells with deeply basophilic nuclei and minimal pleomorphism. Mitoses may be seen in these cells. A multinodular cortical component with microcystic changes may be seen which is devoid of desmoplasia. Areas of calcification may be seen. There is sharp demarcation between the tumour and the underlying cortex, but



Figs 2A to D: (A and B) Desmoplastic infantile Astrocytoma (DIA) showing neoplastic astrocytes arranged in streams with marked desmoplastic components. (C) Reticulin stain demonstrates desmoplastic component encircling the glial components. (D) GFAP immunostain highlights the glial component [A:HE x 100, B:HE x 240, C:Reticulin silver x 120, D:GFAP immunoperoxidase x 120]

perivascular invasion along the Virchow-Robin spaces may be seen.

The desmoplastic component is immunopositive to GFAP (Fig. 2D), vimentin and rarely smooth muscle actin indicating a possible origin of this tumour from glial progenitors or subpial astrocytes. Neuroepithelial cells are positive for GFAP while the neuronal cells are positive for synaptophysin, NF and class III β tubulin. The poorly differentiated neuroepithelial component shows positivity for GFAP, vimentin, MAP-2 and rarely desmin. MIB-1 LI is generally low but may rarely be high, which does not connote aggressiveness.

The desmoplastic component can be mistaken for a mesenchymal tumour and the poorly differentiated neuroepithelial component for a high grade glioma, especially when mitoses are present. The younger age at presentation and radiological findings are important in these situations.[14]

CENTRAL NEUROCYTOMA AND EXTRAVENTRICULAR NEUROCYTOMA

WHO defines central neurocytoma as a neuronal tumour comprising of uniform round cells, typically located in the lateral ventricle in the foramen of Monro region and corresponds to WHO Grade II.[25]

The term central neurocytoma was coined in 1982 by Hassoun et al. They used this term to describe an intraventricular tumour which mimics morphologically an oligodendroglioma but after ultrastructural studies and immunohistochemistry was found to be of neuronal nature. Earlier these tumours were misdiagnosed as intraventicular oligodendrogliomas or ependymomas of the foramen of Monro.[21] Tumours which occur in the lateral, third or fourth ventricle are designated as central neurocytoma (CN), but those which are outside the ventricular system are designated as extraventricular neurocytomas (EVN).[13,16,37,40,57,58,62,64] They comprise about 0.1–0.5% of all intracranial tumours.[25]

Clinical Features

Central neurocytomas are typically located in the supratentorial ventricular system near the foramen of Monro in the lateral or third ventricle. The most common locations are the anterior portion of the lateral ventricle with attachment to the septum pellucidum with or without biventricular extension or extension into the third ventricle.

No gender predilection is noted and the majority of the tumours occur in the second and third decades of life. The duration of symptoms is usually long and patients present with headache, vomiting and visual disturbances. Rarely, an acute presentation due to haemorrhage has been reported.[50,55]

Imaging

Radiologically these tumours are isodense to hyperdense on CT scanning with cystic areas and contrast enhancing areas. Foci of calcification are commonly seen in about half of the patients and, sometimes, these tumours are densely calcified. On MRI, these tumours are isointense on T1WI but hyperintense on T2WI and uniformly to heterogeneously enhancing with contrast.

Histopathology

Intraventricular tumours are well demarcated, greyish and friable with areas of calcification.

On light microscopy, neurocytoma is a perfect caricature of an oligodendroglioma. Neurocytoma is a tumour of variable cellularity and classically shows cellular areas alternating with fibrillary areas. The cellular areas are composed of uniform cells with perinuclear clearing of cytoplasm, and a central, round to oval nucleus with speckled chromatin (Fig. 3A). The background shows a fine fibrillary neuropil-like matrix (Fig. 3B) and intervening thin walled blood vessels, at times hyalinised or dilated and congested. At places, the cells are arranged around the fibrillary areas giving the appearance of vague rosette formation. Rarely, large ganglionic cells are seen amidst them. The fibrillary areas, at places, project on to the blood vessels mimicking the perivascular rosettes of ependymomas. Mitoses are usually absent or occasional.[25,50,55] Increased numbers of mitoses, focal areas of vascular endothelial proliferation and necrosis are rarely seen and these tumours are designated as atypical neurocytomas.[42,61] Microscopic foci of calcification are seen in 50% of the cases (Fig. 3A). Some tumours with extensive ganglionic differentiation are labelled as ganglioneurocytomas.

Tumour cells are positive for synaptophysin (Fig. 3C) and neuron specific enolase (NSE), but negative for GFAP except for focal positivity mainly at the tumour periphery or around blood vessels. Nuclear positivity for NeuN is universally seen, but tumour cells are non-reactive to NF and chromogranin except in the ganglion cells.[50,55,69] MIB-1 LI is usually below 2% and tumours with more than 3% LI are atypical neurocytomas.[54,56]

Ultra structural examination shows dense core neurosecretory granules, microtubules in the cell processes and clear vesicles, but well formed synapses are rare.[28]

Morphologically central neurocytomas resemble oligodendrogliomas. Only by their immunohistochemical profile and ultrastructural characteristics, they can be differentiated from the latter. The striking feature of neurocytomas is the very fine neuropil-like fibrillary matrix as compared to the coarser glial fibrillary matrix of ependymomas. The alternating cellular and sparsely cellular or fibrillary areas, like ependymomas, do occur in neurocytomas, but synaptophysin positivity and lack of ependymal differentiation on ultra structure, differentiate them from ependymomas.[50,55]

The molecular pathogenesis of central neurocytoma is not known, but some genetic changes, like gain on chromosome 7, 2p, 10q, 18q and 13q, are commonly noted and TP53 mutations are not found in this tumour.[24]

Histogenesis

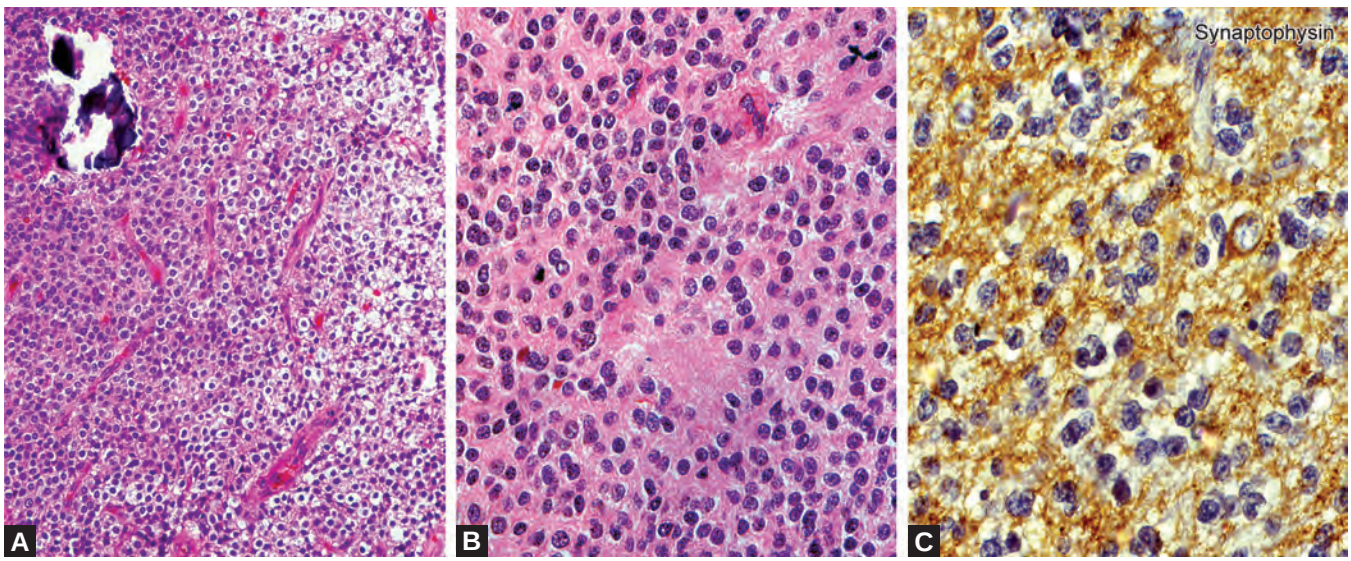
Central neurocytoma supposedly arises from the nuclei of the septum pellucidum and is of neuronal origin, but the presence of reactive looking astrocytic components in the tumour and tissue culture studies support the hypothesis that this tumour arises from primitive neuroglial cells with the capacity to differentiate towards both neuronal as well as astroglial lines.[70]

Treatment and Prognosis

Surgical excision is the treatment of choice but total excision may not be possible due to attachment to the surrounding structures. Some tumours remain stable even after partial excision. Radiotherapy should be reserved for recurrent or partially excised tumours or when surgery is not possible, or in atypical neurocytomas. Some studies have shown that radiotherapy is useful in local control of the tumour. Overall prognosis is good but recurrences are common in atypical cases with high MIB-1 LI. Craniospinal dissemination is rare.

EXTRAVENTRICULAR NEUROCYTOMA

These are neurocytic tumours which are remote from the foramen of Monro and are parenchymal in location, but



Figs 3A to C: (A) Central neurocytoma showing round cells with oligodendroglia-like appearance separated by thin vascular channels and focal calcification. (B) In many areas the cells are separated by intervening fibrillary matrix. (C) The tumour cells are immunopositive for synaptophysin indicating neuronal lineage [A:HE x 160, B:HE x 240, C:Synaptophysin x 300]

can impinge the ventricular system when located near the ventricle. Extraventricular neurocytomas resemble central neurocytomas with some differences.[25]

Clinical Features

The common sites of occurrence are the cerebral hemispheres, cerebellum and spinal cord. Children and young adults are commonly affected. Most of the patients present with mass effect or seizures. Radiologically, these lesions are discrete with frequent calcification and occasional cystic change.

Histopathology

Like central neurocytomas, they are composed of oligodendrocyte-like cells arranged in sheets in a variable fibrillary background. Ganglionic differentiation and areas of dystrophic calcification are common. These tumours are discrete, yet entrap neurons from the normal tissue which needs to be differentiated from ganglionic differentiation of the tumour.[13] The immunohistochemical profile is similar to central neurocytomas.

A radiologically discrete lesion with microscopic appearances of an oligodendroglioma and immunopositivity for synaptophysin favours the diagnosis of a neurocytic tumour rather than a tumour of glial origin.

Treatment and Prognosis

Like classic neurocytomas, extraventricular neurocytomas are expected to have a benign histology and an indolent clinical behaviour. Gross total resection is the treatment of choice. The residual tumour behaves in an indolent manner. Radiotherapy and chemotherapy should be reserved for recurrent or for atypical tumours. Neurocytomas of the spinal cord behave in an aggressive manner and can metastasise.

CEREBELLAR LIPONEUROCYTOMA

Liponeurocytoma is a rare cerebellar tumour of adults with consistent neuronal, variable astrocytic and focal lipomatous differentiation (WHO Grade II).[32]

Clinical Features

The presenting age range of this tumour is 25–77 years (mean age of 50 years) without any gender predilection. The most common location is the cerebellar hemispheres followed by the vermis and cerebellopontine angle. They are rarely seen in the supratentorial compartment. Most of the patients present with cerebellar signs, headache and signs and symptoms of raised intracranial pressure or obstructive hydrocephalus when they impinge on the fourth ventricle.

Neuroimaging

Radiological features vary according to the proportion of lipomatous tissue and, when abundant, can be suspected on imaging. On T1WI they are heterogeneously hyperintense. The adipose tissue corresponds to hyperintense streaks on T2WI and are heterogeneously enhancing.

Histopathology

Classically, this tumour is biphasic comprising of a variable admixture of neuronal and adipose tissue. The tumour cells resemble oligodendrocytes with a central round to oval nucleus surrounded by clear cytoplasm. Mitoses are absent or rare. The lipomatous component resembles mature fat cells but transition from cells with small vacuoles to large vacuoles imparting the signet ring cell appearance can be seen. Necrosis or vascular proliferation is classically absent.[43]

The tumour cells are immunopositive for synaptophysin, NSE and MAP-2. GFAP positive labelling can be seen both in neurocytoma and adipose cells. Rarely, the cells show myogenic differentiation and are desmin positive. MIB-1 LI is low both in the neuronal as well as in the lipomatous components.

The most important differentiation is from lipidised medulloblastoma and ependymoma. Medulloblastoma is a mitotically active small cell tumour, commonly occurring in children. In contrast, this tumour occurs in middle or old age with a low proliferation index. The lipidised cells of medulloblastoma are foamy macrophages rather than the mature looking adipose cells of this tumour. Rarely, medulloblastoma with lipomatous change, akin to this tumour, has been reported in children, but these are mitotically active with high MIB-1 LI. Some ependymomas do show lipomatous change which is focal but other features, like ependymal canals and perivascular pseudorosettes, are present when carefully examined. The clear cell variants of ependymoma are immunopositive to GFAP and show dot-like positivity for epithelial membrane antigen, indicative of intracellular micro lumina formation. Oligodendrogliomas are uncommon in the cerebellum and typically immunonegative to the neuronal markers.

Histogenesis

Immunopositivity for both neuronal and glial markers indicates that this tumour originates from precursor cells with a divergent differentiation potential and possibly arises from the external granular layer. TP53 mutations are common.[32]

Treatment and Prognosis

Surgery is the treatment of choice. The prognosis is favourable and survival varies from 5 to 16 years. Recurrences are common but malignant progression with recurrence has not been reported. No histopathological feature is predictive of recurrence.

PAPILLARY GLIONEURONAL TUMOUR

The WHO defines this entity as a relatively circumscribed, clinically indolent and histologically biphasic cerebral neoplasm comprising of astrocytic and neuronal components (WHO Grade I).[43,45]

Clinical Features

Papillary glioneuronal tumour is a new entity first described by Komori et al. in 1998 as a distinct entity, but tumours described earlier as pseudopapillary neurocytoma with glial differentiation and pseudopapillary ganglioglioneurocytoma probably belong to this category.[12] There is no gender predilection and the age of presentation ranges from 4 to 75 years (mean age of 23.1 years).[3,35,67] Occurrence in the young paediatric population is rare. The most common site of occurrence is in the cerebral hemispheres with a predilection for the temporal lobe, but any lobe can be involved. The most common clinical presentations included headache, visual disturbances, mood changes, gait disturbances and seizures of variable duration.

Neuroimaging

Most of the tumours present as well circumscribed solid and cystic masses, contrast enhancing and without much mass effect. Many of these tumours are cystic with a mural nodule and are close mimics of pilocytic astrocytomas, gangliogliomas, haemangioblastoma and pleomorphic xanthoastrocytoma in this aspect.

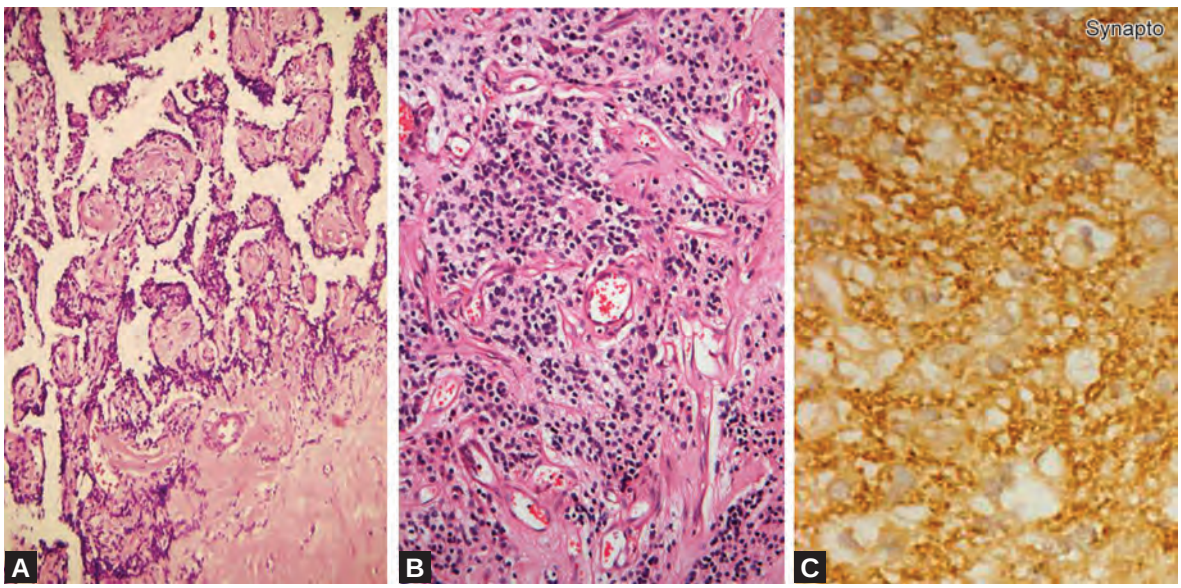
Histopathology

Radiologically as well as pathologically, these tumours are well circumscribed but, rarely, they can be infiltrative. These tumours have predominantly fibrovascular papillae with hyalinised fibrovascular cores, lined by a single to pseudostratified layer of cuboidal astrocytic cells along with sheets of neurocytes amidst papillae (Figs 4A and B). Some of the tumour cells in interpapillary areas are larger with abundant cytoplasm and vesicular nuclei with prominent nucleoli representing ganglion cells. The interpapillary neurocytes have round to oval hyperchromatic nuclei and scant eosinophilic cytoplasm without significant pleomorphism and necrosis. Mitotic activity is usually low. Immunohistochemistry shows diffuse positivity for glial fibrillary acidic protein in the cells along the hyalinised fibrovascular papillae, but the interpapillary cells are positive for synaptophysin (Fig. 4C), Neu N and NCAM. Only ganglionic looking cells are immunopositive for NF. MIB-1 LI is usually low but, rarely, can be high.[2,5,15,20,31,33,38,34,49,65]

The papillary architecture with GFAP positive cells lining these papillae is a helpful feature in the diagnosis of PGNT. Absence of nodular arrangement of ganglionic cells, perivascular lymphocytic collection, calcification and associated cortical dysplasia are helpful features to exclude other mixed glioneural tumours. Location of the lesion along with absence of staining for cytokeratin, epithelial membrane antigen, alfa-feto protein, transthyritin and c-kit (CD117) are helpful to rule out papillary metastatic epithelial tumours.

Histogenesis

The histogenesis of this tumour is not known. However, based on ultrastructural and double labelling immunohistochemical studies, it has been proposed that these neoplasms are neuroepithelial tumours which are capable of differentiating into glial as well as neuronal cells.[2]



Figs 4A to C: (A) Papillary glioneuronal tumour showing papillary gliovascular structures. (B) Higher magnification highlights clustering of small round neuroepithelial cells in interpapillary zones. (C) The cells in interpapillary zones are synaptophysin positive indicating neuronal lineage [A:HE x 80, B:HE x 200, C:Synaptophysin x 240]

Treatment and Prognosis

Surgical excision is the key for management, and chemotherapy/radiotherapy is not recommended if completely excised. Most of the PGNTs reported in the literature had a benign histology but recurrences are described. Cyst formation, hyalinisation of vessels, low mitotic activity and gross total resection of the tumour are indicative of a favourable prognosis.[11]

ROSETTE FORMING GLIONEURAL TUMOUR OF THE FOURTH VENTRICLE

Rosette forming glioneural tumours (RGNTs) are rare slow growing tumours of the fourth ventricular region, preferentially affecting young adults. They are composed of two distinct histological components consisting of neurocytes and a glial component (WHO Grade I).[27]

Clinical Features

RGNT is a rare tumour of young adults with female predominance. The range varies from 12 to 59 years with a mean age of 33 years. The most common location is midline fourth ventricle or aqueduct, but they can extend to involve the adjacent parenchyma of the cerebellar vermis, brainstem or pineal gland. Most of the patients present with signs and symptoms of obstructive hydrocephalus.

Radiologically, these tumours are well circumscribed and are hypointense on T1WI, hyperintense on T2WI with irregular contrast enhancement. Associated hydrocephalus is evident in most of the patients.

Histopathology

Although these tumours are well demarcated radiologically and macroscopically, some microscopic infiltration can be seen. This tumour is typically composed of a dual population of cells consisting of neurocytic and glial components. The neurocytic component consists of a uniform population of cells arranged in a ring-like pattern around a delicate eosinophilic neuropil. Perivascular pseudorosettes are seen. The neurocytic cells show scant amount of cytoplasm, spherical nuclei with fine granular chromatin and indistinct nucleoli. When observed carefully, fine delicate cytoplasmic processes are visible. Associated microcystic and mucoid change like in dysembryoplastic neuroepithelial tumours can be seen in some cases. The glial component looks like a pilocytic astrocytoma and may be the dominant component in some cases. At some places, this may resemble an oligodendroglioma. Mitosis and necrosis are absent, but glomeruloid vascular proliferation is seen in some cases in the astrocytic areas. Dystrophic calcification, eosinophilic granular bodies and haemosiderin deposits may be observed in some.[27]

The neuropil in the centre of the rosette and around the blood vessels is immunoreactive to synaptophysin. The neurocytes are positive to MAP-2 and NSE; the glial component is typically positive to GFAP and S-100 protein, but rosettes are negative to these markers. MIB-1 LI is typically low.[27]

Histogenesis

RGNT is classically seen in the fourth ventricle; therefore, its origin from the periventricular germinal matrix is suggested.

Treatment and Prognosis

Surgery is the treatment of choice, but inherent complications of the surgical procedure do occur due to the location of this tumour. Prognosis is favourable.

DYSEMBRYOPLASTIC NEUROEPITHELIAL TUMOUR

Dysembryoplastic neuroepithelial tumour (DNET) is a benign, usually supratentorial tumour, occurring in childhood or in young adults, characterised by a cortical location, drug resistant partial seizures and characteristic morphology (WHO Grade I).[17]

Clinical Features

In epilepsy surgery, the incidence of DNET is 12% in adults and 13.5% in children. Among all neuroepithelial tumours diagnosed in a single institution, DNET occurs in 1.2% of patients below 20 years of age and in 0.2% beyond 20 years of age with a male preponderance. Most patients present with pharmacoresistant partial seizures with or without secondary generalisation. The most common location is the temporal lobe, but it may occur in the caudate nucleus, septum pellucidum, lateral ventricle, floor of third ventricle, brainstem and cerebellum. Rarely, these tumours are multifocal.

Neuroimaging

MRI shows a well defined cortical lesion which is nodular or triangular in appearance with its apex towards the white matter. They are hypointense on T1WI and hyperintense on T2WI and show single or multiple ring enhancements on contrast injection. Scalloping of the inner table of the skull is a common finding.

Pathology

These tumours are located in the superficial cortex forming nodular expansions indenting the subcortical fibres (Fig. 5A). Extension into the underlying white matter is extremely rare. Grossly, they are mucoid in appearance.

The histological hallmark is the 'specific glioneuronal element' (SGE) described by Dumas-Duport. SGE shows columns formed by bundles of axons lined by oligodendroglial-like cells (OLC) (Fig. 5B), oriented perpendicular to the cortical surface. The lining cells are small with perinuclear clear cytoplasm simulating oligodendroglial

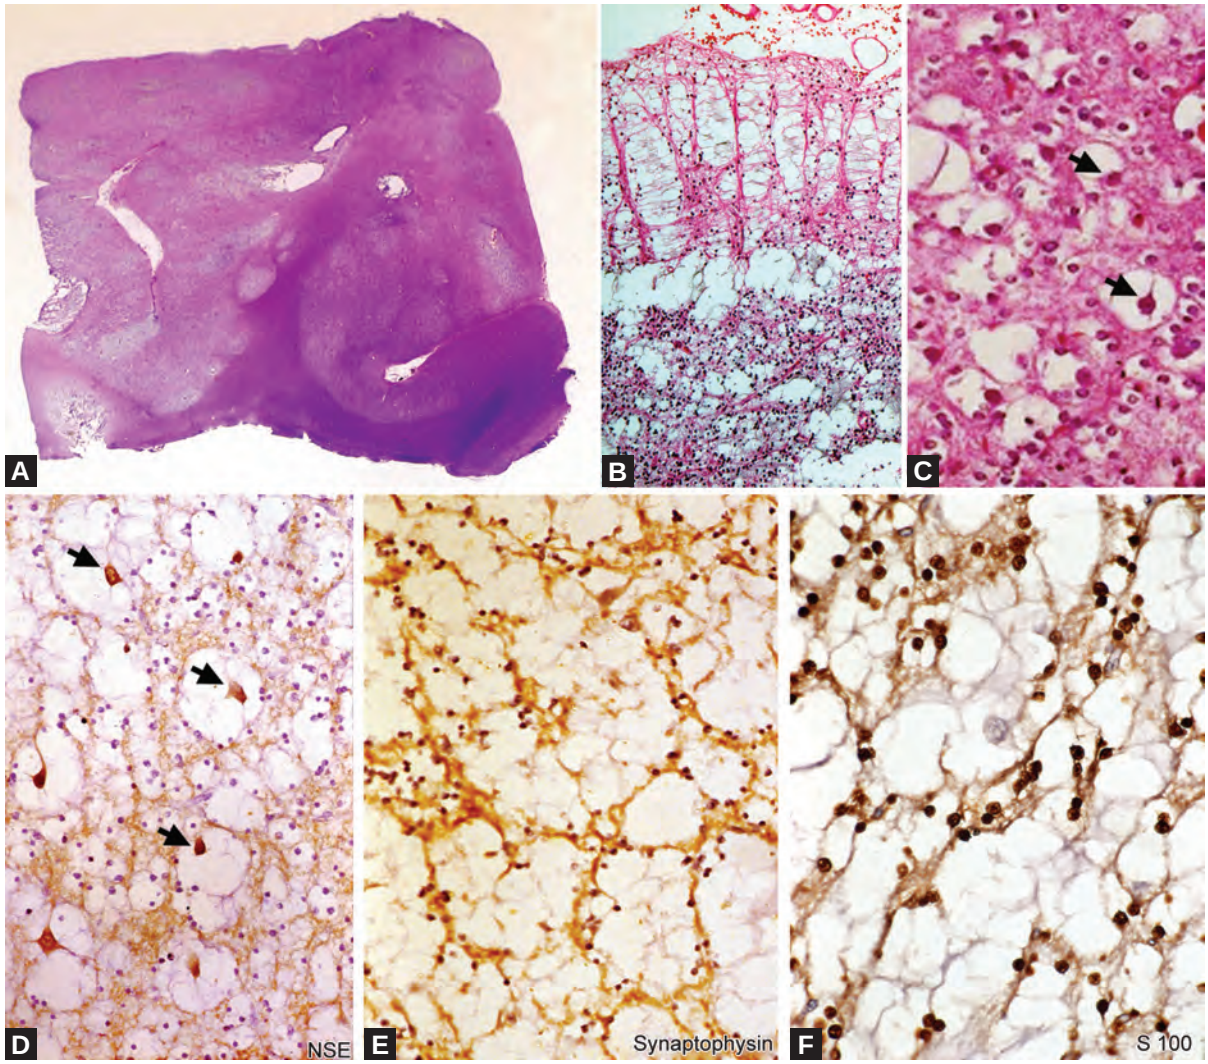
cells. Between these columns normal appearing neurons or large neurons float in a pale basophilic matrix (Fig. 5C) which is positive to alcian blue stain indicating its mucopolysaccharide nature. The scattered cells are positive for NeuN, NSE (Fig. 5D), synaptophysin (Fig. 5E), neurofilaments and class III β tubulin. MIB-1 LI is low.[55] GFAP positive astrocytes are seen between these cells. The small cells of DNT resemble oligodendroglia and are S-100 positive (Fig. 5F). On EM, neurosecretory granules and clear vesicles are seen in the OLC, but synapses are rare. Several morphological variants are described but the following two are well recognised.

Simple Form

This morphological variant shows a unique glioneural element which is focal and juxtaposed to a well recognisable normal cortex.

Complex Form

This variant is multinodular, the nodules containing either glioneuronal elements (SGE) or only a glial component juxtaposed to the cortex or nuclear areas. The constituent cells vary from each focus and from case to case. The 'glial alone' component resembles a low grade glioma, either as a nodule or in a diffuse form. Mitosis is low, but cellular pleomorphism and glomeruloid vascular proliferation resembling high grade gliomas can be present. In between, islands of calcified vessels or tetrangiectatic vessels resembling a vascular malformation can be seen. Cortical dysplasia (CD) of the surrounding cortex is seen in 80% of patients with DNT in the form of disorganisation of the laminar architecture, misaligned cytologically abnormal neurons or neurons in the white matter. A rare pigmented variant and, sometimes, association with a ganglioglioma is also reported.



Figs 5A to F: (A) Dysembryoplastic neuroepithelial tumour (DNET). Whole mount preparation of a lesionectomy specimen showing pale, nodular myxoid lesions expanding the cortical ribbon and indenting the subcortical white matter. (B) Characteristic glioneuronal element in a case of cerebellar DNET showing columns of axon bundles in a myxoid background with oligodendroglia-like cells attached to the columns. (C) Floating neurons in the midst of oligodendroglia-like cells (arrows). (D to F) NSE (D) Labels the floating neurons (arrows), while synaptophysin (E) S100. (F) Mark the glioneuronal element [A:HE x 8, B:HE x 100, C:HE x 240, D:NSE x 160, E:Synaptophysin x 200, F:S100 x 300]

Although DNT has a classical history as well as radiological and pathological features, these glial tumours are sometimes mistaken for other tumours, especially when biopsies are fragmented. The most common differential diagnoses include oligodendroglioma, low grade diffuse astrocytoma and ganglioglioma. Both oligodendrogliomas and DNT involve the cerebral cortex, often possess basophilic mucoid stroma and are composed of similar cells. Normal residual neurons may appear as floating neurons similar to that observed in DNT due to the infiltrating nature of the former lesions. The predominant involvement of white matter, unpatterned nodules, larger nuclei, neuronal satellitosis and presence of mitoses are common in oligodendrogliomas. Moreover, DNET are tumours of young age in contrast to oligodendrogliomas. Gangliogliomas can pose a problem in the differential diagnosis, but the presence of nodules of ganglionic cells, perivascular lymphocytic collection and rich reticulin are helpful in discrimination. Sometimes, DNT can be mistaken for a low grade diffuse astrocytoma, but the radiological appearance, infiltrative nature and absence of floating neurons helps in distinguishing them.

These tumours may occasionally occur in patients with NF-1 or XYY syndrome. No other abnormalities or mutations have been detected in these tumours so far.

Histogenesis

Association with cortical dysplasia, cortical location and young age at the onset of symptoms favours the theory of the malformative nature of this lesion, supposedly arising from the secondary germinal layers. A malignant progression in an occasional case indicates the neoplastic nature.[17]

Treatment and Prognosis

Surgical resection is the treatment of choice and is rewarding, as these tumours are benign and the prognosis is excellent. The tumours which are associated with diffuse cortical dysplasia may continue to produce seizures after surgery. Malignant progression has been described only twice in the literature and both of them presented with atypical features. In one patient, this malignant progression was seen after radiotherapy and chemotherapy.

SPINAL PARAGANGLIOMA

It is a unique neuroendocrine neoplasm, usually encapsulated and benign, arising from specialised neural crest cells associated with segmental or collateral autonomic ganglia (paraganglia) (WHO Grade I).[26,52]

Clinical Features

Earlier paragangliomas were classified as chromaffin and non-chromaffin based on their reaction to chromic acid, but this classification has been discarded as it does not reflect the true functional status. The current terminology is based upon their anatomical location, e.g. carotid body paraganglioma (chemodectoma), jugulotympanic paraganglioma (glomus jugulare tumour), spinal paraganglioma, etc. Usually, a description of functional status, e.g. functional or non-functional is also added.[26]

Paragangliomas of the CNS are rare, but most commonly the CNS is involved due to the intracranial extension of a glomus jugulare tumour of the jugulotympanic paraganglia. Although numerous other locations, like the sellar region, cerebellopontine angle,[18] cerebellar parenchyma, frontotemporal lobes, dura and pineal region, have been described, paraganglioma of the nervous system almost exclusively occurs in the cauda equina region comprising 3.4–3.8% of all tumours in that reg ion.[1,22,30,36,48,51,53,59,60,63,66] The other spinal levels involved are thoracic and cervical regions. The tumours in these locations are usually intradural in location with an intravertebral and paraspinal component.

These tumours are noted between the ages of 9–74 years, the peak age being the fourth to sixth decades with a male preponderance. The commonest clinical presentations are low back pain, followed by motor and sensory deficits in the form of paraparesis, sphincter disturbances and sciatica. Thoracic paragangliomas present with symptoms of spinal cord compression. Tumours producing excess catecholamine present with hypertension. Rarely, the patient may present with ataxia secondary to superficial siderosis following a bleed in the tumour. Patients with jugulotympanic paraganglioma present with pulsatile tinnitus.[30,59,60]

Neuroimaging

MR imaging typically reveals a well-circumscribed mass that is isointense relative to the spinal cord on T1WI and isointense to hyperintense on T2WI. Haemorrhage is common, and a low-signal-intensity rim (cap sign) may be seen on T2WI. Intense enhancement of these highly vascular lesions is virtually always seen after the administration of contrast medium. Serpentine flow voids are sometimes seen capping the tumour, which are believed to be caused by either hypervascularity of the tumour or compression of veins by the mass. Associated syringohydromyelia has been reported in some cases. Radiological features are characteristic and pre-operative diagnosis is possible.

Histopathology

Most spinal paragangliomas are well encapsulated and intradural in location, and are attached either to the filum terminale or caudal spinal nerves. They are sausage shaped reddish brown in colour and may show capsular calcification.

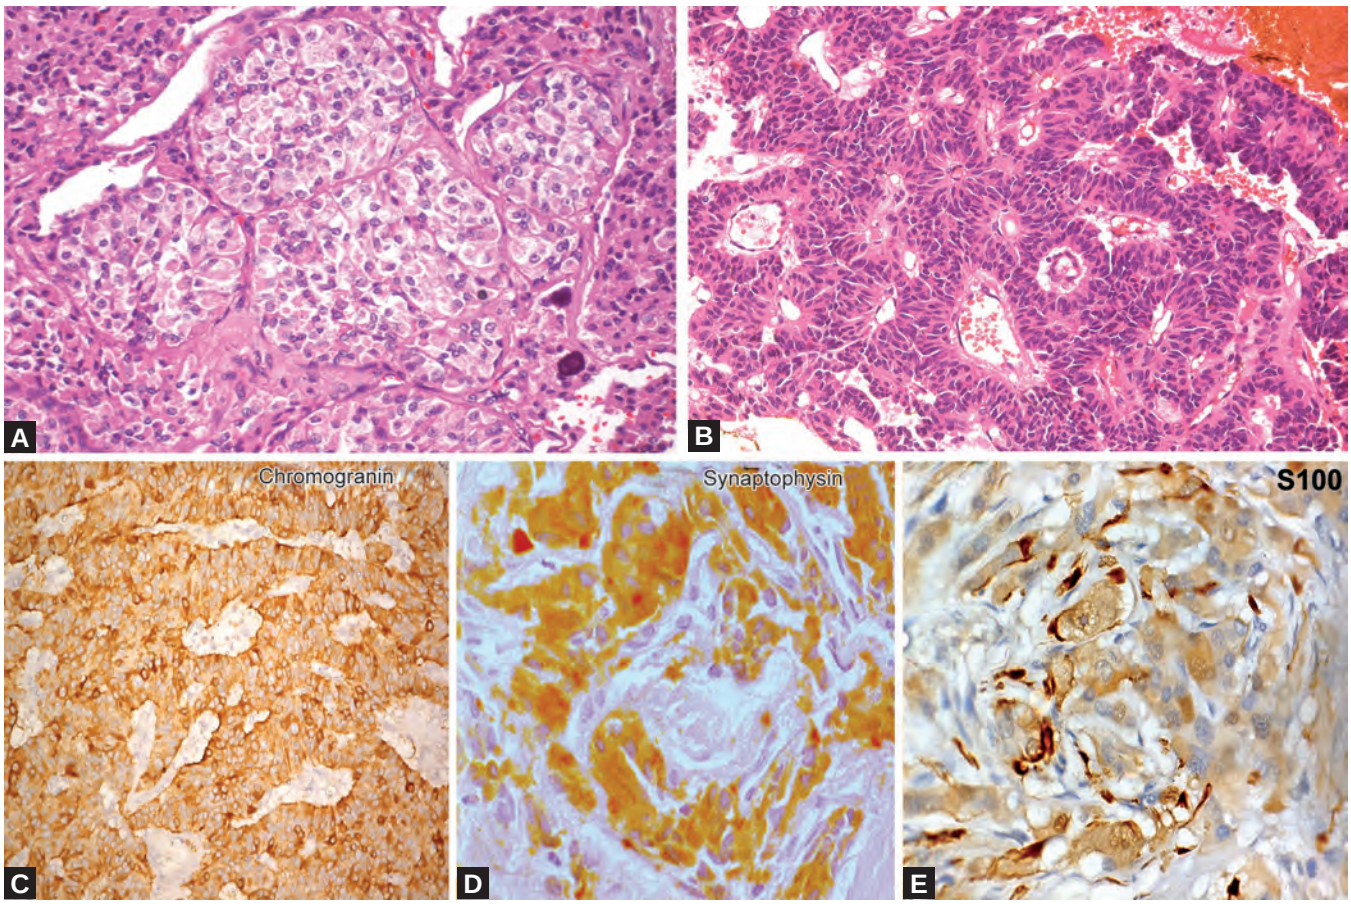
These tumours are composed of sheets and nests of chief (type 1) cells with a neuroendocrine nesting pattern to form "zellballen" (Fig. 6A). These lobules are separated by thin vascular channels with a fine endothelial

lining and occasional dilated sinusoids. There is usually a fine supporting reticulin fibre network separating the tumour islands. Individual cells are polygonal with moderate to abundant eosinophlic finely granular cytoplasm and a centrally placed nucleus. At times, the tumour cells are also seen to be arranged around small vessels reminiscent of pseudorosettes with papillary structures resembling ependymal tumours and are likely to be misdiagnosed as extra-axial ependymomas (Fig. 6B). The nuclear chromatin is fine and granular, and nucleoli are not prominent. The presence of mitosis or necrosis is not the usual feature in spinal paragangliomas, but nuclear pleomorphism secondary to degenerative changes can be seen like other endocrine tumours (endocrine anaplasia). Ganglionic differentiation is seen in some tumours. The sustentacular cells are interstitial spindle shaped cells that encompass the lobules of chief cells.[30,59,60]

The chief cells are immunoreactive to NSE, chromogranin (Fig. 6C), synaptophysin (Fig. 6D) and neurofilament (NF) proteins but negative for GFAP and EMA. Interestingly, dot like positivity for cytokeratin may be present in some cases of spinal paragangliomas. Sustentacular cells are immunopositive for S-100 protein (Fig. 6E) and rarely GFAP positive. Positivity for neuropeptides and serotonin is also reported in some cases. MIB-1 LI is usually low (< 2%) including in recurrent tumours.[30,41]

Ultrastructural examination shows electron dense neurosecretory granules, basal lamina at the interface of Zellballen and surrounding stroma. The sustentacular cells lack neurosecretory granules but contain abundant intermediate filaments.[30,60]

There are no distinct clinical and radiological features. In such a situation, it is difficult to differentiate these tumours from ependymomas or neurofibromas, or other potential causes of cauda equina syndrome. These tumours can even be mistaken for cavernous haemangioma due to the high vascularity at surgery. Even microscopically, these tumours may be misdiagnosed as an ependymoma, as perivascular pseudorosettes, epithelial cords and the papillary nature are a frequent occurrence. The most helpful differentiating features of paraganglioma include: (a) "zellballen" pattern; (b) granular argyrophilia; (c) immunoreactivity for S100 in sustentacular cells and (d) cytoplasmic immunoreactivity for chromogranin, synaptophysin and NSE. Spinal paragangliomas are non-familial.



Figs 6A to E: (A) Paraganglioma of cauda equina shows characteristic 'zellballen' arrangement of tumour cells with intervening thin vascular septa. Focal calcification is present. (B) Trabecular and pseudopapillary arrangement of elongated paraganglioma cells arranged around blood vessels resembling an ependymoma. (C to E) Immunostaining panel shows positive labelling of chief cells with (C) Chromogranin and (D) Synaptophysin. (E) While sustentacular cells are labelled by S100 [A:HE x 160, B:HE x 160, C, D and E:Immunoperoxidase x 240]

Histogenesis

Previously, this tumour was thought to be an unusual form of ependymoma. One school of thought is that these tumours arise from paraganglion cells associated with regional autonomic nerves and blood vessels, whereas others proposed its origin from peripheral neuroblasts normally present in the adult filum terminale which undergo paraganglionic differentiation.

Treatment and Prognosis

Surgical excision is the treatment of choice but the local anatomy may impose a restriction. Recurrences can occur even late following incomplete excision. Rarely, CSF seeding, CNS and bony metastases or metastases outside the CNS can occur. No histological feature is predictive of recurrence or metastasis.[51]

Third Edition: **2012**

ISBN 978-93-5025-072-3

Printed at

This book is dedicated to

Prof B Ramamurthi (1922-2003)

Doyen of Indian Neurosurgery

Contributors

Aadil S Chagla MCh
Professor
Department of Neurosurgery
Seth GS Medical College and KEM Hospital, Parel, Mumbai
Maharashtra, India

Aaron Mohanty MD
Division of Neurosurgery
University of Texas Medical Branch at Galveston, Texas, USA

Abhijit Guha MSc MD FRCS FACS
Professor
Toronto Western Hospital
University of Toronto, Canada

Abrar Ahad Wani MCh
Department of Neurosurgery
Sher-i-Kashmir Institute of Medical Sciences, Srinagar, J & K, India

Ahmad FU
Department of Neurosurgery
University of Miami
Miller School of Medicine, Miami
Florida, USA

Ajay Garg
Department of Neuroradiology
Neurosciences Centre
All India Institute of Medical Sciences
New Delhi, India

Ajaya Nand Jha MCh
Director of Neurosurgery
Max Institute of Neurosciencs
Max Superspeciality Hospital
1, Press Enclave Road, Saket
New Delhi, India

Amit Kapoor DNB
Research Fellow
Indraprastha Apollo Hospital
New Delhi, India

Amit Kumar T
Department of Neurosurgery
Nizam's Institute of Medical Sciences
Hyderabad, Andhra Pradesh, India

Amitabha Chanda MS MCh
Consultant Neurosurgeon
Fortis Hospital, Kolkata
West Bengal, India

Anand S
Division of Interventional Neuroradiology
Seth GS Medical College and KEM Hospital, Parel, Mumbai
Maharashtra, India

Anil Karapurkar MS (General Surgery)
MS (Neurosurgery)
Endovascular Neurosurgeon
Jupiter Hospitals, Mumbai
Maharashtra, India

Anil Kumar Singh MCh
Director, Neurosciences
Fortis Hospitals, Noida, UP, India

Anil Nanda
Professor and Chairman
Department of Neurosurgery
LSU Health Sciences Center
Shreveport, Louisiana (LA), USA

Anil Pande BSc MBBS DNB MNAMS
Consultant Neurosurgeon and Spine Surgeon, Postgraduate Institute of Neurological Surgery
Dr A Lakshmipathi Neurosurgical Centre
VHS Hospital, Chennai
Tamil Nadu, India

Animesh Upadhyay
Department of Neurosurgery
Seth GS Medical College and KEM Hospital, Parel, Mumbai
Maharashtra, India

Anita Mahadevan MD
Assistant Professor
Department of Neuropathology
NIMHANS, Bengaluru, Karnataka, India

Anooj Chatley MS MCh
Department of Neurosurgery
Ludhiana Medi Citi Hospital
Ludhiana, Punjab, India

Anthony Sin MD
Assistant Professor of Neurosurgery
Director of Complex Spinal Disorder
LSU Health Science
Shreveport, Louisiana (LA), USA

Anuj Chaitley
Department of Neurosurgery
Sanjay Gandhi Postgraduate Institute of Medical Sciences
Lucknow, UP, India

Archana Juneja DM DNB [Endo] MNAMS
Consultant Endocrinologist
Seven Hills Hospital
Mumbai, Maharashtra, India

Arivazhagan A
Assistant Professor
National Institute of Mental Health and Neurosciences, Bengaluru
Karnataka, India

Arun Kumar Singh MS MCh (Plastic)
Department of Plastic and Reconstructive Surgery
Chattrapati Shahuji Maharaj
Medical University, Lucknow, UP, India

Ashalatha
R Madhavan Nayar Centre for Comprehensive Epilepsy Care
Sree Chitra Tirunal Institute for Medical Sciences and Technology
Trivandrum, Kerala, India

Ashish Suri MCh DNB
Associate Professor, Neurosurgery
All India Institute of Medical Sciences
New Delhi, India

Ashok Kumar Mahapatra
Professor and Head
Department of Neurosurgery
All India Institute of Medical Sciences
New Delhi, India

Atul Goel MCh
Professor and Head
Department of Neurosurgery
Seth GS Medical College and KEM Hospital, Parel, Mumbai
Maharashtra, India

Awadhesh K Jaiswal
Department of Neurosurgery
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, UP, India

Babu KS MSc MPhil PhD
Sr Scientist
Christian Medical College
Vellore, Tamil Nadu, India

Balasubramaniam V
Former Professor of Neurosurgery
Madras Medical College
Chennai, Tamil Nadu, India

Bernard Lyngdoh
Consultant Neurosurgeon
Nazareth Hospital, Shillong
Meghalaya, India

Bhagwati SN MCh
Director of Neurosurgery and Chief Neurosurgeon
Bombay Hospital Institute of Medical Sciences, Mumbai, Maharashtra, India

Bhaskara Rao Malla DNB (Neurosurgery)
Consultant Neurosurgeon
Kokilaben Dhirubhai Ambani Hospital and Medical Research Institute
Mumbai, Maharashtra, India

Bhawani S Sharma
Professor and Head
Department of Neurosurgery
All India Institute of Medical Sciences
New Delhi, India

Bijoy Thomas MD
Department of Imaging Sciences and Interventional Radiology
Sree Chitra Tirunal Institute for Medical Sciences and Technology
Trivandrum, Kerala, India

Bobby Jose DNB
Consultant Neurosurgeon
MOSC Medical College
Kolenchery, Kerala, India

Chandramouli BA
Consultant Neurosurgeon
Vikram Hospital, Millers Road
Bengaluru, Karnataka, India

Chandranath Sen MD
Department of Neurosurgery
NYU Langone Medical Center, USA

Chhabra DK
Department of Neurosurgery
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, UP, India

Chhabra R MS MCh
Associate Professor
Department of Neurosurgery
Postgraduate Institute of Medical Education and Research
Chandigarh, India

Chidambaram Balasubramaniam MCh
Consultant Neurosurgeon
Department of Paediatric Neurosurgery
Kanchi Kamakoti Childs Trust Hospital
Chennai, Tamil Nadu, India

Chitra Sarkar MD FASc FNASc FICP
Professor of Pathology
All India Institute of Medical Sciences
New Delhi, India

Das NK MS MCh
Department of Neurosurgery
Bokaro General Hospital
Bokaro, Jharkhand, India

David A Omahen MD FRCSC
Clinical Fellows in Neuro-oncology
Toronto Western Hospital
University of Toronto, Canada

Debabrat Biswas
Department of Neurosurgery
NIMS, Hyderabad
Andhra Pradesh, India

Deepak Agrawal MS MCh
Assistant Professor (Neurosurgery)
Department of Neurosurgery
Neurosciences and Gamma Knife Centre
All India Institute of Medical Sciences
New Delhi, India

Deepak Kumar Gupta MS MCh
Assistant Professor Neurosurgery
Neurosciences Centre and Assoc JPN
Apex Trauma Centre, All India Institute of Medical Sciences, New Delhi, India

Deepu Banerji MCh
Consultant Neurosurgeon
Fortis Hospitals, Mulund, Mumbai
Maharashtra, India

Deopujari CE MCh
Department of Neurosurgery
Bombay Hospital and Medical Research Centre, Mumbai
Maharashtra, India

Dharkar SR
Director of Neurosurgery
SK Soni Hospital, Jaipur, Rajasthan, India

Dilip Panicker MCh
Department of Neurosurgery
Amrita Institute of Medical Sciences and Research Centre, Kochi, Kerala, India

Dinesh Nayak S
R Madhavan Nayar Centre for Comprehensive Epilepsy Care
Sree Chitra Tirunal Institute for Medical Sciences and Technology
Trivandrum, Kerala, India

Ganapathy K MS (Neuro) FACS FICS FAMS PhD
Senior Consultant Neurosurgeon and Head, Division of Stereotactic Radiosurgery, Apollo Hospitals
Chennai, Tamil Nadu, India

Ganesh K Murthy MCh
Professor
Sri Sathya Sai Institute of Higher Medical Sciences
Bengaluru, Karnataka, India

Geeta Chacko MD
Department of Neurological Sciences and Pathology
Section of Neuropathology
Christian Medical College
Vellore, Tamil Nadu, India

Girish Menon MCh, Dip NB
Additional Professor
Sree Chitra Tirunal Institute of Medical Education and Technology
Trivandrum, Kerala, India

Goutham Cugati DNB (Neurosurg)
Assistant Professor
Department of Neurosurgery
JSS Medical College
Mysore, Karnataka, India

Grover VK MCh
Department of Neurosurgery
Postgraduate Institute of Medical Education and Research
Chandigarh, India

Gupta A
Department of Neurosurgery
All India Institute of Medical Sciences
New Delhi, India

Gupta D
Department of Anaesthesiology
Sanjay Gandhi Postgraduate Institute of Medical Sciences
Lucknow, UP, India

Gupta SK MS MCh MAMS
Professor
Department of Neurosurgery
Postgraduate Institute of Medical Education and Research
Chandigarh, India

Gupta Vivek MCh
Department of Neurosurgery
Postgraduate Institute of Medical Education and Research
Chandigarh, India

Haresh KP
Department of Radiation and Oncology
Dr BRA IRCH
All India Institute of Medical Sciences
New Delhi, India

Harinivas
Resident
Postgraduate Institute of Neurological Surgery
Dr A Lakshmipathi Neurosurgical Centre
VHS Hospital, Chennai
Tamil Nadu, India

Harjinder S Bhatoe MCh
Department of Neurosurgery
Command Hospital, Pune
Maharashtra, India

Hazem Eltahawy MD PhD FRCSI
Clinical Fellows in Neuro-oncology
Toronto Western Hospital
University of Toronto, Canada

Indira Devi
Professor
Department of Neurosurgery
National Institute of Mental Health and Neurosciences, Bengaluru
Karnataka, India

Jagan Mohan Reddy K MCh
Department of Neurosurgery
NIMS, Hyderabad
Andhra Pradesh, India

Jain S MD
Department of Neurosurgery
Tampa, Florida, USA

Jayanti Mani DM
Consultant Neurologist and Epileptologist
Kokilaben Dhirubhai Ambani Hospital and Medical Research Institute
Mumbai, Maharashtra, India

Julka PK
Professpr of Radiation and Oncology
Dr BRA IRCH
All India Institute of Medical Sciences
New Delhi, India

Kanaka TS MCh PhD
Former Professor of Neurosurgery
Madras Medical College
Chennai, Tamil Nadu, India

Kakani AB MCh
Department of Neurosurgery
Bombay Hospital Institute of
Medical Science, Mumbai
Maharashtra, India

Kesavdas
Consultant Radiologist
Imaging Sciences and Interventional
Radiology
Sree Chitra Tirunal Institute for
Medical Sciences and Technology
Trivandrum, Kerala, India

Khan Z
Department of Neurosurgery
Max Superspeciality Hospital
West Wing, Saket, New Delhi, India

Khandelwal N MCh
Department of Neurosurgery
Postgraduate Institute of Medical
Education and Research
Chandigarh, India

Khosla VK
Former Professor and Head
Department of Neurosurgery
Postgraduate Institute of Medical
Education and Research
Chandigarh, India

Krishna Reddy A MS MCh
Chief Neurosurgeon
KIMS Hospital
Hyderabad, Andhra Pradesh, India

Mahmoud Rashidi MD
Consultant Neurosurgeon
New Hampshire Neurospine Institute
4 Hawthorne Drive, Bedford, USA

Manas Kumar Panigrahi MCh
(NIMHANS)
Consultant Neurosurgeon
Krishna Institute of Medical Sciences
Secunderabad, Andhra Pradesh, India

Manish S Sharma
Assistant Professor of Neurosurgery
(Gamma Knife)
Department of Neurosurgery
All India Institute of Medical Sciences
New Delhi, India

Manish Singh DNB
Senior Resident
Department of Neurosurgery
The Jawaharlal Institute of Postgraduate
Medical Education and Research
Puducherry, India

Manjari Tripathi MBBS DM
Additional Professor
Department of Neurology
Neurosciences Centre
All India Institute of Medical Sciences
New Delhi, India

Manoj Jain
Associate Professor
Pathology Department
Sanjay Gandhi Postgraduate Institute of
Medical Sciences, Lucknow
UP, India

Mathew A MS FRCS MCh
Associate Professor
Department of Neurosurgery
Sree Chitra Tirunal Institute of Medical
Education and Technology
Trivandrum, Kerala, India

Mathuriya SN
Professor and Head
Department of Neurosurgery
Postgraduate Institute of Medical
Education and Research
Chandigarh, India

Mehta VS
Consultant Neurosurgeon
Paras Hospitals, Gurgaon
Haryana, India

Menezes AH
Department of Neurosurgery
University of Iowa Hospitals and Clinics
Iowa City, Iowa, USA

Mohan Kameswaran MS FRCS
Edinburgh
Managing Director and Senior Consultant
Madras ENT Research Foundation
Chennai, Tamil Nadu, India

Mukherjee KK MCh
Additional Professor
Department of Neurosurgery
Postgraduate Institute of Medical
Education and Research
Chandigarh, India

Murali Mohan S DNB (Neurosurg)
Assistant Professor
Department of Neurosurgery
MS Ramaiah Medical College
Bengaluru, Karnataka, India

Murthy S MD DM
Consultant Endocrinologist
Endocrine Diagnostics and
Research Centre, Chennai
Tamil Nadu, India

Muthukumar N MCh MNAMS
Department of Neurosurgery
Madurai Medical College
Madurai, Tamil Nadu, India

Muzumdar D MCh
Associate Professor
Department of Neurosurgery
Seth GS Medical College and KEM
Hospital, Parel, Mumbai
Maharashtra, India

Nalin K Mishra
Professor and Head
Department of Neuroradiology
All India Institute of Medical Sciences
New Delhi, India

Narayanan R
Consultant Neurosurgeon
Life Line Hospital, Chennai
Tamil Nadu, India

Naveen Mehrotra MS MCh
Consultant Neurosurgeon
Sunshine Hospitals, Secunderabad
Andhra Pradesh, India

Nigel Peter Symss Dip NBE
Consultant Neurosurgeon
Postgraduate Institute of
Neurological Surgery
Dr A Lakshmipathi Neurosurgical Centre
VHS Hospital, Chennai
Tamil Nadu, India

Nishant Aditya MD (Radiology)
Interventional Neuroradiologist
Hospital, Mumbai, Maharashtra, India

Nitin Garg
Department of Neurosurgery
National Institute of Mental Health and
Neurosciences, Bengaluru
Karnataka, India

Nitin Mokal
Plastic Surgeon
Grant Medical and Sir JJ Group of
Hospitals, Mumbai, Maharashtra, India

Pallav Garg
Department of Neuropathology
Sanjay Gandhi Postgraduate Institute of
Medical Sciences, Lucknow, UP, India

Paresh K Doshi MS MCh
Consultant Neurosurgeon-in-charge
Functional and Stereotactic
Neurosurgery, Jaslok Hospital and
Research Centre Mumbai
Maharashtra, India

Pathak A MCh
Professor
Department of Neurosurgery
Postgraduate Institute of Medical
Education and Research
Chandigarh, India

Phuljhele S
Dr Rajendra Prasad Centre for
Ophthalmic Sciences
All India Institute of Medical Sciences
New Delhi, India

Pradeep Kumar Jain N
Senior Resident
Postgraduate Institute of
Neurological Surgery
Dr A Lakshmipathi Neurosurgical Centre
VHS Hospital, Chennai
Tamil Nadu, India

Prakash Singh MD
Department of Neurosurgery
Command Hospital (SC) and
Armed Forces Medical College
Pune, Maharashtra, India

Pramod Giri MS MCh
Department of Neurosurgery
Government Medical College and
Superspeciality Hospital
Nagpur, Maharashtra, India

Prasad AN DNB
Senior Registrar
Department of Neurosurgery
Royal Preston Hospital
Preston, United Kingdom

Priya Gupta
Senior Resident
Department of Neurology
All India Institute of Medical Sciences
New Delhi, India

Punita Lal
Department of Radiotherapy
Sanjay Gandhi Postgraduate Institute of
Medical Sciences, Lucknow, UP, India

Purohit AK MS MCh
Professor and Head
Department of Neurosurgery
NIMS, Hyderabad
Andhra Pradesh, India

Purohit D MCh
Associate Professor
SMS Medical College Hospital
Jaipur, Rajasthan, India

Purushothaman V
Consultant Plastic Surgeon
Malar Hospital, Chennai
Tamil Nadu, India

Rabi N Sahu
Department of Neurosurgery
Sanjay Gandhi Postgraduate Institute of
Medical Sciences, Lucknow, UP, India

Radhakrishnan K
Professor and Head
Department of Neurology
Sree Chitra Tirunal Institute for
Medical Sciences and Technology
Trivandrum, Kerala, India

Radhakrishnan VV MD
Head of Department
Department of Pathology
Sree Chitra Tirunal Institute for
Medical Sciences and Technology
Thiruvananthapuram, Kerala, India

Rahmathulla G DNB
Clinical Scholar
Department of Neurosurgery
Cleveland Clinic Foundation, Ohio
USA

Raja Reddy D MS MCh
Emeritus Professor of Neurosurgery
Nizam's Institute of Medical Sciences
Hyderabad, Andhra Pradesh, India

Rajan Shah MCh
Department of Neurosurgery
Bombay Hospital Institute of
Medical Science, Mumbai
Maharashtra, India

Rajasekar V MBBS MCh (Neuro)
Professor of Neurosurgery
Department of Neurological Sciences
Christian Medical College
Vellore, Tamil Nadu, India

Rajesh Reddy S
Department of Neurosurgery
NIMS, Hyderabad
Andhra Pradesh, India

Rajiv Kumar MCh
Department of Neurosurgery
Bombay Hospital Institute of
Medical Science, Mumbai
Maharashtra, India

Rajkumar MCh
Head of the Department
Department of Neurosurgery
Sanjay Gandhi Postgraduate Institute of
Medical Sciences, Lucknow
UP, India

Ramachandran B
Department of Paediatric Neurosurgery
Kanchi Kamakoti Childs Trust Hospital
Chennai, Tamil Nadu, India

Ramakrishna Eswaran MCh
Consultant Neurosurgeon
Maruti Brain and Spine Centre
Maruti Hospital, Trichy, Tamil Nadu, India

Ramamurthi B (Late)
Founder, Professor and Head
Postgraduate Institute of
Neurological Surgery
Dr A Lakshmipathi Neurosurgical Centre
VHS Hospital
Chennai, Tamil Nadu, India

Ramdurg S
Department of Neurosurgery
All India Institute of Medical Sciences
New Delhi, India

Ramesh Kumar Sharma
Professor and Head
Department of Plastic Surgery
Postgraduate Institute of Medical
Education and Research
Chandigarh, India

Rao BRM
Department of Neurosurgery
Sree Chitra Tirunal Institute for
Medical Sciences and Technology
Trivandrum, Kerala, India

Rath GK
Department of Radiation and Oncology
Dr BRA IRCH, All India Institute of
Medical Sciences, New Delhi, India

Ravi Ramamurthi MS (Neurosurgery)
FRCS Ed (SN)
Head of the Department of
Neurosurgery
Postgraduate Institute of
Neurological Surgery
Dr A Lakshmipathi Neurosurgical Centre
VHS Hospital, Chennai
Tamil Nadu, India

Ravi Shankar S
Department of Neurosurgery
BGS Global Hospital
Bengaluru, Karnataka, India

Ravikant Palur
Associate Professor
Department of Neurosurgery
University Technology, MARA, Malaysia

Ravindranath Kapu
Senior Resident
Postgraduate Institute of
Neurological Surgery
Dr A Lakshmipathi Neurosurgical
Centre, VHS Hospital, Chennai
Tamil Nadu, India

Roshni Paul T
Associate Professor in Pathology
Department of Pathology
Nizam's Institute of Medical Sciences
Hyderabad, Andhra Pradesh, India

Rupant K Das
Department of Neurosurgery
Sanjay Gandhi Postgraduate Institute of
Medical Sciences, Lucknow, UP, India

Sachin A Borkar MCh

Preface

Since the publication of the second edition of this Textbook in 1996, phenomenal advances have been made towards improved understanding of the pathophysiology of various neurosurgical disorders, their diagnosis and therapy. Advances in molecular biology and genetics on one hand, the refinements of imaging technologies, introduction of image-guided techniques for neuronavigation, and refinements in endoscopic and minimally invasive procedures on the other hand have markedly reduced the morbidity and mortality of neurosurgery. Simultaneously, better availability of radiosurgery and safer endovascular approaches have led to the development of non-surgical therapy for a variety of lesions.

Recent years have witnessed a rapid increase in the number of well-equipped neurosurgical departments across the country providing both state-of-the-art services to the patients and training to specialists in the diverse subdisciplines of neurosurgery. It has been our endeavour to meet their needs for an updated account of the current knowledge of the subject.

The third edition of the textbook includes a comprehensive account of all the recent advances succinctly provided by a galaxy of outstanding contributors especially selected on the basis of their expertise and experience. Care has been taken to include relevant published literature both from India and abroad.

As in earlier editions, special attention has been given to tropical disorders not often adequately covered in publications of the West. This may be an additional attraction for neurosurgeons in other developing countries as also to those in the developed ones who often encounter such conditions in their practice.

The present editors deeply miss the invaluable, wise and experienced guidance of the Senior Editor Prof B Ramamurthi who was the moving spirit behind the earlier editions. The editors would like to thank all the contributors, their associates and the secretarial staff for their co-operation. The Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India deserve our special thanks for the excellent quality of the publication.

Caraka Samhita

The early medical writer Caraka tells us that when setting out to learn about Indian medicine, we should have certain criteria in mind for choosing the texts we wish to study (Caraka. 3.8.3):

"A discerning person who wants to become a physician should start by selecting a text based on a consideration of his ability to cope with hard or easy tasks, the results he is after, the likely aftermath, the place and the time. After all, there are numerous physicians' manuals in circulation in the world, so he should apply himself only to a text which is extremely famous, which is used by scholars, which covers a lot of topics and is respected by qualified people. It has to be good for pupils of all three levels of ability, and it should not be flawed by repetitiousness. It should be derived from the tradition of the saints. The connection and the sequence of the text and commentary should be well organised. It should be solidly based, and have no corrupt or missing words. It should be full of significance, its ideas should follow in sequence and it should give importance to the exactness of what ideas really refer to. Its ideas should be coherent and its topics should not be haphazard. It should have both definitions and examples.

This type of text is like a flawless sun; it dispels darkness and throws light on everything."

132 Clinical Features of Intracranial Tumours

Ravi Ramamurthi, Santosh Mohan Rao K

INTRODUCTION

The early and accurate diagnosis of intracranial space occupying lesions (ICSOL) and their skilful removal with minimal resultant neurological deficit is the most important aspect of a neurosurgeon's work. ICSOL are problems of concern for the neurosurgeons due to the associated increase in intracranial pressure (ICP) and the haunting spectre of a resultant permanent neurological deficit. Compared to some decades ago, widespread awareness of the incidence of intracranial lesions among the public and the profession, along with modern non-invasive diagnostic techniques, help us to diagnose early and adopt a safer surgical approach.[22] However, due to various social, economic and environmental factors, there will continue to be many patients who may seek neurological help late. Such cases need all our diagnostic acumen and surgical skill.

IMPORTANCE OF CLINICAL ASSESSMENT

Based on a precise knowledge of neural organisation in the brain and a careful assessment of the symptoms and signs of a patient with an intracranial tumour, it should be possible to accurately localise the majority of lesions. This is true for a large number of tumours, except in very early cases and in those occurring in the so-called silent areas of the brain. In the late stages, non-specific pressure effects result in false localising signs which complicate the clinical picture and create confusion in localisation.[85] Advances in neuroradiology and imaging techniques, like CT scanning and MR, have resulted in great reliance being placed upon these methods for localisation. This has led to the tendency to minimise the efforts spent over history-taking and careful neurological examination. In spite of all technical diagnostic advances, only careful recording of the history and clinical examination can lead to a proper overall evaluation necessary for the rational planning of investigations and treatment. Clinical wisdom lies in checking this tendency to rush the patient through a number of unnecessary investigations and in realising the importance of the clinical picture and its evolution.

Physical signs of derangement of neurological or mental functions provide the clues to the site of involvement in the nervous system and the answer to the question, 'Where is the lesion?' Careful elicitation of the history provides information about the mode of onset and the pattern and temporal profile of the progress of the disease. This is valuable for determining the pathology of the lesion to answer the question— "What is the lesion?" For example, the sudden onset of symptoms in a vascular lesion or the rapid progression of a highly malignant lesion, the slow progress of a benign neoplasm and the remission and exacerbation of symptoms in some special types of vascular lesions, in some varieties of meningiomas and some neurological conditions like multiple sclerosis.

The term 'intracranial tumours' includes, in a loose fashion, all space-occupying lesions within the cranial cavity including non-neoplastic lesions like cysts, granulomas, chronic abscesses and haematomas. This is because the pathogenesis and evolution of symptoms and localising features are common to many of these lesions, irrespective of their pathology. The term ICSOL is more acceptable.

ICSOL cause clinical symptoms by: (1) raising the ICP; (2) interfering with the function of the area involved by the lesion; (3) disturbing the function of neighbouring structures due to oedema or vascular disturbances and (4) by displacement and distortion of remote structures due to various herniations. As neural function has often a hierarchical organisation, damage to one region may, by removing its inhibitory control over the "lower" region, result in the manifestation of release symptoms and signs. One of the symptoms may manifest itself first or these may all begin to appear at the same time and progress at varying rates.

RAISED INTRACRANIAL PRESSURE— PATHOGENESIS

Except in infants and young children, the cranial cavity is not expansile and thus any addition of matter inside the cranial cavity results in an increase in pressure. In the early stages, some amount of adjustment may occur by displacement of a small quantity of CSF and venous blood. But this can accommodate only a small amount of extra matter. If the lesion increases in size, it has to accommodate itself by compressing the brain and the other intracranial structures with a resultant increase in ICP. The factors that determine the rise in ICP are: (1) the bulk of the tumour and the rapidity of its growth;

(2) associated cerebral oedema; (3) its effect on the CSF pathways with obstruction of CSF circulation and (4) compression of the major venous channels.

1. *The bulk of the tumour and rapidly of its growth*: A slow growing lesion, like a meningioma, may grow to a large size without manifesting any symptoms or signs of raised ICP. Over months and years, the tumour makes a bed for itself by compressing and indenting the brain slowly. On the contrary, a rapidly growing tumour, even when small in size, raises the ICP early in its evolution. Any event, like haemorrhage or cystic degeneration that may suddenly increase the size of a slow growing lesion, may also lead to decompensation and result in raised ICP.
2. *Associated cerebral oedema*: Some space occupying lesions have a tendency to break down the blood-brain barrier and cause extensive oedema, e.g. glioblastoma, some varieties of metastases, meningioma, tuberculoma, cysticercus and abscess. In these cases, the ICP may show a rapid rise, even though the tumour may be small in size.
3. *Proximity to CSF pathways*: Tumours occurring near the midline tend to obstruct the CSF flow and thus lead to hydrocephalus and increased ICP. Tumours arising in the medial temporal region, in the suprasellar region in the third ventricle and in the posterior fossa near the fourth ventricle are such examples. In these locations, even a small lesion may lead to an early rise of ICP.
4. *Compression of the major venous channels*: A tumour arising near a major venous channel may compress it and lead to venous stasis. This is rare, as generally other venous pathways open up rapidly and restore cerebral venous outflow.

EFFECTS OF RAISED INTRACRANIAL PRESSURE ON VARIOUS STRUCTURES

Increasing ICP causes varying effects on the different structures of the cranial cavity depending on their vascular supply and resistance.

1. *The skull and the scalp*: Due to the free communication between the scalp veins, the diploic channels and the dural and subdural veins, increasing ICP may be transmitted to the veins of the skull and scalp. The scalp veins may become dilated and prominent when the patient bends forward. They may appear especially prominent on the side of the tumour when the tumour is near the surface. The enlarged diploic veins become apparent on plain X-rays. The posterior clinoid processes get demineralised and may get absorbed and the pituitary fossa may get enlarged. In children and young adults separation of the sutures and beaten silver appearance are common.
2. *The dura mater*: As the ICP rises, the dura mater gets stretched. The basal dura being sensitive, the patient develops headache, which may be frontal, occipital or generalised. Stretching of either the falx cerebri or the tentorium may also result in localised or generalised headache. The dura, if stretched over the surface of a tumour, may get thinned out.
3. *Veins*: The intracranial veins are one of the earliest structures to suffer the effects of increased ICP. The walls of the veins near the tumour get stretched and compressed and the veins get obliterated leading to back pressure. As the ICP rises, a large number of veins get occluded but as the venous sinuses are enclosed in rigid dura, pressure on the sinuses is not common except when there is direct pressure by a tumour arising near the sinus. Pressure on the veins leads not only to retrograde congestion but also interferes with the absorption of CSF. Blockage of the venous flow from the orbit may result in a mild unilateral or bilateral proptosis. Tumours occurring in the middle cranial fossa or the temporal lobe may lead to a mild but perceptible proptosis on the side involved due to pressure on the veins draining through the superior orbital fissure.
4. *Cerebrospinal fluid*: The subarachnoid spaces along the base of the brain and over the convexity gradually get obliterated. A tumour adjacent to the CSF pathway may exude proteins into the CSF which may further increase the ICP. A spinal neurofibroma which elevates the protein levels in the CSF may raise the ICP and cause papilloedema.
5. *Major arteries*: In the initial stages, there are no alterations in the major cerebral arteries. However, as the tumour enlarges, local distortion of the neighbouring arteries may take place. The patient may complain of frontal headaches due to stretching of the vessels of the circle of Willis. In the late stages, the ICP may rise as high as the arterial pressure; this causes a reflex rise of blood pressure in an attempt to keep up the cerebral blood flow (CBF). In an acute and severe rise in ICP, when the ICP equals the arterial blood pressure, carotid and vertebral arterial flow into the brain may stop. At this stage, the patient is deeply unconscious and without spontaneous respiration. Angiography shows a 'carotid stop' or total circulatory failure. This phenomenon is more often seen terminally in cases of acute massive increase in pressure, as in sudden severe subarachnoid or intracerebral haemorrhage, fulminating post-traumatic brain swelling and only rarely in brain tumours. Reduction of ICP by diuretics or hyperventilation may help to restore the blood flow for a short while.
6. *Cranial nerves*: Owing to their pliability, the cranial nerves may get stretched without any apparent deficit. The nerves most liable to be involved in rising ICP are the sixth nerves, because of their long intracranial course and their angulation over the petroclinoid ligament and passage through Dorello's canal. Increased ICP may result in unilateral or bilateral external rectus palsy. In general, this is not of localising value. The third nerve is likely to be compressed in supratentorial lesions when there is transtentorial

herniation. The pupillary fibres being more superficial in the nerve, dilatation of the pupil is more frequently encountered than ptosis or ocular muscle weakness. Raised ICP can produce impairment of hearing, as has been documented in a series of studies from AIIMS.[86] The hearing deficit may be either conductive or sensorineural. Initially or predominantly, it may be unilateral, thus confusing the clinical localisation of the lesion. When the ICP rises further or in posterior fossa lesions when the cerebellar tonsils herniate through the foramen magnum, the first and second spinal nerves get stretched leading to spasm of the suboccipital muscles, as well as pain and paraesthesia over the occipital region. The effect of raised ICP on the optic nerve is dealt with elsewhere (refer Visual Field Defects). Besides paresis, stretching or pressure on the cranial nerves may result in positive phenomena. Thus, a tumour of the temporal lobe may produce trigeminal neuralgia by pressing on the Gasserian ganglion or a tumour in the CP angle may present with hemifacial spasm.

7. *Cerebral blood flow*: When the ICP is marginally raised, there is no change in the CBF. However, enlarging lesions may cause alterations in the blood flow of circumscribed areas depending on the local pressure and the pathology of the lesion. A very vascular growth or an arteriovenous malformation causes a considerable reduction in the blood flow to the surrounding areas due to the phenomenon of steal. As the ICP rises further, there is a gradual reduction in CBF leading to incipient cerebral anoxia. The rapid clinical improvement, often seen after the administration of diuretics or CSF diversion procedures, can be attributed not only to the reduction in ICP but also to improved CBF. On the other hand, when the ICP rises rapidly there may be a paralysis of autoregulation, resulting in a sudden increase in CBF which is responsible for the rapid deterioration in the condition of the patient.
8. *Effects on the brain*: The white matter is liable to be affected by a dilating ventricular system.[51] In long standing hydrocephalus, signs of pyramidal tract involvement appear due to stretching of the white matter of the corona radiata by the enlarging ventricles. In general, however, the brain substance suffers more from local pressure, venous congestion and oedema rather than from any general effect of raised ICP. This is true for both of the grey and white matter.

Secondary phenomena: Increasing pressure on the brain, the blood vessels and the CSF results in the secondary phenomena of herniations, false localising signs and systemic disturbances.

SIGNS AND SYMPTOMS OF RAISED INTRACRANIAL PRESSURE

These signs get modified according to age. The elastic skull of the infant and young child can accommodate the increase in intracranial contents by a slow expansion secondary to separation of the sutures. A tense fontanelle or a progressive increase in the size of the head may be the only sign of raised ICP for months. Percussion of the head elicits a cracked pot sound (MacEwen's sign) in some children. Young children often do not complain of headaches and the presenting symptoms may be abdominal discomfort, vomiting, irritability or listlessness. The optic fundus is often normal; papilloedema is uncommon but pallor of the disc may be seen in some children with raised ICP.

In old people, the brain shrinks a little due to atrophy and thus there is more space for the lesion to grow before causing an increase in pressure. Thus, slow growing lesions may attain a considerable size in elderly persons before pressure effects begin to appear.

Headache

Headache occurs frequently in patients with increased ICP and acquires special significance if it occurs in a person not previously subjected to headaches. The brain itself is insensitive to pain but the dura mater, especially at the base of the skull as well as the major blood vessels in the brain, are pain sensitive structures. Headache, in increasing ICP results from stretching of the dural coverings, shifting of the dural partitions and stretching and kinking of the major blood vessels. The headache may be frontal, bitemporal or occipital. The anterior parts of the dura are supplied by the trigeminal nerve and the posterior half by the second cervical nerve, frontal headache may indicate an anterior lesion and an occipital headache a more posterior tumour but this is often not true. Only occasionally the site of has headache any localising value. Anterior basal tumours often cause retro-orbital pain for months, before generalised headache appears. Pain over the vertex is uncommon, except in cases of parasagittal tumours arising near the vertex. Surface tumours, like meningiomas, may present with localised pain and tenderness.

Headache caused by raised ICP has certain features which may arouse suspicion of the possibility of a space occupying lesion. The headache is throbbing in character and gets aggravated by stooping, straining or exertion. It is common in the early hours of the morning and towards late in the evening. A characteristic feature of the headache due to raised ICP is its occurrence when the patient is sleeping. The throbbing headache often wakes the patient up in the early hours of the morning. Such headaches coincide with REM sleep (dream sleep) during which normally the ICP shows a tendency to rise due to cerebral vasodilatation. In patients whose ICP is already high, a further increase in pressure, during sleep, causes an increase in the severity of headache. Alcohol or other vasodilating drugs tend to increase this headache. A small percentage of patients (about 10%), for some obscure reason do not complain of headache in spite of severely raised ICP.

Pain in the suboccipital region has a serious import and requires urgent action. Suboccipital pain, occurring in a patient who has already been diagnosed as suffering from raised ICP, indicates tonsillar herniation. The herniating cerebellar tonsils irritate the C1 nerve root causing spasm of the suboccipital muscles which causes headache. The head may be tilted or rotated to one side and this is often seen in children. At a later stage, the C2 nerve root is similarly stretched leading to muscular pain. Such pain is often mistaken for upper cervical pathology both in children as well as in adults. Cough syncope may occur with herniated cerebellar tonsils.[48]

Localised Tenderness of the Skull

This has a localising value in tumours involving the cranium or the dura mater. More commonly, inflammatory lesions underlying these structures cause localised tenderness over the affected area. Some patients with cerebellopontine angle (CPA) lesions will give a history of transient severe ear ache or retromastoid pain on the side ipsilateral to the lesion.[22]

Vomiting

This is a frequent symptom of raised ICP and is caused by irritation of the vomiting centre in the medulla. While vomiting is prominent in some patients, it may be absent in others. Usually, vomiting occurs sometime after the headache sets in. Vomiting is a common and early symptom of increased ICP in children and may be the only symptom of a space-occupying lesion for a long time. Unexplained vomiting in a child has to be taken seriously and investigated.

Generally, the vomiting is described as projectile without any feeling of nausea but this is not always so. As the vomiting is not due to gastric causes, it is often possible to feed a patient with small amounts of nourishment soon after the vomiting. This must be remembered as otherwise the patient may get dehydrated and malnourished in a very short time.

Vertigo

This is often seen in intracranial tumours, especially in posterior fossa lesions. The patient will complain of an unsteady feeling and a disturbance of the sense of balance in space. This may occur with or without alteration in posture. Giddiness may be due to vestibular disturbances, pressure on the brainstem or visual disturbances like diplopia or transient blurring of vision.

Visual Changes[28,77]

When ICP has existed for sometime, the function of the optic nerves is affected. Ophthalmoscopic examination is essential in examining a patient suspected of harbouring a brain tumour.

Papilloedema

A blockage of the venous return from the retina results in papilloedema. This occurs in the majority of cases of raised ICP, except in young children[31], in whom raised ICP is compensated for a long period of time by separation of the sutures. Papilloedema is also late in appearance in benign low grade gliomas, epidermoids, meningiomas and in frontoparietal tumours, whereas posterior fossa lesions cause papilloedema early. Very rarely, papilloedema may not occur in raised ICP if the venous drainage of the retina is embryologically different, draining chiefly into the inframaxillary venous plexus. In pituitary and parapituitary lesions, the optic nerve gets compressed initially leading to primary optic atrophy; in such cases, even when the ICP increases later on, papilloedema does not develop in the eye with optic atrophy.

The earliest change in the optic fundus secondary to rise in ICP is loss of spontaneous venous pulsations (SVP). The presence of the pulsations indicates that the ICP is less than 200 mm H_2O. In about 10–20% of normal patients the SVP may be absent.[17]

The earliest indication of papilloedema is the enlargement of the blind spot. This is a useful diagnostic sign and should be carefully looked for whenever there is any doubt about the existence of papilloedema. The size of the blind spot corresponds to the area of exit of the optic nerve from the retina, i.e. the optic nerve head; hence the size of the blind spot increases when the optic nerve head begins to swell. Another early sign of increasing ICP is the enlargement and congestion of the retinal veins.

The normal optic disc is slightly pink and circular, with the temporal side being slightly paler than the nasal side. In papilloedema the disc projects forwards in relation to the retina, the projection being more obvious on the nasal side when seen through the ophthalmoscope. Normally, the optic nerve head is depressed below the surface of the retina by about two or three millimetres, thus forming the optic cup. From the centre of the depression, the retinal arteries and veins may be seen coursing in four directions. Pigment is often seen at the edge of the optic cup. An initial change that may often be observed in raised ICP is the obliteration of the optic cup, with the margins of the optic cup becoming ill defined. A little later, the origin of the retinal vessels from the optic cup cannot be visualised. As the swelling of the optic disc progresses further, the retinal vessels get narrowed and obliterated near the optic disc. At this stage, haemorrhages may develop and a generalised congested picture of the retina will become obvious. Even after such an oedema has occurred along with haemorrhages, the patient does not complain of diminution of vision except in some rare cases where a haemorrhage may have occurred over the macula.

A small cupless disc is vulnerable to anterior ischaemic optic neuropathy (AION). This is termed "disc at risk".[41] Measurement of dioptres with an ophthalmoscope is not worthwhile.[17]

Examination of the fields may show only a mild concentric contraction. In the late stages, when the papilloedema is advanced, there may be attacks of transient dimness of vision. Transient obscuration of vision may be complained of when the patient straightens himself after bending down or on getting up from bed. This is a danger signal and should be understood as a sign of impending visual failure. It is thus obvious that papilloedema may exist for weeks before visual failure occurs, and when it does, it may be sudden and the patient may say that the loss of vision has been acute.

This picture may be contrasted with that of optic neuritis. It is essential to differentiate between the two conditions, as early papilloedema may be mistaken for optic neuritis. In optic neuritis or retrobulbar neuritis, the changes in the optic discs are minimal compared to the degree of loss of vision. The failure of central vision occurring in optic neuritis leads the patient to complain of severe loss of vision, whereas the optic disc itself may be normal or may show mild congestion or slight pallor. It is uncommon to have retrobulbar pain in papilloedema. Papilloedema has also to be distinguished from pseudopapilloedema. Hypermetropia, congenital anomaly of the disc or deposits of Drusen may simulate papilloedema. Drusen is an inherited anomaly occurring in about 0.3% of the population. Deposits occurring deep to the disc give an appearance simulating disc swelling. There is no visual loss and the prognosis is good.

Papilloedma may occur in only one eye if the subarachnoid space around the optic nerve in the other eye is obliterated due to direct pressure by a tumour. In such cases, the patient presents with primary optic atrophy in the eye on the side of the tumour and papilloedema in the opposite eye (Foster Kennedy syndrome).

When papilloedema has been persistent for a long time, visual failure may occur even after the ICP has been reduced. In other words, onset of visual failure may occur after successful surgery for a tumour and the unfortunate patient may attribute this visual failure to the surgery.

The stages of papilloedema as graded by Frisen et al.[32] are as follows:

Grade 0: Normal
Grade 1: Minimal papilloedema characterised by a C-shaped halo
Grade 2: Mild papilloedema which is characterised by a complete halo
Grade 3: Moderate papilloedema which is characterised by obscuration of disc vessels off the disc
Grade 4: Marked papilloedema characterised by obscuration of vessels on the disc
Grade 5: Severe papilloedema characterised by mushroom disc with cup obliteration

Optic Atrophy

Long standing papilloedema leads to blindness with secondary optic atrophy. The disc becomes white, the vessels attenuated and the disc margins continue to be indistinct (as contrasted with primary optic atrophy). In the early days of neurosurgery in India and in the developing countries, a number of patients with intracranial tumours reported with blindness. Diagnosis of a brain tumour is possible and desirable before papilloedema sets in and the frequency of such diagnosis reflects the medical awareness of society and of the doctors.

Abducens Palsy

The patient may complain of diplopia and on examination show evidence of unilateral or rarely bilateral, external rectus paralysis. Owing to the long course of the VI nerve inside the cranial cavity, both in the posterior fossa as well as in the middle fossa, space occupying lesions and increased ICP tend to interfere with the function of this nerve more often than any other cranial nerve. Nathan et al.[58] have drawn attention to the anatomical variations in the course of the VI nerve. In some patients, they have seen two trunks arising from the brainstem and reaching the orbit separately. This may explain the partial involvement of the VI nerve seen in some instances. These variations explain why only some patients with raised ICP develop abducens palsy. Thus, abducens palsy occurring in raised ICP has generally no localising value. Diplopia may be a presenting symptom of intracranial tumours.

Proptosis

A mild proptosis may be seen in raised ICP.[84] Unilateral proptosis of a mild degree is of localising value. The lesion is often in the region of the lesser wing of the sphenoid bone or the middle cranial fossa of the concerned side.

Disturbance of Higher Functions

The higher functions of the brain, like concentration, judgement and memory, get impaired to a varying degree when ICP rises. In the early stages, the patient is often aware of these defects; occasionally the impairment may be reported by friends and relatives. Such changes occurring before the appearance of localising signs are often attributed to systemic disorders like arteriosclerosis. The general slowing of higher functions should not be mistaken as an indication of a frontal lobe tumour,[81] as it may occur with tumours in any part of the cerebral hemisphere. In elderly patients with neurodegenerative diseases, the great toe is upwardly pointing. This is called the striatal toe.[17] These patients also have a slow flexor plantar response known as the tonic flexor plantar response.[17] In frontal tumours such symptoms occur early, commonly preceding the signs of increased ICP. On the contrary, most children who develop raised ICP due to tumours are well behaved, quiet and remarkably mature in their actions.[14]

Generalised epilepsy may occur as a sign of raised ICP without localising significance. This has been attributed to anoxia, venous congestion or oedema in a brain with a low threshold for convulsions. Sleep rhythm is occasionally disturbed when ICP increases, the patient being restless and sleepy alternatively during the day and night.

Systemic Changes

Increased ICP may result in abnormal impulses being transmitted to the kidneys, resulting in renal ischaemia and leading to a rise in blood urea, non-protein nitrogen and extracellular potassium. The urinary output is normal. The patient becomes drowsy and irritable and may develop tachycardia, fits or generalised oedema. The urine may show albumin with marked decrease in sodium and chlorides. As the urine volume remains normal, the diagnosis may be missed.

Paroxysmal hypertension may be seen in the late stages of intracranial tumours, especially in posterior fossa lesions[16] Palpitation, perspiration and headache may be present with the acute rise in blood pressure and may be mistaken as due to a phaeochromocytoma. Bradycardia is a late sign of raised ICP and may also be caused by cerebral anoxia.

In the late stages, stupor, bradycardia and rising blood pressure are apparent along with respiratory depression. Rarely, neurogenic hyperventilation may be seen before respiratory depression ensues. Pulmonary oedema may be produced by increased ICP. The mechanism is mediated through the upper cervical cord.[26] The severe ICP leads to systemic vasoconstriction, systemic arterial hypertension, pulmonary venous hypertension and pulmonary oedema. Even in such a stage, a reduction of ICP by proper therapy leads to a reversal of the signs.

It will thus be noted that the non-specific signs of increased ICP may resemble systemic disease in their earlier stages. Hypertension may cause headaches similar to those of a brain tumour and in the late stages the ophthalmoscopic findings also may be similar.

Cerebrovascular disease also simulates the symptoms of brain tumour in elderly people, the convulsions and deterioration in personality being attributed to cerebral ischaemia. Toxic and metabolic encephalopathy, especially lead encephalopathy and also incipient uraemia may mimic symptoms of raised ICP.

Signs of Interference with Local Functions

Irrespective of the nature of the tumour, neurological signs appear depending upon the site of the lesion. Clinical localisation of a brain tumour is an exercise in neuroanatomy. After the demonstration, in 1870, by Fritsch and Hitzig[33] of the electrical excitability of the cortex, it was possible for Hughlings Jackson to vindicate his theory of cerebral localisation of function[57] MacEwen, in 1876, correctly localised a brain abscess[11] and in 1879, removed a meningioma localised on the basis of the onset of focal convulsions.[50] The first glioma was removed in 1884.[7] Thus, it became evident that recognition of the significance of early symptoms of either irritation or paralysis is possible,[88] depending upon one's knowledge of brain function and the meticulousness of the examination.

In early cases, various combinations of signs and symptoms or syndromes can be recognised. In late cases, secondary phenomena, like distant effects, neighbourhood effects and increasing ICP, confuse the clinical picture. Hence, a careful recording of the history of the onset and of early symptoms of the illness greatly contributes to localisation.

The local effects of the tumour may be either irritative or paralytic. Irritation results in abnormal increase of function, e.g. generalised or focal fits, flashes of light, tinnitus and in other bodily sensations. Depending upon the site of the lesion, paralysis of local areas of the brain manifests itself by negative signs like loss of motor power, sensation, speech and hearing. In addition, there may be positive signs of increased activity of the lower levels of the nervous system due to release phenomena, e.g. spasticity, grasp reflex.

Epilepsy and Brain Tumour

Epilepsy is a common symptom of intracranial tumours occurring in about a third of all patients with tumours. Supratentorial tumours, both extracerebral and intracerebral, manifest epileptic seizures as a symptom in about 50% of cases.[87] These may be focal or generalised, presenting as the initial symptom and remaining as the only symptom for a long time. Convulsions may also occur in the late stages of the disease due to increased ICP. When epilepsy marks the presence of a tumour, it occurs early in the course of the disease. It was the first symptom in 50% of temporal tumours, 78% of frontal tumours and 93% of central tumours.[49]

Focal epilepsy often suggests the site of the lesion. Postictal weakness (Todd's paralysis) is common and clears in a short time. When it occurs consistently and persists for a long time, the chances of an organic lesion being the cause of the fit are much higher.[69] General and focal convulsions may occur in the same patient. Variation in the pattern of the fits with passage of time or the occurrence of fits in clusters favours the possibility of a tumour. Sudden unheralded status epilepticus in an otherwise healthy individual may be the first symptom of a brain tumour. Oxbury and Whitty[63] found that the majority of such patients have a frontal tumour. However, this has not been confirmed.

About 1% of all patients with epilepsy have intracranial tumours. The onset of epilepsy in adult life above 35–40 years is more likely to be due to a tumour. Such patients should be carefully evaluated and advised frequent follow-up. Epilepsy as a symptom of tumours usually indicates a slow-growing tumour. Rasmussen and Blundell[72] found that many patients with seizures

as the first or the main symptom of the tumour harbour tumours with a low growth potential. A patient may have convulsions for a number of years before other symptoms of a tumour begin to manifest themselves. This is often seen in low grade gliomas and meningiomas. Glioblastomas are least likely to be accompanied by convulsions of a long duration.

Meningiomas cause convulsions by pressure on the cortex with the resultant local oedema and venous stasis. Sixty per cent of convexity meningiomas may have epilepsy as the first symptom. This is also true of tuberculomas, especially those involving the cortex.[68]

Regional Signs

Subfrontal Tumours

Tumours in the subfrontal region grow upwards into the under surface of the frontal lobe and may exist for a long time without causing any apparent neurological signs. In larger tumours, lack of inhibition and impulsive laughter or crying may occur, as also pointless silly joking (moria) associated with euphoria.[59] Rage attacks may also occur. There may be impairment of recent memory. Excitement or hallucinations may occur due to irritation of the frontobasal region. Epilepsy may be generalised or adversive in onset. Subfrontal midline lesions cause anosmia in the absence of rhinitis, as seen in olfactory groove meningioma. When the lesion extends posteriorly, optic atrophy results from pressure on the optic nerve or chiasma or there may be a Foster Kennedy syndrome.

Frontal Lobe Tumours

These may exist for a long time without any physical or mental sign or symptom, resulting in delay in diagnosis. The patient may be able to carry on routine work without impairment. When the lesion begins to spread posteriorly and involves the connections with the opposite frontal lobe, symptoms appear, commonly termed frontal lobe signs. The signs progress rapidly if the lesion is intra-parenchymal, whereas, with extrinsic tumours the symptoms progress more slowly. Lack of drive or reduction in initiative may be the first symptom and a failure to observe accepted social norms becomes obvious. There may be undue jocularity ('Witzelsucht'). There is an absence of inhibition naturally expected of a normal person in a particular social environment. This may manifest itself in an unnaturally familiar behaviour which may be mistaken for taking liberties or for impertinence. Later, the capacity for insight is impaired. These symptoms become more pronounced when the lesion extends backwards to involve the association fibres of the corpus callosum. Interference with memory is not a common sign in frontal lobe lesions, although occasionally, recent memory may be impaired. Visual inattention, confabulation and apathy may be observed.

There are three distinct prefrontal lobe dysfunction syndromes. They are: (1) Dorsolateral prefrontal lobe dysfunction which is important for working memory and adjusted behaviour; (2) medial prefrontal syndrome which is concerned with initiation of activity and causes akinetic-abulia syndromes and (3) orbital pre-frontal syndrome which is characterised by hyperactivity.[18]

A comparison of intelligence quotient scores between patients with frontal tumour and tumours elsewhere did not show any significant difference. But a comparison of the scoring between right and left frontal lobe tumours showed a greater loss of intellectual function in right handed individuals with left frontal tumours than in those with right frontal tumours.[8] Special psychometric tests can easily differentiate between frontal and temporal lobe dysfunction (as established by Brenda Milner of the Montreal Neurological Institute).

The motor signs of frontal lobe lesions are a manifestation of impairment of voluntary motor control, e.g. difficulty in performing serial alternating tasks, motor perseveration and ataxia of the contralateral leg. Apraxia of gait, occasionally seen in these patients, may be mistaken for ataxia. Dysphagia, as a presenting symptom in tumours of the posterior part of the inferior frontal region, has been reported by Meadows,[54] who attributed this to the involvement of the lowest part of the precentral gyrus or the inferior frontal gyrus.

Psychoses may be simulated by a long standing frontal lesion like a meningioma. Involutional depression or presenile dementia may be diagnosed when the patient has incontinence, apathy and dementia due to a frontal lesion. Basal frontal lesions may cause excitement or hallucinations which may lead to a mistaken diagnosis of hypomania or schizophrenia.[42] In advanced cases, the patient may have a leucotomy effect and may not even complain of severe pain, for example that of a strangulated hernia.[23]

When the lateral surface of the frontal lobe is irritated, adversive fits may occur with the head and eyes turning to the opposite side. In acute frontal lesions, conjugate deviation of the eyes to the opposite side occurs. In some chronic lesions, the eyes may tend to turn ipsilaterally. In frontal lobe lesions there is also difficulty in moving the eyes to the side on command, whereas follow-on movements are possible. When both the frontal lobes are affected, signs of dementia may be apparent.

Frontal lobe symptoms may be simulated by posterior fossa lesions and vice versa. When the anterior horns dilate due to hydrocephalus, the frontal fibres are compressed resulting in the production of frontal lobe signs. Intention tremor and other cerebellar signs may be seen in frontal lobe lesions. A variety of explanations have been given for this phenomenon.

Bilateral frontal lobe lesions may uncover primitive reflexes, e.g. grasp reflex in the hand or the tonic foot response. Lesions confined to the anterior part of the lobes on either side cause no symptoms, which become obvious only when the frontal lobes are involved more posteriorly. Posterior frontal tumours may rarely

produce contralateral or bilateral tremors simulating Parkinsonism. This may occur even when the basal ganglia are not directly involved. Incontinence of urine occurs when the medial surfaces of both the frontal lobes are involved or when the corpus callosum is affected. Frequency of micturition or urgency may be present in some patients. Incontinence occurring in an otherwise conscious patient has localising significance. As the lesion extends backwards, weakness of the contralateral limbs with exaggerated reflexes is seen.

Tumours in the Sensorimotor Region

Tumours involving the sensorimotor strip are more easily diagnosed because of the obvious impairment of motor and sensory function in the contralateral limbs. Epilepsy is a common symptom of such lesions. This may be focal motor or focal sensory with or without the Jacksonian march or generalisation. Loss of power or sensation, lasting for some time after a focal attack, is suggestive of local pathology. When the function is further affected, paralysis occurs which is more pronounced in one limb (monoplegia), or in one part of a limb. Isolated digit palsies may occur. Such circumscribed pareses are common in cortical lesions. Superior and medial lesions cause weakness of the hand or face, or dysphasia if the tumour is on the dominant side. Initially, this weakness may be flaccid with diminished reflexes but soon becomes spastic. When the lesion is deep seated, even a small tumour may cause hemiplegia with exaggerated reflexes. Primitive reflexes are unmasked, e.g. grasp reflex, the bulldog reflex, i.e. involuntary hold on an object placed between the teeth and the tonic plantar reflex. When the supplementary motor area of the dominant hemisphere is involved, the rare clinical phenomenon of dysphonia may be observed due to interference with the circuits linking the cortical speech area with the thalamus. Involvement of the sensory cortex is indicated by a feeling of tingling, dysaesthesia or numbness in the contralateral limbs.

Parietal Lobe Tumours

The cortical sensory area forms the anterior boundary of the parietal lobe. When the lesion spreads posteriorly, parietal lobe signs become more obvious. Discrete areas of sensory loss may be detected in small focal lesions. In anterior parietal lesions, tactile localisation, two point discrimination and light touch are affected, as also joint sense, vibration sense, stereognosis and appreciation of form and weight. Spontaneous pain and dysaesthesia of the opposite half of the body may be seen in some parietal lobe lesions and may resemble thalamic pain.[76] There will be difficulty in tactile localisation. The patient is not able to appreciate differences in texture of materials, e.g. between cotton and silk. There is also an impairment of appreciation of differences in temperature. While a normal person can appreciate differences between 2°C and 5°C, in parietal lobe lesions differences of 10°C may not be appreciated. There is difficulty in recognising numbers written on the skin (graphaesthesia), as also difficulty in appreciating differences in weight (abarognosia).

The joint position sense is impaired and thus, the posture of the limb is affected. This results in a drift of the outstretched arm and a pseudoathetotic posture. An early sign of a parietal lobe lesion is the fall of the outstretched arm. If the patient is asked to keep both his arms stretched out in front with the eyes closed, the arm opposite to the side of the lesion will slowly drift downwards and outwards. This is seen even when there is no apparent weakness of the arm. Occasionally, two or three fingers alone may drop downwards if a small lesion involves the concerned area.[40] The outstretched hand shows a peculiar hyperextended position of the fingers (pseudoathetosis). A left parietal lesion may produce a significant arm drift on the ipsilateral side in addition to the contralateral arm drift, whereas a right parietal lesion produces postural impairment on the left side only.[92] Trophic changes in the form of anhydrosis, or soft skin, along with muscle wasting may be seen.

In pure parietal lobe lesions, inattention is an early feature. This sensory inattention can be detected by simultaneous stimulation of identical areas on both sides of the body. On a simple command like, 'lift up your arms' the patient raises only the unaffected arm, even though there is no motor weakness on the affected side. In more extensive lesions, awareness of body image is lost. This may involve not only recognition of one's own body image but may extend to other persons also. As a part of this, the patient has finger agnosia, (an inability to identify the different fingers of his hand). Somatoagnosia leads to non-recognition of one half of the body, not shaving one half of the face or difficulty in dressing.[19] When the loss of the body image extends to outside objects, the patient is unable to identify parts in a human figure and also finds it difficult to draw objects, only one-half of the human figure or the face of a clock may be drawn. The patient also has difficulty in identifying familiar places or familiar routes.

Loss of awareness of the affected half of the body may also result in the patient denying his disability or asserting that the normal side of his body is the one that is diseased. As an extension of this, one may see the phantom limb phenomenon; the patient claims to have an extra limb or an extra half of the body which requires to be clothed or covered. When the lesion is near the parieto-occipital junction, the patient has difficulty in identifying faces. This may go to such an extent that he may not be able to recognise his own face in the mirror.

An inferior quadrantic hemianopia is often seen in such posterior lesions. Auditory neglect, similar to somatic neglect, has been observed in inferior parietal lesions.[24] The patient hears the sound in both ears but always reports that the direction of the sound is from the side ipsilateral to the cerebral lesion, i.e. neglecting stimuli from the contralateral side.

Apraxia is often seen, especially in lesions of the left side, leading to difficulty in writing (agraphia). Copying is not difficult. Apraxia of eye movements may be observed in bilateral parietal lesions. Apraxia of gait or apraxia of dressing may be an important manifestation. Voluntary fixation of gaze on an object is not possible although involuntary eye movements are full and normal. This apraxia is different from paresis of conjugate movement seen in frontal lesions. Rarely, parietal ataxia has been described.[2] All these symptoms are more prominent in intrinsic lesions. In right-handed people, right parietal lesions result in a greater disturbance of parietal lobe functions.

Gerstmann[34] described a syndrome with the chief components of: (1) finger agnosia; (2) agraphia-apraxia of writing confined to single letters or words, (while copying is not affected); (3) dyscalculia—difficulty in calculations; (4) right-left disorientation. Gerstmann believed that this syndrome was due to a lesion in the dominant (left) angular gyrus. However, the whole syndrome or a part of it may be seen in lesions involving the angular and supramarginal gyri and the contiguous area of the occipital lobe.[20]

Parietal lobe symptomatology may vary in extent and severity during different parts of the day, the difficulty being more prominent when the patient is tired. Epilepsy is common in lesions of the parietal lobe and often starts with a sensory aura. Occasionally, epigastric sensations may be present.

Parietal lobe dysfunction can be summarised as follows:

The dominant lobe is concerned with spatial motor skills while the non-dominant lobe is concerned with spatial orientation skills. Left superior parietal lobule lesions cause aphasia, agnosia, astereognosis and agraphaesthesia. Right superior parietal lobule lesions cause spatial agnosia, sensory neglect, astereognosis, agraphaesthesia and dressing apraxia. Left inferior parietal lobule lesions cause ideomotor/ideational apraxia and Gerstmann's syndrome (angular gyrus-Geschwind's area lesion—area 39) while right IPL lesions cause aprosody. Bilateral parietal lesions cause Balint's syndrome and movement agnosia.[18]

Temporal Lobe Lesion

Affection of the dominant temporal lobe leads to more pronounced disability than affection of the non-dominant temporal lobe. In the human, as speech and intellect are closely associated, early disturbance of speech may be mistaken for impairment of intelligence.

A careful study of the patient's difficulty is needed to diagnose early disturbances of speech. When the disturbance is more pronounced, the diagnosis is easier and the differentiation of aphasia or dysphasia into motor or sensory, serves a useful purpose. Cerebral speech disorders, resulting from lesions in different parts of the hemispheres, vary fairly significantly to be of localising value. Lesions in Broca's area (posterior part of the inferior frontal gyrus) result in non-fluent aphasia with difficulty in naming objects and with good comprehension. Lesions in Wernicke's area (posterior superior temporal lobe) cause fluent aphasia, with poor naming and impaired comprehension. In Jargon aphasia, the tone, inflection, etc. resemble speech but the words and phrases carry no meaning. Conduction aphasia (resulting from lesions in the arcuate fasciculus connecting Broca's area with Wernicke's area) resembles Wernicke's aphasia except that comprehension in these patients is good. Paroxysmal disturbances of speech may also be observed. Auditory disturbances are rare with unilateral temporal lobe lesions. When the medial temporal lobe is affected, the most common manifestation is complex partial seizures (temporal lobe epilepsy). The patient may have a cephalic or a visceral sensation as an aura. There may be psychosensory or psychomotor disorders like déjà vu phenomenon and a dreamy state. Hallucinations of taste or smell are a common feature of limbic lobe epilepsy and are more often seen in patients with tumours as compared to the more common medial sclerosis. Focal motor epilepsy starting in the face may occur in a small percentage of cases. The onset of temporal lobe symptoms, in an adult, without any preceding history of epilepsy, should arouse the suspicion of a space occupying lesion.

Lesions of the medial temporal region may lead to loss of memory, especially for recent events. The patient may be unduly irritable or aggressive and show emotional instability. When the lesion is in the more posterior part of the temporal lobe, the optic radiations are affected. As the optic radiation makes a loop (Meyer's loop) into the temporal lobe before proceeding to the occipital lobe, posterior temporal lesions result in a superior quadrantanopia. (Note inferior quadrantic defect in parietal lesions.) In more medial temporal lobe lesions, the optic tract could be affected leading to typical homonymous hemianopia.

Temporal lobe tumours, especially in the non-dominant side may exist for a long time and may even raise the ICP without any apparent localising sign. They show a greater tendency for uncal herniation than other tumours.

Occipital Lobe Lesions

The characteristic sign of an occipital lobe lesion is loss of vision in the opposite visual field, the extent of the defect varying with the site and size of the tumour (see chapter on Visual Field Defects).

Tumours compressing the outer surface of the occipital lobe usually spare the fixation area. These may also cause impairment of follow-on conjugate movement of the eyes. In occipital lesions causing homonymous hemianopia, the patient can detect moving objects but not stationary objects in the visual field.[40] Homonymous hemianopia is diagnosed at the bedside by the patient failing to look at persons on one side of his bed. During conversation the patient turns his head to one side to see

well. Thrusting a finger near the eyes on the hemianopic side fails to elicit the menace reflex.

Occipital lobe lesions may also show the phenomenon of visual inattention or extinction. When two objects are placed on either side simultaneously, the object in the defective field is not recognised. But as soon as the object in the normal field is removed, the object in the defective field becomes visible and is also recognised.

Seizures are less common in occipital lobe lesions compared to the other lobes. Seizures with uniform visual hallucinations like flashes of light may present as an early symptom of occipital lobe lesions and there may be an adversive element at the onset of fits. Unlike temporal lobe fits, these hallucinations are crude and not organised. Distortions of images and objects (metamorphopsia) may form the visual aura.

Lesions Near the Falx

These lesions compress the medial surface of the hemispheres and may cause bilateral signs. Spastic paraparesis occurs if the lesion is near the motor strip. Similarly, focal epilepsy irregularly involving either lower limb may be observed. Irritation of the supplementary motor area may result in focal seizures with adversion and tonic posturing of the limbs or generalised convulsions with loss of consciousness as the initial phenomenon. When the pressure is chiefly on the supplementary motor area of the dominant hemisphere, the patient may have the rare clinical phenomenon of spastic dysphonia.

Lesions of the Corpus Callosum

Being an extensive structure connecting the two hemispheres, the corpus callosum is involved in about a third of all cerebral gliomas. In an autopsy analysis of 200 cases of cerebral gliomas, Bull[15] found that the corpus callosum was involved in 36%. Being essentially a commissure between the two hemispheres, symptoms of corpus callosum involvement depend upon the areas of the brain that are 'disconnected' by the lesion. In discrete lesions of the corpus callosum or in experimental situations, specific disconnection syndromes may be established by special tests.[35,65] In tumours, however, the signs and symptoms depend upon the part of the hemisphere the lesion predominantly involves. In anterior lesions, frontal lobe symptoms appear more pronounced. In this area, the tumours may extend into both the hemispheres as a butterfly growth. Lesions in the middle of the corpus callosum result in impairment of sensory and motor functions. Posterior lesions cause early pressure on the third ventricle and the brainstem. Pressure on the colliculi may result in symptoms simulating a pineal tumour.

The common sign of callosal dysfunction is a unilateral left tactile anomia. The subjects are unable to name objects placed in the left hand although they are able to describe their features. There is also a difficulty in the cross replication of finger positions.[52]

Assessment of Lobar and Higher Cognitive Functions—Brief Outline

The routine neurological examination evaluates only the Rolandic lobe. Often, patients may have a normal gross neurological examination. It is in these cases that higher cognitive functions are indicated to aid lesion localisation. In clinical parlance right frontal and temporal lobe signs of dysfunction are subtle. An important feature to note is that higher function assessment cannot be done in patients who have a decreased attention span or have sensory dysphasia.

The basic initial step in the assessment of higher functions is the mini-mental state examination (MMSE).[29]

Score	Feature
	(a) Orientation:
5-	*Ask the patient to state the date, month, season, year.
5-	*Location—country, state, city, hospital, floor of the hospital.
	(b) Registration:
3-	*Name three objects—1 point for each object. Ask the patient to repeat all the names. Continue the repetition until all three names are registered.
	(c) Attention and calculation:
5-	*Serial 7s subtraction. One point for each correct answer. Stop after five answers. Alternatively a word can be spelt backwards.
3-	(d) Recall: Ask for three objects. Repeat all the words. Give one point for each correct answer.
	(e) Language:
9-	#1 name a pencil and watch (2pts) #2 repeat the following: No ifs and buts- (1pt) #3 three stage commands: Take a piece of paper in your right hand, fold it in half, put it on the floor (3pts) #4 read and obey the following: Close your eyes (1pt) #5 Write a sentence (1pt) #6 Copy a design

The MMSE is 80% sensitive and 98% specific. The average score adjusted for age and level of education is 25–30.

Frontal Lobe Dysfunction

Frontal lobe dysfunction is not easily picked up on psychological testing. The patients may have a normal MMSE. The Luria fist-edge-palm pattern repetition test is of value.[17] Digit repetition is the best test for attention span.[83]

Parietal Lobe Dysfunction

The clock drawing test which tests for constructional apraxia is a very sensitive test for detecting cognitive disturbance. It is based on the principle that to draw a

clock showing a particular time, one must know what a clock is and should have the motor co-ordination to draw the object and also have an ability to understand the examiner; which in effect tests the frontal, temporal, parietal and occipital lobes in one test. Those with left parietal dysfunction are unable to get the form right and those with right parietal lesions are unable to place the numbers in the correct spatial orientation.[30,83]

Temporal Lobe

Language and memory are important functions to be tested. The Babcock sentence (nonsense sentence) is useful for assessing language. Wertheim's test is useful for assessing non-dominant temporal lobe function-non-verbal language.[17] Lesions of the dominant temporal lobe result in impairment of intelligence quotient (IQ) while those in the non-dominant side affect the performance quotient (PQ).

Lateral Ventricle Tumours

These lesions are often silent till they grow to a large size. Meningiomas, ependymomas, choroid plexus papillomas and epidermoids occur inside the lateral ventricles. Cushing and Eisenhardt[21] described the syndrome produced by tumours in the lateral ventricles, which is characterised by headache on the side of the tumour, contralateral homonymous hemianopia, often with macular splitting, contralateral hemiparesis with pronounced sensory loss sometimes associated with trigeminal numbness, cerebellar symptoms and paralexia when the tumour is on the left side (as it commonly is).[38,46] All or any of these symptoms may be present. Posterior hemispheral signs are pronounced, because the majority of lateral ventricle tumours occur in the trigone. Signs due to raised ICP may occur alone without any of the above lateralising signs. The most common false localising signs are those that point to a posterior fossa lesion.

Lesions Involving the Basal Ganglia

These may result in abnormal movements, rigidity or tremors. Unilateral tremors may closely resemble those of Parkinson's disease. Chorea, athetosis and dystonia have been reported as the presenting symptoms of basal ganglia tumours in children.[5,55,61,64] Such symptoms are seen only when critical pathways are involved and not in all basal ganglia tumours. It is seldom possible to clinically suspect extension of hemispherical gliomas to the basal ganglia, a fairly common occurrence.

Due to the close association with the internal capsule, these tumours often cause contralateral motor, sensory or visual field defects. Pupillary inequality and impairment of conjugate movements have been described[53] and are due to pressure on the midbrain. Seizures may occur as drop attacks, with or without accompanying disturbances in the eyes and limbs. Loss of mirror movements is considered to be an early sign of basal ganglia dysfunction.[62]

Middle Cranial Fossa Lesions

These may be divided into sellar lesions, parasellar lesions, lesions near the cavernous sinus and lesions of the temporal fossa.

Sellar lesions: See Chapter "Pituitary Tumours".

Parasellar lesions: The common parasellar lesions are meningiomas, carotid aneurysms and tumours of the base of the skull. In medial lesions, obstruction of the cavernous sinus leads to a mild proptosis. A complete or incomplete ophthalmoplegia follows due to involvement of the III, IV and VI nerves. Often, the pupillomotor fibres are not affected and thus the pupils may remain normal. Involvement of the ophthalmic division of the trigeminal nerve causes hyperaesthesia or anaesthesia of the forehead. Anterior parasellar lesions in the carotid region (aneurysms) press on the optic nerve leading to loss of vision and optic atrophy.

Temporal fossa lesions: This being a fairly large fossa containing numerous structures, various disturbances may arise depending on the location and direction of growth of the tumour.

Anterior lesions of the middle cranial fossa may be asymptomatic for a long time and attain a large size (meningioma). Fits due to irritation of the cortex may be the only sign, followed much later by papilloedema. Of these lesions, the medial ones cause pressure on the optic nerve, while lateral lesions may cause early bony changes, at times visible and palpable externally. Lesions in the middle may cause only a mild proptosis for a long time, due to obstruction of the venous outflow from the orbit through the orbital fissure.

In posterior lesions of the middle cranial fossa, the motor division of the trigeminal nerve is affected with resulting weakness of the masseter, temporalis and pterygoids on the affected side. Pain and paraesthesia may be present over the trigeminal distribution. Raeder[67] described, in 1924, a paratrigeminal syndrome which included pain or numbness over the ophthalmic division and Horner's syndrome without facial anhydrosis. The latter is due to oculosympathetic paresis. This syndrome, accompanied by weakness of the III, IV, V or VI cranial nerves, is indicative of a mass in the middle cranial fossa. This closely resembles the syndrome of painful ophthalmoplegia commonly seen in India. A similar syndrome, without cranial nerve signs, may accompany vascular headaches.

The optic tract may be affected by lesions extending medially, resulting in visual changes. All middle cranial fossa lesions, if they extend superomedially, may cause temporal lobe seizures. Large lesions compressing the temporal lobe may produce temporal lobe signs in the later stages.

Midline Lesions of the Brain

Tumours of the third ventricle region can be conveniently divided into five groups: (1) anterosuperior; (2) anteroinferior; (3) inferior; (4) posterior and (5) lateral.[13]

The onset and progress of symptoms vary in these groups, although there may be a lot of overlap in the latter.

Anterior third ventricle tumours (e.g. craniopharyngioma or a colloid cyst) extending superiorly, often block the foramen of Monro. This blockage is usually intermittent in the case of a colloid cyst and thus the patient may suffer from intermittent bouts of headache, which in a few, gets dramatically relieved by a change in the position of the head. The dilating anterior horn may lead to dementia in adults. In children, anterior third ventricle tumours may be associated with mental retardation, memory loss, weakness of the lower limbs and occasional somnolence.

Anteroinferiorly, the lesions compress the hypothalamus and cause endocrine symptoms. Hypersomnia, diabetes insipidus and hyperthermia have been noted[82] and are more common in infiltrating tumours of the third ventricle.[60] Pressure on the chiasma leads to field defects in such inferior lesions. Disturbances of micturition or defaecation may occur in anterior diencephalic lesions.[1]

Posterior Third Ventricle Tumours

These infiltrate the thalamus and cause symptoms of contralateral pain, tremors, rigidity or weakness. Laterally placed tumours may simulate an early case of Parkinsonism. Pinealomas and posterior third ventricle tumours may present with the classical sign of difficulty in conjugate upward deviation of the eyes with or without other ocular nerve paralysis (Parinaud's syndrome). This is seen only in about 50% of the cases and is due to pressure on the superior colliculi by the tumour. Pressure on the inferior colliculus may cause tinnitus. Posterior pressure on the cerebellar peduncles may cause incoordination and ataxia, simulating a cerebellar tumour.[71] Cysts of the third ventricle have been reported to result in to and fro movement of the head and trunk in children: 'bobble-head doll syndrome'.[5,8,9,25,78,90] Pubertas precox, a rare clinical entity seen in association with third ventricle tumours, is due to interference with the hypothalamus.

Tumours Involving the Hypothalamus

Hypothalamic signs may be seen in patients with posterior fossa tumours due to pressure on the hypothalamic nuclei by the dilating third ventricle. Thus, children and adolescents with posterior fossa lesions may present with symptoms suggestive of hypothalamic involvement. A chubby child, too well behaved for his age, may be the early clinical picture of a posterior fossa lesion.[12]

The hypothalamus may also get compressed by tumours of the third ventricle and adjacent lesions like a craniopharyngioma and other sellar lesions. An increase in the subcutaneous fat, docility leading on to lethargy and lack of growth of hair over the body may be seen. Puberty is delayed in both boys and girls. In adults, libido is decreased and amenorrhoea may occur. These symptoms often simulate hypopituitarism.

Intrinsic lesions arising from or including the hypothalamus may cause signs of irritation or deficiencies of hypothalamic function. Precocious puberty is one such sign and is due to destruction of the posterior hypothalamus, leading to uninhibited action of the anterior hypothalamus on the pituitary and the gonads. Precocious puberty due to hypothalamic involvement is characterised by excessive development of the penis and testes, adolescent body contours and adult levels of 17 ketosteroids; whereas in adrenal precocity, the testis is immature, the body contours are that of a child and the 17 ketosteroids are greatly in excess of the adult values.[56]

Other signs of serious interference with function may also occur like diabetes insipidus.[6] The syndrome of inappropriate ADH secretion (SIADH) may occur. In some cases, fat metabolism is disturbed leading to fat depletion, resulting in marasmus or progeria (premature ageing). A typical diencephalic syndrome characterised by marasmus, euphoria and nystagmoid eye movements has been described in infants. The failure to thrive is obvious, the child is cachectic, but the sensorium is normal and the child remains active and playful. In other cases, hyperphagia and obesity may be seen as well as a lowered threshold for aggressive behaviour.[75]

Lesions of the Midbrain

Being situated in a strategic area between the edges of the tentorium, the midbrain is often involved in tumours of the cerebral hemispheres due to brain shifts and herniations. Intrinsic tumours may extend into the midbrain from the hemispheres above or from the pons below. When the lesion arises in the ventral part of the midbrain, the oculomotor nerve is affected as well as the crus. This leads to an ipsilateral ptosis with contralateral hemiparesis (Weber's syndrome). The signs become bilateral as the tumour spreads to the opposite side. Involvement of the tegmentum may result in coarse tremors on the contralateral side; occasionally, when the subthalamic nucleus gets affected, hemiballismus may result. Dorsal tumours will involve the superior colliculus leading to disturbances in upward gaze and pupillary reaction. This is also seen in tumours dorsal to the midbrain, e.g. pineal tumours. Intrinsic lesions of the brainstem occurring lower down will cause internuclear ophthalmoplegia. Occasionally peduncular hallucinosis can occur.[18]

Tumours of the Posterior Fossa

Posterior fossa lesions may be situated in six different locations: (1) posterior midline; (2) laterally, in the cerebellar hemisphere; (3) anterolaterally, in the cerebellopontine angle; (4) anterior midline, in front of the pons and the medulla; (5) intrinsic, inside the brainstem or (6) inside the fourth ventricle or aqueduct.

Cerebellar functions may be affected by lesions of the vermis, of the cerebellar hemispheres or of the cerebellopontine angle. Cerebellar disturbances may also be seen in brainstem lesions if the fibre connections passing

through the cerebellar peduncles get involved.[3,10] All the manifestations of motor cerebellar dysfunction, whether of the lobes or of the vermis, are attributable to asynergia, ataxia, dysmetria and hypotonia of the muscles. Based on these basic disturbances, many symptoms and signs appear, and numerous tests have been devised to reveal early dysfunction.

Posterior Midline Lesions

The vermis of the cerebellum occupies the posterior midline and is involved in lesions of this region, e.g. vermian astrocytomas, ependymomas, medulloblastomas, a dilating fourth ventricle, posterior midline cysts, tuberculomas and dermoids. The vermis of the cerebellum is concerned mainly with the control of the muscles of the trunk and the muscles of posture, whereas the cerebellar lobes exert control over the muscles of the ipsilateral limbs, chiefly of the upper limb. In lesions of the vermis an early symptom is truncal ataxia and difficulty in controlling the lower limbs. The first evidence of such a disability in a child may be its tripping over steps which it could previously negotiate easily.

This may be followed by mild unsteadiness of gait,[91] leading to an inability to walk or stand. At the same time it will be apparent that the child can use its upper limbs effectively, e.g. while sitting it can take its hand or a spoon to its mouth. The finger-nose test is normal. Such pure midline vermis syndromes are seen in early cases, before the tumour extends to the cerebellar lobes. Nystagmus is usually absent, but when seen, is rapid, fine and symmetrical.

Large tumours of the vermis extend into the cerebellar lobes producing signs in the upper limb. They also compress the fourth ventricle resulting in increased ICP, headache and vomiting. When extending higher up, functions of the fourth cranial nerve may be involved. Parkinsonism like tremors have been described.

Cerebellar Hemisphere Lesions

Both in man and in birds, the cerebellar lobes are developed, indicating the importance of the function of the upper limbs in man and the wings in birds. The common symptom of a cerebellar lobe lesion is the difficulty in using the ipsilateral upper limb, although the lower limb may also be involved. The patient complains of clumsiness of movement of the upper limb. In a right handed individual, this may manifest itself early as difficulty in writing. The letters become bigger than usual (macrographia). There is difficulty in picking up objects or in holding them steady. On examination there is a drift of the outstretched hand. The cerebellar disturbance is obvious only when the limb is put to action (action tremor) and disappears if the limb is supported or is resting. The finger-nose test reveals intention tremors and past-pointing. In early cases, an involuntary closure of the eyelid as the finger reaches the nose may indicate a cerebellar dysfunction.[70]

There is an inability to make rapid alternate movements of the limb (dysdiadochokinesia). The heel-knee test is impaired. The knee jerk is pendular and all the deep tendon reflexes are intact. Hypotonia is evident on testing the muscle tone. If the forearm is jerked quickly up and down, the hand will flap, indicating lack of tone in the forearm muscles. In an unconscious patient, the way in which an upheld limb drops on the bed can indicate hypotonia. Until the lesion begins to invade the vermis or the brainstem all the symptoms are confined to the ipsilateral limb.

Asynergia of the pharyngeal and tongue muscles leads to slurred (words running into each other) or staccato or scanning speech (words split syllable by syllable). Nystagmus, evidence of asynergia of eye muscles, is seen in cerebellar lesions only when the vestibulo-cerebellar connections (dentate nucleus) begin to get affected. Nystagmus is not seen in laterally placed cerebellar hemisphere lesions. In unilateral cerebellar lesions, the nystagmus is slower and coarser when the eyes are directed towards the side of the lesion than towards the opposite side. Such nystagmus disappears in a few weeks. If persistent, it will indicate pressure on or invasion of the vestibular nuclei.[36,40]

The cerebellum has a role in cognition as well. Diseases of the cerebellum are known to cause attention deficits and disturbed executive function, visuospatial disorganisation and impaired visuospatial memory, personality change and linguistic difficulties such as dysprosodia, agrammatism and mild anomia. So, the attention span must be assessed in all cerebellar lesions.[17] Lesions of the cerebellum in children have been reported to produce mutism.

Cerebellopontine Angle Tumours

This region is a frequent site of occurrence of space occupying lesions which exhibit a characteristic symptomatology. The structures in this region are the V, VII and the VIII nerves anteriorly, the cerebellum posteriorly, the brainstem medially and the lower cranial nerves inferiorly. Any one or all these structures get involved gradually as the lesion enlarges. When the tumour arises primarily from the eighth nerve, tinnitus and impairment of hearing are early symptoms. Disturbances of vestibular function, like giddiness or vertigo, are usually transient phenomena, compensation taking place very early.

An early sign of trigeminal affection is the loss of corneal sensation as shown in a diminution or abolition of the corneal reflex. This is elicited by touching the cornea gently with a wisp of cotton wool. The examiner's hand with the wisp of cotton should approach the cornea from the lateral side to prevent blinking due to the menace reflex. As the cotton wool touches the cornea, there is a brisk closure of the eyelid. If there is a fully established seventh nerve palsy preventing closure of the ipsilateral eyelid, the efficacy of the corneal reflex is judged by observing the rolling up of the ipsilateral eyeball (Bell's phenomenon) and closure of the opposite eyelid (see chapter on "Acoustic Neurinoma").

Prepontine or Clival Tumours

Anterior midline tumours, especially when slow growing, may exist for a long time without any apparent clinical signs. Unprovoked, uncontrolled laughter is a characteristic symptom of prepontine tumours. Pressure on the anterior aspect of the brainstem may lead to bilateral pyramidal or bilateral cerebellar signs. Other long tract signs are not obvious. However, as the tumour enlarges, multiple cranial nerves may be involved bilaterally. The lesions located anterior to the brainstem are chordomas, chondromas, clivus meningiomas, nasopharyngeal growths and basilar aneurysms).

Intrinsic Lesions of the Brainstem

The most common lesion is a glioma, rarely a metastatic lesion or an angioma may be seen. In India, the possibility of a brainstem tumour being a tuberculoma must always be kept in mind. These constitute more than 10% of all brainstem tumours. Likewise, it must be remembered that tuberculous meningitis may mimic a brainstem tumour. Headache is uncommon in brainstem gliomas, whereas it is a predominant symptom in tuberculous meningitis. Exacerbations and remissions of symptoms have been noted in some brainstem gliomas, thus mimicking multiple sclerosis.[79] Rarer symptoms of brainstem gliomas include continuous facial spasm[45,80] and hyperventilation.[47]

Gaze palsy, multiple cranial nerve involvement, cerebellar signs and bilateral long tract signs, in various combinations, constitute the clinical features of brainstem lesions. An early sign of an intrinsic brainstem tumour is external rectus weakness in one eye followed by facial palsy, swallowing difficulty and unsteadiness. Examination shows a combination of multiple lower cranial nerve palsies and motor and sensory long tract signs. This is specially seen in exophytic brainstem tumours. Unilateral or bilateral horizontal conjugate gaze palsy is characteristic of a lesion at this site. Internuclear ophthalmoplegia due to involvement of the medial longitudinal fasciculus, when seen, is diagnostic of an intrinsic brainstem lesion. On attempted gaze towards either side, there is paresis of adduction and an associated nystagmus of the abducting eye. Another ocular phenomenon seen in brainstem lesions is vertical nystagmus. This sign is always indicative of nervous system involvement, especially of the caudal brainstem, as labyrinthine disease cannot produce vertical nystagmus. Papilloedema is seen in only 15% of cases.[73,74] With modern imaging techniques and early suspicion of brainstem lesions, the incidence of papilloedema has become less. This combination of a variety of neurological symptoms of the brainstem, without apparent increased ICP, points to an intrinsic involvement of the brainstem. Periodic disturbances of the level of consciousness may be seen.

Tumours of the Fourth Ventricle

These tumours usually grow to a large size and fill up the ventricle before causing signs and symptoms of increased pressure. Small tumours may obstruct the aqueduct early. A common and early symptom, especially in children, is vomiting unassociated with abdominal discomfort or nausea. An otherwise healthy child that begins to vomit without reason and falters in its gait must immediately be suspected of harbouring a midline vermis lesion encroaching onto the fourth ventricle. Unsteady gait, giddiness or vertigo, nystagmus and lower cranial nerve palsies become evident much later.

Tumours at the Craniovertebral Junction

These are difficult to diagnose, being in the borderline between the brain and the spinal cord.[66] In the absence of symptoms and signs of raised ICP, lesions at the CV junction may masquerade as disseminated sclerosis, amyotrophic lateral sclerosis or spinocerebellar degeneration. They may mimic the clinical picture of craniovertebral anomalies. Lesions at this level may exist for a long time without causing any apparent neurological deficit. A large cisterna magna provides a lot of space for the growth of such tumours. Those arising intracranially cause obstruction to the CSF flow and raise the ICP without producing localising signs. They may also cause lower cranial nerve palsies. Occasionally, the hypoglossal nerve may be involved leading to wasting and weakness of one-half of the tongue. Pressure on the brainstem may lead to bilateral pyramidal signs. Cerebellar signs are occasionally seen. If the tumour is inferior, occipital neuralgia with a stiff neck, often mistaken for a long time for tension headache, may be the only symptom. Numbness over the occipital nerve distribution with signs in the upper and lower limbs that occur later, give a clue to localisation. Varying degrees of signs and symptoms of upper cervical cord involvement confuse the clinical picture.

Neighbourhood Signs

In addition to the local signs, neighbourhood effects are often seen in ICSOL. As the lesion grows in size, the neighbouring structures get compressed or infiltrated, the resulting symptomatology depending on the direction of growth of the lesion. The neighbourhood effects may also be caused by secondary phenomena, the most common being oedema. Oedema surrounding a space-occupying lesion varies in its intensity and severity depending upon the nature of the original lesion. Oedema around a tuberculoma, a glioblastoma or a metastasis could be pronounced and thus lead to neurological symptoms far more extensive than could be caused by the actual size of the tumour. Neighbouring structures may also suffer from a steal of blood supply as may happen in an arteriovenous malformation or in a highly vascular tumour.

Herniation

Owing to the softness and compressibility of the brain a growing tumour is able to displace the brain substance.

This displacement modified by the presence of dural partitions inside the cranial cavity results in brain herniations. Depending on the site of the tumour and the direction of the pressure, the herniation may take place under the falx, through the tentorium or the foramen magnum. In very acute and severe rise of ICP, brain matter may herniate through the exit foramina of the cranial nerves.

Subfalcine Herniation

In supratentorial space occupying lesions, the ipsilateral cerebral hemisphere is compressed and pushed against the falx cerebri. The portion nearest the dural partition, namely the cingulate gyrus, herniates under the free edge of the falx. Although, on rare occasions, this may result in occlusion of the anterior cerebral artery, such herniation does not cause any serious problem. Transtentorial and tonsillar herniations are more significant as they may threaten life.

Tentorial Herniation

As the supratentorial lesion grows in size, the brain not only gets pushed across the midline but herniates downwards through the tentorial hiatus. The structures (close to the tentorial edge) that herniate are the uncus and hippocampal gyrus which insinuate themselves between the brainstem and the tentorial edge. On the other hand, instead of the temporal lobe, the brainstem may itself be pushed down.

Depending on the site of the causative lesion and the direction of the pressure, tentorial herniation may chiefly be in its anterior or posterior part and in advanced stages may be complete. In anterior herniation, the third nerve and the crus are involved leading to a dilating pupil and a contralateral hemiplegia. In some cases, when the brainstem is pushed against the opposite tentorial edge, an ipsilateral hemiplegia may result (Kernohan's notch). The shift of the brainstem also leads to a kinking of the aqueduct with secondary blockage of the CSF flow, which further aggravates the supratentorial pressure. A complete bilateral tentorial herniation may block the CSF pathways around the brainstem and further disturb the CSF flow and absorption. In rare instances, the posterior cerebral artery may get compressed, resulting in occipital infarction and hemianopia or cortical blindness if both arteries are involved.

In posterior lesions, the anteromedial portion of the occipital lobe (the precuneus) herniates into the cisterna ambiens and presses on the colliculi and the midbrain. This may lead to varying degrees of oculomotor palsy, progressive deafness and decerebrate rigidity. There may also be paralysis of upward gaze, as well as hemianopia.

Cerebellar Herniation (Tonsillar Herniation)

In generalised increased ICP, as well as in posterior fossa lesions, the ICP may force the posterior fossa structures down through the foramen magnum. The cisterna magna gets obliterated. The tonsils of the cerebellum, which are situated near the margin of the foramen magnum, are pushed down through it and may reach the level of the second cervical vertebra. The crowding of structures in the foramen magnum aggravates the ICP by a secondary blockage of the exit of CSF.

Pressure on the upper cervical nerves leads to neck rigidity and torticollis. In the presence of a persistent herniation, a sudden rise in ICP precipitated by coughing or sneezing may quickly squeeze the medulla resulting in rapid respiratory failure followed by cardiac failure and death. Usually the stage of respiratory failure lasts for some minutes before cardiac failure sets in. Even at this stage, it is possible to save the patient by energetic treatment to reduce the ICP. Mild degrees of tonsillar herniation are seen in most cases of increased ICP. In unilateral cerebellar lesions, only the tonsil of the affected side may be found herniated.

Retrograde Tentorial Herniation

In some cases of posterior fossa tumours, when the pressure in the posterior fossa is much higher than the pressure in the supratentorial compartment, the structures near the tentorial hiatus may be pushed upwards. This may cause secondary pressure on the brainstem. Such an emergency sometimes arises as a consequence of a CSF diversion procedure for hydrocephalus. The patient may suddenly go into decerebrate rigidity with autonomic disturbances, followed later by respiratory failure.

Distant Signs

These are caused by obstruction to the CSF pathways, a disturbance of blood supply to distant areas or by shifts and changes in the position of various structures as the lesion grows in size. These lead to false localising signs.

False Localising Signs

Neighbourhood or distant effects may present themselves as primary symptoms, before any localising sign of the tumour becomes obvious. In such cases the primary presenting symptom may mislead the clinician to localise the lesion to a wrong part of the brain.[27] Practically, all possible neurological signs have been reported as false localising signs. Only a few common ones are mentioned here.

1. Ipsilateral hemiplegia lateralising the lesion to the wrong side. Gould[37] explained, in 1926, this false lateralising sign as due to a mechanical compression of the crus on the side opposite to the tumour against the lateral edge of the tentorium. This was confirmed, in 1929, by Kernohan and Woltman,[44] who demonstrated the notching of the crus in pathological specimens. Ipsilateral hemiplegia may also occur due to: (a) direct pressure acting on the opposite internal capsule due to the configuration of the falx cerebri; (b) longitudinal stretching of the opposite internal capsule;[39] (c) dilatation of the opposite lateral ventricle, especially when there

is a block of the foramen of Munro and (d) uncrossed pyramidal tracts.[89]

2. The presence of frontal lobe signs in cerebellar tumours and cerebellar signs in frontal lobe tumours have already been mentioned.
3. A highly vascular lesion of the temporal lobe may steal blood from the frontal region leading to the appearance of frontal lobe localising signs.
4. Cerebellar signs in a craniopharyngioma.[4,43]

In summary, therefore, a patient with an intracranial space occupying lesion may present with one or more of the following:

1. Symptoms and signs of raised ICP
2. Focal neurological deficit
3. Focal or generalised epilepsy
4. Psychiatric symptoms
5. Endocrine disturbances
6. Visible deformity of the head
7. A combination of any or all of these

The evolution of the illness, generally characterised by an insidious onset and a progressive course, may be occasionally apoplectic or rarely intermittent.

It is obvious from a study of the various phenomena described above that early diagnosis gives the best chance for good results to the patient and the neurosurgeon. This is not always possible in developing countries, where awareness of the existence of intracranial tumours as well as the facilities available to deal with them may vary widely.

It is important to quantify the extent of disability a patient with a brain tumour has. For brain tumours, it is the Karnofsky score which is as follows:

Score	Feature
100-	Normal, no complications.
90-	Normal activity is pursued with minimal signs or symptoms.
80-	Normal activity is pursued with effort and the patient has some symptoms.
70-	The patient is able to care for self but is unable to work.
60-	The patient requires occasional assistance but is able to cater to most of his needs.
50-	The patient needs continuous assistance and frequent medical care.
40-	The patient is disabled and requires special care.
30-	The patient is severely disabled and requires hospital care.
20-	The patient is very ill and is in hospital and requires supportive care.
10-	Moribund.
00-	Dead.

Early referral of patients leads to better localisation of the lesion due to the absence of secondary phenomena, and to better results of treatment, due to the minimal increase of ICP. With advanced imaging techniques and surgical expertise, the outlook in neurosurgery is far more optimistic than five decades ago.

133 Supratentorial Astrocytomas

Ramakrishna Easwaran

INTRODUCTION

Gliomas are the most common group of intracranial neoplasms. They consist of a heterogeneous variety of tumours, with varying grades of malignancy. At one end of the spectrum is the well-behaved juvenile pilocytic astrocytoma and on the other, glioblastoma multiforme with a dismal prognosis. In between, there is a whole range of tumours with hoverlapping morphological and biological characteristics. Almost every area of "gliomology" is mired in controversy, be it the basic biology, classification, grading or the need for aggressive resection. After more than a century of a love-hate relationship with gliomas, the neurosurgical community is now closer than ever to evolving a consensus on these issues. This chapter deals with supratentorial gliomas and the focus is on astrocytomas and glioblastomas. Oligodendroglioma and ependymoma are dealt with in other chapters.

HISTORY

The term 'glioma' was coined by Virchow in 1863. Rickman J Godlee removed a glioma from the motor area on 25th November 1884 after the tumour was localised clinically by A Hughes Bennett. Thus was born glioma surgery and indeed neurological surgery. Gliomas accounted for 42% of the 2,000 brain tumours operated upon by Harvey Cushing and the proportion remains the same today. The difference since Cushing's times is the 20-fold drop in the peri-operative mortality of gliomas.[20] Corticosteroids, safer neuroanaesthesia and improved intensive care must take the credit for this falling mortality. Advances in biology (immunochemistry, cell cultures, immunology and genetics) have kept pace with the advances in imaging and surgical technology (computed tomography (CT), magnetic resonance (MR) imaging, operating microscope, stereotaxy, neuronavigation and functional localisation). While these developments have contributed to mitigating the morbidity, they have done little to improve the ultimate prognosis of the scourge that is glioblastoma.

INCIDENCE

Overall Incidence

Gliomas constitute 35–50% of all intracranial neoplasms. There are only minor variations in the total incidence of gliomas in intracranial tumour series reported from different centres in the world. After excluding granulomas, the incidence of gliomas among intracranial tumours in various Indian neurosurgical series is similar to that in the rest of the world.[45] The correct incidence has to be judged from population-based studies. The annual incidence of glioma per 100,000 persons has been reported as 2.2 in Japan[11 7] and 5.4 in the United States (US).[46] The incidence of primary malignant brain tumours was reported to be increasing until 1990, significantly so in the elderly, in a Florida study. This is not merely because of better detection with neuroimaging as the increase has been detected between two time periods after CT became available.[257] The incidence of glioblastoma was also reported to be increasing in Canada in a 1991 study.[134] However, in the last 20 years the incidence seems to have decreased in the US.[54]

Frequency of Subtypes

In a consecutive series of 500 verified supratentorial gliomas at the All India Institute of Medical Sciences (AIIMS), New Delhi, the distribution of various histological types was as given in Table 1.[240] This table also compares the incidence of the histological types from the Central Brain Tumour Registry of the US (CBTRUS) for the period 1998–2002.[27] The higher incidence of glioblastoma in the Western countries is apparent. Since glioblastoma incidence tends to peak at a later age, the higher proportion of the aged in the Western population may account for at least a part of this difference.

Table 1: Distribution of various histological types of supratentorial gliomas

Histological type of glioma	*AIIMS, Delhi N=500%*	*CBTR, US N=25539%*
Astrocytoma	37	13
Malignant astrocytoma	23	14
Glioblastoma	21	50
Mixed glioma	10	7
Oligodendroglioma	5	9
Ependymoma/Malignant ependymoma	3	5
Others	1	2
	100	100

Age and Incidence

Gliomas are seen at all ages from the just born to the nonagenarian. Congenital glioma, producing symptoms at birth or shortly thereafter, though rare, is well reported.[94] Nearly two-thirds of all cases of supratentorial gliomas occur in the third to fifth decade. In the AIIMS series 44% of the astrocytomas occurred below the age of 30 years. In contrast to this, 72% of glioblastomas occurred above the age of 30 years.[240] The mean age for astrocytomas was 37.4 years, for malignant astrocytomas 45.8 years and for glioblastomas 52 years in one report.[141] The relative risk of brain cancer is 3.18 for elderly persons as compared with young adults.[54]

Gender and Incidence

With the exception of meningioma, all brain tumours occur more frequently in males. About 74% of the 500 gliomas in the AIIMS study were in males.[240] The relative risk of brain cancer was 1.48 for men as compared with women.[54] In the CBTRUS data, 56% of all gliomas occurred in men. The increased incidence in men is mainly due to increased frequency of malignant astrocytoma and glioblastoma.[46]

Other Epidemiological Factors

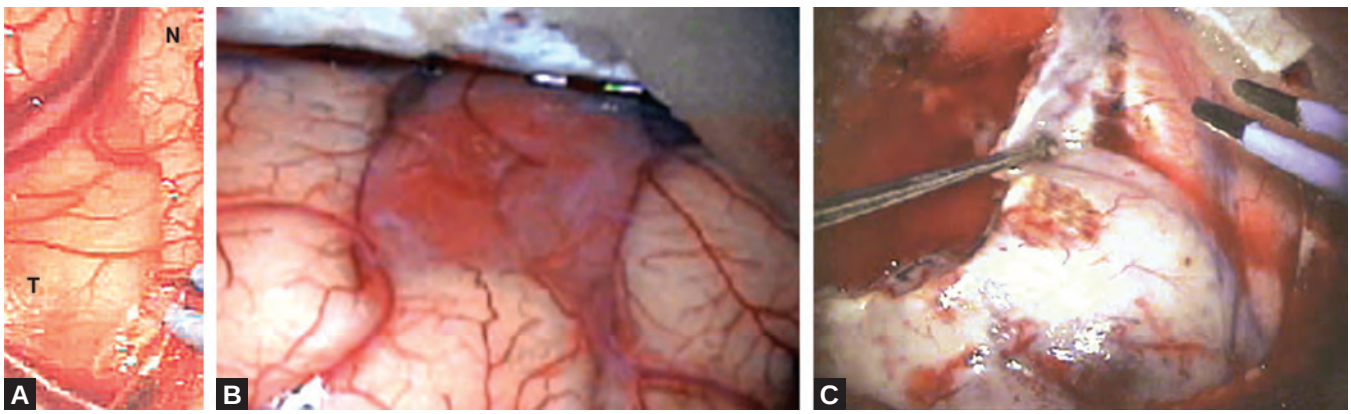
Malignant gliomas occur more frequently in Caucasians than in African-Americans, the relative risk being 1.86. The incidence is 1.35 times greater in the urban areas as compared to rural ones.[54] Most of the Northern Europe, North America and Israel are considered as high-incidence regions while Africa, India, China and Japan are considered low-incidence areas for malignant nervous system tumours in the age group of 35–64 years.[46] Those born in winter have been shown to have a higher risk of developing a glioma in later life. This was particularly so for left handed individuals in a case-control study.[25] Familial gliomas of the non-genetically determined type are extremely rare. The small number of cases does not permit us to conclusively say if relatives of the index glioma patient are at a greater risk of developing a glioma.[19]

Children of mothers residing within a mile of certain toxic chemical factories during pregnancy have been shown to have a risk of brain cancer.[37] Ionising radiation exposure (therapeutic, occupational or accidental) has been proved to increase the risk of malignant glioma (see section "Aetiology and Pathogenesis"). Less clear is the effect of diagnostic X-ray examinations, cosmic radiation in frequent fliers and high electromagnetic field exposures.[46] Recently, concern has been expressed about the radiofrequency exposure from cell phones. It was suggested in a Swedish study that gliomas were more frequent on the side of habitual use of mobile phone.[77] But in a recent British case-control study, the overall odds ratio for regular phone use was only 0.94 indicating that cell phone usage did not increase the chance of developing a glioma. There was no relation between risk of glioma and time since first use, lifetime years of use, and cumulative number of calls and hours of use of mobile phones.[81] There have been criticisms of the methodology of studies showing a negative correlation of cell phone use with glioma occurrence.[78] The last word on the matter has not yet been said.

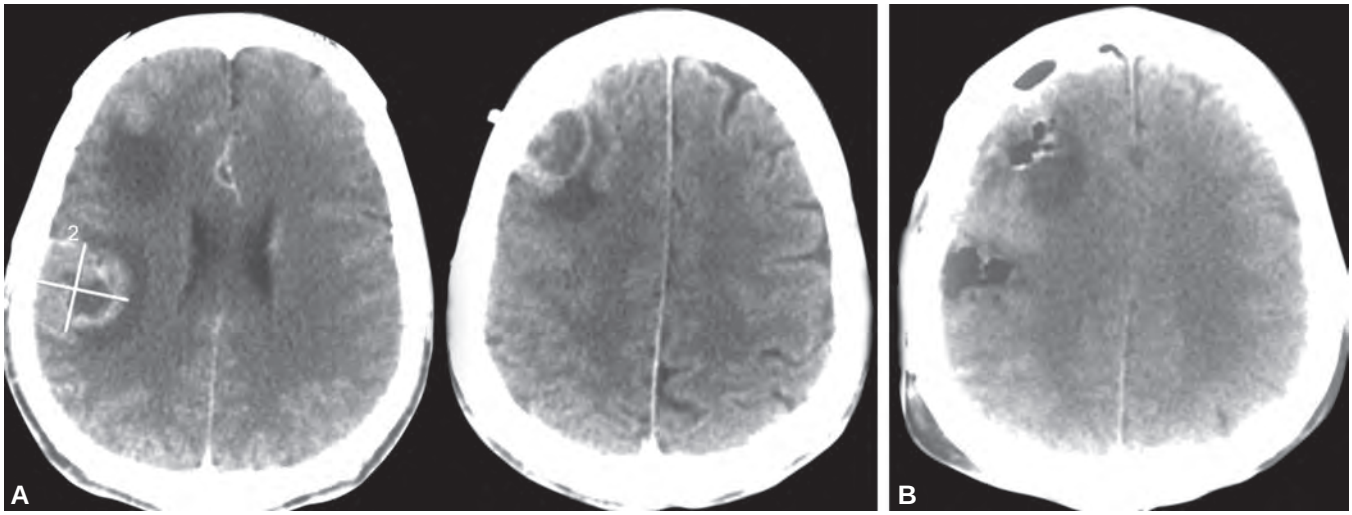
PATHOLOGY

Location of Gliomas

The majority of cerebral gliomas are located in the frontal, temporal and parietal lobes and the incidence is proportional to the size of each lobe. Tumours often transcend anatomical boundaries, though in the early stages many tumours are confined to the area of the gyrus and grow in size expanding the gyrus. Tumours that extend to the surface are easily identified at surgery. The distinction from the normal brain surface is subtler in lower grade tumours and more obvious in glioblastoma (Figs 1A to C). In subcortical tumours, the expanded gyrus can be identified at craniotomy. Two gyri, distant from one another in the same lobe may



Figs 1A to C: Surface appearance of gliomas at surgery. (A) Surface appearance of grade 2 astrocytoma. Note the glazed distended appearance of the tumour (T) as compared to the normal cortex (N). (B) Surface appearance of grade 3 astrocytoma. (C) Surface appearance of glioblastoma



Figs 2A and B: Two foci of gyral glioma. (A) Contrast enhanced computed tomography (CECT) of astrocytoma (grade 3) arising independently in two different gyri of the frontal lobe. The lesions were approached through a single craniotomy flap and excised through two gyrotomies. (B) Post-operative CECT (right) showing the two resection cavities

separately harbour a glioma each (Figs 2A and B). In a CT study from India, 20% of gliomas crossed the midline and 5.5% involved the basal ganglia.[240] The corpus callosum is often invaded by a lobar tumour but it may be the site of origin too. The thalamus, corpus striatum, pineal gland and pituitary fossa are the less frequent sites of origin. Rarely, gliomas are multicentric in origin or may occur in the same patient at two different sites after a long time interval. In an imaging and histology based study, 51 cases of multicentric glioma have been reported.[120] In 26 cases, the tumours were multicentric at presentation while in the rest, it developed during the course of treatment. In 14 cases, no pathway of dissemination could be found and these were the true multicentric gliomas. Bilateral synchronous tumours are reported from India in the frontal lobe[18] and in the thalamus.[145] Figure 3 shows an example from the author's personal collection. Consecutive cerebellar and cerebral astrocytomas have been reported.[17]

Gross Pathology

This is the pathology relevant to the surgeon as it can be readily seen and felt during the operation. The low-grade tumours tend to be poorly demarcated from the surrounding brain. They are relatively less vascular and appear grey. There is hardly any oedema in the surrounding white matter. In fibrillary astrocytomas, the consistency is tougher than the normal white matter. The subtle colour difference between the tumour and the normal brain is more apparent under the lighting and magnification of the operating microscope than to the naked eye. The difference in consistency is better appreciated by the tactile feedback the surgeon gets from the dissectors or bipolar forceps than from the use of the ultrasonic aspirator. A single large cyst or a honeycombed appearance due to multiple small cysts may be seen. The more malignant tumours may be more granular, pinkish and vascular. As the tumour grows, the central part becomes necrotic. The term "angioglioma" is used to describe a low-grade tumour with vascularity mimicking a cavernous angioma or arteriovenous malformation. Figures 4A and B show an example. They do not represent a distinct clinicopathological entity and the behaviour is no different from the less-vascular low-grade tumours.[127] The "angioglioma" is not to be confused with the recently described angiocentric glioma (see below).[186] Calcific foci are common in mixed glioma but profuse calcification along axonal pathways has been observed.[72] Though radiologically and histologically the calcification is impressive, the tissue feels only slightly gritty and never as hard as the calcification in a meningioma or craniopharyngioma (Figs 5A and B).

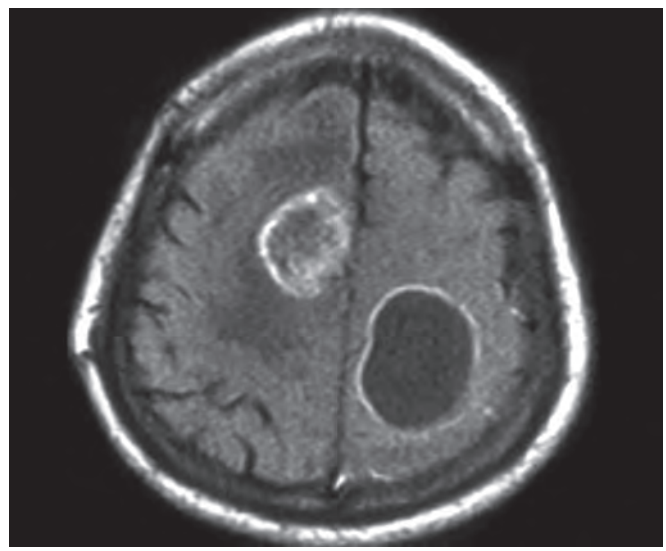


Fig. 3: Synchronous bilateral astrocytoma. Contrast magnetic resonance imaging. The tumour on the left was non-cystic and grade 2, while the tumour on the right was grade 3 by computed tomography guided stereotactic biopsy

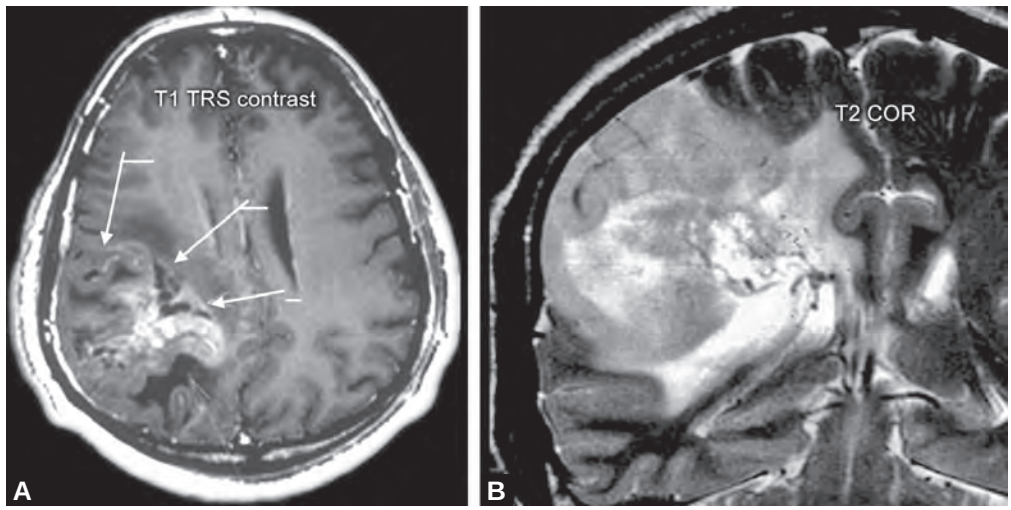
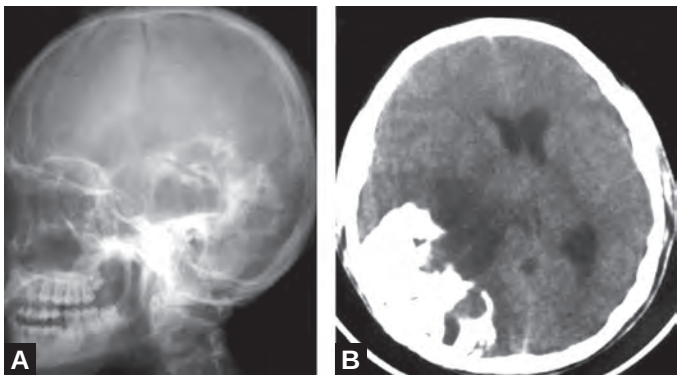


Figs 4A and B: "Angioglioma". Magnetic resonance of tumour in the parietal lobe. Note the multiple flow voids in the tumour. This patient presented with seizures and when the seizures became refractory 4 years later, consented to resectional surgery. The tumour was a mixed glioma with extreme vascularity. The patient remains without deficits or tumour progression, free of seizures on medication 5 years after surgery

The glioblastoma shows a variegated appearance, true to the tag of "multiforme" in its name. Pale yellow areas of necrosis or lipid accumulation, black areas of old haemorrhages, purple thrombosed vessels and cystic areas containing bright yellow fluid are interspersed in a soft pinkish-grey mass that is deceptively well circumscribed. The swelling and peritumoural oedema are disproportionately more for the size of the tumour. Involvement of an entire frontal or temporal lobe is characteristic. A glioblastoma that starts *de novo* and grows rapidly is called primary glioblastoma. A pre-existing low-grade astrocytoma may turn anaplastic and this gives rise to the secondary glioblastoma.

Spread

Gliomas spread within the neuraxis through the subarachnoid, subependymal, intraventricular or direct brain penetration routes in the descending order of frequency.[120] Superficial gliomas may invade the meninges.



Figs 5A and B: Calcification in mixed glioma. Lateral skull radiograph and unenhanced computed tomography of a young man with mixed glioma with mostly oligodendroglial component. Despite the extensive calcification in the tumour, the feel of the tumour was merely firm with only rare gritty areas

This invokes a fibroblastic proliferation and the tumour then simulates a meningioma at surgery. Biopsies from the superficial part of such a tumour may mistakenly be reported as meningioma. Gliomas are also known to arise from heterotopic glial rests in the leptomeninges.[143] Spread along the subarachnoid cerebrospinal fluid (CSF) pathways as happens in an ependymoma or a medulloblastoma is rare. If extensive, such a spread is called "leptomeningeal gliomatosis".[71,50] From the meninges, there may be a re-invasion of the parenchyma at a different site.[120] Glioblastomas are seen to spread subependymally along the walls of the third or lateral ventricle.

Periaqueductal gliomas are usually low-grade pilocytic tumours that block the aqueduct. They are amenable to endoscopic biopsy and ventriculostomy. These indolent tumours may even spread to the ventriculostomy site and block it.[138] A rare case of grade 2 astrocytoma occupying all the ventricles has been reported from Chennai as "holoventricular glioma".[82] Dissemination in to the posterior fossa from primary supratentorial glioma and its treatment is the subject of a recent paper.[223] The case of vermian spread reported from Vellore is unusual because it was from a grade 2 oligoastrocytoma and it occurred 4 years after the primary frontal tumour was treated.[231] Low-grade tumours tend to spread along fibre tracts without infiltration. The patterns of spread can be studied with magnetic resonance imaging (MRI).[22]

Extracranial Metastases

Extracranial metastases of brain tumours are uncommon because of the absence of lymphatic drainage. They may occur after a craniotomy that opens paths of exit from the brain. Extracranial metastases in the absence of a previous craniotomy have been reported in a few cases. In these cases, tumour cells were seen in the lumen of venous channels.[84] A case has been reported in which lymph node metastasis was the first manifestation of a

glioblastoma, the intracranial signs becoming manifest 3 weeks after the biopsy of the lymph node.[57] Tumour spread through ventricular shunts to the pleural and peritoneal cavity is well known for medulloblastoma, but is also reported with glioblastoma.[163] Spread to the lungs, liver and bones is rarely seen.[67,174]

CLASSIFICATION AND GRADING

Bailey and Cushing (1926) put forth the classification of gliomas on the basis of possible histogenesis. Penfield, Cone and Elvidge (1931) retained some of the 14 terms from this terminology (such as medulloblastoma) but replaced others (e.g. spongioblastoma multiforme was changed to glioblastoma multiforme). Since their time, the lumpers and the splitters among neuropathologists have modified the classification systems.[45]

The criteria of a grading system of gliomas are:

- The grade should predict clinical behaviour
- The system must be objective and should not allow inter-observer variation

There may be a small focus of malignancy in a well-differentiated tumour, but it is that tiny focus that would decide the prognosis. Any grading system can work only if the sampling has been representative and adequate. Grading is not of mere academic importance, but it is the basis on which therapy is recommended. The ideal grading system would allow easier organisation of prospective multicentre trials and help compare retrospective results from various centres meaningfully. It is to be remembered that grades are merely arbitrary stations in an oncological continuum.

Kernohan at Mayo Clinic divided astrocytomas in to grades 1 to 4 in the increasing order of malignancy (Table 2). The problem with Kernohan grades was that it placed the pilocytic astrocytoma and the low-grade fibrillary astrocytoma in grade 1, though they have widely differing behaviour and prognosis.[143] Follow-up studies also showed no prognostic difference between grade 3 and grade 4 in this scheme.[65] Ringertz in Stockholm recognised pilocytic astrocytoma as a distinct entity and placed the remaining astrocytic tumours in a three-tier system (Table 2). This system was shown to correlate better with clinical behaviour and prognosis.[143] Daumas-Duport made the scheme more objective so as to reduce inter-observer variability (Table 2). The mean survival time was 45 months for grade 2 tumours, 16 months for grade 3 tumours and 8 months for grade 4 tumours according to this scheme in a follow-up study.[100] However, the three-tier system is not without its detractors.[70] The inter-observer (and indeed the intra-observer) variability is so much that a computer aided morphometric analysis may be needed to classify the malignancy.[214]

Table 2: A comparison of grading systems of astrocytomas in the ascending order of malignancy

Kernohan (1949)	*Ringertz (1950), Burger (1982)*	*Daumas-Duport (1988)*
Astrocytoma grade 1 Hypercellularity No pleomorphism or mitotic figures or nuclear atypia (Includes pilocytic and low grade fibrillary)	Pilocytic astrocytoma Fibrillary astrocytoma	Pilocytic astrocytoma Astrocytomas-classified based on following features: 1. Pleomorphism 2. Mitotic figures 3. Vascular proliferation 4. Necrosis
Astrocytoma grade 2 Hypercellularity Nuclear hyperchromasia No mitosis or necrosis Minimal endothelial proliferation	*Astrocytoma* Hypercellularity Slight pleomorphism No necrosis or vascular proliferation	*Astrocytoma grade 1* None of above features *Astrocytoma grade 2* Any one of features 1 to 3 above
Astrocytoma grade 3 Many but not all cells appear astrocytic Pleomorphism Mitotic figures Necrosis in places Endothelial proliferation	*Anaplastic astrocytoma* Pleomorphism moderate No necrosis Vascular proliferation +	*Astrocytoma grade 3* Any two of features 1 to 4 above
Astrocytoma grade 4 Only few cells are recognizably astrocytic Severe pleomorphism Mitosis (numerous, bizarre) Widespread necrosis Marked endothelial proliferation	*Glioblastoma multiforme* Pleomorphism marked Necrosis Vascular proliferation ±	*Astrocytoma grade 4* 3 or 4 features listed above

Zulch (1979) authored the World Health Organization (WHO) classification of brain tumours. The Russell and Rubinstein school slightly modifies the 1993 WHO revised scheme of Kleihues, Burger and Scheithauer. The term "glioblastoma" is retained, as its morphology may be so bizarre that the origin from the astrocyte may be obscured. Astroblastoma is placed with the ependymal tumours as it shows tanycytes.[53] The less commonly seen histological subtypes are also included in this scheme (Table 3). The fourth edition of the WHO classification (2007) adds several new tumour types and recognises genetic profiling.[130] The new glial-neural tumours added in this edition are pilomyxoid astrocytoma, papillary glioneuronal tumour, angiocentric glioma and pituicytoma.[24] The future of grading will lie in identifying molecular signatures of the genetic subsets of histologically similar tumours that have differences in outcome.[51,129]

Table 3: Classification of central neuroepithelial tumours (the variants mentioned in parenthesis)

i. Papilloma
ii. Carcinoma

MICROSCOPIC PATHOLOGY

The histological features of astrocytic tumours are dealt with in detail in this textbook. Only certain variants and recent findings are highlighted here.

Types of Specimens

The squash or frozen section biopsy has been proved to be a reliable method of diagnosing glial tumours.[192,210,220] Discrepancies between the frozen section diagnosis and the final diagnosis arise in distinguishing astrocytoma from oligodendroglioma, in differentiating reactive astrocytic changes from tumour and in grading.[181] Stereotactic biopsies are small but usually accurate.[189] The low-grade tumour and glioblastoma are readily distinguished, but there is an inter-observer variation in grading anaplastic astrocytomas in stereotactic biopsies.[150]

Histological Variants

Pilocytic Astrocytoma

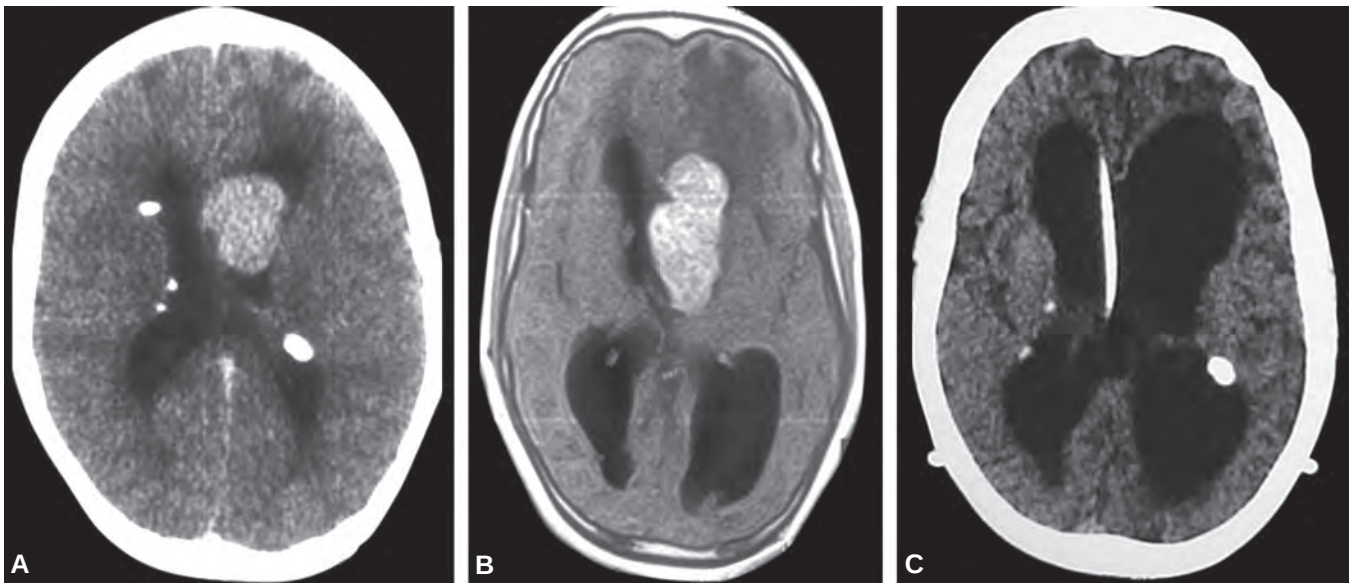
It occurs in the cerebellum and hypothalamus-optic pathway and it is described in the relevant chapters. Pilocytic astrocytomas with identical radiological appearance, histological findings and good prognosis are seen in the temporal and parieto-occipital lobes in the first three decades of life.[95] Adult pilocytic astrocytomas might recur frequently and may not behave in a benign fashion unlike the juvenile cases.[228]

Protoplasmic Astrocytoma

It has not been accorded a separate status in the recent classification. It is composed of process-poor astrocytic cells and a microcystic background. It is a rare variant occurring in about 5% of low-grade astrocytomas affecting mainly young males. Complete excision may be beneficial, but adjuvant therapy appears to have no effect on outcome.[185]

Subependymal Giant Cell Astrocytoma

This type of astrocytoma is characteristic of tuberose sclerosis (Figs 6A to C). The lesions arise in the lateral ventricle near the foramen of Monro. The CT and MR appearances are stereotyped as in the example shown.[38] Cellular pleomorphism, mitosis and foci of necrosis are seen, but do not indicate a worse prognosis in this tumour. Immunohistochemistry often (but not always) shows negativity for glial fibrillary acidic protein (GFAP) and surprisingly, positivity for neuron specific enolase (NSE) or synaptophysin. Adjuvant therapy is not needed and recurrence free survival is long.



Figs 6A to C: Subependymal giant cell astrocytoma. Computed tomography and magnetic resonance imaging of a boy with tuberose sclerosis who had a slow growing intraventricular tumour. Note the calcific and non-calcific tubers causing candle-drip appearance. The patient underwent a transfrontal total excision followed by ventriculoperitoneal shunting and endoscopic third ventriculostomy later on. Contrast enhanced computed tomography shows no recurrence 3 years after resection

Desmoplastic Infantile Astrocytoma

It appears to arise from the subpial astrocyte. The tumour is seen in the frontal or parietal lobe and grows to a large size with a big cyst. The cyst wall, even if enhancing, does not contain tumour.[13] Additional neuronal differentiation is possible and then it is called *desmoplastic infantile ganglioglioma*. They are usually resectable and the prognosis is favourable.

Angiocentric Glioma

It has been recently included in the WHO classification. It occurs in the cortical-subcortical areas of the temporal or parietal lobes and presents with refractory epilepsy from childhood. The characteristic is prominent perivascular tumour cell arrangements with features of astrocytic/ependymal differentiation, but lacking neoplastic neuronal features. Mitosis, necrosis and vascular proliferation are not seen. Resection provides long-term cure.[186]

Pilomyxoid Astrocytoma

It is a recently described solid, circumscribed tumour occurring in the hypothalamic region of young children. It is composed of a monomorphous population of bipolar tumour cells within a rich myxoid background, with a conspicuous angiocentric arrangement. This tumour is graded as WHO grade II.[24] It behaves more aggressively than pilocytic astrocytomas in the same location.[102]

Chordoid Glioma

It is an uncommon low-grade tumour arising in the third ventricular region, in middle-aged women. It shows chordoma-like histologic features including lymphoplasmacytic infiltrates and Russell bodies. Immunohistochemically, the tumour cells are positive for GFAP, neurofilaments and NSE, suggesting a divergent neuronal and glial differentiation. The Ki-67 index is low.[26]

Pleomorphic Xanthoastrocytoma

It is seen in the second decade. Most are in the temporal lobe and involve the cortex, accounting for their presentation with epilepsy. The radiological findings are similar to the cystic pilocytic astrocytoma. Their well-circumscribed nature allows total excision. The tumour shows a high degree of cellular pleomorphism. The characteristic yellow colour is due to lipid accumulation. Therefore, it needs to be differentiated from the lipidised glioblastoma.[116] An abundant reticulin network is produced due to infiltration of the meninges. The GFAP positivity proves its astrocytic origin. Demonstration of a basal lamina by electron microscopy suggests that the tumour might arise from the subpial astrocyte. The clinical behaviour is like a low-grade astrocytoma in spite of the pleomorphic and strikingly "malignant" histological appearance. Recurrences with malignant transformation are exceptional, but reported.[83]

Gliofibroma

It is a rare glio-mesenchymal tumour composed of astrocytic and benign mesenchymal components, usually seen in the first two decades of life. It has not been accorded a separate status in the recent classification. On imaging and at surgery it mimics a meningioma. The clinical behaviour correlates with the degree of anaplasia in the glial component.[48]

Gemistocytic Astrocytoma

Gemistocytic astrocytoma, recognised for long, is not a separate entity. It consists entirely of large astrocytes

with short, thick or no processes called gemistocytes. The cell bodies rather than the processes are GFAP positive. Often they are only a component within a fibrillary astrocytoma. If gemistocytes constitute more than 20% of the cells, the tumour is to be graded as an anaplastic astrocytoma independent of other features used to assess grading.[112]

Giant Cell Glioblastoma

It is a variant of glioblastoma that seems to have a better prognosis than the garden variety glioblastoma multiforme.[218] A few multinucleated giant cells may be seen in any glioblastoma, especially after radiotherapy. In the giant cell glioblastoma variant practically every cell is a giant cell.[135] The giant cells are GFAP positive and sometimes they are lipidised.

Gliomatosis Cerebri

It involves a whole hemisphere or even both hemispheres and spinal cord. This can be looked upon as a diffuse astrocytoma in an extreme form. The MRI is more sensitive than CT in detecting gliomatosis.[216] The areas of enhancement are the foci of higher grade of malignancy. Gliomatous change occurring simultaneously over a wide field and extreme motility of the transformed cells has been held as the cause of a very wide area of involvement. Stereotactic biopsy and initial temozolomide therapy have been recommended to delay radiation therapy in those patients who are often young children.[124]

Gliosarcoma

It is a rare malignancy consisting of gliomatous and sarcomatous elements (Figs 7A to C). They formed 2.4% of 748 glioblastomas in one report.[66] It shares the aggressive clinical behaviour and genetic similarities with glioblastoma. The tumour is reported to invade outside the dura directly.[197]

Table 4: Classification of low and high-grade gliomas

Low-grade gliomas (WHO grade)	*High-grade gliomas (WHO grade)*
Pilocytic astrocytoma (grade 1)	Anaplastic astrocytoma (grade 3)
Fibrillary astrocytoma (grade 2)	Anaplastic oligodendroglioma (grade 3)
Oligodendroglioma (grade 2)	Anaplastic oligoastrocytoma (grade 3)
Mixed oligoastrocytoma (grade 2)	Anaplastic ependymoma (grade 3)
Ependymoma	Glioblastoma multiforme (grade 4)
Subependymal giant cell astrocytoma (grade 1)	Gliosarcoma
Pleomorphic xanthoastrocytoma	
Desmoplastic infantile astrocytoma	
Pilomyxoid astrocytoma (grade 2)	
Angiocentric glioma	

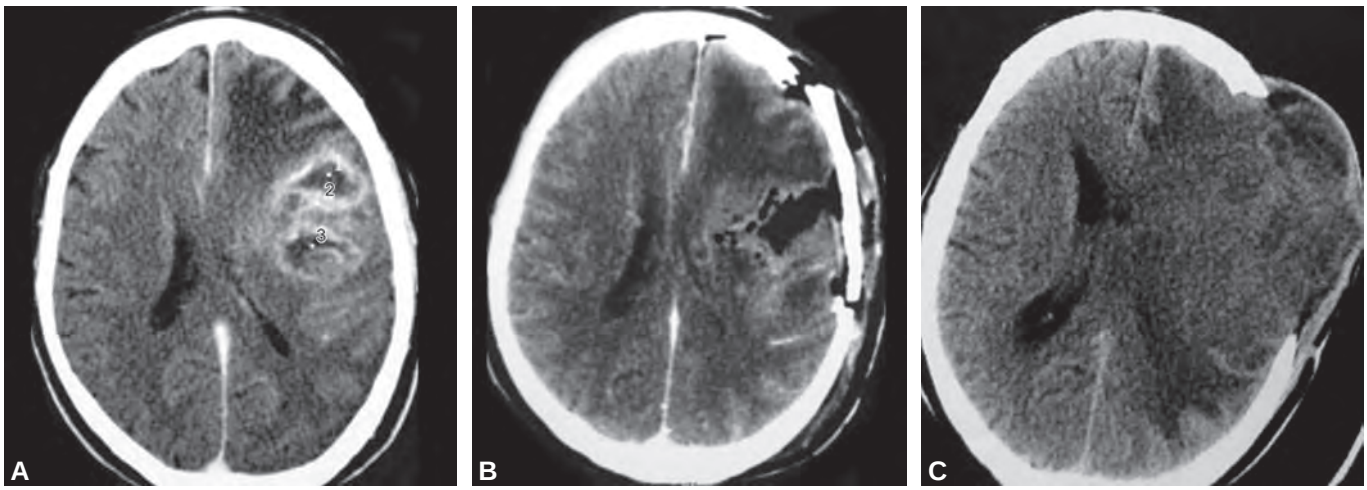
It is convenient to group gliomas in to low[128] and high-grade neoplasms based on usual clinical behaviour (Table 4).

AETIOLOGY AND PATHOGENESIS

The aetiology of the majority of gliomas is not known. The known causes include exposure to ionising radiation and genetic predisposition, but these are rare. Viral aetiology has been suggested but not proved. Glioma arising at the site of traumatic cerebral contusion has been reported and criteria for diagnosing a post-traumatic glioma have been set out.[153]

Radiation Therapy Induced Gliomas

(see above "Other epidemiological factors") Radiotherapy for other scalp, brain or head and neck lesions has been



Figs 7A to C: Gliosarcoma. Contrast computed tomography of a 42-year-old man with gliosarcoma. Despite an apparent complete excision there was residue and rapid regrowth in 3 months even while he was undergoing radiotherapy and chemotherapy. (A) Pre-operative. (B) Immediate post-operative. (C) 3 months later

reported to cause glioma. They generally arise after a latency of 8–25 years and are within the previous field of radiation. They are generally anaplastic and carry a poor prognosis. In one study of 305 irradiated pituitary tumours, four developed a secondary glioma. Their risk of developing a glioma was 16 times higher than the rest of the population.[245] Sellar radiation for craniopharyngioma also carries this risk.[146] Children treated for acute lymphoblastic leukaemia with craniospinal irradiation have been reported to develop malignant glioma. One wonders if chemotherapy also had a potentiating role in such tumours.[211] There are now reports of patients developing malignant glioma after stereotactic radiosurgery (SRS) for acoustic tumours or AVMs.[5]

Hereditary Syndromes and Glioma

There are five hereditary neurological tumour syndromes associated with gliomas. Table 5 gives the type of glial tumour, the gene mutation and chromosomal site in each of these syndromes.[34]

Children with trisomy 21 (Down's syndrome) have been reported to have a higher incidence of gliomas.[201] Though rare, the heritable neurological tumour syndromes are important, as they throw light on glioma genesis.

Cytokinetic Studies and Labelling Index

The factors determining the growth of the tumour are the cell cycle time, the growth fraction, tumour doubling time and cell loss. The parameter most commonly studied is the labelling index (LI), which reflects the proportion of cells in the DNA synthesis phase. The initial studies showed LI < 1% in low-grade glioma and LI > 5% in glioblastomas. The malignant tumours show greater degree of aneuploidy or polyploidy and greater proportion of cells in S phase of mitosis.[122] Increasing values of Ki-67/MIB-1 LI with increasing grade of malignancy in astrocytoma has been noted.[89] Combined Ki-67 and p53 indices higher than 15% indicate a worse outcome than suggested by the histologic grading in diffuse astrocytomas.[243]

Genetic Abnormalities in Non-Syndromic Glioma

The glioma cells show many altered genes leading to over-expression or under-expression of their products. Tumour results when tumour promoter genes are over-expressed or when tumour suppressor genes are under-expressed. The genetic alterations are recognised from the losses or gains in the chromosomal arms and loss of heterozygosity (LOH). Glial tumours are genetically heterogeneous. Primary glioblastoma, which occurs predominantly in elderly males, has a short evolution and a rapidly fatal course. The secondary glioblastoma that arises from a previous low-grade astrocytoma is seen in younger patients, has no gender predilection, presents with a longer history and runs a slower course. Though histologically the primary and secondary glioblastomatous areas are indistinguishable, their genetic makeup is quite different. The primary glioblastoma shows LOH on chromosome 10q, epidermal growth factor receptor (EGFR) amplification, $p16^{INK4a}$ deletion, and phosphatase tensin homology gene on chromosome 10 (PTEN) mutations. The secondary glioblastomas show p53 mutations and LOH on 10q.[168] There seems to be a difference in the chromosomal imbalances seen in adult and paediatric malignant gliomas of similar grade.[191] Patients with malignant gliomas demonstrating a chromosome 1q gain show longer survival and good response to chemotherapy.[234] Genetic subgroups of pilocytic astrocytomas, depending on loss or gain on 19q, might explain their diverse clinical behaviours.[233] The 1p/19q codeletion predicts a favourable response to chemotherapy in low-grade gliomas.[92]

The tumour suppressor gene p53, located on chromosome 17p, is known as the "guardian of the genome". The normal (wild) p53 product is a protein that has a very short half-life and cannot be detected routinely. The abnormal (mutated) p53 product is stable and can be detected. Hence, immunoreactivity to p53 product (TP53) indicates a mutated abnormal gene. The p53 protects cells from cancer by preventing cells with damaged DNA from proliferating wantonly. This is achieved by cell-cycle arrest, which facilitates cell repair; and apoptosis, which ensures the death of cells too severely damaged to be repaired. The p53 also has an important role in angiogenesis and tumour invasion, processes fundamental to malignancy. It is no wonder that TP53 is commonly seen in astrocytic tumours, except pilocytic tumours.[199] Over-expression of p53 has been correlated with adverse prognosis in childhood malignant glioma.[183] Another important gene is the Bc12 proto-oncogene located on

Table 5: Hereditary neurological tumour syndromes

Syndrome	*Glial tumour*	*Gene mutation and chromosomal site*
Neurofibromatosis 1 (NF1)	Optic pathway glioma, astrocytoma elsewhere	NF1 gene, chromo 17q
Neurofibromatosis 2 (NF2)	Astrocytoma, ependymoma	NF2 gene, chromo 22q
Tuberose sclerosis (TS)	Subependymal giant cell astrocytoma	TS1 gene, chromo 9q TS2 gene, chromo 16p TS3 gene, chromo 12q
Turcot syndrome	Malignant glioma	APC gene, chromo 5q
Li-Fraumeni cancer syndrome	Malignant glioma	p53 gene, chromo 17p

Note: p = short arm of the chromosome; q = long arm of the chromosome; APC = adenomatosis polyposis coli

chromosome 18. The Bc12 product is antiapoptotic. Over-expression of Bc12 gene product found in primary central nervous system tumours is known to make tumours resistant to chemotherapy or radiotherapy.[245] Aurora kinase family proteins are related to mitosis. Aurora B over-expression correlates with aggressive behaviour in glioblastoma.[267] Telomerase confers cell immortality. It has been found to be over-expressed in secondary glioblastomas.[76] Gains at the 1p36 chromosomal region are associated with symptomatic leptomeningeal dissemination of supratentorial glioblastomas.[105]

Role of Growth Factors

The mutations in glioma cells cause amplification and over-expression of epidermal, platelet derived and fibroblast growth factor receptors. In addition, the vascular endothelial growth factor (VEGFR) amplification causes angiogenesis. On the other hand, the inactivation of brain angiogenesis inhibitor also promotes angiogenesis.[96] The LOH in 10q causes inactivation of PTEN, a gene downstream of focal adhesion kinase, which controls cell migration and invasiveness. Neural cell adhesion molecule is down-regulated in the development of the malignancy of astrocytic tumours and its expression is inversely correlated to the degree of malignancy.[200] There is high degree of correlation between vascular endothelial growth/permeability factor (VEG/PF) expression by gliomas and the occurrence of peritumoural vasogenic brain oedema or tumour-associated cysts, irrespective of tumour grade, thus supporting VEG/PF's pivotal role as the common pathophysiological link between these processes.[227] Cyclo-oxygenase 2 (COX-2) is an enzyme that is over-expressed in glioma cells as compared to normal astrocytes. This over-expression is associated with angiogenesis and resistance to apoptosis.[162]

Role of Stem Cells

The malignant gliomas retain a small number of brain tumour stem cells (BTSC), which are derived from the neural progenitor/stem cells. These are responsible for recurrence of tumour. The BTSC progresses in to tumour due to changes in signalling and control pathways such as ras, retinoblastoma (Rb), Notch and sonic hedgehog (Shh). For further details the interested reader is referred to a review article.[265] It appears that dysregulation of the cadherin/catenin (cell adhesion molecules) assembly contributes to the malignant transformation and increased motility and migration of glioma cells into the parenchyma.[7]

Role of Environmental Factors

Recently, human cytomegalovirus (HCMV) antigen and DNA have been demonstrated in glioma cells. This herpes virus exhibits glial tropism. The higher grade tumours have a larger fraction of HCMV infected cells indicating a possible aetiological connection.[204] Patients with HIV infection developing a glioma are rarely reported.[250] Tumour hypoxia is known to promote tumour recurrence and decreases the efficacy of radiotherapy or chemotherapy.[88] This effect may be mediated by erythropoietin.[152] Vitronectin in CSF promotes glial tumour cell mobility.[64]

Glioma Models

Our knowledge about the basic biology of gliomas has come mainly from analysis of material obtained from patients. Teratogen (ethylnitrosourea) induced animal gliomas and established human astrocytoma cell lines have been used to study gliomas. Transgenic mouse models have recently been introduced. Models are essential to identify the molecular aberrations and the molecular targets that will eventually be therapeutically exploited. For further details the interested reader is referred to a review article.[56]

Several pieces of the jigsaw puzzle of glioma genesis have now been fitted in[260] (Flow chart 1). Active research is being done to devise molecular therapies for stopping the signalling pathways that promote tumour and enhancing those that suppress tumour (see section "Emerging Therapies").[244]

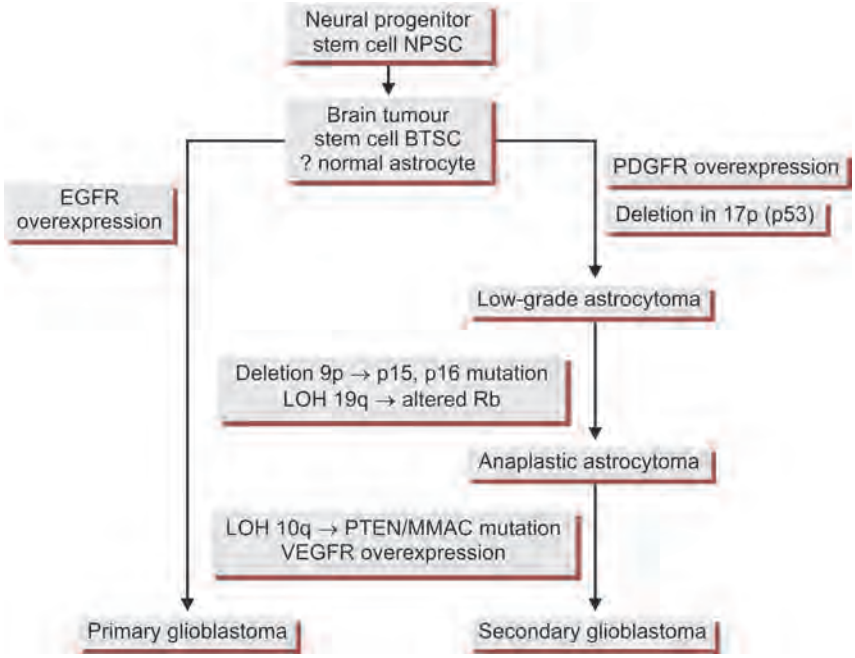
CLINICAL FEATURES

The signs and symptoms of supratentorial glial tumours depend upon the site, the size, the histological nature and the rate of growth of the tumour. The onset of symptoms is usually insidious and the course progressive.

Duration and Progression

The duration of symptoms is usually 2–3 years for low-grade tumours, 1–2 years for the intermediate grades and a few months or weeks for glioblastomas.[141] It is much longer for oligoastrocytomas and oligodendrogliomas. Stepwise deterioration may be observed with anaplastic astrocytomas. Sudden deterioration may set in during an otherwise gradual course, due to haemorrhage in the tumour or rapid necrosis or onset of oedema. These are seen more frequently in glioblastomas. A slow growing astrocytoma may suddenly change its character and turn into a glioblastoma, resulting in a rapid downhill course in a patient with an otherwise slow course. Slow growing tumours in the so-called silent areas of the brain, (the frontal lobes and the non-dominant temporal lobe) may acquire a large size without producing any symptoms and then show rapid deterioration and present with a short history due to decompensation of the intracranial pressure (ICP) dynamics. On the other hand, a small strategically located astrocytoma may, by manifesting an epileptic attack or early focal deficit, be associated with a short history. Thus, the duration of the illness may not provide a true indication of the histological nature.

Flow chart 1: Possible molecular pathways in astrocytoma and glioblastoma



Note: EGFR = epidermal growth factor receptor; PDGFR = platelet derived growth factor receptor; VEGFR: vascular endothelial growth factor; Rb = retinoblastoma gene; PTEN = phosphatase tensin homology gene on chromosome 10; MMAC = mutated in multiple advanced cancers; LOH = loss of heterozygosity, p53, Rb and p16 are tumour suppressor genes.[33]

Supratentorial gliomas may manifest themselves by symptoms and signs of raised ICP, epilepsy, progressive neurological deficits and cognitive/behavioural dysfunction.

Raised Intracranial Pressure

Headache and vomiting are the initial symptoms in about one-third of patients with supratentorial gliomas.[141] The headache is generalised and progressive, sometimes lateralised to the side of the tumour. The frequency and severity of symptoms of raised ICP is greater in patients with more malignant tumours and with gliomas situated nearer the midline. Signs of ICP like papillo-oedema and abducens palsy are less common nowadays, due to earlier diagnosis with the widespread use of imaging.

Epileptic Seizure

Two-thirds of patients with a supratentorial glioma are likely to get a seizure sometime during the course of their illness. In an Indian study, seizure history was present in 61% of patients before the operation and seizures were the only symptom in about 10% of patients. Seizure was the first symptom in 45% of patients. The incidence of seizures was higher (65%) in slow growing tumours and lower (29%) in glioblastomas.[239] Low-grade tumours also tend to present with seizure as their only manifestation. Adult onset focal seizures, changing character of seizure over time, prolonged postictal (Todd's) paralysis, and onset with status epilepticus have been traditionally held to arouse the suspicion of a tumour. Postictal paralysis may be prolonged or may not recover fully and may increase with every seizure. Generalised epilepsy of long duration and seizure history in childhood do not rule out the possibility of an underlying tumour.

Simple partial seizure, with or without generalisation, is the most frequent type accounting for 47% of patients with glioma presenting with seizure. Generalised tonic-clonic seizure was seen in 35% of patients and complex partial seizure in 10% of patients.[239] Tumour is the most likely cause in patients with olfactory or gustatory aura. The recurrence of attacks after a long seizure free interval in a treated patient generally indicates recurrence of tumour. There is a suggestion that glioblastomas presenting with seizures have a slightly longer survival, probably because the seizure brings them to medical attention earlier.[172] The occurrence of seizures at diagnosis was a strong predictor of subsequent seizures, and in many patients, seizures prove to be refractory to standard anticonvulsant therapy.[154]

Focal Neurological Dysfunction

Neurological deficit is not a common initial symptom, since a large percentage of hemispheric gliomas are located in the "silent" frontal and temporal lobes. It is predominantly a feature of tumours located in or near the sensorimotor cortex. Here, it generally starts as postictal deficit. Comprehension dysphasia is often overlooked or confused with memory impairment or a psychiatric illness. Patients developing hemianopia are often unaware of the deficit but bump in to objects on the hemianopic side. Similarly, the patient also ignores

sensory symptoms due to parietal lobe involvement. Dressing apraxia or the neglect of the contralateral half of the body or visual field may be observed by others rather than the patient. While a neurological deficit, as the initial symptom, is observed in 3% of cases only, nearly 60% of patients have some deficit at presentation. Motor weakness is more common with malignant glioma than low-grade glioma. Incontinence, when awake, may be the presenting symptom in frontal or midline tumours.

Cognitive Dysfunction

Apathy, change in personality, impairment of memory, inattention, inappropriate social behaviour, irritability, verbal-motor perseveration and psychomotor retardation are common symptoms. This is especially true for tumours of the frontal lobe and temporal lobe. Basal frontal tumours present with pseudomania, lateral frontal tumours with pseudodepression and medial frontal lesions with pseudodementia and akinetic state.[193] Impairment of memory is seen with frontal and temporal lobe tumours. Some of the mental changes are due to the raised ICP, but others are directly due to neurological dysfunction at the location of the tumour caused by compression or infiltration. Neuropsychological testing helps localise the lesion and aids post-operative follow-up.

Uncommon Presentations

Enlarging size of the head, irritability and a delay in achieving developmental milestones may be the presenting features of gliomas in children. Temporal lobe tumours may present in to the orbit or infratemporal fossa.[111,197] Cranial nerve involvement (other than the VI cranial nerve) has been reported rarely.[235] Hemiatrophy of the contralateral half of the body (seen in slow-growing parietal lobe tumours occurring at a young age) is a rare manifestation. "Man-in-the-barrel" syndrome, with disproportionate weakness of the arms as compared to the legs, has been reported with multicentric glioma.[18]

INVESTIGATIONS

Imaging

The CT and MRI are the only investigations used in clinical practice today for the diagnosis of supratentorial gliomas. The CT is generally the first investigation done for a patient with a suspected intracranial mass lesion, as it is more rapid, less expensive and more available. The CT can be done more easily than MRI in demented, restless or intubated patients. It can also be done in claustrophobics and patients with pacemakers. Calcification, fresh haemorrhage and bony anatomical landmarks are well made out in CT. Contrast CT study may be avoided if gadolinium enhanced MRI is going to be done. The MRI is more sensitive to pathological changes in the tissue and superior in assessing tumour volume or tissue characteristics. Patients presenting with seizures alone are generally investigated directly with MRI.

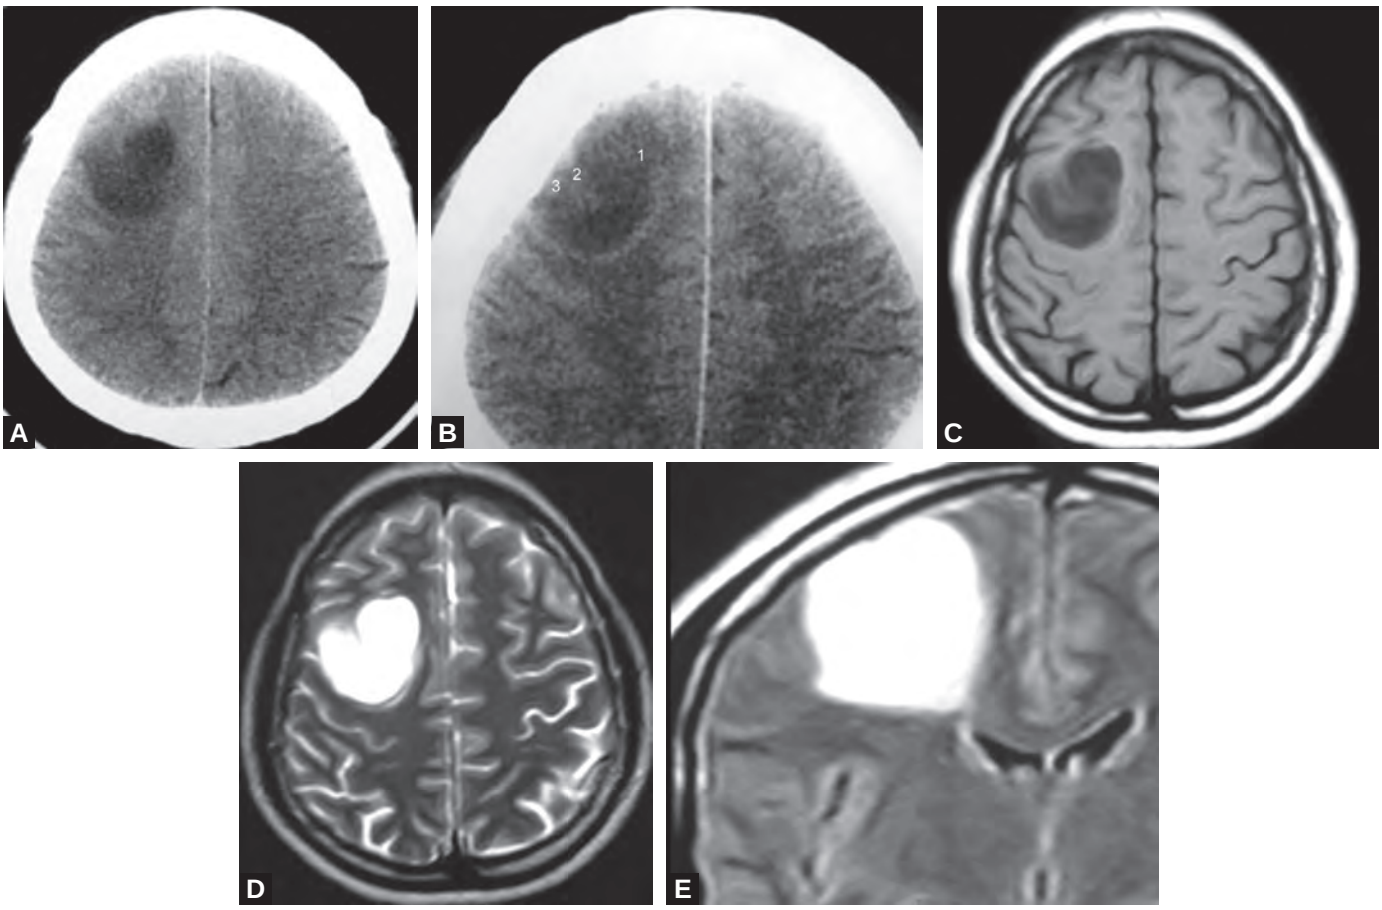
Low-Grade Astrocytomas

Low-grade astrocytomas take on one of two morphologies on imaging. The diffuse infiltrative low-grade astrocytoma is seen as a homogeneous hypodense (about 20 HU) area with indistinct borders on non-contrast CT (Figs 8A to E). They are hypointense in T1W and hyperintense in T2W, PD and fluid-attenuated inversion recovery (FLAIR) MR images. There is little or no peritumoural oedema. Since both the tumour and the oedema appear hypodense on CT, the judgment about the absence of oedema is made from the lack of much mass effect. There is usually no contrast enhancement. Focal hyperdensities on CT may be due to calcium or blood. Calcification is seen in about 20% of astrocytomas. It is better appreciated on CT and generally indicates slow growth (Fig. 5). Haemorrhage is seen if there is an oligodendroglial component. Attenuation values approaching that of water may indicate a cystic area, but even such hypodense tumours may be solid. This is because the "solid" area is in fact made up of microscopic cysts containing fluid. The isodense non-enhancing tumour is invisible on CT (about 5% of low-grade gliomas) and requires MRI for diagnosis. The closest imaging mimic is infarction.

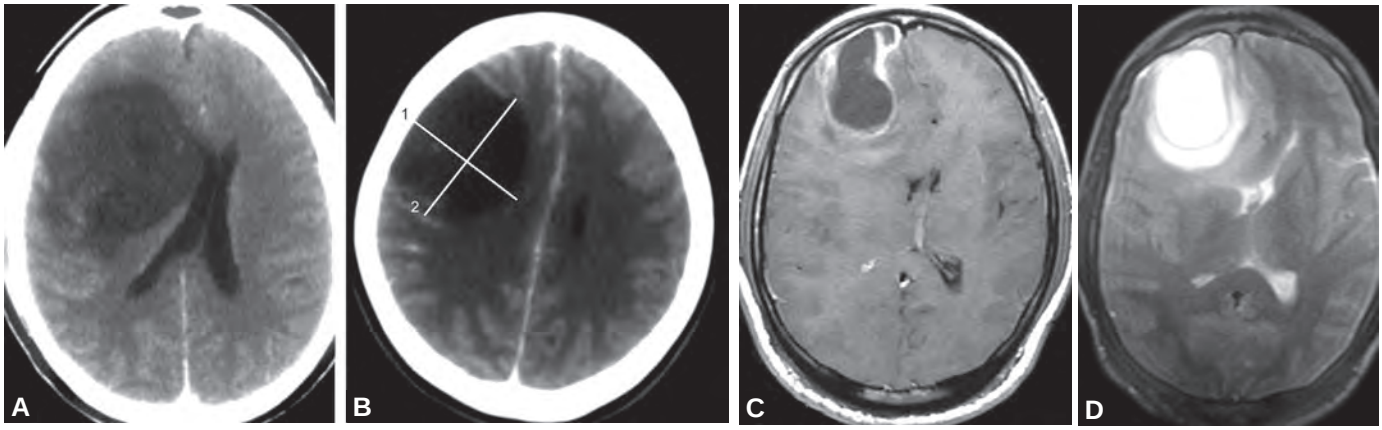
The other imaging variety of low-grade astrocytoma is the circumscribed one (e.g. pilocytic astrocytoma), which is sharply marginated. The circumscribed astrocytomas show contrast enhancement as globular masses or thick irregular rings on CT or MR (Figs 9A to D). Macrocystic change is common in these tumours. As mentioned in Table 1 in the chapter on cerebellar astrocytoma, the tumour can be true cystic (no tumour or enhancement in the wall) or false cystic (there is tumour and enhancement in the wall).

Anaplastic Astrocytoma

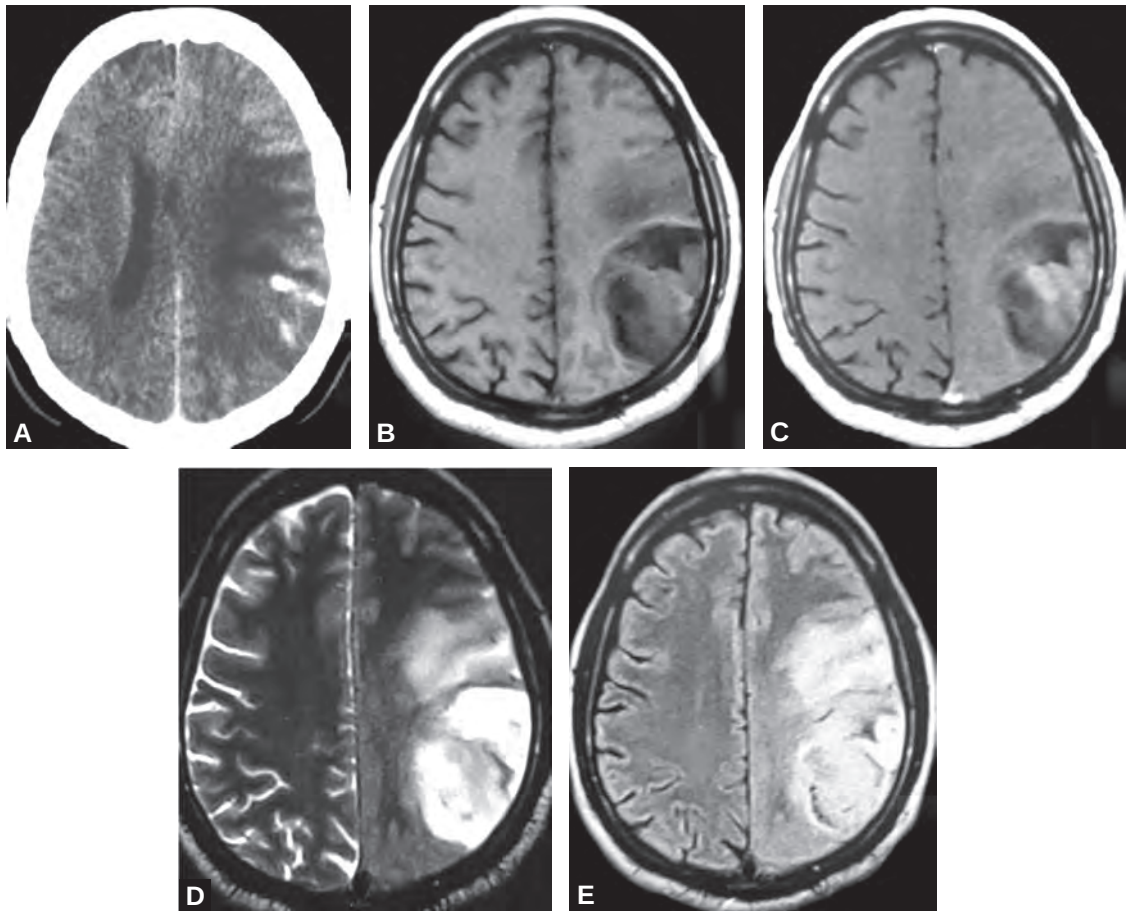
It is marked by the heterogeneity in appearance on imaging. There are areas of low density, isodensity and even areas of hyperdensity on non-contrast CT. Similarly, on MR, variations in intensities in the various imaging sequences are noted (Figs 10A to E). The cystic and necrotic areas both appear hypodense in CT. Delayed contrast CT may show contrast-fluid levels in cysts while this sign is absent in necrotic areas. The border of the lesion may be apparently better defined than in a low-grade tumour. The enhancement on CT or MR takes the form of a thick ring or a nodule. There is more oedema than in a low-grade tumour. This lesion needs to be distinguished from granuloma, abscess and metastasis. It has been found that an abscess appears hyperintense on diffusion-weighted MR images, whereas a tumour is hypointense. The apparent diffusion coefficient (ADC) values are lower in an abscess than tumour cysts.[73] The size of the lesion may increase in a few months (Figs 11A and B). Enhancement alone does not predict



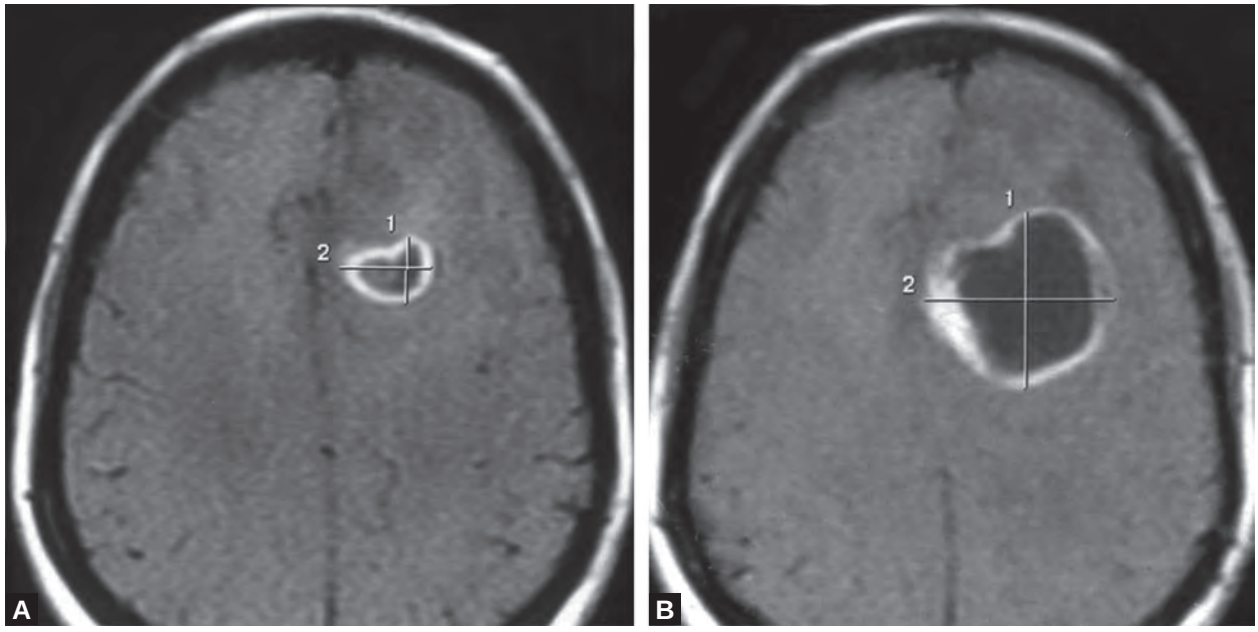
Figs 8A to E: Imaging characteristics of grade 1 astrocytoma. Note the absence of mass effect or oedema. (A) Non-contrast computed tomography. (B) Contrast-enhanced computed tomography. (C) T1-weighted image. (D) T2-weighted image (E) Fluid-attenuated inversion recovery (FLAIR)



Figs 9A to D: Imaging characteristics of grade 2 astrocytomas. Note the mass effect in the computed tomography scans of one patient on the left and lack of enhancement. In the magnetic resonance imaging of another patient on the right, the lesion is more circumscribed and enhances irregularly in the periphery. The T2-weighted images show the hyperintense central necrotic portion, the hypointense cellular part of the tumour and the hyperintense surrounding oedema. (A) Non-contrast computed tomography. (B) Contrast-enhanced computed tomography (C) Post gadolinium T1-weighted image. (D) T2-weighted image



Figs 10A to E: Imaging characteristics of grade 3 astrocytoma. The non-contrast computed tomography on the left shows areas of calcification in the tumour. The variegated intensity is well appreciated in T1-weighted magnetic resonance but the calcification is not seen. The enhancement with gadolinium is variegated. The surrounding oedema and the tumour can be differentiated in T2-weighted imaging but not in the proton density weighted images. The calcification is seen as intensely hypointense areas. (A) Non-contrast computed tomography. (B) T1-weighted image. (C) Post gadolinium T1-weighted image. (D) T2-weighted image. (E) Proton density (PD) image



Figs 11A and B: Rapid growth in an anaplastic astrocytoma. The size of the contrast enhancing mass on magnetic resonance imaging has increased in 5 months

the malignant nature. Enhancing tumours may have a benign histology (e.g. desmoplastic infantile astrocytoma)[13] and one-third of non-enhancing tumours may be malignant.[207] Absence of contrast enhancement on CT is observed in 54% of anaplastic astrocytoma and in 4% of glioblastomas.[30]

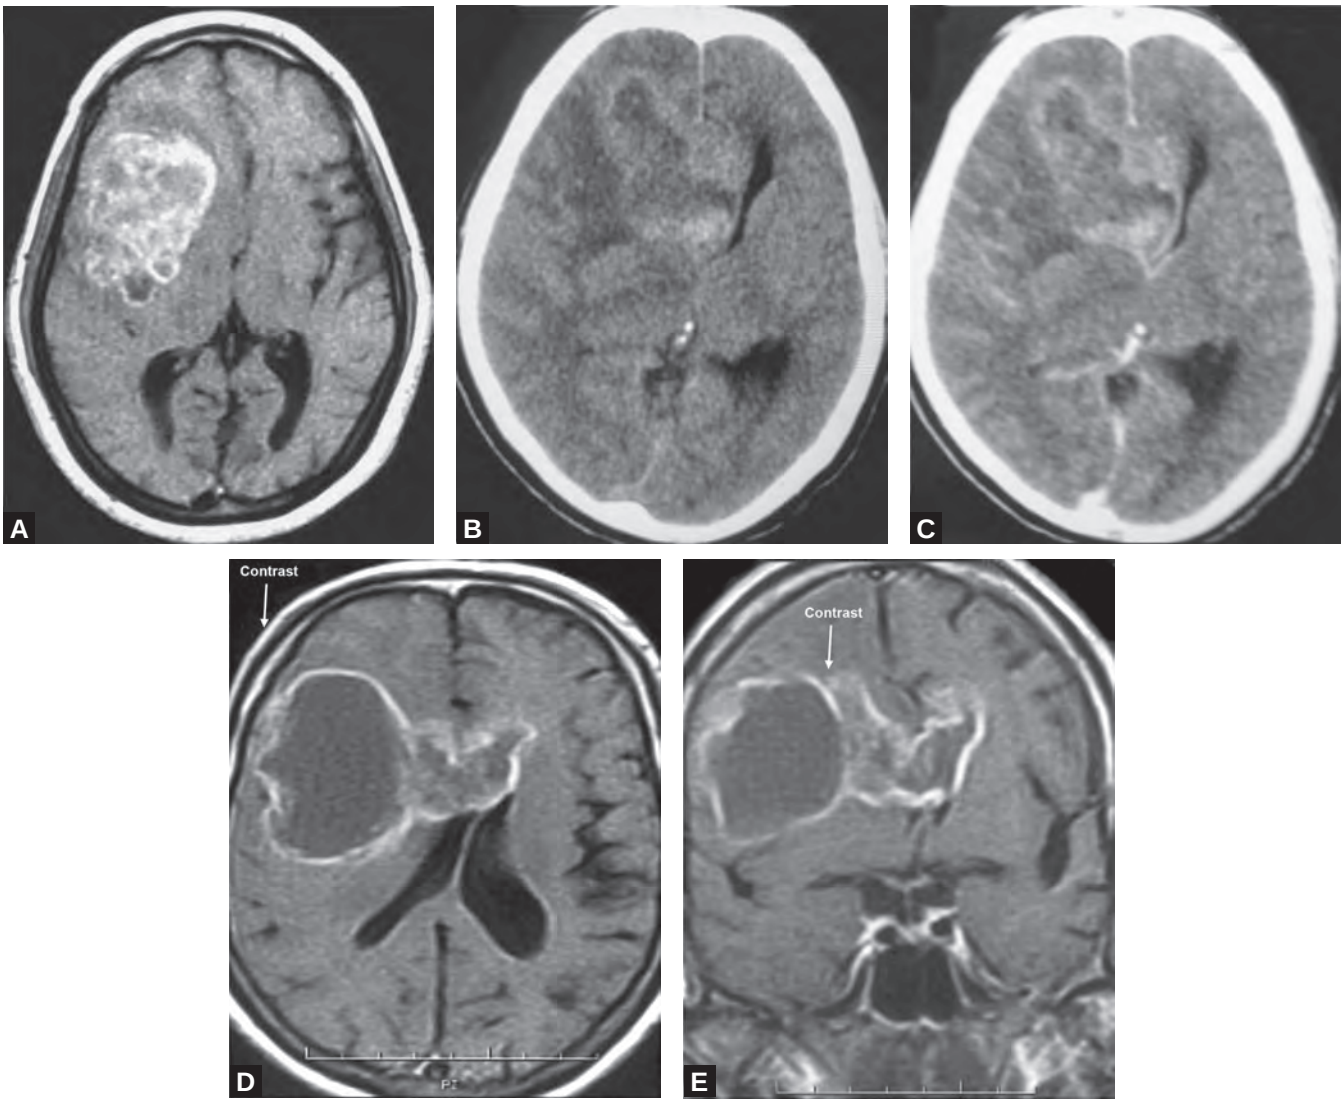
Glioblastoma Multiforme

It is marked by its variegated appearance and mass effect (Figs 12A to E). The secondary glioblastoma retains the imaging characteristics of the low-grade tumour from which it developed and adds the imaging features of neovascularity, haemorrhage or necrosis. The primary tumours on the other hand show a thick, shaggy and serpigenous pattern of enhancement all over the tumour. Infiltration of the opposite frontal lobe through the corpus callosum produces the famous "butterfly" glioma. In glioblastoma, and to some extent with anaplastic astrocytomas, the tumour cells have been detected in radiologically normal brain around the tumour. Though the MR gives a better estimate of the tumour volume, it must be remembered that there is tumour beyond the imaging edge.[98] Recently, it has been reported that glioblastomas with high p53 positivity show a ring enhancement pattern and well-defined borders in T1W imaging.[156]

Recent Trends in Imaging

Proton Magnetic Resonance Spectroscopy

Proton magnetic resonance spectroscopy (MRS) has been employed to predict tissue characteristics. The molecules



Figs 12A to E: Imaging characteristics of grade 4 astrocytoma and glioblastoma multiforme. The gadolinium enhanced T1-weighted (T1W) magnetic resonance (MR) (left) of a patient with grade 4 astrocytoma shows variegated rich enhancement and multiple necrotic areas. The computed tomography (CT) scans (centre) of another patient with glioblastoma. Note the hyperdense appearance of the growing edge in plain CT and the serpigenous but moderate enhancement. The infiltration of the corpus callosum is characteristic. The contrast MR (right) of another patient showing the "butterfly" appearance. (A) Post gadolinium-T1-weighted image. (B) Non-contrast computed tomography. (C) Contrast-enhanced computed tomography. (D) Post gadolinium-axial image. (E) Post gadolinium-coronal image

studied are N-acetyl aspartate (NAA), that reflects loss of neuronal integrity; creatinine (Cr), a measure of energy stores; lactate (Lac), that reflects anaerobic metabolism; and choline (Cho), that is elevated in tumours and inflammatory processes, reflecting rapid cell turnover. Generally, in highly metabolic tumours, including glioblastoma, the levels of NAA and Cr are decreased, and the rapid growth results in elevated Cho and Lac levels. Thus, in comparison with normal tissues, glioblastoma demonstrates an increase in Cho/Cr and Cho/NAA peak ratios, an increased Lac/Cho peak ratio, and a decreased NAA/Cr ratio.[85]

MRS is useful for distinguishing infarcts or inflammatory lesions that mimic a glioma on MR imaging.[114] Cho appears to correlate best with the degree of tumour infiltration. MRS appears more accurate than conventional MRI in defining the tumour boundary and quantifying the degree of tumour infiltration.[41] The relative levels of Cho and NAA correlated with the cell density in grade 2 and grade 3 gliomas. The association was irrespective of the presence of contrast enhancement. MRS can be used to identify regions of aggressive growth in presumed grade 2 or 3 gliomas that would be suitable for biopsy.[142] The role of MRS in distinguishing recurrent tumour form radionecrosis is mentioned below (See section "Imaging of Recurrence").

Perfusion and Diffusion Magnetic Resonance

The blood flow in the tumour can be assessed with perfusion MRI. Glioblastoma shows higher regional cerebral blood flow (rCBF) than lower grade tumours or lymphomas.[256] A high correlation between degree of contrast enhancement on dynamic contrast-enhanced images and regional cerebral blood volume (rCBV) values as measured by T2W imaging in high-grade glial tumours has been noted. This indicates that the areas of enhancement have high rCBV.[187] The pre-operative ADC in diffusion-weighted MR has emerged as a prognostic factor. Low ADC carries a poor prognosis.[155] Diffusion tensor imaging is a new modality that can delineate fibre tracts and depict their displacements or infiltration by gliomas. It can also be used for delineating accurately the tumour margin and oedema from the surrounding healthy white matter.[222]

In spite of the sophistication of neuroimaging, it must be stressed that imaging cannot substitute for tissue diagnosis. In one study of 20 patients thought to have a low-grade astrocytoma, nine had anaplastic astrocytoma and one had encephalitis when subjected to stereotactic biopsy.[103] In a more recent study, MRI was found to have high specificity but variable sensitivity for grading of glial tumours.[90] Pre-operative MRI and even positron emission tomography (PET) may underestimate or overestimate the grade.[4]

Positron Emission Tomography

Thus far a research tool, PET is now available to the clinician in some centres in India. Its spatial resolution is poor but, since it can be combined with CT, the resolution is improving. The advantage is that it is able to show the areas of active tumour growth by demonstrating hypermetabolism. PET using 18 F-fluorodeoxyglucose (FDG) has been shown to correlate with survival in anaplastic astrocytomas, those with higher uptake succumbing earlier.[175] PET studies using L-(methyl-11C) methionine have shown that methionine uptake was heterogeneous even among the homogeneous tumour areas demonstrated on MRI. Malignant pathological features were detected in the areas with the highest methionine uptake.[159] The combination of MRI and PET improves the accuracy of targeting and the diagnostic yield of biopsy, but does not replace histological diagnosis.[137] Increased[18] FDG uptake on PET may not necessarily reflect malignant transformation as similar changes can be induced by seizures.[166]

Serum and Cerebrospinal Fluid Markers

GFAP has been detected by enzyme linked immunosorbent assay test in serum samples of 80% of patients with glioblastomas. The levels are higher in those with larger tumours, larger areas of necrosis and greater tumour cell positivity for GFAP. It is not detectable in healthy controls or those with non-glioblastoma tumours.[91] Though CSF cytology may prove positive for tumour cells in glioblastomas, it is not advisable to obtain lumbar CSF in patients with large mass lesions. Ventricular CSF may be obtained during shunt surgery or endoscopy.[35]

TREATMENT

Goals of Therapy

There is no complete cure for gliomas, nor is one as yet in sight, notwithstanding the intense research efforts. As long as no other effective treatment is available, surgery will continue to be central to the management of gliomas. In spite of this, there is no unanimity in the approach of neurosurgeons as to the extent or nature of surgery. The lack of consensus adds to the difficulty in decision-making. The goals of management of an individual patient can be summarised as:

- To establish an unequivocal diagnosis
- To determine the degree of malignancy
- To relieve distressing symptoms
- To prolong useful survival without inflicting unacceptable neurological deficits
- To achieve as complete an excision of the tumour as possible
- Improve the effectiveness of adjuvant therapy like radiotherapy, chemotherapy and immunotherapy by cytoreduction.

To achieve these objectives the following alternatives are available:

- Image guided stereotactic biopsy (frame based or frameless)
- Tumour removal: partial; subtotal; macroscopically total; lobectomy

- Procedures for relieving ICP: drainage of cyst; CSF diversion (shunt or ventriculostomy); craniectomy for external decompression
- Procedures to facilitate adjuvant therapies (implanting catheters for intralesional therapy, radioactive material for brachytherapy, etc.).

Biopsy

Need for Biopsy

It is not always possible to ensure that the lesion seen on imaging is a glioma and not some other lesion such as infarction, abscess, granuloma or demyelination by imaging alone. Even if the imaging characteristics strongly suggest a glioma, its grading can only be suggested but not confirmed by the most sophisticated neuroradiological technique.[103] Hence, in all cases, it is necessary to obtain a histological diagnosis before deciding on further therapy. If the tumour is in a resectable region and the patient is fit for surgery, there is no need to do a preliminary biopsy before proceeding with tumour excision. Similarly, in a patient who needs a resectional procedure for relieving symptoms, there would be no need for a preliminary biopsy.

Indications for Biopsy

Biopsy-alone approach will be indicated in the following cases:

- Deep-seated lesions
- Small lesions
- Lesion associated with a large cyst
- Lesions affecting eloquent areas
- Multiple lesions
- Lesions where there is a differential diagnosis with a medically treatable lesion such as tuberculoma
- Patients who are not fit to undergo major surgery.

Accuracy

Stereotactic biopsy is generally accurate. About 80% accuracy on comparing with the subsequent resection specimen has been reported. More importantly, it leads to the correct treatment in about 96% of cases.[140] Small samples do not decrease the diagnostic yield when there is an expert team that does and interprets the biopsy.[80] The CT is usually used for stereotactic biopsy while MRI has proved to be as accurate in the axial plane coordinates and may be used for lesions not seen well on CT.[69] It is possible to obtain accurate samples with frameless stereotaxy also.[15] A better yield with frameless image-guided stereotactic biopsy in comparison to conventional frame-based CT-guided stereotactic biopsy and ultrasound-guided biopsy was noted in a study from AIIMS, Delhi.[87]

Rationale of Biopsy

Several surgeons have favoured the biopsy-followed-by-radiotherapy approach for malignant tumours.[39,132] Their argument is that there is no survival difference between those who undergo biopsy alone and those who undergo major resections for malignant gliomas as long as the patient undergoes radiotherapy.[160] They also point to the morbidity of major resections.[106] However, in the recent years, the safety of resectional surgery has increased and resection has been shown to confer a survival advantage (see below). While most radiotherapists believe that cytoreduction is a prerequisite for radiation therapy, some have cast a doubt on the role of cytoreduction in glioblastoma.[109] The resectionists feel that a limited biopsy may fail to reveal tumour heterogeneity and thus give an erroneous impression about its grade of malignancy. In one study, the stereotactic biopsy diagnosis and the diagnosis on the subsequent resection specimen differed in 49% of cases.[86] It must be remembered that the basis of the argument on both sides of the issue rests mainly on retrospective studies.[196] Patients with large tumours who have marked increase in ICP are obviously not suitable for this line of management.

Technical Issues

Conventional free hand biopsy is now passé, except in an emergency where the patient has already coned and prompt drainage of a cyst is aimed at. Image guided minimally invasive biopsy is the current standard. Open biopsy is nowadays seldom required. Wherever possible, the biopsy should be obtained separately from sites that appear different on imaging. It is erroneous to assume that it is sufficient to biopsy the enhancing portion alone as the non-enhancing portion also may show anaplastic areas.[207,159] Cyst fluid obtained during biopsy may be subjected to cytology. The trajectory must be planned so as to avoid ventricular entry to ensure that there is no shifting of the target. It is ideal to have the pathologist at hand to do a squash preparation and judge the adequacy of the sample before the biopsy procedure is completed. The post-procedure imaging can be done with the stereotactic frame on the patient to check the appropriateness of targeting and the procedure can be redone in the unlikely event of a miss. Tumours visible in the ventricular system are best biopsied with the endoscope. In that situation, additional tumour debulking to open a blocked foramen of Monro or a CSF diversion procedure such as third ventriculostomy/septum pellucidotomy also can be combined in the same sitting.

Safety and Risks

Stereotactic biopsy is generally a safe procedure. The minor morbidity (3%) and mortality/major morbidity (3%) are lesser than for major resections.[16] Haemorrhage is less if biopsy cannulae or 1 mm biopsy forceps are used. The haemorrhage related morbidity is hardly 1%.[108] An increased risk of morbidity is associated with the pre-operative use of antiplatelet agents, deep-seated lesions, malignant gliomas and a greater number of biopsy attempts.[203] Seeding along the track of biopsy is possible but rare.[226]

Tumour Removal

This section describes resectional surgery for anaplastic astrocytoma and glioblastoma. Low-grade astrocytomas are dealt with in a separate section (see below).

Differences Between Radical Cancer Surgery Elsewhere and in the Brain

Radical cancer surgery in other areas of the body has aimed at complete en bloc excision with surrounding normal tissue to assure a tumour free margin. None of these goals is possible to achieve in malignant brain tumours. The technique of neurosurgery involves intralesional decompression before piecemeal excision and so en bloc excision is not generally possible.[236] The en bloc removal technique using spoon retractors[119] may not ensure prevention of tumour spillage. It is important to recognise that a malignant glioma, even if it appears to be well circumscribed, is an infiltrating tumour. During surgery, the bulk of the tumour can be differentiated from the normal brain tissue by its colour, consistency and texture. However, even when using microsurgical techniques, it is impossible to be sure of the precise extent of tumour infiltration. Thus, the microsurgical limit of the tumour is well within the histological limits revealed by pathological examination.[98] Resection of surrounding brain to assure a tumour free margin is only rarely possible in small tumours in silent areas of the brain. Hence, though gliomas may be resectable, they are not amenable to oncologically radical excision. "Radical" or "aggressive" glioma removal is tantamount to a gross or macroscopic total removal. It should be considered a cytoreductive procedure and as the first step in a multimodality treatment regime.

Impact of Maximal Tumour Removal on Survival

The champions of resectional surgery hold that gross total resection of supratentorial glioblastomas and anaplastic astrocytomas is feasible and that it is directly associated with longer and better survival when compared to subtotal resection or mere biopsy. In one early study, the mean survival was 90 weeks for the gross total excision group and 43 weeks for the subtotal or partial resection group.[2] The Glioma Outcomes Project reports near doubling of mean survival time for patients undergoing resection as compared to biopsy.[123] Resection of the contrast enhancing mass alone in grade 4 gliomas prolonged the survival to 50 weeks as compared to 33 weeks for those undergoing biopsy.[55] Gross total excision has been shown to improve not only the length of survival but also the quality of life.[44] Benefits of resection have been demonstrated at all ages. In children with malignant gliomas, radical tumour resection (greater than 90%) is the only therapeutic variable that significantly improves the progression-free survival rates.[263] In 102 elderly patients with glioblastoma, those who underwent gross total resection had median survival of 69 weeks while it was only 20 weeks for those undergoing biopsy and radiation.[151] The volume of residual tumour after resection has been found to strongly correlate negatively with outcome.[1,97] This residual tumour assessment is not to be based on the surgeon's estimation but on contrast MR done within 72 hours of surgery. Totality of resection was associated with greater survival though the level of statistical significance was lower than that of the influence of age or pre-operative Karnofsky performance status (KPS) in a recent single institution study of 267 patients with glioblastoma.[225]

The enthusiasm for aggressive excision must be tempered by the sobering fact that none of the foregoing constitutes Class I evidence. In fact a Cochrane report in 2001 could not draw any conclusion as there was insufficient randomised data.[147] Only the Radiation Therapy Oncology Group's studies provide at least Class II evidence but this was in the early 1990s. The extent of surgery did not reach statistical significance in multivariate analysis even though it was significantly correlated with survival in univariate analysis.[43] The Glioma Outcomes Project also gives Class II evidence that extent of resection is a significant factor but no effort was made to quantify the degree of excision.[123]

Strategies to Maximise the Resection

These have been summarised in Table 6. Knowing the exact extent of the tumour by pre-operative MRI in all three dimensions is a *sine qua non*. The value of three-dimensional (3D) image reconstruction has been stressed.[29]

Use of a 7–10 MHz ultrasound probe can show up the higher echogenicity of the glioma tissue (irrespective of its contrast enhancing property) and can help in detecting residual tumour in the bed of an apparently complete excision. The more anaplastic areas are variegated in their echogenicity but always more echogenic than normal brain tissue.[75] The intra-operative ultrasound characteristics of malignant tumours as opposed to low-grade tumours have been well-described using a 3–4 MHz probe.[28]

Stereotactic craniotomy involves performing the craniotomy in the stereotaxy frame. The extent of resection

Table 6: Strategies to maximise the resection of malignant glioma

Strategies aimed at saving neurological function

can be physically verified by matching the coordinates obtained during surgery with the pre-operative stereotactic data in the simple and non-volumetric system.[9] With the sophisticated system developed by Kelly, it is possible to place tumour volume interpolated from the CT and MRI-defined boundaries into a 3D computer image matrix. This information can then be used for surgical planning for interactive volumetric stereotactic removal of the lesion.[125]

Neuronavigation [image guided resection (IGR)] achieves the same purpose and has been demonstrated to result in more complete excision and longer patient survival as compared to conventional microsurgery without navigation at least in univariate analysis.[118] A recent study shows that the apparent prolongation of survival with IGR might be because of selection bias. Those with favourable prognosis such as younger patients, smaller tumours and pathology other than glioblastoma are over-represented in series that report longer survival with IGR.[126] Addition of PET data to the MR data for IGR improves the extent of resection.[137,179] The problem with neuronavigation is the shift of targets that occurs after CSF drainage, brain shrinkage, displacement during removal of large lesions or ventricular opening. Frameless stereotactic technique is accurate for tumour volume of less than 30 ml and for lesions not near the ventricle.[11] Intra-operative MRI can address this deficiency of neuronavigation.

Intra-operative MRI to assess completeness of excision is logical, but is expensive and available in a very few centres only. The operating room needs to be dedicated to suit the magnetic environment. A low-field strength permanent magnet or an open short bore high-field strength magnet is used.[136] Contrast enhancement in the intra-operative MR has to be interpreted carefully as it may not be specific for residual tumour alone. Is intra-operative MRI a technical overkill or the future of brain tumour surgery? Only time will tell.[208]

5-aminolevulinic acid is a non-fluorescent prodrug that leads to intracellular accumulation of fluorescent protoporphyrin IX in malignant gliomas. This fluorescence, visible under violet-blue light distinguishes tumour from normal tissue and results in a better resection than with conventional white light. This requires appropriate modifications to the operating microsope.[229]

The strategies to save neurological function (see below) also help in clearing tumour from eloquent areas. Therefore, these strategies also help maximise resection of tumour.

Risks of Aggressive Resection

The risk of neurological worsening is foremost in the mind of the neurosurgeon attempting radical excision of gliomas. This fear is profound in dealing with lesions of the dominant hemisphere and in the eloquent (motor, sensory, speech or visual) areas.[237] Damage to the surrounding structures that may result from manipulation, excessive retraction or damage to important vessels (arteries or veins) in and around the tumour is likely to cause the deficit. Though the risk of neurological worsening is real it is often overestimated. In a series of 200 cases of supratentorial gliomas excised radically, hemiparesis became worse in four patients or developed post-operatively in three patients only. Similarly, dysphasia became worse in two patients and appeared post-operatively in six patients. In short, a new deficit developed in about 10% of cases. On the other hand, pre-operative hemiparesis recovered or improved in 41% of cases and pre-existing dysphasia recovered or improved in 12% of cases.[241] The Glioma Outcomes Project did not show any difference in the survival or functional outcome in the dominant and non-dominant hemispheric high-grade gliomas.[182] In a prospective study with aphasia measurement, left hemispheric tumour resection significantly improved language function in dysphasic patients, and was unlikely to impair language functions in non-dysphasic patients.[258] The same group reported worsening of language function in 9% of patients who were not aphasic before surgery and high risk of worsening of speech function in those already aphasic after stereotactic biopsy.[242]

Vascular damage is an important cause of morbidity in certain locations. The sites of tumour where the vessels are at risk are the medial surface of the frontal lobe (anterior cerebral branches), insular-opercular areas (middle cerebral branches)[113] and the medial temporal lobe (posterior cerebral branches). Venous damage is likely in the parasagittal region where the draining superolateral surface veins are vulnerable. A vein sparing excision may be done by performing multiple gyrotomies (Fig. 13). Vasospasm may occur after two or three days and cause ischaemic neurological deficit.[33] Peri-operative infarcts after tumour excision might mimic

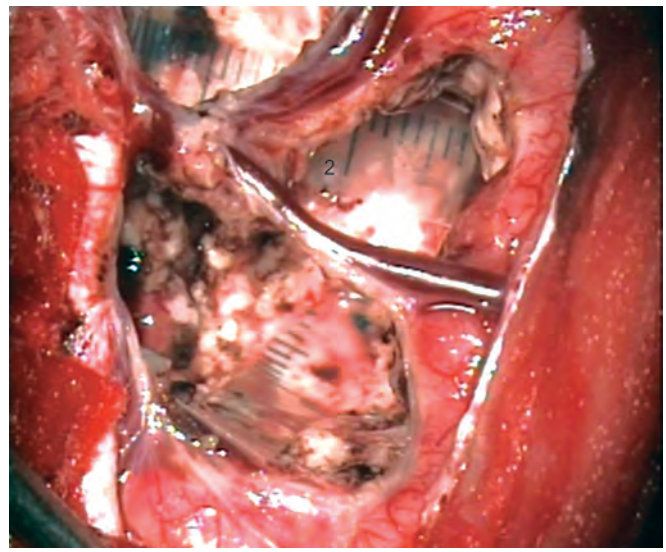

Fig. 13: Vein sparing glioma excision. This patient had a medial frontal astrocytoma grade 2. All the draining cortical veins were saved by making three transgyral approaches anterior, lateral and posterior to the veins. The exposures met at the depth. The lesion was excised totally

tumour residue or recurrence on enhanced MRI.[247] The tendency of brain surgery to set off a local version of consumption coagulopathy contributes to post-operative haemorrhage in the tumour resection bed or elsewhere in the brain. Such haemorrhage occurring in the unoperated tumour in a patient with multiple tumours is known by the fanciful name of "distant wounded glioma syndrome".[101] The incidence of venous thrombosis and pulmonary embolism is higher in patients with malignant glioma and they contribute to mortality.[209]

Strategies to Minimise the Risk to Neurological Function in Glioma Surgery

These have been summarised in Table 7. Broadly, they may be looked upon as anatomical or physiological methods.

Blood Oxygen Level Dependent imaging is known as functional MRI (fMR) and it can be used to map the eloquent areas pre-operatively. The increase in blood flow occurs after repetitive 12–30 seconds tasks (motor, sensory, visual or verbal). Artifacts are introduced by veins in the neighbourhood and by patient motion. In the ideal case, the spatial localisation accuracy is 5 mm, which is better than the 10 mm accuracy of stimulation methods (due to current spread). The fMR can detect areas deep within a sulcus, which can be missed by surface stimulation studies.[99] The fMR is best used with intra-operative neuronavigation. In one study no patient out of 19 had increased motor deficit after surgery on lesions near the motor area by the combined use of these two techniques.[262]

Motor pathway monitoring with motor evoked potentials (MEP) is especially needed for insular glioma surgery. Unchanged MEP or reversible deterioration of MEP indicates a good motor function while irreversible change indicates dense deficit.[161] Awake craniotomy, which is popular in epilepsy surgery, is less commonly used for glioma surgery. Resecting tumour just up to the point of producing deficit allows good functional recovery.[148] Awake language mapping shows much variability in the "language area".[198] The combination of fMR, neuronavigation and cortical stimulation during awake craniotomy has helped achieve excision of gliomas from Broca's area without producing any speech deficit in a Moroccan series of seven patients.[12] Pre-operative MR tractography to identify the pyramidal tract, integration of fibre tracking data with neuronavigation and MEP monitoring helped avoid motor deficit in removing tumours up to 1 cm of the pyramidal tract.[149] Intra-operative navigated 3D ultrasound angiography identifies hidden blood vessels and helps save them during resection. Ultrasound data can be easily updated and hence brain shift is not a problem in using ultrasonographic navigation.[195]

Technical Aspects of Glioma Resection

Peri-operative dexamethasone therapy is now routinely used and it can be used for most diabetics also. Mannitol can be used if glycaemic control cannot be obtained on dexamethasone. In the past, generous flaps were advocated to allow for brain swelling and to identify normal structures. Nowadays, the recommendation is to tailor the craniotomy to the size of the lesion, thus minimising the exposure of the normal gyri and to ensure that the tumour is in the centre of the flap. Lesions close to the surface of a gyrus are approached through a gyrotomy and lesions at the depth of a sulcus are approached by the trans-sulcal approach. For lesions in the eloquent brain, a short (2 cm) cortical incision perpendicular to the axis of the gyrus directly over the tumour causes less damage than a far away incision on adjacent non-eloquent brain. This is because the dissection from a distant area would involve retraction, which is potentially more deleterious than incision. Oblique approaches also mean poor visualisation of tumour, less complete excision and difficulty in obtaining haemostasis. Self-retaining brain retractors must be used judiciously. Any cystic part is decompressed early to allow for brain relaxation.

Tumours up to 2–3 cm in diameter are best removed as a whole. Tumours larger than this will usually require internal decompression with suction-dissection, ultrasonic aspiration, evaporation with defocused CO_2 laser or shaving with diathermy loops depending on the consistency and vascularity. This should be followed by dissection in the apparent cleavage plane with the white matter. The dissection is best done with the spreading action of the bipolar forceps, while drawing the tumour towards the cavity of decompression. The developed plane is maintained with moist, tailed cottonoid patties. Often the decompression and peripheral dissection have to be done alternately. Ventricular entry during surgery does not necessarily promote CSF seedling.[61] Tumours involving a whole lobe may be approached by an anatomically defined lobectomy. The vessels to watch out for and protect have already been mentioned (see section "Risks of Aggressive Resection"). At the end of the resection, there must be crystal-clear haemostasis and the brain should be lax. Dural closure must be performed and, if needed, with a pericranial graft. The bone flap is replaced except in the rare case where the brain is not lax enough. Peri-operative anticonvulsants are necessary even in patients who have not had a seizure. Our practice is to obtain a non-contrast CT within 12 hours in all patients, even those who are

neurologically intact. Contrast MR is done within 24–72 hours to assess any residual tumour. Later than this, there can be enhancement of the resection margin due to the surgical trauma that might persist for several weeks. Enhancing residue predicts recurrence.[1]

In conclusion, for malignant gliomas, if tumour removal is decided upon, the aim should be to achieve maximal removal without risking damage to the surrounding normal brain. There has been an attempt at stratifying the risk and balancing it with the benefits of aggressive excision by pre-operative staging.[217] The pros and cons of resective surgery for glioma are summarised in Table 8.

Low-Grade Gliomas

Low-grade glioma presents a therapeutic dilemma. The patients are often in the prime of life. The sole symptom is seizures in about two-thirds of patients. The lesion might not show growth over several years. Early complete excision gives a reasonable chance of cure without any adjuvant therapy and avoids progression to an anaplastic tumour. Such an anaplastic progression has been found to occur in about 40% of patients.[128] But the catch is they often occur in functionally eloquent areas. In fact 82% of low-grade gliomas (compared with 54% of glioblastomas) were situated within functional regions in one study. The supplementary motor area and insula alone accounted for 52% of the sites for low-grade gliomas.[58] Injudicious surgery in these critical areas might make the patient worse off. Total excision is sometimes not possible because of the difficulty in defining the edge of the tumour from normal brain. The key questions that the neurosurgeon faces in dealing with a supratentorial non-optic pathway, non-enhancing lesion that is consistent with a non-pilocytic astrocytoma are:[131]

- Should the patient be observed without a tissue diagnosis?
- Should biopsy be done?
- Should tumour resection be done? If so should it be subtotal or gross total?
- Should radiation therapy be given?

Table 8: The pros and cons of resection of gliomas

Pros	*Cons*
Cytoreduction to facilitate adjuvant therapy	Oncologically curative resection not possible
Improves the existing neurological deficit	Neurological worsening after resection
Reduces intracranial pressure	Resection does not change the outcome substantially
Improves seizure control	No randomised trial showing resection is better
Avoids sampling error of stereotactic biopsy	Studies reporting superiority of resection have flaws (not multivariate analysis)
For certain low-grade tumours, adjuvant therapy is not effective	Extent of resection not objectively controlled with imaging in some studies

Observation

Observation seems to be a reasonable option with smaller non-enhancing lesions in neurologically intact, young patients who are imaged immediately after a seizure. This option is often exercised when the lesion is in an eloquent area. The possibility of a postictal evanescent imaging lesion necessitates that a repeat imaging is done in 3–12 weeks. Only if the lesion persists, one can be sure that it is not a mere postictal change. The observation period can be extended to years in patients who remain neurologically normal with adequate seizure control and have no increase in tumour volume on follow-up. This conclusion is bolstered by a retrospective comparison of "wait" and "no wait" groups of patients with suspected low-grade glioma. The rate of malignant transformation from the time of diagnosis and the survival or quality of life is no different in the two groups.[188] The patient must be made aware that 30% of lesions appearing to be low-grade gliomas might turn out to be anaplastic tumours or non-tumour lesions on biopsy.[103] The MRI occasionally discloses an entirely asymptomatic brain glioma (not even a single seizure) while looking for cervical spine disease. Such patients are also best managed by watchful expectancy.

Biopsy

It is an essential requirement before radiotherapy without resection. The rationale, the benefits and risks are similar to that discussed under malignant tumours (see above). The tendency would be to choose biopsy for lesions in eloquent or deep areas and resection for silent areas. The biopsy related morbidity and mortality is much less (near-zero) for low-grade tumours than for the malignant ones.[261]

Resection

Resection has been shown to give a survival advantage. The 5-year survival was 80% for total resection, 50% for partial resection and 45% for biopsy in low-grade astrocytomas.[178] The seizure control is also better after resection.[32] In a critical study of tumour volume, no recurrences were detected in those who had 100% resection in mean follow-up of 4.5 years. There was an inverse correlation between the residual tumour volume and the time for progression. The incidence of anaplastic transformation was also higher in those with larger pre-operative tumour volume and larger post-operative residual tumour volume.[14] The current practice is to choose early surgical resection for patients presenting with raised ICP, the older patients, those with enhancing or large lesions and tumours in non-eloquent areas. The strategies to maximise the excision and minimise the collateral damage (explained above) are all the more

relevant to low-grade gliomas. The Low-Grade Glioma Guidelines Team Members have evolved practice parameters based on evidence for adults with suspected or known supratentorial non-optic pathway low-grade glioma.[131] In general, age below 40 years, good KPS, seizure as a presenting symptom, imaging findings of circumscribed or homogeneous enhancement, hypometabolism on PET and microcystic or pilocytic histology predict a good prognosis.[128]

Radiotherapy

External Radiotherapy

While surgeons might disagree on how much tumour is to be removed, there is no question about the use of radiotherapy for malignant gliomas. This is in spite of the low radiation sensitivity of gliomas as compared to lymphoma or germinoma. Radiotherapy has the advantage of tackling the "unseen" tumour infiltration inaccessible to the surgeon's tools. The value of radiotherapy was documented three decades ago in the Brain Tumour Study Group's prospective randomised trial of malignant gliomas. It showed prolongation of median survival from 17 weeks for those who had no radiotherapy to 37 weeks for those given at least 50 Gy of radiation. The addition of nitrosourea chemotherapy did little to improve the survival.[254] The mean survival time was 48 months in those receiving greater than 60 Gy as compared to 21 months in those receiving less than 60 Gy in a recent study of 170 anaplastic astrocytomas.[165] Conventionally, 40 Gy of whole brain radiation (20 fractions in 4 weeks) has been followed by 20 Gy (10 fractions in 2 weeks) of booster to the tumour site. Radiation planning for the booster is ideally done with a mid-treatment T2W MRI as the tumour might have changed in size by then.[219] Avoiding whole brain radiation in favour of localised field radiation has been shown to improve the KPS without adversely affecting recurrence rate or time.[213] Accelerated hyperfractionation (1.2 Gy twice daily) allows the treatment to be completed faster. Hypofractionation (5 doses) is the standard technique of stereotactic radiotherapy. Though doses up to 90 Gy have been administered by conformal therapy techniques using micro-multileaf collimators and computerised treatment planning, there is no clear survival advantage.[157] Treatment planning with MRI is better than that with CT.[184] Intensity modulated radiotherapy has at least enabled reducing the irradiation to the normal tissues, if not enhancing the delivery to the tumour area.[158]

The efficacy of radiotherapy for low-grade tumours is less certain. For tumours such as pilocytic astrocytoma that are totally excised there is no need for radiotherapy. Short-term studies show no difference in outcome between irradiated and non-irradiated patients. The long-term studies show improvement in the 5-year or 10-year survival rates in the irradiated patients who have residual tumour and these studies demonstrate a dose related positive effect. Early radiotherapy (immediately after surgery) is preferable to delayed radiotherapy (at the time of demonstrable progression).[215] In eloquent areas, radiotherapy is the usual option for low-grade astrocytomas.[212]

Brachytherapy

It has been used along with external radiotherapy in an effort to increase the glioblastoma dose without increasing normal brain dose. Radioactive iodine (^{125}I) seeds and temporary iridium (^{192}Ir) wires have been used to improve the survival by about 6 months.[104] In low-grade astrocytomas brachytherapy has been tried, but not found to be a factor in determining outcome.[107] Since it requires a second operation for implantation, it can be considered an option for recurrent glioma requiring surgery. Methods to enhance radiation response have been surgical cytoreduction and the use of radiosensitisers. Most attempts with misonidazole and paclitaxel as radiation sensitisers have failed to improve the prognosis in glioblastoma. The COX-2 inhibitors are being tried now to enhance apoptosis induced by radiotherapy.[162]

Risks of Radiotherapy

Risks of radiotherapy that need to be highlighted are radiation necrosis and cognitive dysfunction. Radiation necrosis typically appears 1–3 years after therapy. Its incidence is reported as 5–24%, being higher at autopsy.[115] The risk increases significantly with higher radiation dose, fraction size and the subsequent administration of chemotherapy.[194] Radionecrosis has a predilection for the periventricular white matter and may be distant from the original tumour site. The imaging findings of radionecrosis can mimic enhancing tumour regrowth.[115] The MRS, PET and pMRS may be useful in distinguishing tumour from radionecrosis (see Table 8). The differential diagnosis might need stereotactic biopsy.[63] Radionecrosis might cause enough mass effect to warrant surgical excision if it does not respond to steroid therapy. Radionecrosis and tumour recurrence can coexist.[59]

Stereotactic Radiosurgery

SRS involves delivering the radiation dose on a single day with stereotactic precision to the tumour and its margin. The radiation can be from gamma ray sources (gamma knife radiosurgery) or from a linear accelerator (X-knife radiosurgery). SRS is a potential alternative in the management of small-volume low-grade astrocytomas in unresectable areas. It avoids the risks of larger-field fractionated radiotherapy.[74] Ten-year survival of 65% after SRS for low-grade astrocytoma has been reported.[255] Morphological redifferentiation in a case of grade 3 astrocytic tumour after gamma knife radiosurgery in to a grade 2 tumour, proved by methionone-PET, histology, Ki-67 labelling index and p53 expression is of importance from the glioma biology viewpoint.[232] Glioblastomas have also been treated by SRS. While the

small single institution studies showed some efficacy, the only randomised trial that has been done failed to yield any benefit for patients with glioblastoma who were treated with radiosurgery.[42] SRS has been done before and after external radiotherapy.

Chemotherapy

The initial attempts at chemotherapy with nitrosoureas [parenteral bischloroethylnitrosourea (BCNU) or oral chloroethyl-cyclohexyl-nitrosourea (CCNU)] did not add much to improve the bleak outlook of malignant glioma and posed significant toxicity risks.[254] BCNU has been re-evaluated for recurrent glioblastoma.[23] Combination therapy with procarbazine, CCNU and vincristine (PCV regime) was the next to be tried. There is a high incidence of haematotoxicity with this regime used for recurrent glioblastoma.[205] Carboplatin-vincristine therapy has been used for low-grade gliomas in children who cannot be given radiotherapy.[173] In order to reduce the systemic toxicity, intra-arterial chemotherapy and interstitial therapy have been tried. Intra-arterial cisplatin-etoposide chemotherapy (with or without osmotic opening of blood-brain barrier) administered prior to radiotherapy appears to be better than concomitant radiation and chemotherapy.[133] "Gliadel" is a BCNU impregnated wafer, implanted surgically in to the tumour resection bed that provides interstitial chemotherapy.[176] This approach carries the risk of brain oedema.

Temozolomide

It is an oral alkylating agent that received Food and Drug Administration approval in 1999 for recurrent anaplastic astrocytoma and in 2005 for newly diagnosed glioblastoma. The publication of the phase III randomised trial comparing radiotherapy alone and radiotherapy plus temozolomide for glioblastoma by the European Organisation for Research and Treatment of Cancer—Brain Tumour and Radiotherapy Groups and National Cancer Institute of Canada Clinical Trials Group was a landmark.[230] The dose used was daily temozolomide (75 mg/m^2/day, all seven days of the week from the first to the last day of radiotherapy), followed by six cycles of adjuvant temozolomide (150–200 mg/m^2 for 5 days during each 28–day cycle). This resulted in prolongation of median survival time from 12 months with radiation alone to 14.6 months when temozolomide was added. More significant was the rise in the 2-year survival rates (from 10 to 27%). Severe haematotoxic side effects occurred only in 7% of these chemoradiotherapy patients. Several other dosing schedules have also been tried. Methylguanine methyltransferase (MGMT) promoter hypermethylation (detected by a polymerase chain reaction test on frozen tissue) may be used as a predictive factor in selecting patients most likely to benefit from temozolomide.[52] The efficacy and relative safety of temozolomide has been shown in children[164] and in elderly patients.[36] Since children and the elderly tolerate radiation poorly, temozolomide alone has been used in these groups. The role of temozolomide in recurrent anaplastic astrocytoma is mentioned later (see section "Treatment of Recurrence"). Chemotherapy-alone approach has been used for low-grade gliomas in the hope of avoiding long-term side effects of radiotherapy. Temozolomide has been tried as sole adjuvant therapy for the chemosensitive low-grade tumours with 1p/19q deletion.[92] Topotecan, a topoisomerase inhibitor, has been used with some success in childhood high-grade gliomas.[253]

The adverse effects and costs are the real deterrents to the widespread use of chemotherapy. Results are better when chemotherapy is administered by a medical oncologist according to strict protocol.

PROGNOSIS

The prognosis of glioblastoma and anaplastic astrocytoma remains poor despite significant recent advances. A recent study showed that, although the tumours are being diagnosed earlier as compared to three decades ago and that the peri-operative mortality and morbidity have come down, there was no difference in the post-operative survival time in high-grade gliomas over the decades.[167] In retrospective studies reporting multivariate analysis, the universally agreed predictors of prognosis are the age of the patient, pre-treatment Karnofsky performance score and the use of radiotherapy for both glioblastomas and anaplastic astrocytomas.[121] The less consistent predictors are sex (females carry better prognosis), extent of surgical resection, pre-operative seizure as a symptom, imaging variables, histological grade, proliferation index and molecular markers.[100,123,128,155,172,199,218,240] These factors have already

Table 9: Compilation of data from the literature on outcome of astrocytomas, anaplastic astrocytomas and glioblastomas

Tumour	*OS*	*MST*	*PFS/TTP*	*Survival percentage*			
				1 year	2 years	5 years	10 years
Astrocytoma		118 months[132]	13% at 5 years[14]	-	-	50-80%[128,178]	39[215]-65%[255]
Anaplastic astrocytoma	22–42 months[98]	21–48 months[39,165]	27–35% at 5 years[263,183]		14–84%[155]	17–54%[165]	?
Glioblastoma multiforme	14 months[23]	13 months[121]	7.2 months[23]	53%[217]	14%[217]	5%[218]	Rare[266]

Note: OS = Overall survival; MST = Median or mean survival time; PFS/TTP = Progression free survival/Time to progress

been mentioned in the relevant sections. Table 9 gives a general idea of the outlook in astrocytomas and glioblastoma. It must be remembered that the figures from various studies are not directly comparable due to the differences in selection criteria, treatment methods and outcome measurement parameters.

A six-tier grading scheme has been proposed to stratify the surgical risk and outcome in gliomas. This scheme identifies the five most significant risk factors of age, preoperative KPS score, previous radiation therapy, depth of tumour invasion and location in eloquent regions.[252] It is traditional to measure the overall survival, median or mean survival time, progression free survival and survival percentage as a function of time. It is important that we include quality of life parameters in the assessment.[6] Cognitive changes can be not only due to tumour or surgery but also due to radiotherapy, and only a few patients are capable of fully independent living.[3]

Although the median survival in glioblastoma multiforme is about 1 year, 3–5% of patients survive for greater than 3 years.[110] Young age, presence of oligodendroglial foci, giant cells, low proliferative index, p53 expression and MGMT promoter hypermethylation have been observed in the long term survivors.[49,110] Two cases of glioblastoma surviving for a decade have been reported.[266]

RECURRENCES

The most common cause of death of a patient treated for a supratentorial glioma is recurrence. For a given patient, irrespective of histology, there is an uncanny uncertainty regarding the time of recurrence. It is easy to imagine a glioblastoma recurring, but even low-grade tumours may recur after imaging proved complete excision and after a considerable time lag.[206] Recurrence generally occurs at the site of the original tumour or within 4 cm from it.[68] This clinical finding correlates well with the experimental fact that glioma cells have been cultured from the histologically normal brain within 4 cm of the tumour margin.[221] Occasionally, the tumour may spread along the CSF pathways and present at a different site in the neuraxis. In such cases, genetic profiling of the first and second tumour may help establish if the second tumour is a distant recurrence or a new tumour.[248] Technically, a tumour might be deemed to have recurred only when there is evidence of complete excision in the early post-operative contrast imaging study. If there had been a residue, the more appropriate term is re-growth or progression. In clinical parlance, the two terms are often used interchangeably. Some studies have stipulated a 25% increase in tumour area or volume on imaging to be deemed as recurrence.[85] In some patients, a small residue that had not shown any progression over time on serial imaging surveillance might start proliferating all on a sudden and take on all the characteristics of a recurrent tumour. In most cases, the recurrent astrocytoma is more anaplastic than the initial tumour. Indian series of recurrences of supratentorial gliomas was published in 1997.[238]

Clinical Features of Recurrence

A recurrence manifests with recurrent seizures, symptoms of raised ICP or progressive neurological deficit. Epileptic fits occurring for the first time following treatment, or recurring after a seizure free post-operative period, indicate a recurrence.[239] Recurrence of neurological deficits that had improved post-operatively or appearance of new neurological deficits should arouse suspicion of tumour recurrence. Clinical deterioration does not necessarily imply tumour recurrence. In one-third of the patients clinically suspected to have a recurrence, there may be other factors such as reactive oedema following chemoradiotherapy, postictal weakness, infection, haemorrhage or radionecrosis that mimic symptoms of tumour recurrence. Equally, not all recurrences produce symptoms as some are detected only on imaging surveillance.[85]

Imaging of Recurrence

The MR is better than CT in investigating a possible recurrence. Most recurrent tumours are more T1 hyperintense than the original tumour and enhance with gadolinium. In one study, in nine out of 32 patients, the first post-radiotherapy MRI showed progressive enhancement that would suggest recurrence. In three of these nine, the MRI improved or stabilised for 6 months without additional treatment, thus ruling out recurrence.[47] PET demonstration of hypermetabolism indicates recurrence, but this is not as infallible as it was thought to be.[166] The MR and CT signs of radiation necrosis may be indistinguishable from recurrent tumour. The similarities and differences are enumerated in Table 10.[85] The difficult case might require stereotactic biopsy.[63] It has been recently found that increased CSF matrix metalloproteinase (MMP-9) activity could be a marker of recurrent malignant glioma, before any changes are detectable on MRI.[264]

Treatment of Recurrence

The choices for recurrent glioma are re-operation, radiosurgery, radiotherapy, chemotherapy and comfort therapy.

Re-operation

Re-operation is considered under the following conditions:

- Young age
- Low-grade of initial tumour
- Progression free survival of at least 1 year or longer
- KARNOFSKY performance score greater than 70
- Tumour causing a mass effect
- Tumour in non-eloquent area.[85]

Biopsy is occasionally required for differentiating true recurrence from imaging mimics. Except in this situation, the surgery is always resective and it aims at maximising tumour removal without provoking new neurological deficit. Surgery also allows interstitial chemotherapy and brachyradiotherapy. In a study of

Table 10: Imaging comparison of recurrent glioma and radionecrosis

Modality	*Recurrent/residual glioma*	*Radionecrosis*
Location	At previous tumour site, rarely at distant site	At previous tumour site, not uncommonly distant or contralateral side
Contrast enhanced Computed tomography or contrast enhanced Magnetic resonance	Ring enhancing	Ring enhancing, soap bubble or Swiss-cheese appearance
Oedema and mass effect	Present	Present
Central necrosis	Present	Present
Serial imaging	Growth	Growth, stabilisation or regression
Magnetic resonance spectroscopy- N-acetyl aspartate/creatinine ratio	Decreased	Increased
Perfusion magnetic resonance-regional cerebral blood flow	Increased	Decreased
Positron emission tomography	Hypermetabolism	Hypometabolism

46 patients undergoing re-operation for glioblastoma, 28% improved, 49% were stable and 23% experienced decline in Karnofsky performance levels. The median survival after re-operation was 36 weeks while, it was only 23 weeks in those who did not undergo re-operation.[8]

Radiosurgery

Radiosurgery is usually reserved for small recurrences and it can be done for those who have already had external radiotherapy. It resulted in median overall survival of 10 months in a group of 32 patients with glioblastoma.[40] Most radiotherapists would desist from giving a second course of radiation to the same brain field. In cases where the recurrence occurs after 1 or more years of the initial therapy and for those in whom an adjacent field needs radiation, re-radiation therapy may be considered. Re-irradiation therapy gave 10 months of median overall survival and clinical response in one-third of 42 patients.[251]

Chemotherapy

It is offered to patients who have recurrence within the 1st year of initial treatment and those in whom re-operation is not a choice (older age, poorer Karnofsky performance score, location in eloquent area, lack of mass effect). Temozolomide is the choice for those who have not had this drug earlier. Higher doses and one week on/one week off temozolomide schedule have resulted in median progression-free survival of 5 months in glioblastoma.[259] Cyclophosphamide has been used for temozolomide resistant recurrences.[31] Multi agent chemotherapy does not confer an advantage and poses a significant toxicity.[205] It is hoped that the emerging therapies (see below) might improve the bleak outlook of recurrent glioma.

EMERGING THERAPIES

Molecularly Targeted Therapies

The past decade has seen a spate of novel approaches to treating malignant gliomas. Broadly, they target growth promoting factors or stop the signalling pathways. These include EGFR tyrosine kinase inhibitors (gefitinib and erlotinib), mammalian target of rapamycin (mTOR) inhibitors (temsirolimus and everolimus), and VEGFR, protein kinase C-beta, and other angiogenesis pathways inhibitors (vatalanib, bevacizumab and enzastaurin).[171,244] These are generally not useful as sole strategies, but are used in combination with conventional methods. There are phase 2 studies of some of these agents (e.g. bevacizumab and irinotecan) that are promising, but randomised studies are needed to prove the efficacy of molecularly targeted therapies.[202] Notch activation contributes to Ras-induced transformation of glial cells and glioma growth. This pathway may be a new target for glioblastoma therapy.[93] Thalidomide has potent antiangiogenetic properties and it has been combined with temozolomide therapy.[10] Anti mutagenic therapy with chloroquine has been added to conventional regimens with good effect.[224]

Convection Enhanced Delivery

Convection enhanced delivery of therapeutic macromolecules through a stereotactically implanted catheter in to the tumour ensures coverage for a 2 cm margin of brain around the tumour. This is far more than the 2 mm penetration of drugs from implanted wafers. The chimeric macromolecule delivered is a conjugate consisting of a monoclonal antibody that specifically attaches to the tumour cells in preference to normal cells and another portion that is tumouricidal. The attachment may be to partly specific receptors such as transferrin or interleukin-13 receptors or highly specific tumour receptors.

The tumouricidal portion may be a biotoxin (modified pseudomonas/diphtheria toxin or plant derived ricin) or a radioisotope (^{131}I). This delivery method circumvents the blood brain barrier, provides high local drug concentrations and minimises systemic exposure.[246,249] Using biodegradable polymer microspheres is another approach to deliver therapeutic macromolecules in to the tumour. BCNU and interleukin-2 have been tried in the experimental setting in this fashion.[190] 5-fluorouracil has also been delivered using this vehicle stereotactically in the clinical setting.[144]

Gene Therapy

It has been explored for malignant gliomas. One concept is to deliver a cytotoxic gene in to the tumour cell through a viral vector. Retrovirus, adenovirus and herpes simplex virus have been tried as the vectors. The virus can be redirected in such a way as to specifically attach to tumour specific sites such as fibroblast growth factor receptor on the tumour cells and the endothelial cells in the tumour. The cytotoxic effect can then be increased with the antiadenoviral drug, ganciclovir.[268] The interested reader is referred to a review article for details of genetic therapy in gliomas.[139] Use of neural stem cells (NSCs) as delivery vehicles for therapeutic tumour-toxic molecules is aimed at targeting disseminated tumour pockets as NSCs possess tropism for infiltrating tumour cells.[60]

Other Drugs

Matrix metalloproteinase (MMP) activity in tumour cells controls the invasive nature of the tumour. This can be blocked by cannabinoids which downregulate the MMP-2 gene.[21] Doxycycline also blocks MMP-9 activity.[264] Another novel approach is the use of COX-2 inhibitors (celecoxib) and peroxisome proliferator-activated receptor-gamma agonists (pioglitazone) to enhance the chemosensitivity and enable low-dose chemotherapy.[79]

Immunotherapy

It has had a long but unsuccessful history. Non-specific therapy using Bacillus of Calmette and Guerin (BCG) vaccine or interferons has failed. Adoptive immunotherapy using activated lymph node derived T cells was an early approach.[180] Only recently, specific glioma associated antigens have been identified. These include EphA2, IL-13Ralpha2 and Survivin.[170] Vaccinations with autologous fibroblasts retrovirally transfected with TFG-IL4-Neo-TK vector admixed with irradiated autologous glioma cells or with type-1 dendritic cells loaded with autologous tumour lysate have been tried. The problem is the time taken to produce these vaccines from the patient's own cells.[169] Another approach is using whole-cell vaccine comprising autologous tumour cells genetically modified by a transforming growth factor-beta2 (TGF-beta2) antisense vector. Blocking secretion of the immunosuppressive molecule TGF-beta in this manner should inhibit one of the major mechanisms by which tumour cells evade immune surveillance and should lead to clinically effective antitumour immunity.[62] The efficacy of such treatment approaches need to be proved in larger studies.

The benefits of surgery, radiotherapy and chemotherapy for malignant gliomas seem to have hit a plateau. While phase I and phase II trials of emerging therapies appear promising, many do not pass muster in phase III testing.[177] The neurosurgeon has to decide on the extent of aggressive excision based on several factors such as age, pre-operative Karnofsky performance score and location of the tumour. The non-availability of sophisticated technology to the surgeon is a limiting factor, especially in third world nations, that drives management decisions. Protocol driven management should not lose sight of the individual patient's needs, aspirations and affordability. The neurosurgeon must keep abreast of the newer treatment modalities to face the inquisitive patient's relatives, who have learnt of the "latest" therapy from the Internet.

ACKNOWLEDGEMENT

This chapter contains material from the chapter on Supratentorial Astrocytoma by Prof PN Tandon from the 2nd edition of this textbook. The present author thanks the previous author and editors for the use of this material.

134 Cerebellar Astrocytomas

Ramakrishna Easwaran

INTRODUCTION

"The cerebellar astrocytoma offers the best prognosis for normal survival of any brain tumour in any age group"—so said Matson in his monograph on Paediatric Neurosurgery.[37] Pilocytic cerebellar astrocytomas of childhood especially the cystic variety behave in a rather benign manner with several reports of long survival even after incomplete resection.[34] The same is not true of other histological types and in tumours that arise in adults.

INCIDENCE

Mishra et al. reported the incidence of cerebellar astrocytomas to be 23% out of 419 cases of childhood brain tumours seen at All India Institute of Medical Sciences, New Delhi, India.[39] Cerebellar astrocytomas constituted 11.6% of 482 intracranial gliomas reported from Christian Medical College and Hospital Vellore, India.[12] In a recent population based study from Switzerland, the incidence of pilocytic astrocytoma was 4.8 per 1 million per year, with 40% occurring in the cerebellum.[10]

Cerebellar astrocytoma is predominantly a tumour of childhood, 75% occurring in the first two decades of life. The youngest reported case of cerebellar astrocytoma was in a 5-week-old infant, which raises the possibility of origin *in utero*.[21] The average age at presentation was 13 years in Cushing's series and many patients were then blind with chronic papilloedema at presentation. The median age at presentation has dropped to 6–8 years in most modern series, indicating that these tumours are being diagnosed earlier, thanks to advances in imaging.[13,47] Cases have been reported in the sixth decade too, but these have often been recurrences after several decades, or histological variants such as xanthoastrocytomas.[24,49]

PATHOLOGY

Gross Pathology

Cerebellar astrocytoma is described classically as arising from one cerebellar hemisphere with a well-defined cyst containing yellow-brown fluid and a mural nodule. In two different series, the location was 28% in the cerebellar hemisphere, 30% in the vermis and the rest were tumours involving both the hemisphere and the vermis.[12,25] The tumours can be divided into the true cystic, false cystic and solid types.[25] The differences between the two cystic types are set out in Table 1 and Figures 1 to 3.

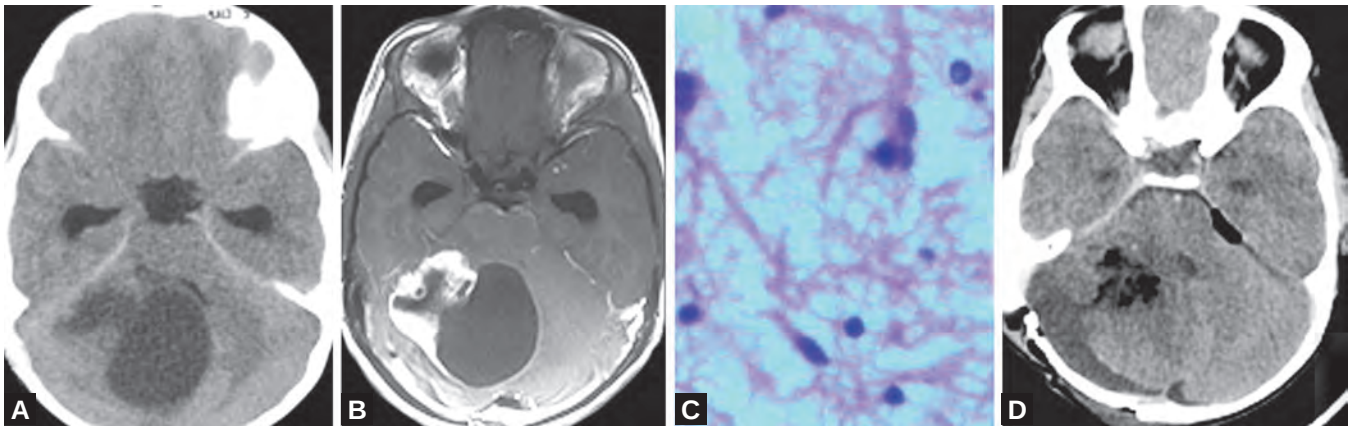
However, a recent report suggests that enhancing cyst walls, which appear smooth and shiny at surgery, may be non-tumourous.[6] There may not be a mural nodule at all, the entire tumour being in the cyst wall. Even the so-called solid tumours may have microcystic areas. Brainstem infiltration is more common in the solid and midline tumours, a reflection of their more malignant histology.[59] A rare case of benign cerebellar astrocytoma with extensive leptomeningeal spread has been reported.[46]

Microscopic Pathology

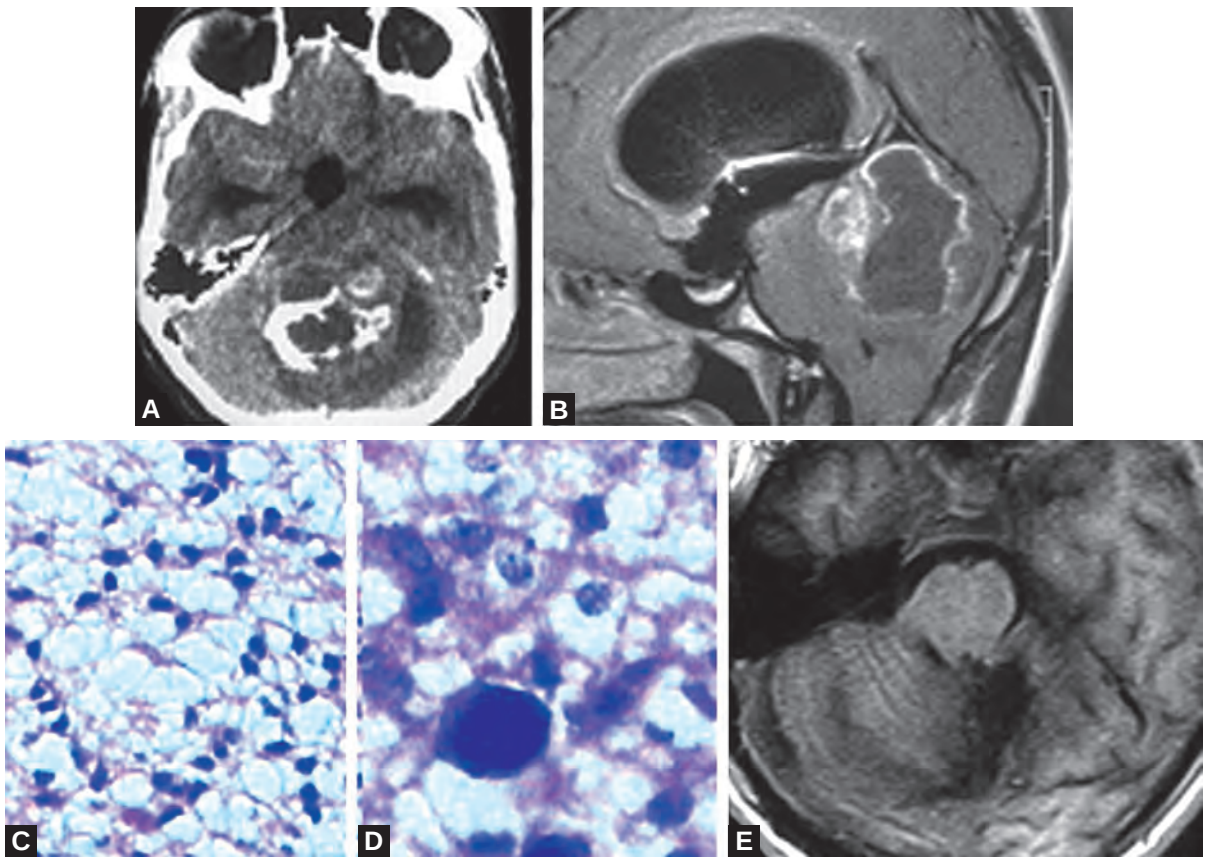
Pilocytic astrocytes, which are "hair-like" elongated bipolar astrocytes, are the histological hallmark of the paediatric cerebellar astrocytoma.[50] However, the most abundant cells in these tumours are the fibrillary astrocytes, arranged in alternating compact and loose areas resembling a honeycomb. Rosenthal fibres, the stout eosinophilic cytoplasmic rods made of heat shock protein, are more common in the compact zones. The absence of nuclear pleomorphism, mitotic figures, endothelial proliferation, necrosis and haemorrhage ensures that these tumours are graded as World Health Organisation (WHO) grade 1 (Fig. 1C). The tumour cells are positive for glial fibrillary acidic protein. About 20% of the paediatric cerebellar astrocytomas are histologically

Table 1: True and false cystic cerebellar astrocytoma

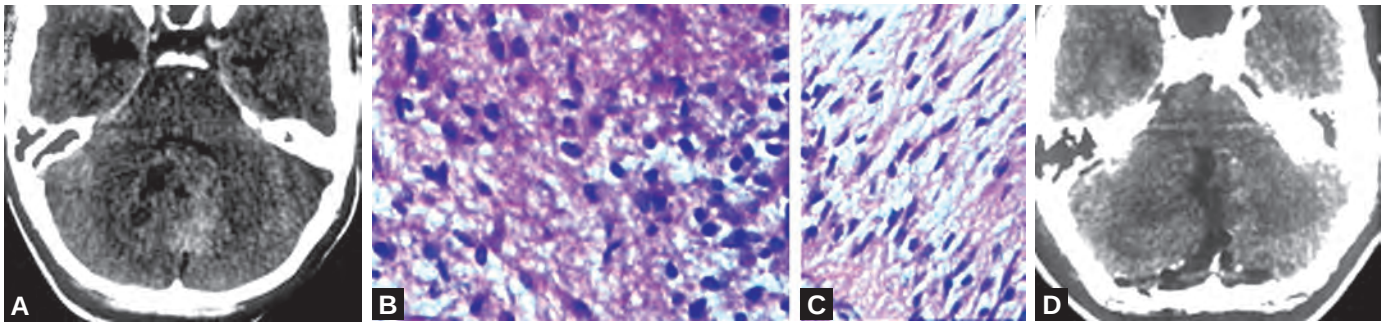
True cystic	*False cystic*
Mural tumour nodule within a glial cyst	Tumour lining the wall of the cyst
No tumour in the wall, which is thin	Wall is thicker, varies in thickness from part to part
Wall does not enhance with contrast	Wall enhances with contrast but to a varying degree
Wall shiny and translucent	Wall shaggy and opaque
Cyst content clear	Cyst content not always clear, usually xanthochromic



Figs 1A to D: (A) Non-contrast computerised tomography (CT) and (B) Gadolinium-enhanced magnetic resonance imaging of a 2-year-old child with cystic and solid hemispheric cerebellar tumour. Note the lack of enhancement in the wall of the cyst. The tumour was approached through a lateral suboccipital craniotomy in the prone position. Though the cyst wall appeared shiny, since it peeled off easily, it was excised along with the entire solid portion. (C) Histologically, there was only reactive gliosis in the wall while the solid part was a low-grade astrocytoma. Thus, this tumour may be described as a true cystic tumour. The child had a smooth post-operative course with no deficits. (D) The post-operative contrast CT done within 24 hours showed no enhancing remnant. Note the restoration of the fourth ventricle, reduction in the hydrocephalus as evidenced by the size of the temporal horns and the replacement of the craniotomy bone flap. The child did not need any shunting or ventricular drainage



Figs 2A to E: (A) Contrast computerised tomography (CT) and (B) Gadolinium-enhanced sagittal magnetic resonance imaging (MRI) of a 20-year-old male with cystic and solid midline cerebellar tumour. Note the calcifications in the tumour on CT and the crinkled enhancing nature of the wall of the cyst in MRI. The tumour was approached through a midline suboccipital craniotomy and vermiotomy in the prone position. The cyst wall appeared shaggy and did not peel off easily. The wall was excised completely along with the entire solid portion. (C) Histologically, the tumour showed astrocytic elements in the cyst wall. (D) The calcifications and "poached egg" appearance of oligodendroglioma in the solid part. Thus, this tumour may be described as a false cystic tumour. The patient had a stormy post-operative course with supratentorial extradural haematoma within 6 hours needing evacuation. By the 3rd day he required ventriculoperitoneal shunting for persistent hydrocephalus. He then had cerebellar mutism. Delayed supratentorial subdural hygroma appeared in the 6th week and was evacuated. (E) The post-operative MRI done in the 6th week showed no remnant tumour. The patient showed modest improvement with bromocriptine therapy over the next 4 months



Figs 3A to D: (A) Contrast computerised tomography (CT) of an 18-year-old female with poorly demarcated solid midline cerebellar tumour. Note the focal hypodense areas that appear to be cysts within the solid tumour. The tumour was approached through a midline suboccipital craniotomy and vermiotomy in the prone position. There were no cystic areas and the tumour had variable demarcation with the surrounding white matter. (B) Histologically, the tumour was a high-grade astrocytoma with compact cellular areas with cellular/nuclear pleomorphism. (C) Loose areas of recognisable astrocytes. (D) The post-operative contrast CT showed complete excision. The patient had self-limiting aseptic meningitis (in spite of dural closure and bone flap replacement) and mild residual ataxia but was otherwise well. She was given radiotherapy

classified as the diffuse fibrillary astrocytoma (Table 2). This group was reported by some to have a poorer prognosis than the juvenile pilocytic astrocytoma.[19] Others feel that there is no difference in prognosis between the two varieties as long as the lesion is totally excised.[4,34]

Malignant Astrocytomas

Anaplastic (WHO grade 3) astrocytomas account for 9–12% of cerebellar astrocytomas.[50,59] Malignant astrocytoma (Figs 3B and C) may either arise *de novo* or may result from malignant progression of a pilocytic astrocytoma.[2] Such a progression may occur even after three decades of original diagnosis.[9] Anaplasia may be localised to a focal region within the pilocytic astrocytoma and this focus appears radiologically distinct.[33] The solid nature and the tendency to infiltrate the brainstem or peduncle limit the extent of resection of anaplastic astrocytomas. Malignant astrocytoma has been reported to occur at the site of a previously treated medulloblastoma.[43]

Other Histological Types

Primary oligoastrocytoma is recognisable by the calcification pattern (Fig. 2D). Oligoastrocytoma metastasising from the frontal lobe to the cerebellum has also been reported.[55] Pleomorphic xanthoastrocytomas are rare in the cerebellum, but have been reported in a wide range of ages.[32,49] The surgeon should be aware that these tumours are harder in consistency (due to desmoplasia) and that they may involve the overlying dura or venous sinus. Glioblastoma multiforme is rare in the cerebellum, but carries as poor a prognosis as its supratentorial counterpart.[22] A case report of a patient who had a normal computerised tomography (CT) scan 2 months before the diagnosis of a large vermian glioblastoma suggests that the tumour arises *de novo* and grows rapidly, even in children.[31] Dysembryoplastic neuroepithelial tumour of the cerebellum is very rare.[30]

Table 2: Histological subtypes of cerebellar astrocytic tumours

Histological subtypes of cerebellar astrocytic tumours
Pilocytic astrocytoma (juvenile)
Diffuse fibrillary astrocytoma (low-grade)
Oligoastrocytoma
Anaplastic (malignant) astrocytoma (high-grade)
Glioblastoma multiforme
Lipidised glioblastoma[32]
Pleomorphic xanthoastrocytoma

Tumour Biology

Vascular endothelial growth factor expression and changes in the blood-brain barrier have both been proposed as mechanisms for the cystic change in pilocytic cerebellar astrocytomas.[35,36] In one study of 78 cases, none of the novel parameters such as MIB-1 labelling index, flow cytometry, *p53* immunoreactivity or apoptosis rate significantly predicted recurrence or survival, but they indicated substantial biological variation among cerebellar pilocytic astrocytomas.[23] The occurrence of cerebellar astrocytoma in association with ataxia-telangiectasia, Albright's disease, von Hippel-Lindau disease and neurofibromatosis suggests a genetic mechanism of causation, quite unlike the sporadic cerebellar astrocytoma.[29,40,45,54] The gene expression profiles of pilocytic astrocytomas differ significantly from those of diffusely infiltrating low-grade gliomas and their benign biologic behaviour may be related to up-regulation of immune defence-associated genes.[26]

CLINICAL PRESENTATION

The symptoms and signs vary with the age of the patient and the site of the tumour. In infancy, cerebellar tumours present with enlarging head size due to hydrocephalus, irritability and vomiting. The tense fontanel, rather than papilloedema, indicates raised pressure at this age. Older children and adults complain of headache, seen in about 80% of patients.[13,59] The headache is usually frontal, but

may later become generalised. Localised headache in the occipital region is rarely an early symptom. Headache occurring in the early morning hours has been attributed to sleep induced hypoventilation causing hypercarbia and postural cerebrospinal fluid (CSF) accumulation in the intracranial compartment during recumbency. The headache may be accompanied by vomiting, diplopia or irritability. Vomiting relieves the headache, probably due to the associated hyperventilation. Amaurosis fugax, especially on rising from the stooped posture, is a symptom of advanced papilloedema and may indicate impending loss of vision.

Vomiting alone, without headache, is also seen, though this story is more typical of a fourth ventricular tumour such as ependymoma. "Robin's rule" states that if the vomiting occurs before the headache, it is an ependymoma but, if the headache occurs before the vomiting, it is a medulloblastoma or astrocytoma.[60] Many children have undergone gastroenterological investigations for persistent vomiting before their posterior fossa tumour is detected. Some children arrive at the emergency department with brief episodic loss of consciousness and tonic stiffening of the limbs during the height of the headache—the so-called "hydrocephalic fit". Torticollis to the side of the tumour may be a symptom, sometimes a sole symptom.[58] This symptom indicates tonsillar herniation. Presentation with a spontaneous haemorrhage into the tumour cyst is known, but rare.[38]

The mean duration of symptoms before presentation was 2 years in Cushing's series (1930s) for childhood cerebellar astrocytoma. It came down to 11 months in the 1950s and is down to about 6 months in most modern series.[13,21,59] Clinical examination reveals signs of raised intracranial pressure (ICP) (80%) and those of cerebellar dysfunction (70%).[13,59] Neck stiffness without Kernig's sign in an afebrile patient indicates tonsillar herniation. Gait and stance ataxia denote a vermian lesion while unilateral appendicular ataxia is seen in the deeper hemispheric masses. Horizontal nystagmus is found in midline or lateral cerebellar lesions while vertical nystagmus or gaze palsy is caused by anterior vermian lesions compressing the collicular region. Acute concomitant esotropia, unilateral hearing loss mimicking an acoustic schwannoma and peduncular hallucinosis have been other reported rare presentations.[15,42,56]

NEURORADIOLOGY

While magnetic resonance imaging (MRI) has superseded CT in the detection and characterisation of posterior fossa tumours, a good quality CT may often yield the necessary information for management of the patient. Dilatation of the third and lateral ventricles is seen in the majority of patients, as the tumours tend to be large enough to cause compression of the fourth ventricle at the time of diagnosis. Periventricular lucencies suggest high intraventricular pressure. The solid part of the tumour is hypodense in non-contrast CT as compared to the cerebellum. The cystic part is hypodense compared with the cerebellum or the solid part, but it shows a higher attenuation coefficient as compared to the CSF due to its protein content (Fig. 1A). The tumour shows a varying degree of demarcation with the surrounding normal tissue. Calcific foci are uncommon, being reported in about 15%.[61] Calcification is displayed more graphically by CT than MRI and extensive calcification should suggest oligoastrocytoma (Fig. 2A). Pilocytic astrocytomas enhance well, while the more fibrillary variety may not. The enhancement may be non-uniform due to the presence of microcysts in the solid part of the tumour (Fig. 3A). The cyst wall enhances in the false cystic tumour due to the presence of tumour in the wall (Fig. 2B).

The cystic and solid parts of the tumour appear hypointense in T1-weighted magnetic resonance images and hyperintense in proton density or T2-weighted images. The solid part is hyperintense to the cerebellum in T2-weighted images and the cystic part slightly hyperintense to the CSF in T1-weighted images.[3] Presence of haemosiderin causes a rim of hypointensity in the cysts suggesting an old bleed. Gadolinium enhancement patterns are similar to CT contrast enhancement. Haemangioblastoma, ependymoma, medulloblastoma, dermoid tumour, choroid plexus papilloma, metastasis, tuberculoma and cerebellar abscess must be considered in the differential diagnosis. Magnetic resonance spectroscopy (MRS) may help in narrowing the differential diagnosis. Taurine detection by short-echo proton MRS is present in medulloblastoma and absent in cerebellar astrocytoma.[41]

MANAGEMENT

In the past, it was a routine practice to place a ventriculoperitoneal shunt a week or so before resecting cerebellar astrocytomas. The current opinion is against pre-operative routine shunting for all the disadvantages given in Table 3.[34]

Table 3: Pre-operative shunting for cerebellar astrocytoma

Advantages	*Disadvantages*
Rapid symptom improvement	Upward transtentorial herniation[17]
Life/vision saving in an emergency	Tumour dissemination through the shunt[28]
Lax brain during resective surgery	Shunt block/infection prior to resection
Luxury of converting an emergency into an elective operation	Increased risk of infection after posterior fossa surgery
	Supratentorial subdural haematomas
	Shunt no longer necessary in the long-term[14]
	Higher cost
	A rare patient may refuse resectional surgery, as the patient is relieved of symptoms by the shunt

Pre-operative dexamethasone preparation suffices in most cases. Peri-operative external ventricular drainage has been employed by some.[14] Endoscopic third ventriculostomy seems to be a better option when relief of hydrocephalus is needed before or after posterior fossa tumour extirpation.[51]

Surgery

Goal

Total excision of the tumour is the goal of cerebellar astrocytoma surgery. It used to be advocated that removal of the mural nodule in case of a cystic astrocytoma was all that was necessary if the cyst wall was thin and transparent. However, the uncertainity of tumour growth along the cyst wall makes it desirable to excise the tumour completely. Recurrence is likely to occur if tumour is left behind.[4,23] However, long-term survival following subtotal resection is well known. Invasion of the brainstem by the tumour is the only reason for partial or subtotal excision in current neurosurgical practice.

Approach

The surgical approach to a cerebellar astrocytoma is decided by the location of the tumour as summarised in Table 4. Positioning of the patient is a matter of the surgeon's preference. The sitting position, which could be a viable alternative to any of the positions advocated in Table 4, is not favoured in many departments nowadays due to its inherent complications such as air embolism, tension pneumocephalus, supratentorial haematoma, etc.

Exposure

Preparation is made for placing an occipital burr hole for ventricular drainage even though this is required only occasionally. The availability of powered bone tools helps in fashioning a craniotomy flap in the posterior fossa as opposed to craniectomy. This is especially easy in children (Fig. 1D). Apart from the obvious cosmetic and psychological value, the incidence of pseudomeningocoele and pain at the operation site are less on replacing the bone flap at the end of the tumour excision.[20] Should a re-operation be needed later, the planes are easier to define if the bone has been replaced. The posterior rim of the foramen magnum can be removed with the bone flap and replaced. Removal of the posterior arch of the atlas is not routinely necessary. It is generally safe to cross above the transverse sinus or torcula with a craniotome. Titanium ligating clips are preferred to sutures or bipolar coagulation for controlling the bleeding from the occipital and circular venous sinuses while opening the dura. The cystic component can be tapped transdurally to relax the brain before formally opening the dura. Cyst drainage causes the cerebellum to collapse and this may lead to intra-operative or post-operative subdural bleeding from the bridging veins. Such a complication must be foreseen and prevented. Placement of wet gelatine sponge, head elevation and patiently waiting are effective in controlling the bleed from the bridging veins. Desperate blind bipolar coagulation only worsens the bleeding. Wide opening of the arachnoid of the cisterna magna is avoided to prevent tumour spread along the subarachnoid space.

Tumour Excision

For midline tumours a vertical vermis incision through the avascular midline is well tolerated and does not worsen the gait ataxia permanently. A paravermian vertical incision is to be avoided as it carries a higher risk of post-operative mutism.[11] For lateral tumours, it is preferable to incise the cerebellar hemisphere horizontally along the direction of the folia. The mural nodule, all solid parts and contrast enhancing or shaggy cyst walls are excised under the magnification of the operating microscope. Small mural nodules can be excised as a whole. The bigger solid masses may require internal debulking (done elegantly with ultrasonic aspirator) before dissection of the plane between the tumour and the surrounding normal cerebellar tissue. The plane is well defined in pilocytic astrocytomas but may not be so in the fibrillary or, the rare malignant varieties. Shiny, thin, translucent cyst walls need not be excised even if they are enhancing.[6] Attachment to the pons or major invasion of the middle cerebellar peduncle may limit the completeness of excision.

Closure

After ensuring perfect haemostasis, the dura is closed. The dura always shrinks and primary closure is often not possible. Pericranium, fascia lata or dural substitutes are needed. Complete dural closure, replacement of the bone flap and meticulous layered wound closure reduce the incidence of, but do not totally eliminate the occurrence of aseptic meningitis, pseudomeningocoele or external CSF leak (Fig. 3). If the lateral ventricle had

Table 4: Choosing the surgical approach according to the location of cerebellar astrocytoma

Location	*Approach*	*Position*
Inferior vermian, medial hemispheric	Midline suboccipital	Prone
Lateral hemispheric	Lateral suboccipital	Prone
Cerebellopontine angle	Retromastoid	Lateral
Superior vermian	Infratentorial supracerebellar	Concorde
Anterosuperior	Occipital transtentorial[53]	Sitting

been tapped during surgery, the catheter may be left behind for post-operative ICP monitoring and control. The patient is observed in the intensive care setting until a CT is done within 24 hours.

Complications

The CT must be done emergently if the patient becomes less responsive or drowsy or complains of severe headache in the post-operative period. Possible causes include tumour bed haemorrhage, supratentorial subdural or extradural haemorrhage, infratentorial subdural haemorrhage, unrelieved hydrocephalus, pneumocephalus and venous or arterial infarction in the cerebellum. As with any posterior fossa surgery, complications such as pseudomeningocoele, aseptic or infective meningitis and external CSF leak can occur.

A complication that requires special mention is *transient cerebellar mutism*.[7,18] In this condition, the child or young adult, who has a relatively normal speech for 1 or 2 days after posterior fossa tumour surgery, becomes mute. These patients, additionally, may have long tract signs or behavioural abnormalities. Routine imaging fails to reveal any specific abnormality that can explain the deficits. The deficit is not nearly as transient as the name suggests; recovery is a slow and incomplete process taking several months. Bromocriptine has been anecdotally reported to be of help.[1] Many patients are left behind with speech and cognitive abnormalities.[27] The cause is believed to be damage in the region of the dentate and interpositus nucleus. The finding of contralateral cerebral hemispheric hypometabolism (diaschisis) by F^{18} fluorodeoxyglucose positron emission tomography study in a patient who had undergone cerebellar astrocytoma excision suggests that such vascular events may also be responsible.[44]

Adjuvant Therapies

Radiotherapy is not indicated for pilocytic astrocytoma as these can be "cured" by total excision. Even when a tumour residue has been left behind, radiotherapy may not prevent regrowth.[4] In case a residue has to be left behind, it can be observed with periodic imaging. Re-operation or adjuvant therapy can be advised for remnants documented to be progressing. Stereotactic radiosurgery has been used for remnants and those pilocytic astrocytomas exhibiting progression.[24,52] Though it is appealing to the patient, those advocating and practicing stereotactic radiosurgery must remember that it has its own complications, sometimes serious.[57] The more malignant varieties must be subjected to adjuvant radiotherapy and/or chemotherapy. Chemotherapy is the only possible adjuvant method for children younger than 2 years.

PROGNOSIS

The extent of surgical resection is the strongest determinant of prognosis.[13,23,47] In a study of 102 childhood cerebellar astrocytomas from Mumbai, India, the survival was 94% at 2 years, 87% at 5 years and 73% at 10 years.[13] Even after complete excision, recurrence can be seen several decades later.[8] Re-operation and total excision again is feasible in such cases. The recurrence may be malignant.[2] While the surgeon may think that the tumour has been excised completely, post-operative MRI may show residual tumour. The recurrence/progression rate was 19% in a study and 14% had stable size of the remnant or actual regression.[16] Previous studies had focused only on tumour progression and survival, but recent studies show increased cognitive and adaptive dysfunction in children operated upon for low-grade cerebellar astrocytomas.[5,48]

Cerebellar astrocytomas often behave in a benign fashion and total surgical excision has been the mainstay of therapy since Cushing's times. CSF shunting is less often needed in today's practice. Hopefully, future work would show us why certain tumours behave more aggressively than others.

135 Brainstem Gliomas

Sarat Chandra P, VS Mehta

INTRODUCTION

Intrinsic brainstem tumours are common in childhood, comprising approximately 20% of all paediatric brain tumours, but are not uncommon in adults.[8] Pool,[2] as early as in 1968, reported useful long-term survival following surgical and X-ray treatment for verified brainstem gliomas. He suggested that if a brainstem tumour is suspected an exploratory craniotomy is generally advisable, otherwise a benign lesion might be overlooked. Magnetic resonance imaging (MRI) has completely changed the management of brainstem tumours; it not only accurately localises the tumours, but also identifies those subgroups, which may be subjected to radical surgery. The term "brainstem glioma" is an imprecise description as it suggests that all such tumours behave in the same manner. It is now appreciated that brainstem tumours are not a homogeneous group with regard to their clinical, pathobiological or histological features and that their prognosis may be directly related to tumour type and location.[2,3,24,38,41] The advent and the use of the operating microscope, the ultrasonic aspirator, laser or tissue vapouriser, and intra-operative evoked potentials and brain mapping has led to a more aggressive surgical approach to lesions in the brainstem.[14,16,23]

In the pre-computerised tomography (CT) scan era and the early CT scan era, all tumours between the thalamus and the cervicomedullary junction were called brainstem gliomas and were regarded as one entity. The traditional treatment of these tumours consisted of irradiation, often preceded by a biopsy, and sometimes followed by adjunctive chemotherapy.[35] This has met with little overall success. In part, this is because previous reports vary in their definition of "brainstem" tumours.[1-3,8,24,38,41] Some authors regard lesions of the midbrain, pons and medulla oblongata all as brainstem lesions, whereas others make a distinction between the thalamic and midbrain lesions on the one hand and pons and medulla lesions on the other. In addition, many studies include patients from the era before CT scans,[1,12,21] as well as cases of brainstem tumours that were not histologically proven.[1,12,21]

CLASSIFICATION

A number of classifications have been provided based on location, imaging and histopathology, but most of them obscure the fact that there exist basically two categories of brainstem tumours:

1. Focal, discrete and sometimes exophytic lesions associated with a favourable prognosis.
2. Classic diffusely infiltrative lesions known for their relentless growth, resistance to radiotherapy and chemotherapy, and a bleak prognosis.

Many authors[2,3,14,16,19,23,24,38,41] believe that the former mostly consist of pilocytic astrocytomas and the latter belong to a family of fibrillary astrocytomas, anaplastic astrocytomas and glioblastoma multiforme. The focal tumours are particularly amenable to total excision, and the patients have a good prognosis provided the surgery has been performed by an experienced surgeon who has had enough exposure in operating upon such lesions.

A number of classifications are available. Brainstem gliomas have been classified by site, imaging and pathology.

Location: The terms applied include midbrain tumour,[4,13,18] tectal tumour,[5,18,40] pontine glioma,[7,32] focal medullary tumour[17] and cervicomedullary tumour.[7,17]

Imaging: Diffuse gliomas,[17,20] intrinsic gliomas,[15] pencil gliomas,[43] exophytic tumours (dorsal; ventral and lateral),[7,17,20] focal and cystic tumours.[15]

Histopathology: Low grade or benign tumours (pilocytic and grade II) and high grade tumours (World Health Organization Grades III and IV).[7,15,17,20,32]

These classification systems by various authors are mentioned in greater detail in Table 1.

Currently, the most commonly used classification in clinical practise is based on imaging and location. This includes focal (solid or cystic), diffuse, exophytic (ventral, lateral or dorsal), tectal plate and cervicomedullary. However, as mentioned above, for practical purposes there are two categories of tumours:

1. *Focal*: discrete sometimes exophytic lesions.
2. *Classic*: diffusely infiltrative lesions known for their relentless growth and resistance to radiotherapy.[1,19] It is the former category of tumours that need to be tackled aggressively.

The description of "intrinsic" brainstem gliomas has been somewhat neglected in the literature. By the term "intrinsic" the authors mean tumours which are within the brainstem axis and are surrounded by normal parenchyma. One of the main reasons could be perhaps that

these tumours are difficult to access surgically and only surgeons with significant experience could perhaps do a radical decompression without producing any major morbidity. The present classifications (Table 1) with regard to this have several shortcomings:

- The surgical plan is still difficult to decide in many cases as most of the classifications are usually based on their anatomical location only. In this aspect the classification by Choux et al.[9] perhaps comes closest in helping to define a surgical plan.
- The difference between a diffuse brainstem glioma and large focal intrinsic brainstem glioma is not clearly differentiated in most of the classifications. Thus, it is sometimes possible that a large focal intrinsic tumour, which is actually a benign lesion is not subjected to surgery and sent for radiotherapy directly.
- It is usually not possible to determine radiologically whether the tumour is benign or malignant. A stereotactic biopsy too may not provide a holistic representative picture [e.g. may pick up a benign portion of a malignant tumour or vice versa].

Table 1: Different forms of classification systems

Author	*Classification system*
Epstein[14,16]	Intrinsic Diffuse Focal Cervicomedullary Exophytic Anterolateral into cerebellopontine angle Posterolateral and into pontine brachium Disseminated Positive cytology Positive myelography
Epstein and McCleary[16]	Diffuse Focal Cervicomedullary
Stroink et al.[46]	Group I—dorsal exophytic glioma Group IIA—intrinsic brainstem glioma Group IIB—intrinsic brainstem glioma, hyperdense, contrast enhancing, exophytic Group III—focal cystic tumour with contrast enhancement Group IV—focal intrinsic isodense, with contrast enhancement
Barkovich et al.[4]	Location (midbrain, pons, medulla) Focality (diffuse or focal) Direction and extent of tumour growth Degree of brainstem enlargement Exophytic growth Haemorrhage or necrosis Evidence of hydrocephalus
Allbright et al.[1]	Focal (midbrain, pons, medulla) Diffuse
Fischbein et al.[18]	Midbrain Diffuse Focal Tectal Pons Diffuse Focal Medulla Diffuse Focal Dorsal exophytic
Choux et al.[9]	Type I—diffuse Type II—intrinsic, focal Type III—exophytic, focal Type IV—cervicomedullary

In this respect, the authors feel that a more prudent method would be to classify the "intrinsic" brainstem gliomas in the categories given below. This is based on the senior author's personal experience of 40 cases (managed between Jan 1998–June 2007).

Expanding variety: These tumours have the following characteristics:

- Well delineated as seen on gadolinium contrast MRI, located posteriorly, posterolaterally or ventrolaterally.
- They have a slow progression of neurological deficits with a relatively long clinical history (here a period of 6 months was considered).
- Motor function is usually well preserved with the patient being independent for all activities of daily living.

Infiltrating diffuse variety: Here, the margin between the tumour and the brainstem parenchyma is not well defined. Patients usually have a short clinical history and there is a rapid progression of symptoms.

Ventrally located tumours: Here, the tumour is located completely ventrally without any lateral or posterolateral extension. They have been included in a different subset because of the "very difficult to access" surgical location. It has been felt by the authors that these tumours should not be operated upon as surgical intervention may cause more complications.

According to the authors only the "expanding variety" should be subjected to surgery. If surgery is undertaken, a radical removal should be done. Radiotherapy is given only if the tumour is found to be malignant on histology. Thus, a more important approach would be to try to remove the tumour as radically as possible, yet remaining within the tumour, provided the radiological image reveals such a possibility. A word of caution, however, that such pathology should be dealt with only by surgeons who have sufficient experience in this area. It should be remembered that this is a surgical strategical classification only for "intrinsic" brainstem gliomas. Surgery is anyway indicated for all exophytic tumours (Table 2).

PATHOLOGY

Most astrocytomas of the brainstem are infiltrative tumours of the fibrillary type, similar to diffuse cerebral astrocytomas. Macroscopically, they are usually characterised by a symmetrical enlargement of the pons (diffuse hypertrophy). The expanding lesion encroaches posteriorly and superiorly upon the fourth ventricle. Occasionally, there may be anterior enlargement. The

Table 2: The classification proposed by the authors for intrinsic brainstem tumours. Note that classification for exophytic tumours are same as proposed by earlier authors, but has been included here to provide completeness

Type of brainstem glioma	*Features*	*Comparison with other classifications*	*Surgery*
I. Intrinsic only	The tumour is well within the brainstem axis without any breach of the parenchyma		
A. Expanding variety	• Well delineated on gadolinium-magnetic resonance imaging (Gd-MRI)	Epstein et al. [1985]:[14] Focal (< 2 cm)*, cervicomedullary	Yes Radical excision
	• Slow progression of clinical symptoms (> 6 months)	Stroink et al [1987]†:[46] Group III, IV	
	• Well preservation of motor function with independent activities of daily living	Choux et al§ [2000]:[9] Type II, IV	
	• Size may be > 2 cm		
B. Diffuse infiltrative variety	• No margin of delineation on Gd-MRI	Epstein et al. [1985]¶: diffuse	No
	• Rapid progression of symptoms	Stroink et al. (1987)**: IIA Choux et al. (2000): Type I	
C. Ventrally located	Pure ventral location	May be kept as focal in other classifications, but authors prefer not to operate in view of the difficult location and associated high risk of complications	No No
II. Exophytic brainstem glioma	The tumour breaches the bordering brainstem parenchyma to become exophytic		Yes
A. Focal with exophytic	Has a well defined focal component with a dorsal or dorsolateral exophytic component		The exophytic portion removed radically. The intrinsic part may or may not be removed radically
B. Diffuse with exophytic	The intrinsic component is not well defined and the tumour has a dorsal or dorsolateral exophytic component		The exophytic portion removed radically. The intrinsic part may not be removed radically

*Tumours > 2 cm could still be expanding variety.

†Based on contrast enhancement and radiology only; clinical features not taken into consideration.

§Based more on anatomical localisation, clinical features not mentioned again.

¶Tumour looking focal but > 2 cm is still considered diffuse.

**Clinical features not taken into account.

medulla is often spared. Sometimes, however, it originates from the medulla and may spread to the upper cervical region.[42] Histologically, there is a diffuse replacement of nerve tissue by small and large astrocytic cells (stellate, pilocytic and gemistocytic), either randomly dispersed or arranged in small or large groups. This morphologic diversity reflects the cellular heterogeneity even in the absence of anaplasia. In some cases there may be frank features of anaplasia, necrosis and endothelial proliferation as seen in glioblastoma multiforme.[42] Depending on the macroscopic appearance, brainstem gliomas have been divided into the following categories.[34,42,47]

Diffuse

This is a classical example of brainstem tumours that have been recognised since the beginning of neurosurgery. These neoplasms present with a short history and with multiple cranial nerve palsies along with involvement of long tracts. The MRI is virtually diagnostic of these lesions. The tumour is invariably malignant and the only form of therapy advisable is radiotherapy or chemotherapy. Surgery is not indicated. Even stereotactic biopsy is not advised as the procedure may cause additional morbidity, and the biopsy may not contain representative tissue.

Focal

These more commonly involve the medulla and are often associated with a relatively long clinical history. Neurological examination usually reveals focal deficits, i.e. either a VI or VII nerve palsy. These neoplasms are

commonly low-grade astrocytomas and are amenable to surgical excision.

Cervicomedullary Tumours

These are usually low-grade astrocytomas and gangliogliomas and amenable to radical excision. Furthermore, they have well defined tumour margins and are thus amenable to a radical excision.

Cystic Tumours

These are usually low-grade pilocytic astrocytomas and highly amenable for surgical excision.

Exophytic Tumours

These tumours are characterised by exophytic growth either ventrally, laterally into the cerebellopontine (CP) angle or dorsally into the fourth ventricle. Of these, the dorsally exophytic tumours have the best prognosis, are amenable for radical excision and are associated with long-term neurological recovery. The other variants have a poor prognosis.

Tectal Plate Gliomas

These are uncommon in the paediatric age group. They have been reported to be one of the commonest causes for adult hydrocephalus in the Western literature. The main presenting feature is hydrocephalus. These are diagnosed on MRI with gadolinium contrast and are managed by performing a ventriculoperitoneal shunt.[40] These may be simply followed up and if they increase in size may be subjected to radiotherapy. Radiosurgery has also been used recently. We have performed endoscopic stenting of the aqueduct along with simultaneous biopsy in 12 cases. Endoscopic third ventriculostomy or aqueductal stenting may be a better alternative to shunt surgery.

Histology from a series of 40 cases of brainstem gliomas revealed pilocytic astrocytomas in 10 cases, grade II in 17 cases and grade III in 13 cases.

CLINICAL FEATURES

Albright et al.[2] stated that approximately 70% of children with diencephalic tumours live 5 years after diagnosis, whereas only 30% of children with brainstem gliomas survive for that long. However, it is now widely recognised that brainstem tumours are a very heterogeneous group with regard to their clinical, histopathological and biological features, and it is essential that they be therefore regarded as distinct entities.

Vomiting is a common symptom and is usually due to involvement of the area postrema and the other medullary nuclei by the tumour. Ataxia is usually due to involvement of the cerebellar peduncles. Motor weakness due to involvement of the pyramidal tracts is common. Extraocular motor palsy is characterised by squint usually noticed by the parents or school teachers. Additional signs include nystagmus, skew deviation and internuclear ophthalmoplegia.[14,16,19,23] The latter sign is a hallmark of intrinsic brainstem involvement characterised by failure to adduct the eye on the side of the lesion and presence of nystagmus of the abducting eye on the opposite side. This occurs due to involvement of the medial longitudinal fasciculus. Other signs of cranial nerve involvement include facial weakness, dysarthria and swallowing difficulties. Features of raised intracranial pressure may occur due to obstruction of cerebrospinal fluid (CSF) pathways in dorsally exophytic tumours. Focal intrinsic tumours from the tectum can cause obstruction of CSF pathways early in the course of illness.[40] The following features are characteristic of an intrinsic brainstem neoplasm:

- Internuclear ophthalmoplegia
- Horner's syndrome
- Cranial nerve involvement with crossed motor involvement, e.g. ipsilateral III nerve paresis with contralateral hemiparesis (Weber's syndrome)
- Combination of certain cranial nerve nuclei, e.g. VI and VII cranial involvement on one side indicates an intrinsic pathology
- Partial involvement of some large sized cranial nerve nuclei, e.g. III cranial nerve nucleus. This has many components, so a diffusely infiltrative tumour may cause bilateral ptosis (involvement of bilateral levator palpabrae superioris), or bilateral superior rectus palsy (involvement of unilateral superior rectus nucleus can still cause bilateral superior rectus palsy as the tract of the opposite superior rectus crosses contralaterally and passes through the opposite superior rectus nucleus) or unilateral complete III nerve palsy and opposite partial III nerve palsy.

Patients with tumours at the cervicomedullary junction exhibit lower cranial nerve dysfunction and pyramidal tract signs, similar to those occurring in the upper cervical spinal cord. In these patients, radical excision is possible with little morbidity, and usually a very protracted clinical course. Histopathologically, the vast majority of the tumours are low-grade gliomas.[14,16,19,23]

Intrinsic tumours of the pons are infiltrative in nature and are mostly malignant. Symptoms at the time of admission are usually cranial nerve palsy, pyramidal tract signs and ataxia. It is characteristic for these tumours to progress to an advanced stage without the development of increased intracranial pressure.[33] The course of the disease is steadily progressive, and most patients die within 2 years, even after radiation therapy. Epstein[13,14,16] refers to this group of tumours as "diffuse" and strongly advises against surgical intervention because this in no way alters the ultimate outcome. Even biopsy is not recommended by many authors, as it may not show the representative tissue due to the heterogeneous nature of the tumour and it poses a high risk to the patient. However, in the authors' experience, focal tumours even in the pons, if associated with

paucity of neurological signs, may be benefited from radical surgery.

However, it is important to differentiate these tumours from diffuse brainstem swelling which may occur in neurofibromatosis type 1 (NF-1).[7,10,26,36] Among patients with NF-1, histological confirmation, when available, is consistent with low-grade glioma in the majority of cases. These two entities, diffuse pontine glioma in patients without NF-1 and diffuse brainstem enlargement in children with NF-1, are different in their natural histories and may represent different pathophysiological processes. A recent study has demonstrated the use of magnetic resonance spectroscopy (MRS) in differentiating the two entities. The MRS neuronal marker (NA) peak was preserved in patients with NF-1, but significantly decreased in diffuse gliomas. They hypothesised that this finding reflects preservation of brainstem neuronal elements in the NF-1 group, consistent with their minor or absent symptoms of brainstem involvement. In contrast, patients with diffuse gliomas show significantly decreased NA and have major neurological deficits attributable to neuronal damage from their brainstem tumours.

A subgroup of benign brainstem gliomas, identified by Hoffman et al.[24,25] is the dorsally exophytic transependymal benign brainstem glioma. The duration of the onset of symptoms is longer in this group, and these children often have hydrocephalus (75%). Ataxia is also common, whereas cranial nerve deficit and long tract signs are relatively rare. These tumours are very amenable to surgical resection, frequently requiring no further therapy.[29,30]

Focal midbrain astrocytomas form a special entity. About 50% of all tumours occur predominantly in the tectal region, giving rise to obstructive hydrocephalus in 83% of cases.[14,16,23,41] Most patients with hydrocephalus exhibit headaches, vomiting and florid papilloedema as a result of increased intracranial pressure. The other 50% of focal midbrain tumours occur predominantly in the tegmentum and cause either long tract signs, due to compression of the cerebellar peduncles, or cranial nerve deficits, and signs and symptoms referable to the eyes (up-gaze paresis, Parinaud's syndrome) caused by pressure on the nuclei of the oculomotor nerves and their connecting pathways.[7,14-16,23,41,43]

In our series, the clinical features and demographical data are mentioned below as per our classification scheme.

Expanding variety: The ages of the patients ranged from 4 to 55 years with a mean of 19.2 years and a male:female ratio of 3:2. The majority of the patients were within 21–40 years [13] followed by 11–20 years [11], less than 10 years [10] and greater than 40 years [6]. The commonest clinical feature included cerebellar signs [28], followed by pyramidal involvement [27] [10 cases had hemiparesis and 5 quadriparesis, but ambulatory; 12 others had pyramidal involvement in the form of brisk deep tendon reflexes/upgoing plantars], ocular palsy [19], V nerve involvement [13], facial palsy [12], lower cranial nerve palsy [9], Horner's syndrome [4] and sensorineural deafness [2]. Prolonged headache was present in 9 patients. One patient lapsed into altered sensorium a day earlier; underwent an emergency shunt for obstructive hydrocephalus and returned to his pre-operative clinical status. The duration of clinical features ranged from 2–96 months with a mean of 13.6 months.

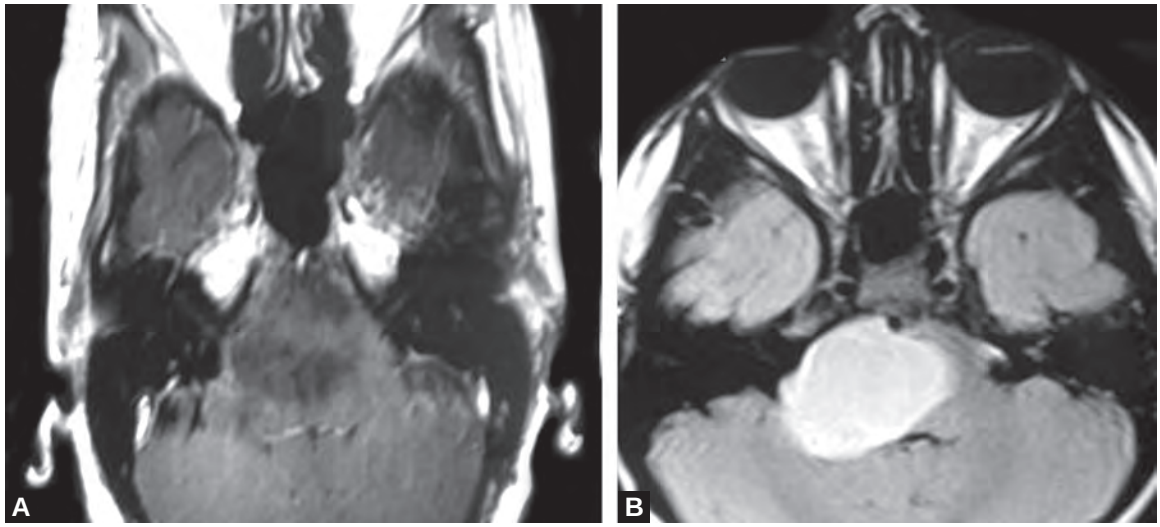
Diffuse infiltrative and pure ventral variety: The age of this group of patients ranged from 0.9–16 years with a mean of 5.2 years. Out of 32 patients, 17 had onset of symptoms in less than 3 months. Onset of symptoms in 12 patients was within 6 months. The remaining two patients had onset of symptoms between 6–12 months. The commonest clinical features in this group included pyramidal signs in 26 cases [16 hemiparesis, 10 quadriparesis; 11 were dependent for all activities of daily living], and cerebellar signs in 16 cases.

NEURORADIOLOGY

The advent of the MRI scan, with its readily available sagittal and coronal planes of imaging, has facilitated accurate localisation of pathological lesions within the brainstem. Tumours should be assessed for location, signal intensity, focality, extent of infiltration, degree of brainstem enlargement, presence of cyst, necrosis or haemorrhage, or an exophytic component. Following this the morphology should be categorised, whether it comes under focal, diffuse, cervicomedullary or exophytic type. The MR imaging should be always correlated with the clinical history. Finally, it is important to identify the benign subgroup of brainstem gliomas. Epstein et al.[14,16,23] have retrospectively analyzed 88 cases of brainstem gliomas and have proposed that the more benign tumours tend to displace rather than infiltrate the secondary structures like the pia, fibre tracts and the ependyma, the characteristics of which may be identified on good quality MRI's. As mentioned earlier, we prefer to first categorise whether the tumour is "intrinsic" or a "tumour with an exophytic component". In the former, we then identify whether the tumour is an "expanding variety", "diffuse infiltrative" or a "pure ventral type" of tumour (Figs 1A and B). Exophytic, cystic and expanding tumours should be subjected to surgery, while direct radiotherapy and/or chemotherapy is preferable for diffusely infiltrative and pure ventral type of tumours.

MANAGEMENT

The surgical approach should be according to the location and projection of the tumour. Most of the tumours in the pons, medulla and cervicomedullary junction can be approached through a midline suboccipital craniectomy/craniotomy in the prone position with or without vermian splitting. Tumours in the midbrain are approached by the authors in the sitting position through a midline suboccipital craniectomy/craniotomy through a vermian splitting approach. Tumours with an exophytic



Figs 1A and B: Magnetic resonance imaging axial sections showing: (A) "Diffuse infiltrating type" as compared to. (B) "Expanding type" of brainstem glioma. In the latter, the tumour is well differentiated from the surrounding parenchyma and even though is well beyond the cut-off size of 2 cm (to be classified as a focal tumour) would be (according the authors) still amenable for surgical excision

component laterally are preferably removed through a paramedian or a CP angle approach. Surgery in our 40 cases were performed in sitting [20], prone [9], lateral [7], and supine [3] positions. The sitting position was preferred for dorsal midbrain or upper pontine lesions. The prone position was used in dorsally situated lower pontine, medullary or cervicomedullary lesions. The lateral position was preferred in ventrolateral lesions of the lower pons, while the supine position was used for ventrolateral midbrain or thalamic lesions. A midline suboccipital approach with or without vermian split was most commonly preferred [27] followed by the retromastoid suboccipital CP angle approach [7], subtemporal approach [3], and the supra-cerebellar infratentorial approach was performed in 2 cases.

Mapping of the Cranial Nerve Nuclei

Because the rhomboid fossa and the brainstem are densely packed with cranial nerve nuclei and neural tracts,[6,45] surgery in this area carries a substantial risk of new or increased neurological deficits. For the same reason, neurosurgeons have long considered lesions in this so-called "no-man's land" at least among the most difficult to manage and even inoperable. However, new diagnostic and surgical techniques have reduced the risk of neurological deficit resulting from such surgery, and surgeries are being performed more frequently to treat intrinsic brainstem lesions.[6,11,37] Recent anatomic studies have identified safer approaches to the brainstem via the fourth ventricle,[25] but because disease often distorts the anatomy, landmarks may be difficult or impossible to identify with the aid of the operating microscope alone. Thus, electrophysiological techniques need to be developed to help distinguish the neural structures so that surgeons can avoid manipulating or injuring these structures. Two kinds of monitoring methods are commonly used.

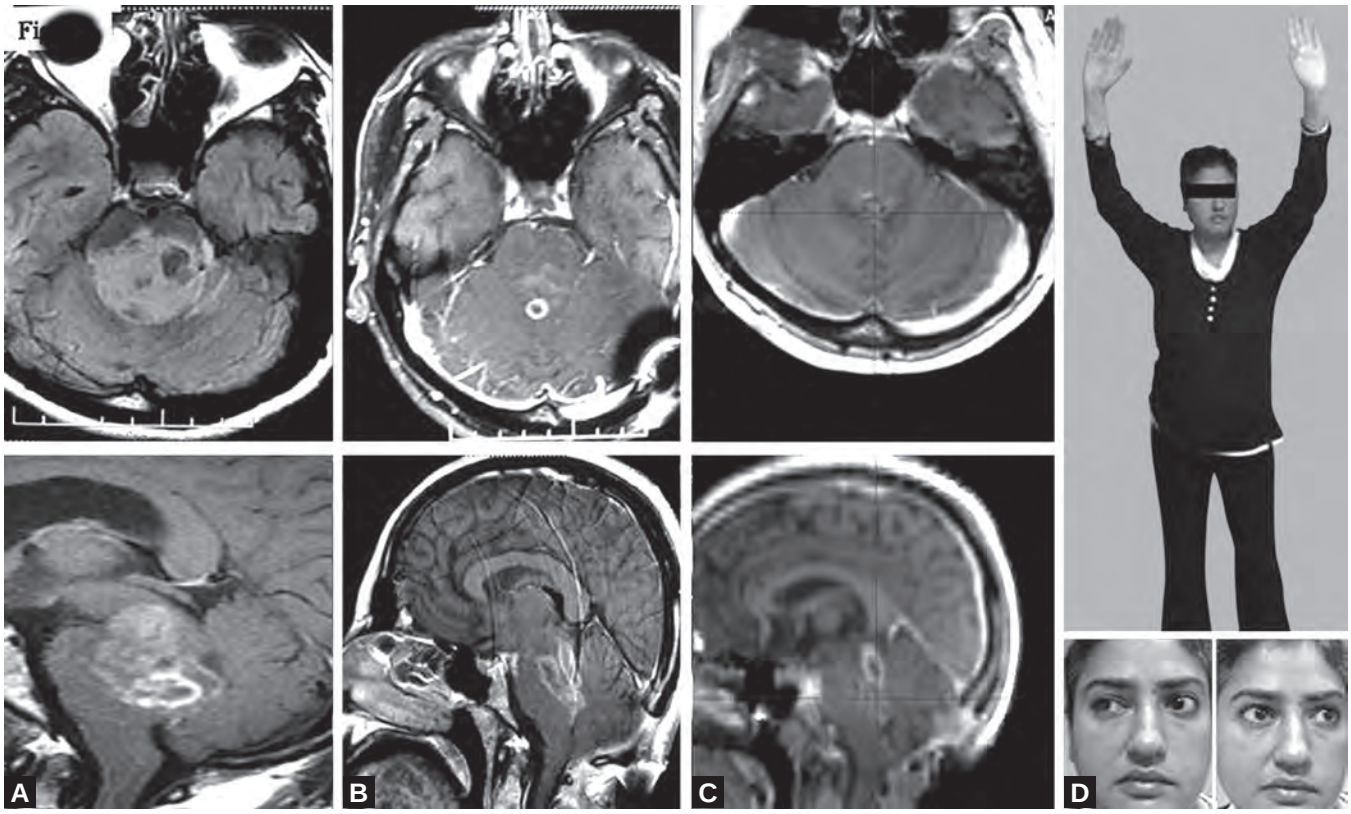
Intra-Operative Motor Nucleus Mapping

During motor mapping in the brainstem, electrical stimulation of the hypoglossal or the vagal triangle elicits continuous motor action potentials (CMAP) from the tongue muscles and the soft palate, respectively. Stimulating the facial colliculus, which contains facial and abducens nerve fibres, elicits CMAPs simultaneously from the lateral rectus and facial muscles. Stimulating other ocular motor pathways elicits CMAPs from corresponding extraocular muscles.

Continuous Intra-Operative Electromyographic Monitoring

Because muscles amplify the electrical activity in the individual motor units, continuous monitoring of the electromyographic (EMG) activity from certain muscles of the head can provide information about the status of the respective motor cranial nerves. Use of this technique has been described for monitoring the motor function of the facial nerve[22,28] and other motor cranial nerve nuclei.[44]

The prognostic value of these manipulation-evoked discharges is based on empirical information, rather than on the results of controlled studies or on a detailed understanding of the pathophysiological mechanisms involved. However, for practical purposes, the continuous recording of the EMG activity seems to provide a reliable way for the surgeon to identify the exact location of various cranial nerve nuclei to plan the incision on the brainstem. For dorsally located lesions, we usually use electrodes connected to the orbicularis oris, orbicularis oculi and the tongue muscles with either intermittent or continuous stimuli. A single stimulus of



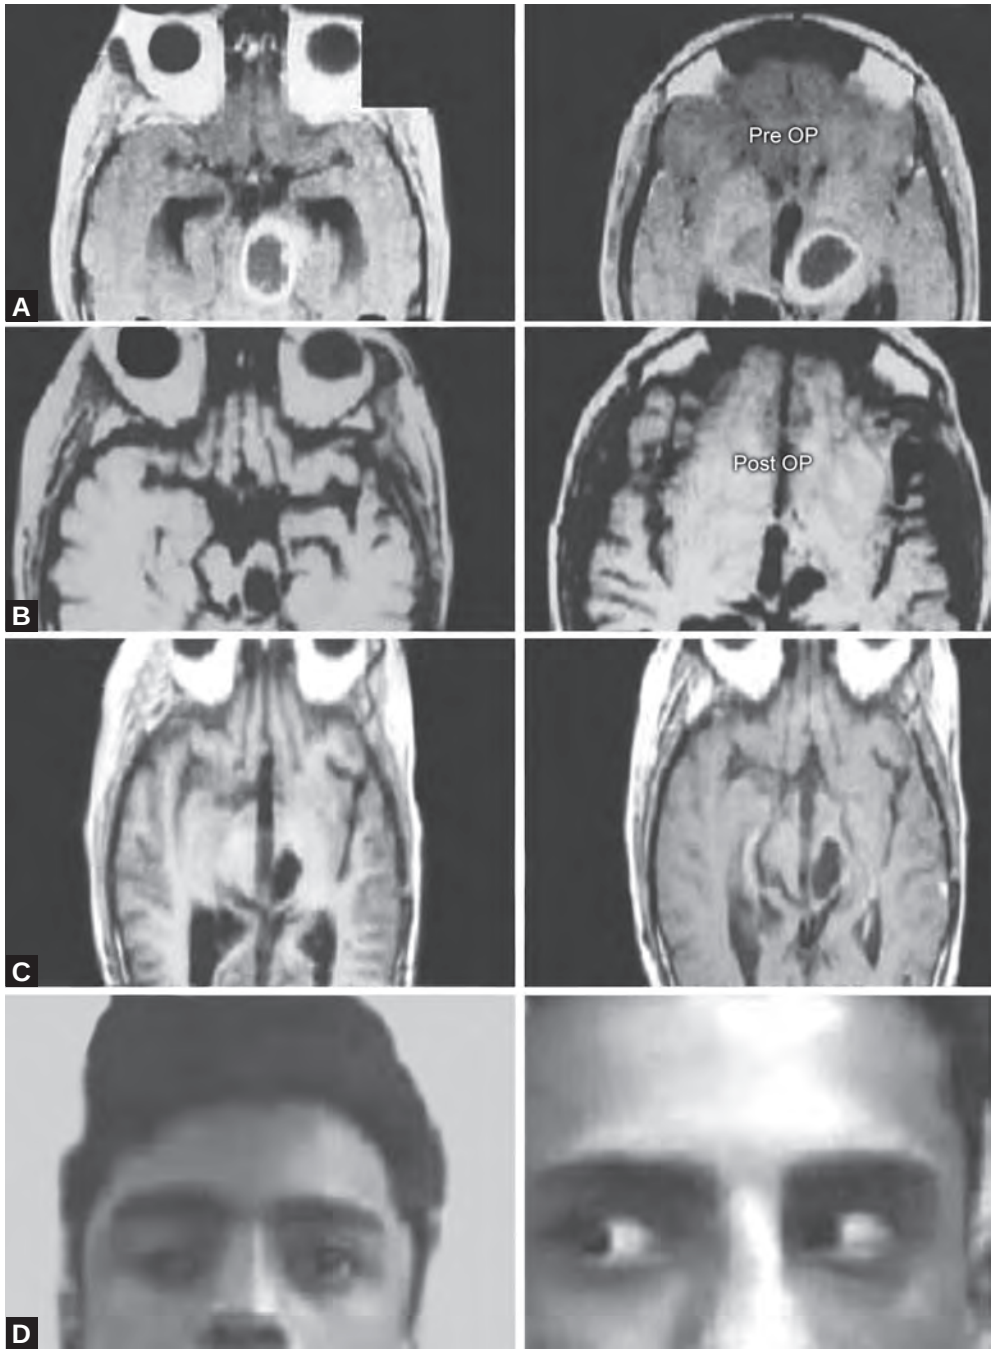
Figs 2A to D: (A) Magnetic resonance imaging showing a large "expanding type" of tumour situated dorsally, heterogeneously enhancing with contrast with a cystic component. Note the well-defined margins and the size well beyond 2 cm. The patient underwent a radical excision. Histopathology showed a grade II tumour with a low MIB labelling index of 8%. (B) Post-operative imaging at 3 months showed a small residual tumour. In view of the relatively higher MIB labelling index, the patient underwent radiotherapy. (C) The tumour was still of the same size at year of follow-up. (D) The patient at 6 months of follow-up shows preserved oculomotor movements with a grade I facial palsy. There has been no deterioration of the patient's clinical status, and like most of the patients with "expanding type" of tumours was independent for all activities of daily living before surgery

0.1–1 mA or a continuous stimulus of 10 Hz (50–400 mS) is generally used.

Surgical Approaches

Surgery is indicated for focal solid or cystic tumours, cervicomedullary tumours and exophytic (particularly dorsal) tumours.[13,14,23,27] The patients need to be followed up with regular neuroimaging. Patients with focal cystic tumours may undergo decompression of the cyst, which is a fairly easy procedure. However, focal radiotherapy may be required to prevent recollection of the cyst. In patients with dorsally exophytic tumours, decompression may be carried out till the tumour is shaved off flush with the floor of the fourth ventricle. It is advisable not to remove a thin carpet of tumour if it is not coming off easily from the floor, to prevent serious morbidity. A large number of patients with low-grade astrocytomas and gangliogliomas will have a good outcome.[25,30,33] Patients with tectal plate tumours may be subjected to a shunting procedure followed by direct radiotherapy or radiosurgery.[5,40] Recently, we have performed endoscopic third ventriculostomy and stenting in 12 cases of tectal plate gliomas along with simultaneous biopsy during the endoscopic procedure. This has an advantage of performing a biopsy and a shunting procedure at the same sitting.

Once the floor of the fourth ventricle is exposed (or the lateral surface of brainstem), it should be carefully inspected under high magnification for any abnormal "bulges" or any "discolouration". A mapping of the floor should be then performed as per the technique described earlier. We have found direct stimulation of cranial nerve nuclei quite useful to map out the eloquent areas. The floor of the fourth ventricle is usually screened first with a low intensity bipolar. Following this a stimulation of 0.1 mA single or continuous stimulation with 10 Hz frequencies at 50–400 mS is given. The evoked response may then be recorded with electrodes from the orbiculi oculi, oris and the tongue muscles. We have not found somatosensory evoked potentials or auditory evoked potentials very useful. This helps in localising the VI and the lower cranial nerve nuclei. If no exophytic component is seen, then one of the "safe areas"[31] should be used to make an incision after mapping. This usually includes the dorsolateral sulcus lateral to the cranial nerve nuclei. Otherwise the exophytic component should be tackled first. The incision should be as small as possible, longitudinal nearest to the tumour surface and away from the nuclei. The senior author prefers to use



Figs 3A to D: (A) Magnetic resonance imaging (MRI) shows another example of an "expanding type" of tumour located in the midbrain. The margin of the tumour is well enhancing and within the brainstem axis. (B) The patient underwent a total excision (MRI-gadolinium enhanced at 3 months). No radiotherapy was given. (C) A follow-up MRI (with contrast) 6 years after surgery still showed no recurrence. (D) The patient had right ptosis and ophthalmoparesis (left picture) immediately following surgery that resolved at 1 year. Photo at 6 years (right picture) shows complete resolution of eye movements

the tissue vapouriser, as there is minimum heat dissipation to the surrounding structures even when applied close to the cranial nerve nuclei. Cyst aspiration, if any, should be performed before removal of the solid component. Use of micro-tip ultrasonic aspirators and irrigating non-stick bipolar forceps are very useful. The tumour rim should be left behind if no distinct plane is seen.[6,13-15,19,23,30,33,35] All the patients should be started on methylprednisolone just before making an incision on the brainstem and this should be continued for 24–48 hours in doses of 30 mg/kg for the 1st hour followed by 5.4 mg/kg/hour for the next 24 hours. All patients should be electively ventilated with sedation for 24 hours (Figs 2A to D and 3A to D).

Management of Diffuse Tumours

The diffuse tumours carry the worst prognosis and the survival is usually not more than 18 months after diagnosis. Parts of the tumour may start off as a fibrillary astrocytoma but, by the time of death, usually the entire tumour is either a malignant astrocytoma or a

glioblastoma multiforme. Thus, a stereotactic biopsy is totally unreliable for diagnosis, while the imaging characteristics are almost diagnostic of this dreadful condition.[7–10] These patients may be directly subjected to radiotherapy. The type of radiotherapy is undergoing a change. The standard therapy has been 55 Gy to the tumour area with a weekly dose of 800–1000 cGy. In hyper-fractionated therapy, higher doses up to 76 Gy may be tolerated and has improved short-term survival without obvious toxicity.[1,14,16,19,23,35,39,47]

CONCLUSION

The identification of various subgroups of brainstem tumours has led to more rational treatment strategies and allows for a more accurate assessment of prognosis. The focal tumours with paucity of neurological signs are a distinct subgroup of brainstem tumours. Most of them are low-grade astrocytomas and are amenable to radical surgical resection, but this should be performed by an experienced surgeon in a set-up with adequate intra-operative and post-operative facilities. Surgical intervention in this subgroup of brainstem tumours may be associated with a good long-term prognosis. Exophytic tumours, particularly those associated with diffuse brainstem enlargement, should undergo a limited decompression. Purely diffuse tumours should preferably undergo direct radiotherapy.

136 Hypothalamic-Optic Nerve Gliomas

Ramakrishna Easwaran

INTRODUCTION

Optic pathway gliomas (OPGs) are unique in many ways. They occur commonly in children and young adults. They may show little growth over years. Their location makes them a surgical challenge. Controversy surrounds the optimal management.

INCIDENCE

Optic pathway gliomas are rare. They account for 1% of all intracranial tumours, 3–5% of paediatric brain tumours and 6% of all orbital tumours.[18] Gliomas account for two-thirds of all tumours in the optic nerve. About 25% of OPGs are in the optic nerve [Optic nerve glioma (ONG)] and 60% involve the chiasm (Optic chiasm glioma).[8] Nearly one-third of patients with OPG have neurofibromatosis-1 (NF-1). Symptomatic OPG occurs only in 5% of patients with NF-1, but imaging series report a 15–20% incidence, as computed tomography (CT) and magnetic resonance imaging (MRI) are able to detect several asymptomatic OPGs in NF-1 patients.[31] The OPGs in NF-1 differ in many ways from the non-NF-1 OPGs and these differences are summarised in Table 1.[27,30,40] The mean age at diagnosis was 8.8 years in a review of 2297 patients reported till 1992. About 60% of OPGs are diagnosed before the age of 5 years, 75% before the age of 10 years and 90% before the age of 20 years.[18] The male:female ratio is nearly equal but pure optic nerve tumours are commoner in girls.

PATHOLOGY

Macroscopic Appearance

ONG can be purely intraorbital or purely intracranial. Often the tumour starts in one compartment and spreads to the other through the optic foramen causing a dumb-bell pattern with smooth enlargement of the bony optic canal and foramen. The nerve is expanded by the tumour and also by the extension of the tumour into the subarachnoid space. The chiasmal variety may diffusely infiltrate the hypothalamus and the floor of the third ventricle. There is difficulty in distinguishing whether the primary site of origin is in the chiasma or in the hypothalamus and so they are dubbed as hypothalamic-chiasmatic glioma.[16] The non-NF-1 OPG in the chiasma may become a large mass and show areas of cystic change. Large cysts have been reported to extend to the middle fossa or third ventricle.[21] The largest OPGs (up to 9 cm) are seen in non-NF-1 patients.[3] Involvement of the optic radiation may indicate aggressive behaviour in NF-1 patients.[32]

Microscopic Pathology

The histology of OPG is almost always a pilocytic astrocytoma. Of all pilocytic astrocytomas, 11% occur in the optic pathways.[10] The astrocytes in the tumour have hair-like long processes, which give the tumour the appellation "pilocytic". The pilocytic growth is compact in some areas and loose-textured in others (biphasic pattern). Rosenthal fibres and eosinophilic granular bodies are characteristic (see the chapter on cerebellar astrocytoma in this textbook for details of these histological features of pilocytic astrocytoma). Microcystic change is seen. The cells are positive for glial fibrillary acidic protein. The typical pilocytic astrocytoma is graded as World Health Organization (WHO) grade 1. The majority of pilocytic astrocytomas have a very low growth potential but undoubtedly a few show aggressive clinical behaviour. Why some tumours remain indolent while others progress is not clear. Age may be one factor as adults with pilocytic astrocytoma might have frequent recurrences and progress to WHO grade 3, unlike children.[43] A higher microvessel density (as assessed by immunostaining for factor VIII) is thought to indicate progression.[6] The details of the genetic abnormalities in NF-1 associated glioma are discussed in the chapter on supratentorial astrocytoma in this textbook.

Pilomyxoid astrocytoma has been recently recognised as a separate entity. It is a solid, circumscribed tumour that occurs in the chiasma-hypothalamus area of very young children. It is composed of a monomorphous population of bipolar tumour cells within a rich myxoid background, with a conspicuous angiocentric arrangement. This tumour is graded as WHO grade 2 and shows more aggressive behaviour than pilocytic astrocytoma, with 14% spreading through the cerebrospinal fluid (CSF) pathways.[26] The presumed cell of origin of pilomyxoid astrocytoma is the embryonic radial glial cell in the chiasma.[13]

Chordoid glioma is described in the chapter on supratentorial astrocytoma. It may be an asymptomatic lesion detected incidentally on imaging.[20] Fibrillary

Table 1: Differences between optic pathway gliomas in those without and with neurofibromatosis-1

Characteristic	*Non-neurofibromatosis-1 (NF-1) Optic pathway glioma (OPG)*	*OPG in NF-1*
Demographic		
Incidence	3–5% of childhood tumours	10–15% of patients with NF-1
Male : Female ratio	1:1	2:3
Mean age ± SD	6 ± 3.3 years	4.3 ± 2.1 years
Gross pathology		
Involvement		
Orbital optic nerve	32%	66%
Chiasma	91%	62%
Hypothalamus	70%	36%
Beyond optic pathway	68%	2%
Bilaterality	7%	24%
Average size	4.5 cm	2.5 cm
Shape	Globular mass	90% conform to optic pathway shape
Cystic areas	66%	9%
Growth pattern	Intraneural	Perineural
Microscopic pathology		
Infiltration of leptomeninges	Rare	Florid
Arachnoid hyperplasia	Absent	50% of cases
Non-pilocytic histology	Rarely reported	Not reported
Malignant transformation	Seen in adults	Not seen
Clinical features		
Progression	60%	12%
Asymptomatic	0%	32%
Visual symptoms	84%	21%
Proptosis	5%	21%
Hypothalamic symptoms	33%	Rare, but precocious puberty occurs
Raised pressure symptoms	66%	Rare
Hydrocephalus	75%	Not seen
Regression	Not likely	Reported
Imaging features		
Diffuse enlargement of optic nerve or chiasma	27%	91%
Vessel encasement	32%	2%
Prognosis		
5-year survival	83%	93%
10-year survival	76%	81%
Time to progression	2.3 years	8.3 years

astrocytoma is rare and is seen in the chiasma/hypothalamus only in non-NF-1 patients.[16] Adult patients may harbour anaplastic astrocytoma or glioblastoma multiforme which might mimic a cystic craniopharyngioma or pituitary adenoma on imaging.[5,17] Ganglioglioma of the optic nerve is rare.[34]

CLINICAL FEATURES

Visual Dysfunction

Visual impairment occurs in about 85% of cases of OPG.[29] It may escape being noticed, as the onset is insidious and because the tumour occurs in children too young to discern the symptom. Drop in visual acuity occurs before field cuts are detected. The differential diagnosis is with retrobulbar neuritis.[45] Primary optic atrophy takes time to set in, but is seen in about 60% of cases of OPG. Rarely the visual loss stops progressing and indeed regresses.[33] Bitemporal hemianopia progressing to bilateral visual loss occurs in adults due to chiasmal involvement. Acute visual loss might occur due to intratumoural haemorrhage.[47]

Proptosis

Painless axial proptosis is commoner in NF-1 patients with OPG, due to the frequent location of the tumour in the orbit. This may be the only symptom in young children. Painful proptosis is seen only with large tumours and may be due to compression of branches of the

ophthalmic division of the trigeminal nerve or orbital venous occlusion.

Hypothalamic Dysfunction

The symptoms of hypothalamic dysfunction in OPG are commoner in non-NF-1 patients. Emaciation despite normal caloric intake in an alert child is known as the "diencephalic syndrome of infancy". This has been found to be associated with dissemination of the hypothalamic pilocytic astrocytoma.[39] The somatic growth rate is normal in spite of the emaciation and so is the pituitary hormonal function. Ironically, some of these children become very obese in later years.[11] The diencephalic syndrome has been attributed to the dysfunction of the leptin-ghrelin system.[9] Gigantism due to OPG has been reported.[35] Spasmus nutans consists of disconjugate nystagmus, torticollis and titubation. While OPG can cause spasmus nutans, the prevalence of glioma in patients presenting with spasmus nutans is very low.[2] Precocious puberty is common in NF-1 children with OPG.[30] Adult patients may present with hypersomnolence due to involvement of the posterior hypothalamus. Diabetes insipidus is rare as a presenting symptom of OPG and must raise the suspicion of germinoma or craniopharyngioma.[46]

Symptoms of Increased Intracranial Pressure

Due to the larger size of the mass and association with hydrocephalus, symptoms of raised intracranial pressure are commoner with OPGs in non-NF-1 patients. Papilloedema is seen in about 38% of patients.[29] Foster Kennedy syndrome due to optic glioma presents with unilateral optic atrophy first followed by contralateral papilloedema.[7] Of course, the third component of this syndrome, anosmia, described with olfactory groove meningioma is never seen with OPG.

INVESTIGATIONS

The CT scan and MRI are the currently used modalities for imaging OPG. On CT the tumour is hypodense and shows variable enhancement. The MRI has the advantage of showing the extent of optic pathway involvement in all three planes without bone artifacts. Fat suppressed T1-weighted (T1W) images with contrast must be obtained. In the orbital ONG, the tubular or fusiform enlargement of the nerve is seen well in axial images. Since the small tumours may be isointense with the nerve in T1W and T2-weighted (T2W) images, the diagnosis might rest solely on detecting the smooth enlargement of the nerve that is well appreciated on comparing with the opposite nerve in coronal images. Most lesions are T1 hypointense and T2 hyperintense. The redundancy of the nerve manifested by a downwards kink of the nerve in the midorbit is a characteristic feature of the NF-1 associated OPG.[25] There is usually good but non-uniform enhancement with gadolinium. The "tram track" sign on MRI refers to a hyperintense core on T1W images, surrounded by lower signal intensity. On T2W images, the exact opposite is seen. This is due to perineural arachnoidal gliomatosis. The tram track sign is not specific for glioma and is seen with optic sheath meningioma, pseudotumour or optic neuritis. The dumb-bell extension in to the intracranial compartment is well seen in axial or oblique reformatted images. Extension in to the optic tracts, lateral geniculate bodies and to the optic radiation may be detected with T2W images. The bony optic canal enlargement is better appreciated with CT. Similarly, the calcification pattern of meningioma (which is the closest differential diagnosis of OPG) is also better appreciated on CT.

The non-NF lesions tend to be larger and have cysts (Figs 1 to 3). Calcification is rare. The non-uniform enhancement differentiates the mass from suprasellar germinoma, which is a common differential diagnosis in children. The larger tumours fill the third ventricle (Figs 1A to F), extend to the subfrontal region (Fig. 3) and may encase the vessels of the circle of Willis. Intratumoural haemorrhage is rare.[47] There are no MRI findings that can reliably predict subsequent clinically aggressive behaviour. The MRI is the modality of choice for monitoring progression or treatment response. Positron emission tomography is likely to show such changes even earlier than MRI.[38]

MANAGEMENT

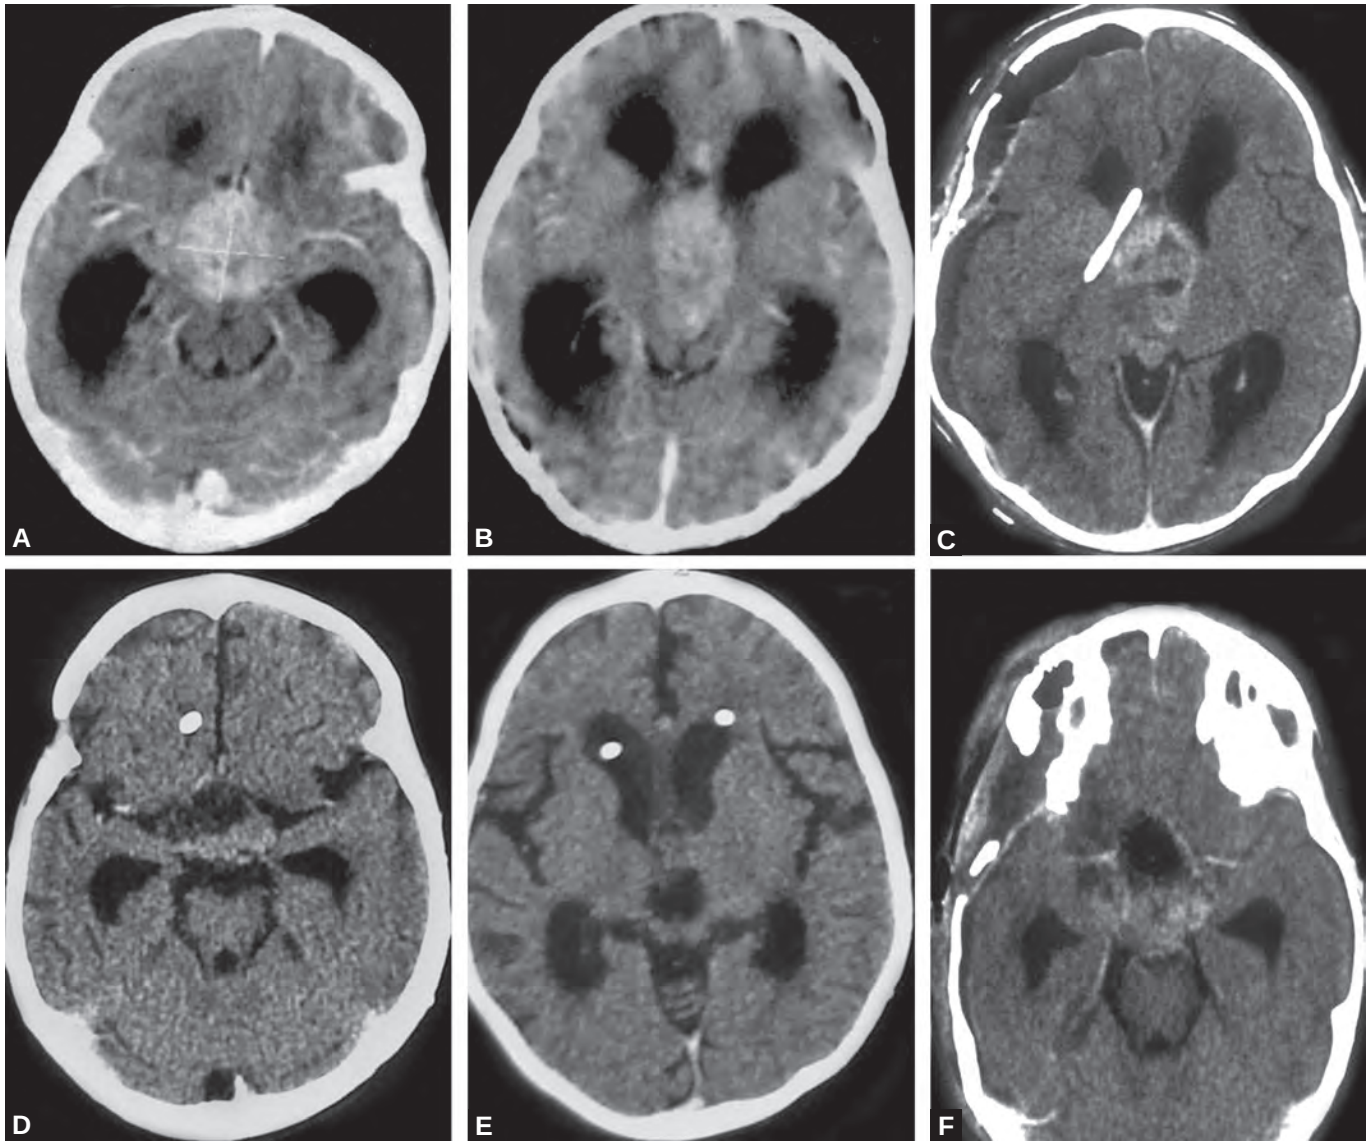
The management of OPG is influenced by several variables such as age, presence or absence of NF-1, location in optic pathway, size and symptoms (visual acuity, proptosis, raised pressure). The available methods of management are observation, surgery, chemotherapy and radiotherapy. Since OPGs are slow growing lesions, any one or more of these modalities may be needed during the course of management.

Observation

Since the growth rate of most OPGs is low, mere watchful expectancy is an acceptable choice of initial management. It has been found that on long-term follow-up (up to 11 years), the vision was good (stable or improved) in about 78% of patients.[18] The wait-and-watch approach applies to the incidentally detected asymptomatic tumours, small tumours, patients who have well-preserved vision with little proptosis and those with NF-1. The surgeon has to instruct the family about the signs of progression and maintain a meticulous clinical, neuro-ophthalmic and imaging follow-up.

Surgery

In contrast to the cerebellar juvenile pilocytic astrocytoma, surgery plays only a limited role in the tumour



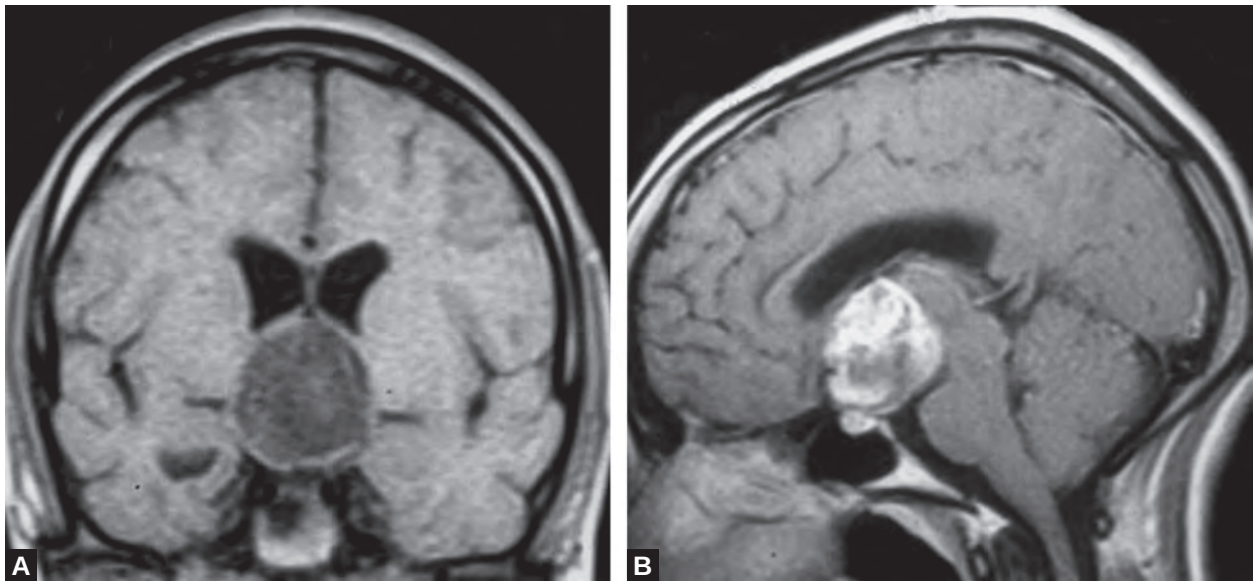
Figs 1A to F: (A and B) Contrast-enhanced computed tomography (CECT) of a 4-year-old boy without neurofibromatosis-1 presenting with loss of vision in the right eye. Note the non-uniform enhancement in the suprasellar mass, which fills the third ventricle. The boy underwent right pterional craniotomy and partial excision of chiasmal pilocytic astrocytoma followed by bilateral shunt placement. (C and D) The CECT scans after surgery—note the residual tumour. He was given chemotherapy initially. Radiation was given after he completed 7 years of age. (E and F) The CECT scans obtained 5 years after initial presentation—note the tumour shrinkage. The vision remains stable in the left eye and the growth is near normal

with the same histology occurring in the optic pathway. The indications for surgery are listed in Table 2. Radical surgery has not been proved to increase the length or quality of survival.[1]

Table 2: Indications for surgery in optic pathway glioma

- Biopsy for tumours with atypical imaging findings
- Mass reduction by cyst drainage and tumour decompression for relieving raised pressure symptoms or neighbourhood compression syndromes
- Disfiguring or painful proptosis
- Total excision for orbital optic nerve tumours with total visual loss, so as to prevent intracranial extension and to provide cure without adjuvant therapies
- Excision of exophytic masses (mainly chiasmal)
- Ventricular shunt placement for hydrocephalus

Biopsy of intraorbital tumours can be performed by lateral orbitotomy or by fine needle aspiration. Resection of ONG requires transcranial superior orbitotomy and cannot be done adequately through the lateral orbitotomy approach. Transcranial orbitotomy can be done through an eyebrow incision but the traditional method is to raise a flap from behind the hairline. Removing the superior orbital rim allows a lower trajectory and reduces frontal lobe retraction. The orbital rim may be taken with the frontal bone flap or as a separate osteotomy piece. Extradural approach is reserved for lesions that do not extend to the optic canal. Intradural approach is done for gliomas that reach into the canalicular or the



Figs 2A and B: (A) Non-contrast coronal magnetic resonance (MR). (B) Contrast sagittal MR of a 20-year-old female with non-neurofibromatosis-1 hypothalamic-chiasmal glioma. The patient underwent subfrontal approach and partial excision of grade 2 fibrillary astrocytoma followed by radiotherapy. The clinical status was normal with stable vision until 4 years later when she died of progressive infiltrative recurrence

intracranial portions of the optic nerve. The periorbita is opened medial to the superior rectus and the annulus of Zinn must be sectioned to approach the canalicular part.

The approaches to chiasmal-hypothalamic gliomas are listed in Table 3. The infiltrative chiasmal gliomas cannot be radically excised. Biopsy and sufficient decompression to open the CSF pathways can be done in big masses (Figs 1 and 3).

Chemotherapy

The risks of irradiating young children have caused a swing towards the "chemotherapy-first" approach. Carboplatin based regimes are the most studied.[29] The Packer regimen of concurrent carboplatin and vincristine in a 10-week induction phase, followed by 48 weeks of maintenance carboplatin/vincristine resulted in progression-free survival of 75% at 2 years and 50% at 5 years. Imaging evidence of tumour shrinkage was seen in 63% of patients with this regimen. Children 5 years of age or younger had a more favourable rate of response.[36] Recently, single agent temozolomide therapy has also been found to be successful.[23]

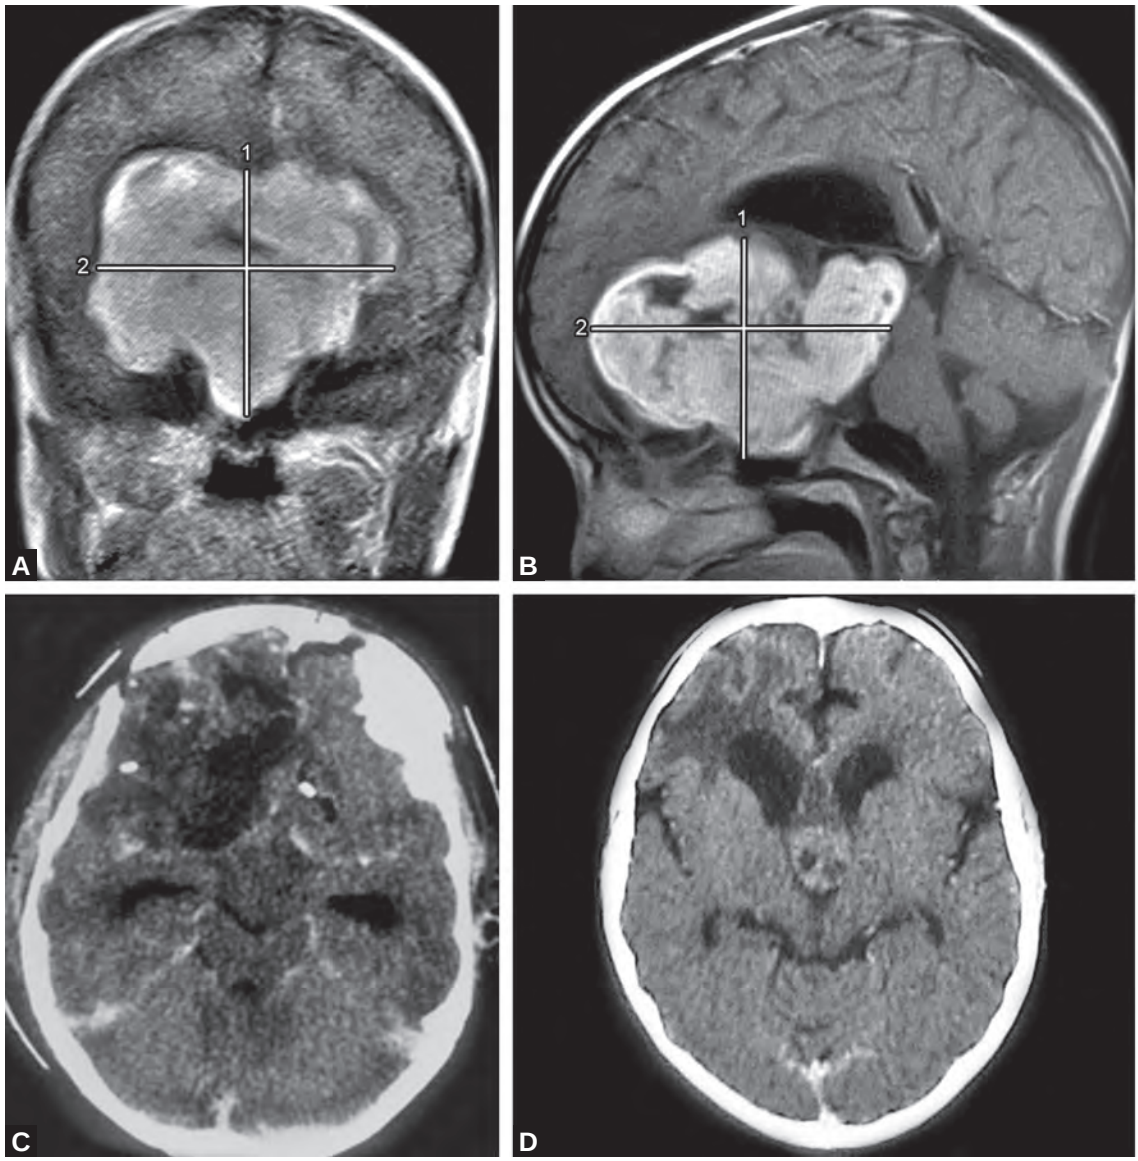
  - Interhemispheric transcallosal
  - Anterior interhemispheric, trans-lamina terminalis
  - Endoscopic transventricular

Radiotherapy

Radiotherapy was the initial treatment modality until a decade back. The recognition of endocrine and cognitive side effects of radiotherapy in young children has made chemotherapy the choice in this age. Sixty nine per cent of children below 10 years developed hypothalamic-pituitary endocrine deficiency after radiation in one study as compared to only 25% of those above this age.[22] Radiotherapy is the initial modality in older children and adults. The standard prescription is 45–50 Gy in 2 Gy daily fractions to the tumour and the surrounding 0.5–1 cm margin. Progression-free survival probabilities after radiotherapy were 82% at 5 years and 77% at 10 years after radiotherapy for OPG in a Turkish study.[19] The visual acuity improved in 36%, remained stable in 52% and deteriorated in 12% after radiotherapy in a German series of 25 patients.[22] The risk of developing a second (usually malignant and lethal) tumour after radiotherapy is real and is more so for NF-1 patients.[41] Fractionated stereotactic radiotherapy has been recently reported to provide 90% survival at 5 years while reducing the endocrine side effects and the possibility of a second tumour.[15] There are case reports of gamma knife radiosurgery for OPG.[28] Novalis (shaped beam) radiosurgery has been recently reported to be useful in OPG.[24]

PROGNOSIS

Optic pathway gliomas are known for their erratic behaviour.[42] Spontaneous regression (involution) of OPG has been recorded well in the literature.[37] Regression may manifest either as an overall shrinkage in tumour size, or as signal intensity change on MRI. A variable degree of improvement in visual function may accompany



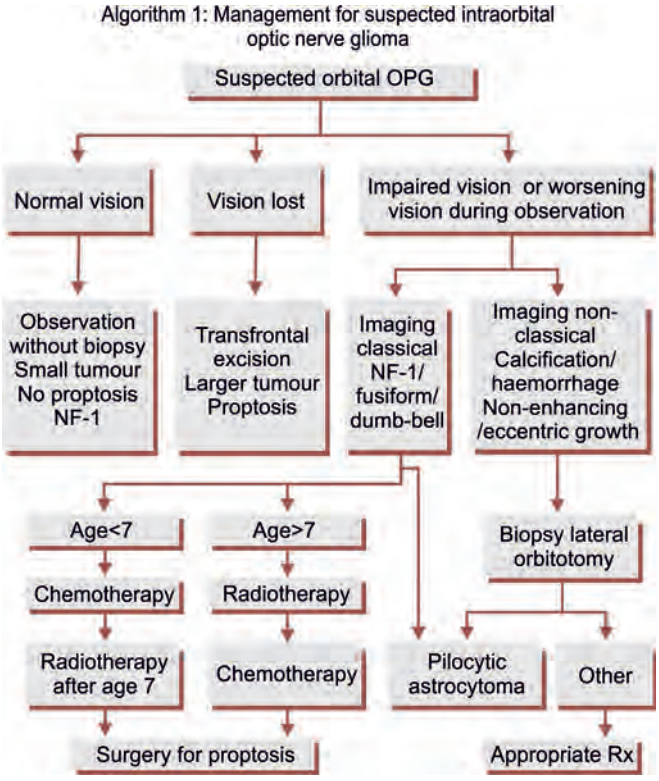
Figs 3A to D: (A and B) Pre-operative contrast magnetic resonance of a 7-year-old boy with a massive hypothalamic-chiasmal pilocytic astrocytoma. There was no light perception in the right eye and the acuity was 6/36 in the left eye. Debulking was done by the subfrontal approach. (C) Immediate post-operative contrast-enhanced computed tomography (CECT) showed good reduction in tumour size. He underwent radiotherapy. (D) The CECT at 1-year follow-up. The vision remains the same as before operation

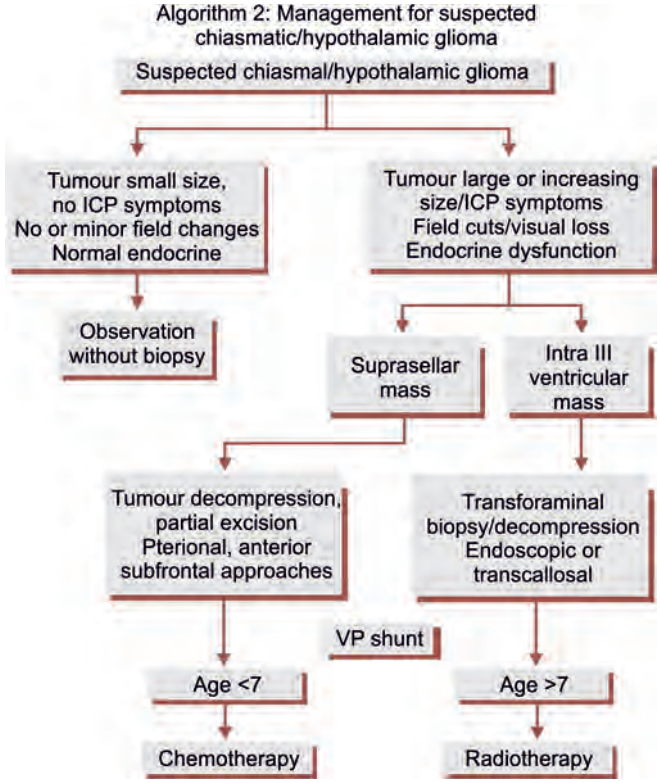
regression. While involution has been associated with childhood OPG in NF-1, adult tumours and non-NF-1 tumours have also been reported to regress.[4] The visual function has also been found to improve without treatment though the imaging does not show reduction in tumour size.[33]

In a study of patients followed up for 10 years or longer, 16 patients (mostly with NF-1) received no treatment and there was no mortality or tumour related morbidity. Thirty one patients (mostly non-NF-1) received treatment and they subsequently developed neurologic, endocrine or visual morbidity. This has led to the recommendation that OPGs should not be treated unless they demonstrate clear disease progression.[31,44] There is a two-fold difference in the visual deterioration rates of ONG (21%) and chiasmatic glioma (42%).[18] The tumour related mortality is 0–5% for optic nerve tumours, 29% for chiasmal tumours and 43% for hypothalamic tumours.[18] Visual improvement after therapy is often not seen but complete recovery has been occasionally reported.[12] Endocrine defects in survivors are mainly due to therapy and growth hormone deficiency is the commonest.[14]

CONCLUSION

Optic pathway gliomas are slow growing tumours but may behave erratically. The treatment recommendation is to observe the course and intervene only when one is forced to. Chemotherapy for younger children and radiotherapy for older patients is effective in achieving long-term tumour control. Surgery does little to alter





the natural course of the tumour. The management is summarised in Algorithms 1 and 2.

137 Oligodendrogliomas

Ravi Ramamurthi, Nigel Peter Symss

INTRODUCTION

The oligodendrocyte, Cajal's third element of neuroglia, is reported to have been first recognised by Ford Robertson in 1900, using the platinum impregnation technique. He called it "mesoglia".[15] Hortega, in 1918, identified it by using silver carbonate impregnation techniques and designated it oligodendroglia because of its few dendritic processes. Bailey and Cushing[2] were the first to describe oligodendroglioma as a distinct pathological entity. Bailey and Bucy[1] further defined the morphological features of this tumour based on a study of 13 cases. Cushing[9] in his classical monograph, in 1932, recorded 27 oligodendrogliomas in a series of 2023 tumours of the brain, 862 of which were gliomas. The first large series (200 cases) of these tumours was reported by Earnest et al. in 1950.[15] The largest series documented so far, consisting of 323 cases, has been by Ludwig et al.[30] from the Armed Forces Institute of Pathology, USA.

Recently published series have shown that oligodendroglial tumours represent a type of tumour in which molecular alterations may become a significant prognostic factor. During the last decade, enormous progress has been made in understanding these alterations. Oligodendrogliomas show distinct genetic alterations, allowing us to distinguish them from other types of gliomas and this has increased our insight into the response of these tumours to therapy.

CLASSIFICATION

Oligodendrogliomas are now generally accepted as a distinct pathological entity with special clinical features. However, there has been some divergence of view regarding their classification and histogenesis. Elvidge et al.[16] divided these into two groups: (1) oligodendroglioma and (2) oligodendroblastoma. Kernohan[23] further elaborated the morphological characteristics of these two subgroups. Attempts were later made by the Mayo Clinic group to grade these tumours on the same lines as astrocytomas (grade 1–4).[24] It is interesting to note that Kernohan's group itself concluded that these tumours did not lend themselves well to grading with respect to the degree of malignancy.[15] Smith et al.[42] defined histological criteria that allowed an effective grading system pertinent to prognosis. Based on the presence, absence and degree (high or low) of the following criteria, viz. endothelial proliferation, necrosis, nuclear/cytoplasmic ratio, cell density and pleomorphism, they graded these tumours into four groups: A to D. While most pathologists have given up this grading system, a recent report found definite correlation between the grade of the tumour and post-operative survival.[40] The WHO classification[51] recognises three subgroups: (1) oligodendroglioma; (2) mixed oligoastrocytoma and (3) anaplastic (malignant) oligodendroglioma. Sarkar et al.[39] on the basis of a detailed immunohistochemical and electron microscopic study on 55 cases of this tumour observed that both oligodendrogliomas and oligoastrocytomas arise from a common progenitor cell capable of differentiation into both oligodendrocyte and astrocyte. Earlier studies based only on GFAP immunohistochemistry had arrived at a similar conclusion.[6,19] It was proposed that the nature and degree of differentiation depends probably on gene expression and/or some micro environmental factors.

A more recently used classification is the one proposed by the Sainte-Anne Hospital (SA). According to the WHO, the typing of diffuse gliomas is based on the predominant cell type, oligodendroglial versus astrocytic. In contrast, the SA classification is based on the distinction of two patterns of tumour growth, solid tumour tissue versus isolated tumour cells and also relies on imaging and clinical features. The SA classification includes in the category of oligodendrogliomas, the fibrillary or gemistocytic diffuse astrocytomas (WHO grade II), as well as a substantial proportion of astrocytomas WHO grade III. The WHO uses multiple histological criteria for the grading of oligodendrogliomas (grade II versus grade III), including the degree of differentiation, cellular atypia, mitotic activity and necrosis. In contrast, the SA grading of these tumours (grade A versus B) only uses two criteria: (1) the presence or absence of endothelial hyperplasia and (2) the presence or absence of contrast enhancement on imaging. This last criterion allows overcoming the problems related to the representativeness of surgical samples. Difficulties and discrepancies regarding the diagnosis of oligodendrogliomas are in part due to the lack of an immuno-marker for the identification of tumoural oligodendrocytes.[48] The grading system proposed by Daumas-Duport et al. separating oligodendrogliomas

into low and high grade (grade A and grade B), found tumour grade to be a strong prognostic indicator, but the degree of nuclear atypia and presence of mitosis did not correlate with survival.[14]

INCIDENCE AND SITE

Oligodendrogliomas constitute approximately 5–7% of all primary brain tumours. Mork et al.[32] found their incidence to be 4.2% of all primary brain tumours diagnosed in the Norwegian population in 25 years. Most of these tumours are supratentorial, predominantly affecting the frontal lobes, 50–75% in different series (Figs 1A to D). In a series of 323 cases of oligodendrogliomas, the incidence at various sites was found to be frontal 55%, parietal 20%, temporal 17% and spinal 1%.[30] Most of these are subcortical but, as the tumour grows, it mushrooms through the cortex. Lesions that are close to the ventricles or the subarachnoid spaces may spread along the CSF pathways.[5] Intraventricular oligodendrogliomas are very rare and infrequently reported.[44] Das et al. reported an oligodendroglioma of the pineal region in a 59-year-old woman. The patient presented with intermittent confusion, memory disturbance and headache associated with a cystic pineal region mass demonstrated on magnetic resonance imaging.[11] Packer et al. reported 4 oligodendrogliomas of the posterior fossa in children and found that these tumours may behave more aggressively in this location and may require post-operative craniospinal radiation.[34] Oligodendrogliomas of the spinal cord are uncommon.[17,35] Uzuka et al. reported a rare case of cerebral anaplastic oligodendroglioma developing in adolescence, with rapid haematogenous spread of the glioma cells into the systemic organs, occurring after a relatively long clinical course.[46] Gliomatosis cerebri of oligodendroglial origin is very unusual.[13]

PATHOLOGY

Details are described in the "Neuropathology Section".

Gross Morphological Features

Briefly, the tumour is a pinkish red, vascular and friable mass with a rather deceptive pseudoplane of demarcation. These tumours have been reported to have a tendency for haemorrhage; an incidence of 22% was reported by Ludwig et al.[30] Central foci of necrosis and cystic degeneration occur in the larger lesions. There is a propensity for calcification and a marked tendency to infiltrate the cortex.

Microscopic Features

It consists of a monotonous pattern of small round nuclei, with perinuclear halos, scanty cytoplasm and a prominent cell wall. Like any other glioma, these neoplasms form a spectrum from the cytologically well differentiated to the anaplastic.

Ultrastructural Features

Oligodendroglial tumour cells may have either scanty or abundant cytoplasm, rich in organelles, including microtubules, free ribosomes, mitochondria and prominent Golgi apparatus. Polygonal intracytoplasmic crystalline inclusions have been described, but are not specific. Laminated cell processes overlying the cell body are commonly present and are typical of oligodendroglioma.

Immunohistochemistry

Angiogenesis has been proposed as essential for the growth of solid tumours. The determinants of this process, the growth factors and the vascular endothelial receptors have a role in determination of tumour prognosis, as well as perspectives of "targets" for antiangiogenic therapy. In oligodendrogliomas (OL), angiogenesis is little known. In order to clarify angiogenesis in OL, Corteze Netto et al. have evaluated the immunohistochemical expression of vascular endothelial growth factor (VEGF) and the microvascular density (MVD) through the expression of TGF-beta (CD105/endoglin) (MVD-CD105) and CD34 (MVD-CD34) receptors, using the Chalkley point method in 30 OL. No significant immune reaction was found for the VEGF. If present, the expression was restricted to tumour and endothelial cells. Their findings suggest that VEGF has little

influence on OL angiogenesis. All specimens showed CD105 and CD34 expression in the intratumour vascular endothelium, suggesting involvement of CD105 in OL angiogenesis. The absence of correlation between DMV-CD105, DMV-CD34 and tumour grades suggests that anti-CD105 and anti-CD34 antibodies have different vascular specificities. MVD-CD105 was greater in OL grade III than in OL grade II ($p = 0.0032$), indicating an increase in the vascular neo-formation, something which must be evaluated as a possible prognostic factor in OL. Both TGF-beta and CD105 bring perspectives as "targets" for antiangiogenic treatments in OL.[8] OLIG2 is a basic helix-loop-helix transcription factor regulating the generation of oligodendrocytes from neural progenitor cells and the function of OLIG2 is inhibited post-translationally through the interaction with ID2. Mikami et al., in their study, found that OLIG2 expression was predominant over ID2 expression in oligodendroglial tumours, while ID2 expression was predominant over OLIG2 expression in astrocytic tumours. Comparative genomic hybridisation revealed that gliomas with loss on chromosome 1p, which is closely associated with chemosensitivity, also showed the predominant expression of OLIG2 over ID2. Their results indicate that the immunohistochemical study on the relative expression level of OLIG2 to ID2 can be a useful screening for oligodendroglial tumours.[31] Carbonic anhydrase IX is a hypoxia-induced enzyme that has many biologically important functions, including its role in cell adhesion and invasion. Jarvela et al. studied the role of CA IX expression in a series of 86 oligodendroglial brain tumours (71 primary and 15 recurrent; 48 pure oligodendrogliomas and 40 mixed oligoastrocytomas). 80% of the tumours showed CA IX expression by immunohistochemistry. Tumours with moderate or strong CA IX expression had decreased level of cell proliferation compared to weak or no CA IX expression (median 2.9 vs. 5.8, $p=0.015$). CA IX correlated with two antioxidative enzymes, manganese superoxide dismutase (MnSOD) and regulatory gammaglutamylcysteine synthetase (GLCL-R): CA IX expression was significantly higher in MnSOD-positive tumours ($p=0.008$) and decreased in GLCL-R-positive tumours ($p=0.044$). In Cox multivariate analysis CA IX expression, patient age and histological component (pure oligodendroglioma vs. mixed oligoastrocytoma) showed independent prognostic values ($p=0.009$, $p=0.003$ and $p=0.022$, respectively), CA IX positivity predicting poorer outcome. They concluded CA IX proved to be an independent prognostic indicator in oligodendroglial brain tumours and it also correlates reversely with cell proliferation. It may have a role in the biology of oligodendrogliomas and most interestingly, as it is mainly expressed in tumour tissue, CA IX could serve as a target molecule for anticancer treatments.[22]

Cytogenetic and Molecular Studies

During the last decade, enormous progress in understanding of these molecular alterations has been accomplished. Oligodendrogliomas show distinct genetic alterations, allowing us to distinguish them from other types of gliomas. The loss of heterozygosity (LOH) on chromosomes 1p and 19q were reported to be the most frequently observed alterations. While loss of heterozygosity on chromosome 1p is a statistically significant predictor of chemosensitivity, combination with deletions on chromosome 19q was reported to be associated with both chemosensitivity and longer recurrence-free survival after therapy. Conversely, allelic loss on chromosome 10q, observed in many anaplastic oligodendrogliomas, predicts rather poor outcome.[18] The favourable response of oligodendrogliomas correlates well with characteristic chromosomal losses, of which loss of the short arm of chromosome 1 is most predictive. Oligodendrogliomas are histopathologically heterogeneous tumours and, in addition to the classic honeycomb histology, fields of non-classic histology are often encountered. Information about the distribution of 1p loss in various regions of oligodendroglioma is, therefore, important to interpret findings in tumour biopsies. Kros et al. investigated the distribution of 1p loss in multiple fields in 24 biopsy specimens of oligodendroglioma, consisting of classic and non-classic histology by fluorescent in situ hybridisation and loss of heterozygosity analysis. By fluorescent in situ hybridisation analysis, loss of 1p was found in all fields examined in 37% of the tumour samples and no loss was detected in 46%. In fields of classic oligodendroglial and polar spongioblastoma-like histology, significantly more loss for 1p was found ($p < 0.001$ and $p < 0.01$, respectively). Although fluorescent in situ hybridisation analysis indicated heterogeneity for 1p loss in the other 17% of tumours, loss of heterozygosity analysis of these samples pointed to homogeneity of 1p status in all fields. The 1p status of the fields with classic histology significantly correlated with the status of the other fields in the same tumours (Spearman's rho 0.918, $p < 0.001$). These results point to genotypic homogeneity for 1p in oligodendroglial tumours.[26] Importantly, the possible effect of combined 1p/19q loss has not been studied in patients who were not treated with radiotherapy or chemotherapy. Weller et al. identified 76 patients with oligodendroglioma (n = 33), oligoastrocytoma (n = 30), anaplastic oligodendroglioma (n = 6) or anaplastic oligoastrocytoma (n = 7) who had not received radiotherapy or chemotherapy after their first operation, until the end of follow-up or until the first progression and had tissue for 1p/19q status available. 1p/19q status was assessed by multiplex ligation-dependent probe amplification. They concluded that combined 1p/19q loss is not a sensitive prognostic biomarker in patients with oligodendroglial tumours who do not receive radiotherapy or chemotherapy. The gene products lost as a consequence of this codeletion may include mediators of resistance to genotoxic therapies. Alternatively, 1p/19q loss might be an early oncogenic lesion, promoting the formation of glial neoplasms, which retain high sensitivity to genotoxic stress.[50]

The functional single-nucleotide polymorphism (SNP) in codon 72 of TP53 has been shown to be both a risk factor and a prognostic biomarker in various cancers. Such results were also reported in other brain tumours, notably in astrocytomas. This SNP has never been precisely investigated in oligodendroglial tumours. Idbaih et al. retrospectively analysed blood samples of 275 oligodendroglial tumour patients for the TP53 codon 72 polymorphism and compared them with a series of 144 healthy controls. Arg/Arg, Arg/Pro and Pro/Pro genotypes were found in 54.2 versus 60.4%, 39.3 versus 34.0% and 7.3 versus 5.6% of patients and controls, respectively. This suggests no association between oligodendroglial tumours and the SNP in codon 72 of TP53. Similarly, no correlation was found among the TP53 codon 72 polymorphism and prognosis, p53 expression and chromosomes 1p and 19q status.[20] The expression of coronin-3 varies in different brain tumour entities. However, in diffuse gliomas, the number of coronin-3 expressing tumour cells correlates with the degree of malignancy. High-grade gliomas, such as anaplastic astrocytomas, anaplastic oligodendrogliomas, anaplastic oligoastrocytomas and glioblastomas show high numbers of tumour cells positive for coronin-3, while diffuse low-grade gliomas, such as diffuse astrocytomas, oligodendrogliomas and oligoastrocytomas, exhibit low numbers of coronin-3-positive tumour cells. In order to explore and verify a contribution of coronin-3 to the malignant phenotype of diffuse gliomas, Thal et al. employed an efficient shRNA-mediated coronin-3 knockdown in U373 and A172 human glioblastoma cells. Coronin-3 knockdown glioblastoma cells exhibited reduced levels of cell proliferation, cell motility and invasion into the extracellular matrix compared to control cells. Their findings demonstrate evidence for a contribution of coronin-3 expression in the malignant progression of diffuse gliomas.[45] Abnormal expression of peroxiredoxin 6 and rho GDP dissociation inhibitor alpha may be associated with malignant transformation in oligodendroglioma and these proteins might be candidates of molecular predictive factors.[36]

AGE AND SEX

Characteristically it is a tumour of middle-aged persons, although the age range has been recorded from 3 years to 76 years, with a biphasic peak between the ages of 6 years and 12 years and a second peak between the ages of 26 years and 46 years. In several large series, the median age was around 44 years.[30,40] Only 5–6% of tumours occurred in the paediatric age group. Males are more frequently affected (60–65%). Ludwig et al.[30] reported a male to female ratio of 3:1.

CLINICAL FEATURES

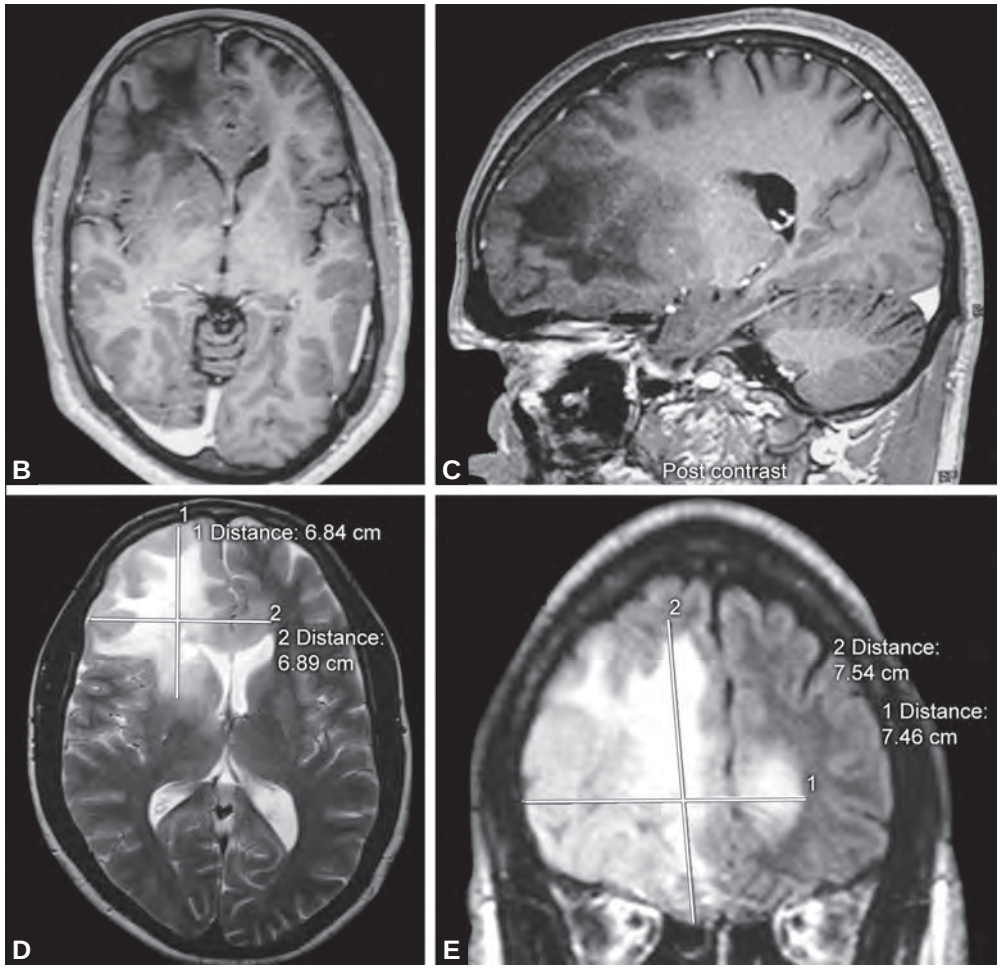
These tumours tend to grow relatively slowly. The average duration of symptoms has been reported to vary from 33 months to 43 months, the range being 3 days to 29.9 years.[40] Due to the predominantly frontal location and a relatively slow growth rate, the tumour attains a large size before symptoms occur. Epileptic fits constitute the most common initial symptom. The highest incidence of epilepsy in patients with supratentorial gliomas was observed in oligodendrogliomas. The other presenting symptoms include headache, visual disturbances, papilloedema and focal neurological deficits. There are no characteristic clinical features attributable to this tumour, except a high propensity for calcification, seen in 25–30% even in plain X-rays of the skull.

RADIOLOGY

The age of the patient, the location of the tumour in the frontal lobe and the presence of calcification in plain X-rays of the skull should arouse the suspicion of an oligodendroglioma. On CT scan, the lesion appears as a heterogeneous mass, isodense to hypodense, as compared with normal brain. With contrast, the tumour may show variable enhancement, usually to a mild to moderate degree (Fig. 2A). Low-grade oligodendrogliomas usually do not enhance with contrast. More malignant lesions are characterised by more intense, irregular enhancement, associated with vasogenic oedema and mass effect. Linear or nodular calcification has been reported in 50–90% of oligodendrogliomas on CT.[28] On MR, (Figs 2B to E) oligodendrogliomas are usually heterogeneous and isointense to grey matter on long TR images. Calcification, which cannot be seen on conventional spin echo MR, can be demonstrated on gradient echo imaging. Fifty percent show contrast enhancement.

Positron emission tomography (PET) has the ability to differentiate low-grade oligodendroglioma from astrocytoma, based on the methionine uptake. Low-grade oligodendrogliomas have a high methionine uptake, while in astrocytomas it can be decreased, moderately increased or may be normal.[12] [11C]-L-methyl-methionine (MET)

Fig. 2A: CT scan of the brain contrast study



Figs 2B to E: (B) MRI brain T1 axial. (C) MRI brain T1 sagittal. (D) MRI brain T2 axial. (E) MRI brain T2 coronal

appears more sensitive than [18F]-flurodeoxyglucose (FDG) to detect proliferation in ODG. The preferential protein metabolism, already noticeable for low-grade tumour, correlated with glucose metabolism and helped to separate, *in vivo*, high-grade and low-grade tumours. (11)-C methionine (MET) PET image fusion may facilitate the targeting of anaplastic foci in homogeneous MRI non-enhancing gliomas for biopsy, may identify oligodendroglial histology pre-operatively, as well as characterise biologically active tumour volumes within MRI T(1)/FLAIR tumour areas of candidate patients for resection.[38]

DIFFERENTIAL DIAGNOSIS

The dysembryoplastic neuroepithelial tumour (DNET) is a tumour which contains foci similar in appearance to oligodendrogliomas. Dural based oligodendrogliomas may be confused with meningiomas. Intraventricular oligodendrogliomas must be differentiated from central neurocytomas which histologically can be very similar in appearance.[25] Clear cell variant of ependymoma is a rare entity which morphologically mimics oligodendroglioma and poses a diagnostic dilemma. Jain et al. described three cases of clear cell ependymoma in male children which were supratentorial in location. On microscopic examination, these tumours were composed of sheets of clear cells and resembled oligodendroglioma. Electron microscopy confirmed the ependymal nature of these tumours.[21] High-grade oligodendrogliomas should be differentiated from other anaplastic gliomas and metastatic carcinoma.

TREATMENT

General Management Plan

The optimal treatment for patients with oligodendrogliomas is unknown and current management strategies remain controversial. It is becoming increasingly apparent that oligodendrogliomas are a distinct disease on a molecular level and that key genetic derangements can signify a response to treatment and favourable outcome. The combination of improved imaging techniques, molecular profiling and new therapies should result in improved outcome with reduced treatment-related toxicity for patients with newly diagnosed, progressive and recurrent oligodendrogliomas. Most patients harbouring oligodendrogliomas present with a long-standing history of epilepsy. However, the seizures due to these lesions are commonly refractory to medication.[41] The efficacy of surgical resection in decreasing seizure frequency has been reported.[27] It is necessary to obtain a histological

diagnosis in all cases of suspected oligodendroglioma. This can be achieved by a stereotactic biopsy or excisional biopsy. Subsequent treatment options available are surgical resection of the lesion, followed by post-operative radiotherapy and/or chemotherapy.

Surgical Management

Oligodendrogliomas are managed (Figs 1C and D) like any other glioma, with as radical a removal as possible. However, the role of resection on prognosis, the most appropriate time for surgery along the natural history of these tumours and the best operative strategy remain debatable. Surgical or stereotactic biopsy is the first surgical procedure which enables confirmation of the diagnosis suggested on imaging, assessment of extension of tumour cell infiltration beyond the abnormalities limit described on imaging and currently available molecular biology studies. Biopsies may be the only surgical procedure in patients having a deep-seated tumour with minimal mass effect or prior to a surgical resection or a "wait and watch" strategy. Surgical resection may be indicated for the other patients. However, it has not been demonstrated that time for resection has an influence on survival, except in patients with rapidly growing tumours with mass effect causing increased intracranial pressure. The present trend is for maximal safe resection, preserving 'eloquent' cerebral areas, since truly large or complete resection of the tumour based on imaging is not associated with significantly longer survival. Neuronavigation guidance, intra-operative imaging and cortical stimulation techniques are helpful neurosurgical techniques enabling maximal safe resection with preservation of functional areas. In a series of 170 non-randomised patients treated for cerebral oligodendrogliomas, Lindegaard et al.[29] observed a significant prolongation of post-operative survival, if irradiation was given in addition to surgery.

Radiation Therapy

The 5-year survival for the group who had surgery plus irradiation was 36%, as compared to 26.5 for surgery alone. However, 8 years post-operatively, there was no significant difference between the two groups. Radiation doses between 40 Gy and 50 Gy were as effective as doses between 50 Gy and 60 Gy. Wallner et al.[49] reported 10-year survival of 56% for those treated with surgery and irradiation, as compared to 18% with surgery alone. It has been suggested that selected patients who undergo gross total resection, particularly younger patients with low-grade tumours, may not require post-operative radiation therapy.[40]

Chemotherapy

Cairncross et al.[7] have identified a sub-group of aggressive oligodendrogliomas which proved to be highly chemosensitive. Fifty to seventy percent of patients with recurrent oligodendroglial tumours may respond to chemotherapy. Genetically, 60–70% of oligodendroglial tumours are characterised by the loss of the short arm of chromosome 1 (1p) and the loss of the long arm of chromosome 19 (19q). Virtually all tumours with the combined loss of 1p/19q respond to chemotherapy, which has been the first demonstration of the clinical usefulness of the genotyping of brain tumours. These tumours have a classical oligodendroglial histology and more often have a much better prognosis than oligodendrogliomas without 1p/19q loss.[47]

Two independent large Phase III trials on adjuvant procarbazine, lomustine and vincristine chemotherapy in anaplastic oligodendroglial tumours have shown improvement in progression-free survival, but not overall survival, regardless of 1p/19q status. If given sequentially, the timing of procarbazine, lomustine and vincristine chemotherapy has no clear effect on the survival of anaplastic oligodendroglioma. Virtually, none of the many new targeted agents directed against pathways that are up-regulated in high-grade gliomas has shown significant clinical activity as a single agent in phase II studies. The exceptions are trials with the vascular endothelial growth factor signalling system inhibiting agents bevacizumab and AZD2171 (cediranib), that showed high response rates (which might be due to vessel normalisation similar to the effects of steroid treatment) and promising 6-month progression-free survival rates in glioblastoma. Further research to define the role of vascular endothelial growth factor inhibition in the management is indicated.[4]

Temozolomide is a methylating agent that is typically administered once daily. Because preclinical studies suggested that a twice daily dosing schedule might be more effective, Balmaceda et al. studied the safety and efficacy of twice-daily dosing of temozolomide in patients with recurrent gliomas at their first, second or third recurrence. They concluded twice-daily dosing may enhance the efficacy of temozolomide in the treatment of recurrent gliomas, without increasing toxicity.[3]

Sunyach et al. found front-line exclusive chemotherapy results in prolonged overall survival in patients with confirmed pure oligodendroglioma. Whether this strategy improves quality of life remains debatable.[43]

Chemoresistance is a widespread therapeutic challenge in glial tumours. The molecular basis of chemoresistance is poorly understood, precluding advances in glioma treatment and leaving gliomas among the most lethal tumours. Oligodendrogliomas provide a unique model to study the molecular basis of chemoresistance, as there are two distinct genetic subtypes with significant differences in chemosensitivity. Despite a high morphological similarity, tumours with allelic loss on the short arm of chromosome 1 (1pLOH) are more chemosensitive than those without 1pLOH. Okamoto et al. identified seven candidate proteins that are overexpressed in oligodendrogliomas without 1pLOH. Two of these proteins (glyoxalase I and Rho GDP dissociation inhibitor)

have previously been shown to enhance chemoresistance in other tumours. In turn, they identified twelve overexpressed proteins in tumours with 1pLOH that have previously been reported to induce chemosensitivity in other forms of human neoplasia. They concluded that these identified proteins are potential targets for pharmacological therapy and may also be useful as biomarkers for differentiation of chemoresistant and chemosensitive oligodendroglioma.[33]

What is the safety and efficacy of interstitial chemotherapy with carmustine-loaded polymers (Gliadel® wafers) in the treatment of newly diagnosed or recurrent malignant gliomas? Perry et al. from their study found Gliadel® to be an option for selected patients with newly diagnosed malignant glioma, where a near gross total resection is possible. No evidence is available comparing Gliadel® with systemic therapy and a decision to combine Gliadel® with systemic therapy should be made for patients individually. The most frequently reported adverse events were convulsions, confusion, brain oedema, infection, hemiparesis, aphasia and visual field defects.[37] Da Fonseca et al. reported a case of a patient with anaplastic oligodendroglioma managed with intranasal delivery of 0.3% concentration of perillyl alcohol (POH), following a radical surgical excision of the lesion.[10]

PROGNOSIS

The median duration of disease from the onset of symptoms to death was 14 months in nine untreated cases. The median post-operative survival period was 14 months longer in those patients who were considered to have gross total removal of the tumour.[32] Histopathologically, using univariate analysis, Burger et al.[6] observed five prognostically significant factors, in order of decreasing importance: mitoses, necrosis, nuclear cytologic atypia, vascular hypertrophy and vascular proliferation. When studied by stepwise regression, the presence of necrosis and the number of mitoses contained all of the prognostically useful information. Post-operative radiotherapy improved the 5-year survival rate of patients who had subtotal tumour removal. The presence of calcification and the absence of CT enhancement were associated with longer survival.[40]

138 Ependymomas

Harjinder S Bhatoe

DEFINITION

Ependymoma is a slow-growing tumour arising from the wall of the cerebral ventricles or from the ependymal lining of the central canal of the spinal cord and filum terminale and is composed of neoplastic ependymal cells. The tumour is of neuroectodermal origin and corresponds histologically to WHO grade II (Table 1).

INCIDENCE

Of all neuroepithelial tumours, 3–9% are ependymomas. Ependymoma is a tumour of childhood and accounts for 6–12% of all paediatric intracranial tumours. Nearly 30% of intracranial tumours in children less than 3 years of age are ependymomas.[11] Ependymoma is the most common spinal cord tumour, comprising 50–60% of glial tumours of the spinal cord.[40]

ORIGIN

Ependymomas arise probably from a differentiated ependymal cell, although there is another view of their origin, being from a less differentiated ependymoglial precursor cell.[24] Rare, familial cases have been reported. Adult tumour cells show allelic losses of chromosome 22, suggesting the presence of a tumour suppressor gene.[29]

LOCATION

Although these tumours can occur at any site where there is an ependymal lining, nearly two-thirds of the ependymomas are infratentorial, while one-third are above the tentorium.[39] Most infratentorial ependymomas occur in the midline, often involving the floor of the fourth ventricle, particularly in the region of the obex, and hypoglossal and vagal triangles (Fig. 1). These infratentorial tumours are solid and can grow laterally into the lateral recesses and foramina of Luschka. A tongue of tumour may extend below the foramen magnum[22] and the tumour can infiltrate into the pons and medullary tegmentum. Rarely, extraventricular ependymomas may be seen in the supratentorial region, especially in children. These probably originate from embryonic remnants in the brain parenchyma. Anecdotal case reports of extraneural ependymomas originating in the ovaries, mediastinum and sacrococcygeal region have been described.[26] In adults, infratentorial and spinal ependymomas occur with equal frequency, while infratentorial ependymomas are predominant in children.[21]

In the spinal cord, the cervical and cervicothoracic segments are most frequently affected. The conus and cauda equina regions are the preferred sites for occurrence of myxopapillary ependymoma.

CLINICAL PROFILE

Ependymomas, as with other posterior fossa tumours of childhood, often present with features of raised intracranial pressure due to obstructive hydrocephalus. Generally, this manifests as headache and repeated vomiting. Infants can present with lethargy and macrocephaly.[1] Symptoms are worse in the morning, as recumbency and raised carbon dioxide blood levels during sleep cause an increase in cerebral blood flow and a consequent rise in intracranial pressure. Vomiting may precede other symptoms in case the tumour originates in the caudal part of the fourth ventricular floor and these children may often undergo initial evaluation by a paediatric gastroenterologist. Gait or truncal ataxia may be seen with involvement of the cerebellar vermis. Nystagmus, papilloedema and ocular cranial nerve palsy may be seen, and lower cranial involvement may be seen in tumours with lateral extension. Neck pain, head tilt and nuchal rigidity can occur if the tumour extends caudally through the foramen magnum. Seizures occur in one-third of patients with supratentorial tumours.[15]

Supratentorial ependymomas constitute about 30% of all intracranial ependymomas.[25,42] The tumours may be intra-or extraventricular. Of the intraventricular tumours, the ones in the lateral ventricles are more common.[30] Intraventricular tumours present more often with obstructive hydrocephalus, while extraventricular tumours may manifest as seizure disorder with raised intracranial pressure. Some supratentorial tumours reach the pial surface.[2,35]

Intraspinal Ependymomas

These are intramedullary, filum terminale or sacral in location and often have a long history spanning several years. The intramedullary tumour extends over several segments, is usually discrete, elongated and sausage-like with a clear plane between it and the cord tissue, causing fusiform expansion of the cord. Backache is often the only symptom for some time and sphincter dysfunction occurs late. Clinical features reveal myelopathy and there may be a suspended zone of sensory impairment. There may be syrinx above or below the tumour. Tumours involving the filum terminale arise from ectopic ependymal cell rests and may attain a large size before detection. Presentation is in the form of cauda equina syndrome, wasting of calves and talipes deformity of the feet and ankles.

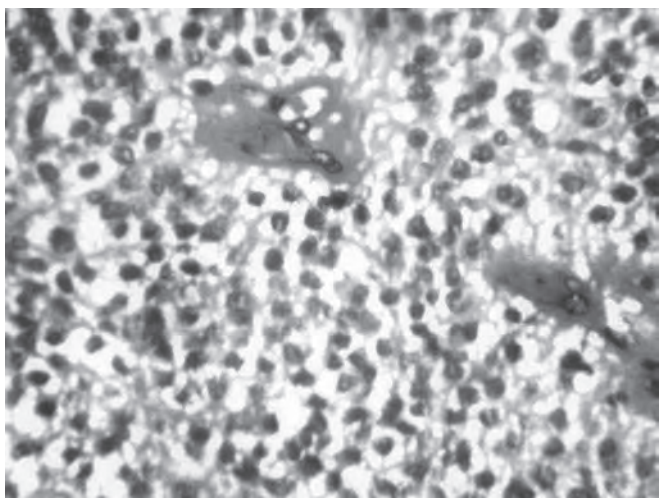
PATHOLOGY

(See Section 11)
(Figs 2 and 3)

IMAGING

Ependymomas are generally solid tumours. CT shows calcification in nearly 50% of cases and areas of haemorrhage and cyst formation may be seen (Fig. 4). On MRI, these tumours are circumscribed, and appear isointense or hypointense on T1-weighted images and intensely enhance with contrast. They appear hyperintense on T2-weighted and proton-density images. They appear heterogeneous on MRI in the presence of cyst formation, calcification, haemorrhage and necrosis. Cyst formation is often seen in supratentorial tumours.

Spinal ependymomas may appear like astrocytomas on MRI. A "tumour cap" at either pole of the intramedullary tumour is highly suggestive of an ependymoma. On administration of intravenous Gadolinium, tumoural contours are clearly defined in ependymomas, unlike that of astrocytomas (Figs 5 to 11). Nearly a fifth of ependymomas may, however, show no contrast enhancement. Besides astrocytoma, an intramedullary ependymoma should be distinguished from sarcoidosis, a rare condition which responds to corticosteroids.



Figs 2: Histopathology showing pseudorosettes typical of ependymoma (H & E, X40)

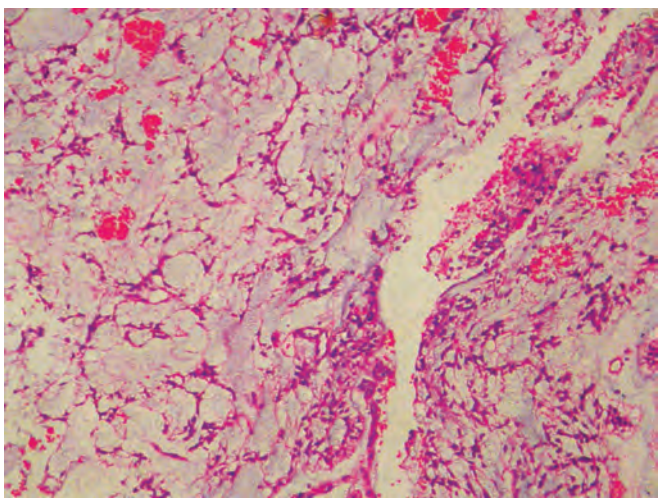


Fig. 3: Histopathology showing myxopapillary ependymoma (H & E, X40)

MANAGEMENT

Surgical excision is the mainstay in the management of these tumours – whether supratentorial, infratentorial or spinal intramedullary. In patients with supratentorial tumours, a craniotomy is performed and the tumour—intraventricular or extraventricular—is approached. Real-time ultrasound can reliably demarcate the tumour and a cystic component can be tapped to relax the brain. Gross total excision is the desired goal, so as to achieve satisfactory cytoreduction.

Infratentorial tumours often lead to hydrocephalus by the time treatment is sought. Although hydrocephalus can resolve with excision of the tumour, it is preferable to divert the CSF pre-operatively. This will reduce intracranial pressure and improve the general well-being of the patient. CSF diversion can be achieved by ventriculoperitoneal shunt (with a filter device to prevent tumour seeding) or by endoscopic third ventriculostomy. Alternatively, a ventricular catheter can be placed at the time of surgery to release CSF and reduce brain swelling and intracranial pressure. Treatment with parenteral glucocorticoids for several days helps in reducing intracranial pressure pre-operatively.

Posterior fossa lesions occurring in the fourth ventricle can be exposed by suboccipital craniectomy or craniotomy. The patient is positioned prone with the neck flexed. The arch of the atlas and the lamina of the axis are removed to facilitate exposure in cases with intraspinal extension. After dural opening, the operating microscope is brought into the operative field. CSF is released from the cisterna magna and the vermis is split to a variable extent. The tumour is excised by cutting and coagulation and the ultrasonic aspirator can be used to reduce the tumour bulk. A thin layer adherent to the fourth ventricular floor may have to be left to avoid post-operative dysfunction of the upper aerodigestive track. Complete vermis section and excessive lateral retraction should be avoided to prevent post-operative cerebellar mutism. The dura should be closed after haemostasis, if necessary, with a dural graft. Repeat surgery by the lateral approach may be required when tumour extends into the lateral recesses. Children in whom the posterior arch of atlas and lamina of the axis are removed will require post-operative assessment for instability at the craniovertebral junction.

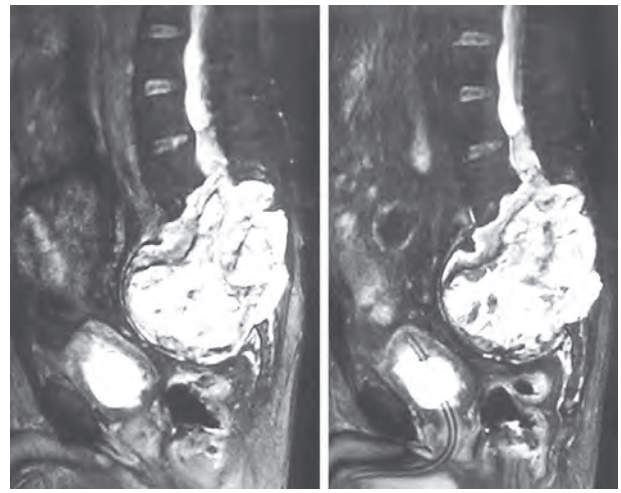

Fig. 11: MRI (T2-weighted) lumbosacral spine showing giant ependymoma

Intramedullary spinal cord ependymomas are best treated by surgical excision (Figs 12 to 14). The MRI data in three planes should be analysed and it is essential to define the length and depth of the tumour. Most ependymomas are centromedullary, although uncommonly, they may be exophytic. Limits of the tumour's solid portion will determine the extent of laminectomy/laminotomy. However, one must bear in mind that with rare exceptions, patients do not recover from severe pre-operative neurological deficits and patients with little or no deficits are the ones who are likely to remain free from deficits post-operatively. Post-operative quality of life depends upon the pre-operative neurological status.

Adjunctive Therapy

Radiotherapy

The role of radiotherapy in ependymomas has been difficult to validate, although these tumours are radiosensitive. Local field irradiation is the treatment recommended. The recommended dose is 4500–6000 cGy over 5–6 weeks. Prophylactic irradiation of the spinal cord is not advised, since the incidence of spinal seeding is low. However, for adults, craniospinal irradiation has been advocated in case of incomplete resection. Children below three years do not receive radiotherapy and in the presence of anaplastic tumours, have a lower progression-free-survival. Stereotactic implantation of iodine-125 seeds has been reported in a case of large benign intraventricular ependymoma and the tumour shrank within a few weeks and the patient had a long progression-free survival.[46] Efficacy of chemotherapy is still not established in ependymomas.

ANAPLASTIC EPENDYMOMA

As with other glial cell tumours, ependymomas can show aggressive behaviour in their malignant forms. Anaplastic ependymoma is a high grade malignant tumour (WHO III) with an aggressive course and unfavourable outcome. Histologically, they exhibit high mitotic activity, microvascular proliferation, perivascular

Fig. 14: Intramedullary ependymoma of the cervical cord—excised specimen

rosettes of narrow width and pseudopalisading necrosis. GFAP expression is reduced but other immunohistochemical markers of ependymomas are positive. Anaplastic tumours in children less than three years of age with evidence of CSF metastases have an adverse outcome.[16]

PROGNOSIS

Recurrence rate is high in incompletely resected ependymomas.[45] Deterioration after initial treatment occurs due to local recurrence and subarachnoid seeding. Seeding of ependymal tumours through the cerebrospinal fluid pathways is reported with varied frequency and often follows recurrence at the site of previous excision, suggesting the surgical procedure as the initiating factor.[31] Autopsy studies have revealed 30% incidence of seeding of the spinal subarachnoid space in infratentorial tumours, while no such seeding was observed in supratentorial tumours.[44] Other studies too have documented frequent CSF seeding with infratentorial tumours, while the overall incidence of seeding through the cerebrospinal fluid is less than 3–5%,[28] an incidence of 75% too has been reported.[13] Seeding is seen more often in infratentorial tumours and anaplastic histology.[33]

Extraneural metastases, usually to the cervical lymph nodes and lungs, are seen in high grade tumours.[12,23,41] Such metastases have been seen even in low grade neoplasms and ependymomas occurring in the spinal cord.[12,36] As with subarachnoid seeding, most of the cases of extraneural metastases occur after surgical excision of the primary tumour.

Overall 5-year-survival with surgery and post-operative radiation therapy is about 50–60%, and long-term survival drops to 40% or less.[9] Prognosis is poor in children with high grade anaplastic lesions in the posterior fossa. Supratentorial lesions, unless they are high-grade extraventricular tumours, carry a better prognosis. Spinal ependymomas have a better prognosis with a 5-year-survival of 83%.[14] Thus, the overall prognosis in ependymomas is determined by a matrix of variables comprising age, location, completeness of surgical resection and histological type and grade.[32]

MYXOPAPILLARY EPENDYMOMA

This tumour is listed as an independent subgroup of ependymal tumours in the WHO classification. The tumour preferentially involves the filum terminale and is known for its striking histological appearance. The overall incidence is about 5% of all ependymal tumours[7] and in the region of the cauda equina, they account for nearly 50% of ependymomas, most of them arising from the filum terminale.[4,34] They arise from ependymal glia of the filum terminale and can grow to a large size. Rarely, they involve the nerve roots or the sacrum, where they may be extradural.[37] Rare occurrences have been reported in the cervicothoracic cord,[43] lateral ventricle[38] or brain parenchyma.[47] Subcutaneous sacrococcygeal and presacral myxopapillary ependymomas represent a distinct subgroup. They probably arise from ectopic ependymal remnants.[17]

Presentation

Myxopapillary ependymomas typically present with back pain, often of long duration. Large tumours cause pressure and stretching of nerve roots causing wasted legs, foot drop and sphincter dysfunction with saddle anaesthesia and absent tendon jerks in the lower limbs. Small tumours can be suspected by virtue of their intradural location on MRI, while large, sacral and subcutaneous tumours can be mistaken for chordoma. In contrast to other ependymomas, myxopapillary tumours are hyperintense on T1-weighted images.[19]

Management

Intradural tumours need excision through a laminectomy. Total excision with preservation of neural function is the goal of surgery. Large tumours involving the sacrum may need spinopelvic stabilisation, if involvement of the sacroiliac joints causes instability.

Histopathology

These tumours are characterised by radially arranged cuboidal cells in a papillary manner around a vascular stroma, with a background of mucoid matrix that forms microcysts. The mucoid matrix can be deposited by tumour cells and vascular extravasation via endothelial fenestrations.[5] There is low mitotic activity. The tumour cells are positive for GFAP, S-100 and vimentin with lack of reactivity for cytokeratin.[6,20]

Prognosis

Myxopapillary ependymomas show good outcome with more than 10-year-survival after total or even partial excision.[43] Sacrococcygeal ependymoma, however, can recur early and distant metastases may appear.[17]

EXTRANEURAL EPENDYMOMAS

Ependymomas can rarely occur ectopically in the parasacral region and in the abdomen, although there are only case reports of such tumours.

PARASACRAL EPENDYMOMAS

These can occur in an anterior or posterior (subcutaneous) location. They originate from ependymal cell nests and present from infancy to the fifth decade of life. Posterior lesions generally present as a subcutaneous mass, while anterior lesions present as an abdomino-pelvic mass with sphincter disturbances. Imaging studies show a sacral mass and the diagnosis of an ependymoma is often made only after surgery. These tumours are well circumscribed and histologically are typical of myxopapillary ependymomas. These tumours have to be distinguished from other mucinous or myxoid lesions, such as chordomas, chondroid tumours and mucinous metastatic adenocarcinomas. However, there have been reports of non-myxoid or anaplastic ependymomas or even ependymoblastomas in the sacrum.[27] The possibility of a teratoma should also be kept in mind in children.

INTRA-ABDOMINAL EPENDYMOMAS

These tumours can occur in the ovary and adnexae.[3,10] Tumour occurring in the omentum too has been reported.[8] The aetiology is obscure and presentation is in the form of an abdominopelvic mass. Histology is like that of a typical ependymoma, with ependymal rosettes and perivascular pseudorosettes. The tumour should be distinguished from serous carcinoma of the ovary, the differentiating feature being expression of GFAP in ependymoma.

ACKNOWLEDGEMENT

The author wishes to thank Col Vibha Dutta MD, PhD for contributing section concerning pathology of ependymomas in this chapter.

139 Medulloblastomas

BS Sharma

Medulloblastomas account for approximately 20% of all childhood brain tumours and 40% of all paediatric posterior fossa tumours. In a series of 419 cases of intracranial neoplasms in childhood, Misra et al. (1984) reported an incidence of 14.4%. The term medulloblastoma was first used by Bailey and Cushing in 1925. Medulloblastomas occur more frequently in children with 70% of all cases occurring below 10 years of age. Twenty per cent of medulloblastomas are seen below 2 years of age. The peak age of incidence is 5 years. Cases have been reported in neonates and infants. Twenty per cent of all medulloblastomas may occur in adults, of which 80% are paramedian (i.e. cerebellar hemisphere) and 40% desmoplastic.[25]

PATHOLOGY

In 1934, Stevenson and Echlin postulated that a medulloblastoma arises from the foetal external granular layer of Obersteiner—a sub-pial layer of small, primitive cells present throughout the cerebellar cortex at birth, which gradually disappears during the 1st year of life.[26] This external granular cell layer provides cells which ultimately give rise to the definitive, internal granular layer as well as basket cells and stellate cells. Alternative cells of origin include the sub-ependymal cells of the medullary velum and possibly the internal granular cell layer.[16]

GROSS APPEARANCE

The tumour is soft, greyish-purple, granular and deceptively circumscribed, with areas of necrosis. Cyst formation and calcification are rare. The desmoplastic form of the tumour seen more commonly in adults is darker in colour, firmer and often occupies a lateral cerebellar location. Medulloblastomas have also been reported in the cerebellopontine angle and rarely in the supratentorial region.

HISTOLOGY

The tumour is composed of small blue cells. It is highly cellular with frequent mitoses, occasional necrosis and clustering in Homer-Wright rosettes (Fig. 1). The cells have a high nuclear-cytoplasmic ratio, coarse chromatin and angular/carrot-shaped nuclei. Angiogenesis and endothelial cell proliferation is less striking. Five histological variants are recognised. Neuronal, as well as rhabdomyomatous or melanocytic differentiation, may point to a multipotential, undifferentiated precursor cell, which suggests that medulloblastomas may have a PNET origin. The WHO classification of brain tumours (1979) prefers to designate it as a primitive neuroectodermal tumour (PNET). Neuronal differentiation is indicated by immunohistochemical positivity for beta 3 tubulin, MAP 2, TAO, synaptophysin, somatostatin, substance P and bombasin. Astrocytic differentiation may reveal areas of GFAP positivity. Neuronal differentiation may reduce the malignant potential and show a decrease in cellular proliferation, as indicated by a low Ki-67 labelling index.[23] The relationship of desmoplasia to prognosis is controversial.[7,23,29]

MOLECULAR GENETICS

Medulloblastomas may also arise in association with the naevoid basal cell carcinoma syndrome (Gorlin's syndrome), the Li Fraumani syndrome associated with a germline p53 mutation on chromosome 17p, familial Wilms' tumour and the APC form of Turcot's syndrome.[23]

Molecular markers, such as amplification of MYCC, ERB B2 and a low apoptotic index, have been shown to have a poor prognosis. Tumours with high TRKC (neurotrophin-3 receptor) have a better outcome.[19]

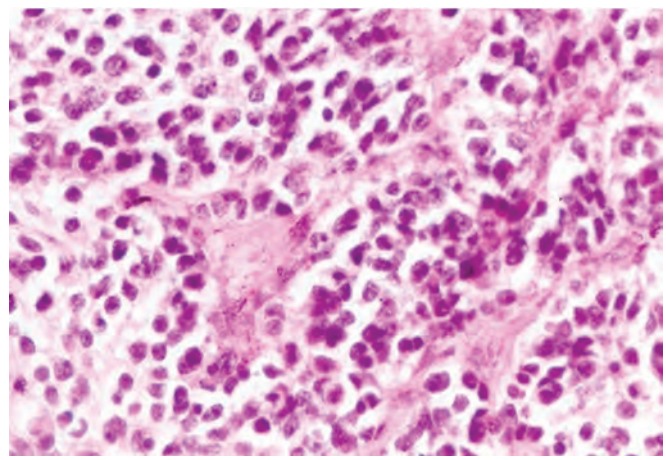

Fig. 1: Photomicrograph (H&E) revealing classical small round blue cells arranged in sheets, as well as around pale pinkish areas of fibrillarity (Homer Wright rosettes)

Aberrant signal transduction in medulloblastomas has been implicated in its tumourigenesis and has opened exciting avenues for development of newer chemotherapeutic regimens and risk stratification. These are:

a. Wingless (WNT) signalling. The WNT pathway, when activated, inactivates the adenomatous polyposis coli (APC) complex, resulting in the transcription of genes such as Cyclin D1 and MYCC.
b. The Sonic Hedgehog (SHH) pathway is implicated in Gorlin's syndrome, which is a familial predisposition to basal cell carcinomas, medulloblastomas and rhabdomyosarcomas. Medulloblastomas that carry mutations in the SHH pathway preferentially show a nodular, desmoplastic morphology.
c. ERB B2 pathway—Up-regulation of the tyrosine kinase 1 ERB B2 receptor signalling results in cell transformation and may be seen in 80% of paediatric medulloblastomas. These may amplify the metastatic and angiogenetic cascade, resulting in a poor prognosis.[9]

CLINICAL FEATURES

Medulloblastomas characteristically arise from the cerebellar vermis and grow into the fourth ventricle obstructing the flow of CSF.[21] They frequently infiltrate the brainstem and hence, produce clinical features attributable to it.

INVESTIGATIONS

Medulloblastomas on CT scans appear as hyperdense, intensely enhancing, well-defined vermian masses, usually accompanied by hydrocephalus (Fig. 2). Twenty per cent of tumours may show calcification.

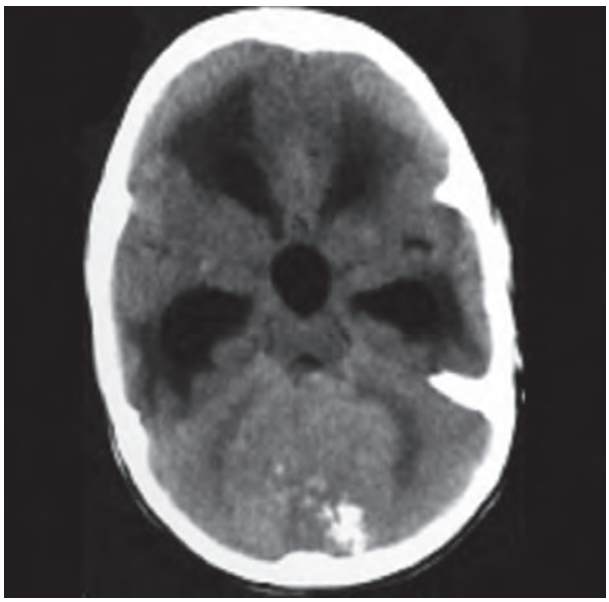

Fig. 2: Axial section of an unenhanced CT head, revealing a hyperdense vermian mass and obstructive hydrocephalus

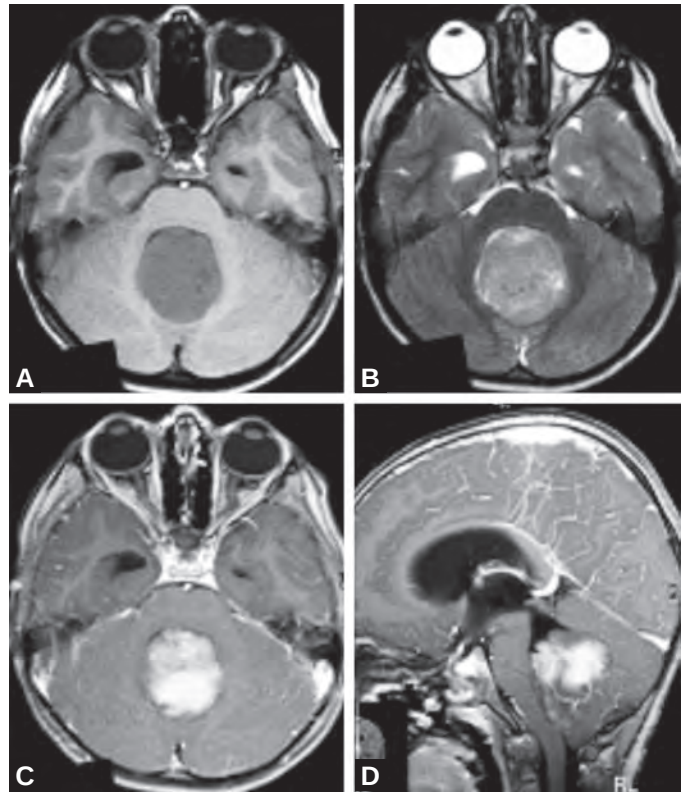

Figs 3A to D: (A) Weighted axial MR image revealing a hypointense midline cerebellar mass separated by a CSF cleft from the floor of the fourth ventricle. (B) T2-weighted axial MR image revealing a hypointense signal from the mass with a hyperintense CSF cleft indicating a good plain of cleavage from the brainstem. (C) Gd-enhanced sequences of the same mass indicating bright enhancement. (D) Gd-enhanced sagittal sequences revealing inhomogeneous enhancement and a dilated aqueduct

MRI reveals a vermian mass usually separate from the floor of the fourth ventricle on axial and sagittal (sign of the superior medullary velum) sequences, which is homogeneously hypointense on T1-images. On T2-weighted images, the signal is intermediate between grey matter and white matter, while it is isointense to grey matter on FLAIR sequences (Figs 3A to D). These findings are in contrast to other CNS tumours which are mostly hyperintense to grey matter on T2 and FLAIR sequences.

Magnetic Resonance Spectroscopy (MRS) is non-specific indicating high choline and lactic acid with low N-acetyl aspartate levels.[24]

STAGING

Medulloblastoma is the most common CNS tumour with a propensity for extra-neural spread to the bone, bone marrow, liver and lymph nodes. These may occur in approximately 1–2% of all cases at the initial presentation itself. Tumour staging, based on surgical findings was proposed by Chang et al. in 1969.[1] Langston proposed an MRI-based modification of Chang's system with the main difference being that the T stage did not account for hydrocephalus or the number of structures

involved. The T stage has not been as powerful a prognostic factor for disease free survival, as has the M stage.

Currently, children are divided into two risk groups:[14]

a. Standard risk—includes patients with non-disseminated (MO) disease with less than 1.5 cm^2 of residual tumour and > 3 years of age.
b. High risk—includes all cases with disseminated disease and with residual tumour greater than 1.5 cm^2 and children < 3 years.

PROGNOSTIC FACTORS

Age

Very young children less than 3 years of age represent 25–30% of the case load and their 5-year survival rate is 12%. Poor prognosis may be linked to larger tumours at presentation, as this age group tends to be relatively clinically silent. More aggressive tumours, a low rate of complete surgical resection, higher proportion of CNS dissemination and the inability of the immature brain to tolerate radiotherapy may also account for the poor outcome in this age group. Adults with medulloblastomas have a better prognosis than the less than 3 population, but have a shorter median survival than children.[21]

Histology

The prognostic significance of a desmoplastic component amongst tumours remains uncertain with variable results emanating from a search of the literature.[2,3,10,12,13,25]

Glial Differentiation

In a study of 86 patients with PNETs, tumours expressing GFAP but not neuronal intermediate filament had a 5.9 fold greater risk of relapse than those tumours which did not express either. The risk for relapse was also directly proportional to the amount of GFAP expressed.[15]

ERB-B2 Expression

Multicentre analysis of molecular defects in paediatric medulloblastomas reveals that children with standard risk ERB-B2 negative disease had a median survival of 100% at 5 years, compared to 54% of children with average risk ERB-B2 tumours ($p = 0.0001$).8 Pomeroy et al. using an eight-gene model divided 16 patients into low-risk and high-risk groups with an 80% and 17% 5-year overall survival, respectively.[22]

The Children's oncology group (COG), International Society for Paediatric Oncology (SIOP) and the St. Jude Children's Research Hospital (SJMB) all plan to redefine a molecular disease risk stratification system for medulloblastomas.

In summary, children less than 3 years old, amplification of MYCC, ERB-B2, a low apoptotic index, distant metastases, partial resection, brainstem infiltration and glial differentiation are poor prognostic indicators, whereas adults and patients whose tumours are desmoplastic or have neuronal differentiation fare better.

MANAGEMENT

SURGERY

Microsurgical Anatomy

The fourth ventricle is roughly a pyramid with its floor formed by the pons and the medulla; the superior and inferior medullary vella are the roves; the superior, middle and inferior cerebellar peduncles form the lateral boundaries; the inferior apex opens into the cisterna magna through the foramen of Magendie; the superior apex opens anteriorly into the cerebral aqueduct; and the lateral apices open into the cerebellopontine angle. The floor is divided by the transverse medullary stria and the vertical median sulcus. Cranially, the median sulcus is flanked by the facial colliculi and inferiorly by the hypoglossal trigone, the vagal trigone and the area postrema. They derive their blood supply from the tonsillo-hemispheric branch of the posterior inferior cerebellar artery. Medulloblastomas arise commonly from the superior medullary vellum and may invade the cerebellar peduncles and the dorsal brainstem in about one-third of cases.

Surgical Strategies

Management of Hydrocephalus

The basic principles for surgery were described by Cushing and have changed little. However, advances in anaesthesia, introduction of the operating microscope and intra-operative use of electrophysiology have made surgery far safer. Most patients present with hydrocephalus and therein lies the first controversy in the surgical management of this illness. Some centres believe that ventriculoperitoneal shunting may decrease operative mortality, by affording time to perform diagnostic tests, prepare the patient and schedule a major neurosurgical procedure electively. Reduction in intracranial pressure also permits safer resection.

The other stratagem is a course of pre-operative steroids, external ventricular drain placement and emergent surgery. If the patient is stabilised with steroids alone, surgery may be scheduled at the next elective operating date. This latter approach prevents the need for shunting and, therefore, all the possible shunt related complications, such as infection, migration, intracranial haematomas, shunt block, dissemination of malignant cells into the peritoneal cavity, delaying definitive treatment, reverse herniation and tumour haemorrhage.

Either strategy is acceptable. Intermediate stratagems involve the use of Millipore filters to prevent tumour dissemination and endoscopic ventriculostomy.[28]

Definitive Surgery

Positioning: In the prone position, the risks of air embolism, pneumocephalus and hypotension, which are often associated with the sitting position, are reduced. It is also less tiring for the operating surgeon. The advantages of

the sitting position, however, are, a more anatomical orientation, gravity assisted drainage of CSF and blood, lesser retraction and the ability to look directly up into the superior recess of the fourth ventricle.

Three-point pin fixation with short paediatric pins at a pressure of 40 pounds/sq. inch is recommended in children above the age of 3 years, whereas, a horse-shoe shaped padded head rest is preferred in children less than 3 years. Surgery is begun with an occipital burr hole to permit ventricular puncture, if required. A midline vertical skin incision is placed from the inion to the mid-cervical region and a wide craniectomy is performed from the transverse sinuses up to the arch of C1, where the tonsils may be impacted. It is advisable not to remove the arch of atlas. The alternative procedure involves raising a free bone flap with a craniotome. The dura is opened with a Y-shaped incision, taking great care to control bleeding from the occipital and other dural sinuses. Desmoplastic tumours generally presenting on the surface may be adherent to the dura. Care is necessary in dissecting these adhesions, when reflecting the dural flap. If the dura is bulging and tense, it is advisable to drain the ventricle prior to opening the dura.

To relax the cerebellum, CSF can either be drained by a ventricular puncture or by opening the cisterna magna via a small, vertical midline cervical durotomy. The tumour may be visible in the vallecula itself or after retracting the cerebellar tonsils. Before incising the vermis, it is important to identify the obex and the floor of the fourth ventricle. After delivering the herniated tonsils and draining the CSF, the cisterna magna should be packed to prevent seeding of tumour cells. The vermis may either be retracted or split. The dorsal surface of the tumour is cauterised, incised and then penetrated with a suction-cannula or a CUSA for internal decompression. The tumour is soft, suckable and highly vascular with the blood supply derived from the branches of the PICA. In very young children, even a small amount of blood loss during tumour decompression could cause serious hypotension. All efforts must be made to reduce blood loss and promptly replace the amount lost. As the tumour collapses, a plane is usually evident along the cerebellar vermis, the hemispheres, the cerebellar peduncles and most importantly the ivory white floor of the fourth ventricle, which must be guarded with a cottonoid. The ventral plane of the tumour is breached first at that portion where the tumour is free from the brainstem. The rest of the tumour is subsequently removed. Medulloblastomas are not truly encapsulated and are highly vascular. One has to work fast as haemostasis is generally spontaneous, but achieved only when the major part of the tumour is gutted. The aqueductal section of the tumour is the last to be removed, to prevent blood from entering the third ventricle and producing obstructive hydrocephalus or shunt dysfunction.

Medulloblastomas may infiltrate the brainstem and cerebellar peduncles. Attempts at removal can permanently harm the child. Small bits of tumour adherent to the brainstem or vessels should be left behind and have not been shown to diminish survival or increase relapse.[28] CO_2 laser can help in removing the tumour adherent to the brainstem and in achieving haemostasis. At the end of surgery, bleeding points from the floor of the fourth ventricle should be controlled either by saline irrigation or small strips of oxidised cellulose. Using haemostatic agents extravagantly is to be strictly avoided, as the CSF pathways will obstruct if they float away. Patients should be extubated on the table, but in the event of elective ventilation, an external ventricular drain may be used for monitoring intracranial pressure and draining CSF. Forty per cent of patients may require eventual VP shunts. Surgical mortality is less than 1% in experienced hands due to improvement in anaesthesia, surgical techniques and diagnostic and monitoring equipment.

Peri-operative Complications and their Management

Air Embolism

Early detection and prevention is the key. It usually occurs in patients operated upon in the sitting position during the bone-nibbling phase but has been reported at any time during the operation from pin fixation itself. The anaesthetist needs to be continuously informed about the operative steps and in turn should place a precordial Doppler, trans-oesophageal echo, $ETCO_2$ monitor and an atrial catheter. In the absence of these, a stethoscope may be taped on to the chest to detect the characteristic 'millwheel' murmur of venous air embolism. The earliest indication is a drop in $ETCO_2$ followed by a rise in CVP, a drop in cardiac output, hypotension and arrhythmias. Management involves the application of bone wax to the bleeding calvarial edge, copious saline irrigation and smothering the wound with a soaked sponge. The head end is immediately lowered and bilateral jugular vein compression attempted. The anaesthetist should institute cardiac support, increase the fraction of inspired oxygen to 100% and aspirate the atrial central venous catheter. In the event of a cardiac arrest, towel clips are applied to the skin edges and the patient is immediately turned supine to enable cardiopulmonary resuscitation.

Pressure Sores

When a horse shoe support is used in children less than 3 years of age, pressure necrosis of the forehead is often encountered and catastrophic blindness secondary to orbital compression may also occur. The use of fixation pins may result in scalp laceration, air embolism, depressed skull fracture, epidural haematomas or even osteomyelitis later on.

Delayed Anaesthetic Arousal

Unless the patient wakes up fully at the end of the operation and anaesthesia, it is best not to extubate the patient and if necessary institute artificial ventilation. An

emergent CT scan will detect treatable possibilities, such as hydrocephalus, extradural or subdural haemorrhage, operative site haematoma, cerebellar infarction or tension pneumocephalus. In the absence of these, brainstem dysfunction secondary to either operative trauma or retraction may be a possibility. Infarction secondary to vascular injury is a dreaded complication with little chance of recovery. Brainstem injury can be minimised by newer operating aids, such as CUSA and evoked potential monitoring. The treatment is supportive and includes feeding gastrostomy, tracheostomy and long-term ventilation.

Pseudobulbar Palsy

Patients may develop irritability, emotional lability, dysarthria, nystagmus and bilateral facial palsy, 1–3 days after surgery, secondary to retraction-induced oedema of the cerebellar peduncles and brainstem. It tends to resolve over time.

Cerebellar Mutism

This is seen particularly in young children with large, vermian medulloblastomas, when for a day or two after surgery, the patient may speak normally but then becomes mute. This may be accompanied by personality changes, dysphagia and akinesia. It recovers spontaneously within weeks to 4 months but may be accompanied by dysarthria. The aetiology remains unknown but dentate nucleus manipulation and the bilateral interruption of the dentato-thalamo-cortical pathways have been implicated. It may affect between 8% and 25% of children and is not thought to be influenced by the degree of surgical resection.[21]

Aseptic Meningitis

This syndrome appears 5–7 days after surgery, as steroids are being tapered. Signs classically suggest pyogenic meningitis with fever, neck rigidity, photophobia, irritability and CSF pleocytosis. Bacterial cultures are essential after a spinal tap to rule out the same. If cultures are sterile and CSF sugar level is not significantly low increasing the dose of steroids and tapering them over two weeks may prove to be beneficial.

Stress Ulcers

There appears to be a predilection for GI haemorrhage in patients with posterior fossa tumours, which is unrelated to steroids. Neutralising gastric acidity has to be balanced against the increased incidence of nosocomial pneumonia.

Post-Operative Pseudomeningocoele

Whenever possible, a dural patch should be used to achieve anatomical closure. A truly water-tight closure may be more a myth than a reality. Lumbar punctures and compression bandages can be tried initially; else ventriculoperitoneal shunting may be resorted to, especially if serial brain scans show a progressive ventricular dilatation. Some pseudomeningocoeles may resolve in due course of time, as the bone reforms. Replacing bone flaps after craniotomies is thought to reduce this risk.

Cervical Spine Instability

This is a rare complication, which may be seen at the end of a year after surgery. It is associated with a C2 laminectomy and local infection.

RADIATION THERAPY

Historical Perspective

The initial attempts at irradiation with a 3,600 cGy craniospinal dose coupled with a posterior fossa boost of 5,000 cGy yielded survival rates of 50% at 5 years. This, however, resulted in tremendous cognitive decline and hence, a combined Children's cancer group/Paediatric oncology group randomised trial (CCG 9014/POG9331) was undertaken to compare standard dose neuraxis radiation (3600 centigrade/20 fractions) with reduced neuraxis radiation(2340 centigrade/30 fractions) in patients with standard risk medulloblastoma, with the use of adjuvant chemotherapy. Chemotherapy consisted of weekly vincristine during radiotherapy followed by seven cycles of cisplatin, vincristine and cyclophosphamide.

In Europe, the neuraxis dose remains 3,500 cGy, whereas, in the US, the standard radiation dose has been decreased to 2,340 cGy from 3,600 cGy. However, even this dose has been associated with neurological toxicity. Thus, a Children's Oncology Group Phase-3 study is planned for further reduction of the neuraxis dose to 1,800 cGy for patients with standard risk medulloblastomas, aged between 3 years and 8 years. This will evaluate the benefits of decreasing morbidity at the expense of disease control.

Intensity modulated radiation therapy, which involves conformal radiation delivery, using multileaf collimators, multiple beam angles, varied exposure times and fused digital imaging helps deliver stereotactic radiation, while reducing normal brain exposure. Its main benefit would appear to be reduced cochlear radiation and hearing loss.[11]

CHEMOTHERAPY

Adjuvant chemotherapy was first used in high-risk medulloblastomas by the Children's Cancer Group (CCG) and the International Society of Paediatric Oncology (SIOP). These trials employed 3,600 cGy craniospinal irradiation and a posterior fossa boost to 5,600 cGy, as well as a randomisation between adjuvant chemotherapy versus none. The CCG group used vincristine with radiotherapy followed by post-radiation vincristine, prednisone and CCNU.[5] The SOIP study did not use prednisone.

Both trials demonstrated significant success. Other regimens include methotrexate, carboplatin, iproplatin,

etoposide, cyclophosphamide,[18] cisplatin,[20] in addition to CCNU and vincristine.[18,20,27]

At present, chemotherapy allows greater survival in high-risk medulloblastomas and helps reduce the craniospinal radiation dose for paediatric patients with standard risk. Chemotherapy has not been proven to better outcomes in adult medulloblastoma patients, as tolerance is poor.

Management Strategies

High-Risk Disease

Clinical trials employ radiation therapy along with radiosensitising chemotherapy and high-dose chemotherapy with peripheral blood stem cell rescue in patients greater than 3 years of age.

Average Risk Disease

The Children's Cancer Group managed to maintain a progression-free survival of 79% at 5 years, by reducing the craniospinal dose from the standard 3,600 cGy to 2,340 cGy, while maintaining the posterior fossa boost at 5,580 cGy total dose and adding adjuvant chemotherapy consisting of vincristine, cisplatin and CCNU.

Infant Medulloblastoma

In children less than 3 years of age, chemotherapy is used to delay or eliminate the need for irradiation. Protocols include chemotherapy with cyclophosphamide/vincristine and cisplatin/etoposide till the patient is 3 years of age following which radiation therapy is instituted. Other protocols deal with high dose chemotherapy to overcome the blood-brain barrier, followed by bone marrow rescue with autologous stem cells.[4,17] A third alternative is the direct intrathecal infusion of chemotherapy, using Maphosphamide along with vincristine, cisplatin, etoposide and cyclophosphamide, followed by stereotactic radiotherapy and further chemotherapy.[24]

Relapsed Medulloblastoma

Medulloblastoma remains relatively haemosensitive, despite relapse. Conventional chemotherapy has disappointing results. High dose chemotherapy supported by PBSC rescue dose demonstrate a response in 1/3rd of patients but carries a toxic death rate of 16%.[6]

Chemoradiotherapy Sequelae

Radiation therapy to the developing, immature brain can result in most of the side effects mentioned below:

Neurocognitive Decline

This is delayed in onset and then progresses over 3–5 years, depending on the age at onset, dose of radiation and volume irradiated. Children may experience a drop in IQ of about 25 points and suffer from lapses of memory and fine motor, visual motor skills, visuospatial skills and poor organisation, attention, learning and processing speed. This underlines the rationale for reducing the dose of radiotherapy with adjuvant chemotherapy.

Neuroendocrinologic Dysfunction

- *Growth failure:* Decreased growth velocities remain the most common form for neuroendocrinologic dysfunction. Growth hormone replacement therapy can be employed safely, but 2 years should elapse after completion of therapy.
- *Hypothyroidism:* It may be due to either irradiational damage to the hypothalamus or thyroid gland. Routine screening and hormone replacement is essential.
- *Secondary malignancies:* As survival improves, secondary malignancies occurring in the fringes of the radiational fields have assumed greater importance. Meningiomas and high-grade gliomas may occur in survivors of medulloblastomas. Secondary acute myeloid leukaemias may occur in patients who have undergone chemotherapy, as can cancers of the salivary glands, cervix, central nervous system, thyroid and acute lymphoblastic leukaemia.
- *Hearing loss:* Ototoxicity may be secondary to either whole brain irradiation with cochlear exposure or may be cisplatin induced. Consequently, oxaloplatin, a cisplatin derivative may be preferred, since there is no ototoxicity and nephrotoxicity.

Newer Chemotherapeutic Agents

Molecular genetics studies may provide some of the best chemotherapeutic agents in the years to come, by targeting abnormal signalling sequences within the cancerous MB cells. These include erlotinib, an ERBB2 receptor inhibitor. SCH66336 is an oral farnesyl transferase inhibitor that blocks the ras pathway. Gefitinib, a PDGF inhibitor is also undergoing trials.

CONCLUSION

Surgery, along with craniospinal irradiation and chemotherapy has led to 5-year survivals in excess of 75% with feasible cure. Reported 10 year survival rates approach 50% in average risk disease. Future directions will involve better and safer drugs, targeted drug delivery systems focused on abnormal signalling sequences, lower dose craniospinal irradiation and stereotactic radiation in an effort to reduce long-term morbidity, without increasing mortality and relapse.

140 Metastatic Brain Tumours

Ravi Ramamurthi, Harinivas

Metastatic deposits in the brain were first reported by Bucholz in 1898.[14]

DEFINITION

Metastasis is defined as the spread of malignant tumour cells from a primary neoplasm to distant tissue to form a new growth.[93] Single brain metastasis (BM) is defined as a single cerebral lesion arising outside the central nervous system (CNS) without any reference to systemic status. A solitary metastasis is a single brain lesion without evidence of metastatic spread elsewhere in the body. When there is more than one brain lesion it is called multiple metastases. A metastasis is called synchronous when it is detected at the time of diagnosis of the primary tumour and metachronous when diagnosed later, sometimes several years later.

INCIDENCE OF BRAIN METASTASIS

Metastatic brain tumours are the most common intracranial neoplasms in adults.[134]

The incidence of metastases is much higher if it is based on autopsy series as compared to clinical series. Approximately 10% of patients with cancer develop BMs.[50]

The incidence of metastases is thought to be rising due to better detection and treatment of systemic malignancy.[90,95] It is more common in adults compared to children. Among adults the highest incidence is seen in the fifth to seventh decades.[116] Approximately 75–85% of lesions are supratentorial and 15–25% are infratentorial.[130] The reported incidence in India by Ramamurthi[94] and by Dastur and Lalitha[24] were lower, but these were in the pre-computerised tomography (CT) era.

FACTORS GOVERNING THE METASTATIC PROCESS

The first phase of pathogenesis is invasion of cancer cells into blood, lymph or cerebrospinal fluid (CSF). In the second phase, there is dissemination with transport of cancer cells. Most of the cells are killed and only viable cells which reach the target organs develop into micrometastasis.[99] The final phase involves the growth of these viable cells into either single or multiple metastases.[3] The factors which determine the detachment of tumour cells from the primary tumour are growth rate of the tumour, tumour necrosis, enzymes and stress.[125]

CLASSIFICATION DEPENDING ON SITE OF ORIGIN[89]

Skull and Dura

The deposits are mainly located in the vertex or low occiput. They are seen commonly with prostate carcinoma, lymphoma, breast carcinoma, melanoma, neuroblastoma and osteosarcoma.

Leptomeninges

The spread is usually via the CSF pathways. Obliteration of the subarachnoid space with development of hydrocephalus is more common.

Parenchyma

Most common
- Cerebrum—80%
- Cerebellum—16%
- Brainstem—3%.

PATHOPHYSIOLOGY

Pagets Seed and Soil Theory

The first process in the formation of metastasis is tumour cell adhesion to the local extracellular matrix, cell locomotion and proteolysis, which is followed by invasion into lymphatics, venules and capillaries. This is followed by haematogenous embolism to distant sites and the tumour cells interact with various blood components to survive the hostile environment of circulation. Once again adhesion and extravasation should take place at the new host site. If the new host (soil) is conducive to proliferation of the cells (seed) then metastasis is established.[130]

MOLECULAR BIOLOGY OF BRAIN METASTASIS

Following any type of brain insult such as a lesion, stroke and tumour/cancer invasion, microglia are rapidly activated and recruited to the site of insult. Microglia is the main immune effector cell population of the CNS and control immune cell recruitment. However, the

molecular mechanism of BM and interaction between neuron-glia-tumour cells is poorly understood.[77]

The Hedgehog (Hh)/glioma-associated oncogene signalling network is among the most important and fascinating signal transduction systems that have critical functions in the regulation of many developmental and physiological processes involved in tumour progression. The target gene products induced through persistent Hh activation can contribute to the self-renewal, survival, migration and metastasis of cancer stem/progenitor cells and their progenies.[70]

The transcriptional regulator SnoN has a fundamental role as a modulator of signalling and responses by the transforming growth beta family (TGFb) of cytokines, though how SnoN regulates TGFb responses remains incompletely understood. Due to the critical and complex roles of TGFb in tumour genesis and metastasis, identification of novel SnoN regulatory and effector mechanisms holds the promise of advances being made at the interface of cancer biology and neurobiology.[92]

MOLECULAR GENETICS OF NON-SMALL CELL LUNG CANCER

Patients with non-small cell lung cancer (NSCLC) harbour mutations in the epidermal growth factor receptor (EGFR) that predict the unique sensitivity to EGFR tyrosine kinase inhibitors (TKIs). In NSCLC patients with BM, EGFR mutation status is associated with improved survival, independent of age, functional status, extracranial disease status and number of BMs.[37,104]

MOLECULAR GENETICS OF BREAST CARCINOMA

Aneuploidy is commonly observed in breast cancer and is associated with poor prognosis.[2] The frequently found type of aneuploidy is hypertetraploidy. The hypertetraploid progenies show increased metastatic potential to lung and brain, but not to bone, which may be partially explained by the distinct capillary structures in these organs that confer differential lodging advantages to tumour cells with enlarged size.[66] Hexokinase 2 (HK2) is important in glucose metabolism and apoptosis. The HK2 levels (both mRNA and protein) are elevated in brain metastatic derivatives.[82]

MOLECULAR GENETICS USING REAL TIME IMAGING

Using multiphoton laser scanning microscopy the single steps of metastasis formation in real time can be found out. The essential steps are arrest at vascular branch points, early extravasation, persistent close contact to microvessels and perivascular growth by vessel co-option (melanoma), or early angiogenesis (lung cancer). The inefficient steps differ between tumour types. Vascular endothelial growth factor-A inhibition induces long-term dormancy of lung cancer micrometastases by preventing angiogenic growth to macrometastases.[52]

The common neoplasms metastasing to the brain are carcinoma of the bronchus, breast, kidney, stomach, colon, prostate, thyroid, lymphomas and melanomas. In the fifth to seventh decades, the most common primary sites are lung, breast and skin.[60] In children, leukaemia is the most common followed by lymphoma.[118] Osteogenic sarcoma and rhabdomyosarcoma are the most common solid metastasis to the brain among children younger than 15 years.[30] Germ cell tumours are the most frequent cause between 15–21 years.[41] A review of some of the publications on BMs[8,17,28,29,42,61] shows the following trend in the frequency of primary sites: Bronchial adenocarcinoma (19–23%), squamous cell carcinoma of the lung (11%), breast cancer (5–19%), and melanoma (12%), followed by renal tumours, carcinomas of thyroid,[36] parotid, pancreas, testis and bladder. In about 18–37% of metastatic carcinomas, the primary is not traceable in spite of extensive investigation. Neoplasms of the reticuloendothelial system like lymphoma, Hodgkin's disease and leukaemia are also known to spread to the brain. In leukaemias and lymphomas meningeal deposits are well known.[89] Various types of sarcomas can cause cerebral metastases. Rarely, a glioblastoma of the spinal cord can spread to the brain through CSF pathways. Bronchogenic tumours and cancers of the breast that spread to the lung more commonly also exhibit a high incidence of BMs. Multiple metastases are common in melanoma, choriocarcinoma and small cell lung cancer. Single metastasis is common in breast, thyroid, renal cell, colon, as well as adenocarcinoma lung.[130]

Metastatic melanomas have the highest tendency for spontaneous haemorrhage. Secondary deposits may occur anywhere in the brain, but are more common in the supratentorial compartment. They may be single or multiple, small or large. Meningeal carcinomatosis results from metastatic deposits along the arachnoid.[112] This leads to vague neurological signs, symptoms and signs of raised intracranial pressure. Extensive meningeal enhancement in the absence of infection gives the clue on CT scan in a patient with known malignancy elsewhere in the body. This picture may also be seen in patients with leukaemia.

A patient with cerebral metastasis may present like a stroke due to tumour emboli in the blood vessels leading to cerebral infarction without any obvious deposit,[80] the aetiology becoming apparent only at autopsy. A metastasis in the pituitary may be missed at autopsy. It has been reported in 6% of all patients with cancer and in 20% of patients dying from carcinoma of the breast.

In an anatomical sense most of the secondaries in the brain are extracerebral as they are outside the blood-brain barrier. The majority of these lesions can be easily shelled out from the brain. A small lesion with extensive oedema and mass effect disproportionate to the lesion is generally indicative of metastasis though intracranial tuberculomas may produce an identical picture. The profound oedema is the result of breach of the blood-brain barrier and immunological barrier which incites a reaction in the surrounding brain tissue.

PATHOLOGY

On gross examination a secondary deposit is usually well circumscribed and spheroidal in shape.[98] The cut surface is pinkish-grey, granular and soft. Cystic degeneration and necrosis may be seen on CT scan.[135] Choriocarcinomas are haemorrhagic. Calcification has been noted in some metastases usually from the gastrointestinal tract and these have a relatively benign course.[47]

Histopathology

Histopathology of the lesion usually reflects the tissue of origin, i.e. the primary site. Occasionally, in anaplastic and undifferentiated metastases, the differential diagnosis will be highly anaplastic glioma, lymphoma, amelanotic melanoma[58] and a small round-cell tumour like a medulloblastoma. Immunohistochemistry will usually settle the issue.

Immunohistochemistry

The chemokine/receptor system CXCL12/CXCR4 plays a key role in multiple biological functions including homing of neoplastic cells from the primary site to the target and metastasis progression.[62] CXCL12 is expressed in tumour cells and in tumour vessels. CXCR7 is expressed by tumour and endothelial cells (both within the tumour and in the adjacent brain tissue).[20] CXCR4 showed positivity in all samples with a nuclear pattern. Among the investigated immunohistochemical parameters, only CXCL12 expression in tumour endothelial cells showed a statistically significant correlation with shorter survival, identifying more aggressive tumours.[102]

CLINICAL FEATURES

In a solitary cerebral metastasis, symptoms and signs of the cerebral lesion may precede those of the primary malignancy. In such cases, only after the tumour is removed at surgery, its true nature becomes apparent. Symptoms and signs depend on the site and size of the metastasic deposit. Metastases in the brain become symptomatic more often and earlier than in other organs such as liver and lungs, though the incidence is much higher in these organs. Increased intracranial pressure or focal signs may be the presenting feature.

The usual symptoms are headache, decrease in cognitive function, nausea and vomiting. Seizures occur less commonly in BM than in primary neoplasms.[115] Papilloedema is also common. Features of raised intracranial pressure are usually caused by cerebral oedema, but it can be present due to ventricular obstruction secondary to cerebellar and brainstem metastasis, and also obstruction of venous sinuses by the neoplasm.[116] Neuropsychological disturbances are common as the frontal lobe is a common site for secondary deposits (33%).[29] Metastasis from the highly vascular choriocarcinoma may present as a cerebrovascular accident due to tumour emboli dislodging from the pulmonary secondary, where the pulmonary lesion may be misdiagnosed as a primary lesion.[1]

Stroke like picture may also result from haemorrhage in the metastasis.[67] The duration of symptoms is often short with rapid progression.[117] This can be explained on the basis of extensive oedema associated even with small subcortical lesions.

Whenever a secondary deposit is detected in the brain, either pre-operatively or post-operatively on the basis of histopathology, a thorough search for the primary lesion is mandatory. In a patient with carcinoma of the breast, the suspected cerebral lesion may turn out as a meningioma.[54] Occasionally, because of high blood flow, meningiomas themselves may harbour metastases.[136]

INVESTIGATIONS

Computerised Tomography

On CT metastasis are isodense with abundant hypodense perilesional oedema disproportionate to their size.

Magnetic Resonance Imaging

On the non-enhanced T1-weighted magnetic resonance (MR) image metastases are hypointense to isointense compared to grey matter and are surrounded by vasogenic oedema.[53] They are hyperintense in T2 images.[25] Usually metastasis are located at the grey-white junction, often in watershed territories such as in the parieto-occipital regions.[130]

Magnetic Resonance Spectroscopy

Proton MR spectroscopic imaging is a non-invasive diagnostic tool for the investigation of cancer metabolism.[7] As an adjunct to morphologic and dynamic magnetic resonance imaging (MRI), it is used for the staging, assessment of treatment response, and therapy monitoring in brain, breast and prostate cancer. Recently, its application was extended to other cancerous diseases, such as malignant soft-tissue tumours, gastrointestinal and gynaecological cancers, as well as nodal metastasis.[88]

Positron Emission Tomography

High-grade and low-grade tumours, recurrence and radionecrosis can be distinguished by using positron emission tomography (PET) with fluorine–18. The PET does not distinguish secondary from primary neoplasms.[26] Several clinical reports have suggested that 18F-flouorodeoxyglucose PET is useful for detecting unknown primary tumours in patients with BM. The PET has incomparable abilities to determine the metabolic activity of tissues, but it needs the assistance of higher-resolution anatomic information. The CT is the easiest and highest-resolution tomographic modality to be integrated into PET imaging. Because of this, the market for PET devices has shifted so dramatically towards PET-CT.[48]

Whole-Body Magnetic Resonance Imaging

The advent of whole-body MRI (WB-MRI) has introduced tumour imaging with a systemic approach compared to established sequential, multi-modal diagnostic algorithms. Assessment of individual organs with various soft-tissue contrast, spatial resolution and contrast media dynamics can be combined with whole-body anatomic coverage in a multi-planar imaging approach. For initial tumour staging PET-CT as a competing whole-body modality in oncologic imaging has proved more accurate for the definition of T-stage and lymph node assessment, using the additional metabolic information of PET for the assessment of tumour viability and therapy response.

The WB-MRI has shown advantages for the detection of distant metastatic disease, especially from tumours frequently spreading to the liver or brain, and it is especially useful as a radiation-free alternative for the surveillance of tumour patients with multiple follow-up exams. Furthermore, it has been introduced as a whole-body bone marrow screening application. The WB-MRI is highly accurate for the detection of skeletal metastases and staging of haematologic diseases such as multiple myeloma or lymphoma.[105]

Using diffusion tensor imaging, metastasis can be differentiated from glioblastoma using metrics from the tumour volume and surrounding peritumoural oedema,[15] unlike the gradient-echo-planar perfusion-weighted imaging technique. Spin-echo (SE) planar perfusion weighted imaging enables cerebral blood volume maps select for blood volume in microvessels less than 8 micron in diameter. This helps to differentiate metastasis from glioma.[131]

DIFFERENTIAL DIAGNOSIS

- Primary brain tumour:[55] Meningioma, the most common primary intracranial tumour to be associated with breast carcinoma
- Brain abscess[59]
- Infarction and haemorrhage[40]
- Encephalitis
- Demyelinating lesion
- Resolving haematoma
- Radiation necrosis.[114,130]

TREATMENT

To select the appropriate therapy, one must consider the extent of the systemic disease, primary histology, and patient age and performance status, as well as the number, size and location of the BMs.[95] A tissue diagnosis is necessary when the primary tumour is unknown or the findings on CT/MRI are atypical.[111]

Ideal management of BMs requires simultaneous control of the existing BM (local brain control), prevention of future BM and control of the systemic cancer (systemic control).[119] The available tools include whole brain radiation therapy (WBRT), surgery, stereotactic radiosurgery (SRS), and systemic therapies, such as chemotherapies, biologic agents and radiosensitising agents.[119]

Medical Management

Dexamethasone is the corticosteroid of choice for cerebral oedema associated with metastasis as it has high glucocorticoid potency and minimal mineralocorticoid potency. Anticonvulsants should not be prescribed prophylactically.[111]

Treatment must be directed not only at the BM (definitive care), but also at a multitude of other symptoms that plague patients with BMs (supportive care). Judicious selection of pharmacologic agents and non-pharmacologic techniques can effectively treat many serious symptoms in patients with BMs, but injudicious selection of pharmacologic agents may have side effects and make the patient's quality of life worse.[32] A solitary cerebral metastasis in malignant disease poses a particular therapeutic challenge. The options consist of surgical resection, stereotactic radiation and total brain irradiation.[18,91] No significant therapeutic advantage for any of these methods has as yet been demonstrated in the literature.[127]

Surgery

Surgical excision of solitary metastases offers a good chance for reducing intracranial pressure and improving neurological deficits.[79] The incidence of solitary metastasis varies from 50 to 89%.[8,17,29,35] Renal cell carcinoma (RCC) is well known for manifesting with a single deposit, and in one series was seen in 10 out of 11 patients.[89] A notable feature was the long interval between the removal of the primary growth and occurrence of the deposit in the brain.[96,123] Surgical excision of a solitary lesion also helps in diagnosis, especially in cases where the primary has not been detected.[33] Surgical mortality is defined as death within 30 days of surgery and varies from 0 to 10% after resection of a single metastasis.[39]

The ideal candidates for surgical excision are:

- Patients with good performance status [Karnofsky performance scale (KPS)]
- Minimal or no evidence of extracranial disease
- Surgically accessible single BM amenable to complete excision.

To reduce the risk of tumour recurrence for patients who have undergone resection of a single BM, postoperative WBRT should be considered. The optimal dose and fractionation schedule for WBRT is 3,000 cGy in 10 fractions or 2,000 cGy in 5 fractions.[95] Surgical adjuncts such as bischloroethylnitrosourea (carmustine) wafers and the glia site radiation system may be useful in the future in achieving optimal local tumour control.[86]

Alternatives to surgical excision in solitary metastasis: WBRT followed by SRS should be considered.[11] The

evidence is insufficient to recommend SRS alone as a single-modality therapy.[71]

Factors influencing the risk of local recurrence after resection of a single BM are:

- Biological factors (such as tumour volume)
- Treatment (such as the resection method).

Early administration of post-operative WBRT may be particularly useful when negative tumour-related prognostic factors are noted.[83] Surgery should be considered in patients with up to three BMs, being effective in prolonging survival when the systemic disease is absent/controlled and the performance status is high.[111] Surgical resection followed by WBRT represents a superior treatment modality in terms of improving tumour control at the original site of the metastasis and in the brain overall, when compared to surgical resection alone.[49] Surgical resection plus WBRT and SRS plus WBRT, both represent effective treatment strategies, resulting in relatively equal survival rates.[49]

Further investigation and treatment of the primary may follow excision of the secondary.

Stereotactic biopsy of a solitary deep lesion in an eloquent area may be helpful in achieving the diagnosis. Debevec[28] reported complete removal in 22 out of 35 patients, partial removal in seven patients and biopsy in six patients. All their patients received post-operative irradiation. Delarine and de Tribolet[29] found solitary metastasis in 89% of their patients and reported total removal in 70%, sub-total removal in 19% and partial removal in 11% of patients. They gave post-operative WBRT.

The prognosis for long-term survival of patients operated for solitary cerebral metastasis depends on the site of the metastasis, the extent of removal, the age of the patient and the tissue of origin, the kidney being the most favourable.[126]

The effect of the concomitant therapy of gefitinib and WBRT[45] in patients with BMs is better than WBRT alone, and the concomitant therapy is well tolerated.[84] The dose of gefitinib is 150 mg/d and the radiotherapy dose is (3,000–3,600) cGy/(10–12) F.[133] Gefitinib is one of the small molecule inhibitors of the EGFR tyrosine kinase (EGFR TKIs). Gefitinib has been generally considered to be a relatively safe agent. Besides a small proportion of fatal interstitial pneumonia, the common adverse drug reactions of gefitinib include diarrhoea and skin rash, and occasionally haemorrhage.[129]

WBRT alone is the treatment of choice for patients with single or multiple BMs not amenable to surgery or radiosurgery. Chemotherapy may be the initial treatment for patients with BMs from chemosensitive tumours.[111]

Chemotherapeutic Regimen

In the TP regimen paclitaxol 175 mg/m^2 on day 1 and cisplatin 20 mg/m^2 on days 1–5 are given. The NP regimen consists of navelbine 25 mg/m^2 on days 1 and 8 and cisplatin 20 mg/m^2 on days 1–5. Gemcitabine 1 g/m^2 on days 1 and 8 and cisplatin 20 mg/m^2 on days 1–5 are given in the GP regimen. All regimens were repeated every 3 weeks. Each regimen must be given for at least two cycles and but not more than four cycles.[19] The third generation regimen-based sequential chemotherapy combined with WBRT was effective for NSCLC patients with BM with an encouraging survival and acceptable tolerability.[19]

Stereotactic Radiosurgery

SRS using the gamma knife or cyberknife has been employed for solitary cerebral metastasis. Lesions less than 3 cm in size can be targeted using 1,600–3,500 cGy in a single session and may be a safe alternative to surgical excision in old frail patients with associated medical conditions like diabetes and hypertension. Loeffler and Alexander have reported a survival rate of 88% as compared to 45% with WBRT alone.[22] Short hospital stay and lower steroid requirement is an added advantage. SRS provides good tumour control for small BMs from various primary cancers, with minimal untoward effects on surrounding normal brain. This excellent tumour control prevents neurological death and maintains good activity of daily life.[106]

The cyberknife can greatly raise the fractional dose of SRS, thus improving its clinical efficacy.[46] Cyberknife has produced perfect clinical outcomes by using a higher dosage per fraction. It is an appropriate and valid treatment shortcut for BM.[123]

Radiosurgery is an effective and safe minimally invasive option for patients with BMs from an unknown primary site.[76] Image-guided radiosurgical treatment of BMs resulted in high rates of tumour control comparable to control rates reported for frame-based methods. High control rates were seen for small lesions in which spatial precision in dose delivery is critical.[18] The combined treatment of SRS and WBRT is effective in the control of brainstem metastasis, improving the neurological symptoms and, therefore, early diagnosis and treatment is important.[103] Gamma knife SRS is a safe and feasible strategy for treatment of patients with a single radioresistant BM. Radiosurgery alone is a reasonable treatment option, but may carry a greater likelihood of distant brain recurrence.[21]

Surgery is indicated in patients with a single lesion located in an accessible zone and SRS is indicated for lesions up to 3 cm in diameter, and in patients with up to three or four metastasis, no matter their location.[101]

In those patients with symptomatic mass effect after radiosurgery, resection may be warranted. Patients who have delayed local progression after SRS (greater than 3 months) have the best outcomes after resection.[51]

PROGNOSIS

In the short-term, extent of resection of the metastasis (complete or incomplete), location (supratentorial or infratentorial) and size of the metastasis were found to be statistically significant factors in predicting prognosis.[128]

Prognostic Factors Associated with Better Survival

- KPS higher than 70
- Solitary BM[100]
- Age less than 65 years
- Controlled primary tumour and no extracranial metastasis.[19]

Lung Metastasis to Brain

Aggressive treatment, including resection of both metastasis and primary tumour, has been found useful in patients with NSCLC with synchronous solitary BM.[31] Involvement of mediastinal lymph nodes is considered a poor prognostic factor and a contraindication to surgical resection of the primary lung tumour after treatment for BM.[107] A high carcinoembryonic antigen serum level is a risk factor for BM development and is associated with a poor prognosis in patients with advanced NSCLC.[4]

Factors leading to a good prognosis:

- Absence of mediastinal lymph node involvement
- Surgical resection of NSCLC with complete resection of the BM
- Low CEA levels at presentation[57]
- Response to pre-operative chemotherapy before focal treatment
- A high KPS.[73]

Breast Metastasis to the Brain

The prognosis of BMs from breast cancer is poor, especially in patients with HER-2 and TN subtypes.[121] Usually WBRT in combination with chemotherapy is the standard treatment modality.[6] In HER2+ breast cancer, trastuzumab has been shown to be very effective, although it cannot cross the blood-brain barrier.[13]

Novel biologic agents like lapatinib, which is the most promising, are currently being investigated in the treatment of BMs of breast cancer with promising results.[5]

Germ Cell Tumour Metastasis to the Brain

Although most patients with BM have a poor clinical outcome, aggressive local treatment and employment of novel anticancerous agents may contribute to improve the clinical course in selected patients with germ cell tumours and BM. Testicular germ cell tumours with BMs can be managed with the combination of WBRT, stereotactic radiotherapy, and/or surgical resection in combination with chemotherapy.[78]

Chemotherapy consisting of irinotecan and nedaplatin resulted in normalisation of the tumour markers and complete remission was proved by the subsequent surgical resection.[68]

Renal Metastasis to the Brain

Surgical resection and/or radiosurgery contribute to prolonged survival. Systemic treatment might play a role in the management of these patients. Recent advances like immunotherapy, angiogenesis inhibition and other signal transduction inhibitor approaches might be helpful.[75]

Patients with metastatic RCC should undergo CNS screening to allow the identification of smaller lesions that are more amenable to treatment.[122] Those patients with solitary metastasis are less likely to develop CNS recurrence after local therapy. Selected patients with good performance status may exhibit prolonged survival and should be offered aggressive therapy.[108]

Melanoma Metastasis to the Brain

WBRT, microsurgery and radiosurgery alone or in combination is the treatment of choice for patients with BM from a melanoma.[69] Chemotherapy has been ineffective.[109]

RECENT ADVANCES

The molecular targeting of distinct deregulated gene products, including Hh and EGFR signalling components and other signalling elements that are frequently deregulated in highly tumourigenic cancer-initiating cells and their progenies, might constitute a potential therapeutic strategy to eradicate the total cancer cell mass.[70]

MULTIPLE METASTASES

The decision to treat or not, and how to treat metastases when multiple is difficult. One of the large life-threatening symptomatic metastasis in a young patient may be removed, followed by WBRT if the primary neoplasm is known to be radiosensitive.

Steroids and diuretics are helpful in alleviating symptoms by reducing the oedema surrounding the lesions. In terminal cases, steroids can be used with good effect; of course the side effects may dictate the cessation of therapy. This may be followed by remission for a few months. The radiation therapy oncology group[6] has demonstrated that high dose fractionated therapy 2,000 cGy in 1 week or 3,000 cGy in 2 weeks is quite effective in palliation. This is based on the assumption that even if primary investigations have revealed a single lesion and the operative removal of a solitary lesion has been complete, there always exist multiple microscopic undetected metastases.[27,110]

However in a small series of patients, no difference in survival has been found in patients who did and did not receive radiation after resection of a solitary lesion.[34] When the primary is unknown in a patient with multiple cerebral metastases, stereotactic biopsy will be required to confirm the diagnosis.

RECURRENCE OF BRAIN METASTASIS

The probabiltity of local or distant recurrence in the brain after local excision and radiotherapy for single metastasis is 10–20%. The rate of distant metastasis in the absence of radiotherapy is 30–40%. The median time to recurrence is 5–7 months.[9]

MENINGEAL CARCINOMATOSIS

Meningeal carcinomatosis refers to diffuse metastasis in the leptomeninges by systemic cancer. Saenger (1900) and Lilienfeld and Benda (1901) described it.[63] The most frequent primary sites are the breast and lung.[64] Malignant melanoma is the third most common primary tumour.[72] This condition is distinct from both metastatic deposits that occur in the substance of the brain and spinal cord and nodular deposits in the dura. Meningeal carcinomatosis is characterised by a diffuse widespread involvement of the meninges by carcinomatous infiltration.[65] The dura appears thickened over a wide area both at the base of the brain as well as the vault. This may occasionally cause occlusion of the CSF circulation leading to hydrocephalus. The patients are also known to present with pseudotumour cerebri as is seen in leukaemic deposits of the meninges.[56]

Aetiopathogenesis

The aetiopathogenesis of this condition is not clear; the CSF may be involved via the choroid plexus which may be affected by the malignancy.[74,81] A deposit in the nerve root or the surface of the brain may spread along the leptomeninges. Lymphomas may metastasise exclusively to the leptomeninges. Meningeal carcinomatosis is a better term than neoplastic meningitis. Lymphocytic leukaemia, non-Hodgkin's lymphoma, carcinoma breast, carcinoma lung and melanoma are reported to spread in this manner.[124] Spread may occur via the venous route from the Batson's plexus.[81]

Clinical Features

Because the symptoms resemble a meningeal infection, it has also been referred to as carcinomatous meningitis. There may be cranial nerve palsies and if the spinal dura is involved, the patient may present with paraparesis.[44] Olson et al.[81] have classified the symptoms as cerebral, cranial and spinal. They may antedate any symptoms of malignancy and, therefore, may be confused with tuberculous meningitis, cysticercosis, cryptococcal meningitis or sarcoidosis.

Investigations

Cerebrospinal Fluid Analysis

The diagnosis is confirmed by CSF examination, sometimes with the help of multiple filters to filter the CSF, or examining a centrifugate revealing carcinomatous cells will clinch the diagnosis.

Computerised Tomography/Magnetic Resonance Imaging

The MRI shows nodular contrast enhancement lining the CSF. There may be hydrocephalus as well.[113] Gadolinium-enhanced MRI will show neoplastic spread involving the spinal cord and spinal nerves.[132]

Unenhanced fluid-attenuated inversion recovery (FLAIR) images are of more value than SE T2-weighted images for the diagnosis of intracranial meningeal carcinomatosis. Contrast-enhanced FLAIR images are more useful than contrast-enhanced T1-weighted images in their quality.[120]

Meningeal Biopsy

It is helpful when the diagnosis is strongly suspected and clinical and other investigations fail to demonstrate it.

Staging of leptomeningeal metastasis requires contrast-enhanced brain and spine MRI and radionuclide CSF flow study.[16]

Treatment

- Irradiation of part or of entire neuraxis[87]
- Chemotherapy (methotrexate, cytosine arabinoside and thiotepa).[10]

Intra-CSF drug therapy primarily utilises one of three chemotherapeutic agents (e.g. methotrexate, cytosine arabinoside and thiotepa) administered by a variety of schedules either by intralumbar or intraventricular drug delivery.[16]

A good prognosis is possible in the following:

- Lymphomatous or leukaemic meningitis
- Chemosensitive tumours such as breast cancer
- Low tumour burden
- Minimal neurological deficits
- Good performance status
- Controllable systemic disease.

Recent Advances

Novel intra-CSF agents, such as targeted monoclonal antibodies rituximab (anti-CD20 for B-cell lymphoma-related leptomeningeal metastasis) and trastuzumab (anti-Her-2/neu for breast cancer-related leptomeningeal metastasis) are being utilised now.[16]

Treatment is largely palliative (median survival 2–4 months). The prognosis for meningeal carcinomatosis is gloomy. However, Olson et al.[81] have reported that with early diagnosis it is possible to eradicate the disease with radiotherapy and intrathecal methotrexate as done in leukaemia.

CARCINOMATOUS ENCEPHALOPATHY

Neurological signs of encephalopathy or myelopathy may appear when there is an occult malignancy elsewhere in the body.[12] Sensory neuropathy[23] and proximal myelopathy in the elderly may be seen. This is known as carcinomatosis neuromyeloencephalopathy.[43]

This may be the first manifestation of an occult malignancy in the body and is described as a non-metastatic manifestation with an immunological basis for its pathogenesis. Central pontine myelinolysis may occur as a reaction to a systemic tumour.[97] Histological examination of the brain in these cases reveals neuronal

loss, gliosis and tract degeneration without any evidence of infiltration by malignant cells. The immunological mechanisms involved in carcinomatous neuromyopathy have been described by Paty et al.[85]

141 Radiation Therapy for Malignant Brain Tumours

Julka PK, Haresh KP, Rath GK

INTRODUCTION

According to the Globocan 2002, cancers of the brain and nervous system account for some 189,000 new cases and 142,000 deaths annually (1.7% of new cancers; 2.1% of cancer deaths). The corresponding figures for India are 19,680 and 16,086, respectively. The highest rates are observed in developed areas (Australia/New Zealand, Europe and North America) and are lowest in Africa and the Pacific Islands.[49] Surgery is the primary modality of treatment for the majority of primary brain tumours. Radiotherapy is an essential component in the management in most of them after a maximal safe surgical resection. Radiotherapy can be delivered by fractionated external beam irradiation, small field stereotactic irradiation or by interstitial implantation. Current regimens generally use 50–60 Gy delivered in 25–30 fractions over 5–6 weeks. Regimens with either higher dose or more than 2 Gy per fraction are associated with late neurotoxicity.

Radiation treatment volumes for these tumours generally include the enhancing volume (which contains solid tumour tissue), surrounding oedema (which is comprised of normal brain infiltrated by microscopic tumour) and a margin of normal brain. Thus, even with the use of very conformal techniques, a substantial amount of "normal" brain is included in the full dose volume. One should remember that the volume of normal brain irradiated should be kept to a minimum, in order to decrease the late side effects. The tolerance of normal brain (and spinal cord in the case of cord tumours) is the major limiting factor in achieving local control and cure. Tolerance dose is usually expressed as TD5/5 and TD 50/5. "TD 5/5" is the dose that leads to 5% risk at 5 years. "TD 50/5" is the dose that leads to 50% risk at 5 years. TD 5/5 and TD 50/5 values for whole-brain fractionated radiotherapy at 2 Gy per fraction are 60 Gy and 70 Gy, respectively. With partial brain irradiation, the corresponding values are 70 Gy and 80 Gy, respectively. For tumours with high-risk to spread to the CSF space, elective irradiation of the whole craniospinal axis with localised boost to the area of gross tumour is necessary.

Adverse reactions associated with cranial irradiation include: (1) acute reactions; and (2) late reactions.

Acute reactions: A transient worsening of pre-treatment symptoms can occur due to peritumoral oedema. This is very well managed by corticosteroids. Other acute side effects include nausea, vomiting, skin discolouration, alopecia, otitis externa, serous otitis media, fatigue, mucositis, oesophagitis (last two only in craniospinal irradiation) and haematologic toxicity.

The late sequelae include:

- Radiation necrosis, which can mimic a recurrent tumour both symptomatically and on radiology.
- Auditory apparatus damage can occur due to the inclusion of the middle or inner ear in the field.
- Visual disturbance can occur due to damage to the eye, optic nerve or chiasm.
- Endocrine dysfunction due to damage to the hypothalamo-pituitary axis
- Neuropsychological changes.

RADIOTHERAPY TECHNIQUES

Proper immobilisation is necessary for better planning. One can restrict the clinical target volume (CTV) to planning target volume (PTV) margins, only if proper and reproducible immobilisation is done. The most important aspect in stereotactic radiotherapy and stereotactic radiosurgery is the superb immobilisation that is used in these situations. Depending on the condition, the radiotherapy may be partial brain, whole brain or craniospinal. Initially, people used simple two-dimensional planning with point dose calculation. Patients were treated by parallel opposed portals, ipsilateral wedge fields, a combination of vertex and wedge fields, etc. With the advancement in computer technology and treatment planning systems, we moved to three-dimensional conformal radiation (3DCRT) and now to intensity modulated radiotherapy (IMRT). In 3DCRT, we limit the dose to much of the normal structures, focusing the beams to the target. IMRT is a further refined conformal radiation where we can modulate the intensity of the beam by further restricting the dose to normal brain and adequately treating the involved region. Non-coplanar beams are also used in the treatment of brain tumours, especially in stereotactic radiotherapy (SRT) and stereotactic radiosurgery (SRS). Craniospinal irradiation needs considerable expertise as it involves different techniques of field matching.

Stereotactic Radiosurgery

It involves the combined work of the neurosurgeon, radiation oncologist and physicist. SRS can be delivered using a Gamma Knife or a linear accelerator. Gamma Knife contains 201 cobalt-60 (^{60}Co) sources and it is collimated using a helmet with circular apertures ranging from 4mm to 18 mm focusing a single point. Linac based radiosurgery can be either cone-based or multileaf collimator-based. The treatment is delivered using multiple non-coplanar arcs that intersect at a single point to treat a tumour of less than 4 cm in diameter.

Stereotactic Radiotherapy

It is delivered using a linear accelerator. A fractionated schedule is followed maintaining the precision targeting techniques of SRS. Either cone or MLC with non-coplanar beams are used as in the case of SRS.

TREATMENT OF INDIVIDUAL TUMOURS

Gliomas

High-Grade Gliomas (Anaplastic Astrocytoma, Glioblastoma Multiforme)

They are highly aggressive tumours that have a characteristic ring like enhancing appearance on CT/MRI with central necrosis, infiltrative margins and surrounding low density changes. They account for 35–45% of adult brain tumours. They can occur in any age group but the peak incidence is in the fifth and sixth decade of life. Of the high-grade gliomas, glioblastoma multiforme (GBM) constitute 85% and anaplastic astrocytoma (AA) constitute 10–15%. These tumours typically infiltrate the adjacent normal structures. Halperin compared antemortem CT scan findings with postmortem topographic distribution of tumour cells and found that radiotherapy with fields designed to treat the contrast enhancing region alone or this region plus "oedema" with a tight margin will frequently miss tumour, whereas a 3 cm margin around the "oedema" would have covered histologically identified tumour in all cases.[26,28]

Surgery is never complete in high-grade gliomas. Even macroscopic complete removal is possible in 10–20% of cases only. One needs to add post-operative radiotherapy in these cases. The less the residual tumour after surgery, the better is the prognosis. Radiotherapy has been used in malignant gliomas for the last six decades. The first randomised trial to demonstrate the benefit of RT is the BTSG 69-01. Walker et al. in the randomised control trial, evaluated the role of radiotherapy in the treatment of anaplastic gliomas. Median survival of patients in this study is as follows:

- Best conventional care: 14 weeks;
- BCNU: 18.5 weeks;
- Radiotherapy: 35 weeks; and
- BCNU plus radiotherapy: 34.5 weeks.[72]

The second one is the SGSG, Scandinavian Glioblastoma Study Group trial, where the median survival rates of patients were 10.8 months in the radiotherapy group versus 5.2 months in the supportive care group.[36,43]

RT can only delay the disease progression or recurrence. Almost all GBMs and 65–80% of AA recur within 2–5 years and lead to death. Garden studied the patterns of recurrence in these tumours and found that recurrence almost always occurs in the central or enhancing portion of the tumour.[20] Perhaps the central tumour is radioresistant because of hypoxia. Several trials tried to overcome this by using hypoxic cell sensitisers[9,42] and by different techniques like interstitial brachytherapy, SRT, etc. Altered fractionation schedules were also tried by many authors to improve survival. Hyperfractionation,[18,27,42] acceleration[7,23,39,40] and hypofractionation all did not prove to be of benefit. Boost with radioactive implants also did not reveal any added advantage.[37,57]

Dose of Radiotherapy

Results from BTSG 69-01 and two successive BTSG studies were pooled together to evaluate the median survival for 60 Gy versus 50 Gy. It was 10.5 months versus 7 months (p=0.004).[73] The MRC trial compared 45 Gy with 60 Gy and suggested a statistically significant prolongation of median survival from 9 months in the 45 Gy group to 12 months in the 60 Gy group (hazard ratio = 0.75).[4] RTOG 7401/ECOG 1374 study showed that there is no added survival advantage by escalating the dose to 70 Gy.[9] So the present standard dose is 60 Gy in conventional fractionation.

Volume of Irradiation

It was assumed that it was impossible to accurately localise these tumours because of inadequate imaging modalities available and the tendency of these tumours to infiltrate the surrounding brain. So, initial studies treated patients with parallel opposed lateral portals and treated whole brain. Hochberg et al. evaluated CT scans, performed on glioblastoma patients within 2 months of postmortem examination and showed that CT defined both gross and microscopic tumour extent within a 2 cm margin in the majority of patients evaluated. Serial CT scans revealed that glioblastoma recurred within a 2 cm margin of the primary site in 90%.[29] Wallner et al. showed that 78% of unifocal tumours recurred within 2.0 cm of the pre-surgical, initial tumour margin, defined as the enhancing edge of the tumour on CT scan.[74] The present standard is to take the tumour (enhancing T1 contrast volume on MRI) and oedema (Flair or T2 abnormality) with an added margin of 2–3 cm around.

Role of Chemoradiation

Chemotherapy is mainly added as a radiosensitiser. The main concern in brain tumours is that to be active, the chemotherapeutic agents must reach the brain crossing

the blood-brain barrier. The chemotherapeutic agents that are used include the nitrosoureas-CCNU, BCNU, Procarbazine, etc. We have published the results of concurrent chemoradiation with Paclitaxel in 18 cases of glioblastoma. The overall 1-year survival rate was 70%, with 12 patients alive at 13 months.[32,38]

The newer drug is temozolomide, which is a lipophilic second-generation alkylating agent. At physiological pH, it is converted into MTIC. Stupp et al. conducted an open-label, phase II trial in GBM in which Temozolomide (75 mg/m^2/d x 7 d/wk for 6 weeks) was administered orally concomitant with fractionated radiotherapy (60 Gy total dose: 2 Gy x 5 d/wk for 6 weeks), followed by temozolomide monotherapy (200 mg/m^2/d x 5 days, every 28 days for six cycles).[64] They observed that concomitant radiation plus temozolomide therapy was safe and well tolerated. Median survival was 16 months and the 1-year and 2-year survival rates were 58% and 31%, respectively. This regimen of concomitant chemoradiotherapy followed by adjuvant chemotherapy prolonged the survival of patients with glioblastoma. Jalali et al. studied 42 patients of glioblastoma treated with a similar approach. At a median follow-up of 12.5 months, they observed 1-year and 2-year survival of 67% and 29%, respectively. The median overall and progression-free survival was 16.4 and 14.9 months, respectively.[31]

Based on randomised data available, chemotherapy has consistently failed to improve the outcome of patients with anaplastic astrocytoma, while a meta-analysis showed a small, but significant improvement in survival favouring the use of chemotherapy. Outside a clinical trial, post-operative radiotherapy (30 x 2Gy) remains the standard adjuvant therapy for most patients.[65]

Brachytherapy

Permanent or temporary I-125 or temporary Ir-192 sources can be after loaded into catheters placed in the tumour bed. The catheters can be placed either during craniotomy or stereotactically. This can be used as a boost dose after external beam radiation in glioblastoma. Most trials are limited to supratentorial tumours less than 6 cm and that do not involve the corpus callosum. Only some authorities showed a slight advantage.[24]

Low-Grade Gliomas

Low-grade gliomas account for approximately 20% of gliomas and approximately 10% of all primary intracranial tumours in adults. This is constituted by low-grade astrocytomas 67%, mixed oligoastrocytomas 19% and oligodendrogliomas 13%. Astrocytomas are well differentiated tumours. They show increased cellularity and mild to moderate pleomorphism. The presence of microcysts differentiates it from reactive gliosis. The different subtypes of astrocytomas include the fibrillary, protoplasmic, gemistocytic and pilocytic ones. They are differentiated by the intracytoplasmic fibrillary processes, which stain with GFAP. With time, 50% of the fibrillary and protoplasmic types transform to more anaplastic ones. Since the majority of the gemistocytes transform to highly anaplastic ones and behave in an aggressive fashion, they should be treated like anaplastic astrocytomas. Pilocytic astrocytomas have a long natural history and rarely dedifferentiate into more malignant ones. The biologic behaviour of the different astrocytomas varies considerably. This can be predicted to an extent by the DNA labelling index,[29] which shows the proliferative potential of a cell.

The majority of low-grade gliomas are present with seizures without any neurologic symptoms. Other presentations include headache, vomiting, motor deficit, visual or sensory loss, language deficit or personality changes.[2] Pilocytic astrocytomas grow by expansion, while non-pilocytic ones diffusely infiltrate the surrounding structures like malignant gliomas.

Complete resection is the treatment of choice for pilocytic astrocytomas. Post-operative radiotherapy is indicated only in incompletely resected tumours. Complete resection is associated with excellent survival with more than 90% cured of the disease, whereas incomplete resection is associated with 10-year cure rates of 70–80%.[58]

In non-pilocytic astrocytomas (Grade 2 gliomas), the initial treatment is surgery. Since these tumours are diffusely infiltrative, complete resection is rarely possible. The dose and timing (immediate versus delayed) of post-operative radiotherapy in grade 2 gliomas is debated. In EORTC 22844,[33] 379 adult patients with cerebral LGGs were randomised centrally at the EORTC Data Centre to receive irradiation post-operatively (or post-biopsy) with either 45 Gy in 5 weeks or 59.4 Gy in 6.6 weeks. With 343 (91%) eligible and evaluable patients followed-up for at least 50 months with a median of 74 months, there is no significant difference in terms of survival (58% for the low-dose arm and 59% for the high-dose arm) or the progression free survival (47% and 50%) between the two arms of the trial. In EORTC 22845,[68] after surgery, LGG patients from 24 centres across Europe were randomly assigned to either early radiotherapy of 54 Gy in fractions of 1.8 Gy or deferred radiotherapy, until the time of progression (control group). One hundred and fifty-seven patients were assigned early radiotherapy and 157 controls. Median progression-free survival was 5.3 years in the early radiotherapy group and 3.4 years in the control group (hazard ratio 0.59, 95% CI 0.45–0.77; p<0.0001). However, overall survival was similar between the groups: median survival in the radiotherapy group was 7.4 years compared with 7.2 years in the control group (hazard ratio 0.97, 95% CI 0.71–1.34; p=0.872). In the control group, 65% of patients received radiotherapy at progression. At 1 year, seizures were better controlled in the early radiotherapy group. An intergroup study conducted by the North Central Cancer Treatment Group (NCCTG), Radiation Therapy Oncology Group (RTOG) and Eastern Co-operative Group (ECOG) randomised 211 adults to low versus high-dose RT. There was no difference in the 5-year OS or PFS rates between

the two dose groups in either study.[60] The Southwest Oncology Group (SWOG) study randomised 60 adults with incompletely resected LGG to RT alone or RT plus lomustine (CCNU) chemotherapy. There was no difference in outcome between the two treatment arms. Five-year overall survival (OS) and progression-free survival (PFS) rates in low-grade gliomas ranged from 58 to 72% and from 37 to 55%, respectively.[60] Our institutional policy presently is to deliver immediate post-operative radiotherapy for Grade 2 gliomas with a dose of 50 Gy in 25 fractions over 5 weeks delivered to the Flair or T2 abnormality on MRI with a margin of 1–1.5 cm, followed by a boost of 6 Gy in three fractions to the gross tumour without margin.

Brainstem Gliomas

Brainstem gliomas (Table 1) occur in the pons, the midbrain or the medulla. The tumour may contiguously involve the cerebellar peduncles, cerebellum and/or thalamus. About two thirds of brainstem gliomas occur in children. The survival and prognostic factors are entirely different for adults compared with children. The majority of childhood brainstem gliomas are diffuse pontine gliomas, which have a very poor prognosis. Focal pilocytic astrocytomas have a better prognosis. They most frequently arise in the tectum of the midbrain, focally, within the pons or at the cervicomedullary junction. Generally, the diagnosis is made radiologically and biopsy is not mandatory. The tumours of the midbrain, especially in the tectal plate region, are usually low-grade and have a greater likelihood of long-term survival (approximately 80% 5-year progression-free survival vs less than 20% for tumours of the pons and medulla).

The standard treatment for children with diffuse intrinsic pontine glioma is radiation therapy to involved areas, but 90% of patients will die within 18 months of diagnosis. The conventional dose of radiation therapy ranges between 5,400 cGy and 6,000 cGy given locally to the primary tumour site in daily fractions of 1.8 Gy. The utility of chemotherapy in the treatment of patients with newly diagnosed diffuse pontine gliomas is unproven.[1,8,15,76] To date, neither adjuvant or neoadjuvant chemotherapy nor immunotherapy when added to radiation therapy, has been demonstrated to improve survival for children with diffuse intrinsic pontine glioma. High-dose therapy with stem cell rescue also failed to extend the survival.[6]

In focal or low-grade brainstem gliomas, maximal surgical resection should be attempted, followed by adjuvant radiotherapy.[69] Mehta et al. have recently published a series of focal intrinsic brainstem gliomas treated initially with surgery. They have also proposed a surgical strategy oriented classification. The intrinsic brainstem tumours were classified into three types: Expanding, diffuse infiltrative and pure ventral varieties. Surgical intervention in the expanding variety was associated with excellent long-term prognosis. The other two varieties were associated with poor outcome and the authors recommend that they should be subjected to radiotherapy only.[39] Patients with small tectal lesions and hydrocephalus but no other neurological deficits may be treated with cerebrospinal fluid diversion alone and have follow-up with sequential neuroradiographic studies, unless there is evidence of progressive disease.[69]

Ependymomas

Ependymomas (Table 2) occur in both adults and children. The peak incidence is at 5 years and 34 years. In adults, approximately 33% of ependymomas arise infratentorially and 66% arise supratentorially; the opposite is true in children. It is classified into ependymomas (low-grade) and anaplastic ependymomas (high-grade) according to WHO classification. The 5-year survival ranges from 60 to 80% in low-grade versus 10 and 47% in high-grade tumours. They usually originate in the ependymal linings of the ventricles in the posterior fossa or supratentorial region and have access to the cerebral spinal fluid (CSF) and, therefore, may spread throughout the entire neuraxis. These tumours can cause hydrocephalus and increased intracranial pressure, mimic brainstem lesions, cause multiple cranial nerve palsies, produce localising cerebellar deficits and cause neck stiffness and head tilt if they infiltrate the upper portion of the cervical cord. Every patient with ependymoma should be evaluated with diagnostic imaging (CT/MRI) of the spinal cord and whole brain. In addition, CSF cytological evaluation should be conducted.

Patients with totally resected tumours tend to have the best prognosis. Surgery should be performed in an attempt at maximal tumour reduction. Supratentorial ependymomas generally have a poorer prognosis than their infratentorial counterparts. Radiotherapy significantly improves tumour control and survival. The volume of CNS to be irradiated is controversial. Many authors recommend the inclusion of the entire craniospinal axis

Table 1: Selected studies of brainstem gliomas in adults

or whole brain in the treatment of anaplastic ependymomas.[75] In a review by Vanuytsel et al. the spinal seeding was 9.5% (15/157) in the event of failure at the primary site compared to 3.3% (4/122), when local control was achieved and the development of spinal metastases was not influenced by the extent of irradiation. Spinal metastases are not prevented by prophylactic spinal irradiation, regardless of tumour grade and site.[70] With the availability of MRI to detect involvement of the spine, it is generally agreed that one can go ahead with local RT even in anaplastic ependymomas, unless the spine or CSF are involved.

The treatment algorithm for adult ependymomas revolves around histology, extent of surgical resection and extent of disease in the craniospinal axis. Patients with a well differentiated ependymoma who have undergone a gross total resection and have a negative screening spinal MRI scan, may be treated by limited-field radiation. However, if a contrast enhanced spinal MRI scan reveals disease, craniospinal irradiation should be administered. In patients with anaplastic ependymoma, if the spinal MRI scan is negative, limited-field RT is normally given. However, if the spinal MRI scan is positive, craniospinal irradiation is indicated.

Based on dose-response analyses for ependymomas, the typical radiation dose is between 50 Gy and 55 Gy locally using 1.8–2.0 Gy per fraction.[71] For a low-grade ependymoma, the usual dose is 54 Gy to tumour plus 2 cm margin. For a high-grade ependymoma, it is 60 Gy to tumour plus 2–3 cm margin. If CSI is used, then the entire craniospinal axis receives 36 Gy and the tumour with margin is boosted for the rest of the dose.

Ependymomas do not appear particularly responsive to chemotherapy. However, chemotherapy is sometimes considered as a salvage option to best supportive care in cases of recurrence.

Medulloblastoma

Medulloblastoma is the most common type of malignant brain tumour in childhood (peak 5–10 years). About 15–20% of cases occur in adults. It belongs to the group of tumours known as primitive neuroectodermal tumour, which is a highly malignant, small round blue cell tumour of the central nervous system. This tumor usually originates in the cerebellum. It may spread contiguously to the cerebellar peduncle, floor of the fourth ventricle, into the cervical spine or above the tentorium. In addition, it may spread via the cerebrospinal fluid intracranially and/or to the spinal cord. The incidence of CSF spread at diagnosis is 10–15%.

The work up investigations include contrast enhanced MRI of the brain and whole spine and CSF cytology. A bone scan as well as a bone marrow aspiration and biopsy may be useful in symptomatic patients or in those with abnormal blood cell counts at diagnosis. Two major risk categories are now being used:

1. Average risk: Children older than 3 years with posterior fossa tumours; tumour is totally or near-totally (<1.5 cc's of residual disease) resected; no dissemination.
2. Poor risk: Children 3 years old or younger or those with metastatic disease and/or subtotal resection (>1.5 cc's of residual disease) and/or non-posterior fossa location.

The patients should undergo maximal resection. The traditional post-surgical treatment for these patients has been radiation therapy consisting of 5,400–5,580 cGy to the posterior fossa and approximately 3,600 cGy to the entire neuraxis (i.e. the whole brain and spine). The standard boost in medulloblastoma is the entire posterior fossa. Some studies suggest that a tumour-bed boost would be equally effective.[17] Thomas et al. reduced the dose to the neuraxis without adding chemotherapy and found that reduced-dose neuraxis irradiation (23.4 Gy) is associated with increased risk of early relapse, early isolated neuraxis relapse and lower 5-year EFS and overall survival than standard irradiation (36 Gy).[66] But the lower radiation dose to the neuraxis (2,340 cGy), when coupled with chemotherapy, has been shown to result in disease control in up to 80% of patients and may decrease the severity of neurocognitive sequelae.[19,46,47,54]

In poor-risk patients, the addition of chemotherapy has improved the duration of disease-free survival. Some studies show that approximately 50–60% of such patients will experience long-term disease control.[13,48] Children younger than 3 years are particularly susceptible to the adverse effect of radiation on brain development. Debilitating effects on growth and neurologic development have frequently been observed, especially in younger children. For this reason, chemotherapy is administered to delay the administration of radiation

therapy. Different chemotherapeutic regimens have been employed and most have utilised an alkylator (cyclophosphamide or ifosfamide), cisplatin and/or carboplatin, oral or intravenous etoposide and vincristine. Outcome of such treatment has been relatively disappointing, resulting in disease control in only 20–30% of patients.[12] High-dose chemotherapy and autologous stem cell rescue is also tried in children less than 3 years.[67]

The treatment of medulloblastoma in adults is similar to that of children. The management is by surgery followed by radiotherapy to the neuraxis. Chemotherapy is added for poor-risk patients. The 5-year survival ranges from 46 to 78% and the 10-year rates from 38 to 55%, as shown in the Table 3.

Primary Central Nervous System Lymphoma

Primary central nervous system lymphoma (PCNSL) is a rare form of non-Hodgkin's lymphoma (NHL) that is restricted entirely to the brain, leptomeninges, eyes and rarely the spinal cord, without systemic disease. It accounts for 0.5–2% of all primary brain tumours. This disease is seen more commonly among patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised states. Primary central nervous system lymphoma is probably a substantially different disease in persons with and without AIDS with regard to patient characteristics, clinical and radiographic presentation and prognosis.[14]

More than 50% of the lesions on computed tomographic (CT) scans in patients with AIDS are ring-enhancing and multifocal, a pattern rarely described in immunocompetent patients. Patients without AIDS almost always show only homogeneous enhancement.[14] A periventricular, diffusely enhancing lesion on magnetic resonance imaging (MRI) is suggestive of primary CNS lymphoma.[41] Tumours are often periventricular and may involve ependymal lining cells or, if more peripherally located, may extend to the leptomeninges. Leptomeningeal involvement may remain localised to adjacent parenchymal sites or can be more diffuse with positive CSF cytology. Ocular involvement may develop independently in 10–20% of primary CNS lymphoma patients with primary brain disease. Less often, the tumour arises within the eye as the initial manifestation of primary CNS lymphoma. In rare cases, the spinal cord parenchyma may be an initial or secondary site of primary CNS lymphoma.

The work up investigations include haemogram, liver and kidney function tests, HIV, chest X-ray, MRI of brain and spine, and a biopsy from the lesion (preferably a stereotactic biopsy). If there is no risk of herniation, a lumbar puncture with evaluation of CSF is recommended. An ophthalmologic evaluation including a slit-lamp examination should be done to exclude an obvious malignant uveitis. If there is a reasonably high suspicion of primary CNS lymphoma, it is preferable not to start therapy empirically with steroids, unless medically indicated.

Because of the diffuse nature of central nervous system (CNS) lymphomas, aggressive surgical decompression with partial or gross total removal of the tumour is of no benefit to the patient. Systemic treatment is compromised by the blood-brain barrier, which is impermeable to several cytostatic agents. The role of RT for patients with primary CNS lymphoma continues to evolve. Early studies demonstrated that these tumours were radiosensitive and that complete and partial responses could be obtained using doses ranging from 3,000 cGy to 5,000 cGy. However, the responses were brief and patients often developed recurrent disease within a matter of months. Between 1983 and 1987, the Radiation Therapy Oncology Group conducted a prospective phase II study on 41 patients to evaluate survival in primary non-Hodgkin's lymphoma of the brain treated with whole brain irradiation to 40 Gy and a 20 Gy boost to tumour plus a 2 cm margin. Overall median survival was 12.2 months, with 48% surviving 1 year and 28% surviving 2 years. Patients with a Karnofsky Performance Status of 70–100 had a median survival of 21.1 months compared to 5.6 months for patients with a status of 40–60 ($p < 0.001$). Fourteen patients less than 60 years of age had a median survival of 23.1 months, while 27 patients older than or equal to 60 years of age had a median survival of 7.6 months (log-rank $p = 0.001$).[44]

The currently recommended dose of RT for cerebral primary CNS lymphoma is between 4,000 cGy and 5,000 cGy (whole brain), without a boost. However, RT should be avoided in patients older than 60 years. For patients

with ocular lymphoma, irradiation is the treatment of choice; 3,600 cGy should be administered to both eyes.

Median survival times for studies with pre-irradiation CHOP (cyclophosphamide, doxorubicin, vincristine and dexamethasone) were no better than for radiation therapy alone.[45,56] In a retrospective series of 226 patients, it was shown that patients with PCL treated with regimens that included HDMTX followed by radiotherapy, have an improved survival, but not a higher risk of late neurotoxicity, as compared with other treatment modalities.[3] RTOG 9310 study, published in 2002, showed that high-dose methotrexate combined with cranial irradiation is an effective therapeutic approach to PCNSL.[11] A multicentric study evaluated two cycles of MBVP (MTX 3 g/m^2 days 1 and 15, teniposide 100 mg/m^2 days 2 and 3, carmustine 100 mg/m^2 day 4, methylprednisolone 60 mg/m^2 days 1–5 and two intrathecal injections of MTX 15 mg, cytarabine 40 mg and hydrocortisone 25 mg) followed by 40 Gy of RT. The overall response rate of all 52 patients was 81% and the median estimated overall survival was 46 months with 10% toxic death rate during treatment.[50] Several different chemotherapy regimens and agents have been used with no current consensus on the optimal regimen. However, high-dose methotrexate (≥ 3 g/m^2) is the single most active agent against primary CNS lymphoma and should be a part of any chemotherapy regimen chosen to treat this disease. For healthier patients (i.e those 60 years or younger with a KPS ≥ 40 and a creatinine clearance ≥ 50; those older than 60 years with a KPS > 50), some type of pre-radiation chemotherapy is generally recommended; a high-dose methotrexate based regimen is most commonly used. In patients older than 60 years, RT may be omitted to avoid neurotoxicity. For patients with extremely poor KPS (< 40) or creatinine clearance less than 50, it is recommended that treatment consist of whole brain irradiation (45 Gy), in order to rapidly induce a response, diminish neurologic morbidity and optimise quality of life.

The survival is very poor without therapy (1–3 month mean survival). The overall survival for treated patients without AIDS is 18.9 months compared with 2.6 months for patients with AIDS.[14]

142 Adjuvant Therapies for Malignant Brain Tumours

Raj Kumar R, Ashok Kumar Mahapatra

Over the years, extensive research has been done to improve management strategy for central nervous system tumours. Advances have been made in both surgical and adjuvant therapy.[2,14] It has been progressively realised that adjuvant therapy plays a very significant role in the management of CNS tumours. Adjuvant therapy has helped in increasing both the duration of survival and the quality of life.[14] Adjuvant therapy, for long, has meant radiotherapy and chemotherapy. However, over the past decade, new fields such as immunotherapy and gene therapy have come a long way in providing us with a wider repertoire of treatment options to choose from. The fields of radiotherapy and chemotherapy have also been evolving with regards to technological advancements. Now radiotherapy can be provided with far more accuracy with minimal damage to surrounding structures. Similarly, new chemotherapeutic agents are finding acceptance. In this chapter, we discuss the present available options for adjuvant therapy for central nervous system tumours.

CHEMOTHERAPY

Major strides have been made in the management of brain tumours within both the surgical and radiotherapy fields. However, advances in chemotherapy have been restricted. This has been attributed to certain distinctive properties of brain tumours which are discussed below.

Blood-Brain Barrier

The highly effective blood-brain barrier (BBB) is one of the main reasons for the relative inaccessibility of the brain.[7] The continuity of this barrier is maintained by the tight junctions of the capillary endothelial cells, lack of fenestrations with the endothelial cells, limited pinocytosis, normal astrocytes and the presence of 'P' glycoprotein. The capillary permeability, the molecular weight of the drug and its lipophilicity regulate drug penetrance in the CNS. Drugs with a molecular weight greater than 450 kDa cannot cross the BBB, despite being lipophilic.[7] The BBB may get partially disrupted by malignant gliomas. Similarly, higher doses of chemotherapeutic agents increase BBB penetration. The intrathecal route of drug administration is an effective route for bypassing the BBB.

Tumour Heterogeneity

Following BBB penetration, the availability of the drug at the tumour site is dependent upon the transcapillary flow of the drug to the tumour. This is restricted due to the heterogeneity of the tumour seen more commonly in brain tumours. The tumour cells are in various stages of the cell cycle which is another factor in limiting drug efficacy, since the sensitivity varies in different portions of the tumour, hence resulting in the variable response.

Drug-Drug Interaction[7]

Drugs which induce hepatic cytochrome 450 enzymes reduce the efficacy of the chemotherapeutic aspects, by altering and increasing drug metabolism and clearance of the drugs. This in turn allows suboptimal dosage at the tumour site, resulting in treatment failure (Fig. 1).

Tumour Resistance[7]

Over the years, inherent tumour resistance to chemotherapy has been noticed, resulting in a low response rate. Glioblastoma has been shown to have the least response rate. Some anaplastic oligodendrogliomas,

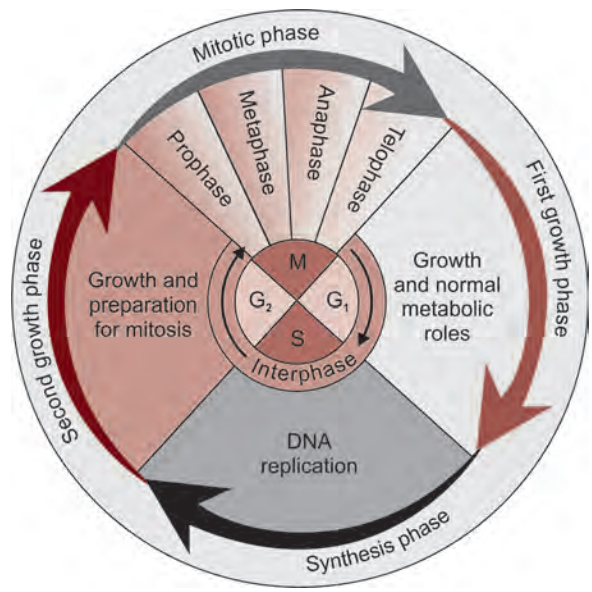

Fig. 1: Cell cycle

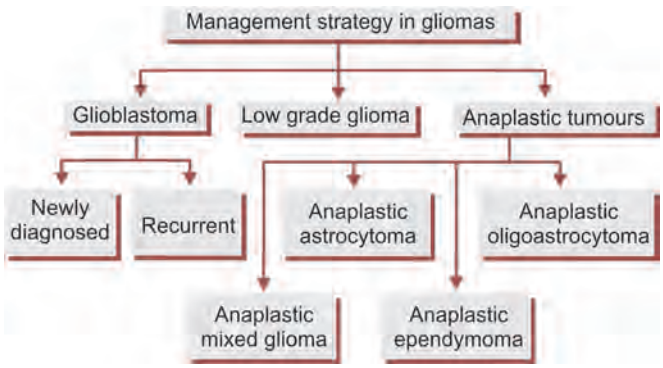
especially those with LOH at 1p/19q, have been shown to have a higher response rate. Sometimes it has been noticed that tumours which were initially responsive demonstrate progressively decreasing levels of response. This indicates that the tumour had certain resistant cells, the population of which has grown rapidly.

Chemotherapeutic Agents

Group	*Agent*		*Mechanism*
Nitrosourea	Carmustine Lomustine Nimustine	BCNU CCNU ACNU	DNA cross links, carbamoylation of amino groups
Alkylating (methylating) agents	Procarbazine Temozolamide Carboplatin Cisplatin	P TMZ	DNA alkylation, interferes with protein synthesis Chelation via intrastrand crosslinks
Nitrogen mustard	Cyclophosphamide Isofamide Cytoxan		DNA alkylation, carbonium ion formation
Vinca alkaloids	Vincristine Vinblastine Pacilataxel		Microtubule formation inhibitor
Epidophy-llotoxins	Etoposide Teniposide	ETOP VM26	Topoisomerase II inhibitor
Miscellaneous	Topoteca Irinotecan Tamoxifen Hydroxyurea Bleomycin Methotrexate	CPT11	Topoisomerase I inhibitor Protein kinase inhibitor



Newly Diagnosed Glioblastoma

Neo-adjuvant chemotherapy: Neo-adjuvant refers to administration of chemotherapy prior to radiotherapy. Repeated trials have failed to demonstrate any benefit of neo-adjuvant therapy, despite using different combination regimes.

Concurrent radiotherapy and chemotherapy: This is the widely accepted treatment of choice following surgical cytoreduction. Trials using temozolamide at 75 mg/m^2 orally for 42 days, concurrently with external beam radiotherapy have shown promising results with survival up to 16 months.[13] Presently, radiotherapy followed by TMZ (100 mg/m^2) for 5 days every 28 days for 6 cycles is the standard treatment.

Carmustine (BCNU) is the other agent for which a standard protocol has been described. This involves surgical cytoreduction followed by radiotherapy and then BCNU at 6 weeks intervals at 110 mg/m^2.

Local delivery of chemotherapeutic agent: Agents used for local delivery of chemotherapeutic drugs to the tumour cavity are in the form of biodegradable polymer wafers. These are loaded with BCNU (Gliadel® wafers) and are designed to release the drug over 2–3 weeks after their placement within the surgical cavity. Trials have shown them to be more effective than placebos.[3] Gliadel® wafers are, however, not appropriate for use in deep, multifocal bilateral disease, tumour in eloquent areas and in a juxtaventricular location.[7]

Treatment of Recurrent Gliomas

Treatment of recurrent GBM presents a challenge to the treating unit. Despite the use of different combination regimes no data supports the supremacy of any one over the other.[7]

The treatment involves the use of first line drugs and if they fail to have an adequate response can be followed-up with the second line drugs. The first line drugs are temozolamide, BCNU and CCNU. Patients who have already received TMZ should undergo treatment with a nitrosourea, such as BCNU or CCNU.[15] Sometimes they may also be used in combination.

The second line drugs are carboplatin, etoposide and irinotecan. Carboplatin alone or in combination with tyrosine kinase inhibitors have been used. Hydroxyurea is used for its radiosensitising properties, along with cell specific cytotoxic activity.[7]

Anaplastic Astrocytomas

Neo-adjuvant therapy has not shown any beneficial result. Trials have been conducted using PCV and BCNU, following surgery and radiotherapy. Patients undergoing treatment with the PCV regime have shown higher response rates.[9]

The outcome of patients with recurrent anaplastic astrocytoma is dismal with a maximum survival period of 47 weeks, despite adoption of aggressive measures. Although nitrosoureas are the most frequently used, development of resistance with myelosuppression limits their use in recurrent cases.[7] Irinotecan has recently been shown to give encouraging results in recurrent malignant gliomas.[8]

Anaplastic Oligodendroglioma

Ongoing trials have reported high response rates to chemotherapy, most commonly using PCV regimes. Hence, keen interest is being shown in order to further

improve the survival. It has been demonstrated that patients with LOH (1p/19q) have much better response rates.[4]

In a trial, patients with anaplastic oligodendrogliomas were divided into two groups. One group received radiotherapy alone followed by surgery. In the other group, radiotherapy was followed by six cycles of PCV. Although survival rates in both the groups were identical, the progression rate was significantly less in the latter group.[4]

Presently the use of PCV as adjuvant therapy has become the treatment of choice. Temozolamide has been increasingly used due to a better toxicity profile. PCV is effective as salvage therapy in patients having recurrence following temozolamide administration.[7]

Low Grade Gliomas

Low grade gliomas include WHO grade II tumours mainly oligodendrogliomas, astrocytomas and oligoastrocytomas. The role of chemotherapy in these tumours is still under scrutiny and many ongoing trials are evaluating their usefulness. So far, trials using PCV/TMZ for recurrent/previously untreated oligodendrogliomas and astrocytomas have reported higher response rates.

Although definitive results of the trials have yet to come in, available data suggests that chemotherapy for low grade gliomas can be used for oligodendrogliomas with LOH at 1p/19q in patients older than 40 years, patients with incompletely resected tumours, residual tumours after surgical resection/radiotherapy or oligodendroglioma with or without LOH 1p/19q with extensive tumour infiltration. Observation alone is recommended in patients younger than 40 years and patients having low grade gliomas.[7]

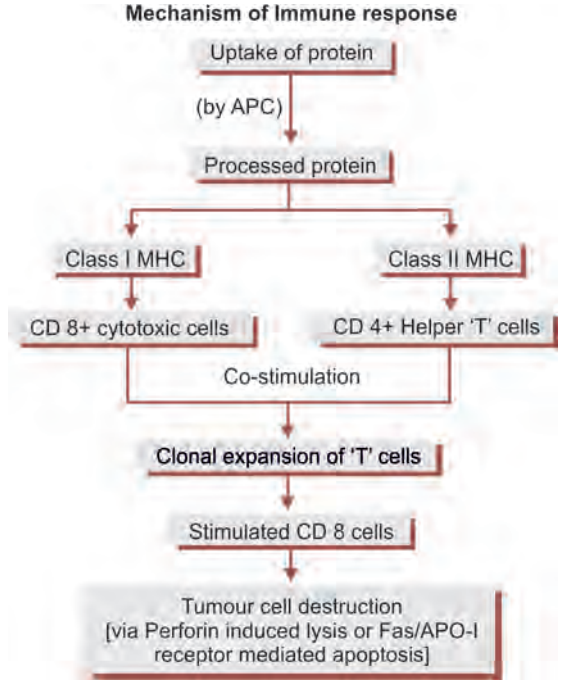
IMMUNOTHERAPY

Immunotherapy has been recognised to be a potent weapon against gliomas for many years, but research in this field has only gained momentum during the past decade. Various modalities of treatment which result in enhancement of the immune response have been developed to enhance the armoury against gliomas.

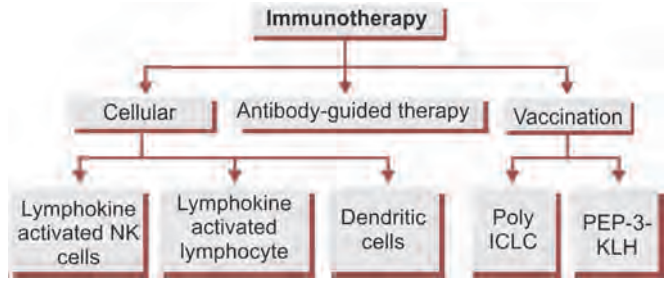
Over the years, it has been noted that patients with gliomas are immunosuppressed. Many factors have been studied in this regard: TGB-β, IL-10 and PGE2[7] have been found to be responsible for the immunosuppression. The immunosuppressive state results in defects which have been enumerated in the Table 1.

Table 1: Causes for immunosuppressive state

- Decreased CD4 'T' cell activity
- Increased CD4 suppressor T cells
- Low reticulocyte count
- Decreased delayed type hypersensitivity
- Diminished immunoglobulin synthesis by B cells



CLASSIFICATION

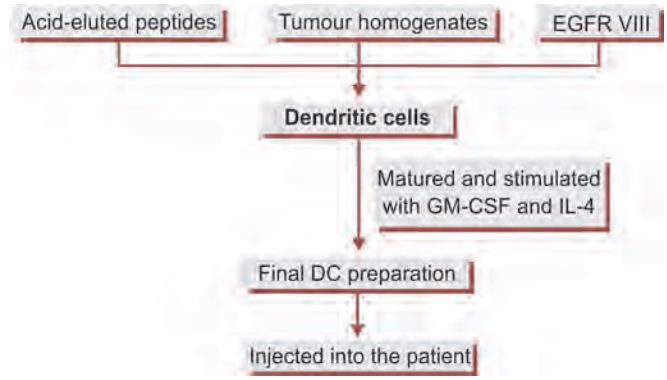


Cellular

This involves the isolation of immune effector cells from a patient, following which they are multiplied using stimulating factors and are then activated. Finally they are injected back into the patient to cause tumour lysis.

The immune effector cells are lymphokine activated natural killer cells, lymphokine activated lymphocytes, tumour infiltrating lymphocytes and dendritic cells.

Dendritic cells have been studied with great interest recently to evaluate their efficacy and have been giving promising results. Dendritic cells are loaded with acid-eluted peptides, tumour homogenates or tumour specific antigen EGFR VIII and are then stimulated and matured.



Yu et al. 2001[16] had reported median survival time of 15.1 months [vs 8.6 months in a control population] in a phase I clinical trial using dendritic cell preparations in malignant astrocytoma. Another trial[1] using dendritic cells against EGFR VIII showed median survival of 20 months in patients with GBM [vs 7 months for control population]. Plauz et al.[10] have utilised the 'T' cells generated in the patients in response to tumour cells. The tumour cells obtained during surgery are cultured and injected back subcutaneously into the patient. Following this, draining lymph nodes are resected to obtain tumour activated lymphocytes. These in turn are stimulated to produce clonal expansion. The 'T' cells hence produced are infused back into the patient. Out of the 10 patients, two showed tumour regression in the study. The extensive set-up and costs required for the *ex vivo* techniques of cellular immunotherapy are a major drawback for widespread usage of this technique.

Antibody-Guided Therapy

Antibodies can be used either as delivery vehicles for chemotherapeutic agents or as apoptosis inducers themselves. Tenascin, the extracellular matrix glycoprotein expressed in malignant gliomas has often been targeted. 81C6 monoclonal antibody binds to the epitope within the spliced fibronectin type III region of Tenascin. In a trial,[11] Iodine^{137} labelled murine 81C6 was injected into the surgical cavity. The survival of newly diagnosed GBMs was 19.9 months and for recurrent GBMs was 12 months. MD Anderson is planning to undertake a phase III clinical trial of 81C6 antibody.

Vaccination

This method of therapy involves utilising the patient's own immune system to counter high grade gliomas. Theoretically speaking, this is the ideal method of treatment. Poly ICLC, a double stranded RNA has been investigated for these purposes. The trials[12] have reported significant improvement in survival rate of patients with anaplastic astrocytomas (96 months vs 22 months with conventional chemotherapy). This has, however, not been demonstrated in patients with GBM.

GENE THERAPY

Better understanding of the molecular genetics of brain tumours has opened new options. Attempts have been made to manipulate the molecular biology of tumours by making alterations in the genome of tumour cells. This, in turn, either inhibits the growth of the tumour or makes the tumour cells more susceptible to the other modes of adjuvant therapy.

It is important to ensure that these alterations in the genome are restricted to the tumour cells and do not affect the normal neural tissue. These alterations in the genome are carried out by the use of genetically engineered viruses which are inserted into the tumour cells. The retrovirus and the herpes virus have been the most popular agents to be used. The genome of the retrovirus has been mapped in detail[5] and has the advantage that it tends to integrate only in the dividing cells, thereby not affecting the normal neural tissue which is in the post-mitotic state. Retrovirus that carries the thymidine kinase gene[6] tends to render the cell sensitive to ganciclovir, resulting in the death of the cells containing this gene. Herpes virus has the advantage of having a large genome and retains replication competence. However, it does not differentiate between dividing and non-dividing cells.

ACKNOWLEDGEMENT

The authors express their sincere thanks to Dr Pallav Garg who had been instrumental in preparing this manuscript and arranging the references.

143 Colloid Cyst

Nigel Peter Symss, Ravi Ramamurthi

INTRODUCTION

In 1858, Wallmann published the first description of a colloid cyst. It was found on autopsy in a 50-year-old man who presented with "staggering gait and involuntary micturition and defecation".[58] The term "Colloid cyst" has been used since the late nineteenth century to describe these cysts because of their glue-like contents.

These constitute less than 1% of all intracranial tumours.[10] Ante-mortem diagnosis of this entity was possible only after the introduction of ventriculography and pneumoencephalography by Dandy, who incidentally was also the first one to excise this tumour completely. Dandy performed this surgery through a posterior transcallosal approach to the third ventricle. He stated that no treatment short of total removal could have any possible value in the treatment of tumours in this region and that there could be no relief of hydrocephalus, except by removal of the obstructing lesion. In 1933, he reported removing five colloid cysts with only one death.[14] The anterior transcallosal approach was suggested by George Ehni who used this approach for different pathological entities over a period of 38 years.[17]

REGIONAL EMBRYOLOGY OF THIRD VENTRICLE

The third ventricle develops from the diencephalic vesicle at the rostral end of the neural tube during the third week of gestation. Soon it is surrounded by the rapidly developing cerebral vesicles except at its roof. The roof of the third ventricle then begins to invaginate and forms the pia mater that eventually covers the floor of the third ventricle. Rathke's cleft pouch forms an invagination of the distal end of the stomodeum into the overlying mesoderm. This eventually gives rise to the anterior pituitary. The posterior pituitary and pituitary stalk are derived from the cerebral vesicle posterior to Rathke's cleft pouch. This invagination of mesodermal tissues into the neuroepithelium may give rise to a number of developmental anomalies and tumours that characterise the third ventricle.[12]

INCIDENCE

Although colloid cysts have been reported in all age groups, they more commonly present between the age of 20 and 40 years. The incidence is equal in both sexes. Isolated case-reports suggest a genetic predisposition in certain cases. Akins et al. also pointed out that a number of congenital conditions (including agenesis of the corpus callosum and frontal encephalocoeles) and tumours (astrocytoma, craniopharyngioma, neurofibromatosis and capillary hemangiomas of the choroid plexus) may be associated with colloid cysts.[3] Familial cases have also been reported. Ahmed et al. have reported colloid cysts of the third ventricle in identical twins.[2]

Incidental Colloid Cyst

Colloid cysts have been found incidentally. The rapidly increasing availability of CT and MRI scanning for the investigation of patients with unrelated symptoms and minor trauma has resulted in an increase in the frequency of diagnosis of a colloid cyst. The management of incidental colloid cysts is a topic of debate. The rate of growth of the cyst is uncertain and whether these cysts eventually become symptomatic is unclear. Sudden deterioration followed by death has not been reported in patients with a colloid cyst of less than 1 cm in size.[8,11,53] Patients with colloid cysts larger than 1.5 cm should be considered for surgical excision, as these cysts are more likely to become symptomatic.[48] MacDonald et al. stressed that younger patients are more likely to become symptomatic during their life time and thus require surgery.[40] Desai et al.[15] reported 5 patients with colloid cysts detected incidentally. Out of these, three had small colloid cysts, which were asymptomatic and managed conservatively.

We are reluctant to recommend conservative management for asymptomatic and incidentally discovered patients with colloid cysts. We have found the transcallosal approach with limited anterior callosotomy a good and safe approach, and have been able to remove anterior third ventricular colloid cysts with an accepted surgical morbidity and mortality less than the one arising from the natural progressive history of the disease.[50]

PATHOLOGY

The wall of a colloid cyst usually consists of a single layer of columnar epithelial lining and a collagenous connective tissue stroma. Although electron microscopy suggests a secretory function for these cells, there is some

controversy regarding their development.[52] A neuroepithelial origin is suggested by most authors, although some believe that it originates from the ependymal epithelium.[52] Others believe that it derives its origin from the epithelium of the choroids plexus.[23,55] A recent immunohistochemical study of colloid cyst suggests that it is not a derivative of the ependyma or the choroid plexus[33] but that it is derived from the primitive neuroectoderm, involved in the formation of the tela choroidea. A non-epithelial origin has also been proposed.[35] Stochdorph, on the basis of light microscopy, suggested its origin from ectopic epithelium of the upper respiratory tract.[52] Ho and Garcia[25] and Lach et al.[37] confirm this view by ultrastructural studies which show that colloid cysts are endodermal in origin. The cyst contents may consist of soft suckable pultaceous material or could be firm, non-suckable and hyaline. This PAS positive material is presumably derived from the secretory activity and desquamation of the lining epithelium.[52]

LOCATION

Except in rare instances, colloid cysts are located in the anterior third ventricle and the wall of the cyst is often firmly adherent to the walls of the foramen of Monro, the fornix or the lateral wall of the third ventricle. They are located in the roof of the third ventricle, usually attached to the tela choroidea or rarely to the choroid plexus by a narrow pedicle and are located just behind the fornices and between the foramina of Monro. Occasionally, they are found more posteriorly and obstruct the posterior segment of the third ventricle. Intrasellar occurrence of a colloid cyst has also been reported.[54] Rarely, a colloid cyst may grow to a large size, compressing the surrounding structures and simulating a glioma clinically and on CT.[6] A colloid cyst occurring in the fourth ventricle has been reported.[28] Campbell and Varma found a right frontoparietal extracerebral colloid cyst.[9] A rare occurrence of intracerebellar colloid cyst has been reported by Muller et al.[45] Jaskolski et al. reported a case of a 44-year-old man showing an oval lesion located at the anterior surface of the pons on CT and MRI scans. The tumour was excised through a right pterional-transsylvian approach.[30]

CLINICAL FEATURES

Colloid cysts display a typical constellation of symptoms because of their strategic location in the anterior third ventricle. They act as pure mass lesions, possessing no intrinsic pathologic properties and they cause symptoms by acting as inert masses. Most of the symptoms are related to hydrocephalus secondary to obstruction of cerebrospinal fluid (CSF) flow within the middle or posterior third ventricle, as evidenced by the symmetrical widening of both the lateral ventricles as seen in Figure 1.

More than 75% of patients report with headache due to raised intracranial pressure, as the presenting complaint.

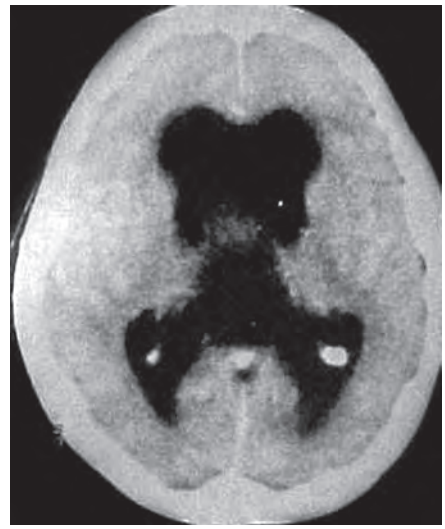

Fig. 1: CT scan of the brain showing symmetrical dilatation of both the lateral ventricles secondary to the obstruction of foramen of Monro

It may be insidious in onset and progressive in nature or it may be intermittent or of sudden onset. The second common pattern of presentation has been named by Kelly as "the classical story"[32] which is characterised by the intermittent and postural nature of the attacks with remissions. The postural component of the classic headache invokes the "ball valve" theory, implying a movable mass that dislodges from the foramina when the patient is recumbent. These paroxysmal attacks are generally considered to be due to intermittent obstruction and disimpaction of the cysts in the third ventricle.

A drop attack due to sudden weakness of the lower limbs accompanied with features of raised intracranial pressure may be the presenting feature.[33] Progressive or fluctuating dementia may be seen or there may be a normal pressure hydrocephalus syndrome.[7] Seizures may occur in about 20% of cases. The dangers of asymptomatic colloid cysts have been underestimated.[36] There have been several reported instances of sudden death in patients with colloid cyst,[4] but the reasons are not clear. The sudden elevation of intracranial pressure, with the subsequent decreased cerebral perfusion pressure induces a vigorous cerebroprotective neuroendocrine system activation that can lead to the neurogenic stunned myocardium. Sudden death in patients with colloid cysts may be related to acute neurogenic cardiac dysfunction and not necessarily cerebral herniations, as previously thought.[29] Another explanation for the acute deterioration of patients is haemorrhagic changes in the cysts. This complication has been published only four times before, all diagnosed at post-mortem examination.[5] Neither the size of the cyst, the degree of dilatation of the ventricles, nor the duration of symptoms seem to provide reliable prognostic indications for this fatal complication. Patients have been discovered to be harbouring a colloid cyst after diagnostic work-up for

spontaneous CSF rhinorrhoea.[31] This rhinorrhoea most likely results from chronically elevated intracranial pressure causing erosion of the cribriform plate and meninges, with a resultant CSF fistula. The coexistence of colloid cyst of the third ventricle with pituitary dwarfism has been reported.[44] As the dangers cannot be underestimated, surgical excision may be advisable even for asymptomatic colloid cysts.

INVESTIGATIONS

When the cyst is situated at its usual location, the venous phase of the cerebral angiogram shows elevation of the anterior part of the internal cerebral vein, resulting in a curve which is concave downwards. The posterior part of the internal cerebral vein is flattened and depressed due to the dilated lateral ventricles. The CT appearance is of a lesion located at the foramen of Monro, varying from hypodensity or isodensity to moderate or marked hyperdensity on the plain scan. This hyperdensity is secondary to a combination of desquamated material within the cyst, haemosiderin and calcium.[18] However, the colloid cyst is frequently isodense or only slightly hyperdense. It enhances with contrast to a mild degree in some cases. Enhancement may be secondary to blood vessels in the wall of the cyst or leakage of contrast into the cyst cavity.[18] Figure 2A shows CT scan of the brain highlighting an anterior third ventricular colloid cyst. Figure 2B shows the CT scan of the same case, post-operatively, following cyst removal.

MR findings are very variable, ranging from hypo-to-iso to hyperintense in all sequences (Figs 3A and B). The signals may be homogeneous or heterogeneous.[38,59] High signals on short TR/TE sequences are correlated with high cholesterol content.[41] Wilms et al. reported a group of colloid cysts that show an isointense peripheral thick rim and extremely hypointense centre on T2-weighted images. These cysts are usually large.[59] MR venography gives a better visualisation of the adjacent venous structures, including the internal cerebral vein.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of third ventricular lesions may be divided into intraventricular extra-axial lesions (colloid cyst, cysticercal cysts, meningiomas, haemangioblastomas, xanthogranulomas and cavernous angiomas); intraventricular intra-axial lesions (gliomas, choroid plexus tumours, teratomas, ependymomas and subependymal giant cell astrocytomas) and lesions with basal origin but third ventricular extension (meningiomas, craniopharyngiomas, giant basilar aneurysms and pituitary adenomas).

TREATMENT

For a lesion that is relatively rare, substantial literature on various methods has accumulated since Dandy's first report of a surgical extirpation. Each technique has its advantages and disadvantages. The surgeon must select the approach best tailored to his patient's unique presentation, his own experience and training and a clear understanding of the strengths and limitations of each approach.

The various microsurgical approaches to colloid cysts are:

1. Transfrontal/transventricular
   a. Transforaminal
   b. Subchoroidal
2. Transcallosal/transventricular
   a. Transforaminal
   b. Interforniceal
   c. Subchoroidal
3. Subfrontal Translamina terminalis.

Opening the CSF pathway obstruction is the goal of treatment. There are various options available.[8,57] Total surgical excision would be the ideal therapy, provided that the complications are kept to a minimum. A transcallosal transventricular approach, when the lateral ventricle is small and an anterior transcortical (middle frontal gyrus) transventricular approach, when the ventricle is dilated, are the options available to reach the foramen of Monro (Fig. 4).[51] The tumour in the third ventricle could then be dissected, either through the dilated foramen of Monro or by widening the opening anteriorly by cutting one fornix, widening the opening posteriorly by coagulating the thalamostriate vein, or by the subchoroidal approach. A direct approach to the third ventricle following the transcallosal approach may be made between the fornices, following the midline strictly and incising the tela choroidea and entering the third ventricle between the internal cerebral veins. The transcallosal approach allows safer access if the ventricles are normal sized or small and has greater flexibility in exploring the entire extent of the third ventricle. There is no cortical incision, the ventricular size is irrelevant and an excellent unobstructed view of the third ventricle may be obtained. The disadvantages of the transcallosal approach include less familiarity with the anatomy for some neurosurgeons, thereby increasing possible injury to frontal draining veins and the sagittal sinus, injury to the pericallosal arteries, problems related to corpus callosal section and forniceal damage (Fig. 5). Good results from the transcallosal approach have been reported by many authors.[27,50]

Dandy first used the transcortical approach in lateral ventricular and third ventricular lesions. It is useful, if the ventricles are enlarged and access to the foramen of Monro and third ventricle is readily obtained. The transcortical approach avoids injury to the frontal draining veins of the sagittal sinus and decreases the chance of injury to the pericallosal arteries. However, in the presence of small or normal sized ventricles, it may be difficult to enter the lateral ventricles without undue trauma and retraction, thereby increasing the incidence of post-operative morbidity. Moreover, in the presence of large lesions, the angle of vision of the foramina and of the third ventricle is limited.

Fig. 5: Post-operative CT scan showing bifrontal pneumocephalus and frontal venous infarct

The transcortical-transventricular approach has been associated with the following complications: Seizure in 8.6–27% of cases,[4,7,39] hemiparesis in 4.3–20%,[4,39] memory loss, usually transient in 4.2–27%,[4,7] subdural fluid collection, meningitis in 9%,[7] ventriculitis in 4.3%,[4] confusion and mutism. In two of the reported series, the mortality rate has been about 17%.[4,39]

The reported complications in the transcallosal approach have been hemiparesis in 2.5–16%,[21,56] transient memory loss in 33%,[26] transient akinetic mutism in 8.3%,[56] impairment of interhemispheric transfer of sensory information, bacterial meningitis and aseptic meningitis in up to 12%,[21,56] confabulation, aphasia and obtundation. There are also complications pertaining to the approaches used to enter the third ventricle, once the foramen of Monro has been reached. In the transforaminal approach, haemorrhage and memory loss has been reported.[4,39] Transient memory loss up to 33% and transient paresis may occur with the interforniceal approach. Transient hemiplegia, drowsiness, mutism and haemorrhagic infarction of the basal ganglia have been found with the subchoroidal and the trans-velum interpositum approach.[47]

Palliative ventricular shunting, although a simple way of avoiding surgical complications, is not advisable because there is no tissue confirmation, the signs due to the tumour mass *per se* are not alleviated and it exposes the patient to the risks of infection, epilepsy and shunt blocks.[13,19] Although advocated by some neurosurgeons,[22] unilateral shunting of the ventricles may lead to sudden enlargement of the opposite ventricles resulting in coma or even sudden death.

Some authors believe that, except for cases where surgical intervention is urgent (acutely raised intracranial pressure), CT-guided stereotactic aspiration should be routinely used for the management of colloid cysts.[16,46,49] The advantage of this procedure is the low morbidity and mortality rates. The disadvantages are the occasional inability to aspirate the cyst contents and recurrence 6–15 years after successful aspiration.[42] The aspirability of the cyst may be predicted by its CT appearance. When the pre-operative CT showed a hypodense or isodense lesion, it was possible to aspirate the cyst successfully.[34] In view of the risks of open surgery and failure to aspirate the colloid cyst with CT-guided stereotactic techniques,[21] stereotactic microsurgical approach and total removal of the colloid cyst by laser has been advocated.[1,43] Stereotactic-guided endoscopic laser therapy has also been employed. The advantages claimed for this technique are:

- Limited cortical dissection.
- Avoidance of callosal or forniceal injury.
- Ease of localisation of the lesion, regardless of ventricular size.
- Good haemostasis achieved by bipolar or LASER.
- Possibility of total resection.

Neuroendoscopic treatment of colloid cysts has gained increasing acceptance and is being used more widely.[24] Continued improvement in endoscopic techniques and instruments, together with good long-term results in endoscopically treated patients, have established this method as an alternative to microsurgical techniques and might even set a new standard for treatment.[24] Endoscopes have also been used with interactive image-guided methodology.[20]

For the practising neurosurgeons, without other special facilities, direct excision of the cyst using microsurgical techniques preferably via the trancallosal route or the transcortical transventricular route is the best course of action. It is against these two approaches that new surgical methods should be measured. Direct surgical approach and complete removal of the colloid cysts are possible through both of these open procedures. The goal of both the transcallosal and the transcortical approach is to gain access to the lateral ventricle, with secondary access to the foramen and fornix.

144 Choroid Plexus Tumours

Vasudevan MC

Tumours of the choroid plexus are rare neoplasms of neuroectodermal origin, accounting for less than 1% of all intracranial tumours. These tumours primarily occur in children but they are also observed in adults and infants.[20,25,27-29,41] Prenatal occurrence has also been reported.[1,39]

HISTORY

Choroid plexus papilloma was first described in an autopsy specimen of a 3-year-old girl by Guerard in 1832. In Cushing's series, papilloma of the choroid plexus was present in 0.06% cases. Papers between 1833 and 1925 emphasised the rarity of this tumour and its association with hydrocephalus.[10,11,48] The first surgical resection of a choroid plexus tumour in an adult was reported by Bielschowsky and Unger in 1906. The first long-term survival of an adult with choroid plexus tumour was reported by Perthes in the year 1919. Van Wagenen in 1930 reported excision of the tumour from the lateral ventricle of a 3-month-old child and Dandy in 1934 described the removal from a 14-year-old girl.[49] It was Dandy who described the transcallosal route to the third ventricular region and was the first to describe it for removal of a choroid plexus tumour in 1922. The first transfrontal removal of third ventricular choroid plexus papilloma was published by Masson in 1934.

Choroid plexus tumours are among the more frequent tumours in children under the age of 3 years.[23] Among 245 patients of all ages, the distribution was as follows: lateral ventricle, 43%; third ventricle, 9%; fourth ventricle, 39%; CP angle, 9% and multiple sites, 3.7%.[40] In children, tumours of the choroid plexus are located most often in the lateral ventricle but they can also be found in the third ventricle and in the posterior fossa.[21,22,41] Choroid plexus tumours of the posterior fossa in adults are likely to be benign, whereas, in children, tumours occurring in the lateral ventricle tend to be anaplastic.[40] Third ventricular tumours are usually prevalent in adults and children and most such tumours are benign.[16] Lateral ventricle tumours equally occur on either side,[26] though some reports indicate a preference for the left lateral ventricle.[43] A predominance of males has also been reported.[24] Malignant changes occur in less than 20%[26] and a majority of such tumours are found in infants and children less than 4 years of age, mostly in the lateral ventricle. Choroid plexus carcinomas are rare and according to Russell and Rubinstein,[43] they are likely to be secondary from an undiagnosed primary bronchial carcinoma (Table 1).

The papilloma appears as a pink or reddish grey globular mass with a rough irregular surface resembling a cauliflower and is usually attached to the plexus at the trigone. The consistency is firm and occasionally, significant calcification may be present. These tumours are very vascular. Although evidence of leptomeningeal spread has been reported on post-mortem examination, there are no symptoms to indicate this during life.[43] The microscopic appearance of choroids plexus papilloma resembles the normal architecture of the choroid plexus and shows papillae composed of a single layer of columnar or cuboidal epithelium lining a stroma of vascularised connective tissue. It is important to differentiate it from an ependymoma where the stroma contains neuroglial tissue, epithelial cells with cilia and blepharoplasts.[43] Features of microscopic invasion, especially mitotic activity and pleomorphism should raise the possibility of malignancy, even when the general architecture indicates a well differentiated papilloma.[26] The two characteristics that are suggestive of malignancy in choroid plexus tumours are: (i) invasion of the brain by malignant-looking cells and (ii) loss of the regular papillary architecture of the tumour in the region where the normal brain has been invaded. In young patients, in whom metastatic adenocarcinoma is highly unlikely, it may be difficult to distinguish these tumours from medulloepithelioma, an embryonal carcinoma or an endodermal sinus tumour. Immunohistochemistry may be useful. Leptomeningeal spread is common in choroid plexus carcinoma and extraneural metastasis has also been reported.[43]

Hydrocephalus in choroid plexus tumours is due to several following factors: (i) overproduction of CSF; (ii) obstruction of the CSF pathways due to tumour and (iii) recurrent occult bleeding from the tumour resulting in subarachnoid fibrosis and adhesions.[13,17,33,34,42,43]

Table 1: WHO classification of choroid plexus tumours

Tumours of the choroid plexus	*Grade*
Choroid plexus papilloma	I
Atypical choroid plexus papilloma	II
Choroid plexus carcinoma	III

From their attachment to the choroids plexus, the tumours frequently extend from one ventricular compartment to another and to the subarachnoid space.[19] Lateral ventricular tumours may extend through the foramen of Monro into the third ventricle and to the quadrigeminal cistern or to the contralateral ventricle through the choroidal fissure. Third ventricular tumours are usually situated posterosuperiorly.[7,40] Tumours in the fourth ventricle may, occasionally, burrow into the cerebellum or the floor of the fourth ventricle or may extend to the CP angle.

CLINICAL COURSE

The symptoms are insidious in onset. Acute symptoms appear when brain herniation occurs secondary to hydrocephalus or when the tumour bleeds into the ventricle. Headache is the most common symptom and is later associated with vomiting and visual disturbances. The headache is the result of raised intracranial pressure secondary to the tumour mass or due to obstructive hydrocephalus. In supratentorial tumours, headache could be positional and intermittent. Seizure, hemisyndromes and mental changes also occur.[4,7,16,36] Progressive enlargement of the head is present in the majority of infants and young children.[31]

Choroid plexus tumours of the anterior third ventricle present with obstructive hydrocephalus and posterior third ventricular tumours have tectal syndromes in addition. In fourth ventricular tumours, headache, gait ataxia, nystagmus, cerebellar signs, loss of vision, vomiting and diplopia are seen.[7] Exophytic fourth ventricular lesions with extension into the foramen magnum presenting as CSF rhinorrhoea have been reported.[47] Tumours extending into the CP angle can give rise to cranial nerve deficits, apart from hydrocephalus.[9,50]

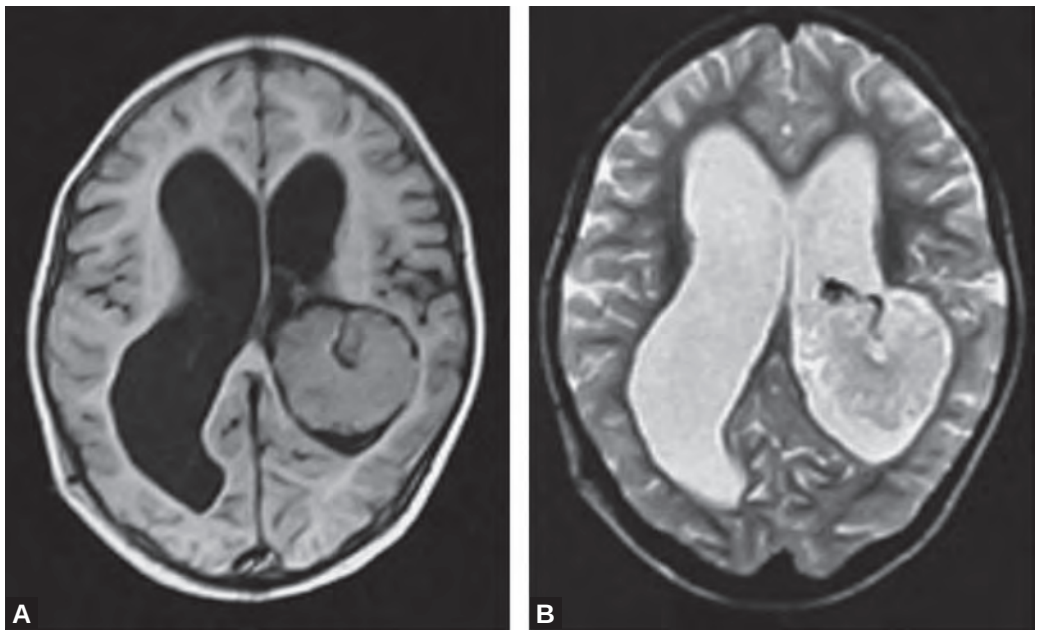
INVESTIGATIONS

Plain X-ray shows only non-specific signs of raised intracranial pressure and tumour calcifications are generally not apparent.[38,42] Angiograms may show an enlargement of the corresponding arteries, depending on the location and a tumour blush is often seen. The CT scan shows a lobulated hyperdense intraventricular mass which enhances brightly with contrast. Finely speckled calcification is often present within the tumour. The MR shows a hypointense or isointense lesion which is hyperintense relative to CSF in T1-weighted images and a hyperintense mass in T2-weighted images. Following gadolinium injection the tumour becomes hyperintense in T1-weighted images (Figs 1A and B).

Magnetic resonance spectroscopy (MRS) is a novel *in vivo* technique to identify biochemical features of choroid plexus tumours that facilitate diagnosis and treatment. Both, the choroid plexus papilloma and carcinoma characteristically contain high levels of choline compounds (CHO), and a complete absence of creatine and the neuronal/axonal marker N-acetyl aspartate (NAA). However, a choroid plexus carcinoma demonstrates higher levels of choline compared to the papilloma and in addition, it also has elevated lactate.[2] The myo-inositol (mI) level is significantly higher in choroid plexus papillomas (10 mmol/kg), uniquely distinguishing these tumours. The absolute 'mI' levels and the 'mI/Cr' ratio can be used to differentiate these tumours from choroid plexus carcinomas and all other tumours. Choroid plexus carcinomas, on the other hand, have significantly elevated levels of choline, when compared to choroid plexus papillomas.[30]

TREATMENT

The majority of patients are younger than 3 years of age at the time of presentation. This makes management of



Figs 1A and B: (A) T1W axial MRI of the brain showing choroids plexus papilloma in the atrium of the left lateral ventricle which is slightly hypointense. (B) T2W axial MRI of the brain showing choroids plexus papilloma in the atrium of the left lateral ventricle which is hyperintense

their disease challenging. Total excision of the tumour is the surgical goal and the treatment of choice. Choroid plexus tumours tend to be large, fragile and very vascular. This presents a particular challenge in a baby with a small total circulating blood volume, risking intra-operative death from uncontrollable haemorrhage.[21,39] This complication occurs more commonly in carcinomas than in papillomas.

The critical aspect of the surgical approach is to expose the vascular pedicle during the initial stage of the procedure, to avoid avulsion of the feeding arteries, which can occur when manipulating these large lesions. This does not always prove successful because of the large size of the tumour that prevents access to the vascular pedicle, which usually is deeply situated, away from a direct approach.[39]

Attempts to debulk the tumour without control of the vascular pedicle can result in significant blood loss and subsequent high morbidity and/or mortality.[39,45] For these reasons, microsurgical rather than endoscopic approaches are favoured, although small CPPs have successfully been resected using endoscopic techniques.[38] Endoscopy can be used as an adjunct to microsurgery to get at the vascular pedicle in the early stages of surgery. Pre-operative angiographic evaluation and embolisation can be extremely useful in cases of highly vascular lesions.[46] Hypertrophy of one of the choroidal arteries is a usual angiographic feature and tumour blush is commonly seen, occasionally with several minor feeding vessels contributing. Although pre-operative embolisation would appear to be easy, in clinical practice it is very difficult to cannulate these feeding vessels.[3,39]

Gross total resection of tumour is possible in 60–90% of cases.[7,18] The mortality rate in a relatively recent series has been reported to be 20%.[18] Hydrocephalus is generally relieved following removal of the tumour but in certain cases it may persist and is attributed to subarachnoid fibrosis. A ventriculoperitoneal shunt may then be necessary.

Not uncommonly, the predominant symptoms of intracranial hypertension, in relation to acute hydrocephalus, demand controlled CSF diversion for a short duration (few days) prior to performing surgery for excision of the tumour. The objective of such a staged treatment would be to improve the condition of the brain by relieving raised intracranial pressure, in preparation for a major intervention, while at the same time the advantage of ventriculomegaly is maintained. In the presence of dilated ventricles, excision of a choroid plexus papilloma is easier because the tumour is floating inside the ventricular cavity. If this advantage is lost and the ventricles are dramatically reduced in size, the operation is significantly complicated.[39]

Previously, attention was focussed on the relationship between cerebral mantle thickness and the risk for chronic subdural fluid collection. Pre-operative controlled CSF diversion allows the cerebral mantle to expand. An important detail of surgical technique is the closure of the corticotomy with biological glue at the end of the procedure. This is better achieved when the cerebral mantle has expanded. Closure of the corticotomy will isolate the ventricular system from the subdural space, thus significantly decreasing the chances of post-operative subdural hygroma that requires subduroperitoneal diversion. In the presence of such a communication, any diversion of the subdural space is likely to be insufficient.[39]

Alternatively, an intersulcal splitting approach to the lateral ventricular trigone, combined with a peri-operative external ventricular drainage, may be of value in the avoidance of symptomatic subdural effusions.[35]

Pre-operative radiation to reduce the vascularity is not advisable, as it may produce adhesions that hinder resection.[8] Post-operative radiation therapy has been recommended for patients with incomplete excision, although its validity is doubtful.[9]

In choroid plexus papilloma, it is accepted that complete excision is curative.[37] Choroid plexus carcinomas have a high propensity for recurrence and despite some reports adjuvant treatment has not been found to be very effective in these tumours. In older children, radiotherapy can be effective against recurrence. Unfortunately, radiotherapy is not an option in the majority of cases because of the young age of the patients and the size of the field to be irradiated.[3,6]

Total excision is the major predictor of long-term survival in patients with CPC,[12] the 5-year-survival rates range from 26% to 50%. Because of their invasive nature and propensity to metastasise, most CPCs are not amenable to gross-total resection.[6,46] Although it contributes to long-term survival,[12] chemotherapy cannot prevent recurrence. At present, total surgical excision is the main predictor of long-term survival and achieving total excision should be the goal of any treatment strategy.[3,5,6,32,41,44]

Diffuse enlargement of the choroid plexus, termed as 'villous hypertrophy of the choroid plexus' by Davis,[15] can pose considerable confusion in its differentiation from a papilloma, as both of them present with hydrocephalus as a consequence of excessive production of CSF. Bilateral choroid plexus papilloma is extremely rare and distinct from diffuse villous hypertrophy and, if suspected, total surgical resection should be performed.[14]

145 Pineal Region Tumours: Clinical Features and Management

Ramakrishna Easwaran

INTRODUCTION

The epiphysis cerebri (pineal gland) has fascinated scientists and philosophers for centuries. Historically, in Galenic times, it was thought to be a sphincter between the third and the fourth ventricle, controlling the flow of 'spirits'. Descartes, in the 17th century, described it as the "seat of the soul". Evolution has transformed this organ from a superficially located third eye in amphibians and reptiles to a structure buried in the depths of the human brain. The human pineal retains this phylogenetic link to the visual system by connections with the retina by a circuitous route (optic chiasma → suprachiasmatic nucleus → medial forebrain bundle → intermediolateral column of the upper thoracic spinal cord → superior cervical sympathetic ganglion → pericarotid sympathetic fibres → nervi conarii on the tentorium → pineal gland). The pineal output is mediated through the release of melatonin into the vascular system. Serotonin and several neuropeptides are also produced by the pineal. Through these afferent and efferent mechanisms, the pineal has now been proved to play a central role in the modulation of circadian rhythms, sleep-wake cycles, growth and puberty, reproduction, ageing, immune responses, cancer inhibition, epilepsy inhibition, mood, behaviour and even motor activity.[4] We are perhaps fortunate that pineal tumours leave these myriad functions intact and instead only cause symptoms due to mechanical compression.

PATHOLOGY

It is indeed surprising that a gland that is just 8 mm × 4 mm × 4 mm in size is home to more than 40 different types of tumours. Pineal tumours account for 1% of all brain tumours and about 3% of childhood brain tumours.[16] Table 1 summarises the classification of the tumours in the pineal region. This table also indicates the typical frequency of some of the major tumour types across nations. Of course, the data from neuroradiological, surgical-histopathological, autopsy based and population-based studies cannot be compared directly. Nevertheless, the difference in the geographical incidence of the various tumour types is striking, but the reasons for this difference are unknown. The details of the histopathology of pineal tumours are dealt with in another chapter. Certain special features are highlighted in this chapter.

Pineoblastomas may be associated with bilateral retinoblastoma in children and is known as 'trilateral retinoblastoma'.[81] Trilateral retinoblastoma is genetically determined and is associated with inactivation of the tumour suppressor gene (rb1) in the chromosome 13q14.[60] Apart from histology, the presence of neurofilament protein (NF) and low MIB-1 labelling index demonstrable by immunohistochemistry seem to confer a survival advantage in primary pineal tumour according to a recent study from NIMHANS, Bangalore.[5]

Germinoma may appear synchronously or metachronously in the pineal and suprasellar regions.[42] Note that the term 'pinealoma' is an archaic description for pineal germinoma and the term 'ectopic pinealoma' was used to refer to a germinoma in a non-pineal location. Germ cell tumours (GCTs) of the pineal have a strong male preponderance.[121] Klinefelter's syndrome and Down's syndrome may predispose to intracranial GCTs.[91,110] Distinguishing a pineocytoma with lymphocytic infiltration and a true germinoma might be a close call, especially on small endoscopic or stereotactic biopsies, as both these tumours display a 'two-cell pattern'. Immunohistochemical demonstration of placental alkaline phosphatase in the cells helps to identify a germinoma.[38] To add to the confusion, there is a prominent granulomatous component in certain germinomas and this might lead to an erroneous diagnosis of an inflammatory disease on small samples.[75] The original theory that the germinomas and the non-germinomatous germ cell tumours (NGGCTs) arose from the midline rests of the primordial germ cells is contested by Keiji Sano. He has advanced the theory that the only true GCT is germinoma. The so-called NGGCTs are, according to his theory, only enfolded cell-derived dysembryogenetic tumours.[100]

Gliomas are known to arise in the pineal gland but the majority of the glial tumours in this region arise in the neighbourhood structures such as the posterior third ventricle or dorsal midbrain.[6] Synchronous pilocytic astrocytoma in the optic pathway and pineal region occur in neurofibromatosis (NF-1).[84]

The histological type of tumour in the pineal region depends on the age of the patient. This information,

Table 1: Classification of pineal tumours and their incidence

Type of tumour	*Indian series*[55]	*Japanese series*[103]	*Western series*[15]
	Surgical series N = 54	*Tumour registry*	*Surgical series N = 191*
Pineal parenchymal tumours	39%	14%	25%
Pineoblastoma		5%	6%
Pineocytoma	19%	9%	14%
Pineal parenchymal tumour of intermediate	7%		5%
differentiation (PPTID)[101]	13%		
Germ cell tumours (GCT)	8%	61%	32%
Germinoma[70]			16%
Non-germinomatous germ cell tumours (NGGCT)		50%	2%
Embryonal carcinoma			
Endodermal sinus tumour (yolk sac tumour)			6%
Choriocarcinoma			
Teratoma		11%	
Mature			
Immature			8%
Teratoma with malignant transformation			
Mixed germ cell tumour[111]			
Glial cell tumours	37%	6%	27%
Astrocytoma[6]			14%
Giant cell astrocytoma (in tuberous sclerosis)[27]			1%
Oligodendroglioma[26]			7%
Ependymoma[86]	1.8%		1%
Choroid plexus papilloma[108]			4%
Anaplastic astrocytoma and glioblastoma multiforme[3]			
Mesenchymal cell tumours			
Meningioma[52]	3.7%		
Cavernous angioma[77]			5%
Hemangioblastoma[45]			
Other tumours			
Epidermoid tumour[28]	3.7%		
Craniopharyngioma[117]	3.7%		5%
Ganglioglioma[113]			
Lipoma[107]			
Chemodectoma			
Myxoid chondrosarcoma[106]			1%
Metastatic tumours[58]			
Lymphoma[88]			
Fibrosarcoma[61]			
Primary melanoma[64]			
Primary osteosarcoma[98]			
Non-neoplastic masses			
Pineal cyst[112]			
Arachnoid cyst[34]			5%
Cysticercosis[55]	1.8%		
Tuberculoma[9]	1.8%		
Sarcoidosis[126]			
Aneurysm of vein of Galen[96]			
Recently described tumours			
Atypical teratoid rhabdoid tumour (ATRT)[21]			
Papillary tumour of pineal region (PTPR)[49]			

Table 2: Frequency of pineal mass lesions at different ages

Age group	*Most common*	*Next so common*
Infants	Pineoblastoma	Arachnoid cyst, aneurysm of vein of Galen
Childhood	Germinoma, NGGCT	Pineoblastoma, glioma, tuberculoma
Young adults	NGGCT, glioma	Pineocytoma, pineal cyst
Older adults	Pineocytoma, glioma	Meningioma, epidermoid, metastasis

important in making clinical decisions, is presented in Table 2.

SYMPTOMS AND SIGNS

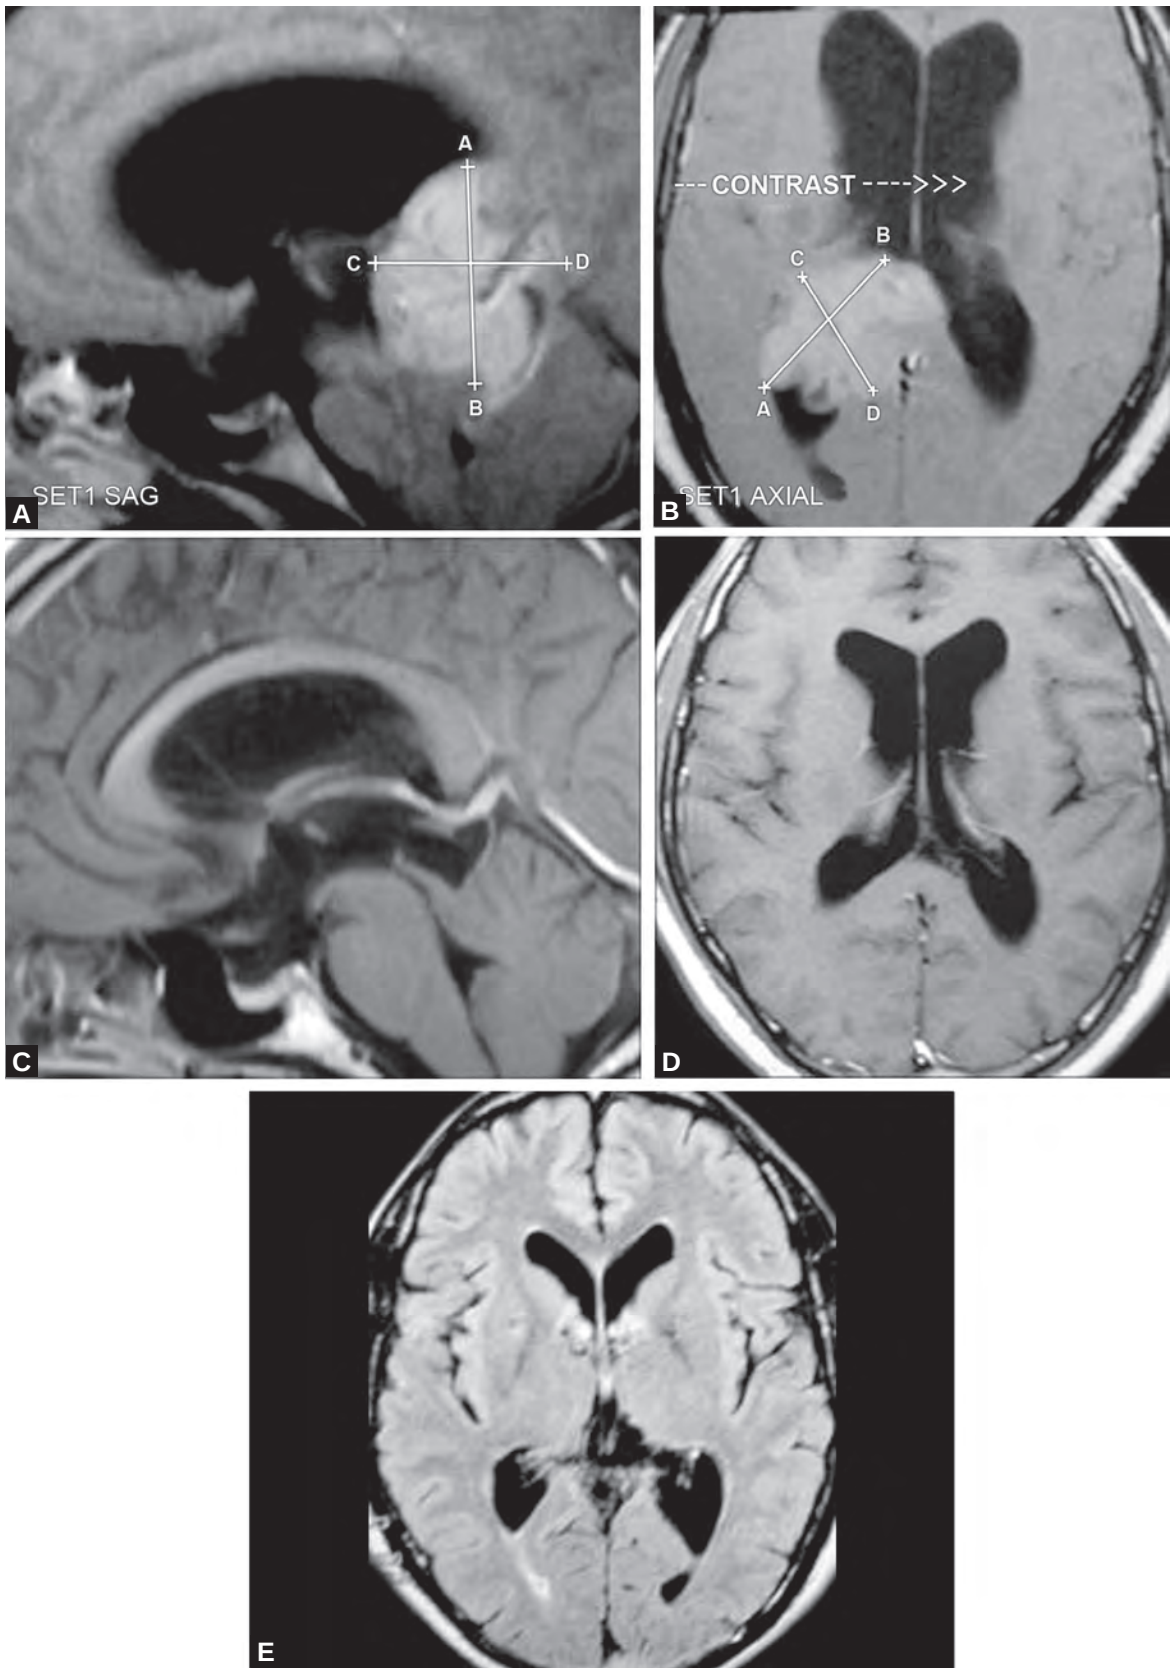
Pineal masses present in a variety of ways. The mechanisms of production of symptoms are: (1) Raised intracranial pressure due to obstruction of the posterior third ventricle or aqueduct or both; (2) Direct compression or infiltration of the neighbourhood neurological structures such as the tectum and the midbrain nuclei or white matter tracts; and (3) Endocrine dysfunction.

Raised intracranial pressure syndrome is the most common presentation of pineal masses across the ages. Older children or adults with raised pressure syndrome present mainly with headache. Vomiting or rapidly increasing head size is the symptom in younger children. Lethargy and obtunded mentation are seen in the later stages. Three fourths of the patients have papilloedema at presentation. Spells of loss of consciousness with limb rigidity might occur and is known as hydrocephalic attack. Sudden neurological deterioration may also be due to intratumoral haemorrhage (pineal apoplexy), which seems to be common in pineoblastoma and choriocarcinomas of children.[43] The intratumoural haemorrhage can also be precipitated by shunt or endoscopic procedures.[65,76]

Ocular signs are seen in about 50% of patients with pineal tumour. The differentiation of the ocular syndrome into Parinaud's syndrome, dorsal midbrain syndrome, pretectal syndrome and syndrome of the aqueduct of Sylvius (Koerber-Salus-Elschnig syndrome) appears to be a mere hair-splitting academic exercise. Paralysis of vertical gaze (up gaze alone or up and down gaze), deficiency of convergence, convergence-retraction nystagmus, disjunctive horizontal eye position, pupillary light-near dissociation, lid retraction (Collier's sign) and ptosis are seen in descending frequency.[50] Parinaud's syndrome is not pathognomonic of a pineal mass, as stroke, demyelination and hydrocephalus account for about 75% of the causes of the syndrome. The other eye signs reported with pineal tumours are reverse Parinaud's syndrome (paralysis of downgaze alone instead of upgaze),[67] unilateral supranuclear abducent paresis (lack of abduction during saccadic or pursuit volitional movements but preserved reflex abduction while performing oculocephalic manoeuvre or caloric testing),[127] bilateral superior oblique palsy,[7] contralateral relative afferent pupillary defect,[20] isolated vertical diplopia,[72] and paroxysmal tonic upgaze of childhood.[87]

Neurological signs are less common than signs of raised pressure or ocular signs. Involvement of the superior cerebellar peduncles can cause the ataxia-dysmetria syndrome even when hydrocephalus is absent. Gait ataxia is mostly due to hydrocephalus. Inferior colliculular involvement may present with tinnitus or hearing impairment. Hearing disturbance could be a symptom of a pineal mass and has been found in 18% in one series.[68] The hearing impairment has been noted to recover on treating the tumour.[40] Parkinson syndrome has been reported as a presenting manifestation of childhood pineal immature teratoma. This syndrome is known to remit with treatment of the tumour and might relapse when the tumour recurs.[30] Alexia, agnosia and amnesia have been rarely reported.[120] Vivid, coloured, formed visual or multi-sensory, long-lasting, non-epileptic hallucinations known as "peduncular hallucinosis" have also been reported with pineal tumour.[69] An example of such a presentation is given in Figures 1A to E from the author's case material.

Endocrine dysfunction is a childhood phenomenon restricted to pineal GCTs. Diabetes insipidus has been shown by neuroendoscopy to be due to involvement of the floor of the third ventricle, even when the MR imaging does not show such an involvement.[122] Precocious puberty is seen in 10% of boys with pineal GCTs. The most obvious explanation for the precocious puberty is the secretion of human chorionic gonadotrophin (β-HCG) from the syncytiotrophoblastic (choriocarcinomatous) elements in the tumour, but this is not the most common. It is believed that compression of the posterior hypothalamus by the mass results in loss of its inhibition of the median eminence resulting in excess of gonadotrophin releasing hormone (GnRH). There might also be a deficiency of antigonadotrophic substances (melatonin and others) that should normally be released by the pineal. Pineal tumour is only a rare cause of isosexual male precocious puberty as proved by a study from India.[29] Most of the cases were due to an adrenal or testicular cause; among the central causes the idiopathic variety and hypothalamic hamartoma were commonly seen. There was only one patient with a pineal tumour in this series of 22 boys. Anorexia nervosa may rarely be due to a pineal germinoma that involves the hypothalamic feeding centre.[123] Insomnia due to melatonin deficiency



Figs 1A to E: A 32-year-old male presented with three episodes of vivid, formed, coloured visual hallucinations lasting 30–60 minutes ('peduncular hallucinosis'), on a background of headache and gait ataxia. (A and B) Contrast MRI showed a pineal-posterior third ventricular mass extending into the right lateral ventricle. Endoscopic third ventriculostomy and biopsy of the mass in the lateral ventricle was done through a single coronal burr hole. Histopathology showed a primitive neuroectodermal tumour. He was given external beam radiotherapy (36 Gy for the neurospinal axis and a booster of 18 Gy to the tumour area). (C and D) The follow-up contrast MRI after 4 months. (E) After 18 months, showed total resolution of the tumour and normal ventricular size

caused by pineal germinoma has been reported and oral melatonin can be used to treat it.[35]

Rarer presentations include myelopathy or radiculopathy with spinal drop metastasis, which might predate the detection of the primary pineal tumour. They might also appear years after the pineal tumour has been eradicated by therapy. Similarly, delayed extraneural growth into bone or the chest is rare.[118] A clinical presentation similar to tuberculous basal arachnoiditis can occur due to extensive subarachnoid seeding of germinoma.[109] Haematogenous spread to bone has been reported with pineoblastoma.[24] Spread to the peritoneal cavity via shunt tubes[116] and spread along the endoscopy tract have also been observed.[23] Recurrent subarachnoid haemorrhage from a pineocytoma has been reported.[83] Progressive enlargement of an immature teratoma or NGGCT, following chemotherapy or radiotherapy, despite the normalisation of tumour markers, has been dubbed as the "growing teratoma syndrome". The enlarging mass is histologically a mature teratoma and is generally amenable to surgical excision.[11,71] An example of this syndrome is given in Figures 2A to C. In a neonate, presentation of a pineal cystic mature teratoma mimicking an encephalocoele has been reported.[8]

Asymptomatic patients with pineal masses are being increasingly detected with widespread use of neuroimaging. Asymptomatic small glial cysts are found in routine autopsies in about 25–40% but, until recently, they were seen only in less than 10% of cases on neuroimaging. The newer high-resolution MRI scanners can detect pineal cysts in about 23% of healthy adults.[90]

NEUROIMAGING

Calcification of the pineal is a physiological phenomenon. It is readily seen in plain radiographs and CT. Calcification increases with age; below the age of 6 years calcification is seen in only 1% of glands and by 14 years, 40% of glands are calcified as seen on CT.[32] In the days of plain radiographs, calcification larger than 1 cm in any one diameter, or any calcification before the age of 4 years were considered pathological.

MRI, with or without gadolinium, is the investigation of choice for diagnosing pineal masses. MRI gives information on the size, content, intratumoural haemorrhage or necrosis, degree of invasion and vascularity of the tumour and also shows the degree of ventriculomegaly. The sagittal and coronal images help to depict the slope of the tent and the relation of the tumour to the neighbourhood brain structures/deep venous system. This information is invaluable in planning the operative approach. MR imaging of the entire spinal cord is recommended to detect spinal seeding in children with malignant pineal tumours. Computed tomography demonstrates abnormal calcification in the tumour more obviously than MR and is useful for planning stereotactic approaches.[94]

Purely cystic lesions in the pineal region include pineal cysts, pineocytomas, arachnoid cyst, cysticercal cyst, low-grade astrocytoma and, rarely, teratoma.[34] Magnetic resonance imaging can generally distinguish pineal cyst from pineocytoma.[36] A recent report suggests that intrinsic T1 hyperintensity may be a characteristic imaging appearance of a papillary tumour of the pineal region provided the presence of fat and haemorrhage are ruled out.[18] Highly cellular tumours such as germinomas and childhood pineoblastomas may appear isointense or hypointense in T2-weighted images. In spite of the advances in neuroimaging, an exact histopathological diagnosis for most tumours can be made only by obtaining tissue. Table 3 gives some characteristic neuroimaging findings of pineal tumours. Figures 1(A to E) to 8(A to D) give examples of neuroimaging in various pineal lesions.

TUMOUR MARKERS

Pineal GCTs declare their presence by characteristic cell products that are found in the ventricular or lumbar CSF and in the serum. Alpha-fetoprotein (AFP), an oncofetal glycoprotein, is a marker for tumours with yolk sac elements, while β-human chorionic gonadotrophin (β-HCG) indicates a tumour with trophoblastic elements. Placental alkaline phosphatase (PLAP) is a marker for germinoma, but this is less widely used.[104] The normal levels and the extent of elevation of these markers in various tumours are given in Table 4. The CSF levels are more sensitive than serum levels.[92] Of course, lumbar puncture cannot be done unless the raised intracranial pressure is dealt with first. In a small subset of patients with characteristic imaging and elevated tumour markers, surgical biopsy may be avoidable. Figures 8A to D show an example of a patient in whom the diagnosis was based initially on detection of tumour markers. The analysis of tumour markers helps in follow-up and in detecting recurrence or spinal seeding. The diagnosis of growing teratoma syndrome rests on finding an enlarging mass on imaging even though the tumour markers have normalised[11] (see Figs 2A to C).

MANAGEMENT

The goals of management of pineal tumour are: (1) Management of hydrocephalus; (2) Establishing a firm diagnosis, preferably from tumour tissue; (3) Excision or mass reduction; (4) Avoidance of surgical morbidity and complications; and (5) Effective adjuvant therapy.

Direct surgical attacks on pineal tumours in the first half of the 20th century carried an unacceptable mortality. Hence, shunt placement and direct radiotherapy became the choice of treatment in the 1960s. In the 1970s, using the operating microscope, it was possible to approach pineal tumours with acceptable morbidity. In the 1980s, CT guided stereotaxy was introduced and it provided tissue diagnosis for the non-excisable lesions.

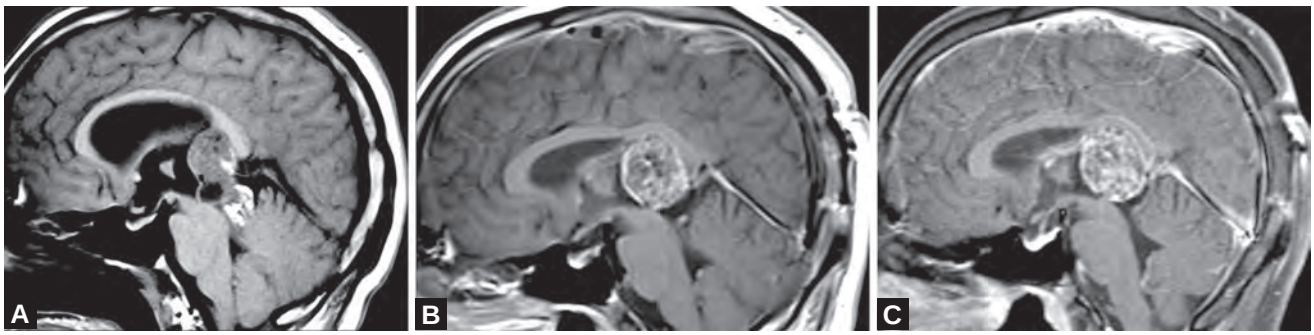
Table 3: Neuroimaging of pineal masses

Tumour type	*CT*	*T1 MR*	*T2 MR*	*Contrast CT/MR*	*Special features*
Pineoblastoma	Homogeneous, iso-hypodense, fine calcifications	Iso- or hypointense	Iso- or hypointense	Intense, slightly non-uniform enhancement	Occurrence in infancy or childhood, intratumoural haemorrhage, surrounding oedema, invasion, association with retinoblastoma
Pineocytoma	Non-homogeneous, iso-hypodense, peripheral calcifications	Iso- or hypointense	Hyperintense	Non-uniform enhancement, some nodular enhancement and > 2 mm rim enhancement	Occurrence in adults, intratumoural haemorrhage, expansive rather than invasive
Germinoma	Homogeneous iso- or hypodense, non-calcific	Well circumscribed iso- or hypointense	Iso- or hypointense	Intense uniform enhancement	Occurrence in young boys, spread to suprasellar region or basal ganglia surrounding oedema, intratumoural haemorrhage, subarachnoid seeding
Mature teratoma	Strikingly heterogeneous with areas of iso, hypo and hyperdensity, dense calcification	Well circumscribed mixed intensities	Mixed intensities	Heterogeneous enhancement	Occurrence in young adults
Malignant NGGCT	Heterogeneous, variable calcification	Mixed intensities	Mixed intensities	Non-uniform enhancement	Occurrence in young males, haemorrhages in choriocarcinoma
Glioma	Homogeneous hypodense, rare calcification	Iso- or hypointense	Hyperintense	Variable, inhomogeneous enhancement	Occurrence in adults, extension from or to midbrain, thalamus, splenium
Meningioma	Homogeneous hyperdense	Isointense	Hyperintense	Marked homogeneous	Attachment to falx, tent, velum interpositum
Pineal cyst	Hypodense centre and isodense rim	Hypointense centre, isointense to CSF with wall less than 2 mm thick	Hyperintense centre and isointense rim	Peripheral enhancement, no nodularity	Non-evolution over time, no hydrocephalus

Table 4: Tumour markers in pineal tumours

	AFP	*β-HCG*	*PLAP*
Normal serum level	0-8.5 ng/ml	0-7 mIU/ml	0.2 IU/L
Normal lumbar CSF level	< 5 ng/ml	< 2 mIU/ml	0.11 IU/L
Test	CLIA	CLIA	ELISA
Germinoma	Normal	Mild elevation < 770 mIU/ml	Highly elevated 1-9 IU/L
Endodermal sinus tumour	Highly elevated > 1000 ng/ml	Normal	Normal
Embryonal carcinoma	Moderately elevated < 1000 ng/ml	Mild elevation < 770 mIU/ml	Slight elevation
Choriocarcinoma	Normal	Highly elevated > 2000 mIU/ml, CSF level > serum level	Normal
Immature teratoma	Rarely and mildly elevated	Normal	Normal
All other pineal tumours	Normal	Normal	Normal
Systemic choriocarcinoma	Normal	Highly elevated > 2000 mIU/ml CSF level < serum level	Normal

(AFP = Alpha fetoprotein, β-HCG = β-human chorionic gonadotrophin, PLAP = placental alkaline phosphatase, CLIA = chemiluminescence immunoassay, ELISA = enzyme linked immunosorbent assay)



Figs 2A to C: A 19-year-old male presented with headache and diplopia. (A) MRI showed a markedly heterogeneous (calcific, cystic and lipomatous) pineal region mass with variable enhancement suggestive of teratoma. Through a right parieto-occipital interhemispheric approach, the tumour was partially excised. Histopathology showed immature teratoma. The serum AFP was 65 ng/ml in CSF after surgery but it came down to 0.6 ng/ml in CSF after three cycles of PEB (cisplatin, etoposide and bleomycin) chemotherapy by the 4th month. However, the tumour size progressively enlarged in the MRI done. (B) 2 months. (C) 4 months later. This is classical example of growing teratoma syndrome (Case courtesy: Dr KN Krishna, Neurosurgeon, Bangalore)

The late 1990s saw the emergence of endoscopy, which provided not only a solution to hydrocephalus but also made direct tissue biopsy and some tumour debulking possible. Thus, we now have a variety of methods to deal with a pineal tumour.

Decision-Making in Pineal Tumours

The main factors that impact the decision-making are: (1) Age of the patient; (2) Neurological status; (3) Imaging characteristics; (4) Presence of hydrocephalus; (5) Available technology; and (6) Experience of the surgeon.

Young children with pineal masses are likely to have a pineoblastoma or germinoma and these tumours do not lend themselves to aggressive excision. These tumours which are hypointense in T2-weighted images are homogeneous except for areas of haemorrhage and only rarely show calcification. Both these tumours are not associated with elevation of AFP or β-HCG. Ventricular diversion, preferably by endoscopic third ventriculostomy (so as to avoid seeding along the shunt tract) is often necessary. It is a common practice in the Eastern nations to subject these children to 20 Gy local field radiation without tissue diagnosis, as these countries have a high incidence of the very radiosensitive germinoma. If the tumour disappears, an additional 30 Gy radiation is given and the child followed-up. If the tumour does not disappear and the residue is more than 2 cm, microsurgical excision is recommended.[85] With the low incidence of germinoma in India, this is not the general approach in any Indian centre. Stereotactic biopsy might be difficult in young children, sampling errors may occur and some hold that stereotactic procedures in the pineal region are more prone to complications, although this is not necessarily so.[93] Endoscopic biopsy enables one, nowadays, to establish the tissue diagnosis at the same time as the third ventriculostomy, thus providing a basis for adjuvant therapy.[105] Endoscopic debulking is not a goal in these tumours.

Older children and young adults, especially males, have a higher likelihood of harbouring other GCTs. Marked heterogeneity on imaging suggests a teratoma and surgical excision is needed. A pre-operative ventricular diversion procedure may be needed only in patients presenting as an emergency with visual failure (from papilloedema) or altered sensorium. In non-emergent situations, one can directly proceed with microsurgical excision of the tumour. Only rarely is a ventricular diversion needed after total excision of the tumour. Mature teratomas do not require any further therapy. Even if there is a small post-operative residual mature teratoma, it only needs to be carefully followed up. The immature teratomas and teratomas with malignant transformation need adjuvant therapy. On the other hand, an enhancing tumour that shows only some inhomogeneity on imaging in a young male may be: (1) Embryonal carcinoma; (2) Endodermal sinus tumour; (3) Choriocarcinoma; or (4) Mixed GCT. Elevation of AFP suggests endodermal sinus tumour or mixed GCT with yolk sac elements (see an example in Fig. 4). Very high levels of β-HCG would indicate choriocarcinoma or mixed GCT with syncytiotrophoblastic element (see an example in Figs 8A to D). Moderate elevations of both the markers might mean an embryonal carcinoma. All these four tumours carry a poor prognosis. Even though they show an initial response to radiation, they tend to recur and metastasise.[100] Stereotactic biopsy might sample only one area in a mixed tumour and this might vitiate the prediction of prognosis. Surgical excision not only rids the patient of the mass effect but also produces a complete histopathological analysis of the tumour. In the situation of elevated tumour markers, it is acceptable to give radiation first and reserve microsurgery for sizeable residual tumour mass.[100] The residue might be the mature teratomatous component of the tumour and this might continue to enlarge after radiochemotherapy, in spite of the fact that the tumour marker level has become normal.

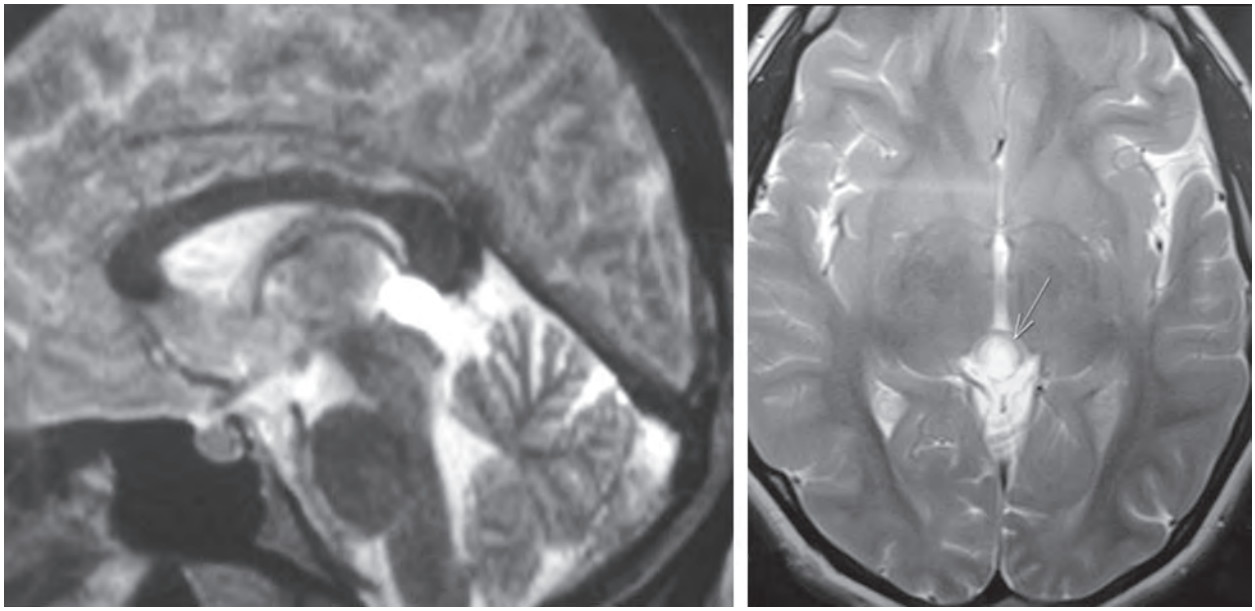


Fig. 3: MRI of an asymptomatic pineal cyst in a 17-year-old girl

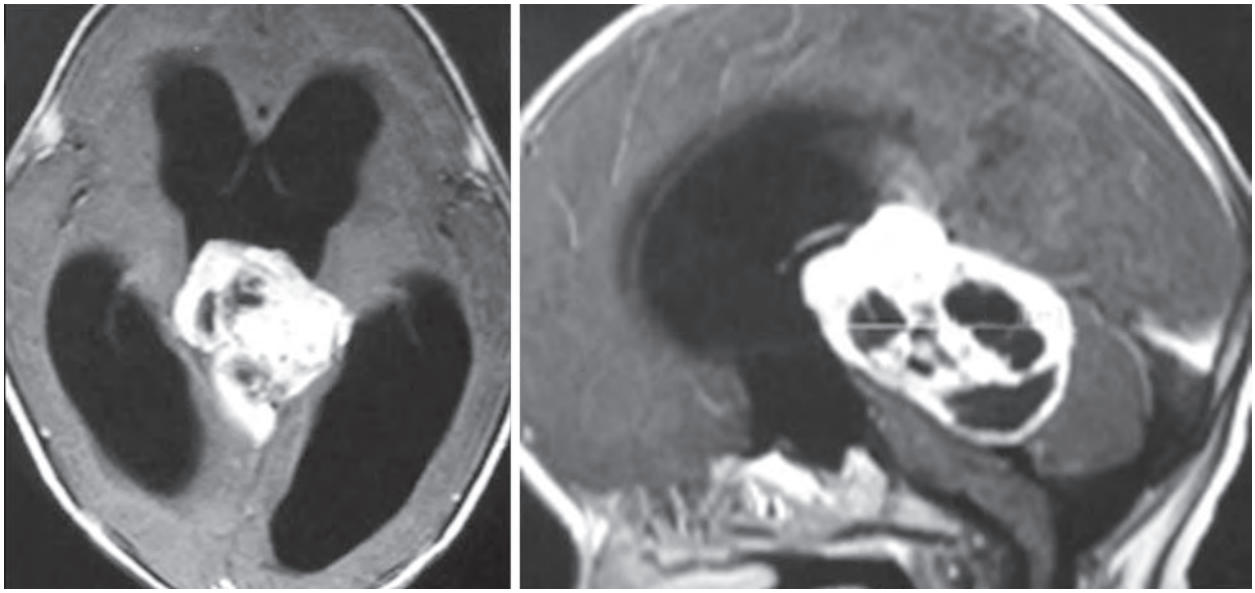

Fig. 4: A 1¼ -year-old baby presented with vomiting and loss of walking ability. MRI showed a richly enhancing large mass in the pineal region with necrotic areas. The serum AFP was 225 ng/ml. Endoscopic third ventriculostomy and biopsy through a single burr hole showed a mixed malignant germ cell tumour with components of immature teratoma and endodermal sinus (yolk sac) tumour. The family refused definitive surgery or adjuvant therapy

This 'growing teratoma syndrome' calls for microsurgical excision.[39]

Among older adults, meningiomas and epidermoids have characteristic imaging appearances and need microsurgical excision. However, pineocytomas and gliomas are the most likely lesions in this age. Masses larger than 2 cm can directly be accessed and excised using the most appropriate microsurgical route. Total excision is possible in many cases, but not all. Adjuvant therapy then is based on the histology and the post-operative residue on imaging. Smaller masses can be excised or at least biopsied by endoscopy. Stereotactic biopsy is more accurate in the smaller lesions.

SURGICAL APPROACHES

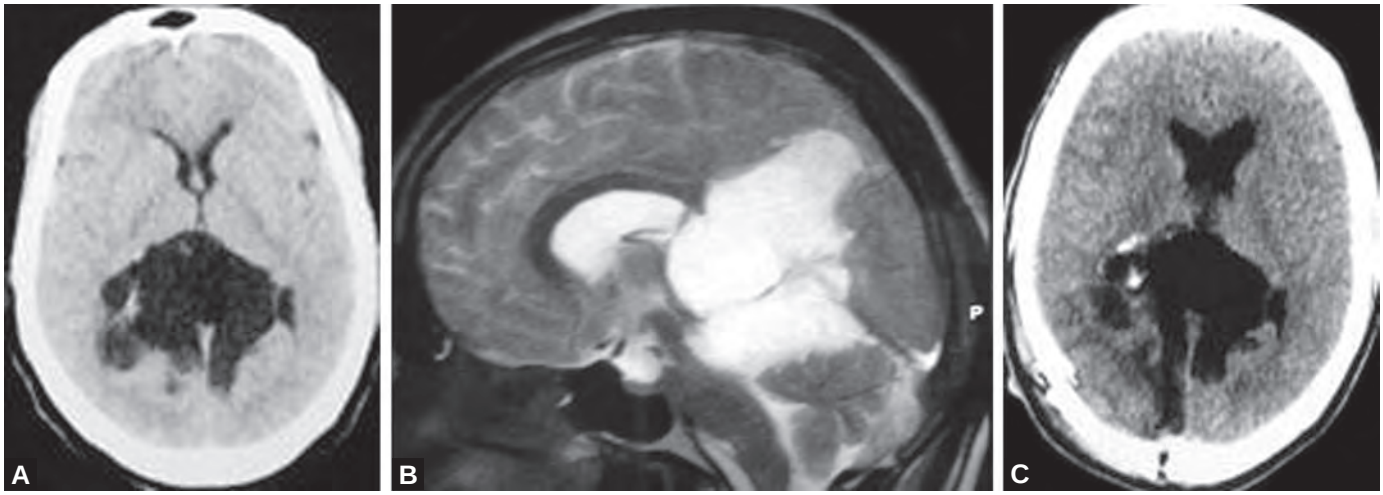
Pineal tumours are located in the geometric centre of the head and this makes them equidistant from the surface regardless of the site of surgical entry into the skull.

The depth of location, the proximity to the deep veins and the malignant nature of some of the tumours have deterred generations of surgeons from approaching pineal tumours. Even a stalwart, like Cushing, felt that he was never able to expose a pineal tumour well enough to justify its removal. Nevertheless, intrepid neurosurgeons, such as Krause (infratentorial supracerebellar approach—1926), van Wagenen (translateral ventricular approach—1931), Dandy (parafalcine trans-splenial approach—1936) and Poppen (occipital approach—1966), described operative approaches to pineal tumours with modest success. The mortality and morbidity were high in the era before steroids, safe anaesthesia and operative magnification. Shunt placement followed by radiotherapy was, therefore, perceived to be the safer choice. Availability of operating microscopes and neuroimaging rekindled interest in the direct operative approaches during the last 25 years of the 20th century. Although the mortality came down during this period, the surgical complication rate (morbidity) was still a deterrent. The trend shifted towards minimally invasive procedures such as CT guided stereotactic biopsy and neuroendoscopic intervention.

Surgical Anatomy

The pineal gland is attached to the posterior wall of the third ventricle and is between the posterior commissure below and the habenular commissure above. The suprapineal recess located above the habenular commissure is larger than the tiny pineal recess. Anteroinferior to the posterior commissure is the opening of the cerebral aqueduct and these structures are well seen through the endoscope introduced through the foramen of Monro, after passing the massa intermedia (interthalamic adhesion). The paired choroid plexus in the roof of the third ventricle and the dark internal cerebral veins shining through the ependyma of the roof are also seen.

The microsurgical anatomy of the infratentorial and supratentorial approaches has been described and compared.[125] When seen from the inferior perspective of the supracerebellar approach, on retracting the culmen of the vermis inferiorly, the thick opaque arachnoid passing up to the posterior tentorial incisura is first encountered. On opening the arachnoid, the right and left basal veins of Rosenthal coursing from below and laterally upwards towards the vein of Galen are seen lying lateral and superior to the pineal. The basal vein may also join the internal cerebral vein of the same side (35%), or the straight sinus (9%). The precentral cerebellar vein passes from the vermis to empty into the vein of Galen in the midline, in normal persons. However, in the presence of a pineal tumour, it may be found shifted to one side or the other. Sacrifice of the precentral cerebellar vein is often necessary and this only rarely results in major venous infarction in the cerebellum.[47] There may be a pair of precentral cerebellar veins in about 50% and at least one can be spared in such cases. The precentral cerebellar vein might also empty into the straight sinus. The vein of Galen above obscures the vision of the splenium and the mass itself obscures the quadrigeminal plate. After removing the tumour, the colliculi may be seen if the tumour has not infiltrated them. The posterior third ventricle often gets opened after removing the mass. The massa intermedia, the paired choroid plexus in the roof of the third ventricle, the columns of the fornix and foramina of Monro can be seen within the third ventricle. The blood vessels nourishing the tumour come from the choroidal arteries on either side and from the velum interpositum above the roof of the third ventricle. Branches of the superior cerebellar artery



Figs 5A to C: A 50-year-old man presented with headache, left haemianopia and left limb ataxia. (A) CT scan showed a hypodense, non-enhancing mass in the pineal region with finger-like extensions and peripheral calcifications. (B) T2-weighted MR images showed that the lesion surrounded the deep veins. Through a right occipital transtentorial approach, most of the epidermoid tumour could be decompressed. The lining membrane adherent to the tectum and splenium was left behind. (C) Post-operative CT showed the empty space left behind by the tumour resection to be filled with CSF. The medial occipital surgical corridor is well seen. The headache and ataxia improved but the haemianopia persists

to the inferior colliculi get exposed inferiorly and must be saved. Damage to the inferior colliculi can result in hearing impairment and word deafness.[63]

When seen from the superior perspective of the posterior transcallosal approach, the splenium of the corpus callosum covers the pineal region and posterior callosotomy is always needed. Splitting the splenium exposes the terminal portions of the internal cerebral veins and the point where they merge to form the vein of Galen. The dorsal surface of the tumour may have splayed the internal cerebral veins slightly and this corridor can be used to decompress and excise part of the tumour. The other corridor available is below and medial to the right basal vein of Rosenthal. Division of the right tentorial leaflet enhances the room available in this approach and helps to reach the infratentorial part of the tumour.

When seen from the posterior perspective of the occipital transtentorial approach, the venous anatomy is similar and the veins are often seen without the need for sectioning the splenium. The tumour might also have lifted up the splenium. The view of the colliculi is better with both the supratentorial approaches.

Endoscopic Approach

Indications

The minimally invasive nature of endoscopy is appealing to the neurosurgeon and the patient. The primary indication for endoscopy for a pineal mass is for performing third ventriculostomy to relieve hydrocephalus. If the foramen of Monro is large enough and if the mass is visible in the posterior wall of the third ventricle, a biopsy of the tumour can also be performed. Lesions less than 2 cm or larger cystic lesions can adequately be managed endoscopically, if they are not highly vascular. A second open microsurgical procedure may not be necessary in the smaller, radiosensitive malignant lesions such as germinoma, NGGCT and pineoblastoma. Endoscopic biopsy has also been used for differentiating recurrent tumour from radionecrosis.[22] It must be explained to the patient that open microsurgery might still be necessary even after a successful endoscopic approach. A new minimally invasive technique, computer-assisted cisternal endoscopy (CACE), for the biopsy of pineal tumours, has been studied in cadavers and is purported to be used even when there is no hydrocephalus.[128]

Technique

The procedure is done through the non-dominant hemisphere, generally the right. In the supine position with 20 degree head elevation, through a coronal scalp flap, a burr hole is placed just anterior to the coronal suture. Ventricular CSF sample can be collected for tumour marker analysis before introducing the endoscope. If the foramen of Monro is large enough, the rigid endoscope can be manoeuvred backwards through the same burr hole anteroinferiorly for the third ventriculostomy and posteriorly for lesion biopsy, without causing damage to the anterior column of the fornix (see examples in Figs 1A to E, 4 and 6A to D). If the foramen is small, a rigid scope can be used for the third ventriculostomy and a flexible scope for the tumour biopsy. Alternatively, a second burr hole can be placed about 2–2.5 cm more anteriorly to provide a convenient trajectory for the biopsy using the rigid endoscope (see example in Figs 7A to D). The optimal trajectory for the ventriculostomy and biopsy can be planned and executed with neuronavigation.[51]

The technique of third ventriculostomy is the same as in other cases. There may be obscuration of the floor of the third ventricle by tumour spread, especially with germinoma or tectal glioma. It is possible to work one's way through a thin layer of tumour into the subarachnoid space.[44] There is, however, a risk of the stoma shutting off over time in such cases.[62] We prefer doing the third ventriculostomy before the biopsy, as the bleeding during the biopsy might obscure the landmarks for ventriculostomy. The mass is often found covered by the ependyma and this must be opened with bipolar cautery. The outer surface of the tumour is then opened and multiple bits must be taken from the inside of the tumour for biopsy so as to minimise sampling error. It is a luxury to have a pathologist standing by for performing frozen section or smear analysis immediately.[89] If the lesion appears highly vascular, it is better to avoid endoscopic biopsy. An external ventricular drain is not used unless there has been significant bleeding during the biopsy.

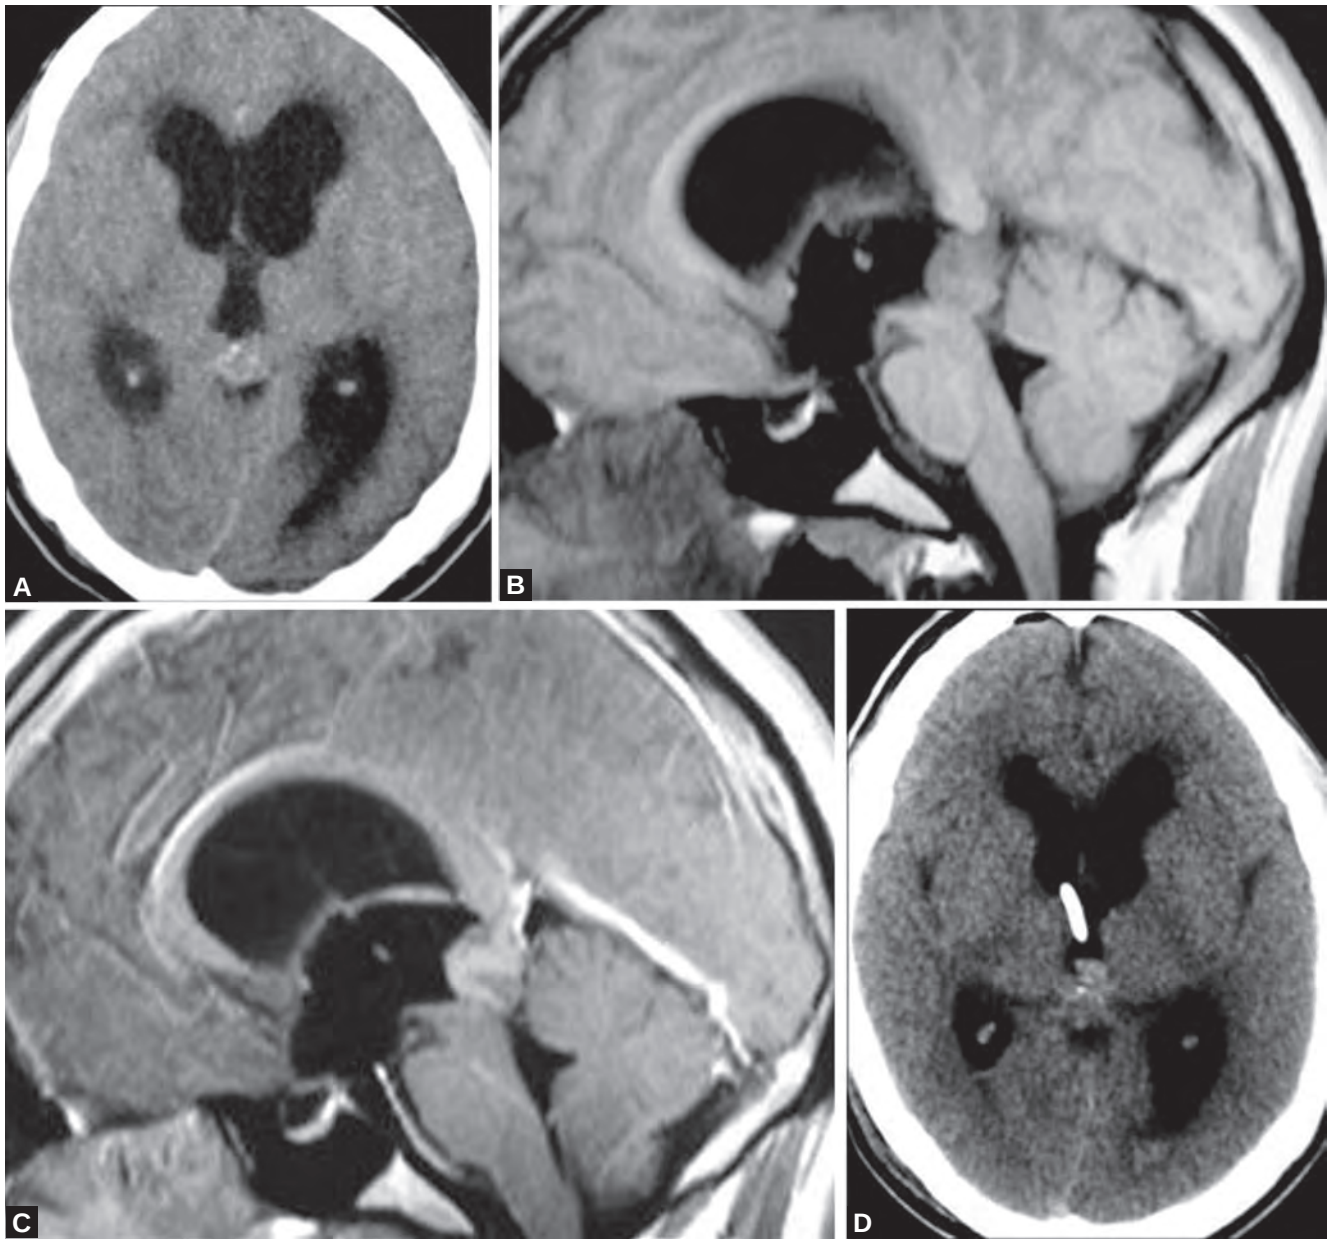
Complications

Bleeding from the tumour can be a significant problem during endoscopic biopsy or decompression. The bleeding usually comes under control with prolonged irrigation and ventricular filling. Inadequate tissue sampling by endoscopy has made some prefer the open or stereotactic approach. Damage to the fornix, resulting in memory loss, is possible after excessive manipulation of the endoscope thorough a minimally dilated foramen of Monro. Spread of tumour through the endoscopy track[23] or into the third ventriculostomy site[22,62] is known. No mortality or permanent morbidity was seen following endoscopic biopsy of pineal lesions in a recent series of 12 cases. Two cases of transient worsening of preoperative diplopia were noted. Diagnostic sensitivity for endoscopic biopsy was 75%.[2] In a long-term follow-up study, shunts were needed in nearly 25% of the patients and the biopsy yield was non-diagnostic in about 25% of cases.[82]

Stereotactic Approach

Indications

CT guided stereotactic biopsy has been viewed as being risky due to the surrounding major veins in the pineal region. This fear persists, in spite of the demonstration about a decade back by the French neurosurgeons, that

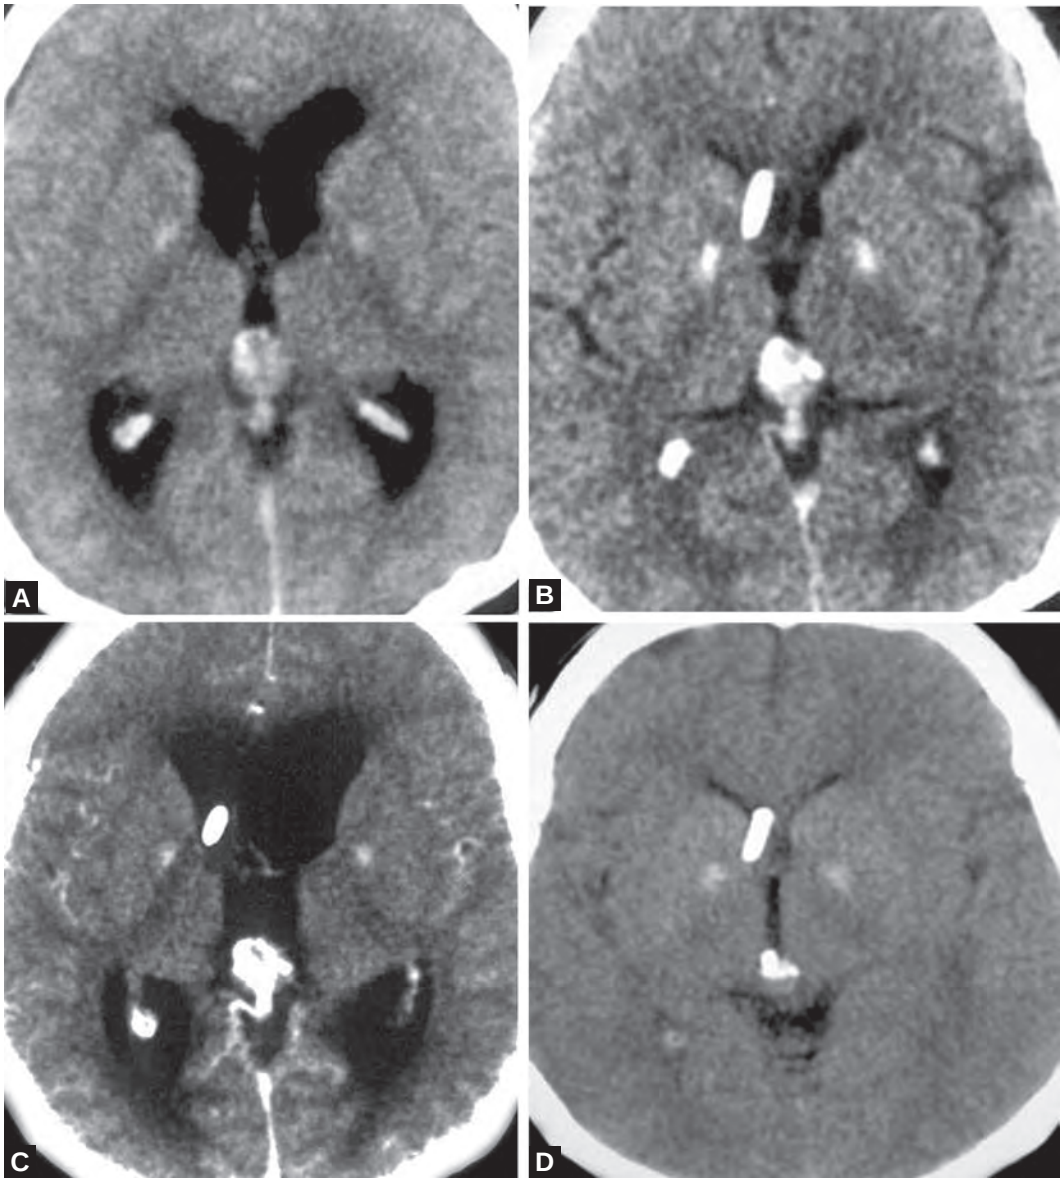


Figs 6A to D: A 20-year-old man presented with headache, papilloedema, ataxia and tremors. (A) The plain CT showed a pineal mass with punctate calcification. (B) MRI showed a T1-isointense tumour and T2-hypointense tumour. (C) There was non-uniform contrast enhancement. Endoscopic third ventriculostomy and biopsy-decompression of the tumour was done. The pathology was pineoblastoma. (D) The immediate post-operative CT, before removing the ventricle drain, showed reduction in size of tumour and no significant haemorrhage. He underwent craniospinal axis irradiation and remained asymptomatic 6 months later

stereotactic biopsy is as safe in the pineal region as elsewhere in the brain.[93] The larger tumours anyway need excision and do not need a preliminary stereotactic biopsy. If a malignant radiosensitive lesion is clinically thought to be likely, stereotactic biopsy and radiotherapy, without tumour resection, is a viable alternative. Since endoscopy is not recommended for those without hydrocephalus, stereotactic biopsy is a good choice in such patients. Aspiration of cystic lesions can be done by the stereotactic approach. Stereotaxy is also employed for implanting radioactive material (iodine-125) for brachytherapy.[53]

Technique

CT guided stereotactic biopsy is usually done through a non-dominant side pre-coronal trajectory, that is planned so as to avoid lateral ventricular entry and the internal cerebral vein. Tumours that extend laterally towards the thalamus can also be approached through a parietal trajectory. In tumours that are markedly heterogeneous on imaging multiple sites of biopsy are recommended to reduce the sampling error. Interactive image guided (frameless) surgical biopsy has also been reported to be successful.[97]



Figs 7A to D: (A) A 38-year-old woman had been diagnosed to have a pineal tumour 2 years earlier and had undergone ventriculoperitoneal shunting in another city. No definitive therapy had been given. She had improved in her headache and visual symptoms. (B) There was no ventricular dilatation and a persisting pineal tumour in the CT one year later. (C) 2 years later she returned with recurrent spells of altered sensorium. She had Parinaud's syndrome with Parkinsonian tremor and she progressed to drowsy-akinetic mute state. (C) CT showed recurrent hydrocephalus without increase in the size of the mass lesion. Endoscopic third ventriculostomy was done through a coronal burr hole. Since the foramen of Monro was small, a second frontal (precoronal) burr hole was placed and through this trajectory, the mass was biopsied and decompressed. Histologically, it was a pineocytoma. Radiotherapy was given. She made a rapid and full recovery and continues to be neurologically normal at follow-up 4 years after the procedure. (D) CT scan 18 months after the endoscopic surgery showed only a small speck of residual calcification. Note the resolution of hydrocephalus

Complications

Haematoma formation is a much feared but rare complication.[37] Implantation metastasis is distinctly rare and has been reported in a case of pineoblastoma.[95] In a series of 370 cases across several centres, the mortality of stereotactic biopsy was 1.5% and neurological complications occurred in less than 1% of cases.[93]

Microsurgical Approaches

Indications

All benign pineal lesions that can be diagnosed with reasonable certainty on imaging would certainly require open microsurgical excision. These include meningiomas, cavernomas, epidermoids and mature teratomas.

Such lesions account for about 15% of all lesions in the pineal region. A recent study showed that microsurgical removal is the only effective treatment for teratomas, even in children.[80]

Some malignant lesions are radiosensitive and they can be diagnosed by tumour marker study, endoscopic biopsy or stereotactic biopsy. Examples are germinomas and some NGGCTs (choriocarcinoma, endodermal sinus tumour, embryonal carcinoma). There is not much point in performing an open microsurgical procedure in such cases. The proportion of such tumours is variable in different races and is generally low in India.

All the remaining lesions do not have a distinctive imaging appearance and cannot be diagnosed by tumour marker study. The histological heterogeneity of the immature or mixed teratomas makes limited, minimally invasive biopsies unreliable. A more complete histological diagnosis can be expected with the entire resected tumour specimen. The poor radiosensitivity of the low-grade pineal parenchymal tumours and gliomas necessitates gross total resection. These lesions make up over a third of the pineal lesions in most countries (except in the Eastern Asian nations). In many of such low-grade lesions, further adjuvant therapy (with their potential toxicity) can be avoided or deferred when gross total resection is accomplished. Gross total resection is possible in about a third of the malignant tumours and an aggressive resection offers a survival advantage.[14] The potential benefits of open microsurgical resection must be weighed against the potential risks. The operative mortality in expert hands was 4% with 3% permanent major morbidity in a series of 160 aggressive operations on pineal tumours.[14]

Pineal tumours can be approached from either above or below the tentorium. The midline infratentorial supracerebellar approach, as described by Stein in the microsurgical era, is the most commonly employed approach.[15] The lateral paramedian infratentorial approach described by Van den Bergh is a variation.[119] The various supratentorial approaches are:

- Occipital transtentorial approach described by Poppen and modified by Jamieson[115]
- Posterior transcallosal approach, first used by Dandy[33]
- Posterior transventricular approach, first used by van Wagenen[10]
- Anterior transcallosal, transventricular, transvelum interpositum approach, described by Sano.[99]

Large tumours, especially meningiomas, may require a combined supratentorial and infratentorial trans-sinus approach, as described by Ziyal and Sekhar.[129] The advantages, disadvantages and specific indications for these various approaches are summarised in Table 5. In the following section, the two principal procedures of midline infratentorial supracerebellar and occipital transtentorial approaches are discussed in some detail.

A preliminary ventriculoperitoneal shunt or endoscopic third ventriculostomy is often necessary, before definitive surgery for the pineal tumour in patients with severe raised intracranial pressure. If the hydrocephalus is mild, a ventriculostomy catheter can be placed at surgery, left behind for 2–3 days after surgery and then either removed or converted to a shunt. Posterior third ventriculostomy that naturally occurs or is intentionally done after resecting the pineal mass may also provide relief of hydrocephalus.

Infratentorial Supracerebellar Approach

Technique

The patient is positioned sitting with the neck flexed forwards such that the tentorial slope along the straight sinus is almost parallel to the floor. Gravity assists cerebellar retraction in the sitting position. The head is fixed in a pin clamp such as Mayfield or Sugita system. The prone 'Concorde' or lateral decubitus positions are also used and they reduce the risk of air embolism. These alternative positions do not eliminate the need for air embolism monitoring (end tidal carbon dioxide or transoesophageal Doppler monitoring). There is less fatigue for the surgeon in these alternative positions as compared to the sitting position.

The incision can be a straight midline or a 'lazy S' incision that starts 5 cm above the external occipital protuberance and extends to the C2 spinous process. The pericranium above the external occipital protuberance is lifted off as a flap but left attached on one side. This can be used as dural substitute during closure. The muscles are split in the midline right down to the bone and raised on both sides, so that they can be approximated again. Burr holes are made just above the transverse sinuses and over the cerebellar convexities on either side. These burr holes are connected with a craniotome after separating the undersurface of the bone from the sinuses with a Penfield dissector. The craniotomy exposes the transverse sinuses, torcula and the lower end of the superior sagittal sinus. The posterior rim of the foramen magnum is left intact to prevent excessive sagging of the cerebellum. Performing a free bone flap craniotomy allows replacement of the bone at the end of surgery. Craniectomy is a less preferred alternative. The thick bone over the torcula must be thinned down and removed with high-speed cutting burrs so that it will not impede upwards retraction of the dural flap.

The dura is opened as a semilunar flap or three triangular flaps based on the transverse sinuses. The dural flaps are retracted upwards with sutures. If the brain is sufficiently relaxed, the undersurface of the tent should be seen at this stage. If not, further relaxation must be achieved with mannitol, hyperventilation and CSF drainage either by opening the cisterna magna or by tapping the lateral ventricle. The arachnoid adhesions between the superior surface of the cerebellum and the tentorium are sharply divided under the operating microscope. The draining veins on the superior surface of the cerebellum passing to the undersurface

Table 5: Advantages, disadvantages and specific indications of the various microsurgical approaches to pineal masses

Approach	*Advantage*	*Disadvantage*	*Indication*
Midline infratentorial supracerebellar	Midline approach Tumour is below major veins and they do not hamper resection Gravity assists in retracting cerebellum and separating tumour from the veins above, if the patient is in the sitting position No intentional neural damage	Air embolism in sitting position Narrow operative corridor, especially if the tent is steeply sloped Sacrifice of superior cerebellar draining veins and precentral cerebellar vein may cause cerebellar infarction Difficult to reach above tentorial incisura or lateral extensions of tumour	Midline pineal masses Tumour does not have lateral extension or superior extension high above the incisura Tumour not larger than 3 cm
Lateral paramedian infratentorial	No sacrifice of precentral cerebellar vein Can be done when the tent is steeply sloped in the midline No intentional neural damage Lateral decubitus position avoids risk of air embolism	Only small tumours can be approached Superior cerebellar artery and its branches may be at risk Cannot see the posterior third ventricle	Small tumour below tentorial notch with unilateral lateral extension, in patients with steep slope of the tent in the midline
Occipital transtentorial	Good view of structures and tumour above and below the tent	Retraction damage to occipital lobe and resulting haemianopia Damage to splenium, disconnection syndrome Unilateral approach, so difficult to reach across the midline to the opposite side	Tumours that extend entirely above or equally above and below the tentorial notch Tumours with unilateral (usually right) lateral extension
Posterior transcallosal (through parieto-occipital bone flap crossing the midline)	Ease of approaching lesions above the tentorial notch with extension to the third ventricle	Internal cerebral veins come in the way Callosotomy may lead to disconnection syndromes Cannot reach inferior portions of the tumour Parietal lobe retraction damage or venous damage	Posterior third ventricular mass, mass arises below the splenium, above the venous system
Posterior transventricular (through high parietal craniotomy and superior parietal lobule corticotomy)	Exposure of atrium and posterior portion of the body of lateral ventricle	Fornix sectioning needed for entering third ventricle and this may cause memory deficit Seizure risk due to corticotomy	Tumour extends laterally from the third ventricle to the posterior part of the lateral ventricle
Anterior transcallosal, transventricular, transvelum interpositum (through precoronal parasagittal craniotomy)	Wider room to deal with the anterior extent of tumour No fornix section as the approach is through the velum between the (right) internal cerebral vein and the choroid plexus of (right) lateral ventricle Supine positioning is easy and risk-free	Increased depth of approach Callosotomy deficits Fornix damage from retraction	Large tumour that extends anteriorly in the third ventricle up to the interthalamic adhesions
Combined supra and infratentorial trans-sinus (semiprone position, suboccipital and bilateral two piece occipital craniotomy, non-dominant transverse sinus and tent divided)	View of tumour above and below the tent Ample room The divided transverse sinus may be resutured	Division of transverse sinus may produce venous infarction or delayed intracranial hypertension	Large meningioma, epidermoid, teratoma

of the tent must be coagulated and divided before they snap due to the effect of gravity. Self-retaining retractors are placed on the undersurface of the straight sinus and tent and over the superior cerebellar surface. The thick arachnoid posterior to the pineal region is opened with sharp microdissection to expose the venous anatomy (mentioned above in the section on surgical anatomy). The microscope must be angled cranially towards the apex of the tentorial notch for the arachnoid dissection. The precentral cerebellar vein generally needs to be coagulated and divided. Once this is done, the posterior surface of the tumour comes into view. As the dissection proceeds, the microscope is angled inferiorly.

The surface of the tumour is devascularised and opened with long non-stick bipolar forceps. Tissue from the tumour is sent for squash/frozen section histology. Internal debulking of the tumour can be done with tumour forceps until adequate material is obtained for regular histopathological examination. The remaining portion is dealt with by suction-dissection or ultrasonic surgical aspirator using the long narrow hand piece. The wall of the tumour is then drawn away and, if it tends to separate well, the tumour can be excised in toto. This is generally possible with benign tumours and the non-infiltrating malignant tumours. The portions that infiltrate the brainstem or those that are intimately attached to the veins would have to be left behind. Venous bleeding in a narrow corridor can cause malignant brain swelling and must be avoided.[47] Through this approach, the superior portion of the tumour towards the velum interpositum is better visualised than the inferior portion towards the colliculi. Opening through-and-through the tumour into third ventricle and performing a front-to-back dissection helps to separate the lateral attachments of the tumour. Meticulous haemostasis is essential. Complete dural closure is advocated to minimise the chance of aseptic meningitis and usually needs a patch of pericranium or artificial dura. Replacing the bone flap helps to avoid pain and pseudomeningocoele.

Complications

The intra-operative complications related to the sitting position are hypotension, air embolism and cervical myelopathy.[79] Ventricular collapse might cause a supratentorial subdural haematoma. Extraocular movement disorder or ataxia that worsens after surgery is expected to recover to the baseline status over some weeks. Mental obtundation and even mutism have been observed.[102]

Occipital Transtentorial Approach

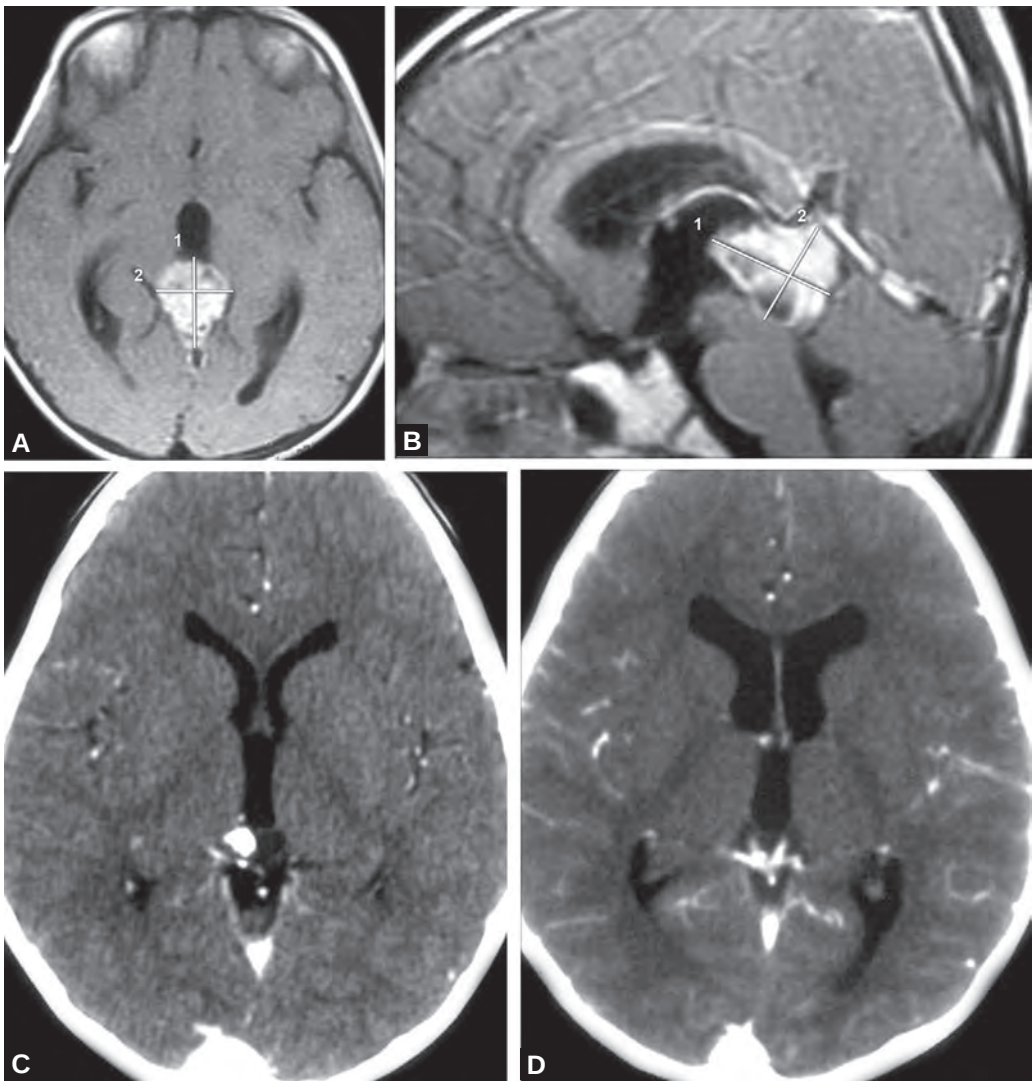
Technique

The procedure is done on the non-dominant side, usually the right. The occipital transtentorial approach can be done conveniently with the patient in the prone position and the head rotated to the left to allow some gravity retraction of the right occipital lobe. The three-quarter prone position achieves the same end.[12] The left lateral position was the originally described position. Sitting slouch position is a less preferred alternative. The incision starts below the external occipital protuberance just to the left of the midline and runs parallel to the midline before turning laterally and downwards to the lateral end of the transverse sinus. The low parieto-occipital bone flap exposes the right edge of the superior sagittal sinus but does not need to crossover to the left side. The upper edge of the sinus and the right lateral edge of the torcula are also exposed.

The dura is opened as two triangular flaps, one based on the transverse sinus and the other on the superior sagittal sinus. The right occipital horn can be cannulated if the brain is not lax. In the ideal case, the medial inferior edge of the occipital lobe drops away from the falcotentorial junction. If not, a bent self-retaining brain spatula is placed over the medial edge to retract it laterally. Lifting the inferior surface of the occipital lobe upwards is not recommended as it does not give additional room and as it damages the calcarine area. There are usually no major draining veins passing to the sinuses from the medial inferior border. Any small draining vein can be coagulated and divided. Once the tentorial edge is seen anteriorly, the tent is divided parallel to and about 1.5 cm lateral to the straight sinus from an anterior to posterior direction under the operating microscope. The division of the tent is for about 2–3 cm only and not all the way posteriorly to the transverse sinus. The arachnoid posterolateral to the venous complex is then seen and must be opened by sharp dissection. The right basal vein and the vein of Galen are first seen, the internal cerebral vein being hidden from view by the splenium. The tumour is discernible medial and inferior to the right basal vein. Small tumours without anterior extension and the larger tumours that have displaced the splenium upwards can be removed without sectioning the splenium. Only those that extend anteriorly and upwards may require splitting of the splenium. The extent of splenial section is much less than that needed for the posterior transcallosal approach. The tumour removal proceeds as described in the infratentorial approach. It is far easier to see the quadrigeminal plate after tumour removal in this approach. The anterior and left lateral extensions are difficult to approach through this corridor.

Complications

The mortality rate of supratentorial approaches has fallen from 70% in Dandy's time to about 5% in the microscopic era. In one series of 86 cases, there was only one procedure related death.[57] Mortality is related to deep venous system damage or haemorrhage. Left haemianopia is seen immediately after the surgery in nearly three quarters of the patients, but it tends to recover in most of them.[78] Ataxia, transient worsening of eye movement disorders and seizures can also



Figs 8A to D: A 6-year-old boy presented with morning headache and papilloedema. (A and B) MRI showed an enhancing pineal mass. Ventricular CSF collected during shunt placement and lumbar CSF obtained after shunting were analysed for tumour markers along with serum sample. The AFP was normal in the serum and CSF. The β-HCG level was 23.0 mIU/ml in the serum, 80.9 mIU/ml in the ventricular CSF and 127 mIU/ml in the lumbar CSF. This suggested a syncytiotrophoblastic component in the tumour. He was given radiotherapy. The shunt malfunctioned in a month and was removed at another centre. Endoscopic third ventriculostomy was done there with biopsy, which confirmed a mixed malignant non-germinomatous germ cell tumour with syncytiotrophoblastic elements. He was asymptomatic after radiotherapy. (C) The follow-up CT at 1 year showed no trace of the tumour and a small calcific speck. (D) Two years after the initial diagnosis, he became ill with diffuse encephalomyelopathy even though there was no tumour recurrence in the pineal region and the β-HCG levels were normal. MRI of the spine and lumbar CSF cytology did not show tumour. He succumbed to the encephalomyelopathy 2½ years after diagnosis

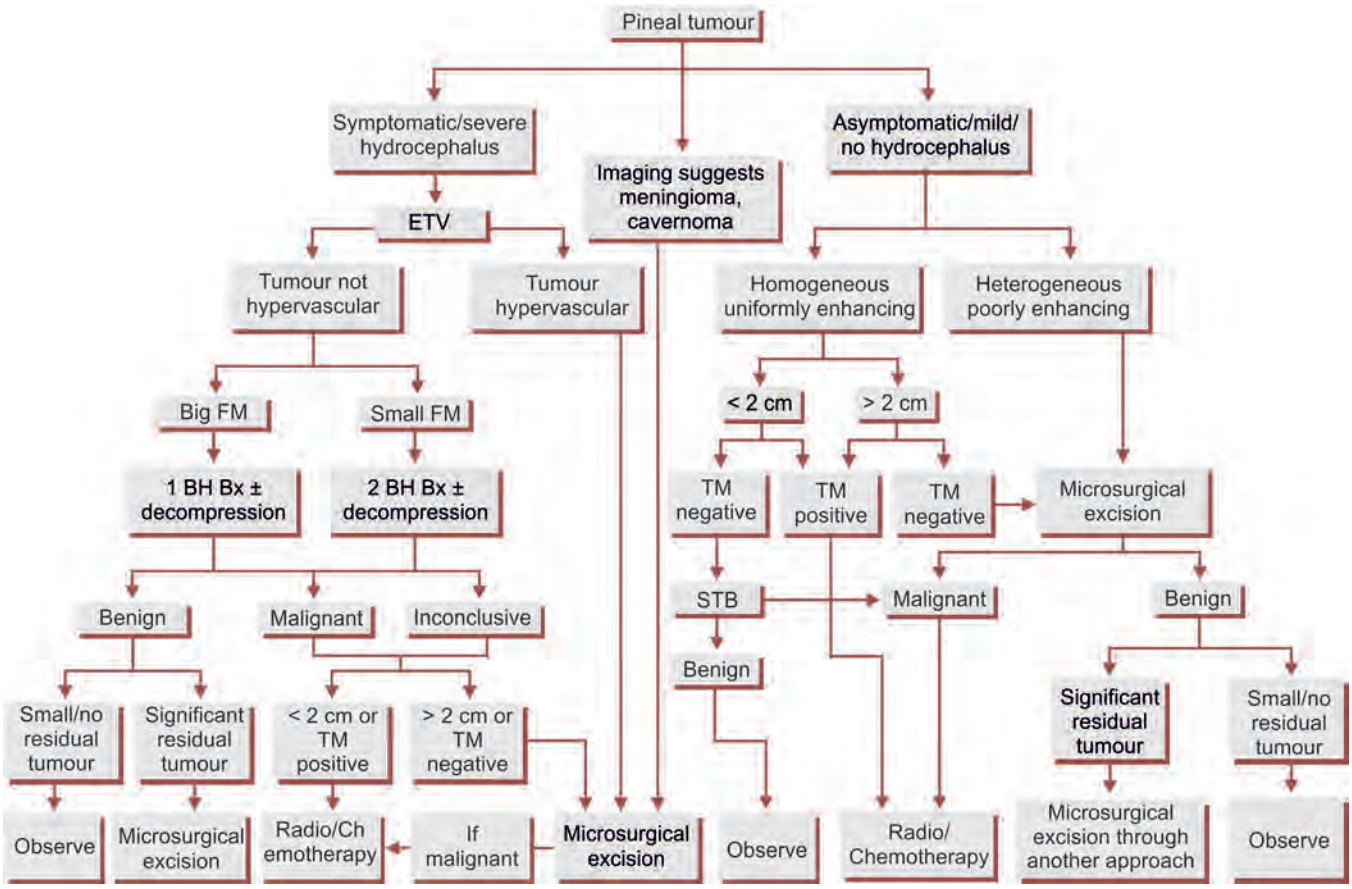
occur. Post-operative occurrence of subdural haematoma or hygroma is not peculiar to this approach and is the result of ventricular collapse.

Pineal tumours pose a challenge for the neurosurgeon due to their deep location. Microsurgical approaches have become safe in the last three decades and minimally invasive methods have become a viable alternative. Algorithm 1 summarises our present algorithm for management of pineal tumours. Algorithm 2 indicates how we choose the approach when microsurgical excision is deemed necessary.

STEREOTACTIC RADIOSURGERY

Stereotactic radiosurgery (SRS) of pineal tumours is a new therapeutic choice. The highly conformal nature of therapy makes SRS ideal for irradiating deep targets in the brain and yet allows for sparing of radiation damage to the vital structures in the neighbourhood. Performing SRS for a radiosensitive tumour, such as a germinoma, seems to be overkilled and it also does not prevent ventricular recurrence that is common with this tumour. SRS has been used: (1) As an alternative to surgical excision

Algorithm 1: Algorithm of management of pineal tumour



(ETV: endoscopic third ventriculostomy, FM: Foramen of Monro, TM: Tumour markers in serum, BH: Burr hole, Bx: Biopsy, ±: with or without, STB: Stereotactic biopsy). VP shunts are reserved for ETV failures. For the choice of microsurgical approach, see algorithm 2

for the smaller low-grade lesions; (2) For treatment of tumour residue after resection; (3) As an alternative to external beam radiotherapy so that radiotoxicity can be reduced; and (4) As an adjunct to external radiotherapy in the form of tumour boost dose for the more malignant lesions.[59] The availability of SRS does not obviate the need for histopathological diagnosis; in fact, tissue diagnosis is even more essential. In one recent report of 17 patients with varied histology, excellent local control was achieved in 16 patients and maintained for a mean follow-up of about 2½ years with gamma knife radiosurgery.[59] A group of 20 pineal parenchymal tumours treated by SRS has been shown to have 5-year survival of 68%, whereas it was 92% when only the pineocytomas were analysed. Imaging showed complete regression in 26%, partial regression in 47%, stable tumours in 11% and local in-field progression in 11%.[48] Similar success rates have been reported for SRS of GCTs from a Japanese centre.[73]

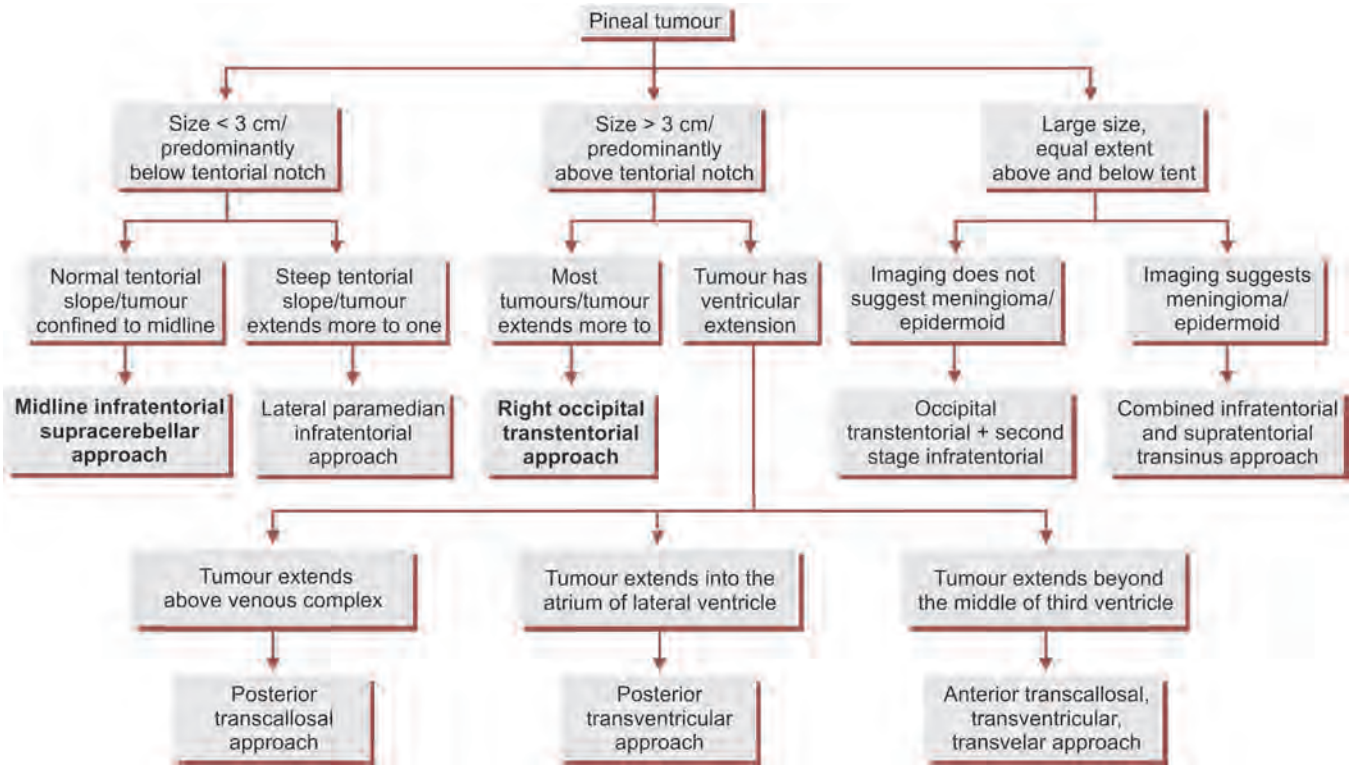
RADIOTHERAPY

Radiotherapy is the principal method of tumour control for the radiosensitive tumours such as germinoma. Limited field external beam radiation therapy (24–40 Gy) suffices for pineal germinoma, even when it involves the suprasellar region.[56] NGGCTs require 50–54 Gy and craniospinal axis radiation is recommended. Some centres favour dissemination evaluation and reserve whole neuraxis radiation for only those with documented spread.[124] Five-year disease-free survival rate is 91% for germinomas, but only 60% for NGGCTs with radiotherapy.[124] In a child younger than 3 years, radiotherapy can be deferred until that age by using chemotherapy. Pre-radiation chemotherapy has been used to reduce the dose of radiation in the responders.[54] The totally excised low-grade lesions, such as pineocytoma, do not need radiotherapy. The side effects of radiotherapy are cognitive dysfunction, growth failure, endocrine changes, radionecrosis and development of new neoplasms after decades.

CHEMOTHERAPY

The success of chemotherapy for gonadal GCTs suggests that the results might be similar with intracranial GCTs. Unfortunately, it is not so. Carboplatin-etoposide regimen or ifosphamide-cisplatin-etoposide combinations

Algorithm 2: Selection of microsurgical approaches for excision of pineal tumours. The two most commonly employed approaches are in bold letters



have been used in GCTs. When combined with radiotherapy, these regimens result in 93% remission rate in germinomas and 76% in the other malignant NGGCTs.[66] Although germinomas are exquisitely radiosensitive, cisplatin based chemotherapy is used to reduce the radiation dose and field.[31] Chemotherapy has also been used to salvage recurrences at the radiation field margin. Pineoblastoma has a poor prognosis but recent reports show a fairly good survival with gross total resection, radiotherapy and multimodality chemotherapy.[41] Pineocytoma generally does not need adjuvant therapy, but in cases where gross total resection has not been achieved or for recurrent tumours, platinum-based chemotherapy has been found useful.[46]

PROGNOSIS

Benign masses in the pineal region, such as meningiomas, epidermoids and mature teratomas, were studied in Vellore, India, over a 14-year period. Shunting followed by surgical excision resulted in most of the patients being in good or excellent condition.[17] There are a number of case series, which indicate that the extent of tumour resection positively impacts the survival for all kinds of pineal tumours and especially for the low-grade lesions.[13] However, a recent review of the Surveillance, Epidemiology and End Results (SEER) data base suggests that extent of surgical tumour resection did not affect survival in any histological subgroup and hence recommended that an aggressive surgical approach should be considered with caution in this region.[1] The 5-year overall survival was 79% for germinomas, followed by 61% for gliomas and 47% for pineal parenchymal tumours in this review.

Long-term results of multimodality therapy for GCTs are now available. The 20-year survival rate was 80% for germinoma, the 10-year survival rate was 70% for malignant teratoma and 3-year survival rate was 27% for malignant NGGCTs (embryonal carcinoma, yolk sac tumour or choriocarcinoma). The mixed tumours had a prognosis similar to a tumour of the most malignant cell type.[66] Cases of spontaneous regression of germinomas have been reported.[74]

Endoscopic management of pineal region tumours produces improved post-operative quality of life in all health domains.[114] In spite of multimodality therapy, only 50% of children with pineoblastoma are alive at 5 years.[25] In adults with pineoblastomas, the extent of spread of tumour at diagnosis has a strong bearing on the prognosis.[19]

146 Pituitary Tumours Overview

Ravi Ramamurthi

INTRODUCTION

Tumours in the sellar and parasellar regions constitute 12–15% of all brain tumours. The most common of these are pituitary tumours, which constitute 8–12% of all intracranial neoplasms and are found in 2.7–27% of unselected routine autopsies in humans who had no symptoms of pituitary disease.[6,11,16,24,48,50,55,68] Incidentalomas or lesions of the pituitary, picked up by imaging in asymptomatic patients, have been reported in 10–37% of patients and on a follow-up, 40% of these lesions increased in size, 20% become symptomatic and 9.5% of these incidental tumours developed apoplexy. In children and adolescents, these tumours are rare and in a large series of these tumours, children accounted for 2–3.5%.[19,26,35] Pituitary tumours are more common among women. Among the elderly (65 years and above), pituitary adenomas are mostly non-functional and the incidence of gonadotrophic tumours increases with age.[23]

HISTORICAL

The pituitary gland was so named by Vesalius in 1543[1] who thought that the gland cleared noxious secretions from the brain by discharging them as nasal mucus (in Latin, Pituita means thick nasal mucus). In 1778, Hypophysis cerebri was the term used by Soemmering.[1]

Descriptions of endocrine abnormalities in humans date back to about 1365 BC. Aldred and Sandison[2] studied the monuments of the pharaoh Akhenaten and came to the conclusion that he was acromegalic and had truncal obesity. The Talmud and the Bible have descriptions of giants, probably of pituitary origin, the famous one being Goliath of Gath.[34] Rathke, in 1838,[58] described a part of the development of the pituitary gland. Lieutand, in 1742,[45] first suggested that the pituitary stalk vessels communicated with the gland. The existence of the portal circulation was confirmed by Popa, Fielding,[51] Henderson and Daniel.[29] In 1933, Riddle[58] described prolactin. Contributions to modern knowledge about the pituitary were made by Pierre Marie (1886), a French neurologist, who first described acromegaly and Sir Victor Horsley (1886), who did hypophysectomy in dogs. Harvey Cushing, Sir Victor Horsley, Caton and Paul, Herman Schloffer (who introduced the transnasal trans-sphenoidal route in 1906), Krause, Dandy, Frazier, Norman Dott, Guiot and Hardy are pioneers who developed, improved and popularised pituitary surgery. Oscar Hirsch described the endonasal approach in 1910 and later the sub-mucosal trans-septal trans-sphenoidal approach.[3,22,30,43,44]

ANATOMY OF THE PITUITARY GLAND AND ITS SURROUNDINGS

The pituitary gland or hypophysis cerebri lies in the pituitary or hypophyseal fossa of the sphenoid bone. It is basically made up of two divisions, viz. the adenohypophysis and the neurohypophysis, which have different embryological, morphological and functional characteristics. It is continuous with the infundibulum, which is a horizontal conical projection from the inferior aspect of the tuber cinereum.

Embryology

Rathke, in 1838, described the embryology of the pituitary gland. The adenohypophysis or the anterior pituitary is believed to arise from a diverticulum of the stomodeum or the primitive foregut. Prior to the rupture of the oropharyngeal membrane, a saccular recess forms in the ectodermal lining of the roof of the stomodeum. This rudiment of the anterior lobe of the pituitary (the 'pouch of Rathke') forms a closed vesicle but remains connected for some time to the ectoderm of the stomodeum by a solid cord of cells. This solid cord can be traced to the posterior end of the nasal septum. A craniopharyngeal canal from the anterior part of the pituitary fossa to the exterior of the skull can occasionally be traced and is said to mark the original position of the pouch of Rathke. Arey[5] found the craniopharyngeal canal in 0.42% of adults. However, there have been claims that the canal is formed by the growth of blood vessels and is unconnected to the formation of the anterior lobe.

A diverticulum from the floor of the diencephalon grows caudally towards the pouch of Ratkhe to form the posterior hypophysis. The walls of this hollow diverticulum increase in thickness till the contained cavity is obliterated, except at its upper end, which persists as the infundibular recess of the third ventricle.

The posterior lobe becomes invested by the anterior, which extends laterally on either side of it. The anterior lobe also gives off two processes from its ventral wall, which grows along the infundibulum and fuses with it. This forms the tuberal portion of the hypophysis. The original cavity of the stomodeum remains as a cleft and is easily identified in the fully formed gland. The dorsal wall of the stomodeal part fuses with the posterior lobe and forms the intermediate lobe of the pituitary.

Some adenohypophyseal cells have been found to be capable of amine precursor uptake and decarboxylation, thus forming part of the APUD system. These cells are believed to take origin from the neural crest. Takor and Pearse[62] suggest that the 'ventral neural ridge' gives rise to the adenohypophysis and is, therefore, of neuroectodermal origin, contrary to the classical view. The finding of occasional hypothalamic neurons capable of synthesising ACTH and MSH lends support to the theory that the posterior and anterior hypophyses shares the same embryonal origin.

Pituitary Gland

The normal adult hypophysis or pituitary gland is a horizontally positioned extra-arachnoid ovoid body measuring about 12–15 mm in transverse diameter, 8–10 mm in anteroposterior diameter and 5–7 mm in height.[38] It weighs about 0.5–0.7 gm in an adult male. The weight in a non-pregnant woman is about 100 mg more than in a man. During pregnancy, its weight increases to an average of 0.8–1.0 gm.[38,63] In Indians, the average weight of the pituitary gland in adult males is 401.26 mg +/– 105.89 mg. In females, it is (417.32 mg +/– 104.07 mg).[60] The mean weight of the gland in females is always more than in males of the corresponding age till 35 years. The maximum weight was noted in adolescent females.

The gland is continuous with the infundibulum, which arises from the inferior surface of the tuber cinereum. The infundibulum or the hypophyseal stalk contains an inner core, called infundibular stem, which contains the neural connections of the hypophysis. It is continuous with the median eminence of the tuber cinereum. The neurohypophysis is normally taken to include the median eminence, the infundibular stem and the posterior lobe of the pituitary gland. The adenohypophysis is made up of the pars tuberalis (which surrounds the neural infundibular stem) and the anterior lobe of the pituitary gland, which is divisible into pars anterior and pars intermedia. A histological pseudocapsule,[49] which develops due to the growth of the adenoma and compression of the normal gland tissue and in large adenomas a multi-layered reticulin capsule has been observed. This pseudocapsule helps in the localisation and surgical excision of an adenoma.

Blood Supply

The pituitary gland has a dual blood supply. There is a direct arterial supply[25] common to the anterior and posterior lobes and a portal supply exclusive to the anterior lobe. In 1860, Luschka described the inferior and superior hypophyseal arteries. In 1930, Popa and Fielding described the portal system of the pituitary.

The arterial supply to the anterior lobe of the pituitary gland may be divided into two groups in relation to the diaphragm sella.[25] The infradiaphragmatic supply to the gland is a capsular network which also vascularises the diaphragm.[25] This network is made up of branches of the inferior hypophyseal artery, which arises from the meningohypophyseal trunk and direct branches from the intracavernous internal carotid artery (the inferior and the anterior capsular arteries). Occasionally, direct branches from the stem of the inferior hypophyseal artery supply the posterolateral part of the anterior lobe and penetrate deeper into the gland than the capsular arteries. The inferior hypophyseal artery is the most important artery supplying the pituitary gland, its diameter being larger than any other arterial structure coursing through the region.[42] The supradiaphragmatic supply is through the middle hypophyseal artery, which is a branch of the superior hypophyseal artery. The vessel is paired and runs on the anterior surface of the stalk. The end arteries of these vessels are found mainly in the subcapsular peripheral zone and the lateral wings of the anterior lobe.

The anterior lobe of the gland receives the portal system, which originates from the capillary bed of the lower infundibular stem. There are two groups of portal vessels, the long and the short, each with their own area of supply. The blood flowing in these two groups of veins does not mix. The long portal vessels supply approximately 90% of the parenchyma of the anterior lobe, mainly the anterior and the central portions. The short portal vessels supply a small part of the anterior lobe lying adjacent to the posterior lobe. The blood derived from the portal vessels reaches the sinusoids, which form the vascular bed of the gland and lie between secretory cells. The significance of the portal system is in that it carries the hypothalamic regulating hormones to the anterior lobe, thus controlling the secretion of the anterior pituitary hormones.

The infundibulum and the posterior lobe of the pituitary are supplied by branches from the superior and the inferior hypophyseal arteries which form a confluent capillary bed, extending from the median eminence through the infundibulum to the posterior pituitary.[37] The medial and the lateral branches of the inferior hypophyseal artery form an arterial ring around the infundibular process of the neurohypophysis, while the superior hypophyseal artery supplies branches, termed the arteries of the trabeculae to the lower infundibular stem.

The venous drainage of the anterior lobe of the pituitary is via the inferior hypophyseal veins. The possibility of flow reversal in the portal system raises the possibility of the short portal system acting as a drainage system and providing the short loop feedback for endocrine

secretory control. The venous drainage of the neurohypophysis is to the inferior hypophyseal veins, the portal system and the hypothalamus via small capillaries, which pass between it and the median eminence.

Sella Turcica

The pituitary gland is housed in the hypophyseal or pituitary fossa of the body of the sphenoid bone. There are many variations in the bony surroundings of the pituitary gland due to the complex embryology of the region. The pituitary fossa is delineated in front by the tuberculum sella and chiasmatic sulcus. The dorsum sella and the posterior clinoid processes form the posterior relationship. The sellar floor, which separates the sellar contents from the underlying sphenoid sinus, extends from the tuberculum sella in front to the base of the dorsum sella posteriorly. Renn and Rhoton[57] found the thickness of the sellar floor to be equal to or less than 1 mm in 82% of specimens and more than 1 mm thick in 18%. Occasionally, the floor was very thin, only a few microns thick.

The pituitary fossa has a depth of 10–12 mm with an upper limit of 13 mm; an anteroposterior diameter of 5.16 mm with an upper limit of 17 mm and a width of 10–15 mm.[57] DiChiro and Nelson[17] have found the mean sellar volume to be 594 mm^3 using their simplified mathematical formula:

$$\text{Volume in } mm^3 = \frac{0.5 \text{ (length x width x depth in mm)}}{1000}$$

Sellar bridges are bony structures running between the anterior and the posterior clinoid processes. When present they are bilateral, although they may be incomplete. They may be found in up to 5.9% of individuals.[41] The carotico-clinoid foramen is demarcated by a bony bridge between the lateral border of the pituitary fossa and the apex of the anterior clinoid process. It transmits the internal carotid artery. The sellar spine is an osseous spine, which is a remnant of the anterior end of the notochord and protrudes from the dorsal side of the pituitary fossa into the fossa itself.

Diaphragma Sella

The diaphragma sella forms the roof of the pituitary fossa. It is a fold of dura mater, more often rectangular than circular and has a central opening, which transmits the infundibulum. Anatomical variations of the diaphragma sella are frequent. These have been classified by Busch[12] into: Type I—a funnel shaped depression of the diaphragma sella; Type II—incomplete closure of the diaphragm around the pituitary stalk; Type III—a wide defect in the diaphragm, so that there is only a peripheral rim of tissue measuring less than 2 mm in width. This may leave the pituitary gland completely exposed and covered only with arachnoid (III a) or may be associated with symmetrical or asymmetrical indentation of the pituitary gland by the herniated arachnoid pouch (III b) or there may be a complete remodelling or flattening of the pituitary gland (III c). The last defect has been found in 5.5–6.7% of autopsy series.[10,12] Bergland et al.[10] found anatomical defects in the diaphragma sella of greater than 5 mm in 37% of consecutive autopsy cases without pituitary disease. These defects in the diaphragma sella occur six times more often in females than in males. Through the defect in the diaphragm, the arachnoid invariably extends and spreads out on the upper surface of the anterior lobe of the pituitary gland. This CSF filled space, called the pituitary cistern,[40,41] usually enlarges with advancing age. The cistern can extend for a variable distance forwards and laterally and occasionally, can even cover the posterior lobe. Bergland et al.[10] could identify such a cistern in 20% of cases, studied radiologically by them. The diaphragm is usually thick at the periphery and thin at the centre. In 38% of cases, it is at least as thick as one layer of dura, while in 62%, it is extremely thin over areas of the pituitary gland.[57]

Sphenoid Sinuses

The sphenoidal sinuses are described as paired cavities lying side by side in the body of the sphenoid bone. They are separated by a bony septum, which is commonly deflected to one side or the other. The cavities vary in shape and size, are usually asymmetrical and are subdivided by minor septae.[57] The main septum separating the sinus into the two major cavities was seen in 68% of Renn and Rhoton's specimens.[57] It is usually directed anteroposteriorly and may be vertical in 25%.[28] The position of the septum can be located by tomograms and by CT scan and if located near the midline, can be used as a guide during the trans-sphenoidal approach to the pituitary fossa (Fig. 1). However, the major septum

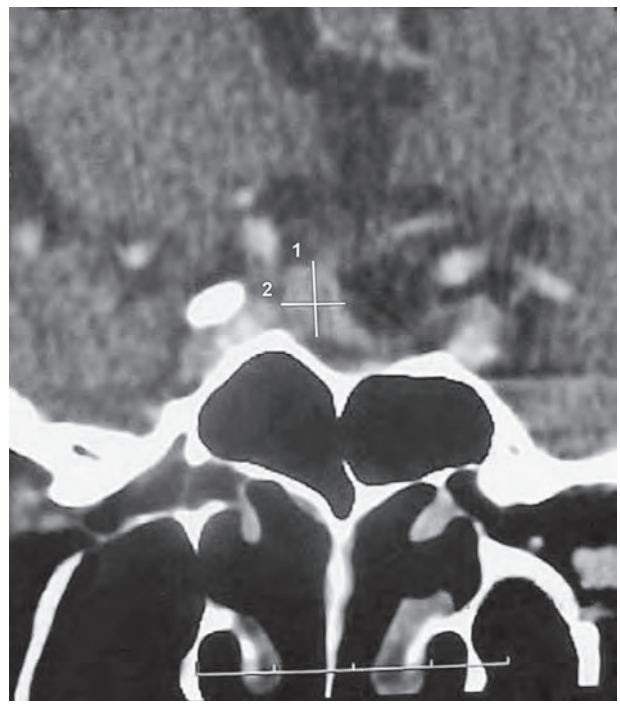

Fig. 1: CT coronal section showing the septum in the sphenoid sinus near the midline

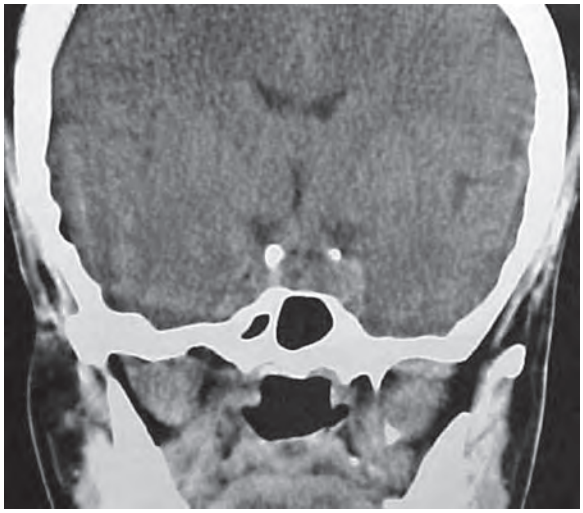

Fig. 2: CT coronal section showing the septum in the sphenoid located away from the midline

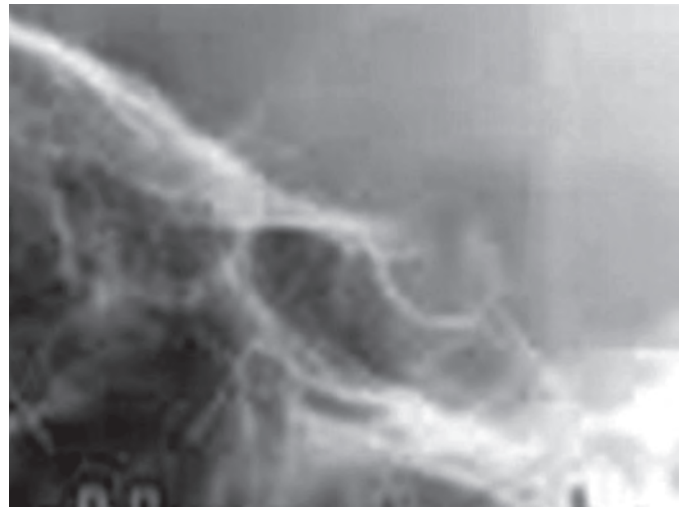

Fig. 4: Presellar type of sphenoid sinus

has been seen to be away from the midline in up to 46%.[57] (Fig. 2). In 43%, only the anterior part lies in the midline, while the rest of the septum is S, C or L shaped. The septum lies in the midline only in 27%.[39] Accessory septae arising from the synchondroses of the sphenoid are found in 76%. In 48%, they are unilateral while in 28%, they are found bilaterally.[20,57]

Hamberger et al.[27] classified the sphenoid sinus into three main anatomical types: (1) The conchal type is usually found in children but may be seen in up to 3% of adults. In this type, the sinus does not extend into the body of the sphenoid. It is small, and between it and the pituitary fossa is spongy bone, which may be as thick as 10 mm (Fig. 3); (2) The presellar type is found in 11–20% of adults. The sphenoid sinus does not penetrate the body of the sphenoid bone beyond a plane perpendicular to the planum sphenoidale. The anterior wall of the sella, therefore, does not bulge into the sphenoid sinus (Fig. 4); (3) Sellar type of sphenoid sinus occurs in 80–86% of adults. In this type, the sella has a thin floor and bulges into the sinus and occasionally, the sinus can extend from the dorsum sella to the upper clivus[38] (Fig. 5).

Carotid Arteries

The proximity of the carotid arteries to the midline is extremely important in pituitary surgery. The carotid arteries bulge into the superolateral wall of the sphenoid sinus in 71%.[57] These are usually covered by bone but in 4%, there may be no bone between the carotid arteries and the mucosa of the sinus. The average distance between the intracavernous portions of the two carotid arteries is 12–14 mm. However, the carotid siphon can be quite tortuous, sometimes narrowing the distance to 4 mm or occasionally, coursing laterally to an intercarotid distance of 23 mm (Fig. 6). The intercavernous venous connections traverse the anterior surface of the pituitary gland in 76–85% of cases or the posterior surface in 37%.

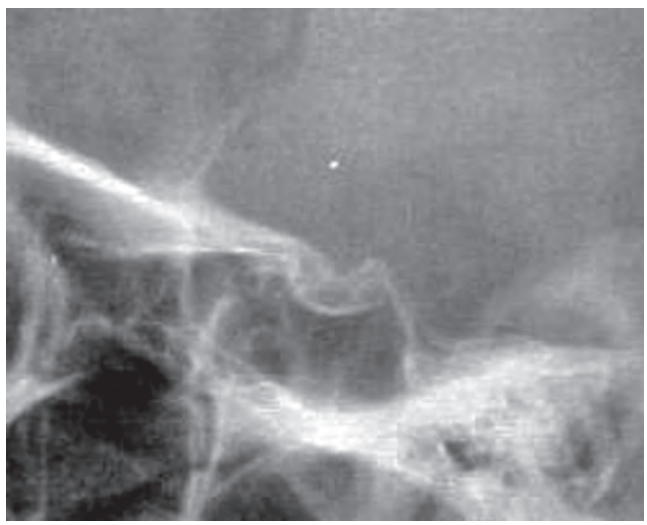

Fig. 5: Sellar type of sphenoid sinus

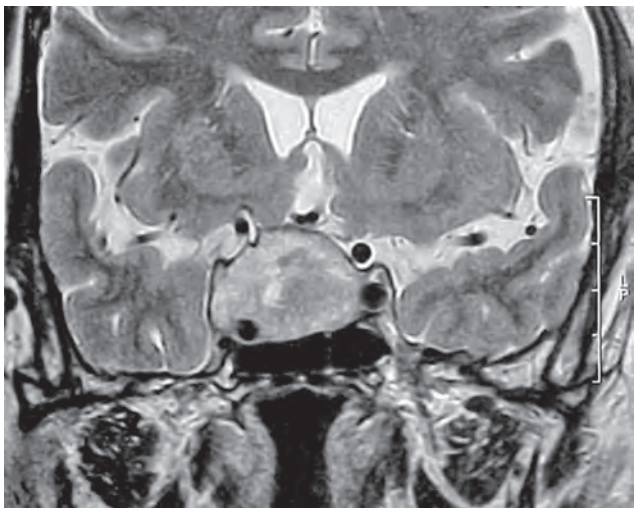

Fig. 6: MRI T2W coronal image showing pituitary adenoma extending up to the carotid artery on the left side and on the right side the adenoma is displacing the carotid inferolaterally and extending beyond it

Optic Chiasm

The position of the optic chiasma varies. Schaeffer[61] found that it lies in the sulcus chiasmaticus in 5% and over the diaphragma sella in 12%. These two positions are termed prefixed. The chiasma lies over the dorsum sella, which is its normal position in 79%. In the post-fixed position the chiasma lies over and behind the dorsum sella and is found in 4% (Fig. 7).

SYMPTOMS AND SIGNS

The symptoms and signs of pituitary tumours depend on the endocrine activity (hyper or hypo), the size of the tumour (micro, macro or invasive) and the effect on the neighbouring structures due to growth and expansion.

Visual manifestations occur when the tumour grows into the cranial cavity and compresses the optic nerve, chiasm or tract. The optic chiasm is situated 8–13 mm above the diaphragma sella and therefore, there should be considerable growth of the tumour before vision is affected.[52] Visual examination, therefore, is not of much use in following-up microadenomas. The anatomy and the pathophysiology of the field defects are described in the chapter on Visual Field Defects in intracranial lesions.

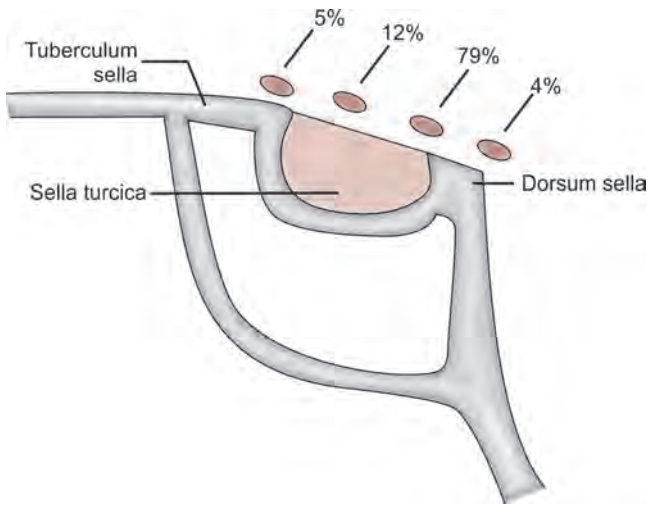

Fig. 7: Diagrammatic representation of positions of the optic chiasm in relation to the pituitary fossa

Pituitary tumours, by compressing the optic apparatus, may produce: (1) Reduction or loss of visual acuity due to compression of fibres subserving central vision; (2) Various types of field defects; (3) Positive visual phenomena in the form of hallucinations.[4]

The visual field defects that commonly occur due to pituitary tumours are: (1) Bitemporal hemianopia either incomplete or complete; (2) Temporal field defect in one eye with loss of vision in the other eye; (3) Central scotoma; (4) Junctional scotoma; (5) Homonymous hemianopia.

The percentage of patients with visual manifestations due to pituitary tumours has come down in recent years in developing countries, although not to that great an extent. In various series, from 1940 to 1974, the percentage of patients with visual involvement ranged from 69 to 96%.[13,46,47,54,56] In later years, the percentage has come down in developed countries, but is still high in developing countries.[8,33,47]

Visual hallucinations may occur in pituitary tumours. They may be formed, consisting of recognisable shapes, or unformed, and may include sparks, flashes or coloured lights.[15,53] Some may have photophobia. Amaurosis fugax, lasting 5–45 minutes, has been reported in a patient with a large pituitary tumour.[18] Foster Kennedy syndrome may be found in large tumours with compression of an optic nerve, producing optic atrophy and the mass of the tumour raising the ICP and producing papilloedema in the other eye.[54,57] This occurred in 5% of cases reported by Ramamurthi.[54]

The visual field defects may develop or worsen during pregnancy and clear after delivery.[21,54,65] This may be due to the compression of the chiasma, secondary to an increase in size of the tumour due to the pregnancy. Sudden visual loss and field defects may occur due to pituitary apoplexy,[31] which at times may be catastrophic, leading to total blindness in both eyes.

Effect on Neighbouring Structures

The tumour, once it grows outside the sella, can compress and invade the neighbouring structures, producing various symptoms and signs.

Headache

Headache is initially caused by stretching of the diaphragma sella, which is innervated by the ophthalmic division of the trigeminal nerve. When the tumour expands further, it may lead to raised ICP and headache as a result of the mass effect itself or by hydrocephalus due to third ventricular obstruction. The latter is, however, rather uncommon.

Ocular Palsies and Ptosis

Paralysis of the extraocular muscles either partial or total may occur; the III nerve being the most commonly involved there may be ptosis and the pupil may or may not be involved.[67] This is due to invasion or compression of the cavernous sinus or due to lateral extension of the tumour. The onset of III nerve palsy may be preceded by retro-ocular pain.[54] Unilateral proptosis may also occur and indicates the side of lateral extension of the tumour. The incidence of ocular palsies reported in the various series ranges from 0% to 25%.[7,8,54,59,64,66]

Fifth Nerve Involvement

The first and second divisions of the trigeminal nerve may be involved. It is essential to test the corneal reflex.[64] Facial hypoaesthesia may be present.[54] Rarely, facial pain resembling trigeminal neuralgia occur.[36]

Hypothalamic Involvement

This occurs when the tumour expands upwards and compresses the hypothalamus. This may further aggravate the existing endocrinological symptoms. There may be disturbances of consciousness.

Hydrocephalus

This can develop either unilaterally or bilaterally, as one or both the foramina of Monro may get obstructed. This may lead to headache, vomiting, papilloedema, lethargy and coma.

Psychological Changes

Dullness, apathy, loss of memory, confusion, confabulation, irrability, delusion and hallucinations may be seen. These may result from pressure effects on the frontal and temporal lobes, the third ventricle and the hypothalamus.

In 1940,[32] Jefferson made an extensive study of extrasellar extensions of pituitary tumours and described the following varieties:

- Hypothalamic extension by massive tumours growing behind a prefixed chiasma
- Extension under the frontal lobes producing personality changes
- Parasellar extension compressing the temporal lobe and producing temporal lobe epilepsy
- Extension into the sphenoid sinus and the nasopharynx. Large tumours may also extend through the tentorial hiatus and grow into the posterior fossa.[9,66]

Endocrine

The endocrine symptoms and signs may be due to hypersecretion or hyposecretion. Those due to hypersecretion[14] will be dealt within the sections on the various hypersecreting tumours. Hyposecretion can be of individual hormones or there could be panhypopituitarism. There may be diabetes insipidus, hypogonadism, hypothyroidism and abnormalities of secretion of ACTH, GH and PRL.

In panhypopituitarism, there is a pale waxy pallor, prominent fine wrinkles around the eyes and mouth, a reduction in axillary and pubic hair, diminished growth of the beard in men with a corresponding diminution in the need to shave and anaemia as a result of diminished function of the bone marrow. There may be truncal obesity.

A reduction in function of the pituitary adrenal axis (Addison's disease) may produce nausea, vomiting, postural hypotension and hyperthermia. Complete failure produces an Addisonian crisis and collapse. Reduction in thyroid function leads to myxoedema with the manifestations of sluggishness, relative inactivity, cold intolerance, dryness of the skin and in severe cases, coma. Gonadal dysfunction produces amenorrhoea, decreased libido and uterine and vaginal atrophy in women. In men, the testes become atrophic; there is reduction in libido and potency, as well as azoospermia.

147 Prolactinomas

Ravi Ramamurthi, Prasad AN

INTRODUCTION

Prolactinomas are the most common pituitary tumours and account for 25–40% in different series.[29,56,57] Trisomy of chromosome 12 is a non-random chromosomal change in pituitary adenomas, particularly prolactinomas. There is a critical role of HMGA2 over expression in the generation of prolactin-secreting pituitary adenomas in humans.[21] They may be seen as micro or macro tumours. The symptoms and signs are either due to hypersecretion of prolactin or related to the size of the tumour.

SIGNS AND SYMPTOMS

The endocrinopathy produced in women is the galactorrhoea-amenorrhoea syndrome (Forbes-Albright syndrome). There may be various menstrual disorders like amenorrhoea, oligomenorrhoea and irregular periods. About 30% of women have frank galactorrhoea.[7,28] There is also associated infertility. In men, there may be loss of libido, oligospermia and, occasionally, galactorrhoea. The tumours are likely to be larger in men when they seek medical help, as the mild endocrine symptoms may be overlooked, whereas in women, generally, the endocrinopathy predominates and therefore a larger proportion of microadenomas are seen. In men, the signs and symptoms of mass effect generally predominate.[9] The predominance of large prolactinomas in men may also be due to a high frequency of rapidly growing tumours, which are often invasive and frequently bromocriptine resistant.[15] Prolactinoma has been associated with obesity. As opposed to ACTH- and GH-secreting adenomas, the mechanism by which macroprolactinoma causes obesity has not been fully understood. In a subgroup of individuals, obesity and macroprolactinoma may share a common basis, namely decreased dopamine 2 receptor-mediated actions.[16,51]

ENDOCRINOLOGY

Elevations in serum prolactin can occur due to secretion by the tumour itself or from compression of the pituitary stalk or hypothalamus. Hyperprolactinaemia can also occur in several other conditions which include pregnancy, renal failure, hypothyroidism, other sellar and parasellar tumours and ingestion of drugs such as phenothiazines, tricyclic antidepressants and centrally acting antihypertensives.

The normal range of serum of prolactin (PRL) is 10–20 ng/ml. Elevation of the fasting PRL level above 150 ng/ml is strongly suggestive of a prolactinoma, preferably, if observed in two different samples tested at different times. Values between 30–100 ng/ml may be due to other causes which have to be ruled out before a diagnosis of prolactinoma is made.[43] A PRL level higher than 1000 ng/ml is indicative of an invasive adenoma, especially invasion of the cavernous sinus. Pituitary tumour transforming gene (PTTG) abundance is a molecular marker for invasiveness in hormone-secreting pituitary tumours. The ubiquitous and prevalent expression of pituitary adenoma PTTG suggests that PTTG plays a role in pituitary tumourigenesis and invasiveness.[67] Macroprolactinaemia, defined as hyperprolactinaemia with a predominance of, or only the big big prolactin (bbPRL) isoform, is considered idiopathic and poorly symptomatic. PRL adenoma may be associated with macroprolactinaemia.[41]

There is a large body of literature showing that PRL exerts growth-promoting activities in breast cancer and possibly in prostate cancer and prostate hyperplasia. In addition, increasing evidence argues for the involvement of locally produced (autocrine) PRL, perhaps even more than pituitary-secreted (endocrine) PRL, in tumour growth. Because dopamine analogues are unable to inhibit PRL production in extra-pituitary sites, alternative strategies need investigation. To that end, several PRL receptor antagonists have been developed by introducing various mutations into its natural ligands. For all but one of these analogues, the mechanism of action involves a competition with endogenous PRL for receptor binding. Such compounds are thus candidates to counteract the undesired actions of PRL, not only in tumours but also in dopamine-resistant prolactinomas. The most recently developed antagonist, Delta1-9-G129R-hPRL, is the only one that is totally devoid of residual agonistic activity, meaning it acts as a pure antagonist.[24]

Patients with prolactinomas and patients with acromegaly often have heterogeneous adenomas. There is a common group of patients with a pituitary adenoma who secrete PRL and GH unsynchronously. Some of these patients have clinical acromegaly at diagnosis and some patients diagnosed as prolactinomas will develop acromegaly. An annual IGF-I measurement should be used as a screening test.[1]

It is necessary to have a baseline evaluation of T3, T4, TSH, cortisol, LH, FSH, oestrogen and testosterone. This helps in diagnosis, in determining the need for therapy and in the follow-up.

MANAGEMENT

There has been a lot of controversy about the management of prolactinomas, but in the past few decades a reasonable consensus has been reached regarding the indications for their medical and surgical therapy. Medical therapy is now accepted as the first line of treatment in microprolactinomas and macroprolactinomas. Medical treatment with dopaminergic compounds is effective and safe in patients with prolactinoma with onset in childhood, allowing preservation of anterior pituitary function.[11]

The drugs available are: bromocriptine, pergolide, cabergoline and quinagolide (CV 205-502).

Bromocriptine (2 bromo-ergocryptine) is an ergot alkaloid and a dopamine agonist, which was introduced into clinical trials in 1971. It acts by stimulating the dopamine receptors on the lactotroph in the pituitary gland and is considered a potent analogue of dopamine.[23]

Bromocriptine is given in a dosage of 5–20 mg/day in three divided doses. The dosage should be increased gradually, as this reduces the side effects. Indian patients do not tolerate the higher doses recommended in the Western literature.[48] A long acting depot injection of bromocriptine, which is given once in 28 days, has been developed and is in use (Parlodel LAR).[6,30] A slow release oral preparation (Parlodel SRO) is also available and helps in avoiding repeated medication and ensuring patient compliance.[38] In patients who are unable to tolerate the orally administered drug, it can be given per rectum with good effect.[22]

Bromocriptine lowers the PRL level in patients with or without pituitary tumours, significantly reduces the size of a macroprolactinoma and restores normal gonadal function.[6,7,37,58,60] Pronounced visual improvement also occurs due to reduction in the size of the tumour.[50,64] Bromocriptine is effective in restoring normal menstruation in 80% of women, abolishing galactorrhoea in 90%[58] and reversing the hypogonadal state in 80% of men.[64] Serum-prolactin levels revert to normal in 65–75% of patients with macroprolactinomas and there is significant reduction in tumour size in 50–60%.[19,36,39] In microadenomas, there is a reduction in symptoms and in serum PRL levels in over 90%.[3,40,61]

The most conspicuous pathological changes that occur in a prolactinoma after dopamine agonist therapy are a decrease in the size of tumour cells and interstitial and perivascular fibrosis.[31] In some tumours, connective tissue accumulation is pronounced. The cellular response is not uniform and large and small cells are still seen. The large cells contain immunoreactive PRL and express the PRL gene, indicating resistance to dopamine agonists. In the small cells, PRL immunoreactivity and PRL gene expression are decreased, indicating that both PRL synthesis and release are blocked.[31] In some tumours these small cells persist, but are irreversibly suppressed. This may explain why some tumours do not proliferate after dopamine agonist therapy is discontinued.

The side effects of bromocriptine include nausea and vomiting which may occur initially in 30% of patients, although it may be troublesome in only about 10%. Numbness and tingling of the toes and fingers, weakness in the legs and muscle pains may be complained of by some patients. Hypotension may occur. Visual and auditory hallucinations, inflammatory pleuropulmonary reactions or erythromelalgia in the lower extremities may be seen rarely. Orofacial and other dyskinesias may be troublesome.[36] In macroprolactinomas, CSF rhinorrhoea may occur during therapy due to shrinkage of the tumour unblocking a dural rupture in the sellar floor.

Most patients require bromocriptine indefinitely, because discontinuation of therapy may result in rapid expansion of the tumour, especially in macroprolactinomas.[55,63,66] In a small subgroup of patients, the prolactin levels may continue to remain normal after stopping the drug so it is better to discontinue bromocriptine every two years on a trial basis to decide on the need to continue therapy. Some tumours may be resistant to dopamine agonist therapy and may not respond.[2,32] In univariate and multivariate analysis there were no statistically significant differences regarding age, gender, initial dose of BRC, length of BRC use, tumour size, pregnancy during treatment, previous surgery or radiotherapy among patients who persisted with normoprolactinaemia and those who did not. BRC-induced prolactinoma cell alterations are highly controversial so whether the mechanism of PRL normalisation after BRC withdrawal is related to BRC use or whether it is attributable to natural history is a matter for debate.[45]

A special problem arises with regard to continuation of bromocriptine therapy during pregnancy. The tumour, especially a macroadenoma, may expand during pregnancy if the drug is stopped. This occurs in 1% of microadenomas and 5–20% of macroadenomas.[25] There have been no known teratogenic effects of bromocriptine in a large series of pregnancies.[59] Pregnancy is safe in patients with hyperprolactinaemia and can frequently be beneficial, inducing a decrease in prolactin levels.[4,14] It is therefore wise to continue bromocriptine during pregnancy, especially in macroprolactinomas, unless close surveillance is possible with repeated CT examination. If there is rapid growth of the tumour with visual compromise or apoplexy, trans-sphenoidal surgery has to be undertaken, with the attendant risks of major surgery during pregnancy.

Pergolide

This is a synthetic ergoline derivative with highly potent long acting PRL lowering activity. It is administered as

a once daily dose of 50–100 micrograms. In a comparative study between pergolide and bromocriptine, it was found that the effectiveness and side effects of both drugs were the same with the advantage of a once daily administration with pergolide.[8,34]

Cabergoline

This is a long acting dopamine agonist. It is administered orally at a weekly dose of 0.2–3.5 mg which may also be given in divided doses, twice or thrice a week. Good results with regard to reduction in PRL levels and tumour size were obtained. Mild adverse effects were seen in 23% and none required discontinuation of medication.[20] The successful response to cabergoline (CAB) treatment for 6 months was higher in microprolactinoma than in macroprolactinoma patients and was similar in women and men.[9] The prevalence of macroprolactinoma shrinkage after CAB treatment at standard doses for 1–3 years was higher in naive patients (92.3%) than in intolerant (42.1%), resistant (30.3%) and responsive patients (38.4%).[10]

Long-term low dose of the D2 receptor agonist CAB significantly reduced tumour volume and normalised serum PRL levels in a great majority of patients bearing macroprolactinoma. This treatment met with excellent patient compliance. CAB can be used as a first choice drug treatment in macroprolactinomas, as already shown for microprolactinomas and idiopathic hyperprolactinaemia.[12]

CAB may represent, at the moment, the only successful therapy for prolactinoma-bearing patients resistant to bromocriptine and quinagolide, as it normalised PRL levels in 22 of 27 patients, reduced tumour size in 13 of 27 patients and improved clinical symptoms in 25 of 27 patients.[13]

Quinagolide

CV 205-502 is a potent, long acting non-ergot D2-dopamine agonist. It is administered orally in a single daily dose of 75–300 micrograms. Side effects are mild and include mainly headache, nausea and dizziness. The efficacy of this drug in reducing PRL level and tumour size is similar to that of bromocriptine.[53,62,65] It has also been found useful in the treatment of non-functioning gonadotroph or alpha subunit secreting adenomas.[33]

Somatostatin receptor 5 exclusively regulates PRL secretion from prolactinoma cells. Thus, somatostatin analogues with improved selective binding affinity for these receptor subtypes may be effective in the treatment of either GH or PRL secreting adenomas.[54]

Resistance to dopamine agonists occurs in a subset of patients with prolactin-secreting pituitary tumours. The resistance is mediated by loss of pituitary D2 receptors and occurs in both microadenomas and macroadenomas. New drugs, such as antioestrogens, new DA, specific analogues for somatostatin receptor subtypes, chimeric molecules associating dopamine and somatostatin effect and PRL antagonists, are under investigation and can be future alternatives for DA resistance.[42] Invasive prolactinoma resistant to conventional therapy has been reported to have responded to the administration of the alkylating agent, temozolomide.[44]

Surgery

Surgery was the mainstay in the treatment of microprolactinomas and macroprolactinomas till the efficacy of dopamine agonists was established beyond doubt. Earlier surgical series[17,26,29] reported 65–80% endocrine normality in microadenomas and 25–35% in macroadenomas. On long-term follow-up, the endocrine cure rate dropped to 50% in microprolactinomas[49,52] and 15–20% in macroprolactinomas.

The present indications for surgery, either transsphenoidal or transcranial are limited to:

- Patients in whom the tumours are unresponsive to dopamine agonist treatment, especially cystic prolactinomas.
- Patients who are unable to tolerate dopamine agonist medication.
- Patients in whom there is rapid progression of visual loss.
- Patients in whom the tumour grows while on dopamine agonist therapy.
- Pituitary apoplexy.

In India and the developing countries, the cost factor for prolonged treatment and drug compliance should also be taken into account. These are important in patients who do not have easy access to neurosurgical and endocrinological facilities and the facility to have frequent PRL estimations and CT or MR scans. In these countries, the wisest course would be to operate on most of these patients and start dopamine agonist therapy in those in whom the PRL levels do not revert to normal and in those who have persistent symptoms.

The complications from trans-sphenoidal surgery are few and occur in 1–2% of patients. The mortality rate in microadenomas is nil and the overall morbidity is 0.4%.[18,56,57] The complications that may occur are persistent CSF rhinorrhoea which requires reoperation, meningitis, visual deterioration and non-fatal vascular injuries.

The use of a dopamine agonist, prior to surgery, has not been shown to be of much benefit in prolactinomas.[27,32] Long-term administration of a dopamine agonist may lead to tumour fibrosis and cause difficulties in surgical removal.[5,31,35] Surgery for prolactinomas, when indicated, is best performed within twelve months of starting dopamine agonist therapy.

Radiation therapy has a limited role in treatment of resistant prolactinomas and should be reserved for patients in whom medical and surgical therapy has failed.[46] Gamma knife radiosurgery should be a part of the armamentarium for treating refractory prolactinomas. Patients with tumours smaller than 3.0 cm^3 and who are not receiving dopamine agonist at the time of treatment will likely benefit the most.[47]

In summary, the current management of prolactinomas is different from what it was earlier. Surgery is done only for specific indications and the mainstay of treatment is the long-term administration of a dopamine agonist. The criteria for successful management include resolution of mass effect, normalisation of PRL values, resumption of menstruation and successful pregnancy in women, and restoration of potency and spermatogenesis in men. The overall results are much better in microadenomas and in patients who have an initial PRL level of less than 200 ng/ml.

148 Growth Hormone Secreting Adenomas

Ravi Ramamurthi, Goutham Cugati

Disorders of growth hormone (GH) secretion can result in an excess or shortage. Reduction in GH is significant in children. Gigantism results when hypersecretion occurs before the epiphyses have fused and acromegaly after fusion of the epiphysis.

PATHOGENESIS

The excess secretion of GH can be primary or due to an excess of growth hormone releasing hormone (GHRH) from hypothalamic disease. Primary hypersecretion of GH is most commonly due to a GH secreting adenoma. Of the adenomas that secrete GH, 80% are somatotrophs and the rest are mammosomatotrophs with accompanying hyperprolactinaemia.[50] GH may also be secreted ectopically by malignant tumours of the breast, lungs, pancreas or ovaries. In rare cases, they may arise in the sphenoid sinus from ectopic tissue[65] or may be located in the lateral end of the lesser wing of the sphenoid.[27] Acromegaly due to GH secreting bronchial carcinoid has also been reported.[8]

GHRH increase may occur as a result of involvement of the hypothalamus by hamartoma, glioma, ganglioglioma or choristoma. Ectopic GHRH secretion may occur in carcinoids of the lungs, GI tract and pancreas, carcinoma lung, islet cell tumours, phaeochromocytomas and adrenal adenomas.[50] Acromegaly can occur both sporadically and in the setting of familial conditions, such as multiple endocrine neoplasia type 1 (MEN1), Carney complex (CNC) and isolated familial somatotropinomas (IFS). Each of the familial syndromes is associated with a tumour-suppressor gene, that was initially recognised by an observed loss of heterozygosity on chromosome 11q13 in MEN-1 and IFS, and on chromosome 17q in CNC.[16,24]

A study in Finland to find a genetic association for pituitary tumourigenesis showed a mutation of the aryl hydrocarbon receptor-interacting protein (AIP) gene located on 11q13 in 16% of patients suffering from acromegaly. The term pituitary adenoma predisposition (PAP) was proposed to describe a person with an AIP germline mutation.[1,33] It is now well documented that cytokines of the gp130 family, such as interleukin-6, that use gp130 as a common signalling protein stimulate not only the proliferation but also the hormone secretion of pituitary cells. It has recently been described that bone morphogenetic protein-4 (BMP-4), a member of the TGF-beta family, has a stimulatory role on lactosomatotropic cells promoting the development of prolactinomas and acromegaly, but it has an inhibitory action on the corticotropic lineage.[26] Familial acromegaly without features of MEN-I, has been found to have the same HLA halotypes.[73]

CLINICAL FEATURES

The mean age of diagnosis of acromegalic patients is 45 years with a slight female predominance.[51] In gigantism, the limbs and long bones uniformly enlarge and there is a proportionate enlargement of the other organs also. These results in increased height, enlargement of hands and feet, prognathism, prominent frontal sinuses and puberty may be delayed, due to the associated hypogonadism, causing a further delay in closure of the epiphyses. The usual age of onset of acromegaly is in the third to fifth decade. Distinctive changes occur in various parts of the body, making the diagnosis easy.[3,71] In the early stages, the changes in appearance may be subtle. Comparison with previous photographs of the patient helps considerably in diagnosis. Figure 1A shows an early picture of a patient with pituitary adenoma and Figure 1B shows the same patient once diagnosed with a GH secreting adenoma.

Headache occurs in 50–75% of patients with acromegaly and gigantism. The mechanism of the headaches is not clear. In large tumours, stretching of the diaphragma sella may be responsible. Intractable headache is often the presenting symptom in many patients in the developing countries, as most people do not seem to be bothered too much by the change in their facial appearance.

Changes take place in the bones and soft tissues, especially of the hands, feet, face and skull. The fingers and the hands thicken and take on a 'spade-like' appearance. Overgrowth of the mandible leads to prognathism and malocclusion of the jaws. In association with an enlarged tongue it may lead to respiratory distress. The frontal bone and sinuses, malar and nasal bones and the soft issues of the face enlarge, leading to a 'beetle brow' appearance and the characteristic facies. The cartilages in the joints, nose, ear and larynx overgrow. The sleep apnoea syndrome reportedly affects between 67% and

Figs 1A and B: (A) Earlier photograph of a patient with pituitary adenoma. (B) Photograph of the same patient after he was diagnosed with a GH secreting adenoma, showing coarsening of facial features and spade-like appearance of the hands

75% of acromegalic patients when investigated prospectively.[9] There is visceromegaly involving the kidneys, lungs, liver, heart, spleen, stomach, intestines and salivary glands.

Skin changes occur in the form of hyperhidrosis and oiliness of the skin with an abnormal odour. Multiple and excessive sebaceous cyst formation may occur. Body hair may be increased. Entrapment of peripheral nerves may occur, leading to entrapment neuropathies, the commonest being the carpal tunnel syndrome. The peripheral neuropathy may also be related to diabetes mellitus. Multiple joint pains leading to severe arthritis may occur, as a result of bony overgrowth and distortion of the articular surfaces. Fibrous thickening of the joint capsule and ligaments may occur, as in the wrist, which leads to carpal tunnel syndrome. Muscle weakness and easy fatigability may occur due to myopathy. The exact mechanism of the myopathy is not known.[49]

SYSTEMIC CHANGES

Cardiac disease is common and the exact mechanism is not known. Hypertension, coronary artery disease, valvular heart disease and compensatory hypertrophy due to generalised splanchnic hypertrophy are some of the proposed aetiological factors. The previously reported prevalence of hypertension in acromegalic patients is around 35%, but varies widely between 18% and 60%.[9] Cardiomegaly occurs and is related to the duration of acromegaly.[47] Concentric hypertrophy (biventricular) is the most common feature of cardiac involvement in acromegaly found in more than two thirds of patients at diagnosis.[81] The Tei index reflects both systolic and diastolic ventricular function. The Tei index may be superior to conventional mitral Doppler indices for identification of LV diastolic dysfunction in patients with acromegaly.[4] Hepatomegaly and renal enlargement may cause hepatic and renal insufficiency. The best characterised respiratory disease is sleep apnoea. Ventilatory dysfunction occurs as a result of bony changes of the thoracic cage, and lung overgrowth.[14]

A retrospective analysis performed on 140 patients with active acromegaly showed colonic cancer in 10, thyroid cancer in 5, breast cancer in 4 and gastric cancer in 2 patients. Hence, cancer screening is necessary in acromegalic patients.[42]

About 50% of acromegalics have impaired glucose tolerance and about 10% have diabetes mellitus. The diabetes is usually reversible after treatment of acromegaly. Menstrual disturbances and galactorrhoea in women and decreased libido and impotence in men may occur, as a result of associated hyperprolactinaemia, pituitary stalk effect or reduction in FSH and LH.

Low serum IGF-I/GH ratio was associated with abnormal glucose tolerance in acromegaly. IGF-I/GH ratio is a useful marker to understand the metabolic status in acromegaly.[25]

Acromegaly is associated with increased mortality. An average reduction in life expectancy of around 10 years and an overall 72% increase in mortality are seen. The excess deaths are due predominantly to cardiovascular, cerebrovascular and respiratory disease.[2,20]

Factors accounting for the increased mortality ratio in acromegaly are:

- Age at the time of diagnosis. Older patients had higher mortality.
- Male gender.
- Disease duration. Exposure to GH excess is associated with increased cardiovascular risk profile due to cardiac hypertrophy, diastolic dysfunction, myocardial valve insufficiency, insulin resistance, dyslipidaemia and obesity. Increased cardiovascular and cerebrovascular mortalities.
- Lowest levels of GH (less than 2–2.5 ng/ml) are associated with the lowest mortality rates.

- IGF-I concentrations were found to be related to mortality.
- Active disease.
- Hypopituitarism, present in 10–40% of patients with acromegaly is associated with increased mortality.
- Increased association of systemic cancers.
- Increased mortality seen in patients having received irradiation.

Studies conducted show that even a biochemical cure rate of 100% will not result in complete normalisation of mortality rates.[9,14,20,31,40,42,67,74]

In a nationwide survey conducted in Finland by Kauppinen-Makelin et al.[40] data did not support IGF-1 as a significant prognostic marker for survival in acromegaly. The increased mortality among patients having received irradiation was possibly linked to more aggressive disease and poorer control of acromegaly in these patients. There was no difference in the severity of disease at the time of diagnosis but men seem to have a poorer outcome. Men seemed to die more often than women from cerebrovascular disease. Malignancy was a common cause of death among women. Breast cancer was the most common cancer death. Older patients were less actively operated and achieved a poorer treatment outcome than younger patients.

The main cause of death in the large retrospective British study on 1362 patients was cardiovascular, accounting for 36.6% of the deaths followed by cancer in 22.7%. In a Spanish study cardiovascular causes resulted in death in 39.4% and cancer in 23.7%.[9,53]

AcroQoL is a disease-generated questionnaire, developed to assess quality-of-life (QoL) in patients with acromegaly. Other quality of life assessment tools include 'Psychological general well-being schedule' (PGWBS), EuroQoL (EQ-5D), HR QoL and the disease-specific signs and symptoms score (SSS). Previous radiotherapy, severe impairment, active disease, ageing, disease duration and joint symptoms have a negative effect on the quality of life.[74,83]

TREATMENT

The modalites available are surgery, medical therapy and radiotherapy.

Surgery

Surgery is the primary mode of treatment in all patients. Transcranial surgery, which was practised in the earlier days, rarely resulted in improvement of either the endocrine status or the persistent headache and, hence, is not recommended. Trans-sphenoidal microsurgery is ideal in microadenomas and macroadenomas.[28,45] Surgery offers the best chance for cure and normalisation of endocrine status. Following surgery, there is rapid clinical improvement, the beneficial changes in the hands being often apparent within a day or two and in the facies within a week. The persistent headache disappears rapidly. Surgery alone seems to be sufficient in about 50–60% of the patients.[37]

The criteria for cure and successful therapy should be: (a) GH level less than 5 ng/ml; (b) GH level less than 2 ng/ml following a glucose tolerance test; (c) normalisation of somatomedin C levels (SM-C); (d) a normal response to LTRH stimulation and (e) clinical improvement.[1] For practical purposes, (a), (b) and (c) are important.[12] The best results are obtained when the tumour is a microadenoma and the basal GH level is less than 40 ng/ml.

Complete removal of the pituitary tumour inevitably included a portion of normal tissue (microsurgical pseudocapsule). Intensive resection of the microsurgical pseudocapsule is essential to accomplish histological total resection of GH-secreting pituitary adenomas for remission of acromegaly.[32,41]

Laws[45] reported on a series of 360 patients and found normalisation of GH in 85% of microadenomas, 65% of diffuse adenomas and 48% of invasive adenomas. GH levels were normal in 82% of patients with initial GH levels below 40 ng/ml and in 35% with a level above 40 ng/ml. Ross and Wilson[61] reported that 54% had GH levels below 5 ng/ml and 74% had levels below 10 ng/ml. On longer follow-up, 79.4% had less than 5 ng/ml and 92.7% less than 10 ng/ml. They also analysed the results in 30 series comprising a total of 1360 patients. Serri et al.[66] found a 14% recurrence rate in macroadenomas on long-term follow-up.

The cure rates for microadenoma after surgery have been found to vary from 37 to 91%. Analysis of the same has shown that the number of neurosurgeons in a centre has an inverse correlation and the years of experience have a direct correlation on the cure rates.[51]

In a study conducted at Wales to evaluate the effectiveness of trans-sphenoidal surgery, 57 of 90 (63%) patients remained in remission after surgery. Seventy-nine per cent of patients with microadenomas but only 56% of patients with macroadenomas achieved remission. Meningitis occurred in 3% of patients, cerebrospinal fluid rhinorrhoea in 7% and permanent diabetes insipidus in 15%.[19]

The complications that occur with trans-sphenodial microsurgery are very low, with the mortality being 0–1%.[44,57,61] The problems that have been seen are transient and permanent DI, excessive bleeding, CSF rhinorrhoea requiring reoperation, hypopituitarism, infection, meningitis, panhypopituitarism and, occasionally, reduction in vision. Tindall et al.[72] have done a multivariate analysis of factors that may be responsible for surgical failure. The important factors are tumour stage, pre-operative GH and SM-C levels.

Medical Treatment

Octreotide and bromocriptine are the drugs that are used as adjuvants to surgery, when the GH levels remain high after surgery or when there is recurrence of tumour. GH

induced cardiomyopathy may not allow safe anaesthesia and surgery and Octreotide and Sandostatin-LAR treatment dramatically improves ejection fraction in these patients.

Somatostatin Analogues (Octreotide, Lanreotide and Pasireotide)

Octreotide is a cyclic octapeptide analogue of somatostatin, and has been used extensively for the treatment of acromegaly. The response of a GH tumour may depend on the number of somatostatin receptors in the tumour cells.[58] It is given subcutaneously in a dose of 300 micrograms per day in three divided doses. The GH levels normalise in about 25–60% of patients.[29,62,37,59] Insulin like growth factor 1 concentrations were found to return to normal in 37–81% of patients. Incremental doses up to 1500 micrograms are useful in a few patients. No additional improvement or escape from control occurred with time. A reduction in the size of the tumour ranging from 14 to 32% has also been recorded. Somatostatin analogues given pre-operatively optimise the cardiovascular, respiratory and metabolic functions and prevent peri-operative morbidity.[15] Sandostatin LAR is long-acting depot octreotide. Long-acting somatostatin analogues are given IM every 2–4 weeks and normalise serum IGF-I levels in about 65% of patients.[10,52]

Octreotide has also been used in the treatment of non-secreting,[17] subunit secreting[39] and TSH secreting[46] tumours with some benefit. It is well tolerated, but reduces gall bladder contractility and leads to the formation of gall stones.[21,29,77] It has beneficial effects in the form of improvement of acromegalic cardiomyopathy, also in patients who did not achieve biochemical control of the disease.[18] Resistance to octreotide was associated with low expression of SST2 mRNA, mutational changes of SSTR2 and SSTR5 and loss of heterozygosis at SSTR5 gene locus.[42] Lanreotide is another somatostatin analogue and a short acting preparation of lanreotide (Somatulin) is given every 7–14 days by intramuscular injection and normalises serum IGF-I levels in about 48% of patients.[22]

Dopamine subtype 2 receptor (D2DR) and Somatostatin receptor (SSTR) 1, 2, 3 and 5 are present in most pituitary adenomas. Currently available somatostatin analogues, like octreotide and lantreotide, show affinity for SSTR 2. New chimeric compounds with SSTR 2, D2DR and SSTR 5 affinity have shown an increased control of secretion and/or proliferation of different types of pituitary adenomas in cell culture.[43,63,69]

Pasireotide (SOM-230) is a small somatostatin (SST) analogue which has high binding affinity to four of the five human SST receptor subtypes and is under clinical trials.[6] It potently suppresses GH, IGF-I and ACTH secretion, indicating potential efficacy in acromegaly and Cushing's disease.[64]

Surgical debulking of the pituitary tumour causing acromegaly improves the effectiveness of somatostatin analogues. Hence, surgery should be done even when there is little chance of complete cure from surgery alone.[38]

A study conducted on 99 patients with somatostatin analogues showed 25% or greater reduction in the size of the tumour in more than 75% of the patients.[13,48]

Dopamine Agonists (Bromocriptine, Quinagolide, and Cabergoline)

Bromocriptine is less effective than octreotide. Reduction of GH levels to below 5 ng/ml has been reported in 5–40% of patients.[5,82] It is useful in mild cases. Larger doses than those used for prolactinomas are necessary and may lead to increased side effects. Cabergoline can be used in patients with adenomas cosecreting GH and prolactin, even in large tumours.[80] There have been reports of patients who continue to be in remission even after stopping cabergoline which was being given long term.[78] Dopamine agonists are generally not effective at reducing the size of pure GH-secreting pituitary tumours.[22]

Growth Hormone Receptor Antagonists

The GH receptor antagonist was first developed in the late 1980s by Chen et al. To enhance the half-life of the GHR antagonist (from 30 minutes to more than 100 hours), several polyethylene glycol (PEG) molecules were added to the molecule. A nine amino acid residue was added to it, which resulted in a molecule PEG-hGH G120K (with pegvisomant as the generic name). Pegvisomant has increased affinity to binding site 1 and inactivates binding site 2, blocking the GH receptor and eliminating the adverse effects of elevated GH levels. Studies on long-term pegvisomant therapy in the treatment of acromegaly showed decrease in serum IGF-I concentrations in all treatment groups, and 82% of patients treated with the highest dose achieved normal serum IGF-I concentrations.[76] Long-term treatment with GHRA improves acromegalic cardiomyopathy.[55]

Various studies showed deranged liver functions in 2–6% of the patients.[70] There have been case reports of tumour enlargement while on pegvisomant, especially those who have not received prior radiotherapy.[23] It has no action on tumour activity and the cost is more (AA). A newer GH receptor antagonist BVT-A is being tried on animal models.[60]

Both GHR antagonists and somatostatin analogues are useful in preventing long-term diabetic complications. Combined treatment using a somatostatin analogue with pegvisomant appears to be an effective and rational approach.[52,75] But the high cost of lifelong medical treatment is to be weighed against the cost of a single surgical procedure.[7]

Radiotherapy

First line treatment remains surgery, but remission rates vary between 50% and 90%. In case of lack of surgical remission or recurrence, somatostatin agonists can be

proposed. However, about 30% of patients are partially or totally resistant to this treatment. The indications for radiotherapy are: non-curative surgery; poor response or inaccessibility to medical treatment; growth restraining of aggressive macroadenomas; comorbidities that contraindicate surgery and surgery refusal.[34]

Conventional radiotherapy and radiosurgery are two radiation treatment modalities that can be proposed to these resistant patients. Reported rates of remission for conventional radiotherapy range between 50% and 60% in patients with acromegaly, with a time to remission delayed by several years, and adverse effects including high rates of hypopituitarism. This treatment could be proposed to patients with aggressive adenomas, in whom surgery does not lead to biochemical control. In contrast, studies on stereotactic radiosurgery reported faster GH hypersecretion decline, and a lower risk of adverse effects. Tumour shrinkage in 90% and biochemical remission in 80% have been reported. However, this latter technique requires a well defined target volume, which limits its indications.[11] In a study conducted on 22 patients treated with PSRS at an institution in USA for persistent acromegaly, who had undergone at least one trans-sphenoidal surgical procedure without biochemical cure, showed 59% of patients attaining normal insulin like growth factor-I levels, without use of any medication after a median of 6.3 years.[54]

Radiation can be delivered in a single sitting by stereotactic radiosurgery or in fractionated form of smaller doses delivered over typically 5–6 weeks in 25–30 treatments.[68] More than 95% of pituitary adenoma patients have either tumour shrinkage or stabilisation after radiosurgery. Biochemical remission is possible in approximately 80% of properly selected patients. The time to endocrine normalisation typically ranges from 1 year to 5 years. Delayed anterior pituitary deficits occur in 20–50% of patients.[56]

Gamma knife (GK) radiosurgery is being accepted as an adjuvant form of treatment. Vik-Mo EO et al. have achieved post-operative normal IGF-I levels in 86%, normal IGF-I and GH levels below 5 mIU/l were found in 38% out of the 61 patients treated with GKS.[79] Jezková J et al. achieved normal IGF-I and GH below 2.5 ng/ml in 51% of the 96 patients treated.[36] In a study conducted by Frédéric Castinetti, et al.[12] on 82 patients who underwent GK radiosurgery, with mean follow-up of more than 4 years, in 40% (17% in remission and 23% under somatostatin agonists) of the patients, the GH and IGF-I concentrations were decreased to so-called "safe" levels. In this, GK was indicated because trans-sphenoidal surgery failed to achieve remission and there was no significant difference in success rate, whether GK was used as primary treatment (16%) or after surgery (21%). The mean margin dose used was 25.8 Gy. Higher success rates were observed with higher margin doses, but with the drawback of more severe complications. Mean time of GH and IGF-I normalisation was 36 months. GK induces far fewer complications than conventional radiotherapy with 82% patients in this series having no side effects after GK versus less than 50% with conventional radiotherapy in most other studies.[30,12] In another series of 64 patients treated with GKS for acromegaly at University of Virginia, biochemical remission occurred in 36% of the patients. GK surgery offers an important treatment modality in patients with secretory adenomas refractory to surgical and medical intervention.[35]

150 Other Secreting Adenomas of the Pituitary

Deepu Banerji, Archana Juneja

INTRODUCTION

Pituitary adenomas secreting thyroid-stimulating hormone (TSH) are rare tumours that cause hyperthyroidism by chronic stimulation of an intrinsically normal thyroid gland.[2] The first case of a TSH-oma diagnosed by measuring TSH with a bioassay was reported in 1960.[15] Hamilton et al.[13] reported the first case of a TSH secreting pituitary adenoma proven by radioimmunoassay.

Older series indicate that these tumours accounted for 0.5–1% of all pituitary adenomas.[20] The overall prevalence is around 1–2 cases per million. However, with the availability of the new generation ultrasensitive immunoradiometric assays for TSH, the prevalence rates have increased in the last decade to 1–2.8%.[22]

Early series reported these tumours to be invasive macroadenomas, but with the advent of the new TSH assays and assays for direct measurement of free thyroid hormones and improved radiological techniques, these tumours can now be identified at the microadenoma stage, permitting better therapeutic outcomes.

PHYSIOLOGY OF THE PITUITARY THYROID AXIS

The production of TSH by the pituitary is under control by TSH-releasing hormone (TRH), produced by the periventricular nucleus of the hypothalamus. TSH is a 280 kd glycoprotein composed of two subunits, the α-and β-subunits, each coded by separate genes. The α-subunit is common to other glycoprotein hormones like LH, FSH and hCG. The β-subunit is unique and confers specificity of action. The binding of TSH to its receptor on the thyroid follicular cells is influenced by the degree of glycosylation of the α and β-subunits. TSH secreting tumours secrete heterogeneous isoforms of TSH which differ in the extent of oligosaccharide residues and the degree of sialylation and fucosylation. Tumours tend to have TSH isoforms with increased fucosylation and decreased or normal sialylation. Other studies have found an increase in the ratio of biologic to immunologic activity in TSH-omas. A disproportionate release of the bioactive hormone can explain why most patients with TSH secreting tumours have a hyperthyroidism with normal TSH levels.[3,4,21]

TSH causes enlargement of the thyroid follicular cells and promotes synthesis of thyroxine (T4), which gets deiodinated in the periphery to triiodothyronine (T3). T4 and T3 have negative feedback effects on both the production and the release of hypothalamic TRH and pituitary TSH.

PATHOLOGY

The thyrotroph cells account for about 5% of the functional anterior pituitary cells and are the cells of origin of a TSH-oma. Most TSH-omas are benign, and malignant transformation is extremely uncommon.[23,24] These are invasive macroadenomas with a fibrous consistency even in the absence of prior surgery or radiotherapy.

The adenomatous cells are mostly chromophobic and monomorphous.[5] Some poorly differentiated adenomas show pleomorphic fusiform cells with sparse endoplasmic reticulum, small secretory granules with abnormal mitotic figures which do not always represent malignancy. The only hallmark of a pituitary carcinoma is the presence of distant metastasis. Immunohistochemistry is positive for TSH-B and the α-subunit in 20–75% of the cells.[25] Although most TSH secreting tumours produce only TSH, about 30% also show co-secretion of other hormones, mainly GH (16%) and prolactin (10.4%), as they are derived from a common transcription factor Pit-1.[5,14] Occasionally, FSH and LH co-secretion are seen (1.4%) and very few cases of ACTH co-secretion have been documented. Positive immunostaining, however, does not always correlate with hormone secretion *in vivo* and a tumour should be classified as a TSH secreting adenoma only if there is evidence of inappropriate excess of the pituitary-thyroid axis.

CLINICAL PRESENTATION

TSH-omas occur with equal frequency in males and females and are more common in the third to sixth decade of life, although cases have also been reported in children as young as 11 years old.[13]

Patients with TSH-omas present with symptoms and signs of either hormone hypersecretion or mass effect from an expanding sellar lesion. Goitre is the rule and is seen in more than 90% of patients, even in those who have had a partial thyroidectomy. Autonomous thyroid

nodules and multinodular goitres have been reported. This occurs because of the sustained TSH secretion over many years. Most patients have a history of long standing thyroid dysfunction with typical features of hyperthyroidism, including heat intolerance, tremors, weight loss, palpitation and diarrhoea. The severity of symptoms varies but most have mild degrees of hyperthyroidism in relation to their hormone levels, probably due to the slow development of the hyperthyroidism, leading to compensatory mechanisms like receptor down regulation. Severe features, like exophthalmos, cardiac failure and periodic paralysis, are very rare.[2,19] Often, many patients are mistakenly diagnosed as Graves' disease and have had ablative thyroid treatment in the form of thyroidectomy or radioiodine therapy. An average delay of 8–9 years has been reported before these tumours are diagnosed.[7,19] Thyroid ablative treatment eliminates the normal negative feedback by the thyroid hormone on thyrotrophs and alters the natural history of the disease. TSH-omas are usually large with 88% being macroadenomas,[7] 60% of the tumours are locally invasive. Most patients seek medical attention because of mass effects of the expanding sellar lesion. Headaches, visual field defects and cavernous sinus involvement are common. In fact, previous thyroid ablative treatment worsens the invasiveness of the tumour. Symptoms of hypopituitarism occur due to involvement of the other pituitary cells by the tumour. Signs of acromegaly, galactorrhoea, menstrual disorders and reduced libido are seen in both sexes. Rarely, TSH-omas have been described in families with MEN-1 and McCune-Albright syndrome.[12,18,26] An ectopic TSH producing tumour in the pharyngeal hypophysis has been described.[10]

EVALUATION

High levels of T3 and T4 in the presence of detectable levels of TSH are characteristically seen in patients with TSH secreting tumours or pituitary resistance to thyroid hormones. However, more common conditions which can cause similar biochemical profiles need to be ruled out first. Increase in levels of TSH transport proteins (thyroxine binding globulin or transthyretin or albumin) caused by drugs or estrogens; familial dysalbuminaemia; drugs, like amiodarone and acute psychiatric disorders, can cause elevation in total T4 levels. Heterophilic antibodies to T4 and T3 can cause spurious elevations of these hormones. These errors are obviated by measuring the free T4 and T3 levels, which are essentially normal in the above conditions but increased in central hyperthyroidism and resistance to thyroid hormones (RTH). Once increased levels of free thyroid hormones are documented in the presence of detectable TSH levels (i.e. central hyperthyroidism) by the immunoradiometric assays, the next step is to distinguish a TSH-oma from RTH. The α-subunit levels are elevated in two thirds of patients with a TSH-oma. Calculating the molar ratio of α-subunit to TSH, improves the sensitivity of detection to 80%. A ratio of more than 1 indicates a TSH-oma, although similar values have been observed in menopausal women.[16] Patients with primary hyperthyroidism and those with RTH have ratios less than 1. Measures of peripheral thyroid hormone action, like SHBG (sex-hormone binding globulin), cholesterol, angiotensin converting enzyme and carboxy terminal cross-linked telopeptide of type 1 collagen (1 CTP), can be used to distinguish a TSH-oma from RTH. Levels are elevated in TSH secreting tumours but normal in RTH states.[3]

DYNAMIC TESTING

Several stimulatory and inhibitory tests have been described to evaluate a TSH-oma. Although none of them have clear cut diagnostic values, a combination of the tests helps to improve the diagnostic yield. The stimulatory test includes the TRH induced TSH secretion, which is absent or blunted in a majority of patients with TSH-omas. This test has a good sensitivity and excellent specificity in patients with an intact thyroid but was less sensitive in patients who had a prior thyroidectomy. Patients with resistance to thyroid hormones typically have a robust response of TSH to TRH. The exact cause for the relative autonomy of TSH secreting tumours in terms of absence or functional impairment of the TRH receptor has not yet been demonstrated and remains unexplained. The inhibitory test includes the T3 suppression test, which checks for the degree of TSH suppression following T3 administration. Both basal and TRH stimulated TSH levels are not suppressed, following T3 administration in patients with TSH-omas. This test is especially useful to diagnose a TSH-oma in patients who have undergone a prior thyroid ablation and to predict long-term cure in patients with TSH secreting tumours.[7]

In summary, the combination of TRH test, α-subunit and α-subunit to TSH ratio was diagnostic in the majority of untreated patients. In patients with an intact thyroid the best combined sensitivity and specificity were seen with the TRH test (71% and 96%) and α-subunit (75% and 90%). For patients with previous thyroid treatment, the best combined sensitivity and specificity was seen in the α-subunit (90% and 82%) and the α-subunit/TSH ratio (90% and 73%). In addition, IGF-1 and prolactin levels should be measured in all patients.

RADIOLOGICAL DIAGNOSIS

The advent of MRI has made the diagnosis of pituitary tumours easier and demonstrates the extent of the tumour with more accuracy. Gadolinium contrast scans are an excellent tool to demonstrate microadenomas, which now account for 13% of all reported cases. But the presence of a microadenoma in a patient with central hyperthyroidism should always be tested by immunohistochemical analysis, before labelling it as a TSH-oma. Nuclear scintigraphy using ^{111}I labelled octreotide are more useful in ectopic tumours. Petrosal sinus sampling has also been described but reports are still preliminary.

THERAPY

Surgery is recommended as the first line of management but the cure rates are around 40% in most series.[7,20,22] Most of these tumours are hard and have a fibrous consistency and are locally invasive, making complete excision difficult. Two deaths were reported in the early post-operative period in the NIH series. These patients had macroadenomas and had a long delay in diagnosis. Complications include transient or permanent diabetes insipidus, syndrome of inappropriate secretion of antidiuretic hormone and permanent central hypothyroidism. Radiotherapy is mainly employed as an adjunctive therapy to surgery and not used as a primary modality of therapy. As most TSH-omas are macroadenomas that extend into the suprasellar cistern, they typically do not meet the criteria for safe use of stereotactic radiosurgery.

Medical Treatment

Antithyroid drugs should not be used as a treatment for patients with TSH-omas, as they increase the tumour growth and invasiveness. Their probable role is only in the preparation of the patient prior to neurosurgery. Beta blockers can be given to control the hyperthyroid symptoms. Somatostatin analogues, like octreotide or lanreotide, are the current drugs of choice in patients with TSH secreting adenomas.[1,8,9,11] Somatostatin receptors are expressed on these tumours and stimulation of these receptors by analogues reduces TSH secretion.[6] Tumour shrinkage occurs in 50% and vision improvement in 75% of patients treated with octreotide. A reduction in α-subunit, T3 and T4 confirms efficacy of the drug. It takes about 2 weeks for the full effects of the drug to occur. Normal TSH dynamics is restored and the suppression of TSH secretion with octreotide with consequent central hypothyroidism requires thyroxine supplementation. Tachyphylaxis is seen in about 25% patients necessitating dose increase. Patients need to be monitored for side effects like cholelithiasis and glucose intolerance. Lanreotide, the new long acting formulation of somatostatin is a better alternative, as it can be given once or twice a month. These new analogues may have a role in the long-term treatment of patients with TSH-oma, who have not been cured by surgery.[17] Thus no single therapy is expected to be curative for a TSH-oma. A combination of the above modalities is frequently required in a majority of patients to achieve clinical remission and cure.

Criteria of Cure

Cure is not defined by mere euthyroidism and absence of visible tumour on imaging. The most sensitive and specific test to document cure remains the complete inhibition of both basal and TRH stimulated TSH secretion, following T3 administration. Other tests include an undetectable TSH one week after surgery and a normalisation of the α-subunit/TSH ratio.[7,19,21]

Recurrence rates, although not available, seem to be low at least for a year following documenting a cure. Patients should be followed up at 3–6 monthly intervals in the first year and then every year. Pituitary imaging needs to be performed every 2–3 years.

CONCLUSION

TSH secreting adenomas, the rarest of functional pituitary tumours, are now being increasingly detected due to the advent of ultrasensitive TSH and free hormone assays. Increased awareness and early recognition of these tumours will prevent inappropriate treatment which can increase tumour invasiveness. Biochemical evaluation with measurement of thyroid hormones, TSH, α-subunit and dynamic stimulation and suppression tests are important to plan and assess therapeutic outcomes. Trans-sphenoidal surgery is the initial therapy of choice, but with cure rates of around 40%. Radiotherapy and medical management with long acting somatostatin analogues are adjunctive to control hormone hypersecretion tumour growth and cure in the long-term.

151 Non-Functioning Pituitary Adenomas

Manas Kumar Panigrahi, Naveen Mehrotra, Amit Kumar T

INTRODUCTION

Pituitary tumours are defined by the characteristic clinical syndromes that accompany tumour hormone overproduction. Approximately 25–30% of patients who present with pituitary adenomas have no clinical evidence of hormone hypersecretion; such tumours are classified as non-functioning adenomas.[18,23,36,37] The term "clinically non-functioning" appears to be preferable to "non-secreting" because many of them do secrete, but do not produce a recognisable clinical syndrome or do not elevate above normal the serum concentration of the secreted hormone. Any kind of pituitary adenoma can be clinically non-functioning, but some types are clinically non-functioning usually and other types are clinically non-functioning unusually. Gonadotroph and thyrotroph adenomas are examples of usually clinically non-functioning. At the other end of the spectrum are somatotroph and corticotroph adenomas, which usually produce recognisable clinical syndromes, acromegaly and Cushing's syndrome, respectively.[44] Several cases of each have been reported in which the adenomas were identified immunocytochemically, but the patient did not, even on re-examination, have the usual clinical syndrome or even elevated serum concentration of growth hormone or ACTH.[14,22,25,32] Silent corticotroph and somatotroph adenomas may be detected in up to 8.1% and 2.7% of tumours, respectively.[19] To say that a pituitary adenoma is clinically non-functioning, therefore, is to say that the cell of origin is not readily apparent from the clinical presentation, not that it cannot be determined. In fact, the cell of origin can usually be determined if one looks carefully.[44]

PATHOLOGY

Pituitary adenomas have long been classified according to their tinctorial affinity for acidic or basic dyes into acidophilic, basophilic or chromophobic adenomas. Acidophil adenomas were traditionally associated with acromegaly, basophil adenomas with Cushing's syndrome and chromophobe adenomas were thought to be non-functioning.[31] However, it has become obvious that this classification is inadequate to cover the diverse clinicopathologic spectrum of pituitary adenomas. Horavth and Kovacs developed a useful system of classifying pituitary adenomas that is based on the immunocytological findings and electron microscopy. It attempts to identify the cell type from which the tumour is derived and aims to correlate the morphological findings with the clinical history, immunohistochemistry, biological behaviour and endocrine activity.[47]

CLASSIFICATION OF PITUITARY ADENOMAS[12,42]

- Prolactin cell adenomas
  - Sparsely granulated
  - Densely granulated
- Growth hormone cell adenomas
  - Sparsely granulated
  - Densely granulated
- Mixed prolactin cell-growth hormone cell adenomas
- Acidophilic stem cell adenomas
- Mammosomatotroph cell adenomas
- Corticotroph cell adenomas
  - Sparsely granulated
  - Densely granulated
- Gonadotroph cell adenomas
- Thyrotroph cell adenomas
- Plurihormonal adenomas
- Null cell adenomas
- Oncocytomas.

Ultrastructural studies allowed classification of non-functioning adenomas as null cell adenomas and oncocytomas.[40] Null cell adenomas are composed of polyhedral cells, possess irregular nuclei and poorly developed cytoplasm containing short scattered rough endoplasmic reticulum profiles, a moderately developed Golgi apparatus and rod-shaped mitochondria. Secretory granules are sparse and spherical and form a single row along the plasma membrane without evidence of granule extrusion. Null cell adenomas contain a varying number of cells (< 75%) exhibiting oncocytic changes.[8] Oncocytomas appear to be a variant of null cell adenomas with the appearance and prominence of most cytoplasmic components being similar to those in null cell adenomas. The single characteristic feature is the striking abundance of mitochondria, some of them curiously shaped, filling a large part of the cytoplasm of more than 75% of adenoma cells.[8] Null cell adenomas and oncocytomas are characterized by lack of immunocytochemical markers and clinically

do not show symptoms and signs of excess hormone production.[41] These are slow growing macroadenomas occurring in older age group individuals and locally invasive.

A pituitary adenoma can be differentiated from the normal pituitary gland both in gross and microscopic appearance. Grossly a normal pituitary gland is firm in consistency and an adenoma is soft to semi-solid. Microscopically, in a pituitary adenoma, the cells are monomorphous, but they lack acinar arrangement whereas, in a normal pituitary gland, the cells are of different size, shape, types and are arranged in an acinar pattern. The loss of acinar pattern is one of the pathological hallmarks of pituitary adenoma.[46]

IMMUNOHISTOCHEMISTRY

With the advent of immunohistochemical techniques and the use of specific antisera we can identify the hormones stored within the cells. All the hormones have been found in non-functioning adenomas by immunohistochemistry. Apart from immunohistochemistry, the secretory activity of non-functioning adenomas have been established by other *in vitro* studies like tissue culture,[3,28,45,55] analysis of pituitary hormone gene expression[15] and the reverse haemolytic plaque assay.[54]

Immunocytochemical data suggest that many of these non-functioning tumours produce subunits of glycoprotein hormones, which are endocrinologically inactive. The glycoprotein hormones include follicle stimulating hormone (FSH), luteinizing hormone (LH), thyroid-stimulating hormone (TSH) and the placental hormone chorionic gonadotropin (CG). They contain two subunits: (1) The alpha-subunit, which is common to each of them, and (2) A beta-subunit (β-FSH, β-LH, β-TSH and β-CG), which confers biological and immunological specificity.[4] Several investigators have shown that many clinically non-functioning pituitary tumours are unrecognised prolactinomas or gonadotroph adenomas.[43,50] Immunoperoxidase staining using specific antibodies has shown that chromophobe adenomas less commonly show staining for ACTH despite the clinical absence of Cushing's syndrome. Horvath et al. found that 4.3% of tumours staining for ACTH were clinically silent[14] and small numbers of "silent" ACTH-secreting adenomas have been found in several other series.[13,50]

In the series by Black et al, of 160 patients referred for pituitary surgery, 37 (23%) had no evidence of excess hormone secretion on pre-operative endocrine evaluation but on immunocytochemical staining of these tumours one or more of pituitary hormones was detected in 73% of cases. The α- and β-subunits were detected most frequently, being found in 68% of cases; 27% had staining for one or more β-subunits and 37.9% had staining for both α and β-subunits. The incidence was β-FSH in 58%, β-LH in 47%, β-TSH in 33% and α-subunit in 42%. Staining for multiple glycoprotein hormones was common in 52% and mixed glycoprotein hormones and prolactin cell types were found in 16% of cases.[4] Similarly, Jameson et al. reported production of one or more pituitary hormones in 93% of non-functioning tumours on immunocytochemical studies and noted expression of one or more of the anterior pituitary hormone genes in 86% of the patients with clinically classified non-functioning adenomas.[15] Asa et al. studied 99 non-functioning adenomas (41 null cell adenomas and 58 oncocytomas) *in vitro* and found that 96/99 tumours released LH, FSH and/or alpha-subunit of glycoprotein hormones and only three tumours released no detectable hormones.[2]

Apart from immunohistochemistry, electron microscopy of cells of non-functioning tumours appears to contain secretory granules despite their apparent lack of assayable hormone product. Although secretion of intact gonadotropins or glycoprotein subunits can be demonstrated in the majority of non-functioning pituitary adenomas, clinical and serum studies in these patients typically fail to demonstrate evidence of hormone hypersecretion. The plausible explanations for this may be that: (1) The specific radioimmunoassay (RIA) for glycoprotein subunits are less available and as the sensitivity and specificity of glycoprotein subunit RIA increases, detection becomes more frequent, (2) Low levels of hormone production, (3) Abnormalities may occur in cellular processing of these hormones and despite normal biosynthesis active secretion does not take place, (4) To be endocrinologically active the β-subunit must be combined with the alpha-subunit and these tumours may therefore be producing uncombined subunits that are hormonally inactive.[4,23]

The cellular origin of non-functioning pituitary adenomas has yet not been established, but according to hypothesis by Asa et al. null cell adenomas and their oncocytic counterparts may represent neoplasms derived from uncommitted or committed precursor cells that can undergo differentiation towards several cell lines.[2] Kontogeorgoes has reported a case with multidirectional differentiation of endocrinologically inactive null cells into well differentiated somatotrophs, lactotrophs and cells of glycoprotein hormone cell line.[24]

CLINICAL PROFILE

Patients with non-functioning tumours lack a characteristic clinical syndrome or serum tumour hormone marker. They present with symptoms related to tumour mass effect such as headache, visual loss or symptoms of hypopituitarism. Visual manifestations either in the form of impairment of visual fields or loss of acuity are the most common presenting symptoms reported to be seen in as many as 72% by Ebersold et al.[10] In its most recognisable form, vision is impaired first in the upper outer quadrants of the visual fields (bilateral superior temporal quadrantanopia), which may progress to involve the entire temporal fields bilaterally (bitemporal haemianopia). The visual field impairment may be asymmetric and, when the chiasmal compression is severe, central visual acuity is also affected. The visual

deficit may be so gradual that many patients are not aware of their visual loss, until it is demonstrated on a routine eye examination. The mechanism responsible for visual field impairment may be direct mechanical compression of the optic nerve or chiasm, ischaemia or a combination of the two.[35,43]

Headache, seen in as many as 36%[10] of patients, may be due to stretching of the diaphragma sellae, elevation of intracranial pressure due to obstructive hydrocephalus or an excruciating type of headache due to pituitary apoplexy.

Paralysis/paresis of extraocular muscles may be caused by cavernous sinus extension of the adenoma, although it is a relatively rare presentation.[19] Diplopia with sudden severe headache may suggest apoplexy. Rarer presentations may include epileptic seizures and CSF rhinorrhoea.

The symptoms due to pituitary hormonal dysfunction are not the one for which the patient seeks medical attention but, according to Ebersold et al.[10] 61% of patients had pre-operative hypopituitarism. LH deficiency is the most common and results in reduced testosterone secretion, resulting in decreased energy and libido and in premenopausal women results in amenorrhoea. Symptoms of hypothyroidism and hypoadrenalism may also occur.

In our experience also, visual impairment was the most common symptom seen in 74/108 (68.5%), followed by headache in 50/108 (64.2%). Endocrinopathy was noted in a lesser number of cases 24/108 (22.2%), as compared to the results observed by Ebersold et al. and pituitary apoplexy in 6/108 (5.5%) cases.

ENDOCRINE DIAGNOSIS

The most common endocrinological abnormality observed in non-functioning pituitary macroadenomas is hypopituitarism clinically manifested as gonadal hypofunction.

Endocrine tests are divided into tests that provide assessment of pituitary hormone reserve and tests that evaluate patients who have or are suspected to have an endocrinopathy due to functioning pituitary tumours. In general, tests that provide information about the pituitary hormone reserve should be done in all patients. Baseline serum levels of prolactin, growth hormone, T3, T4, TSH, cortisol, FSH and LH should be ascertained.

The serum prolactin levels may be elevated because of stalk effect. A large sellar suprasellar tumour with prolactin levels less than 200 ng/ml is more likely to be a non-functioning adenoma than a prolactinoma.

The serum levels of TSH, FSH and LH may be elevated, as a majority of pituitary adenomas that are clinically non-functioning are gonadotroph adenomas and a significant minority are thyrotroph adenomas. Some large apparently non-functioning adenomas have solely been associated with the production of alpha-subunit.

GH and cortisol levels will usually be normal but, if on provocative testing, the levels of these hormones fail to rise, it is suggestive of hypofunctioning of the pituitary.

IMAGING

MRI is currently the best technique for imaging the pituitary gland, due to its superior resolution and ability to demonstrate the optic chiasm. In addition, MRI is able to demonstrate blood, so an aneurysm can be distinguished from other intrasellar lesions and haemorrhage into pituitary adenomas.

A pituitary microadenoma is usually hypointense compared with the normal gland on T1W images. After contrast injection, the tumour typically does not enhance to the same extent as the normal pituitary gland and thus stands out as an area of relative hypointensity. Focal hypointensity within the pituitary is the most reliable indicator of a microadenoma. Important secondary signs of microadenoma include asymmetric upwards convexity of the gland surface, deviation of the infundibulum and focal erosion of the sellar floor. The preferred imaging planes are coronal and sagittal.

A pituitary macroadenoma is generally isointense to the normal gland and brain parenchyma, unless there are cystic and haemorrhagic components. Homogeneous contrast enhancement permits clear demarcation of the tumour from normal suprasellar structures. MRI is ideal for demonstrating extension of the tumour to the cavernous sinus, optic chiasm, third ventricle and hypothalamus. Upwards extension of a pituitary adenoma through the diaphragma sella accounts for one third to one-half of all suprasella masses in adults (Figs 1A to C).

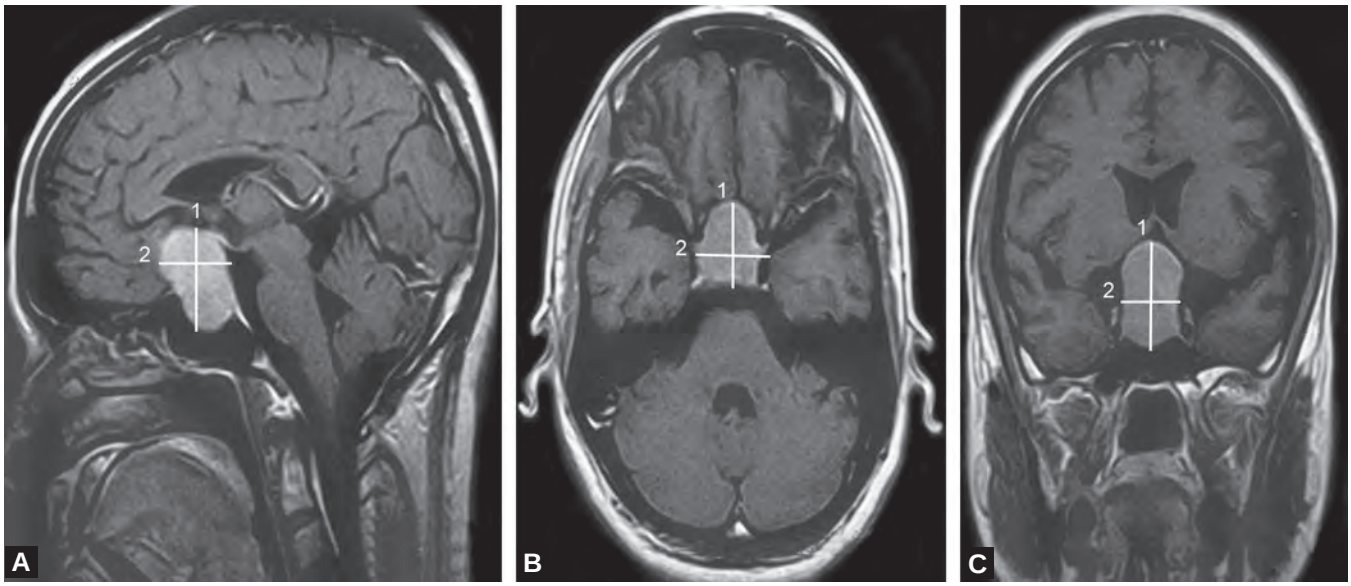
Pituitary adenomas with suprasellar extension typically have a "figure of eight" appearance and the mass is indistinguishable from the pituitary gland.[16]

CT scan with or without contrast may be done when the patient is unable to get an MRI. Typically a pituitary adenoma appears as well circumscribed, isodense to brain and with homogeneous contrast enhancement. Regions of necrosis or cyst formation in the tumour produce internal areas of low density. Microadenomas are usually less dense than the normal pituitary gland. CT scan can demonstrate adjacent bone erosion and extension of tumour beyond the confines of the sella.

Plain X-ray of the skull has limited value in the diagnostic evaluation of patients with sellar/parasellar lesions. It reveals: (1) An enlargement of the sella also known as ballooning of the sella; (2) Undercutting of the anterior clinoid process in which the processes are thinned and sharp; (3) Erosion of the sellar floor; (4) Unequal downwards displacement of the sellar floor called as double floor; (5) Thinning and erosion of the dorsum sella; (6) Degree of pneumatisation of the sphenoid sinus as presellar, sellar or conchal and (7) Supra/intra sellar calcification.

TREATMENT

The goal of therapy is directed towards reduction of tumour mass, rather than treatment of hypersecretory syndrome.[19] The extraordinary success of dopamine agonists in reducing the size as well as secretion by



Figs 1A to C: T1W image showing an enhancing pituitary macroadenoma with suprasellar extension in sagittal, axial and coronal views

lactotroph adenomas has prompted attempts to find a pharmacologic treatment for gonadotroph and thyrotroph adenomas. These attempts have so far been successful in reducing excessive secretion by the adenoma than in reducing its size. The presence of somatostatin receptors on the cell membrane of clinically non-functioning and alpha-subunit secreting pituitary macroadenomas, provides the possibility of treating these tumours with octreotide.[26,28,34] De Bruin et al. attempted to correlate the presence of somatostatin receptors in the adenomas and the outcome of octreotide treatment as measured by tumour size, improvement in visual field defects and hormonal response. High dose (1200 μg sc daily) octreotide treatment was given to four subjects, 3 of whom were somatostatin receptor (SSR) positive. Improvement of visual field defect was observed in 3 of 4 patients (including SSR negative), although no computed tomographic assessed tumour size reduction was found. Two of the four patients showed small but significant reduction in serum FSH concentrations to 83% and 93% of initial values following treatment.[9] Inhibition of gonadotrophin and/or alpha-subunit secretion by somatostatin and octreotide has also been demonstrated, both *in vitro* and *in vivo*.[9,20,39,53] Tumour shrinkage (> 20%) has been reported in 1of 3 alpha-subunit secreting pituitary adenomas[20] and in 1 of 8 non-functioning adenomas,[11] but in none out of 4[9] and none out of 17,[29] patients who were treated with 300–1200 μg of octreotide daily for periods up to 12 months. De Bruin et al. also concluded that bromocriptine was a more effective inhibitor of hormone or subunit release than octreotide in cell culture.[9] Bromocriptine has also been reported to cause reduction in tumour size.[1,21,27,52] Johnston et al. reported a case of recurrent non-functioning adenoma (14 years post-surgery and radiation) put on 20 mg bromocriptine daily for 25 months; the intrasellar tumour recurrence had diminished in size and suprasellar extension had almost disappeared.[17] Further studies with the aim to reduce tumour size in patients with clinically non-functioning adenomas could include treatment with dopamine agonists or a combination of octreotide and dopamine agonists.[27,28]

SURGERY

Trans-sphenoidal surgery is currently accepted as the procedure of choice for the initial management of most clinically non-functioning adenomas. The trans-sphenoidal approach is preferable to transcranial approaches, as it helps to preserve normal pituitary function and allows recovery of visual function.[5,7,30,33] The immediate indication for surgery is visual field loss and with decompression of the optic chiasm, improvement in visual field abnormalities is seen in the majority of patients. The principle of treatment differs between functioning and non-functioning adenomas. The primary goal of surgery for non-functioning adenomas is gross total or subtotal removal of the tumour, with preservation of normal pituitary function. Secreting adenomas must be removed completely for an endocrinological cure, although prolactinomas or growth hormone producing adenomas can be treated with bromocriptine or octreotide.[38]

The trans-sphenoidal approach is employed at our institute and is through the endonasal route, using the microscope from the beginning. After intubation, the oropharyngeal airway is packed. The patient is positioned supine with the head elevated by 30 degrees with the neck flexed and the head turned contralaterally by about 20 degrees so that the nasal septum is parallel to the visual axis (Fig. 2).

Use of C-arm fluoroscope is usually avoided. The choice of nostril used is decided on the position of the nasal septum, size of the middle turbinate and lateral extension of tumour. The nostril with more space and contralateral to the side of lateral extension of the

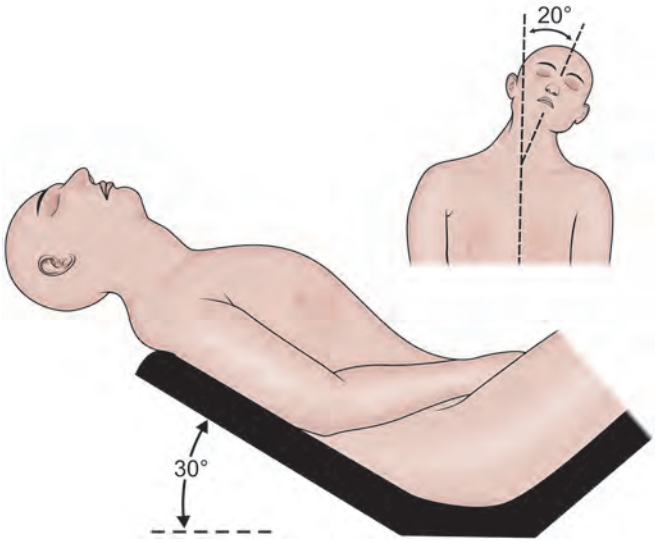


Fig. 2: Position of the patient for trans-sphenoidal approach to pituitary adenomas

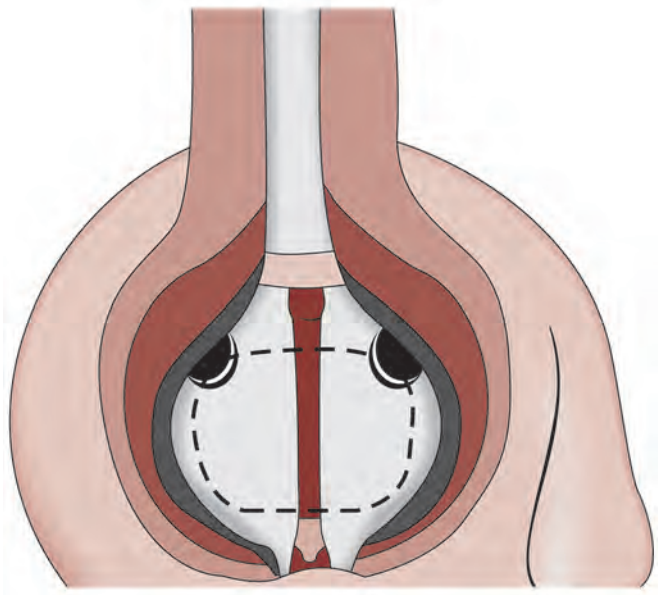

Fig. 3: Bilateral sphenoid sinus ostia and the extent of sphenoidotomy

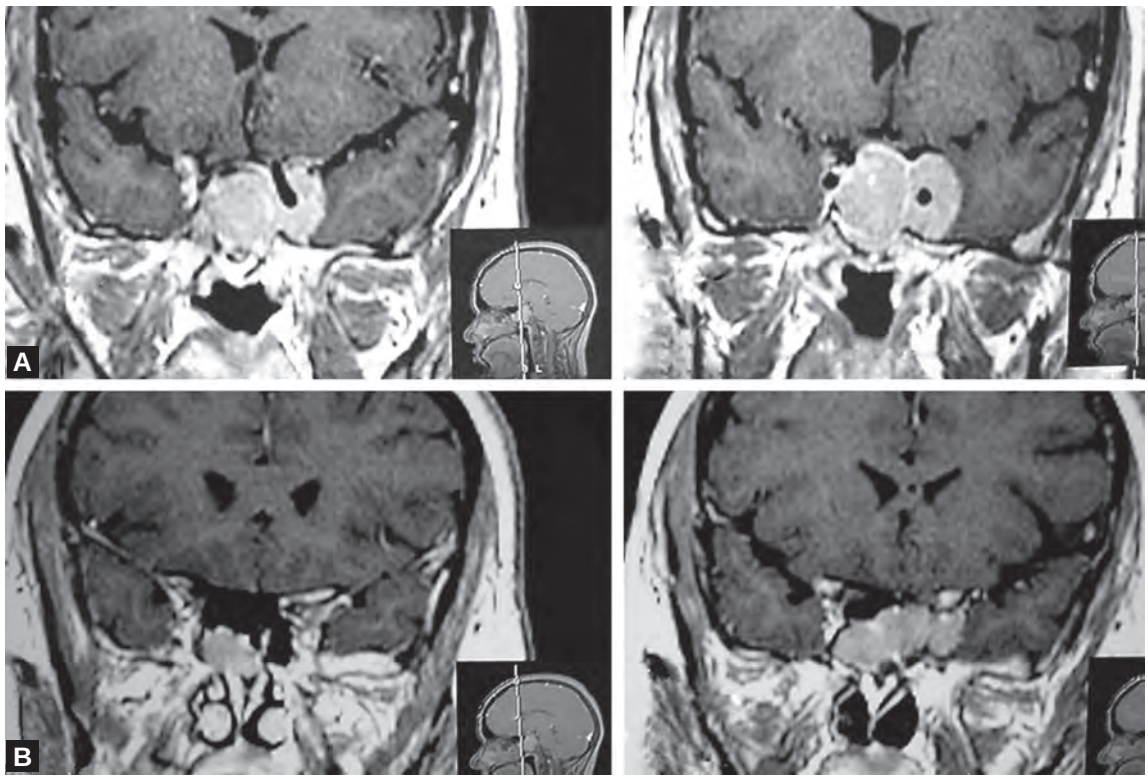
tumour is selected. If the surgeon prefers the left nostril, then it is easier to operate standing on the left side of the patient with the head flexed and turned to the contralateral side. The first step of surgery is to identify the sphenoid ostium under the microscope. This is located usually just above the posterior end of the middle turbinate. If the ostium is covered by mucosa it is perforated. The ostium is enlarged inferiorly and medially. A branch of the sphenopalatine artery is usually located at the inferior border of the ostium, which needs to be coagulated. The septum is fractured at the level of the rostrum/keel junction to identify the ostium of the opposite side. Bone in between the ostia is removed and a larger opening is made in the sphenoid sinus (Fig. 3).

The sphenoid sinus mucosa is stripped to prevent mucocoele formation, infection and bleeding. The sellar floor is exposed and erosion of the sellar floor/maximal thinned out portion is identified and the floor is removed using rongeurs to expose the dura. The anterior wall of sella is removed from one cavernous sinus to the other and from the sellar floor to the tuberculum sellae. Durotomy is done in a cruciate fashion and the leaves of the dura are coagulated. Valsalva manoeuvre is done before starting decompression. The tumour removal is initially done from the inferior and posterior region, followed by lateral removal and finally the superior aspect of the tumour is removed. The normal pituitary gland is firmer than the tumour tissue and is yellowish orange in colour. The pituitary gland with the stalk has to be preserved as far as possible. After removal of the macroadenoma, the sinus is packed with abdominal fat and the sellar floor is reconstructed with the autogenous bone graft obtained at the time of sphenoidotomy. Abdominal fat may not be necessary, if there is no CSF leak and if it is a microadenoma. The nasal cavity is packed with lubricated betadine packs on one side for 12 hours. The removal of a pituitary tumour with suprasellar extension, in its entirety by a trans-sphenoidal approach, is sometimes difficult. If the suprasellar tumour does not descend after complete removal of the intrasellar tumour, care is taken not to induce CSF leakage and endoscope assistance is used for further removal. The remaining suprasellar tumour typically descends into the sellar space within a couple of months, at which time it can be safely removed during a second operation. We know by experience that the suprasellar tumour typically descends within 2 months and 2–3 months is the optimal interval for second surgery. The second surgery may be deferred for several months because we are not sure after how many months we could still expect descent of the remaining suprasellar mass. Trans-sphenoidal excision of pituitary adenoma can be accomplished, either by an endoscope or microscope or both. At NIMS we had operated upon 108 patients with pituitary adenomas, via the trans-sphenoidal approach over the past five years, using the endoscope in 58 cases, microscope in 45 cases and both in 5 cases. Both the groups had age-matched patient population and were analysed for extent of tumour excision and complication rates. Total/near total excision was achieved in 44/58 (74%) and 30/45 (67%) by endoscope and microscope, respectively. The incidence of CSF leak was 24% as against 13.3% by endoscope and microscope, respectively. There was no statistical difference between endoscopic and microscopic endonasal trans-sphenoidal approach to pituitary adenomas.

Transcranial Surgery

Rarely, transcranial surgery should be considered in patients with giant macroadenomas, where the bulk of tumour is suprasellar and parasellar, and symptoms are arising from tumour compression of the brain (Figs 4A and B).



Figs 4A and B: Post-gadolinium T1W coronal images showing pituitary adenoma with parasellar extension for transcranial approach

Patients with recurrent tumours with failed multi-staged trans-sphenoidal excision may require transcranial surgery.

Complications of Surgery

Trans-sphenoidal surgery has low morbidity. Surgical complications from removal of large pituitary adenomas have been reported in 5–17% of patients.[5–7,10,30] CSF rhinorrhoea is one of the most common complications occurring in 3% in most large series.[48] Injury to the cavernous sinus/carotid artery are serious complications. Cranial nerve injury may occur, especially of the III and VI nerves, if the tumour is extending into the cavernus sinus. Visual deterioration may occur after trans-sphenoidal surgery, either because of direct operative trauma, compression due to a haematoma, ischaemia or prolapse of the chiasm. Hypopituitarism, diabetes insipidus (DI) and hypothalamic damage are also known to occur. DI is one of the most frequent complications of trans-sphenoidal surgery with permanent DI occurring in less than 3% and transient DI in up to 60% of patients.[48] Meningitis and nasal/sphenoidal problems are other complications. We encountered CSF rhinorrhoea in 20/108 (18.5%) of patients with trans-sphenoidal excision of pituitary adenomas. Transient DI occurred in 12/108 (11.1%) of patients with permanent DI occurring in only one patient. One patient developed III nerve palsy.

RADIATION

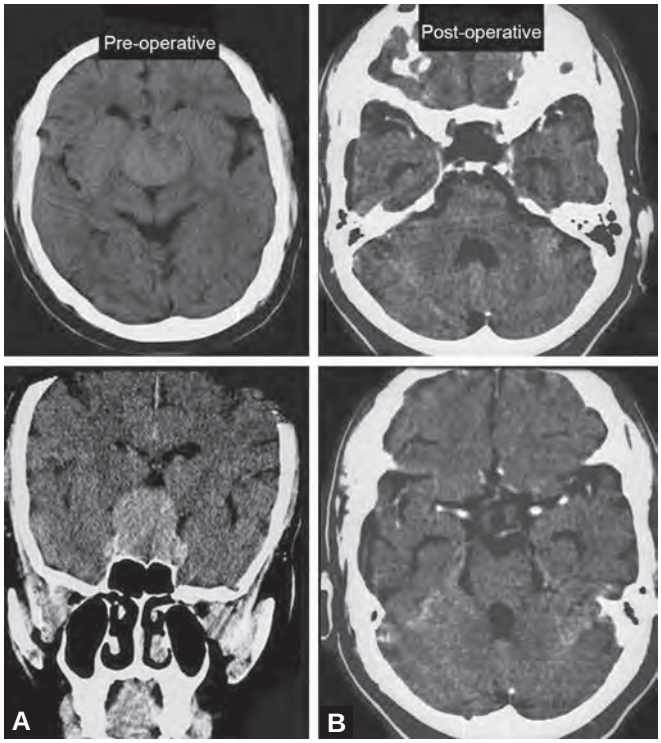
Radio-surgery/stereotactic radiotherapy is indicated, when there is inadequate tumour resection at the time of surgery and post-operative CT/MRI show evidence of residual tumour, and the patient is symptomatic. If there is no radiologic evidence of residual tumour, opinion is divided as to the role of post-operative radiation therapy, although most neurosurgeons would reserve radiation for recurrence.

FOLLOW-UP

Follow-up evaluation should include determination of the extent of residual tumour, the status of visual function and function of the non-adenomatous pituitary. All the patients with large non-functioning pituitary adenomas should be evaluated for the presence of residual tumour with a CT/MRI scan approximately 1 month following surgery, then at 6 months, 12 months and, if stable, at yearly intervals. Whatever intact pituitary hormones or subunits were abnormal before surgery should be measured again at this time, because surgery can impair previously normal function by excision of non-adenomatous pituitary tissue, but can also restore previously subnormal function. Neuro-opthalmological evaluation should include determination of visual acuity and field. These results will indicate if additional treatment is required and provide a new set of criteria by which to assess the subsequent course of the adenoma.

OUTCOME

About 70–80% of patients improve in their visual field after trans-sphenoidal surgery.[49] Saito et al. reported 72% enlargement in visual field and 76% improvement



Figs 5A and B: Pre-operative and post-operative CT scan showing complete removal of pituitary adenoma

in visual acuity.[38] Ebersold et al. observed that of 72 patients who presented with visual loss 53 improved, 15 remained stable, 3 patients had additional visual loss after the procedure and 1 died.[10] Regarding completeness of tumour removal, gross total and subtotal (≥90%) removal was achieved in 76% of tumours by Saito et al. with higher rates achieved in patients with less suprasellar extension, but completeness of tumour removal fell to 50% for tumours with a suprasellar height over 30 mm.[38] The recurrence rate reported in various series ranges from 12 to 24%.[6,7,10,51] In our experience, 54/74 (73%) patients had improvement in visual symptoms and gross total/near total resection being achieved in approximately 68% of cases (Figs 5A and B).

RECOVERY OF PITUITARY FUNCTION FOLLOWING MANAGEMENT OF NON-FUNCTIONING ADENOMAS

Partial or complete hypopituitarism is commonly found in patients with non-functioning adenoma at the time of presentation. The majority of patients with normal anterior lobe function pre-operatively have preserved function following surgery. Patients with a selected deficiency in anterior pituitary hormones often showed no change or improvement following surgery. Arafah et al. documented pituitary function studies in 26 patients with non-functioning pituitary macroadenoma before and after trans-sphenoidal surgery. Deficiency in growth hormone, gonadotropins, TSH and ACTH were found in 100%, 96%, 81% and 62% of patients respectively. Following surgery normal somatotroph and gonadotroph function was restored in 15% and 32% of patients, respectively. Normal thyroid function was restored in 57% of patients who had hypothyroidism pre-operatively and 38% of patients with adrenal insufficiency recovered normal corticotroph function post-operatively. Arafah et al. also found that normal or mildly elevated prolactin levels pre-operatively or a response in serum TSH concentrations following TRH administration was useful in predicting post-operative recovery of pituitary function.[1]

152 Pituitary Apoplexy

Ravi Ramamurthi, Vikram M, Goutham Cugati

Pituitary apoplexy is a potentially disastrous condition, which occurs as a result of rapid expansion of, usually a pre-existing, often not yet known, adenoma by massive haemorrhage or infarction. Pressure, among other things, causes hypopituitarism, meningism and visual disturbances.[47,51] In 1905, Bliebtreu was the first to describe haemorrhage into a pituitary tumour.[6] In 1950, Brougham et al. described five post-mortem cases and drew attention to this clinical condition.[8] In 1954, Ramamurthi et al.[41] reported on two patients with pituitary apoplexy and this was the first report from India. The term "pituitary apoplexy" also describes acute enlargement of a non-tumourous gland, termed "Sheehan's syndrome", when seen in the context of obstetric haemorrhage.[20,37] Diagnosis is made by the typical clinical presentation, eye examination, CT/MRI and by measuring pituitary hormones.

INCIDENCE

The incidence varies in different series from 1 to 21%.[12,15,25,26,35,36,45,55] The incidence varies depending on the criteria used for diagnosis. The incidence of subclinical pituitary adenoma apoplexy was higher than acute pituitary apoplexy.[27,38,39] When subclinical presentations and patients with evidence of haemorrhage, cyst or necrosis on imaging or at surgery are also included, the incidence increases. There are also incidences of post-operative pituitary apoplexy reported following surgery for giant pituitary adenomas.[3]

PATHOGENESIS

Various mechanisms have been postulated for the occurrence of apoplexy. The growth of the tumour may outstrip the blood supply and lead to necrosis and haemorrhage.[9,26] This is more likely in tumours growing in an enclosed place like the sella turcica. The other proposed mechanism is compression of the infundibulum by an expanding mass, thus compromising the blood flow from the portal vessels, resulting in necrosis of the entire gland with haemorrhage as a secondary occurrence.[3] PRL adenomas were the most common tumour type (56.2%). Subclinical pituitary apoplexy usually occurs in patients with big or giant adenomas.[27,38] The blood supply is also limited, with the main supply to the anterior lobe being through the hypothalamo-hypophyseal portal circulation.[58] An expanding tumour may compress the infundibulum against the rigid dural opening in the diaphragma sella, leading to acute necrosis and infarction in the tumour.[44]

Pituitary apoplexy usually occurs *de novo*, but some precipitating factors may be responsible for producing the haemorrhage. Head injury,[28,52] chronic coughing and sneezing,[14] radiotherapy,[54] idiopathic thrombocytopaenic purpura,[30] lymphocytic hypophysitis,[33] spinal anaesthesia,[7] intensive thrombolytic therapy[19] and open heart surgery[46] have been reported to be associated with apoplexy. Medications, like leuprolide,[16] clomiphene,[56] goserlin,[4] GnRH and CRH administration[24,29,43] and oestrogen administration,[13] are reported to precipitate apoplexy. Bromocriptine therapy[32,55] and cabergoline administration have also been found to precipitate apoplexy.[24] Hypertension and diabetes mellitus were the possible predisposing factors. Post-operative 'pituitary apoplexy' in giant pituitary adenomas has been noticed in a series of cases with fatal outcome by Goel et al. and Mahapatra AK et al.[22,3] Mohanty et al.[34] have suggested that the incidence of apoplexy is related to the size and vascularity of the tumour, but this has not been borne out by other authors. A significant number occur in non-secreting tumours.[11]

In post-operative apoplexy, the proposed mechanisms are sudden release of tumour vessels from the internal carotid artery due to reduced tumour burden and compromise of the venous drainage of the tumour during surgery, tumour manipulation during surgery and swelling and subsequent compression of the hypophyseal arteries causing haemorrhagic necrosis.[3]

CLINICAL FEATURES

Haemorrhage into a pituitary tumour may be subclinical and not produce any symptoms or signs, or may produce signs and symptoms of varying severity, ranging from sudden onset of headache, rapid onset of visual loss, unconsciousness or death.[38] The most common features are headache (85–90%),[35,38,55] visual disturbances (70–80%)[31,53] and nausea and vomiting (50–60%).[38] Meningismus, seizures, frontal lobe syndrome,[5] ocular nerve palsies and signs resembling subarachnoid haemorrhage may occur. Altered mental status, stupor and coma have also been seen. Rarely, the presentation can be of non-ketotic hyperglycaemic coma[23] or diabetes insipidus.[50] The combination of headache, acute visual loss and ipsilateral Horner's syndrome without

ophthalmoplegia, mimicking carotid artery dissection has been reported as an unusual presentation.[47] The onset of apoplectic symptoms may be the first indication of an underlying pituitary tumour.

Endocrinologic manifestations of pre-existing hypersecretion like acromegaly, Cushing's or galactorrhoea and amenorrhoea may be present. Severe and acute hypopituitarism result either due to destruction of normal pituitary tissue or due to compression of the stalk. The hypopituitarism may be mild. In some instances, the haemorrhage may destroy the tumour tissue and amelioration of symptoms of hypersecretion may occur.[10,17]

The visual defects that may occur are diminished visual acuity, blindness in one or both eyes or field defects like central scotomata, bitemporal or binasal hemianopia or generalised constriction.[31] Ocular movement disorders occur when the tumour expands and compresses the cavernous sinus. III, IV and VI nerve palsies can occur in various combinations producing ptosis, dilated pupil and diplopia.[49] Isolated III and VI nerve palsies as the sole presenting features have been reported.[42,51] Trigeminal signs involving the first and second division may be found.

Because of its varied clinical presentation and its resemblance to other acute neurological conditions, the onset of pituitary apoplexy is often missed, unless the diagnosis of pituitary tumour has already been made. The clinical features may also be insignificant enough to escape attention. The differential diagnosis should include SAH due to aneurysmal rupture, stroke,[41] meningitis, encephalitis and uncal herniation, due to an expanding intracranial mass lesion.

INVESTIGATIONS

When the clinical presentation suggests pituitary apoplexy, plain skull films are valuable, as in the majority of patients changes consistent with an intrasellar mass are likely to be seen.[2,18]

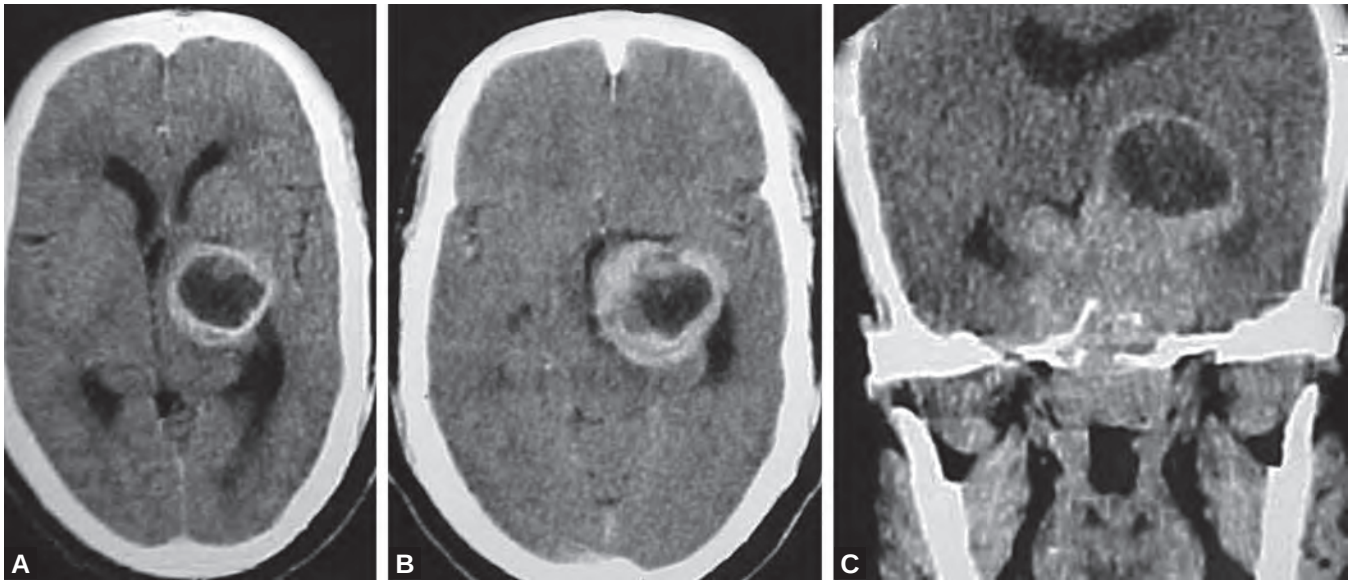
CT scan is useful, and plain and contrast enhanced scans must be done. A hyperdense non-enhancing lesion will be seen in the acute stage, representing blood. Surrounding enhancing tumour tissue may be seen. The mass usually extends into the suprasellar cistern and may displace the third ventricle producing hydrocephalus, which will be seen on the CT. When the CT is done weeks later or when there is necrosis without haemorrhage, a central isointense or hypointense lesion may be seen surrounded by a rim of contrast enhancement[39] (Figs 1A to C). CT is better than MR in the acute stages.

MR is useful, especially in the detection of silent or subclinical haemorrhage and in following up patients with apoplexy.[21,39] The MR changes due to haemorrhage will vary depending on the age of the haematoma in days and weeks (Figs 2 and 3).

Endocrine assessment is essential to decide on immediate and long-term replacement therapy. Levels of GH, PRL, cortisol and thyroid hormones should be done immediately. If necessary, provocative tests are done to evaluate the functioning of the hypothalamic-pituitary axis and to know the reserve capacity. Lumbar puncture to rule out meningitis or SAH should be done only when the plain X-rays and the CT are normal.

MANAGEMENT

The first step after diagnosis is to administer corticosteroids. When there is visual involvement, progressive decrease in the level of consciousness or involvement of the cranial nerves, emergency surgery must be undertaken to save life and vision. When there are only mild symptoms and no visual problems, the patients may be investigated further and the treatment options exercised as in any other patient with a pituitary tumour. Sibal



Figs 1A to C: CT scan axial and coronal section showing evidence of apoplexy. Hypodense core representing blood with surrounding enhancement of tumour

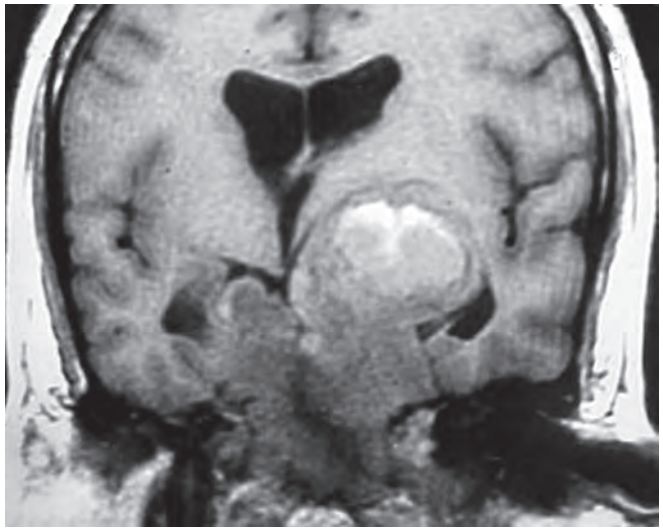


Fig. 2: MRI coronal sections of the same patient as in Figure 1 showing evidence of apoplexy

et al.[48] in their analysis of 45 patients managed conservatively found that the patients with classical pituitary apoplexy, who are without neuro-ophthalmic signs or exhibit mild and non-progressive signs, can be managed conservatively in the acute stage as their neurological symptoms improved significantly on follow-up.

Trans-sphenoidal surgery is indicated in patients with diminished levels of consciousness, hypothalamic dysfunction and visual deterioration. Trans-sphenoidal excision and decompression of the optic nerve and cavernous sinus is the ideal. Occasionally, transcranial surgery may be indicated when the sella is not enlarged or a dumb bell tumour is suggested.[55] Hydrocephalus will be relieved with tumour decompression, but occasionally a CSF diversion procedure may be required. Conservative management for patients with isolated cranial nerve palsies has been advocated but remains controversial.[51] Endocrine replacement therapy as appropriate must be instituted post-operatively, depending on the post-operative endocrine profile. Post-apoplexy long-term endocrine deficits are quite common.[53] Improvement in endocrine status may take place after surgery and this is probably due to release of stalk compression, which occurs during the apoplexy.

Since radiotherapy has been found to initiate apoplexy in some, it has been suggested that radiotherapy should not be given to patients who had apoplexy.[54,57] This contention is not supported by other data and radiotherapy may be given when indicated.[44]

Visual improvement usually occurs following decompression.[1,2,31] Visual outcome depends on the duration and severity of compression prior to the apoplexy and also on the time lag between the apoplexy and the surgery. Useful recovery of vision has been reported after total bilateral blindness[1,40] and, therefore, it is necessary to take urgent action even when the patient is blind. Recovery of cranial nerve dysfunction occurs usually and may take 8–12 weeks. Some patients are left with permanent devastating neurological deficits like blindness, hemiplegia or a chronic vegetative state.

153 Giant Invasive Pituitary Adenomas

Ravi Ramamurthi, Goutham Cugati

INTRODUCTION

Pituitary adenomas are the most common intrasellar tumours and account for 10% of all intracranial tumours. Of these tumours, approximately 5–6% behave aggressively and grow to gigantic sizes.[20] Those tumours measuring less than 10 mm are termed microadenoma and those measuring more than 10 mm are termed macroadenoma. Pituitary tumours with size in excess of 40 mm, or those extending less than 6 mm from the foramen of Monro are referred to as giant pituitary adenomas.[7,11,12,20,31,33] These tumours although benign, occasionally pose difficulty in management, due to technical problems in surgical resection and invasion of surrounding structures.

EXTENSION

Extension of pituitary adenoma can occur in various directions and results in various signs and symptoms, depending on the structures compressed.

Wilson[39] has classified suprasellar extension of pituitary tumours into:

Type A: Tumour occupying suprasellar cistern
Type B: Tumour obliterating the recess of the third ventricle
Type C: Tumour grossly displacing the third ventricle and having parasellar extension
Type D: Tumour having intradural extension
Type E: Tumour extending into the cavernous sinus.

Fahlbusch[6] has classified parasellar tumour extension into:

Type 1: Localised lateral
Type 2: Basal
Type 3: Massive lateral extension without invasion
Type 4a: Localised lateral invasion
Type 4b: Generalised lateral invasion
Type 5a: Supracavernous and subtemporal extension
Type 5b: Extrasellar extension with generalised invasion.

INVASION

Although pituitary adenomas grow to a very large size, they usually maintain a plane of cleavage from the surrounding tissues.[14,21,37] When the adenomas are seen infiltrating the dura, bone, blood vessel, adventitia or nerve sheath, they are termed invasive adenomas.[16] The evidence of invasion may be detected radiologically or seen peri-operatively. Simple microscopic dural involvement alone is not considered significant, as microscopic involvement of paratumoural dura was found in 69% of microadenomas, 88% of macroadenomas and 94% of macroadenomas with suprasellar extension, in the study conducted by Selman et al.[30] The frequency of gross operatively apparent invasion was found in only 40% in the same series. Endocrinologically functional tumours are more invasive than the non-functioning adenomas. Compared to non-invasive adenomas, invasive adenomas more often appear cellular, demonstrate mitotic activity and exhibit some degree of nuclear atypia.[28]

MOLECULAR BIOLOGY

It was previously thought that all the tumours have the same invasive potential but are in different stages of growth. When the ultrastructural features were studied, this proved to be wrong. A study of the genetic mutation of the retinoblastoma gene on chromosome 13, by Pei et al.,[26] showed that loss of heterozygosity is associated with aggressive behaviour of the tumour. In another study, Thaper et al.[36] found expression of the P53 gene in more than 15% of invasive tumours, as compared to non-invasive tumours which did not exhibit P53 expression in any of them. NM-23 is a metastasising suppressive gene, the activity of which, when reduced, indicates a high metastatic potential of a tumour. This was studied by Takino et al.[34] The expression NM-23 was grossly reduced in invasive pituitary adenomas. Protein kinase C alpha-isoform was over expressed in invasive pituitary adenomas,[27] as studied by Alvaro et al.[2] Excessive expression of the proliferative marker MIB-1, which is an antibody to cell cycle specific nuclear antigen Ki-67, is associated with invasive adenomas. MIB proliferation indices of more than 3% was found to be associated with invasive growth and increased incidence of recurrence by Thaper et al.[35] Similar studies by Kitz et al. and Knsop et al. showed that dural infiltration was associated with a higher Ki-67 labelling index.[17,18] Cytokine interleukin 6, heat shock protein-27,[8] type IV collagenase and matrix metalloproteinase-9[16] were also found to be increased in invasive adenomas.

CLINICAL PRESENTATION

An increased incidence of invasiveness was observed in those patients with onset of symptoms during the pubertal years, compared to patients whose symptoms first occurred during the post-pubertal years.[15] The majority of these patients present with visual symptoms, the predominant visual symptom being bitemporal haemianopia. Others like progressive or sudden visual loss in one or both the eyes are also seen. Sudden visual loss may be due to apoplexy.[11,20] Pituitary adenomas are softer than other tumours in this region and, therefore, they present with cranial nerve paresis at later stages, resulting in weakness of ocular movements. In most giant pituitary adenomas features of mass effect are more common than endocrine disturbances. Hyposecretion in the form of hypothyroidism and hypocortisolaemia is more common than hypersecretion of prolactin.[11,20] The sellar floor may be eroded resulting in CSF rhinorrhoea. A case of massive invasive pituitary adenoma with the unusual presentation of nasal obstruction has been reported.[4]

INVESTIGATION

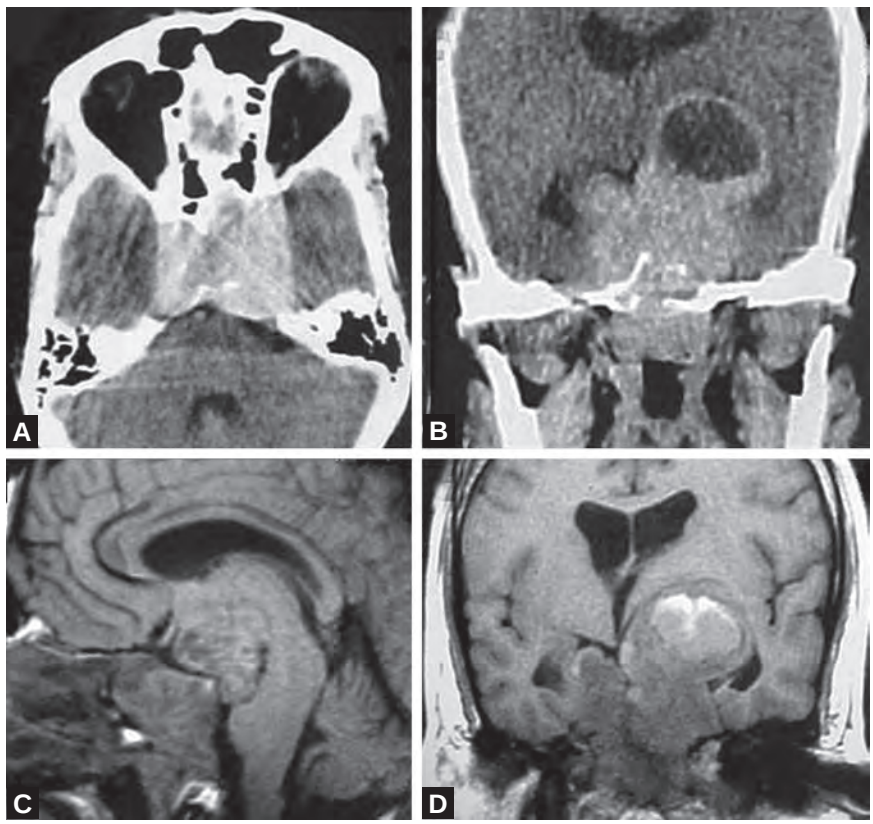
Plain skull radiographs have been proven to be insensitive and non-specific for pituitary lesions. On CT scans pituitary adenomas appear as hypodense lesions. CT scan provides better details about the bony erosion and calcification. The pituitary gland and the adjacent soft tissues, like the carotids and optic chiasma, are not well visualised. Coronal views will be required. MRI is now the imaging technique of choice. MRI shows the relation of the gland to the surrounding structures like the cavernous sinus, floor of the third ventricle and optic pathways with more clarity and has the advantage of multiplanar imaging. The internal features of the macroadenoma help in surgical planning.[5] The tumours that are soft and easily aspirated at surgery mostly appear hyperintense on T2W and those tumours that are firm appear isointense.[32]

Features suggesting aggressive behaviour in imaging:[20]

- Extensive invasion of the cavernous sinus
- Extensive suprasellar and parasellar extension
- Erosion of the skull base and invasion into the sphenoid sinus.

Figure 1 represents post-contrast CT scan axial and coronal views (A and B) and MRI T1W sagittal and coronal views (C and D).

There are many studies on parasellar extension and cavernous sinus invasion of pituitary tumours.[3,19,38] Lee et al.[24] have described that obliteration of the vein of the carotid sulcus on dynamic contrast enhanced MRI is the most reliable sign of cavernous sinus invasion. Pituitary adenomas with sinus invasion enhance less than the adjacent cavernous sinus on the side of invasion



Figs 1A to D: (A and B) Post-contrast CT scan axial and coronal views showing bony erosion with parasellar and suprasellar extension. (C and D) MRI T1W sagittal and coronal views showing retrosellar and suprasellar extension

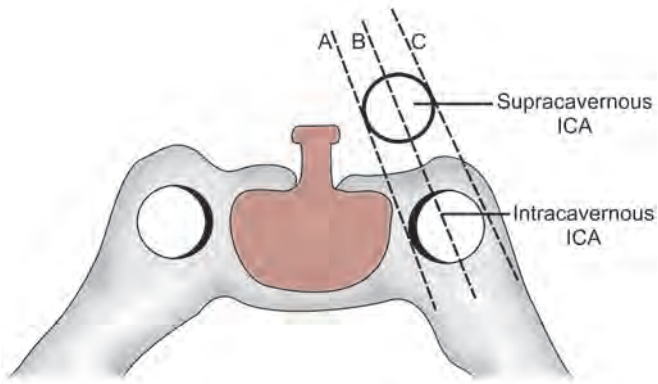


Fig. 2: Intercarotid lines which are drawn from intracavernous to supracavernous portions of the internal carotid artery. (A) Medial intercarotid line: along the medial walls. (B) Median intercarotid line: along the median walls. (C) Lateral intercarotid line: along the lateral walls

in post-gadolinium images.[23] The most sensitive sign of cavernous sinus invasion is an asymmetry in the signal intensity between the two sides. Encasement of the cavernous carotid artery is a specific but insensitive sign of cavernous sinus invasion.[5]

Knosp-Steiner classification[19] of cavernous sinus invasion based on MRI (Fig. 2):

Grade 0: When the adenoma did not cross the medial intercarotid line.

Grade 1: When the tumour passed the medial intercarotid line but did not cross the median intercarotid line.

Grade 2: When the tumour passed the median intercarotid line but did not cross the lateral intercarotid line.

Grade 3: When the adenoma passed the lateral intercarotid line.

Grade 4: When the ICA was totally encased by the tumour.

Vieira et al. have defined the following magnetic resonance criteria for cavernous sinus invasion:[38]

- Percentage of encasement of the intracavernous internal carotid artery is higher than 45%
- Occlusion of three or more cavernous sinus venous compartments
- Occlusion of the cavernous sinus lateral venous compartment.

Magnetic resonance criteria for the absence of cavernous sinus invasion in patients with pituitary adenoma were also defined by Vieira et al.:[38]

- Normal pituitary gland interposed between the tumour and the CS
- Intact CS medial venous compartment
- Tumour not crossing the medial intercarotid line
- Percentage of ICA encasement by the lesion lower than 25%.

The most useful sign to predict cavernous sinus invasion is encasement of the internal carotid artery greater than 30%. This finding has the best sensitivity (92.1%), specificity (93.5%) and positive predictive value (82.5%).[38]

TREATMENT

The clinical course and surgical outcome in cases with giant pituitary adenomas have generally been reported to be poor.[11,20,28] Treatment of giant invasive adenomas by the conventional trans-sphenoid approach, followed by adjuvant therapy, leads to a relatively high recurrence rate. Although this treatment option has improved vision in a significant number, the long-term follow-up is not satisfactory, especially in young individuals.[20] Radical surgery by a trans-sphenoidal route in Grade I–III pituitary tumours and biopsy of the tumour, followed by radiotherapy in Grade IV tumours was suggested by Goel et al.[11] Except for fibrous and dumbbell-shaped adenomas, the trans-sphenoidal approach is a safe and effective way to remove large pituitary adenomas.[40,41] It allows rapid and adequate decompression of the optic nerves and chiasm, avoids major pituitary insufficiency and is associated with low morbidity-mortality rates.[22] Simultaneous trans-sphenoidal and pterional approach has been described for resection of giant pituitary tumours with dumbbell shape, where the surgeon cannot achieve complete resection by a single approach.[1] Combined treatment with initial surgical debulking followed by radiotherapy yields tumour control rates in giant pituitary adenomas similar to those of smaller pituitary adenomas without undue morbidity.[7] In patients with cavernous sinus invasion, the extended transnasal trans-sphenoidal approach and contralateral subfrontal approach have been described.[11,12,42] Oruçkaptan has reported that topical application of bromocriptine (1 mgr/mL slow-releasing gel) into the sellar cavity, immediately after tumour removal, seems to provide superior results, compared with the conventional treatment modalities.[25]

Figure 3 represents pre-operative post-contrast mid-sagittal (A) and coronal (B) T1W images. Post-operative images are shown in Figs 3C and D, respectively.

In giant prolactinomas, medical management is considered to be the first choice. Many of these tumours respond to drugs. Decrease in the serum prolactin level can be noticed within hours of starting the medication. Surgical intervention is indicated only if there is progressive visual loss or if the tumour is resistant to medical therapy. In young patients with significant parasellar extension, transcranial surgery with radical excision is to be aimed at. Patients with GH and ACTH secreting tumours have a significant morbidity. Long-term tumour control is rarely achieved by medical management. With modern skull base techniques, most of these tumours have become surgically accessible and direct radiotherapy is to be avoided. Although non-functional pituitary adenomas have a relatively benign course, radical excision is to be aimed at in younger patients with a long life expectancy.[21]

(C) Post-operative midsagittal T1W images with fat suppression. (D) Post-operative coronal T1W images showing evidence of packing of sphenoid sinus with fat and fascia

A partial or a subtotal resection can lead to infarction and oedema of the residual tumour termed as post-operative pituitary apoplexy.[9] Other complications like worsened visual status, pituitary and hypothalamic dysfunction, cerebral ischaemic attacks, coma and mortality have been described. High surgical mortality has been attributed to the breach of subarachnoid spaces, and ischaemia within the hypothalamus, brainstem or cerebral hemisphere caused by small and large vessel traction.[9,13]

RADIATION

In the series of Goel et al.,[10] radiotherapy was given to all the patients with Grade IV tumour. In Grade III, with significant post-surgical residue radiotherapy was given in spite of the patients being asymptomatic, while only symptomatic patients with Grade II tumours received radiotherapy. In Grade I cases, radiotherapy was generally avoided and re-exploration of the tumour was preferred in patients with large or symptomatic residual or recurrent tumours.[11] Combined modality treatment with initial surgical debulking followed by radiotherapy in the dose range of 4500–5000 cGy over 25 fractions yields adequate tumour control rates, although normalisation of the secretory function is seen in a much less number of patients.[7] Conventional radiotherapy is not as effective as expected. The increased side effects of radiotherapy in patients with supra-parasellar extension, especially to the optic pathway and hypothalamus, limit its benefits.[25] Clinical and neuroradiological signs of radiogenic encephalopathy were encountered in 28% of patients with invasive pituitary adenoma by Rauhut et al.[29] Complications of radiotherapy, like hypopituitarism, have seriously affected the quality of life in these patients.[13] Late onset of worsening in endocrine function, seen in a significant number of patients, is attributed to delayed onset of radiation effect.[24]

Giant pituitary adenomas have a different genetic makeup which results in their more aggressive behaviour. Recent advances in medical management and adjuvant therapies, along with the use of endoscope, have helped to increase survival time, improve the quality of life and decrease the morbidity and mortality.

154 Perioperative Endocrine Management

Murthy S

INTRODUCTION

Pituitary hormone deficiencies are of significant concern in the management of patients with pituitary tumours. Fortunately many patients undergoing trans-sphenoidal surgery have microadenomas and do not have significant pre-operative or post-operative endocrine deficiencies. However, patients with larger tumours and some of those with hypersecreting states have abnormalities that need endocrine attention before surgery, immediately after surgery, later on and sometimes lifelong.

PRE-OPERATIVE ASSESSMENT

All patients require a thorough pre-operative laboratory evaluation before surgery. Evaluation should include a complete blood count to assess the presence of anaemia or other haematologic abnormalities.

A metabolic panel to evaluate possible hyponatraemia, hypercalcaemia, hyperglycaemia and other metabolic abnormalities is also indicated.

Patients with hypercalcaemia are evaluated for the possible diagnosis of multiple endocrine neoplasia, type I. The endocrine evaluation of each patient should include a thyroid panel (T3, T4, TSH), serum levels of cortisol, adrenocorticotropic hormone, growth hormone, IGF1, insulin like growth factor-1, testosterone, lutenizing hormone, follicle-stimulating hormone and prolactin.

The frequency of deficiency among the anterior pituitary hormones at the time of diagnosis of a pituitary tumour presents a spectrum of prevalence with GH > LH > FSH > TSH > ACTH and PRL.[25]

Pituitary-Thyroid Axis

Secondary hypothyroidism is strongly suggested by low levels of free T4 in association with low, normal or minimally elevated levels of TSH. However, it should be remembered that sick patients with non-endocrine disease ('sick euthyroid') can also exhibit a similar pattern of thyroid function tests.

Pituitary-Adrenal Axis

Assessment of the hypothalamo-pituitary-adrenal (HPA) axis, and thus defining a possible need for glucocorticoid replacement therapy, is a crucial aspect of anterior pituitary function testing. Under normal circumstances, ACTH secretion shows a marked circadian rhythm with highest levels in the early morning and lowest at around midnight. Measurement of the target hormone cortisol is common to all tests of the HPA axis and cortisol has the advantage of being a more stable hormone in serum/plasma than ACTH. Exogenously administered hydrocortisone or prednisolone interferes with the measurement of endogenous cortisol secretion. Dexamethasone administration will render cortisol measurements uninterpretable, both during treatment and for several days after steroid withdrawal depending on the dose and duration of therapy. Total cortisol levels are significantly raised in patients taking oral oestrogens. Ideally, basal cortisol should be measured between 8.00 AM and 9.00 AM since HPA axis activity is maximal at this time. Random cortisol measurements, for example, during afternoon clinics are much less useful and often difficult to interpret. If the basal morning cortisol is lower than 3.5 μg/dl, it strongly suggests ACTH deficiency and glucocorticoid replacement should be commenced. If basal cortisol is higher than 15 μg/dl, adrenal insufficiency is very unlikely. An intermediate value requires interpretation based on the clinical setting. Stimulation tests, like insulin tolerance test or ACTH stimulation test, are rarely required to assess the pituitary-adrenal axis.[8,12,21]

Serum Prolactin

It is important to exclude pregnancy, PRL—elevating drugs, primary hypothyroidism and polycystic ovarian syndrome in all patients with hyperprolactinaemia. In hyperprolactinaemic patients with a pituitary mass lesion, the main challenge is to distinguish between tumoural secretion of PRL and pituitary stalk interruption. The basal PRL is of considerable diagnostic value. A value greater than 200 ng/ml is usually diagnostic of macroprolactinoma. A serum PRL level lower than 80 ng/ml in a patient with a pituitary macrolesion usually indicates pituitary stalk interruption rather than tumoural secretion. An intermediate PRL level of 80–200 ng/ml is usually diagnostic of a microprolactinoma.[6,16]

Growth Hormone—IGF-1 Axis

Basal GH levels and serum IGF-1 levels are assayed. Rarely, stimulation or suppression tests are done when there is growth hormone deficiency or excess.[23]

Pituitary-Gonadal Axis

Basal measurements of gonadotrophins (LH and FSH) and sex steroids (oestradiol and testosterone) will assess the hypothalamo-pituitary-gonadal axis.

Vasopressin

Central diabetes insipidus is rarely a presenting feature in patients with pituitary adenomas, even if the tumour is very large. However, diabetes insipidus occurs commonly in patients with craniopharyngioma or other hypothalamic pathologies. The diagnosis can usually be established by measuring serum sodium (more than 145 mEq/l) and osmolality (more than 300 mOsm/kg), together with urine output (often more than 3L/day) and urinary osmolality (less than 300 mOsm/kg). Vasopressin deficiency may be masked by adrenal insufficiency. After glucocorticoid replacement central diabetes insipidus may get unmasked.[22]

Pre-Operative Management

Glucocorticoid therapy before and during trans-sphenoidal pituitary surgery has been the conventional treatment in the past. The rationale for this practice has been the assumption that ACTH secretion is compromised by the trauma of surgery. Current data and available literature indicates that patients with normal pre-operative adrenal functions do not require glucocorticoid therapy before or during pituitary microsurgery. The argument in favour of this hypothesis is that exogenous steroid administration inhibits endogenous ADH release and precipitates diabetes insipidus.

The recommendation is that glucocorticoid therapy is not administered before or during selective pituitary surgery. Serum cortisol levels are measured twice daily during the immediate post-operative period. Those with levels above 15 μg/dl do not require therapy. If serum cortisol is below 5 μg/dl therapy is started.

For those with documented pre-operative glucocorticoid therapy, oral hydrocortisone 30 mg daily in three divided doses is started at the time of diagnosis. It is switched to injection hydrocortisone 50 mg IM twice daily the day before surgery and hydrocortisone 100 mg as an IV drip administered during surgery.

Most patients with macroadenomas do not manifest signs and symptoms of hypopituitarism until after treatment with surgery/irradiation.

Deficiency of other pituitary hormones other than TSH need not be addressed in the peri-operative period. If hypothyroidism is detected, thyroxine replacement (50–200 μg/day) is started immediately. It takes 3 weeks for the patient to become euthyroid.

Unless the hypothyroidism is severe, surgery need not be delayed in those requiring immediate surgery. In this situation, the management team should be aware of the potential impact on anaesthesia, as well as fluid and pain management. Dosages of all medications, particularly narcotics need to be decreased in hypothyroid patients because of lower metabolic rate.

Blood pressure, blood sugar levels, serum electrolytes, and fluid intake and output should closely be monitored in the post-operative period.[3,7,9,10,27,32] (Table 1).

Table 1: Pre-operative assessment

- Rule out haematological problems
- Evaluate for hyponatraemia, hypercalcaemia and hyperglycaemia
- Thyroid and cortisol deficiency should be corrected before surgery
- Other hormonal imbalances are less important

EARLY POST-OPERATIVE EVALUATION/ MANAGEMENT (1–2 WEEKS)

General Principles of Pituitary Function Assessment

Monitoring of anterior pituitary function is crucial to the peri-operative care of patients who undergo surgery for pituitary tumours. Although the development of new pituitary hormone deficiencies after trans-sphenoidal surgery is uncommon when performed by an experienced pituitary surgeon, all patients require monitoring for these possible complications in the first few days after surgery. Uniform procedures for this monitoring can be adopted and then modified, as indicated by each individual patient's history and clinical picture. Knowledge of the patient's pre-operative endocrinological function can help predict the need for post-operative hormone replacement therapy. Pre-operative hypopituitarism should always be treated in the early post-operative period as this rarely resolves immediately. In addition, the suspicion of new hypopituitarism should be heightened in patients with partial hypopituitarism pre-operatively.

The course of surgery and the operative findings provide useful information for planning post-operative monitoring. When the surgical procedure is more extensive, haemorrhage or necrosis within the tumour are seen or other complications occur at the time of surgery, concern for new hypopituitarism should be heightened. In particular, the likelihood of post-operative adrenal insufficiency is increased fourfold in patients who had post-operative diabetes insipidus, which may be a consequence of more extensive surgery. Non-pituitary lesions, such as craniopharyngiomas, are more likely to be accompanied by hypopituitarism or diabetes insipidus.

Diabetes Insipidus

The most common pattern is transient abnormality and affects most cases. It consists of the abrupt onset of polyuria within 24 hours of surgery, with resolution in 1–3 days. It may be secondary to the release of bio-inactive

arginine vasopressin (AVP) precursors, local oedema of ADH producing neurons with a temporary functional impairment or a disruption of the inferior hypophyseal artery that supplies the ADH transport and storage structures.

Proximal damage to the pituitary stalk or hypothalamus can cause a second variant of DI. After previously formed ADH is used up in 1–3 days, permanent DI ensues, with a minimal or only partial decrease in urine volume over several days. The partial improvement sometimes seen is likely caused by resolution of oedema.

The third pattern of post-operative DI is triphasic in nature. The first phase is marked by the abrupt onset of DI within 24 hours of surgery, which then lasts 1–3 days and is thought to be caused by neuronal shock and diminished or absent hormone release. An interphase then follows, during which AVP escapes from degenerating neurons. Urine output comes down and urine osmolality rises, making the patient vulnerable to hyponatraemia if intravenous fluid administration is not tapered. This interphase may last 1–14 days and is followed by a return of DI, which is often permanent owing to the loss of magnocellular neurons by retograde axonal degeneration. Polyuria in mild DI is usually 4–6 L/24 hours and in severe DI up to 18 L/day.

A urine flow of 150–200 ml/h maintained for several hours is highly likely to result from DI, although in any situation in which urine output exceeds fluid intake an abnormal cause of polyuria should be suspected. Differentiating DI from a diuresis of fluids given perioperatively, or diuresis secondary to osmotic or non-osmotic diuretics, can create a confusing clinical picture.

Polyuria of DI is associated with abnormally high serum osmolality (more than 200 mOsm/kg), an elevated serum Na level (more than 145 mEq/l) an inappropriately dilute urine (less than 300 mOsm/l). In a clinical setting measuring urine specific gravity, serum Na and blood glucose could differentiate causes of polyuria.

Patients who are not very sick and who can take oral fluids should be allowed to regulate their own intake and water balance. Patients with DI prefer ice-cold fluids as this elicits a strong oropharyngeal reflex, compared to warm fluids promptly suppressing ADH release. If not, 5% GDW could be given intravenously. As soon as possible intravenous fluids should be stopped and glucocorticoid dosage tapered. By the second or third post-operative day, the polyuria and polydipsia have usually attenuated to several litres a day and do not require any treatment. Only when adequate fluid intake cannot be maintained because of lethargy or an impaired thirst mechanism is specific drug therapy instituted in the early post-operative period.

The preferred agent is DDAVP orally 0.5 mg once or twice daily increased up to 0.4 mg every eighth hourly.

If oral medications cannot be taken, DDAVP 2–4 mg (0.5–1 ml) intravenous or subcutaneous or aqueous vasopressin (20 U/ml) in a dose of 0.1–0.3 ml every 4–6 hours could be used. In case of severe water loss and hypernatraemia, intravenous fluids in addition could be administered. Short acting preparations are preferred since DI may be transient and recovery occurs.

Permanent DI is unusual with microadenoma surgery but may occur in patients with macroadenomas. One should keep in mind that transient DI may be followed by the syndrome of inappropriate ADH secretion (SIADH). Patients with unrecognised coexistent adrenal insufficiency may not develop symptoms of DI, as glucocorticoid deficiency is a stimulus for release of ADH. The polyuria of DI may follow when steroids are replaced.[26,29]

Hyponatraemia

Post-operative hyponatraemia is a relatively common disorder. The presenting signs and symptoms are nausea, lethargy, confusion and headaches. It can be seen in patients who are hypovolaemic, euvolaemic or hypervolaemic. The causes are SIADH, hypothyroidism, hypocortisolism and hyperglycaemia. SIADH is rare and occurs in 1% of patients who have undergone pituitary surgery and usually presents 1–2 weeks after surgery.[11,20,24]

The clinical features, pathophysiology, diagnostic features and treatment modalities are listed in Table 2.

Pituitary Adrenal Insufficiency

For those on pre-operative hydrocortisone therapy, Inj. hydrocortisone 50 mg x 8 hourly is administered on the first post-operative day, followed by 25 mg x 8 hourly for 2 days, followed by 25 mg x 12 hourly for 2 days, followed by oral hydrocortisone 30 mg/day in three divided doses (physiological replacement). Since oral hydrocortisone is expensive and not easily available, the alternate would be oral prednisolone 5 mg in the morning and 2.5 mg in the evening.

In patients with macroadenomas where hypopituitarism is not permanent and there is bound to be recovery of pituitary functions, it is recommended that glucocorticoid is withdrawn abruptly after 3–4 days after surgery. Serum cortisol is measured 24 hours after withdrawal. If serum cortisol at 8.00 AM is 15 μg/dl or more, it indicates recovery of the HPA axis and further steroid therapy is not required. If serum cortisol at 8.00 AM is less than 5 μg/dl recovery of the HPA axis has not occurred and glucocorticoid therapy has to be restarted. Patients with intermediate values are monitored carefully until a determination is made, whether there has been recovery of pituitary function. An alternative approach to the protocol of rapid discontinuation of steroid therapy is to taper steroid over several weeks and then assess the patient's pituitary-adrenal axis at a later date.

In patients with ACTH secreting pituitary adenoma some advocate glucocorticoid use before, during and after surgery, others restrict their use to the post-operative period. If surgical adenomectomy is complete, signs and symptoms of glucocorticoid deficiency develop within 24–48 hours and are associated with 8.00 AM

Table 2: Differential diagnosis of hyponatraemic state in the post-operative pituitary patients

Disorder	*Clinical features*	*Hydration*	*Pathophysiology*	*Diagnostic features*	*Treatment*
SIADH	Asymptomatic to neurological symptoms	Normal	Increased ADH release	Hyponatraemia Serum Na < 130 mEq/l Urine Na > 40 mEq/l Serum Osm ↓ Urine Osm ↓	*Acute* Fluid restriction if Na^+ = 120 mEq/l or more if Na^+ < 120 mEq/l 3% NaCl + Diuretics *Chronic* Demeclocycline 600–1200 mg/day
Hypothyroidism	Bradycardia, slow mentation, coarse voice	Normal	Impaired water excretion	Low T4 Low or normal TSH	Thyroid hormone replacement
Hypocortisolism	Weight loss, malaise, nausea/emesis, hypotension	Dehydrated	Impaired water excretion	Hypoglycaemia Low serum cortisol	Steroid replacement
Hyperglycaemia Diabetes mellitus Cushing's acromegaly	Polyuria, polydipsia	Normal or dehydrated	Dilutional (Pseudohyponatraemia)	Hyperglycaemia	Lowering blood sugar

serum cortisol levels below 5 μg/dl. These patients are started on glucocorticoid therapy; Inj. hydrocortisone 50 mg × 6 hourly tapered down and later switched over to oral hydrocortisone 30–50 mg in three divided doses. It is expected that most of them will recover pituitary adrenal functions over the next 24 hours and could discontinue exogenous steroid therapy.

In our set-up, taking into consideration patient compliance, financial implications, close monitoring and assessment requirement, non-availability and cost of oral hydrocortisone, in most patients, conventional therapy of Inj. hydrocortisone 100 mg thrice daily, started pre-operatively and tapered during the post-operative period, will still be justifiable, as the risk of development of transient diabetes insipidus is much less than the risk of development of adrenal insufficiency/crisis, if not closely monitored. Instead of oral hydrocortisone 30 mg/day [physiological replacement prednisolone 7.5 mg/daily (5 mg in the morning and 2.5 mg in the evening)] could be advised.[2,4,15,28]

Functioning Tumours

Follow-up management of patients with Cushing's disease is directed towards tapering and discontinuing glucocorticoid replacement. Patients who do not have evidence of early cure are obviously not treated with steroids. Tapering protocols vary greatly and depend largely on an individual patient's symptoms. For patients taking hydrocortisone, a reasonable approach would be to decrease the dose by 5 mg/d every week and to obtain a fasting serum cortisol level 24 hours after the last dose. A serum cortisol value less than 3 μg/dl would indicate a persistent defect in corticotrophin secretion and resumption of glucocorticoid therapy would be indicated, followed by repeating the tapering and testing process again after an interval. Most patients do not require post-operative steroid replacement after approximately 3 or 4 months and, indeed, the longer the requirement for glucocorticoid therapy, the greater is the likelihood of cure. A fasting serum cortisol level of greater than 20 μg/dl after cessation of steroid therapy would raise the concern of early recurrence; in such circumstances, obtaining a 24-hour urine collection for free cortisol would be indicated.

One should be cautious about tapering of steroid dosage, as due to chronic suppression of the HPA axis, acute adrenal insufficiency or crisis could be precipitated.

In GH secreting tumours/prolactinomas or other functioning tumours, GH, prolactin, FSH, LH, oestradiol or testosterone need not be measured in the early post-operative period, as early intervention is not required.[17]

LATE POST-OPERATIVE EVALUATION/ MANAGEMENT (AFTER ONE MONTH)

Testing at this time will address the presence or absence of residual tumour, as well as to assess the function of the normal gland. It is important to document hormone deficiency before long-term replacement therapy is established. As discussed earlier, hormone deficiencies associated with pituitary adenomas are often reversible with surgical resection of the adenoma. Similarly, the surgical procedure/radiotherapy itself can, at times, result in partial or complete loss of pituitary hormone function. From a practical standpoint, pituitary function can be assessed easily through outpatient services and dynamic testing can often be avoided.

Testing of pituitary function at this time can be done in a similar way to that described earlier. A practical and clinically valuable approach commonly used in evaluating pituitary function is the determination of serum levels of pituitary hormones as well as hormones secreted by peripheral glands such as the thyroid, adrenal and gonadal steroids. This combination of hormone levels provides reasonably adequate evaluation of pituitary gland function in most patients. In some patients, especially those with mild adrenal insufficiency, dynamic testing may be necessary to accurately define pituitary function.[1]

Pituitary-Adrenal Axis

It is rare and unusual to have a patient acquire adrenal insufficiency so late after pituitary surgery, unless other treatments were given or complications occurred to explain that event. Patients with persistent or acquired glucocorticoid deficiency in the immediate post-operative period are more likely to maintain similar function months after surgery. If ACTH secretion is shown to be abnormal in the immediate post-operative period only an unusual patient will show signs of recovery of pituitary-adrenal axis weeks or months later. The only exception to this rule is patients with ACTH secreting adenomas who develop adrenal insufficiency after complete resection of the adenoma and then recover pituitary adrenal function in 6–24 months.

If there is a doubt about the integrity of the pituitary-adrenal axis and if the patient is on oral steroids (hydrocortisone or prednisolone), it is stopped for 48 hours and serum cortisol measured. If basal cortisol at 8.00 AM is below 3 μg/dl, the diagnosis of adrenal insufficiency is confirmed; if above 20 μg/dl, it indicates normal function. Intermediate values may require further evaluation. In a situation like this, dynamic testing with ACTH would be useful.

The physiological replacement dosage required for various steroids is as follows (Table 3):

During periods of stress the dose should be appropriately increased. The usual replacement dose should be doubled or tripled during fever, infection, invasive diagnostic procedures, minor surgeries (cataract, laparoscopic, dental) and radiotherapy. For those with severe infections and major surgeries, parenteral steroids and IV fluids will be required. Patients and their immediate relatives should be cautioned about this and they have to always carry a medical alert card. Once they get over the stress period, it could be changed to the physiological replacement dosage. For patients who have undergone pituitary surgery for Cushing's disease, it would take 6–18 months for recovery of the HPA axis and steroid cover over this period is required[13,14,19] (Table 4).

Table 3: Relative potencies of different steroids

Compound	*Physiological replacement dosage (mg)*	*Glucocorticoid activity*
Hydrocortisone	20–25	1.0
Cortisone	20–30	0.7
Prednisolone	7.5	4.0
Dexamethasone	0.5–0.75	30.0

Table 4: Stress dose of steroids

Minor Stress

- Febrile illness, moderate infection, trauma, invasive diagnostic procedures, minor surgical procedures (dental, cataract, laparascopic) labour delivery
- Double or triple dosage of oral steroids

Major Stress

- Severe acute illnesses, severe infection, major surgeries, inability to take oral steroids
- Inj. hydrocortisone 100 mg x 8 hourly IM or IV along with fluids
- Tapered over 1–2 days after recovery and return to previous steroid replacement

Chronic DI/SIADH

Persistence of DI beyond the immediate post-operative period presages a poor long-term outlook for recovery. It is unusual to see permanent DI in a patient following trans-sphenoidal pituitary surgery. The treatment of choice for chronic DI is DDAVP, either an intranasal preparation (100 mcg/0.1 ml/spray) starting with 0.05–0.1 ml once or twice a day or oral tablet (0.1 mg) 0.1–0.4 mg in divided doses twice or thrice daily. Chronic SIADH is managed with fluid restrictions and demeclocycline 600–1200 mg/day in divided doses[5] (Table 5).

Pituitary-Thyroid Axis

Central hypothyroidism is associated with low T4 and low or normal TSH, and requires lifelong replacement therapy (100–200 μg/day).

Pituitary-Gonadal/Prolactin Axis

Serum FSH, LH assay, prolactin and testosterone/oestradiol are useful guides to treatment. The most sensitive tests of fertility are the sperm count in the male and menstrual cycles with evidence of ovulation in the female. The concentrations of gonadotrophins (luteinizing hormone, follicle-stimulating hormone) are frequently in the normal range in pituitary hypogonadism.

It may be necessary to enquire specifically about sex drive, because many patients hesitate to complain about decreased libido, believing that this is an effect of their illness for which there is no treatment. Elevated serum prolactin levels also result in decreased libido. In males who have low testosterone and elevated prolactin levels, testosterone replacement alone will not restore normal libido; it is also necessary to lower the serum prolactin level, for example, by using a dopamine agonist like

Table 5: SIADH vs DI

	SIADH	*DI*
Presentation	Hyponatraemia	Polyuria
Plasma osmolality	Hypotonic (< 275 mOsm/l)	Hypertonic (> 310 mOsm/l)
Serum sodium	Hyponatraemia (< 135 mEq/l)	Hyponatraemia (> 145 mEq/l)
Urine volume	Low	Polyuria (4–18 L/d)
Urine osmolality	Relatively high (> 100 mOsm/l)	Relatively low (< 200 mOsm/l)
Urinary sodium	> 20 mEq/l	> 20 mEq/l
Treatment	Fluid restriction If Na < 120 mEq/l, consider 3% hypertonic saline Demeclocyline 600–1200 mg/day	DDAVP

bromocriptine/cabergoline. Hyperprolactinaemia results from disruption of the pituitary stalk.

Chronic replacement therapy consists of 200–300 mg testosterone propionate intramuscularly every 2–4 weeks in men and cyclical hormonal therapy (oestrogen + progesterone) in pre-menopausal women.

Successful treatment of infertility, using sequential combinations of human menopausal gonadotrophin (hMG) and human chronic gonadotrophin (hCG) in patients who have undergone hypophysectomy is now well established, so that hypophyseal deficiency need not preclude the possibility of parenthood. Due to its great expense and the occurrence, in some women, of ovarian hyperstimulation, this form of therapy should be administered only by physicians who are familiar with its application. After treatment, men may successfully impregnate their partners even when sperm concentrations do not exceed 10×10^6 ml.[30,31]

Pituitary-Growth Hormone Axis

Most patients with growth hormone secreting pituitary microadenoma are cured by trans-sphenoidal surgery and those with larger tumours have partial cure. They may require additional stereotactic radiosurgery. Serum GH and IGF1 should be assessed one month after surgery and repeated every 6–12 months.

Criteria for cure are normal serum IGF1 level and growth hormone levels less than 0.4 ng/ml 1 hour after oral administration of 100 gm glucose. Children with growth hormone deficiency confirmed by dynamic studies will benefit from growth hormone therapy[18] (Table 6).

CONCLUSION

Patients undergoing pituitary surgery are a heterogeneous group and management requires a multidisciplinary team approach, involving neurosurgery, anaesthesiology and endocrinology. Protocols for evaluation and monitoring have to be individualised by the centre taking into consideration practicality, financial implications and patient compliance.

Table 6: Long-term management of pituitary insufficiency

Deficiency	*Replacement regimens*
Adrenal insufficiency	Prednisolone 5 mg AM, 2.5 mg PM
	Oral hydrocortisone 10–15 mg AM; 5–10 mg PM
Hypothyroidism	100–300 µg daily morning
Hypogonadism (men)	Inj. Testosterone 100–250 mg IM once in 2–4 weeks
	Testosterone gel 5–10 gm daily
Hypogonadism (women)	Cyclical hormone therapy (estrogen + progesterone)
Fertility	hMG/hCG therapy
Hyperprolactinaemia	Bromocriptine (2.5–7.5 mg/day) or Cabergoline (0.5–3.0 mg/week)
Growth hormone deficiency	Inj. Growth hormone 0.1 U/kg body weight
	6 times a week
Diabetes insipidus	DDAVP nasal spray 0.1–0.2 ml bedtime
	DDAVP tablets 0.1–0.4 mg in divided doses

Although for most patients the post-operative period is uneventful, an individual patient developing complications may require close monitoring and the management team with the relevant knowledge could efficiently handle this. This chapter has been written keeping this goal in mind.

155 Empty Sella Syndrome

Ravi Ramamurthi, Murali Mohan S

An empty sella is defined as a sella, which, regardless of its size, is completely or partially filled with cerebrospinal fluid (CSF). The pituitary gland is compressed and lies posteriorly and inferiorly in the sella. To describe this finding, several different terms were used in the past such as intrasellar arachnoid diverticulum, intrasellar cyst, deficient sellar diaphragm and intrasellar cistern.[2,37,39,46] In 1951,[14] Busch, in a series of autopsy studies, found that in 5.6% the diaphragma sella was deficient and the arachnoid had herniated into the sella, enlarging it and displacing the pituitary gland posteriorly and inferiorly. He coined the term empty sella for this anatomical finding. However, the term empty sella is, in fact, a misnomer as the sella is not completely empty, but the pituitary is always present both anatomically and functionally, although often it is displaced downwards and compressed by CSF pressure.[37] Bergland et al. and Kaufman et al.,[34] in 1968, elucidated the condition further with anatomical and radiological studies. Le Clercq et al.,[38] in 1974, called it intrasellar arachnoidocoele.

Empty sella syndrome can be primary or secondary. Primary empty sella (PES) syndrome is that which occurs in the absence of pituitary surgery or irradiation for pituitary disease and secondary empty sella is that which occurs following these procedures. Although the sella is empty in both these conditions, they form two distinct entities with differing aetiology, symptomatology and prognosis.

PATHOGENESIS

The diaphragma sella forms the roof of the pituitary fossa. It has a central opening which transmits the infundibulum. The diaphragm separates the cranial subarachnoid space from the pituitary fossa. Anatomical variations in the diaphragm have been seen in 22–72% of cases.[6,14,35] Defects in the diaphragm may lead to herniation of the arachnoid into the sella and accumulation of CSF.[20] These defects are more common in women than men, in a ratio of 5:1.[14] In 1926, Scaeffer was the first to observe various anatomical forms of the diaphragma sellae; these ranged from densely thick with a complete roof to that composed of a peripheral veil. Busch, in his study of 788 sellae in patients without a history of pituitary disorders, classified the diaphragma sella into the following categories, which were later referred to by Kaufman in l972.

Type 1-A: The diaphragma sellae forms a complete seal.
Type 1-B: A slight tunnel-shaped depression is present in the intact diaphragma sellae.
Type 2-A: An opening about 3 mm or smaller in the diaphragma sellae exists around the hypophyseal stalk.
Type 2-B: A slight funnel-shaped indentation towards the middle of the diaphragma sellae is present.
Type 3-A: The diaphragma sellae is composed of a 2 mm or smaller peripheral veil, leaving the pituitary gland freely exposed and covered with arachnoid.
Type 3-B: The diaphragma sellae is as described for Type 3-A but the pituitary gland is indented, often eccentrically.
Type 3-C: The deficient diaphragma sellae is as described in Type 3-A; however, indentation of the pituitary gland is marked.[1,34]

An incomplete sellar diaphragm is an essential prerequisite for the development of the empty sella.[5] All other factors are only predisposing to the development of intrasellar subarachnoid herniation, whether by causing increased pressure in the suprasellar subarachnoid space or by reduction in the size of the pituitary gland.[37]

Congenital Factors

Deficiency of the diaphragma sellae.

Suprasellar Factors

When the diaphragma sellae is incomplete, CSF pulsations act directly on the upper aspect of the pituitary gland. In addition, a posteriorly placed optic chiasma may also expose the upper surface of the pituitary gland and thereby increase the CSF pressure on it. The suprasellar cistern pressure is accentuated when the intracranial pressure is raised, secondary to hydrocephalus, brain tumours (Fig. 1), Arnold-Chiari malformation,[8] periorbital venous vasculitis,[28] superior sagittal sinus thrombosis with a dural arteriovenous malformation,[27] etc.

Impaired CSF circulation was demonstrated in more than 80% of patients by Brismar and Bergstrand, who

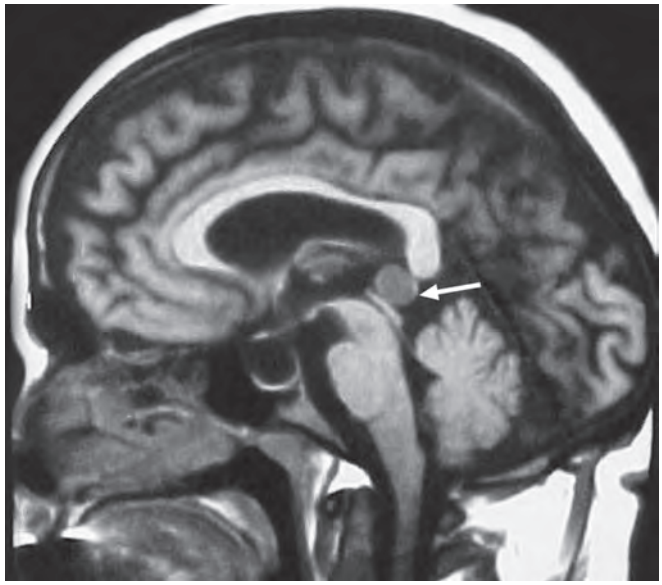

Fig. 1: MRI of a patient having a pineal tumour (white arrow) and empty sella

also pointed out the similarity between empty sella syndrome and normal pressure hydrocephalus, in their symptomatology.[10]

Intrasellar Factors

Any reduction in size of the pituitary gland favours intrasellar extension of the suprasellar subarachnoid space. Such reductions may be due to:

i. *Physiological involution:* This often occurs in women. Pregnancies bring about a large variation in the size of the pituitary gland and after delivery there is an involution. Similarly, after menopause there is a reduction in the pituitary volume. A similar situation occurs in cases of primary end-organ failure (thyroid, adrenal, gonad), wherein pituitary hyperplasia occurs due to loss of feedback control. Replacement of the deficient hormone results in feedback suppression of the pituitary tropic hormone secretion and involution of the hyperplastic pituitary gland, resulting in an 'empty sella'.[7]
ii. *Pathological involution:* Shrinkage of the pituitary gland may occur after post-partum pituitary necrosis (Sheehan's syndrome) or pituitary infarction in patients with vascular diseases, diabetes, increased intracranial pressure, head injury, meningitis or cavernous sinus thrombosis.

Pituitary apoplexy: Pituitary adenomas undergoing spontaneous necrosis (ischaemia or haemorrhage). The arachnoid descends into the sella, to occupy the space created by resolution of the tumour.

Rupture of an intrasellar or parasellar cyst: Fluid-filled cysts of the sellar region are well known and may cause visual or endocrine symptoms, as well as changes in the contour of the sella. Rupture of such a cyst allows intrasellar extension of the subarachnoid space. However, such rupture probably occurs only rarely.[37]

Systemic Factors

Hypertension

PES may be associated with systemic hypertension, which may cause an intermittent rise in intracranial pressure.[34]

Obesity

It is proposed that morbid obesity may induce hypercapnia, which can be the cause of chronic CSF pressure elevation and in turn may lead, in subjects with hypoplastic diaphragma sellae, to the intrasellar herniation of the suprasellar subarachnoid space.[4,20,42]

PRIMARY EMPTY SELLA

PES may be associated with variable clinical conditions ranging from the occasional discovery of a clinically asymptomatic arachnoid pouch within the sella turcica to severe intracranial hypertension and rhinorrhoea.[44,48]

PES may be seen anatomically and radiologically without producing any symptoms or signs. Large defects in the diaphragm without herniation of the arachnoid have also been seen.[14,35]

On routine MR screening of patients without any pituitary disease or symptoms of empty sella, a significant number had been found to have empty sella. Foresti et al.[22] found a totally empty sella in 11.3% of males and 13.5% of females. Partially empty sella was seen in 16.1% of males and 15.1% of females. The incidence of empty sella increases with age.[29] On the whole, empty sella was found in 9.6% of patients below the age of 40 and in 39.9% above 40 years.[22] It has been suggested that an empty sella found on routine MR scanning is usually of no clinical significance.[29]

Raised ICP is an important factor in the pathogenesis of PES syndrome. Empty sella is commonly symptomatic in middle aged obese women and resembles the occurrence of benign intracranial hypertension (BIH) in this respect. An empty sella has been found in 10–12% of patients with BIH.[17,18,21,56] The causal relationship between ESS and BIH can be explained by two mechanisms. Raised intracranial pressure could produce a herniation of the subarachnoid cistern into the sella turcica if the diaphragma sellae is incomplete. Alternatively, infarction in a pituitary adenoma could result in both an ESS and a CSF flow obstruction, which could lead to BIH.[17]

The diaphragm may be congenitally deficient or might have been destroyed by the tumour. In summary, the factors that lead to PES syndrome are insufficiency or absence of the diaphragma sella, increased CSF pressure due to various causes and pituitary involution.

Symptoms and Signs

These may be divided into systemic, neurological and endocrine. The majority of patients who exhibit symptoms form a fairly homogeneous group. About 80% are

females in the fourth and the fifth decades of life with predominant obesity.[32,47,57] About 30% have hypertension. These are the systemic manifestations.

The most common neurological symptom is headache, which occurs in 50–70%.[23,32,47,53] In many, the empty sella is discovered on routine skull X-rays taken during the investigation of chronic headache.[43] The pulsations of the CSF against the dura have been thought to be the cause of the headache.[45]

Visual disturbances may occur and have been reported in up to 34%,[23] although in some other series, it is not so common.[7,13,54] The visual field defects that are seen are bitemporal and binasal haemianopia. The defects are due to the descent of the optic chiasm into the sella producing traction on the optic apparatus.[12] Decreased visual acuity and papilloedema may be seen when there is raised ICP. A typical glaucomatous visual field and optic disc changes have been reported in association with empty sella.[4]

Memory disturbances, imbalance, dizziness, convulsions and CSF rhinorrhoea are the other neurological manifestations that may occur. CSF pulsations inside the sella cause bony erosions in the sellar floor and lead to dural deficiencies and CSF leak into the sphenoid sinus, leading to rhinorrhoea. It has been reported to occur in up to 11.8% of patients with empty sella.[3,23,24,48]

Endocrine symptoms are not common, being reported in 10–15%[11,19,47] of patients. Endocrine function tests have been found to be abnormal in 30–50%.[23,53] The most common is deficiency of growth hormone and reduced response of GH to insulin-induced hypoglycaemia.

Hyperprolactinaemia is not as high as in a prolactin secreting adenoma,[11] unless the partially empty sella is associated with a prolactinoma. The prolactin level is usually below 100–125 ng/ml. The pituitary stalk gets kinked against the diaphragm, as it descends into the sella, giving rise to pituitary stalk effect.[9,25] Hyperprolactinaemia, resulting in galactorrhoea and ammenorrhoea in a middle aged woman associated with a PES syndrome, has been reported.[25,49] Hypersecretion of ACTH and GH may be found, if associated with a secreting tumour.

Hypopituitarism may occur and this is most likely due to compression of the infundibulum as it descends into the sella and not due to flattening and compression of the pituitary gland. Normal morphology and secretory granules have been demonstrated in the compressed gland.[5] When the empty sella is due to necrosis or apoplexy in a pituitary tumour, hypopituitarism can occur.[28] Precocious puberty has been reported in a young girl with empty sella.[52] Hypogonadotrophic hypogonadism has been seen in association with empty sella.[16] Around 10.9% of children evaluated for disorders of the hypothalamic-pituitary axis were found to have empty sella.[15] Antipituitary hormone autoantibodies were evaluated in patients with pituitary tumours and empty sella.[43] Discrimination between the two was not possible. The presence of antipituitary hormone antibodies was neither specific for nor predictive of the endocrine deficiencies.

Radiology

Radiographs of the skull, when done for symptoms such as headache, may show an enlarged sella and this may lead to a diagnosis of empty sella. There may be uniform remodelling of the sella which assumes a globular shape. The lamina dura is intact. The globular shape occurs early and further enlargement follows that pattern. There is thinning of the dorsum sellae and slight bowing posteriorly. Displacement of the dorsum sellae does not occur. The floor of the sella is concave in the AP projection. Double contour of the floor and erosion, which are characteristic of intrasellar tumours, may be seen in PES.[33] Before the advent of CT and MR, pneumoencephalography was the procedure of choice. It was demonstrated by entry of air into the intrasellar space in the sitting or brow-up position.[41]

On the CT, low density similar to that of CSF is seen in the sella. It may be difficult to differentiate an empty sella from other conditions due to artefact. CECT and thin high resolution coronal sections make identification of the infundibulum easier. The "infundibulum sign" differentiates empty sella from other similar CSF density lesions like a cystic tumour. The infundibulum will be seen to traverse a low density space and end in the posteroinferior aspect of the sella.[30] Water soluble contrast or air cisternography may be used when MR is not available.[2,31,50] In the differential diagnosis, one should bear in mind cystic intrasellar tumours, intrasellar cyst and dilated intrasellar third ventricular recess.[41]

MR will clearly delineate the infundibulum and the flattened pituitary gland. The normally high signal seen in the posterior lobe may be absent due to compression. Herniation of the optic nerves and chiasm can be seen very clearly and the degree of descent assessed.[36] This is especially important in secondary empty sella when a differentiation has to be made between empty sella, recurrence of tumour or radiation necrosis, when there is delayed visual loss.

SECONDARY EMPTY SELLA

Secondary empty sella occurs after surgical and/or radiation therapy of a pituitary tumour (Fig. 2).

The arachnoid descends into the sella through a congenitally deficient diaphragm or due to destruction of the diaphragm by tumour. Secondary empty sella occurs when the tumour shrinks and leaves an empty space.

The predominant clinical finding in these patients is visual abnormality, occurring due to arachnoidal adhesions and traction on the optic apparatus. They may have initial improvement in visual symptoms with surgery, followed by recurrence of symptoms due to the development of empty sella. Some patients who do not have visual symptoms initially may present with a fresh onset of these symptoms.[37]

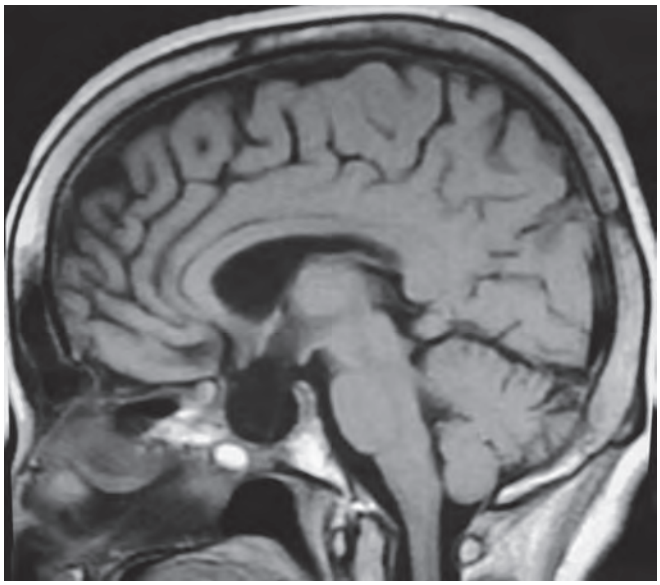

Fig. 2: MRI sagittal of a patient with secondary empty sella showing evidence of trans-sphenoidal surgery with empty sella

The presenting symptom will usually be visual deterioration, which may occur even years after the initial treatment. Bitemporal and binasal haemianopia are common, but other defects, like peripheral field constriction, central scotoma or segmental defects, can occur.[13,38,40,55] These have to be differentiated from the visual defects that arise due to recurrence of pituitary tumours, arachnoidal adhesions around the optic nerve and chiasm and radiation necrosis.

Endocrine symptoms due to hypersecretion or hyposecretion are more common in secondary empty sella than in the primary variety. This is mainly due to the tumour itself and not due to the empty sella. CSF rhinorrhoea can occur due to shrinkage of the tumour.[42]

Treatment

Empty sella syndrome is usually a benign condition. The majority of cases do not require treatment, except symptomatic, for headache. Hypertension must be treated and weight reduction advised in obese patients. Endocrine tests should be done and appropriate replacement given, if there is hyposecretion of any of the hormones including gonadotrophins. Hyperprolactinaemia is easily controlled with bromocriptine and smaller doses are required, when compared to doses used in the treatment of prolactinomas.[9]

CSF rhinorrhoea requires prompt surgical treatment, as the fistula rarely closes spontaneously. When associated with hydrocephalus or BIH, an initial CSF diversion procedure, like ventriculoperitoneal or lumboperitoneal shunt should be done and, if the leak persists, definitive surgery must be undertaken. When the fistula is from the sella into the sphenoid, the trans-sphenoidal route is ideal. The sellar dura should be opened and the sella packed with fat covered over by fascia. The sphenoid sinus is packed with fat. While operating inside the sella, care should be taken to avoid injury to the infundibulum, especially while exploring for a possible recurrence of tumour. The infundibulum descends into the sella bringing with it the median eminence and, therefore, damage to the infundibulum can occur close to the median eminence, producing permanent diabetes insipidus.

When visual symptoms are present, especially in secondary empty sella, the cause should clearly be identified. On MR, if there is a clear demonstration of descent of the optic apparatus into the sella and there is kinking of the optic nerves or chiasm, chiasmapexy is indicated.[55,58] This involves elevation of the optic apparatus and is ideally done through the trans-sphenoidal route. The dura should be elevated and the space between the dura and the bone packed with autologous tissues such as muscle, fat, fascia, bone and cartilage. Fat and muscle may get absorbed over the long term after surgery. Cartilage is more suitable due to the rigidity and resistance to absorption. Synthetic materials, such as silicone balloons and tubings, have been used with good success.[37] Opening the dura and packing intradurally may lead to troublesome CSF rhinorrhoea.[51]

Patients diagnosed to have an empty sella should be followed up regularly and any progression of symptoms should appropriately be treated. Sudden and rapid deterioration, especially in vision, may occur and the patient should be warned of this.

Patients with no abnormalities at baseline are unlikely to develop neurological/ophthalmological symptoms or endocrine abnormalities in the follow-up. Moreover, the radiological degree of PES also tends to remain constant over time. However, because of the theoretical risk of progression, a re-evaluation after 24–36 months (if there are no clinical indications before) of the endocrine, neurological/ophthalmological and radiological picture is reasonable. If progression is not observed, additional control evaluation could be even less frequent and limited to those patients requiring it clinically.[42]

156 Diencephalic Syndrome

Anil Pande, Murali Mohan S

Russel's diencephalic syndrome was described in 1951 as a syndrome of emaciation and loss of subcutaneous fat, with normal height and muscle mass in infancy and childhood.[18,22] He observed that the symptomatology was due to a neoplasm involving the anterior thalamus, hypothalamus, optic chiasm and anterior third ventricle. This has since been elaborated by several others.[2,6,7,10]

DIENCEPHALON

The brain develops from the expanded cephalic part of the neural tube (encephalon) and the caudal part (myelon) forms the spinal cord. Two constrictions first appear in the encephalon, dividing it into three primary vesicles: (1) the forebrain (prosencephalon); (2) the midbrain (mesencephalon) and (3) the hindbrain (rhombencephalon). At approximately 2 months of gestational age, these three primary vesicles differentiate into five cerebral vesicles. The prosencephalon divides into two vesicles—the telencephalon (the end brain) and the diencephalon (the inter-brain). The mesencephalon does not divide. The rhombencephalon divides to form two vesicles—the metencephalon and the myelencephalon. The telencephalon further differentiates and separates to form two telencephalic vesicles, which eventually become the cerebral hemispheres and encircle the underlying diencephalon, making the latter, the central region of the vertebrate brain. The lateral walls of the diencephalon later differentiate to form the thalamus on either side, the ventral floor forms the hypothalamus and the dorsal wall gives origin to the pineal body (the epithalamus), but remains undifferentiated for a considerable distance to form the lamina epithelialis. The thalamus is separated from the hypothalamus by a prominent sulcus called the hypothalamic sulcus. The median telocoele and the cavity of the diencephalon transform to form the third ventricle.

The diencephalon is thus the central region of the vertebrate brain, where the thalamic nuclear complex, pretectum and anterior tegmental structures are generated. Table 1 represents the structures comprising the diencephalon. It comprises of the synencephalon, dorsal and ventral thalamus. The hypothalamus is the ventral part of the alar derived diencephalon. The median telocoele and the cavity of the diencephalon form the third ventricle. The diencephalon is derived solely from the alar plate and a hypothalamic sulcus divides the alar diencephalic area into a dorsal region of thalamus and ventral hypothalamus. The third ventricle is an important diencephalic cavity.

Table 1: Structures comprising the diencephalon

1. Derivatives of dorsal thalamus
   a. Thalamus
   b. Metathalamus—medial and lateral geniculate bodies
2. Derivatives of ventral thalamus
   a. Zona incerta
   b. Nucleus reticularis thalami
3. Derivatives of hypothalamus
   a. Dorsal nuclear group—globus pallidus, subthalamic nucleus, interstitial nuclei of the inferior thalamic peduncle and the entopeduncular nucleus
   b. Ventral nuclear group—hypothalamus
   c. Evaginations—neurohypophysis and the optic stalk derivatives
4. Derivatives of epithalamus
   a. Habenular nuclei and the commissure, stria medularis and taenia tectae
   b. Evagination—pineal body

DIENCEPHALIC SYNDROME

Russel's diencephalic cachexia (always) indicates the involvement of the hypothalamus by compression or invagination by lesions arising from the floor of third ventricle or adjacent area.[18,19] There is a uniform loss of body fat with normal linear growth, pallor, hyperkinesis, hypertension, hypoglycaemia, hyperhydrosis, increase in the size of hands and feet, precocious puberty, emesis, headache and increasing head circumference due to hydrocephalus. Ocular signs include nystagmoid rotary eye movements, optic atrophy and visual loss.[2,7]

Clinical Features

This syndrome is a disease of childhood, usually seen in children less than 2 years of age, with an age range of 14–26 months.[4,13,16] There is a slight male preponderance.[13,16] Failure to thrive and progressive emaciation with normal linear growth is the characteristic clinical presentation of this syndrome. Nystagmoid eye movements are described to be present in up to 60% of these patients, and may be the first sign of a CNS cause for

failure to thrive. Other common presentations includes lid retraction (87%), increased vigour (72%), euphoria (59%), pallor (55%), hydrocephalus with features of raised ICP (33%), optic atrophy (24%), hyperhidrosis (15%), precocious puberty (8%) and polydipsia (< 5%).[2,10,11,16] There is a reported case of this syndrome in an adult who had associated von Recklinghausen's disease.[21]

Pathophysiology

The "failure to thrive" is seen in up to 25% of children with hypothalamic lesions. This is due to failure of inhibition of GH and LHRH secreting mechanisms in the anterior hypothalamus. The growth hormone levels are elevated with no diurnal rhythm and are non-responsive to hyperglycaemic or hypoglycaemic changes.[5,6] The Somatomedin C and IGF levels are normal in these patients.[6] Lipolysis is attributed to elevated GH levels, acquired partial GH resistance, low level of leptin and impaired metabolic regulation of adiposity.[6] This lipolysis causes the look of profound emaciation with complete loss of subcutaneous fatty tissue. Leptin is an adipocyte hormone, deficiency of which causes severe obesity in children. Loss of weight in these patients is believed to be due to the effect of dysregulation of leptin secretion on transient hypothalamus-pituitary-gonadal axis activation in the 1st year of life.[5,6] Dysregulation of ghrelin, a gastric hormone found to be a secretagogue for GH and to influence appetite and adiposity, might result in loss of adipose tissues in association with elevated GH levels.[6]

Pathology

Lesions causing diencephalic syndrome are mostly astrocytic tumours (80%). Less commonly ependymomas, craniopharyngiomas, germinomas, suprasellar epidermoids, hamartomas and cysts may produce this constellation of signs and symptoms.[16]

Raimondi[17] classified paediatric supratentorial tumours as hemispheric, suprasellar, diencephalic and lateral ventricular tumours. Of the diencephalic tumours, 40% were astrocytomas, 16% glioblastoma, 6% choroid plexus papillomas, 6% PNET, 3% ependymomas, 3% colloid cysts, 3% oligodendrogliomas and 23% unknown.[17]

The astrocytomas which are associated with the diencephalic syndrome are larger, occur at a younger age and have a more aggressive behaviour.[6,7] Juvenile pilocytic astrocytomas and the recently described chondroid astrocytoma which is a glioma variant are unique to the hypothalamus and anterior third ventricle. Gross appearance of the tumour is usually soft, translucent and gelatinous; rarely it maybe large, reddish, fleshy, firm and vascular. The molecular biology of these paediatric astrocytic tumours is very different from the adults, with only 15% showing 17p mutation, and p53 mutation is very rare. Many low grade tumours often demonstrate no genetic abnormality. MIBI labelling index correlates positively with survival.[15]

Histologically, these tumours have moderate cellularity with biphasic pattern of compact pilocytic zones that stain for GFAP, which are centred round the blood vessels and loosely arranged microcystic protoplasmic cellular areas with associated open honeycomb background. There are brightly eosinophillic rounded or elongated fusiform or sausage like Rosenthal fibres, which are considered to be of degenerative origin.[15,16]

MANAGEMENT

Children with failure to thrive and associated nystagmoid movements of the eyes should have CNS screening done to rule out the possibility of lesions in the diencephalic area.[2,7,16]

Imaging Studies

X-ray of the skull can show enlarged optic foramina in cases of optic nerve gliomas, suprasellar calcification in craniopharyngiomas and features of raised ICP in the form of erosion of dorsum sella, silver beaten appearance and sutural diastases.

Cranial ultrasound, in children with an open fontanel, may reveal a third ventricular lesion with or without hydrocephalus.[6]

Juvenile pilocytic astocytoma occurs in the region of the diencephalon, including the hypothalamus, visual pathway and the basal ganglia. These are usually solid infiltrating masses but may have an associated cyst. These are usually hypodense on plain CT and seldom enhance with contrast.[16] MRI is the investigation of choice and can be supplemented by MR spectroscopy, which is extremely useful for a non-invasive probable histological diagnosis. On MRI, these are hypointense to isointense on T1 images and mildly hyperintense in T2 images with ill defined margins and irregular patchy contrast enhancement, with or without associated hydrocephalus (Figs 1 and 2).[16]

Thirty per cent of these tumours present with a large size at diagnosis, making it difficult to determine their site of origin (chiasmatic or hypothalamic). Optic nerve gliomas are seen in 15% of the patients with neurofibromatosis type I and only about 20% of the chiasmal gliomas behave aggressively.[13] Seventy per cent of these lesions occur in the first decade of life. Chiasmatic gliomas are more aggressive than optic nerve gliomas and invade the hypothalamus and the floor of the third ventricle causing obstructive hydrocephalus.[2,4]

Suprasellar germinomas are rare and only 20% of these lesions occur in this area; most of them occur in the pineal region where these are isodense to slightly hyperdense and enhance homogeneously with contrast. On MRI they are hypointense or isointense on T1 and isointense to hyperintense on T2 images, with homogeneous enhancement.

Craniopharyngiomas are seen as well circumscribed and multilobulated tumours and 90% may have an associated cystic component. Both cysts and calcification are

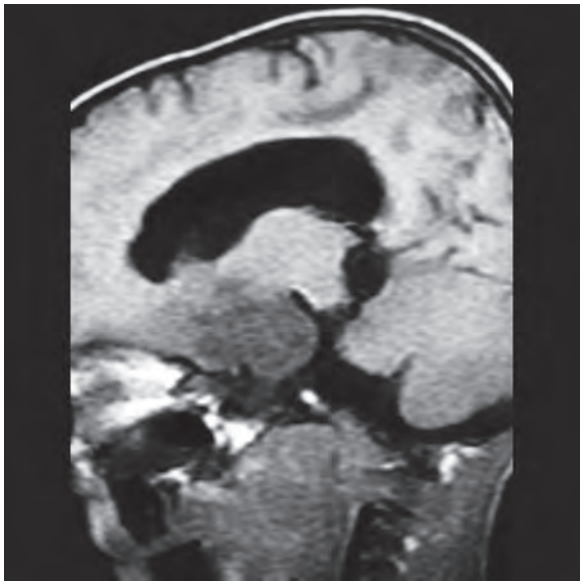

Fig. 1: MRI of the brain sagittal section showing hypointense lesion involving the hypothalamus

common in children. On MRI, the hyperintensity correlates with protein and methaemoglobin components on T1 images. T2 images will show a typically hyperintense lesion, with calcification seen as signal void areas.

Ependymomas are heterogeneous lesions and may have associated intratumoural cysts. These lesions are usually contrast enhancing. Fifty per cent of these lesions may have calcification, which can be small and flecky or less commonly large and lumpy. On MRI, they have heterogeneous intensity, with the cystic part being slightly hyperintense to CSF. The heterogeneous hyperintensity on T2 images is due to necrosis, calcification, blood degradations and intratumoural cysts.

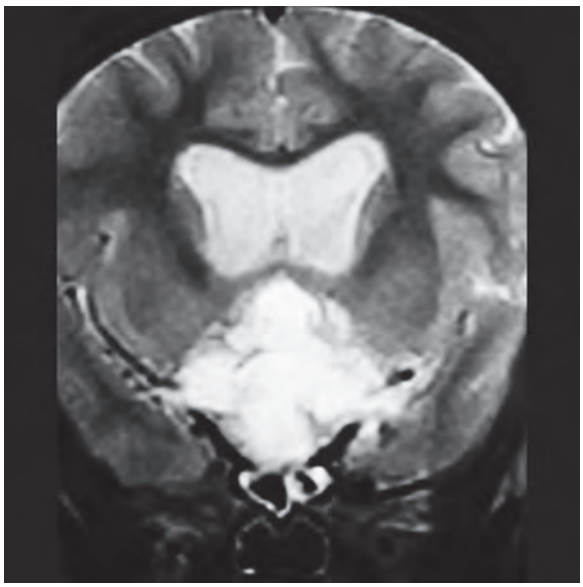

Fig. 2: MRI of the brain coronal section showing hyperintense lesion involving the hypothalamus with dilated lateral ventricles

Hamartomas of the tuber cinereum are seen as isodense masses in the suprasellar region, with no enhancement with contrast. In MRI, they are isointense on T1 images and isointense to slightly hyperintense on T2 images and are non-enhancing with contrast. Hydrocephalus has been associated with these lesions with an incidence of 55–58%.[4,6] Leptomeningeal spinal and cranial seeding has been reported in these lesions and requires clinical suspicion and may warrant a screening of the whole neuraxis.[16]

Endocrine Assessment

These children, once diagnosed, must be evaluated endocrinologically.[1,3] A complete endocrine immunoassay is performed. The T3, T4 and TSH are within normal range. ACTH stimulation and metyrapone test are abnormal and point towards an abnormal hypothalamic-hypophyseal-adrenal axis. Somatomedin levels are usually low. The growth hormone levels are usually elevated and are not influenced by change in blood glucose levels. On administration of propranolol and L-dopa there is an inappropriate fall in the levels of growth hormone.

Germinomas may present with diabetes insipidus and precocious puberty, which can occur in the male child due to elevated levels of beta-hCG. Female children do not present with precocity, as the beta-hCG requires the priming effect of oestrogen on the ovary for its action.[10]

Treatment

The treatment modalities include observation,[20] biopsy using CT or MRI based stereotaxy, surgery,[9,20] radiotherapy and chemotherapy.[12,14] The management of these lesions is difficult and although histological conformation of the lesion has been advocated as an initial step, MR spectroscopy will perhaps play a large role in the histological characterisation of these lesions non-invasively. Pre-operatively inadequate caloric and malabsorption problems have to be excluded along with proper imaging and endocrine and electrolyte evaluation.

Surgery for the lesions causing diencephalic syndrome is difficult due to a varied spectrum of pathology, younger age group, large size of the tumour at presentation, diffuse and infiltrating nature of these lesions, eloquence of the area and lastly, the problem of finding a safe corridor to these lesions. Poor prognosis has been reported by Raimondi for children under the age of 1 year, who harbour a hypothalamic optic nerve glioma and present with diencephalic syndrome.[17] Russel,[18] in his original monograph and others,[3,8,11,13] have reported survival ranging 8–12 years without treatment.

A progression-free survival period of 70–90% at 5 years has been reported for low grade astrocytic tumours. The extent of surgical resection is the only reliable prognostic factor, but this has to be taken into consideration along with a much higher morbidity, associated with

aggressive surgery in diffuse and infiltrating lesions. Surgical approaches are tailored according to the experience of the surgeon, the clinical features and imaging.[9,11]

Conventional frame based stereotactic surgery may be difficult in these small children and frameless stereotaxy has a much larger role to play. CSF diversion procedures like endoscopic third ventriculostomy or ventriculoperitoneal shunt may be required for the management of hydrocephalus.[4]

Chemotherapy has now proved to be useful in these children and can delay, if not replace, radiotherapy. In very young children, the first option of a combination of actinomycin D and vincristine can be tried out. There are reports suggesting disease stabilisation in 80% of cases, which lasted for a mean of 3 years and thereafter radiation could be given at a median age of 4.5 years, instead of 1.5 years. Carboplatin along with vincristine and vincristine with lomustine and prednisolone are other combinations, which have been tried and have demonstrated significant disease control. However, for ependymomas and germ cell tumours, chemotherapy has a limited role.[12,14,15]

Radiotherapy is beneficial in the treatment of residual and recurrent tumours and even as a primary treatment for unresectable tumours of the hypothalamus and optic pathway. Reports of chiasmatic glioma children, treated with radiotherapy alone, show that they have a 10 year progression-free survival in 89% and an overall survival of 100%.[15] The use of radiation is limited, due to its adverse effect on the developing brain. Long-term complications of radiotherapy in children include CNS necrosis, myelopathy, leucoencephalopathy, vascular injury, neuropsychological defects, hormonal imbalance, bone and teeth abnormalities, ocular toxicity, ototoxicity and secondary malignancies.[15] Recently, stereotactic radiosurgery has been advocated.

157 Other Tumours of the Sellar Region

Sanjay Behari, Anooj Chatley, Abrar Ahad Wani, Manoj Jain

INTRODUCTION

The sellar region is a small but complex area with neural, vascular, endocrine, osseous and meningeal structures. This accounts for the broad-spectrum of tumours and tumour-like conditions affecting this area. Although pituitary adenomas, craniopharyngiomas, meningiomas (tuberculum sellae, planum sphenoidale, diaphragma sellae, etc.), gliomas (optic nerve, infundibulum, posterior lobe and hypothalamus) and epidermoids/dermoids form the majority of tumours arising in the sellar and juxtasellar region, there is an impressive list of other rare tumours which may involve this area. This is of practical importance to a neurosurgeon, as these tumours may mimic the commonly occurring lesions in this area, both clinically as well as at radiology. The differential diagnosis of the many tumours and tumour-like conditions occurring in the sellar region is listed in Table 1.

Table 1: Differential diagnosis of sellar region masses

The most common tumours in this region—pituitary adenoma, craniopharyngioma, meningioma—are described in separate chapters. This chapter deals with uncommon lesions in the sellar region.

Tumours of adenohypophyseal origin
- Pituitary adenoma
- Pituitary carcinoma

Tumours of neurohypophyseal origin
- Granular cell tumours
- Neurohypophyseal gliomas
- Tumours of non-pituitary origin
- Craniopharyngiomas
- Gliomas
- Meningiomas
- Haemangiopericytomas
- Germ cell tumours
- Chordomas
- Chondromas/Chondrosarcomas
- Haemangioblastomas
- Giant cell tumours of the bone
- Lipomas
- Fibrous dysplasia
- Sarcomas
- Gangliogliomas

PITUITARY CARCINOMA

It is a rare entity. Fewer than 140 reports exist in the English literature.[35] Pituitary carcinoma is defined as any tumour of adenohypophyseal origin with demonstrated

craniospinal and/or extracranial metastatic dissemination.[14,25,41] Diagnosis is based on tumour behaviour, rather than histology as features like nuclear atypia, mitotic activity, necrosis and haemorrhage, may also be seen in pituitary adenomas. Craniospinal metastasis occurs by dissemination via cerebrospinal fluid. Extraneural metastases to bone, liver, lymph nodes, lungs, kidney and heart have been reported.

The criteria that need to be fulfilled for classifying a lesion as pituitary carcinoma are:[26]

- The primary tumour must be identified as a pituitary tumour at histology.
- An alternative primary tumour has to be excluded.
- Discontinuous spread in the form of single or multiple, nodular subarachnoid metastatic deposits, occasionally invasive of underlying brain or overlying dura, may be seen.
- Single or multiple systemic deposits broadly similar to and grossly indistinguishable from metastases of carcinomas, arising in other organs, may be seen.
- The structural features or marker expressions of the metastases should correspond or be similar to those of the pituitary tumour.

Less than 0.5% of all pituitary tumours turn out to be malignant. They usually affect adults with a slight female preponderance. They may be hormonally active or inactive. Most common are the ACTH producing tumours. Next in frequency is prolactin producing tumours. Although GH producing pituitary carcinomas have been described, they are very rare.

Pathology

The mode of spread of these carcinomas is by means of local invasion and through the venous system, the CSF pathways and the lymphatics. It is thought that venous spread occurs through the cavernous sinus initially. From here, spread occurs to the internal jugular vein through the petrosal system. It has also been postulated that retrograde spread through the cortical draining veins may affect the superior sagittal sinus. Spread occurs through the CSF pathway once the subarachnoid space is invaded and may involve the supratentorial, infratentorial or spinal compartment. Although the pituitary gland lacks lymphatic drainage, spread through lymphatics may occur once the tumour invades the skull base, which provides access to a rich lymphatic network. Systemic spread through the bloodstream may involve the lungs, liver, bones, kidney and the heart. Pituitary carcinomas that spread to the craniospinal axis are often non-functional, while those that metastasise to extracranial sites are usually functional. Most of the tumours which spread systemically are ACTH producing tumours.

Microscopically, pituitary carcinomas originate from and are composed of adenohypophyseal cells. The histological criteria for malignancy, like hypercellularity, nuclear pleomorphism, mitotic figures, necrosis, haemorrhage and even invasion, are not reliable indicators of the malignant nature of the tumour.

Clinical Features

The age of onset of symptoms is similar to that of patients harbouring pituitary adenomas. The rate of progression of these symptoms depends upon the biological behaviour of the tumour. The initial course may be indistinguishable from that of a pituitary adenoma. However, patients may have multiple recurrences and then disseminated disease may eventually manifest. It may be that in such cases there is malignant transformation in a previously benign tumour. Alternately, the clinical course may be fulminant with rapid deterioration of vision, multiple cranial nerve palsy and evidence of metastatic disease. In these cases, the tumour is probably a carcinoma *de novo*.[33] In addition, features of endocrine hyperactivity may be present. Tic like facial pain due to involvement of the Gasserian ganglion and early onset of diabetes insipidus are poor prognostic indicators.[20,27] Features of central nervous system or systemic metastasis may be present, depending upon the site of metastasis.

Radiological Features

There are no characteristic radiological features which distinguish pituitary carcinoma from a pituitary adenoma. Scintigraphy with ^{111}I-labelled octreotide has been used to establish the diagnosis of a metastatic GH-secreting carcinoma[21] and has revealed additional lesions in an ACTH-secreting carcinoma[19] and/or tumour recurrences at follow-up.[12] More recently, PET scan using 18F-labelled deoxyglucose has revealed unsuspected pituitary macroadenomas and also identified metastases from a pituitary carcinoma.[1,17,28] Other radiotracers, such as radiolabelled 5-hydroxytryptamine, are considered to be more sensitive than 18F-labelled deoxyglucose and may lead to the recognition of additional lesions.

Treatment

The treatment of pituitary carcinoma is similar to that of large and aggressive pituitary tumours and includes surgery (usually via the trans-sphenoidal route), external beam radiotherapy and adjuvant medical treatment. The treatment of pituitary carcinomas is mainly palliative and may not prolong survival to any major extent. However, there is retrospective data suggesting that patients who received aggressive treatment may achieve a better survival rate.[25]

Medical treatment is directed against hypersecretory syndromes. Dopamine agonists have successfully been used for the treatment of prolactin-secreting tumours. Although partial biochemical or even objective tumour responses to treatment with dopamine agonists have been described, the great majority of reports have demonstrated either lack of response or tumour progression after treatment with bromocriptine or newer dopamine agonists, such as quinagolide and cabergoline. Tamoxifen has also been given to achieve a synergistic

effect. Dopamine agonists have been used in ACTH-secreting and TSH-secreting carcinomas, but with only minimal benefit. Somatostatin analogues such as octreotide, have been used to control the hypersecretory syndrome in GH- and TSH-secreting pituitary carcinomas, usually with a variable response.

Chemotherapy

5-fluorouracil and methotrexate have been used. However, there is limited experience in the use of chemotherapeutic agents in the treatment of pituitary carcinoma. Newer agents, like paclitaxel, are under investigation.

GRANULAR CELL TUMOURS

Diverse nomenclature has been used to describe this entity in the past, including choristoma, tumorette, myoblastoma and pituicytoma. The generally accepted hypothesis regarding their histogenesis suggests that they are derived from supporting glial elements of the infundibulum and posterior lobe of the pituitary. They may be incidentally detected at autopsy in as many as 17% of cases,[31] usually as barely visible aggregates of tumorettes. Symptomatic granular cell tumours occur as a result of enlargement of these tiny tumorettes. Symptomatic patients usually present in the fourth or fifth decade of life. Women are affected almost twice as often as men. They may present with diabetes mellitus, visual disturbance or other symptoms of a sellar/suprasellar expanding mass lesion. Despite the neurohypophyseal origin of these tumours, diabetes insipidus may not always be present. Histologically, these tumours consist of large polygonal or round cells with eccentric nuclei. There are abundant eosinophilic cytoplasmic granules that are PAS positive and diastase resistant. On immunohistochemistry, they may be positive for S-100, usually negative for GFAP and uniformly negative for all anterior pituitary hormones.

Radiographically, they appear as small rounded masses which are generally isointense on T1- and hyperintense on T2-weighted MR images. They may be mistaken for a meningioma on radiological evaluation, as they enhance intensely on contrast due to their high vascularity. However, they are primarily intrasellar and do not invade surrounding structures. Calcification is generally not seen in these tumours. As granular cell tumours are benign slow growing neoplasms, the prognosis of patients with these tumours is generally favourable following total or subtotal resection, although recurrences are known to occur. Recurrences may be treated with reoperation or radiotherapy.

NEUROHYPOPHYSEAL GLIOMAS

These are rare tumours, generally pilocytic astrocytomas which arise from the infundibulum or the posterior pituitary. They are also known as infundibulomas or pituicytomas. These tumours probably arise from the heterotopic glial tissue which may be present in the subarachnoid space (Fig. 1).

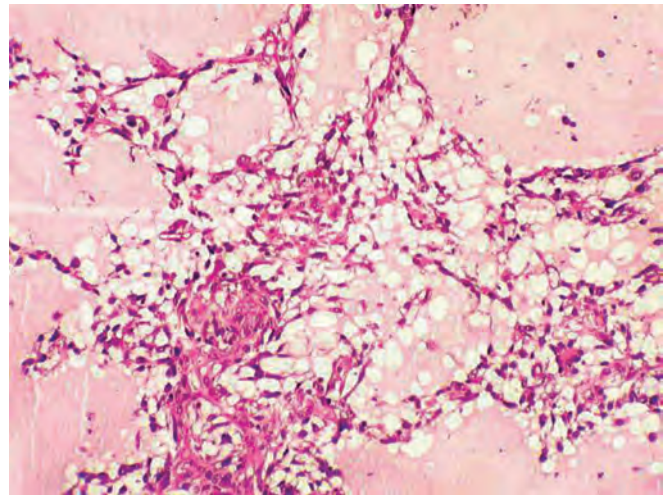

Fig. 1: Pilocytic astrocytoma: Histology reveals a biphasic tumour composed of densely packed piloid cells, displaying oval mildly anisomorphic hyperchromatic nuclei, embedded in fibrillary matrix admixed with loosely cellular areas of stellate cells with microcystic degeneration. (H and E × 100 original magnification)

GERM CELL TUMOURS

Intracranial germinomas (Fig. 2) account for 0.3–3.5% of all intracranial tumours and generally arise in the midline. They are commonly located in the pineal region, although a minority of them may be seen in the sellar/suprasellar region in isolation or in combination with pineal lesions. Therefore, they remain one of the diagnostic considerations in the evaluation of a sellar mass, especially in children.[5,22,24,29,38] Germ cell tumours are

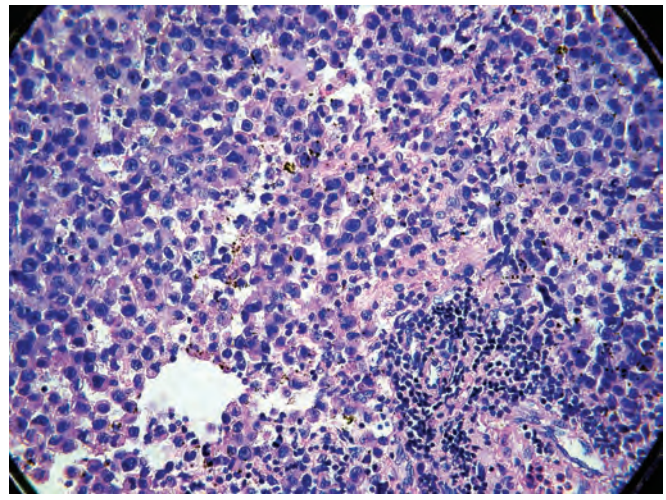

Fig. 2: Germinoma: Histology reveals structure of a tumour, composed of sheets of large uniform polygonal cells traversed by fibrous septa, infiltrated by plenty of small lymphocytes. The tumour cells display large central nuclei with vesicular chromatin, prominent nucleoli and abundant pale cytoplasm with well defined cell borders. (H and E × 100 original magnification)

broadly classified into germinomas and non-germinomatous germ cell tumours which include teratomas, embryonal cell carcinomas, endodermal sinus tumours and choriocarcinomas. Germinoma is the most commonly occurring germ cell tumour in the suprasellar region and generally affects patients in the paediatric age group.

Pathology

Suprasellar germinomas are generally infiltrative lesions, which may involve the hypothalamus, pituitary stalk, third ventricular floor, posterior pituitary and the optic chiasm, nerves or tracts. The site of origin of these tumours is generally not clearly discernable. In most cases, the tumour is located on the under surface of the hypothalamus and is intimately related to the pituitary stalk and optic chiasm. Intrasellar extension occurs in approximately 20%. Rarely, a pure intrasellar lesion may be seen.[5,22,24,29,34,38] All germ cell tumours, except benign teratomas, are known to metastasise. However, most instances of metastasis are within the neuraxis. Non-germinomatous lesions are more likely to metastasise.

Macroscopically germinomas are generally soft, greyish, homogeneous and at times, may resemble lymphomas on gross examination. The cut surface is granular and usually solid. Haemorrhage and necrosis is uncommon, the presence of which indicates a high-grade tumour like embryonal cell carcinoma, endodermal sinus tumour or a choriocarcinoma. Teratomas have solid and cystic components. Mature teratomas are grossly well defined and the cut surface has a variegated appearance. Derivatives of all three germ layers may be seen. Mucin, hair, bone, cartilage and occasionally, teeth may be recognisable.

Microscopically germinomas are composed of large round to oval cells with large nuclei and prominent nucleoli, arranged in islands or trabeculae separated by fibrovascular stroma, containing bands of lymphocytes. In 50%, syncytiotrophoblastic giant cells may be seen and in such cases, human chorionic gonadotropin levels in CSF and/or serum are elevated. Embryonal cell carcinomas are composed of cuboidal/columnar cells arranged in varied patterns. These lesions may have focal differentiation into extraembryonic or embryonic structures leading to expression of alpha fetoprotein (AFP) or human chorionic gonadotropin (HCG) in body fluids (serum/CSF/urine). Endodermal sinus tumours are generally composed of cuboidal cells with intracellular and extracellular globules, which contain AFP and alpha-1 antitrypsin, respectively, which can be demonstrated on immunohistochemistry. Elevated levels of AFP may be found in serum, CSF or urine in these cases. Choriocarcinomas are composed of large cytotrophoblastic cells surrounded by syncytiotrophoblastic cells, which are multinucleated. Human chorionic gonadotropin levels may be increased in CSF, serum or urine and may be demonstrable by immunohistochemistry in tissue sections. In teratomas, a varied combination of tissue elements from various germ cell layers may be seen.

Clinical Features

Characteristically, these tumours appear in childhood and usually present with diabetes insipidus and only later with features of hypopituitarism and visual loss. Hyperprolactinaemia is often present.

Radiological Features

Suprasellar germinomas are typically midline lesions, which are centred at or just behind the pituitary infundibulum. On MRI, they appear mildly hypointense on T1-weighted images and hyperintense on T2-weighted images. They enhance brightly on post-contrast images. Other germ cell tumours may display more heterogeneity, due to more diverse histological elements forming the tumours.

Treatment

Due to the anatomical location of these tumours and their infiltrative nature, total surgical excision is generally not possible. Germinomas are very radiosensitive. It is necessary that the subarachnoid cisterns and ventricular system are included in the radiation field to prevent recurrence from CSF spread. Radiotherapy is not very effective in the treatment of other germ cell tumours. Chemotherapy with cisplatin combined with bleomycin and vinblastin is used, in addition to radiotherapy, for disease control.[15]

CHORDOMAS

Chordomas (Figs 3A and B), derived from notocordal remnants, are uncommon tumours of the bone which may arise from any site along the axial skeleton. The preferred location is the sacrococcygeal spine. Intracranial

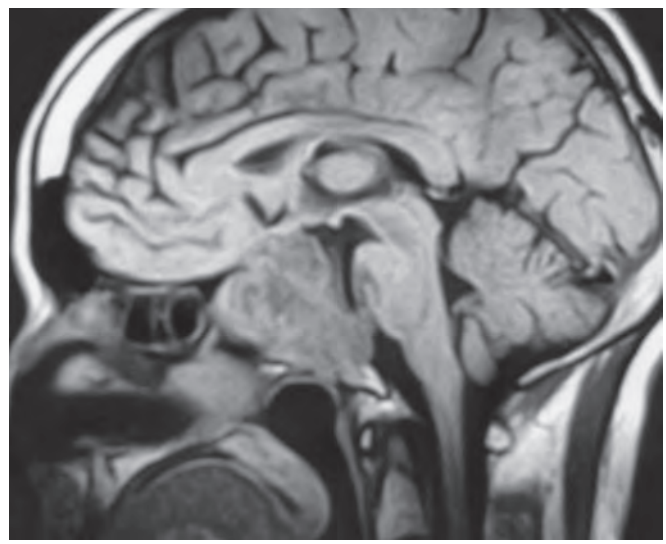

Fig. 3A: T1-weighted sagittal MR image showing a clival chordoma reaching superiorly to the sellar-suprasellar region

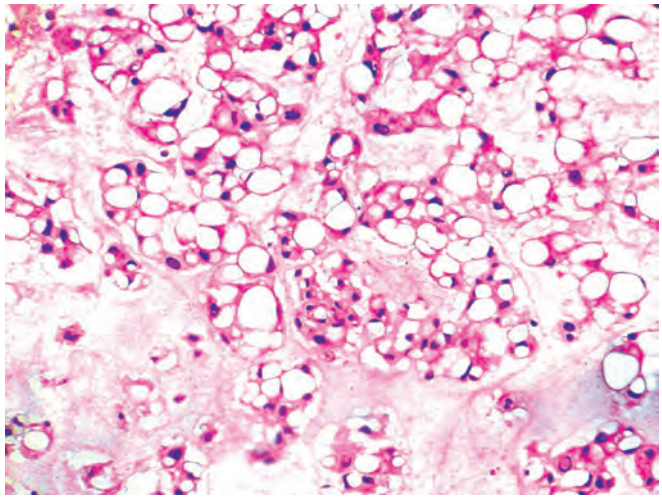

Fig. 3B: Chordoma: Histology reveals lobules of sheets, cords and islands of cells with round to polygonal appearance, abundant vacuolated and bubbly cytoplasm, with hyperchromatic mildly anisomorphic small nuclei, embedded in an abundant myxoid matrix. The physaliphorous cells are interspersed with sheets of large polygonal cells with epithelioid morphology, displaying abundant eosinophilic cytoplasm and pleomorphic hyperchromatic nuclei (H and E × 200 original magnification)

chordomas constitute about 35% of all chordomas and 0.2% of all intracranial tumours.[37] They are typically midline lesions originating in the region of the clivus. They expand the clivus and may extend intracranially to compress adjacent anatomical structures. Extension may occur laterally into the cavernous sinus, anteriorly into the sella and inferiorly into the nasopharyngeal region. Lesions which are limited exclusively to the sellar region are relatively rare.[32]

Pathology

Cranial base chordomas are slow growing, histologically benign lesions, which cause expansile bone destruction at the site of origin and later infiltrate the dura and extend intradurally to displace and compress intracranial structures. They usually arise extradurally but may rarely extend intradurally as well. Although they are histologically benign, due to their osteodestructive nature, progressive course, tendency to recur and capacity to metastasise, they are included among malignant neoplasms. Metastatic dissemination occurs in 10–20% and is generally a late occurrence. Sites most commonly involved are liver, lungs, bone, heart and lymph nodes.

Clinical Features

The clinical manifestations of these tumours depend upon the direction of growth. Lesions which are limited to the midline cause varying degrees of hypopituitarism and chiasmal syndrome due to compression of the pituitary and the optic chiasm, respectively. Lateral extension leads to involvement of the cavernous sinus with proptosis and multiple cranial nerve palsies.

Radiological Features

CT scan may reveal foci of sequestrated bone or irregular calcifications amid the destroyed clival marrow. On MRI, the lesion appears isointense to hyperintense on T1-weighted images and heterogeneously hyperintense on T2-weighted images. Variable post-contrast enhancement is seen. Foci of calcification are seen as dark foci in the soft tissue component of the tumour.

Treatment

The aim of treatment is to increase the likelihood of recurrence free survival. Options include surgery alone or surgery/biopsy, followed by radiotherapy. Radiotherapy may consist of conventional fractionated radiotherapy, proton beam radiation, brachytherapy or radiosurgery.

METASTATIC TUMOURS TO THE SELLAR REGION

A variety of systemic and haemopoietic malignancies may metastasise to the sellar region. In an autopsy series, the occurrence of carcinomatous and haemopoietic metastasis to the pituitary and parasellar region have been reported to be as high as 26.6%[36] and 23%, respectively.[10] However, regional symptom-producing pituitary metastasis is uncommon, presenting only in cases with advanced systemic disease. In many cases, pituitary involvement may be subclinical and the patients may succumb to their advanced systemic disease, before the pituitary metastasis become manifest. Rarely, symptom-producing pituitary metastasis may be the first manifestation of a systemic malignancy.[9] Most of the pituitary metastases involve the posterior pituitary. This is due to the fact that the posterior pituitary has a direct arterial blood supply, as compared to the portal circulation of the anterior pituitary. Therefore, diabetes insipidus is the most common presenting feature in these patients.

Amongst the systemic malignancies which metastasise to the sellar region, the most common are lung, breast, prostate, stomach and bladder carcinomas. The general pattern of metastasis is that of osseous involvement of the sella turcica with contiguous deposits in the pituitary, especially the posterior lobe. Hypothalamic involvement may occur by contiguous involvement from the sellar region. Rarely, isolated hypothalamic involvement may occur. Patients with metastatic systemic malignancies to the sellar region most commonly present with diabetes insipidus. Suprasellar metastasis may present with rapidly progressive visual loss due to chiasmal compression. Ophthalmoplegia may be seen due to involvement of the cavernous sinus region. Hypopituitarism occurs infrequently due to the remarkable functional reserves of the pituitary.

Among the haemopoietic malignancies, leukaemias, lymphomas and plasmacytomas may metastasise to the sellar region. Most primary CNS lymphomas involve the brain parenchyma. Sellar region lymphomas usually

originate in the hypothalamus and infiltrate the pituitary stalk and posterior pituitary. They may present with hypothalamic dysfunction, chiasmal syndrome or secondary hypopituitarism. Secondary lymphomas involving the sellar region are generally non-Hodgkin's lymphomas. The deposits of the lymphomatous lesion are generally periglandular, limited to the pituitary capsule with infrequent involvement of the pituitary substance. Lymphocytic and myeloblastic leukaemias may also metastasise to the sellar region with primarily a periglandular distribution. Patients with secondary lymphomatous deposits or leukaemic deposits in the periglandular region have diabetes insipidus as the most common presentation. Symptoms due to compression of parasellar structures and hypopituitarism are rare.

Metastatic lesions in the sellar region usually appear homogeneous on the CT scan and enhance intensely with contrast. They are isointense to brain on T1-weighted MR images, moderately hyperintense on T2-weighted images and enhance intensely.

Surgery is indicated either for diagnostic reasons or when decompression is required to relieve mass effect. Prognosis is poor in patients with metastatic disease and the average survival is approximately 8–9 months. Radiotherapy may be an option mainly for palliation.

RATHKE'S CLEFT CYST

These are epithelium-lined cysts derived from remnants of the Rathke's pouch.[44] In 1913, Goldzieher described the first case of Rathke's cleft cyst (RCC) as an incidental post-mortem finding. Rathke's pouch appears during the 4th week of gestation as a stomodeal ectodermal evagination, which extends cranially to form the craniopharyngeal duct. The proximal end of the duct obliterates by the 11th week of gestation, while the cranial part comes in contact with the infundi bulum. The anterior wall of the pouch forms the anterior lobe of the pituitary and the pars tuberalis, while the posterior wall forms the pars intermedia. The residual lumen of the pouch involutes. Cystic remnants of the pouch may persist mainly at the anterior and posterior pituitary interface. These may be seen in up to 20% of autopsy cases. Rarely, they may be large enough to cause symptoms. There are secretory cells in the walls of the cyst and the cyst enlarges due to accumulation of the secretions.

Pathology

On pathologic examination, the cysts vary in size from 2 to 40 mm. The cystic capsule frequently is described as thin and transparent. The cystic fluid commonly is thick or gelatinous but it also can be watery, serous or similar in consistency to motor oil. The cystic fluid most often is yellowish in colour. At histological examination, the cysts typically are composed of vascularised stroma of connective tissue and three types of epithelial cells: (1) ciliated; (2) non-ciliated epithelial and (3) mucous secreting. Non-ciliated cells appear as a single layer of flat cells or as stratified columnar cells. The presence of ciliated epithelial and mucous-secreting cells in a pituitary gland is pathognomonic for Rathke's cleft cyst.

Clinical Presentation

The patient's age at presentation ranges 4–73 years (mean age, 38 years). The greatest frequency is in persons aged 50–60 years. Voelker et al. reported a male-to-female ratio of 1:2.[44] RCCs often produce no symptoms and so are usually discovered incidentally, when radiographic or necropsy findings are reviewed. Symptomatic RCCs are uncommon but cysts can enlarge and cause symptoms secondary to compression of the pituitary gland, pituitary stalk, optic chiasm or hypothalamus. The most common presenting symptoms are pituitary dysfunction, visual field defects and headache. Endocrinal abnormalities include gonadotropin failure, which manifests early. Features of hyposecretion of growth hormone, hypothyroidism and hypoadrenalism occur late. Hyperprolactinaemia is common and diabetes insipidus may also occur, although late. Infrequently, hydrocephalus due to obstruction at the foramen of Monroe, aseptic meningitis due to leakage of cyst contents into the subarachnoid space and pituitary apoplexy from haemorrhage into the cyst may manifest.

Radiological Features

RCCs frequently appear as well-circumscribed, hypodense sellar masses that may have a suprasellar extension. As a result of the different cystic contents, RCCs may appear isodense or hyperdense relative to the brain parenchyma. RCCs usually have a thin wall that may enhance. Variability in CT scan contrast enhancement among individual cysts may reflect squamous metaplasia in the wall or a peripherally displaced rim of pituitary tissue. Calcification characteristically is not seen on CT scans.

MRI appearances of RCCs are highly variable (Figs 4A and B). One group of cases may be hypointense on T1-weighted images and hyperintense on T2-weighted images. The cystic contents of the group resemble those of cerebrospinal fluid (CSF). In the second group are RCCs with hyperintensity on T1-weighted images and variable signal intensity on T2-weighted images. An increase in the signal on T1-weighted images has been related to the high content of mucopolysaccharides, which is believed to result from an increase in the number of mucin-secreting cells in the cyst wall, as well as from an increase in the activity of these cells. Uncommon cases with high signal intensity on T1-weighted images and low signal intensity on T2-weighted images have been suggested to result from a combination of factors, including the presence of mucopolysaccharides, chronic haemorrhage, a high cholesterol content and cellular debris from the cyst wall. RCCs almost always are homogeneous in signal intensity, whereas other lesions, such as cystic

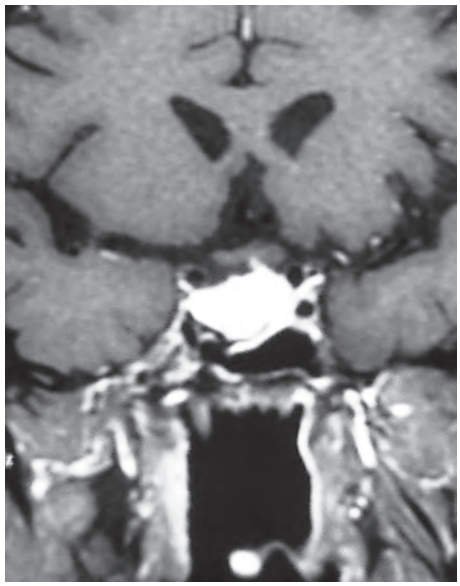

Fig. 4A: Coronal T1-weighted contrast MR image showing the sellar suprasellar Rathke's cleft cyst

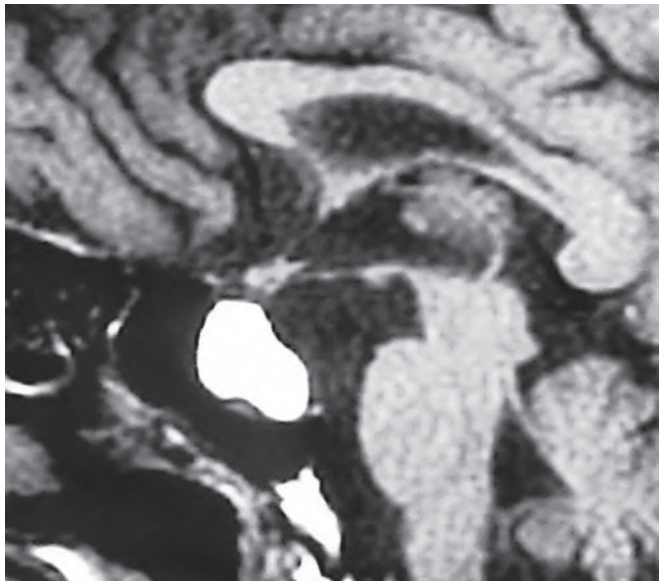

Fig. 4B: Sagittal T1-weighted contrast image showing the well defined uniformly hyperintense content of the Rathke's cleft cyst

craniopharyngiomas and haemorrhagic adenomas, more frequently have heterogeneous signal intensity. RCCs usually have a thin wall that may enhance with contrast. Variability in the gadolinium enhancement, among individual cysts, may reflect squamous metaplasia in the wall or a peripherally displaced rim of pituitary tissue.

Treatment

The most common approach in the treatment is transsphenoidal surgery, in which the cyst is partially excised and drained.[11,18] This method is effective and helps to preserve pituitary function. Radical excision can cause additional and unnecessary pituitary damage. In transsphenoidal surgery, the cyst is opened, a biopsy specimen is obtained from the wall and the cyst is drained into the sphenoid sinus. Patients in whom this approach is not appropriate because of an inaccessible cyst, craniotomy is performed.

The recurrence rate after craniotomy is twice as high as that after trans-sphenoidal surgery. In addition, leakage of the cystic contents into the subarachnoid space has been reported; this can cause aseptic meningitis. In cases with recurrence, extensive removal of the cyst wall is most appropriate and some studies recommend external beam pituitary radiation therapy, although its role in preventing further recurrence remains unclear.

HAMARTOMAS, CHORISTOMAS AND GANGLIOCYTOMAS OF THE SELLAR REGION

These are a group of histologically similar lesions, which consist of mature neurons which are clustered within a stroma of axons and astroglial elements. Various terms, like hamartomas, choristomas and gangliocytomas, have been used to describe these tumour-like lesions. These types of lesions arising in the hypothalamus are known as hypothalamic hamartomas and those arising in the sella without attachment to the hypothalamus are called choristomas.

Hypothalamic Hamartomas

Minute nodular hamartomatous foci of hypothalamic tissue are a common incidental finding on autopsy. These hamartomatous nodules are clinically insignificant. However, they may be large enough to compress surrounding structures and cause symptoms. These lesions are commonly found in the region of the suprasellar cistern or the interpeduncular cistern. In most of the cases they retain some anatomic continuity with the hypothalamus. However, they may not have a distinct attachment to the hypothalamus and may lie free in the suprasellar cistern. Others may have a wide attachment by a distinct stalk to the ventral surface of the hypothalamus or may even lie embedded in the parenchyma of the hypothalamus.

Pathology

Hamartomas usually resemble normal grey matter. Microscopically, they contain neurons which are indistinguishable from normal hypothalamic neurons and may contain secretory granules. These secretory granules may contain luteinising hormone releasing factor (LH-RF), beta-endorphin, corticotropin releasing factor or oxytocin. Immunohistochemistry reveals positivity for hypothalamic hormones in the neurons of these lesions.

Clinical Features

Hypothalamic hamartomas are rare tumours affecting young children below the age of 3 years. Characteristically, children present with precocious puberty[2], which may be as a result of either simple hypothalamic compression

or due to release of gonadotropin-releasing hormone (GnRH). Patients may present with behavioural or intellectual disturbances. There may be a variety of autonomic disturbances including abnormalities of thermoregulation, behavioural disorders, somnolence and hyperphagia. Gelastic epilepsy and complex partial seizures are also known to occur in these patients. Hemiparesis or nystagmus may occur occasionally. Occasionally, these children may present with cachexia.

Radiological Features

Plain X-ray of the skull is often unremarkable. However, it may show erosion of the dorsum sellae. On CT scan, a hypothalamic hamartoma appears as an isodense, non-enhancing suprasellar or interpeduncular cisternal mass. On MRI it appears isointense on both T1- and T2-weighted images with attachment to the tuber cinereum or posteromedial hypothalamus by a distinct stalk, giving it the so-called collar button shape. The lesion may lie entirely within the substance of the hypothalamus and may, therefore, be easily missed if small.

Treatment

Surgery is indicated in most symptomatic cases. Radiotherapy is ineffective in the treatment of these lesions. Total removal may not be possible, due to risk of hypothalamic injury in cases where there is broad-based attachment to the hypothalamus or when the tumour lies within the substance of the hypothalamus. However, subtotal removal may result in regression of precocious puberty in some cases. Surgical treatment is useful to confirm the diagnosis and to regress or abolish precocious sexual features and skeletal growth. It also results in better seizure control and improvement in behavioural and intellectual disturbances. Drugs such as medroxyprogesterone acetate and cyproterone acetate have been used to inhibit gonadotropin production in patients with precocious puberty.

Intrasellar Choristomas (Gangliocytomas)

These lesions are histologically similar to hypothalamic hamartomas. However, they differ from hypothalamic hamartomas in that they are primary intrasellar lesions with no attachment to the hypothalamus. They are generally associated with a functional pituitary adenoma. In most of the cases reported, intrasellar choristomas are seen in association with a GH producing pituitary adenoma. It has been hypothesised that the development of pituitary adenoma may be a secondary phenomenon, as these choristomas release hypothalamic hormones, which may induce adenomatous transformation of adjacent adenohypophyseal cells. This is supported by the finding of GHRH within the neurons of these choristomas. Corticotroph-releasing factor producing choristomas have also been found in association with Cushing's disease.

TUMOUR-LIKE CONDITIONS

Pituitary Abscess

Pituitary abscess, first described by Simmonds in 1914, is a rare but potentially life-threatening condition, if not adequately diagnosed and treated. It has a low incidence. Jain et al.[23] reported that pituitary abscesses constituted 0.6% of all pituitary lesions operated by them. Of 500 expansive pituitary lesions encountered by Scanarini et al.[40] during a 27-year period, only two were abscesses.

Aetiology of Pituitary Abscess

- Pituitary abscess may be the result of direct extension or haematogenous spread of infection from sphenoid sinusitis, meningitis, cavernous sinus thrombophlebitis or a contaminated cerebrospinal fluid (CSF) leakage.[8,43] When pituitary abscess does not coexist with meningitis or an adjacent sinus infection, it is difficult to determine the original site of infection.
- Pituitary abscesses may also develop, although rarely, as a result of generalised sepsis or haematogenous dissemination from a variety of distant septic foci like pneumonia, osteomyelitis, endocarditis, etc.
- They may complicate pre-existing lesions, usually adenomas, craniopharyngiomas and Rathke's cleft cyst. Tumours are possibly vulnerable to infection because of impaired circulation, areas of necrosis or local immunological impairment.

The incidence of intrasellar abscess is surprisingly low after trans-sphenoidal pituitary surgery. These abscesses may be due to intra-operative contamination or due to CSF leakage (secondary abscesses).

When culture is positive, the most commonly identified pathogens are *Staphylococcus* sp, *Streptococcus* sp, *Neisseria* sp, *E. coli, Corynebacterium* sp and *Diphtheroids*. Cases of mycotic abscesses have been reported due to aspergillus, candida, coccidiodomycosis, histoplasmosis and blastomycosis. In contrast to bacterial pituitary abscesses, most fungal infections occur when some type of immunosuppression coexists in the patients. Cases of parasitic pituitary infection have also been reported, including cysticercosis and echinococcosis.

Clinical features of pituitary abscesses resemble those of pituitary adenomas. Pituitary abscesses usually present either with endocrinologic disturbance or with symptoms related to mass effect. Headache is the most common presenting complaint. Signs of meningitis may be associated in up to 90% of cases. Fever is present in 50% of cases.

No pre-operative investigation is specific for pituitary abscess. However, several clues can suggest its presence. A past history of meningitis, sepsis and sinusitis may suggest the diagnosis. Rapid neurological deterioration in a patient with sellar tumour after a presumed bacteraemia should point to the possibility of abscess formation. CSF examination may be useful even when there are no signs of meningitis. It may reveal increased

cell count, elevated protein content or depressed glucose concentration.

Standard X-rays of the skull, centred on the sella may show widening of the sella turcica, erosion of the sellar floor and opacity of the sphenoid sinus.

CT scan findings in pituitary abscess were first reported by Enzmann and Sieling[16] as an intrasellar lesion, eventually expanding to the suprasellar region and devoid of specificity. The presence of hypodensity in the pituitary gland with enhancement of its outline by contrast injection and filling the sphenoid sinus with destruction of the sellar floor are also non-specific. The differential diagnosis of rim enhancement would include cystic lesions with or without superimposed infection.

The MRI findings in a case of pituitary abscess were first described by Dickob et al.[13] Pituitary abscess appears hypointense on T1-weighted images and hyperintense on T2-weighted images. Two important signs may lead to a correct diagnosis. The first includes disparity between the important sphenoid features (effusion within the sinus, wide sellar floor destruction) and the relatively small volume of the pituitary lesion. The second sign is the enhancement of the sellar lesion outline by both CT and MRI contrast, with simultaneous extensions to the sphenoidal sinus.

Pituitary abscess is usually treated by antibiotic and corticosteroid therapy, followed by surgery. The transsphenoidal approach is usually chosen for drainage to protect the cerebrospinal fluid from contamination and to avoid post-operative infection.

LYMPHOCYTIC HYPOPHYSITIS

It is a rare destructive inflammatory disorder affecting the anterior pituitary and is presumed to be of autoimmune origin. It occurs almost exclusively in female patients and commonly affects them, either during pregnancy or within the first year of parturition. It may coexist with other autoimmune diseases including Hashimoto's thyroiditis, idiopathic adrenalitis, pernicious anaemia and parathyroiditis.

Pathology

Lymphocytic hypophysitis is thought to be an autoimmune disease which may be precipitated following a viral infection. Prior or concurrent lymphocytic meningitis/meningoencephalitis has been considered to be an aetiological factor. In experimental studies, viral specific peptides (e.g. Rubella virus E-1 and E-2 proteins) have been shown to induce lymphocytic hypophysitis in animals.

The pathological process starts as an acute inflammation and enlargement of the gland. In chronic cases, the gland becomes atrophic and fibrotic. Microscopically, the normal glandular architecture of the anterior pituitary is replaced by infiltration of lymphocytes, plasma cells, macrophages and eosinophils. Occasionally, lymphoid follicles and germinal centres may be seen. Varying degree of diffuse interstitial fibrosis is present.

Clinical Presentation

As mentioned earlier, this disorder primarily affects females and is often related temporally to pregnancy.[3,4] Patients may present with headache, vomiting, emotional disturbances or visual field defects. The hormonal disturbances which may occur include single hormonal disturbance like hyperprolactinaemia, hypoadrenalism and hypothyroidism or panhypopituitarism. As the posterior pituitary is not involved, diabetes insipidus is rare.

Radiological Features

Plain X-ray skull is usually normal but may demonstrate an enlarged sella with occasional erosion of the dorsum sellae. On CT scan, lymphocytic hypophysitis appears as an enhancing intrasellar mass which may extend to the suprasellar region with enlargement of the sella. MRI is the investigation of choice and reveals a lesion in the sella which is either hypointense or isointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 5). It enhances uniformly on contrast injection. The pattern of signal enhancement after contrast may be helpful to differentiate this lesion from a macroadenoma. A strong and homogeneous enhancement of the anterior pituitary, similar to the cavernous sinus, is more suggestive of an inflammatory process such as lymphocytic hypophysitis rather than a macroadenoma.

Treatment

Surgical intervention, in addition to providing a histological diagnosis, is very effective in achieving decompression of the sellar mass and thereby resolving

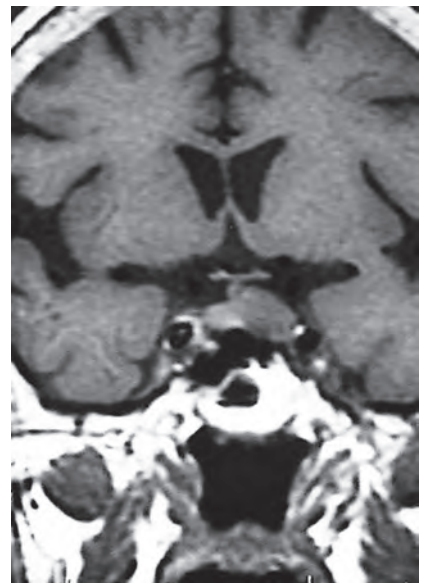

Fig. 5: Lymphocytic hypophysitis: A contrast enhanced T1-weighted coronal MR image showing an infiltrative lesion in the sella which is hypointense or isointense on T1-weighted images and hyperintense on T2-weighted images. It enhances heterogeneously on contrast with thickening of the pituitary stalk

headache and visual deficits. The aim of surgery should be to reduce the pituitary mass and associated compressive effects on surrounding structures, without introducing new endocrinal or neurological deficits. This is best achieved by the trans-sphenoidal approach. Supraphysiological doses of glucocorticoids can be effective in the treatment of lymphocytic hypophysitis. They help both by reducing the mass of the pituitary by their anti-inflammatory effects and as replacement for defective adrenal function. Other immunosuppressive drugs, such as azathioprine, methotrexate and cyclosporine, have been used with some success in patients responding poorly to corticosteroids.

MUCOCOELE

These are benign, cystic lesions arising in the paranasal sinuses. Sphenoethmoidal mucocoeles are relatively rare lesions which may erode the sellar floor to present as intrasellar, parasellar or suprasellar masses. Mucocoeles are filled with mucus and the walls consist of psuedostratified or low columnar epithelium, which contains goblet cells.

Isolated involvement of the sella is very rare. In such cases, they cause enlargement of the sella and chiasmal compression. Hypopituitarism rarely occurs. More often, involvement of the sella may just be a small component of a much wider intracranial extension involving the orbital apex and superior orbital fissure, wherein oculomotor palsies and exophthalmos may be the presenting features.

SARCOIDOSIS

Sarcoidosis is a multi-system inflammatory disorder which may involve the nervous system in approximately 5% of cases. Neurosarcoidosis is considered as a great imitator of intracranial lesions. Intracranially, it generally involves the base of the brain with infiltrative arachnoiditis, which causes entrapment of cranial nerves and may also involve hypothalamic-pituitary structures. Often it results in polyneuritis cranialis, manifesting as fluctuating or recurring paralysis of cranial nerves, specially the facial. Rarely, isolated involvement of these structures may be seen.

Histological appearance of these lesions is characterised by non-caseating granulomas consisting of lymphocytes, giant cells and macrophages. Clinical manifestations are generally due to hypothalamic or infundibular damage. MRI demonstrates enhancement of the hypothalamus, thickening of the infundibulum and meningeal enhancement, especially in the region of the suprasellar cistern.

Neurosarcoidosis has no known cure. Immunosuppression is the principal method of controlling the disease and corticosteroids are the mainstay of therapy. Alternative medications, including azathioprine, cyclophosphamide, cyclosporine, chloroquine and methotrexate have been used with variable success. Some patients demonstrate symptomatic benefits from low-dose radiation. Surgical intervention is indicated in cases of hydrocephalus or when an expanding mass lesion causes an increase in intracranial pressure.

HISTIOCYTOSIS X (LANGERHAN'S CELL HISTIOCYTOSIS)

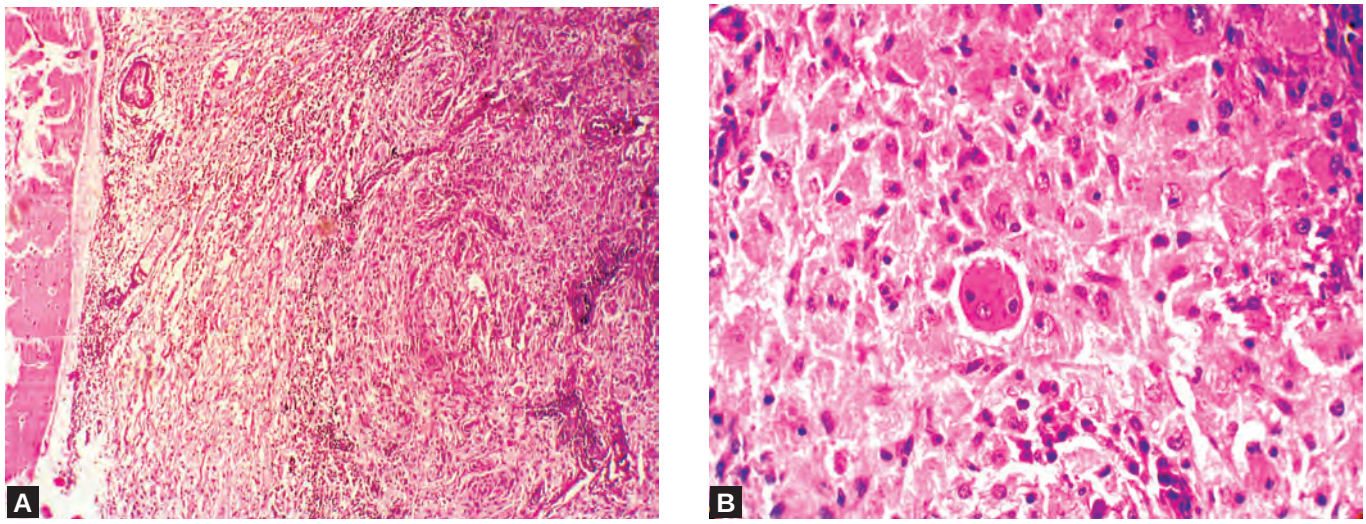
It is a systemic disease primarily affecting the reticuloendothelial system. It may involve the central nervous system with a predilection for the hypothalamus, infundibulum and posterior pituitary. Involvement of the anterior pituitary is far less common. It generally represents extension from an adjacent bony lesion. Patients generally present with diabetes insipidus. Growth hormone deficiency and hyperprolactinaemia may also be present. Histologically, the lesions consist of infiltrates of histiocytes, eosinophils and lymphocytes (Figs 6A and B). Characteristic Langerhan's giant cells are present, which express S-100 protein and HLA-DR (CD-1) antigen. Neuroimaging shows a thickened infundibulum which enhances on contrast and the presence of hypothalamic granulomas. Destructive osseous lesions may be seen in the calvarium.

CAVERNOUS ANGIOMA OF CAVERNOUS SINUS[6,28,37]

Cavernous angiomas of the cavernous sinus are rare lesions with an incidence of 1–3% of all lesions of that area. Their origin may be extracavernous with enlargement into the middle cranial fossa or primary intracavernous with enlargement into the middle cranial fossa. Growth in these lesions occurs by progressive ectasia of vascular channels, capillary outgrowth from cavernous spaces into the interstitium, internal microhaemorrhages causing thrombosis of contiguous blood vessels, followed by organisation and sclerosis and cyst formation by rupture of septae between adjacent sinusoids. Subsequent rapid expansion of the cyst may be due to imbibing water through osmosis.

These lesions occur between the second and the fifth decades of life with the male:female ratio being 1.7:2.8. The gradually expanding lesion may cause cavernous cranial nerves deficit and sellar hypothalamic involvement may result in endocrinopathies. Pregnancy, steroid administration or even physical exertion may cause exacerbation of symptoms due to engorgement of the lesion. Spontaneous haemorrhage is rarer in these extradural haemangiomas compared to their intra-cerebral counterparts.

CT scan shows an isodense to hyperdense lesion with dense homogeneous enhancement on contrast. Bony erosion in the sellar region may be seen. These lesions are angiographically occult due to the small size of the nutrient vessels, as well as extensive thrombosis within the malformation so that adequate concentration of the dye for clear definition of the lesion is not provided. Thus, angiography may be negative or



Figs 6A and B: Histiocytosis X: Histology reveals sheets of histiocytes, displaying bland vesicular nuclei and abundant foamy cytoplasm. Interspersed thin fibrous bands and focal aggregates of mature lymphocytes, plasma cells and giant cells are also seen. A rim of brain parenchyma with reactive gliosis is also seen. (H and E × 100 original magnification) (some of the histiocytes show engulfed intact lymphocytes and plasma cells within their cytoplasm Fig. 6A)

may show displacement of adjacent normal vessels, a focal capillary blush or venous pooling. This apparent avascularity is deceptive as the lesions bleed profusely during surgery. Occasionally, feeding arteries including the meningohypophyseal trunk, artery of the inferior cavernous sinus, the middle meningeal artery and the accessory meningeal artery have been identified. MRI may show an isointense to mildly hyperintense lesion on the T1-weighted image, markedly hyperintense on T2-weighted images, enhancing brilliantly with contrast administration (Fig. 7). The intensity pattern may vary. The lesion may have a reticulated core of mixed intensity with a surrounding rim of decreased intensity on T2-weighted images caused by haemosiderin-laden macrophages. The lesion may contain foci of haemorrhages with resultant intensity variations depending upon the age of haemorrhage.

Fig. 7: Cavernous angioma of the cavernous sinus: Contrast enhanced T1-weighted MRI shows a uniformly enhancing lesion in the cavernous sinus surrounding the ipsilateral cavernous internal carotid artery

Surgical excision may cause extensive haemorrhage. The surgery is facilitated by proximal internal carotid artery control in the neck or the petrous segment, preparation for extracranial-intracranial bypass, incising the dura between the III, IV, V cranial nerves, early devascularisation of the lesion by coagulating its blood supply, developing a plane of cleavage between the pseudocapsule formed by the inner and outer layers of the dura, and avoiding piecemeal dissection. The VIth nerve and internal carotid artery, being intracavernous, have to be skeletonised from the tumour. Frontotemporal craniotomy with orbitozygomatic osteotomy with drilling of medial sphenoidal wing and anterior clinoids, facilitates the exposure.[6,30,39] A course of pre-operative radiation has been recommended to help shrink the lesion and reduce its vascularity.

MISCELLANEOUS TUMOURS

A few very rare tumours which may arise in the sellar-parasellar region include:

Schwannomas

Schwannomas may arise from the cranial nerves of the cavernous sinus, especially the trigeminal nerve and may secondarily involve the sellar region. Although a few cases of purely intrasellar schwannomas have been reported in literature, they are extremely rare. The current histopathological hypothesis for the origin of these lesions include perivascular or ectopic Schwann cells, lateral nerve plexus within the cavernous sinus, as well

Fig. 8A: T1-weighted contrast enhanced sagittal image showing the heterogeneously enhancing giant cell tumour of the sphenoid occupying the entire clivus, sphenoid and sella

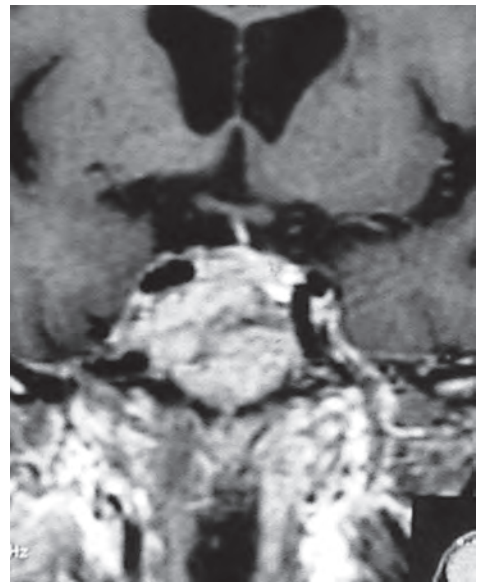


Fig. 8B: T1-weighted contrast enhanced coronal image showing the same lesion

as Schwann cells from small nerve twigs of the dura. These tumours may mimic pituitary adenoma clinically, endocrinologically and radiologically. Intrasellar schwannomas presenting with hypopituitarism, hyperprolactinaemia and visual disturbance due to chiasmal compression have been reported.

Giant Cell Tumours of the Sphenoid

These constitute 3–7% of primary bony neoplasms. Involvement of the skull is rare and occurs in less than 1% of cases of giant cell tumours and occurs in the sphenoid and temporal bones, reflecting the genesis of these bones through endochondral calcification. CT scan showing an expansile lytic lesion in the body of sphenoid or temporal bones, with marked contrast enhancement, is characteristic of this lesion. MRI reveals a low to moderate signal intensity on T1- and T2-weighted images (Figs 8A and B). Haemorrhage within the tumour may produce high signal intensities on both the sequences. A "soap bubble" image may be seen on the T2-weighted image.[7]

The histological features include oval, undifferentiated mononuclear cells with evenly dispersed, large multinucleated giant cells (Fig. 8C), with closely packed nuclei in them.

Giant cell tumours display aggressive local behaviour. Soft tissue extension may compromise vital neurovascular structures. Dural penetration, cerebral invasion and sarcomatous change may occur. The ideal treatment is wide local excision with a good margin of healthy tissue. In case of local recurrence, local resection is safer than radiotherapy. However, in many cases, radiotherapy following surgery has achieved good local control without tumour recurrence or malignant transformation.[7]

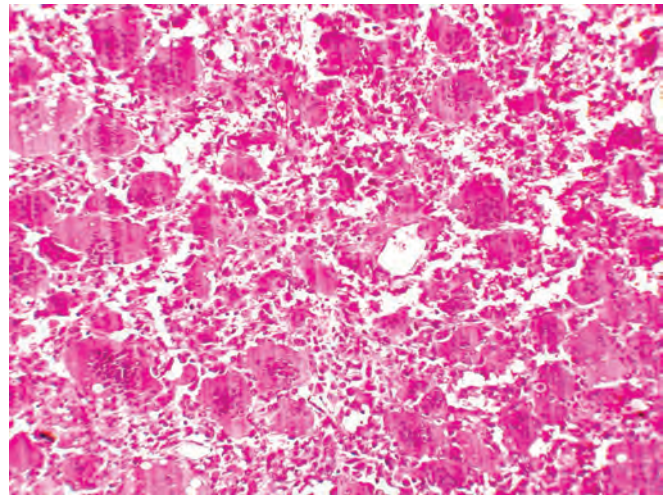

Fig. 8C: Giant cell tumour of the sphenoid: Tumour is consisting of uniformly distributed giant cells surrounded by round to oval mononuclear cells that lack cytological atypia. (H and E × 100 original magnification)

Paragangliomas

This tumour is very rare in the sellar area where there are no paraganglionic cells. The cellular origin of these tumours is thought to be from the paraganglionic tissue rests which persist from early pituitary embryogenesis.

Glomangiomas

These are tumours which arise from glomus bodies and typically affect the nail beds. Intrasellar glomangiomas are extremely rare and two cases have been reported in literature.

Lipomas

Lipomas may present as suprasellar masses. They generally arise from the hypothalamus or tuber cinereum and extend downwards. Hypothalamic dysfunction and secondary hypopituitarism may occur in these cases.

Primary Melanoma

Only a few cases of primary melanoma of the pituitary gland have been reported. They may arise from melanin containing cells of the posterior pituitary or from the meninges overlying the diaphragma sellae.

Angiofibroma

It is a benign tumour that tends to bleed and occurs in the nasopharynx of prepubertal and adolescent males. The lesion occurs commonly in the second decade with the age ranging 7–19 years. The tumour starts in the nasopharynx and pterygopalatine fossa. The rare superior growth is directed towards the sphenoid sinus, cavernous sinus and sella. Occasionally, the greater wing of the sphenoid may be eroded, exposing the middle fossa dura. Proptosis and optic nerve atrophy result if the orbital fissures are encroached upon by the tumour. Nasopharyngeal angiofibroma is usually encapsulated and composed of vascular tissue and fibrous stroma, with coarse or fine collagen fibres. Vessels are thin-walled, lack elastic fibres and have absent or incomplete smooth muscle. Stromal cells have plump nuclei and tend to radiate around the vessels. There is an abundance of mast cells in the stroma and a lack of other inflammatory cells. Localised areas of myxomatous degeneration may be observed in the stroma. Pre-operative embolisation and radiotherapy may reduce the vascularity and the size of the lesion. Surgery usually aims at complete excision but exsanguinating haemorrhage from the tumour may often be encountered during its surgical excision.[42]

Esthesioneuroblastoma

This is a neuroblastoma arising from the olfactory epithelium invading the skull base, cranial vault, orbit, sphenoid sinus and sellar area (Fig. 9). On histology, there is a lobulated structure with sheets of cells having poorly defined cytoplasm and round to oval nuclei in a densely neurofibrillary background. Sometimes, olfactory rosettes or pseudorosettes may be present. Surgery followed by radio and chemotherapy provides relief but local recurrences and metastasis are frequent.

Fibrous Dysplasia

This consists of proliferative connective tissue, causing thickening of bones (Fig. 10). There are three forms: (1) Compact form is a dense thickening of bone, especially of the skull base, resulting in ground glass appearance. It may cause stenosis of the optic foramen, superior orbital fissure, shallow orbits with proptosis, sellar and

Fig. 10: Fibrous dysplasia: Coronal CT scan showing the ground glass appearance of an extensive lesion that is expanding the inner and outer skull tables and extending to the sellar-suprasellar region. These patients may present with hypopituitarism due to sellar involvement

sphenoid involvement causing hypopituitarism and expansion of the temporal bone and greater wing of the sphenoid. (2) Lytic form takes the shape of a radiolucent area limited by a thin sclerotic line. (3) Pseudo pagetoid form is characterised by both sclerotic and radiolucent forms. The lesion stabilises after the age of 25–30. There is a small risk of malignant transformation.

This chapter summarises the salient features of some rare sellar-suprasellar lesions that should always be considered in the differential diagnosis, along with

the commonly seen lesions such as pituitary adenomas, craniopharyngiomas, meningiomas, astrocytomas and epidermoids.

158 Craniopharyngioma

SN Bhagwathi, Suresh Sankhla

INTRODUCTION

Craniopharyngiomas are the most common intracranial tumours of non-glial origin in children.[50,115,248] As a group, they have been among the most challenging and difficult tumours for neurosurgeons to treat. These neoplasms arise from cell rests from the remnants of Rathke's pouch and are histologically benign. Although a number of terms including ameloblastoma, adamantinoma, epidermoid, Rathke's pouch tumour, craniopharyngeal duct tumour, hypophyseal duct tumour, epithelioma and interpeduncular cyst have been used in the past to describe this tumour, the commonly used term "craniopharyngioma" was first coined by McLean[194] in 1930, and Frazier and Alpers[81] in 1931. Cushing[56] adopted the same nomenclature in 1932 and stated that "this admittedly cumbersome term has been employed for want of something more brief, to include the kaleidoscopic tumours, solid and cystic, which take their origin from epithelial nests ascribable to an imperfect closure of the hypophyseal or craniopharyngeal duct".

HISTORICAL PERSPECTIVE

In 1838, Rathke[234] first noted the significance of a globular, somewhat irregular depression, like a thin walled diverticulum (Rathke's pouch), lying posteriorly in the roof of the primitive mouth under the developing skull base, which was later to form the pituitary gland. Zenker[318] was the first to identify in an autopsy study in 1857, masses of squamous epithelium located along the pars distalis and pars tuberalis. In 1860, Luschka[182] performed an extensive autopsy study of the squamous epithelial cell rests in the hypophyseal area and noted that they existed as group of islets varying in number in different individuals, but were larger in elderly people, suggesting an increase in size and number with age. An increase in the frequency of squamous cell rests with age has also been observed by others.[95,183] Carmichael[43] found that the majority of these cell rests were located in the superior portion of the pars distalis and in the lower third of the pars tuberalis. Erdheim,[72] in 1904, first proposed the commonly held view that these cell rests give rise to tumours. However, these cells are usually scanty or not present during childhood and adolescence, the most common age for these tumours. Hunter[124] suggested that these cells are probably formed by metaplasia of pituitary glandular cells. Due to the different behaviour patterns of tumours in children and adults, Kahn[137] suggested that adult tumours arise in adult life and have not been present since birth or childhood.

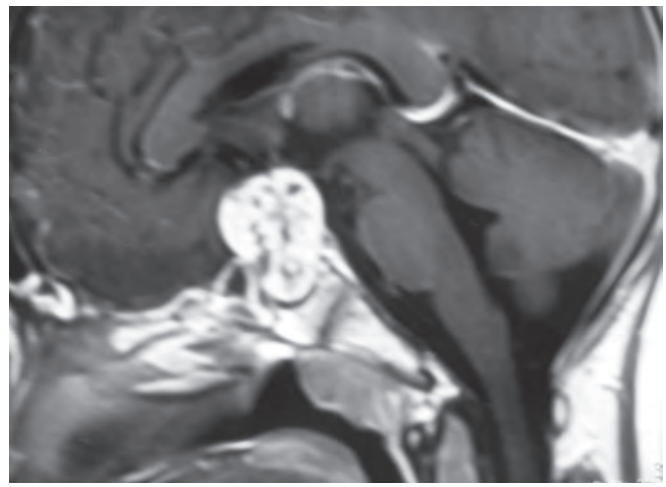

Fig. 1: Magnetic resonance imaging showing suprasellar lesion going totally into the sella

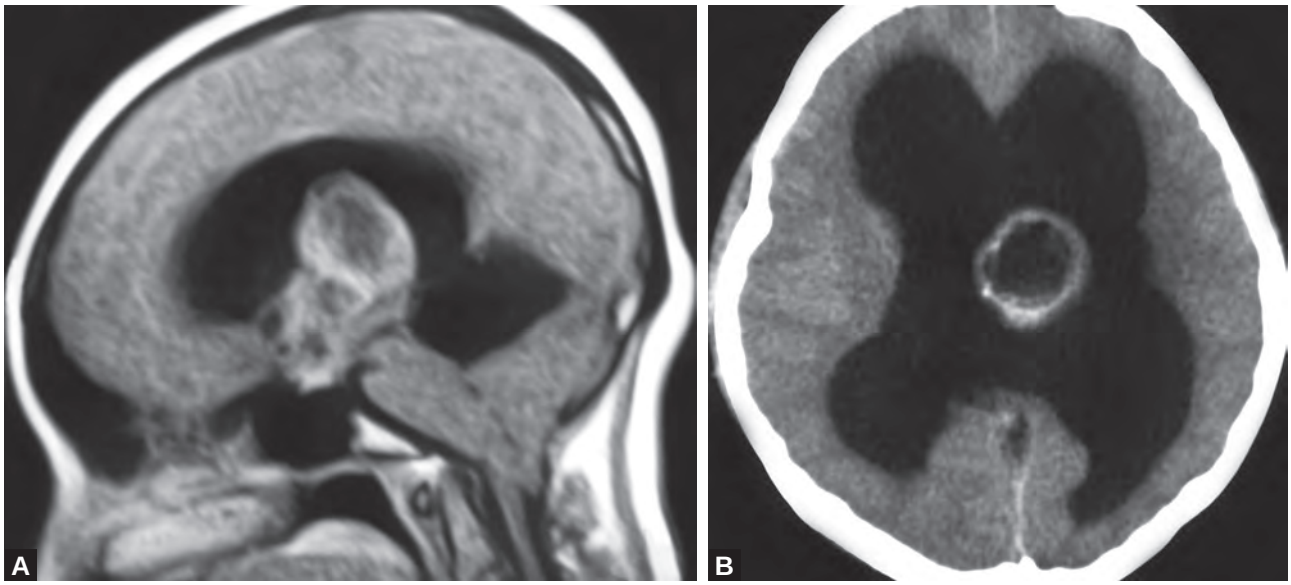
PATHOLOGY

Craniopharyngiomas are most frequently cystic tumours or have a large cystic component, although sometimes they can be entirely solid or may present as a solid rock of calcium.

These tumours are located mainly in the suprasellar region, as the site of origin is usually along the infundibulum at the floor of the third ventricle. As the tumour enlarges, it often extends into the sella inferiorly and elevates the floor of the third ventricle superiorly or it may develop preferentially in one direction (Fig. 1).

Tumours restricted to the sella or the third ventricle has been well documented. Intrasellar tumours are least common and were found in three out of 27 cases by Northfield[212] and a 10–15% incidence is reported by others,[215,275] while a predominantly sellar location is reported in 33% of the cases by Love et al.[177] An intrathird ventricular location has frequently been reported,[45,68,96,129,160,176,199,222] although Hoffman[116] feels that many of these are primarily retrochiasmal tumours, which have grown into the third ventricle (Figs 2A and B).



Figs 2A and B: (A) Sagittal view of magnetic resonance imaging showing a totally intraventricular craniopharyngioma. (B) Showing the same in axial view

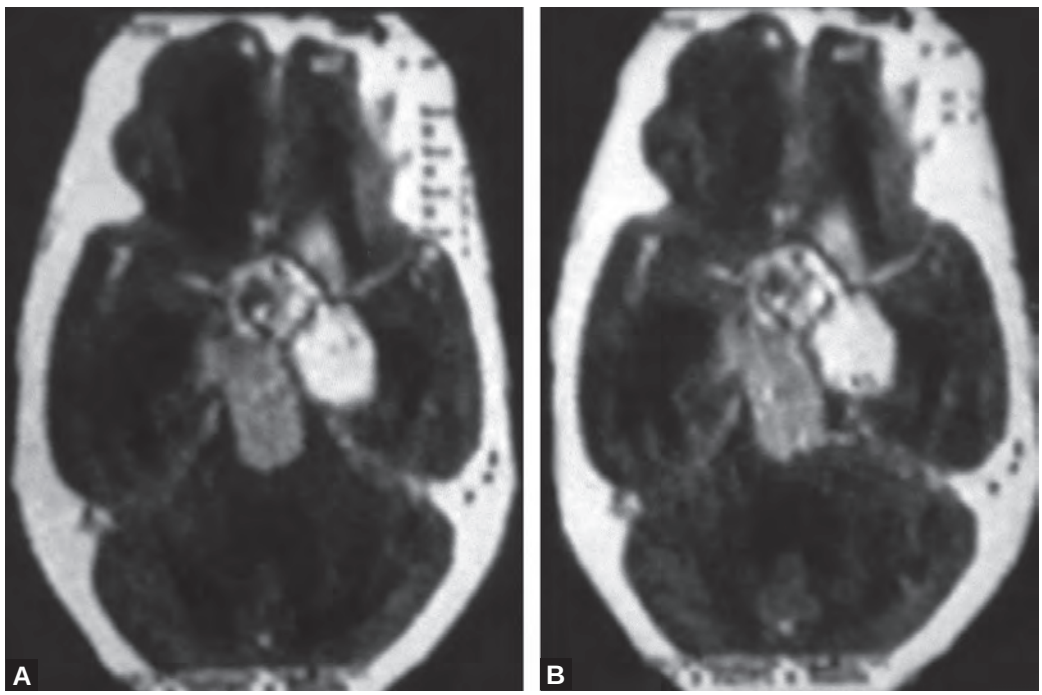
The size of the tumour varies from a centimetre in diameter to large tumours occupying the anterior and middle fossae. Involvement of the posterior fossa is also well known[94] (Figs 3A and B) and as many as 12% of the 245 craniopharyngiomas studied at the Armed Forces Pathology Institute had posterior fossa extension. Posterior extension has also been observed in the pineal region by Baskin et al.[21]

Ectopic craniopharyngiomas have been observed in the cerebellopontine angle[6,84] and even in the calvarium and the epidural space, along the tract of previous surgery.[187,229] Two unconnected craniopharyngiomas, one in the suprasellar and the other in the third ventricle, have been reported in one patient.[297]

Invasion of the skull base was seen in two of our cases (Fig. 4).

Invasion of the sphenoid bone,[54,223,297] nasopharynx,[25,77,186,204] the orbit[41] and the cavernous sinus[61] has also been reported. A rare case has been reported by Block et al.[32] where the tumour extended into both optic canals causing enlargement of the optic foramina.

Growth of the tumour superiorly into the third ventricle can cause blockage of one or both foramina of Monro, leading to hydrocephalus. A few years ago,



Figs 3A and B: CT scan showing extension of craniopharyngioma into the posterior fossa in the axial view

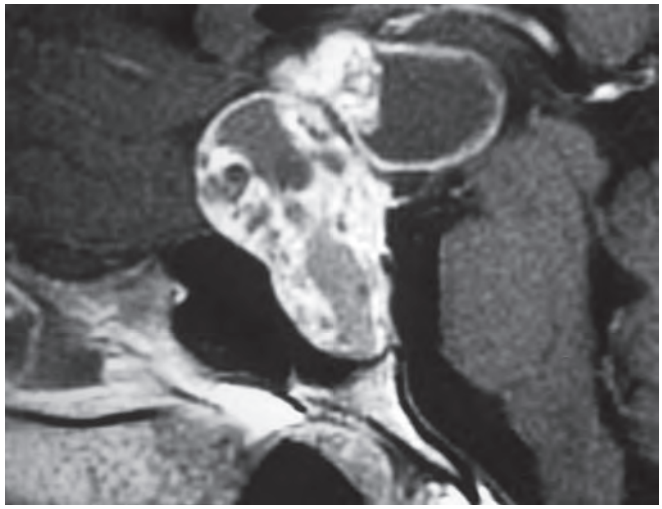


Fig. 4: Magnetic resonance imaging showing destruction of the sphenoid sinus by the tumour

an unpublished CT scan study from Mumbai showed superior extension of the tumour in 87% of patients and resultant hydrocephalus in 67%. Rarely, communicating hydrocephalus may be caused in these patients due to chemical meningitis.

The outer surface of the tumour is greyish pink in appearance. It is often irregular and adherent to the surrounding structures. A layer of arachnoid separates the tumour from almost all the structures, except in the region of the tuber cinereum. Calcification in the wall of the cyst is a common feature. The cyst contains chocolate-coloured fluid with shimmering cholesterol crystals ("machine oil" fluid). Occasionally, the cyst fluid may be lighter in colour, mildly xanthochromic or even watery. The cholesterol is derived from the epidermal layer lining the cyst. Histochemical investigations reveal such a secretion in a microcyst and electron microscopy has demonstrated zymogen granules in the epithelial cells, suggesting a secretory function to these tumours.[282] The immunohistochemical distribution of the subunits of S100 proteins for these tumours had shown them to be S100 alpha (+ve) and beta (–ve) (like pituitary adenomas and pinealomas).[100] Insulin like growth factors have been demonstrated in the cyst fluid in craniopharyngiomas.[319] Immunocytochemistry of the tumour, for pituitary hormones, has shown positivity for at least one hormone in the majority of the cases.[283] Carbohydrate moieties, such as those of blood group antigen and also those reported to be found in human skin epidermis, exist in a similar form in craniopharyngioma, epidermoid and Rathke's cleft cyst.[209]

Histologically these are epithelial tumours, the cyst being lined by simple stratified squamous epithelium over a collagenous basement membrane. The tumour enlarges by desquamation of epithelial debris, formation of cyst fluid and simple cellular proliferation. The growth of the tumour, therefore, is generally slow. However, there is experimental evidence that the craniopharyngioma cells are really neoplastic and this may explain rapid growth or recurrence in some.[210] Calcification is common on histology and is reported in over 90%.[41] Occasionally, the whole tumour may be calcified.[62] Calcification is more common in the paediatric age group than in adults.

Adamson et al.[1] correlated the clinical and pathological features in 107 craniopharyngiomas and noted two different types: either a classic adamantinous or a squamous papillary structure. The solid, uncalcified squamous papillary type of tumour was found in one third of the adult patients and not in children. It was associated with good functional outcome after surgery and showed no recurrence.

The blood supply of a craniopharyngioma is the same as that of the diencephalon, as it evolves from the embryological remnants of Rathke's pouch.[161,168] Pertuiset[221] has summarised the arterial supply of the tumour. Two branches arising on each side from the intracavernous portion of the internal carotid or the inferior hypophyseal arteries supply the intrasellar portion of the tumour. The suprasellar portion receives its supply anteriorly from branches coming off the anterior cerebral and the anterior communicating arteries and laterally on either side from branches of the posterior communicating arteries. They do not receive blood supply from the posterior circulation, except when the tumour is intraventricular or very close to the floor of the third ventricle, when the arterial supply arises from the proximal posterior cerebral arteries.

Other Epithelial Cysts in the Suprasellar Region

Other types of epithelial tumours may occur in the suprasellar region, namely, epidermoid cysts, Rathke's cleft cysts, arachnoid cysts and germinomas. Epidermoid cysts develop within the region of the infundibulum or tuber cinereum, from small nests of squamous epithelial cells which border on the pars tuberalis. They contain kerato hyaline material.

Rathke's cleft, separating the anterior (pars distalis) from the posterior (pars intermedia) part of the pituitary, is lined by cuboidal or columnar epithelium, which may be ciliated and contains mucus secreting glands. Cystic transformation of the cleft results in Rathke's cleft cyst.[23,27,53,69,75,82,93,239] They have also been described as pituitary,[8,207,235,264,312] colloid[244] or intrasellar epithelial cysts.[86,262] Gillman[92] and Shanklin[256] reported that they are found in 13.22% of normal pituitary glands. The morphological study carried out with light and electron microscopy and tissue culture by Yoshida et al.[315] suggests that they are similar to the prickle cells seen in the epidermis, and craniopharyngiomas and Rathke's cyst, therefore, have the same origin, although they may show histological differentiation. They generally contain mucoid material within, although occasionally, larger collections of xanthomatous cells like in a colloid cyst[311] and subepithelial tissue comprised of pituitary gland cells may be seen.[127] Rarely abscess formation[33,266] and haemorrhage[214] within the cyst have also been

reported. They are generally less than 3 cm in size, remain clinically asymptomatic and have a favourable prognosis.[73,241,278,307] Occasionally, however, they cause chiasmal syndrome, hypopituitarism[241] and, rarely, periodic fever due to chemical irritation and meningitis.[213,269,302] Acute adrenal insufficiency has also been reported.[286]

Arachnoid cysts may be congenital (or primary) or acquired.[267] Congenital or true cysts may be an outpouching of the membrane of Liliequist, while acquired ones are usually the result of trauma, haemorrhage or inflammation. However, arachnoid cysts occurring in the chiasmal region are still a subject of controversy, both in respect of their aetiopathology and anatomical definition.[67] Anatomically, two groups can be identified: suprasellar (developing above the diaphragma sellae) and intrasellar (within the sellar cavity). The true cyst is suprasellar, while varying degrees of outpouching may occur into the sella through the central opening in the diaphragm to form an intrasellar cyst. Pure intrasellar cysts are extremely rare and may result from a maldevelopmental splitting of the arachnoid membrane within the subdiaphragmatic cistern and it may rarely be symptomatic.[107]

Germinomas or ectopic pinealomas located in the infundibular region are identical to the atypical teratomas of the pineal gland and are morphologically similar to the germ cell tumours of gonadal origin, viz. testicular seminoma.[105,245] The suprasellar germinoma is usually situated beneath and behind the optic chiasm, which it both displaces and infiltrates as it spreads along the optic nerves and tracts to extend into the infundibulum and hypothalamus.[230] Precocious puberty, diabetes insipidus and other hypothalamic manifestations are commonly seen and, like other intracranial germinomas, they may sequestrate or spread to different sites.

INCIDENCE

Craniopharyngiomas are one of the most common intracranial tumours of childhood, forming 9% in Matson's series of paediatric tumours.[192] They formed 6% of tumours at the Hospital for Sick Children in Toronto.[118] However, they account for only 2.5–4% of intracranial tumours at all ages.[50,142,246] Indian reports show a prevalence of 3.9% of all intracranial tumours, forming 12–16% of tumours in childhood.[62,227,232,287] Dastur et al.[59] in a consecutive series of one thousand tumours, found craniopharyngiomas to account for 2.6% of all intracranial neoplasms and 16.8% of all intrasellar tumours. Selby and Pereira[251] also found craniopharyngiomas to be more common in children in Malaysia. A higher incidence is also reported from Japan, where they form 8% of intracranial tumours at all ages.[5,7]

A bimodal age distribution is seen for these tumours at presentation, with the first peak between 5 years and 10 years and the second between 55 years and 60 years.[18,39,153] Tumours may rarely develop in foetal life[87,89,130,230] and can now be diagnosed by ultrasound and MR in intrauterine life.[15]

Seventy per cent of craniopharyngiomas occur below the age of 20 years.[138,306] Eighty-five per cent of our 122 cases were under 20 years of age, the youngest patient being one and a half years old, while the oldest was 62. Males predominated 3:2. Equal sex distribution has been reported in most other large studies.[41,117] The symptoms and signs depend on the direction of the growth of the tumour: optic apparatus anterosuperiorly, hypothalamus posterosuperiorly, pituitary gland inferiorly and brainstem posteriorly.

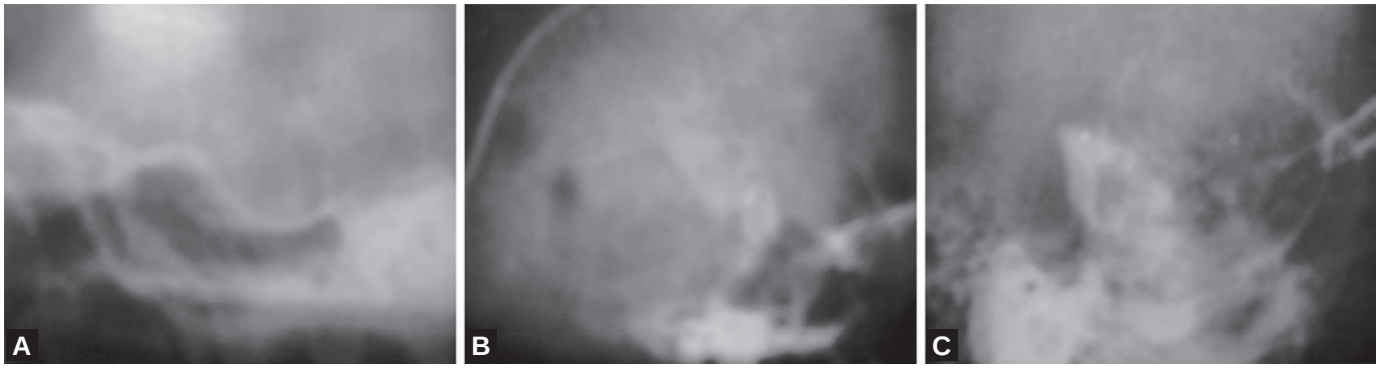
CLINICAL FEATURES

The most common triad of presenting symptoms in a child with craniopharyngioma is: (a) visual failure due to compression of the optic nerves, chiasm or tracts; (b) hormonal disturbances, most frequently growth hormone (GH) or antidiuretic hormone (ADH) deficiencies and (c) raised intracranial pressure, usually a result of large tumour mass, obstructive hydrocephalus, or both. The symptoms of hypothalamic disturbances including obesity and somnolence may be seen in large tumours.

Symptoms and signs of raised intracranial pressure predominate in children and endocrinological deficits in adolescents. Visual symptoms predominate in adults,[19,112,250] while the elderly present with mental disturbances. Although only a few children complain of visual problems, clinical examination may show visual disturbances in the majority.[52] The discrepancy between symptoms and signs in the paediatric age group is due to younger children not noticing visual impairment or a field defect. Apart from incomplete temporal field defects, diminished visual acuity, papilloedema and optic atrophy are seen in many children. Jawahar et al.[131] found some visual loss in 84% and either primary or secondary optic atrophy in 74%. Only 5% of the children had normal vision, emphasising late referrals. An aetiological profile of optic atrophy in India, in 1992, has shown craniopharyngioma to be the most frequent tumour responsible for bilateral optic atrophy before the age of 20 years.[197]

It is felt that, in India, the clinical differences between adults and children get blurred, mainly because of late presentation.[299] Fifty-three per cent of children and 76% of adults in our series had diminished vision and over 80% of children and 66% of adults had optic changes. Four children and one adult were blind in one eye. Blindness is uncommon, although still occasionally encountered. Others have reported similar experience.[63,203,243] Retrochiasmal tumours do not cause any visual signs and symptoms apart from papilloedema.[28]

Involvement of extraocular muscles has been reported infrequently. It was seen in 10 of our cases. Nystagmus and oculomotor paresis have also been reported.[296] Exophthalmos [65,202] and internal ophthalmoplegia[83] may occur rarely.



Figs 5A to C: (A) Plain X-ray skull showing enlarged sella with erosion of posterior clinoids. (B) Plain X-ray showing rim of calcification above the sella. (C) Plain X-ray showing dense suprasellar calcification of craniopharyngioma

Endocrine Manifestations

About a third of the patients are stunted, although somatotrophic function is found to be deficient in 90–100%. The second most common manifestation is delayed sexual development. Precocious puberty is extremely rare with craniopharyngiomas (4%), in contrast to other suprasellar tumours like hamartomas and germinomas. This is because craniopharyngiomas extend usually anterosuperiorly, unlike the other lesions which commonly spread posterosuperiorly into the hypothalamus. In adults, gonadal failure leads to loss of libido and secondary amenorrhoea can occur.[221] Obesity may be seen, but the emaciation syndrome common to hypothalamic tumours is extremely rare.[254,255] Diabetes insipidus was noted in only 14% pre-operatively, while it is a more common presenting feature in germinomas and histiocytosis. Hypothyroidism, hypocortisolaemia or panhypopituitarism are very rare. Disturbance of consciousness, viz. coma or hypersomnolence is due to raised intracranial pressure, rather than involvement of the hypothalamic sleep-awake mechanism. An extremely atypical presentation, like pituitary apoplexy, has also been reported.[191,225]

Neurobehavioural disorders are uncommon in children, but are a fairly common presenting feature in adults and the elderly.[19,20,39,50,221] These are due to either subfrontal extension of the tumour or to hydrocephalus and often appear before other signs of raised intracranial pressure develop.[247] They usually comprise of intermittent confusion, hypersomnia, dementia, apathy, severe depression and Korsakoff's syndrome.[138,177] A rare presentation, with intermittent explosive speech disorder, has also been reported.[294]

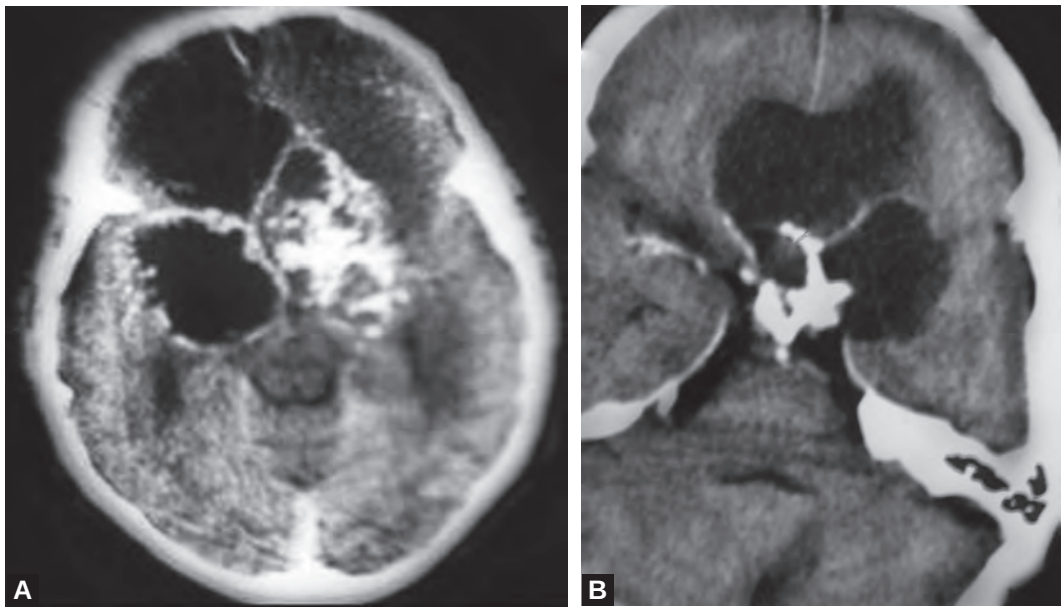
In very slow growing tumours, pressure on the cerebral peduncle may cause hemiparesis or paraparesis; pressure posteriorly on the brainstem may result in a broad based gait and ataxia, simulating a midline cerebellar tumour.[14,138,177] Aseptic meningitis has also been observed as a rare presentation of craniopharyngiomas, presumably from a leakage of keratin or cholesterol.[162,190,218,219]

Trigeminal neuralgia has also been reported as the first manifestation in a craniopharyngioma.[90] Occasionally, it may be revealed during investigations for unrelated problems, viz. head trauma.[257]

IMAGING

In spite of new modalities of imaging, plain X-rays of the skull continue to be useful in the workup of a patient suspected to harbour a craniopharyngioma (Figs 5A to C).

These are often diagnostic, especially in children. The characteristic feature is the presence of irregular, speckled calcification just above the sella turcica. Such calcification was reported in 96% of Matson's cases[193] and in 66% of cases reported by Kanaka and Ramamurthi.[138] Another type of calcification, seen less frequently, is the semicircular shell outlining the wall of a cystic lesion. Varadarajan et al.[303] reported that the density of calcification is low in Indian subjects. Calcification is much less common in adults.[19] In the authors' series, 80% of skull X-rays in children showed calcification, while it was seen in only 25% in adults. However, Sambisivan and Pillai[250] noted calcification in 60% of adults. Rarely, small specks of calcium may be seen only inside the sella. Fine flaky calcium is encountered with fast growing tumours, while slow growing tumours show dense calcification.[20,133] Other sellar changes include a ballooned sella and decalcified or eroded clinoids. In India and other developing countries, suprasellar calcification due to healed tubercular meningitis may simulate a calcified craniopharyngioma.[138] The calcification in these cases is commonly in the leptomeninges or, occasionally, in the brain parenchyma rendered ischaemic by tubercular arteritis. In elderly patients, a calcification in the wall of an aneurysm or the carotid artery may simulate tumour calcification. Sutural diastasis and even silver beaten appearance of the skull are seen in an advanced stage of the disease in children.



Figs 6A and B: CT scan images showing multicompartmental multicystic lesions with calcification in a craniopharyngioma

Computed tomography (CT) is probably the most useful investigation for evaluating these calcareous tumours.[38] A typical craniopharyngioma would show a cyst with a partially calcified contrast enhancing capsule (Figs 6A and B).

Solid portions containing calcium and isodense areas with some enhancement on contrast may be seen in solid tumours, but more commonly a mixed picture containing solid and cystic areas of varying degrees is seen. Effacement of the suprasellar cistern is seen frequently and compression of the third ventricle may be observed in larger suprasellar tumours. Distortion of the interventricular foramina may result in unilateral or bilateral lateral ventricular dilatation. This is more common in craniopharyngiomas than in pituitary adenomas.[184] Density of the cysts on the CT scan may vary from that of water to that of the brain, depending upon the content of cholesterol and other components within it. A cyst containing high protein appears isodense to hyperdense, while occasionally, keratin may have a lower density than water. Rarely, there may be layering within the cyst, cholesterol lying superiorly because of its low density. Calcification is seen more frequently in the CT scan than in plain X-rays.[279]

The cystic component in the tumour is more often seen in children than in adults, as is the enhancement of the tumour on contrast CT.[285] Coronal CT helps in defining the superolateral relationship with the optic pathways and the hypothalamus; sagittal reconstruction is useful in confirming the retrochiasmal location of the tumour.

Pituitary adenomas, meningiomas, giant aneurysms, optic and hypothalamic gliomas, arachnoid cysts, tuberculomas, and hamartomas occurring in the suprasellar region can pose problems in differential diagnosis. However, most of these lesions have distinguishing features and in difficult cases, other modalities, like dynamic CT, CT cisternography, MRI and MR angiography, are extremely helpful to clarify the diagnosis. CT scan is more reliable than MRI in detecting calcification.[66] The characteristic features of craniopharyngiomas, tumour cyst, calcification and enhancement on contrast administration are seen in over 75% of cases.[77,195] Singh and Chandy[263] have proposed a CT classification system for craniopharyngiomas, based on the extent and contents of the tumour, in order to facilitate proper planning of surgery and analysis of results.

Magnetic resonance (MR) imaging of craniopharyngiomas requires both T1- and T2-weighted images obtained in the sagittal, coronal and axial planes to determine the extent of the lesion and its relationship to the surrounding vital structures. The sagittal and coronal images are sensitive for evaluating the chiasm and its relationship with the tumour, and the signal characteristics depend upon the contents.[252] The usual cystic lesions, with a predominantly cholesterol content, are hyperintense on T1- and relatively hypointense on T2-weighted images. The cystic lesions predominantly containing keratin are hypointense on T2-weighted images, resembling water. The solid lesions are isointense to hypointense on T1- and turn isointense to hyperintense on T2-weighted images. Occasionally, the tumours are very heterogeneous, showing a solid-cystic appearance or a fluid level of cholesterol/keratin. A quantitative analysis of the cyst fluid and correlation with MR showed that the increased signal intensity of the cyst fluid on T1-weighted images is caused by a protein concentration of 9,000 or more mg per cent or the presence of methaemoglobin, while cholesterol and triglycerides do not increase the signal intensity.[2]

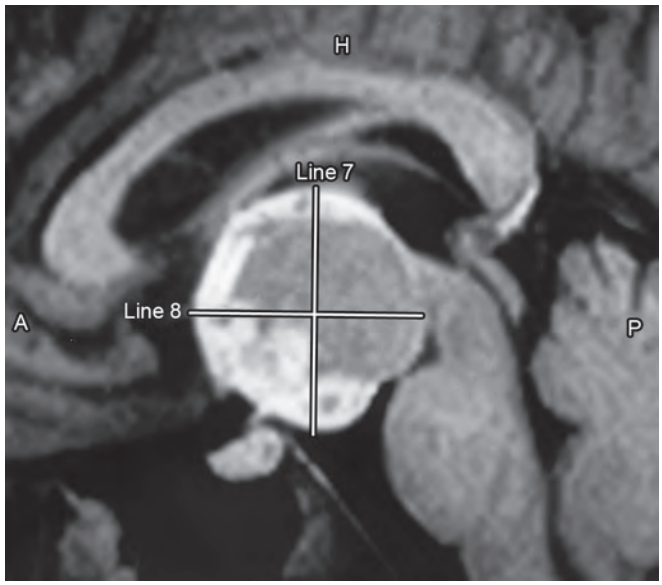


Fig. 7: Magnetic resonance imaging showing a large heterogeneous craniopharyngioma on contrast administration

Calcium in the lesion may be visualised as areas of signal dropout. Occasionally, calcium cannot be appreciated on MR, particularly if it is finely dispersed thoughout the tumour or is of a thin capsular type. Enhancement with Gd-DTPA is seen in the non-calcified solid portion of the tumour (Fig. 7).

Perifocal oedema along the optic pathways, causing a unique characteristic 'moustache' appearance, has been observed infrequently with certain craniopharyngiomas.[111]

Intraventricular craniopahryngiomas are not associated with tumoural calcification or cyst formation and are isointense on T1, hyperintense in T2 and enhance homogeneously with contrast.[125,247] Chiasmal thickening with pot belly expansion and a bilobed shape of an intraventricular tumour on the MR have been described.[85,249]

Although, generally it is possible to differentiate a pituitary adenoma with suprasellar extension because of its sellar origin and lack of calcification, it may be difficult on MR to differentiate adenomas with apoplexy from a craniopharyngioma. The signal characteristics due to haemorrhage are of a mixed intensity and may resemble a cholesterol containing craniopharyngioma.

Pituitary microadenomas, after treatment with bromocriptine may also cause difficulty in differentiation from an intrasellar craniopharyngioma, as they also contain haemorrhagic products. Rathke's cleft cyst is another lesion which may be indistinguishable from a cystic craniopharyngioma, due to its similar diverse location and signal characteristics.[241] Arachnoid cysts and an empty sella will show CSF intensity on all images and there is usually no distortion of the infundibulum. Non-neoplastic cysts and cystic craniopharyngioma and astrocytoma can further be differentiated by the administration of contrast (Gd-DTPA), where cyst wall enhancement is characteristic of the neoplastic cyst. Any confusion that may arise due to enhancement of normal pituitary tissue surrounding a non-neoplastic cyst can be cleared by dynamic studies, which show rapid enhancement in the early post-contrast period only in the neoplasm.[122] Chiasmal-hypothalamic gliomas in children can be differentiated by the demonstration of enlargement of the chiasma, spread along the optic nerves and tracts, predominantly solid tumour with microcysts, lower T1 and T2 relaxation times and homogeneous enhancement on administration of contrast.[257] Parasagittal imaging can further help in differentiation by demonstrating the lesion to be intra-axial or extra-axial. Occasionally, it may be extremely difficulty to distinguish between the two lesions.[36,316]

The presence of diabetes insipidus in conjunction with the MR findings of a well marginated round and lobular tumour, with prolonged T1 and T2 relaxation time and strong enhancement, characterise suprasellar germinomas, while teratoma can be differentiated on the basis of their internal heterogenicity with the presence of fat, calcium and various soft tissue densities.[150] Hamartomas, arising in the region of the tuber cinereum, usually project posteriorly into the interpeduncular cistern and may be difficult to differentiate from the solid non-calcified retrochiasmal craniopharyngioma.

Vascular lesions can easily be differentiated from the tumour on MR, because of their characteristic flow void on all imaging sequences. A thrombosed aneurysm may occasionally pose difficulty, because of its varied signal intensity, although the classical lamellated pattern of the thrombosis and no signal changes in T1 and T2 images should be helpful in distinguishing between the two. Further studies, with oblique imaging sequences, may demonstrate its exact relationship with the parent artery. MR angiography may be required, occasionally, for differentiation in difficult cases and is also very useful to study displacement and the relationship of the tumour to the basilar and carotid arteries and the circle of Willis.

Contrast angiography may occasionally be required, especially if facilities for MR and MRA are not available. It can also be useful for studying the circle of Willis, especially the pattern of dominance in the anterior cerebral arteries and the usefulness or otherwise of the anterior communicating artery, as it may have to be occasionally sectioned for radical removal of a retrochiasmal tumour.[155,275] Classical angiographic appearances of craniopharyngioma are of a sellar, suprasellar mass with some parasellar extension. Usually there is opening of the carotid siphon and the supraclinoid ICA is vertically oriented with lateral displacement and varying degrees of narrowing, while the A1 segments of the anterior cerebral arteries are often elevated.[47,60]

TREATMENT

Aims of Treatment

The treatment of craniopharyngioma should be aimed at reversing or halting progression of symptoms and

prevention of tumour recurrence, while leaving the child's physical, visual, hormonal and intellectual state at an acceptable functional level.[29] The modalities of treatment that may be employed are: (a) Surgery, which may include radical removal, partial removal or simple drainage of the cyst. It may be a staged procedure, especially if total excision is planned for a large tumour, to try and avoid hypothalamic damage. (b) Radiotherapy, external beam fractionated radiation or stereotaxic radiotherapy (SRT) for residual tumours or tumour recurrences.

Pre-Operative Evaluation and Management

Complete endocrinological evaluation is done to establish a baseline and to uncover hypopituitarism, especially with respect to growth hormone, cortisol and thyroid hormones. These need corrections throughout the course of management. Corticosteroid replacement is done and diabetes insipidus treated with DDAVP. Even in the absence of specific complaints, diabetes insipidus should be excluded by appropriate investigations. As thyroid replacement takes several days to two weeks with oral L-thyroxin, intravenous therapy may be given if the patient needs immediate surgery. This has to be done very carefully in elderly patients, as it may produce arrythmias and acute myocardial ischaemia.[217]

Dilemmas in Management Decisions

The treatment of a patient with craniopharyngioma calls for a wise and correct decision that will help the patient in the long run to play an appropriate social role.

Many controversies still exist in the management of patients with craniopharyngiomas. Should the tumour be totally excised? Is such excision feasible or desirable and will this cause problems in the long run? Or is subtotal excision safer and preferable from all points of view?

How much tumour removal is subtotal removal? Between these two alternatives, in which procedure are hormonal disturbances minimal? Will hormone replacement over many years become necessary and if so, can the patient or his family afford such long-term therapy?

If subtotal excision is advised, what are the chances of tumour recurrence? Does radiotherapy minimise recurrence and minimise hormonal dependence? What could be the ill effects of radiation near the base of the brain in children? In small tumours, will radiotherapy alone be effective to control further growth? These are the questions that face the surgeon and they have to be answered to suit each individual patient, bearing in mind the preservation and prolongation of a useful and active life.

Surgical Management

In 1910, Lewis[172] reported the first successful craniotomy for excision of a craniopharyngioma. Cushing[56] encountered 92 craniopharyngiomas between 1908 and 1927. Although he, as also Frazier,[81,82] used the trans-sphenoidal approach in 13 of these cases, he later pioneered the transcranial approach.

Associated Hydrocephalus

Although hydrocephalus is often associated with craniopharyngiomas, especially in children, the tumour can be tackled directly in many cases. However, if there are signs of rapidly rising intracranial pressure, the patient may require CSF diversion by a ventriculoperitoneal shunt. This is also a useful procedure in children presenting in a moribund condition or with gross metabolic disturbances, while preparing them for major surgery. It is important to drain both the ventricles separately, in view of obstruction of the foramina of Monro; this can be achieved by attaching a Y-connector to the tubing to connect both the ventricles or by inserting two separate shunts.

Hydrocephalus is more common in retrochiasmal tumours than in the prechiasmal variety.[119] Recurrent or residual tumour, aseptic meningitis or CSF rhinorrhoea may necessitate a shunt insertion post-operatively.[119,278] External ventricular drainage can be used as a temporary measure in moribund patients.

Operative Approaches

The important factors that decide the route of approach to a craniopharyngioma are the location and extent of the tumour, the configuration of the visual pathways, and the blood supply to the tumour and the optic apparatus.[238] Enlargement of the sella and the type of sphenoid sinus are also important if a trans-sphenoidal approach is being considered.[84]

Four varieties of craniopharyngiomas are recognised for surgical management: sellar, prechiasmal; retrochiasmal and intraventricular. Multicompartmental giant tumours are frequently encountered in our country and need special consideration. Atypical forms involving the sphenoid sinus, the pharynx or other basal areas need to be appropriately tackled.

The blood supply of craniopharyngiomas has already been described and the absence of blood supply from the posterior aspect is a major factor in enabling radical excision of the tumour. The blood supply to the chiasma is mainly from the inferior aspect, arising from the internal carotid, posterior cerebral and communicating arteries; and to the optic nerves from the superior aspect, from the anterior cerebral and anterior communicating arteries.[24] The lamina terminalis is completely avascular and can be entered safely to deal with retrochiasmal tumours.

The relation of the chiasma to the sella and to the tumour is an important determinant of the ease with which the tumour can be tackled. While the normal chiasma overlies the diaphragm sella in 70%, the prefixed chiasma overlies the tuberculum sella and the postfixed chiasma overlies the dorsum sella in the remaining 30% with almost equal incidence.[238] A prefixed chiasma make

the surgical task more difficult, as there is hardly any interoptic space to approach the tumour.

The operative approaches (Table 1) for tumours at different locations are summarised here:

I. Subfrontal
   a. Interoptic
   b. Opticocarotid
   c. Translamina terminalis
   d. Combined
II. Pterional
   a. Interoptic
   b. Opticocarotid
   c. Lateral carotid
   d. Translamina terminalis
   e. Combined
III. Trans-sphenoidal
   a. Transnasal
   b. Transcranial
IV. Transventricular
   a. Transcortical
   b. Transcallosal
V. Subtemporal
VI. Cyst aspiration
VII. Intracystic bleomycin
VIII. Combined approaches for giant tumours.

Radical Surgery Versus Conservative Surgery and Radiation

The optimal treatment of childhood craniopharyngioma remains controversial.[48] Most neurosurgeons advocate total excision of the tumour, both for its curative role and in order to avoid the potential side effects of radiation. Recent advances in neuroimaging and microsurgical techniques have made radical excision of craniopharyngiomas increasingly possible, and the operative results have improved remarkably, following improvement in the anaesthetic and peri-operative management in the past few years. The mortality of total excision has reduced dramatically from more than 40% in the preglucocorticoid period to less than 5% in the recent studies.[21,41,97,126,136,177,201,215,242,271,274,276,292,298,314] The risks may be higher when total removal is attempted for recurrent craniopharyngiomas.[193] Total excision in the majority of patients with craniopharyngioma has been recommended by several authors including Sweet,[227] Matson and Crigler,[193] Hoffmann,[119] Yasargil,[314] Symon,[279] Tomita and McLone[295] and Konovalov.[151,152] From a study of these series and some others, it becomes obvious that total excision, if carried out without damage to the adjacent vital neurovascular structures, would be most desirable in the management of craniopharyngiomas.

However, total excision of certain craniopharyngiomas may extremely be difficult and hazardous. A craniopharyngioma that is small or prechiasmatic in location can be easily excised completely with relative impunity (Figs 8A and B, 9A and B).

Table 1: Operative procedures used by author

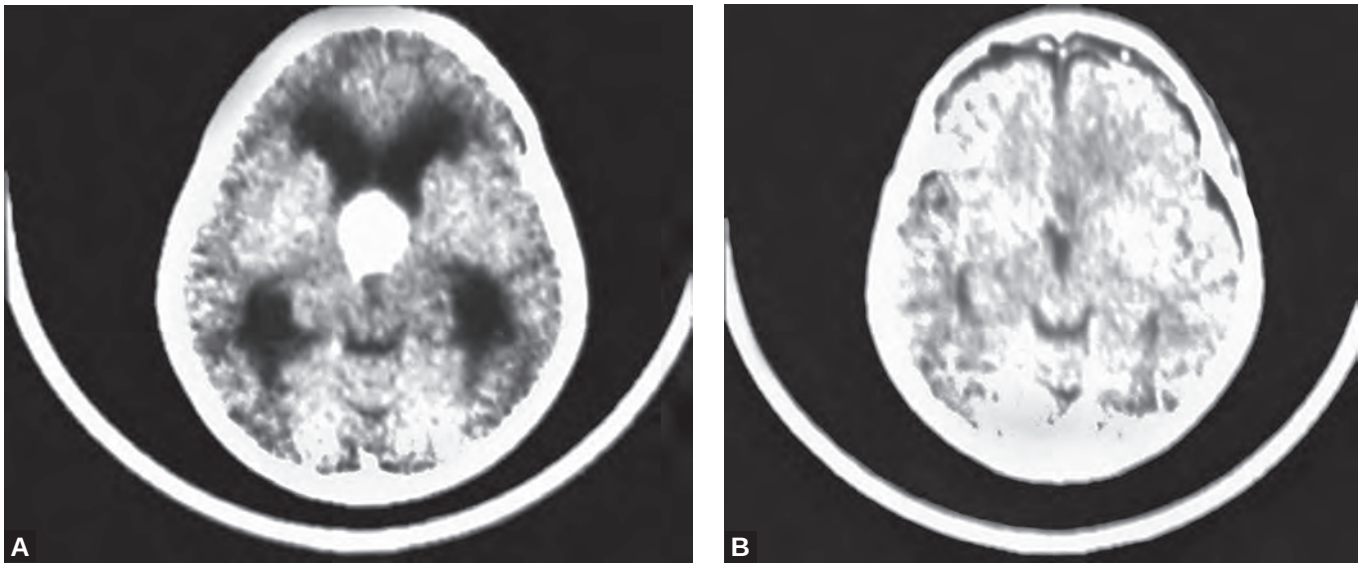
Surgical approach	*No. of cases*
1. Subfrontal: unilateral	59
2. Subfrontal: bilateral	37
3. Interhemispheric	10
4. Pterional trans-sylvian	15
Multistaged procedure	1
5. Transcallosal	3
6. Subtemporal	1
7. Trans-sphenoidal	2
8. Intracystic bleomycin	3
9. Aspiration only	2
Total	133
10. Translamina terminalis	16

When the tumour is large or multicompartmental or retrochiasmatic in location, total excision is difficult (Fig. 10).

Weiss et al.[307] found that total gross excision was felt to be accomplished in only 19 of the 31 patients on whom it was attempted and 4 of these totally removed tumours had evidence of residual tumour on post-operative imaging. Yasargil et al.[314] analysing their series of 144 patients found that in nearly 10% of their patients the tumour could not be totally excised. Even confirmed total resection can be associated with high recurrence rates.[110,119,308] Hoffman et al.[119] reported a 34% recurrence rate in patients felt to have had a complete resection. The recurrence after complete tumour removal was reported to be 10 out of 20 (Wen et al.[310]), 4 out of 16 (Cabezudo[37]), 2 out of 13 (Klun[144]) and 3 out of 38 (Symon[280]). Of our series of 133 patients treated between 1972 and 2005, 38 children and 26 adults had a total excision of their tumours (Figs 8A and B, 9A and B, 11A to C and 12A to D).

Tumour recurrence was observed in 11 children and 5 adults at a follow-up ranging from 2 to 28 years.

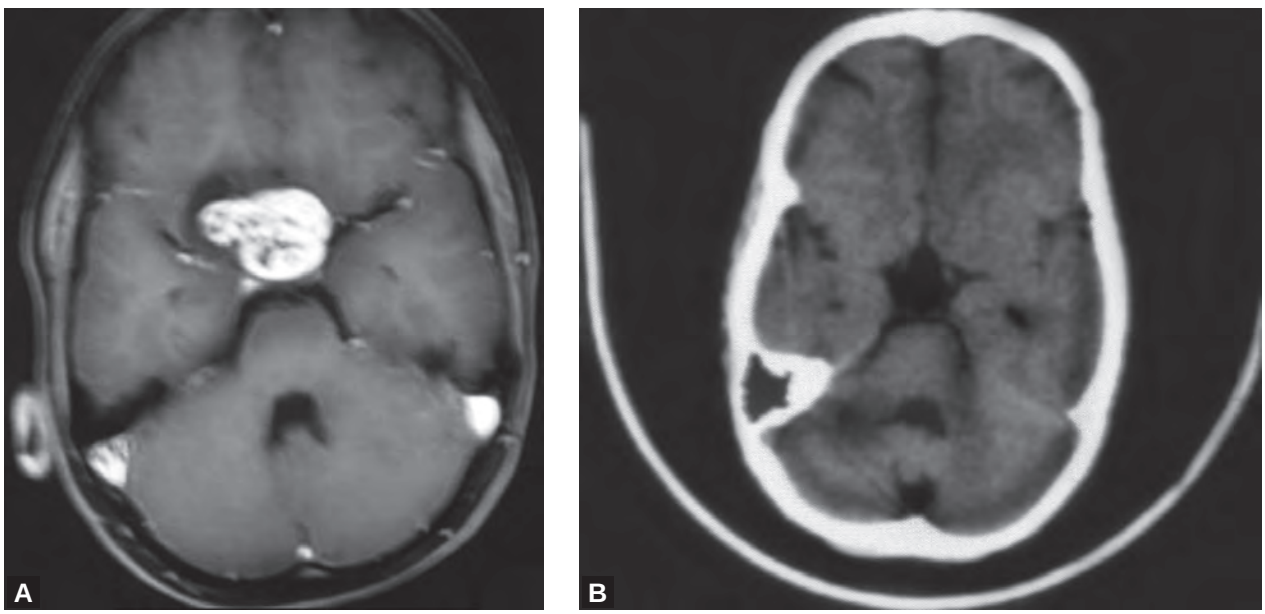
The main difficulty in removing the tumour radically is due to its adherence to the optic nerves, chiasm and tracts, pituitary stalk, hypothalamus and vessels of the circle of Willis.[40,46,62,117,137,221,278,280] The tendency of these tumours to form villous elongations or finger-like processes into the hypothalamus is well documented.[146,147,176] These tumour projections are difficult to separate from the brain and often make total excision hazardous. Although Sweet[227] and Lisczac[175] believed that there is a definite plane of cleavage between the tumour capsule and the hypothalamus that would enable one to radically excise the tumour relatively safely, Kobayashi et al.[146] have noted that these finger-like processes of tumour cells do infiltrate the hypothalamus and that reactive gliosis frequently prevents total tumour removal, without damage to the hypothalamus. Pertuiset[221] and Kempe[141] also felt that the glial or collagenous layer penetrates the hypothalamus and



Figs 8A and B: (A) CT scan showing a small prechiasmatic craniopharyngioma. (B) Post-operative MR scan showing total excision of the tumour

precludes complete resection. Shillito[259] has shown that there may not be any layer of glial tissue between the tumour and the brain and fingers of tumour tissue often invade the brain directly. Brain infiltration by tumour cells has been observed by several other authors also. A morphological study by Vichert and Korshunov[304] has revealed that in some cases the tumour does not have its own capsule and the cystic wall is formed by thickened fibrous tunica vasculosa or arachnoidea and that the tumour may penetrate the tunica vasculosa and invade the brain. The glial reaction in the infiltrated tissue, observed in our patients, was characterised by varying stages of astrocyte proliferation and fibrillary gliosis and Rosenthal fibres. Most authors who favour radical removal, including Sweet,[236] Hoffman,[114] Symon and Sprich[279] and Carmel,[40] have also indicated that one of the major obstacles to achieving total tumour removal is usually a tenacious adhesion of the tumour to an artery on the anterior part of the circle of Willis.

Aggressive surgery is usually associated with high mortality and increased incidence of hypothalamic, endocrinologic, metabolic and visual disturbances.[64,260] In the surgical series of Yasargil et al.[314] the operative mortality rate in children was 20%. Even tumours measuring less than 2 cm in size were associated with operative mortality of 6% in his hands. Fischer et al.[76] reported 12% mortality in children with craniopharyngioma who had radical excision, as compared to 7% death rate in the subtotal excision group. Ivkov et al.[128] had 33% and 20% mortality for radical and subtotal excision, respectively. The mortality rate published by Gordy et al.[97] in 1949 was 32% after radical excision and 0% in cases treated



Figs 9A and B: (A) MR scan showing a slightly larger craniopharyngioma. (B) Post-operative CT scan showing complete excision of the tumour

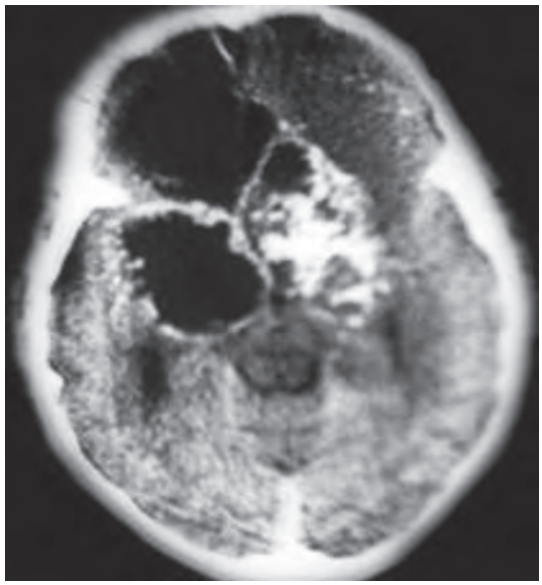


Fig. 10: CT scan showing a multicompartmental lesion not suitable for total excision

by subtotal excision. In our series of 133 cases, total excision in 64 cases was associated with 10 deaths, mainly due to hypothalamic disturbances, status epilepticus and pyogenic meningitis.

Hypothalamic damage and endocrinological disturbances are more frequently associated with extensive surgery in the suprasellar area. De Vile et al.[64] and others have reported high incidence of pathological obesity, abnormal hunger, disturbed sense of thirst, reversal of the normal circadian sleep patterns, cognitive and behavioural problems, learning difficulties and defective short-term memory as sequelae of aggressive surgery. Hoffman et al.[117] found that 43 of 46 children, undergoing attempted total excision, developed diabetes insipidus, 41 became hypocortisolemic, 38 developed hypothyroidism and 14 required six hormonal replacements. Almost 80% of the patients treated by Yasargil et al.[314] developed permanent diabetes insipidus and 79% required hormonal replacement for other endocrinological abnormalities. Matson and Crigler[193] also found a higher incidence of diabetes insipidus, persistent

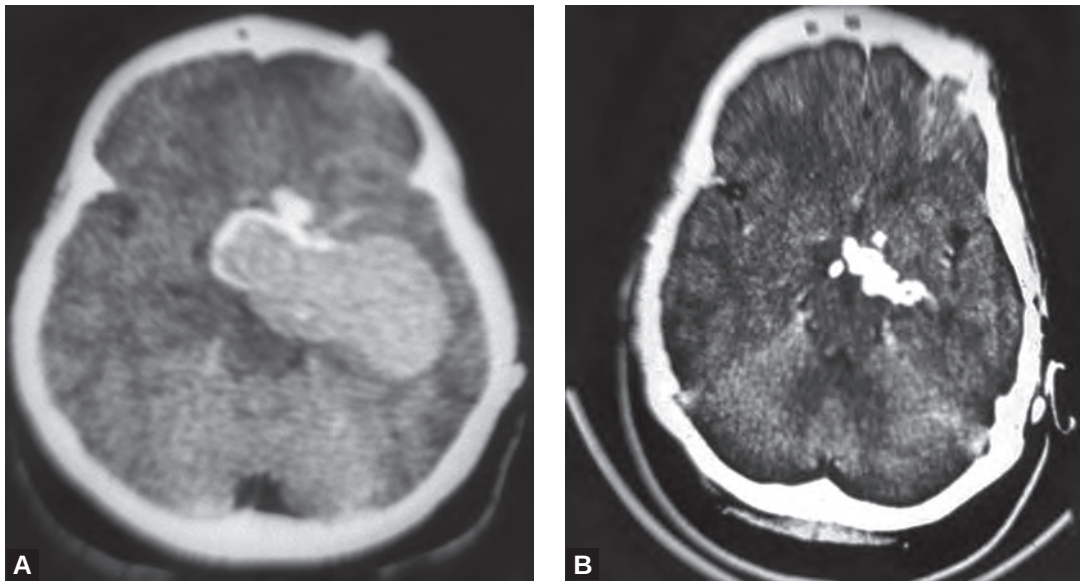
(D) Sagittal view of MRI showing good excision of the lesion with small residual calcium in the sella

hypernatraemia, secondary hypothyroidism and hypocortisolemic with radical removal of the tumour. A recent study has reported panhypopituitarism in significantly higher number of patients after extensive surgery for craniopharyngioma.[63] Sixty-eight (56%) patients in our series developed transient diabetes insipidus, while the other 28 (23%) patients had prolonged diabetes insipidus requiring long-term DDAVP or oral carbamazepine. The incidence of hypothyroidism, hypocortisolemic and hypogonadism was significantly higher in patients with total excision. Most of these patients required endocrine support during surgery and sustained replacement therapy for many years following surgery.

Surgical resection is often advocated to alleviate visual symptoms promptly. However, surgeons must acknowledge that aggressive surgery may also be associated with new or increased visual problems.[10,22,48,224] Hoffman et al.[117] observed that while 9 children experienced improvement in their vision, 3 worsened and 16 children with no visual complaints prior to surgery were left with visual field defects following excision. In addition, 12 children with normal visual acuity prior to surgery experienced visual deterioration. Radical tumour surgery is also believed to have an adverse effect on cognitive and intellectual functions.[76] Detailed follow-up psychometric evaluation in Hoffman's series was carried out in 27 children with total tumour excision. Although only one child had an IQ score below 69, 57% had impairment of memory function. A fair number of children with radical surgery seemed to have had worsening of learning abilities, defective short-term memory and limitation of concentration span. Unfortunately, no comparable study has been carried out in patients with subtotal excision with adjunctive therapy.

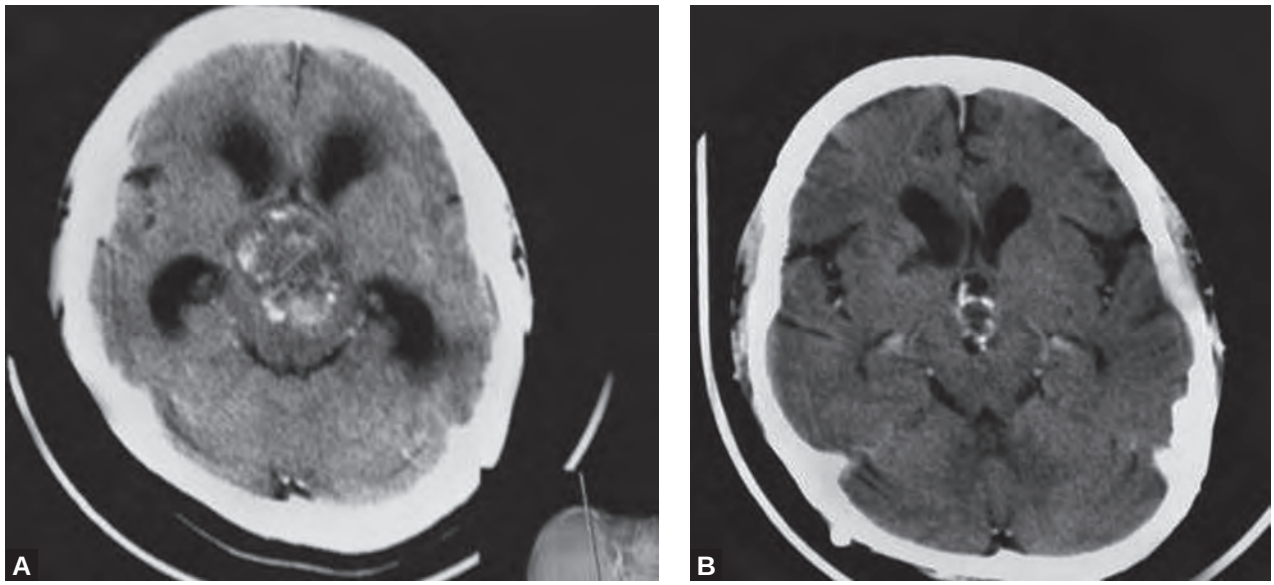


Figs 13A and B: (A) CT scan showing residual lesion in a boy of 10 years. (B) Residue on CT scan done 18 years after radiotherapy

The mortality and morbidity for planned subtotal excision is definitely less than that for total excision,[58,80,109,121,188,198,236,274,309,310] presumably due to lesser vascular and hypothalamic injury. The best results concerning tumour remission in a large series of patients with craniopharyngiomas have been reported by Baskin and Wilson.[21] In this series, a less radical surgical approach was used and recurrence of tumour was controlled with radiotherapy. Although the follow-up period in this group was short, they were able to report that 91% of these patients were in remission. However, it is clearly evident from the literature that subtotal resection alone, without radiotherapy, is not an adequate treatment for craniopharyngioma and the incidence of tumour recurrence after incomplete removal alone is high.[30,35,107,168,191,260,279] In Weiss's series,[308] all 7 patients treated with only subtotal excision experienced tumour recurrence with a median time to recurrence of 12 months. All 10 out of 144 cases reported by Yasargil et al.[314] in whom complete resection of the tumour was not possible, experienced tumour recurrence and had a high post-operative morbidity and mortality.

Radiotherapy, as an adjuvant to surgery, has been proven to offer good tumour growth control. A review of the literature shows that there is low operative mortality, 50–80% disease-free survival and good long-term functional outcome when conservative surgery is combined with adjuvant radiation therapy.[58,157,158,159,188,274] Baskin and Wilson[21] in 1986 reported that treatment with conservative surgery followed by radiotherapy was effective. The operative mortality was 3% and approximately 91% of their patients had no recurrence of the tumour. A series of patients who were treated conservatively and followed for more than 10 years was published by Fischer et al.[76] in 1990. Only 2 (7%) out of 27 patients in the conservative treatment group had tumour recurrence. The endocrinological and psychological dysfunction also seemed to be less than those treated with radical excision. The authors emphasised the good functional results of this group of patients. Regine and Kramer[236] found an overall 20 year survival of 62% of their patients who were treated with external beam radiation post-surgery.

At the Royal Marsden Hospital, 173 patients with craniopharyngioma were treated with external beam radiation between 1950 and 1986 following various modes of surgical therapy.[134,229] The 10 and 20 years survival rates were 77% and 66% respectively at a median follow-up of 12 years. The overall survival and the progression-free interval did not seem to be affected by the extent of surgical resection and there was improvement in the visual acuity and fields by 30% and 36%, respectively. The group concluded that conservative surgery with adjunctive radiotherapy achieved excellent long-term tumour control and survival with low morbidity. A similar experience has been noted by other authors (Regine et al.[237] Wen et al.[310] and Nagpal[206]) who also felt that those patients who underwent subtotal resection with radiation therapy had a significantly better recurrence free interval, compared with those who had surgery alone. In the authors' series of 23 patients who had subtotal resection and radiotherapy, 9 remained recurrence-free for a period varying from 2 to 21 years. Of 56 patients with gross total resection, 16 (28%) had recurrences. Nine of these had supplementary radiation therapy and remained recurrence-free for a mean follow-up period of 7.5 years (range 5 to 14 years). This experience confirms that radiation therapy is efficacious in delaying or preventing a recurrence in over three fourths of the cases and that it has a definite role in the management of incompletely excised or recurrent craniopharyngioma as an adjunctive therapy (Figs 13A and B, 14A and B).



Figs 14A and B: (A) Scan showing residue after partial excision of a large craniopharyngioma. (B) Scan showing the residue 2 years after radiotherapy

The outcome of contemporary management of craniopharyngiomas should reflect the twin goal of tumour control and enhanced quality of survival. Although with modern technology it has become possible to excise a larger number of tumours radically with acceptable mortality, the success of treatment should be measured not only by low mortality or by the length of survival but also by the residual morbidity and functional usefulness, and good quality of life should be the primary objective.[113] In the last 14 cases, keeping this goal in mind, we have totally excised 8 small and moderate sized tumours without a recurrence for 3 to 8 years in six (Figs 15A and B) and a small recurrence in one.

One was lost to follow-up. Of the six large multicompartmental tumours, three had subtotal excision with radiotherapy with recurrence free follow-up in one case, recurrence with surgery with a follow-up of 6 years, one being lost to follow-up. Two of those with a large cystic component had Omayya reservoir placement with instillation of bleomycin (Figs 16A to D).

The cysts became smaller but did not reduce sufficiently in size and required craniotomy with partial excision of cyst wall. They are receiving radiotherapy. All of them have had a better quality of life. One patient has had subtotal excision through the trans-sphenoidal route, the suprasellar extension being essentially cystic.

Hormone Therapy in Craniopharyngioma

Dosage Schedule

Pre-operative Hormone Schedule

1. Glucocorticoids — 50 mg/m^2 IM/IV
   Hydrocortisone sodium succinate — Evening prior to surgery
2. Thyroid hormone
   Sodium L-thyroxine — 100 μg/m^2/24hr PO 4–6 weeks pre-operatively
3. ADH: Diabetes insipidus — 0.1–0.3 ml IM/SC (2–6 units)
   Aqueous vasopressin (20 U/ml) — 4–6 hourly

Intra-operative Hormone Therapy

1. Glucocorticoids
   Hydrocortisone sodium succinate — 100 mg/m^2 IV
   Morning of the scheduled operative procedure
   If surgery is prolonged — Additional 50 mg/m^2 IV
   Beyond 4 hours — 4 hourly
2. Adequate fluid/blood replacement
   If surgery is prolonged and brisk, diuresis occurs:
   Aqueous vasopressin — 2–6 units IM/SC 4 hourly sos

Immediate Post-operative Replacement Therapy

1. Glucocorticoids
   Day 1: Hydrocortisone sodium succinate
   Infants: — 25 mg/IV 6 hourly
   Adolescents: — 75 mg/IV 6 hourly
   Reduce during next 24 hours, if progress is satisfactory
   Day 3: Prednisolone
   Taper rapidly to physiological replacement dosage
2. Thyroid hormone
   Sodium L-thyroxine — 100 μg/m^2/24 hour PO
3. ADH: Diabetes insipidus
   Fluid replacement
   Aqueous vasopressin (20 U/ml) — 0.1–0.3 ml IM/SC 4–6 hourly (2–6 units)
   or
   Vasopressin tannate in oil every 24 hours (5 U/ml) — 0.25–0.5 ml IM to 48 hours (1.25–2.5 units)

Long-term Hormonal Replacement Therapy: Dosage Schedule

1. Glucocorticoids	
a. Hydrocortisone acetate (cortisol)	20 mg/m^2/24 hours PO
To be given in two divided doses:	Two-thirds of the dose in the morning and one-third in the evening
Infants:	10 mg/24 hours PO 7.5 mg morning 2.5 mg evening
Adolescents:	30 mg/24 hours PO 20 mg morning 10 mg evening
or	
b. Prednisolone	One-fourth the dose of hydrocortisone
2. Antidiuretic hormone	
a. Desmovasopressin acetate (DDAVP)	2.5–15 μg, twice a day intranasal spray. Start with 2.5 μg at night—bed time dose
Increase gradually in increments of 2.5 μg until satisfactory antidiuresis obtained	
b. Chlorpropamide	4 mg/kg/24 hours PO
c. Carbamazepine	10–20 mg/kg/24 hours PO in three divided doses
3. Thyroid hormone	
Sodium L-thyroxine	100 mg/m^2 /24 hour PO
Infants:	6–8 μg/kg/24 hours PO
Adolescents:	4 μg/kg/24 hours PO
4. Growth hormone	
Human growth hormone (HGH)	UK: 5 IU thrice a week IM/SC USA: 15 IU/m^2/week divided into 6–7 Inj SC/IM
Current recommendation	0.42 IU/kg/week in divided doses daily for 6 days/week at night

Following table reproduced with the kind permission of Chandalia HB and Chopra KP (Eds). Endocrine management in childhood craniopharyngioma. Neurology India. 1991;39:64.

Radiotherapy

The first group of patients treated with radiation, following subtotal removal of suprasellar craniopharyngiomas, was reported by Carpenter et al.[44] more than 50 years ago. At that time, it was felt that only the cells that produced secretions and formed cysts could be destroyed by X-rays and the solid tumour cells essentially remained unaffected. Doubts continued for many years as to whether or not craniopharyngioma epithelium would be effectively killed by radiotherapy. A dramatic change in this attitude occurred in 1961 when Kramer and his associates[157,158,159] reported excellent results with conservative tumour surgery and supravoltage irradiation. Since then, many studies have shown the efficacy of radiation therapy in both, increasing the recurrence-free survival and improving the quality of life.

A review of the literature shows that radiation therapy added to surgery results in a 50–80% disease-free survival.[156–159,188] In 1986, Baskin and Wilson[21] reported that treatment with conservative surgery, followed by radiotherapy, was effective. Excellent recurrence-free survival rates in the patients treated with external beam radiation have been published by the Royal Marsden group in 1993.[134,231] The 10 and 20 year survival rates were 77 and 66%, respectively at a median follow-up of 12 years. The survival and progression-free survival did not seem to be affected by the extent of surgical resection and there was improvement in visual acuity in 30% and visual field defects in 36% of patients. They concluded that adjunctive radiotherapy can definitely improve the overall outcome, regardless of the degree of surgical excision. Fischer,[76] Nagpal[206] and Regine and Kramer[236] also observed better functional outcome and lesser endocrinological and psychological dysfunction in this group of patients, when the long-term results are compared with those who had radical surgery. All of their patients who underwent aggressive tumour resection developed adverse surgical sequelae, whereas vascular or neurological complications attributable to radiation were minimal when the dose did not exceed 5000 cGy.

Although radiotherapy has proven to be beneficial in the management of craniopharyngioma, complications from this form of treatment are also well known.[55,57,76,91,106,136,260,305] Increasing attention is given to the effects of high dose radiation therapy on brains of children. Duffner et al.[70] found that 40% of the children who received radiotherapy for brain tumours had IQs below 70 and only 40% had IQs in the normal range. A very detailed and careful study was published by Packer et al.[216] in 1989. In this study, children with brain tumours treated with radiation therapy had a fall in full-scale IQ from 105 at diagnosis to 91 by the end of the second year after radiation therapy. Children who did not receive radiotherapy did not demonstrate a fall in any cognitive parameter over time. The younger the child at the time of treatment, the greater was the likelihood and severity of damage. Evaluation of children, who had been given brain irradiation under the age of 3 years and who survived for a long period, showed that 55% required a special education school.

Optic neuropathy and radionecrosis of brain have been noted by Flickinger et al.[80] the risks being greater with a higher dose of radiation. Their study of 21 patients, who were subjected to megavoltage external beam irradiation with more than 5 years follow-up, showed a marked difference in the complication rate between those patients who had 51.3–60 Gy and those who had higher doses in the range of 60–70 Gy. In the high-dose group, the actuarial risk at 5 years from optic neuropathy was 30.5% and for brain necrosis was 12.5%.

However, there did not seem to be a significant difference in tumour control or recurrence rate in the high- and low-dose groups.

One of the long-term hazards of radiation therapy is the induction of a secondary tumour, following radiation therapy.[40,185,265,300,305] Tumours reported, following irradiation of craniopharyngiomas, include brainstem gliomas, supratentorial and infratentorial sarcomas and meningiomas. Occlusion of major vessels may result in ischaemic attacks or strokes.[200] Nishizawa et al.[211] reported the case of a 13-year-old girl who developed post-radiation stenosis of the internal carotid, middle cerebral and anterior cerebral arteries with development of moyamoya vessels, which had ruptured and formed an intracerebral haematoma. Endocrine deficiencies, like GH failure, hypothyroidism and hypogonadism, are not uncommon.[139,156,159] Delayed side effects of irradiation were noted by Al Mefty et al.[3] in their study which included visual deterioration, pituitary dysfunction, varying degree of parenchymal degeneration of the brain and development of a chordoma in a patient of acromegaly treated 30 years earlier with radiotherapy.

Some authors believe that although radiotherapy without doubt decreases cyst fluid, it probably does not completely destroy the craniopharyngioma epithelium. Amacher[4] has demonstrated that the mass remaining after radiotherapy can largely be necrotic with some viable tumour cells, which can lead to tumour recurrence. Numerous examples of recurrent tumours in patients who have received radiotherapy can be found in the literature.[21,76] Although it is believed that an attempt to remove a craniopharyngioma that has been treated with radiotherapy presents a difficult problem because of the development of numerous adhesions, we have been able to achieve a complete excision in a majority of our patients with recurrent tumours who had received radiotherapy earlier.

It is quite clear that radiotherapy is integral to the treatment of craniopharyngiomas. The conventional methods of radiation therapy have been associated with significant morbidity because the irradiated volume includes a significant amount of normal tissue. The degree and extent of morbidity associated with radiotherapy was related to the high dose of radiation (60–70 Gy) and lack of precise localisation of the target. Modern three dimensional conformal radiation treatment (3D CRT) using CT and MRI leads to accurate localisation. The dose of radiation also does not need to increase beyond 5400 Gy. Use of this type of irradiation has improved the therapeutic outcome; the 10 year survival was 85–96% compared to 56–78% among children treated without utilising modern imaging.[99] These complications can further be reduced with the newer modalities of treatment using more precise stereotactic methods. The stereotactic techniques permit precise delivery of highly focal ionising radiation to the tumour. Either a Linear Accelerator[163] (LINAC) is used to deliver the radiation dose to the target or intensity modulated radiation therapy (IMRT) in which conformal radiation is given to a target, using multiple small beamlets varying radiation intensity or SRT (stereotaxically) directed multifractional radiotherapy may be given.[270] This form of therapy is found to be fairly effective in either destroying small tumours or stopping their growth and is now routinely used at a number of specialised centres for the treatment of brain tumours, including craniopharyngiomas.

Surgical Technique

Various surgical approaches used to excise the tumour radically have already been described. As the tumour is located in close relationship with the optic pathways, the hypothalamus and the adjacent vascular tree, the approach should be such that these structures are well visualised and protected during removal of the tumour. The size and extent of the craniopharyngioma would often determine the optimal approach for its total excision.

The unilateral or bilateral frontal approach appears to be ideal for excision of most of the tumours, as it gives a good view of the optic nerves, chiasma and the interoptic space.[30,42] There is good scope for preservation of the olfactory tracts (Figs 15A and B). As the optic chiasm and the hypothalamus are elevated by the tumour, good debulking of the tumour can be done through the interoptic space. A gradual separation of the tumour from the floor of the third ventricle thereafter becomes easier with a gentle pull on the capsule. The perforating vessels that supply the hypothalamus need to be carefully preserved. The capsule of a cystic tumour, if it is thin, may tear and render its total removal difficult. Removal of a calcified lesion may become hazardous and result in damage to the optic pathways or adjacent vascular tree, unless it can easily be disintegrated into small bits. A large solid rock of calcium that cannot be pulverised is best left alone.

At times, a small lateral extension of the tumour can open out the optico-carotid space. The tumour can then be tackled through this space, gradually debulking it and gently pulling it into the field of exposure. This optico-carotid approach is possible with a subfrontal exposure. The pterional exposure, however, is better for such extensions.

Subfrontal exposure is ideal for the retrochiasmatic trans-lamina terminalis approach, when the chiasm is prefixed. The tumour can gradually be debulked and separated from the optic pathways, as well as the hypothalamus with good visualisation up to the membrane of Liliequist and the prepontine area. The membrane presents a plane between the tumour and the basilar artery and its branches. The anterior cerebral vessels form the posterior limit of the exposure. We have successfully utilised this approach in radically excising 13 retrochiasmatic tumours with only one mortality.

More room can be obtained in patients with a prefixed chiasm in front of the optic nerves, by the transcranial trans-sphenoidal approach.[233] Patterson and Danylevich[220] have used a combined transcranial

approach through the lamina terminalis and the sphenoid sinus in excising craniopharyngiomas with a prefixed chiasm. They excised the tuberculum sellae and gained extra space in the interoptic recess and removed the lesion by a rail-road manoeuvre. Injury to the optic nerves, while removing the tumour, was thus avoided. They feel that the pterional approach does give good access behind the tumour but the optic pathways and the carotid artery on the side of the exposure preclude good visualisation and exposure of the optic nerve and arteries on the opposite side.

Suzuki[275] advocated an interhemispheric approach through the lamina terminalis for excision of retrochiasmatic intraventricular lesions. With this approach, both the olfactory nerves can be spared; the main arteries can be exposed sufficiently with a wide operation field, to render the procedure safe; damage to the lateral wall of the third ventricle can be avoided and large tumours can be removed safely. Kanno et al.[140] have drawn attention to a pitfall in this approach. They have shown that occlusion of the bridging veins from the frontal lobe to the sagittal sinus decreased the regional blood flow and increased the chances of development of a haematoma in the retracted and infarcted portion of the frontal lobes.

A transpetrosal transtentorial approach is advocated by Hakuba et al.[101] for retrochiasmatic craniopharyngioma. They claim better visualisation of the lesion and its surrounding structures. They could totally excise the tumour in five of their eight cases. All of them had transient third nerve paresis, all developed diabetes insipidus, one became blind and developed left hemiplegia and one died in the immediate post-operative period. Being a difficult approach with possibilities of many complications, it may be used only by those familiar with it.

The subtemporal approach gives good visualisation of the tumour between the third nerve and the posterior communicating artery inferiorly and the optic tract superiorly. Symon[279,280] has used this approach for tackling most of the craniopharyngiomas and has been able to excise tumours totally. The tip of the temporal lobe may be excised to facilitate exposure. This approach can be used in combination with the pterional approach for excising small retrochiasmatic tumours or parasellar lesions with extension into the middle fossa. Banerji[17] has found this to be a good approach for radical excision of the tumour.

The transventricular approach may be used for lesions located essentially in the third ventricle.[176] We have used this approach in three of our cases.

The trans-sphenoidal approach is useful in a small proportion of cases that are intrasellar and infradiaphragmatic in location and mainly cystic with a primarily enlarged sella[49,104,164,167,258,268] (Figs 12A to D). Laws et al.[166,228] feel that these may originate in the sella and remain predominantly extra-arachnoidal, flattening the pituitary gland anteriorly. They reported a success rate of 86% in 76 cases in whom the trans-sphenoidal approach was used. Fahlbusch[74] has excised 40% of lesions trans-sphenoidally. Nagpal[205] presented a series of 11 cases of craniopharyngioma tackled through the trans-sphenoidal route and stated that predominantly calcified, firm fleshy tumours lend themselves poorly to removal by this route. Honegger et al.[120] could totally excise the tumour in 15 of 19 patients (79%) with primary trans-sphenoidal surgery and in 8 of 13 patients (62%) with the trans-sphenoidal approach following previous surgical procedures. Diabetes insipidus seemed to be a frequent complication. Transmaxillary–trans-sphenoidal as well as transpalatal approaches have been described by ENT surgeons.[103,132]

In our series of 133 cases, the subfrontal approach, unilateral or bilateral, was used most frequently. For those lesions that needed a more lateral approach, the pterional or subtemporal approach was used, whereas for essentially intraventricular lesions, either the transcortical–transventricular or the transcallosal approach was used. We had two intrasellar lesions that were tackled through the trans-sphenoidal route.

Complications

Most of the reported series have shown that radical excision results in a higher morbidity with functional impairment for life in quite a few patients.[260,261,274] The common disturbances are in visual functions and in functions of the hypothalamus and the pituitary, resulting in endocrinological deficiencies with need for hormonal replacement. Diabetes insipidus or SIADH, psychosocial impairment resulting in mental dullness, poor educability and poor intellectual performance also occur.

The morbidity is supposed to be less with conservative surgery, if it is carried out as a planned procedure in the appropriately selected cases. However, a higher percentage of mortality and morbidity have been reported with subtotal tumour resection in some studies.[88,253,292] It is likely that subtotal resection in these patients may be a result of having had to give up total excision after repeated attempts at total excision, subtotal excision not being really a planned procedure.

The incidence of immediate treatment-related complications is relatively lower with other modes of treatment including intracavitary chemotherapy, stereotactic brachytherapy, Linac therapy or radiosurgery (SRS) with gamma knife or stereotaxic radiotherapy (SRT). However, more experience and long-term results may be required to evaluate the efficacy, delayed side effects and overall outcome associated with these treatment modalities.

Other Treatment Modalities

In the management of craniopharyngioma, there are several goals: tumour control, combined with preservation of endocrine, visual, and cognitive functions. The likelihood of achieving these goals is enhanced by a multimodality approach in which staged excision of tumour,

drainage of the cyst, instillation of radioactive or chemotherapeutic agents into the cyst through a reservoir or stereotactic radiosurgery (SRS) may be employed.

Cyst Aspiration

Stereotactic aspiration of a cystic craniopharyngioma or periodic percutaneous aspiration of the cyst, using a reservoir/catheter system can be carried out easily without any significant morbidity.[98,240] This form of treatment is simple and effective in certain cases of recurrent cystic tumours. Two of our patients with recurrence of cystic craniopharyngioma were successfully managed with repeated aspirations of the cyst, using a reservoir/catheter system. However, other authors have discouraged the use of a reservoir/catheter system for multiple aspirations of the cyst.[181] In their experience, such catheters often tend to aggravate the clinical problem presented by a cystic craniopharyngioma. Cyst fluid production seems to be stimulated, leading to progressively more frequent need for aspiration. The authors also cautioned about the potential hazards of leakage of the radioactive substances outside the cyst cavity, when injected through the reservoir-catheter whose distal holes are lying outside the cyst.

Intracavitary Bleomycin Injection

A fair number of tumours are essentially cystic or have a large cystic component. These are the lesions that can respond reasonably well to intracystic instillation of bleomycin. A catheter is placed in the cavity with an Omayya reservoir either stereotactically or through an open craniotomy. If there is more than one large cyst, a catheter is placed in each cyst. A contrast cystogram is performed to make sure that there is no leakage from the cyst. Thereafter 3–5 mgm of bleomycin is instilled 2–3 times a week through the Omayya reservoir. A total of 40–50 mgm may be injected. Takahashi[284] was the first one to report the use of bleomycin in 7 patients, four of whom had excellent response with no recurrence at 5 years follow-up. Subsequently, several authors have reported their series with varying results. Significant series were those of Zanan,[317] wherein 57% of 21 patients had favourable results; Mattolesse,[202] whose 70% of 24 patients had a good response and Broggi et al.[35] whose 43% patients did well. We have used it in two cases recently. If there is a leakage from the cyst, visual impairment may occur. The worldwide experience makes one wonder whether this should be the first line of treatment, especially in young children in whom radiation may be avoided.

Intracavitary Irradiation

Stereotactic intracavitary irradiation, using beta emitting colloids is an effective alternative method to treat cystic craniopharyngiomas.[135,290] This mode of therapy is less invasive and is associated with low risks of mortality and morbidity and a high rate of endocrinological, visual and cognitive preservation.[51] Intracavitary irradiation was first advocated by Leksell et al.[170] in 1951. Wycis[313] in the United States reported his initial experience with this method of treatment in 1954. Backlund et al.[9,10,11] have been primary advocates and expostulators of the role of stereotactic modalities. He and his associates demonstrated a high tumour control rate and safety and efficacy of this procedure, in more than 100 patients in his longitudinal experience of more than 20 years at the Karolinska Hospital in Stockholm.

A variety of isotopes for intracavitary radiation have been tried and eliminated including rhenium, gold and bismuth.[34,149,174,272] Radioactive isotopes, such as ^{32}P, ^{198}Au and ^{90}Y, have been used successfully for intracavitary irradiation of large cystic craniopharyngiomas.[289,291] The isotope available in Europe and Japan is ^{90}Y, an isotope with a shorter half-life (less than 3 days) and a reduced beta-emission range. It is preferred, combining a short half-life of 64.1 hours with pure beta emission of acceptable penetration.[123,145,273,301] The only beta-emitting radioisotope approved for use in the United States is ^{32}P, which has a 0.9 mm tissue half value layer and a longer half-life (14 days).[171,178–180,226] Since ^{32}P appears to coat the cyst wall rapidly, it can be used effectively in those patients who require early and frequent aspiration of the cyst without losing a significant fraction of the therapeutic dose of the radioisotope. The lining epithelium of the cyst wall is destroyed by the isotope, resulting in gradual shrinkage of the cystic tumour.[281] Hasegawa et al.[108] treated 25 primary and 24 recurrent cysts with ^{32}P. There was a cyst control of 76% at 5 years and 70% at 10 years. There was an effective control of the tumour cysts but not of solid components. Van den Bergh et al.[301] used intracavitary brachytherapy with ^{90}Y in 31 patients harbouring cystic craniopharyngiomas. Complete resolution in size was observed in 12 patients with new cyst formation in 3 patients. Bernstein and Laperriere[26] felt that intracavitary irradiation was quite effective in controlling cystic craniopharyngiomas. Blackburn et al.[31] reported a series of 6 patients with cystic recurrence who were treated with ^{90}Y radioisotope. Five patients did not need further aspiration whereas 2 required further instillation of ^{90}Y. There was neither any visual deterioration nor hypothalamic dysfunction. Shapiro et al.[253] pointed out that intracystic instillation of radioisotope permits a far higher radiation dose than by external radiation to the cyst lining, resulting in cyst shrinkage in up to 80% of cases. Intracavitary instillation of bleomycin is also being used in the management of essentially cystic craniopharyngioma. It stimulates reactionary fibrosis with thickening of the capsule and some shrinkage of the lesion, which in turn makes its excision easier.[165]

Intracavitary irradiation should be considered as a primary management strategy in patients with a solitary cystic craniopharyngioma. Significant cyst shrinkage occurs in up to 80% of cases with more than 50% chance of endocrinological preservation and maintenance or improvement of visual functions. Patients with recurrent tumour cysts have lesser chance of improving

vision than those being treated primarily. It does not affect the solid component for which stereotaxic radiosurgery (SRS) would be needed. For those patients with multicystic lesions, intracavitary irradiation can be performed for each cyst separately if they do not communicate.

Stereotactic Radiosurgery

There is increasing enthusiasm for treatment of craniopharyngiomas by SRS and fractionated stereotactic radiotherapy (SRT).[12,13,16,148,179] SRS is a highly accurate and precise technique that utilises stereotactically directed convergent beams of ionising radiation (proton beam or gamma-knife) to treat a small and distinct volume of tissue with a single dose.[79,169] The minimum dose prescribed is 9–20 Gy. Use of stereotactic technique permits accurate localisation of the tumour, a proper planning of the treatment and exact delivery of the radiation with a proper fixation of the head in a stereotactic frame. As a result, the optic chiasm, hypothalamus and pituitary are spared. The multiple beam approach of radiosurgery results in sharp dose fall-off beyond the target, sparing adjacent normal tissue. This method, however, should be reserved for selected small lesions since it ablates normal and abnormal tissue within the treatment volume.

However, further clinical experience seems to indicate that certain parameters are associated with complications from radiosurgery.[102,189,208,293] The parameters are related to the size and location of the target volume. Certain intracranial lesions cannot safely or effectively be treated with SRS, once the target volume is relatively large or located near the brainstem, retina and optic pathways or cranial nerves. In fact there is evidence to suggest that complications from radiosurgery might be higher than those associated with conventional radiotherapy, if used in larger lesions.[71,78,143] Therefore, although precise in the administration of a large single fraction, complications associated with large volumes (more than 3 cm) and critical location (brainstem, optic pathways) limit its use to only those craniopharyngiomas which are less than 2.5 cm in size and at least 2 mm away from the optic pathways, like primary or residual/recurrent intrasellar tumours. Tumour control rates of 70–100% have been reported 1–5 years after radiosurgery.

Stereotactic Radiotherapy

Fractionation is necessary to provide highly focal and precise dose delivery to larger lesions or lesions located within the vicinity of vital neurovascular structures, without producing significant morbidity. This form of therapy is called SRT and it includes the use of SRS techniques in combination with routine fractionation (180–200 cGy/day) or some form of altered fractionation, such as hyperfractionation (a few large fractions of 400–800 cGy). SRT combines the advantages of conventional fractionation used in external beam irradiation with the accurate and focal distribution of radiation as in SRS. Relocatable stereotactic frames are preferably used or plastic masks for immobilisation so that radiotherapy is delivered at a precise location. Thus, highly focussed and precise radiotherapy can be delivered in fractioned form, enabling the treatment of selected tumours with a potentially improved therapeutic index. Dose optimisation using SRT is very important, particularly for the paediatric population. For many paediatric intracranial tumours, such as craniopharyngioma, it is likely that SRT will largely replace conventional radiotherapy in order to reduce long-term side effects.[154]

For an optimal outcome, a team comprised of a neurosurgeon, ophthalmologist, endocrinologist, physician and radiation oncologist should work together to improve the quality of life of patients diagnosed with craniopharyngioma.

Treatment Summary

The best management of craniopharyngioma in children remains a controversial topic among paediatric neurosurgeons. A review of the natural history of children, following subtotal excision without further therapy, demonstrates that approximately 71% of the tumours will show progressive growth in a relatively short period of time requiring further therapy—repeat surgery, intracyst isotope or irradiation.[112,117,173,196,268,277,288] This data effectively dispels the argument for limited surgery alone. Currently, the debate centres round the merits of radical surgical removal versus limited resection followed by irradiation. Published series document excellent and equivalent long-term survival following each treatment modality, but the most important aspect is the quality of life following each therapy.

In order to compare the two most commonly employed therapeutic strategies for childhood craniopharyngiomas, one must look at four factors: (1) recurrence rate; (2) salvageability of the recurrent tumour; (3) quality of life and (4) complications.

Recurrent Tumours

Total excision does not necessarily equate to cure. The best published results of the studies with complete excision of craniopharyngioma utilising the latest microsurgical techniques show the recurrence rate ranging from 7 to 34% with an average of 23%.[20,37,41,112,119,173,196,268,288,314] These can then be subjected to further surgery or radiotherapy which can prolong life further in nearly 75–80% of cases for several years without compromising its quality. The average recurrence rate following partial removal followed by radiotherapy, as judged from the literature, is approximately 21%.[20] The risk of recurrence, therefore, appears to be equal for both treatment regimens.

Salvageability

Studies demonstrate that approximately 80% of the 23% of children whose tumour recurred after gross total resection, can be salvaged with radiation. Surveys suggest that 50% would have a good quality of life.

Jose et al.[134] reported a 77% 10 year survival among 25 patients whose tumours recurred after radical surgery. Radical surgery remains a vital treatment option in those 21% of patients who had tumour recurrence after limited surgery and irradiation. It is a general belief that operating in a previously irradiated or operated case is more difficult and hazardous. The more vigourous the initial surgical procedure, the more extensive the post-operative scarring and the greater difficulty encountered. However, we have been able to totally excise quite a few recurrent craniopharyngiomas.

Quality of Life

Most published series list outcome based on the clinical impressions of the authors and only a few studies have reported a systematic attempt to characterise the quality of life by intelligence (IQ) testing, psychological profiles and school or job performances. Good results as reported by experienced neurosurgeons range from 60 to 87%.[119,238,314] It has been observed that such a good outcome may not be possible when an attempt at total removal is made by a relatively inexperienced surgeon. Good results following a planned subtotal excision or limited excision plus irradiation have been extensively documented in the literature. In the last 13 cases we have tackled, we had complete excision of 8 small and moderate sized tumours, without any hypothalamic disturbances. The remaining 5 large multicompartmental lesions had subtotal excisions with radiotherapy, again without any significant sequlae and a good quality of life. Two patients with intracystic instillation of bleomycin have also remained without any hypothalamic disturbances, so also the one treated through the trans-sphenoidal route. It is therefore clear that the outcome in terms of quality of life largely depends on the experience and judgement of the surgeon, regarding the mode of treatment.

Hayward et al.[109] have noted that in children below 5 years of age, in those with hydrocephalus and pre-operative hypothalamic disturbances, the morbidity following radical surgery is unacceptable due to hypothalamic damage. Even though tumour control may be achieved, the quality of life is very poor.

Complications

The surgical mortality rate has varied from 4% to nearly 20% in radical surgery, especially in children below the age of 5 years and those with large or multicompartmental tumours.[119,238,314] Death from limited surgery is 1–4%. The incidence of delayed complications due to radiation is approximately 7% including radiation vasculitis, vascular occlusion and radiation-induced neoplasms. The endocrine complications are high following both therapies, and major hormone replacement is required 95% of the time.[119,295,314] The morbidly obese and hypersomnolent child, the severe endocrine cripple who alternates between SIADH and DI only seems to occur as a complication of radical surgery.

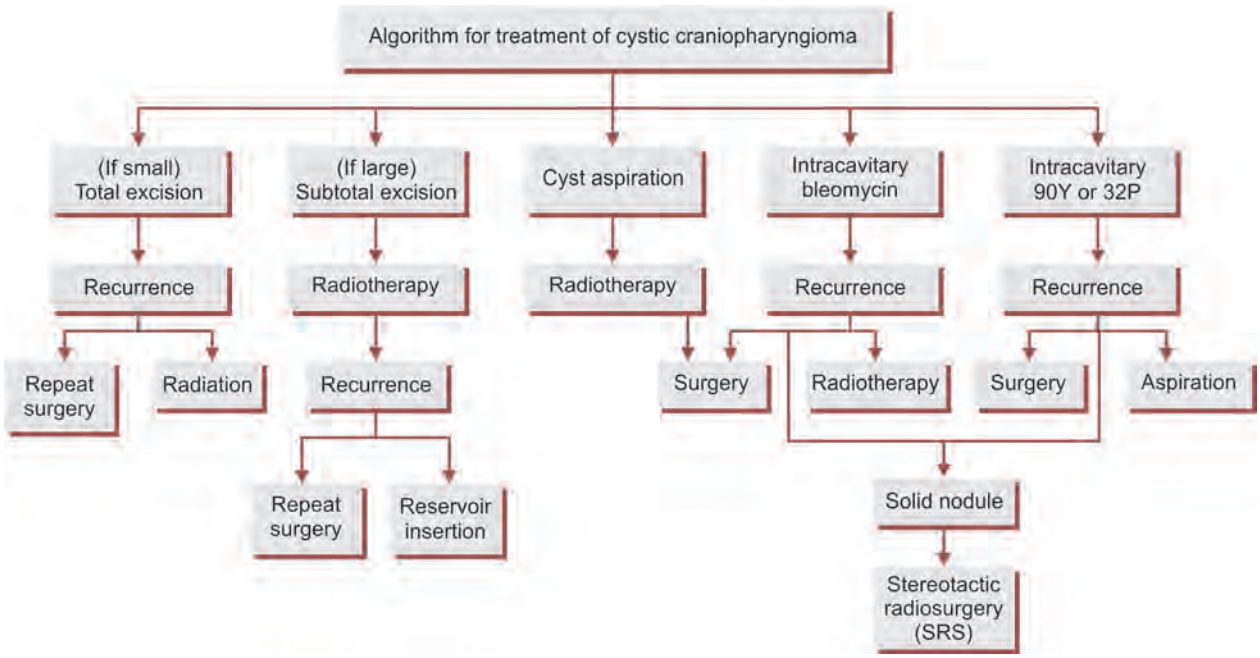
Based on this information the following recommendations can be made:

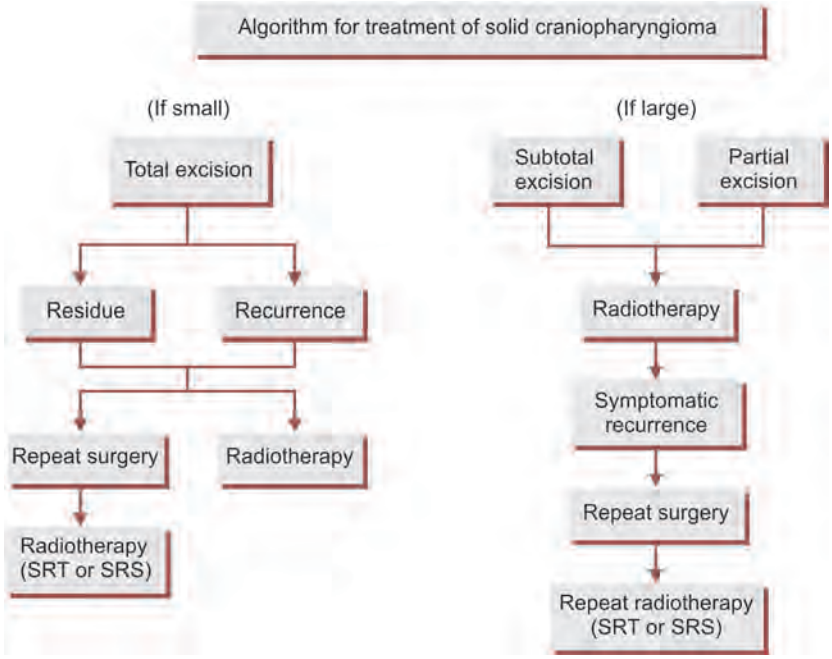
Radical surgery

1. Children older than 5 years of age
2. Tumours less than 3 cm in size
3. Favourable location—intrasellar, prechiasmatic or pure intraventricular.

Limited surgery plus irradiation

1. Large tumours greater than 3 cm in size
2. Multicompartmental tumours
3. Pre-operative hypothalamic disturbances.





Ommaya reservoir with intracystic instillation

1. Essentially cystic tumours
2. Bleomycin
3. Radioactive isotopes—^{90}Y, ^{32}P.

Stereotactic radiosurgery

1. Smaller tumours less than 3 cm in size
2. Intrasellar tumours
3. Tumours away from optic pathways.

Radiation or SRT

1. Residual tumours
2. Recurrent tumours.

Cranial and Intracranial Tumours

CE Deopujari

159 Dermoids and Epidermoids

Ravi Ramamurthi, Amit Kapoor

Tumours of disordered embryogenesis are a heterogeneous group of neoplasms of the nervous system of congenital origin. They include dermoids, epidermoids, teratomas, chordomas and craniopharyngiomas. They are characterised by a slow rate of growth, the growth potential in some of these being so slow that they are often considered as hamartomas. Due to the slow rate of growth in some, the initial clinical manifestations may not appear till adulthood.

EPIDERMOIDS

History

In 1829, Curveilhier,[16] described the epidermoid and named it "pearly tumour". Muller, in 1938,[57] described a bony tumour of the skull containing masses of cholesterol crystals and termed it as "cholesteatoma". This resulted in some confusion later, when similar encrustations were found in chronic infection of the middle ear and the mastoid. It is best not to use the term cholesteatoma to denote cranial epidermoids, even though the desquamated epithelial cells filling the lesion are rich in cholesterol crystals.

In 1897, Bostroem[8] proposed that these lesions arise from inclusion of epithelial rests during the period of neural tube closure in the third to fifth week of gestation. Tumours from the same rests may be epidermoids or dermoids, the capsule in the former consisting mainly of squamous epithelium, whereas in the latter, dermal elements, like hair and sweat glands, are also found.

Pathogenesis

Congenital epidermoids are believed to arise as a result of cellular dysfunction during embryogenesis, which leads to an abnormal migration of ectodermal cells.[36,63] When the neural tube separates from the overlying ectoderm along the mid-dorsal aspect of the embryo, misplaced epithelial rests may be deposited between the neural canal and the skin. This epithelium lined ectopic tube may expand into a cyst, either at its inner or outer end or both and form an epidermoid or a dermoid cyst. Secondary vesicles, like otic and optic vesicles formed during development, may also have epithelial misplacement, accounting for laterally placed squamous lined cysts.[29]

This theory explains the frequency of association of intraspinal midline lesions with spinal anomalies, dermal sinus tracts and laterally situated lesions in the cerebellopontine angle and the orbit. Experimental skin implants along the neuraxis of rats have resulted in the production of dermoids and epidermoids, thus supporting the epithelial cell rest theory of histogenesis of these tumours.[96] Misplaced epithelium alone, or mesenchyme without organiser substances early in development results in a simple squamous lined cyst (epidermoid), whereas misplaced epithelium and mesenchyme in later foetal life with the organiser substances lead to the formation of a squamous lined cyst with skin appendages (dermoid).[91]

Another mode of pathogenesis is iatrogenic. Intraspinal dermoids and epidermoids may also form, as a result of inclusion of epidermis, following repeated lumbar punctures, when done using a needle without the stylet.[14] A single lumbar puncture rarely produces an epidermoid.[87,88] The Currarino triad is a unique complex of congenital caudal anomalies, including anorectal malformation, sacral bone abnormality and a presacral mass. Epidermoid cysts have been described in patients with the triad.[41]

Location

Intracranially, epidermoids are more common than dermoids. They have an affinity for the subarachnoid cisterns at the base of the brain. The suprasellar and cerebellopontine angle cisterns are the most favoured sites, whereas the lateral ventricles, optic chiasm, colliculer plate, pineal gland and paratrigeminal area, sphenoid sinus, temporal bone[36] brainstem,[73] intradiploic, and lateral orbital wall[5] are less favoured sites.[40] A rare case of a prepontine epidermoid traversing the brainstem has been reported by Bhatia et al.[3] When these are extradural, the most common location is intraosseus in the diploe of the calvarial bones. Epithelial rests may give rise to a primary congenital epidermoid in the petrous bone with gradual onset of facial palsy, hearing loss and vestibular disturbances. The roof of the petrous bone is usually eroded. Intraorbital lesions are usually located superolaterally at the site of fusion of bones and gradually push the eyeball downwards and medially. Epidermoids do not occur in the vertebrae and are uncommon in the scalp.

Over three quarters of all intracranial epidermoids occur in the basal cisterns.[44,87,92] Many involve more than one cranial fossa. A few occur entirely within the substance of the brain.[12,43,56] Intraspinally, they occur much

less frequently in the cervical region, being more frequent in the mid-dorsal area.[46] One-fifth are intramedullary in location, two-thirds are found in the leptomeninges and the remaining in the epidural space.[46] Those that occur following lumbar punctures are usually seen in the lumbar region.[51]

They may be classified as per their location as follows:

A. Extracranial
   1. Spinal
   2. Orbital
B. Cranial-extradural
   1. Intraosseous (intradiploic)
   2. Orbital
   3. Paranasal sinuses
C. Intracranial-intradural
   1. Intraventricular
   2. Suprasellar—chiasmatic
   3. Parasellar—Sylvian fissure
   4. Restrosellar—cerebellopontine angle
   5. Basilar—posterior fossa
   6. Multicompartmental

Pathology

Epidermoid is a well-delineated encapsulated lesion that has a characteristic "pearly shine" that permits diagnosis merely on inspection. It may be cystic in suprasellar[89] and intraventricular locations, but is usually solid, especially in the cerebellopontine angle, quadrigeminal cistern and over the corpus callosum.[22] The solid lesion is characteristically filled with whitish, often cheesy material rich in cholesterol crystals and a debris of desquamated keratinised epidermal cells that accumulate centrally and add to the bulk of the growth.[78] These lesions are often large, almost giant sized, insinuating between fissures and sulci, starting from one compartment and extending into adjacent ones and becoming multicompartmental. The capsule may be thin at places and nodular at others. It is often adherent to the vascular structures, cranial nerves, and brainstem, making total excision difficult without damage to these structures. Foci of calcification may be found in the cyst wall.

The diagnostic histological finding is a simple stratified squamous epithelial lining. The epithelial cells rest on an outer layer of collagenous tissue. Progressive exfoliation of keratinous material towards the centre increases the bulk of the lesion and produces a lamellar appearance of the contents. The outermost layer consists of homogeneous material, for the most part quite structureless. It is this layer that has the beautiful pearly sheen, so characteristic of these tumours. Irritation of the surrounding brain may produce fibrillary gliosis and thickening of the leptomeninges with foreign body giant cells. Daughter cysts may be found within the main mass. Their mode of production is obscure. Multiple cysts may also arise in the same location. Granulomatous meningitis may result from rupture of the lesion and contamination of the CSF by lipid and cellular debris.[47]

The tumour is entirely benign. It can recur after a long time if incompletely removed, but usually does not turn malignant. Malignant changes have been reported in the literature.[24,53,88] Squamous cell carc inomas (epidermoid carcinomas), cytologically malignant and histologically invasive, occurring essentially in the parapontine and cerebellopontine angle, have been reported. All these patients died within a year.[61]

Incidence

Epidermoids constitute 0.5–1.8% of all intracranial tumours.[97] The incidence is higher in Japan at 2.2%.[91] They become symptomatic usually in the third or fourth decades, the average age incidence being 34 years as reported by Tan.[88] In India, it is a decade earlier.[21,22,59]

Clinical Features

Epidermoid tumours typically present with symptoms related to pressure or intracranial rupture in the fourth or fifth decade of life.[83] As epidermoids are soft with a pliable capsule, they grow very slowly and tend to fill up any available space. They often reach a large size before becoming symptomatic. For the same reasons, many of these lesions attain a large size without producing signs of raised intracranial pressure. Lesions are large at presentation and the initial symptoms usually involve the cranial nerves.[36]

Papilloedema is noted in only a small percentage of cases. In the more laterally placed tumours, clinical symptoms are produced by compression and deformation of adjacent neural and vascular structures. In nearly three fourths of the patients, soft symptoms may be present for several years before they seek treatment.[62,67]

Intradiploic epidermoids present essentially as painless masses with characteristic radiological appearances.[98] These occur more commonly in the frontal and parietal bones and may occasionally be tender. They are usually small, but may be large and accompanied by signs of raised intracranial pressure and focal neurological deficit.[15,50,58,59,64,70,71] A primary epidermoid occurring in the petrous bone grows slowly, erodes the bone steadily and produces tinnitus, progressive impairment of hearing and facial nerve paresis. Orbital epidermoids are usually located in the upper outer quadrant and push the eyeball downwards and medially. They usually do not compress the optic nerve and do not produce visual impairment, although Sushil Kumar et al.[86] have reported a case of a large frontal intradiploic epidermoid that led to proptosis and visual impairment.

The clinical picture of intracranial epidermoids varies according to their location, direction and rate of growth, interference with cerebrospinal fluid pathways, compression of neural and vascular structures or chemical meningitis following rupture into the subarachnoid space or ventricle.

When the epidermoid is located in the frontal region, impairment of memory, emotional lability, depression and incontinence of urine may occur. When located in

the suprasellar-chiasmatic region, they compress the optic apparatus and produce visual impairment, optic atrophy and bitemporal haemianopia.[49] There may be associated widening of the optic foramina with a normal sella turcica and normal pituitary function. Occasionally, the patient may develop diabetes insipidus.

Epidermoids in the parasellar area extend into the Sylvian fissure laterally and spread to the temporal and frontal lobes. Depending on the direction of extension, the person may suffer from focal, complex partial or grand-mal type of seizure disorder. It may extend towards the thalamus and involve post-ganglionic fibres of the Vth nerve with occurrence of trigeminal neuralgia.[84]

Epidermoids in the parapontine and cerebellopontine angle cisterns may present initially with irritative manifestations, like trigeminal neuralgia, hemifacial spasm or tinnitus, till they grow sufficiently large to produce paresis of the trigeminal, facial and auditory nerves. Paresis of the sixth nerve will result in diplopia. Pressure on the cerebellum will result in nystagmus and ataxia and that on the brainstem in hemiparesis or quadriparesis (Fig. 1).

Symptoms like headache appear only occasionally. When located in the pineal region, these produce classical symptoms of a posterior third ventricular tumour.[50,79,89,100]

Jacksonian seizures appearing in a young patient with a slow evolution of mental symptoms without significant signs of raised intracranial pressure characterise a supracallosal epidermoid.[74] Cases have been reported of epidermoid tumours of the corpus callosum presenting with raised intracranial pressure, generalised seizure, hemiparesis and behaviour disturbances.[46,65,90] Dastur[20] reported a large bifrontal epidermoid in a middle aged patient which resulted in a bilateral lobotomy effect, making the patient unaware of severe pain due to strangulated inguinal hernia. Mental changes may also occur in basal and intraventricular epidermoids when they are associated with hydrocephalus.[2,75]

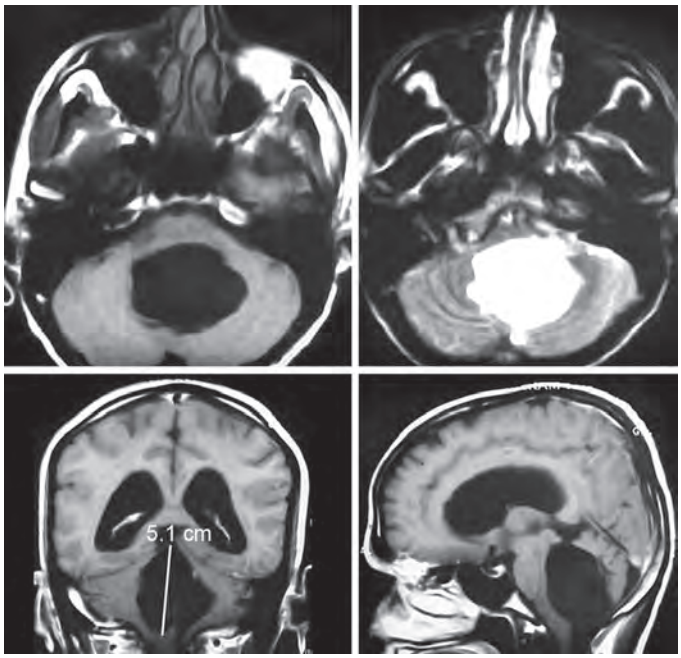

Fig. 1: MRI of the brain showing fourth ventricular epidermoid causing pressure over the brainstem

In intraventricular epidermoids, headache, dementia, psychiatric problems, ataxia, hemiparesis and cranial nerve palsies are often seen when obstruction to the CSF pathways is significant.[49] However, at times, in spite of the lesion filling up the fourth and the third ventricle and extending into the aqueduct, no manifestations of hydrocephalus may be found.[75] This is essentially due to percolation of CSF through the interstices of the tumour. At times, waxing and waning of the symptoms may occur as in demyelinating disease.[2] Remissions may occur due to the emergence of the tumour from the fourth ventricle into the cisterna magna[28,48] and it may fill up the cervical perimedullary space.[75,76]

Pineal region tumours most commonly present with headache, diplopia and vertigo. Neurological examination may demonstrate papilloedema, impaired pupillary reaction, ataxia, Parinaud's syndrome and long-pathways deficit.[41]

Leakage of cholestrin and fatty acids into the subarachnoid space may give rise to chemical meningitis, presenting with headache, irritability, and neck stiffness.[22] Repeated spinal fluid cultures are sterile. A foreign body giant cell reaction occurs around the cholesterol crystals, with the production of granulomatous ependymitis and meningitis.[93]

Spinal epidermoids have a predilection for the conus and for the low to mid dorsal region and are largely intramedullary.[51] They may be associated with other abnormalities of the spinal cord and bony vertebral column. Being slow growing lesions they may become apparent in the second decade of life. They present with backache, progressive paraparesis, sphincter impairment and sensory dysfunction or may present with recurrent aseptic meningitis.

Radiological Findings

Plain X-rays of the skull do not reveal any abnormality in intracranial epidermoids, except for occasional stippled calcification in a third ventricular epidermoid or amputation of the apex of the petrous bone in a cerebellopontine angle lesion. Rarely, one may see radiological signs of raised intracranial pressure.

Cushing[17] was the first to note that epidermoids of the skull produce a discrete area of osteolysis with a thin surrounding margin of sclerosis. The destructive area may be rounded or may appear scalloped and may cause expansion of the calvarial bones. The intracranial extension, which is always limited by the dura, can be seen only on CT and MR. In orbital lesions there is an erosion of the upper and outer margins of the orbit, whereas in the petrous bone possible thinning or destruction of the tegmen tympani is found.

Computed Tomography Scan

The lesion usually appears as a hypodense mass with an attenuation value of 22–32 Hounsfield units, although

lesions of relatively high density (80-I 20 HU) can occur[9,85,91] (Figs 2 and 3).

The varying density is due to low-density lipid and high-density keratin in the desquamated debris of the tumour. Fat and fluid may also be seen within the tumour or in the ventricle or subarachnoid space after it ruptures. Foci of calcification may occasionally be seen in the tumour capsule. Hyperdense lesions, with no enhancement on contrast injection and hypodense lesions with marginal calcification were reported by Furuhata et al.[30] in three epidermoid cysts of the callosal region.

As epidermoids grow slowly, they tend to conform to the shape of the space in which they are located. Intraventricular lesions grow slowly and distend and dilate the ventricular system, allowing cerebrospinal fluid to flow between and around the tumour, rather than obstruct it. Fissural epidermoids grow insidiously, tend to fill up and distend the subarachnoid space and present as irregular shaped masses in the CT scan. A characteristic filigree appearance may be seen on intrathecal water-soluble contrast cisternography[32] or ventriculography. Hydrocephalus is only occasionally seen. This is an important differentiating factor between an epidermoid and other tumours that act as obstructive space occupying lesions.

Epidermoids do not enhance following intravenous contrast administration.[23,26] Only one case of epidermoid with enhancement of its periphery, thought to be due to gliosis and thickening of the wall, has been reported.[53] Three cases of malignant epidermoids have been reported to show enhancement of a part of the wall after contrast administration.[24] Malignant transformation must be considered in the differential diagnosis when new contrast enhancement on imaging studies and progressive neurological deficit are seen in a patient harbouring an epidermoid cyst.[45]

Magnetic Resonance Imaging

Epidermoid tumours have variable MR features. In T1-weighted images, the signal intensity is between the brain parenchyma and the CSF and in T2-weighted images it exceeds both brain and CSF signals.[81] The signal intensity of some of the lesions is virtually the same as that of CSF in short and long T images. The presence of a cerebellopontine angle mass is usually suggested by displacement of the brainstem (Fig. 4).

Intravenous gadolinium does not show enhancement of the lesion or its capsule. In contrast, acquired cholesteatomas of the middle ear contain predominantly keratinising stratified squamous epithelium and may have moderate signal intensity in TR/TE images. Intravenous gadolinium may show enhancement in such inflammatory and neoplastic lesions.

Petrous apex epidermoids are well delineated in short TR/TE images due to the negligible signal from the adjacent bone and CSF. They may have high intensity signals from cholesterol or other fatty material in short TR/TE images.

Apparent diffusion coefficient (ADC) of epidermoid tumours is lower than that of chordomas with the accuracy reaching 100%.[102] Spontaneous (non-traumatic) seeding of multiple daughter cysts from intracranial epidermoid cysts is very rare and their multiple appearances on MR imaging should be distinguished from the simple scattering of oily contents due to cyst rupture.[55] The rarity of brainstem epidermoid cysts can make their diagnosis difficult; thus diffusion weighted MR imaging sequence of the brain is a useful diagnostic modality.[73]

Treatment

The ideal treatment consists of complete excision of the cyst and its contents. Surgery is the only effective treatment modality for these lesions and as radical a

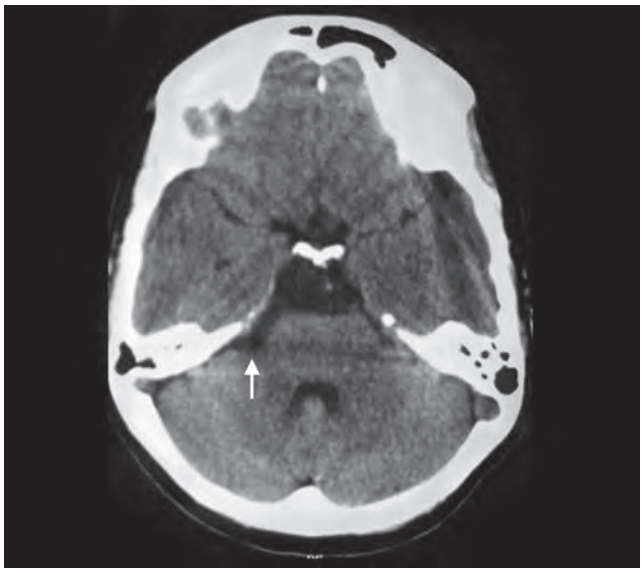

Fig. 2: CT scan of the brain showing CP angle epidermoid (white arrow) with extension into the prepontine cistern

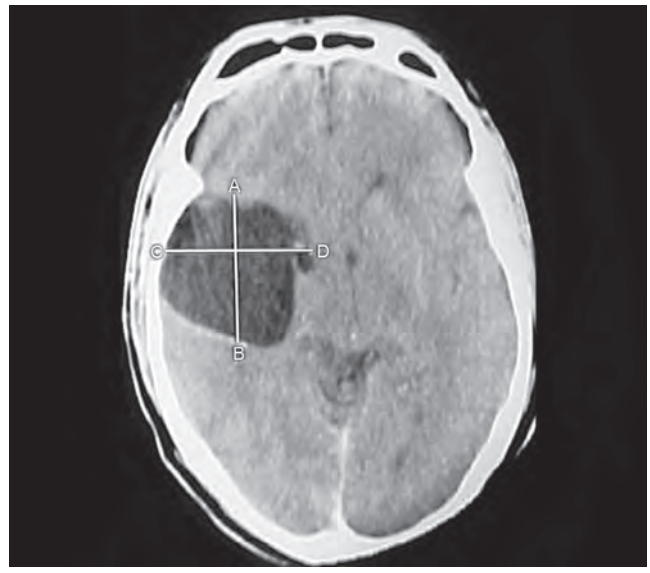

Fig. 3: CT scan of the brain showing epidermoid in the right Sylvian fissure

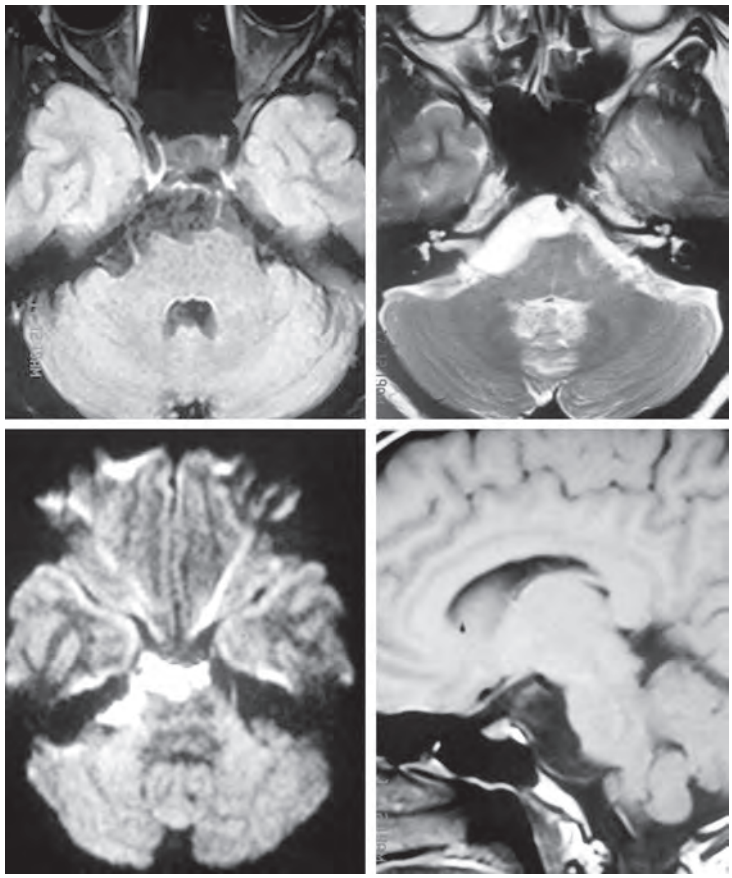

Fig. 4: MRI of the brain showing CP angle epidermoid hypointense on T1 and hyperintense on T2 and brilliant hyperintensity with diffusion restriction on diffusion weighted images

resection as possible should be performed in all cases to avoid tumour recurrence; however, because the cyst capsule can adhere firmly to vital structures and attempts at its radical removal can be dangerous, subtotal resection may be a wise option in selected cases.[11]

There is no role for radiation or chemotherapy. It is possible to excise epidermoids of the scalp and intradiploic epidermoids totally by removing them enbloc along with a margin of healthy bone or by evacuating their contents and scraping the cyst lining of the bone or the dura to which they may have become adherent. Some of these lesions may have an epidural or an intracranial extension, as indicated by the pre-operative CT or MR and this has to be tackled at the same time the calvarial lesion is excised. The extension of the lesion into a major venous sinus may necessitate surgical repair of the sinus after excision of the lesion.[70]

Many epidermoids have a clear plane of cleavage between their lining and the arachnoid membrane, enabling the surgeon to excise it totally with impunity. However, in some cases, due to a granulomatous reaction the cyst lining becomes nodular and gets densely adherent to important neurovascular structures.[96] In such circumstances it is wiser to excise the easily separable portions of the capsule and to leave the densely adherent portions behind, to prevent irreparable damage to vital structures. Tumour growth being very slow, several years may elapse before symptomatic recurrence. This is true also of intramedullary spinal lesions. The use of the operating microscope, a good knowledge of surgical anatomy and patient, gentle handling allows many tumours to be excised totally.[103] Flemming and Boterell,[39] reported only one case of recurrence in their series of 27 cases with a minimum follow-up of 7 years and maximum of 24 years.

The extended trans-sphenoidal approach, which requires a bone and dural opening through the tuberculum sellae and posterior planum sphenoidale, is increasingly used for the treatment of nonadenomatous suprasellar tumours[25] (Fig. 5).

Endoscope-assisted microsurgical techniques enable safe removal even when tumour parts are not visible in a straight line. Tumour extensions into adjacent cranial compartments can be removed with the same approach without retracting neurovascular structures or enlarging the craniotomy.[82] Endoscopic transpterygoid approach to the lateral sphenoid recess has been used to marsupialise a symptomatic epidermoid cyst.[7] The retrolabrynthine approach combined with endoscopy may be used for excision of cerebellopontine angle epidermoid cysts.[19] Pineal region epidermoids can be removed by using either the supracerebellar or occipital-transtentorial approach.[41]

Complications

While excising the tumour, spilling the contents into the subarachnoid space should be prevented, as cholesterin and desquamated keratin act as irritating agents and

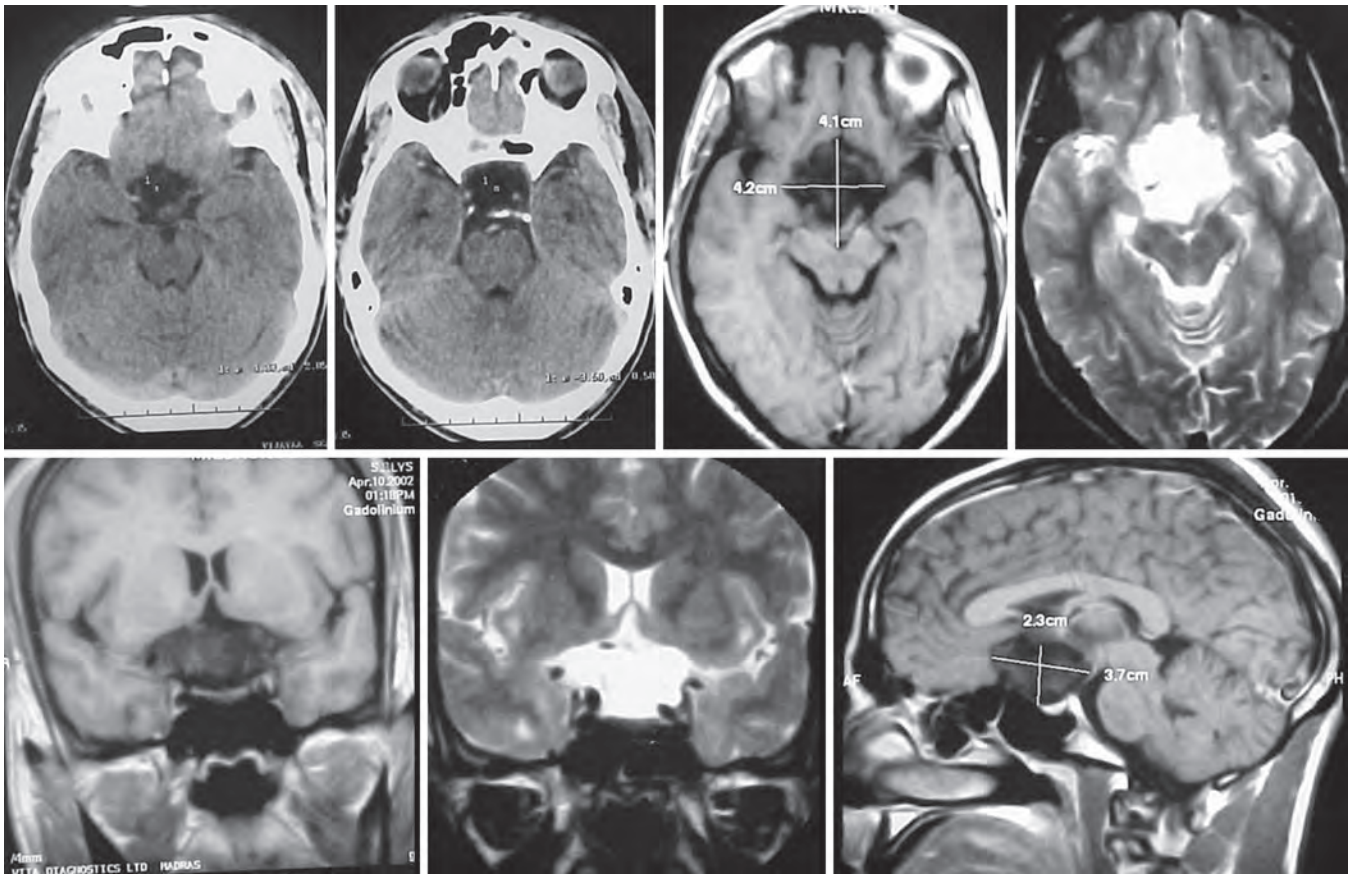

Fig. 5: CT scan of the brain showing epidermoid in the suprasellar region which is hypodense. MRI scan of the brain showing the lesion which is hypointense on T1- and hyperintense on T2-weighted images

cause aseptic chemical meningitis. Thirty-seven percent of the cases, reported by Tytus and Pennybacker,[94] experienced aseptic meningitis post-operatively. Preoperative administration of steroids and irrigation of the operative field with fluids containing steroids is said to help in alleviating the chemical irritation. Post-operative administration of steroids, similarly, helps in reducing the risk of chemical meningitis. Dastur and Deshpande[22] did not encounter a single instance of chemical meningitis in their series of 22 cases, whereas Abraham et al.[1] and Natrajan,[68] encountered it frequently. Lumbar puncture and drainage of contaminated CSF also helps in alleviating the headache and pyrexia that sometimes occur with chemical meningitis.

Chemical meningitis may end in basal arachnoiditis and communicating hydrocephalus, requiring ventriculo or theco-peritoneal shunt insertion. Transient paresis of cranial nerves may occur due to their being handled during surgery. Attempts at excising densely adherent tags of capsule from neural and vascular structures may result in permanent dysfunction and cause significant morbidity. Earlier attempts at total surgical resection were attendant with a high mortality, but the use of the operating microscope, enabling gentle handling, has significantly reduced the mortality from 20% in the 1950s to 10% in 1977 and much lower at present.[35] A review of case reports after 1970s suggests further reduction in operative mortality and morbidity. This is also partly due to early diagnosis with the availability of computed axial tomography. In spite of this, a fair number of multicompartmental giant epidermoids are still being encountered. Complete excision of these lesions poses a difficult problem.

DERMOIDS

Incidence

Dermoids develop from congenital ectodermal inclusions as a result of imperfect embryogenesis. These are usually found at the sites of epithelial fusion lines and have a tendency to occur in the midline. Their incidence varies from 0.1–0.72% of all intracranial tumours.[6] These occur more commonly in the paediatric age group. Paediatric dermoid cysts are unusual lesions with the mean age at presentation being 22 months.[68]

Dermoid cyst is by far the most common orbital cystic lesion in children, accounting for over 40% of all orbital lesions of childhood and for 89% of all orbital cystic lesions of childhood that come to biopsy or surgical removal.[84]

Location

Dermoids can occur in the scalp, the calvarium, the epidural space, intracranially at various locations and in the spinal canal.

Dermoids in the scalp usually occur in the midline over the region of the anterior fontanelle or laterally as angular dermoids over the outer aspect of the eye. These are frequently associated with midline fusion defects and in nearly a fourth of the cases these are connected with the intracranial structures or the spinal canal by a congenital dermal sinus or a stalk.

In the skull, dermoids occur more frequently in the nasal and paranasal regions and the orbits. These occupy the region of the glabella, bridge of the nose and deep part of the septum. They may extend into the anterior cranial fossa. Orbital lesions arise superolaterally at the site of embryologic fusion, erode the orbit and may enter the anterior or middle cranial fossa.[13] It is connected to the dura mater and the orbital periosteum.[31] At times, it may present as a laterally situated dermal sinus with an associated intradiploic frontotemporal dermoid. Intracranially, these occur essentially in the posterior fossa as midline dermoids associated with a dermal sinus and often present as a cerebellar lesion. Usually, these lie in the cerebellar parenchyma, but may be mainly in the meninges.

Dermoid cysts may infrequently occur "primarily" in the temporal fossa. Bone involvement and anterior temporalis muscle displacement are common. An origin from the area anterior to the confluence of the greater wing of the sphenoid, frontal, and zygomatic bones is seen.[54] Dermoids may also occur in the suprasellar region where they have to be differentiated from craniopharyngiomas. They may be intraventricular in location either in the fourth or the third ventricle.

Intraspinal dermoids are more common than epidermoids and are often associated with dermal sinuses and spinal dysraphism. They may coexist with dermoids in other organs. An intraspinal dermoid associated with another dermoid in the ovary was reported by Ramamurthi.[69]

Pathology

Dermoid cysts are developmental lesions and not true neoplasms. These occur as rounded or oval, opaque masses that may have a pearly shine externally with a wall of varying thickness. The wall is composed of dermal epithelium with external collagenous tissue and contains dermal appendages such as hair follicles, sweat glands, and adipose tissue. Dermoids contain sebaceous material and hair in addition to keratinised desquamated debris. The contents are fluid or pultaceous and resemble soft butter.

A dermoid may rarely rupture into the subarachnoid space resulting in severe reactive meningitis which may prove fatal. The most irritant element is cholesterol, which is derived from the breakdown of keratin. It excites a granulomatous form of meningitis.

Neurocutaneous melanosis (NCM), Dandy-Walker malformation and primary intracranial melanocytic and dermoid tumours have been reported to coexist, suggesting a common insult during embryogenesis.[38] The Currarino triad is a unique complex of congenital caudal anomalies including anorectal malformation, sacral bone abnormality, and presacral mass. Dermoid cysts have been described in patients with the triad.[42]

Clinical Features

Dermoids of the scalp usually occur in the midline and are mostly located over the region of the anterior fontanelle or the inion. They are globular, soft, and slightly mobile and the overlying skin may show a skin dimple. They may erode both the tables of the bone and may be adherent to the underlying sinus. When located over the inion, they may have a communication with a similar lesion in the posterior fossa.[31] When inflamed, they present as tender globular swellings.

Not infrequently, an orbital dermoid presents as a discharging dermal sinus situated superolaterally over the orbit. The underlying dermoid is responsible for the festering infection. The dermoid situated superolaterally at the site of embryological fusion tends to erode the orbit and may enter the anterior or middle cranial fossa.[13] It is connected to the dura mater and the orbital periosteum.[31]

A dermoid in the posterior fossa is usually situated in the midline. It is mostly intracerebellar, although it may be found just underneath the dura. It may present with manifestations of raised intracranial pressure and ataxia or with recurrent bacterial meningitis or as a cerebellar abscess when it is associated with a dermal sinus.[66] This brings about the need to inspect carefully the midline areas of the scalp and the skin over the spine, whenever meningitis occurs in a newborn or a young child.[34] Examination of these children with magnetic resonance imaging would be worthwhile, whenever a midline lesion is suspected.[66] Suprasellar dermoids present with visual impairment and bitemporal hemianopia and may be associated with diabetes insipidus. Intra third ventricular dermoids present with manifestations of raised intracranial pressure due to obstructive hydrocephalus. An acute picture of meningitis, often fatal, may evolve if it ruptures into the ventricle. Supratentorial dermoids are rare and may be found in connection with the cavernous sinus. The dermoid may then present with acute third nerve palsy with pupillary sparing.[60]

Nasal dermoids may be located over the glabella, the bridge of the nose or deep in the septum and are usually a consequence of an abnormality of anterior neural tube closure.[33] These may present either as a cyst or as a midline congenital fistula of the nose with an intracranial extension.[52,77] Such a presentation is less common than the sinus over the posterior fossa or the lumbar spine.[10] The sinus traverses either the cribriform plate or foramen caecum[99] and may be associated with nasal anomalies requiring rhinoplasty. Infection may result in cellulitis, abscess, osteomyelitis, and recurrent

meningitis. Uglietta et al.[95] have reported an uncommon case of a congenital dermoid cyst in a 46-year-old man that extended intracranially to form a large bifrontal intra-axial dermoid cyst.

Dermoids in the fourth ventricle may present with progressive headache, unsteady gait, balance disturbances, deglutition disorder and diplopia.[18] A large cystic tumour may displace the cerebellar lobes, push the vermis upwards and present in the cisterna magna. If it ruptures into the fourth ventricle or the subarachnoid space, it may present with acute aseptic or pyogenic meningitis. Tokkok et al.[92] have reported an unusual case of intra fourth ventricular dermoid that presented with bilateral internuclear ophthalmoplegia. Occasionally, a dermoid may mimic a haematoma or transient ischaemia in the posterior fossa, when it presents with an acute onset, waxing and waning of symptoms and a hyperdense appearance on the CT.[4] Waning of the symptoms may be due to its extension into the cisterna magna through the foramina of the fourth ventricle.

Spinal dermoids usually present with recurrent attacks of meningitis when they are associated with a communicating dermal sinus and other stigmata of spinal dysraphism. These are located mostly over the lower dorsal and dorsolumbar regions.[72] Compressing the dorsal cord, the conus or the nerve roots, they produce progressive paraparesis, sensory impairment, and sphincter disturbances. Spinal dermoids may occur at the cranio-cervical junction and may be associated with a spinal anomaly like Klippel-Feil syndrome.[28]

Radiological Findings

Dermoids of the scalp may cause erosion of the bone, often the outer table of the skull. The margins of the erosion are typically sclerotic. Plain X-ray may, at times, show the opening through which a dermal sinus traverses or erosion of the bone when a dumb-bell orbital dermoid extends into the frontal or temporal fossae. Dermoids may, occasionally, contain teeth.

CT scan often shows a cystic mass with flakes of calcium which may not be seen on plain X-ray. There is a large range of attenuation values depending on the nature of the contents, viz. desquamated debris, sebaceous secretions, hair, and fatty tissue. The dermoid may appear as a hyperdense mass if it contains oily cystic fluid.[18] Dermoid cysts are typically hypodense on computed tomography, but when hyperdense may mimic a haemorrhage.[80]

It is often associated with a dermal sinus and may show associated developmental anomalies. Associated hydrocephalus may be seen. In ruptured dermoid cysts multiple fatty globules are visualised in the ventricles or subarachnoid space.[37,100] A typical low fat density is seen in the tumour as well as in the ventricle and/or the subarachnoid space.[101]

MR scan shows the above changes more graphically, especially the tract of the dermal sinus, the relationship of the dermoid cyst to the various structures in the posterior fossa and its exact location within the spinal cord or the conus. Often, the associated tethering of the cord may be vividly seen. In case of ruptured dermoid cysts, fat appears strongly hyperintense on Tl-weighted images.[37,100,101] The imaging characteristics of dermoids and lipomas are extremely similar. Given the difference in the natural history and resectability of these lesions, lipomas should be included in the differential diagnosis of lesions with imaging characteristics similar to dermoids.[27]

Treatment

Ideal treatment consists of total excision of the dermoid cyst along with any associated dermal sinus. Radical excision of intracranial dermoids is usually possible, unless adhesions have developed following attacks of aseptic or purulent meningitis. Yasargil[103] reported a series of eight dermoid and 35 epidermoid tumours with total excision in all, except one densely adherent dermoid and one epidermoid. Excellent to good results were seen in 86% of patients.

Dermoids do not usually undergo malignant change, although a case of a 59-year-old female, who developed a squamous cell carcinoma from the epithelial component of a pre-existing intracranial frontal dermoid cyst, has been reported.[40]
