160 Teratomas

Ravi Ramamurthi, Amit Kapoor

As defined by Willis,[22] "a teratoma is a true neoplasm composed of multiple tissues of kinds foreign to the part in which it arises". It is composed of tissues of adult type and organic pattern derived from all three germinal layers.[17] When the derivatives of all the three germinal layers are not clearly defined, the lesion has been called teratoid.[6] Many of these tumours grow rapidly and may become malignant and according to Willis[22] such teratomas almost always display some tissue elements which are embryologically immature.

Teratomas most commonly arise in the ovaries and testes. In relation to the nervous system, the most common site is the sacrococcygeal region. Within the brain, most of these tumours arise in the midline anywhere from the optic chiasma to the pineal gland, mostly in the latter situation. Hosoi[6] pointed out that almost all intracranial teratomas originate somewhere near the midline, a location with great potential for misplacement of embryonal tissue. The incidence of intraspinal teratomas is approximately five times more than that of intracranial teratomas.[7]

INCIDENCE

Teratomas constitute 3.5% of all paediatric tumours.[18] The brain is considered to be one of the rare sites for teratomas. The intracranial incidence of these tumours varies in different series from 0.2 to 2%,[2,4,7,20,21,23] and is somewhat higher in children. In Japan, it is 0.4% in children. In newborn infants, the incidence is 61.9% of all intracranial space occupying lesions discovered at birth.[9,19]

Teratomas usually occur in younger age groups and males are affected more than females.[17] Nearly 50% of the teratomas are located in the pineal gland. The other preferential sites are the ventricular system and the posterior fossa. In a series of 99 cases of intracranial teratomas, 49 were pineal teratomas, 14 were in the ventricular system, 27 in the supratentorial region (of them 8 in the hypophyseal region), 4 in the posterior fossa and 5 in undefined locations.[1] Intracranial teratomas of the newborn have several characteristics different from the teratoma of the pineal region seen in older children. In the former, the sex ratio of female to male is about 2:1, while the pineal teratoma is predominantly reported in males.

PATHOGENESIS

Willis[22] felt that teratomas arise at early stages of embryonic development. For unknown reasons, many do not manifest themselves until several years after birth, occasionally not until several years into adult life. Those occurring in the newborn are a special variety, which grow to an appreciable extent at a very early period. Differences in the rate of growth seem to account for the various forms in which these tumours present themselves in infancy.

Of the various theories on the pathogenesis of these tumours (the blastomeric theory, Masson's twin theory, the parthenogenetic theory), anomalies of the primitive streak alone appear to be applicable to the nervous system. Teratomas are assumed to develop, following inclusion within the embryo of a fragment of the primitive streak in the multipotent stage. This theory lends support to the role of the neural groove, thus explaining fairly satisfactorily the appearance of sacrococcygeal spinal, midline supratentorial and infratentorial teratomas.

PATHOLOGY

Macroscopically the striking characteristic of a teratoma is its partly cystic nature, the cysts usually being multiple and containing whitish fluid from desquamation of the lining cells. The solid portion of the tumour is firm, greyish-white and discoloured yellow by previous haemorrhage. Some of the teratomas are sharply demarcated from the adjacent nervous structures and can readily be dissected away from them. Others, especially in the intraspinal group, are blended so closely with the neural tissue that no plane of cleavage can be identified. An outstanding feature is a tendency to obstruct the CSF pathways. Congenital teratomas manifesting early in life may attain massive proportions, replacing the greater part of the brain.[16,17]

Microscopically, the tumour tissue consists of elements of all the three germinal layers. Depending upon the different proportions of embryonic and mature tissues, the tumour may be classified benign or malignant. If the cells are mature and well differentiated then it is labelled benign. As a general rule, the more embryonic the tissue, the more malignant is the tumour. Typical foci of germinomas may be seen in pineal, suprasellar and other teratomas.[8,13]

CLINICAL FEATURES

The symptoms and signs are those of any space occupying lesion. There are local effects depending upon the site of tumour and pressure effects resulting from an increase in the volume of the cranial contents. There are no specific clinical signs which may suggest the pathological diagnosis pre-operatively, unless an associated congenital anomaly is present. The presence of a congenital anomaly in a patient with signs and symptoms of a space-occupying lesion does not establish the diagnosis of a teratoma or teratoid tumour but makes the chances of finding this lesion somewhat greater.

In infants, the onset is marked by rapidly progressing hydrocephalus with occasional localising signs, such as gaze palsy, pupillary change and hemiparesis and lucency on transillumination of the head. Teratomas in infants and the newborn may be classified into three groups on the basis of clinical and autopsy findings:

1. The infant may be born dead with complete replacement of the brain tissue above the brainstem by the tumour. The birth of these infants may be associated with dystocia. The lesion is inoperable because of replacement of brain tissue.
2. The infant may be born alive but show progressive cranial expansion.
3. The infant may look normal at birth but subsequently develop hydrocephalus and focal neurological deficits.

These infants may be saved if the diagnosis is made early in the course of the illness,[5,10,19] although Odeku[12] expressed a pessimistic view.

In older children and adults, localising signs are infrequent. Endocrinal disturbances, as also Parinaud's syndrome, may be found, if the teratoma develops near the pineal region. Suprasellar teratomas cause a characteristic syndrome of diabetes insipidus, visual disturbances and hypopituitarism. Occasionally, increased intracranial pressure may be present.[20]

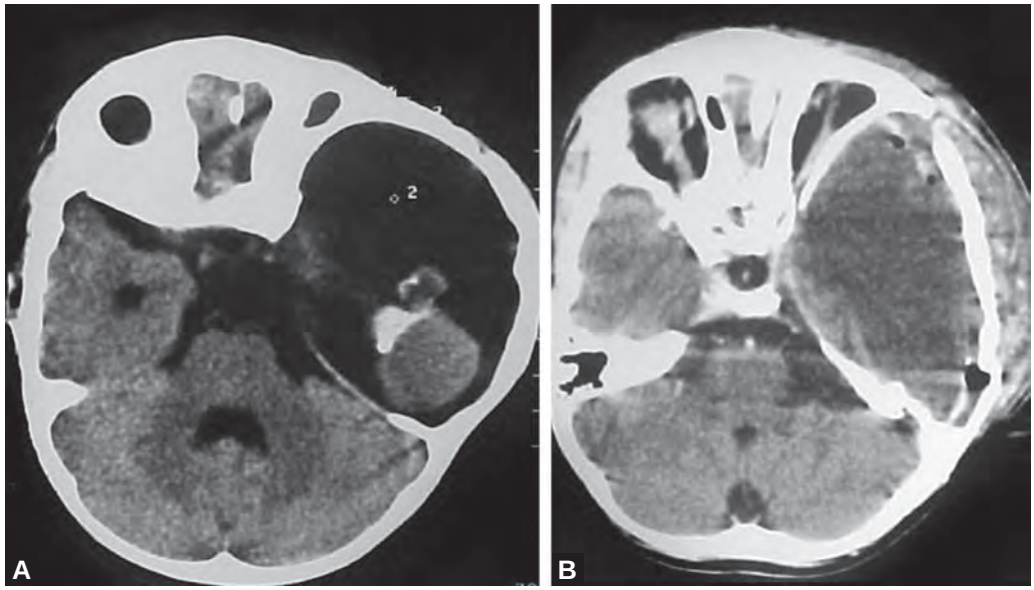
IMAGING

Roentgenograms of the skull show widened sutures, craniofacial disproportion and calcification of the tumour mass or other organoid structures like a tooth in the tumour.[15] CT is useful in demonstrating even small tumours, provided they contain fat or calcium. The CT pattern of a malformative tumour is that of a relatively well defined extra-axial mass lesion with or without calcification that fills or moderately expands the pre-existing CSF spaces.[11] While the fat components have a low attenuation value, other components may show hyperdensity (Figs 1A to H).

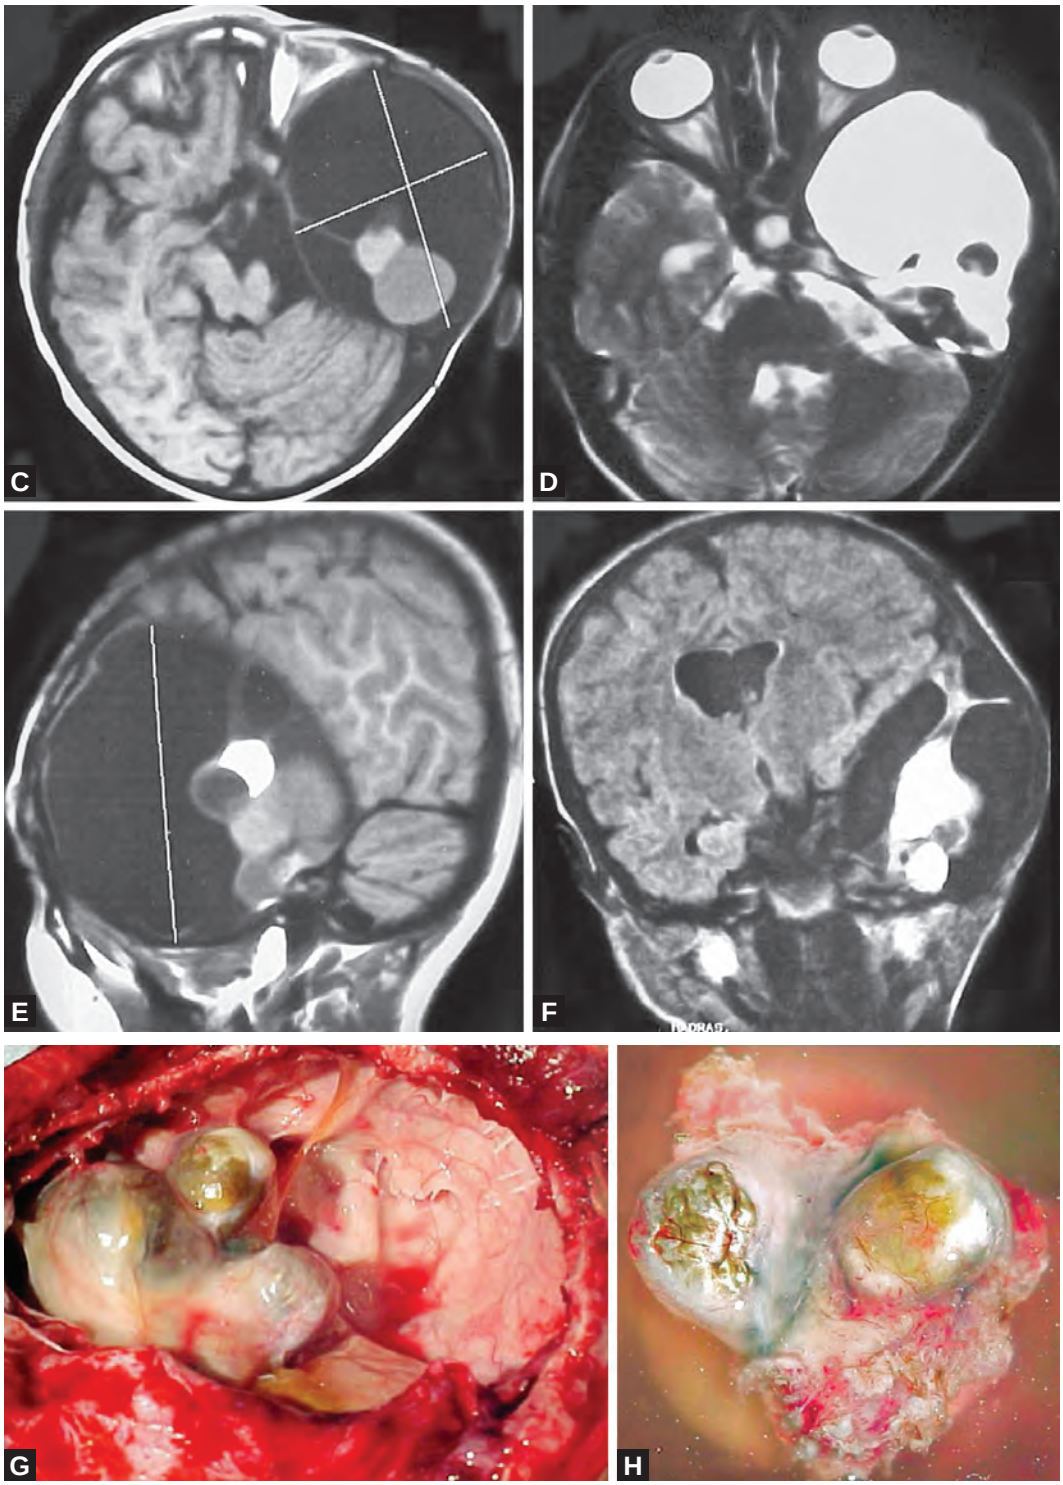
MR findings vary with the tissue component of the teratoma. The characteristic angiographic findings of intracranial teratomas are deviation of the main cerebral arteries by a large mass of tumour, a fine vascular network and early venous shunting.

TREATMENT

The ideal treatment, wherever possible, is excision. Mature teratomas have a good prognosis if completely excised.[3] This may, however, not always be possible, in which case a shunting procedure may be necessary to relieve the hydrocephalus. Aggressive resection seems to be of utmost importance in the treatment of immature teratomas of the CNS.[14] Ten-year survival for surgical excision alone varies with histological type, being more than 90% for mature teratomas, less than 70% for immature teratomas and less than 50% for teratomas with malignant components.[18] Adjuvant chemotherapy and radiotherapy can be deferred if gross total resection is achieved in low-grade, immature teratomas but



Figs 1A and B: (A) Pre-operative CT scan of the brain of a patient with left temporal teratoma. (B) Post-operative CT scan of the brain of the above patient



Figs 1C to H: (C to F) Pre-operative MRI brain axial T1, axial T2, sagittal T1 and coronal T1. (G and H) Per-operative pictures of the tumour

adjuvant therapies may be warranted in high-grade ones.[14] Diverse therapeutic protocol based on histological diagnosis is necessary to plan appropriate management. Treatment recommendations are:

- Mature teratomas completely resected and no adjuvant therapy;
- Sub-total resection: Adjuvant therapy (cisplatin) followed by second look surgery, and
- Immature teratomas: Radiotherapy and chemotherapy both are used with variable efficacy.

Chemotherapeutic agents used include carboplatin, etoposide, bleomycin, ifostamide, vincristine and dactinomycin. High recurrence rates are encountered with chemotherapy alone even if beta HCG/alpha fetoprotein levels come to normal post-operatively. Teratomas with highly malignant components including embryonic

carcinoma, yolk sac tumour, squamous cell carcinoma, adenocarcinoma and sarcoma are chemo-resistant. Chemotherapy along with craniospinal irradiation with local booster radiotherapy is indicated.

Second look surgery is indicated in cases where tumour markers are elevated and suggestive of malignancy. Non-malignant teratoma lesions or teratomas mixed with haemorrhagic necrosis or inflammatory cells may also benefit from second look surgery. Higher tumour marker levels indicate poorer treatment response and although useful for monitoring disease status, tumour markers have no impact on the patient's final outcome. Chemotherapy eliminates the malignant elements of a mixed tumour, leaving pure teratoma which paradoxically begins to grow very rapidly and this increase in the size of lesion post-chemotherapy is described in literature as growing teratoma syndrome.[18]

161 Acoustic Schwannomas

Ravi Ramamurthi, Murali Mohan S

INTRODUCTION

Intracranial schwannomas can arise from any of the cranial nerves with a Schwann cell investing layer. However, the VIII nerve accounts for a disproportionately large number of these tumours, with the V nerve a distant second and the others being rare. Even rarer are reports of intraparenchymal schwannomas in the cerebellum and cerebrum.

A schwannoma arising from the VIII cranial nerve is called acoustic schwannoma [synonyms—acoustic neurinoma, acoustic neuroma, acoustic neurofibroma and vestibular schwannoma (VS)]. This tumour should ideally be termed as VS as they arise from the Schwann cells investing the vestibular nerve, but the term acoustic schwannomas is so firmly entrenched in the literature that its use is continued.

HISTORY

The earliest description of an acoustic schwannoma was by Sandifort in 1777 while Leveque-Lasoure in 1810 documented the first correlation of the tumour. Other notable clinicopathological observations were by Sir Charles Bell in 1830 and Cruveilhier in 1842. The history of acoustic schwannoma surgery began with the unsuccessful posterior fossa explorations performed by Von Bergmann in 1890, and by McBurney in 1891. Sir Charles Ballance is credited with the first successful removal of an acoustic schwannoma in 1894. However, Cushing felt that the tumour was a meningioma and attributed the first successful removal of a true acoustic schwannoma to Annandale in 1895. After Sir Charles Ballance and Annandale introduced the suboccipital craniectomy (SOC) approach for removal of acoustic schwannomas other neurosurgeons attempted surgery through this route without much success. Horsley, Von Eiselberg and Krause in 1913 reported a 67–84% mortality using the unilateral suboccipital approach.[158] Cushing made the first major advance in acoustic schwannoma surgery by decreasing the operative mortality to 15%.[37] Thus, he achieved by large bilateral craniectomies to relieve the raised intracranial pressure (ICP) and a palliative subtotal intracapsular decompression of the tumour. Though many patients succumbed to recurrence of the tumour, Cushing's 5-year survival rates were as high as 50%.[137] In his last 50 cases, however, Cushing's operative mortality was only 4%.[36] The classical monograph by Cushing, in 1917,[37] elaborated the clinical picture and diagnosis, and at the same time helped to dispense the pessimism regarding its surgical treatment. During the years 1890–1925, the SOC approach, the translabyrinthine and the transsigmoidal (combined translabyrinthine and suboccipital) approaches were introduced.[158]

Dandy[38] advocated total excision of the tumour and perfected the unilateral approach, which has undergone technical modifications, but has remained the prototype for the suboccipital approach. In 1925, he reported 5 patients operated upon via the bilateral SOC approach with total excision of the tumour.[38] He advocated tapping the lateral ventricle, releasing cerebrospinal fluid (CSF) from the cisterna magna, resecting the lateral third of the cerebellar hemisphere and deroofing of the internal auditory meatus (IAM) to achieve a safe and total removal. Though Dandy's operative mortality in cases where total excision was performed was 9.3%, his overall mortality in the 140 acoustics in his career was 22%.[158] Panse, in 1904, was the first to suggest a translabyrinthine approach to acoustic schwannomas. However, in view of the strong criticism by both Cushing and Dandy, it was abandoned till William House revived this approach to remove large tumours.[97]

Olivecrona was the first surgeon who attempted to save the facial nerve in a large series of patients while achieving complete tumour removal (31.8% of 217 patients),[177] though Cairns, in 1931, reported first on facial nerve preservation.[22] The first report on hearing conservation with "total removal" of the tumour was by Elliot and McKissock.[55] The first use of microsurgical techniques in acoustic schwannoma surgery was by House and Doyle who used the middle fossa approach to the tumours. In 1964, House reported a 5.4% operative mortality using microsurgical techniques.[97] He used the SOC, translabyrinthine and the middle fossa approaches and saved the facial nerve in 79% of patients. Rand and Kurze[197] used microsurgical techniques in the SOC approach and advocated its use for tumours of all sizes. Though the first report of hearing preservation was as early as in 1954, it was not until after the 1970s that emphasis was placed on hearing preservation.[158]

EPIDEMIOLOGY

Schwannomas constitute about 8% of all intracranial tumours[195,253] which present clinically. A significant number that were not symptomatic while the patients were alive have been found at autopsy.[87] The majority of acoustic schwannomas are sporadic and unilateral.[187,200]

Bilateral acoustic schwannomas are hereditary and constitute less than 5% of all schwannomas.[53]

Age and Sex Distribution

Acoustic schwannomas are commonest in the fourth to sixth decades[88] with the average age at presentation being almost a decade earlier in our country.[193,209] Acoustic schwannomas developing in patients with neurofibromatosis type-2 (NF-II) tend to present earlier, with a peak incidence around the third decade.[54,208] Acoustic schwannomas can occur in children.[124,128,149] Sambasivan et al.,[209] reported a nine-year-old patient with an acoustic nerve tumour. There is a slight female preponderance in most series,[88,187] with an aggravation of symptoms during pregnancy. This is not true of tumours in childhood, where an equal sex distribution is seen.[91]

Racial and Geographic Distribution

Acoustic schwannomas have been rarely reported in black Africans. Its incidence in Kenya was 2.6% and 0.9% in Nigeria. The incidence reported from England is 4.9% and from USA it is 4%. The incidence is greatest in Asian countries, with a rate of 10.2% from China and 9% from Egypt. Various reports from India suggest an incidence around 10%.[117]

Tumour Syndromes and Genetic Factors

Most of the acoustic schwannomas are unilateral and are sporadic in nature, accounting for 96% of cases. Hereditary acoustic schwannoma occurs in NF-II more frequently than neurofibromatosis type-1 (NF-I), though the latter is much more common. Unilateral acoustic schwannoma has been reported only in 2–4% of cases with NF-I.[117] Bilateral acoustic schwannoma is a hallmark of NF-II. Until 1980, it was considered to be a central form of Von Recklinghausen's disease. It was Kanter et al.[115] who described that these two entities were different and this was later confirmed by genetic studies.[117] Both these conditions have high penetrance and are autosomal dominant. The defective genetic locus has been localised to chromosome 17 in NF-I and chromosome 22 in NF-II.

The NF-II gene is considered to be a tumour suppressor gene. Germline transmission of the mutant gene in NF-II patients predisposes to tumour formation which results via somatic mutation of the remaining wild type allele.[117] The difference between the sporadic and hereditary forms of the disease is that the defect in bilateral acoustic schwannomas is present in the germline. The patient inherits only one copy of the tumour suppressor gene and undergoes spontaneous mutation of the other antioncogene in a somatic cell. In sporadic forms, homozygous mutation of both NF-II genes has to occur in one specific Schwann cell precursor. A subset of patients with NF-II inherits this genetic defect not only in Schwann cells, but in all cells. These patients are prone to develop multiple meningiomas in addition to bilateral acoustic schwannomas.[117]

Natural History

The growth rates of these tumours are generally slow, usually less than 2 mm per year,[6,161,287] however, there are reports of rapid growth rate of about 2.5–4 mm per year.[199] There are marked differences in the duration of symptoms at the time of presentation, and an important factor determining the future course in these cases is the initial size of the tumour at presentation. Though there are reports stating that a slow or absent growth over a period of 2–3 years makes it unlikely that there will be significant enlargement subsequently, there are other reports about significant growth after an initial period of quiescence. The growth rates in bilateral acoustic schwannomas are on an average considered to be faster than in unilateral lesions.[16,81,203]

SURGICAL ANATOMY

Modern microsurgical techniques used in cerebellopontine angle (CPA) surgery require a detailed and intimate knowledge of all structures in and around the CPA and the brainstem.

The CPA or fissure is V-shaped and is formed by the folding of the petrosal surface of the cerebellum around the lateral side of the pons and the middle cerebellar peduncle. The floor of this space is formed by the middle cerebellar peduncle. The cerebello-medullary cistern is situated between the cerebellar tonsils and the medulla, and communicates with the CPA cistern near the foramen of Luschka. The trigeminal, the abducent, the facial, the vestibulocochlear and the glossopharyngeal nerves arise between the superior and inferior limbs of the CPA. There are four nerves at the IAM; the facial (with the nervus intermedius), the cochlear and the superior and inferior vestibular nerves. The nerves are most constant in the lateral end of the meatus where a horizontal ridge (transverse or falciform crest) divides the meatus into superior and inferior portions. The facial nerve and the superior vestibular nerve are superior to the crest. Further, the facial nerve is anterior to the superior vestibular nerve and is separated from it by a vertical crest of bone. The cochlear nerve and the inferior vestibular nerve are in the inferior portion of the meatus, with the cochlear nerve anterior to the inferior vestibular. The internal acoustic pore has a width of 9–10 mm and a height of 3–6 mm. The internal auditory canal (IAC) has a length of 6–7 mm and a height of 3–7 mm.[122]

The facial nerve arises from the brainstem near the lateral end of the pontomedullary sulcus, 1–2 cm anterior to the point where the vestibulocochlear nerve enters the brainstem at the lateral end of the same sulcus. The sulcus ends just medial to the lateral recess of the fourth ventricle. The facial nerve and the vestibulocochlear nerve are furthest apart at the brainstem and converge and meet at the IAM. The facial nerve also shares a constant relationship with the IX, X and XI cranial nerves at the brainstem. The facial nerve arises 2–3 cm above the emergence of the superior most rootlets of these nerves from the brainstem. The intracisternal length of the facial nerve is 9–26 mm. As the nerve runs

medial to the vestibulocochlear nerve, it is not visible to the surgeon during the lateral approach to the posterior cranial fossa.

The vestibulocochlear nerve is usually oval and enters the brainstem 13–17 mm from the midline, slightly caudal and lateral to the exit zone of the facial nerve. The intracisternal length of the nerve averages 14.9 mm. During its course, it undergoes rotation, so that on entering the brainstem the cochlear part is lateral most, the superior vestibular the medial most, with the inferior vestibular in between. The length of the nerve with central myelin (oligodendroglia) is 8–12 mm, the transition zone normally lying near the IAM.

The average length of the trigeminal nerve in the CPA and the posterior fossa is 12.3 mm for the sensory root and 14.1 mm for the motor root. The nerve forms an angle of 10–35 degrees with the median plane as it courses from the pons to Meckel's cave. It exits from the posterior fossa through a dural opening situated at the anterior end of the medial surface of the tentorium cerebelli. Here the superior petrosal sinus is in close relationship to the nerve. The superior cerebellar artery forms a close relationship to the nerve.

The abducent nerve emerges from the brainstem approximately 3.9 mm lateral to the midline and has an intracisternal course of 15 mm in the posterior fossa. When looking into the posterior fossa through the suboccipital approach, the nerve may be seen in the depth, coursing through the CPA. When large tumours rotate the brainstem, the VI nerve may be confused for the VII, as both emerge from the brainstem at the same level and their exits are in the same horizontal plane.

The IX and X cranial nerves emerge from the brainstem from the paraolivary area caudal to the pontomedullary sulcus. They bear a constant relationship to the facial nerve at this point. The IX nerve rootlets form two delicate bundles, while the X cranial nerve emerges as multiple fine rootlets. They run approximately 15.6 mm in the CPA.

The anterior inferior cerebellar artery (AICA) is closely related to the facial and vestibulocochlear nerves. After originating from the basilar artery it passes around the pons near the pontomedullary sulcus. In most cases the AICA passes below the facial and the vestibulocochlear nerves as it encircles the brainstem. It may, however, occasionally pass between or above the nerves. The internal auditory artery (which supplies the VII and VIII cranial nerves), recurrent perforating arteries and the sub-arcuate artery are branches of the AICA which are in close relation to the facial and vestibulocochlear nerves in the CPA.

The veins on the side of the brainstem are fairly constant and have a predictable relationship to the facial and the vestibulocochlear nerves. The vein of the pontomedullary sulcus, the lateral medullary vein, the veins of the cerebellopontine fissure and the cerebellomedullary fissure and the vein of the middle cerebellar peduncle course near the lateral recess of the IV ventricle and the junction of the VII and VIII nerves with the brainstem. The superior petrosal vein (Dandy's vein) is the principal draining vein of the anterolateral posterior fossa structures. It courses anterolaterally, more or less parallel to the V nerve to enter the superior petrosal sinus between the IAM and Meckel's cave. The vein is 1–2 mm in diameter, though occasionally it may be made up of a leash of veins. The inferior petrosal vein courses along the vagus nerve.

PATHOLOGICAL ANATOMY

Acoustic schwannomas arise most commonly from the vestibular nerves (80%) with an origin from the cochlear part in only about 5–7%. Considering the nerves involved in the tumour at the fundus of the IAM, Koos et al.[122] found the inferior vestibular nerve involved in 70% of patients, the superior vestibular in 20% and the cochlear nerve in 10% of patients. The origin of the tumour is from the junctional (Obersteiner-Redlich) zone where the central and peripheral myelin meets. This zone is situated at the region of the IAM or within the IAC in most instances. The tumour grows initially within the canal and thereafter extrudes into the CPA. Inside the petrous bone, the tumour may compress the cochlear component of the nerve or the labyrinthine artery, causing sudden severe hearing loss.[226] Tumour growth into the CPA results in anterior displacement of the facial and cochlear nerves. The relationship of the tumour to the vestibulocochlear nerve varies:[122]

- In about 50% the nerve fibres are intimately involved with the tumour making separation impossible
- In 40%, though the nerve is in the form of a bundle initially, it becomes adherent to a part of the tumour capsule making functional preservation impossible
- In 10% the uninvolved portion of the nerve maintains anatomical integrity and the nerve is displaced as a separate bundle.

Clinically, this last group of cases present with preserved hearing and this should alert the surgeon to the possibility of hearing preservation. In this group of cases, the vestibulocochlear nerve is displaced inferiorly in 80%, anteriorly in 18% and posteriorly in 2% of cases.

Depending on the direction of growth of the tumour, the facial nerve may run one of four courses around acoustic schwannomas:[122]

- The nerve runs anterior to the tumour in about 70% of cases
- Superior in about 10% of cases
- Posterior in about 7% of cases
- Inferior in about 13% of cases.

The position of the facial nerve is most constant at the lateral end of the IAM and it is best to locate the nerve here, rather than more medially, where displacement may make its position more variable. The nerve may anatomically be distorted by the tumour; in about two-thirds of cases the nerve maintains the shape of a thin bundle, while in about a third of cases the nerve fibres are splayed over the tumour capsule.[122] In cases of Von Recklinghausen's disease, the proportions are reversed.

Once the tumour emerges from the canal it abuts onto softer structures and tends to grow in a symmetrical

fashion centred on the porus. Since the tumour arises from outside the CSF space, it pushes the lateral layer of the arachnoid inwards till it comes into contact with the more medial layer. The double layer thus formed contains the important vessels and nerves of the CPA and is an important aid to dissection. There is often a loculation of CSF which presents as an arachnoid cyst dorsolateral to the tumour.

The cerebellar hemisphere is displaced backwards and the brainstem is compressed and rotated along its long axis with gross displacement and stretching of the basilar artery and its branches. Nubbins of tumour may grow between the blood vessels. The tumour comes to lie in contact with the tentorium and may grow up through the tentorial hiatus into the middle cranial fossa. Some tumours may also herniate through the foramen magnum. Ramamurthi et al.[193] reported that the further direction of growth seems to be determined by the shape of the posterior fossa, the tumour tending to grow inferiorly when the posterior fossa is shallow and more superiorly if the tentorium is high and the posterior fossa deep.

As the AICA most often passes below the VII and VIII nerves, it is displaced inferiorly. In large lesions, the AICA may be seen lying in close relation to the IX and X cranial nerves. The superior cerebellar artery is displaced rostrally and the posterior inferior cerebellar artery caudally. The veins surrounding the tumour form bridging veins which empty into the superior petrosal sinus. While small tumours can be removed without sacrificing these veins, in large tumours it may be necessary to sacrifice one, if not more, or even the superior petrosal vein, to reach the superior pole of the tumour.

PATHOLOGY

Grossly the tumour is usually firm, rubbery and pale grey in colour with varying degrees of vascularity and has a well-defined capsule, which may be covered by displaced and stretched nerve fibres. The cut surface is usually pale grey and firm with a finely whorled or trabeculated appearance. In large tumours there is, frequently, evidence of cystic degeneration, haemorrhage, xanthomatous change and occasionally foci of calcification. These changes give a variegated appearance in colour and consistency to the large tumours. The blood supply of the tumour is initially derived from the internal auditory artery, which provides multiple minute ramifications over the surface of the tumour. As the tumour grows, small branches from the neighbouring cerebellar and pontine arteries may supply the tumour. Depending on the histology, the consistency of the large tumours varies. Some are firm and thus push the surrounding vascular and neural structures which lie stretched over them. These tumours are easier to excise than the softer variety, which have a tendency to grow all around the neurovascular structures and creep into the crevices.[193] Such tumours, hence, are more difficult to dissect free from important arteries and nerves.

Microscopic Features

On light microscopy, the tumour is composed of spindle cells with elongated nuclei and fibrillary cytoplasm,[21,204] arranged in two distinctive patterns termed Antoni A and Antoni B. Antoni A tissue is compact, with fairly prominent interwoven streams of elongated bipolar cells. The tendency for the nuclei to be aligned in straight or curved rows with their long axes parallel to one another gives the classical pallisading pattern. At times, the arrangement of the nuclei and fibres results in structures simulating the whorls seen in meningiomas. Antoni B is less structured and consists of random collections of cells clustered around areas of cystic change, necrosis, blood vessels and old haemorrhage. There is a variable amount of lymphocytic infiltration of this tissue. The Antoni B type of tissue, seen mostly in large tumours, is believed to be the result of ischaemia. The relative amounts of these two types determine the consistency of the tumour. Nuclear pleomorphism is common in schwannomas, but these are benign changes, as malignant transformation almost never occurs. Mitotic figures are rare. Necrosis, when seen, is also more a reflection of a poor blood supply rather than of rapid growth. The degenerative changes in the tumour tissue include oedema, formation of micro or macro cysts, xanthomatous alteration, hyalinisation and foci of calcification. Dastur et al.,[41] reported a melanotic tumour of the acoustic nerve, where the histology suggested phagocytic ingestion of melanin granules by the Schwann cells. A variety of vascular changes have been observed, especially in large tumours. These consist of acute necrosis and recanalised thrombi, aneurysmal dilatation of vessels and acute and old haemorrhages.

Electron microscopy (EM) reveals the characteristic basement membrane of the Schwann cells and the presence of wide-spaced collagen. The EM is not necessary for routine diagnosis of schwannomas, as the light microscopic picture is characteristic. Similarly, immunohistochemistry is rarely required.

A detailed pathological study of 102 cases of benign nerve sheath tumours, utilising light microscopy, EM and immunohistochemistry has been done by Sharma et al.[237] They provided evidence that all nerve sheath tumours are basically of Schwann cell origin and that the intermediate cells are fibroblast like cells which are variants of Schwann cells. The different morphological appearances and biological behaviour of schwannomas and neurofibromas may be related to some other factors like microenvironment or genetic predisposition.

CLINICAL FEATURES

The signs and symptoms of an acoustic schwannoma are those referable to the VIII nerve itself, as well as those due to involvement of the adjacent cranial nerves (VII, V, IX and X), the cerebellum and the brainstem. To these may be added the symptoms and signs of raised ICP. Small tumours may exist for a long time producing only VIII nerve symptoms. The most common symptoms of

acoustic schwannomas are unilateral sensorineural hearing loss (96%), unsteadiness (77%), tinnitus (71%), headache (29%), mastoid pain or otalgia (28%), facial numbness (7%) and diplopia (7%).[86] Usually slow growing and presenting insidiously, they can have acute presentations when there is haemorrhage within the tumour, or due to rapid expansion of a cyst.

Auditory

Though the tumour originates from the vestibular nerve, the commonest presenting symptom in acoustic schwannomas is unilateral hearing impairment, which is found in almost all cases. The hearing loss is a high frequency retrocochlear sensorineural type and is slowly progressive. Being insidious in onset, the impairment of hearing, which commonly precedes all other symptoms by several years, may pass unnoticed for a long time. An occasional patient may never complain of auditory symptoms even when the tumour has acquired a large size. Some of the patients who do not give any history of hearing defect initially accept its existence on direct questioning. They consider their hearing defect unrelated to the other distressing symptoms like those of raised ICP. The lack of importance our patients appear to give to a hearing deficit is confirmed by Sambasivan et al.[209] and Ramamurthi et al.[193] Thus, it is not surprising that small acoustic tumours are rarely diagnosed. Sudden onset of deafness has been reported in a few acoustic schwannomas.[184,226]

Even though some patients may not complain of unilateral deafness, the way they turn their normal ear towards the examiner to listen better is a characteristic sign. Deafness may be tested in the consulting room; speech discrimination by using whispered words and tone deafness by using tuning forks of varying frequency (256–1018 Hz). High tone deafness will be apparent from this. Air conduction is tested by placing the tuning fork near the external ear and bone conduction by placing it on the mastoid process and the frontal bone (Weber's test and Rinne's test). These give an approximate idea of whether the deafness is of the conduction or sensorineural type.

Tinnitus is another common symptom of acoustic schwannomas being reported as the initial symptom in about 30% of cases.[72] Tinnitus may precede or accompany the onset of hearing loss. It may be intermittent or may completely disappear after some time.

Vestibular

Subjective symptoms of vestibular dysfunction are uncommon as the presenting complaint; though on objective testing 80–96% of patients may have signs of vestibular dysfunction.[57,192] This is thought to be due to suppression of the abnormal impulses by higher centres.[57] The commonest vestibular symptom is a sensation of instability on movement of the head. A true whirling vertigo is uncommon, though a few patients may suffer from episodes not unlike those seen in Meniere's disease.

Nystagmus may be seen in a number of cases and is usually due to a vestibular disturbance in the early stages and pressure on the brainstem in the later stages. This may be spontaneous, positional (when the head is hyperextended and the head turned to the right or left) or optokinetic. The most common variety is the fine horizontal beats directed away from the side of the lesion produced due to unilateral labyrinthine dysfunction. Large tumours producing significant brainstem compression manifest as bidirectional nystagmus with a coarse gaze evoked optokinetic nystagmus on looking to the ipsilateral side and a high frequency fine small amplitude vestibular nystagmus on looking to the contralateral side. Spontaneous nystagmus, though bilateral, is usually more marked on looking to the opposite side. It is not dependent on visual fixation, but on conjugate deviation of the eyes. Dix and Halpike termed it deviation maintenance nystagmus.[46] Hyperventilation induced nystagmus beating to the side of reduced caloric response, hearing impairment or abnormal auditory brainstem responses may be a valuable sign for bedside detection of CPA tumours.[29]

Some of the above otoneurological symptoms and signs may be present in patients with raised ICP without a CPA lesion.[140,251,252]

Facial Nerve

The facial nerve has been clinically observed to be remarkably resistant to stretch, and symptoms and signs due to involvement of this nerve appear late and are minimal, except in very large tumours.[253] A slight lag in blinking of the eyelid on the affected side is an indication of early facial palsy.[193] Signs of irritation of the facial nerve, like twitching or increased lacrimation have occasionally been reported.[52,209] The increased incidence of facial paresis in Indian series compared to series from the Western countries,[194,253] reflects the large size of tumours still seen and the late referrals to the neurosurgeon. A minimal facial weakness may be detected by electromyography. Contralateral or bilateral facial weakness has been reported in isolated cases.[253]

Other Cranial Nerves

The trigeminal is the next common nerve to be involved, the nerve being stretched by the upward growth of the tumour when it reaches an extracanalicular size of about 3 cm. Symptoms and signs of trigeminal dysfunction were seen pre-operatively in 66% of 196 patients operated upon by Ramamurthi and Ravi[194] between 1980 and 1993. The common abnormality referable to the fifth nerve is impairment of the corneal reflex. Subjective numbness and/or paraesthesia in the trigeminal distribution may be complained of by many patients. Tingling of the tongue may be the first symptom of an acoustic neurinoma for many weeks. Infrequently, there may be pain which may mimic typical trigeminal neuralgia in a given case. Sambasivan et al.,[209] reported trigeminal neuralgia as the only symptom without any other neurological deficit in 3% of their cases of acoustic schwannomas. Symptoms referable to the motor root are seldom complained of even though objective evidence of such an involvement is observed in 10–15% of cases.[253]

In advanced cases, due to twisting of the brainstem, there may be impairment of corneal sensation on the opposite side.[2]

The glossopharyngeal and vagus nerves are involved usually late, and manifest as palatal paresis, hoarseness of voice and dysphagia. Though rare in most studies in developed countries, lower cranial nerve involvement has been reported in up to 20% of patients in India.[194]

Cerebellar

Symptoms related to cerebellar dysfunction are found in patients with large tumours. These have been reported in nearly 46% of patients with acoustic schwannomas.[194] The deficits are commonly gait ataxia and incoordination of the upper limb, dysarthria being rare. When nystagmus is present, it is usually due to vestibular and brainstem involvement rather than cerebellar involvement. In the presence of brainstem compression the nystagmus is slow and prolonged and there may also be a vertical nystagmus.

Brainstem

A large tumour can cause compression and later torsion of the brainstem with resultant pyramidal weakness and contralateral cranial nerve deficits.[2]

Raised Intracranial Pressure

Though the technical capacity now exists to diagnose an acoustic schwannoma when it is still intracanalicular, a significant number of patients still present for the first time only after the onset of features of raised ICP. Mental symptoms due to chronic hydrocephalus have been the presenting feature in some elderly patients with large acoustic tumours.

Headache

Headache in most of these cases results from increased ICP. Headache may also occur in the absence of raised ICP due to pressure or traction upon blood vessels. It may also be caused by pressure on the tentorium, which is innervated principally by branches of the first division of the trigeminal nerve.[188] The pain may thus be frontal or retro-orbital in the initial stages.

Papilloedema

The number of patients presenting with papilloedema is much less now than two decades ago. Ramamurthi et al.[193] reported in 1970, only three patients out of 140 without papilloedema; however, in his series of 196 cases between 1980 and 1993, it was seen in only 55% of cases.[194] Papilloedema may range in its manifestations from slight to severe. A four-tier grading scheme ranging from slight to moderate to severe and atrophic papilloedema has been used. Frisén proposed a grading scale from 0 to 5. Papilloedema that is clinically detectable can develop over 1–7 days of increased ICP.[228]

INVESTIGATIONS

Neuro-Otological Workup

Most of these tests can be performed only if the affected ear has usable hearing. A baseline workup is necessary for later comparison and to document the deterioration during follow-up or post-operatively. They also give valuable inputs in treatment planning and in decision making.[82] There are several systems for grading hearing; the modified Gardner-Robertson system is described in Table 1.

Clinical Testing of the Auditory System

The use of the tuning fork gives specific information regarding the patient's hearing. The examiner compares the patient's hearing with his or her own.

Schwabach test: In this test, a tuning fork of 256 Hz or 512 Hz is used and the patient's bone conduction is examined. The 512 Hz tuning fork is preferred. The duration of perception of the tone is noted. The stem of the tuning fork is placed on the patient's mastoid process and transferred to the examiner's, once the former can no longer hear it. The test may be repeated for the evaluation of air conduction.

Rinne test: In this test, the patient's air and bone conduction are compared. The stem of the tuning fork is first placed firmly on the mastoid process of the patient while closing the external auditory meatus (EAM). The patient is asked to indicate when he can no longer hear the sound. The tuning fork is then immediately transferred to the front of the EAM and the time up to when the sound is heard is noted. In normal individuals or a positive Rinne test, air conduction is better than bone conduction, i.e. the patient continues to hear the sound when the tuning fork is placed in front of the EAM after he has stopped hearing it from on the mastoid. In a negative Rinne test, bone conduction is better than air conduction, with the tuning fork heard better over the

Table 1: Gardner and Robertson modified hearing classification

Class	*Description*	*Pure tone audiogram# (dB)*	*Speech discrimination#*
I	Good–excellent	0–30	70–100%
II	Serviceable	31–50	50–59%
III	Non-serviceable	51–90	5–49%
IV	Poor	91–maximum	1–4%
V	None	Not testable	0

#if audiogram and speech discrimination score do not qualify in the same class, use the lower class

mastoid process. The Rinne test is negative in conductive deafness. In sensorineural hearing loss, both bone and air conduction are reduced, but maintain a normal relationship to one another.

Weber test: This test is performed by placing the stem of the tuning fork on the forehead or over the vertex of the skull. In normal individuals the sound is heard equally in both ears. In conductive deafness, the sound is heard best in the involved ear, while in sensorineural deafness the sound is best heard in the uninvolved ear.

Specialised Testing

Behavioural auditory testing in patients with suspected acoustic nerve tumours gives useful qualitative and quantitative data which enables the neuro-otologist to diagnose and workup patients with acoustic nerve lesions.

Pure tone audiometry: It differentiates between conductive and sensorineural deafness. In patients with a conductive deafness, the pure tone bone conduction has a normal threshold, while pure tone air conduction has elevated thresholds. In patients with sensorineural hearing loss, both air and bone conduction thresholds are elevated (Fig. 1).

Loudness recruitment: In patients with sensorineural deafness it is essential to further characterise the deafness, whether it is cochlear or retrocochlear in origin. A phenomenon of abnormal growth of loudness, termed as loudness recruitment serves to differentiate between cochlear and retrocochlear lesions as purely VIII nerve lesions are not characterised by this phenomenon. The alternate binaural loudness balance test (ABLB)[60] and the short increment sensitivity index (SISI)[108] are tests of recruitment.

Alternate binaural loudness balance (ABLB) test: The ABLB compares the loudness of a tone in an impaired ear with the same or a different tone in the normal ear. In the ear where recruitment is positive, tones of equal intensity will be judged equally loud in both the impaired and the normal ear, despite the fact that the threshold for hearing is elevated in the impaired ear.

Short increment sensitivity index: The SISI is measured by superimposing 1 db intensity increments on a continuous tone. The ability to perceive these small increments is associated with cochlear pathology while with lesions of the VIII nerve the scores are low.[178]

Speech discrimination: It is another phenomenon which is associated with cochlear damage. It is tested by using standardised monosyllables using a live voice or taped material. Patients with both cochlear and retrocochlear lesions have low speech discrimination scores, with patients with retrocochlear lesions having lower scores than those with cochlear lesions.

Non-behavioural auditory testing is now being used mainly in two forms: impedance audiometry and brainstem auditory evoked response audiometry.

Impedance audiometry: This is an extremely sensitive index of retrocochlear disease.[118] It consists of three separate measurements:

1. Static compliance or measurement of the "stiffness" of the conducting apparatus of the ear.
2. Tympanometry or measurement of the pressure differentials between the external auditory canal and the middle ear.
3. Acoustic or stapedial reflex.

The measurements of static compliance and tympanometry assess middle ear disease. The acoustic or stapedial reflex is a sensitive indicator of retrocochlear

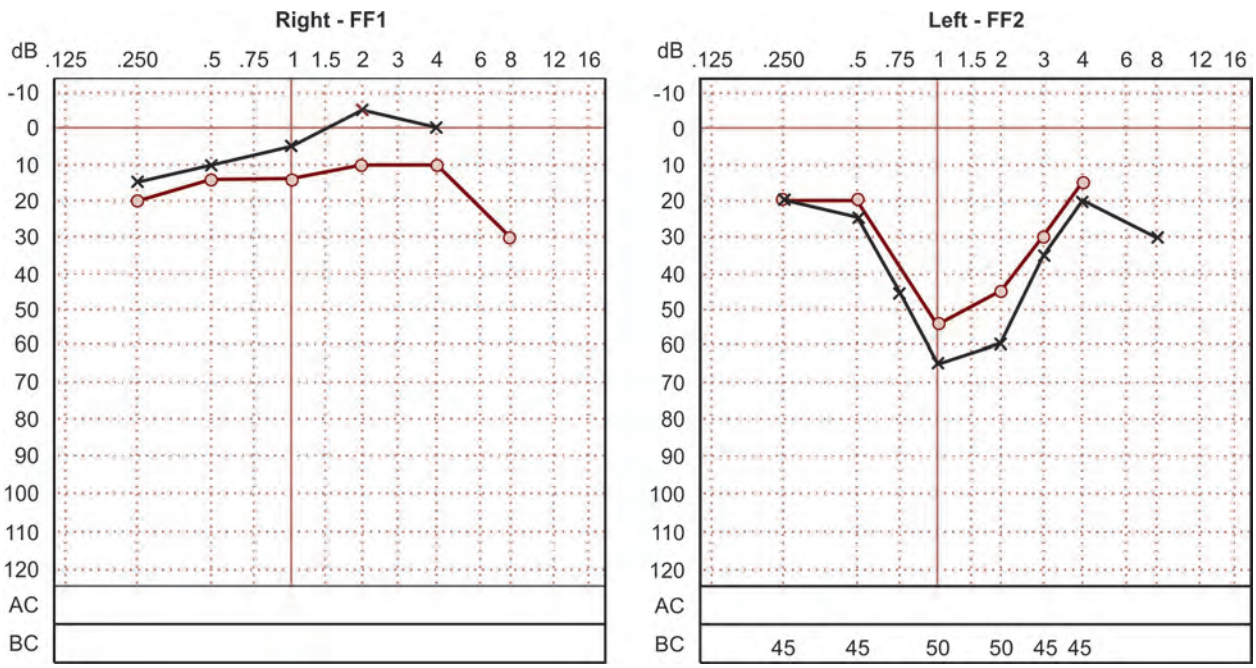

Fig. 1: Pure tone audiometry showing severe sensorineural hearing loss in the left ear

pathology. The reflex has an afferent arc in the form of an intense sound signal delivered to the VIII nerve. This produces a reflex contraction of the stapedius muscle innervated by the VII nerve. It is detected as a marked increase in the amplitude of sound reflected off the tympanic membrane when the stapedius muscle contracts and stiffens the middle ear mechanism.[238] About 95% of normal individuals demonstrate the acoustic reflex at about 85 db above their normal behavioural threshold.[107] In patients with a cochlear lesion, the gap between the behavioural threshold and the acoustic reflex threshold is small (less than 55 db). Patients with retrocochlear lesions show absent or elevated acoustic reflex thresholds.

The acoustic reflex decay measures the rate of adaptation of the reflex. To measure the decay, a sustained tone is presented at 10 db above the patient's reflex threshold for a period of 10 seconds. The testing is conducted at frequencies below 2000 Hz, because normal persons frequently show reflex decay at higher frequencies. If the reflex amplitude reduces more than 50% during the 10 second tune period, the results point towards a retrocochlear lesion.

Brainstem auditory evoked response audiometry: It has a 96% detection rate with an 8% false positive and 4% false negative rate.[236]

Imaging

Plain X-rays of the skull with special views to visualise the petrous bones are still useful as a first step. Enlargement and/or erosion of the porus acousticus and the IAC are diagnostic of an acoustic schwannoma. Different views of X-ray have been advocated to demonstrate this. Schuller, in 1911,[229] studied the petrous pyramid through the orbit. Stenver, in 1917,[245] suggested a view of the petrous temporal bone at a right angle to the long axis of the bone. Towne, in 1926, employed a 30 degrees frontal occipital projection. Schuller, Caldwell and Towne's views are employed routinely in most clinics. Of these, the transorbital projection (Caldwell view) is more useful in demonstrating the canals without interference from other natural artifacts. On the contrary, in the Towne's view, the many natural variations of the posterior surface of the petrous bone and petrous ridge may simulate canal or meatal erosion. In the Stenver view, the IAM is visualised in a shortened form, whereas the transorbital view depicts the canal and the meatus in actual form and size in one single film. Variations from the normal may be seen in these views in a small percentage of cases without any pathology and awareness of such variations help in the early diagnosis of acoustic tumours.[12]

The shape of the IAC may be bulbous in two-thirds of normal people.[132] Hence, it is important to look for suprameatal erosion, intrameatal erosion and enlargement leading to a flaring of the meatus. In a few cases, the IAC may be normal, with the tumour arising from the intracranial part of the nerve. In such cases, the canal may show no widening, though the meatus may be enlarged or eroded. The size of the IAC may vary on the two sides in the same individual. However, a measurable difference of more than 1 mm between the two sides, especially if accompanied by areas of erosion or difference in shape is of diagnostic significance. In a number of cases seen in developing countries, there are early or late signs of increased ICP.

Computerised axial tomography is now the most popular initial investigation in the diagnosis of acoustic schwannoma. A contrast-enhanced computerised tomography (CT) can easily detect a tumour with an extracanalicular extension of 1–1.5 cm. The presence of even smaller tumours may be inferred by taking the appropriate cuts with bone windows to demonstrate the classical widening of the IAM (Figs 2 and 3). However, the smaller tumours cannot be directly visualised due to artifact from contiguous bone. It is always advisable to do both unenhanced and enhanced CT as otherwise, a prominent jugular tubercle may be mistaken for a tumour in a contrast-enhanced CT.

On the non-contrast CT scan the tumours are seen as well marginated lesions centred on the IAM. A majority

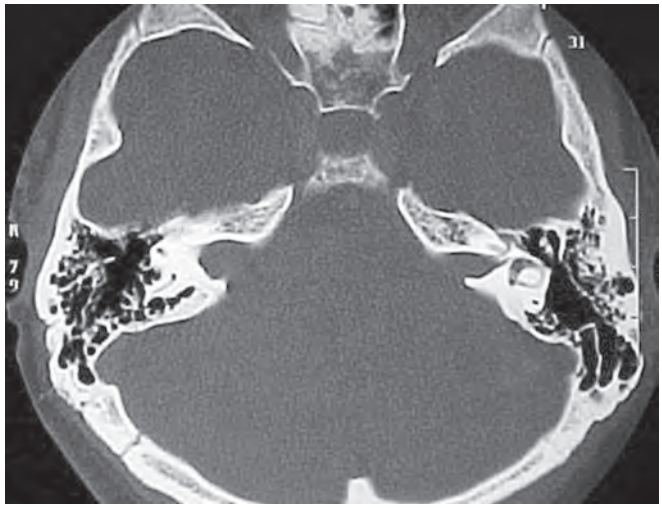

Fig. 2: Computerised tomography scan bone windows of a patient showing widening of the meatus on the right side with normal meatus on the left

Fig. 3: Computerised tomography scan bone windows of a patient showing flaring of the meatus on the left side with normal meatus on the right

of tumours are isodense (63.3%).[261] Hypodense lesions may be seen in 17–18% and 14–15% may be hyperdense.[42,256,263] The proportion of hypodensity or mixed density lesions increases with increasing tumour size.[261] Calcification is rare and may represent a "collision tumour".[49] In NF-II patients, non-neoplastic cerebellar calcification may be seen. This is unilateral, involves the cerebellar folia and may represent "meningioangiomatosis".[266]

Following contrast injection, almost all tumours show enhancement.[49,261] Two-thirds of the tumours enhance homogeneously and have well-defined margins.[49] Approximately one-third of the tumours show ring enhancement.[160] In these cases, delayed scanning done 30–90 minutes after injection of the contrast will show diffusion of the contrast into the centre of the tumour. A good correlation exists between the cytoarchitecture of the tumour and contrast enhancement.[261] Antoni type B tumours enhance irregularly with contrast while Antoni type A tumours enhance homogeneously. Cysts are uncommon. These are usually small and often close to the arachnoidal surface of the tumour[49,181] (Figs 4 and 5).

The CT using bone window settings characteristically demonstrate the widening of the porus acousticus. 74.3% of the cases seen by Unni et al.[261] showed definite widening of the IAM, while 22.1% had equivocal erosion of the meatus. Large tumours which are purely extracanalicular may not show any erosion of the bone.

Auditory evoked response (AER) monitoring is a sensitive tool in the diagnosis of acoustic schwannomas, with a sensitivity of 98%, though a false positive rate of 7% has been reported. A combination of AER and a contrast-enhanced CT scan has been reported to detect 99% of all acoustic schwannomas[5] at a much lower cost than a MRI.

MR imaging (MRI) with its capacity to disregard surrounding bone has become the investigation of choice in the diagnosis of small acoustic schwannomas, and to study the CPA.[35,191,264] On MR, the tumour is usually hypointense in relation to the pons in T1-weighted images and isointense to mildly hyperintense on proton density and T2-weighted images.[225] Intracanalicular lesions are recognised on the basis of a differential signal between the tumour and CSF on T1-weighted images, the tumour being relatively hyperintense compared to CSF.[225] Focal swelling or obscuration of the VIII nerve may be the earliest sign of tumour growth on the MR.

The addition of gadolinium-diethylenetriamine pentaacetic acid contrast, though not routinely necessary for diagnosis, may prove helpful in certain situations[89,225] (Figs 6A and B). Small tumours may be missed because of the partial volume averaging effect, especially if they lie within the IAC (Fig. 7). The use of contrast is also helpful to exclude or demonstrate residual or recurrent tumour; the study should be done at least 6 weeks after surgery. The differentiation of an acoustic schwannoma from a meningioma is more easily done with an enhanced MR.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a CPA mass is given in Table 2.

The pre-operative distinction between meningiomas and acoustic schwannomas is important for technical and prognostic reasons (Fig. 8). It allows the surgeon to choose the best approach and minimise the surgical risks. The facial nerve typically is located on the anterior or anterosuperior surface of an acoustic neuroma. This relationship is lost in the case of a CPA meningioma. The facial nerve may be displaced in any direction or may

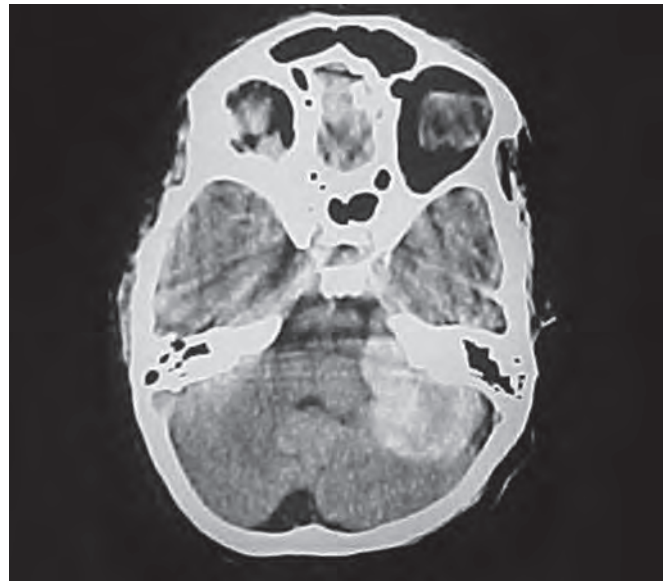

Fig. 8: Computerised tomography scan of the brain contrast axial view showing cerebellopontine angle meningioma

be engulfed by tumour, thus making its preservation more difficult. Unlike acoustic neuromas, meningiomas have a propensity to track along posterior fossa nerves and may involve Meckel's cave or the jugular foramen; the surgeon should be prepared for this eventuality. Dramatic post-operative hearing improvements have been reported in CPA meningiomas, hence if a meningioma is suspected, then one should be very cautious before resorting to an approach that results in decreased hearing (such as the translabyrinthine or the transcochlear approach).[129,268]

An important differentiating feature is that an acoustic neuroma is usually centred over the IAM, whereas CPA meningiomas are usually eccentric. The enhancement after gadolinium administration of a tail of dura adjacent to the main tumour has been termed the meningeal sign. Also known as dural tail, it was described in 1989 by Wilms et al.[279,280] It is a thickening of the dura around a meningioma. The dural tail represents enhancement of thickened dura, adjacent to and tapering away from a dura-based lesion on MRI. Goldsher et al.[77] adopted three criteria for the definition of a dural tail:

Table 2: Differential diagnosis of acoustic schwannoma

- Acoustic schwannoma [80–90% of cerebellopontine angle (CPA) lesions]
- Meningioma (5–10% of CPA lesions)
- Ectodermal inclusion tumours
  - Epidermoid (5–7% of CPA lesions)
  - Dermoid
- Metastases
- Neuroma from cranial nerves other than VIII (also see below):
  - Trigeminal neuroma: expands towards Meckel's cave
  - Facial nerve neuroma
  - Neurinoma of the lowest four cranial nerves (IX, X, XI, XII)
- Arachnoid cyst
- Neurenteric cyst
- Cholesterol granuloma (distinct from epidermoid)
- Aneurysm
- Dolichobasilar ectasia
- Extensions of:
  - Brainstem or cerebellar glioma
  - Pituitary adenoma
  - Craniopharyngioma
  - Chordoma and tumours of skull base
  - Fourth ventricle tumours (ependymoma, medulloblastoma)
  - Choroids plexus papilloma—from 4th ventricle through Foramen of Luschka
  - Glomus jugulare tumour
  - Primary tumours of temporal bone (e.g. sarcoma or carcinoma)

- Presence on at least two consecutive sections through the tumour at the same site and in more than one plane
- Greatest thickness adjacent to the tumour and tapering away from it
- Enhancement greater than that of the tumour mass itself.

Rarely, an acoustic neuroma may display a pseudomeningeal sign. This is a thin, short dural tail present on a single aspect of the tumour, which is caused by bone marrow adjacent to the porus acousticus. This pseudomeningeal sign is present on T1-weighted images before and after gadolinium enhancement, unlike the true meningeal sign that is present only after the administration of gadolinium.[79,99,126,148]

Both acoustic neuroma and CPA meningioma have a heterogeneous appearance on the T1-weighted MRI. This heterogeneity is due to cystic degeneration in acoustic neuroma, and to calcifications in CPA meningioma. On T2-weighted scans, the cystic areas will appear hyperintense, whereas the calcified areas remain hypointense. Thus, a CPA tumour that has regions of low intensity on T1 and T2-weighted MRI probably is a calcified meningioma. An angiogram or a MR angiogram may be of help in ruling out a giant calcified aneurysm.[125,288]

MANAGEMENT

The options available for the management of VSs include observation, surgery, stereotactic radiosurgery (SRS) and fractionated radiotherapy. The ideal treatment is total excision of the tumour in a single stage with preservation of neurological function.

Resection is indicated for patients harbouring larger tumours that have caused major neurological deficits due to brain compression. Surgeons perform SRS for small-sized or medium-sized tumours, their goals being to preserve neurological function and prevent tumour growth. The long-term outcomes of SRS, particularly gamma knife surgery (GKS), have proven its role in the primary or adjuvant management of this tumour. Fractionated radiotherapy has been suggested as an alternative in selected patients with larger tumours for whom microsurgery may not be feasible, as well as in some patients in whom preservation of cranial nerve function is being attempted.

The goals and acceptable clinical outcomes have evolved over time. Many years ago, the goal was simple debulking of the tumour (which was often large) and relief of regional brainstem compression and hydrocephalus; the goal was life saving. Neurological deficits such as hearing loss, facial weakness or balance disorders were tolerated as simply part of the expected result. However, with the introduction of microneurosurgery, attempts at cranial nerve preservation have been the goal. Over the last 30 years, preservation of facial nerve continuity became more common and hearing preservation became an achievable goal in selected cases. At the same time, improvements in anaesthesia-related technique and wound closure have reduced the risk of cerebellar infarction, meningitis and CSF leakage. Nevertheless, these problems still continue to exist and remain a significant problem after resection.

Before choosing any particular therapy, primary clinical issues such as avoidance of tumour-related or treatment-related mortality, prevention of further tumour-induced neurological disability, minimising treatment risks such as CSF leakage, infections, cardiopulmonary complications, maintaining regional cranial nerve function (facial, trigeminal, cochlear and glossopharyngeal/vagal), avoiding hydrocephalus, maintaining quality of life (QOL) and employment, and reducing cost should be considered and the surgeon should strive to meet all of these goals.

Surgery is indicated for the treatment of small and medium-sized VSs. The resulting QOL matches that after radiosurgery.[86,148,218] Surgery remains a necessary treatment for large VSs, however, it has a significant impact on a patient's QOL, and the patients must be well informed of the consequences of such a surgery.

Observation

There are patients for whom long-term observation may be indicated. Because surgery carries some risk and these tumours are generally slow growing, a conservative policy may be adopted especially in elderly patients without any serious neurological symptoms.[53,110]

Bederson et al.[7] reported that out of 70 patients, who were initially observed, 53% had a mean growth of 3.4 mm in the 1st year and 6% had regression of the tumour. This and another study[265] showed that there was no relationship of tumour growth to age.

A prospective cohort review of unilateral VS with mean duration of 80 months follow-up, with serial MRI for assessment of tumour growth reported the mean tumour growth rate for the entire group to be 1 mm/year (range 0.84–9.65 mm/year). The mean growth rate for CPA tumours (1.3 mm/year) was significantly greater than that of IAC tumours (0 mm/year) (P = 0.005). There was significant tumour growth in 38.9%, no or insignificant growth in 41.7%, and negative growth in 19.4%. Twenty three patients (32%) failed conservative management. Hearing deterioration with pure tone averages (0.5 kHz, 1 kHz, 2 kHz, 3 kHz) and speech discrimination scores occurred irrespective of tumour growth. This prospective study delineates the role of conservative management in selected cases of VSs.[199]

Measurement of the maximal tumour diameter on MRI is a reliable method for following acoustic neuroma growth. There is no need to perform a rigorous analysis of tumour size to determine whether the tumour is growing significantly. The vast majority of patients older than 65 years with small acoustic neuromas do not require intervention. The indications for intervention should be based on a combination of rapid tumour growth with deterioration of symptoms.[203] A substantial number of acoustic schwannomas are discovered incidentally. These incidental schwannomas have a more benign nature, and may be less likely to require intervention.[109] However, conservative management of acoustic schwannomas requires long-term clinical and radiological follow-up. The irregular behaviour of the tumour underlines the importance of monitoring with MRI at least once a year.[156]

Surgery

There are mainly three operative approaches to the IAM and the acoustic neuroma.

1. The lateral suboccipital approach (the retrosigmoid transmeatal approach).
2. The translabyrinthine approach.
3. The middle fossa approach.

Good results have been reported for all three surgical procedures. Each has specific advantages and disadvantages. Other approaches which have been utilised for the removal of acoustic neuromas include:

4. The retrolabyrinthine approach
5. The transcanal approach
6. The suboccipital–translabyrinthine approach
7. The subtemporal transtentorial approach.

The Middle Fossa Approach

This was developed by WF House.[96,97] It offers several advantages for the removal of small laterally placed acoustic neuromas:

- Dissection is mainly extradural and therefore morbidity is less
- As the lateral end of the IAM is exposed, total removal of the tumour is assured
- Early identification of the facial nerve at the lateral end of the IAC and exposure of the labyrinthine and upper tympanic segments of the nerve facilities preservation of the facial nerve
- It enables hearing preservation, especially for tumours arising from the superior vestibular nerve
- In a small group of patients with NF-II it helps decompress the IAC

The disadvantages of this approach are:

- The facial nerve is in the field and the surgeon must work beyond the nerve to remove the tumour
- Post-operative unsteadiness is encountered due to partial preservation of vestibular function
- Limited access to the posterior fossa, especially if there is bleeding at surgery

The complications seen with this approach include:

- Epidural haematoma which may occur early in the post-operative period
- Complications as in other procedures, e.g. meningitis, injury to the temporal lobe, hearing loss and facial nerve paresis. It is generally agreed that the middle fossa approach is indicated only in small laterally placed acoustic neuromas.[18,67,68,158,210]

In a cumulative series[158] serviceable hearing was reported in 32% of cases operated upon by this approach between 1975 and 1990. The facial nerve was preserved in 97% of cases. However, the patients selected for this approach had small intracanalicular tumours.

The prerequisites for hearing conservation in the middle fossa approach include:

- Speech discrimination score of greater than 50%, with a speech reception threshold of less than 50 db
- Presence of an intracanalicular tumour

The average operative mortality in this procedure is 0.8% which is significantly less than the other approaches to these tumours.

The Translabyrinthine Approach

In 1904, Panse first suggested the use of the translabyrinthine approach. In 1911, Quix removed subtotally a small tumour via this route, but the patient died 6 weeks later. House reintroduced this approach[97] when he found that he was unable to remove large tumours completely via the middle fossa approach.

The advantages of this approach are:

- Short distance between the surface and the tumour
- Absence of significant cerebellar and brainstem retraction
- Access to the anterior surface of the brainstem
- Early identification of the facial nerve
- Ability to repair the facial nerve during the primary procedure itself
- Easy access to the operative site for the management of post-operative complications

The disadvantages of the approach are:

- Total deafness on the operated side
- Reduced exposure of the tumour
- Increased incidence of post-operative CSF leaks.

Samii and Draf[210] are of the opinion that tumours that impinge on the brainstem should not be approached by this route as it does not give an adequate exposure of the vessels between the brainstem and tumour capsule. Others feel that the size of the tumour is not a limitation for use of this approach.[19,40,255] This approach would be indicated for tumours where there is no chance of post-operative serviceable hearing. For larger tumours better exposure may be obtained either by more bone removal posterior to the sigmoid sinus[19] or by dividing the tentorium and then sacrificing the superior petrosal sinus (and the sigmoid sinus, if necessary).[40]

Contraindications for this approach are:

- Middle ear infection
- A perforation of the tympanic membrane should be ruled out before surgery
- In patients with externalised mastoid cavities, obliteration with closure of the external auditory canal should be carried out before surgery.

Complications which are seen in this approach include:

- Vascular injury: The most important and potentially fatal injury is one to the AICA. The possibility of damage to the sigmoid sinus and the jugular bulb during the drilling of bone should be borne in mind
- Injury to the facial nerve with loss of continuity is not uncommon. Direct repair or use of an interposition cable graft at the same sitting is the treatment of choice
- Haematoma in the operative bed is a serious complication. Evacuation can be performed at the bedside, if necessary, when this approach is used
- CSF leak is the most common complication with this approach and may lead to meningitis.

The Retromastoid Suboccipital Approach

In 1903, Woolsey performed a unilateral suboccipital craniectomy in one stage; one year later, as Cohen reports, Fraenkel described the technique in great detail. It was, however, Krause who became most closely associated with the suboccipital procedure, after performing a successful unilateral osteoplastic operation in two stages in 1905.[33,39,111,121,145,174,282] This approach is the most commonly used by neurosurgeons and is the recommended approach.

The advantages of the suboccipital approach include:

- Good exposure of the tumour
- Direct visualisation of the major vessels in the cerebellopontine angle
- Possibility of preserving facial and cochlear nerve function
- Familiarity among neurosurgeons

The disadvantages of the approach include:

- Incomplete exposure of the contents of the IAC
- Risks associated with an intracranial procedure.

The Retrolabyrinthine Approach

This approach was first described by Hitselberger and Pulec,[93] in 1972, and was popularised by Silverstein and Norrell.[240] The concept of the procedure is to allow exposure of the CPA anterior to the sigmoid sinus, thus reducing the necessity of cerebellar retraction. Though used mainly for sectioning the sensory root of the trigeminal or the vestibular nerves, it has also been used occasionally for the removal of small acoustic neuromas in cases where it was desirable to preserve hearing. While the major advantage of the procedure is the exposure of the CPA without significant cerebellar retraction and without sacrifice of hearing, the limitation is the limited exposure available when the mastoid air space is small.[242]

The Transcanal Approach

This approach, described by Silverstein, in 1977,[242] exposes the IAC through the external auditory canal using a post-auricular incision. Silverstein felt that this approach helped the otologic surgeons to detect very small acoustic neuromas that may otherwise not be identified. The major disadvantages are the very limited operating space, risk of damage to the facial nerve and the possibility of CSF leak and meningitis.

The Suboccipital Translabyrinthine Approach

Trying to overcome the disadvantages of both the suboccipital and the translabyrinthine approaches, efforts to combine the two were finally successful through the work of Maddox[146] and of Gardner et al.[69] By being able to work on both sides of the sigmoid sinus, the surgeon gets a wider operative field and better control of the anterior and posterior extents of the exposure.

The Subtemporal Transtentorial Approach

The ease with which trigeminal neurofibromas were removed through the subtemporal transtentorial approach encouraged Banerji et al.[4] utilise the approach in large acoustic neuromas. It is an intradural subtemporal approach, and sectioning of the tentorium 1 cm behind the petrosal sinus brings the tumour into view. There is no need for cerebellar retraction. However, there is a risk of temporal lobe injury due to retraction and small tumours which are mainly intracanalicular cannot be reached via this approach. This approach is also not suitable if the tumour extends more inferiorly than superiorly. Large series with results of this approach are not available. The authors of this paper themselves abandoned this approach in favour of the retromastoid suboccipital approach.

Endoscopy

The field of endoscopy has evolved from earlier "endoscope-assisted microsurgery" to complete endoscopic tumour removal.

The adjunctive use of endoscopy offers some advantages including improved visualisation, more complete tumour removal, and a lowered risk of CSF leakage.[119,270]

However, it did not appear to increase the hearing preservation rate.[76] Kabil et al.[112] reported their experience with 112 consecutive cases with unilateral, *de novo* acoustic schwannomas with the tumour size ranging from 0.6–5.7 cm (most tumours were less than 3 cm in diameter and had a mean of 2.6 cm). Tumours were removed via 1.5 cm "keyhole" retrosigmoid craniotomies. Utilising the fully endoscopic technique, 106 out of 112 (95%) tumours were completely removed; subtotal removal was performed in 6 out of 112 (5%) patients in an attempt to preserve their hearing. Anatomic preservation of the facial nerve was achieved in all of the patients and of the cochlear nerve in 83 out of 101 (82%) hearing ears. Functionally measurable hearing (serviceable/some) was preserved in 59/101 (58%) cases who had either "serviceable" or "some" hearing pre-operatively; two patients who had "some" hearing pre-operatively had an improvement that was more than 30 db in their hearing post-operatively. There were no major neurological complications such as quadriparesis, hemiparesis, bacterial or aseptic meningitis, lower cranial nerve deficits or deaths. Endoscopic or endoscope assisted removal of acoustic schwannomas seems to be a technically feasible, effective and safe procedure; however, good equipment and special training are absolutely necessary for attainment of optimal results.[94]

Post-Operative Complications

The incidence of post-operative complications depends on numerous variables including the size of the tumour and the clinical condition of the patient, the approach used and the experience of the anaesthetic and surgical teams. The complications seen include the following:

Mortality: With the use of microsurgical techniques in acoustic neuroma surgery, peri-operative mortality varies between 0% and 3%.[10,51,173,194,216,224,243,250,255,282] Even in India where most tumours are between 2 cm and 4 cm or more in size when first seen, with microsurgical techniques the mortality is about 1% for small tumours and about 4% for large tumours. The causes of death vary and are related to the size of the tumour,[250] thrombosis of the AICA,10 post-operative haematomas[173,207,255] and respiratory and cardiac problems.[10,255]

Haematoma: Haematomas in the tumour bed, in the immediate post-operative period, are a devastating complication. It is best, therefore, to confirm haemostasis at the end of surgery by raising the systolic pressure to rule out arterial bleeding and to perform a few Valsalva manoeuvres to confirm venous haemostasis. If the patient does not recover as expected from the anaesthesia or if the patient deteriorates in conscious level a few hours into the post-operative period, a haematoma must be suspected. If the facility for an immediate CT scan exists, it should be obtained. However, if this cannot be done or if the deterioration is rapid, re-exploration may be lifesaving. Where the translabyrinthine approach is used, drainage of the haematoma may be done at the bedside, if necessary.

A similar clinical picture may be seen with subdural or epidural haematomas. These may develop either in the posterior fossa or in the supratentorial compartment, but the deterioration in neurological status is usually slower than with traumatic haematomas. Thomsen et al.,[255] found haematomas in the tumour bed requiring evacuation in five patients out of a series of 300 operations performed via the translabyrinthine approach. Ojemann[173] had four patients with post-operative haematomas out of his series of 410 patients with unilateral neuromas. Of these, two were haematomas in the cerebellum and two extradural haematomas. Ebersold et al.[51] had only two patients with a haematoma amongst their series of 256 procedures via the retrosigmoid approach.

Post-operative deterioration in sensorium can also be caused by a supratentorial subdural haematoma, due to the sudden decompression and rupture of bridging veins, especially when the ventricles are large pre-operatively. Rarely, a supratentorial extradural haematoma may be caused by penetration during pin fixation.[15]

Pneumocephalus: Tension pneumocephalus is a complication which occurs when the surgery is performed in the sitting position, though it may rarely occur even after surgery in the lateral position. During a posterior fossa procedure the air enters the intracranial space in the same way it enters an inverted bottle of water.[142,144] Symptoms arise soon after surgery, usually within a few hours, and it is specially seen after the resection of a large tumour or draining a significant amount of CSF rapidly. Nitrous oxide when used in anaesthesia diffuses out of the blood vessels into the contiguous air-filled space and potentiates the effects of the pneumocephalus.[259] If the amount of air, assessed by plain X-rays of the skull or by a CT scan is thought to be significant it can be evacuated via a frontal twist drill hole through a water seal. As this is an easily treatable complication, early recognition is important.

Hydrocephalus may become acutely symptomatic in the post-operative period, with a presentation that is difficult to differentiate from intracranial haematomas. If the CT scan confirms this, the problem may temporarily be managed with a ventriculostomy. If hydrocephalus persists a CSF diversion procedure may be performed.

Cranial neuropathies: A common sequel of total extirpation of an acoustic neuroma is injury to the facial nerve.[217] The larger the tumour, the less are the chances of saving the nerve. Facial palsy is disfiguring and disconcerts the patient to no small extent. Dryness of the cornea may be a distressing sequel of minor facial nerve trauma. In the early years it was accepted as an inevitable sequel of total removal. Rand and Kurze[197] described the transmeatal approach using microsurgical techniques and emphasised preservation of the facial nerve. The use of these refinements and the different operative approaches has achieved an overall facial nerve preservation rate of 82.5%.[158] However, anatomical preservation does not imply a good functional outcome.

Where anatomical continuity of the nerve is preserved, the patients are followed up with physiotherapy to watch for improvement in function. Ebersold et al.[51] are of the opinion that the operating team can, by comparing the amplitude of the proximal compound

muscle action potential with that obtained by stimulation of the facial nerve in the distal IAC, predict the degree of initial facial weakness and the long-term result. Electroneurography may be helpful in deciding on the possibility of post-operative recovery of function. Incomplete degeneration is a good predictor of early recovery and carries a good prognosis. Though regeneration provides good recovery, it is rarely perfect.[275] Patients with Wallerian degeneration have a worse prognosis than those with a neuropraxia.[66]

When the facial nerve is cut at surgery, either intentionally or otherwise, there are several choices for repair.[214,220] The continuity of the nerve can be restored during surgery by primary suturing or by gluing the severed ends. If necessary, a cable graft may be used to bridge the gap between the ends of the nerve. Intraoperative suturing seems to be an effective procedure. End-to-end suturing produces a satisfactory result (some facial tone and movement) in 88% of cases, while the use of an interposition graft produces up to 78% satisfactory results.[104] Patients with partial facial nerve injury may be treated using an end-to-side graft without additional risk for the remaining functional fibres from the donor and recipient nerve.[11,56,168,212] Intra-operative restoration usually results in moderate facial symmetry and movement. Typically, the facial appearance is better at rest.

Dott, in 1958, described an intracranial-extracranial graft, suturing one end of the graft to the central stump and the other end to the distal facial nerve beyond the stylomastoid foramen. Using the translabyrinthine approach, the distal anastomosis is performed by mobilising the facial nerve in the Fallopian canal. This procedure may be performed at the end of the operation when the distal stump is found to be inadequate intracranially. Some surgeons prefer this to intracranial grafting or suture.[123,221]

If the proximal stump of the facial nerve is not adequate, procedures to reanimate the facial muscles may be undertaken. These include peripheral nerve procedures (e.g. cross facial nerve grafting, nerve transfers), dynamic muscle reconstruction procedures (e.g. local and distant muscle transfers) and static procedures (e.g. canthoplasty, facial and dermal slings).[134]

The first surgical attempt to treat facial paralysis was performed by Drobnick, in 1879, by anastomosing the spinal accessory nerve to the facial nerve. The first published report of this procedure was by Sir Charles Ballance, in 1895. The first hypoglossal nerve-facial nerve anastomosis was performed by Korte, in 1901. The cross-facial nerve graft anastomosis uses the contralateral facial nerve with interposition grafts between the two nerves. Many authors found the results unsatisfactory.[31,34,260,289] Venkataswamy and Venkataramakrishnan[269] found better results than obtained from faciohypoglossal anastamoses. Nerve transfers or donor nerve techniques tend to have functional results similar to primary anastomosis or nerve grafting.[185] The nerves used for anastomosis include the hypoglossal nerve, the spinal accessory nerve, the phrenic nerve and the glossopharyngeal nerve.

The hypoglossal-facial nerve anastomosis is the most often used technique. Pitty and Tator,[185] found good and fair results following this procedure in 77.2% of cases and a failure in only one patient. The results were better in younger patients and when the anastomosis was performed early.

The trigeminal nerve is usually in contact with even medium-sized tumours, and is stretched by large masses. Post-operative dysfunction of this nerve may result in impaired sensation over the ipsilateral half of the face and masticatory problems, but the real problem is decreased corneal sensation with the risk of developing exposure keratitis and ulceration, especially with a simultaneous facial paresis. This can be conservatively managed with protection of the eye with spectacles, moisturising drops or artificial tears during the day and ointment at night, as long as improvement of facial function is expected. If no return of facial function is anticipated, a lateral tarsorrhaphy should be done, especially if the impaired sensation also persists. In most cases, trigeminal function returns within a few months, in which case the palpebral fissure should be reconstituted. Thomsen et al.,[255] found reduced trigeminal function in only 4% of patients post-operatively, though in only two patients it could be related to the surgery.

Impaired function of the glossopharyngeal and vagus nerves may be seen after excision of large tumours, with resultant difficulty in swallowing, nasal regurgitation and risk of aspiration pneumonitis. As a rule, oral feeds should not be attempted in a patient after excision of a large tumour, unless the gag reflex is checked, and even then the first feed is preferably given under supervision. The paresis is usually transient and feeding may be done through a nasogastric tube until recovery. Damage to other nerves such as the trochlear and abducens is rare.[255]

Cerebellar dysfunction: Signs of cerebellar dysfunction are seen in cases where marked retraction of the cerebellum is necessary when dealing with large tumours. The resultant cerebellar contusion or haematoma and swelling may at times result in mass effect, requiring emergency repeat surgery. Severe and prolonged cerebellar dysfunction may also result from undue traction and contusion of the cerebellar peduncles.

Brainstem: Damage to the pons is the leading cause of mortality in acoustic neuroma surgery. This can occur due to damage to the AICA, which can result in varying degrees of brainstem infarction as well as infarction and swelling of the cerebellum.[207] The brainstem may be damaged during dissection of the capsule of a large tumour off the pons. In these cases, the capsule usually has small vessels entering it from the brainstem. These must be recognised, coagulated and cut, rather than separated by blunt dissection, when they may retract into the parenchyma and form haematomas. The incidence of the complication has decreased steadily and is now rare.[10,255]

Infection: The occurrence of infection is a reflexion on the sterile precautions in the unit. It can be pyogenic meningitis or wound infection, urinary infection due to catheterisation, or chest infection in patients with lower cranial nerve paresis. The fever in post-operative

meningitis generally begins around the 4th day after surgery, earlier rise in temperature and meningism usually being due to spilled blood in the subarachnoid space. It is preferable to do a CT scan to rule out an unsuspected haematoma in the tumour bed or the cerebellum, or cerebellar swelling, before doing a lumbar puncture. If the CSF analysis is suggestive of pyogenic meningitis and the smear is non-contributory, empirical antibiotics based on the known sensitivity patterns of the institution should be started pending the culture report.

CSF leak can occur from the wound, or can be in the form of otorrhoea or paradoxical rhinorrhoea. This is the single most common complication, other than VII nerve dysfunction with the translabyrinthine or suboccipital-transmeatal approaches. Symon et al.[250] found that CSF leak was the only complication which increased in occurrence from 2.4% in the 1950s to 18.7% in the 1980s. They felt that the reason for this was the increased zeal with which the tumour was attacked in the IAM and the porus drilled. Prevention consists mainly in ensuring a water tight dural closure, either primarily or with a graft, and of thoroughly occluding any opened mastoid air cells with bone wax, free fat, muscle, fibrin glue, etc. Once the leak via the air cells occurs, a lumbar subarachnoid drain may be placed and CSF drained for 3–4 days to enable the leak to seal off. If this does not work, the wound has to be reopened and the site of the leak repacked. A wound leak rarely settles with resuturing of the skin and usually requires definitive reclosure of the entire wound. It may be precipitated or aggravated by the raised pressure of hydrocephalus or meningitis. Leak through the wound should therefore be tackled initially with lumbar drainage of CSF and the treatment of infection if any.

Results

Results of surgery via the suboccipital approach are excellent.[10,51,80,105,154,173,250,286] Cumulative data from operative series between 1975 and 1990[158] using the suboccipital approach shows an operative mortality of 2%, with total tumour removal in 95% of cases. The VII nerve was preserved in 72.8% of cases. The VIII nerve was preserved in 40.6% of cases, though hearing and serviceable hearing was preserved only in 15.7% and 14.7% of cases.

Samii et al.[211,216] in their paper on 1,000 acoustic schwannomas operated upon through the suboccipital transmeatal approach, reported complete tumour removal in 979 tumours. Anatomic preservation of the facial nerve was achieved in 93% of cases and cochlear nerve in 68% of cases. Major neurological complications included one case of tetraparesis, 10 cases of hemiparesis and caudal cranial nerve palsies in 5.5% of the cases. Surgical complications included hematomas in 2.2% of the cases, CSF fistulas in 9.2%, hydrocephalus in 2.3%, bacterial meningitis in 1.2% and wound revisions in 1.1% of cases. There were 11 deaths between the 2nd day and 69th day post-operatively (1.1%). In their recent report on 200 patients, the facial nerve was anatomically preserved in all patients, the cochlear nerve in 84% of patients, and there was no mortality. The authors concluded that the goal of acoustic schwannoma treatment should be total removal in one stage and preservation of neurological function, as they determine a patient's QOL and that this goal can be safely and successfully achieved using the retrosigmoid approach.

Jain et al.[105] in 2005 reported a series of 259 cases from India, where most patients had large tumours. About 90% had no useful hearing, 88% had disabling cerebellar ataxia and 45% presented with features of raised ICP. The tumours were large in 41.3% and in 56% they were giant sized. Complete tumour excision was carried out in 96.5% of cases and anatomical preservation of facial nerve was achieved in 79.2% of cases. Hearing preservation was achieved in eight patients. CSF leak with or without meningitis and transient lower cranial nerve paresis were common complications. The mortality was 6%.

Misra[154] has reported his results in the last 100 consecutive cases operated upon by him. About 86% were large tumours and total excision was achieved in 88% of cases. The facial nerve was preserved in 94% and was grade III or better in 88% of cases. There was no mortality.

Between the years 1975 and 1990, 1356 cases of acoustic neuroma were operated on by the translabyrinthine approach.[158] The cumulative data on these patients show an operative mortality of 1.7%, with a 96.8% rate of total tumour removal. The facial nerve was preserved in 75% of cases. Reporting on 216 patients operated upon between 1980 and 1991 by this approach, Brackmann19 had only one death (0.4%) and normal facial nerve function in 83% of the cases one year after surgery. There is a definite correlation between tumour size and the preservation of facial nerve function.[19,40]

Lanman et al. have reported on 190 consecutive cases of large acoustic schwannomas (3 cm or greater) removed via the translabyrinthine approach. Total tumour removal was accomplished in 183 cases (96.3%) and the facial nerve was preserved anatomically in 178 cases (93.7%). They concluded that use of the translabyrinthine approach for removal of large tumours, where hearing preservation is not an issue, resulted in good anatomical and functional preservation of the facial nerve with minimum morbidity and no mortality.[130]

The choice of the operative approach to acoustic neuromas is, therefore, dependent on the size and position of the tumour and the possibility of hearing preservation. For small tumours placed laterally in the IAC, the middle fossa approach is the procedure of choice. In medium or large sized tumours both the suboccipital approach and the translabyrinthine approach are equally effective. If, however, hearing preservation is to be attempted, then the suboccipital approach is to be chosen. Neurosurgeons generally prefer the suboccipital route, while otologists prefer the translabyrinthine approach.

Facial Nerve Preservation

The first report of facial nerve preservation was by Cairns, in 1931.[22] Olivecrona, McKissock and House further advocated the importance of facial nerve

preservation. Gardner and Robertson[70] saved the facial nerve anatomically in 85% of their series of 144 patients. However, 47% of patients showed a complete facial palsy at some time after surgery. Bentivoglio et al.,[10] found that only 32.1% of patients with anatomically preserved facial nerves had normal facial function at the end of 1 year. Grading of facial nerve function has been done variously[10,95] and is used to assess the function on follow-up. The results of facial nerve preservation correlate closely with tumour size.[43,45,85,173,250,283] House and Brackmann[95] devised a grading system to evaluate facial nerve function and this is now used universally (Table 3).[11] The cumulative data collected on reported operative series[158] between 1975 and 1990 shows overall 82.5% facial nerve preservation. When considering each operative approach individually, the facial nerve was preserved most (97.6%) when the middle fossa approach was used. This could be expected as these tumours were very small and mainly intracanalicular. The facial nerve was preserved in 72.8% of patients where the suboccipital approach was used and in 74.9% when the translabyrinthine approach was used. However, the prevalence of normal facial function following removal of acoustic neuromas ranges between 43% and 89%.[10,50,84,104,250,255] In medium and large sized tumours, it may not be possible to dissect the tumour capsule off the facial nerve, which is often very attenuated. Cerullo et al.,[23] however, reported normal facial function in 90% of patients with tumours between 2.5 cm and 4 cm in size and 64% of patients with tumours more than 4 cm in size. The use of facial nerve monitoring[262,281] and/or the use of microstimulators[232] may be useful to locate and delineate the nerve in these circumstances. The decision often is whether to remove the tumour completely dividing the nerve or, whether to leave a small piece of capsule with the nerve.

Anatomical continuity of the nerve, however, does not imply good functional outcome. The status of facial nerve function should be assessed periodically as what appears as reasonably good in the immediate post-operative period may worsen even to a complete paralysis within 48 hours post-operative.[194] The speed of recovery of facial nerve function is variable.[85] It is, therefore, important that patients with a paralysed face have either a tarsorrhaphy or some other procedure to protect the eye.

A retrospective analysis of 611 patients surgically treated for acoustic neuroma between 1973 and 1994 at the Johns Hopkins Hospital has been reported. Anatomical preservation of the facial nerve was achieved in 596 patients (97.5%). In the immediate post-operative period, 62.1% of patients displayed normal or near-normal facial nerve function (House-Brackmann Grade 1 or 2). This number rose to 85.3% at 6 months after surgery, and by 1 year 89.7% of patients who had undergone acoustic neuroma surgery demonstrated normal or near-normal facial nerve function. The surgical approach appeared to have no effect on the incidence of facial nerve injury. Poor facial nerve outcome (House-Brackmann Grade 5 or 6) was seen in 1.58% of patients

Table 3: Clinical grading of facial nerve function by House and Brackmann

Grade	*Description*	*Detailed description*
1	Normal	Normal facial function in all areas
2	Mild dysfunction	• Gross: slight weakness noticeable on close inspection; may have very slight synkinesis • At rest: normal symmetry and tone • Motion: – Forehead: slight to moderate movement – Eye: complete closure with effort – Mouth: slight asymmetry
3	Moderate dysfunction	• Gross: obvious but not disfiguring asymmetry; noticeable but not severe synkinesis • Motion: – Forehead: slight to moderate movement – Eye: complete closure with effort – Mouth: slightly weak with maximal effort
4	Moderate to severe dysfunction	• Gross: obvious weakness and/or asymmetry • Motion: – Forehead: note – Eye: incomplete closure – Mouth: asymmetry with maximum effort
5	Severe dysfunction	• Gross: only barely perceptible motion • At rest: asymmetry • Motion: – Forehead: none – Eye: incomplete closure
6	Total paralysis	No movement

treated via the suboccipital approach and in 2.6% of patients treated via the translabyrinthine approach.[222] When facial nerve outcome was examined with respect to tumour size, there clearly was an increased incidence of facial nerve palsy[20,111,211,244,277] seen in the immediate post-operative period in cases of larger tumours; about 60.8% of patients with tumours smaller than 2.5 cm had normal facial nerve function, whereas only 37.5% of patients with tumours larger than 4 cm had normal function.[222]

Facial nerve weakness that is evident immediately after acoustic neuroma surgery is caused by a number of possible mechanisms. A thorough understanding of these can help minimise intra-operative facial nerve injury.[116] The most common cause of post-operative facial nerve palsy is direct trauma or nerve stretching during surgery. Theoretically, both neuropraxia and axonotmesis are reversible phenomena and facial nerve function should fully return. Not surprisingly, very large tumours place the nerve under greater tension, which increases the likelihood of stretch injury and may explain the high rate of facial palsy seen in patients with tumours larger than 4 cm. Alternatively nerve dysfunction may result from devascularisation of nerve segments that are effaced by large tumours. Measures can be taken to minimise trauma to the facial nerve during surgery. First, the ability to compress and retract the tumour capsule rather than the nerve by debulking the tumour prior to nerve dissection is of major importance, particularly in cases of large tumours. Second, excessive pressure on the facial nerve should be avoided. Cotton and microsuction devices should be used at all times. Sharp dissection should be used until a clear dissection plane is established to avoid unnecessary stretch injury. Third, it is important to avoid excessive cerebellar retraction to minimise the tension placed on the facial nerve. Finally, it is essential that dissection proceed from known to unknown structures. If hearing preservation is not a consideration, early identification of the facial nerve near the lamina spiralis allows better appreciation of its relationship with the tumour.[211,222]

Another common mechanism of facial nerve injury is compromise of the vascular supply to the facial nerve. The facial nerve is supplied by three separate vascular systems:

- The labyrinthine artery of the AICA
- The greater superficial petrosal branch of the middle meningeal artery
- The stylomastoid artery of the external carotid system.

Maintaining the blood supply to the facial nerve is critical if post-operative palsy is to be avoided. The surgeon must be careful to avoid inadvertent vascular injury. Bipolar cautery should be used cautiously; when possible, blunt dissection should be used near all vascular structures. Topical administration of papaverine after tumour resection can also aid in preventing vasospasm.[222] Because most of the microvascular blood supply to the facial nerve is in the subarachnoid space, it is essential that dissection proceed in the correct plane between the tumour capsule and the underlying arachnoid. Overly aggressive dissection of the tumour capsule from the facial nerve may strip the facial nerve of its vital microvascular supply and lead to post-operative nerve dysfunction.[211,222]

Thermal injury can also cause temporary facial nerve palsy or paralysis. Overly cold irrigation may "stun" the nerve and is avoidable with use of warmed saline solutions. This phenomenon is usually transient, but occasionally it may lead to local vasoconstriction and cause secondary ischaemic injury to the nerve. Thermal injury can be more permanent if the laser is used for tumour extirpation. Both potassium-titanyl-phosphate and CO_2 lasers have become increasingly popular in recent years, especially for use in treating vascular tumours.[69,74] Laser vaporisation can be quite helpful in devascularising tumour remnants to prevent recurrence, but it should be used with great caution near the facial nerve. Cool intermittent irrigation and continuous suction of the laser plume can help minimise thermal injury.

If the facial nerve is inadvertently transected during surgery, restoration of facial nerve function becomes much more problematic. Facial nerve disruption generally leads to poor outcome even with apparently satisfactory immediate repair. Close follow-up review is necessary for these patients and facial nerve reanimation (either XII-VII or XI-VII cranial nerve anastomosis) if there is no evidence of recovery by 12 months post-operatively. After 1 year, facial nerve function with reanimation surgery is much less predictable.[211,222]

An aberrant course with distinct splitting of the facial nerve has been reported[248] and adds considerably to the surgical challenge. Use of neurophysiological monitoring allows the differentiation and identification of the aberrant facial nerve fibres, thus avoiding additional risks to facial nerve preservation.

Hearing Preservation

Elliott and McKissock reported, in 1954, the first case of hearing preservation following the surgical removal of an acoustic neuroma.[55] In 1960, House was able to preserve hearing in small intracanalicular tumours using the middle cranial fossa approach.[98] In 1988, Gardner and Robertson found 221 instances of hearing preservation in 621 operated cases.[71] In 1993, Glasscock et al.[73] reviewed 28 pertinent series since 1980, but found it impossible to correlate the results due to lack of uniformity in the series and the lack of information. There is a controversy whether preservation of hearing is a reasonable objective in acoustic neuroma surgery. While some surgeons attempt to preserve hearing in all patients who have pre-operative hearing preserved,[24,58,62,106,219] other surgeons believe that hearing loss is the sequel least important to the patient.[150,162,255,258,257] An attempt at hearing preservation may result in the compromise of gross total removal of the tumour and a subsequent increased risk of recurrence and post-operative morbidity and mortality.

There is no agreement between neurosurgeons and neuro-otologists as to what constitutes "serviceable hearing".[73] However, the most commonly used criteria are a speech reception threshold of less than 50 db and

a speech discrimination score of more than 50%.[71,241,274] Ojemann[170,173,175] uses a speech discrimination score of 35% or more, while Whittaker and Luetje[274] use a score of 70% or more.

The idea to preserve hearing in patients with a unilateral acoustic neuroma is to provide binaural hearing. This enables the individual to perceive stereophonic sound, allows him or her to localise the sound and to suppress background noise. In individuals with good hearing in one ear and a flat loss of 20 db or more in the other, these functions are lost.[73,83] These patients experience a significant range of auditory disabilities. It is important that clinicians be aware of the impact of such a profound unilateral hearing loss and its potential to affect daily life. Patient counselling prior to surgery is essential especially in patients whose loss of binaural hearing could constitute a major disability.[48,215]

Hearing preservation will, therefore, be useful only to those patients in whom the hearing can be aided with a hearing aid. An aidable ear is one that has a pure tone audiometry average of at least 70 db and a speech discrimination score of 70% with a normal dynamic range.

The suboccipital approach and the middle cranial fossa approach are used in hearing preservation surgery. Intra-operative monitoring is extremely useful when hearing preservation is attempted. Brainstem auditory evoked potential (BAEP) and electrocochleography, when used together, monitor the entire auditory system.[173] The BAEP has a slower feedback and in practice only wave V is monitored, as the other potentials are quite small and may be undetectable. Electrocochleography monitors the status of the cochlea and the auditory nerves peripheral to the tumour and provides a rapid feedback of the compound action potential of the auditory nerve and cochlear microphonic potentials generated by the hair cells. The use of monitoring is to indicate early hearing compromise, so that the dissection may be altered. The usefulness of monitoring has been documented by many surgeons,[73,173,227] though some have found it to be of little help.[30]

In intracanalicular tumours which extend for less than 0.5 cm into the posterior fossa with at least 35% speech discrimination score, there is a 60% chance of preservation of hearing at the pre-operative level. This becomes 36% if the tumour size increases to 0.6–1.5 cm. The chances of saving hearing in tumours which are 2 cm or more in size are poor,[73,173] though there are occasional reports of hearing preservation in large tumours too.[23,172] Yokoh et al.,[286] feel that a cystic tumour gives a better chance at hearing preservation than a solid one.

A syndrome of delayed post-operative hearing loss has been described,[179,246,247,284] where patients who have initial hearing preservation gradually lose hearing in the post-operative period. The cause of this deterioration is not known. It is postulated that the post-operative deterioration may be due to a combination of the effects of cerebellar retraction,[231,234,235] disturbances in the microcirculation in the vasa nervorum during mechanical manipulation of the cochlear nerve, or an increased permeability of the endoneural vessels after mechanical compression trauma.[205,206] The patients in whom this deterioration is found may be identified intra-operatively as those who show a gradual deterioration of the BAEP, especially involving the amplitude of wave V.[246] Intermediate delayed post-operative hearing loss may be seen occasionally.[75,233] The factors involved in causing this phenomenon may be similar to those causing progressive deterioration in the immediate post-operative period. Other factors may include progressive scarring in the IAC with constriction of the cochlear nerve or the microvasculature secondary to the placement of muscle bits in the canal at the end of tumour removal.[75] Sekiya et al.[233] feel that in some of these cases there may be a false positive BAEP wave I recording even with axonotmesis of the cochlear nerve. The BAEP then shows gradual deterioration over days or weeks.

The long-term results of hearing preservation are varied. Shelton et al.[239] reported a significant loss of hearing in 56% of patients operated upon by the middle fossa approach over a period of 8 years. Others[179,202] did not find a significant decline in hearing. Good rates of hearing preservation have been reported by different groups of investigators using the middle fossa approach: 52%,[101] 57%,[244] 58%,[47] 59%,[17] 60%[285] and even 100%.[20] However, with increasing tumour size, the rate of preservation lowers. In the study by Yates and his colleagues[285] the rate decreased from 72 to 34% if the tumour extended more than 1 cm into the CPA. Although some authors have stated that the rate of preservation is lower with the retrosigmoid approach, if one compares only tumours of equal size, the results of different approaches are similar.[101]

The possibility of recurrence of tumour in cases where hearing has been preserved has been discussed in the literature. Neely,[162,163] reporting on patients whose tumour was removed "totally" and hearing was conserved, found residual tumour on the cochlear nerve and suggested that "total" surgical removal of the tumour and conservation of hearing may not be compatible. However, Samii et al.[213] and Ojemann[173] have found no recurrences on follow-up in their series.

Though a detailed discussion has been given here about the possibilities of preserving facial and hearing function, it must be pointed out that in many developing countries, where large tumours are the rule, preservation of life and the functions of the lower cranial nerves are still the primary goals of treatment in many centres. Enthusiastic young neurosurgeons have still to operate against odds. While they are striving to improve their facilities and results, they should not be discouraged by the good results of facial function preservation and hearing preservation reported from many sophisticated centres, which have all the necessary facilities and whereas a rule smaller tumours are encountered. In large tumours, where facial function preservation may only be about 30% in spite of best efforts, facio-hypoglossal anastamosis offers the best chance of avoiding facial disfiguration.

In this context, it is worth looking at the evaluation of our results by patients who have undergone surgery for acoustic neurinomas. Weigand and Fickel[276] in 1989, presenting the patients' perspective reported by 541

patients, found deafness in 93% of patients, transient or permanent facial weakness in 80% and post-operative eye problems in 88.5% of patients.[194,196] If meticulous microsurgical excision, aiming at total removal, cannot preserve facial function and prevent eye problems, it is better perhaps in those cases to do subtotal excision leaving the nerves intact. The post-operative life will be more bearable and pleasant in spite of the possibility of a second surgery.

Radiosurgery

Despite major advances in skull base surgery and microsurgical techniques, surgery for acoustic schwannoma carries a risk of complications. Some are inherent to general anaesthesia and surgery of any type and include myocardial infarction, pneumonia, pulmonary embolism and infection. Some are specific to neurosurgery in this area of the brain, and include hydrocephalus, CSF leak, facial nerve paralysis, facial numbness, hearing loss, ataxia, dysphagia and major stroke. Even in the hands of very experienced acoustic surgeons, these risks cannot be eliminated. Radiosurgery provides an outpatient, non-invasive alternative for the treatment of small acoustic schwannomas. Initially radiosurgery was undertaken in "high-risk" patients including the elderly, those with severe medical comorbidities and those in whom tumour recurred after surgery. Additionally, a high rate of cranial nerve morbidity was reported. With improvements in dosimetry planning and dose selection, however, authors practicing at radiosurgical centres now report very low complication rates as well as high tumour control rates.[65]

Radiosurgery is well suited for acoustic neuromas as it is typically well demarcated from surrounding tissues on neuroimaging studies. The sharp borders of this non-invasive tumour makes it a convenient match for the characteristically steep dose gradient produced at the boundary of a radiosurgical target, allowing the radiosurgeon to minimise the radiation affecting the normal tissue.[64,127,201,271] Excellent spatial resolution on gadolinium-enhanced MR images facilitates radiosurgical dose planning. Certainly, the role of radiosurgery is limited by its inability to expeditiously relieve mass effect in patients for whom this is necessary. The radiobiological nature of SRS also requires lower, potentially less effective doses for higher target volumes to avoid complications. This limits the use of SRS to the treatment of smaller tumours.[59,186]

Reporting on their early experience, Linskey et al.,[135,136] found tumour size decreased in 58% of patients and was unchanged in 42% of patients. On the other hand, Lunsford et al.,[141] found the 4-year actuarial tumour control rate (prevention of tumour growth or reduction of tumour size) to be 89% ± 6%. The mean time until tumour shrinkage was 1 year. Post SR imaging studies show a characteristic loss of central contrast enhancement within the tumour, occurring most commonly within 18 months of therapy. This loss of central contrast enhancement has been postulated to be due to radiation induced vascular injury and obliteration. A peritumoural increased T2 signal may appear transiently as may changes in the blood brain barrier with regression in tumour size in the region of the middle cerebellar peduncle. These changes occur more commonly in tumours greater than 15 mm in diameter.

Lunsford et al.,[141] found hearing preservation to be related to tumour size, with 50% of their patients with intracanalicular tumours retaining their pre-operative hearing levels. The actuarial rate for preservation of useful hearing at two years was 34% ± 6%.

The overall risk for the development of delayed facial neuropathy is 29% ± 4% and of trigeminal neuropathy 33% ± 4%. The mean time for developing cranial neuropathy is 5 months. It shows improvement after onset in the majority of patients.

In the University of Florida series[25] of 149 patients treated with linear accelerator (LINAC) radiosurgery between 1988 to 1998, with a median follow-up of 36 months, the overall actuarial incidences of facial and trigeminal neuropathies were 11.8% and 9.5% respectively. In 41 patients treated before 1994, the incidences of facial and trigeminal neuropathies were both 29%, but in the 108 patients treated since January 1994 these rates declined to 5% and 2%, respectively. The overall radiological tumour control rate was 93% (59% of the tumours regressed, 34% remained stable and 7.5% enlarged), and the 5-year actuarial tumour control rate was 87% (95% confidence interval 76–98%). In a recent report from University of Florida,[63 390] patients treated with LINAC from 1988 to 2005 were analysed. When doses were deliberately lowered to 12.50 Gy, only two patients (0.7%) had experienced facial weakness and two (0.7%) experienced facial numbness. Based on the findings, the authors recommended administering a peripheral dose of 12.5 Gy for almost all acoustic lesions, as this dose was most likely to yield long-term tumour control without causing cranial neuropathy.

In 1993, Norén et al.[166] reported on 254 patients who underwent GKS between 1969 and 1991. The minimum tumour dose ranged from 18–20 Gy specified at the 50–90% isodose line. This dose was reduced to 10–15 Gy during the final 3 years of the study. The minimum follow-up duration was 1 year (range 1–17 years). Rates of tumour control (decreased or stable tumour volume evidenced on neuroimaging) were 94% for unilateral tumours and 84% for those associated with NF-II. Delayed facial and trigeminal neuropathies occurred in 17% and 19% of patients, respectively. These were predominantly transient deficits, but severe nerve injuries did occur in both the facial and trigeminal nerves at a rate of 4%. These complication rates had diminished significantly later in the series with the institution of MRI based dose planning and the use of lower radiation doses.[164,165] Reportedly, the rates of facial and trigeminal nerve palsy for most of the 55 patients treated later were 1.8% and 0%, respectively.[167] Of those patients with functional hearing prior to radiosurgery, only 22% had preserved hearing in the overall series. However, in a later analysis of the subset of 44 patients treated between 1991 and 1994, who had functional (Gardner-Robertson Class I or II) hearing prior to treatment, Norén reported the preservation of Class I or II

hearing in 75% of patients after 1 year and 71% after 2 years. He attributed this improvement to better quality imaging and dose-planning accuracy that has resulted in more highly conformal radiation dose delivery.[65] In 2003, Noren reported on 134 patients with unilateral acoustic schwannoma who underwent GKS between 1994 and 2000. The mean marginal dose was 12.6 Gy and the mean maximum dose delivered to the tumour centre was 25.4 Gy (range 17.4–34.3 Gy). The tumour control rate, which was defined as no change or a reduction in size at last follow-up, was 96.7%. Of the patients studied, 97.7% remained free from the need to undergo tumour resection. Overall functional hearing preservation was 61.7%; the preservation rate for intracanalicular tumours was 63.6%, for those with an intracranial diameter less than 1.5 cm it was 54.5%, for those between 1.5 and 3 cm it was 68.2%, and for those larger than 3 cm it was 33.3%. The authors concluded GKS is one of the primary treatment options for patients harbouring tumours 3 cm or smaller in intracranial diameter, regardless of their age and medical condition.[138]

Fractionated Stereotactic Radiotherapy

"Fractionated stereotactic radiotherapy" employs administration of multiple-session treatments by fractionation of radiation dose, in an attempt to reduce complications, especially hearing loss.

Varlotto and his colleagues[267] treated 12 patients with a follow-up period ranging from 16–44 months. Eight patients were treated with primary stereotactic radiotherapy, and four patients were treated after primary surgical intervention for recurrent (three patients) or persistent (one patient) disease. Median tumour volume was 10.1 cm^3. Tumours received 1.8 Gy radiation/day, normalised to the 95% isodose line. Patients received a minimum prescribed dose of 54 Gy in 27–30 fractions during a 6-week period. After a median follow-up of 26.5 months, local control was achieved in all 12 lesions. Tumour regression was noted in three patients, and tumour stabilisation occurred in the remaining nine patients. No new cranial nerve deficits developed in any patient. One patient suffered worsening of pre-existing trigeminal neuropathy, and all nine patients with useful hearing before stereotactic radiotherapy retained useful hearing at the last follow-up.

Williams[278] treated 80 consecutive patients with a prospective schedule permitting increase in fractionation according to lesion size. Seventy patients having VS smaller than 3 cm in diameter received five daily fractions of 5 Gy (total 25 Gy), and 10 patients having an acoustic schwannoma 3 cm or larger received 10 daily fractions of 3 Gy (total 30 Gy). All treatments were prescribed to the 80% isodose line and administered via the dedicated 10 MV accelerator. For both the larger and smaller VSs, the percentage decrease in volume was similar. No tumour increased in size; facial weakness occurred in no patients and hearing was preserved in all patients.

Andrews and his colleagues[1] compared the results in patients treated using GKS with those in patients treated using fractionated radiotherapy. The gamma knife technique involved a fixed-frame, multiple-shot, high-conformality single treatment, whereas the LINAC technique involved daily conventional fraction treatments involving a relocatable frame, fewer isocentres, and lower conformality. Sixty nine patients were treated using the gamma knife, and 56 patients were treated using radiotherapy. Three patients were lost to follow-up; in the remaining 122 patients, the mean follow-up was 119 weeks in those who received SRS and 115 weeks in those who received stereotactic radiotherapy. Tumour control rates were high (97%) for sporadic tumours in both groups. Cranial nerve morbidities were comparably low in both groups, with the exception of functional hearing preservation, which was 2.5-fold higher in patients who had received conventional fractionation. Most recently, Chang and his colleagues[25] reported on 61 patients treated with the cyber knife and followed up for at least 36 months. These patients received either 18 Gy or 21 Gy in three fractions. Only one treated tumour progressed. Among the patients who had serviceable hearing, 74% maintained it. No new trigeminal or facial complications developed.

Long-term outcome studies proving the efficacy of fractionated radiosurgery is awaited, and at present, only SRS administered as a single shot is accepted as one of the primary treatment options for lesions smaller than 3 cm. They are also being increasingly used for residual lesions.[63]

Subtotal Removal and Tumour Recurrence

While the goal of surgery for acoustic neuroma is total excision, it may often be necessary to limit the resection to a subtotal or near total level to prevent post-operative neurological deficit. Radical subtotal removal describes the procedure when an extensive removal is done except for a portion of the capsule left attached to the brainstem or the facial nerve.[173] The reasons for a subtotal removal include adherence of the capsule to the facial nerve or brainstem, vascularity of the tumour, age of the patient and only hearing ear.[155,173,249]

The consequences of leaving small tumour remnants depend on the size of the residual tumour, the growth rate of the tumour and the remaining viable vascularity of the tumour bed.[254] The experience with subtotal removals has been variable, with some authors reporting significant regrowth requiring operation[176,187,254] and yet others[120,173,194,273] following patients over many years without any evidence of growth. Pooling data from three series,[171,189,272] Wallner et al.,[272] found the recurrence rate following radical subtotal excision to be 9% and that following subtotal excision to be 40%. Lownie and Drake[139] reported recurrence in only 2 patients out of 11, two and three years post-operatively.

However, with recent reports clearly showing higher recurrence rates, planned subtotal removal should be reserved for a few selected cases. Near-total resection should be the aim in any patient if needed to preserve neural integrity. Adjunctive treatment with stereotactic radiotherapy may be considered in cases where near total excision is not possible.[13,61,103,182,223]

CYSTIC VESTIBULAR SCHWANNOMA

The incidence of cyst formation in acoustic schwannomas ranges from 4 to 48%.[8] Cystic acoustic schwannomas are believed to be associated with sudden expansion,[28,131] shorter symptom duration,[8,113] atypical initial symptoms (such as dysgeusia, vertigo, facial pain and unsteadiness)[113] and an increased rate of pre-operative facial palsy.[28,113,152] This type of acoustic schwannoma rarely demonstrates enlargement of the IAC in neuroimaging findings despite increased tumour size (Figs 9A to C, 10A and B).[113]

The observation that the rate of cell proliferation, expressed as the number of Ki 67–positive nuclei, was lower in cystic than in solid acoustic schwannomas indicates that the increase in volume is caused by cyst formation and not by genuine tumour growth.[26]

It is known that the cystic portion of acoustic schwannomas is located in the Antoni type B area, which is softer than the type A area.[26,159] In the studies by Charabi and his colleagues,[26] the myxomatous material in the small cysts in the Antoni type B area coalesced into larger cysts, which compressed the surrounding type A tissue, thus creating membrane like structures consisting of type A tissue with immunoreactivity to S100.

Authors of recent studies have suggested that cyst formation accompanying intra-axial tumours is due to an oedematous process caused by blood-brain barrier disruption.[157] However, the mechanism leading to cyst formation in acoustic schwannomas remains unclear. The cyst formation in acoustic schwannomas is generally regarded as resulting from degenerative changes. Other pathogeneses, such as intratumoural haemorrhage,[78] necrosis[131,157] and secretion[26] could also be involved in the mechanism of cyst formation. Fluid accumulation due to a direct osmotic effect or the extravasation of serum proteins from an impaired blood-tumour barrier augments cyst enlargement.[157]

The possibility of haemorrhage in acoustic schwannomas is well known and even massive intratumoural haemorrhage occurs.[9,102,133,153,169] Isolated or repeated microhaemorrhage as a probable mechanism for cyst formation has been commented on in various reports.[27,159,183,190] Histological features of haemosiderin-laden macrophages, haemosiderin deposits and thrombotic vessels are frequently observed in cystic tumours.[27,159,183] The factor that triggers the haemorrhagic tendency is unknown.[180]

Matrix metalloproteinases (MMPs) are zinc endopeptidases that are required for the degradation of the extracellular matrix during normal embryogenesis and in tissue remodelling. These proteolytic enzymes are also derived from tumour cells and have a fundamental effect on tumour growth, invasion, and metastasis.[100,113] They have been detected in cyst fluids and are hypothesised to be the cause for the formation and enlargement of lesions in various cystic diseases. High levels of expression of MMP-2 have been observed in the cyst fluid and wall. It may be partly involved in the pathogenesis of cyst formation and aggravate the adhesion to the facial nerve by either promoting the enlargement of the tumour or engendering the degradation of the tumour-nerve barrier proteolytically.[157]

Surgical treatment of cystic tumours is favoured over radiosurgery,[183] but cyst formation is still predictive of a worse surgical outcome compared with solid tumours.[8,28,159] The "wait and scan" policy is not generally recommended, because the expanding cyst elements cause displacement of the brainstem and compression of the fourth ventricle, resulting in hydrocephalus. Even though the operation in the case of a cystic tumour may appear to be easier and faster in terms of the initial debulking than in a solid tumour[159] there is a higher risk of accidental lesions of the facial nerve, mainly because of adhesion of the cyst to the surrounding structures.[32,198] Moreover, rapid regrowth[32] and fatal haemorrhage have been reported after operation for cystic tumours.[157]

BILATERAL ACOUSTIC NEUROFIBROMAS

Bilateral acoustic neurofibromas (Figs 11A and B) are uncommon, when compared to unilateral neuromas, with the ratio varying from 1:10 to 1:50.[3,90,92,147,255] Bilateral acoustic neuroma was described by Wishart in 1822. Early reports carried a dismal picture regarding the outcome of surgery for these patients. Though with the current diagnostic and surgical facilities, the results are much better, there are still problems exclusive to these patients which have to be understood before managing them.

While bilateral acoustic neuromas are Schwann cell tumours which cannot be distinguished histologically from unilateral Schwann cell tumours, at surgery these tumours present as multilobulated masses engulfing the facial and the cochlear nerves. Studies with G-6-PD suggest a multicentric origin for these tumours.[151] Though hearing has been preserved in a few cases,[92,151,255] there is a high risk of hearing loss and facial paresis after surgery for these tumours. Large tumours showing signs of brainstem compression, hearing loss and facial paresis should be operated upon. There is a definite role for

observation and follow-up in cases where the tumours are small and the clinical condition is stable. Even intratumoural decompression can result in loss of hearing and facial function. Occasionally, decompression of the bony IAC and limited tumour decompression with use of intra-operative BAEP may help preserve hearing. Radiosurgery is a useful option in small tumours.

With large tumours requiring surgery, the side with the larger tumour should be operated on first, so that pressure on the brainstem is relieved. The tumour on the opposite side is removed at a second sitting once the patient recovers from the first surgery.

A major problem exists in the decision regarding when and whether to operate on the side of the remaining hearing ear when hearing has been lost on the other side, particularly when the remaining tumour is small and not immediately incapacitating. Though some authors advocate an early proactive strategy in order to preserve hearing,[16] classically, only symptomatic lesions are to be treated. When treatment is advisable, surgery remains the treatment of choice for tumours and an auditory brainstem implant (ABI) must be considered for hearing rehabilitation (Fig. 12).[81]

In Malis's series, patients who presented with bilateral acoustic neuromas in their thirties had a long and stable life expectancy than patients who presented in childhood. His results of hearing preservation in non-NF-II cases were 50% as opposed to 15% in cases with NF-II.

Recent reports that SRS is safe and effective in management of acoustic schwannomas in NF-II, it should be strongly considered for primary tumour management in selected patients, although results do not seem to be as good as for patients with sporadic unilateral tumours. Regarding the safety of radiosurgery when applied to conditions with abnormal tumour suppressor genes, a study with a cohort of 118 patients with NF-II demonstrated a statistically insignificant causative role for SRS in inducing malignancy.

Fig. 12: Post-operative lateral skull radiograph of a patient who has undergone auditory brain implantation

Most patients in India present late in the course of illness with large tumours and disabling deafness. Sixteen patients with bilateral acoustic schwannomas treated over 10 years in a tertiary referral hospital were analysed and an attempt was made to classify the tumours into two groups by their extent in the CPA cistern (T1-T3a) and, tumours extending to or compressing the brainstem (T3b to T4b), which allows the surgical strategy to be defined.[208]

NEURAL PROSTHESIS IN RESTORING HEARING

The auditory implant provides a new mechanism for hearing when a hearing aid is not enough. The auditory implant is very different from a hearing aid. Hearing aids amplify sound. Auditory implants compensate for damaged or non-working parts of the inner ear because they can directly stimulate the acoustic nerve. There are two principal types of auditory implant: the cochlear implant and the ABI. They have common basic characteristics, but different applications. A cochlear implant attempts to replace a function lost by the cochlea, usually due to an absence of functioning hair cells; the ABI is a modification of the cochlear implant, in which the electrode array is placed directly onto the brain when the acoustic nerve is not anymore able to carry the auditory signal.[44]

The main and first indication for ABI is NF-II. Emergent indications are bilateral total ossified cochlea, VS with controlateral lesions or in a single hearing ear, cochlear nerve aplasia or inner ear malformations. In NF-II patients, best results are obtained in cases of smaller VSs and none or short-term auditory deprivation. Negative prognostic factors are duration of total hearing loss (greater than 10 years), tumour size (greater than 30 mm), difficulties in electrode array placement, complications during the post-operative course and number of active electrodes (less than 10).[14]

The implant is usually placed in the lateral recess of the fourth ventricle at the time of tumour resection to stimulate the cochlear nucleus. A report on the audiologic outcomes in 18 patients with NF-II who received ABI at the time of initial tumour resection was favourable. The authors concluded that ABIs are safe, did not increase surgical morbidity, and allowed most patients to experience improved communication as well as access to environmental sounds.[114] In selected cases of deafness in patients with NF-II where there has been anatomic preservation of the auditory nerve after acoustic neuroma resection or radiation therapy, cochlear implantation may offer some improvement in communication skills, including the possibility of open-set speech communication in some patients.[143]

Most patients with the implant have good appreciation of environmental sounds, but obtain more modest benefit with regard to speech perception. The majority of patients make use of the implant to facilitate lip reading; some can, to varying degrees, comprehend speech directly.[230] The ABI and cochlear implant continues to be an emerging field for hearing rehabilitation in patients who are deafened by NF-II.

162 Trigeminal Schwannomas

BS Sharma, Ramdurg S, Sarat Chandra P

INTRODUCTION

Schwannomas (also known as neuromas, neurilemmomas, neurinomas and Schwann cell tumours) are benign, slow growing nerve sheath tumours composed of Schwann cells, which normally produce the insulating myelin sheath covering peripheral nerves. The tumour cells lie outside of the nerve, thereby causing compression. Intracranial schwannomas arise most commonly from the vestibular nerves but can involve any of the other cranial nerves.

Schwannomas of the trigeminal nerve are uncommon accounting for 0.07–0.36% of all intracranial tumours and 0.8–8% of intracranial schwannomas.[1,4,5,12,15–17] The first case of trigeminal nerve schwannoma was described by Smith in 1849.[21] The first successful removal was documented by Frazier in 1918.

SURGICAL ANATOMY

The trigeminal nerve emerges from the ventrolateral surface of the pons and runs anteriorly 1–2 cm through the cerebellopontine cistern to reach the petrous apex. Vascular structures, such as the petrosal vein and the superior cerebellar artery lie close to the trigeminal nerve. Over the petrous apex, 7 mm from the medial lip of the internal acoustic meatus, the Gasserian ganglion is enveloped by a dural deflection forming Meckel's cave, lateral to the cavernous sinus and the carotid artery.[6] As it leaves Meckel's cave, the trigeminal nerve divides into three branches: (1) The ophthalmic (V1), (2) Maxillary (V2), and (3) Mandibular (V3) branches. These three nerves run under the middle fossa dura mater and leave the temporal bone through the lateral wall of the cavernous sinus (for V1), foramen rotundum (for V2), and foramen ovale (for V3). The trigeminal nerve can also be surgically classified into three segments: (1) Cisternal, from the brainstem to the petrous apex; (2) Intracranial-extradural, from Meckel's cave to the foramina, and (3) Extra cranial (V1, V2, and V3). Functionally, the trigeminal nerve has two portions: (1) The "pars compacta", which constitutes the triangular portion and comprises the primary afferent fibres that are responsible for sensations of the face; and (2) The motor root, which carries the branchiomotor fibres to the muscles of mastication. The motor root runs practically separated from the "pars compacta" but together with the cranial portion of the nerve. At the level of Meckel's cave, it is oriented medially and leaves the skull together with the maxillary nerve. The intracranial-extradural portions of V2 and V3 are surgically identified, using the foramen spinosum as an anatomical landmark, which is located in the sphenoid bone and contains the middle meningeal artery. The foramina ovale and rotundum are located 2–5 mm superoanteriorly and 10–12 mm superomedially to the foramen spinosum, respectively.[23]

SURGICAL PATHOLOGY

Tumours arising from the Gasserian ganglion usually compress the ganglion, which is visualised after tumour removal. The nerve fibres usually are stretched over the tumour, although a few fibres may course through the tumour.

Microscopically they are composed of Antoni A and Antoni B regions. Antoni A regions are characterised by bipolar cells, which are arranged in compact interlacing fascicles. The nuclei line up in palisades with intervening nuclear zones called verocay bodies. A looser arrangement of cells, with poorly arranged vacuolated cells with pyknotic nuclei may be seen in Antoni B regions. These regions may represent degenerative changes. Cystic changes, hyalinised blood vessels, thrombosis and haemosiderin deposition may often be seen. Immunohistochemically, these tumours are positive for S-100 protein.[13] They occasionally are positive for Leu-7 and glial fibrillary acidic protein.

Clinical Presentation

Trigeminal schwannomas present most commonly in the third to fifth decades of life.[2,8,14] The tumours affect women slightly more than men.[17] The clinical presentation of trigeminal neurinomas depends on the site of origin of the tumour and the growth pattern.

Jefferson, in 1954,[12] divided these tumours into four groups depending on their anatomical location:

Type I. Posterior fossa (root type)
Type II. Combined posterior fossa–middle fossa (dumb-bell type)
Type III. Middle fossa (ganglion type) and
Type IV. Peripheral (division type)

Samii et al. in 1995,25 classified tumour extension into four categories based on radiological findings:

Type A. Intracranial tumour predominantly in the middle fossa
Type B. Intracranial tumour predominantly in the posterior fossa

Type C. Intracranial dumb-bell shaped tumour in the middle and posterior fossa, and
Type D. Extra cranial tumour with intracranial extensions

Cranial nerve involvement is the most common presenting symptom. Trigeminal nerve dysfunction is observed in more than 70% of cases. Facial hypoaesthesia is a much more common symptom, as compared to pain. Painless keratitis leading to corneal opacity, prior to any symptom is a rare but well recognised presenting feature of this tumour.[7] On the other hand, classical trigeminal neuralgia is also a rare initial symptom. Tumours arising from the ganglion usually produce constant pain, in contrast to tumours arising in the root, in which pain is frequently absent. The sensory disturbance may involve either one of the divisions or more frequently all the three divisions to a variable degree.

It is important to differentiate the sensory loss on the face due to root involvement, which may occur in V nerve schwannomas from that occurring due to high cervical intramedullary tumours. Usually, Vth nerve hypoaesthesia due to intramedullary pathologies lead to sensory loss starting from the periphery of the face and extending to the centre (like the French 'balaclava helmet') and is more commonly associated with dissociated sensory loss. In contrast to this, root involvement specifically involves the separate divisions (V1/V2/V3) of the face. Wasting of muscles of mastication is another important sign of V nerve involvement and is likely due to a tumour like schwannoma.[7,18,19] Sometimes, when there is a subtle motor weakness, it is of importance to ask the patient to bite a plastic or a wooden spatula and note the depth of the bites.

Abducens nerve paresis is the next common symptom, closely followed by involvement of the VIIth–VIIIth nerve complex. Less than 10% of patients have lower cranial nerve involvement. The IIIrd, IVth and VIth nerve can be involved by the tumour.[19] If the tumour extends to the middle fossa, it may cause exophthalmos. Visual loss can be either due to neuronal compression or raised intracranial pressure. Large tumours tend to present with features of raised intracranial pressure with headache, vomiting and failing vision.[26]

Very rarely, when there is a large infratemporal extracranial extension of the tumour, it may be palpable under the skin below the zygoma. They may also rarely present with pathological laughter and crying.[27]

Radiological Diagnosis

Plain X-Rays

Conventional X-rays (Fig. 1) demonstrate bony erosion of the petrous apex. The margins are smooth without sclerosis differentiating primary or secondary bony tumours of the region. Larger tumours with middle fossa extensions may demonstrate erosion of the sella turcica, clinoid process and widening of the superior orbital fissure. Tumours with a large posterior fossa component cause erosion of the inferomedial aspect of the petrous bone. Sparing of the internal acoustic meatus differentiates these tumours from acoustic neuromas.[10,20,22]

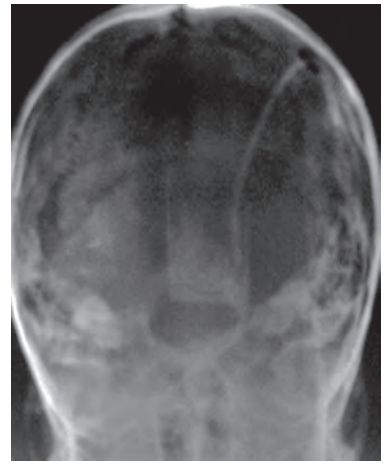

Fig. 1: X-ray skull Towne's view demonstrating bony erosion of the medial petrous bone

Computed Tomography Scans

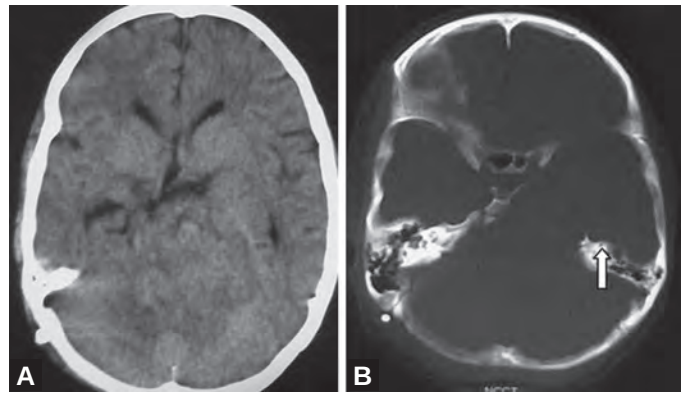
All the above described bony changes are better delineated on CT scans done with bone window settings (Figs 2A and B). The tumours are usually seen as iso- to hyperdense lesions with homogeneous contrast enhancement. However, other patterns of enhancement may be seen. Occasional cystic changes may be seen in the tumour.[9,24]

Magnetic Resonance Imaging (MRI)

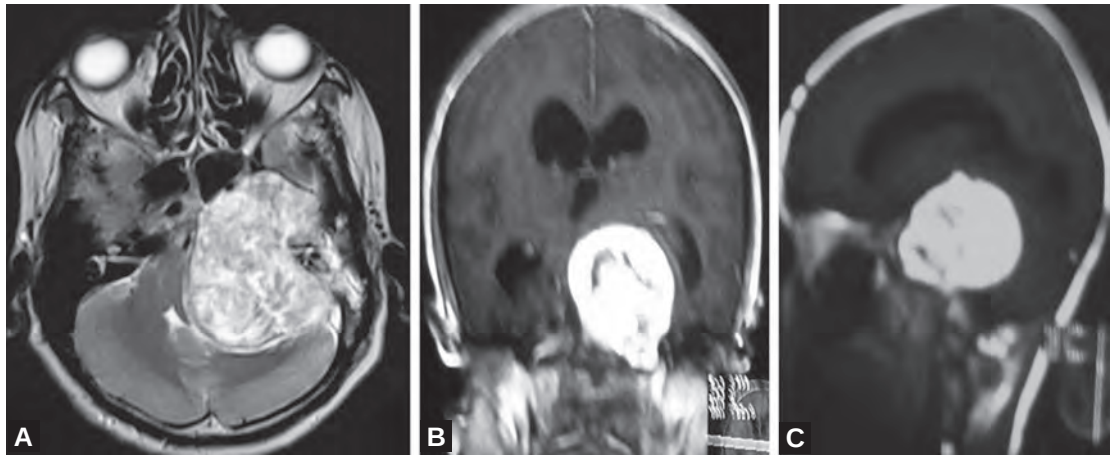
These tumours (Figs 3A to C) appear hypointense on T1W images and hyperintense on T2W images with intense contrast enhancement. These tumours may show cystic changes with occasional calcification. The extensions of the tumour can be demonstrated well with a contrast enhanced MRI scan.[11,24]

Cerebral Angiography

Small tumours do not demonstrate any change or abnormality in the vasculature. Larger tumours, however, may show enlarged feeding vessels which are usually derived from the precavernous and cavernous segments of the carotid artery. Displacement of the precavernous ICA



Figs 2A and B: Plain cranial CT scan with bone window settings showing the tumour with bony erosion of the medial petrous bone shown by solid white arrow



Figs 3A to C: MRI showing the extent of the tumour. (A) With brilliant enhancement as seen on contrast injection. (B and C) Presence of a tumour which straddles over the petrous with extensions both into the middle and posterior fossa is diagnostic of V nerve schwannoma

is the most commonly seen abnormality and it may be anterior and inferior displacement. However, superior and posterior displacement may also be seen. Tumours with a larger posterior fossa component may displace the posterior cerebral arteries medially and superiorly, while the anterior inferior cerebral arteries may be pushed downwards with stretching of the basilar artery.[3]

SURGICAL TECHNIQUES

The location and size of the tumour dictates the most appropriate approach.[19] They are usually easily separable from the cavernous sinus and the carotid artery, which facilitates their radical removal. Often, the tumour does not completely destroy the trigeminal nerve and can be separated from its fascicles, while preserving neurological function. Complete removal of the tumour should be the aim but not at the cost of neurological function. The natural history of these tumours, following sub-total excision is not known; some authors have found a high incidence of symptomatic tumour growth following sub-total excision, whereas others have found long periods of remission. In elderly or medically unfit patients and with tumours with firm adherence to the brainstem, cranial nerves or blood vessels, sub-total tumour excision may still be the optimal treatment.

Most of the tumours with a large middle fossa component may be accessed via the middle fossa approach. The medial part of the petrous may be drilled (Kawase approach) and the posterior fossa tumour may be now delivered through the enlarged opening. Rarely, a sub-temporal trans-zygomatic or an orbitozygomatic approach will be required.

The tumour should be debulked first. For this purpose, an ultrasonic aspirator may be used. It is also convenient to debulk using a sharp curette (no. 1 Penfield dissector or even a bone curette). Once this is done, the tumour should be gently dissected from the nerve fascicles, as the tumour is usually attached to 1–3 fascicles.

However, giant tumours are an exception as they may invade the entire nerve and even the brainstem. Caution must be exercised when reaching the anterior and the superior part of the tumour, where it may infiltrate the cavernous sinus densely and brisk bleeding may occur. Cavernous sinus bleeding may be easily controlled using a 'patty' made of Gelfoam® and Surgicel®, applied gently with suction and wet cotton.

The following approaches are commonly employed at our institute for trigeminal neuromas.[23]

Middle Fossa Approach

The patient is placed in the supine position with the head rotated 30 degrees to the opposite side. A pterional craniotomy is performed and enlarged to the base of the temporal fossa by removing bone with a rongeur to obtain a flat viewing angle across the floor of the middle fossa. The dura mater is then dissected and elevated from the middle fossa, exposing the superior orbital fissure. The middle meningeal artery is coagulated and transected. The second and third branches of the trigeminal nerve are identified. The foramen ovale and rotundum are exposed. The dura mater is elevated from the lateral cavernous sinus wall, revealing the tumour extradurally and the branches of the trigeminal nerve. The tumour is debulked and its capsule is dissected from the intact branches of the trigeminal nerve, which allows radical removal of the lesion. Large tumours can be approached intradurally by opening the Sylvian fissure and exposing the optic nerve, the internal carotid artery and the third cranial nerve. The lateral wall of cavernous sinus is exposed via a temporopolar approach and the tumour is removed. The trigeminal fibres are preserved as much as possible. The petrous apex is drilled and the petroclinoid ligament is cut to expose the posterior fossa portion, allowing complete excision of the remaining tumour.

Retrosigmoid Approach

This approach is used for patients with a large posterior fossa extension and smaller middle fossa component. The patient can be placed in the lateral, park bench or sitting position. A linear incision is made 4 cm behind the external auditory canal. The asterion is exposed to

determine the junction of the transverse and sigmoid sinuses. A craniotomy, 4 cm in diameter, is performed with the superior and anterior margins bordering the transverse and sigmoid sinuses, respectively. The dura mater is opened parallel to the sigmoid sinus, CSF is drained from the cerebello-medullary cistern and cranial nerves VII-XI are identified.

The tumour is thereby exposed near the tentorial margin. After intracapsular tumour debulking, microsurgical radical removal is accomplished. A watertight dural closure is completed and the bone flap is fixed in place. All opened mastoid cells are sealed with bone wax to help prevent CSF leaks.

Presigmoid Approach

The patient is placed in the lateral position with the head in a three point fixator. A 'C' shaped skin incision is made from the superior temporal line to the mastoid tip. Two burr holes are placed anteriorly and two are placed posteriorly at the intersection of the transverse and sigmoid sinuses. The temporal and retromastoid dura mater is exposed through a craniotomy. Mastoidectomy with preservation of the labyrinth and the facial nerve canal is the next surgical step. Parallel dural incisions in the middle fossa floor are made anterior to the sigmoid sinus. The superior petrosal sinus is then ligated and transected. At this point, the inferior temporal lobe and the lateral portion of the cerebellum are slightly retracted so that the vein of Labbé is preserved. The tumour is identified and the VIIth and VIIIth cranial nerves are usually displaced inferiorly. The tumour within the cavernous sinus is removed after opening its lateral wall. After complete excision of the tumour, the dura mater is closed in a watertight fashion and the skull base is reconstructed with myofascial flaps.

POST-OPERATIVE COURSE

Transient cranial nerve deficits are common in the early post-operative period. Abnormalities of trigeminal nerve, either new, or worsening of existing deficits may be seen, which may be permanent. This may be in the form of sensory loss or weakness of muscles of mastication. Prevention of corneal opacity may require an early tarsorraphy.

ROLE OF RADIOSURGERY

Smaller tumours or residual tumours may be subjected to stereotactic radiosurgery. Gamma Knife therapy is used at our institute using a Leksell Gamma Knife (Elekta Instruments, Atlanta, GA, USA), with a tumour margin dose of 12–13 Gy. The mean radiological follow-up was 15.7 months (range 6–37 months) and there was a tumour growth control rate of 85.75%. The mean volumes of tumours that decreased in size, remained stable and increased in size were 2.11, 5.33 and 8.1 cm^3, respectively.[26]

Proponents of Cyberknife radiosurgery demonstrate tumour control rates and clinical outcomes that parallel those of previous reports using Gamma Knife radiosurgery; however, long-term follow-up studies are needed.

AIIMS EXPERIENCE[26]

Sixty-eight patients were treated for TS between January 1993 and December 2005. Most patients were in the fourth decade of life, with the duration of symptoms ranging from 1 month to 13 years. Twenty-nine TSs were classified as Type A, 13 as Type B and 26 as Type C, depending upon their size. A skull base approach was used in every surgically treated case. Of the 46 patients for whom radiological follow-up data were available, complete tumour excision was achieved in 35 cases (76%). Follow-up ranged from 3 months to 12 years (mean 62 months). One patient died and nine (15%) had permanent morbidity in the form of corneal opacity (5), facial (2) or trochlear (2) nerve palsy.

163 Jugular Foramen Lesions

Siddhartha Ghosh

INTRODUCTION

Jugular foramen (JF) lesions, once thought to be one of the most surgically unapproachable ones, are now becoming safely manageable with reasonable morbidity and mortality rates. This advance has become possible due to improvement in microsurgical techniques and instrumentation. Parallel advances in the field of neuroradiology, neuroanaesthesiology, neuroelectrophysiology and neurointensive care, have helped immensely in the successful management of these lesions, as seen today. The highly complex nature of the jugular foramen and the morphological organisation of its surrounding neurovascular structures, coupled with the plethora of pathological conditions in this region, still pose a major challenge to the neurosurgeon. From the pre-microsurgical era to the microsurgical era, various safe approaches have been established. Proper patient selection, a thorough pre-operative work-up, choosing the ideal surgical approach and interdisciplinary teamwork involving the neurosurgeon, otologist, neuroradiologist and plastic surgeon, has made the now preferred single stage procedure feasible in dealing with these lesions.[34]

In this chapter, we review the salient anatomical, pathological, radiological and clinical features of JF lesions and indications, discussing the techniques, merits, demerits and the complications of the major approaches to the JF.

ANATOMICAL CONSIDERATIONS

Since the neural, arterial, venous, muscular and osseous relationships are exhaustive, only the salient features related to the jugular foramen are mentioned here. The jugular foramen is located at the posterolateral skull base with its long axis obliquely directed in the posterolateral to anteromedial and is formed by the petrous temporal bone anterolaterally and by the jugular process of the condylar part of the occipital bone posteromedially (Fig. 1). It is configured around the sigmoid sinus and the inferior petrosal sinus. The junction where the transverse sinus continues as the sigmoid sinus is indicated externally by the asterion at which point the vein of Labbé enters the sinuses. The right foramen is larger than the left in 68%, equal in 12% and smaller than the left in 20%, possibly due to the difference in the size of the sigmoid sinus and the jugular bulb.[24] On the intracranial side, the jugular foramen is inferior to the porus acoustics and superolateral to the intracranial orifice of the hypoglossal canal. On the extracranial side it is located just behind the carotid canal separated by the carotid ridge, lateral to the anterior half of the occipital condyle, anteromedial to the stylomastoid foramen and posteromedial to the styloid process.

The jugular foramen is traditionally divided into a large posterolateral compartment (pars venosa) and a smaller anteromedial compartment (pars nervosa). This view has been challenged by Katsuta et al. who have divided the jugular foramen into three compartments: two venous compartments and one neural intrajugular compartment in between. The venous compartments include a large posterolateral sigmoid part and a small anteromedial petrosal part.[16] At the junction of these two compartments there are two bony prominences (intrajugular processes), arising from the temporal and occipital bones, joined by a fibrous or less commonly osseous bridge forming the intrajugular septum.

The dura over the intrajugular septum has two characteristic perforations: (1) The glossopharyngeal meatus for the IX nerve and (2) A larger vagal meatus for X and XI nerves.[2] Both of the meati are located on the medial side of the intrajugular processes and septum, being consistently separated by a dural septum. Over the upper and lateral margin of the intrajugular part of the jugular foramen, the dura is thickened forming a roof or lip that projects inferiorly and medially to partially cover the IX and X nerves meati. This thick dural fold is called plica occipitalis oblique or jugular dural fold.[19,24,33] The lip projects most prominently over the IX nerve meatus, whereas, the lip over the X nerve is less prominent.

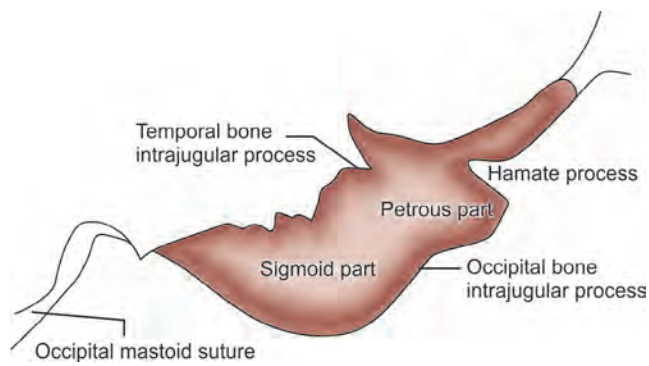

Fig. 1: Anatomy of the jugular fossa

The inferior petrosal sinus (IPS) joins the jugular bulb in 90%, passing between the IX nerve superolaterally and the X and XI nerves inferomedially. In 10% it drains directly into the internal jugular vein. The occipital condyle (OC) contains a condylar emissary vein in 70% of cases. This posterior condylar vein enters the jugular foramen at its posteromedial part and serves as a landmark to the foramen for the posterior approaches. The hypoglossal canal contains a venous plexus, called anterior condylar vein in addition to the XII nerve. The IX nerve enters the jugular foramen just below the cochlear aqueduct, piercing the dura at the pyramid fossa, expands at the site of the superior and inferior ganglia and courses forwards along the medial side of the intrajugular ridge before turning downwards. The X nerve enters the jugular foramen below the IX nerve. Its superior ganglion is located at the level of the dural roof of the JF and the inferior ganglion is located below the JF at the level of the atlanto-occipital (AO) joint. The X nerve, after piercing the dura, quickly turns downwards without having a forwards course within the JF. The XI nerve bundle blends into the lower margin of the X nerve at the level of the JF.

The relationships between the lower cranial nerves (IX–XII) and the major vessels [internal carotid artery (ICA), internal jugular vein (IJV), external carotid artery (ECA) and branches of vertebral artery (VA)], are extremely complex at the level of the JF and in the upper neck.[16,19,21] At the level of the skull base, the IJV courses just posterior to the ICA, being separated by the carotid ridge. At this level, both the artery and the vein are surrounded by a thick fibrous attachment of the carotid sheath to the periosteum of the skull base. The styloid process with the muscles attached to it separates the ECA laterally from the ICA medially. The IX, X, XI, and XII nerves at the exit from their respective foramina, first lie medial to both the ICA and the IJV with IX being most lateral and XII most medial; then IX, XI, and XII nerves pass laterally between the ICA and IJV; later the IX and XII descend forwards along the lateral surface of the ICA while XI descends backwards along the lateral surface of IJV. The posterior branches of the ECA (occipital and ascending pharyngeal) supply the meninges around the JF and are the main feeding arteries of JF lesions. The vertebral branches that are encountered near the JF region include the meningeal and posterior spinal arteries and posterior inferior cerebellar artery (PICA) having a close relationship with IJV, which lies just anterior to the transverse process of the atlas.

PATHOLOGY

Jugular foramen lesions are rare in clinical practice. Owing to the presence of osseous, muscular, neural, vascular, dural and connective tissue elements in the jugular foramen region, lesions arising from these elements are encountered in this region and some are more common than others. They are broadly classified into intrinsic and extrinsic or neoplastic and non-neoplastic.[6] Table 1 lists the lesions involving the jugular foramen region. Since the choice of the surgical approaches is dependent on the site of origin, size and extent of the lesion, attempts were made to classify these lesions into various types or classes, for example, Fisch's and Glasscock and Jacobson's classification for glomus jugular tumours and Keye's and Franklin's classification for schwannoma.[7,8,15,17] The one proposed by Bertalanffy and Ulrich is applicable to any type of lesion, which is as follows:[2]

Type I: Small lesions confined to the jugular foramen.

Type II: Intrinsic lesions of lower brainstem located in the vicinity of the jugular foramen.

Type III: Lesions of the jugular foramen with predominant intradural extension located above the level of foramen magnum.

Type IV: Lesions of the jugular foramen with intradural extension beyond the level of foramen magnum into the spinal canal.

Type V: Lesions of the jugular foramen with intradural and extradural extension into the petrous bone.

Type VI: Lesions of the jugular foramen with predominant extradural extension.

Table 1: Pathological lesions around the jugular foramen

Neoplastic	*Non-neoplastic*
Common	
Paraganglioma	Internal jugular vein thrombosis
Schwannoma	Large jugular bulb (pseudomass) (included because of radiological importance)
Meningioma	
Metastasis (haematogenous, nasopharyngeal, carcinoma)	
Uncommon	
Exophytic brainstem glioma	Aneurysm
Chondroma	Osteomyelitis
Chondroblastoma	Malignant external otitis
Chondrosarcoma	Cholesterol granuloma
Chondromyxoid fibroma	Amyloidoma
Osteoblastoma	
Plasmacytoma	
Chordoma	
Haemangiopericytoma	
Haemangioblastoma	
Choroid plexus papilloma	
Cavernoma	
Rhabdomyosarcoma	
Carcinoma of tympanic cavity	
Neurenteric cyst	

CLINICAL MANIFESTATIONS

The clinical presentation of jugular foramen lesions is dependent on the size, extent and pathology of the tumour. Typically, they produce the jugular foramen syndrome (Vernet's syndrome) and depending on their extension produce other related syndromes (Table 2).[3,26] Patients with IX, X, and XI cranial nerves dysfunction may present with dysphagia, dysarthria, hoarseness of voice, dysphonia, nasal regurgitation, ipsilateral trapezius, and sternomastoid muscle weakness and atrophy, depressed gag reflex, palatal droop on the affected side with ipsilateral vocal cord paralysis and loss of taste on the posterior 1/3rd of the tongue, paresis of the soft palate, uvula, pharynx and larynx. Some patients may present with neuralgic pain in the IX and X nerve distribution.[4] Due to the slow expansile growth of these lesions, the lower cranial nerve dysfunction is of gradual onset and, in most patients, it is well tolerated as a result of gradual compensation. As a result, although imaging studies reveal extensive involvement of these neural structures, patients may have only subtle manifestations of their dysfunction. Even though a positive correlation exists between cranial nerve palsy and tumour invasion, lack of pre-operative nerve dysfunction does not correlate with the degree of nerve invasion found at the time of surgery.[20] The anterior extension encasing the cavernous sinus and internal carotid artery may produce Horner's syndrome and III, IV, V, and VI nerve palsy. Intracranial extension can produce posterior fossa symptoms, such as nystagmus, ataxia, hemiparesis and increased intracranial pressure.[1] Extracranial extension along the internal jugular vein can produce a visible mass in the oropharynx or a palpable mass in the neck. Intraluminal growth can block venous drainage and occlude the sigmoid sinus and, if present bilaterally, increased intracranial pressure can occur. Intracranial extension superiorly can produce the cerebellopontine angle syndrome (deafness, tinnitus, VII nerve palsy) and those extending still laterally can produce bloody otorrhoea, a visible mass through the tympanic membrane and a bruit may be heard over the mastoid.

NEUROIMAGING

The cornerstone in the successful management of jugular foramen lesions is pre-operative high quality and multimodality neuroimaging. Advances in this field have led the surgeon to select the most appropriate surgical approach and technique, to anticipate the possible complications and to prevent or manage them. CT, MRI and angiography of the brain must be done in all cases to get the maximum information pre-operatively.

Plain and contrast CT scan of the brain with 1.5 mm cuts, bone window algorithm and coronal cuts help to reveal normal bony variations and the pathological bony involvement at the site of the jugular foramen and extension into the nearby osseous structures, and also the type of involvement, either expansile (compressive) or invasive (destructive) enlargement. The presence of obstructive hydrocephalus is also visualised. If spiral CT scan is available, this, with a bolus of contrast medium, will give additional information like three dimensional visualisation of the skull base and the relationship between the lesion, vessels and skull base.[18]

MRI images are extremely useful in delineating the exact location, origin, size, limits, margins, vascularity and extent of the lesion, degree of involvement of the important neurovascular structures and also to some extent the pathological diagnosis. For the latter purpose a dynamic, high dose Gd-study with creation of time intensity curves is found to be particularly useful.[37] With this technique, glomus jugulare tumours can be differentiated from schwannomas, meningiomas and metastases. MRI venography is highly predictive in differentiating pseudomas (large and high lying jugular bulb) from the

Table 2: The jugular foramen and related syndromes

Syndrome	*Cranial nerves*	*Site of involvement*
Vernet's syndrome	IX, X XI	Lesions in jugular foramen
Collet-Sicard syndrome	IX, X, XI, XII	Lesions in retroparotid space
Vallaret's syndrome	IX, X, XI, XII Sympathetic chain	Retropharyngeal extension
Schmidt's syndrome	Occasionally VII	Intradural extension
Avellis syndrome	X, XI XI (accessory to X)	Intradural extension, Occasionally inferior margin of JF
Jackson's syndrome	X, XI, XII	Intracranial extension before the nerves leave the skull base
Tapia syndrome	X, XII, occasionally	Lesions high in the neck
Cerebellopontine angle Syndrome	XI, sympathetic chain VII, VIII, V	Extension into CP angle
Garcin's hemibase syndrome	All cranial nerves on one side (often incomplete)	Infiltrative nasopharyngeal carcinoma

pathological lesions.[36] Octreotide scintigraphy, if available, is helpful in the diagnosis of multifocal paragangliomas since these tumours more than 1.5 cm in size take up the radioisotope.[12]

Finally bilateral cerebral angiography with cross-compression or balloon occlusion test will demonstrate enlarged feeding arteries, degree of vascularity, dominance and pathology of sigmoid sinus, jugular bulb and internal carotid artery. If the tumour is highly vascular, then a pre-operative super-selective endovascular embolisation can also be undertaken to assist in safe surgical removal.[35]

SURGICAL APPROACHES

Since the first reported exploration of the jugular bulb for a completely intraluminal mass by Sieffert in 1934, many surgical approaches, their modifications and combinations have been developed and utilised by neurosurgeons and otologists to deal with jugular foramen lesions. Historically, a sequence in developing these approaches with the aim to improve surgical management can be distinguished, for example, realising the need for VII nerve mobilisation, packing of sigmoid sinus, ligation of major vessels, resection of the skull base and so on. As a result, numerous approaches are now available, which vary in skin incision, soft tissue dissection and bone removal, having specific indications depending upon the site, size, extent and vascularity of the tumour, involvement of the surrounding neural (cranial nerves, brainstem and cerebellum), vascular (internal carotid artery, vertebral artery, sigmoid sinus, jugular bulb, internal jugular vein and cavernous sinuses) and osseous (petrous, clivus, condylar part of occipital bone) structures and finally upon the patient's clinical condition (hearing). The choice of the most appropriate surgical approach to a particular lesion in a particular patient has to be individualised and is dictated by the morphology of the lesion and the surgeon's experience and preference.

The surgical approaches used for JF lesions, although not always directed primarily to the jugular foramen, include the suboccipital retrosigmoid, presigmoid and trans-sigmoid, retrolabyrinthine and translabyrinthine, transcochlear and subcochlear, trans-supra and juxtacondylar, far lateral suboccipital, lateral skull base, infratemporal fossa and middle cranial fossa approaches. These approaches can broadly be grouped into posterior, lateral, anterior, superior and inferior approaches and further subdivided into limited, extended and combined approaches. In general, the limited approaches are useful for small lesions and extended and combined approaches for the larger lesions.

The latter two approaches are not suitable when used alone for JF lesions but definitely require to be combined with other approaches to deal with inferior, anterosuperior and medial extensions of the JF lesions.

Major Groups

Posterior (through posterior cranial fossa)	Suboccipital retrosigmoid transcondylar, supracondylar approaches
Lateral (through mastoid)	Lateral skull base, juxtacondylar approaches
Anterior	Preauricular subtemporal infratemporal
Superior	Middle fossa approaches
Inferior	Neck dissection

Lateral Approaches

The classification is shown in Table 3.[28] These are the most commonly used access routes for jugular foramen lesions having large extracranial extensions. These involve basically a mastoidectomy and more often, anterior re-routing of the VII nerve to drill the bone inferior to the labyrinth, to get access to the JF. The exposure can be widened anteriorly by sacrificing the external auditory canal and middle ear structures or medially by drilling away the otic capsule (translabyrinthine) or cochlea (transcochlear). When combined with upper neck dissection, it provides a satisfactory exposure of the JF, mastoid air cells, tympanic cavity and extracranial structures. The

Table 3: Classification of lateral approaches

LATERAL APPROACHES
- Juxtacondylar
- Lateral skull base
  - Approaches conserving otic capsule (extra-labyrinthine)
    1. Passing above otic capsule (supralabyrinthine):
       a. Middle cranial fossa
       b. Extended middle cranial fossa
       c. Middle fossa transpetrous
    2. Passing behind the otic capsule (retrolabyrinthine):
       a. Retrosigmoid
       b. Retrolabyrinthine
       c. Retrolabyrinthine transtentorial
    3. Passing anterior to otic capsule (prelabyrinthine):
       a. Infratemporal fossa Types B and C (Fisch's)
       b. Preauricular subtemporal—infratemporal
    4. Passing inferior to otic capsule (infralabyrinthine):
       a. Approaches to jugular foramen—infratemporal fossa Type A (Fisch's)
          - petro-occipital trans-sigmoid (POTS)
       b. Extreme lateral approach
  - Approaches sacrificing otic capsule
    1. Translabyrinthine
    2. Transcochlear
       - Original
       - Transotic
       - Modified types A–D

removal of the styloid process with transposition of VII nerve facilitates wide opening of the extracranial orifice or JF and provides access to the lower part of the petrous portion of the ICA. Still wider exposure of extracranial tumour is achieved by removing the transverse process of the atlas or dislocating or resecting the mandibular condyle. However, these approaches cannot be used for the removal of large intradural extensions, which require a combination of the posterior approaches.

These are the most suitable approaches for predominantly intradural lesions and for lesions extending down to the foramen magnum and medially to the lower and midclivus. The retrosigmoid approach provides access to the cerebellopontine angle and the intracranial orifice of the JF. Its transcondylar modification and the far lateral approach access the foramen magnum and lower clival regions by opening the posterolateral quadrant of the foramen magnum and by drilling away the posterior part of the occipital condyle.[32] The posterior and posterolateral margin of the JF is approached by removing a part of the jugular process of the occipital bone behind the JF and the portion of the mastoid just behind the mastoid segment of the VII nerve and the stylomastoid foramen. This provides an upwards view from below but to get a flatter view towards the midclivus, an additional drilling of the jugular tubercle is required.

Anterior Approaches

They use the pathway anterior to the external auditory canal and through the tympanic bone, exposed by removal or displacement of the glenoid fossa and temporomandibular joint. The subtemporal-infratemporal fossa approach alone can access the anterior part of the JF after reflecting the petrous portion of the ICA anteriorly. Further drilling exposes the midline and upper clivus anteriorly. However, more commonly, this approach has to be combined with lateral approaches to access the anterior extension of the pathology. These combined procedures are designated by Fisch as infratemporal fossa Type B and C approaches.

Posterior Approaches

- Suboccipital retrosigmoid
- Suboccipital transcondylar
- Suboccipital supracondylar.

Suboccipital Retrosigmoid Approach

This is a limited and posterior approach pioneered by Sir Charles Balance in 1894 and refined by Cushing and Dandy in 1920 and is frequently, one component of more extensive exposures. The main indications are Type A schwannomas of lower cranial nerves, epidermoid cyst and acoustic neurinoma extending down into the jugular foramen.

This is an important standard neurosurgical approach to the posterior fossa and hence does not need elaboration. The retroauricular skin incision exposes the suboccipital region including the asterion and medial portion of the mastoid process and reaches but does not extend inferiorly to the supracondylar fossa. Usually, the lateral rim of the foramen magnum is left in place. The mastoid air cells are usually opened, taking care of the emissary veins draining into the sigmoid sinus. The intracranial part of the jugular foramen is exposed by dissecting the arachnoid around the IX, X, XI nerves.

It is technically simple, familiar and associated with few complications and can be easily combined with other skull base procedures to gain further exposure. But, it has limited applicability in that, only the intradural portion of the tumour can be removed and does not allow removal of either intrajugular pathology or extracranial extensions.

Suboccipital Transcondylar Approach

Termed by Seeger (1978) and refined by Gilsbach (1987) and by Bertalanffy et al., this approach is an extended modification of the retrosigmoid approach providing more extended lateral and inferior exposure than the latter.[10,29,30] This is not synonymous with the far lateral approach for the foramen magnum (FM) lesions, which requires the resection of only the medial one-third of the occipital condyle. The indications are intrinsic lesions of the lower brainstem up to the pontomedullary junction, tumours located anterior or anterolaterally to the lower brainstem, extradural pathology from the lower clivus, occipital condyle, anterolateral rim of the foramen magnum and jugular process of the occipital bone and aneurysms of the vertebrobasilar complex.

Technique: The initial steps are like that of the standard suboccipital retrosigmoid approach. In addition to suboccipital craniotomy, the bone resection extends to include the posterior and medial portion of the occipital condyle and part of the jugular process superior to the condyle to expose the hypoglossal canal and the jugular foramen from dorsally and inferiorly. The distal extradural vertebral artery is exposed up to the point where it pierces the atlanto-occipital membrane and dura. While making the dural incision, it is desirable to leave a cuff around the vertebral artery, which aids in watertight dural closure at the end of the procedure, to prevent post-operative CSF leak. The posterior emissary vein, when present, is a useful landmark in the identification of the jugular foramen.

It provides a straight line view to the anterior rim of the foramen magnum and lower clivus, an excellent exposure of the lower brainstem, without the need to retract the brainstem or overstretching of the lower cranial nerves with an excellent control of vertebral artery in its extradural and intradural course. It can be extended laterally to expose JF lesions, either from an intradural or extradural approach. Ligation and division of the sigmoid sinus to expose the intradural portion is done according to the surgeon's preference.

There is a potential risk of injury to the vertebral artery (VA), and the lower cranial nerves and a risk of craniocervical instability, if the atlanto-occipital joint is opened. For a predominantly extradural growth with a lateral extension into the JF, Sen and Sekhar used this approach from a lateral direction by combining lateral exposure of the foramen magnum with a partial mastoidectomy.[10] Although useful for the above indication, the mastoidectomy and extensive OC resection is not necessary for the predominantly intradural growth.

Supracondylar Approach

Described by Gilsbach et al., this is a limited variation of the transcondylar approach and is indicated for small lesions confined to the hypoglossal canal and to the medial rim of jugular foramen.[11]

Technique: The initial procedure is like that of the standard suboccipital approach. Then the suboccipital craniotomy is extended down to the supracondylar fossa while preserving the foramen magnum and occipital condyles. The jugular tubercle is drilled away extradurally, exposing the medial aspect of the jugular foramen laterally and hypoglossal canal inferiorly. The advantage of this approach is the low morbidity and the disadvantage is that radical excision is not possible and is adequate only for biopsy and for small intradural lesions confined to the hypoglossal canal.

Juxtacondylar Approach

Developed by Geroge et al., it is an important limited and lateral approach and one of the primarily targeted approaches to the JF.[9] The prime indication is for extradural tumours confined to the jugular foramen like lower cranial nerve schwannoma, meningioma, etc.

Technique: The skin incision starts from the superior nuchal line behind the mastoid and extends along the medial border of the sternomastoid muscle to 6 cm below the mastoid tip. The IJV and XI nerves are exposed after resecting the muscles attached to the mastoid. The transverse process of the atlas is freed of it muscular attachments and the VA is exposed above and below the transverse foramen. The transverse process of atlas is removed and the VA can be transpositioned, if necessary. The posterolateral aspects of the atlanto-occipital and atlanto-axial joints are exposed. The posterior belly of the digastric muscle is resected and the occipital artery is ligated. The external and internal carotid arteries are exposed only if necessary. Then a partial mastoidectomy is done, which is continued medially to expose the distal SS. The remaining posteroinferior wall of the jugular bulb is drilled away which opens the jugular foramen posteriorly and inferiorly. Exposure of VII nerve at its exit from the stylomastoid foramen and at its petrosal segment, and dural opening is done only if necessary, in cases of large tumours.

It provides a wide exposure of the posterolateral aspect of the jugular foramen without extensive petrous bone drilling and hence preserves hearing and VII nerve functions. There is no risk of CSF leak because the dura is usually not opened. It can be combined with a supracondylar exposure, which is mainly indicated for intradural pathology or with infratemporal fossa approach Type A.

But this is a limited exposure of the JF with the potential risk of venous bleeding around the VA within the foramen transversarium of the atlas.

Samii and Bini advocated a combined lateral suboccipital-infralabyrinthine approach. Hirsch, Sekhar and Kamerer proposed a transtemporal and infratemporal approach for benign tumours with both extradural and intradural extensions with excellent control of the vertebral artery.[13,27]

Petro-Occipital Trans-Sigmoid (POTS) Approach

It is one of the lateral infralabyrinthine skull base approaches primarily targeting the jugular foramen, described by Mann et al. It is primarily indicated for jugular foramen lesions especially lower cranial nerve schwannomas with intracranial extensions, meningioma of the jugular bulb and some cases of glomus jugulare tumours with predominant posterior extension. It is also indicated in small petroclival meningiomas lying anterior to the internal auditory canal (IAC) with preserved hearing.

Technique: A 'C' shaped skin incision 4 cm posterior to the post-auricular sulcus with its lower limb extending inferiorly 2 cm below the mastoid tip is used. An inferiorly based 'U' shaped musculoperiosteal flap is then raised extending from 1–2 cm above the zygomatic arch superiorly to the level of the mastoid tip inferiorly. Anteriorly a strip of periosteum is left a few millimetres posterior to the EAC to allow re-suturing of this flap during closure. The sternomastoid muscle is retracted posteriorly. The lateral process of the atlas is identified and the IJV anterior to this is dissected free and ligated. Following a complete mastoidectomy, the mastoid portion of the VII nerve and JB are identified and the bone over SS and JB and posterior fossa dura in front of the SS are removed. A 4 × 4 cm suboccipital craniotomy is performed limited anteriorly by the SS and superiorly by the TS. The infralabyrinthine petrous bone is drilled away taking care not to injure the posterior semicircular canal or VII nerve. The occipital condyle is partially drilled up to the hypoglossal canal. The vertical segment of the JCA is exposed by drilling the inferior tympanic bone while preserving the EAC wall. The proximal part of the SS is compressed extraluminally and the SS is then opened and packed distally and proximally. A horizontal dural incision is made starting posterior to the SS, coursing anteriorly traversing the medial wall of the SS. Then the arachnoid is removed from neurovascular structures,

exposing IV–XI nerves and the superior cerebellar artery, AICA and PICA.

The removal of the lateral wall of the JB and, if necessary, its medial wall, fully exposes the intracranial part of IX–XI nerves. The dura over the drilled part of the OC is excised exposing the hypoglossal canal. When needed, IX–XI nerves are retracted or sacrificed if invaded by the tumour. If necessary, drilling is continued to the ipsilateral lower clivus and to the lower border of the foramen magnum. If control of the vertical portion of the ICA and of the infralabyrinthine compartment is needed, the mastoid segment of VII nerve is mobilised as far as the stylomastoid foramen. Only if the tumour extends to the hypotympanum, an extended posterior tympanotomy is performed and the facial nerve is re-routed. The retrosigmoid posterior fossa dura should be closed. The resected cavity is filled with an abdominal fat graft and the wound is closed.

The advantages of this approach are that the middle ear and VII nerve functions are preserved and it can be combined with the transtentorial approach for tumours with supratentorial extension or with the translabyrinthine approach for tumours involving the IAC in the absence of pre-operative serviceable hearing (and if hearing is preserved then the posterior and inferior wall of IAC is drilled away without sacrificing the labyrinth) or with the extreme lateral approach for tumours extending downwards to involve the CV junction ventral to the brainstem.

The disadvantages are that it only provides limited control of the ICA (dorsal and lateral aspects) and hence extensive involvement of the IAC is a contraindication for the POTS approach for which either modified transcochlear or infratemporal fossa Type A approach is indicated. Injury to the lower cranial nerves and CSF leak are the potential complications. Also this is not useful in highly vascular and invasive glomus jugulare tumours for which the infratemporal fossa Type A approach is preferable.

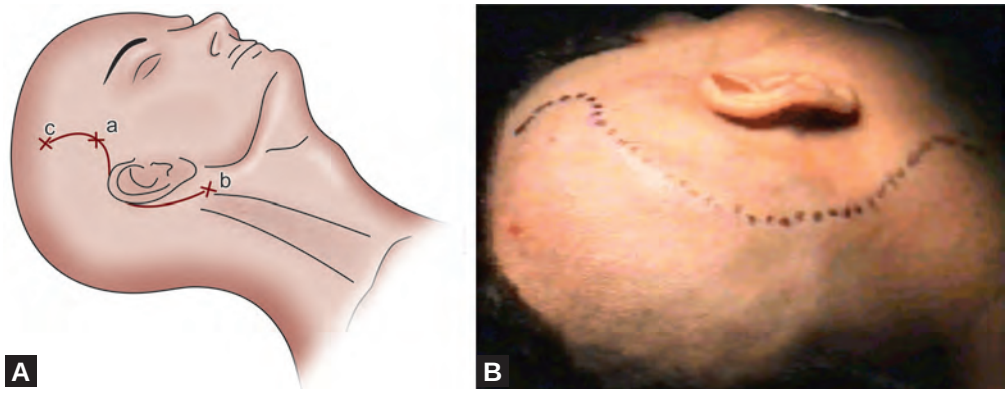
Infratemporal Fossa Approach Type A[5]

Described by Ugo Fisch, it is one of the most important combined approaches to jugular foramen lesions, belonging to the lateral group of approaches.

Indications: Jugular foramen lesions, especially large glomus jugulare tumours, some lower cranial nerve neurinomas and meningiomas and lesions of infralabyrinthine and apical portion of the petrous temporal bone, like cholesteatoma, chordoma of lower clivus and carcinomas invading these regions and extensive facial nerve neurinomas.

Technique: A postauricular skin incision extending superiorly to the temporal region and inferiorly along the anterior border of the sternomastoid muscle 5–6 cm below the mastoid tip with a preauricular limb is used (Figs 2A and B). A small anteriorly based musculoperiosteal flap is raised and a cul-de-sac closure of the external auditory canal is done (Figs 3A and B, 4A and B and 5). By neck dissection, the VII nerve, as it exits the stylomastoid foramen, is identified and its main trunk is traced into the parotid gland till the proximal parts of the temporal and zygomatic branches. The lower cranial nerves, the ECA, ICA and IJV are exposed in the upper neck (Fig. 6). After dividing the sternomastoid muscle and the posterior belly of the digastric muscle, the ECA is ligated distal to its lingual branch. The skin over the external auditory canal, the tympanic membrane, and the malleus and incus are removed. A radical mastoidectomy is done (Figs 7A and B). The VII nerve is freed from the fallopian canal from the geniculate ganglion to the stylomastoid foramen and transposed anteriorly and fixed to the new bony canal drilled in the root of the zygoma superior to the eustachian tube and to the tunnel created in the parotid gland to lodge the nerve. The hypotympanum is drilled completely to expose the vertical portion of ICA. The ascending mandibular ramus is displaced anteriorly and the mandibular condyle is resected in case of large tumours. The SS is either packed or doubly ligated and, if necessary, its lateral wall is removed up to the level of the jugular bulb and lateral wall of the jugular bulb is opened, taking care to pack the IPS and the entry of the condylar emissary veins into it. The IJV is doubly ligated and cut in the neck and elevated superiorly taking care not to injure the XI nerve. In case of limited intradural extension of the tumour, the dura is opened without injuring the endolymphatic sac.

Advantage: It offers wide exposure anterior to the JF and to the infratemporal fossa up to the petrous apex.



Figs 2A and B: Incision

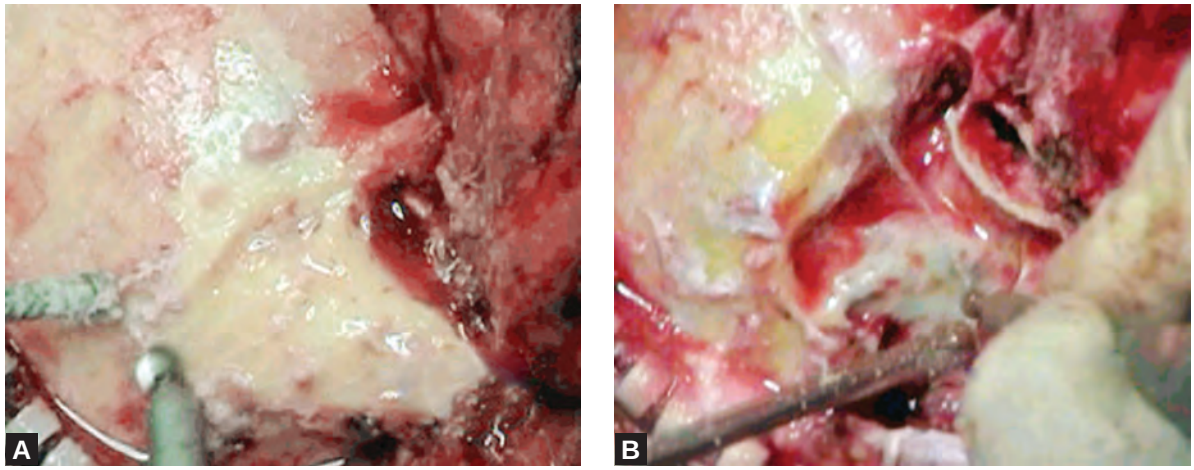
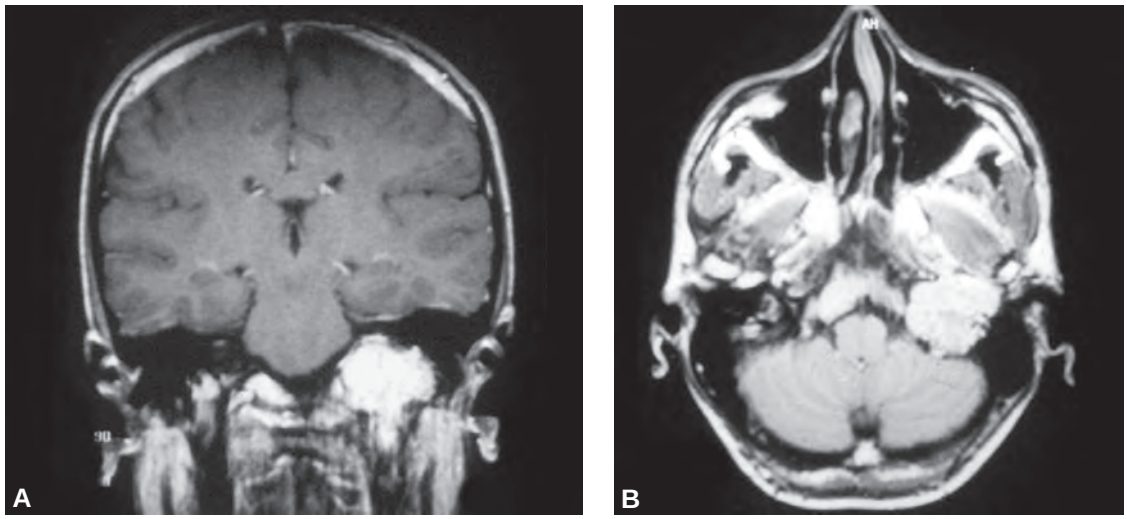
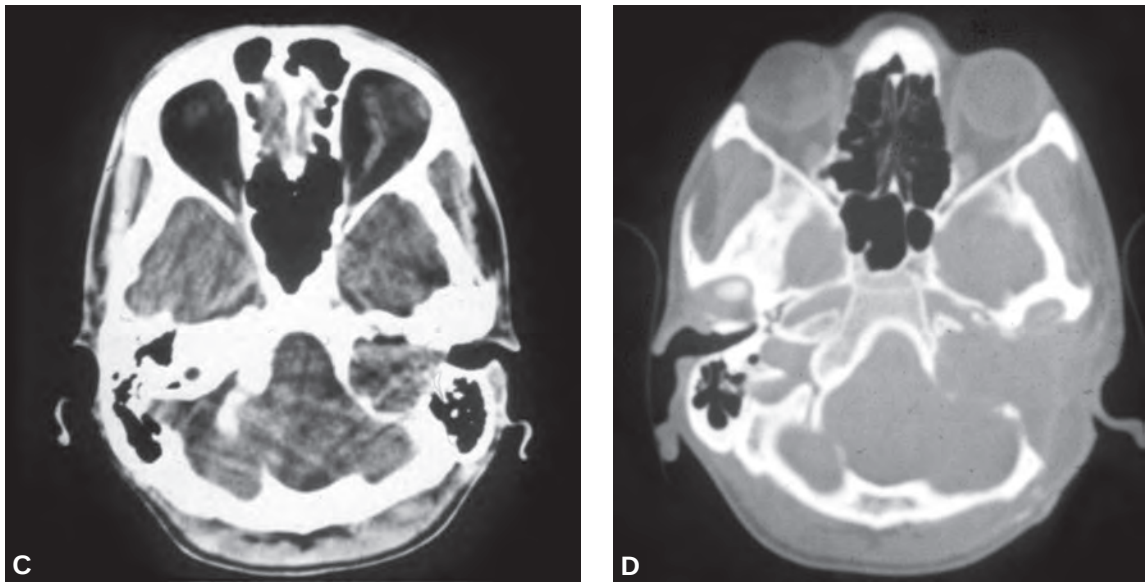


Figs 7A and B: Mastoidectomy



Figs 8A and B: Pre-operative large, highly vascular lesion in the left jugular foramen extending into the CP angle and jugular bulb



Figs 8C and D: Post-operative scans showing total removal

Disadvantage: Apart from hearing loss, facial paralysis and numbness and malocclusion, this is not suitable for large intracranial tumour extension and for the large tumours reaching the foramen lacerum or cavernous sinuses. For this infratemporal fossa, Type B or C (anterior) approaches has to be combined with this Type A (lateral) approach.

Modifications of This Approach

Since hearing cannot be preserved in Type A Fisch's infratemporal fossa approach in patients with preserved hearing, Pensak and Jackler in 1997 advocated an approach that preserves the external auditory canal and middle ear structures and allows working anterior and posterior to the descending segment of VII nerve which is not re-routed.[23] But this is possible only in tumours that do not erode the carotid genu.

Sekhar and Schramm advocated a combined lateral and posterior cranial base approach (preauricular subtemporal-infratemporal fossa) for large tumours, which differs from Fisch's approach in that the VII nerve is not displaced from the temporal bone.[31]

The Type B infratemporal fossa approach is mainly designed for extradural petrous apex and midclival tumours, with preservation of the inner ear function. It is used in association with the Type A infratemporal fossa approach for extensive glomus tumours involving the petrous and the midclivus. This involves reflection of the zygomatic arch inferiorly and division of the middle meningeal artery and mandibular branch of V nerve. This gives exposure up to the foramen lacerum, petrous apex and clivus.

The Type C approach involves an orbitozygomatic reflection, sectioning of some branches of the facial nerve in the parotid area, resection of the pterygoid process and sectioning of V3 nerve. This gives wider exposure to the carotid artery in the cavernous sinus.

Modified Transcochlear Approach[6,22]

One of the lateral skull base approaches described by Mario Sanna provides better visualisation of the ventral brainstem and vertebrobasilar junction by removing the petrous apex and clivus and excellent control of the vertical and horizontal segments of the ICA.[6] It is classified into Types A–D. Type A is the basic approach which, but by itself, provides only limited access to tumours extending into the jugular bulb and down to the foramen magnum. It is indicated for extradural lesions involving the petrous apex with VII nerve and inner ear compromised (e.g. petrous bone cholesteatoma, extensive VII nerve neurinoma, recurrent VIII nerve neurinoma), intradural recurrent VIII neurinomas, large petroclival meningiomas and for transdural lesions invading the petrous bone like residual glomus tumour, chordoma, etc.

Type A Modified Transcochlear Approach

Technique: A 'C' shaped post-auricular skin incision is made. Blind sac closure of the external auditory canal, extended mastoidectomy, posterior re-routing of VII nerve after its complete mobilisation from the stylomastoid foramen up to the geniculate ganglion and labyrinthectomy are done. The greater petrosal nerve and vessels are sacrificed. The internal auditory canal is not opened. The fallopian canal and the cochlear and anterior wall of the IAC are drilled, and the vertical segment of the internal carotid artery is exposed. Then the petrous apex and anterior wall of the EAC are drilled. The mandibular condyle is displaced anteriorly. The petrous apex is drilled up to midline to get full control of the horizontal part of ICA. The dura is incised in front of the internal auditory canal taking care not to injure the VII nerve.

Its disadvantages include risk of injury to the VI nerve while incising the dura of the petrous apex and injury to the VII nerve during its mobilisation.

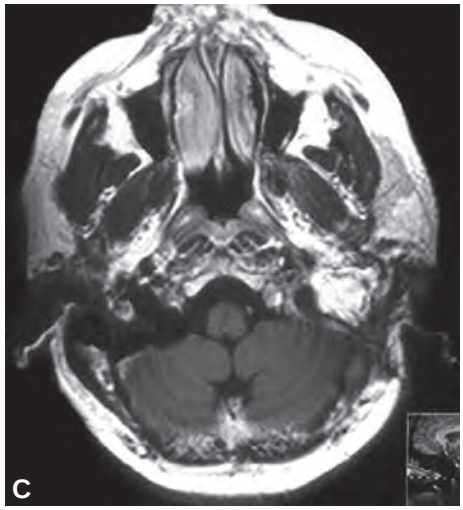

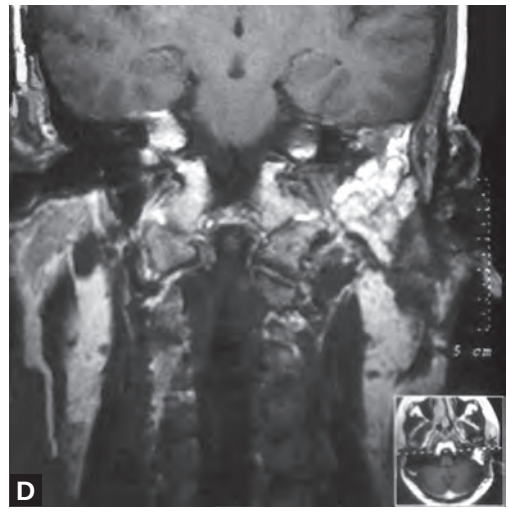

Figs 9C and D: Post-operative scans of the same patient

Fig. 10A: Pre-embolisation angiogram of a highly vascular glomus jugulare tumour

Type B modified transcochlear approach incorporates Fisch's Type B or C infratemporal fossa approach with Type A modified transcochlear approach and is used for lesions extending into the parapharyngeal space.

Type C modified transcochlear approach allows control of both the infratentorial and supratentorial parts of the tumour lying ventral to the pons and midbrain and is indicated for petroclival tumours with supratentorial extension.

Type D modified transcochlear approach incorporates either POTS or the extreme lateral approach Type A modified transcochlear approach. This is indicated in mid and low clival lesions, petroclival meningiomas and extensive lower cranial nerve neurinomas. If it is necessary to get excellent control of the caudal part of the medulla, the VII nerve may be transposed anteriorly.

Few cases successfully managed by the author are shown in Figures 8 to 11.

POST-OPERATIVE COMPLICATIONS

Many of the complications (Table 4) are related to the size, vascularity and extent of the tumour, choice of

Figs 10B and C: Post-embolisation angiogram

the surgical approach, skill of the surgeon and the pre-operative condition of the patient. Some complications (e.g. infarct) that are related to pre-operative endovascular embolisation can also occur in the post-operative period. In general, if there are no neurovascular deficits pre-operatively, then meticulous care is to be taken in order to preserve their functions. In preventing post-operative CSF leak, which is the most frequent complication, a lumbar drain is preferred to intraventricular drain since the latter is fraught with the risk of intraventricular haemorrhage, which may prove fatal.[6] Excessive CSF drainage is also to be avoided, to prevent low intracranial pressure and subsequent subdural haemorrhage. Special mention should be made of cranial nerve dysfunction. This is the most serious complication. The size of the lesion is generally correlated with the dysfunction and the recovery.[14] In smaller lesions the post-operative morbidity is minimal and the chance for long-term improvement is excellent. There are reports of excellent long-term recovery in patients in whom the nerves were sectioned,[14] but functional recovery is dependent on nerve continuity after surgery. Another important point is that if lower cranial nerve dysfunction is already present pre-operatively, the patients will usually be compensated for this deficit and so an aggressive surgical strategy can be undertaken without producing any increase in their pre-operative deficit.[25] In general, complications can be avoided by carefully scrutinising the pre-operative images, selecting the most appropriate approach or its modification, tailored according to the need and by giving enormous attention to the technical details.

Table 4: Post-operative complications and their prevention and treatment

Complication	*Subclassification*	*Prevention*	*Treatment*
CSF leak and impaired wound healing	Incisional Rhinorrhoea Otorrhoea Pseudomeningocoele	Watertight dural closure with graft, packing of the cavity with fat, vascularised muscle flap Pre-operative treatment of middle ear infection	Re-opening and closure of the dural defect
Infection and meningitis	Osteomyelitis Subdural Empyema Brain abscess Sepsis	Peri-operative antibiotics Attention to the technique of dural closure and use of vascularised flap Pre-operative treatment of middle ear infection	CSF culture and antibiogram and appropriate antibiotic therapy
Cranial nerve injury	III, IV, VI—diplopia V, VII—facial numbness and weakness, VIII—hearing loss IX, X—dysphagia, malformation and dysdigestion	Intra-operative neurophysiological monitoring, pre-operative radiotherapy or embolisation to reduce tumour size, choosing the appropriate surgical approach Avoid using the bipolar coagulation near the nerves Intra-operative nerve suturing XII to VII anastomosis	For VII N palsy—eye lubricants tarsorrhaphy, gold weight insertion the upperlid For IX, X, XI N Palsy—Ryles tube nutrition, PEG feeding, tracheostomy, laryngoplasty or injection of Teflon into the vocal cord Treatment of secondary chest infection due to aspiration
Vascular injury	Arterial-infarction, Pseudoaneurysm (ICA, VA, PICA) Venous—infarction, Sinus thrombosis (vein of Labbé, SS, IJV) Haematomas	Attention to pre-operative neuroimaging studies. Attention to meticulous surgical techniques Extra-intracranial or Intra-intracranial bypass procedures	Vascular repair Evacuation of clots after post-operative CT confirmation
Late events	(a) Hydrocephalus (b) Craniocervical instability (c) Catecholamine secretion (carotid sinus syndrome) (d) DVT of lower limbs (e) Trismus and incorrect dental occlusion (f) Eustachian tube dysfunction (recurrent otitis media) (g) Psychological problems (h) Neuropeptides affecting gastrointestinal function (prolonged ileus, pancreatitis, cholecystitis and biliary tract complications)	Careful haemostasis Preserve articular facets, if possible Muscle packing	EVD or rarely VP shunt OC fusion Alpha and beta blockers Fraxiparine S/C, filters in IVC Dental Tr

ACKNOWLEDGEMENTS

164 Other Intracranial Schwannomas

Ashish Suri, Shashwat Mishra, Ajay Garg

INTRODUCTION

Schwannomas are benign, slow-growing, encapsulated tumours, which arise from the proliferation of Schwann cells. They constitute about 8% of all brain tumours.[39] Since Schwann cells myelinate all the cranial nerves with the exception of I cranial nerve and II cranial nerve, schwannomas can potentially originate from any of the remaining cranial nerves. Cranial nerve schwannomas account for 60% of all the schwannomas.[34] Along the course of the nerve root, the site of origin of these tumours is at or distal to the Obersteiner-Reidlich zone where the transition between central and peripheral myelin occurs. The zone of transition is usually within several millimetres of the origin of the nerve from the brainstem. Schwannomas have a predilection for the sensory cranial nerves. Involvement of motor cranial nerves is commonly associated with neurofibromatosis.[3,35,37] Vestibular schwannomas, with an annual incidence of 1/100,000 of the general population, comprise 80–90% of all intracranial schwannomas. The non-vestibular schwannomas most commonly involve the V nerve (40%), followed by the facial (23%) and the lower cranial nerves (LCNs) (20%).[13,31] In the absence of neurofibromatosis, schwannomas arising from the extraocular nerves are extremely rare. An intracranial schwannoma arising from the sympathetic plexus around the intracavernous carotid artery has also been reported.[40]

FACIAL NERVE SCHWANNOMAS

Facial nerve schwannomas (FNSs) make up only about 1.9% of all intracranial neuromas.[38] Although the facial nerve is predominantly motor, association of FNSs with neurofibromatosis is rare. The FNSs may arise from any segment of the nerve, from the cerebellopontine angle (CPA) to the extracranial extent of the nerve. Lipkin et al.[21] have classified FNSs according to the site of origin along the VII nerve into labyrinthine, tympanic, geniculate and vertical segment lesions. The geniculate ganglion and the adjoining labyrinthine segment of the nerve is considered to be the most common site of origin for schwannomas.[38,41] Large FNSs arising from the geniculate ganglion can present as middle cranial fossa masses with erosion of the anterior surface of the petrous bone. Extension along the course of the greater superficial petrosal nerve (GSPN) may also be seen.

Clinical Presentation

These tumours usually occur in the fourth decade and incidence in the sexes, is similar.

The presenting features of FNSs vary according to the facial nerve segment from which they arise. Slowly progressive facial paresis and hearing deficits are the most common symptoms of FNSs (Table 1). Hearing loss may either be conductive or sensorineural depending upon the location of the tumour. A proximally arising tumour may compromise the vestibulocochlear nerve while the middle ear cavity may be involved by distally originating FNS.

Occasionally, hemifacial spasms evolving into progressive facial weakness may also be seen with FNS extending within the internal auditory canal (IAC). Proximally arising intradural FNS can be virtually indistinguishable from vestibular schwannoma. Extension of tumour into the middle cranial fossa and early involvement of the facial nerve by a relatively small sized tumour often provide a clue to the facial nerve origin of a schwannoma. The diagnosis should be entertained in patients with progressive facial paresis or worsening of weakness following an incomplete Bell's palsy.

Otorrhoea and ear canal fullness is observed in tumours arising from the mastoid/vertical segment of the facial nerve. In many cases, the tumour may be incidentally detected during evaluation for other complaints.

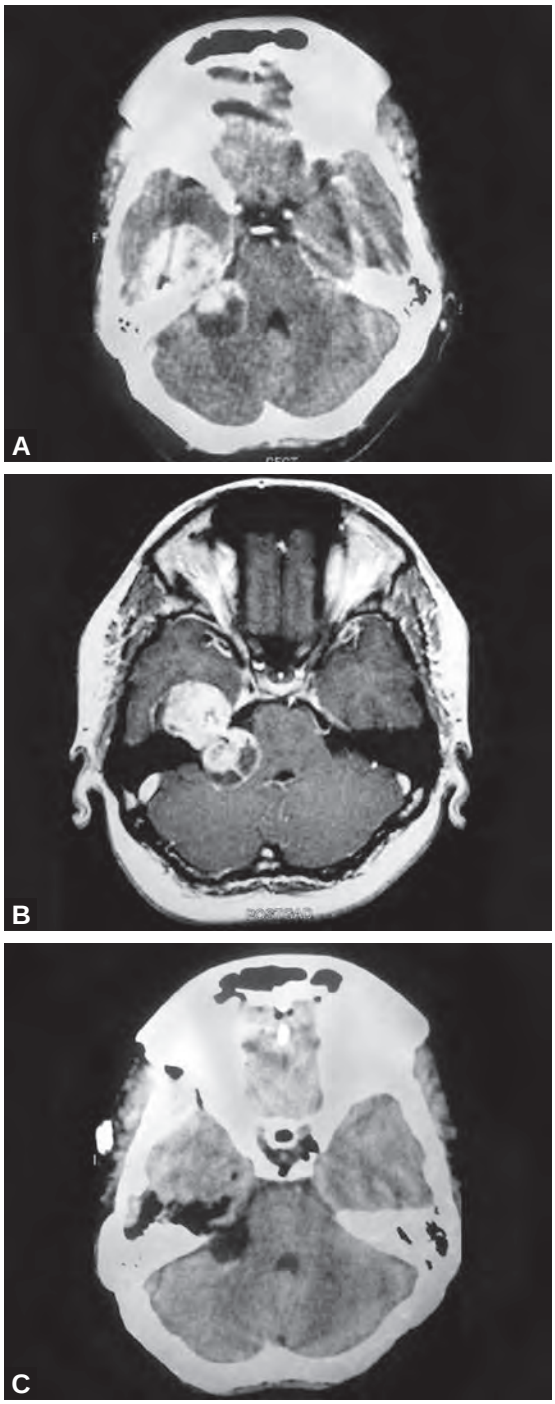
Table 1: Presenting features of facial nerve schwannomas[20]

Symptom	*Number of patients (%)*
Facial weakness	270 (63.2%)
Hearing loss	216 (50.6%)
Tinnitus	88 (20.6%)
Vestibular symptoms	61 (14.3%)
Ear canal mass	47 (11.0%)
Pain	35 (8.2%)
Otorrhoea	15 (3.5%)
Loss of taste	12 (2.8%)
Parotid mass	12 (2.8%)
Facial spasm	9 (2.1%)
Total	427

Diagnosis

FNSs appear as round, well-delineated masses in the CPA, IAC or facial nerve canal. They can extend to the middle cranial fossa, middle ear, the stylomastoid foramen or parotid gland.

The basic imaging features of schwannomas are seen in FNSs (Figs 1A to C). Computerised tomography (CT) scan shows an enhancing soft-tissue density mass. With use of bony algorithm, CT demonstrates a benign type of expansile, lytic change or remodelling of the bone. Aggressive bony destruction is not seen. On magnetic resonance imaging (MRI), FNS is mildly hypointense to isointense on T1-weighted images; is heterogeneously hyperintense on T2-weighted images and enhances following administration of gadolinium. Heterogeneity or cystic change may also be seen in large FNSs.[20]



Figs 1A to C: Facial (VII) nerve schwannoma. (A) Preoperative contrast computerised tomography (CT). (B) MRI showing enhancing dumb-bell shaped tumour in the middle and posterior fossa. (C) Post-operative contrast CT showing complete excision of the tumour using the extended middle fossa approach

Additional distinct imaging features are seen depending on the location of FNS. The FNSs in the CPA or in the IAC may be clinically and radiologically indistinguishable from acoustic schwannomas,[26] however, eccentricity of tumour mass to the axis of the IAC may be a diagnostic clue.[9] In addition, when an IAC FNS enters the labyrinthine segment of the facial nerve, it appears as a double dumb-bell shaped tumour and may be associated with benign, sharply marginated remodelling with enlargement of the labyrinthine segment of the facial nerve canal, often with enlargement of the geniculate fossa.[25] FNS in the region of the geniculate ganglion may also involve the labyrinthine and tympanic segments of the facial nerve and may extend through the facial hiatus for the GSPN to involve the middle cranial fossa. A tympanic segment FNS, often lobulates into the middle ear. Mastoid segment FNS may break into the adjacent mastoid cells. The FNS can also cause enlargement of the chorda tympani canal, situated between the mastoid segment of the facial nerve canal and the middle ear cavity.

Management

The clinical experience with these tumours is limited and no definite treatment guidelines can be proposed. In a series of 12 conservatively managed patients facial function was seen to deteriorate in 38% of the patients over a mean follow-up of 6 years.[29]

The timing of intervention in FNS is debatable. Those in favour of early intervention[34,38] argue that the risk to hearing is less and chances of preservation of facial nerve function/reconstruction of the facial nerve is better in patients with mild paresis. Proponents of the "wait and watch" policy,[17,21] emphasise the slow growing nature of these tumours with potentially prolonged preservation of facial nerve function, which has to be weighed against the risk of deterioration following surgery. Commonly, incidentally detected and small sized tumours with mild facial paresis are managed expectantly.

Microsurgical excision with repair of the facial nerve has traditionally been recommended as the treatment of choice in symptomatic patients. The main concern is facial nerve palsy following surgical excision of the schwannoma. End-to-end anastomosis with interposition cable graft and facial-hypoglossal anastomosis have been used for partial restoration of facial nerve function. However, improvement beyond House-Brackmann grade III has rarely been seen after post-operative facial palsy.

The experience with radiosurgery for FNSs is limited, in part, because of the rarity of these tumours.

Small series of radiosurgically treated patients have demonstrated good tumour control without post-treatment worsening of facial paresis.[22,24] However, longer follow-up is needed before the role of radiosurgery can be clearly established.

Surgical Approach

The approach to these tumours is determined by the location of the tumour.[20,34,36,38] Schwannomas projecting predominantly into the CPA are approached by the retrosigmoid sub-occipital route. Tumours based in the middle fossa are exposed and resected extradurally via the sub-temporal middle fossa approach. Anterior petrosectomy (Kawase's) may be added to the middle fossa approach for tumours extending into the posterior fossa. Transpetrous approaches (retrolabyrinthine, translabyrinthine, transcochlear) can be used in patients with complete loss of hearing and tumour extension into the IAC and middle ear. The transpetrous approach may facilitate anastomotic facial nerve reconstruction by identification of the proximal end of the facial nerve at the IAC and the uninvolved mastoid segment. Sural nerve interposition graft is used in these cases. Large tumours with extensive middle fossa and posterior fossa extension often require staged resection by the sub-temporal and retrosigmoid routes.

LOWER CRANIAL NERVE SCHWANNOMAS

The LCN schwannomas constitute about 2.9–4% of all intracranial neuromas.[32] They include schwannomas arising from the glossopharyngeal, vagus, and accessory and hypoglossal nerves. The IX, X and XI cranial nerves arise from the post-olivary sulcus of the anterior brainstem, traverse the jugular foramen and emerge extracranially in close relation to the internal jugular vein and the internal carotid artery. The hypoglossal nerve originates by a series of rootlets in the pre-olivary sulcus anterior to the IX, X and XI nerve rootlets and exits the posterior skull base through the hypoglossal canal. The schwannomas may arise from the intracisternal, intraforaminal or the extracranial segment of these cranial nerves.

Clinical Presentation

Intracranially, these tumours mainly present as jugular foramen masses. In most cases, the nerve of origin cannot be determined but in cases where the nerve of origin was recognisable, IX nerve origin was the most common followed by the X and XI nerve origin. The site of origin of these tumours along the pars nervosa has been postulated to manifest distinct patterns of tumour growth.[15,18,34] On the basis of this, jugular foramen schwannomas have been classified (Table 2) by Kaye et al[15] with modifications by Pellet et al.[28] and Samii et al.[30]

Overall features of raised intracranial pressure, hearing loss, tinnitus, ataxia and LCN dysfunction are the most common manifestations of jugular foramen schwannoma.[2] Other presentations include facial nerve dysfunction (facial paresis, hemifacial spasm, loss of taste sensation), ear canal masses and neck lumps.

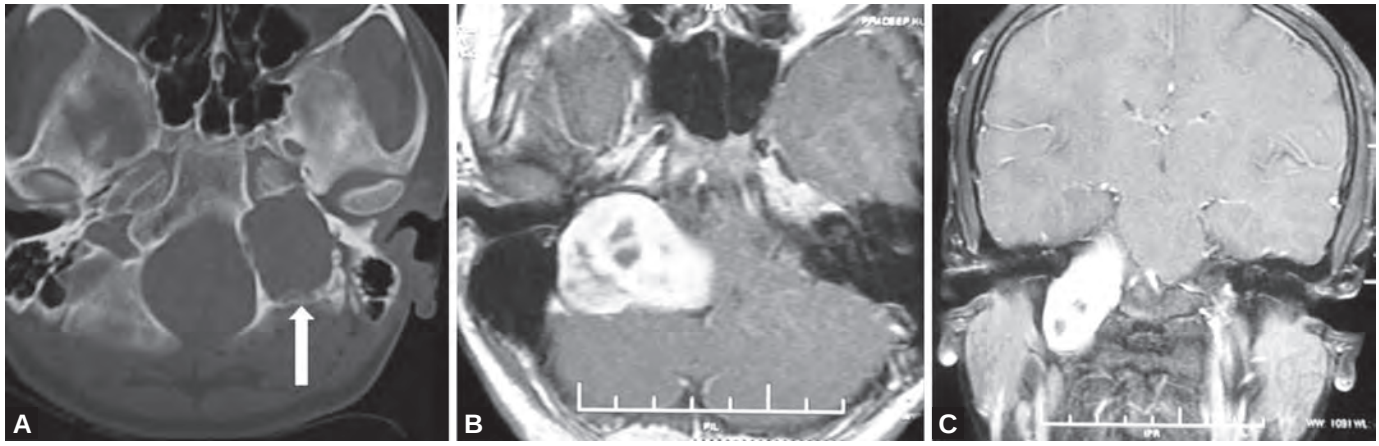
Diagnosis

The CT and MRI appearances of jugular schwannomas are similar to those of other schwannomas, varying with the proportion of cellular and cystic components of the tumour. Jugular schwannomas are isodense or hypodense on CT because of their rich lipid content (Figs 2A to C). Bone algorithm CT shows smooth and sharply-marginated jugular foramen enlargement.[7] Selective enlargement of the pars nervosa can be suggestive of glossopharyngeal schwannomas. In MRI, jugular schwannomas appear as well-circumscribed masses with low-signal intensity on T1-weighted and high-signal intensity on T2-weighted magnetic resonance images (Figs 3A to E). Following administration of gadolinium, dense enhancement with or without intratumoural cysts (in up to 25% cases) is seen.[5] No intratumoural flow-voids are seen.

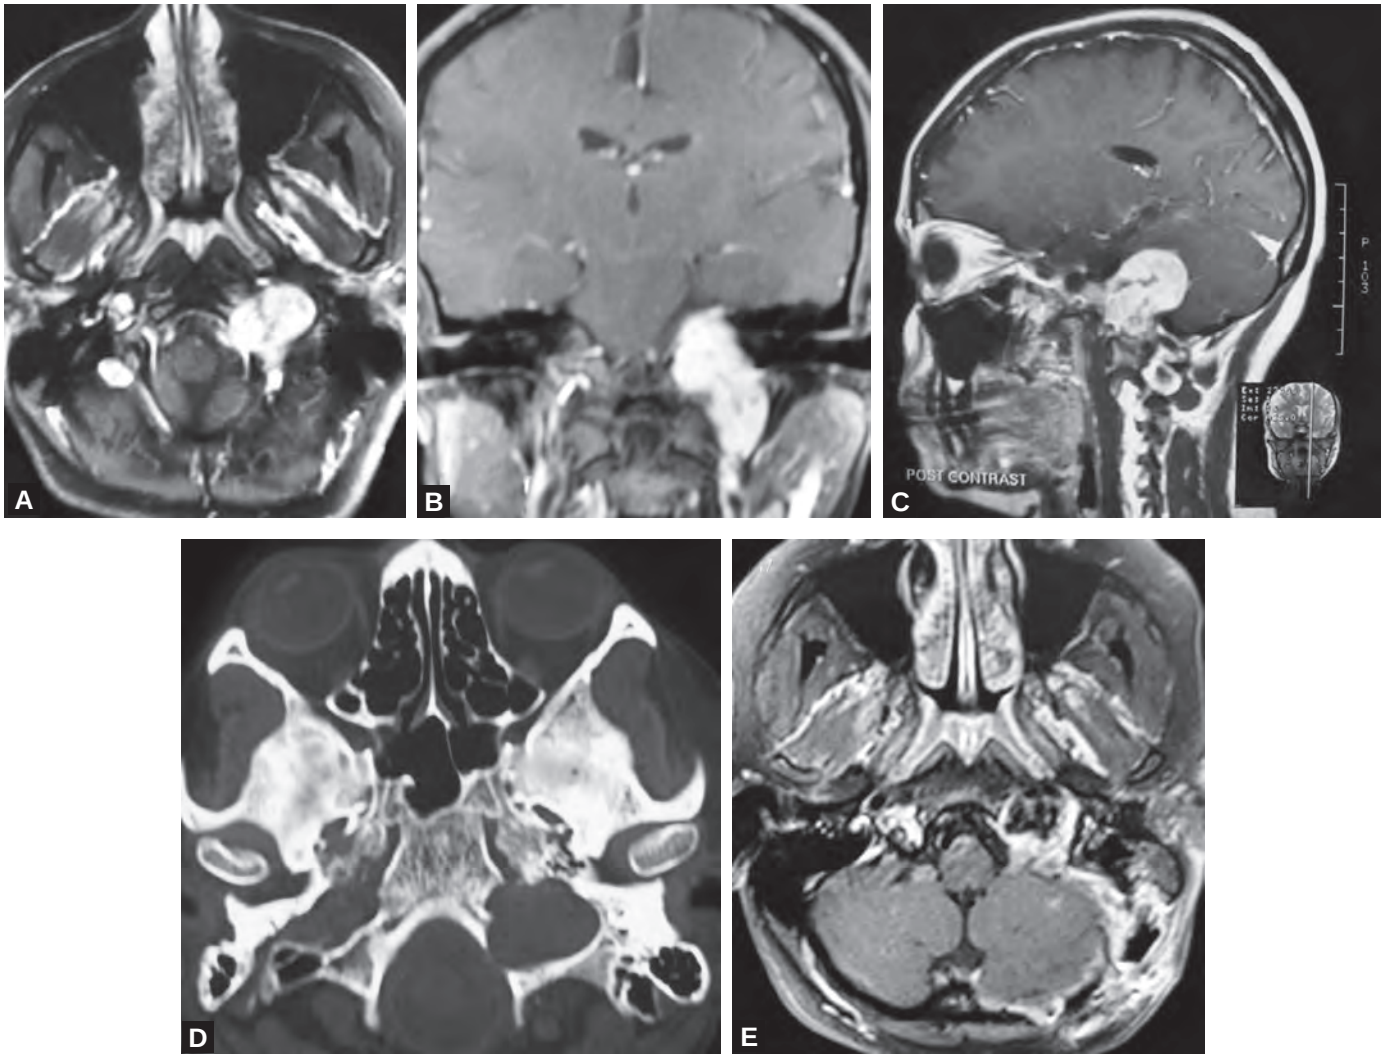
Differential diagnosis of jugular fossa masses includes glomus jugulare and jugular fossa meningioma. Glomus jugulare produces irregular erosion of the margin of the jugular foramen with decalcification or destruction of the surrounding bone. Additionally, glomus jugulare

Table 2: Classification of jugular fossa schwannomas

Class	*Growth pattern*	*Postulated site of origin*	*Clinical presentation*
A	Primary intracranial tumour with small extension into the bone	Proximal, intracisternal pars nervosa	Audiovestibular symptoms and ataxia akin to vestibular schwannoma. Lower cranial nerve involvement uncommon
B	Primary tumour in the jugular foramen with or without intracranial extension	Intraforaminal	Lower cranial nerve paresis
C	Primary extracranial tumour with extension into the jugular foramen or into the posterior fossa	Distal pars nervosa	Jugular foramen syndrome—hoarseness of voice, diminished gag and atrophic weakness of shoulder
D	Dumb-bell shaped tumour with intracranial and extracranial extension		Can have features of all the three above. Extracranial extension may be palpable as neck mass in parapharyngeal space



Figs 2A to C: Type B jugular fossa schwannoma showing. (A) Enlargement of jugular foramen (arrow) in computerised tomography head. In contrast enhanced. (B) Coronal. (C) Axial magnetic resonance imaging sections, a brilliantly enhancing tumour is seen within the jugular foramen with extension into the cerebellopontine angle cistern



Figs 3A to E: Type D jugular fossa schwannoma showing a brilliantly enhancing tumour within the jugular foramen, with extension into the cerebellopontine angle cistern and extracranial extension in contrast enhanced. (E) Post-operative magnetic resonance imaging showing complete removal of intracranial and foraminal portions

are angiographically highly vascular, with an intense contrast stain and readily apparent vascular pedicle(s) and have intratumoral flow-voids on T2-weighted MRI.[8] On the other hand, LCN schwannomas symmetrically expand the jugular foramen with smooth, sharply outlined and sclerotic margin of the eroded adjacent bone, do not appear very vascular at conventional angiography and have no intratumoural flow-voids.[8] Primary jugular foramen meningioma is characterised by a permeatal–sclerotic appearance of the bone margins of the jugular foramen, the presence of dural tails and an absence of flow-voids.[23]

Management

Presently, microsurgical resection and radiosurgery are the available options for the management of these patients. Observation is reserved for patients who are extremely poor surgical risks. Due to limited availability and high cost of radiosurgical apparatus, stereotactic radiotherapy has also been tried in patients with non-acoustic schwannomas.

Surgical Approach

The choice of surgical approach is determined by the size, location of the lesion and pre-operative hearing status.

Type A tumours: Since these tumours are primarily limited to the intracranial compartment with little erosion of the bone, they can safely be excised with the classical retrosigmoid approach.

Type B to D tumours: The complete extirpation of these tumours is difficult. With the evolution of microneurosurgery and refinement of surgical techniques, the optimal choice of approach for these tumours has undergone radical changes. A cervical transmastoid approach is generally recommended for these tumours. A retroauricular skin incision extending up to the level of the hyoid bone is used. The sternocleidomastoid muscle and the posterior belly of the digastric are mobilised to expose the mastoid bone. The LCNs are identified in the neck and followed-up to the skull base. The main stem of the facial nerve is identified in the stylomastoid foramen anterior to the insertion of the digastric muscle. The transverse and the sigmoid sinuses are then exposed through a sub-occipital craniectomy. The petrous temporal bone is then drilled to skeletonise the sigmoid sinus, which is then mobilised. Extent of further drilling then differs according to the growth pattern of the tumour. For type B tumours, an infralabyrinthine approach is recommended to preserve hearing function in patients with preserved hearing. The jugular bulb is skeletonised and the dura is incised in the supra jugular region below the labyrinth. A translabyrinthine-transcochlear approach is chosen in patients with complete loss of hearing. Type C tumours are best approached through an infratemporal approach (Type A) described by Fisch,[10] which enables direct access to the jugular foramen and the neck and provides good control of the adjoining vasculature.

The Type D tumours represent a special case. Though staged resections were the norm earlier, many authors have demonstrated the possibility of a single-stage resection.[14,32] For a single-stage resection, an extreme lateral transcondylar approach is combined with sub-occipital craniotomy. Alternatively, a staged sub-occipital craniotomy followed by an infratemporal approach can be undertaken.

Schwannomas do not infiltrate the cranial nerves or the jugular bulb and safe radical excision of these tumours is possible with acceptable morbidity. The post-operative morbidities generally seen are facial nerve dysfunction, transient worsening of LCN function and CSF leak. In patients with pre-operative LCN paresis, post-operative LCN deficits are generally well tolerated because the slow pre-operative evolution of deficits has allowed the other side to compensate. However, patients with intact LCNs in the pre-operative period are susceptible to life-threatening complications in the event of a lower cranial palsy following surgery and must be observed vigilantly.

Radiosurgery and stereotactic radiotherapy are the treatment options for small LCN schwannomas with intact cranial nerves though microsurgical complete excision is possible in general and is potentially curative. Tumour control rates ranging form 96 to 100% have been reported with tumour shrinkage noticeable in 47–52% patients.[27,42]

SCHWANNOMAS OF THE OCULAR MOTOR NERVES

Schwannomas of the oculomotor, trochlear and abducens nerve are rarely encountered in the absence of neurofibromatosis. Less than 100 cases of schwannomas arising from the ocular motor nerves have been reported in the literature.[16] The oculomotor and the trochlear nerves are most frequently involved. Celli et al.[6] have classified these tumours into cisternal, cisternal-cavernous and cavernous according to their location and the relationship to the course of the cranial nerves.

Clinical Presentation

Trochlear nerve schwannomas are almost always intracisternal in location and originate from the pre-cavernous segment of the nerve.[19,33] From the ambient cistern they may extend medially into the pre-pontine cistern or superiorly above the tentorium. Trochlear nerve paresis in association with these tumours is encountered in a minority with symptoms attributable chiefly to brainstem compression. Frequently, the clinical syndrome constitutes ipsilateral cerebellar ataxia, hemiparesis and sensory disturbances in association with an extra-axial tumour at the tentorial notch.

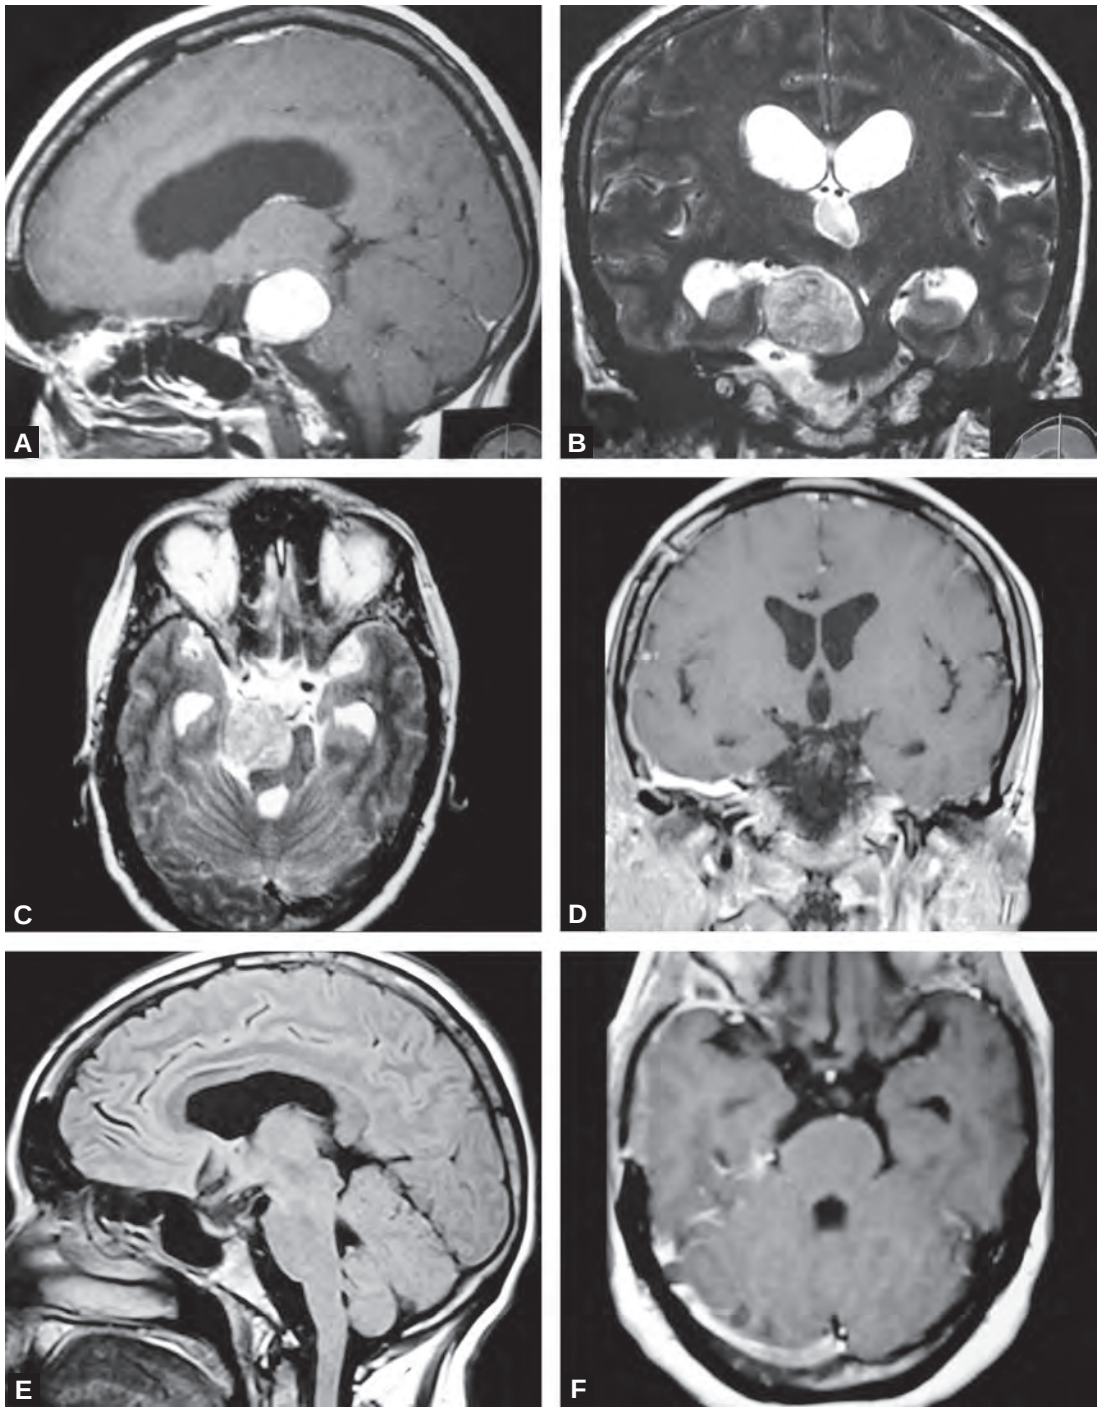
Oculomotor and abducens nerve schwannomas can arise from both the cisternal and cavernous segments of

the nerves. The most common manifestation of III nerve tumours is oculomotor paresis. The VI cranial nerve schwannomas manifest chiefly with VI nerve paresis, but tumours arising proximally within the cistern may have a more malignant course as the tumour growth causes obstructive hydrocephalus.

The nerve of origin is difficult to distinguish in intracavernous schwannomas, and the much more common trigeminal nerve tumour must be strongly considered in the differential diagnosis.

Diagnosis

On CT, schwannomas generally are of lower density than brain parenchyma and show moderate enhancement.[4] The MRI appearances of schwannomas are variable but generally of well-circumscribed lesions (Figs 4A to F), isointense or slightly hypointense to brain parenchyma on T1-weighted images and isointense or heterogeneously hyperintense on T2-weighted images.[11,12,33] The heterogeneity tends to increase with increasing tumour size and may be the result of regions of different



Figs 4A to F: Trochlear nerve schwannoma showing a brilliantly contrast enhancing tumour in the cisternal portion of the right IV nerve in (A) Sagittal. (B) Coronal. (C) Axial magnetic resonance imaging (MRI) sections. (D to F) Post-operative MRI showing complete removal of tumour

histology (hypercellular Antoni A tissue appearing isointense and hypocellular Antoni B tissue appearing hyperintense) or cystic change. Regions of hypointensity on T2-weighted image may be seen corresponding to areas of calcification, haemorrhage or hyalinised stroma. Contrast enhancement is intense but may be inhomogenous.[12]

Management

The surgical morbidity of cavernous sinus exploration for extirpation of intracavernous schwannomas is substantial. Moreover, surgical excision is associated with permanent loss of function of the affected nerve. Hence, stereotactic radiosurgery is generally recommended for intracavernous ocular motor schwannomas.

Trochlear nerve schwannomas are amenable to surgical resection owing to their cisternal location. The sub-temporal approach with division of the tentorium is suitable for the resection of the majority of these tumours. Anterior petrosectomy may be supplemented to this approach for larger tumours with significant extension below the tentorium. Post-operative loss of IV nerve function is generally well tolerated.

Cisternal oculomotor schwannomas should be considered for surgical decompression only in the presence of mass effect from large tumours. Oculomotor palsy resulting from total excision of these lesions is disabling.[1] Either a pterional or sub-temporal, transtentorial transpetrosal corridor can be used depending upon the configuration of the tumour.

165 Phakomatoses

Ravi Ramamurthi, Nigel Peter Symss

INTRODUCTION

Phakomatoses is a term coined by Van der Hoeve, in 1920, to describe a group of hereditary neurological disorders that have cutaneous and ocular stigmata.[5] They were initially divided into:

- Neurofibromatosis (NF)
- Tuberose sclerosis (TS)
- Von Hippel-Lindau disease (VHL)
- Neurocutaneous angiomatosis.

The spectrum has now been extended to include phakomatosis pigmentovascularis, a very rare disease characterised by coexistence of a capillary malformation with melanocytic lesions.[5,16] All the phakomatoses do not manifest ocular and cutaneous findings; VHL shows no skin markers and the neurocutaneous angiomatoses show no ocular lesions. The genetic abnormality in many of these disorders has not yet been identified and the fact that stigmata of more than one of these syndromes have been seen in the same patient. This could indicate that they are all due to an abnormality in a small group of genes.

NEUROFIBROMATOSIS

This is the most common of the phakomatoses, with a reported incidence of one in 3,000 births.[23] It is an autosomal dominant disease with high penetrance but variable expression. This syndrome has been variously classified in literature but consensus is for two types designated NF-1 and NF-2, which account for over 95% of all cases.[17] Other cases of NF represent either poorly expressed or variant types.[19]

Neurofibromatosis-1

Neurofibromatosis-1 (NF-1), previously termed "von Recklinghausen neurofibromatosis" or "peripheral neurofibromatosis", was first described by von Recklinghausen in 1892. The genetic abnormality is thought to be in chromosome 17 and is of extremely variable expression, with members of the same family showing marked differences in clinical features. Individuals with NF-1 present with abnormalities of both astrocytes and neurons that result from reduced or absent expression of the NF type 1 (NF1) gene product neurofibromin. Impaired neurofibromin function in these nervous system cells contributes to the development of astrocytomas, learning disabilities and radiographic abnormalities of the brain.[11] Neurofibromin is expressed in many different tissues and it is now known that one role of neurofibromin is as a GTPase activating protein, very likely in the same pathway of signal transduction as ras. Von Deimling et al. found absence of neurofibromin in mice homozygously mutant for the NF1 gene resulted in profound developmental abnormalities. In mice, that are heterozygous for NF1 gene, an accelerated onset of tumour formation was observed. Combined with studies of tumours from NF1 patients showing homozygous deletions in the NF1 gene, their data suggest a role for NF1 gene as a "tumour suppressor", suggesting other roles played by neurofibromin in control of proliferation in some situations and differentiation in others.[28]

A diagnosis of NF-1 is made if the patient fulfils any two of the following criteria:

- Two or more neurofibromas of any type or one plexiform neurofibroma
- Six or more café-au-lait skin macules visible in room light, each 5 mm or more in size in pre-pubertal patients or 15 mm or more in post-pubertal patients
- Two or more Lisch nodules
- Optic glioma
- Axillary or inguinal freckling
- Characteristic osseous lesions such as sphenoid dysplasia or thinning of long bones' cortices, with or without pseudoarthrosis
- A first degree relative (parent, sibling or offspring) with NF-1 by the above criteria.

Not all the patients of NF-1 fulfil the criteria given above. These patients must be presumed to have the NF-1 gene but with poor gene expression.

Cutaneous neurofibromas are characteristic of NF-1. These Schwann cell tumours occur on the distal cutaneous nerve endings. They are most numerous in the thoracoabdominal region, the presence of neurofibromas on the nipple or areola of the breast suggests an association with pigmentation and/or hormones. They do not pose any serious problem to the patient except cosmetic, or rarely pain or itching. Operative removal of the lesion is done for painful or irritant lesions or for cosmetic purposes.

Plexiform neurofibromas may form along the course of any nerve. While they grow mostly from distal sensory nerves, they tend with growth to engulf major nerve trunks and motor branches, rendering operative removal

Fig. 1: Plexiform neurofibromatosis involving the left cheek and neck

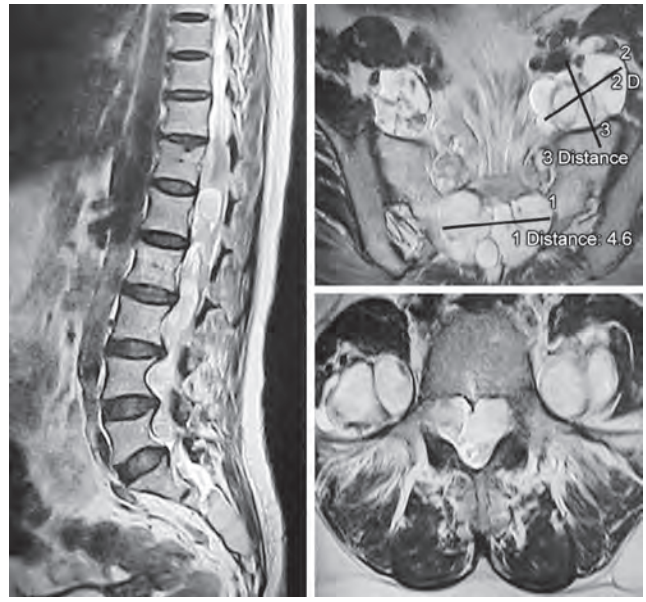

Fig. 2: Magnetic resonance imaging of lumbosacral region showing multiple neurofibromatosis

difficult with the attendant risk of a major motor deficit. There is a definite risk of malignant transformation in these patients (Fig. 1). Recent evidence indicates that the dopamine D(3) receptor [D(3)R] mediates protective roles both in neuronal and non-neuronal cell lines. Castorinal et al. in an earlier study proposed that neurofibromin, a large tumour suppressor protein encoded by the NF1 gene may increase susceptibility to apoptosis after serum deprivation in malignant peripheral nerve sheath tumour (MPNST) cells, thus acting as a proapoptotic gene. They concluded that their findings suggest that D(3)R might mediate the protective response to serum deprivation in MPNST cells through the inhibition of NF1 gene expression, further underlying a subtle role of these receptors in MPNST development.[4]

Neurofibrosarcoma occurs in about 5% of patients and is the most dreaded complication of this disease. Treatment involves amputation of the limb and major resection, followed by radiotherapy and chemotherapy. However, 5-year survival rates are only around 23%.[27]

Lisch nodules are pigmented hamartomas of the iris. Present in up to 94% of NF-1 patients, they are usually seen only after puberty.[18]

Though spinal neurofibromas occur mostly on the dorsal nerve root, the ventral roots may also be involved. These are often multiple and are most common in the cervical and lumbar regions (Fig. 2). Surgery is necessary if cord compression develops. The rare occurrence of neurofibromas within the spinal cord is seen more often in case of NF than in the general population.

Optic nerve gliomas occur in about 5–10% of patients with NF-1. The tumours behave like hamartomas and the treatment is as for these tumours occurring in the general population.

Macrocephaly, learning disorders, sphenoid wing dysplasias, pseudoarthrosis, phaeochromocytoma and kyphoscoliosis are the other lesions which may be seen in NF-1.

Neurofibromatosis-2

Neurofibromatosis-2 (NF-2) was previously called "central NF" or "bilateral acoustic NF". It is an autosomal dominant disease, with the genetic abnormality on chromosome 22, though the method of gene expression is not clear.[17] The criteria for the diagnosis of NF-2 are:

- Radiological evidence of bilateral acoustic neuromas (Fig. 3)
- A first degree relative with NF-2 and either
  - — a unilateral acoustic neuroma, or
  - — two of the following:
    - Neurofibroma
    - Schwannoma
    - Meningioma
    - Glioma
    - Juvenile posterior subcapsular cataract

Patients with NF-2 present with bilateral acoustic neuromas, which are in the majority symmetrical and present with symptoms during adolescence and early adulthood. A diagnosis of NF-2 should be suspected in any patient below 30 years of age, who has an acoustic neuroma, in a patient with multiple meningiomas and in patients with Schwann cell tumours and minimal stigmata of NF-1. All such patients and family members of NF-2 patients should be screened for bilateral acoustic tumours with brainstem auditory evoked response, contrast-enhanced high-resolution computerised tomography (CT) and/or magnetic resonance imaging (MRI).[17]

Patients with NF-2 are liable to have other tumours including multiple Schwann cell tumours on peripheral nerves, spinal roots and cranial nerves, cranial and spinal astrocytomas and meningiomas. Treatment of these patients is aimed at maintaining brainstem and spinal cord function. Surgery is offered for the larger tumours first, while small tumours without any major pressure effects are kept under observation. For the management

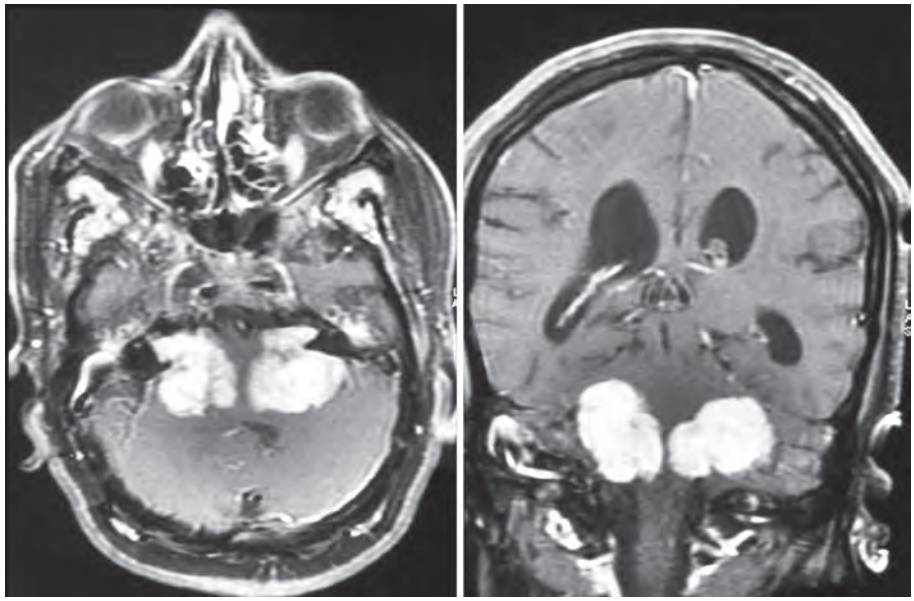

Fig. 3: Magnetic resonance imaging scan of brain showing bilateral acoustic schwannomas

of bilateral acoustic neurofibromas refer Chapter on Acoustic Schwannomas.

Ito et al. retrospectively reviewed patients with NF-2 to look for factors predicting further growth of bilateral vestibular schwannomas (VS). Their analysis included 27 patients with NF-2 with 54 VS, who were followed for a mean period of 86 months. Features distinguishing actively growing from quiescent VS were determined in 28 untreated VS and in 33 treated VS (either resection or radiosurgery). They used a general estimation equation to identify factors affecting tumour growth. Their analysis revealed, during the untreated course, 19 VS showed growth and nine VS were stable and no factors predictive of growth were found. Following the post-treatment course, which included 23 surgical resections and 10 radiosurgeries, 10 treatments were followed by growth and 23 by stability, with growth showing an association with onset at an early age ($p = 0.007$). Their multivariate analysis identified no factors predictive of growth.[14]

TUBEROSE SCLEROSIS

The first recognisable report of TS was that of von Recklinghausen, in 1862. The clinical syndrome of seizures and mental defect with pathological lesions in the brain was postulated by Bourneville (1880), who also coined the term "tuberose sclerosis", sometimes also known as adenoma sebaceum and also recognised its frequent association with renal and cardiac tumours. TS is an autosomal dominant disorder with a variable penetrance. The gene responsible is thought to be on chromosome 9.[7] The incidence is about one in 10,000 births and again the extent of expression is very variable.

Clinical Manifestations

The clinical diagnosis of TS can be made by Vogt's triad of seizures, mental deficit and adenoma sebaceum.[13] The disorder can, however, present variably.

Skin Manifestations

- Ash leaf spots and other depigmented macules are best seen under a Wood's lamp. They are seen mostly on the trunk, arms and legs
- Adenoma sebaceum is an angiofibroma. It is a progressive lesion which develops after birth and which shows rapid growth around puberty. It has a characteristic distribution, over the cheeks, nose and chin, sparing the upper lip. It is often confused for acne vulgaris (Fig. 4)
- Shagreen or sharkskin patches are dermal fibromas which usually develop after 10 years of age. They occur mostly in the lumbosacral region. They are not pathognomonic of TS and may occur in isolation
- Ungual fibromas or Koenen's tumours are angiofibromas which occur in the lateral nail groove, along the proximal nail fold or under the nail. They are more common in the toes than in the fingers.

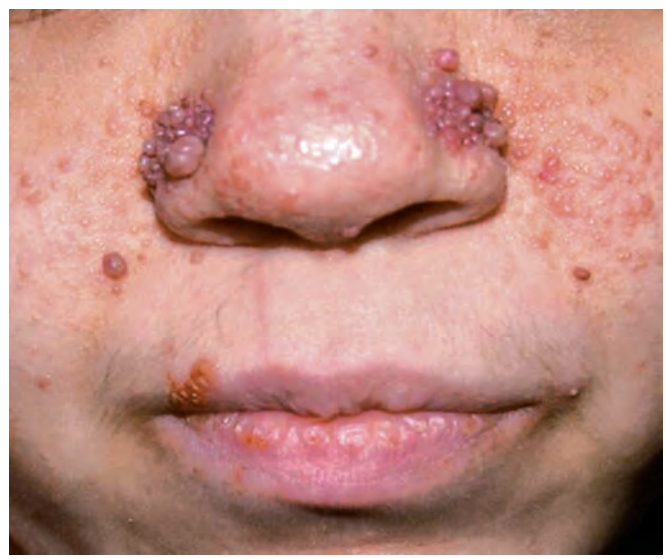

Fig. 4: Adenoma sebaceum

Sogut et al. observed the most frequent manifestations of tuberose sclerosis were those of the skin lesions (97.1%) and of the central nervous system (CNS) [seizures (94.2%), mental retardation (51.4%)], followed by renal (32.2%), cardiac (25.8%) and ocular (22.5%) manifestations. Among cutaneous manifestations, the most common was hypomelanotic macules (94.3%). They conclude the earliest and most frequent complaint is seizure and careful investigation for hypomelanotic macules and other skin manifestations typical for TS in cases presenting with convulsion makes early diagnosis possible and avoids unnecessary investigations.[24]

Nervous System Manifestations

Patients with TS present clinically with seizures and mental retardation. The seizures are mostly tonic-clonic or infantile myoclonic, though partial-motor and complex partial seizures are also seen. Petit mal attacks are not common. The degree of mental retardation in these patients varies and regression has been noticed in older patients. They may be due to either uncontrolled seizures or to the development of a brain tumour. Motor deficits per se are rare, though they may be seen as a manifestation of a brain tumour. Chou et al.[6] analysed the prognostic factors for mental retardation in patients with tuberose sclerosis complex. The most frequent CNS manifestations were seizures (91.4%) and mental abnormality (62.5%), and the most common seizure pattern was generalised tonic clonic seizures (62.9%). Poor control of seizures ($p = 0.006$) and the presence of cortical tubercles in imaging studies ($p = 0.03$) were correlated statistically with mental abnormality.

Cortical plaques (or tubers) and sub-ependymal glial nodules are developmental lesions which do not enlarge once brain growth has stopped. Cortical tubers are hamartomas containing glial and neuronal cell populations. There is no evidence of malignant transformation in these lesions. Degenerative changes take place with gliosis and umbilication of the cortex at the site of the tubers, leaving normal brain in between. Sub-ependymal nodules are scattered along the entire wall of the lateral and third ventricles. They are mainly glial hamartomas and contain prominent calcium deposits.

Sub-ependymal "giant cell astrocytomas" occur in about 10% of patients with TS. They do not develop from the sub-ependymal nodules. These tumours react negatively to GFAP and are probably neuronal in origin.[25,26] They probably arise from the germinal cell matrix which explains their vascularity.

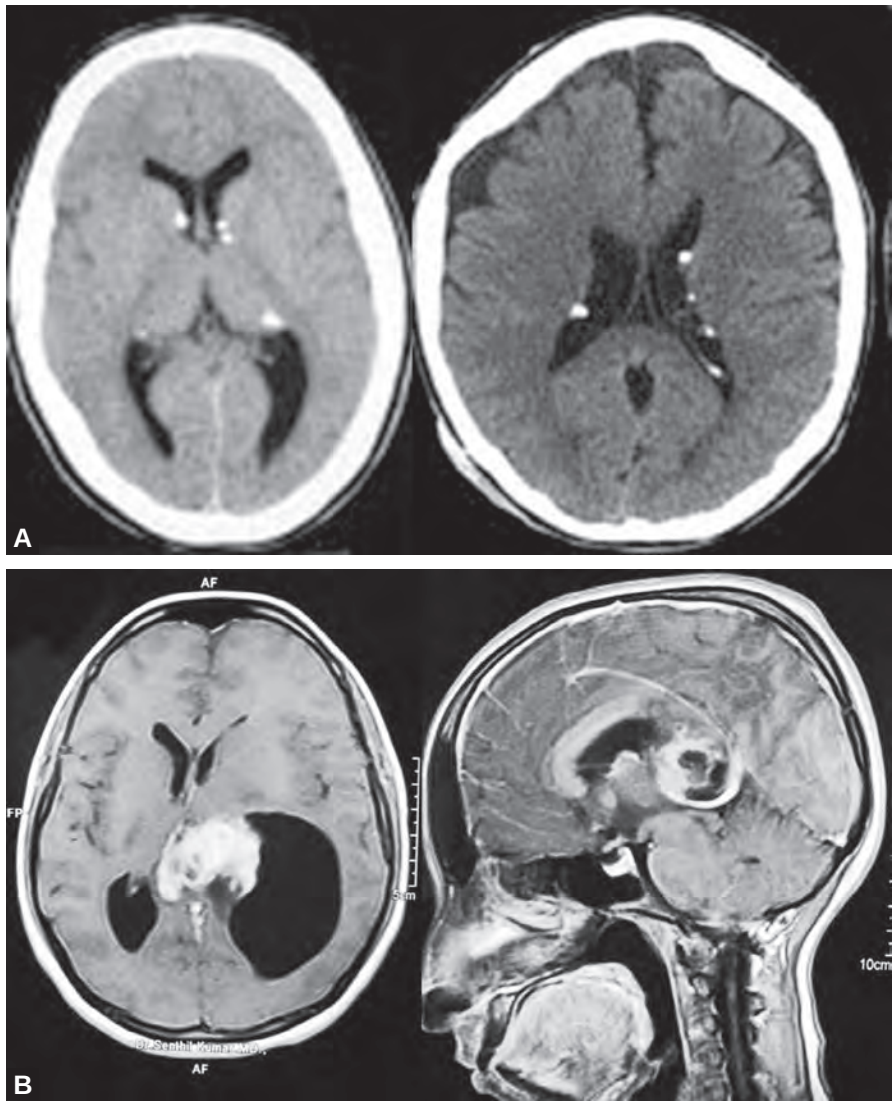
Lesions are also seen in other organs such as the retina, heart, kidney and lungs. In the eye, retinal hamartomas occur. They rarely lead to visual problems. Cardiac rhabdomyomas occur in about 39% of patients with TS. They may remain asymptomatic or may produce symptoms of heart failure early in infancy. Renal angiomyolipomas are commonly found in these patients.

Gomez[9] has listed major and minor criteria for the diagnosis of TS. The presence of any one of the primary criteria or of two or more of the secondary criteria is considered diagnostic.

The CT and magnetic resonance imaging (MRI) scan of the brain is characteristic in patients with TS (Figs 5A and B). Sub-ependymal periventricular calcification is the most frequent and characteristic finding. They are seen in 67–100% of scans done in patients with TS.[13] The tendency for these lesions to protrude into the lateral ventricle ("candle guttering" was seen on ventriculography), distinguishes them from other calcified lesions seen in cytomegalovirus infection, cysticercosis and toxoplasmosis. Other lesions which may encroach into the ventricles, e.g. heterotopic grey matter or ependymomas, either do not calcify or are not multiple. The calcifications are mostly just lateral to the foramen of Munro and in the body of the lateral ventricle, though rarely, they may occur in the wall of the third and fourth ventricles. Multiple hypodense intracerebral lesions are seen especially in the frontal, parietal and occipital lobes. These represent areas of defective myelination and heterotopic hamartomatous tissue which occur particularly at the junction of grey and white matter.[8,20] These are seen in 12–69% of cases but are not diagnostic of TS when they occur in isolation. Sub-ependymal tumours are seen as isodense lesions enhancing uniformly with contrast. They are located mainly at the foramen of Munro and produce obstructive hydrocephalus. They may, occasionally, have a cystic component. Asymmetrical ventricular dilatation may be seen in the absence of tumour. Calcified or hypodense lesions may also be seen in the posterior fossa.

With MRI scan cortical tubers were more frequently demonstrated on spin-echo images obtained with a long repetition time (TR). Because the signal abnormality is located predominantly in the subcortical portion of the tubers, the terms "gyral core" and "sulcal island" have been used to describe the patterns noted on MRI. Sub-ependymal nodules are best seen on inversion-recovery or short TR spin-echo images, although hypointensity within the nodules consistent with calcification was most evident on long TR spin-echo images.[21] Griffiths et al. evaluated which MR sequences show the pathology best and to see if "ultrafast" sequences can show the pathology robustly. Cortical tubers are shown exceptionally well on fluid-attenuated inversion recovery images, whereas sub-ependymal nodules (and calcified tubers) are best shown on gradient echo T(2) images and that single-shot fast spin-echo sequences do not sufficiently show the expected intracranial complications of tuberose sclerosis complex and should not be considered as an alternative to standard sequences in this group.[10]

Treatment involves controlling seizures with antiepileptic drugs and special education for the mentally handicapped. The brain tumours can be excised with a good prognosis. The life expectancy of these patients is decreased, the causes of death being cardiac failure, brain tumours, status epilepticus and renal failure. Koenig et al.[15] reported treating a patient with rapamycin for 5 months for bilateral sub-ependymal giant cell



Figs 5A and B: (A) Computerised tomography scan of brain showing typical candle guttering pattern of tuberous sclerosis (sub-ependymal periventricular calcification). (B) Magnetic resonance imaging scan of brain showing giant cell astrocytoma typically seen in tuberous sclerosis

astrocytomas. The MRI of the brain confirmed reduction in size of both astrocytomas after initiating rapamycin. However, they advocate further studies are needed with prolonged observation to confirm these findings, determine the length of necessary treatment and evaluate recurrence risk after discontinuation of rapamycin.[1]

VON HIPPEL-LINDAU DISEASE

The VHL disease or complex is an autosomal dominant disorder with variable expression, characterised by either more than one haemangioblastoma within the neuraxis associated with at least one visceral manifestation. No cutaneous stigmata are seen in patients with VHL complex. The association of retinal, cerebellar and visceral lesions was made, in 1926, by Arvid Lindau, who started his work by investigating cerebellar cysts. The retinal angiomas had been described earlier, by Collins, in 1894 and by von Hippel in 1904. Brandt published the autopsy results of von Hippel's patient and described tumours in the viscera in addition to those in the brain and the spinal cord.

The typical lesion in the neuraxis is a cerebellar haemangioblastoma, which at autopsy is found in at least 60% of patients with the disease.[17] Haemangioblastomas may also be found in the brainstem, spinal cord and in the supratentorial compartment. The lesions may be solid or cystic. They are commonly multiple, with the tumours appearing metachronously. Further details on the diagnosis and management of these lesions are dealt with the Chapter on "Haemangioblastoma".

Retinal angiomas are seen in over 50% of patients with the VHL complex. The lesions are seen mostly in the peripheral parts of the retina, though they have also been recorded at the macula and the optic disc. They are usually seen in both the eyes. With time, they are covered with exudates which surround the lesion, the feeding artery and the draining vein. Retinal oedema, haemorrhage, retinal detachment, gliosis and secondary

glaucoma may cause loss of vision. Photocoagulation is the treatment of choice. As new lesions may appear in course of time, the patients must be kept under regular ophthalmological follow-up.

Angiomas may also be found in other organs such as the liver, spleen, kidneys, lungs, the skeletal system, epididymis and the adrenal cortex. However, the most common and dangerous tumours are pheochromocytoma and renal cell carcinoma, which cause death in a significant proportion of the VHL patients. Renal cell carcinoma is seen in up to 25% of patients with VHL complex and differs from its sporadic counterpart in its earlier age of onset, multicentricity and synchronous or metachronous bilateral involvement. Pheochromocytomas seen in about 10% of VHL complex patients are often bilateral. Polycythaemia, when present, may be due to either renal involvement or due to the intracranial haemangioblastoma.

Thus, investigation of a patient with suspected VHL complex must include examination of the fundi with a record of the visual acuity and fields, abdominal ultrasound or CT with special focus on the kidneys, pancreas and adrenals, urinary metanephrine screening and haematocrit and blood counts, besides CT scan of the brain and upper cervical cord.

NEUROCUTANEOUS ANGIOMATOSIS

These are a group of genetic disorders which have an abnormality of blood vessels of the skin and nervous system as their only common feature and are classified together for convenience. Each syndrome has other systemic angiomata as well as haematopoietic and immunologic deficiencies.

Ataxia Telangiectasia

It is an autosomal recessive disorder with progressive ataxia, cutaneous telangiectasias and immunological abnormalities. Prognosis is poor, with death usually occurring in the second decade due to infection or neoplasia like lymphomas or leukaemias.

Sturge-Weber Syndrome

It is defined by the association of a facial capillary malformation (port-wine stain), with a vascular malformation of the eye, and/or vascular malformation of the brain (leptomeningeal angioma). Variants exist where only one of these three structures is involved with the vascular malformation. They may be caused by a somatic mutation occurring sporadically, rather than an inherited disorder. No good population-based data exist for how many people have Sturge-Weber syndrome, however, estimates range between one in 20,000–50,000 live births. The characteristic skin lesion is a unilateral facial angioma (port-wine stain) in one or two dermatomes of the trigeminal nerve. There is an ipsilateral parieto-occipital leptomeningeal venous angiomatosis with underlying cortical atrophy. Calcification of the second and third cortical layers of this region appears as the characteristic "rail-road" calcification on plain X-rays. Patients present with seizures or with hemiparesis. Subarachnoid haemorrhage is rare. Pascual et al.[22] found early onset of seizures and poor response to medical treatment, bilateral cerebral involvement and unilateral severe lesions were indicative of a poor prognosis. Uncommonly, glaucoma secondary to retinal angiomatosis may cause loss of vision. Laser therapy is the optimal approach for treating port-wine stains but whether it is effective for patients with facial dermatomal port-wine stains and Sturge-Weber syndrome is undetermined. Laser treatment produced unsatisfactory outcomes in patients with facial dermatomal port-wine stains. V3 port-wine stains responded best and V2 worst to laser.[12]

Klippel-Trenaunay-Weber Syndrome

The cutaneous angioma is unilateral on the body, involving one or more dermatomes, with a haemangioma of the spinal cord at the same level. The lesions are unilateral and may be associated with osseous and muscular hypertrophy of the involved areas. The lesion is seen as a spinal variant of the Sturge-Weber syndrome. Though an autosomal dominant pattern of inheritance is suggested, this too may be the result of a sporadic mutation.

Osler-Weber-Rendu Syndrome or Hereditary Haemorrhagic Telangiectasia

Osler-Weber-Rendu (OWR) syndrome is a rare autosomal dominant disease with angiomas of the skin, mucosal surfaces and nervous system and usually presents with haemorrhage. It is a genetic disorder caused by an abnormality in either the endoglin gene on chromosome 9, or the activin receptor-like kinase 1 gene on chromosome 12. Both of these genes are involved in blood vessel formation. A mutation in either of these genes will result in similar OWR symptoms and those who have the disorder generally only have an abnormality in one of the genes. Majority of the symptoms are the result of haemorrhage due to abnormal formation of capillaries. Arteriovenous malformations (AVMs) may occur on the surface of the skin or in the lungs, brain, liver, stomach or gastrointestinal tract. Brain AVMs may be treated by surgery, embolisation, or stereotactic radiosurgery.

Fabry's Disease

Fabry's disease results from the accumulation of ceramide trihexoside in the media and endothelium of small blood vessels due to a deficiency of alphagalactosidase. It is an X-linked recessive disorder, characterised by telangiectasias of the lower half of the body. Skin lesions apart, renal function may be impaired with resultant hypertension and myocardial infarction. More severe forms have a diffuse involvement of vessels of the

peripheral nerves and of the CNS, leading to neuropathies and strokes.

Wyburn-Mason Syndrome

It is rare, and is characterised by an AVM in the midbrain with unilateral retinal and facial vascular malformations.

Paul Bonnet[3] first described Wyburn-Mason syndrome in 1937 and Roger Wyburn-Mason[29] described it again in 1943 as a rare congenital disorder that has the autosomal dominant inheritance trait, with only one mutated gene necessary for the child to have the traits of the disease. The syndrome is present at birth and the onset of symptoms usually occurs before the age of 30 years. It tends to be more frequent in males. Patients can present with symptoms of visual loss, proptosis, pigmented facial naevi (birthmarks), pigmented retina, severe headache, vomiting, rigid neck, loss of consciousness, tinnitus, deafness, aphasia, cerebellar signs and mental retardation.

Phakomatosis Pigmentovascularis/Speckled Lentiginous Nevus Syndrome

Phakomatosis pigmentovascularis is a very rare disease characterised by coexistence of a capillary malformation with various melanocytic lesions, including dermal melanocytosis (Mongolian spots), nevus spilus and nevus of Ota. As of now about 200 cases have been reported in the literature, most are of Japanese origin and about half of reported cases are associated with various systemic involvements. Patients are prone to develop late-onset open angle glaucoma, suggesting that long-term ophthalmic follow-up is necessary in this type of patient.[2,5]

166 Convexity Meningiomas

Vasudevan MC

INTRODUCTION

Meningiomas are classified as convexity (cranial vault) or basal based on their dural attachment. Convexity meningiomas are those tumours whose attachment is confined to the convexity of the brain and do not involve the dura of the skull base, the venous sinuses or the falx. Convexity meningiomas are the most frequently encountered meningiomas, followed by meningiomas of the sphenoid ridge and cerebellopontine angle.[24,33,36,47] The neurosurgical literature has few studies on supratentorial convexity meningiomas because their treatment does not present serious technical problems.[11] However, after saying so, these lesions can be a real challenge. The operative mortality of these lesions has declined from 15.9% (Cushing 1938), 7.4% (Olivecrona 1967)[39] and 2.4% (Logue 1975) to 0% in modern series.[34]

INCIDENCE

Intracranial meningiomas account for 20% of brain tumours[12] of which 15–25% are convexity meningiomas. These convexity lesions are the most common meningiomas. Morokoff et al.[34] in their series of 163 convexity meningiomas, found them to represent 22% of all meningiomas operated upon. They reported a female:male ratio of 2.7:1 and a median age of 57 (range 20–89 years old). Menon et al.,[29] in their review of 38 paediatric meningiomas, found convexity lesions to comprise 12% of the series. The factors that may predispose to meningioma formation are female sex, previous ionising radiation[15] and neurofibromatosis. Meningiomas may be associated with Werner's syndrome[46] and these are seen to occur two times more frequently in men and are associated with extracranial tumours like sarcomas and thyroid carcinoma.[46] These patients, after excision of the meningioma, require close follow-up to detect recurrence. The incidence of cranial vault or convexity lesions is increasing due to routine imaging, which has become a part of contemporary health care. Almost one-third of these tumours are now discovered as incidental findings on CT or MRI.

LOCATION

Cushing and Eisenhardt[11] subclassified convexity meningiomas as pre-coronal, coronal, post-coronal, paracentral, parietal, occipital and temporal types. Later, for convenience, they were classified as anterior, median, posterior and temporal convexity meningiomas. A meningioma which involves more than one location is classified according to the site of the main attachment. Anterior meningiomas are those which lie at or in front of the coronal suture and include meningiomas of the pterion. Median meningiomas are those astride the Rolandic fissure. Posterior meningiomas are those which involve the posterior parietal and occipital regions. Temporal meningiomas are those which develop in the temporal region and pterion and grow posterior and medially and project on the temporal side of the Sylvian fissure.

CLINICAL FEATURES

Like any other slow growing intracranial lesion, convexity meningiomas have a long clinical history. Zeidman et al.[50] on analysing growth rates of non-operated meningiomas, found the mean relative volumetric growth rate was 5.82% per year and 9.09% demonstrated no growth. Incidental asymptomatic meningiomas are increasingly seen on routine imaging of the neuraxis.

The clinical features are in accordance with the site of the lesion.[37,38,42,43] Patients often have a long history of headache, mental deterioration, visual disturbances, focal neurological deficit, seizures[44] and signs of raised intracranial pressure. In a series of 163 convexity meningiomas reported by Morokoff et al.,[34] headache was the most common symptom followed by seizures and hemiparesis. Thirty-two patients were asymptomatic and their tumours were found incidentally on imaging. Some of the convexity meningiomas are diagnosed solely from the presence of skull or scalp swelling, due to an often associated hyperostosis and rarely due to osteolysis and tumour involving the calvarium and scalp. The growth of meningiomas may increase during pregnancy, due to the presence of receptors for progesterone hormone in the tumour and they may become symptomatic in pregnancy and present as eclampsia. Shehu et al.[44] recommended close follow-up of patients with eclampsia and described a case where a convexity meningioma presented as postpartum eclampsia.

ANTERIOR CONVEXITY MENINGIOMAS

These tumours produce symptoms and signs of frontal lobe dysfunction, mainly mental deterioration (Fig. 1).

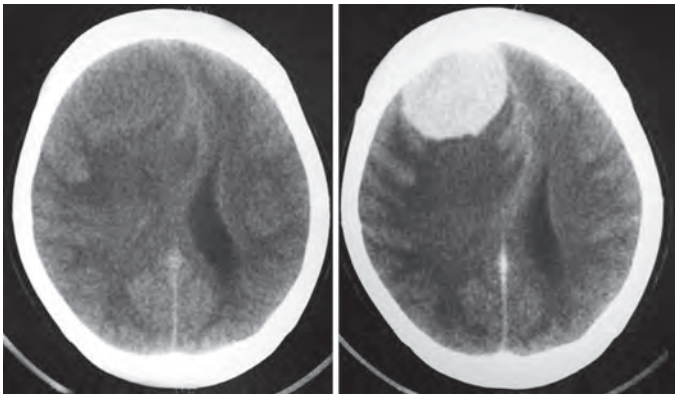

Fig. 1: CT scan showing frontal convexity meningioma isodense on plain study and uniform contrast enhancement

These are often overlooked and attributed to the ageing process as they occur mostly in elderly patients. These tumours attain a large size before showing signs of increased intracranial pressure or papilloedema. Rarely, subtle signs of pyramidal involvement are the only signs and these may be difficult to pickup.

MEDIAN CONVEXITY MENINGIOMAS

Sensory and motor signs and symptoms are characteristic of convexity meningiomas in this location (Figs 2A and B). When the dominant hemisphere is involved, speech disturbances are common. Cushing had noted that Jacksonian type of seizures starting from the face or hand, preceded by motor or sensory aura, may occur.

POSTERIOR CONVEXITY MENINGIOMAS

They often present with signs of increased intracranial pressure, sensory motor symptoms or, characteristically, field defects (homonymous hemianopia) (Figs 3A to D).

TEMPORAL CONVEXITY MENINGIOMAS

These often present with seizures, contralateral motor deficit and visual field defects (due to involvement of visual fibres along the temporal horn) (Figs 4A to D). Speech disturbances are common when the dominant

hemisphere is involved. Rarely, when large, they may compress the ipsilateral cerebral peduncle, leading to contralateral motor disturbances. In some cases,

compression of the contralateral cerebral peduncle against the tentorial edge may result in ipsilateral hemiparesis.

IMAGING

X-rays

X-rays of the skull can show hyperostosis or osteolysis, with expansion of the calvarial bone and prominence of vascular channels, signifying the presence of a meningioma. Calcified lesions and those with specky calcification are easily made out. Plain X-ray of the skull as an initial investigation gives information regarding calcification of the lesion or erosion of the skull associated with convexity meningiomas (Fig. 5).

Computed Tomography

Computed tomography (CT) scan with contrast has a localising value of 100%. The CT scan may show hyperostosis of adjacent bone and prominent vascular channels (Fig. 6). These lesions are generally isodense with brain on non-contrast scan, have smooth contours and are in close proximity to the dura. They may be partially or, rarely, fully calcified. In 15% of cases, they can have atypical radiology with necrosis, cystic degeneration, haemorrhage, indistinct margins, severe brain oedema, multiple nubbins of the tumour which deeply invade the brain and have heterogeneous enhancement. These findings indicate a malignant transformation or an atypical meningioma.[35]

Magnetic Resonance Imaging

Magnetic resonance imaging gives much better soft tissue delineation. On T1-weighed images, they are isointense or hypointense to grey matter and on proton density and T2-weighted images, they are isointense or hyperintense.[21] These tumours compress the adjacent brain and they can extend along and infiltrate Virchow-Robin spaces and can have an infiltrating morphology.[40] Rarely, the scans will show associated pathology, like an aneurysm or subdural haematoma, which may require treatment.[17,21] Gadolinium is a paramagnetic contrast

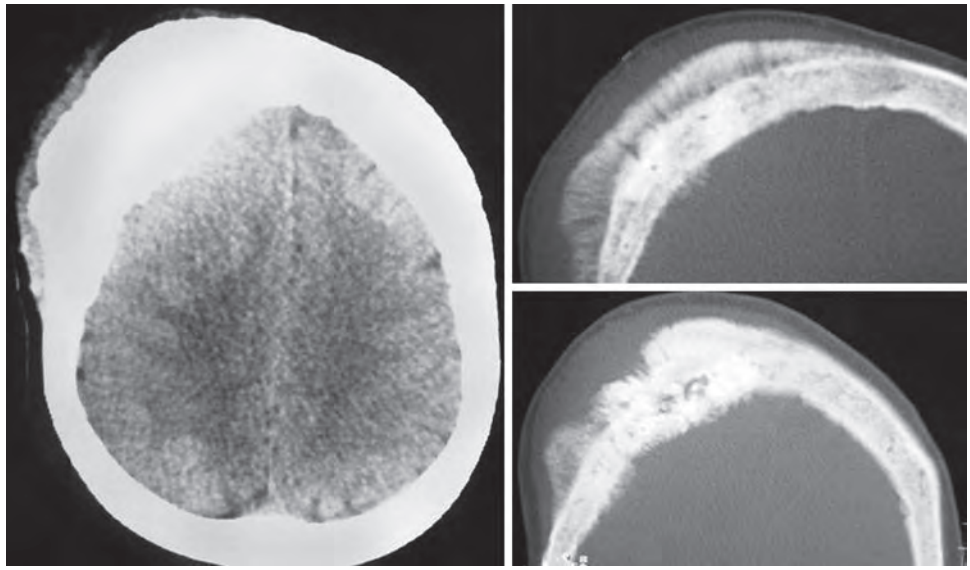

Fig. 6: Plain CT scan and bone cuts showing hyperostosis in a case of frontal convexity meningioma

agent and causes these lesions to enhance brilliantly. MRI scores over CT in demonstrating the "dural tail" and invasion of the sinuses, thereby eliminating the need for angiography. The information thus obtained outweighs the benefit of angiography in determining the vascularity and surgical approach, and avoids the minimum risk involved in angiography.

Electroencephalogram

Electroencephalogram to locate the site of a meningioma is of historical value only, but may be useful in monitoring the epileptogenicity of the affected cortical area for medical therapy.

Angiography

Angiography is done when imaging suggests a highly vascular lesion and one which may require pre-operative embolisation. The external carotid injection shows a "sunburst" pattern and internal carotid injection shows the arterial and pial blood supply.

Pre-operative embolisation is generally not necessary in cases of convexity meningiomas, as the majority of the supply is from meningeal vessels which are cut off in the early stages of surgery.

DIFFERENTIAL DIAGNOSIS

Although most meningiomas have distinct radiological features and are easily diagnosed, rare lesions that can mimic a meningioma need to be considered in the differential diagnosis. The differential diagnosis includes fibrous dysplasia, tuberculoma, sarcomas, lymphomas,[1] non-Hodgkins MALT lymphoma,[41] plasmacytomas, carcinomas, dural based secondaries,[3] Rosai Dorfman's disease,[13] melanocytoma[7] and cavernous haemangioma.[19]

SURGICAL MANAGEMENT

Generally surgery is recommended in patients diagnosed with a convexity meningioma greater than 1.5–2 cm except in the elderly and frail. The operating microscope is very helpful to preserve normal neural structures and vasculature. A good bipolar, loop electrode, CUSA, and laser also form part of the surgical armamentarium.

Pre-Operative Protocol

In the presence of raised ICP and seizures, pre-operative adequate dosage of steroids, furosemide (lasix) and anticonvulsants is essential. If needed, per-operatively, 20% mannitol (1 gm/kg body wt) may be given in the early phase of surgery.[28]

Correct positioning of the patient is essential. The surgeon and anaesthetist should be comfortable. The position of the head is fixed such that the scalp over the lesion is placed at the highest level. This allows for minimal retraction of the brain and good venous drainage. Undue rotation of the neck is to be avoided as it may lead to compression of the neck veins leading to increased venous pressure/raised ICP. If required, mild hypotension and normocapnia may be used in anaesthesia so that there is minimal blood loss.

Scalp Incision

This is of great importance, especially in surgery for convexity meningiomas. The neuroimaging, including the multiplanar MRI and the CT scan, which is better in showing the relationship of the lesion to bony landmarks, like the coronal suture, are studied before marking the appropriate scalp incision. It is also prudent to shave and visualise the patients head to look for signs of hyperostosis, osteolysis and prominent scalp vessels. The scalp incision should be large and care must be taken in cases where re-surgery is under taken. The normal blood supply and scalp anatomy should be reviewed.[2]

Normally, a U-shaped incision is sufficient. With the advent of neuronavigation, Black et al. and Morokoff[8,34] advocate linear incisions and smaller craniotomies in convexity meningiomas. Surface anatomy scanning (SAS) with the help of MRI imaging may precisely localise the tumour and also give information regarding the surrounding venous anatomy. Intra-operative image guidance is useful in precise location of the craniotomy. Navigation also helps to provide visualisation of the relationship of the tumour to the veins.[6] Current surgical strategy is to use neuronavigation, making possible a targeted linear incision and a small craniotomy, followed by resection and taking a 5 mm dural margin around the tumour.

The scalp incision and the craniotomy flap should be wider than the lesion itself. A free bone flap is preferable as it provides an early disruption of the external carotid blood supply. One needs to preserve the pericranial tissue which may be used later as a graft to replace the dural defect. The elevated bone flap needs to be inspected for any tumour invasion and, if found, this needs to be removed in toto. Hitch stitches are applied all around before opening the dura. The area of the dura where the tumour is attached is invariably vascular and one may notice large meningeal vessels coursing through the dura and feeding the tumour. Bleeding from the dural surface can be controlled with bipolar coagulation and Gelfoam®. Prior to opening the dura, any major dural vessel exposed may be ligated or secured with silver clips. This reduces the vascularity of the dura. Rapid opening of the dura helps in controlling the bleeders and minimising the blood loss and also helps to cut off the vascularity of the tumour. Excessive coagulation may lead to shrinkage of the dura, but one need not worry about this aspect, as at the end of the surgery the dura is excised adequately and grafted with pericranial tissue or a dural substitute. Adjacent to the tumour, the dura is known to be infiltrated by meningiomatous cells which are known to cause recurrence and hence resection of the dura to that extent is necessary. The dural exposure around the tumour should be adequate and generous and, at the same time, as little as possible of the

brain should be exposed. Dural substitutes are increasingly being used[25] and Balasubramanium et al.[4] have described the use of dural bridge sutures to prevent the sinking of dural substitutes. Kamitani et al.[20] have proposed that meningioma cell rests may be found in thickened arachnoid adjacent to the lesion and advocate its removal.

The major blood supply to convexity meningiomas is from the dural vessels and once these are under control the rest of the dissection will be relatively blood less. Some of the tumours may also receive blood supply from cortical vessels. The first step in the dissection of the tumour is to identify the tumour arachnoid plane. In the majority of lesions, there will be a good arachnoid plane. When the arachnoid plane is good all around and is preserved, it is fairly easy to remove the tumour without damaging the underlying cortex. Occasionally, the arachnoid layer may be deficient in some places. In such situations, it is difficult, but not impossible to separate the cortex from the surface of the tumour by fine dissection. The cortical edges at the junction of the tumour need to be protected by placing soft cotton lintines. Undue retraction of the cortex should be avoided, and great care is taken to preserve cortical veins at the tumour cortex junction. Cerebral oedema will be more pronounced post-operatively if the venous drainage has been compromised. Occasionally, an apparent feeder to the tumour may not actually feed the tumour but will skirt the tumour and these en-passage vessels need to be identified and these should be carefully dissected and preserved. Sometimes, the blood supply of the tumour comes from the contralateral middle meningeal artery and this can be hard to identify at surgery. Often it is necessary to debulk the tumour to allow the capsule to fall inwards away from the surrounding cortex. The debulking may be done with CUSA, diathermy and cutting loop. Invariably, at the end of the tumour removal, one may encounter one or two vessels supplying the tumour from the bed which need to be preserved. The contact yttrium-aluminium-garnet laser may be used, as this allows haemostasis and carving of tumour similar to the (Bovie) diathermy loop cutting.[49] After tumour removal, getting absolute haemostasis is of paramount importance as it prevents post-operative haematoma. Spontaneous intracranial meningioma bleeding can cause rapid deterioration and a one stage total removal of haemorrhagic meningioma and haematoma is the treatment of choice in these patients.[9] An increased tendency to bleed was found to be associated with two age groups (less than 30 and more than 70 years old), and in convexity, intraventricular and fibrous meningiomas.[9]

Post-Operative Care and Complications

The general principles of supervision and post-operative care as applicable to other intracranial surgery need to be followed. The patient needs constant monitoring of the level of consciousness, blood pressure, pulse rate and oxygenation and coagulation profile. The fluid balance is to be maintained. The central line is left in place, of which one line is connected to a CVP monitor. The patient is nursed in the 30 degree head-up position. Antibiotics are given. Subcutaneous LMW heparin, particularly in hefty individuals, helps to prevent deep vein thrombosis (DVT). Chest physiotherapy and spirometer exercises are helpful in preventing chest congestion, particularly in the elderly. Anticonvulsants need to be continued. Steroids are continued in high doses during the first 3 post-operative days and gradually tapered (4 mg of dexamethasone IV 8 hourly). Apart from this, furosemide 40 mg per day is given. Occasionally, intermittent mannitol is given if the patient deteriorates due to cerebral oedema. Controlled ventilation may be resorted to in this situation. During this period, electrolytes and blood gases are monitored and need to be repeated at least 8 hourly. Sometimes, the patient deteriorates on the third post-operative day due to cerebral oedema.

Post-operative anaemia due to blood loss seldom occurs with microsurgery after correction of intraoperative blood loss. Aspiration pneumonitis may occur and has to be prevented. Small frequent feeds by the "drip feeding" method help to avoid this preventable complication. Other complications include meningitis, CSF leak, chest infection and stress induced gastric bleed.

PROGNOSIS

The prognosis for convexity meningiomas is very good, as total excision is possible.[8,10,14,34] There is no doubt that the single most important prognostic factor is completeness of surgical removal of the meningioma and its surrounding involved dura. Simpsons's grading[45] can be used to prognosticate recurrence.[45]

RECURRENCE

Factors contributing to the recurrence of tumour include the type of removal and pathological patterns of the tumour.[26,31,33] The biological characteristics that are implicated in recurrence are the male sex, lack of calcification, high MIB-1 index, loss of chromosome 1p and vascular endothelial growth factor expression. Increased MIB-1 labelling index which is an immunohistochemical measure of Ki-67 antigen expression has been associated with meningioma recurrence and is useful in planning adjuvant therapy. The term recurrence should be reserved for cases for Type I or Type II excision of Simpson's grading. Some authors have suggested the necessity of an additional margin of 2 cm around the tumour (Simpson grade 0).[22] For growth of tumour after sub-total excision (Type III), the term re-growth should be used. Atypical or anaplastic tumours carry an increased risk of recurrence. Histopathological findings of increased mitosis, focal necrosis, features of atypia or frank malignancy, directly correlate with the rate of recurrence.[12]

The grading system to diagnose atypical meningiomas proposed by Mahmood et al. is the most appropriate and includes the criteria: (1) Increase in mitotic rate; (2) High cellularity; (3) Sheeting of tumour cells with loss of typical histological pattern; (4) Prominent nucleoli; (5) Focal necrosis and (6) Tumour invasion into bone or cortex.[12]

Kamitani et al.[20] emphasise that the thick arachnoid membrane which is contiguous to the meningioma, involves clusters of meningiomas cells and these may be related to recurrence. Recurrence rates have been reported as 3% at 5 years, 9% at 10 years and 21% at 25 years for benign tumours that were removed completely.[18] Morokoff et al.[34] reported a 5-year recurrence rate in convexity meningiomas of 1.8% for benign lesions, 27.2% for atypical meningiomas and 50% for anaplastic meningiomas.

Radiation is resorted to in malignant lesions, and following sub-total resection occasionally.[5,30] Modha and Gutin[32] have suggested that all grade 3 and grade 2 tumours with brain invasion or a MIB-1 index of 4.2% or greater should be treated with fractionated radiotheraphy. In small meningiomas, where primary surgical excision is not possible due to medical and anaesthetic problems, stereotactic radiosurgery may be an option.[23] The role of chemotherapy is debatable. On histopathology, expression of androgen and progesterone receptors in primary human meningiomas may allow hormonal manipulation of lesions.[27,48] The use of antiprogesterone (RU480) to control tumour recurrence has not been clearly established.[16] Vivier et al.[47] found that male patients and patients with a meningioma that has a 22q LOH are more likely to develop tumours exhibiting multiplicity, recurrence or calvarial erosion and recommend that this subset of patients be followed more closely.

Whatever factors may cause recurrence, its possibility should always be mentioned and discussed with the patient. The prognosis after surgical excision should be explained. It is better to have a regular periodic CT scan once in 2 or 3 years to detect early recurrence. About 85% of patients with recurrence can undergo one or more additional operations, usually with good and long lasting results.

LONG-TERM OUTCOME

The late outcomes of operation for convexity meningiomas are still not as good as might be expected from the ease with which they are removed.[14] The late surgical sequelae include:

- Various degrees of contralateral hemiparesis which has gradually been declining due to more general use of microsurgical methods, earlier diagnosis and recent instrumental aids including neuronavigation.
- The other serious disabling sequel is the persistence or *de novo* onset of epilepsy, a sequel that has a higher frequency in convexity meningiomas than in meningiomas at other sites.
- Recurrence is another unsatisfactory outcome which can be avoided if the first operation is truly radical.

167 Parasagittal and Falx Meningiomas

Vasudevan MC

Parasagittal and Falx meningiomas are considered together, as they have a similar clinical presentation. Cushing,[6] in 1922, suggested the term 'Parasagittal' for meningiomas along the superior sagittal sinus (SSS). These tumours arise from the arachnoid villi of the SSS and often involve the adjacent convexity dura and falx. Nearly 50% invade the sinus, 50% get secondary attachment to the falx and 25% are bilateral.[11] Hyperostosis of the adjacent skull is associated with 25% of these tumours and is a valuable pointer to their diagnosis.[7] Falcine meningioma arises from the falx cerebri or inferior sagittal sinus and may rarely invade the SSS. It is usually completely concealed by the overlying cerebral cortex and does not cause bony changes. About 50% of the tumours grow through the falx to become bilateral.[10] Falx meningiomas are about five to seven times less common than parasagittal meningiomas (PSMs). Olivecrona was the first to distinguish these meningiomas according to the site of attachment along the SSS.[15] The distribution of parasagittal and falx meningiomas along the longitudinal axis is about 20%, 50% and 30% in the anterior, middle and posterior-third, respectively.[11]

CLINICAL FEATURES

Tumours in the middle-third, from the coronal suture to the lamboid suture, classically present with contralateral focal motor or sensory epilepsy followed by progressive weakness of the contralateral lower limb (Fig. 1). These tumours are detected at an early stage because of focal epilepsy. Bilateral tumours may, occasionally, give rise to bilateral disturbances and, rarely, paraplegia that may be wrongly attributed to spinal pathology.

Anterior-third meningiomas, located between the crista galli and the coronal suture, have a more insidious onset and often attain a large size before diagnosis (Figs 2 to 4). Headache is the predominant symptom and may be present for years followed by gradually progressive impairment of memory, intelligence and personality changes. Generalised epilepsy is a presenting symptom in 25–30% of patients.[10,14] Ataxia, tremor and ipsilateral facial pain may, occasionally, accompany a large meningioma in this location and thus may be misdiagnosed as a posterior fossa tumour.[9]

Tumours in the posterior-third between the lambdoid suture and the torcular herophili may present with features of raised intracranial pressure alone (Fig. 5). The only characteristic sign, a homonymous field defect, either quadrantanopic or hemianopic, may not be noticed by the patient.[16] Epilepsy is uncommon.

IMAGING

Either computerised tomography (CT) or magnetic resonance (MR) clinches the diagnosis. The CT scan

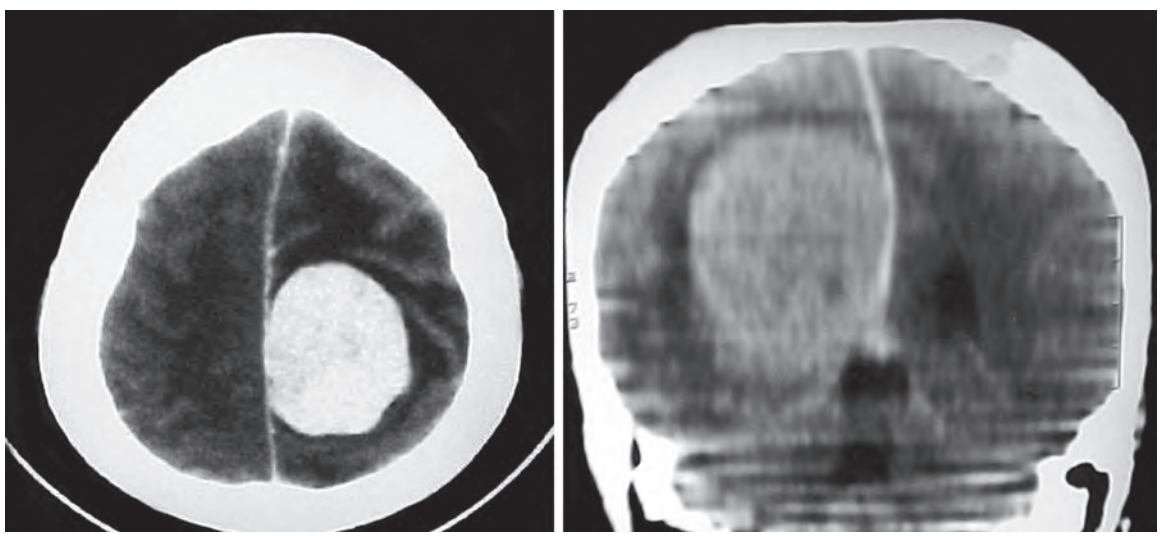

Fig. 1: CT scan showing a middle-third falx meningioma

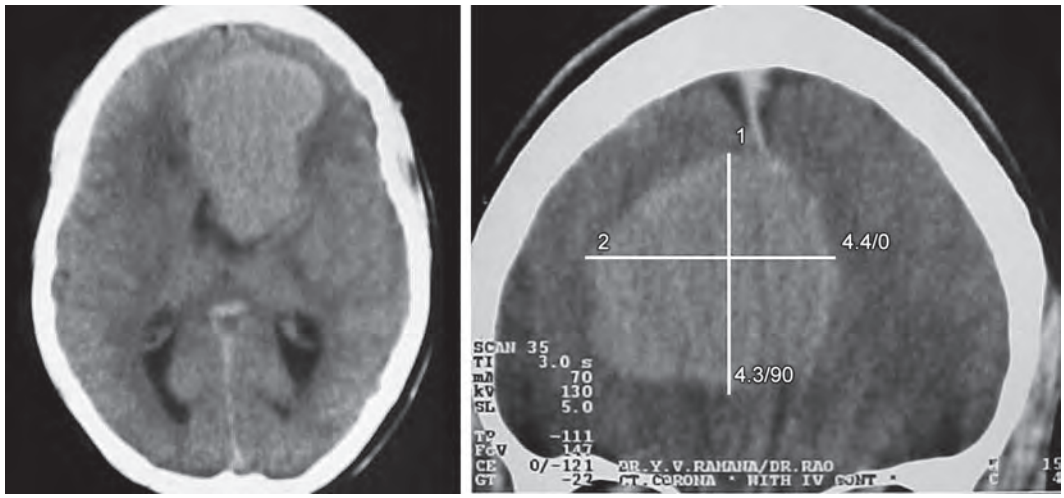

Fig. 2: CT scan showing unilateral falx meningioma with mass effect

Fig. 3: CT scan showing a large anterior-third falx meningioma

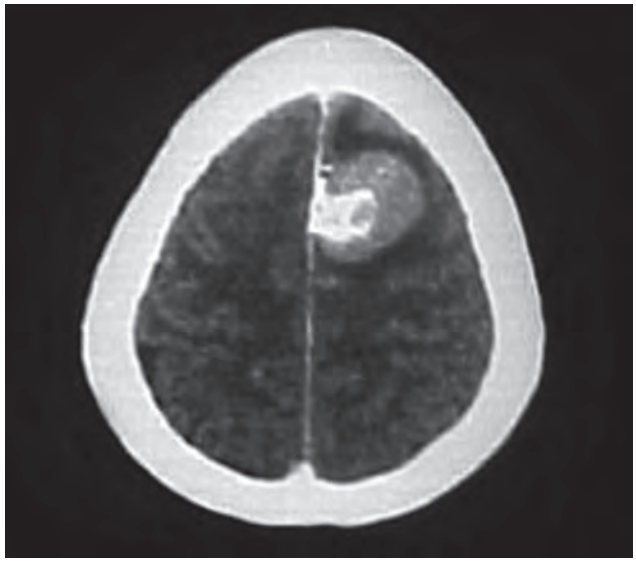

Fig. 4: CT scan showing an anterior-third falx meningioma

best reveals the chronic effects of slowly growing mass lesions on bone remodelling. Calcification in the tumour (seen in 25%) and hyperostosis of overlying skull may be seen. MR imaging reveals a number of characteristics highly suggestive of meningioma. These MR imaging findings include a tumour which is dural-based and isointense with grey matter, demonstrates prominent and homogeneous enhancement (95%), frequent cerebrospinal fluid/vascular cleft(s) and often an enhancing dural tail (60%). However, approximately 10–15% of meningiomas have an atypical appearance on MR images, mimicking metastases or malignant gliomas. In particular, these meningiomas may have a significant amount of peritumoural oedema due to venous compression.[21] Angiography, the most preferred diagnostic procedure in the pre CT era, may still be helpful in revealing the vascularity of the tumour, its blood supply and its relationship to the venous sinuses. Ramamurthi and Varadarajan in 1961 reported that the angiographic

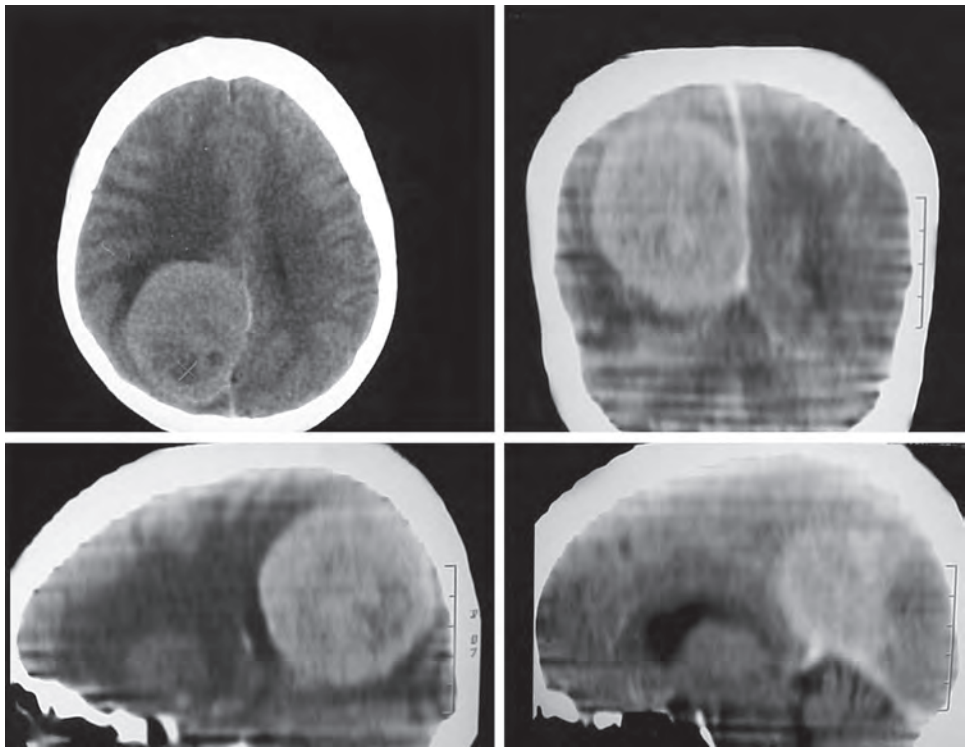

Fig. 5: CT scan of the brain showing a large posterior-third falx meningioma

appearance of a tuberculoma enplaque may mimick a meningioma.

Parasagittal meningiomas may pose a difficult surgical challenge since venous patency and collateral anastomoses have to be clearly defined for correct surgical planning. Contrast-enhanced magnetic resonance venography (CE-MRV) provides additional and more reliable information concerning venous infiltration and the presence of collateral anastomoses compared with phase contrast (PC) sequences.[3] There has also been interest in the use of MR spectroscopy to assist in the diagnosis of meningiomas. This modality may be particularly useful in patients unable to undergo surgery for whatever reason. Creatinine containing peaks in meningioma are 20% that of comparable levels in normal brain. An increase in the choline-containing peaks and the alanine peak has been reported as well. Greater than 63% of atypical meningiomas had a characteristic lactate peak on preoperative MR spectroscopy.[21]

In addition, tumours in the mid and posterior-third may be investigated by angiography, mainly to assess the status of the SSS and the distribution of the cortical veins. Middle PSMs depress the pericallosal arteries and the anterior tumours displace these vessels posteriorly and downwards. The anterior cerebral artery may be displaced to the same side and bilateral tumours often cause spreading of the pericallosal and callosomarginal arteries in opposite directions and outline the extent of the tumour.[5]

Differential diagnosis include dural metastasis, primary dural lymphoma, solitary fibrous tumours, gliosarcomas, leiomyosarcomas, hemangiopericytomas, melanocytomas, plasmacytomas, inflammatory pseudotumours, en-plaque meningiomas, neurosarcoidosis, plasma cell granulomas and Rosai–Dorfman disease.[13]

TREATMENT

Many studies confirm the tenet that many meningiomas grow very slowly and that a decision not to operate is justified in selected asymptomatic patients. As the growth rate is unpredictable in any individual, repeated brain imaging is mandatory to monitor an incidental asymptomatic meningioma. An interval of 6 months after the initial study, followed by images at increasing intervals (as stability is confirmed over the first 1–2 years) appears adequate to assess growth rate and need for intervention.[21]

The treatment of meningiomas is dependent on both patient related factors (age, performance status, medical comorbidities) and treatment-related factors (reasons for symptoms, goals of surgery and resectability which is judged by the location and bilaterality of the tumour, patency of SSS and displacement of the cortical veins). In patients who are considered surgical candidates (surgically accessible symptomatic meningiomas), the goal of therapy is total excision. As with all brain tumours, completeness of resection is determined by early (72 hours)

post-operative, contrast-enhanced brain imaging using either CT or MR imaging.[21]

Data from various studies suggests high morbidity frequently following radical surgery of tumours in central and posterior location.[4,23] Hence, whenever possible, a more conservative approach is adopted. Clearly, at least the bulk of the tumour should be removed whenever possible when the patient is progressively symptomatic. However, a small tumour, without focal deficit, especially in the elderly can be kept under serial observation or may be subjected for primary radiosurgery. Paradoxically, the relatively high morbidity associated with surgical removal of central PSMs once the sinus becomes involved, may justify the more aggressive attitude in younger patients.[1,20]

For anterior-third tumours, the patient is positioned supine and a bicoronal incision is employed.[26] In mid-third tumours, the patient is in a semilateral position and in posterior-third lesions, it is the three quarter prone position. In all these tumours, the bone flap may be carried up to 2 cm across the midline to the side opposite the tumour. For tumours near the central sulcus a generous craniotomy helps in avoiding excessive handling of the primary sensorimotor cortex.

In PSMs, as stated earlier for all meningiomas, the attachment of the tumour to the meninges is dealt with first to reduce the vascular supply. Any attachment to the sinus may be left to be dealt with later on. After internal decompression, the dissection of the capsule is started away from the midline and the tumour gradually lifted with its base towards the area of attachment to the sagittal sinus, so that if there is any brisk haemorrhage from the sinus there is enough space to deal with it under direct vision after delivering the tumour. If the sagittal sinus is completely occluded by tumour, it can be excised along with the tumour anywhere along its length. Anterior to the coronal suture, the involved sinus may be excised even if patent. An involved but patent sinus in mid and posterior-third PSMs calls for careful surgical judgement.[15] Unlike the earlier belief, it is now understood that radical resection together with removal of the sinus is not necessarily safe even when the sinus is already completely occluded before surgery, particularly with meningiomas of the middle-third of the SSS. It is hypothesized that radical resection results in removal of important cortical veins that run within the tumour or on its capsule.[19]

Tumours attached to the lateral wall, without significant infiltration into the sinus lumen can be managed by dissecting the tumour off the SSS and achieving haemostasis by a combination of coagulation and pressure over Surgicel® and Gelfoam®. If the tumour has infiltrated the sinus lumen in the lateral aspect only, it may be excised and the sinus progressively closed with a continuous running suture. Though Bonnal and Brotchi[2] have shown the feasibility of excision of the sinus followed by partial or total autogenous venous grafts to repair it, if the sinus is extensively involved but still patent it may be better left intact and some tumour left behind along the area of the sinus. In both situations, extreme care is vital for preservation of cortical veins, which may offer important collateral drainage.[8]

In falcine tumours, care is taken not to sacrifice cortical veins draining into the SSS while exposing the tumour posterior to the coronal suture. To expose the capsule of the tumour, the thinned out brain covering the tumour may be gently pushed laterally, after incising the arachnoid. Very large tumours may be operated upon in two stages, the feeders on either side of the falx being removed at each stage.[18] For details of operative procedure reference may be made to the chapter, "Surgical Therapy of Parasagittal and Falcine Meningiomas" in Volume 1 of Textbook of Operative Neurosurgery.[26]

PROGNOSIS

Rate of recurrence of parasagittal and falx meningioma significantly increases in cases of non-radical resection of tumour. Aggressive surgical treatment presents several hazards and carries an increased risk of unsatisfactory outcome; the risk of recurrence, however, is significantly decreased.[17] The extent of resection of meningiomas in this region is closely related to tumour recurrence. Recurrence rates after total resection of meningiomas involving the sagittal sinus wall range from 5 to 9%; those after sub-total resection accompanied by sinus wall excision range from 16 to 17%; after sub-total resection of the tumour is approximately 29%; and after partial resection of the tumour it is approximately 39%.[12] A classical paper on the recurrence of intracranial meningiomas was by Simpson in 1957.[22]

Hence, if total resection is aimed at, then sinus repair and reconstruction is required. However, if a conservative and less aggressive approach is adopted, then the patient has to be informed regarding the prognosis and may be given the option of adjuvant radiosurgery.[24,25]

168 Olfactory Groove Meningioma

Ravi Ramamurthi, Nigel Peter Symss

INTRODUCTION

In 1938, Harvey Cushing[4] in his monograph entitled "Meningioma" reported that the first successful operation for removal of an olfactory groove meningioma (OGM) was by Francesco Durante in 1895. Cushing operated on 28 cases, with an operative mortality of 19%. Most of the patients had very large tumours.[4] In his publication, he emphasised the surgical management of internal decompression of the tumour, before attempting to dissect the capsule and the importance of preserving the anterior cerebral arteries which may be involved by the tumour.

ANATOMY

Olfactory groove meningiomas may arise from the anterior cranial fossa near the crista galli, from near the cribriform plate of the ethmoid bone or the planum sphenoidale[26] and account for 8–13% of all intracranial meningiomas.[21,25] The tumour may be symmetric around the midline or extend predominantly to one side. The principle blood supply of the tumour is from the ethmoidal, meningeal and ophthalmic arteries through the base of the skull along the midline. In large tumours, the anterior cerebral arteries may be involved with the tumour capsule. The frontopolar and small branches of the anterior cerebral arteries may be adherent to the superior and posterior part of the tumour capsule. In large tumours, the olfactory nerve is usually adherent and splayed out on the tumour, while the optic nerves and chiasm may be pushed downwards and posteriorly.

CLINICAL FEATURES

These are usually slow-growing tumours. Due to the ability of the brain tissue to adapt to slow compression and the absence of focal functional cortical regions in the adjacent brain tissue, these tumours can grow to large sizes before the patient becomes symptomatic. In Cushing's series of 29 patients, most of whom had large tumours, the primary symptoms were headache, visual disturbances, personality changes and loss of smell.[4]

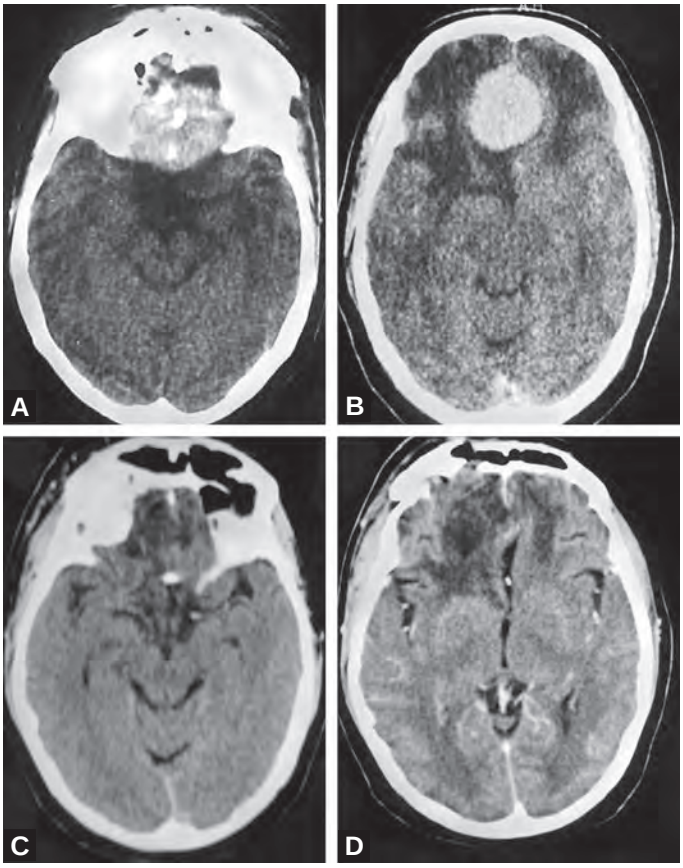
Unlike meningiomas at other locations, there was no female predominance in OGMs operated at SCTIMST.[14] These tumours can be silent for a long time. In the SCTIMST series, the most common initial symptom was long standing headache (75%); the other presenting symptoms were epilepsy (12.5%) and visual dysfunction (8.3%). Although anosmia occurs in 85–90% of cases, it is rarely the initial or presenting symptom. As these tumours grow in size, symptoms of pressure on the frontal lobe may be apparent. Mental symptoms often lead the patient to seek treatment from a psychiatrist.[3,7] While inferior tumours may cause excitement or restlessness, pressure over the convexity of the frontal lobe may lead to indifference and apathy. The more anterior tumours cause a central scotoma and papilloedema. Growing posteriorly, these tumours press on the optic nerve and chiasma, leading to unilateral blindness or bitemporal haemianopia with optic atrophy. With the rise in intracranial pressure, there may be papilloedema in the opposite eye and a Foster Kennedy syndrome may be seen. Although traditionally considered a classical sign, this syndrome is neither common nor diagnostic of this tumour. Foster Kennedy syndrome was noted in 8.3% of patients. Further extension posteriorly puts pressure on the hypothalamus and pituitary gland. By this time, the ICP rises to cause obvious features of raised ICP. It is not unusual, even today, to see large OGMs presenting with blindness and raised ICP. Rarely, by eroding through the orbital roof or the cribiform plate, the tumour may cause proptosis. In the SCTIMST series, deranged mental function and gross visual impairment were each present in nearly 30% of patients.

RADIOLOGY

The diagnosis is confirmed by computed tomography (CT) or magnetic resonance imaging (MRI) scan of the brain. On CT scan the lesion is a well circumscribed, rounded, isodense to slightly hyperdense mass, with dense uniform enhancement after intravenous contrast (Figs 1A to D and 2A to C).

The density is partly due to the cellularity and to the presence of calcified psammoma bodies. Calcification may also be seen and is easily detected by CT. There may be increased thickness of the bone due to hyperostosis at the site of dural attachment. Occasionally, bone destruction may be present due to invasion by the tumour.

With MRI, the configuration of the tumour in all directions, the anatomical extent and the relationship



Figs 1A to D: (A and B) Pre-operative CT scan of the brain contrast study showing olfactory groove meningioma. (C and D) Post-operative CT scan of the brain contrast study showing post-operative changes with total excision of the tumour

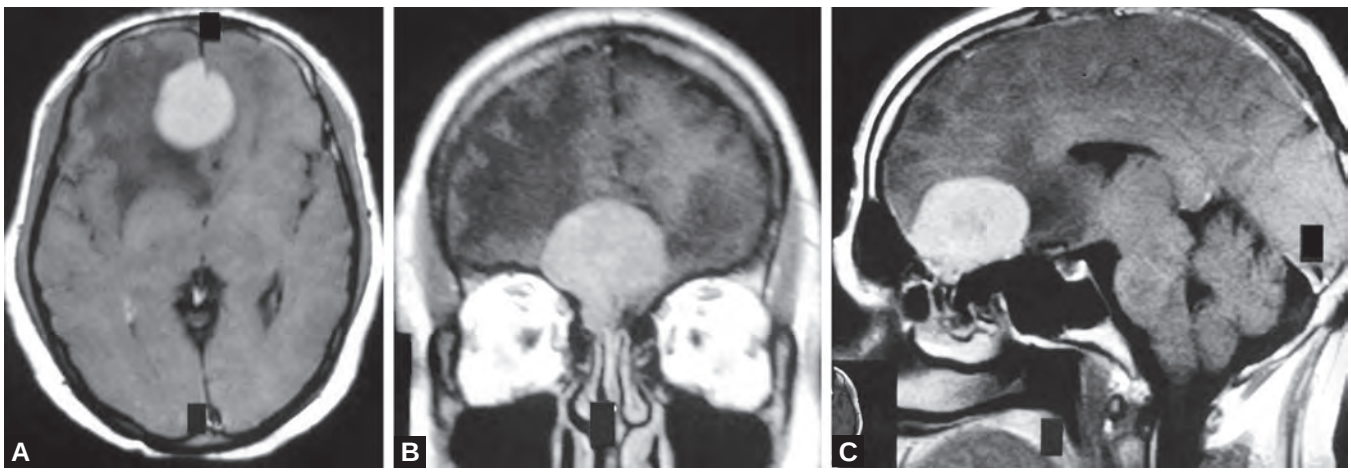
of the anterior cerebral arteries and optic nerves can be clearly defined. On T1-weighted images, the lesion is usually relatively isointense with grey matter but may have variable signal intensity. With contrast, they enhance intensely uniformly and often are seen to have a 'dural tail', probably due to dural reaction. In angioblastic meningiomas, the lesions will show flow voids within them due to rapid flow of the blood in the veins.

Although angiography is not mandatory, when performed, it provides useful information in large tumours, regarding the blood supply and location of the anterior cerebral arteries and their major branches. The anterior cerebral arteries are pushed backwards and upwards and a frontal arterial branch is generally stretched over or involved in the tumour capsule. In large tumours, the anterior cerebral artery and its branches may be involved within the tumour capsule. Care is necessary to avoid injury to these vessels during surgery.

SURGICAL MANAGEMENT

Surgical treatment should aim at total excision which is generally possible even in large tumours. In all cases, a bicoronal skin incision is preferred. Ojemann[16] prefers a bifrontal craniotomy for large tumours that extend to the crista galli and for smaller tumours that are more posteriorly located and do not extend as far anteriorly, he prefers a right lateral subfrontal approach. McCarty et al.[10] prefer a bifrontal approach. Kempe,[8] Logue[9] and Symon[25] advocate a unilateral subfrontal approach with removal of part of the frontal lobe. This will depend upon the precise extent of the tumour. In large tumours that extend equally on both sides of the midline, a bilateral bone flap is preferred. This approach is associated with minimal amount of retraction on the frontal lobes, gives adequate access to all sides of the tumour, allowing the surgeon to decompress the tumour while working along the skull base to cut off the blood supply. The anterior end of the sagittal sinus may be ligated and the falx cerebri detached from its inferior attachment when indicated.

Spektor et al.[24] used a variety of surgical approaches, such as bifrontal craniotomy, a unilateral subfrontal approach, pterional approach, a fronto-orbital craniotomy and a subcranial approach for OGM resection. They advocated an approach tailored to the tumour's size, location and extension and combined with modern microsurgical cranial base techniques, it allows full OGM removal with minimal permanent morbidity,



Figs 2A to C: Contrast MRI. (A) Axial. (B) Coronal. (C) Sagittal sections of the brain showing olfactory groove meningioma

excellent neurological outcome and very low recurrence rates.

In attempting total excision, although a frontal branch of the anterior cerebral artery involved within the tumour capsule can be coagulated and divided, no effort should be spared to preserve the main anterior cerebral artery. The dural attachment is excised and any hyperostotic bone is removed. Any extension of the tumour into the air sinuses can be removed by a frontobasal approach or a combined craniofacial approach.[5,12,23] Meticulous repair of the anterior cranial fossa is necessary to prevent CSF rhinorrhoea.[20]

The endoscopic endonasal technique represents a possible alternative approach for suitably selected cases and could be expected to minimise neuropsychiatric sequelae.[27]

Despite apparent gross total resection, OGMs have a high rate of late recurrence (average, 23%).The cranial base and paranasal sinuses are sites of predilection for recurrence of OGMs. Recurrence is the result of a direct extension, attributable to incomplete resection of involved bone and regrowth at the edge of a previous surgical field. Extensive resection of all suspicious underlying bone is a complement to radical removal of these lesions. Reconstruction of the floor with a vascularised pericranial flap to prevent cerebrospinal fluid leakage, is crucial.[15]

The mechanisms of recurrence are still unclear. Maiuri et al.[11] in their analysis of immunohistological studies, mitotic index (MI), Ki-67 LI, oestrogen and progesterone receptors (ER and PR), vascular endothelial growth factor (VEGF), epidermal growth factor (EGF) and Bcl-2, found that tumour recurrence was not correlated with patient age, tumour location, consistency, vascularity and histology. They concluded, higher mitotic index (MI) and Ki-67 LI and progesterone receptors (PR) negativity are predictive factors of recurrence of benign (WHO I) completely resected meningiomas, particularly when Bcl-2 positivity is associated.

Complications

With the use of proper microsurgical techniques, the incidence of reported complications arising from removal of these tumours has been low. These complications can be encountered during surgical removal of olfactory groove and suprasellar meningiomas, as the surgical approaches are more or less the same. They can be divided into:

a. *Cerebrospinal fluid leak and infection:* CSF leak in the post-operative period can result from any craniotomy that breaches the frontal sinuses and infection can occur by contamination through the paranasal sinuses. Once the sinus has been breached, removal of frontal sinus mucosa, followed by a meticulous repair with muscle and a vascularised pedunculated pericranium is mandatory. The use of cranioplasty material can increase the risk of post-operative infection.
b. *Vascular injury:* The adherence of the tumour to the anterior cerebral arteries and its branches is one reason for inability to achieve total tumour removal. Injury to the anterior cerebral arteries can result in post-operative ACA territory infarct. Sacrifice of the smaller branches, such as the frontopolar arteries, is acceptable, as it is well tolerated.[18] Solero et al.[22] in their series of 98 patients with OGMs, clipped 16 anterior cerebral arteries.
c. *Post-operative seizures:* Seizures occurring in the early post-operative period are about 6% in reported series.[1,25] Ramamurthi et al.[19] reported that 7 of 12 patients (58%) with pre-operative fits and frontal tumours were relieved of their seizures post-operatively, while 6 of 38 (16%) developed new post-operative seizures.
d. *Visual loss:* Visual deterioration in the post-operative period is usually the result of surgery, due to rough manipulation of the optic nerve and chiasm or injury to the chiasmal blood supply. This can occur during removal of the midline posterior pole of the tumour. Finn and Mount reported a visual loss of 12% following excision of these meningiomas.[6] Solero et al.[22] had 20% visual deterioration in their series of large (more than 4 cm) tumours.
e. *Mortality:* Mortality following surgery has been low in most series. Mac Carty et al.[10] reported one death in 27 cases.[10] Bakay had one death in 11 patients.[2] Ojemann[17] reported one death in 17 patients, due to a pulmonary embolus.

Result

Walder[26] reported a mortality of 20% in a series of 77 cases. Use of microsurgical techniques has improved the outcome remarkably.[10,16] There was only one operative mortality in a series of 24 cases operated upon over seven years at SCTIMST.[14] The mortality in Sinha and Prakash's[21] series was 11%.

Nakamura et al.[13] operated on 82 patients with OGMs, through the bifrontal (n = 46), frontolateral (n = 34) and pterional (n = 2) approaches. Total tumour removal (Simpson Grade 1 or 2) was achieved in most cases (91.2% frontolateral, 93.5% bifrontal). The overall recurrence rate was 4.9%, with four patients requiring surgery. Even in large tumours, high rates of total tumour resection could be achieved with low recurrence rates, using the simple and minimally invasive frontolateral approach. In recent years, they preferred to use the frontolateral approach, which provides quick access to the tumour with less brain exposure while still enabling total tumour removal with a low morbidity rate and no mortality.

Suprasellar Meningioma

INTRODUCTION

Suprasellar meningioma was first reported by Stirling[32] in 1897. These were defined as tumours arising from the presellar area around the tuberculum sellae and growing upwards between the two optic nerves and also referred to as tumours of the tuberculum sellae.[5,23,32] Cushing in 1916 was the first to remove a suprasellar meningioma totally but it was reported only in 1929.[29] They comprise 5–10% of all intracranial meningiomas.[17,31]

ANATOMY

Authors of most of the recent series include meningiomas arising from the tuberculum sellae, planum sphenoidale, diaphragma sellae and/or anterior clinoid process under suprasellar meningiomas.[16,22,33] Based on the direction of growth of the tumour, the optic nerves are elevated and laterally displayed when the lesion occupies a subchiasmal position. Lesions arising from the diaphragma sellae grow retrochiasmally and manifest with ocular paresis and endocrine dysfunction. The blood supply to these tumours is predominantly from the posterior ethmoidal arteries and, to some extent, from the smaller branches of the anterior cerebral arteries. This is the area of vital arterial perforators.

CLINICAL FEATURES

The mean age of occurrence is the fourth decade, with a female predominance in a ratio of 3:1.[10]

As these tumours arise in close proximity to the optic chiasma, displacing it posteriorly and superiorly and stretching it, visual symptoms are early and common, leading to earlier detection than olfactory groove meningiomas. Around 90–99% of the patients complain of either monocular (55%) or binocular (45%) visual loss.[16,33] In our series of 50 cases, 34 patients presented with binocular and 11 with monocular visual loss. Forty of these patients had primary optic atrophy and only three had papilloedema. The other common symptoms are headache, epilepsy and mental changes. The presence of bitemporal hemianopic field defects in the presence of a normal sized sella, should suggest the possibility of a suprasellar meningioma. The 'chiasmal syndrome'; primary optic atrophy with bitemporal field defect in adult patients with an essentially normal sella, has been the classic presentation of these tumours, since its recognition in 1927 by Holmes and Sargent,[13] which was later emphasised by Cushing.[7]

However, in the early stages, vision may be affected in only one eye. Symon and Rosenstein[33] found symmetrical visual deficits in 22 cases, whilst 79 cases in a series of 101 suprasellar meningiomas had either asymmetrical binocular involvement or only monocular defects. Pituitary hypofunction is uncommon and is found in only 4–13% of these patients. The size of these meningiomas is a major factor that determines a patient's outcome. Cushing classified these tumours into four stages according to their size: (1) initial stage; (2) pre-symptomatic; (3) favourable for surgery and (4) late, or essentially inoperable.[6]

Anosmia is rarely a presenting in these meningiomas. Poppen found that suprasellar meningiomas present with early visual deficits, while anosmia is a late finding.[26]

RADIOLOGY

Abnormalities in the plain X-rays are seen in 60% of cases.[33] Plain X-rays may show a thickening in the region of the tuberculum sellae or erosion of the dorsum sellae, planum sphenoidale or clinoids. Rarely, calcification in the region may simulate a craniopharyngioma.

The CT scan typically shows an isodense or slightly hyperdense, rounded, mildly lobulated, densely enhancing mass in the suprasellar area. There can be bony hyperostosis at the site of dural attachment to the bone. This may be associated with expansion of the underlying sphenoid sinus, a finding that can be recognised on CT scan and X-ray skull. Such erosion and extension into the subfrontal sinuses has been reported in up to 15% of cases.[9]

MRI with MRA gives additional information about encasement and displacement of vessels and also a more precise extent of the lesion (Figs 3A to F and 4).

In spite of the great advances in CT and MRI, it may not always be possible to differentiate a meningioma from a pituitary macroadenoma by imaging alone. Taylor et al.[34] have proposed a combination of three features in a meningioma that may differentiate it from a pituitary tumour in a gadolinium enhanced MR. These are: (1) bright homogeneous enhancement with gadolinium as opposed to heterogeneous relatively poor enhancement in a pituitary tumour; (2) a suprasellar rather than a sellar epicentre of the tumour and (3) tapered extension of an intracranial tumour base, described as the 'dural tail' which represents a hypervascular non-neoplastic process, not the meningioma.[19] Such a differentiation is worthwhile as the surgical approaches to these lesions are different. Angiography, in addition to showing a vascular tumour in the suprasellar area, may show displacement of the ICA inferiorly (closure of the siphon), posteriorly and laterally and elevation of the A1 segment of the ACA and proximal part of the A2. Narrowing or irregularity of the ICA suggests encasement of the artery by the tumour.

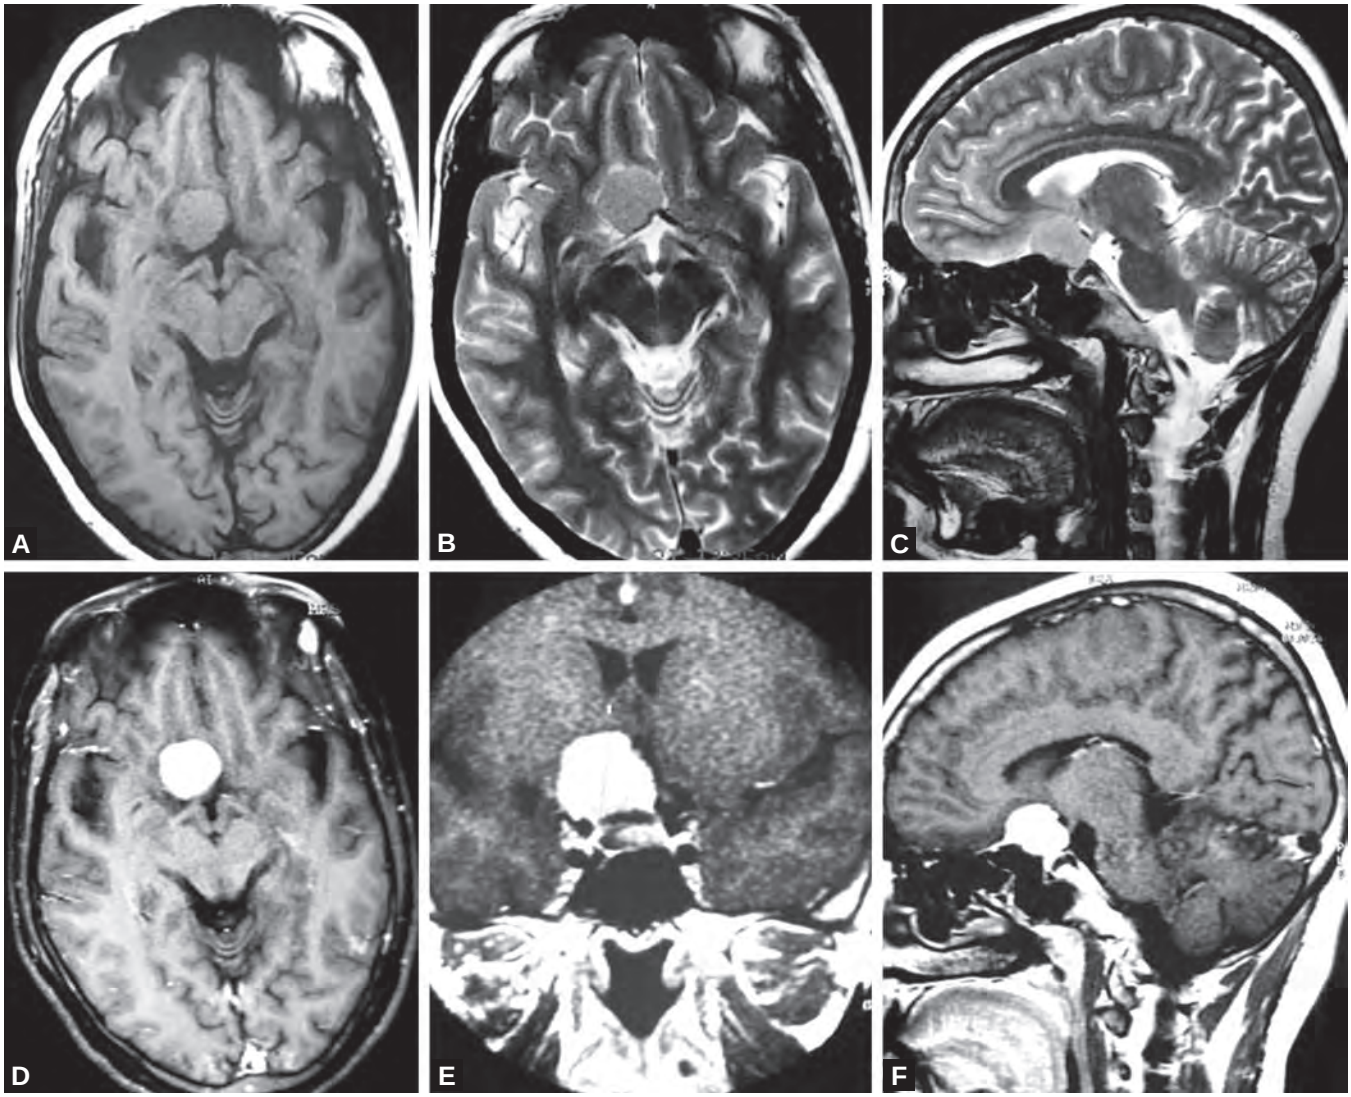
SURGICAL MANAGEMENT

Surgery for tuberculum sellae meningiomas presents a special challenge because of their proximity to arteries of the anterior circulation, anterior visual pathways and the hypothalamus.

The tumour is usually approached by a right frontotemporal craniotomy through a lateral subfrontal microsurgical exposure just in front of the lesser wing of the sphenoid. The tumour is approached from the left side, if the tumour arises from the left anterior clinoid or if the bulk is greater on that side. Occasionally, the tumour grows into the optic canal, necessitating its deroofing for complete extirpation. AI Mefty1 has advocated a basal approach, supraorbital-pterional, to minimise brain retraction and shorten the dissection distance. The best chance of total excision is at the initial operation. Elective partial excision of the tumour followed by a second-stage attempt for total extirpation is usually not successful. The author has never found this strategy helpful in basal meningiomas, as these tumours do not get separated from the vital structures in the intervening period.

Nakamura et al. removed 72 tuberculum sellae meningiomas microsurgically using three different surgical approaches: (1) the bifrontal approach; (2) pterional/frontotemporal approach and (3) the frontolateral approach. Considering the operative morbidity and mortality, the frontolateral and pterional approach provided remarkable improvement, compared with the bifrontal approach. These approaches allowed quick access to the tumour and were minimally invasive with less brain exposure, with high rates of total tumour removal. By comparison, the frontolateral approach provided the best results concerning visual outcome (77.8%) while representing the least invasive surgical approach.[20]

In our series of 50 patients, total excision was achieved in 28 patients, radical excision in 12 and subtotal in 10 patients. Three patients had total visual improvement 18 had partial improvement, in 17 the vision remained the same as pre-operative and in 10 cases the vision worsened. Our mortality was 5 cases (10%).



Figs 3A to F: Pre-operative MRI of the brain showing a suprasellar meningioma which is isointense to brain in T1 and isointense to hyperintense in T2. Post-contrast images show uniform brilliant enhancement with dural tail

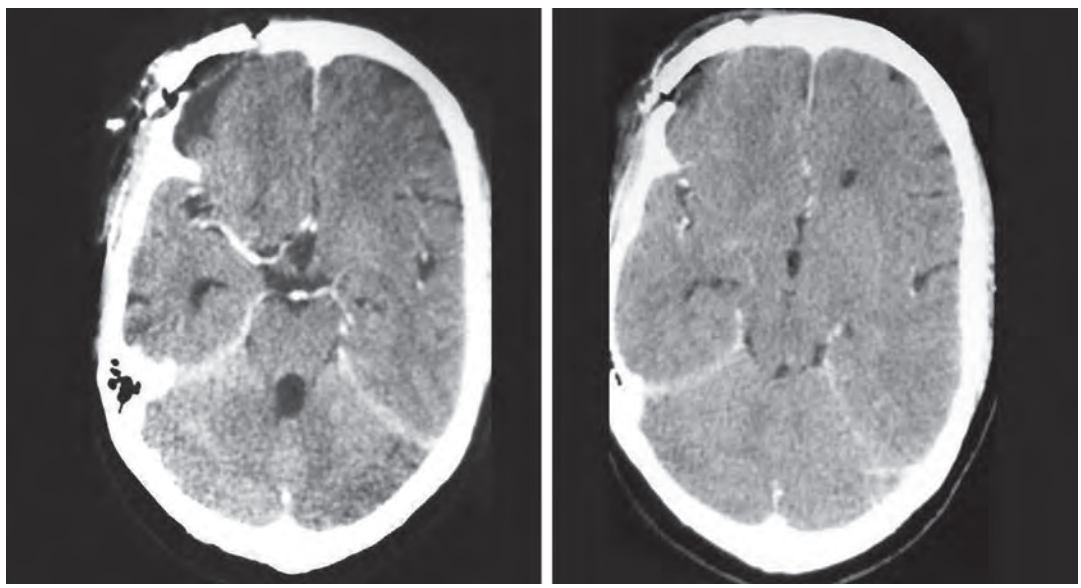


Fig. 4: Post-operative contrast CT scan of the brain showing evidence of craniotomy and total excision of the lesion with post-operative changes

In the series of 101 patients reported by Symon and Rosenstein,[33] total excision was achieved in 78.2% with a mortality of 5.9%. In their series, vision improved, remained static and deteriorated in 63.6%, 12.1% and 24.2%, respectively. In the SCTIMST series, total excision was achieved in 77% of 32 patients operated upon over a period of seven years with a mortality of 12.5%; vision improved, remained static and deteriorated in 66.6%, 20.8% and 12.5% of patients, respectively.[16] Sinha and Prakash[27] reported total excision in 42.8% of 14 patients operated upon over 10 years with one post-operative death.

Fahlbusch reviewed 47 cases of suprasellar meningiomas operated via a unilateral pterional approach. Complete tumour resection was possible in all but one patient. There were no fatalities and the rate of visual improvement was 80%. The best prognoses were found in patients younger than 50 years and in patients in whom the duration of symptoms was less than 1 year. The overall tumour recurrence rate was 2.1% (one of 47 cases). For patients in whom long-term (more than 5 years) follow-up data were available, the recurrence rate was 4.2% (one of 24 cases). In their series, complete resection of suprasellar meningiomas was possible through a unilateral pterional craniotomy and was associated with a low morbidity rate and no deaths.[11]

Pamir et al.[24] and Jallo[15] have also found that the standard pterional craniotomy using microsurgical technique provides the necessary exposure enabling total removal, while keeping the complications to a minimum.

Other Surgical Approaches

Cook et al.[4] described the benefits of the direct endonasal trans-sphenoidal approach for removal of suprasellar meningiomas. All patients underwent tumour removal via an endonasal approach with the operating microscope. Suprasellar exposure was facilitated by removal of the posterior planum sphenoidale. Ultrasound was used to help define tumour location before dural opening. The extent of tumour removal was verified with angled endoscopes in all patients and with intra-operative MRI in one patient. The surgical dural and bony defects were repaired in all patients with abdominal fat, titanium mesh and 2–3 days of cerebrospinal fluid lumbar drainage. Nasal packing was not used. The anterior skull base defect was reconstructed with a pedicled mucosa flap from nasal septum (Hadad-Bassagasteguy flap). They concluded that the endonasal approach with the operating microscope appears to be an effective minimally invasive method for removing relatively small midline tuberculum sellae meningiomas. Intra-operative ultrasound, the micro-Doppler probe and angled endoscopes are useful adjuncts for safely and completely removing such tumours.

Exclusive endoscopic endonasal approaches have also been described for the removal of tuberculum sellae meningiomas.[28] More recently, the sublabial trans-sphenoidal approach has been used to remove such tumours.

Results

Mortality and partial resection rates were lower and prognosis for visual function following craniotomy was better, if the mean duration of symptoms was less than two years and the tumour size was less than 3 cm.[33] Other factors that favourably influenced the prognosis for vision were a normal optic disc and a pre-operative visual loss of less than 50%. Tumours arising from the diaphragma sellae and anterior clinoid had a worse visual outcome.[2,16]

Puchner et al.[29] in their series with long-term follow-up (mean: 5.7 years), could achieve radiologically confirmed radical tumour removal in 84% of patients. However, 12% of patients developed late onset epilepsy. At long-term follow-up, visual function was improved in 67%, unchanged in 9% and worsened in 24%. In more than 50% of patients, the vision showed recovery over a longer time period than the first 10 days after operation. Radiographic control examinations revealed tumour recurrences in 2 patients (both asymptomatic) and progress of residual tumour in 5 patients (2 symptomatic, 3 asymptomatic). They concluded that with the introduction of modern neurosurgery, a clear improvement in the surgical treatment of suprasellar meningiomas can be observed. However, the long delay in diagnosing these tumours correctly prevents a further improvement of the ophthalmological results at long-term follow-up. Due to a relatively high rate of late onset epilepsy, anticonvulsive prophylaxis for 6 months seems to be justified.

Kim et al.[18] in their study on 27 patients, found those with symptom duration of less than 1 year had a greater likelihood of visual improvement than those with a symptom duration of more than 1 year and those with a soft tumour had a greater likelihood of visual improvement than those with a hard tumour, although this was without statistical significance. Also, patients with a high signal intensity lesion on T2-weighted images had a greater likelihood of visual improvement than those with an iso or low signal intensity with statistical significance. They concluded that an excellent correlation exists between tumour consistency and appearance on T2-weighted images ($p = 0.001$) and the results of their study indicate that MRI-T2WI can be used to estimate tumour hardness pre-operatively and that this is an important prognostic factor in visual impairment.[18]

ADJUVANT THERAPIES

Meningiomas, which invade intracranial bone structures and the adjacent areas, are frequently unresectable because of their aggressive and recalcitrant growth behaviour. Also, surgically inaccessible meningiomas may not be removed completely. They have a high recurrence rate and in approximately 10% of these tumours

there is an increased risk of malignancy. Significant morbidity and mortality rates associated with recurrent meningiomas demand non-surgical approaches. There is currently no effective chemotherapy for meningiomas and adjuvant hormonal treatment has not proven beneficial.

Gupta et al.[12] studied the effects of the topoisomerase I inhibitor irinotecan (CPT-11) on primary meningioma cultures and malignant meningioma cell line and demonstrated growth-inhibitory effects in meningiomas both *in vitro* and *in vivo*. Irinotecan was much more effective against the malignant meningioma cell line than against primary meningioma cultures. Therefore, this drug may have an important therapeutic role in the treatment of atypical or malignant meningiomas and should be evaluated further for this purpose.

The anticancer drug hydroxyurea has been tested for its potential use in the treatment of meningiomas. The addition of 5 x 10(-4) and 10(-3) M hydroxyurea over a period of 5–9 days resulted in a remarkable decrease in cell proliferation and even blocked tumour cell growth, when compared with untreated cells. A significant arrest of meningioma cell growth in the S phase of the cell cycle was revealed on DNA flow cytometry. Electron micrographs of hydroxyurea-treated tumour cells showed ultrastructural features consistent with apoptosis and light microscopy demonstrated DNA fragmentation by *in situ* DNA strand break labelling. Short-term treatment of meningioma cell cultures with hydroxyurea for 24–48 hours resulted in discrete oligonucleosomal fragments (DNA ladder), another characteristic sign of apoptosis. In addition to the *in vitro* studies, tissue from five different meningiomas was transplanted into nude mice followed by treatment with 0.5 mg/g body weight hydroxyurea over 15 days. *In situ* DNA strand break labelling demonstrated DNA fragmentation in distinct regions with different tumour cell densities in all hydroxyurea-treated meningioma transplants. These data provide evidence that hydroxyurea is a powerful inhibitor of meningioma cell growth, most likely by causing apoptosis in the tumour cells. Thus, hydroxyurea may be a suitable chemotherapeutic agent for the long-term treatment of unresectable or semi- to malignant meningiomas or for preventing recurrent growth of meningiomas after resection.[21,30]

Black et al.[3] based on their results, advocated that skull base meningiomas can be managed with aggressive surgery and conformal radiation with an acceptable functional status in 99% of cases. Fractionated stereotactic conformal radiosurgery (SCRT) is a feasible high precision irradiation technique for residual and recurrent skull base meningiomas, including both small and larger tumours with excellent early tumour control and low toxicity. Longer follow-up is necessary to demonstrate sustained tumour control and low morbidity of such a high precision localised method of fractionated irradiation.[8,14]

Intensity modulated radiotherapy (IMRT) in the treatment of central nervous system meningiomas is feasible and safe, offering highly conformal irradiation for complex-shaped skull-base tumours, while sparing adjacent critical structures. If the tumour remissions seen here are found in the ongoing treatments, IMRT may be considered the treatment of choice for inoperable or subtotally resected meningiomas and for otherwise difficult-to-treat, complex-shaped tumours of the central nervous system adjacent to critical structures, with the potential of dose escalation for malignant tumours.[25]

169 Sphenoidal Wing Meningiomas

Trimurti D Nadkarni

INTRODUCTION

Meningiomas account for 14–18% of all intracranial neoplasms. Meningiomas arising from the sphenoid ridge constitute approximately 14–20% of all meningiomas.[4,5] The complexity of these tumours is due to the involvement of the anterior circulation, anterior visual pathways and oculomotor nerve. Higher morbidity, mortality and recurrence rates have been observed for these tumours than for meningiomas in other locations.[4,5,7] The rate of recurrence for medial sphenoid wing meningiomas is reported as one of the highest for intracranial meningiomas.[11]

Two main types of tumours have been described according to their presentation: globoid tumours with a nodular shape and en plaque tumour.[7] The nodular type is an encapsulated tumour of variable size that displaces or encases intracranial arteries or cranial nerves (CNs). This tumour has a dural site of implantation through which it receives its blood supply. In meningioma en plaque, the tumour cells fill the haversian canals spreading into the adjacent bones that include the pterion, orbital wall, malar bone, zygomatic, temporal and middle cranial fossa. The tumour produces a hyperostotic reaction of these structures causing exophthalmos and temporal bowing. In addition, an intracranial meningiomatous plaque is always present.

Cushing and Eisenhardt[7] have classified these tumours based on their site of origin along the sphenoid wing as inner third, middle third and outer third tumours. Inner third tumours have been subdivided into sphenocavernous tumours [(arising from the external wall of the cavernous sinus (CS)] and clinoidal tumours (arising from the clinoid process). Middle third tumours or alar tumours and the outer third or sphenotemporal or pterional tumours present with symptoms due to compression. Additional classifications have been put forth: Petit-Dutaillis, Bonnal et al.,[6] Al-Mefty,[2] and Sekhar and Altschuler.[18]

CLINICAL PRESENTATION

Inner Third Sphenoid Wing Meningiomas

Clinoidal meningiomas produce a progressive diminution of vision beginning with ipsilateral nasal hemianopsia. As the tumour grows, a superior temporal field defect occurs and eventually the eye becomes blind. Foster Kennedy syndrome, ipsilateral primary optic atrophy associated with contralateral papilloedema, may result.

In sphenocavernous tumours, abducens palsy is the first presentation. As symptoms evolve, total ophthalmoplegia is associated with hypoesthesia in the ophthalmic division of the trigeminal nerve. Exophthalmos may result due to venous compression at the orbital apex.

Nakamura et al.[12] have subclassified this group into Group 1 comprising tumours without CS involvement and Group 2 that includes tumours with CS involvement.

Middle Third or Alar Meningiomas

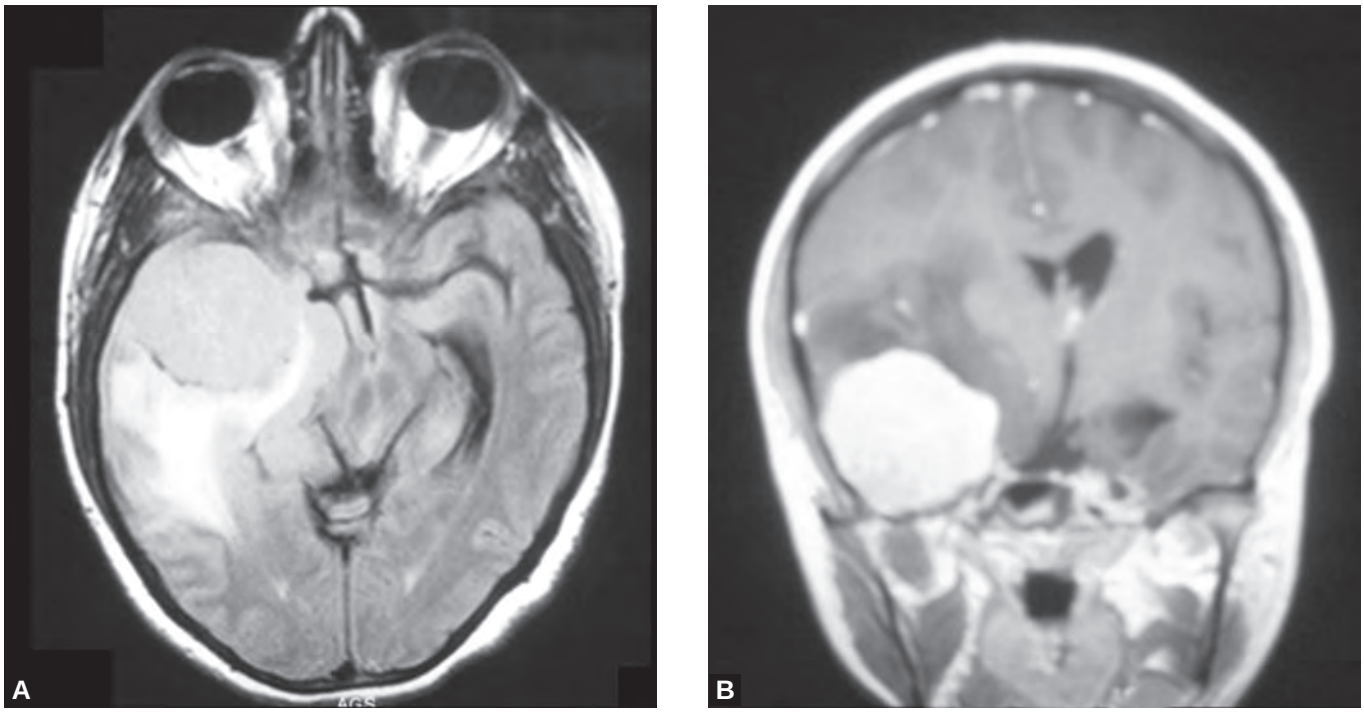
These tumours present with features of raised intracranial pressure. Headache and papilloedema are followed by anosmia, contralateral homonymous hemianopsia, personality changes, visual or olfactory hallucinations, contralateral facial palsy and hemiparesis. Seizures may occur.

External Third or Pterional Meningiomas

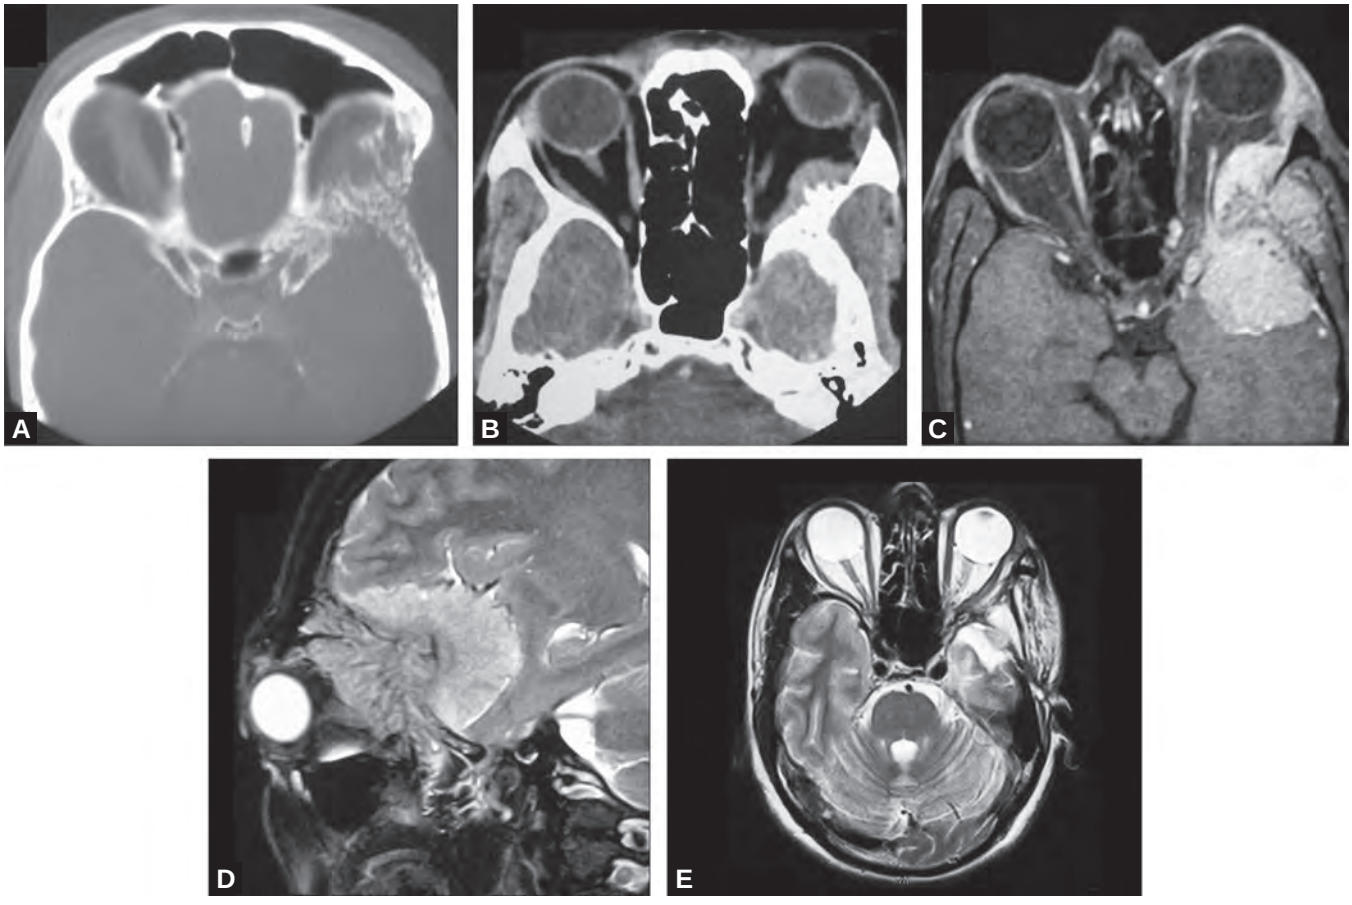
The en plaque variant presents with proptosis or chronic palpebral oedema. Skull deformities, loss of visual acuity leading to blindness, diplopia, epiphora, photophobia and seizures may occur. Globoid pterional meningiomas present with hemicranial headaches, seizures, contralateral hemiparesis and increased intracranial pressure. The tumour behaves either as a temporal or frontal mass. Signs of orbital involvement may also be present.

NEURORADIOLOGY

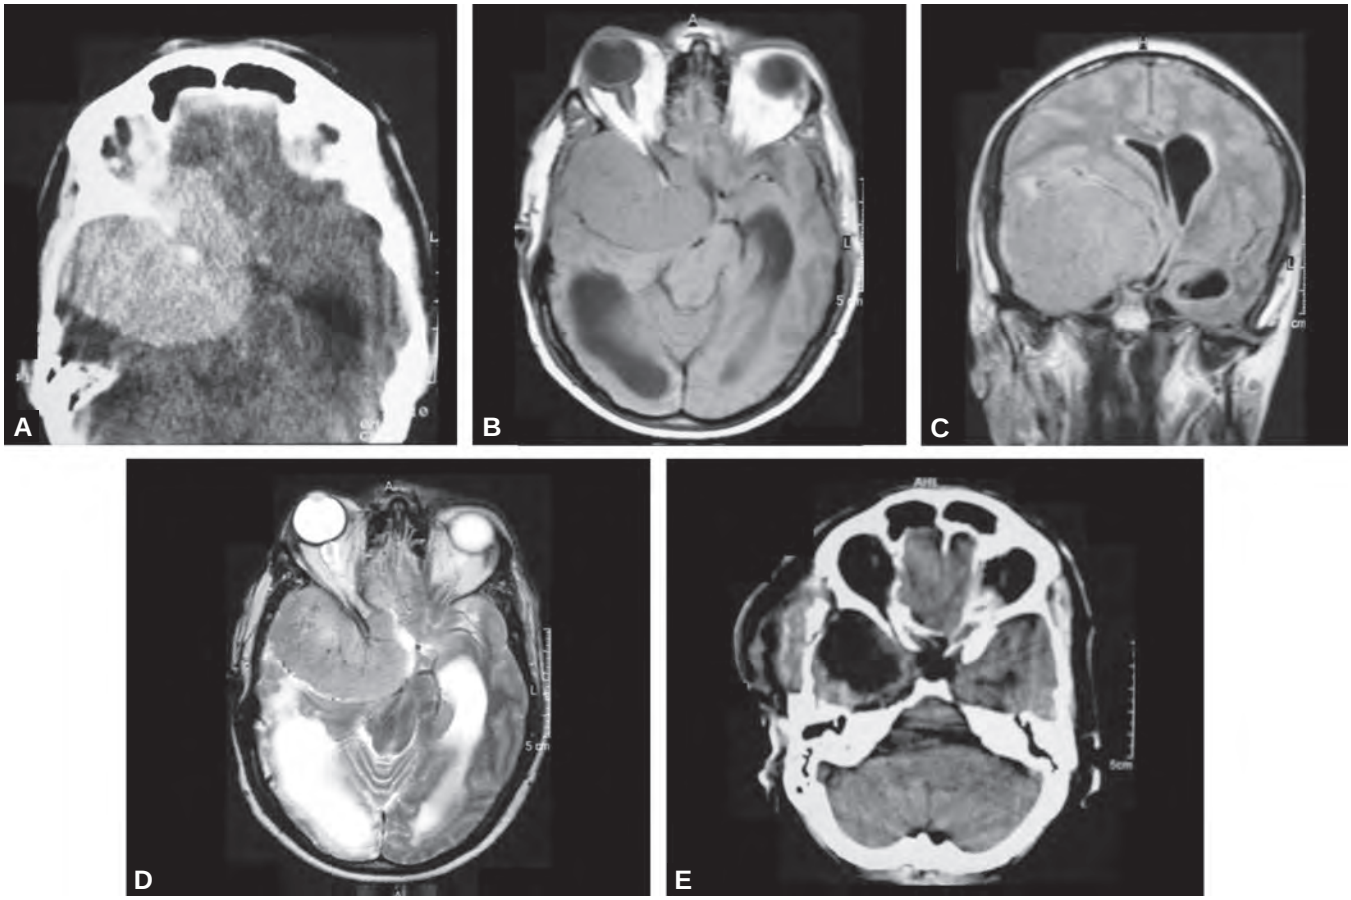
Computed tomographic (CT) and magnetic resonance imaging (MRI) have replaced the conventional radiography used earlier. Focal hyperostosis, sclerosis, erosion at the site of tumour attachment, widening of vascular grooves, superior orbital fissure and narrowing of optic canal are all demonstrated on bone algorithms and three-dimensional CT reconstruction. CT scans clearly demonstrate the bone involvement, the orbit and extension of the tumour plaque. In addition, tumour calcification and peritumoural oedema are observed (Figs 1 to 7).



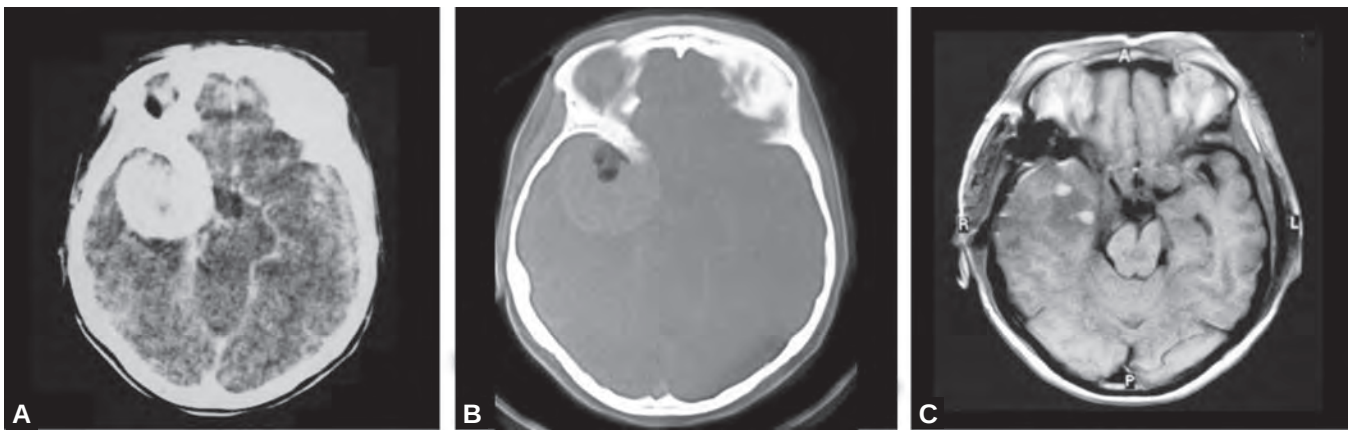
Figs 1A and B: (A) Proton-density axial MR image. (B) Post-contrast MR sagittal image shows an outer third globoid pterional meningioma



Figs 2A to E: (A) Axial CT bone algorithm shows bony hyperostosis and infiltration of anterior clinoid process, lesser sphenoid wing and pterion. (B) Axial CT scan shows the meningioma to involve the orbit, temporal muscles and middle cranial fossa. (C) Post-contrast axial MR image. (D) Post-contrast sagittal image shows the multicompartmental involvement of the en plaque tumour. (E) Post-operative T2-weighted axial image shows complete excision of the tumour



Figs 3A to E: (A) Axial CT scan. (B) Axial T1-weighted MR image. (C) T1-weighted sagittal image shows an extensive sphenoid wing tumour involving the entire ala of sphenoid bone. (D) T2-weighted MR image shows the tumour to maintain the surrounding arachnoidal plane. (E) Post-operative CT scan showing total removal

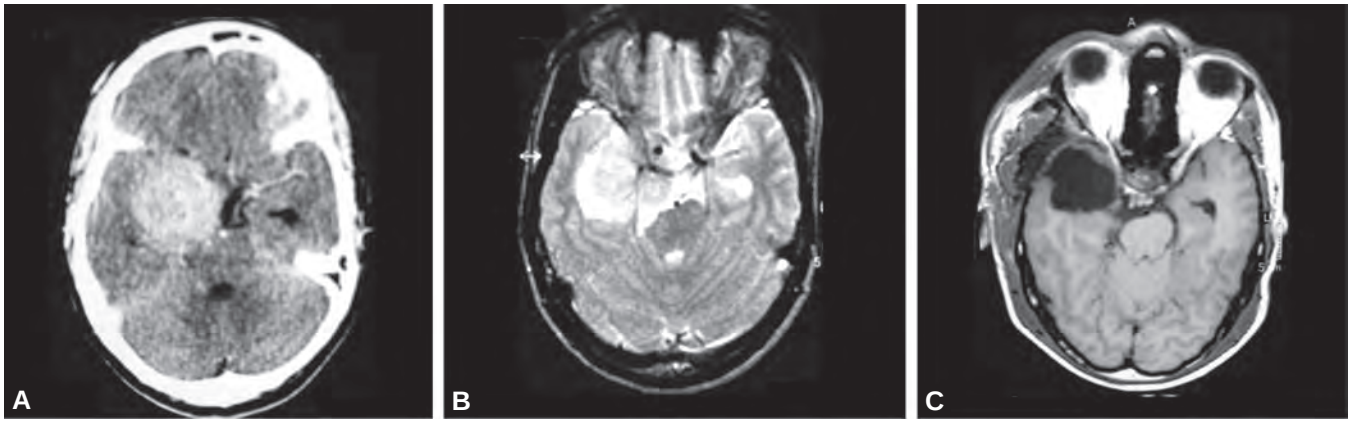


Figs 4A to C: (A) Axial post-contrast CT view shows a right clinoidal meningioma. (B) CT bone algorithm shows hypertrophy of the lesser wing and anterior clinoid. (C) Post-operative axial T1-weighted image shows complete excision of the tumour. A contused right temporal lobe is noted

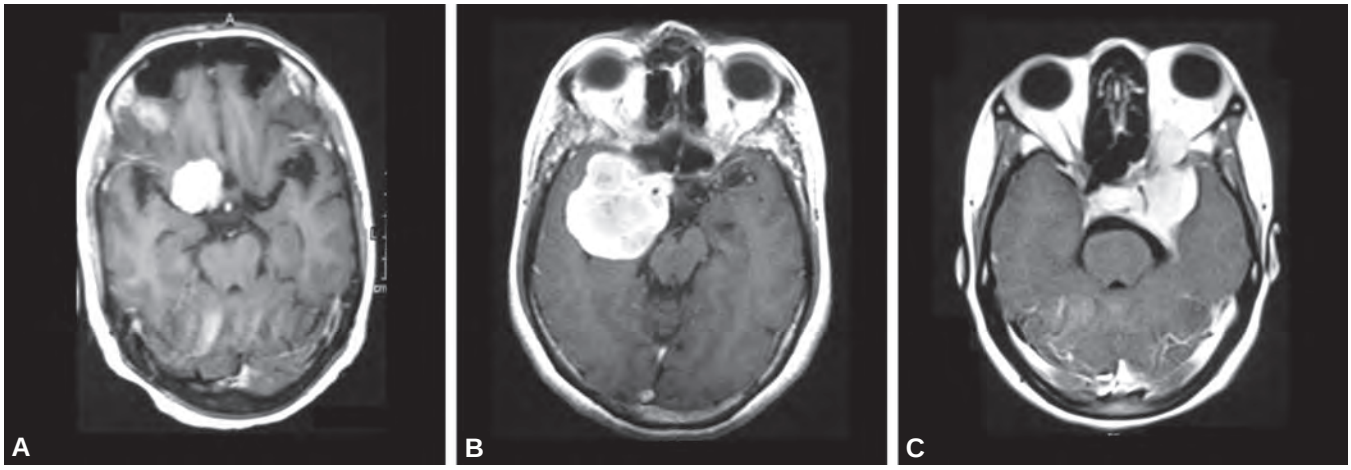
Magnetic resonance (MR) scans clearly show the intracranial extensions of the mass. Meningiomas enhance uniformly after gadolinium injection. The extent of the meningiomatous plaque and thickened adjacent dura (dural tail sign) are clearly defined. The arterial relationship of the tumour is noted as flow voids. The ICA may be encased and may be narrowed or occluded. MR angiography can be done simultaneously to demonstrate the anterior circulation in relation to the tumour. ICA encasement was more commonly seen in tumours that involved the CS.

TREATMENT

Radical excision of the tumour is the primary treatment for meningiomas and is the principle surgical goal.[2,18]



Figs 5A to C: (A) Post-contrast axial CT view demonstrates a moderate sized clinoidal meningioma. (B) T2-weighted axial MR image defines the vascular relationship along the medial border of the tumour. (C) Post-operative T1-weighted image confirms complete excision of the tumour



Figs 6A to C: Medial sphenoid wing meningiomas. Post-contrast axial MR images show: (A) A small tumour. (B) A moderate sized tumour encasing the supraclinoid carotid artery. (C) The tumour has an orbital, cavernous sinus and sellar extension

Inner third meningiomas present problems different from those of the outer third of the sphenoid ridge. Surgery is performed under general anaesthesia using an operative microscope and microsurgical instrumentation in all cases.

Sphenocavernous meningiomas arising from the outer wall of the CS, involving the oculomotor or trigeminal nerve, involve the CS and encase the ICA. In such cases total resection of the tumour is impossible. Similarly, an en plaque pterional meningiomas presenting with proptosis, frontotemporal involvement and palpebral oedema, tumour infiltrating into the dura, periorbital tissues, CS and zygomatic fossa, are difficult to operate upon. It is debatable if radical resection of tumour in the above cases should be achieved including the intracavernous component together with the encased ICA, with or without saphenous vein reconstruction.[8,19,20]

Cerebral angiography earlier used for diagnosis is now used to embolise tumour feeders to permit tumour resection without excessive blood loss.

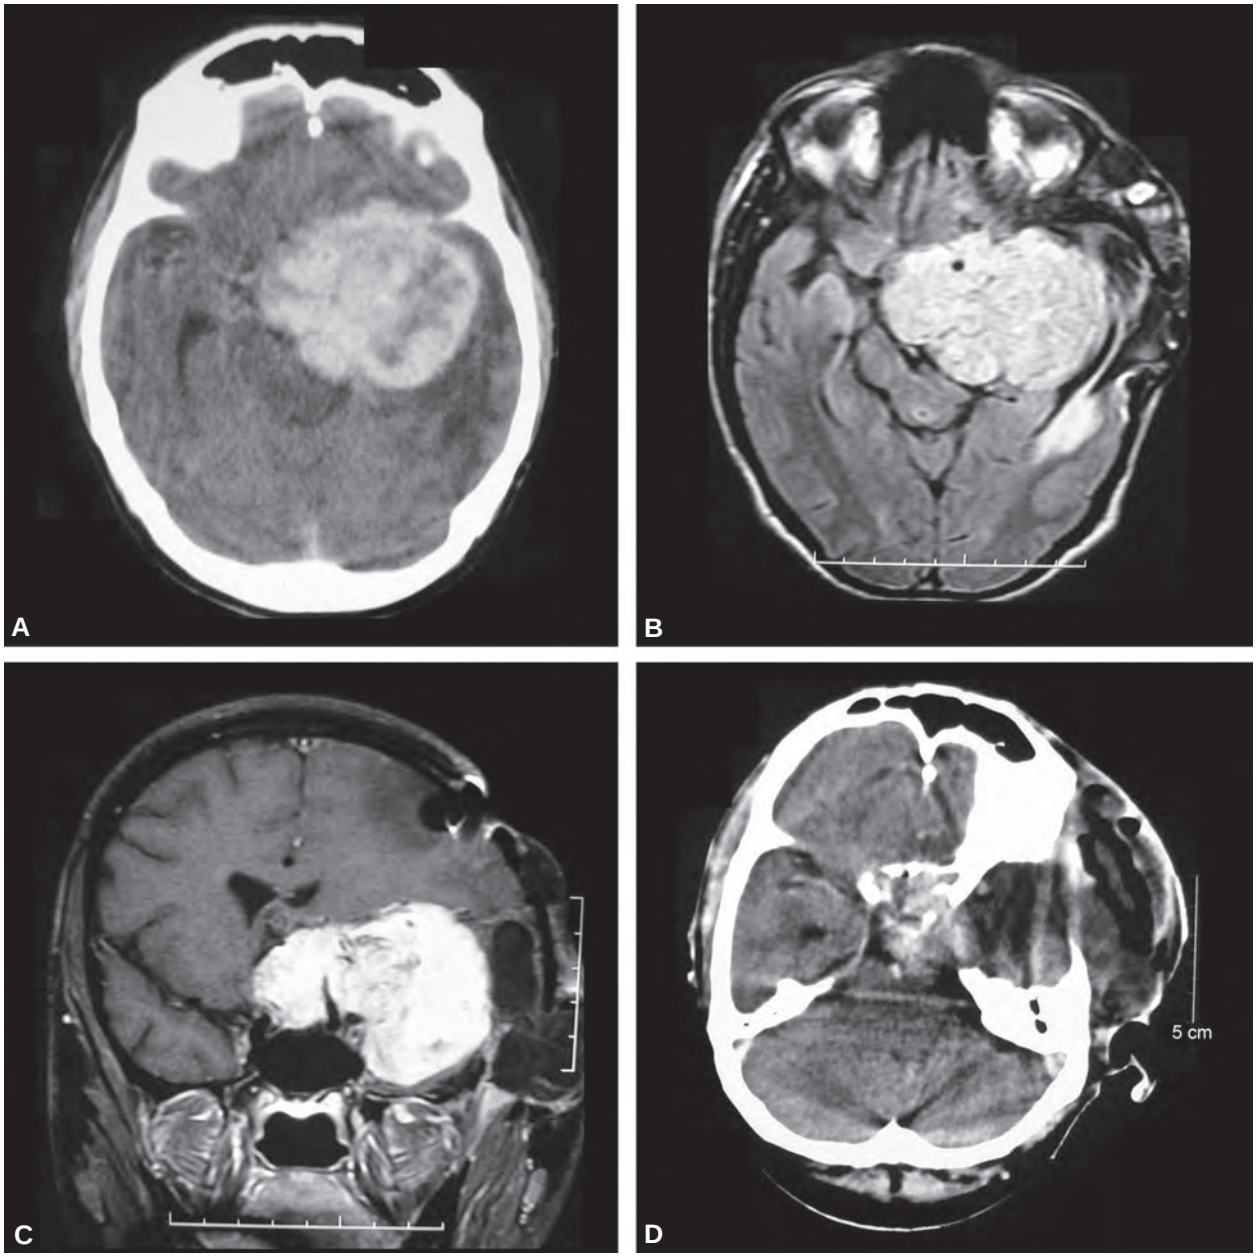
Surgical Treatment

Pterional Meningiomas

The surgery is performed in the supine position with head elevated to aid venous return and turned to the contralateral side. A frontotemporal craniotomy is performed through an incision within the hairline. This permits a wide orbital exposure and provides for a pericranial graft, if necessary. The hyperostotic thickened bone is excised, decompressing the superior orbital fissure and optic canal, along with a wide frontal craniotomy. The thickened dura, intracranial tumour and orbital extension are excised. The middle cerebral artery, carotid artery and optic nerve are preserved. The pericranial graft is used to close the resected dura. Bone reconstruction is done with methyl methacrylate, split calvarial or rib graft if required.

Inner and Middle Third Meningiomas

Clinoidal tumours have a dural attachment on the upper part of the anterior clinoid process, whereas



Figs 7A to D: (A) Post-contrast CT axial image shows a massive left medial sphenoid wing meningioma. (B) Post-contrast axial MR image. (C) Sagittal MR image shows the left carotid is encased. There is evidence of craniotomy and herniation of the brain through the craniotomy defect. (D) Post-operative post-contrast axial CT image shows a small residue in relation to the encased carotid. A large subgaleal CSF collection is noted

sphenocavernous tumours are attached to the sphenocavernous angle. The patient is in the supine position, with the head raised and turned to the opposite side. A frontotemporal craniotomy is performed. The lesser wing of the sphenoid is nibbled to the superior orbital fissure, to allow exposure of the tumour with minimal brain retraction. The tumour is debulked within its capsule. The tumour blood supply is coagulated at the dural attachment. The Sylvian fissure is widely opened and the MCA and its branches are identified in relation to the capsule of the tumour. The supraclinoid ICA, MCA and its branches need meticulous dissection to avoid vascular injury. Grade I Simpson excision of a clinoidal meningioma is possible. For sphenocavernous tumours, extracavernous extirpation with coagulation of dural attachment is advised (Simpson Grade II). In tumours with CS invasion, the CS is opened through its superior wall, the optic canal is opened and tumour is excised. The intracavernous portion of the tumour was not radically removed in 85.5% of cases to prevent any new cranial neuropathies.[12] In 14.5% of cases where only the lateral or superior walls of the CS were involved, the wall was peeled off and carefully coagulated. CSF leak and infection are carefully avoided by using pericranial graft and fibrin glue.

Surgical Complications

The most common surgical complication is post-operative subcutaneous cerebrospinal fluid collection and

hydrocephalus. Post-operative infarction of the middle cerebral artery territory occurred in 3.7% of patients.[12] The other complications seen were haemorrhage, brain oedema and meningitis.

Results

Basso et al.[4] reported that 81.37% had good results (no sequelae) and an operative mortality of 4.13%. Of the six deaths, four resulted from cerebral infarction and the other two from severe cerebral oedema. The use of microsurgical techniques has improved mortality and morbidity rates. The main causes of fair (minor sequelae) and poor (severe sequelae) results were extraocular muscle dysfunction, persistent exophthalmos, hemiparesis and visual impairment. Patients presenting with CN deficits and previous surgery did not show recovery of CN function after removal of recurrent tumour. Patients with new post-operative CN deficits showed much better recovery.[12]

Meningiomas of the skull base are associated with the highest rate of tumour recurrence, related to their wide dural attachment, invasion of the CS, invasion of the underlying bone and extension of the tumour through the foramina and fissures of the skull base into the orbit and zygomatic fossa. Basso et al.[4] have reported a 20.54% recurrence rate at 10 years. All of these received radiotherapy and 14 of 15 were re-operated. The mean time of recurrence was 6.7 years after surgery. Radiotherapy appears to halt the growth of the tumour.[3]

The extent of tumour resection can be classified according to Simpson's classification.[21] Grade I: total resection with excision of infiltrated dura; Grade II: total tumour resection and coagulation of dural attachments; Grade III: gross total resection without excising dural attachment or extradural extension (e.g. infiltrated sinus or bone) and Grade IV, subtotal tumour resection.

GAMMA KNIFE SURGERY FOR MENINGIOMAS OF THE SPHENOIDAL WING

Radiotherapy for meningiomas has been used in recurrent or partially resected tumours, especially when performed to avoid neurological morbidity. As the sphenoid bone forms the lateral and posterior walls of the orbit, these tumours involve the periorbital structures. The tumour displaces rather than invades the orbital contents. Tumour growth has been effectively controlled with a dose of 9 Gy, tolerable to the optic pathway and nerves within the CS. The dose limit for the optic nerve is 8 Gy, 15 Gy for the third, fourth and sixth CNs and 13 Gy for the fifth CN. The tumour responds within 4–20 months. Growth arrest and reduction in tumour volume is achieved in 90% of cases.[16] Actual tumour growth control rates after gamma knife radiosurgery of CS meningiomas ranged from 86.4% at 3 years to 96.5% at 5 years.[16] Neurological status improved after gamma knife surgery in 28.6%, remained stable in 62% and deteriorated in 9%.[10]

MEDIAL SPHENOID WING OR CLINOIDAL MENINGIOMAS

Clinoidal meningiomas are formidable tumours to resect when their size is large and when they involve the optic nerve, ICA and their branches and the oculomotor nerve. During 1938–1982, the rates of total resection ranged between 23% and 50%, and associated mortality rates ranged from 15 to 43%.[7,14] Since 1990, resection rates have been 59–83% with mortality rates between 6% and 14.5%.[1,2,15,17] Goel et al.[9] have classified tumours based upon the extent of visual impairment, size of tumour and the tumour relationship with the internal carotid artery. The grading system is used to plan the operative strategy, anticipating the extent of resectability and possible difficulties in dissecting the carotid artery and optic nerve during the operation. Many neurosurgeons, recognising the relatively high incidence of poor post-operative outcome, prefer to perform a conservative subtotal resection with or without post-operative radiotherapy and some surgeons have recommended radiotherapy as the sole treatment.[13]

Al-Mefty[1,2] has identified three distinct groups of clinoidal meningiomas on the basis of the site of tumour origin and the presence/absence of the arachnoidal plane between the tumour and the ICA.

Group 1 tumours are those encasing and directly attaching to the ICA adventitia, without a definable arachnoidal plane between the tumour and ICA. Total resection is not possible in these cases. Tobias et al.[22] did not encounter a single Group 1 tumour.

Group 2 consists of tumours with a separate arachnoidal plane between the tumour and the ICA that facilitates total removal.

Group 3 tumours are actually optic nerve sheath or optic foramen meningiomas and not truly clinoidal tumours.

Unilateral visual loss is the most common clinical presentation of these tumours. The visual impairment occasionally involves the contralateral eye. The deterioration is in both visual acuity as well as fields. The other presentations include headaches, diplopia, seizures, facial pain, proptosis and ptosis.

The skull base surgical technique involves the following steps:[22] (1) frontotemporal craniotomy; (2) sphenoid ridge drilling; (3) limited posterior orbitotomy; (4) posterolateral orbital wall removal (or osseous decompression of the superior orbital fissure); (5) optic canal unroofing; (6) extradural complete anterior clinoidectomy and (7) optic nerve sheath opening.

The intracranial tumour is excised as described previously. If the CS involvement is extensive and the tumour is fibrous, surgery is stopped after confirmation of the following:

1. Gross-total resection of the intradural extracavernous portion of the tumour and removal of any accessible tumour-involved dura.
2. Decompression of the optic nerve.
3. Decompression of the oculomotor nerve.

Using the above techniques Tobias et al.[22] have reported a total resection rate of 77% and improved visual outcome rate of 71%. By performing the skull base technique, the exact location of the ICA and optic nerve are known early in the surgery. Improved surgical access allows for aggressive removal of tumour, involved bone and surrounding dura (Simpson Grade 2 or even Grade 1 in some cases). Visual improvement was observed in 56% and was preserved at the pre-operative level in 44% of patients in those without CS involvement. However, in those with CS involvement, vision improved in 30% and was stable in 60%.[12]

In conclusion, total resection of clinoidal meningiomas is feasible with an excellent visual outcome, keeping the surgery related morbidity low, by the use of skull base technique. Tumours without involvement of the CS have better resection, less recurrence and neurological improvement. The CS tumours are best managed with adjuvant radiosurgery.

170 Tentorial Meningiomas

Vijendra Kumar Jain, Sanjay Behari, Pramod Giri

INTRODUCTION

Tentorial meningiomas (TM) are relatively uncommon lesions accounting for 2–9% of all intracranial meningiomas and 30% of posterior fossa meningiomas.[6,14,39] In 1833, Antral first reported the presence of a tentorial meningioma as an incidental finding.[50] These tumours remain a formidable challenge for a surgeon since critical neural and vascular structures are often intimately involved by these lesions. Recent advances in skull base surgical techniques have facilitated more aggressive approaches for removing these tumours while maintaining acceptable rates of morbidity and mortality. High definition computed tomography, magnetic resonance imaging and digital subtraction angiography have also facilitated meticulous pre-operative surgical planning in recent times.

RELEVANT MICROSURGICAL ANATOMY

Tentorium

The tentorium separates the cerebellum from the temporal and occipital lobes and contains an opening in the centre, known as the incisura, connecting the supratentorial and infratentorial compartments. The apex of the tent shaped tentorium is formed by the posterior edge of the incisura. From the apex, the tentorium slopes downwards up to its bony attachments to the temporal, occipital and sphenoidal bones. It has three borders, namely, anterior (attached to the petrous ridge and enclosing the superior petrosal sinus) and lateral and posterior (attached to the temporal and occipital bones at the groove of the transverse sinus and internal occipital protuberance) enclosing the transverse sinus and torcula.

The free edge of the tentorium is attached anteriorly to the petrous apex and anterior and posterior clinoid processes. Between these three structures lies the oculomotor trigone through which the IIIrd and IVth cranial nerves enter the cavernous sinus. From the anterior part of the free edge of the tentorium, the dura mater slopes steeply downwards to form the lateral wall of the cavernous sinus and the base of the middle cranial fossa. In the posterior part of the tentorium, the falx cerebri fuses with the dorsal surface of the tentorium in the midline behind the apex and encloses the straight sinus in the falcotentorial junction.

The tentorial incisura is triangular, its anterior edge is based on the dorsum sellae and its apex is dorsal to the midbrain, just posterior to the pineal gland. Its width varies from 26 mm to 35 mm and the anteroposterior diameter from 46 mm to 75 mm. For further details reference may be made to Textbook of Operative Neurosurgery [Ravi Ramamurthi, K Sridhar, MC Vasudevan (Eds) 2005]. Bisaria (1983) described the developmental defects of the tentorium cerebelli with which one should be familiar.

Dural Venous Sinuses

From the torcula, at the level of the internal occipital protuberance, the transverse sinus extends laterally and continues as the sigmoid sinus. The occipital sinus extends inferiorly in the midline of the posterior fossa dura and the superior sagittal sinus joins the torcula from the superior aspect. The straight sinus continues within the leaves of the tentorium in the midline and joins the confluence of the transverse sinuses. The superior petrosal sinus runs along the superior petrosal ridge from the cavernous sinus to the transverse-sigmoid junction. Often, the transverse sinuses are asymmetrical with the right side being dominant.[24] The temporal anastomotic vein of Labbe courses back on the surface of the temporal lobe from the superficial middle cerebral vein to join the transverse-sigmoid sinus junction (Bisaria 1983).

Blood Supply of the Tentorium

The anterior and medial portions of the tentorium are supplied by branches of the meningohypophyseal trunk namely: the artery of Bernasconi and Cassinari (the basal tentorial artery) and the artery of the inferior cavernous sinus (the marginal tentorial artery). These are branches of the cavernous carotid artery. The posterior tentorial margin and apex are supplied by branches from the posterior cerebral and superior cerebellar arteries, as well as from the meningeal branches of the external carotid and vertebral arteries. The relative tumour blood supply from the meningohypophyseal trunk is approximately 48%, from the posterior middle meningeal vessels 14%, the occipital artery 45%, the vertebral artery 3.4%, the ascending pharyngeal artery 3.4% and the vertebrobasilar artery 8%.[5,14,30,39]

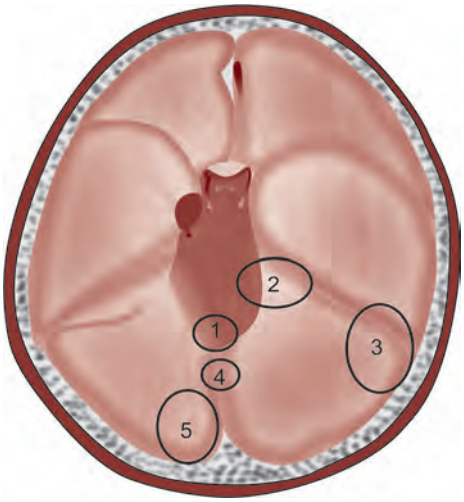

Fig. 1: Schematic diagram showing various locations of TM. 1: Medial tentorial edge; 2: Lateral tentorial edge; 3: Attached margin of tentorial leaf; 4: Falcotentorial; 5: Torcular

CLASSIFICATION (FIG. 1)

TM may have supratentorial, infratentorial or combined supra and infratentorial growth (perforating meningiomas).[14] The true dural attachment is often not reliably defined, because the tumour may extend to the tentorium after originating from the dura of the petrous bone, clivus, anterior clinoid, falx, and transverse and sigmoid sinuses. Cushing and Eisenhardt included TMs in the peritorcular, subtentorial and recess tumours group.[11,12] Castellano et al. analysed Olivecrona's series of posterior fossa meningiomas and described a subgroup of TMs.[9] Mallis has divided TMs into: (a) parasellar; (b) petroclival tentorial angle; (c) tentorial apex; (d) tentorial leaf and (e) torcular.[23] Sugita and Suzuki divided these TMs into medial, lateral and falcotentorial and further sub-grouped the medial and lateral ones into anterior, middle and posterior tumours.[43] Guidetti et al. divided TMs into free edge, petrous ridge, posterolateral, posteromedial and central tentorial.[14] Bassiouni et al. have modified Yasargil's classification of TM as: T1-2: medial; T3-8: falcotentorial; T4: paramedian; T5: peritorcular; T6-7: lateral and falx cerebelli.[49] Bret et al. distinguish the various subtypes of TM according to their relationships to the free edge (inner ring) and to the peripheral tentorium (outer ring). Thus, group I includes anteromedial meningiomas arising from the apex of the tentorial margin; group II includes anterolateral TM arising from the lateral aspect of the tentorial margin; group III includes TM arising from the intermediate aspect of the tentorium remote from the incisura and also from the dural venous sinuses; group IV includes TM arising from the posteromedial aspect of the tentorium close to the venous confluence and group V includes TM arising from the posterolateral aspect of the tentorium close to the sigmoid sinus. All these categories may have a supratentorial and infratentorial extension.[6] Rostomily et al.[32] have classified TM into two categories—those lesions with primary or exclusive involvement of the tentorium are considered as primary TM and may further be sub-divided into medial (incisural or free edge), lateral (tentorial leaf/transverse sinus), falcotentorial or torcular and complex tentorial meningiomas, including parasellar, cerebellopontine angle and petroclival meningiomas.[32]

SIGNS AND SYMPTOMS

The majority of patients are women (approximately 60%) who present in the fourth and fifth decades. The most common presentations of TM include headache, seizures, raised intracranial pressure, papilloedema, bilateral sixth nerve palsy and cognitive disturbances.[13,14] Tumours with extension into the occipital lobe may produce homonymous hemianopia, while those with posterior fossa involvement may present with cerebellar and long tract signs, multiple cranial nerve palsies and hydrocephalus. TMs involving the tentorial incisura may present as fourth nerve palsy and brainstem compression syndrome, while tumours extending up to the posterior third ventricular region may present rarely as Parinaud's syndrome; those with cerebellopontine angle extension may also present with Vth, VIIth, VIIIth, IXth and Xth cranial nerve involvement with cerebellar signs and those extending into the anterior clinoid, cavernous sinus and suprasellar region may produce IIIrd, IVth, Vth and VIth nerve palsies and visual disturbances. Other reported presentations may include impaired mentation, trigeminal neuralgia, hemifacial spasm, gelastic seizures, pituitary and hypothalamic disturbances and predominant contralateral signs due to brainstem distortion.[27,45] Syringomyelia may be associated with TMs, perhaps due to tumour induced tonsillar herniation.[34,44,48] In one patient, resolution of cluster headaches following resection of a TM has been reported. Bret et al.[6] have reported hearing impairment in nearly 30% of their TMs. They have proposed the mechanism of tumour interference with the central auditory pathways, since hearing impairment occurred even when the tumour was remote from the cerebellopontine angle.[6]

INVESTIGATIONS

Computed Tomography and Magnetic Resonance Imaging

Multiplanar CT and MR imaging with contrast (with CT or MR angiography) give an accurate localisation, supra and infratentorial extension, site of dural attachment, involvement and patency of dural venous sinuses and deep venous system, infiltration along the skull base, involvement of adjacent vasculature and relation of the tumour to the brainstem and cranial nerves. Up to 48% of patients with TM may present with cerebrospinal fluid pathway obstruction and hydrocephalus. MR imaging with contrast may often show an extensive dural tail

sign. However, the dural invasion in these benign lesions rarely extends for more than 1 mm from the tumour-dura junction and, therefore, extensive resection of the enhancing dura is not indicated in these meningiomas.[32]

Angiography with Tumour Embolisation

The blood supply to TM as well as the involvement of the dural venous sinuses and their dominance may be defined on the basis of arterial and venous phase angiography, respectively. The displacement of vessels indicating attachment of the tumour to the tentorium may be seen. In case of encasement of major blood vessels by the TM, a balloon occlusion test may be performed to evaluate the capacity of the contralateral circulation to support the circulation on the side of the TM, in the event that the latter circulation is compromised during surgery. Superselective catheterisation of the meningeal supply to the TM and pre-operative embolisation permits surgical resection with minimal blood loss. Embolisation is especially helpful when the major arterial supply is from the external carotid artery by the meningohypophyseal trunk or by the posterior middle meningeal or ascending pharyngeal arteries. It is recommended that surgical resection be performed within 1–10 days of the pre-operative embolisation to allow for maximum vessel thrombosis without recanalisation.[14,32,39] Intraoperative evaluation may be performed by brainstem evoked potential, somatosensory evoked potential and facial nerve electromyographic evaluations.

SURGICAL APPROACHES

The primary goal of surgery is to remove the TM along with its dural attachment and also the involved bone in the case of bony invasion.[41] The selection of the approach (Table 1) and decision of radical excision entirely depend on the location of the lesion. Although the ideal goal is total tumour resection, it should not be achieved at any cost and all attempts should be made to preserve the brainstem, cranial nerves and vascular structures. The tumour, medial or lateral is usually approached through a combined supratentorial-infratentorial exposure, unless the tumour is on one side of the tentorium with only a minimal extension into the other compartment.

A cerebrospinal fluid shunt or an endoscopic third ventriculostomy may be required in some patients, where a rapid normalisation of the raised intracranial pressure is needed. However, contemporary anaesthetic methods provide sufficient brain relaxation to eliminate the need for cerebrospinal fluid drainage and to facilitate retraction during surgery in most patients.

PRIMARY TENTORIAL MENINGIOMAS

Tentorial Free Edge

Anterior supratentorial lesions in this location may be approached by the subtemporal or trans-sylvian frontotemporal route or a combination of both the approaches.[1,3,40,43]

In the subtemporal approach, after a temporal craniotomy, the temporal lobe is gently elevated to expose the tumour in the inner middle fossa. In the trans-sylvian frontotemporal route, after a frontotemporal craniotomy and drilling of the lesser wing of the sphenoid to make the frontal and temporal fossa flush with each other, the Sylvian fissure is opened widely using arachnoidal dissection and the tentorial base and the anterior portion of the incisura reached. With these approaches, one can visualise the superior surface of the tentorium, the anterolateral surfaces of the midbrain and pons, the posterior cerebral, posterior communicating and superior cerebellar arteries and the IIIrd and IVth nerves. Sectioning the tentorium anterior to the tumour interrupts the tumour blood supply. The IVth nerve penetrates the tentorial edge dura 4 mm behind the posterior clinoid process. In

Table 1: Location of tumours and their surgical approaches

Tumour location		*Surgical approach*
T1–T2 (medial)	Infratentorial	Supracerebellar infratentorial
T3–T8 (falcotentorial)	Supratentorial	Suboccipital retrosigmoid
T4 (paramedian)	Supra-infratentorial	Subtemporal
	Supratentorial	Infra-supratentorial presigmoid
T5 (peritorcular)	Supra-infratentorial	Bioccipital interhemispheric
	Infratentorial	Occipital transtentorial
	Supra-infratentorial	Bioccipital/suboccipital
T6–T7 (lateral)	Infratentorial	Supracerebellar infratentorial
	Supratentorial	Bioccipital/suboccipital
Falx cerebelli	Infratentorial	Suboccipital retrosigmoid
		Supracerebellar infratentorial
		Subtemporal
		Supracerebellar infratentorial

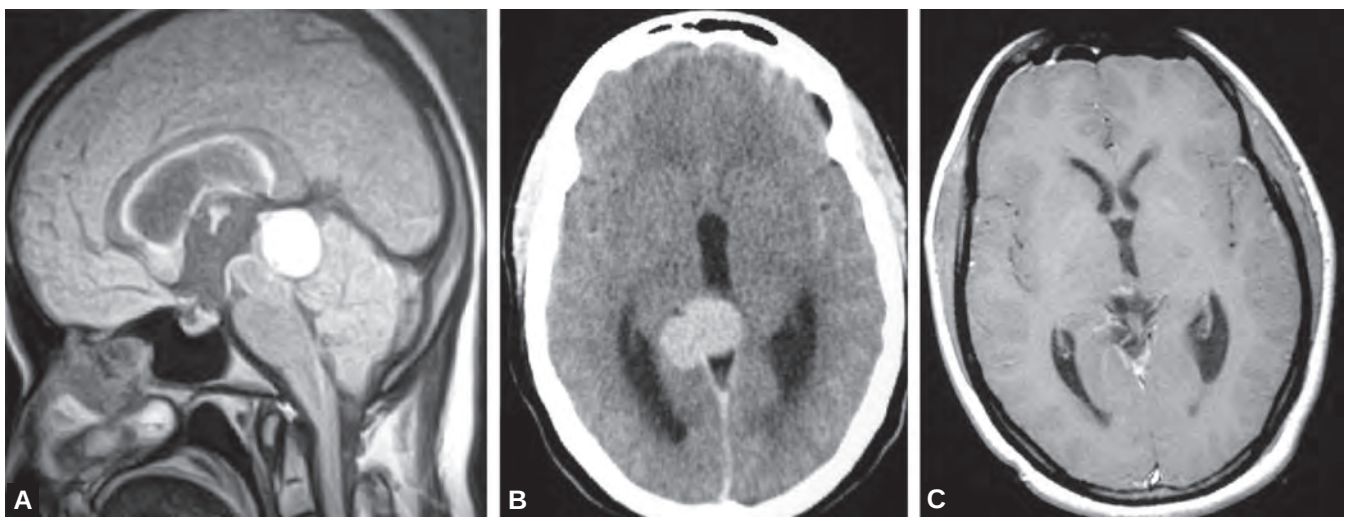
Fig. 2: Axial T1-weighted MR image showing a lateral tentorial edge TM with a predominantly infratentorial component. This was approached using a retrosigmoid suboccipital craniectomy

order to prevent injury to the IVth nerve during tentorial edge cutting, the tentorial edge should be divided posterior to the entry of the IVth nerve. There may be retraction injury to the temporal lobe during the subtemporal approach, which may be minimised by giving mannitol, furosemide, hyperventilation, cerebrospinal fluid drainage, preservation of bridging veins and by the intermittent use and frequent repositioning of retractors. The vein of Labbé requires meticulous preservation during the subtemporal approach, to prevent venous infarction of the temporal lobe. The vein may be skeletonised from the temporal lobe by arachnoidal dissection to facilitate temporal lobe retraction. Adding zygomatic osteotomy provides a flatter angle of view and lesser degree of temporal retraction. Supratentorial tumours of the anterior, outer and inner tentorial rim can be approached via the subtemporal route. Sugita et al.[43] emphasised that preservation of subtemporal veins may be facilitated by wide temporal craniotomy, particularly in horizontal length. Large supratentorial as well as infratentorial incisural meningiomas may also be excised using a combined supratentorial and infratentorial presigmoid approach.[35]

When the tumour extends along the cerebellopontine angle in the posterior fossa, compressing the brainstem and cranial nerves and reaching up to the free edge of the tentorium from the inferior aspect, the retromastiod approach should be considered (Fig. 2). This approach involves a combination of the supracerebellar and of the retrosgimoid approaches to the posterior fossa, simultaneously providing access to the inferior part of the tentorium and to the cerebellopontine angle.[13,14,38,39] The trigeminal, facial, vestibulocochlear and lower cranial nerves are visualised and dissected off the tumour. A combination of the subtemporal and retromastoid approach may also be used in case the tumour extends in both the supratentorial and infratentorial regions, as well as anteromedially to involve the cranial nerves and brainstem.[42] With the combined approach, the transverse/sigmoid sinus junction distal to the vein of Labbé may be divided to facilitate tumour excision from both the compartments.

The supracerebellar (paramedian) transtentorial approach has also been used by Uchiyama for medial temporal meningiomas with a supratentorial extension, but without involvement of the superior surface of the petrous bone.[46]

TM situated at the tentorial edge carry a much higher risk of neural and vascular compromise than at other sites. Resection of a medially situated TM requires



Figs 3A to C: (A) Sagittal contrast enhanced T1-weighted MR image showing a medial tentorial edge meningioma in close proximity to the Galenic venous system. (B) Axial CT scan showing the medial tentorial edge meningioma. (C) Axial T1-weighted MR image at follow-up showing total excision of the lesion that was approached using a suboccipital craniectomy and infratentorial supracerebellar approach

preservation of the vein of Galen and its related veins, posteromedial choroidal and superior cerebellar arteries, IVth cranial nerve and posterior aspect of the mesencephalon including the quadrigeminal plates (Figs 3A to C). The structures usually lie anteriorly or superiorly to the tumour mass and may be preserved by using dissection along the arachnoidal plane of the quadrigeminal cistern, from the vein of Galen above to the cerebellomesencephalic fissure below. Preservation of the vein of Galen is of paramount importance, even if apparently angiographically occluded, although some authors have reported successful results after surgical occlusion.[4,29,33]

When the TM lies along the lateral incisural space, preservation of the basal vein of Rosenthal, posterior cerebral and posterolateral choroidal arteries, IIIrd and IVth nerves, lateral aspect of the mesencephalon and medial aspect of the temporal lobe is required.

Extension of the tumour to the cerebellopontine angle may require dissection from the Vth to the XIth cranial nerves.

Tentorial Leaf and Lateral and Posterior Tentorial Attached Margin

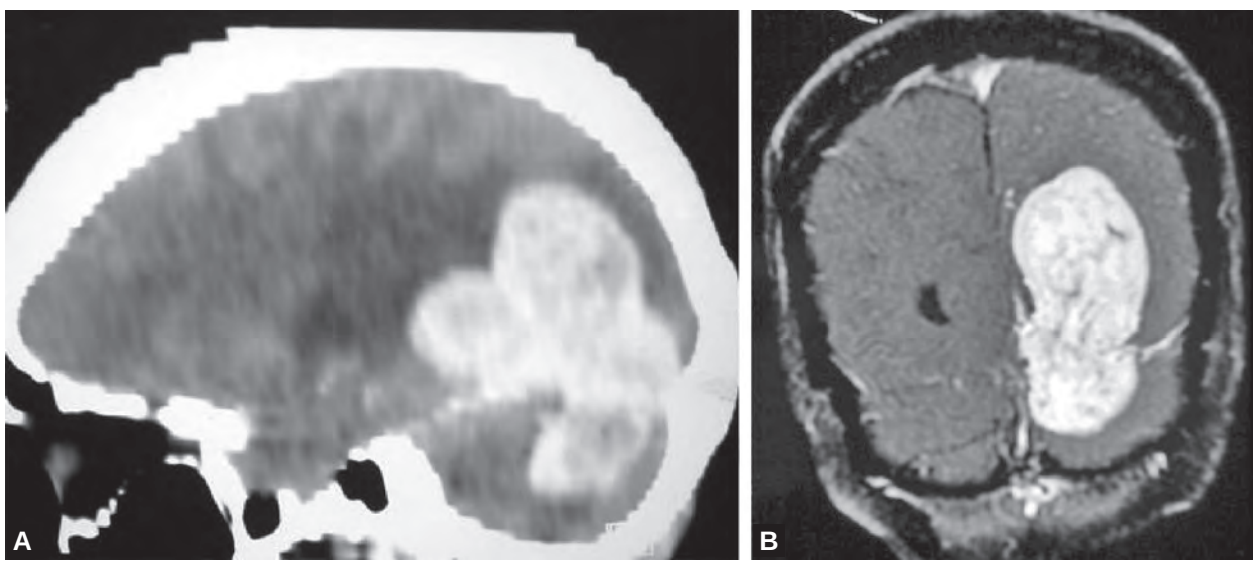
An occipital/parieto-occipital craniotomy or infratentorial supracerebellar approach or a combination of both (on either side of transverse sinus) may be adopted, depending on whether the tumour is mainly supratentorial, infratentorial or both respectively (Figs 4 to 6.[4,6,7,32] In the occipital transtentorial approach, after an occipital craniotomy is made exposing the superior sagittal and transverse sinuses, the occipital lobe is retracted from the falx and the tentorium. The tumour exposure is enhanced by coagulation and division of the tentorium up to the incisura, at least 1 cm lateral to the straight sinus. An optional procedure includes fenestration of the falx to deal with a contralateral extension of the tumour.[14,16]

In the infratentorial supracerebellar approach, after a retromastoid suboccipital craniectomy, the bridging cerebellar veins between the tentorium and the cerebellum are divided, allowing the cerebellum to drop down by gravity. Careful neck flexion brings the tentorium as close as possible to the horizontal plane. The problems include the depth of the operating field requiring long-sized instruments and the risk of cerebellar venous infarction.[38,39]

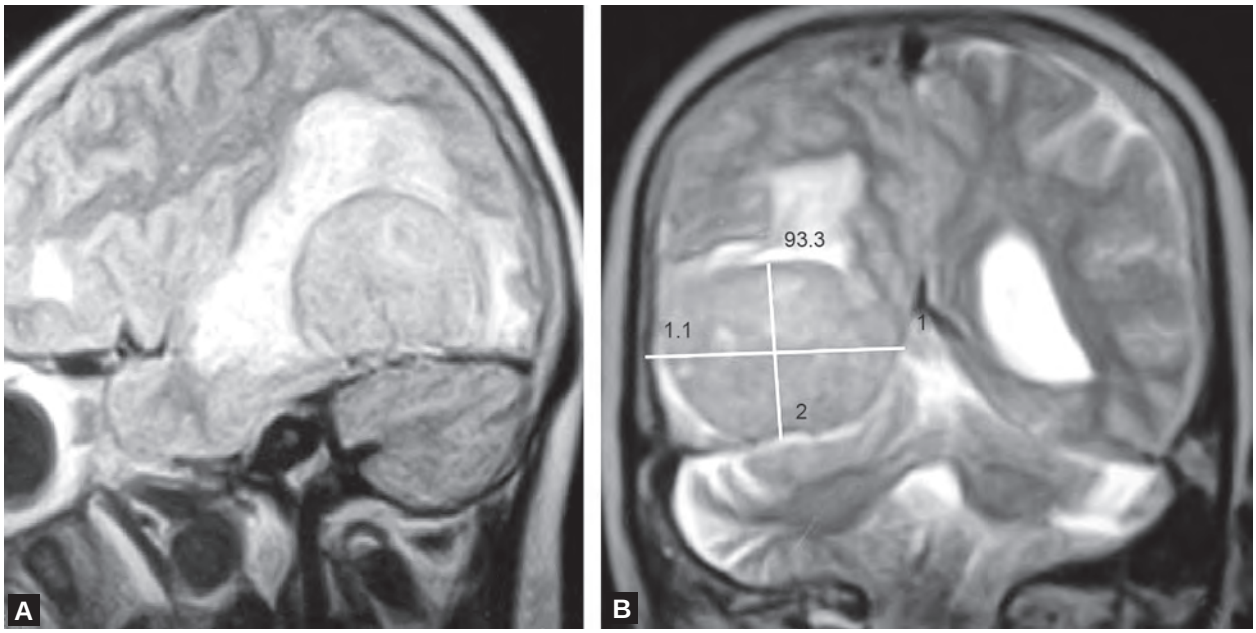
The transverse sinus may only be resected when angiogram shows the sinus on that side to be occluded by the tumour and when there is a clear demonstration of a patent contralateral one. Bleeding, air embolism from the sinus or visual field defects from occipital lobe handling are the major causes of morbidity.[10]

Falcotentorial

These may be approached by an occipital, interhemispheric, transtentorial approach utilising a bilateral or ipsilateral occipital craniotomy (Figs 7A and B).[4,13,14,16] The medial aspect of the occipital pole may be retracted laterally, as most of the draining veins of the occipital lobe drain into the transverse sinus rather than into the sagittal sinus. The falx and the tentorium around the lesion may be divided to devascularise the tumour. The tumour attached to the straight sinus is cauterised *in situ*. In case, the tumour extends anteriorly to the region of the vein of Galen and the internal cerebral vein, a small fraction of the tumour may be left behind to avoid injury to the deep venous system. The supratentorial (with) transtentorial approach may also be used for tumours which have an infratentorial extension.



Figs 4A and B: (A) Contrast enhanced sagittal reconstructed CT image showing a perforating tentorial leaf meningioma with both supratentorial and infratentorial components. (B) Contrast enhanced coronal T1-weighted image of the same patient. This lesion could be completely excised using an occipital interhemispheric transtentorial approach



Figs 5A and B: (A) T2-weighted sagittal MR image showing a tentorial leaf meningioma with a predominantly supratentorial component. (B) T2-weighted coronal MR image of the same patient. This lesion was approached using a posterior temporal craniotomy and a subtemporal approach

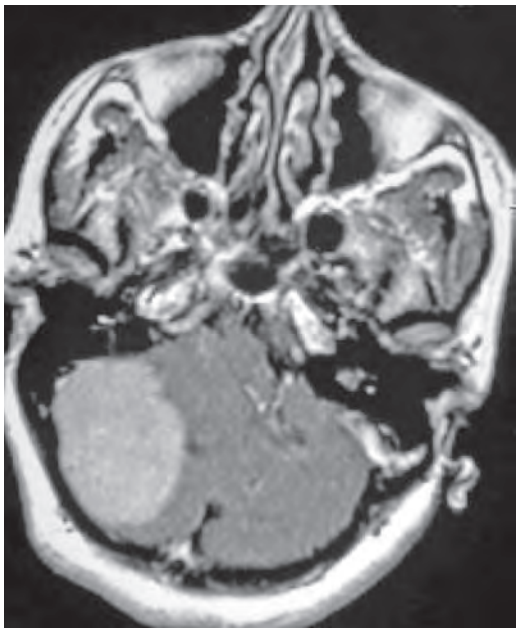


Fig. 6: Contrast enhanced axial MR image showing a lateral tentorial leaf meningioma with a predominately infratentorial component. This lesion was approached using a lateral suboccipital craniectomy and an infratentorial supracerebellar approach

With lesions that are predominantly infratentorial, the infratentorial supracerebellar approach may be used. If located at the posterior part of the tentorial incisura, an occipital interhemispheric transtentorial route may be used to access it from the superior aspect, especially when the tumour is small. In large infratentorial-falcotentorial tumours, the occipital interhemispheric route may be combined with suboccipital craniectomy and supracerebellar infratentorial approach.[28,32] A unilateral approach may cause homonymous hemianopia, while bilateral occipital lobe retraction may result in cortical blindness due to contusion and ischaemia of the calcarine gyrus.

Torcular Meningioma

The torcula consists of the confluence of five sinuses including two transverse, one straight, one superior sagittal and one occipital sinus. The surgical approach depends on tumour growth into one or more of the four quadrants—right, left, supra and infra tentorial (Fig. 8). Patients with a unilateral lesion with both supratentorial and infratentorial extensions may often be approached by a unilateral occipital or suboccipital exposure but the approach may be augmented by a craniotomy both above and below the tentorium and by cutting the tentorium and the falx. Venous infarction secondary to compromise of the venous sinus and cortical blindness due to retraction damage of the occipital lobes are the major hazards.[17,18]

Complex Tentorial Meningioma

Parasellar and Cavernous Meningioma

These may involve the cavernous sinus, the carotid, anterior cerebral, middle cerebral, posterior communicating, anterior choroidal and superior cerebellar arteries and the IIIrd, IVth, Vth and VIth nerves. They may be approached by a pterional craniotomy and trans-sylvian approach and/or subtemporal approach or a combination of both the approaches. In patients with extensive

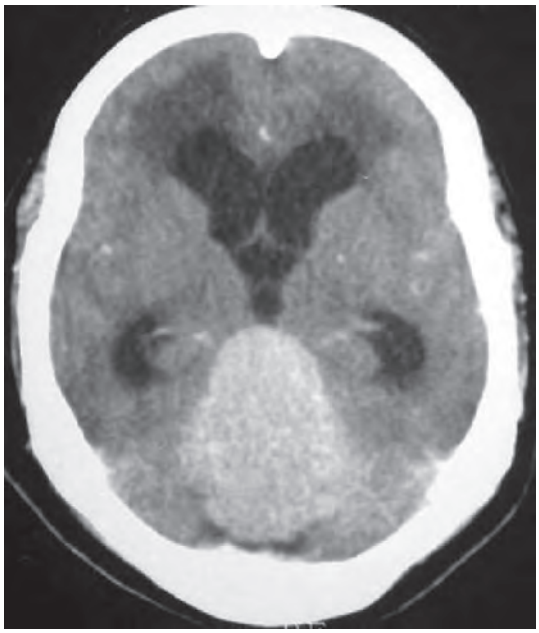

Fig. 7A: Contrast enhanced axial CT scan showing a falcotentorial meningioma with predominantly infratentorial component with associated hydrocephalus. The lesion was extending to the posterior third ventricular region obstructing CSF pathway

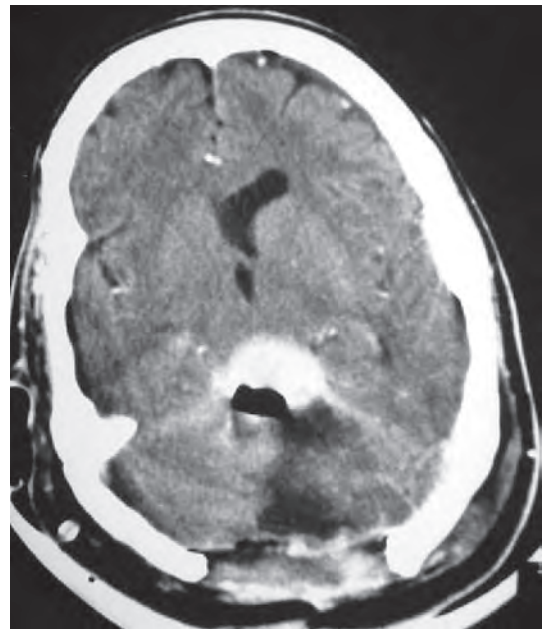

Fig. 7B: Post-operative contrast enhanced axial CT scan of the patient approached via midline suboccipital craniectomy and infratentorial supracerebellar approach. A small part of the lesion in close proximity to the Galenic venous system and the straight sinus was left *in situ*

involvement of the carotids and cavernous sinus, surgical resection may be conservative.[39,40,43]

The need for pre-operative extracranial-intracranial bypass, may be evaluated in case one expects to sacrifice the carotid artery during excision of the tumour.

Cerebellopontine Angle Meningioma

These may be approached by a retromastoid craniectomy. The cerebellopontine angle may be involved with tumours extending from the tentorium to the petrous dura/clival dura.[38]

Petroclival Meningioma

The approaches that may be used include combined subtemporal and retromastoid approach with extra exposure provided by dividing the transverse sinus and superior petrosal sinus distal to the insertion of the vein of Labbé. A large tumour in this location may also be approached by combining the presigmoid and retrosigmoid approach and dividing the tentorium parallel to the superior petrosal sinus towards the incisura.[2,3,15,31,42]

Pineal Meningioma

These arise from the velum interpositum and may be approached using either an infratentorial supracerebellar approach or via an occipital transtentorial approach.[22,25,51]

Basal Approaches to Tentorial Meningiomas

In the excision of predominantly posterior fossa TMs, those meningiomas situated posterior to the internal auditory meatus may be accessed easily using a retrosigmoid approach. However, in TMs that are premeatal, tentorial edge and petroclival, the surgeon has

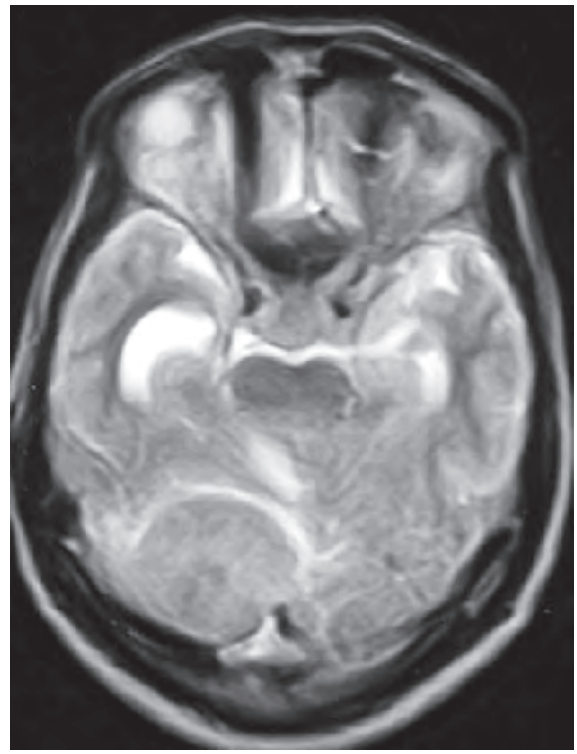

Fig. 8: Axial T2-weighted MR image showing a torcular meningioma in the supratentorial compartment. This lesion was excised using an occipital craniotomy

to traverse the cerebellopontine angle cistern and its neurovascular structures before reaching the tumour in the retrosigmoid approach. The VIIth–VIIIth nerve complex, the AICA and its branches and the perforating arterial branches to the brainstem from the vertebrobasilar complex may be at risk. Thus, these medially situated TMs may be accessed using variations of skull base approaches. These include presigmoid supra-infratentorial approach, presigmoid and retrosigmoid translabyrinthine approach, subtemporal presigmoid approach and transpetrosal approach.[3,36,37,39,42] Broadly speaking, a temporal craniotomy and lateral suboccipital craniectomy exposes the transverse sinus and the transverse sigmoid junction. The tumour exposure is then enhanced by drilling the mastoid process and petrous bone anterior to the sigmoid sinus. Careful drilling is important to avoid entering the bony labyrinth and fallopian canal. The sigmoid sinus is exposed in its full length to provide both a presigmoid and retrosigmoid exposure. The dura is opened parallel to the temporal fossa floor and the incision extended posterior to the junction of the sigmoid and lateral sinuses. Great care is taken to protect the vein of Labbé which usually drains into the lateral sinus just proximal to the junction with the sigmoid sinus. The dura of the posterior fossa is opened anteriorly and parallel to the sigmoid sinus and when required, also behind the sigmoid sinus. The skeletonised petrosal sinus is transected and the tentorium divided. Medially the tentorium is sectioned just posterior to the point where the IVth nerve joins the free edge. In premeatal meningiomas, the Vth nerve is usually splayed on top of the tumour. In tentorial edge meningiomas, the Vth nerve is usually situated inferolaterally to the tumour. In both these lesions, the IIIrd nerve is usually situated superomedial and the VIth nerve, inferomedial to these lesions.

Transection of the sigmoid sinus with the tentorium, with preservation of the vein of Labbé, may occasionally be performed if there is a patent transverse sinus on the contralateral side. These approaches minimise brain retraction and provide a more straightforward exposure of both the supratentorial and infratentorial components of the tumour. However, there is a risk of temporal lobe venous infarction due to prolonged traction on the vein of Labbé and the risk of post-operative deafness due to unintentional opening of the posterior semicircular canal.

Resection of Venous Sinuses to Achieve Complete Tumour Excision

A major issue in surgical resection of TM is resection of dural venous sinuses to achieve complete tumour removal. When a sinus is completely occluded and non-patent, it can be resected safely. However, when there is partial obliteration demonstrated on pre-operative radiology as well as infiltration of the sinus wall by the tumour that is revealed during surgery, a conservative approach should be adopted by coagulating the residual tumour on the sinus wall or resecting only the infiltrated outer dural layer of the sinus.[6,8,16,38]

Resection of the tumour with complete excision of the involved transverse sinus has been advocated in young patients when the pre-operative angiography reveals a widely patent contralateral transverse sinus and when there is evidence of venous collateral formation.[10,28,31] If brain swelling occurs after the intra-operative clamping of the sinus, reconstruction of the venous sinus from dural leaves or with a saphenous venous graft has been used. Intra-operative monitoring of sinus venous pressure along with somatosensory evoked potential monitoring prior to sinus excision has been proposed. Even when sinuses have been completely excised along with the tumour (despite the risk of post-operative venous infarct), recurrences may occur. Sekhar et al.[39] found a recurrence rate of 10% during a mean follow-up period of 5.5 years following venous sinus excision. Cudlip et al.[10] despite achieving 84% total resection, observed a recurrence rate of 21% during a follow-up of 3.5 years. Moreover, some part of the deep venous system may not be visible on angiogram, although the region may not be occluded and may be functionally important. Atresia/septations in the region of the sinus confluence may lead to misinterpretation with regard to dominance of sinuses. Thus, an infiltrated but patent venous sinus should be preserved, since even subtotal removal of a TM may be associated with a long progression free period and a high quality of life.

SURGICAL RESULTS

The rate of total tumour resection according to Simpson's grading for tumour removal has been approximately 77–83%. Rostomily et al.[32] achieved a subtotal resection in 20–40% of patients with overall recurrence rates of 7–15%. The low rates of recurrence, even when subtotal resection was performed, led Bret et al.[6] to propose that dural devascularisation resulting from extensive cauterisation or from separation of the tumour from its dural attachment, was responsible for the minimal growth capabilities of residual meningiomas. The limiting factors to total excision were breach of the pia mater of the brainstem and encasement of critical vascular structures. Series prior to 1980 reported a post-operative death rate from 14% to 44%. With the advent of modern imaging and advances in microsurgery, the mortality has decreased to below 10%; however, morbidity rates still remain high, ranging from 18.9% to 77%.[14,39] Greater surgical difficulties are often encountered with TMs located at the tentorial edge.

Considerations in Elderly Patients

Umansky et al.[47] calculating the surgical outcomes in patients aged more than 70 years with a symptomatic

meningioma, found a mortality rate of only 5.4%. The mean Karnofsky score improved from a pre-operative score of 59 to post-operative score of 80. The median annual tumour volume growth rate for meningiomas is approximately 3.6%. Thus, even elderly symptomatic patients must be given the option of surgery. However, elderly patients with incidental TM may be followed by serial imaging studies with operative treatment reserved for tumours which have a high growth rate or those tumours that become symptomatic.

STEREOTACTIC RADIOSURGERY

Total surgical resection along with the adjacent dura and involved bone may be difficult to achieve in a TM, where the tumour is adherent to the brainstem, cranial nerves and venous sinuses. Occasionally, the tumour attains such a large size that complete excision leads to unacceptable neurological deficits. Since recurrence of the tumour following incomplete resection is always a possibility, alternative management strategies may be used. These are radiotherapy, stereotactic radiosurgery, chemotherapy and steroid receptor antagonists. Radiosurgery is a viable option for TM, due to their lack of brain invasion, tendency to become symptomatic when relatively small, ability to be defined by high resolution imaging and due to their basal blood supply that can be included in the radiosurgical volume. The efficacy of radiosurgery in the treatment of meningiomas is reflected by a tumour control rate of almost 96–98%. Radiosurgery is a valuable option for patients with small tumours (less than 30 mm), those with minimal or no neurological deficits, but with a documented increase in tumour size, those with small residual tumours following microsurgical resection, elderly or medically unfit patients and those who are unwilling to undergo surgery. The maximum tumour dose varies from 24 Gy to 40 Gy; the dose received by the brainstem has to be kept at or below 16 Gy. Tumour control rate of 98% has been reported during a mean follow-up of 3 years.[19,20,21,26]

CONCLUSION

TMs currently remain challenging surgical entities. Tumours located at the tentorial edge carry a definitely worse prognosis than those attached to the peripheral tentorium. Although subtotal resection may often be required due to the critical relationship of the tumour to the brainstem or important neurovascular bundles, often the long-term outcome may remain good with relatively low recurrence rates. Skull base approaches and radiosurgery may further enhance the capability to excise and limit the growth potential of these tumours. Resection of an infiltrated but patent venous sinus is not recommended because the risk of venous infarction is high and a significant decrease in tumour recurrence has not been demonstrated even with this manoeuvre.

171 Posterior Fossa Meningiomas

Amitabha Chanda, Abhijit Guha

INTRODUCTION

From the infancy of neurosurgery, meningiomas have posed a challenge for neurosurgeons. Harvey Cushing remarked, "There is today nothing in the whole realm of surgery more gratifying than successful removal of a meningioma with subsequent perfect functional recovery, especially should a correct pathological diagnosis have been previously made. The difficulties are admittedly great, sometimes insurmountable, and though the disappointments still are many, another generation of neurological surgeons will unquestionably see them largely overcome".[26] Following this historic remark, the science and art of neurosurgery have come a long way during the previous century. Cushing's prediction was right in that a lot of the obstacles have been overcome. For example, with the advent of advanced radiological modalities, pre-operative diagnosis is usually not a mystery. Advanced anaesthesia, microsurgical techniques, and adjuvant treatment, especially in the form of stereotactic radiosurgery, also have changed the scenario. However, there remain a few meningiomas, which are still a nightmare for the surgeons, by virtue of their location, vascularity, and biology. In this chapter, we will discuss meningiomas of the posterior fossa, including meningiomas of the posterior fossa cranial base, which still often remain a management challenge for neurosurgeons.

EPIDEMIOLOGY

Meningiomas comprise about 20% of all primary intracranial neoplasms.[25,52,174,185] The reported incidence of meningiomas per 100,000 population varies from less than 1 to just more than 6.[84,144] However, these statistics are based on a few hospital studies in the United States and in no way represent World statistics. Nevertheless, the frequency of intracranial meningiomas in European and Japanese studies are close to those in the North American studies.[41,70,84,116,124,144,166,187] Of all meningiomas, 10–15% are in the posterior fossa.[24,172] Children show an increased incidence of posterior fossa meningiomas (PFM) in comparison to adults.[29,36,58] In three major studies from North America,[84,124,166] the ratio of male to female incidences ranged from 1:1.4 to 1:2.8. These differences are less evident in Africans and African-Americans,[124] who show equal ratios or a male preponderance. Moreover, reports from Africa also indicate a significantly higher frequency of meningiomas among primary intracranial neoplasms in that population.[42,46,95,99,115,119] The incidence of meningiomas increases with age.[84,124,166] The predisposition of meningioma in Type II neurofibromatosis, multiple meningioma syndrome and post-radiation meningiomas are mentioned later.

AETIOPATHOGENESIS INCLUDING MOLECULAR BIOLOGY

Trauma, although implicated by Cushing[24] as a significant aetiological factor in development of meningiomas, has not been proven unequivocally till date as an aetiological factor. There were a number of reports, as recent as in 1999, pointing trauma as a possible aetiological agent.[80,125] However, there are several reports which have challenged trauma as the aetiological basis.[4,20,64,121]

Papovavirus antigen has been identified in human meningioma by immunocytochemical techniques.[175] Also, BK viral DNA, SV40 viral DNA and adenoviral DNA have been found in meningiomas by DNA hybridisation techniques. However, the viral DNA material was not integrated into the tumour cell DNA in any case.[39,60,61] Although the presence of viral protein, RNA or DNA in human meningiomas cells suggests a possible role in tumour induction, maintenance of transformation, or both, in which case the implicated viruses may act alone or in a permissive manner with other mutagens. The exact role of viruses in human meningiomas is not yet defined accurately.

Many reports have shown that meningiomas have occurred following low levels of radiation, such as were given in the past for *Tinea capitis* (10 Gy), following intermediate dose of radiation and following the high doses of radiation given (55–75 Gy) for the treatment of primary head and neck malignancies.[8,33,98,102,108,173] The latency of occurrence of meningioma is longer following low dose radiation than that for meningiomas following high dose radiation. The latency range is from 24 to 36 years. In these radiation-induced meningiomas there is a higher incidence of atypical meningiomas with more aggressive biological features.

It is well known that meningiomas occur with higher frequency in patients with neurofibromatosis Type II

(NF-2). With this knowledge, extensive cytogenetic examination demonstrated that monosomy of chromosome 22 (or more specifically deletion of the 22q12 locus) was the most common chromosomal abnormality seen in meningiomas.[74,130,147,182] A loss of NF-2 or other tumour suppressive genes along with activation of proto-oncogenes are thought to cause meningiomas to arise. That the prod3uct of the NF-2 tumour suppressor gene, MERLIN, is important in genesis of meningiomas was supported by the fact that over-expression of MERLIN significantly inhibited proliferation of meningioma cells.[62] However, it cannot be overemphasised that alterations of other genes on chromosome 22 and other chromosomes may be involved in the genesis of meningiomas. Chromosomes[1,6,9–11,13,14,18,19] have all been implicated.[74,89,93,94,119,123,176] In familial meningiomas and meningiomatosis, where the entire dura is transformed with meningiomas, a yet to be identified tumour suppressor gene, also on chromosome 22q and adjacent to the NF-2 gene, has been implicated.[103]

Meningiomas, which occur more frequently in females, especially those occurring in the spine, grow more rapidly during the luteal phase of the menstrual cycle and during pregnancy. This epidemiological observation has led to a search for the importance of sex hormones and their receptors in the pathogenesis of meningioma. The initial search identified the oestrogen receptors,[35] with a number of other hormone receptors subsequently found. The oestrogen receptors were found in about 30% of the tumours in a recent study and most of them were the Type II subtype,[105,161] which have lower affinity and specificity for oestrogen than Type I have. The other receptors found were progesterone receptors (50–100%), androgen receptors (almost same frequency as that of progesterone receptor), somatostatin receptors (almost 100%), growth hormone receptor mRNA and dopamine receptors.[10,15,38,59,88,87,112,128,145,161] In fact somatostatin receptor scintigraphy has been found to be a useful diagnostic modality in identifying meningiomas and differentiating residual tumour from other changes seen in the post-operative setting.[75]

Table 1: Classification of posterior fossa meningioma*

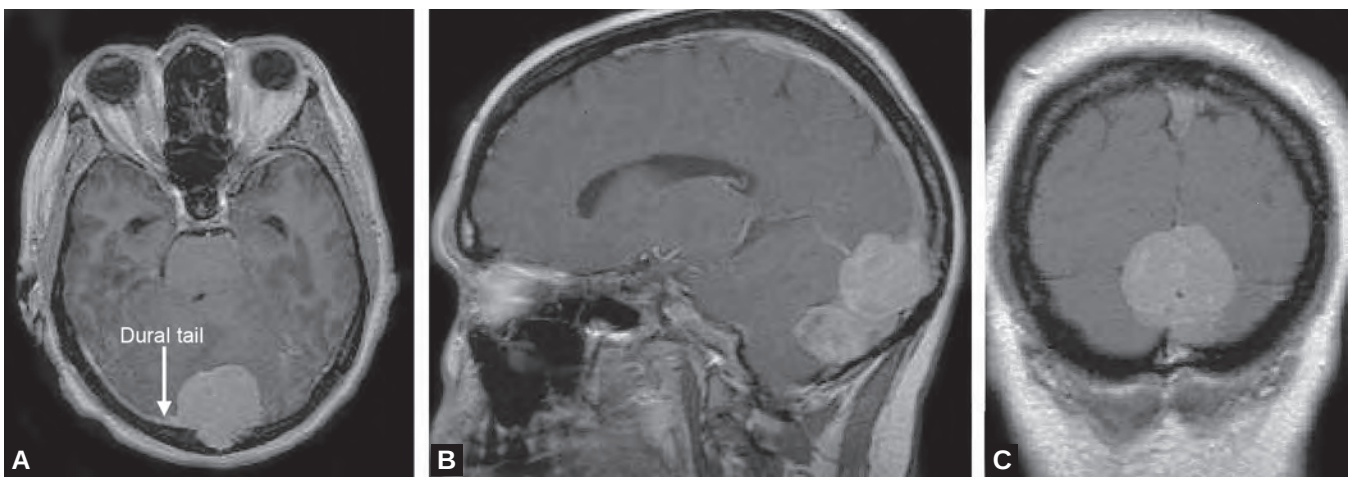
Type I	Cerebellar convexity and lateral tentorial
Type II	Pre-meatal
	Lateral petrous ridge and
	Cerebellopontine angle
	Post-meatal
Type III	Jugular foramen
Type IV	Petroclival
Type V	Foramen magnum
Type VI	Unclassified

Key:*, Modified from Sekhar et al. (1996)

From the mid 1980s, attention was paid towards growth factors and their receptors. Adams et al.[2] supported the presence of an autocrine control of meningioma proliferation. In their study, treatment with a neutralising antibody against platelet-derived growth factor (PDGF) abolished stimulation of meningioma cell culture growth by a meningioma-conditioned medium. The co-expression of PDGF-B (a potent mitogen) and PDGF receptor suggests an autocrine loop and may contribute to the growth and maintenance of these tumours.

CLASSIFICATION

Classification of PFM is a little confusing. Classification based on the site of origin of tumour[14,24,132] may be confused by the distinction between origin, dural attachment and dural adherence.[16,179] The site of profuse bleeding may indicate the site of origin of the tumour and enostosis is a good indication of the origin of lateral petrous tumours.[179] That is why it is sometimes not possible to accurately classify a meningioma before surgery, especially if it is a large one. We prefer to follow the classification by Sekhar et al.,[155] which is a modification of the classification by Castellano and Ruggiero[16] based on dural attachment (Table 1). Type I (Figs 1A to C, and 2) includes meningiomas arising from the cerebellar convexity dura, the lateral tentorium, transverse sinus, sigmoid sinus and the straight sinus.



Figs 1A to C: (A) Gadolinium enhanced T1 axial. (B) Sagittal. (C) Coronal image of torcular meningioma (Type I). Note the bony involvement in the inner surface of the occipital bone and dural tail in axial image (A)

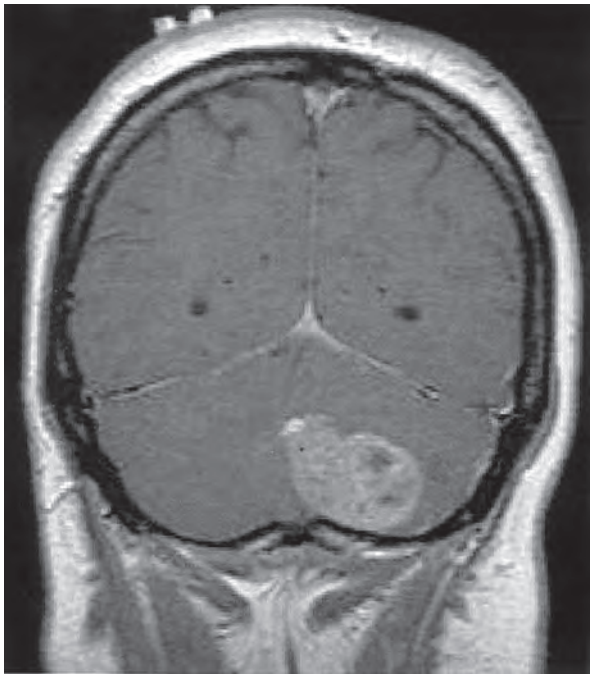


Fig. 2: A gadolinium enhanced T1 coronal image of cerebellar convexity meningioma (Type I) close to the midline

Fig. 3: Gadolinium enhanced T1 axial image of pre-meatal type of CPA meningioma (Type II). Note the relative lack of involvement of the clivus. In cases of large meningiomas, it is often difficult to assess the tumour attachment, whether it is medial or lateral to the trigeminal nerve. In this particular case it was lateral to the trigeminal nerve

These meningiomas have a propensity to invade the major venous sinuses. Torcular meningiomas are also included in this type. Meningiomas arising from the posterior face of the petrous bone dura, lateral to the trigeminal nerve are Type II meningiomas. These can also be classified as cerebellopontine angle meningiomas and can in turn be divided into pre-meatal (Fig. 3) and post-meatal types (Figs 4A to E).

We feel that these two are different entities in terms of clinical presentations and surgical results.[142] Meningiomas arising from the dura mater around the jugular foramen (Fig. 5) with or without extracranial extension,[71] are Type III meningiomas.

Type IV or petroclival meningiomas (Figs 6A to D) arise from the petrous apex, medial petrous ridge medial to the trigeminal nerve, upper two thirds of the clivus with or without extension to the cavernous sinus and/or Meckel's cave.

Meningiomas arising from the foramen magnum region, lower third of the clivus and C1, C2 regions are Type V meningiomas (Figs 7A and B).

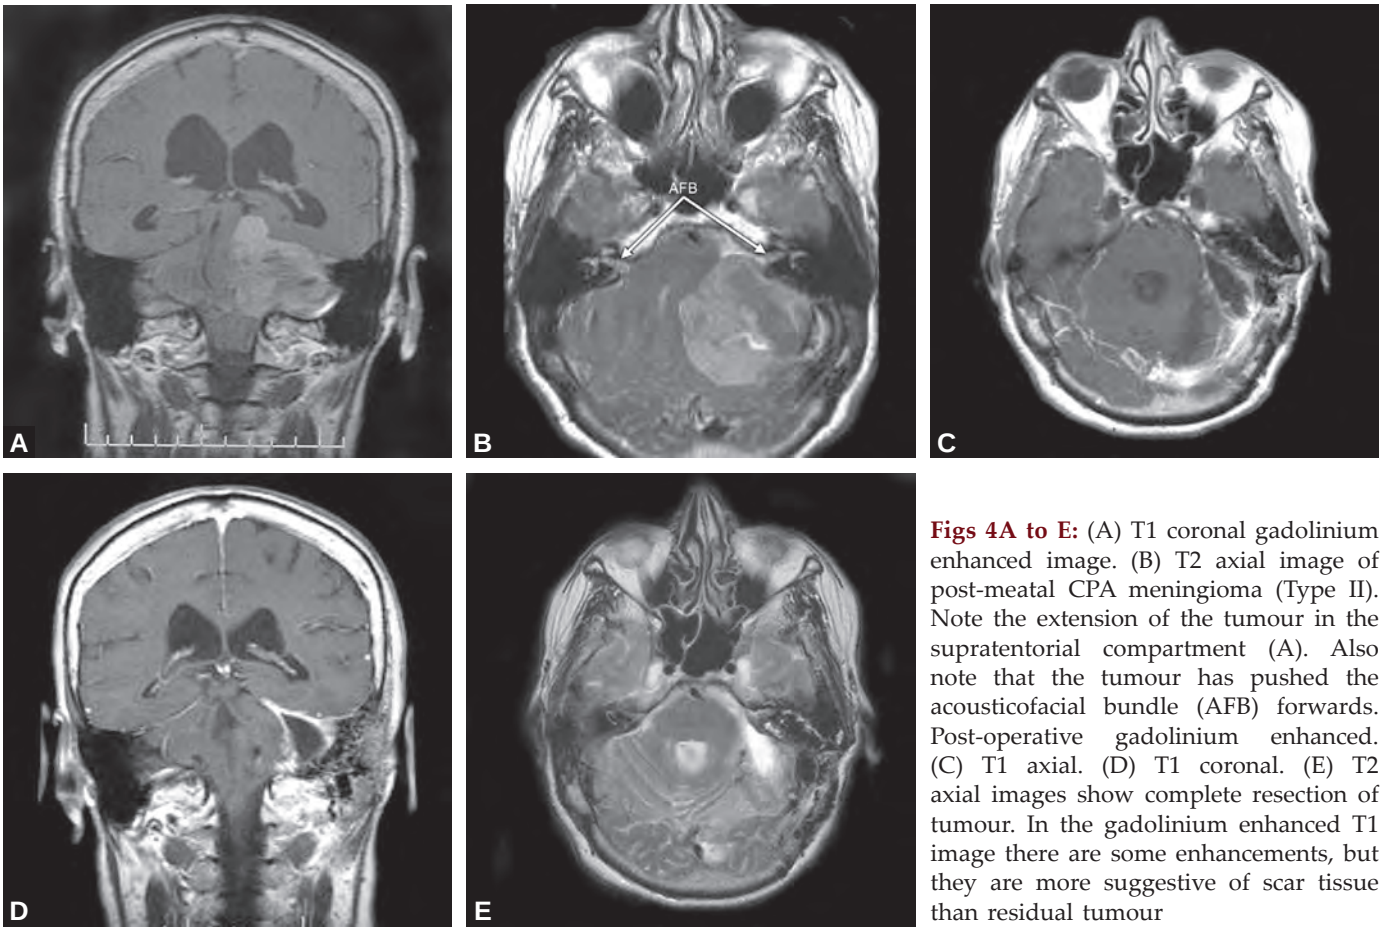
In spite of all these, there are still tumours, which cannot be accommodated in any group or may be in two or more groups. Examples of these are intracanalicular tumours (tumours in the internal auditory canal) or very large posterior fossa cranial base meningiomas, which cannot be fitted into any particular group. These are Type VI PFMs.

In this context, a special note must be made regarding meningiomas of the fourth ventricle. Five per cent of all intraventricular meningiomas arise in the fourth ventricle. PFM without dural attachment were classified by Abraham and Chandy[1] into three types: (1) Meningiomas originating from the choroid plexus of the fourth ventricle and developing solely within the fourth ventricle; (2) Meningiomas originating in the inferior tela choroidea, developing partly in the cerebellar hemisphere and vermis and (3) Meningiomas within the cisterna magna without any attachment to the dura mater.

PATHOLOGY

Meningiomas arise from the arachnoid cap cells.[73,114] This origin was supported by the fact that the arachnoid cap cells parallel in frequency the sites of meningioma formation. Macroscopically, these tumours appear smooth and lobulated with a fine leash of vessels on the surface. More vascular meningiomas are characterised by a reddish meaty appearance. Most of the tumours tend to be globular but other shapes according to the location may also be seen. For example, tentorial meningioma or jugular foramen meningioma with extracranial extension may be dumb-bell shaped. Also they may have diffuse growth (en plaque), such as those seen in diffuse meningiomatosis.

There are several histopathological classification schemes for meningiomas. However, the most popular one is the classification by Russell and Rubenstein,[131] who classified meningioma into meningotheliomatous (syncitial), fibrous, transitional and angioblastic types.



Figs 4A to E: (A) T1 coronal gadolinium enhanced image. (B) T2 axial image of post-meatal CPA meningioma (Type II). Note the extension of the tumour in the supratentorial compartment (A). Also note that the tumour has pushed the acousticofacial bundle (AFB) forwards. Post-operative gadolinium enhanced. (C) T1 axial. (D) T1 coronal. (E) T2 axial images show complete resection of tumour. In the gadolinium enhanced T1 image there are some enhancements, but they are more suggestive of scar tissue than residual tumour

Fatty degeneration, haemorrhage, calcification and cyst formation may occur. However, in this system there is always a controversy whether an angioblastic meningioma is the same as haemangiopericytoma. The World Health Organization (WHO) classification is simpler and distinguishes three grades of meningioma.[143] The meningothelial, fibrous, transitional, psammomatous, secretory, microcystic, clear cell, lymphoplasmacyte-rich and chordoid subtypes all comprise Grade I meningiomas. More aggressive meningiomas, based on histopathological characteristics, are classified as "atypical" meningiomas (Grade II) and the frankly malignant "anaplastic" meningioma (Grade III). The grading is mostly dependent on the proliferating potential of the tumour. Proliferative activity is usually determined by a labelling index (LI).[43] The LI distinguishes Grade I meningiomas (LI: 0.02–0.9%) from "atypical" meningiomas (LI: 1.5–2.0%) and "anaplastic" meningiomas (LI: 9–13%) and predicts the chance of recurrence.[66] Apart from LI and grade, several histopathological features are also associated with recurrence and aggressive behaviour. They are haemosiderin deposition, loss of architectural pattern, growth in sheets, prominent nucleoli, mitotic figures, necrosis, nuclear pleomorphism, frank invasion of brain by meningioma cells and overall atypical or malignant tumour grade.[28] A retrospective study of 160 cases done in Germany showed that grading of meningiomas should take a combined approach involving a Ki-67 proliferation index[76] and histological and cytogenetic characteristics.

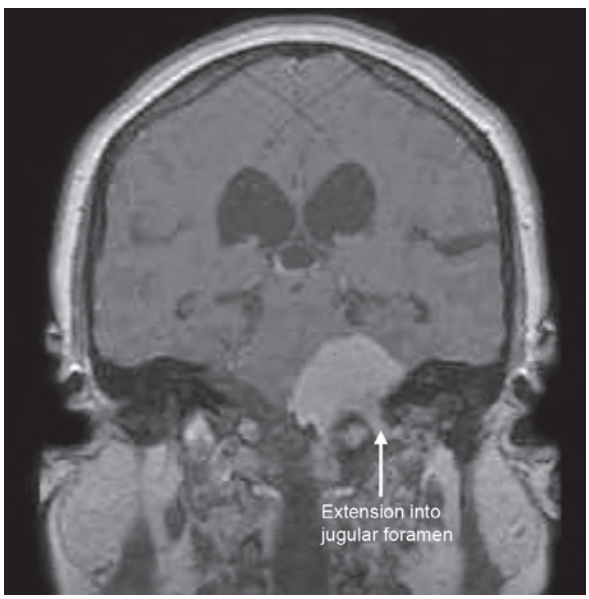


Fig. 5: T1 coronal gadolinium enhanced image of jugular foramen meningioma (Type III). Note the extension of tumour through the jugular foramen

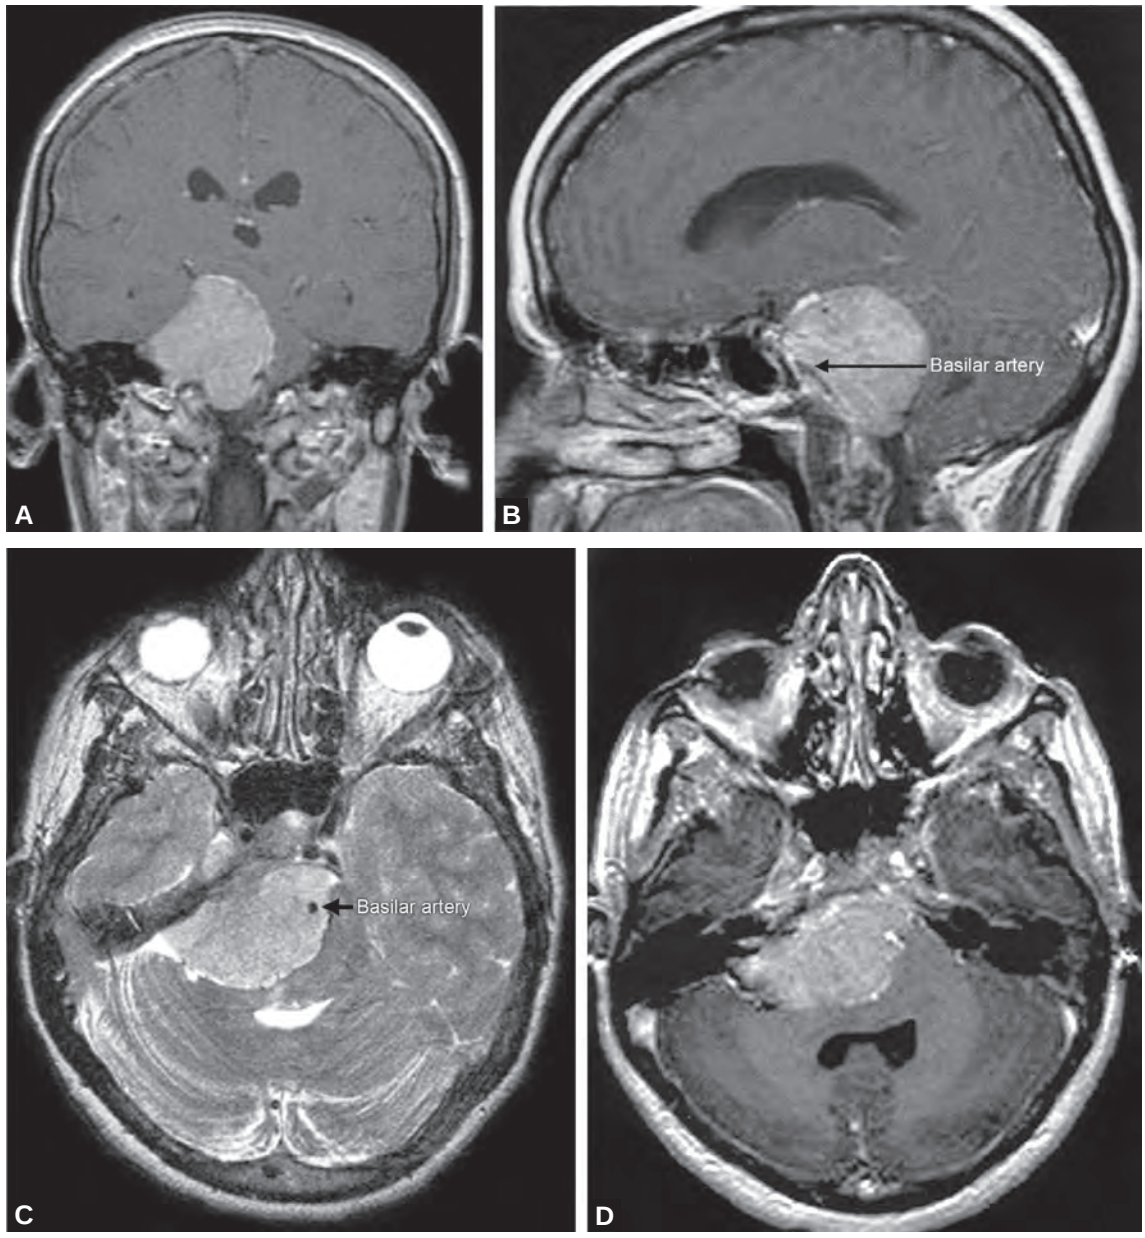
CLINICAL FEATURES

The clinical features of PFMs vary according to the location, size and invasion of the pia mater. It must be remembered that a number of these tumours can be



Figs 6A to D: Gadolinium enhanced. (A) T1 axial. (B) Coronal. (C) Sagittal. (D) T2-axial images of petroclival meningioma (Type IV). Note the difference between the tumour here and that in Fig. 3. Here, the clivus is involved and the attachment of tumour was entirely medial to the trigeminal nerve. Also note the encasement of the basilar artery by the tumour (C and D)

asymptomatic. If the lesion is large enough, they can cause symptoms and signs of intracranial hypertension, irrespective of the site. We will discuss the clinical features according to the type of meningioma.

Type I

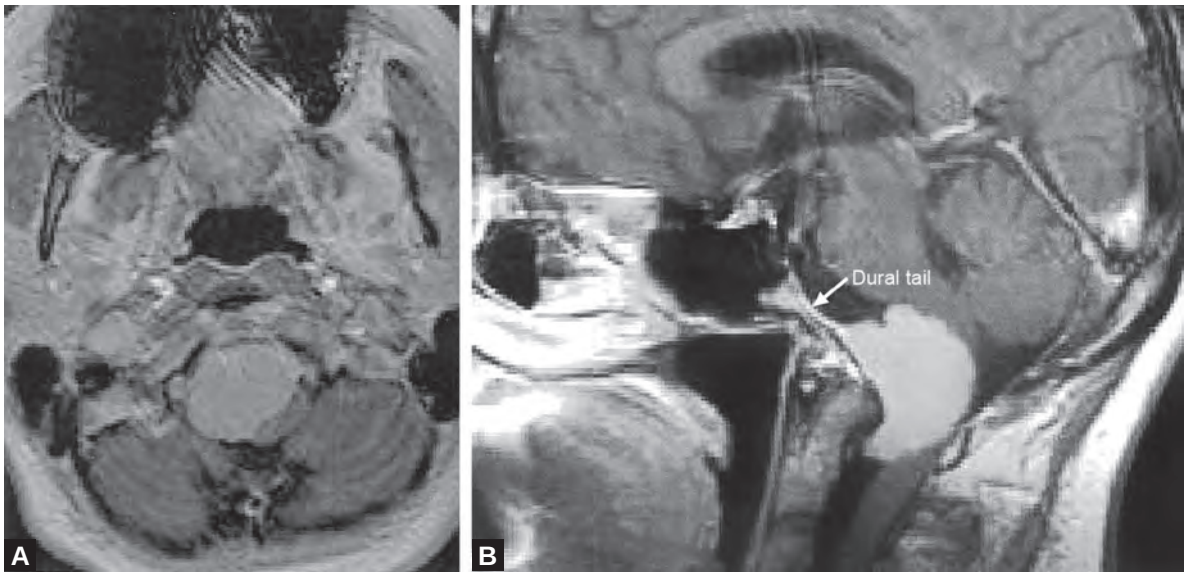
Type I PFMs usually present with raised intracranial pressure and progressive cerebellar signs (ataxia, dysmetria, nystagmus, etc.). When the supratentorial component of a tentorial meningioma is large, there may be visual field defects.

Type II

Type II PFMs commonly present with cranial nerve deficits and/or cerebellar signs and symptoms. Facial pain and/or numbness, facial weakness, hearing loss and ataxia are the usual presenting features. CPA meningiomas tend to involve the trigeminal and facial nerves with less early auditory and vestibular impairment, compared to vestibular schwannomas.[103] These Type II PFMs tend to involve the lower cranial nerves more than vestibular schwannomas. In a study,[142] it was shown that pre-meatal Type II PFMs have a propensity for facial nerve involvement and hearing loss, whereas the post-meatal/retromeatal type has a propensity for cerebellar involvement.

Type III

Type III PFMs usually present with lower cranial nerve symptoms like dysphagia, hoarseness of voice, nasal



Figs 7A and B: Gadolinium enhanced. (A) T1 axial. (B) Sagittal images of foramen magnum meningioma. Note the dural tail in the sagittal image (B)

regurgitation, etc. Additionally, they may also present with a neck mass, when there is significant extracranial extension into the neck. Several syndromes are associated with meningiomas of this group depending on the combination of cranial nerve involvement (e.g. Vernet's syndrome—Cranial nerves IXth, Xth, XIth; Collet's syndrome—Cranial nerves IXth, Xth, XIth, XIIth).

Type IV or the Petroclival Meningiomas

They most commonly present with trigeminal nerve involvement like facial numbness and/or pain. Facial nerve involvement and hearing impairment are not uncommon. The lower cranial nerves and ocular motor nerves (most commonly abducens) are involved in approximately one-third of patients.[32]

Type V

Type V meningiomas arise in the foramen magnum region and commonly present with suboccipital and neck pain (usually in C2 dermatome), ipsilateral upper limb paraesthesia, cold dysaesthesia, contralateral dissociated sensory loss, limb weakness starting in the upper limbs and wasting of small muscles of the hands. Lhermitte's phenomenon in the absence of other evidence of multiple sclerosis or cervical spondylosis may also be present. Patients may also demonstrate "piano-playing fingers", which means when they close their eyes and hold their arms outstretched, they will have slow athetosis-like movements of their arms, hands and particularly fingers.[54]

Type VI or the Unclassified Posterior Fossa Meningiomas

They can have protean manifestations. They may be asymptomatic and the symptoms depend upon the location and size of the tumour. For example, an intracanalicular meningioma will have hearing loss as the presenting feature, while very large PFMs can have multiple cranial nerve palsies, cerebellar involvement, sensory and motor dysfunctions.

The most common presenting symptom for PFM at the House Ear Clinic were otologic, with hearing loss (61%), tinnitus (58%) and imbalance (58%) as the three most common.[156]

Fourth ventricular meningiomas usually present with features of increased intracranial pressure due to hydrocephalus, truncal ataxia, nystagmus, down beat nystagmus, etc.

DIAGNOSTIC RADIOLOGY

Although MRI is the investigation of choice and has become the gold standard, computed tomographic (CT) scan can diagnose most of the meningiomas.[91] CT scans are helpful in assessing the bony changes and calcification and, moreover, is a cheap and good screening test. Plain X-rays are of academic and historic interest in some selected cases.

A typical meningioma on non-enhanced CT scan is isodense to slightly hyperdense to brain with homogeneous density. Calcification may be seen in 15–20% of cases[117] and may be punctate, rim-like, chunky or nodular. Dense calcifications may be confused with haemorrhage but can be differentiated by density numbers. Variable degree of oedema, evidenced as low density on CT scan, may be found, but is usually mild or absent in PFMs.[96] Bone changes may be hyperostotic or destructive. There is usually intense, homogeneous enhancement on contrast administration. Typically, there is sharp demarcation and a broad base against bone or free dural margins. Areas of hyperdensity, hypodensity and non-uniform enhancement may be seen, which may represent haemorrhage, cystic degeneration or necrosis. Often, aggressive meningiomas are characterised by indistinct or irregular margins.

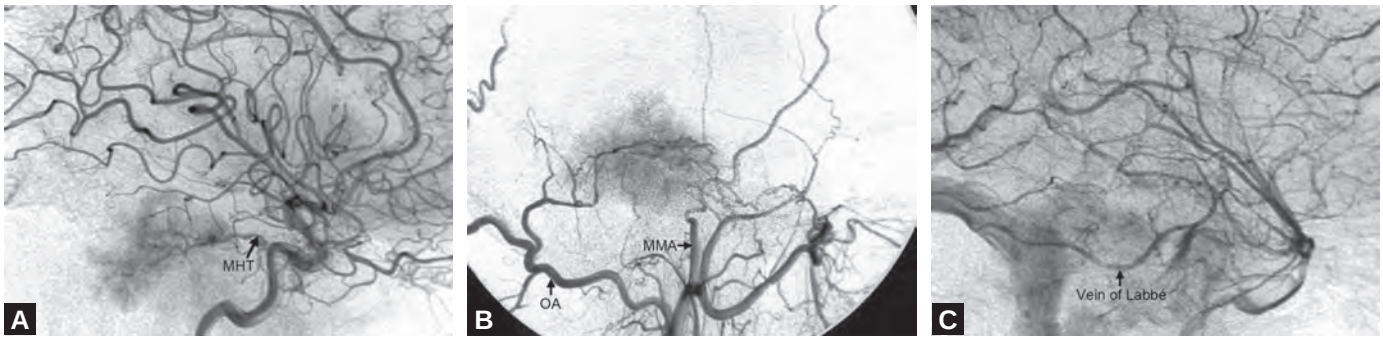
Magnetic resonance imaging (MRI) scan is usually the radiological investigation of choice. On the T1 image most of these tumours are isointense to grey matter. Up to one-third of the tumours are hypointense to grey matter. On the T2 image approximately half of the tumours appear isointense to grey matter and less than half are hyperintense to grey matter.[31,37,162,186] Features like vascular distortion and/or encasement, tumour vascularity and marginating characteristics are much better appreciated on MRI scans than on the CT scan (Figs 6C and D). Displacement of blood vessels, presence of CSF spaces between the tumour and the brain parenchyma and inward displacement of grey-white junction are the typical marginating characteristics.[45] Flow voids produced by flowing blood identify the vasculature in and around the tumour. It has been reported that T2 signal intensity may be reliable in predicting histological subtype, but until now it is at best controversial.[31,37,162] Moreover, associated T2 changes in the brain may also help in predicting the tumour subtype.[31,37] As the intensity in the T2 image depends on water content of the tumour, a hyperintense tumour on the T2 image usually means a softer tumour. It may also help to predict how easily the tumour can be dissected from the surrounding brain. The aetiology of oedema in the adjacent brain parenchyma is controversial. There are many hypotheses like venous obstruction, invasion of parenchyma, pial invasion and secretion of oedemogenic factors. The most likely aetiology is pial invasion in conjunction with release of oedema promoting factors such as vascular endothelial growth factor (VEGF).[126] It has been shown that the peritumoral "oedema" implicates difficulty in microsurgical dissection of the tumour from the brain parenchyma, worse surgical results and increased chance of recurrence.[63,100,153]

On administration of gadolinium contrast, most meningiomas enhance intensely and homogeneously. Contrast MRI is the most sensitive test and the investigation of choice to detect meningioma. Contrast enhancement of the dura mater extending away from the margin of the lesion is the "dural tail" and a characteristic sign to differentiate from other tumours (Figs 1A and 7B). Whether the dural tail represents actual tumour extension or is a juxta-tumour reaction is controversial.[50,170,177] Although once considered almost pathognomonic for meningioma, it may also be rarely seen in other tumours like acoustic neuromas, superficial intra-axial malignancies or dural-based metastasis.[85,117,177,178] Although there are situations when scar tissue (Figs 4C and D) may enhance and mimic a residual tumour, thus making the diagnosis difficult, usually thick and nodular enhancement indicates a residual or recurrent tumour.[175] Magnetic resonance sequences allowing evaluation of the arterial contribution and arterial anatomy from magnetic resonance arteriography (MRA) and more importantly the venous anatomy from magnetic resonance venography (MRV) is sometimes invaluable, especially when looking for the patency of major dural sinuses or the position of critical draining veins. In PFMs the venous anatomy is often very critical in tentorial or torcular meningiomas or the position of vein of Labbé for a subtemporal approach or looking for the position of the major venous complex at the quadrigeminal cistern in tentorial meningiomas.

The role of angiography in management of meningiomas has changed in the modern era, due to the advent of CT and MRI scans. Only in a very few cases can it really help in diagnosis, such as, to differentiate between a glomus jugulare tumour and a jugular foramen meningioma. Some indications for angiography include evaluation of the pertinent collateral circulation if a bypass or vascular sacrifice is planned, or to display the anatomy of the major veins, if MRV does not suffice (Figs 8A to C).

Visualisation of the pial blood supply, in the arterial phase of the angiogram, has been shown to predict difficulty in extrapial dissection.[160]

Magnetic resonance spectroscopy (MRS) is still evolving as a diagnostic tool for meningioma. Although both hydrogen (proton) and phosphorous-based *in vivo* MRS have been reported, proton based MRS is used clinically more often. In normal hydrogen-based MR, the spectrum for brain tissue displays well-defined peaks at 3.2 ppm for choline, 3.0 ppm for phosphocreatine/creatine (PCr/Cr), 2.0 ppm for N-acetyl aspartate (NAA) and a less well-defined peak for lactate at 1.3 ppm.[30] In meningiomas, there is a marked increase in choline



Figs 8A to C: Angiography in a petroclival meningioma. (A) Internal carotid angiography shows the supply of the tumour from the meningohypophyseal trunk (MHT). (B) External carotid angiography shows the same tumour supplied by the occipital artery (OA) and middle meningeal artery (MMA). (C) Venous phase of angiogram shows the position of vein of Labbé

signal and a marked drop in both NAA and PCr/Cr peaks.[30,82] Increase in choline signal implies an elevated concentration of mobile membrane components, which is expected in any tumour. The reduction of NAA is explained by the fact that NAA is confined to neurons. Some authors reported an additional peak at 1.47 ppm. due to alanine.[82,118] Magnetic resonance spectroscopy can be useful in differentiating many slow growing tumours from meningioma and for grading of tumour aggressiveness.[118]

DIAGNOSTIC CHALLENGES

Some CPA meningiomas may be difficult to differentiate from vestibular schwannomas, which are much more common. Certain diagnostic useful points include: (1) Relationship of the tumour to the internal auditory canal and meatus (usually vestibular schwannomas are centred over the internal auditory meatus, whereas meningiomas are eccentric); (2) Presence of dural tail in meningiomas, although dural tail has been reported with vestibular schwannomas also,[85] (3) Hearing preservation is much more likely in larger CPA meningiomas than in larger vestibular schwannomas and (4) Extension into the internal auditory canal suggests, but is in no way pathognomonic of vestibular schwannomas.[34,90]

Another diagnostic challenge is differentiation between a jugular foramen meningioma and a glomus jugulare tumour. Computed tomographic scan shows bony destruction, sclerosis or hyperostosis in meningioma, whereas in glomus jugulare tumour the smooth regular contour of the eroded bone is characteristic. Salt and pepper appearance and serpentine flow voids in MRI and angiograms with early venous drainage are characteristics of glomus tumour. Angiogram shows longer lasting tumour blush in meningiomas. A third diagnostic challenge is distinction between a fourth ventricular meningioma and other fourth ventricular tumours like ependymoma, medulloblastoma or choroid plexus papilloma.

TREATMENT

Observation, radiation treatment and surgical resection are the main treatment options. In this chapter, we will predominantly discuss the surgical management of PFMs. Several factors affect the ease of surgical removal including location, size, consistency, vascular and neural encasement or involvement, prior surgery or radiation treatment. The necessity for resection of not only the tumour but also the involved dura mater and bone are appreciated. To achieve radical resection newer surgical approaches are coming up. However, the balance between the risk and benefit of aggressive surgery must be remembered. Although a number of adjuvant therapies have come up, the only validated form of adjuvant therapy is radiation therapy, of which, gamma knife radiosurgery is a promising one. Observation in a small asymptomatic meningioma or in an elderly or medically sick patient remains a valid option.

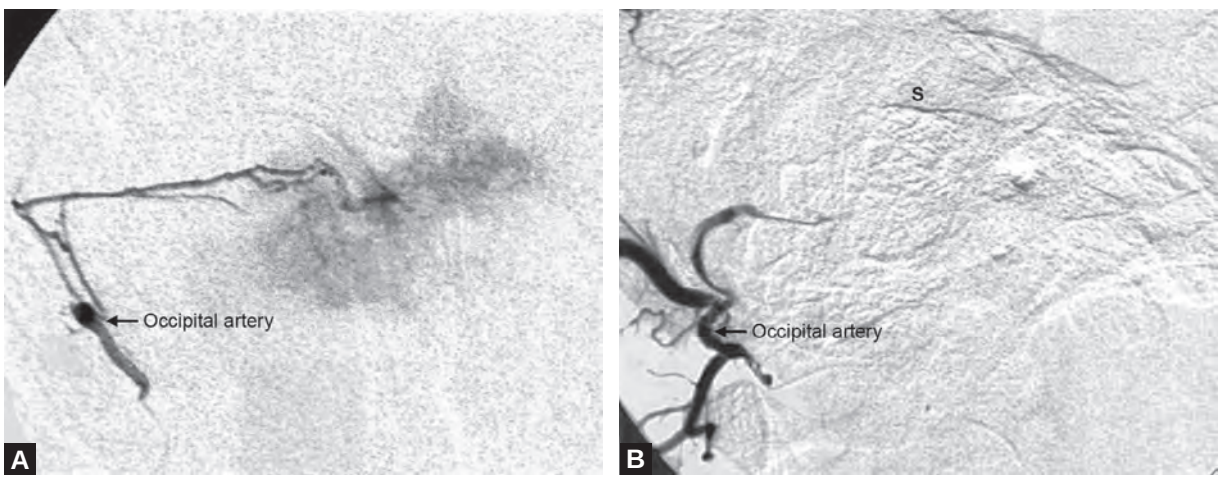
SURGICAL TREATMENT

Factors in the decision to operate include: (1) Tumour is causing symptoms; (2) Tumour is growing as evidenced by serial imaging; (3) Operation can relieve symptoms or at least stop progression of symptoms; (4) Even though asymptomatic the patient is in imminent danger of decompensation, as in a tumour with significant brainstem compression or tonsillar herniation; (5) Tissue diagnosis when diagnosis is in doubt especially when there is a confusion whether the lesion could be a dural based metastasis; and (6) Acceptable risks versus natural history of the tumour and patient characteristics.

General Principles

Pre-Operative Embolisation

Embolisation prior to surgery may reduce the tumour vascularity and decrease tumour bleeding and depends on the availability of expertise and equipment in the institution. Selective embolisation of the feeding vessels (Figs 9A and B), such as the meningohypophyseal trunk in petroclival meningioma is desired.[129]



Figs 9A and B: Process of embolisation. (A) This tumour was supplied by the occipital artery. (B) Following embolisation devascularisation is shown

The optimum time between embolisation and operation is controversial. When non-absorbable particles are used, it is prudent to wait for 7–10 days, allowing time for necrosis of the tumour. If absorbable particles are used, it is advisable to operate within 48 hours of embolisation, i.e. before recanalisation occurs. The greatest contribution of embolisation is the pre-operative occlusion of tumour vessels which, because of their location, can be reached only late in the resection of the tumour. Pre-operative angiography, in addition to arterial and venous anatomy, may also help by occlusion tests to assess whether a tumour-involved vessel can be sacrificed or not if required.

Prophylactic antibiotic should be given. We usually prefer some antistaphylococcal antibiotics like cephazolin or vancomycin. When we know that entry into the ear or mastoid is a possibility, we add metronidazole.

Positioning of the patient should account for: (1) Accessibility to the tumour; (2) Unimpeded venous drainage; (3) Maximum benefit of gravity (so that the brain falls away by gravity and not by retraction); and (4) Position is safe for the patient and comfortable for the surgeon. Most of the PFMs are operated upon either in the prone or lateral position. The sitting or semi-sitting positions can also be used, in which case prophylaxis regarding venous embolism should be addressed. Scalp flaps should be sufficiently thick, wide based, linear or gently curvilinear to allow for a rich blood supply and should be designed in such a way that re-operation, if necessary, should be easy, so far as the scalp incision is concerned. Vascular supply from the external carotid artery branches, such as the occipital artery, can be coagulated during the opening. This can take care of vascularity of the tumour as well.

Several methods are available to minimise brain retraction. The first principle is "to be gentle on the brain and aggressive on the bone", which is the guiding principle of cranial base approaches. By strategic removal of bone, like removing the petrous ridge or skeletonising the sigmoid sinus, or resection of the occipital condyle, or variable parts of the petrous bone, exposure can be made wide and shallow. The second principle is to use drainage of cerebrospinal fluid using several methods, such as ventricular drains, or releasing CSF by opening arachnoid cisterns (sufficient in most cases). The third principle is to use moderate hyperventilation, diuretics, dexamethasone and positioning to relax the brain. The fourth principle is to use gravity to make the brain fall away.

Tumour Resection

Following exposure of the tumour, an exploration to determine the morbid anatomy must be done as much as possible. For resection of cranial base meningiomas, it is necessary that the surgeon has a thorough knowledge of three-dimensional anatomy. The tumour should be devascularised as early as possible, preferably before intratumoral decompression is started. The arachnoid plane should be maintained at all costs as "arachnoid is the best friend of the neurosurgeon". In the majority of meningiomas, which have not been operated upon before, there is an arachnoid plane between the tumour and the brain parenchyma, blood vessels and cranial nerves. In these instances, it is possible to greatly increase the chance of preserving these vital structures by remaining within and respecting this plane. In some instances, it may appear that the tumour is adherent to these structures, but more often than not, this is due to the bulk of the tumour and adequate debulking can make the tumour capsule collapse away from these vital structures and facilitate dissection. The method of debulking is largely dependent on the consistency of the tumour and can include suction, bipolar cautery, sharp excision with scissors or knife (using No. 11 blade), ultrasonic aspirator, laser or even a high speed drill (for a calcified or ossified lesion).

Even after following all the principles of resection, some part may still be found to be adherent to the brainstem or critical neurovascular structures. In these cases, it is prudent to leave that part rather than to risk mortality or a major morbidity. The residual tumour may be followed closely or some form of adjuvant treatment can be given. The role of aggressive resection must be balanced with the major risks involved, with the surgeon's experience and expertise as the fulcrum. Once the tumour is resected in total, attention must be paid to removal of the involved dur amater and bone whenever possible, to achieve Simpson Grade 1 excision.[159] However, it is impossible most of the times to achieve Grade 1 excision for posterior fossa cranial base meningiomas.

Closure

Special care must be taken for the closure to avoid CSF leak.[23] The dura mater should be meticulously repaired, if possible, and following cranial base approaches most often some form of duraplasty using temporalis fascia or fascia lata or artificial dura will be required. Special attention must be paid in packing and obliterating the mastoid air cells and middle ear cavity with fat. Biological glue may be used to reinforce the closure.

Surgical Approaches Used by Tumour Location (Tables 2 to 8)

Type I Posterior Fossa Meningiomas

The status of the lateral sinus is of prime importance in these meningiomas, especially the lateral tentorial meningiomas. If the lateral sinus is completely occluded, the sinus can be transected along with the tumour. In a partially occluded sinus the status of the contralateral sinus is important before one can contemplate excision to achieve total removal. On occasion, a 20 G butterfly needle attached to a manometer can be placed into the transverse sinus just lateral to the torcula and the sinus occluded for 5 minutes. If the venous pressure does not rise more than 5 mm of Hg and if no brain swelling

Fourth ventricular meningioma	Midline suboccipital craniotomy
Cisterna magna meningioma	Midline suboccipital craniotomy

is observed and there is no change in somatosensory evoked potential, the transverse sinus can be divided.[154] However, it must be seen that the sinus is non-dominant and has some collateral flow through the torcula. While making a suboccipital craniotomy for a tentorial meningioma, we usually make sure to expose the lateral sinus completely and about 1 cm of supratentorial dura mater. This helps to expose the inferior surface of the tentorium completely.

For tentorial meningiomas with both supratentorial and infratentorial components, a combined occipital-suboccipital craniotomy is helpful. For this, somatosensory evoked potential (SSEP) should be monitored. Moreover, if possible, visual evoked potential (VEP) should be monitored. For cerebellar convexity meningioma, the surgical approach is suboccipital craniotomy. Depending on the location, the approach can be midline suboccipital or lateral suboccipital. For midline suboccipital craniotomy, the patient is positioned prone and for lateral suboccipital craniotomy the patient is operated upon in the lateral position with side of the approach uppermost. For tentorial meningiomas with both the supratentorial and infratentorial components, the patient is placed in the three-quarter prone position with the side of approach lowermost. This enables the occipital lobe to fall away by effects of gravity and thus retraction is minimised. A midline incision from above the inion down to the C3 level is made for midline suboccipital craniotomy. The craniotomy is made according to the position of the tumour. The decision to resect the rim of the foramen magnum or resect the posterior arch of atlas depends on the lowermost extent and size of the tumour. A lateral suboccipital incision is made for a lateral suboccipital approach. The incision may be straight, lazy S-shaped, hockey stick or C-shaped. The exact location of the incision again depends on the location of the lesion and how much lateral it is necessary to go.

After completion of craniotomy, the dura is opened all around the tumour for convexity meningiomas. For tentorial meningiomas, the dura is opened in a horseshoe fashion with the flap based on dural sinuses. Following dural opening, the tumour is resected following the principles mentioned above. It is possible most of the time to achieve a Simpson's Grade 1 excision[159] in convexity meningiomas. However, for tentorial meningiomas, with involvement of major venous sinuses, the tumour should be resected as much as possible within the limits of safety. The dura is closed with or without duraplasty, whichever is suitable. The bone flap is usually replaced. If the size of the bone flap is significantly smaller than the craniotomy defect, which occurs when bone is drilled to expose the lateral sinus, the residual defect is covered with titanium mesh covered with hydroxyapatite (Bone source®, Leibinger Inc., New Carrolton, TX). Craniectomies for posterior fossa lesions are practically not done nowadays, to avoid post-operative headache.

Type II Posterior Fossa Meningiomas

For post-meatal type of CPA meningiomas usually a standard retrosigmoid approach allows sufficient exposure.[136,149] Brainstem auditory evoked potentials (BSAEP) and SSEP should be monitored in all cases in addition to facial nerve monitoring. Depending on the extent of lesion, trigeminal, glossopharyngeal, vagus, accessory and hypoglossal nerves should also be monitored. Several types of skin incisions, viz. straight, C-shaped, lazy S-shaped, or hockey stick shaped incisions can be used. For craniotomy, the burr holes are usually placed on the asterion, which usually represents the lower margin of the transverse sinus and sigmoid sinus junction, and at the inferomedial corner of the exposure. The decision to resect the foramen magnum or posterior arch of atlas depends on the lower extent of the tumour. Usually if the tumour extends below the jugular foramen, we resect the rim of the foramen magnum. After the craniotomy, bone is drilled to expose the transverse-sigmoid sinus junction well to achieve a good lateral exposure. Exposure of the pre-sigmoid dura is usually desirable to allow retraction of the sigmoid sinus laterally and decrease the obstruction of the surgeon's view. The dura is opened in a C-shaped manner, with the concavity of the 'C' facing medially with a few millimetres of dural cuff kept laterally to facilitate dural closure. A few release incisions are made in this cuff of dura to facilitate retraction. After adequate CSF drainage in small tumours, the petrous pyramid can be dissected to devascularise the tumour with care taken not to injure neurovascular structures. In large tumours, the principle of alternate intratumoural debulking and capsular dissection should be followed. A variety of critical structures must be dissected including cranial nerves (fourth to twelfth), superior cerebellar artery (SCA), anterior inferior cerebellar artery (AICA), posterior inferior cerebellar artery (PICA), basilar artery (BA), vertebral artery (VA) and their branches.

Most pre-meatal type of CPA meningiomas, including the larger ones, can be resected by the retrosigmoid approach. Usually, the larger tumour creates space between the brainstem and the petrous bone to facilitate removal. However, in some smaller pre-meatal tumours, with a posteriorly placed sigmoid sinus and significant anterior brainstem compression, the pre-sigmoid approach is usually done to have an unobstructed and more lateral view, without undue cerebellar retraction. A retrolabyrinthine type of pre-sigmoid petrosal approach

is sufficient in these cases and does not compromise hearing. However, the limitation of the pre-sigmoid petrosal approach is that it is difficult to reach tumours which have attachment below the level of the ninth cranial nerve. In these cases, a retrosigmoid approach can be added to reach the lower part of the tumour. In contrast, tumours reaching the supratentorial compartment, especially the Meckel's cave, may be resected by adding a supratentorial craniotomy[104] or by the retrosigmoid intradural suprameatal approach (RISA). The RISA has recently been described for posterior fossa tumours with small extension into the middle cranial fossa, especially Meckel's cave.[138] In this approach, after standard retrosigmoid craniotomy and tumoural decompression, the suprameatal tubercle is drilled to expose the distal part of the cisternal segment of the trigeminal nerve and the part in Meckel's cave to remove the part of the tumour from Meckel's cave. Although this can help the surgeon to reach Meckel's cave from the posterior fossa, eliminating the need for additional supratentorial craniotomy, the approach is technically demanding. The surgeon needs to drill in a space between the brainstem and petrous bone and through strings of vital cranial nerves and vessels. Any slippage of the drill can be catastrophic. Moreover, venous bleeding from the petrous bone may be troublesome. This approach, thus, must be used very selectively. On the other hand, the combined supratentorial and infratentorial approach is more versatile and technically easier than RISA. However, while using this approach, special care must be taken to preserve the vein of Labbé, otherwise a catastrophic venous infarct of the temporal lobe may result.

The extended middle cranial fossa approach provides excellent access and exposure to tumours in the anterior cerebellopontine angle and petroclival junction. This approach allows a more direct access to the area anterior to the internal auditory canal. The key to the approach is adequate bone removal of the petrous apex, to provide exposure down to the inferior petrosal sinus and anteriorly to Meckel's cave and the petroclival junction and combined with extradural elevation of the temporal lobe with suitable brain relaxation minimises post-operative complications.[27]

Type III Posterior Fossa Meningiomas

These lesions are best approached by a posterior fossa infratemporal,[40] transjugular or infralabyrinthine[86] approach, which are basically similar with very minor variations. The operation can be done in the lateral position or if neck dissection is necessary, in the supine position (ipsilateral shoulder elevated by bolster) with the head elevated and turned away from the side of approach. Monitoring of the lower cranial nerves, BSAEP and SSEP is necessary. A C-shaped post-auricular incision is made and extended down to the neck with neck dissection, if there is tumour extension into the neck or if vascular control is required. The external auditory canal is usually transected but can be preserved, if the anterior exposure desired is limited. The neck dissection is done to expose the major vessels and the vessel supplying the tumour and the lower four cranial nerves. A complete mastoidectomy is done to expose the semicircular canals and the facial nerve along with the chorda tympani. The jugular bulb needs to be completely exposed. After drilling the jugular process of the temporal bone, three structures will come in the way of the anterior aspect of the jugular bulb and lateral aspect of the jugular foramen. These are the facial nerve, styloid process with attached muscles and ligaments and rectus capitis lateralis muscle. The facial nerve is anteriorly mobilised by skeletonising the whole intramastoid and intratympanic part of the facial nerve and cutting the chorda tympani. The styloid process is resected along with the attached structures and reflected downward, exposing the highest portion of the cervical internal carotid artery and internal jugular vein. The rectus capitis lateralis muscle is cut and retracted. If anterior exposure is needed, this can be achieved by transecting and overseeing the cartilaginous external auditory canal and drilling the middle ear structures. If sensorineural hearing preservation is an issue, this can be done by preserving the footplate of the stapes. Significant intradural extension can be dealt with by adding a retrosigmoid craniotomy. Potential complications of this demanding approach are many, including major vascular injury to catastrophic lower cranial nerve palsy. If expertise for these difficult approaches, which benefit from collaboration with a neuro-otologist, does not exist, it may be prudent to remove the intradural portion of the tumour by the retrosigmoid approach, followed by radiation of the residual tumour.

Sanna et al. operated on 13 primary jugular foramen meningiomas, using the petro-occipital transigmoid (POTS) approach; a combined POTS-transotic approach because of massive erosion of the carotid canal; a combined POTS-translabyrinthine approach was used in patients with pre-operative unserviceable hearing and a modified transcochlear approach type D with posterior rerouting of the facial nerve and transection of the sigmoid sinus and jugular bulb was performed in patients with a huge cerebellopontine angle tumour component with extension to the prepontine cistern, together with massive involvement of the petrous bone and middle ear and encasement of the vertical and horizontal segments of the intrapetrous carotid artery. Gross total tumour removal (Simpson Grades I and II) was achieved in 11 (84.6%) cases and subtotal removal of the tumour was possible in two patients. Good facial nerve function (grades I and II) was achieved in 46.1% of cases and hearing was preserved at the pre-operative level in all four patients who underwent surgery via the POTS approach. Following surgery, no patient recovered function of the pre-operatively paralysed lower cranial nerves and a new deficit of one or more of the lower cranial nerves was recorded in 61.5% of cases. Among the various surgical techniques proposed for dealing with these lesions, they prefer the POTS approach alone or combined with the translabyrinthine or transotic approaches.[140]

Type IV Posterior Fossa Meningiomas

For this group of meningiomas, a more lateral approach is needed than in CPA meningiomas, in order to have adequate visualisation without significant cerebellar retraction. A petrosal approach is usually the ideal choice.[3] However, some exceptions are there. For lesions in the upper petroclival region or lesions lying completely above the trigeminal nerve and reaching above the dorsum sellae, a frontotemporal craniotomy with orbitozygomatic osteotomy is recommended. In this approach, the skin incision extends from below the zygomatic arch and just in front of the tragus to the opposite midpupillary line. An interfascial dissection is done to protect the frontotemporal branch of the facial nerve. The temporalis muscle is detached and reflected down, followed by a frontotemporal craniotomy and orbitozygomatic osteotomy as described in the literature.[151,179,180] The dura is opened in a C-shaped manner based anteroinferiorly, with the Sylvian fissure widely split to reach the tumour.

If the tumour is not reaching above the dorsum sellae, a petrosal or partial labyrinthectomy petrous apicoectomy (PLPA) approach[152] is preferred. For this approach the patient is placed in the lateral position with the mastoid of the affected side at the uppermost level. A C-shaped incision is made and the muscles reflected anteroinferiorly. A bone flap is carefully elevated to expose the transverse and sigmoid sinuses. A mastoidectomy is performed with exposure of the sinodural angle, Trautman's triangle, semicircular canals, facial nerve in the fallopian canal and the superior petrosal sinus. If hearing is absent, a total labyrinthectomy can be performed to increase the anterolateral exposure. The dura mater is opened along the floor of the temporal fossa and along the anterior border of the sigmoid sinus. The vein of Labbé is identified and protected with ligation and transection of the superior petrosal sinus. The division is carried medially through the tentorium to reach the tentorial edge taking care not to injure the trochlear nerve or the petrosal vein.[137] Sectioning of the tentorium allows the sigmoid sinus to fall back along with the cerebellum, thus reducing the need for retraction. By angling the microscope, it is possible to visualise the trochlear through to the lower cranial nerves, as well as the entire anterolateral brainstem with the vertebrobasilar system. The tumour resection proceeds in the usual way then. However, when hearing preservation is an issue it is advisable to use PLPA approach. This approach provides much better access to the clivus, petrous apex and posterior cavernous sinus, compared to the retrolabyrinthine approach. This approach has the advantage of preserving hearing in as much as 80% of cases.[152] This approach is different in a few ways from the traditional petrosal approach. First the mastoidectomy exposing the sigmoid sinus, middle fossa dura, retrosigmoid dura, Trautman's triangle, facial nerve in fallopian canal, superior petrosal sinus and semicircular canals is done. A temporal craniotomy is added. The whole superior semicircular canal and part of the posterior canal above the Donaldson line is drilled away. Care must be taken not to lose endolymph and the canals should be packed with bone dust or bone wax. Bone drilling is continued to resect the petrous apex medial to the internal carotid artery. This approach facilitates entry into the cavernous sinus as well. However, an intracavernous dissection is only performed in the presence of extensive cavernous sinus involvement and progressive cranial neuropathies. The dura mater is opened in the usual way and tumour is resected. If the tumour extends well below the jugular foramen, a retrosigmoid craniotomy should be added. There are surgeons, who have achieved good results using the retrosigmoid approach or combined supratentorial and infratentorial craniotomy for these lesions,[11,134,135,138,163] but we prefer to use this approach for these lesions.[18] However, there are instances when total petrosectomy should be done (Table 6). For this approach, the facial nerve is completely skeletonised from the internal auditory canal to the stylomastoid foramen. The greater superficial petrosal nerve is sectioned and the facial nerve is mobilised posteriorly. The petrous internal carotid artery is exposed completely and mobilised anteriorly. The entire petrous bone superior to the jugular foramen and part of the lateral clivus can then be drilled away. The eustachian tube must be packed to prevent CSF leak. Other approaches to this area, like anterior transpetrosal-transtentorial approach,[72] extended middle fossa approach[49] and extended lateral subtemporal approach,[48] have been described in the literature.

Goel et al. found the conventional posterior cranial fossa approach suitable for a select group of petroclival meningiomas. Gross total tumour resection was achieved in 21 cases and a partial tumour resection in the remaining 7 cases, with two patients dying in the post-operative period. The advantages are that it provides easy and quick exposure of the tumour without any petrous bone drilling. It also provides a direct and early exposure of the tumour-cranial nerve-brainstem interface facilitating the dissection. The lateral and inferior tumour extensions in relationship to the clivus can be more easily accessed and the site of attachment of the tumour to the dura overlying the posterior face of the petrous apex can be seen directly.[47]

Cho and Al Mefty advocate the combined petrosal approach, i.e. the posterior petrosal with the anterior petrosal approach for patients who have a large petroclival meningioma and serviceable hearing. This approach enhances petroclival exposure and the degree of tumour resection, especially in the area of the petroclival junction, middle clivus, apical petrous bone, posterior cavernous sinus and Meckel's cave. The approach also allows better visualisation of the contralateral side and the ventral brainstem, which facilitates safe dissection of the tumour from the brainstem, the basilar artery, the perforators and if a patient has an early draining bridging vein to the tentorial sinus or a prominent

sigmoid sinus and jugular bulb, the combined petrosal approach provides significant working space.[19]

Sanna et al. reported their surgical strategy in the management of 81 patients with posterior petrous face meningiomas. Thirty-one patients were approached by the enlarged translabyrinthine approach. The above approach combined with transapical extension Type II was performed in 29 patients. The combined retrosigmoid-retrolabyrinthine approach was used in 8 cases. The modified transcochlear approach Type A with permanent posterior transposition of the facial nerve (FN) was performed in 6 patients. Two patients underwent a retrolabyrinthine subtemporal transapical approach, one patient underwent a transpetrous middle cranial fossa approach and four patients with intracanalicular meningiomas were operated on through the enlarged middle cranial fossa approach. Total removal of the tumour (Simpson Grades I and II) was achieved in most patients (92.5%). The facial nerve was anatomically preserved in 79 of the 81 (97.5%) patients, and hearing-preserving surgery was attempted in 15 patients (18.5%) with pre-operative serviceable hearing, of which 11 had their hearing preserved at the same pre-operative level and 4 experienced post-operative deafness. They concluded total tumour removal (Simpson Grades I and II) remains the treatment of choice, taking priority over hearing preservation. Subtotal removal is preferred in the event of the absence of a plane of cleavage between the tumour and the brainstem, in the presence of encasement of vital neurovascular structures, in elderly patients with tumours adherent to pre-operatively normal facial or lower cranial nerves.[141]

The feasibility of keyhole approach in surgical treatment of petroclival meningioma has not been well evaluated. Zhu et al. treated 25 patients with petroclival meningioma via subtemporal, retrosigmoid or combined keyhole approaches. The maximum diameter of tumours ranged 2–7 cm (mean, 4.5 cm). Gross total resection (GTR) was achieved in 14 patients, giving a GTR rate of 56%. Subtotal resection (STR) was carried out in 8 patients and partial resection in 3. Thirteen patients kept normal neurological status, whereas others suffered from cranial nerve deficits (VIIth, IIIrd and lower CN), and one patient died in the post-operative period. The extent of tumour resection was evaluated by MRI 3 months after surgery. They found keyhole approach surgery, especially the combined keyhole approach is suitable for the treatment of petroclival meningioma, as it provides an easy and quick access to the supratentorial and infratentorial juxta-clival region, without drilling of the petrous bone and complications related to the approach can be minimised.[183,184]

The management of small petroclival meningiomas is still controversial, with clinical observation, radiosurgery and surgical removal being the options of treatment. The natural history of these tumours is not well known. Published series of patients treated with radiosurgery are not comparable with surgical series because the latter also includes large size tumours.

Ramina et al. treated 18 patients with small petroclival meningiomas (diameter less or equal to 2.8 cm) by radical surgical removal. Total resection (Simpson's Grade 1) was possible in all patients, with minimal morbidity and no mortality. The approaches used were retrosigmoid, fronto-orbito-zygomatic and pre-sigmoid. They concluded the effectiveness and outcome of surgery for small petroclival meningiomas should be compared with series treated by radiosurgery.[127]

Type V Posterior Fossa Meningiomas

Despite the introduction of skull base approaches, there is still controversy about the optimum surgical management for foramen magnum meningiomas. The approach depends on the precise location of the lesion. For posteriorly located lesions, it is approached by midline suboccipital craniotomy with resection of the posterior arch of atlas and laminae of axis depending on the size of the lesion. After craniotomy, the dura is opened in a Y-shaped manner with the vertical limb of the Y below the level of marginal sinus. Tumours in the lateral aspect of the foramen magnum can usually be excised by a low retrosigmoid approach. The rim of the foramen magnum is usually resected along with the arch of the atlas and hemilamina of the axis if necessary. A posterior suboccipital approach was utilised with lateral extension of the bone opening, according to the localisation of the tumour which was ventral, ventrolateral, dorsal and dorsolateral. Complete removal of the tumour was possible in 14 cases (Simpson Grade I and II). In their experience, the posterior suboccipital approach is suitable for the removal of the majority of these tumours.[68]

For tumours in the anterior or anterolateral aspect of the foramen magnum, the extreme lateral transcondylar approach[101,156,158] is recommended. However, when the tumour is large and situated anterolaterally a lateral suboccipital approach,[57] which is a modification of the traditional retrosigmoid approach, is often sufficient, as the tumour makes the space for the surgeon. Several modifications have been made of the extreme lateral approach,[133] which is undertaken in a lateral position. A C-shaped or an inverted U-shaped incision is made. The advantage of the inverted U-shaped incision is that, if the patient needs an occipito-cervical fusion, it can be performed through the same incision. The vertebral artery is exposed in the suboccipital triangle, where it is covered by a venous plexus, which can cause troublesome bleeding. The vertebral artery is mobilised by deroofing the foramen transversorium of the atlas. The occipital condyle is then drilled, dictated by the amount of exposure needed. If less than half of the condyle is drilled and the rest of the atlanto-occipital joint is stable, the patient will not need a fusion, otherwise a fusion is necessary. The tumour is resected following the above-mentioned principles. In a typical foramen magnum meningioma, which is either anterolateral or anterior to the brainstem, the vertebral artery and spinal accessory nerve are posterior to it. Care must be taken while

opening the dura, as the nerve and the vertebral artery may be very close to the dural surface. The purely anterior foramen magnum meningioma usually pushes the hypoglossal nerve posterolaterally, while the anterolateral one pushes it anteromedially. Although we prefer to use the transcondylar approach for typical foramen magnum meningiomas, there are surgeons, who have used a lateral suboccipital approach to resect these tumours.[113]

Menezes utilised the posterolateral transcondylar approach to the craniocervical junction in children for various lesions including meningiomas. Pre-operatively, the stability of the craniocervical junction was assessed so that a fusion procedure could be accomplished at the same operative setting, if necessary. Evaluation of the lower cranial nerves was vital. The occipital bone removal was carried out up to the sigmoid sinus and towards the jugular bulb and occipital condyle removal was limited to one third of the medial occipital condyle. Relocation of the vertebral artery was made at the atlas vertebra, thus providing posterolateral exposure into the posterior fossa and upper cervical spinal canal. He found this route to be a versatile avenue to approach a variety of lesions ventrolateral to the brainstem and upper cervical cord and the exposure is quite satisfactory with minimal or no retraction of important neurovascular structures in the region.[106]

Based on the relevant anatomy of the foramen magnum area, Bruneau et al. have a classification system based on the compartment of development, the dural insertion and the relation to the vertebral artery. The compartment of development is mostly intradural and less often extradural or both intra-extradural. They classified intradural foramen magnum meningiomas as posterior, lateral and anterior if their insertion is, respectively, posterior to the dentate ligament, anterior to the dentate ligament and anterior to the dentate ligament with extension over the midline. This classification system helps to define the best surgical approach and the lateral extent of drilling needed and anticipate the relation with the lower cranial nerves. In their department, three basic surgical approaches were used to foramen magnum meningiomas: the posterior midline; the posterolateral and the anterolateral approaches.[12]

Pamir et al. operated on 22 patients (23 surgical procedures) with a diagnosis of foramen magnum meningioma, using the suboccipital approach for two posteriorly located tumours and the paramedian suboccipital approach was replaced by the far-lateral modification in the treatment of ventral meningiomas. A gross-total removal was achieved in 21 patients, with an overall morbidity of 32%, with no specific and clinically significant complications attributable to the far-lateral modification being observed. They concluded that the far-lateral approach has improved the success of surgery in ventrally located lesions, while the posterior suboccipital approach is still indicated in the removal of lesions placed posterior to the dentate ligament.[120]

Borba et al. operated on 15 patients using the lateral approach in all cases. Based on the pre-operative magnetic resonance imaging, the tumours were classified as anterior or anterolateral in the axial slices and clivospinal or spinoclival in the sagittal slices. The extent of bone removal and the management of the vertebral artery were tailored to each patient. The occipital condyle was partially removed in only eight patients. Total removal of the tumour was achieved in 12 patients, subtotal in two, and partial resection in one patient. Post-operative complications occurred in two patients and there was no surgical mortality. They stated that the extent of surgical approach to foramen magnum meningiomas must be based on the main point of dural attachment and tailored individually case-by-case and the differentiation between clivospinal and spinoclival types, as well as anterior and anterolateral types, is crucial for the neurosurgical planning of foramen magnum meningiomas.[9]

Type VI Posterior Fossa Meningiomas

The surgical approach depends on the location of the tumour. Fourth ventricular meningiomas are approached via a standard midline suboccipital approach. After dural opening, the vermis is split to enter the fourth ventricular cavity. The blood supply of these tumours is usually from the branches of the posterior inferior cerebellar artery, which should be taken care of first followed by tumour removal. Utmost care must be taken not to injure the structures in the floor of the fourth ventricle. Purely intracanalicular meningiomas can be resected either by the retrosigmoid transmeatal approach or middle fossa approach.[72]

RADIATION TREATMENT

The usual forms of radiation used are fractionated external beam radiation and stereotactic radiosurgery. Although there are a few reports of brachytherapy,[55,83] it has never become popular.

Fractionated External Beam Radiation

During the 1960s and the 1970s, concerns were raised regarding the effectiveness of external beam radiation treatment for meningiomas. However, a few retrospective well-conducted studies showed its effectiveness in a higher dose of 45 to 60 Gy. This was shown to be effective both after recurrence and after subtotal resection.[6,107,169] Moreover, a longer survival was shown in patients after subtotal resection, who had external beam radiation.[21] Conceptually, external beam radiation should also be more beneficial for aggressive meningiomas, with the recommended radiation dose and target volumes greater for these malignant meningiomas.[13] However, caution must be exercised, as scattering of radiation can induce complications, especially when dealing with lesions close to the brainstem. Other complications include radionecrosis and secondary neoplasms.

Stereotactic Radiosurgery

Stereotactic radiosurgery is being used in increasing frequency and includes proton beam,[164] gamma knife radiosurgery (GKRS)[65,165,168,181] and linear accelerators (LINAC or X-knife). The recent results of gamma knife radiosurgery for meningiomas, used as a primary modality (for tumours less than 3 cm) or as an adjunctive treatment or after recurrence are excellent with a control rate of 93% over a follow-up period of 5–10 years.[77–79,97,110,111,122] However, toxicity of gamma knife or other forms of radiosurgery for meningioma exists. This includes injury to encased cranial nerves,[92,109,171] which tolerate radiation poorly. A major advantage of gamma knife is the possibility of using a larger number of isocentres. This permits greater conformality in treating irregular shaped tumours typically occurring at the cranial base.[79] The experience with LINAC in meningiomas is somewhat limited. Two studies showed a control rate of 89.3%[56] and 100%[157] over a mean follow-up period of 5 years and 23 months, respectively. Hakim et al.[56] showed an overall permanent complication rate of 4.7% and a mortality rate of 10% during the follow-up period. A potential long-term risk of either gamma knife or X-knife radiosurgery is the risk of secondary neoplasms including malignant tumours. The risk of complication is uncertain but linked to the degree of scatter radiation and length of patient survival.

Kreil et al. evaluated the effectiveness and toxicity of radiosurgical treatment for benign skull base meningiomas in 200 patients with a follow-up of 5–12 years. Of these, 99 patients were treated with a combination of microsurgical resection and GKRS, and in 101 patients, GKRS was performed as the sole treatment option. Tumour volumes ranged 0.38–89.8 cm^3 (median 6.5 cm^3) and doses of 7–25 Gy (median 12 Gy) were given to the tumour borders at covering isodose volume curves (range 20–80%, median 45%). The actuarial progression-free survival rate was 98.5% at 5 years and 97.2% at 10 years. The neurological status improved in 83 cases (41.5%), remained unaltered in 108 (54%), deteriorated in 9 (4.5%) and complications were radiation induced oedema in two patients (1%). They concluded GKRS has proved to be an effective alternative to microsurgical resection, radiotherapy and Linac based radiosurgery for adjunctive and primary treatment of selected patients with basal meningiomas. Because of the excellent long-term tumour control rate and low morbidity associated with GKRS, this treatment option should be used more frequently in the therapeutic management of benign skull base meningiomas.[81]

OTHER TREATMENTS

Apart from surgery and radiation treatment very little data is available on the efficacy of chemotherapy, although several agents have been tried. An interesting case report showed that a combination of 5-fluorouracil, folinic acid and levamisole might be effective in some forms of meningiomas,[7] but no further success was reported by those authors or other studies. Chamberlin in 1996[17] showed a modest improvement in survival (median survival 5.3 years) in patients treated with a combination of cyclophosphamide, adriamycin and vincristine for malignant meningioma. Hormonal agents, like tamoxifen and mifepristone (RU-486), have been tried without encouraging results.[51,53] Recombinant interferon α-2b has been used for a small number of patients with aggressive meningiomas[67] and it is apparently more effective than the traditional chemotherapeutic agents. Similarly, hydroxyurea has also been shown to produce some sporadic encouraging results,[146] although these initial encouraging results are not readily duplicated.

RESULTS AND PROGNOSIS

Two major issues are important in the prognosis of meningiomas. The first issue is the recurrence, which was first scientifically addressed in Donald Simpson's hallmark paper[159] based on the extent of resection. He reported a 9% recurrence rate after "complete resection" of the tumour and its neoplastic dural base, a 19% recurrence rate when the tumour was "resected" and the dural base was coagulated, a 29% recurrence rate when the tumour itself was removed but the dural base was not treated and a 40% recurrence rate when the removal was subtotal. However, this study was done in pre-CT and pre-MRI era. Excellent results have been produced by many surgeons over the years,[3,5,11,22,44,124,133–135,138,139,148–150,152,153,155,156,163,167] in terms of recurrence and complications, especially after improved microsurgical technique and advent of cranial base surgery. However, these excellent results, especially the recurrence factor, must be interpreted with caution as most studies have a follow-up period averaging 2–10 years rather than the desirable 15–20 year follow-up. The second issue in management of meningiomas is the morbidity and compromise of the quality of life associated with management options. Intervention with microsurgery, radiosurgery or combination treatment must be addressed in the context of associated morbidity. Occasionally, observation remains the optimal management choice given patient and tumour related characteristics when compared to the risk of active intervention.

Karia et al. analysed the predictive value of recurrence of protein expression in surgical samples of meningiomas, as they have been reported to be associated with prognosis of meningiomas. The study was done in a sample of 59 World Health Organization grade I tumours obtained after Simpson Grades I to III surgical resection (complete excision), that were followed for 6–16 years. The expression was investigated applying immunohistochemical and tissue microarray techniques. They found none of the correlations showed a significant association by means of logistic regression analyses. Their results indicate that the Simpson Grade significantly alters the outcome of a World Health

Organization I grade meningioma and a longer follow-up period significantly increases the risk of recurrence. They concluded that expression of none of the proteins or correlation between protein expressions previously reported to be of significance regarding recurrence can be recommended as a diagnostic tool, while assessing the risk of recurrence of World Health Organization grade I meningiomas.[69]

CONCLUSION

Despite improvements in standards of pre-operative imaging, peri-operative care, microsurgical techniques, cranial base approaches, PFMs still pose a formidable challenge to the contemporary neurosurgeons. The ideal goal of treatment is complete resection, but in some cases, this may not be possible without putting the patient in an enormous risk of severe morbidity and even mortality. In these cases, it is always prudent to back out and, if necessary, take the advantage of the recent advancement of adjuvant treatments, especially stereotactic radiosurgery.

EDITORIAL COMMENT

The variety of surgical approaches described in this chapter for PFM, especially those requiring skull-base surgical approaches require a thorough knowledge of the microanatomy, often the help of an ENT surgeon and must not be undertaken lightly by surgeons in the initial part of their career. Specialised training on cadavers in a laboratory is essential. Such facility is now available in the country, one such being at AIIMS, New Delhi. For further details of these approaches, one may consult Textbook of Operative Neurosurgery (Ravi Ramamurthi, K Sridhar, MC Vasudevan Eds 2005).

172 Petroclival Meningiomas

Trimurti D Nadkarni

INTRODUCTION

Meningiomas account for 14–18% of all primary intracranial tumours. Approximately 10% of these occur in the posterior fossa. Amongst the infratentorial meningiomas, 3–10% are clival and petroclival. These tumours have been associated with a high risk of morbidity and mortality. Some surgeons described these tumours to be inoperable and they are considered to be one of the most difficult tumours of the skull base. Recent advances in neuroradiology, neuroanaesthesia and advanced microneurosurgical skull base approaches have led to better outcome.

Professor Gazi Yasargil laid down the treatment goal 30 years ago. "Clivus meningiomas in particular have until recent years been uniformly lethal. The outlook of such patients must be bettered by achieving earlier and more accurate diagnosis, by improving surgical technique, and better understanding of the pathological anatomy."[19]

Petroclival meningiomas are neurosurgical challenges, despite their usually benign pathology, principally because of involvement of the cavernous sinus, encasement of arteries and nerves, pial breach on the brainstem and extensions into multiple cranial compartments and foramina. The high risk of recurrence in partially resected tumours versus high risk of neurological morbidity and mortality resulting from pursuing radical gross total resection adds to the surgical challenge. Therapy must be tailored to the needs of the individual patient.

Although Simpson Grade I resection[16] is possible in many cases, in most of the patients a sub-total resection with or without radiosurgery has become the preferred treatment to reduce post-operative morbidity. Modern cranial base exposure, resection techniques and cranial base repair techniques have allowed the safe resection of many complex cranial base meningiomas. Radiosurgery has a definite role in the control of small tumour remnants, as well as small unoperated tumours. Thus, we need to incorporate changes in our management protocols with time.

In the large series published, the average reported mortality was 2% (range, 0–9%), major morbidity was 23% (range, 7–39%), permanent cranial deficits occurred in 44% (range, 29–76%), a poor functional outcome in 17% and a recurrence rate of 21% with an average follow-up of 3 years.[1,4,7,9,12–15]

NATURAL HISTORY

Authors[2,3] have described these tumours to have a relentlessly progressive growth with an ultimate fatal outcome. Partially resected tumours recur.[1,4,9,15] Van Havenbergh et al. have observed 21 untreated petroclival meningiomas over a period of 4 years. Tumour growth was observed in 76% and in 63% of these patients, there was functional deterioration.[18] These studies prove that these tumours are slowly growing but with a poor long-term outcome. In women, meningiomas may stop growing after menopause.

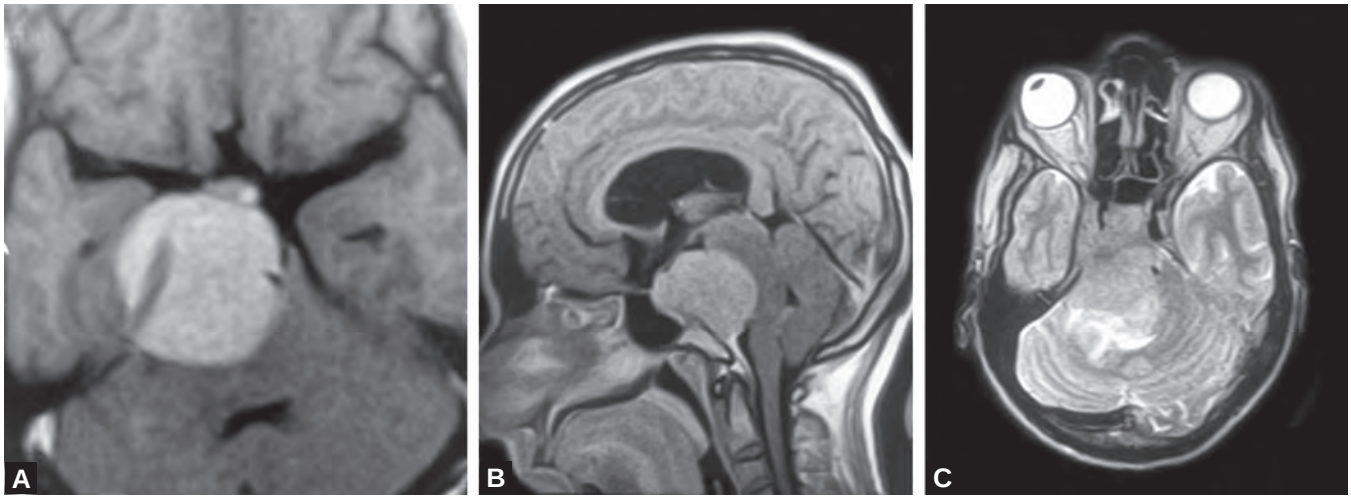
CLINICAL FEATURES

These tumours are predominantly seen in women in the fourth and fifth decades of life.[10,12] The most common neurological deficits include cranial nerve deficits, ataxia and hemiparesis or monoparesis. The clinical syndrome is of insidious onset, often mimicking other pathological processes; in elderly patients, the presenting symptoms are often attributed to vertebrobasilar insufficiency. The cranial nerve deficits include facial hypoaesthesia or anaesthesia with or without dysaesthesia, dysconjugate gaze, decreased hearing, facial paresis and decreased gag reflex.

Headache, gait ataxia, facial dysaesthesia, vertigo and deafness are the more frequent presenting symptoms with the trigeminal nerve as the single structure most often involved from onset. Later symptoms include gait ataxia, diplopia, swallowing difficulty and somatomotor deficits. The typical sign of a petroclival meningioma is a relatively fair preservation of hearing, in contrast to severe trigeminal involvement and impairment of the cranial nerves below VIII, with accompanying cerebellar signs.

NEURORADIOLOGICAL EVALUATION

A contrast computed tomographic (CT) scan with bone algorithm in axial and coronal views and a magnetic resonance imaging (MRI) scan are performed to evaluate the relationship between the meningioma and the cranial base and its bony involvement (Figs 1 to 5). Fine cuts through the temporal bone define temporal bone anatomy and the degree of pneumatisation, which facilitates the surgical exposure when a transpetrosal approach is planned.



Figs 1A to C: Post-contrast MR images. (A) Axial. (B) Sagittal. (C) T2-weighted axial images show a right petroclival meningioma that extends above the tentorium. The tumour has encased the basilar artery. The T2-weighted image clearly shows the loss of the peripheral arachnoidal plane between the tumour and brainstem. Brainstem oedema is noted

The most important information the surgeon needs to know before surgery includes the site and extension of dural attachment, tumour size, consistency, vascularity, bone involvement, tumour-brainstem interface, the position and encasement of arteries and extensions of the tumour specifically to the cavernous sinus.

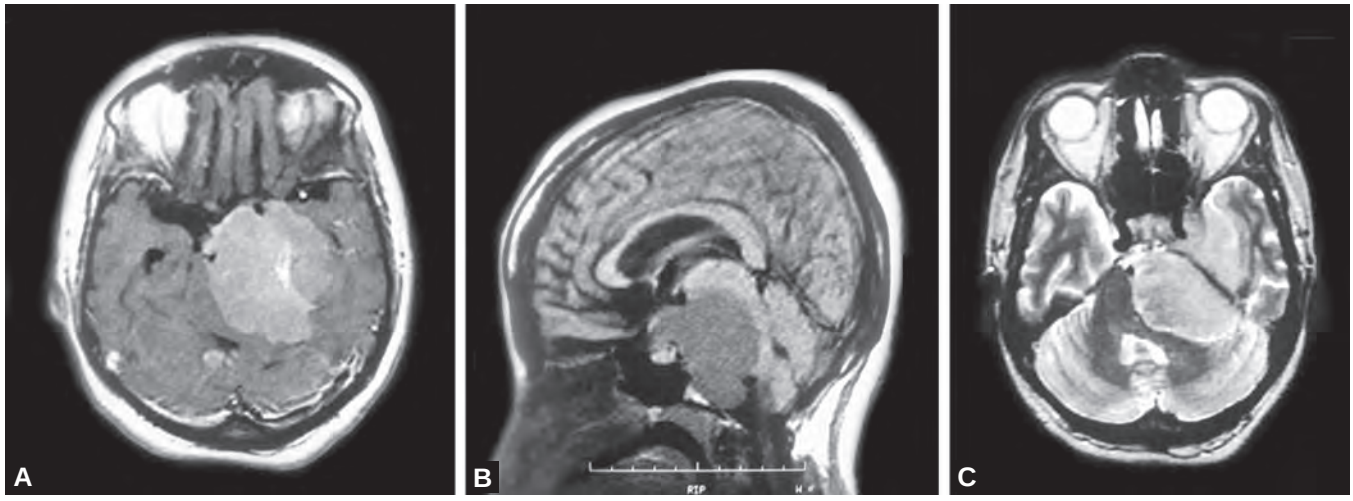
The presence of oedema on T2-weighted MR scans indicates a disruption of the blood-brain barrier and invasion or adherence of the tumour to the brainstem surface. Pial invasion of the tumour is indicated by the loss of the arachnoid plane on T1-weighted images and to the presence of blood supply to the tumour from the vertebrobasilar complex in the arterial phase of angiography.[15]

Patients may undergo cerebral angiography to study the vascular supply of the tumour and to plan the endovascular and surgical procedure. The tumour is principally fed by the meningohypophyseal trunk of the ICA, the posterior branch of the middle meningeal artery, the meningeal artery of the vertebral artery, the clivus artery originating from the carotid siphon, the petrosal branches of the meningeal arteries and the ascending pharyngeal branches of the external carotid artery. Preoperative embolisation should be performed through the main feeding vessels, which makes the surgical procedure easier.

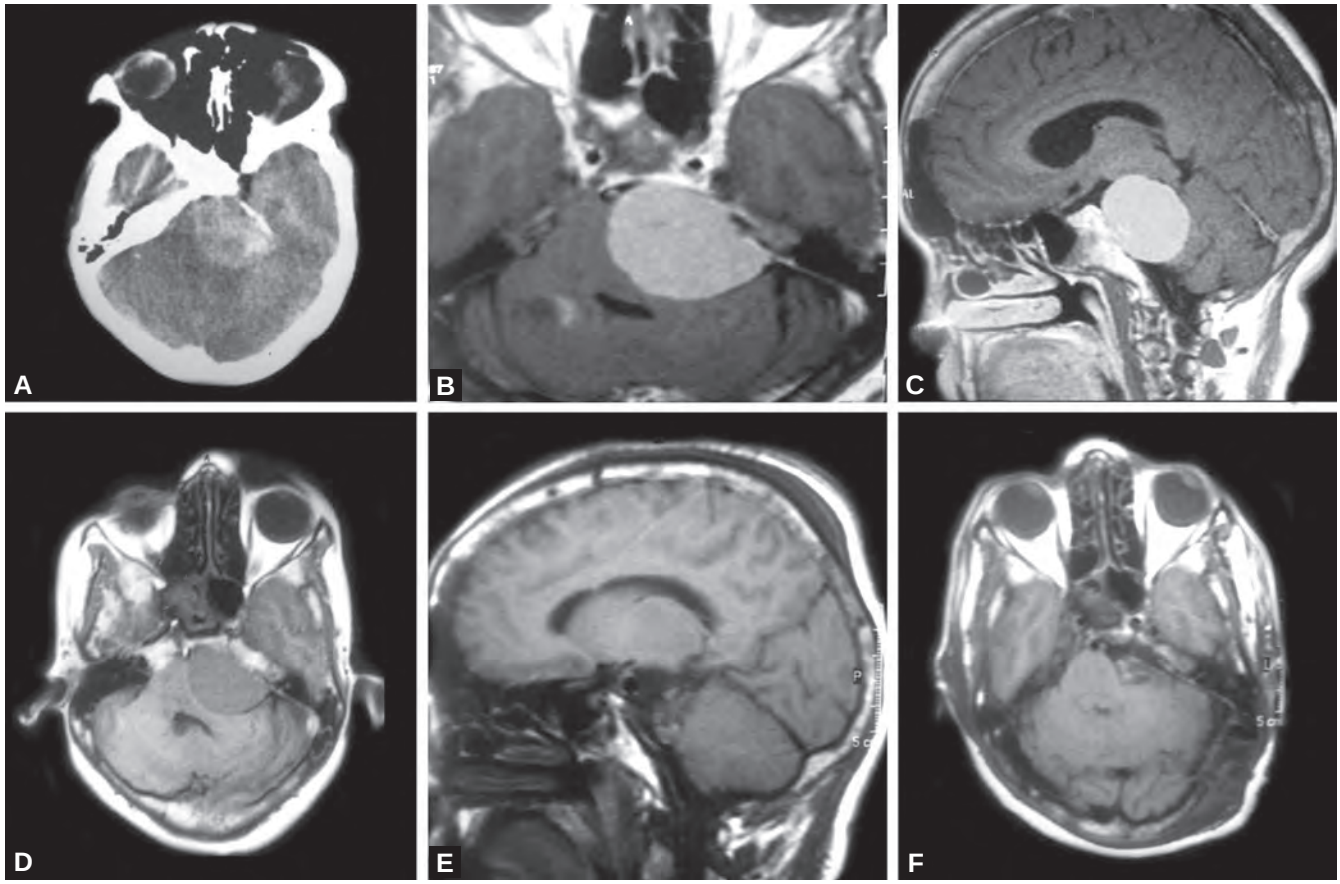
Encasement and narrowing of the main vascular channels may be noted. Venous anatomy should be studied, especially if ligature of a dural sinus is planned during the surgery. Temporal lobe venous anatomy is studied if the presigmoid petrosal approach is planned.

OPERATIVE DETAILS

Treatment strategies for difficult tumours, such as petroclival meningioma, are complex issues, because the



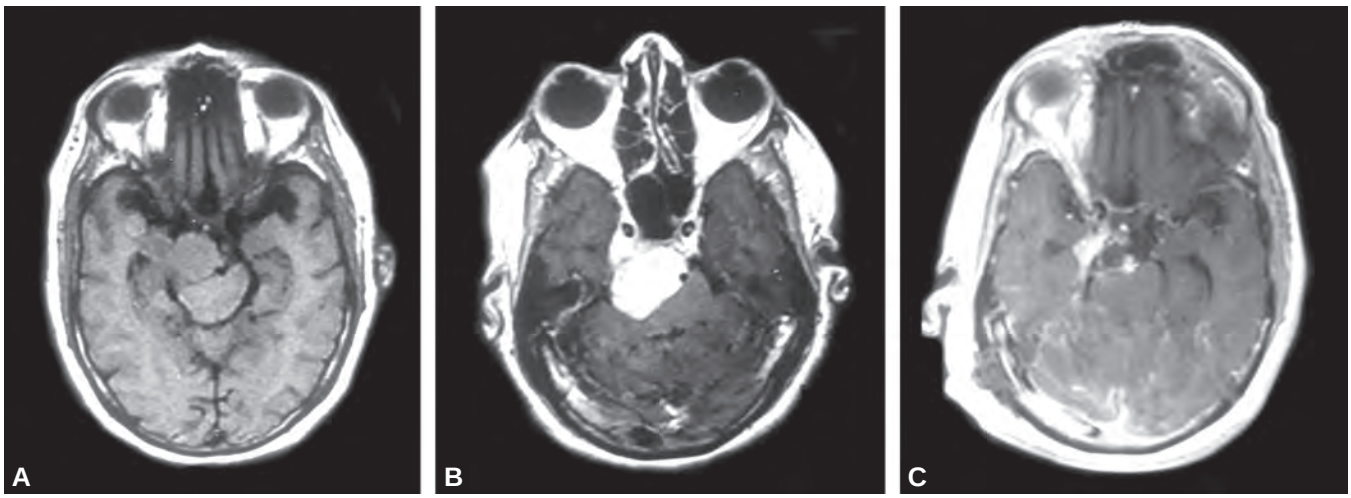
Figs 2A to C: (A) Post-contrast axial MR image shows a massive left petroclival meningioma. Both the basilar artery and supraclinoid carotid arteries are encased. (B) T1-weighted sagittal image shows the severe indentation of the brainstem. The tumour extends up to the sella. (C) T2-weighted MR axial image demonstrates the arachnoidal plane clearly between the tumour and the brainstem



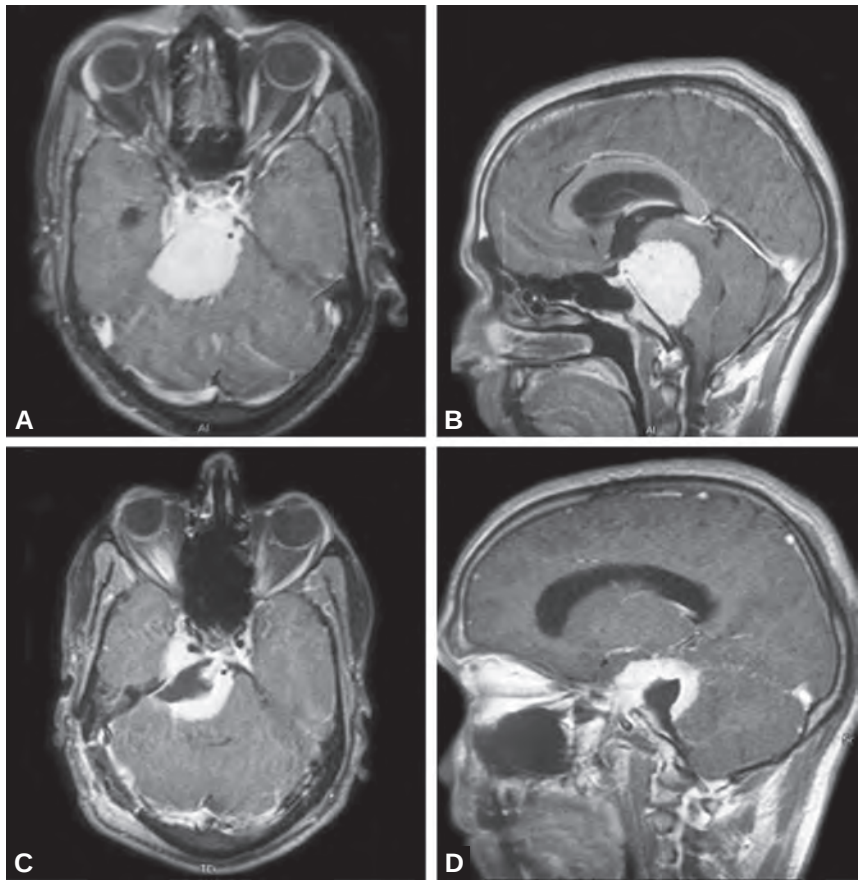
Figs 3A to F: Pre-operative. (A) Post-contrast axial CT image. (B) Post-contrast axial MR image. (C) Post-contrast MR sagittal image. (D) T1-weighted axial MR image shows a left petroclival meningioma. Post-operative. (E) Post-contrast sagittal MR image. (F) Axial MR image shows complete resection of the tumour. The retromastoid craniectomy is noted

patient may have a large tumour and minimal symptoms, the natural history is far from homogeneous and total removal is difficult to achieve. Theoretical considerations and pre-operative planning must be changed, depending on intra-operative findings. The collaboration of a neuron-otologist is sought when needed. Neurophysiological monitoring, when available, should be performed during surgery.

The surgical management of these tumours has been evolving, leading to better outcome and a marked reduction in surgical morbidity and mortality. A judicious evaluation should be done on a case-to-case basis as regards



Figs 4A to C: (A) T1-weighted axial MR image shows a right petroclival meningioma compressing the brainstem. (B) Post-contrast axial MR image shows the basilar artery outside the tumour capsule. A right cavernous sinus extension is noted. (C) Post-operative post-contrast axial MR image shows a small nubbin of tumour adherent to the basilar artery. A tumour remnant is noted in the right cavernous sinus



Figs 5A to D: (A) Post-contrast axial MR. (B) Post-contrast sagittal MR images show a large right petroclival tumour that has encased the basilar artery and invaded into the cavernous sinus. Post-operative imaging. (C) Post-contrast axial. (D) Post-contrast sagittal MR images show a thin rim of tumour residue along the brainstem including the encased basilar artery. Right cavernous sinus remnant is noted

extent of resection. Although gross total resection should be the goal of each surgical procedure, it is important to consider the quality of life of the operated patients. In this sense, the intra-operative decision of whether to continue dissection and removal or stop is crucial. It has to be noted that post-operative deterioration in KPS scores are likely to return to the baseline at one year and neurological function continues to improve with time.

The primary goal of surgery is to define and protect cranial nerves and vascular structures, as the tumour is progressively dissected free and debulked. Facial nerve stimulation with electromyography and brainstem auditory evoked potentials may be used. Meticulous haemostasis is maintained throughout the procedure to improve the visualisation of critical neurovascular structures. The selected approach should allow access to the vascular base during the initial stages of resection. Initial debulking of the exposed tumour and accessible core is followed by dissection of tumour capsule from surrounding structures. This series of debulking, capsule dissection and capsule removal is repeated until all resectable portions of the tumour have been removed. Due care should be taken to identify and protect en passage cranial nerves and arteries during central debulking. Portions of the tumour that are adherent to the brainstem pia, cranial nerve epineurium or arterial adventitia are left behind to protect the underlying structures.

The extent of surgical resection may be gross total, sub-total (more than 90% tumour volume resection) or partial (less than 90% tumour volume resection). This assessment is done on the basis of post-operative MR scan done at 3 months after surgery. Simpson Grades I and II resection include complete excision of the tumour, including dura and bone and reliable excision of the dural attachment including coagulation.[18]

The preferred approach for resection of petroclival meningiomas is controversial. Some surgeons prefer the retrosigmoid approach in the sitting position, arguing for simplicity of approach;[1,6,8,13,14] and others prefer the petrosal approaches.[5,7,12,17] The transpetrosal partial labyrinthectomy petrous apicoectomy approach or the orbitozygomatic frontotemporal approach takes a much longer time to perform than the retrosigmoid approach. The temporal lobe and cerebellum are retracted, respectively. The transpetrosal approach permits a direct view of the tumour, whilst in the retrosigmoid approach the cranial nerve traction is extensive. Transzygomatic approach may be used when the tumour involves the upper clivus. Tumours involving the lower and mid-clivus are approached by a presigmoid approach, occasionally with division of a non-dominant sinus. Skull base

reconstruction is essential in all approaches to avoid CSF leaks.

Editorial Comment: These tumours should not be handled unless the neurosurgeon has enough training and experience with techniques of skull-base surgery, microneurosurgery and support of a trained neuroanaesthetist.

Surgical Approaches

1. Combined petrosal
   - Transpetrosal partial labyrinthectomy petrous apicoectomy
   - Transpetrosal total petrosectomy
   - Transpetrosal translabyrinthine
2. Frontotemporal orbitozygomatic osteotomy (with transcavernous or pericavernous dissection)
3. Retrosigmoid (with or without combined transcondylar exposure)
4. Middle fossa (preauricular sub-temporal with anterior petrosectomy)

Adjunctive Procedures

Arterial bypass with saphenous vein graft after excision of encased ICA and sigmoid sinus division are the adjunctive procedures that may be required.

Tumour Characteristics

The term petroclival implies an involvement of the petrous apex and upper two-thirds of the clivus. Tumours may be classified on size as small (< 1 cm), medium (1–2.4 cm), large (2.5–4 cm) and giant (> 4 cm). These tumours extend from the petroclival region to the cavernous sinus, sphenoid, middle fossa, tentorium, Meckel's cave, cerebellopontine angle, jugular foramen and foramen magnum. There may be vascular encasement, which affects early post-operative neurological function negatively.

Little et al.[10] have described the following tumour characteristics. Vascular tumours were described as those with a rich blood supply and tendency towards persistent haemorrhage during resection that obscured the resection site. Adherent tumours are firmly attached to the pia, epineurium or vascular adventitia and cannot be dissected free or can be separated using sharp dissection. Fibrous tumours are described as hard or rubbery requiring resection with scissors and knife for most of the tumour removal. Engulfing tumours are those that encircle neurovascular structures with an identifiable intervening plane.

Adherent and fibrous tumours are often tethered to the brainstem and cranial nerves. Dissection of these tumours may lead to excessive manipulation of these vital neural structures resulting in morbidity. Tumour remnants are best left attached to neurovascular structures rather than risk direct injury. Factors that limit extent of resection include hypervasularity, tumour adhesion to neurovascular structures, tumour engulfment of neurovascular structures and firm tumour consistency.[10,12]

Post-Operative Radiotherapy

Residual tumours may be subjected to radiosurgery or radiotherapy. Stereotactic radiosurgery affords excellent tumour control with low morbidity of cavernous sinus remnants, rather than the high risk of cranial neuropathy associated with a cavernous sinus exploration.

Surgical Complications

- New onset/progressive cranial nerve palsies
- Long tract deficits
- Brain infarction/cerebral oedema
- Aspiration pneumonia
- Hydrocephalus
- Cerebrospinal fluid leak
- Brainstem haematoma
- Cerebellar haematoma
- Infection
- Stupor and coma
- Sinus thrombosis

The complex anatomy and difficult exposure of the petroclival region has led to the development of multiple techniques designed to minimise morbidity that may potentially obtain a surgical cure with complete resection. Complete resection is sometimes not possible because of the involvement of multiple regions, severe adherence to or invasion of the brainstem, or encasement of the vertebrobasilar circulation by a very firm tumour. Staged, multiple operations and combined approaches are used to achieve maximal tumour removal with a low rate of morbidity. Little et al.[10] have noted four significant operative risk factors: (1) history of prior operation; (2) pre-operative cranial nerve deficit; (3) tumour adhesiveness, and (4) tumour consistency (fibrous). At long-term follow-up, variables with a persistently negative impact on neurological function were: male sex, basilar artery blood supply, difficult dissection, sub-total resection and early post-operative dysfunction.

Even in the hands of the world's most experienced cranial base microsurgeons only in one third (32%) of the patients could the tumours (of which 80% were large) be removed completely.[12] Sub-total resection was achieved in 43% of the patients and partial resection in 25% of the patients. The real limitation in obtaining radical and safe removal is not inadequate exposure but rather the anatomicopathological characteristics of the tumour. Past experience has taught surgeons to be less aggressive in tumour removal in an effort to avoid injury to involved neurovascular structures.

A remarkable change has occurred in treatment strategies.[12] We have gone from a very aggressive approach that includes cavernous sinus dissection and carotid artery replacement to a less aggressive philosophy whereby tumour remnants are left behind for observation or radiosurgery. This change in surgical philosophy has led to a reduced percentage of patients with completely removed tumours but definitely, more importantly in individual patients, it has resulted in a high percentage of patients

with a satisfactory quality of life. Seventy-two per cent of the surviving patients were able to return to full time work or were retired from full-time work.

A complication rate of 27–73%, especially pertaining to cranial nerve deficits, has been reported. Natarajan et al. report the lowest complication rate of 22%.[12] Surgical mortality has varied between 0% and 17%.

Follow-Up and Survival

Natarajan et al.[12] report that during a mean follow-up period of 101[6] months, out of 150 patients, 87 patients (58%) were alive with disease and 45 (30%) had no evidence of disease. Eighteen patients died during the period of which only one death was the result of tumour recurrence. The majority of patients are able to return to their work with minimal disabilities and have a good quality of life without recurrence or progression.

Long-Term Disabilities

These include diplopia, hearing loss, facial numbness, imbalance, trigeminal neuralgia, diminution of vision, xerophthalmia, facial weakness, limb weakness, lower cranial nerve dysfunction and speech difficulties.

Recurrence and Progression

The recurrence rate of petroclival meningiomas, independent of the resection rate, is low and is uncertain, as observed from the long-term follow-up in the series of Natarajan et al.[12] Recurrence rates for published series have ranged from 0 to 42%.[1,4,7,9,10,13,14] Tumour recurrence seems to be negatively influenced by less extensive resection, malignant pathology and cavernous sinus involvement. The two important features of these tumours are the good outcomes and the low recurrence rates even in non-radically treated patients. The latter finding is intriguing and is at variance with previous detection of a high recurrence rate for surgically treated large cranial base meningiomas. This suggests that petroclival tumours may progress only at a slow rate.

Tumour recurrence after complete excision occurred in 4% of patients (2 out of 48), whereas tumour progression occurred in 5% (5 out of 105) after incomplete resection.[10,12] In only 3 out of 150 patients fatal tumour progression occurred, despite radiosurgery and repeat surgery.[12] Similar results have been observed in a series of 120 patients operated upon by Yasargil.[19] This data suggests that these tumours have a more benign nature than we have suspected. If the patient's symptoms are mild, observation may be the best treatment. This incidence is independent of the availability of gamma knife radiosurgery, which does not warrant tumour control in every case. Petroclival meningiomas have low MIB-1 indices[11] comparable to spinal meningiomas than to parasagittal tumours.

CONCLUSION

The ultimate goal of surgical treatment is a complete resection which is, however, not always possible due to the consistency of the tumour, multi-compartment involvement, adherence to the brainstem or encasement of vertebrobasilar branches. The excellent quality of life if the tumour is radically resected warrants aggressive but judicious tumour resection with or without radiosurgical treatment of tumour remnants.

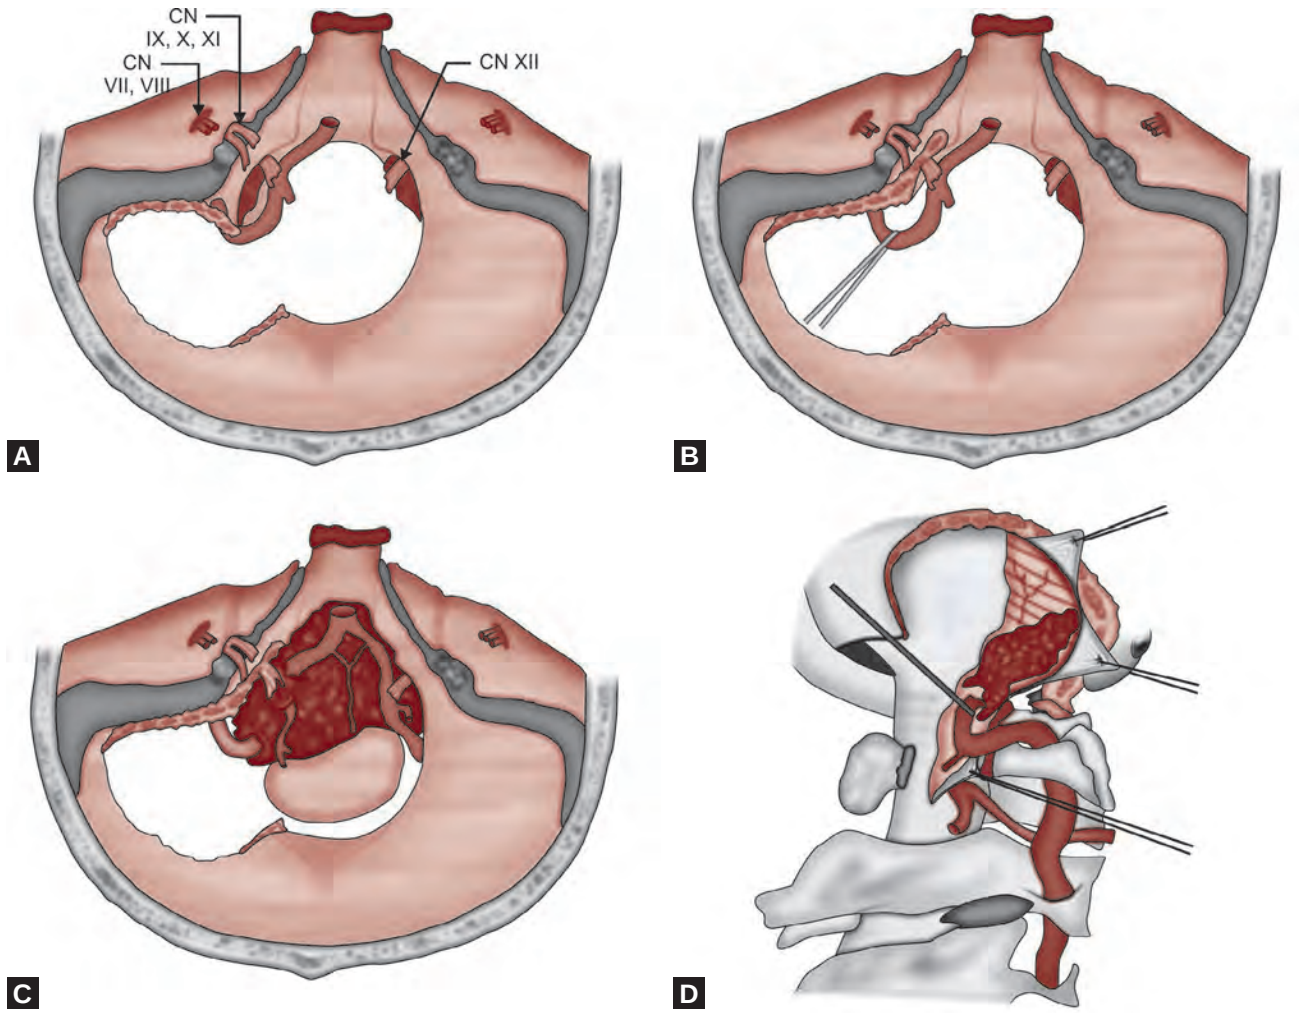
173 Foramen Magnum Meningiomas

Shrivastava RK, Chandranath Sen

INTRODUCTION

Tumours at the foramen magnum comprise some of the most challenging and complex lesions that the neurosurgeon must contend with.[9] The anatomical area of the anterior foramen magnum is comprised of brainstem structures, cranial nerves and blood vessels all in a tight geometric arrangement. Added to this is the association of a variety of tumours that can further distort this anatomy, making a safe resection all the more challenging.[13] The recent development of microsurgical skull-base approaches has greatly opened up these once treacherous corridors for a more safe and successful surgical resection, over the more historical and traditional neurosurgical approaches (Figs 1A to D). Most tumours found at the foramen magnum are located anterolaterally,



Figs 1A to D: (A) An axial view of the standard lateral suboccipital craniectomy. (B) Same view, after partial medial condylar resection. This allows for mobilisation of the ipsilateral vertebral artery, enabling access to the lower clivus. (C) The same illustration, now with intradural tumour *in situ*. The advantage of partial condylar resection is demonstrated in enabling enhanced visualisation of the anterior portion of the tumour and its attachment after posterior mobilisation of the vertebral artery. (D) Lateral view of the same tumour again illustrating partial condylar resection with medial mobilisation of the vertebral artery as well

however, most approaches to these lesions have historically been strictly posterior. This review will briefly outline the three general approaches to the anterior foramen magnum that are employed by neurosurgeons:

1. Posterior/posterolateral suboccipital
2. Transoral
3. Extreme lateral transcondylar

While each approach has many technical modifications and many associated eponyms, the basic approach is the same within each category. Despite the specific pathology of the lesions at the anterior foramen magnum, the general surgical principles employed in their surgical resection are similar. Meningiomas at the foramen magnum will be used as the surgical model for the purposes of discussion in this review, as almost all large series reports and discussions have focused on these tumours. The remaining tumours are often described in anecdotal and case reports only.

The choice of surgical approach is determined by the unique pathological anatomy and each case is evaluated independently. Despite the variety of tumour pathology encountered, the general principles of a meticulous preoperative planning based on the microanatomical details of each patient, as well as an individualised tailoring of the surgical approach is similar for all cases. In the case of meningiomas, the risk of tumour recurrence is based on the tumour resection grade (whether Simpson grade[33] or the modified Kobayashi system). We as well as most authors have adopted the Simpson scale as applied to meningiomas to involve three categories:

1. Gross-total resection, including excision of the dural attachment and drilling of adjacent bone (Simpson I and II)
2. Near-total resection, in which a few millimetres of insulated and cauterised tumour were left on the vertebral artery (VA) or other vital structure if the arachnoid plane could not be established (Simpson grade III)
3. Subtotal removal of more than 50% of the tumour (Simpson grade IV)

The general surgical determinants are:

- Tumour location with respect to the foramen magnum
- Anterior-posterior relationship of the tumour with respect to the caudal medulla/spinal cord
- Rostral-caudal extent
- Laterality
- Encasement/involvement of the VA[35,39]

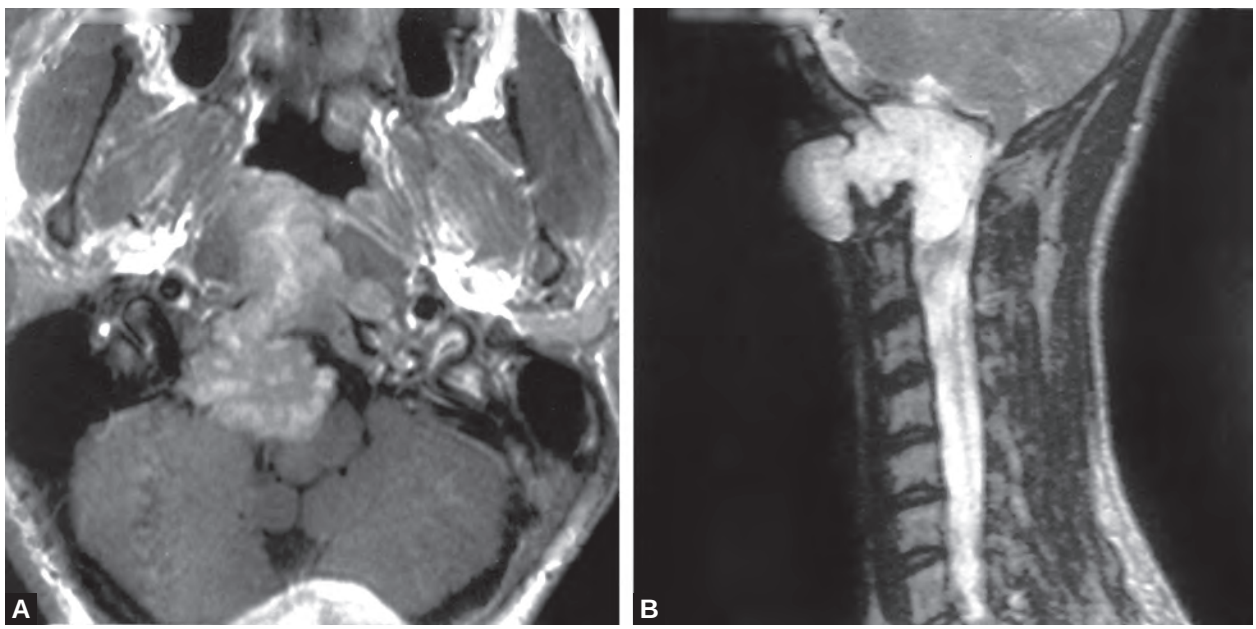
Individual surgeons have defined their surgical determinants more specifically based on their operative preferences in regards to the approaches that they employ. The surgical corridor involves the space between the lateral margin of the cervicomedullary junction and the medial aspect of the occipital condyle. Corridor is defined as "narrow" if it provides a diameter of access to the tumour of less than 1 cm; "adequate" if it is greater than 1 cm but less than 2 cm; and "large" if greater than 2 cm.

TUMOURS AT THE FORAMEN MAGNUM

Tumours at the foramen magnum are characteristically difficult to diagnose clinically. The wide spectrum of presenting signs and symptoms, combined with their often insidious onset have been known to mimic many more common neurological diseases, such as cervical spondylosis, multiple sclerosis, and other degenerating diseases.[13]

The differential diagnosis of extra-axial foramen magnum tumours include:

- Meningiomas as the most common chordomas (Figs 2A and B)



Figs 2A and B: (A) Magnetic resonance imaging T1 axial view with contrast. (B) T2 sagittal view demonstrating an extensive chordoma occupying multiple compartments including the occipital condyle, the lateral mass of C1, clivus, and retropharynx

- Neurilemmomas
- Epidermoids
- Chondroma
- Chondrosarcomas
- Metastatic lesions[32]

While meningiomas at the foramen magnum are the most common tumour at this location, they are still very rare lesions when compared to all intracranial tumours, and account for only 0.3–3.2% of all meningiomas and between 4% and 15% of all posterior fossa meningiomas altogether.[35,39]

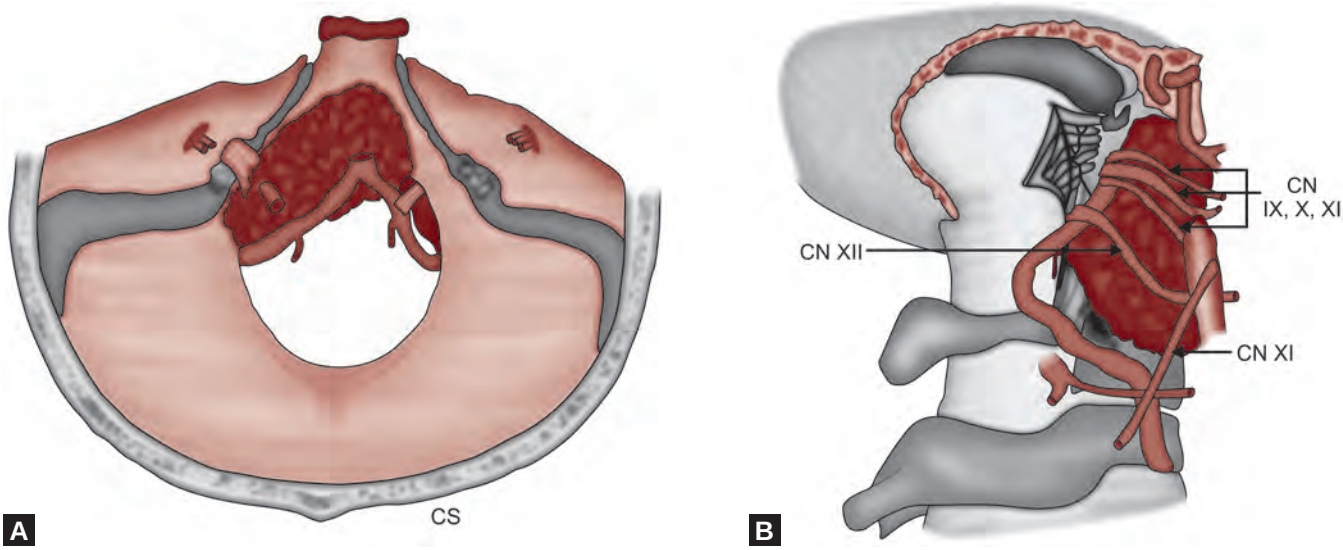
To understand the surgical approaches to the anterior foramen magnum, it is first crucial to define the anatomical terms that comprise the structures in this location. The foramen magnum is a skull base foramen that is composed of the occipital bone. The occipital bone surrounds the foramen magnum[26] and is composed of two parts: the posterior squamosal and the narrower anterior part (basal extension of the clivus). The anterolateral walls are formed by the occipital condyles.[38] The contents of the foramen magnum consist of the caudal medulla, cranial nerve XI (entering the skull), VA, and the anterior and posterior spinal arteries. The XI cranial nerve is the only cranial nerve that passes through the foramen magnum. Its spinal component arises as a series of rootlets midway between the ventral and dorsal rootlets of the upper cervical cord. The transition between medulla and spinal cord is arbitrarily set to be at the upper limit of the dorsal and ventral rootlets forming the first cervical nerve. The rootlets of the XII cranial nerve exit the anterior medulla and pass behind the VA to reach the hypoglossal canal just above and anterior to the occipital condyles. The specific orientation of the VA at this location and its course through the transverse foramina and through the intracranial dura is what corresponds to the landmarks to the surgical approaches to this region. The VA enters the dura inferior to the lateral edge of the foramen magnum through a tunnel approximately 5 mm in length. The posterior inferior cerebellar artery usually has an intradural origin, but may arise below the level of the foramen magnum. A detailed knowledge of this anatomy, practiced in cadaveric dissection, is crucial before attempting these operations for the first time.

GENERAL PERI-OPERATIVE CLINICAL EVALUATION AND NEUROPHYSIOLOGICAL MONITORING

Once the decision has been made to proceed with surgery, all patients should undergo a detailed study of their neurological function, independent of their clinical neurological examination. The critical location of these tumours to vital neurological and vascular structures necessitates a more detailed cranial nerve study. Ophthalmological, audiometric, and electromyographic studies can be supplemented to the pre-operative assessment of the patient's baseline function.[3] Cranial nerves IX through XII are especially important, and a detailed swallowing study and otolaryngological study of the vocal cords and the larynx are also useful as a pre-operative baseline. Careful assessment of the patient's ability to protect the airway is mandatory, and early tracheostomy may be advisable to avoid aspiration pneumonitis. The importance of preserving lower cranial nerve function is crucial in the intra-operative procedure. We employ intra-operative neurophysiological monitoring to prevent injury to the cranial nerves. Somatosensory evoked potentials and brainstem auditory evoked potentials are monitored bilaterally.[4,40] Electromyographic monitoring of the vagal, accessory and hypoglossal nerves are done on the ipsilateral side (or bilaterally if necessary). The vagal nerve can be monitored with an electromyography electrode-endotracheal tube or by laryngeal surface electrode that is placed after intubation. The accessory and hypoglossal nerves are monitored directly with electrodes placed on the ipsilateral trapezius and the inferior aspect of the tongue, respectively. We believe that this type of monitoring helps to preserve cranial nerve function during surgery. The use of intra-operative neurophysiological monitoring prevents the use of muscle relaxants during many stages of the operation. Occasionally, burst suppression with short-acting barbiturates can also be used for cerebral protection. We employ 24 hours of broad-spectrum IV antibiotics and peri-operative steroids at the time of surgery.

THE POSTERIOR/POSTEROLATERAL SUBOCCIPITAL APPROACH

The posterior suboccipital approach and its modifications (posterolateral) have been the traditional approach for lesions of the foramen magnum for many years (Figs 3A and B). The approach typically consists of a suboccipital craniectomy and partial to complete laminectomy of C1/C2 depending on the size of the tumour.[12] A vertical midline or hockey-stick suboccipital incision is used. The prone, three-quarter prone ("park bench") or semi-sitting ("slouch") may be utilised depending upon the surgeon's preference. The vertical incision is used for lesions situated in the upper spinal canal and posterolaterally at or above the foramen magnum. The hockey-stick incision is selected if the lesion extends anterior or anterolateral to the brainstem toward the jugular foramen or the cerebellopontine angle (CPA). This incision allows for removal of the full posterior rim of the foramen magnum, the posterior elements of the atlas and axis and in addition, a unilateral suboccipital craniectomy of sufficient size to expose the anterolateral surface of the brainstem and the nerves in the CPA. The actual amount of the suboccipital craniectomy and cervical laminectomy varies depending upon the rostral/caudal extent of the tumour. For anteriorly located tumours in this approach, the spinal cord is often displaced dorsally and rotated away from the side on which the bulk of the tumour mass is located.



Figs 3A and B: (A) An axial view of an extradural tumour demonstrating bony involvement. (B) Lateral view demonstrating suboccipital craniectomy with mastoidectomy, medial mobilisation of the ipsilateral vertebral artery (after opening the C1 transverse foramen), condylar resection, and ligation of the sigmoid sinus and internal jugular vein

The ventral cervical rootlets are usually displaced dorsally by these tumours. Early identification of these rootlets is crucial as they must be separated from the dorsal rootlets and dentate ligaments, as well as the spinal rootlets of the XI cranial nerve that can often be draped directly over the tumour. During the tumour removal it is also important not to injure the radicular vessels running with the upper cervical roots, since they supply blood to the spinal cord. An important landmark in the posterior approach to anteriorly placed tumours is the most rostral dentate ligament that lies at the level of the foramen magnum and more importantly indicates the point at which the VA pierces the dura. The upper 2–3 dentate ligaments may be sectioned with caution to reduce traction on the spinal cord and to allow for gentle rotation of the cord to facilitate tumour removal.

The advantage of the posterior suboccipital approach to anteriorly based tumours is the familiarity that most neurosurgeons feel with the anatomy and the technique, as this approach is employed for many lesions of the posterior fossa. A laminectomy and its extension into the pedicle may be sufficient to allow removal of ventral tumours when the tumour is not attached by a broad base and there is little adhesion between it and the anterior surface of the cord. The disadvantages of this technique are, however, the inability to safely reach the anterior midline or contralateral component of the tumour. In the case of recurrent or broad-based foramen magnum meningioma, however, the cord-tumour interface and the base of the tumour must be adequately visualised for safe or total removal. This technique relies on a good arachnoid plane existing between the tumour and the spinal cord and often does require division of the upper cervical rootlets and rotation of the spinal cord. The only technique used to help deliver the anterior portion of the tumour with this approach is to pull the lesion into the field along with the surgical debulking, which can be ineffective. The posterolateral modifications of the standard posterior approach as described by George[11] involve a lateral enlargement of the usual posterior opening via exposure of the sigmoid sinus via a posterior mastoidectomy down to the jugular foramen. In those cases in which the tumour extends laterally into the jugular foramen, the sigmoid sinus is sectioned between the vertical and horizontal portions. This technique requires exposure of the VA within its periosteal sheath from C2 to the intradural component. The exposure of the VA by this method allows for superior and lateral retraction of the VA, or medial displacement of the VA, requiring resection of the transverse foramen of C1 and giving access to the tumour lateral to the VA. Other modifications to the posterior approach have included a partial condylar resection,[12] or condylar drilling[25] to improve anterior exposure. These modifications, however, are still limited by those tumours in which there is arachnoid scarring, en plaque formation, and especially post-operative recurrence.[25]

TRANSORAL/TRANSPHARYNGEAL APPROACH

The direct anterior approaches consist of the transcervical or transoral which involve removal of the vertebral bodies to expose the intradural portion of the tumour. These approaches are most suitable for anterior extradural lesions, where direct midline exposure is the most relevant. The transoral route does provide for the most direct route to the clivus and the ventral foramen magnum, but it does have many limitations.

The patient can be positioned one of three ways:

1. Supine with slight neck extension
2. Modified lateral
3. Semi-sitting ("slouching")

A C-arm fluoroscope is often used to help identify bony landmarks during the operation. This surgery

has specialised transoral retractor systems (Crockard, Dingman, McGarver) that allow for tongue, pharyngeal and longus colli retraction. The surgical technique[8,18] generally involves early identification of the anterior tubercle of C1 and a vertical midline incision on the posterior wall of the pharynx. The incision extends from the inferior portion of the clivus to the base of the odontoid (and can be modified accordingly in lower lesions). The anterior arch of C1 is exposed, and the fascia-muscle layers are retracted laterally approximately 20 mm on either side. The VA is 33 mm from the midline at C1, and the hypoglossal foramen is 7.5 mm above the arch of C1 and 18 mm from the midline. The jugular foramen is 26 mm from the midline. After adequate exposure, self-retaining retractors are placed against the pre-vertebral fascia and opened, providing for a hexagonally-shaped opening. A fine-cutting burr is used to drill the anterior arch of C1 and the odontoid (from base to tip). Upon reaching the posterior cortex, the apical and lateral ligaments are visualised and sectioned. The posterior longitudinal ligament can be identified inferiorly and opened to expose the dura. The superoinferior extent of the exposure can be enlarged by the addition of maxillectomy above and mandibulotomy and glossotomy below. The lateral exposure is the limiting factor, as it is not safe to expose greater than 1 cm to either side of the midline. The lateral limitations are due to the pterygoid plates, the occipital condyles and the hypoglossal canals.

The closure in the transoral approach is especially crucial due to the issue of cerebrospinal fluid (CSF) leakage, fistula and post-operative infection because of the potentially contaminated avenue of exposure. The dura is the main determinant of the complexity of the closure, as a good dural closure is the best protection from post-operative meningitis. A multi-layered closure using fibrin glue plus abdominal fat and/or muscle is often employed with post-operative CSF diversion with either a spinal drain or a lumboperitoneal shunt.[8] The specific issue of airway management is the most important issue in the post-operative period, and the nasotracheal tube is often kept in place until pharyngeal swelling has reduced (facilitated by hydrocortisone cream applied locally). Poor wound healing of the pharyngeal incision or protracted CSF leak may also require a more extensive operation by a maxillotomy approach, with repair using a temporalis muscle flap or a microvascular free-flap transfer.[8]

THE EXTREME LATERAL TRANSCONDYLAR APPROACH

The extreme lateral approach[28,29,30] provides excellent exposure of the anterior foramen magnum and allows for proximal control of the VA. This approach has, over the years, taken on many names; however, it is essentially one approach in which there are variations in the patient's position, the skin incision, muscle reflection, the VA complex transposition, amount of condyle drilling and craniotomy. The extreme lateral transcondylar approach (ELTA) has evolved over the recent decades from the initial lateral modifications of the suboccipital approach.[14,16] The ELTA as described by Sen and Sekhar,[28] and Bertalanffy and Seeger[6] incorporates the medial mobilisation of the VA from the dural entrance point to C2, and the resection of the occipital condyle and the lateral mass of C1 (either partially or totally). The ELTA is suitable for both intradural and extradural lesions, allows control of the VA, permits dissection of the brainstem-tumour interface tangentially along this plane, and avoids traversing contaminated spaces. The approach has gained wide acceptance because it avoids entering the contaminated oral cavity, provides early visualisation of the VA and creates wider surgical exposure.[6,11]

Specific pre-operative studies are critical in surgical planning. Magnetic resonance imaging with magnetic resonance venography/magnetic resonance angiography (MRV/MRA) and computerised tomography scanning are routinely done. The MRV/MRA imaging provides information regarding the regional vascular anatomy, including the patency and dominance of the vertebral arteries and dural sinuses. We only use angiography for unresolved or aberrant findings on the MRV/MRA. The patient position can be either lateral or supine with the head turned away from the surgeon (preferred when other approaches are being incorporated). A detailed understanding of the suboccipital muscles (e.g. sternocleidomastoid, splenius capitis, semispinalis and longissimus capitis, superior and inferior obliques and the recti capitis major and minor) is crucial in the ELTA procedure, much more so than in a standard posterior midline approach.[35,38] We use either the inverted U-shaped incision or the C-shaped curvilinear incision. In the U-shaped incision the skin flap is completely away from the area of the operation and allows for the reflection of all the muscles as one large flap. We have used the C-shaped incision more commonly which begins in the retroauricular area and extends into the cervical area along the skin crease. The sternocleidomastoid muscle and fascia are reflected forward with the incision whenever possible, depending on the extent of exposure required. The surgical approach of ELTA essentially involves six steps:

1. C-1 hemilaminectomy and suboccipital craniectomy (small, extending 3 cm posterior to the sigmoid sinus) with unroofing of the sigmoid sinus
2. Partial resection of the occipital condyle (up to the hypoglossal canal)
3. Removal of the jugular tubercle
4. Mastoidectomy (limited to the labyrinth and the Fallopian canal) and retraction of the sigmoid sinus
5. Resection of the lateral mass of C1 with mobilisation of the VA (in the suboccipital triangle)
6. Resection of the remaining portion of the occipital condyle

The exposure involves removal of part of the occipital condyle and the C1 facet, to facilitate ventral exposure of the medullocervical junction with or without transposing the VA from the C1 transverse canal.[10] Condylectomy considerably shortens the distance to the anterior foramen magnum, especially in the superior corridor and widens both transverse and longitudinal planes in the inferior corridor allowing the surgeon to get greater access to work on these lesions.[2] Patterson[22] and Samii et al.[25] suggested that most lesions of the lower clivus can be removed without extensive dissection of the ELTA, which is time consuming. They also considered that condylar resection is unnecessary which may potentially contribute to the morbidity rate by requiring occipitocervical fusion.

To maximise exposure, suboccipital craniectomy, a lower mastoidectomy to skeletonise the lower part of the sigmoid sinus and a partial C1 laminectomy are necessary. The dura must be completely opened around the VA entry area before mobilising this vessel to work anterior to the artery during tumour resection. The dorsal ramus of C2 that runs posterior to the VA between C1 and C2 can serve as a guide to the artery as a landmark. A prominent venous plexus that connects with the condylar emissary vein and the epidural venous plexus surround the VA.[27,31] The presence of a patent jugular bulb can hinder tumour removal medial to this structure. When the jugular bulb is occluded (as is more often the case in an extradural tumour), the sigmoid sinus and the internal jugular vein are ligated above and below the bulb and the bulb is opened directly to remove tumour from the IX, X and XI cranial nerves. This particular technique allows for excellent exposure of the space anterior to the foramen magnum and whole craniocervical junction (from the level of the internal auditory canal to the upper cervical spine). For extradural tumours, the occipital condyle resection extends more anterior to excise the entire condyle. If the tumour extends into the lower clivus, one can resect it by working through the petrous bone and the inferior occipital area. Tumours that extend medially and superiorly can be resected with a combined subtemporal infratemporal approach. For intradural tumours, the dura is opened first vertically, just medial to the entrance of the VA. The arachnoid membrane of the cerebellomedullary cistern is opened and the intradural tumour is often easily visualised.[5] Resection of the C1 intradural rootlets and the upper dentate ligaments will facilitate tumour exposure to better resection. Suhardja did a cadaveric study and emphasised that ELTA provided a significantly greater area of exposure than the retrosigmoid approach.[36]

The dural closure in ETLA can be difficult, and a combination of dural graft and fibrin sealant is often used with the possible addition of local muscle/fat. A spinal drain is often used as a CSF diversion to facilitate wound closure. If more than a partial resection of the occipital condyle is performed, stabilisation may be needed. This occipital-cervical fusion and instrumentation can be performed at the same sitting or as a different stage. Occipitocervical fusion is recommended in condylar resections of 50% or greater.[37]

Complications in this approach are psuedo-meningocoele, CSF leakage, lower cranial nerve injury (especially IX, X and XI) and craniocervical instability.

EXTENDED ENDOSCOPIC ENDONASAL APPROACHES TO SKULL BASE

The standard transnasal endoscopic procedures have been recently expanded to remove lesions involving the skull base. These approaches to caudally located midline anterior skull base and cervicomedullary lesions are feasible and hold great potential for decreased morbidity.[17] The midline skull base is an anatomical area extending from the anterior limit of the anterior cranial fossa down to the anterior border of the foramen magnum. Resection of lesions involving this area requires a variety of innovative skull base approaches. These include anterior, anterolateral and posterolateral routes, performed either alone or in combination. These approaches provide a direct anatomical route to the lesion without traversing any major neurovascular structures, obviating brain retraction.[7]

Approach

The clivus can be localised by orienting the endoscope + 15 degrees rostrally. The inferior wall of the sphenoid sinus and vomer are resected and the overlying mucosa is retracted laterally till the Vidian nerve is seen. This provides sufficient exposure of the clivus. The safe lateral limit of the surgical corridor is the Vidian nerve. The clivus is then resected till the foramen magnum inferiorly. The safe lateral limit of the resection in this step is the proximal cavernous and the distal petrosal portions of the internal carotid artery (ICA). This resection provides a wide exposure of the clival dura. Care should be taken not to injure the basilar plexus, the abducens nerve which passes through the basilar plexus, and the paraclival portion of the ICA. After dural incision, the prepontine cistern and the basilar artery are exposed widely.[1] The disadvantages of this approach are a restricted field of surgery, danger of an inadequate dural repair with CSF leakage and potential for meningitis.[7] In tumours which extend laterally transcondylar and transjugular tubercle "far medial" expansions of the endoscopic endonasal approach to the inferior-third of the clivus provides a better corridor to the inferior clival and the ventrolateral surfaces of pontomedullary junction and cervicomedullary junction lesions.[19]

RADIOSURGERY

The ideal treatment of meningiomas is a safe and complete resection. If contraindications to surgery exist or if the patient elects not to undergo surgical

resection, then radiotherapy should be considered. Because of the vital and critical anatomy within the foramen magnum and the size of most tumours (less than 3 cm in maximum dimension), focused gamma knife surgery is recommended rather than standard conformal radiotherapy.[23] In patients with small residual tumours who are under observation, if the tumour grows, then gamma knife surgery is recommended.[15,20,21]

CONCLUSION

Advances in neurosurgical microsurgical techniques, detailed anatomical understanding, anaesthetic protocols and recent developments in skull-base surgery have dramatically reduced the once very high mortality associated with surgery for tumours located in the anterior foramen magnum. However, despite all these advancements this subset of tumour continues to remain one of the most challenging tumours to treat in all of neurosurgery. While the traditional posterior midline suboccipital approach is safe and useful in most tumours in the anterior foramen magnum, the additional benefits provided by the ELTA far outweigh most other approaches. We have reserved the transoral approach strictly for midline extradural lesions and do not use this approach for intradural lesions or for any lesion with lateral extensions beyond 30 mm from the midline. The other operative complications such as crossing of a contaminated operative field, CSF fistula, meningitis, difficult dural closure and destabilisation of the craniovertebral junction have all made the transoral approach less useful. In ETLA, there exists a wider surgical area of exposure of the tumour-cord/brainstem interface as well as the ventral dura without the need for retraction of the neural structures. The value of condylectomy alone both shortens the distance to the anterior foramen magnum and widens the lateral exposure for a better surgical angle for resection.[34] Control of the involved VA is possible and devascularisation of the tumour can be accomplished early in the operation. While variations of the ETLA procedure already exist and have been reported,[24] the final approach and its various modifications should always be tailored to the unique tumour presentation and the specific goals of surgery in the treatment of the individual patient. To totally resect type I foramen magnum tumours, the ELTA is an optimal choice. Type II foramen magnum tumours can be totally removed with a good prognosis.[41]

174 Intraventricular Meningiomas

Harjinder S Bhatoe, Prakash Singh, Vibha Dutta

INTRODUCTION

Intraventricular meningiomas, together with deep Sylvian meningiomas, constitute the entity of "meningiomas without dural attachment." The cerebral ventricles are unusual sites for occurrence of tumours of the central nervous system. These intraventricular meningiomas, which are rare tumours, account for 0.5–5% of all intracranial meningiomas.[9] The rarity of these tumours underscores the lack of controlled studies and extensive experience and knowledge about the natural history and pathobiology of these tumours. The medical literature is peppered with a few case series of lateral ventricular meningiomas and still fewer case reports of meningiomas involving the third and fourth ventricles. The largest experience in managing these tumours is probably credited to Konovalov et al.[14]

ORIGIN

Meningiomas arise from arachnoid cap cells, which are specialised cells in arachnoid granulations. Intraventricular meningiomas too arise from arachnoid cells, found within the choroid plexus.[16] The presence of arachnoid cell nests in the normal choroid plexus stroma has been illustrated in the literature and a thorough examination of the choroid plexus will reveal a small or large collection of these cells.[8,12,20] The presence of these cells in the choroid plexus has been explained by various workers. The choroid plexus develops initially from an invagination of mesenchyme in the thin roof area of the myelencephalon, during the 6th week of intrauterine life.[22] In the 7–9 week human embryo, the telencephalic choroid plexus has started to develop a loose mesenchymal stroma, covered by a layer of cells derived from ependyma.[7] Arachnoid tissue is carried with the choroid plexus, as the ventricular system invaginates[15] and by 20–40 weeks of intrauterine life, the central stroma of the choroid plexus contains meningocytes, connective tissue and blood vessels.[20] Meningothelial inclusion bodies are normally found in the arachnoid and choroidal tela and meningiomas arise from this mesenchymal stroma of the choroid plexus.[18]

The ventricles are a rare site for occurrence of meningiomas. The incidence of meningiomas of lateral ventricles is variously reported 0.5–5% of all intracranial meningiomas, at least in adults.[1] For some unexplained reasons, meningiomas of the lateral ventricles occur more frequently in the left than in the right one (up to 60% of all lateral ventricular meningiomas).[6,9,10] Since the choroid plexus is more bulky in the lateral ventricles, the incidence of lateral ventricular meningiomas is higher, as compared to those in the third or fourth ventricle. In the lateral ventricles, the tumour originates from the choroid plexus in the region between the posterior portion of the body of the lateral ventricle and the entrance to the inferior horn.[14] This origin explains the predominant location of the tumour in the trigone. Tumour restricted to the frontal horn is extremely rare.[14] Meningiomas are rare in the third and fourth ventricle: an extensive review has shown 83 meningiomas in the third and only 35 meningiomas in the fourth ventricle.[17] Fourth ventricular meningiomas arise from the inferior tela, when they are partly intracerebellar, and from choroid plexus, when they are true intraventricular tumours.

PATHOLOGY AND CLINICAL COURSE

The ventricles of the brain provide space for tumour expansion, and till the CSF pathways are mechanically occluded, manifestations are mild and non-specific. Although Cushing described clinical features of intralateral ventricular tumours, diagnosis of these tumours is usually made after imaging procedures. Regardless of their location, most of the clinical symptoms are due to raised intracranial pressure.[4] Lesions grow into the ventricular cavity till they produce obstructive hydrocephalus. Visual field deficits may be seen in 25% of patients.[9] Seizures are rare.[21] Cerebellar signs may be seen in fourth ventricular tumours and hypothalamic features with or without endocrinopathy may be seen in third ventricular tumours. Manifestations of neurofibromatosis type 2 (NF2) syndrome may be evident on clinical and neurological evaluation. Meningiomas are more common in females, but Bhatoe et al.[4] saw only six out of fifteen female patients with intraventricular meningiomas; two of these patients had features of NF2. Although described to be common in childhood[9,13,21] also, Bhatoe et al. did not see any child with intraventricular meningioma.[4]

The rarity of intraventricular meningiomas, in contrast to those with dural attachment, may also be due to yet unknown factors. Multiple meningiomas arising

from the dura are regarded as due to inherent multicentricity of the dural foci, possibly influenced by hormonal factors.[19] Although there are no reports of multiple intraventricular meningiomas, they have been known to coexist with spinal meningiomas,[11] vestibular schwannomas and optic nerve sheath meningiomas as part of the NF2 syndrome. Meningiomas of the third ventricle, occurring primarily in young children, have a tendency to grow into both lateral ventricles as a trifoliate tumour.

HISTOPATHOLOGY

Intraventricular meningiomas can be of any of the histopathological types of the tumour, as per the WHO classification of meningiomas. These are predominantly either fibrous, fibroblastic or psammomatous.[1] Angiomatous type was the most common type seen in our series, followed by meningothelial, fibroblastic and psammomatous/osteoblastic types. The structure of psammoma bodies in the choroid plexus is very similar to that in meningiomas.[2] In general, meningiomas are diagnosed by morphological features alone. The expression of oestrogen receptor is low in these tumours, and two thirds of these patients are positive for progesterone receptors.[5] Whether these findings can be applicable to intraventricular meningiomas remains yet to be seen, as are the cytogenetic features, like deletion of chromosomes 1 and 14, seen in meningiomas at other sites. In our series, histopathology of the tumours was varied, as given below:[4]

Lateral ventricular tumours:

Psammomatous/osteoblastic	2
Macrocystic angiomatous	1
Angiomatous	5
Meningothelial	4
Papillary	1

Third ventricular tumour

Angiomatous	1

Fourth ventricular tumours

Fibroblastic	1
Meningothelial	1

Nine of these patients exhibited positivity for epithelial membrane antigen and vimentin. The psammomatous meningioma showed densely packed psammoma bodies in an ossified matrix. All sixteen patients have been followed up over 3–10 years, with no evidence of recurrence. Patients with NF2 have undergone surgery for associated tumours.

IMAGING

Lateral ventricular meningiomas are seen most commonly in the trigone or atrium of the ventricle (Fig. 1). Third ventricular meningiomas are seen in the anterior third ventricle, while fourth ventricular meningiomas can appear partially intracerebellar (when they arise from the inferior tela) and as tumours surrounded by CSF when they arise from the choroid plexus. Intraventricular meningiomas may occasionally be densely calcified so as to be visible on plain skull radiograph.[3] MRI is the most valuable imaging modality for evaluating intraventricular meningiomas. The tumour is generally lobulated and appears isointense on T1-weighted and T2-weighted images. Calcification, nodular or punctate, is seen as an area of signal loss. The tumour enhances uniformly with intravenous gadolinium (Fig. 2). Uncommonly, the tumour may be cystic. Cerebral oedema is unusual. The presence of other lesions, like optic nerve sheath tumour and vestibular schwannoma, indicate underlying NF2. Computed tomography supplements MRI by showing calcification. Digital subtraction angiography can be utilised for assessment of the vascularity and location of the principal feeder. Lateral ventricular tumours occurring in the body are fed by the lateral posterior choroidal vessels, while those in the temporal horn receive their blood supply from the anterior choroidal artery. Tumours in

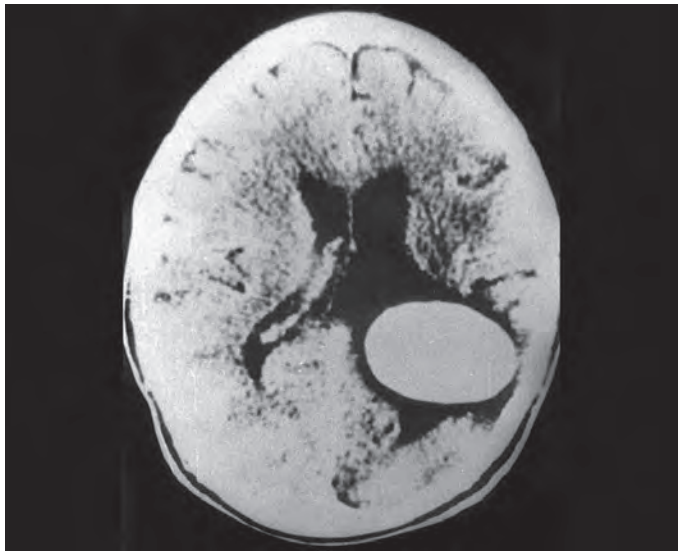

Fig. 1: CT scan of the brain shows well circumscribed lesion in the trigone of the lateral ventricle

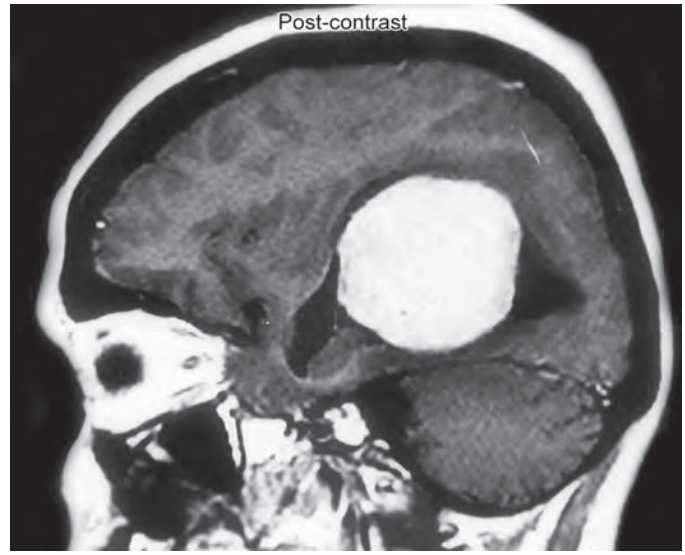

Fig. 2: MRI scan of the brain sagittal view showing uniformly enhancing lesion within the lateral ventricle

the atrium are supplied by both anterior and posterior choroidal arteries. Third ventricular tumours are supplied by the medial posterior choroidal vessels, while fourth ventricular tumours derive their blood supply from choroidal branches of the posterior inferior cerebellar artery (PICA).[14]

SURGICAL MANAGEMENT

Surgical management has to be individualised for each patient, depending upon the tumour location and its vascularity, involved ventricle and the presence of other tumours (as in NF2). Meningiomas are solid, discreet lesions that can be totally excised. The strategy should be to reach the blood supply with minimum neural section/retraction, coagulation of the tumour prior to incision, internal decompression and occluding of the feeding vessel(s). Magnification greatly aids in tumour excision. Since the surgical approach invariably means entry through neural tissue, neurological morbidity due to the approach has to be borne in mind.

Lateral Ventricular Tumours

The proximity of the optic radiation, left sided preponderance with potential for speech and cognitive deficits, the "C" shape of the lateral ventricle and aiming for early control of the vascular pedicle have led to a plethora of surgical approaches for meningiomas of the lateral ventricle. These approaches may be through the cerebral convexity (temporal, parietotemporal, parieto-occipital), involving occipital lobectomy, or through the corpus callosum.[9] Most of these approaches described lead to iatrogenic morbidity in the form of visual field deficit, disconnection syndrome or speech and cognitive deficits. The parieto-occipital approach follows a cranio-caudal orientation parallel to the optic radiation over the cerebral convexity, and is least likely to damage the optic radiation. Moreover, this is often the thinnest region overlying the trigone and the tumour. The capsule is extensively coagulated with bipolar cautery and the tumour is cored out through the area of coagulation, till it can be mobilised to expose its feeding vessel(s) from the posterior choroidal artery. These vessels are then coagulated and divided and the remaining tumour can then be excised in one piece. Initial debulking allows the tumour to be turned, so that the feeding choroidal vessel can be tackled effectively; early attempts to control the feeding vessel may result in undesirable brain retraction and its sequelae. While early control of the feeding vessel is desirable, it may not be possible till the tumour is debulked and turned to expose the vessel. The tumour can completely be excised and speech and cognitive deficits, if any, are mild and transient by this approach. A high cortical incision can be made in the dominant hemisphere, to avoid speech disturbances and frameless stereotaxy can be employed to secure a safe trajectory.[21]

Third Ventricular Tumour

A small third ventricular tumour can be approached by the transcortical transforaminal approach, while large tumours may require transcallosal exposure. There should be no traction on the tumour, so as to avoid hypothalamic injury. Large tumours lend themselves poorly to excision due to morbidity associated with neuroendocrine, hypothalamic dysfunction and deep venous system injury associated with surgery of large third ventricular tumours.

Fourth Ventricular Tumour

These tumours are exposed by suboccipital craniectomy and splitting of the vermis. There can be severe brainstem distortion and the PICA can be seen draped over the tumour. The artery is carefully mobilised and safeguarded. The tumour is coagulated and cored out and can be dissected out in the arachnoid plane and separated from the floor of the fourth ventricle. The dura is closed primarily or by duroplasty utilising pericranium or temporalis fascia.

Results

Lateral Ventricular Tumours

Recovery is smooth in the majority of the patients after tumour excision. However, a left-sided approach can result in cognitive deficits and speech disturbances that usually resolve within 2–4 weeks. Motor deficits can result in infiltrating tumours, when an attempt is made to separate them from the ventricular wall. Intraventricular haemorrhage can occur from choroidal vessels. Transient or persistent post-operative homonymous hemianopia may be seen.

Third Ventricular Tumours

Excision of third ventricular meningiomas carries a higher morbidity, due to neuroendocrine, osmotic and hypothalamic disturbances. The floor of the third ventricle has to be respected during surgery to avoid these complications.

Fourth Ventricular Tumours

Meticulous care of the fourth ventricular floor and PICA avoids potential post-operative respiratory dysrhythmias and oropharyngeal paralysis due to injury to the floor of the fourth ventricle.

CONCLUSION

Intraventricular meningiomas are rare tumours, occasionally seen as part of NF2 complex, most of them occurring in males. There are no unique clinical features in presentation and raised intracranial pressure is the usual presenting feature. Imaging is diagnostic and surgery requires planning to avoid eloquent area damage. Early control of vascular supply to the tumour is vital and the tumour can usually be removed intact

without damage to the vital areas around the ventricles. No recurrences have been reported after complete excision. Histology of these tumours is in no way different from meningiomas with dural attachment.

175 Haemangioblastomas

Ravi Ramamurthi

Haemangioblastoma is a histologically benign tumour and has also been referred to as haemangioma, capillary haemangioendothelioma, Lindau's cyst, Lindau's tumour and angioreticuloma. The name haemangioblastoma was coined by Cushing and Bailey[14] and is widely accepted as preferable to the other names. These tumours may occur independently or may be part of Lindau's disease or von Hippel-Lindau complex (VHL).

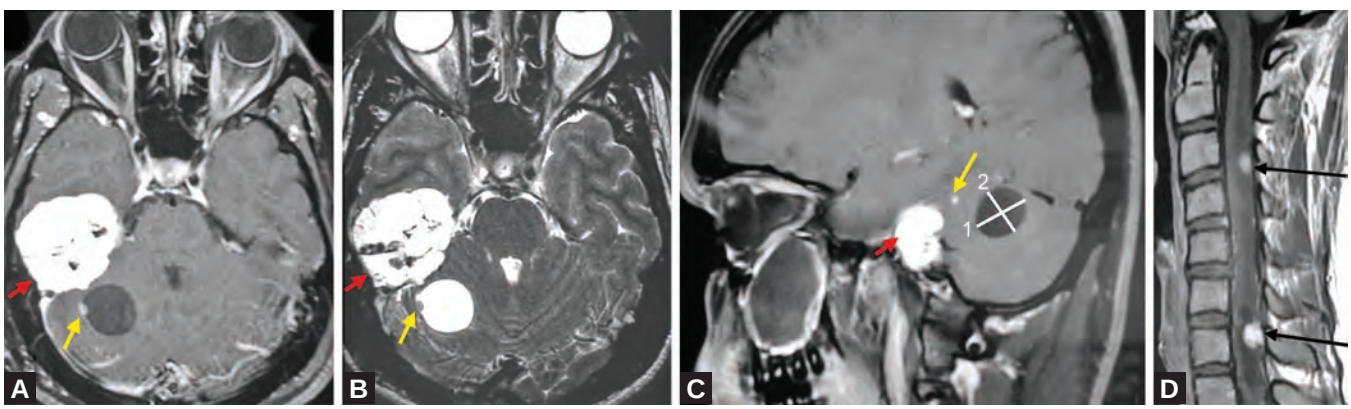
HISTORY[13,39,40,44,59,78]

In 1872, Hughlings Jackson reported in the Medical Times and Gazette the case of a 20-year-old woman and her sister who suffered from failing vision. An autopsy on the sister revealed a cerebellar cyst with clear yellow fluid and an angiomatous tumour in the cyst wall. Further reports by Vigla, Duchenne and Dolbeau (1864) and Paras and Remy (1879) soon followed. An accurate description of the ocular fundus picture was provided by Fuchs in 1882 and Laleyze in 1884. Pye Smith,[59] in 1885, reported the association of these cysts with pancreatic and renal cysts. In 1894, Treacher Collins gave a pathological description of the eye from a case of DJ Wood (1892).

In 1904, von Hippel published his classic paper in which he presented two patients with a retinal mass and retinal detachment and exudation. Seven years later, after becoming aware of Collin's work, he concluded that the retinal lesion was a haemangioblastoma. Lindau,[39] in 1926, wrote a classical monograph on the association of cerebellar cysts with other visceral manifestations. He presented the data on 40 cases, 16 of his own and 24 from the literature. Cushing and Bailey named it Lindau's disease.

GENETICS[6,7,29,30,74]

Haemangioblastomas may occur sporadically or as a part of VHL complex.[5] VHL complex is a familial disorder which has an autosomal dominant inheritance with variable penetrance and can be passed on by affected and unaffected members. This belongs to a group of disorders known as phakomatoses or neurocutaneous syndromes. Of 35 members of a family affected by VHL complex, nine had haemangioblastomas.[5] VHL complex is characterised by single or multiple haemangioblastomas in the neuraxis associated with one or more of the following visceral manifestations: Haemangioblastoma of the retina (von Hippel's tumour), renal carcinoma, renal cysts, pancreatic cysts, cysts and angiomas of the liver, epididymal cysts and adenomata and phaeochromocytoma[30] (Figs 1A to D). Extensive replacement of the spinal cord and brainstem by haemangioblastoma in a case of VHL complex has been reported.[64] Familial occurrence of solitary haemangioblastoma has been recorded without any stigmata of VHL disease.[5] Q-PCR is the method of choice for fast (within 3.5 hours), accurate and sensitive screening in routine DNA diagnosis of



Figs 1A to D: (A to C) MRI of the brain of a 24-year-old patient who was previously diagnosed to have pheochromocytoma showing glomus tumour (red arrow) arising from the middle ear along with cerebellar cystic haemagioblastoma on the same side with a mural nodule (yellow arrow). (D) Contrast MRI of the spine in the same patient showing multiple spinal haemangioblastomas

VHL disease.[27] Mosaicism could provide some genetic explanation for the clinical heterogeneity and variable severity of the VHL phenotype and should be considered as a possible event when evaluating sporadic cases of VHL or patients with isolated VHL-related tumours.[47] Renal cancer constitutes one of the main causes of death. The VHL gene, situated at 3p25–26, is a tumour suppressor gene, which plays a major role in regulation of VEGF transcription and expression. The germ cell mutation can be identified in 70% of patients. Somatic mutations of the VHL gene are also responsible for sporadic clear cell carcinomas. In the urological setting, any patient presenting with "sporadic" bilateral clear cell renal cancer or detected at an early age, or bilateral epididymal cystadenomas, should be investigated for the presence of VHL disease.[62] The von Hippel-Lindau (VHL) disease product is thought to down-regulate transcription, by antagonising elongin-enhanced transcriptional elongation. Germline VHL gene mutations predispose to the development of retinal, cerebellar and spinal haemangioblastomas, renal cell carcinoma and phaeochromocytoma. In addition, somatic inactivation of the VHL gene is frequent in sporadic renal cell carcinoma and haemangioblastoma. Regulation of transcript elongation is an important control mechanism for gene expression and the VHL gene might modify the expression of proto-oncogenes and growth suppressor genes during embryogenesis. VHL-mediated control of transcriptional elongation may have a role in normal human development.[63]

INCIDENCE

Haemangioblastomas constitute 1.5–2.5%[15,45,61,73,81] of intracranial tumours and 7–12%[15,21,45,55] of posterior fossa tumours. There is a complex relationship between CNS haemangioblastoma, retinal haemangioblastoma and Lindau's disease. About 20% of patients with CNS haemangioblastoma have VHL complex. Fifty per cent of patients with VHL complex have CNS haemangioblastoma.[7,30,42,50] The most common age at which they present are the third and fourth decades and there is a slight male preponderance. The age of onset of symptoms in VHL complex is earlier than in the sporadic variety. Cases have been reported in patients as young as 3 years and as old as 83 years.[32,37,42,45,54,55,68,70] Neumann et al.[50] have noted the mean age of onset of CNS symptoms in VHL complex as 39 years (12–73 years) and in the series of Maher et al.,[42] it was 29 years. Supratentorial haemangioblastomas are rare, forming 2–8% of all tumours of this type.[28,31,69] Haemangioblastomas may occur concurrently with other tumours like meningioma or with acoustic neurinoma or AV malformations.[43] Rarely, haemangioblastomas have been reported to occur in locations like the optic nerve, suprasellar region and the lateral ventricle.[25,35,57,58]

PATHOLOGY

Macroscopic Features

Haemangioblastomas occur most commonly in the cerebellar hemisphere. They may also occur in the vermis, brainstem, supratentorial compartment and in the spinal cord. In familial cases, the tumours tend to be multiple. Seventy per cent of haemangioblastomas in the cerebellum and about 20% in the brainstem and supratentorial location are cystic.[32,53,54]

Haemangioblastomas are pinkish or yellow and usually abut the pial surface. Dilated vessels may be seen on the cerebellar cortical surface. They do not have a true capsule, but are well circumscribed from the surrounding tissue. The cyst fluid is xanthochromic and the protein content may be up to 5 g/dl. The cyst wall is smooth and made up of glial cells and compressed cerebellar tissue. The solid portion is seen as a nubbin of varying sizes; the smallest may be even 2 mm and may be missed at surgery. The cut surface of the solid tumour is red in colour due to vascularity. Cavernous spaces and cysts may be seen and some areas may appear yellow from lipid deposition. Occasionally, the tumour may be totally solid as often happens in midline Vermian lesions.

Microscopic Features

The tumour consists of a mesh of vascular spaces lined by plump endothelial cells.[8,33,65] The vascular spaces are separated by numerous polygonal cells called interstitial or stromal cells. The capillary channels are surrounded by reticulin fibres which are demonstrated by reticulin stains. Pericytes, which lie just outside the periendothelial basement membrane and are themselves surrounded completely by a basement membrane, are best seen on electron microscopy. The origin of the stromal cells is still in doubt and various theories have been postulated.

The presence of histological variants of haemangioblastoma is well established. Clinical factors associated with histological subtypes, that is, of the cellular and reticular variant of haemangioblastoma, have been analysed in a series of 88 consecutive primary haemangioblastomas of the central nervous system. Ten haemangioblastomas were classified as 'cellular' according to Cushing and Bailey. As compared to the more common 'reticular' variant (n = 78), the proportion of tumours containing glial fibrillary acidic protein-positive tumour cells (80% vs 7%), as well as median Ki67 (MIB1) proliferation indices [4% (quartiles: 1–8%) vs less than 1% (< 1–2%)], was significantly higher in cellular haemangioblastomas ($p < 0.01$). Recurrences were more frequent in the cellular variant [2/8 (25%) vs 4/51 (8%)]. Kaplan-Meier analysis confirmed a significantly higher probability of recurrence in the cellular variant (Log-Rank test, $p < 0.01$). Cox regression analysis, not only confirmed the well established association of von Hippel-Lindau

disease with tumour recurrence ($p < 0.01$), but also revealed an independent effect of histological subtype on the probability of recurrence ($p < 0.05$), whereas no significant influence of age, sex or tumour location was observed. The results from this retrospective study suggest that histological subtyping of haemangioblastomas has prognostic implications and might contribute to identify patients at risk for recurrence.[24]

Astrocytomas are rarely found in von Hippel-Lindau disease and they may contain genetic changes common to both haemangioblastomas and some astrocytomas.[51] Malignant spread, distant metastases and subarachnoid seeding are very rare. Recurrence and extensive spread are excellently demonstrated by MRI.[23]

Histology of the cyst walls is consistent with reactive gliosis. CNS peritumoral cyst formation is initiated by increased tumour vascular permeability, increased interstitial pressure in the tumour and plasma extravasation with convective distribution into the surrounding tissue. When the delivery of plasma from the tumour exceeds the capacity of the surrounding tissue to absorb the extravasated fluid, oedema (with its associated increased interstitial pressure) and subsequent cyst formation occur.[41]

SYMPTOMS AND SIGNS[29,32,45,53-55]

The most common initial symptom is headache and other symptoms of raised intracranial pressure. Vertigo and diplopia may occur.[45,55] About 25% may have mental changes which may be caused by hydrocephalus. Rarely, they may present as subarachnoid or parenchymal haemorrhage. A full-term neonate presenting with supratentorial and infratentorial haemorrhagic lesions, which occurred as a result of congenital supratentorial haemangioblastoma bleeding has been reported.[36] The overall incidence of haemorrhage in patients with haemangioblastoma is low. An important indicator for the probability of haemorrhage is tumour size, as spontaneous or post-operative haemorrhage occurred exclusively in extraordinarily large tumours. Haemangioblastomas smaller than 1.5 cm (the vast majority of these tumours) harbour virtually no risk of spontaneous haemorrhage.[20] The average duration of symptoms is about 7 months and may extend longer.

Papilloedema occurs in a majority of patients (70%), although the percentage is less now than in earlier years, probably due to early diagnosis.[32,54] Depending on the location in the posterior fossa, there may be cerebellar or brainstem signs or both. Ataxia of gait, upper limb incoordination and nystagmus occur in about 60% of patients. If the tumour is located in the brainstem, cranial nerve and long tract signs may be present. Other presenting symptoms reported are adult cerebellar mutism and intractable hiccoughs.[1,48] Supratentorial lesions may mimic the clinical presentation of meningiomas. Paralysis of upward gaze may occur if the tumour is located in the roof of the fourth ventricle. It must be pointed out that these symptoms and signs are not specific for haemangioblastomas and are only dictated by the location of the tumour. Vascular engorgement of cerebellar haemangioblastomas during pregnancy may cause patients to become symptomatic.[49,76]

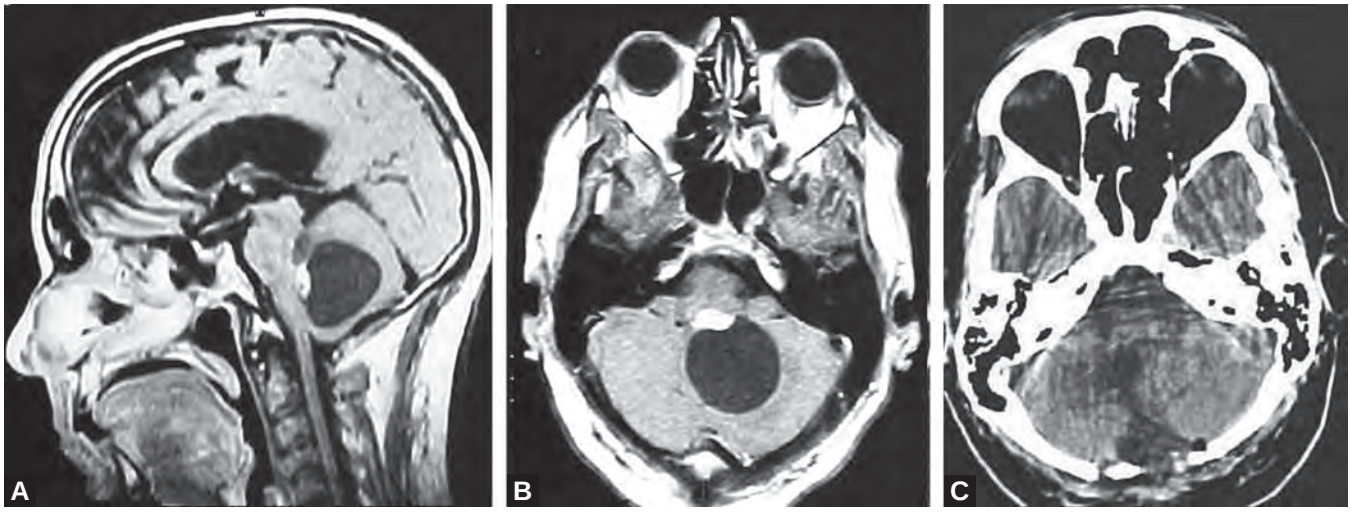
INVESTIGATIONS

The best screening test for haemangioblastomas is computed tomography in the axial and coronal planes.[19,67] The solid lesions generally appear isodense with the cerebellar tissue on plain scans, but enhance intensely with contrast injection. There is either homogenous enhancement or a mottled appearance, due to the presence of intratumoural cysts. The cystic lesion is seen as a sharply defined low density with attenuation values of CSF or slightly higher if the protein content is high. A mural nodule will enhance intensely with contrast, but the cyst wall does not. A small mural nodule may be missed on CT scanning.

Vertebral angiography is very useful, especially in patients with evidence of VHL complex, who have a cerebellar cyst with the mural nodule not visible on the CT. The following vascular patterns have been observed: (i) A vascular mural nodule within an avascular cyst; (ii) A doughnut ring of abnormal vessels surrounding an avascular space representing an intra-tumoural cyst; (iii) A large solid vascular mass and (iv) Multiple small widely separated vascular nodules.[67]

MRI is the most sensitive investigation for haemangioblastomas, especially those with small mural nodules and the ones near the base or the tentorium.[17,18,38,66] The cyst does not appear as hypointense as CSF on T1-weighted images and they may exceed the CSF signal on T2-weighted images. Occasionally, a cyst may show evidence of previous haemorrhage. On T1 and proton density weighted images, mural nodules stand out well against the darker background of cyst fluid (Figs 2A to C). With T2 images, the nodules may become less apparent, since their signal rises along with that of cyst fluid. Highly vascular lesions will remain low on T2 images and will be clearly visible. Prominent feeding arteries and draining veins are characterised by flow void. If larger vessels are present in the tumour, a 'salt and pepper' appearance may be seen. Solid tumours and mural nodules enhance brightly and homogenously after Gd-DTPA injection. Gd-DTPA enhancement is useful to detect multiple tumours, assure complete removal and detect possible recurrence.[3] The apparent diffusion coefficients are increased in haemangioblastomas. These findings may indicate rich vascular spaces of the haemangioblastomas. Diffusion-weighted imaging may be useful for distinguishing haemangioblastomas from other enhancing cerebellar tumours.[60]

Erythrocythaemia occurs in 9–49% of patients.[33,56] This is seen with posterior fossa or supratentorial tumours, but has not been reported in cases of purely spinal tumours. There is neither splenomegaly nor increase in white blood cells or platelets. The erythrocytes have a normal lifespan and the bone marrow may show



Figs 2A to C: (A and B) Pre-operative MRI of the brain sagittal and axial showing cystic haemangioblastoma of the cerebellum with ventrally placed mural nodule. (C) Post-operative CT scan showing total excision of the haemangioblastoma

erythroid hyperplasia. The erythrocytosis is due to secretion of erythropoietin by the tumour. Foci of extramedullary haematopoiesis can be found in some tumours.[10] Trimble et al.[75] have demonstrated erythropoietin RNA in the tumour cyst fluid by Northern blotting. Injection of the cyst fluid into experimental animals may cause erythrocythaemia. Immunohistochemical and electron microscopic studies have shown that the secreting cells are scattered in the vicinity of capillaries. Neither endothelial nor stromal cells were stained. In their morphology and distribution, the positively stained cells were identical to mast cells, as observed by electron microscopy.[34] After removal of the tumour, the polycythaemia regresses and may reappear with either recurrence of tumour or tumour occurring in another area. Estimation of haemoglobin, RBC count and PCV is useful during follow-up of these patients.

TREATMENT AND RESULTS

Surgery with total excision of the tumour leads to good results. The use of the operating microscope and bipolar coagulation are mandatory. Earlier series reported mortality rates of 25–30%.[4] Most current series report mortality rates of approximately 15%.[32,55,68,69,80] These, however, include patients operated upon in earlier years. In the past four decades, the mortality rates have come down to 4–6% and in one series there was zero mortality.[45,46,56] Surgical outcome for patients with CNS haemangioblastomas is favourable, however, management of haemangioblastomas is more difficult and prolonged for patients with VHL syndrome, as these patients present at younger ages and are at risk for development of new lesions, often multiple, and require lifelong follow-up.[11]

Ammerman et al.[2] in their study of 19 patients harbouring a total of 143 haemangioblastomas, concluded that these lesions exhibit a stuttering growth pattern, frequently remain asymptomatic and do not require treatment for long intervals. Unqualified radiographic progression is not an indication for treatment.

Surgery for posterior fossa haemangioblastomas is done through an appropriate craniectomy either midline, paramedian or retromastoid. The sitting, semi-sitting, prone or semiprone position is used, depending on the surgeon's preference. If the dura is tense due to a large cyst, the cyst must be aspirated before opening the dura. During such aspiration, needle injury to the underlying solid tumour should be carefully avoided. These tumours generally involve the pial surface. The location of the tumour can be made out by dilated pial vessels, especially in solid tumours. In cystic lesions, the cyst is entered through a cortical incision. The mural nodule should be looked for. Very often, this will be found superiorly and the superior pole may abut the tentorium. A thorough search must be made to locate the nodule, as this may sometimes be difficult to find. Evacuating the cyst alone, without removing the mural nodule is of no use, as the cyst will rapidly re-accumulate. No attempt should be made to biopsy the tumour or remove it piecemeal, as uncontrollable and catastrophic bleeding may occur. The nodule must be removed en masse by going around it in the cerebellar tissue adjacent to the tumour and coagulating the feeding arteries and veins like in an arteriovenous malformation. This technique is more important for solid tumours. Once a part of the tumour is seen, the dissection is carried out around the tumour. When the tumour is abutting the dorsal surface of the brainstem cardiorespiratory problems can occur during dissection. Those involving the cerebellar peduncles and the lateral surface of the brainstem can be removed without much difficulty and morbidity. Two types of brainstem haemangioblastomas (BSHs) can be identified. Patients with cystic BSH lesions could have an excellent outcome after surgery. Patients with giant or large solid BSHs remain a challenge to neurosurgeons. A combined strategy of pre-operative embolisation, mild hypothermia with or without hypotension, microsurgical

technique and intensive peri-operative management are mandatory for removal of these tumours with acceptable morbidity and mortality.[77] Particle embolisation is not recommended, as it can lead to acute tumour bleeding and death.[12]

Solid haemangioblastomas can be difficult to treat surgically because of their hypervascularity and requirement for circumferential dissection. They can be safely resected utilising wide transtemporal posterolateral skull-base exposures. Good tumour exposure was achieved with trans-cochlear approaches and division of the sigmoid sinus. For large tumours the added complexity of the approach was justified by providing a panoramic exposure to allow safe resection.[16]

A complete excision of the lesion has been achieved by means of endoscopy without any violation of the subarachnoidal space and complete cyst regression was observed on CT follow-up investigations.[52]

The need for pre-operative CSF diversion in patients with hydrocephalus depends on the surgeon's preference and is debatable.[22] Controlled ventilation is essential, except when the tumour is being dissected off the floor of the fourth ventricle, when respiratory monitoring is required. In a vascular cerebellar haemangioblastoma, Williams et al.[79] used profound hypothermia, cardiopulmonary bypass and circulatory arrest for successful removal.

Recurrence after total removal is rare. If there is evidence for recurrence of the tumour, it will most likely be a tumour arising at a different site. Radiation therapy in high doses may retard the growth of the tumour and reduce its size and vascularity. It is only palliative and should be used only in large solid tumours involving the brainstem which are inoperable.[26,71]

Radiosurgery often lends itself particularly well to these discrete lesions allowing highly focused treatment. For patients with multiple and metachronous cerebellar haemangioblastomas as part of the von Hippel-Lindau syndrome, the data support a policy of conventionally fractionated external beam radiotherapy to the whole cerebellum of 50–55 Gy followed, after a period of time, by radiosurgery to persisting lesions.[9,72,77]

The long-term prognosis is good in cystic and in non-familial tumours. The prognosis for tumours involving the brainstem is not very good, as the operative mortality and morbidity are high. In VHL complex, the prognosis depends on multiplicity of tumours and occurrence of carcinoma in the kidney.

176 Primary Central Nervous System Lymphomas

Sanjay Behari, Punita Lal, Samir Kalra, Manoj Jain

INTRODUCTION

Primary central nervous system lymphomas (PCNSLs) are the non-Hodgkin's lymphomas (NHL) arising in and within the central nervous system (CNS). These are extranodal malignant lymphomas arising within the CNS in the absence of obvious lymphoma outside the nervous system at the time of diagnosis. They are usually found in the brain parenchyma but may be present in the eyes, leptomeninges or rarely the spinal cord.[19] CNS lymphomas were first described by Bailey in 1929 as "perithelial sarcoma", since the tumours appeared to be reticuloendothelial in origin and perivascular in location. They have also been classified as reticulum cell sarcoma, microglioma or perivascular sarcoma in an effort to describe the cell of origin. In the 1970s, their lymphoid lineage and correct designation as lymphoma was accepted. An analysis of the tumour cell surface immunoglobulins in the 1980s revealed that PCNSLs were non-Hodgkin's lymphomas of B cell lineage with only 1–3% having a T cell phenotype. In the past two decades, their incidence has risen significantly in both immunocompromised and non-immunocompromised individuals.[3,17,25,27]

The disease has certain unique features. It is usually restricted to, yet disseminated within the CNS. Its radiological appearance, steroid responsiveness and the relative roles of surgery, chemotherapy and radiotherapy have distinctive features that make the management of this disease quite different from all other CNS tumours.

The source of the cell responsible for the development of PCNSLs is not known since the CNS lacks lymphatics and lymph nodes. Under normal circumstances, lymphocytes do move in and out of the CNS and may be the primary source of PCNSLs. However, it is the T cell lymphocytes that move through the CNS and B cells are usually not found there and yet PCNSLs are predominantly B cell tumours.

It has also been postulated that PCNSLs arise as metastasis from an occult systemic lymphoma. However, this is unlikely since PCNSLs are almost never associated with systemic NHL at diagnosis or autopsy; CNS spread of lymphoma usually occurs in patients with advanced systemic disease, a state never found in PCNSLs; and CNS metastasis from a peripheral NHL is usually leptomeningeal or spinal epidural and very rarely parenchymal. If a lymphoma at an extra CNS site is found coexisting with the lesion in the brain then, by definition, the brain lesion is no longer considered as a PCNL but a lesion that has metastasised to the CNS. Systemic lymphomas and leukaemias involve the CNS in approximately 5–35% of patients and their lesions are often confined to the leptomeninges and cranial or spinal nerve roots.

Another hypothesis postulates that since CNS is an immunologically privileged organ, lymphoma cells that arise elsewhere in the body migrate into and preferentially reside in the CNS. The normal immune system in the rest of the body would destroy these tumour cells. However, there is an absence of tumour cells in other immunologically privileged organs such as the testis.

The transformed tumour cells become receptors for the endothelium of cerebral blood vessels. This led to the postulation that the presence of unique cell surface markers would induce migration of these cells into the CNS. However, no specific adhesion molecule has been identified. Another hypothesis states that a B cell attracted to a CNS inflammatory lesion and targeting the organism responsible for inflammation, undergoes malignant transformation due to chronic antigenic stimulation within the CNS.[19] However, the incidence of PCNSLs is not increased in inflammatory disease like bacterial infections, multiple sclerosis or encephalitis. Moreover, no source of chronic antigenic stimulation coexists in the CNS of PCNSL patients.

Until the 1980s, PCNSLs represented 0.5–2% of intracranial neoplasms. Over the last two decades, there has been a 3–6 fold increase in its incidence. It now accounts for approximately 3% of all brain neoplasms and less than 1–4% of all non-Hodgkin's lymphomas.[15] This has been associated with an overall increase in the other systemic non-Hodgkin's lymphomas (NHL) as well as a higher prevalence of AIDS related PCNSLs.[27,39,40] PCNSLs may often be associated with other immunodeficiency states both congenital (e.g. hereditary immune deficiency, Wiskott-Aldrich syndrome, immunoglobulin A deficiency, hyperimmunoglobulin M syndrome or severe combined immune deficiency) and acquired (e.g. organ transplantation recipients or chronic pharmacologic immune suppression). The Ebstein-Barr virus (EBV) is an important cause in the genesis of PCNSLs in immunocompromised patients. However, EBV genome

has been identified in only a small portion of PCNSLs arising in immunocompetent patients.[26] Human herpes virus 8 (HHV-8) DNA has also been identified in PCNSLs in patients with or without AIDS. The other risk factors for PCNSLs include myasthenia gravis, vasculitis, autoimmune disease, rheumatoid arthritis, systemic lupus erythematosis, sarcoidosis and Sjogern's syndrome.

PCNSLs may occur in all age groups. Its peak incidence is in the sixth and seventh decades (mean approximately 58–60 years) in immunocompetent patients,[7] but it occurs in a much younger age group (mean approximately 37–43 years) in immunocompromised patients. Among the immunocompetent individuals, there is a 3:2 male-to-female ratio, but in the AIDS population, more than 90% of patients are men.

CLINICAL FEATURES

PCNSLs generally grow more rapidly than gliomas and may have a history of progression of only a few weeks to months. The presenting symptoms depend on the location of the tumour. Most PCNSLs present with pressure symptoms caused by the mass lesion. Focal cerebral deficits occur in nearly half of the patients. Behavioural and personality changes are also common presenting symptoms. PCNSLs often have a deep periventricular location and, therefore, seizures are less common (occurring in approximately 10% of patients). Diencephalon infiltration may cause hypothalamic syndromes including diabetes insipidus or the syndrome of inappropriate antidiuretic hormone secretion; altered sexual behaviour and eating disorders. Posterior fossa lesions may cause cerebellar syndromes and hydrocephalus. Brainstem lesions may produce long tract signs, internuclear ophthalmoplegia, vertigo and diplopia. Spinal cord lymphomas are rare and cause transverse myelopathies. The thoracic cord is usually involved, but lumbar infiltration with nerve root involvement may also occur. The leptomeningeal involvement is usually close to the site of the parenchymal lesions in the CNS and is usually asymptomatic. However, in an advanced stage, signs of meningism may occur.

Neurolymphomatosis is the painful or painless selective invasion of either cranial or peripheral nerves or the plexus they form. Sensory symptoms are common and include burning paraesthesias, allodynia, vibratory/position sense deficit or numbness. Cranial or peripheral nerve motor deficits, such as Bell's palsy, facial pain or limb weakness, are less common.

PCNSLs widely infiltrate the brain parenchyma. An autopsy usually shows microscopic disease even in areas that were appearing normal on magnetic resonance imaging (MRI).[29, 37] Multifocality is seen in nearly 40% of immunocompetent patients and in almost 100% of immunocompromised patients.[7] Due to the multiplicity of lesions in PCNSLs, the disease may often be mistaken for brain metastases, especially since approximately 13% of PCNSL patients already have a prior history of systemic malignancy. Most lesions are periventricular, allowing tumour cells to gain easy access into the cerebrospinal fluid (CSF). At least 40% of patients have demonstrable CSF seedling on examination or on MRI. The CSF spread of the disease is, however, often asymptomatic.

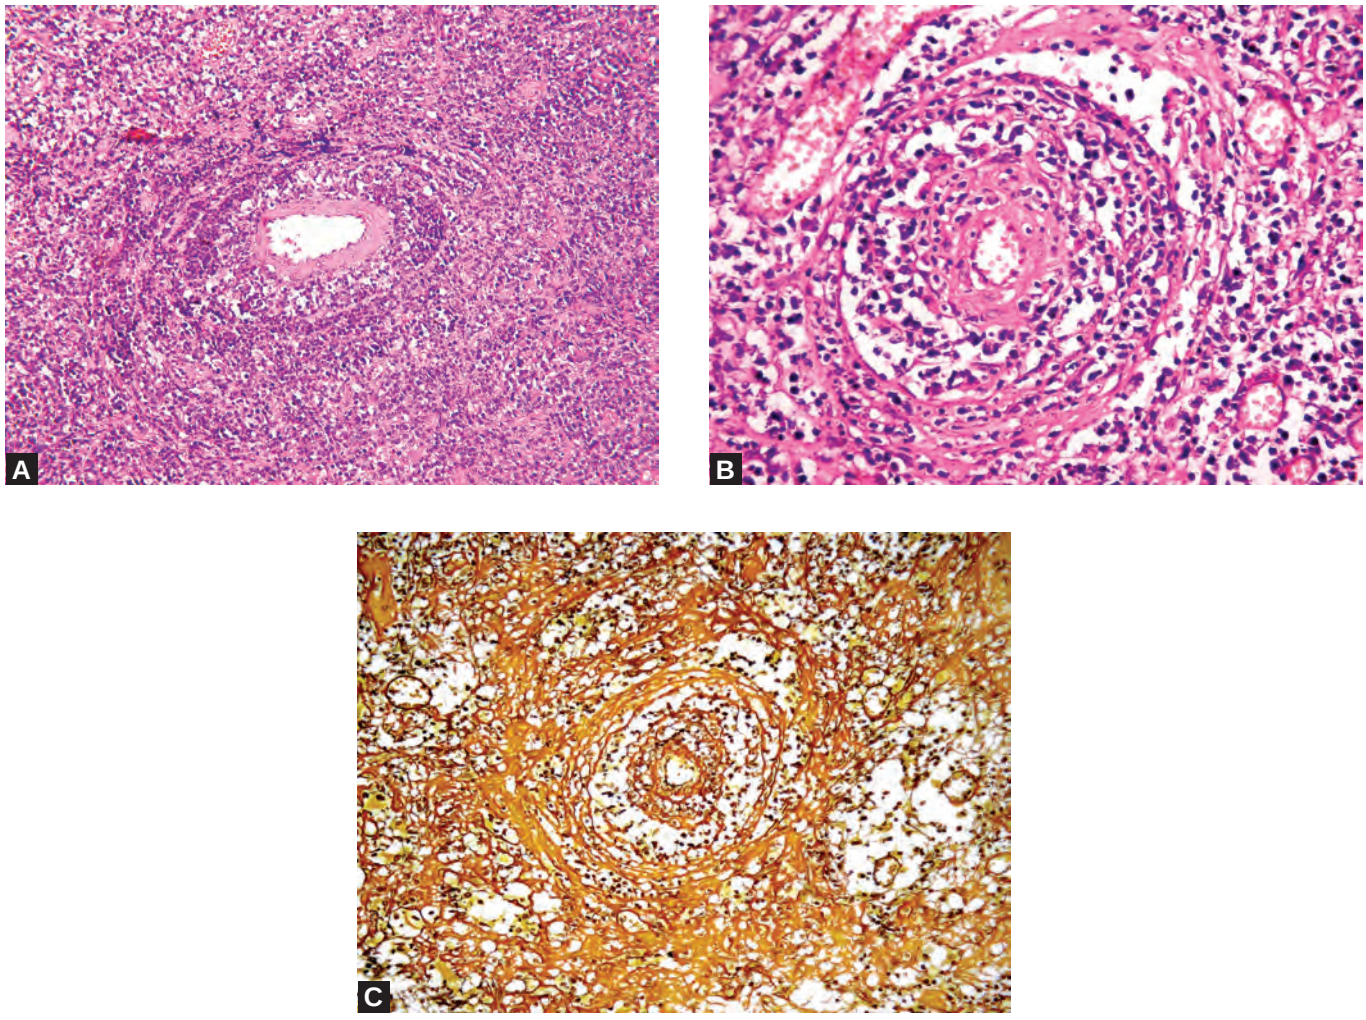
Ocular lymphoma involving either of the layers of the eye is a fairly common manifestation of PCNSL (in 12–18% of patients with cerebral PCNSLs). Fifty to eighty per cent of patients who present with ocular lymphoma develop PCNSLs over a period of time (median 9 months; range 2–94 months). This may cause visual deterioration, floaters in the eye fields, uveitis or retinitis. Indirect fundoscopy with slit lamp examination may be required to detect the ocular lymphoma.[9] An orbital lymphoma, on the other hand, is usually associated with metastatic NHL.

PATHOLOGY

About 60% of PCNSLs involve the supratentorial space, especially the cerebral hemispheres (52%) [frontal (15%), temporal (8%), parietal (7%), occipital (3%), basal ganglia/periventricular region (10%) and corpus callosum (5%)]. In the posterior fossa it occurs in the cerebellum in 11.5% and the brainstem in 2.3%. The spinal cord is involved in 0.6–1% patients. Approximately, 25–50% of lesions are multiple. Secondary meningeal spread is seen in 30–40% of PCNSLs, while leptomeningeal lymphoma may account for up to 8% of these tumours. The lesions are, however, solitary in 60–70% of cases. On the other hand, secondary CNS malignant lymphomas usually occur in the dura and leptomeniges but parenchymal lesions may also occur. Systemic dissemination occurs late in the course of the disease in 7–8% of cases, often in the lymph nodes in the abdomen and retroperitoneum. These metastatic lesions from PCNSLs do not usually cause any symptoms during the course of the disease and are usually found at autopsy.[29]

On gross examination, PCNSLs occur as single or multiple masses in the cerebral hemispheres. Commonly, they are deep seated and adjacent to the ventricular system. The tumours can be firm, friable, granular, centrally necrotic, focally haemorrhagic, grey, tan, yellow or virtually indistinguishable from the adjacent neuropil. Some tumours appear well-demarcated, like a metastatic lesion. When diffuse borders and architectural effacement are present, the lesions resemble gliomas. Macroscopically, meningeal lymphoma mimics a meningioma or meningitis.

On microscopic examination, a PCNSL diffusely infiltrates the brain parenchyma in an angiocentric pattern forming collars of tumour cells within concentric perivascular reticulin deposits (Figs 1A to C). Virtually, all PCNSLs show a diffusely infiltrating pattern. When tumours become confluent, geographic necrosis may be seen with perivascular islands of viable tumour cells surrounded by large regions of coagulative necrosis.

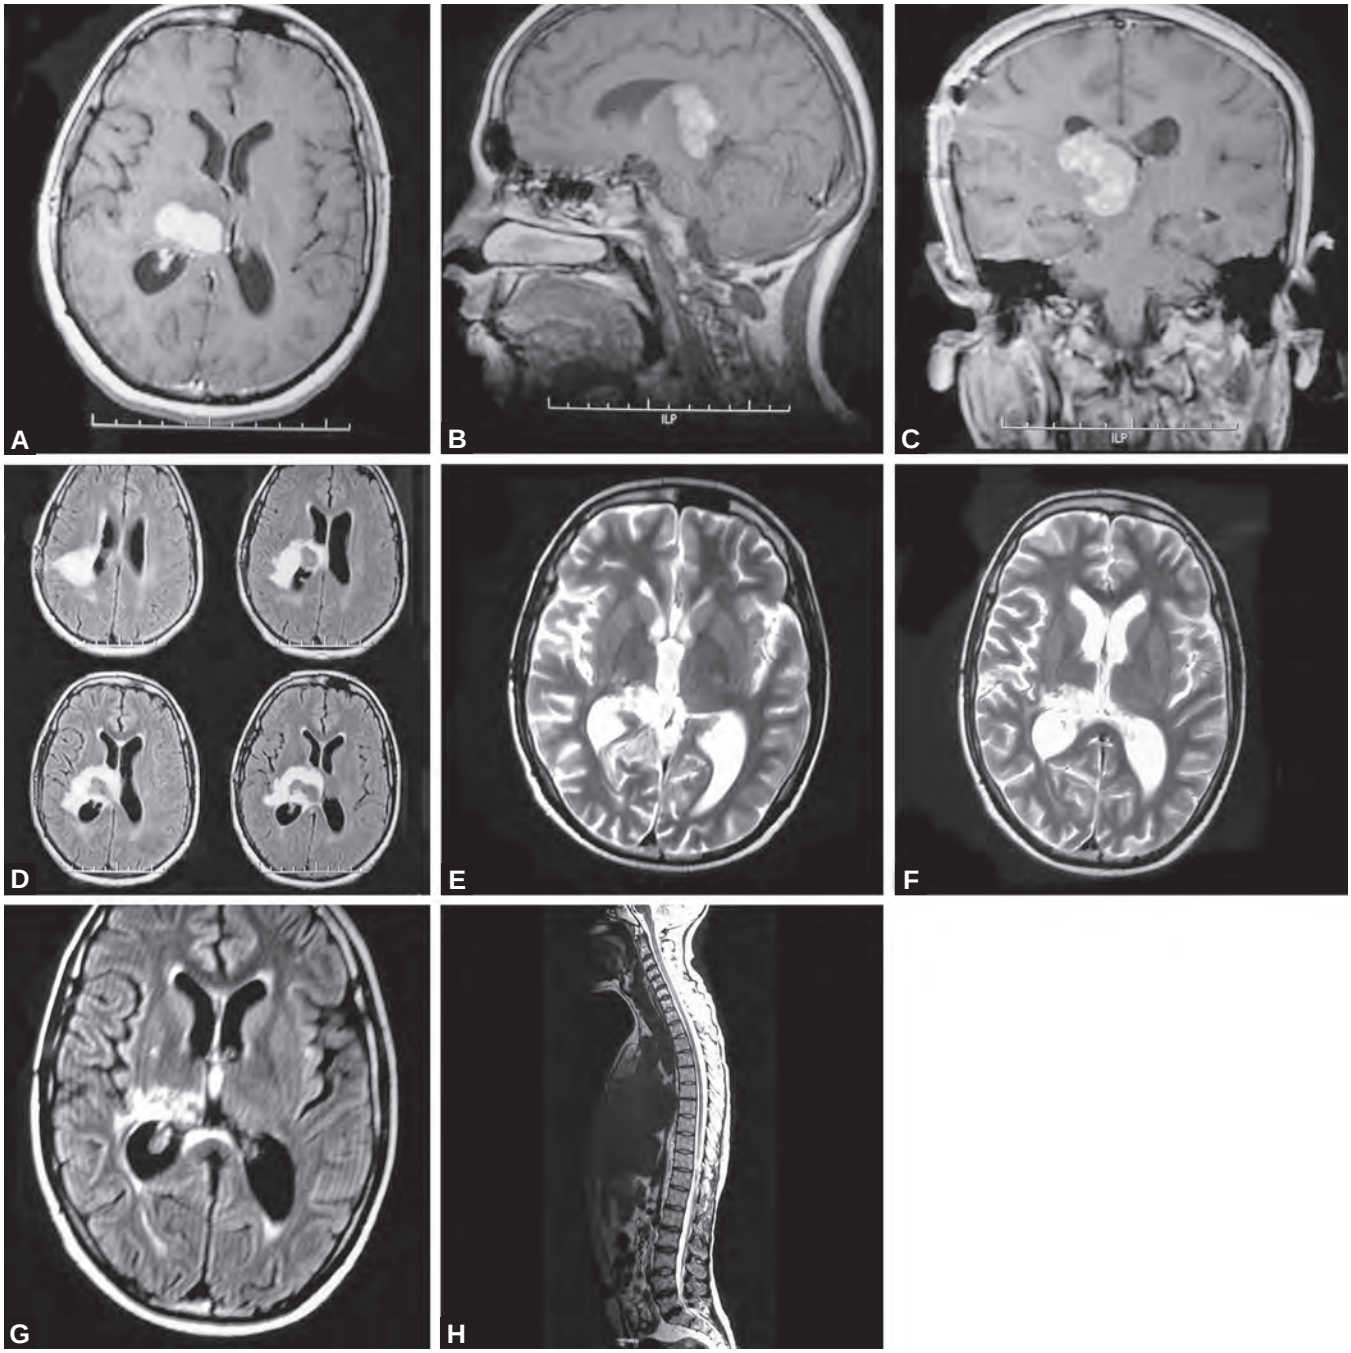


Figs 1A to C: (A) Malignant diffuse large cell lymphoma, diffusely infiltrating the brain and perivascular accumulation of neoplastic cells (H and E stain, Original Magnification x 40). (B) Malignant diffuse large cell lymphoma, perivascular accumulation of neoplastic cells (H and E stain, Original Magnification x 200). (C) Malignant diffuse large cell lymphoma, perivascular accumulation of lymphoma cells embedded in a concentric network of reticulin fibres (Reticulin stain, Original Magnification x 200)

A focally prominent astrocytic and microglial response, large macrophages and reactive lymphocytic infiltrates are common. On higher magnification, PCNSLs show lymphoid cells with a variable appearance.

Approximately 98% of PCNSLs are B-cell lymphomas with the immunohistochemical expression of pan-B markers, such as CD20 and CD79a, usually with IgM-κ production. According to a meta-analysis, sub-types of 590 sporadic PCNSLs were classified according to the working formulation, including diffuse large cell (43.4%), diffuse large cell immunoblastic (19.7%), diffuse small cleaved cell (9.5%), small non-cleaved cells/non-Burkitt (8.8%), atypical/unclassified (7.1%), diffuse mixed small and large cell (7.1%), lymphoblastic (2.9%) and small lymphocytic (1.5%). The major sub-types of HIV associated PCNSLs have been diffuse large cell immunoblastic (33.6%), diffuse large cell (32.7%) and small non-cleaved cell (21.6%). Revised European-American Lymphoma (REAL) classification and the WHO classification of lymphoma have greatly simplified the sub-typing of CNS lymphomas. Since the great majority of tumours can be classified as diffuse large B-cell lymphoma having large cells with round or lobulated nuclei with vesicular chromatin and prominent nucleoli typically mixed with reactive lymphocytes, histiocytes, microglia and astrocytes, supplemental immunohistochemistry (to determine the immunophenotype and to exclude the gliomas and carcinoma) is often necessary, especially with the limited biopsy from stereotactic procedures (Figs 2A to H and 3A to F).

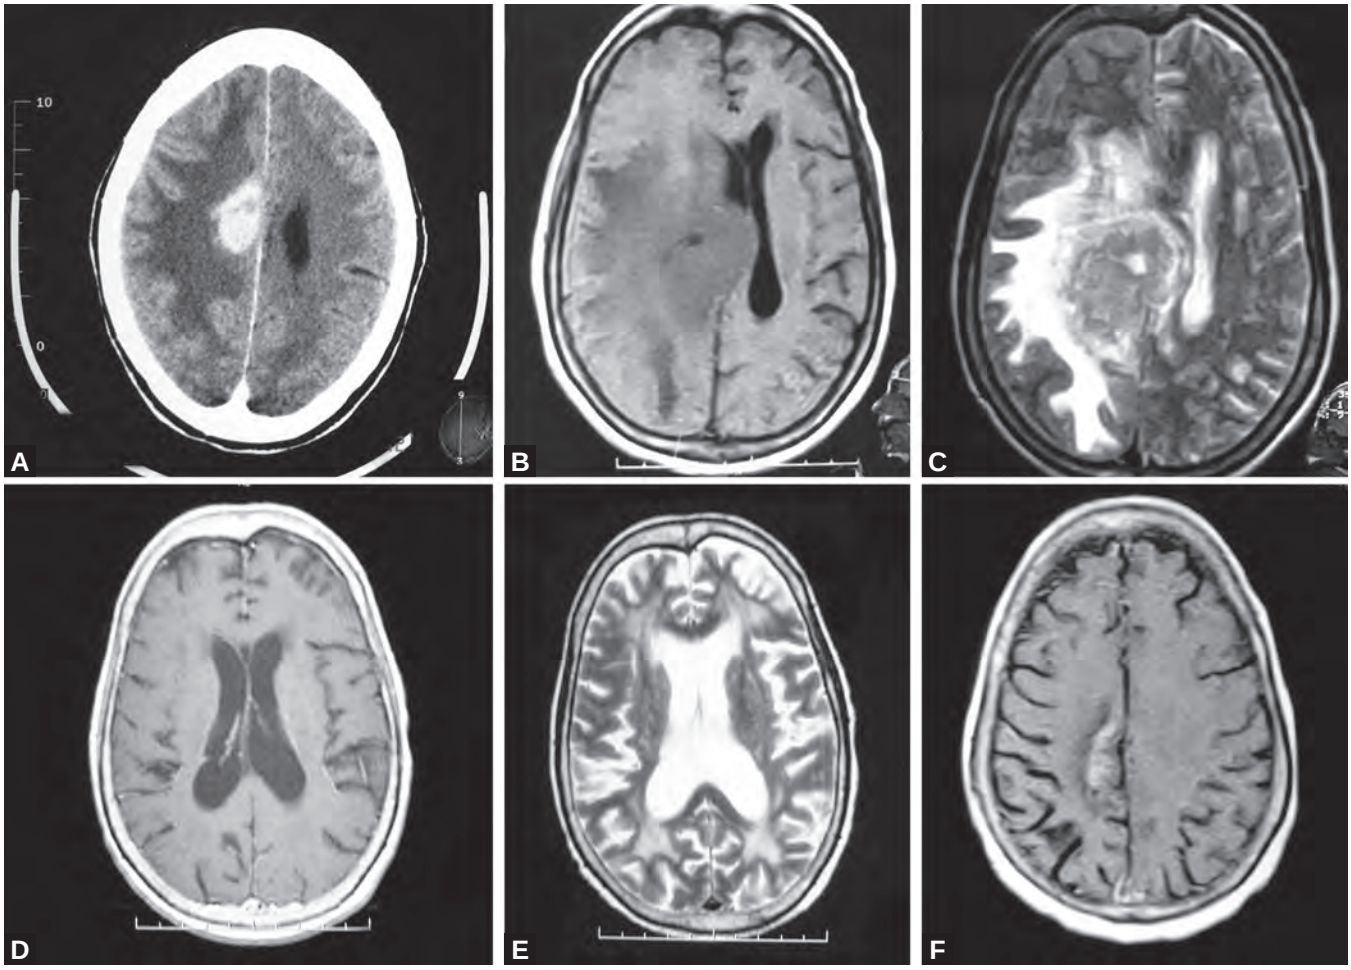
T-cell lymphomas constitute about 2% of PCNSLs and have mainly been seen in immunocompetent patients. They occur as solitary or multiple intraparenchymal masses, often having more frequent posterior fossa localisation, particularly in the cerebellum and with a propensity to arise in the leptomeninges.[7]



Figs 2A to H:. (A) Ti-weighted contrast axial image. (B) Sagittal image. (C) Coronal image showing a brilliantly enhancing thalamic lymphoma causing mild ventriculomegaly. The lesion is periventricular in location, extending to right caudate nucleus and causing effacement of right lateral and third ventricle and dilatation of contralateral lateral ventricle. (D) Axial flair images showing perifocal oedema around the lymphoma (E and F) T2-weighted axial MR images showing significant resolution of the lesion following radiotherapy chemotherapy. (G) Axial flair image showing significant decrease in perifocal oedema as well as tumour size and opening up of the ventricular system. (H) Whole spine T2-weighted MR sagittal image showing no evidence of spinal metastasis

Angiotropic lymphoma, also known as intravascular lymphoma, affects multiple organ systems. The CNS is involved in more than 30% of cases. Accumulation of large B-cells within small and medium vessels leads to vascular occlusion and disseminated small infarcts.

Hodgkin's disease is rare in the CNS and is most often seen in the setting of Grade III or IV systemic disease but primary CNS presentations have been described. Lesions are typically dural based but firm and well demarcated parenchymal tumours do occur. The diagnosis of Hodgkin's disease rests upon the identification of Reed-Sternberg cells or their variants in the background of appropriate non-neoplastic haematopoetic cells (lymphocytes, plasma cells, histiocyte and eosinophils).



Figs 3A to F: (A) Contrast enhanced axial CT scan showing a right hyperdense enhancing irregular lesion with significant perifocal oedema in centrum semiovale causing ipsilateral ventricular and gyral and sulcal effacement. (B) T1-weighted axial MR images showing hypointense right periventricular lesion causing effacement of body of lateral ventricle. (C) T2-weighted axial MR images showing intense perifocal oedema around the lesion. (D) T1-weighted. (E) T2-weighted. (F) Contrast enhanced T1-weighted axial MR images showing significant resolution of the lesion following radiotherapy and chemotherapy

Rare variants of PCNSLs have unusual sites of presentation and are uncommon pathological entities (e.g. neurolymphomatosis and primary leptomeningeal lymphoma). Neurolymphomatosis involves peripheral nerves and nerve roots in addition to systemic and CNS sites. The diagnosis requires a high index of suspicion and treatment incorporates the principles of therapy for systemic and CNS lymphoma. Primary leptomeningeal lymphoma can present with symptoms of raised intracranial pressure or cranial or spinal polyradiculopathies. Diagnosis can be made by examining CSF and incorporating immunophenotyping and molecular pathology techniques.

DIAGNOSTIC TESTS

Imaging Radiology

On non-contrast CT scans, these lesions are often hyperdense. They enhance brilliantly on contrast administration. The tumours are typically hypointense on T1-weighted images. On T2-weighted MR images, these lesions may be isointense to hyperintense due to their hypercellularity. Dense, homogeneous enhancement occurs on gadolinium administration. Only rarely are the lesions non-enhancing. The oedema is usually less than that seen in a malignant glioma of similar size. There may be multifocality in nearly 50% of tumours, especially in immunocompromised patients and calcification is not a feature of these lesions. They characteristically occur in the deep white matter of the centrum semiovale of the cerebral hemispheres and often have a periventricular location. There may be a subependymal spread or along the corpus callosum or they may occur as diffusely infiltrative lesions without a primary mass. In immunocompromised patients, they may show ring enhancement with significant oedema and a hyperintense signal on T2-weighted images reflecting the higher incidence of necrosis seen on pathological examination in this group. Spontaneous haemorrhage may also occur. PCNSLs lesions (as all other malignant lesions) show restriction in proton diffusion producing a hyperintense appearance on diffusion weighted images. MR spectroscopy reveals decreased N-acetylaspartate peak and an

increased ratio of choline to creatine (> 3:1). PCNSLs in immunocompromised individuals mimic infections and MRI may not be able to differentiate between the two. SPECT using Thallium-201 (a potassium analogue that only enters the region of disrupted blood-brain barrier proportional to the activity of the sodium-potassium adenosine triphosphatase pump)[2] or PET scans (using fluorodeoxyglucose) are usually effective in differentiating lymphoma from toxoplasmosis in immunocompromised patients since a PCNSL lesion shows a greater hypermetabolic state than is seen in infection.

Cerebrospinal Fluid Examination

The CSF cytology (consisting of reactive or malignant lymphocytes) may be positive in nearly 35–40% of the cases and may obviate the need for a brain biopsy. Immunohistochemistry may often demonstrate the monoclonal population of malignant cells. The protein concentration may be mildly elevated in 85% of patients (≤ 150 mg/dL). The glucose concentration is usually normal. However, low glucose concentrations with an increase in levels of tumour markers like β2-microglobulin, lactic dehydrogenase and β-glucuronidase may suggest a leptomeningeal invasion. In large supratentorial or posterior fossa lesions, performing a lumbar puncture may precipitate transtentorial or tonsillar herniation respectively or even both.

Vitreous Fluid Examination

Vitrectomy may also establish the diagnosis particularly in patients with isolated ocular lymphoma. Identification of interleukin 10 levels in the vitreous fluid and the immunophenotyping of vitreous cells may be done.

Systemic Evaluation

Staging for patients with PCNSLs includes CSF cytology, slit lamp examination of the eyes, CT scan of chest, abdomen and pelvis, bone marrow biopsy and serological testing for HIV. An extra CNS site is seen in less than 4% of patients with PCNSLs, so a comprehensive systemic evaluation may be eliminated. Since PCNSLs are frequently seen in AIDS patients, systemic evaluation for AIDS is recommended for these patients. In the immunodeficient patient, detection of Epstein Barr virus DNA by polymerase chain reaction of the CSF is a reliable indicator of PCNSLs.[2,4] The radiographical appearance of PCNSLs may resemble toxoplasmosis and therefore, most patients with AIDS and a cerebral mass lesion are initially treated with antitoxoplasmosis therapy. An early brain biopsy should be considered in patients who have negative toxoplasma titres and those who continue to deteriorate during the first week of antitoxoplasma therapy. Toxoplasmosis and other CNS infections, like tuberculosis, may also coexist with PCNSLs mass lesions. However, there is an increased risk of CNS haemorrhage during brain biopsy of immunocompromised patients, when compared to the procedure performed in immunocompetent patients.

Evaluation for systemic lymphoma is usually negative in immunocompetent patients but may often turn out to be positive for immunocompromised individuals where a high incidence of CNS metastatic lymphoma is seen.

RESPONSE TO CORTICOSTEROIDS

PCNSLs are corticosteroid responsive and may induce lysis of tumour cells. If the diagnosis of PCNSLs is suspected, then steroids should be avoided (unless impending herniation due to severe raised intracranial pressure makes their use mandatory) until a definitive diagnosis has been established since the biopsy may only yield reactive T cells after steroid administration. Astrocytomas, metastasis and multiple sclerosis plaques also respond to steroid therapy and so, steroid responsiveness of the lesion is not diagnostic of PCNSLs. If corticosteroids have been administered and the biopsy has proven to be inconclusive in a patient suspected to be having a PCNSL, the drug should be withdrawn and a re-biopsy of the lesion attempted. The patient should be kept under constant observation during the period of withdrawal of the corticosteroids because, occasionally, the tumour may enlarge rapidly.

PROGNOSTIC FACTORS

Correlation between the histological type and the survival in PCNSLs has led to conflicting opinions. Most authors have found no correlation, whereas others have maintained that histological sub-types have a direct correlation with survival. Like histological types, proliferation markers do not show any correlation with survival. The favourable prognostic factors include a single intracranial lesion, absence of meningeal or periventricular tumours, absence of immunodeficiency, age under 60 years and a pre-operative Karnofsky score of over 70. Absence of systemic B symptoms, like fever and weight loss and complete response to initial therapy, are also important prognostic markers. Amongst the tumour factors, Blay et al. report that a CSF protein concentration of more than 600 mg/dL is associated with a bad prognosis. They also report that after adjustment of the entire host and tumour factors, high dose MTX administration is the only treatment related factor that correlates with survival.

MANAGEMENT AND THERAPY

All PCNSLs are treated in the same manner regardless of the sub-type or the cell of origin, since the response to treatment and prognosis is not related to the pathological sub-type.

Using the clinical staging criteria for systemic lymphomas, PCNSLs correspond to stage IE (Ann Arbor staging system), that is, disease confined to a single

extra-nodal site. Systemic stage IE disease has a 100% complete response rate and at least a 70% 10-year survival rate with focal radiotherapy (RT). Despite the high responsiveness, the median survival with RT alone for PCNSLs is 12–18 months with a 3–4% 5-year survival rate. This is due to recurrence at other sites inside the fields, which may be distinct from the original site. The median survival, however, increases to 41–44.4 months with a combined modality treatment.

Immunocompetent Individuals

Corticosteroids

PCNSLs respond dramatically to steroids. At least 90% of patients improve clinically and 40% of patients have significant shrinkage or disappearance of tumour masses (as evident on MRI) after steroids. This is due to a direct cytotoxic effect of the steroids; biopsy after steroid administration often yields normal, necrotic or non-diagnostic tissue. The patients often become clinically asymptomatic after steroid administration for a short period of time. This may be due to regression in the mass or stabilisation of the blood-brain barrier without any detectable change in the tumour size. However, the steroid-induced remission is short-lived. Thus, steroids are generally used only for the first few weeks of treatment, often for symptomatic management of raised intracranial pressure and for prevention of oedema during radiotherapy.[7]

Surgery

Surgery is performed for these tumours to obtain a histological diagnosis. Tumour decompression has no therapeutic advantage. This is because of its multifocal and infiltrative nature. The mean survival of these patients after surgical resection is 3–5 months. Therefore, stereotactic biopsy is the diagnostic method of choice.[10] Excision of large lesions situated in deep periventricular locations is often associated with a high morbidity and, therefore, should not be attempted once a diagnosis of PCNSLs has been established by a minimally invasive technique. If a frozen section of a small surgical specimen reveals a PCNL, no further resection of the tumour is performed and the patient is treated with radiotherapy and chemotherapy.

Radiotherapy

Conventionally whole brain radiotherapy (WBRT) given under the cover of steroids is an effective modality for the treatment of PCNSLs. Although a complete response may be obtained, the median survival with RT alone has been between 12 and 18 months with only a 3–4% five-year survival rate. The dose-response relationship derived from retrospective data suggests that a dose of 40–50 Gy improved survival, when compared to smaller radiation doses. The Radiation Therapy Oncology Group (RTOG) conducted a prospective study of PCNSL patients treated with 40 Gy WBRT plus a 20 Gy boost to the involved area, to assess whether dose intensification improved outcome. The median survival was approximately 12 months in their study. Unfortunately, recurrences occurred within and outside the boost field. This suggested that local radiation boost did not enhance local control. The boosts are, therefore, limited to nodular subarachnoid deposits more bigger than 3 mm, symptomatic or painful nerve or root deposits or provided for palliation.[30]

The problem with whole brain radiation is that of delayed development of cognitive and intellectual deterioration. In patients treated with RT alone, this cognitive impairment may not be noticeable as patients often relapse within approximately a year after the diagnosis; however, patients receiving combined therapy, who have a prolonged disease-free interval, are often affected by this RT induced neurotoxicity.[11, 38]

Bessel et al. combined chemotherapy and RT, i.e. cyclophosphamide, doxorubicin and vincristine with dexamethasone plus carmustine, vincristine and cytarabine to two schedules of RT, i.e. WBRT of 45 Gy versus 30.60 Gy. In this study, it was seen that younger patients (< 60 years of age) showed a significantly superior survival. RTOG on the other hand, used a high-dose methotrexate-based regimen followed by 45 Gy WBRT. During this trial, the protocol was modified and the dose was reduced to 36 Gy delivered to whole brain by hyperfractionated RT. There was no difference in the disease-free or overall survival in the two groups. This trial suggested that when combined with chemotherapy, delivery of a lower RT dose is equally effective in achieving the desired response and with lesser risk of leukoencephalopathy. The use of high dose methotrexate as a pre-RT regime may also help in decreasing the whole brain RT dose and thereby in decreasing the risk of radiation related toxicity.[30] Shibamoto et al. reviewed the patients treated by partial brain RT to the local site. They observed that patients treated with RT, using margins of less than 4 cm around the tumours had higher out-field recurrences (83%) compared with those treated with 4 cm or more margins. This study suggested that large field RT is better than focal RT in prevention of recurrences.

It was initially believed that craniospinal irradiation (CSI) should be given in PCNSLs in view of the relatively high incidence of leptomeningeal involvement. However, this school of thought is no longer prevalent. This is because CSI compromises bone marrow and consequentially impairs the patient's ability to tolerate further systemic chemotherapy. Intrathecal chemotherapy may be used as an effective substitute for CSI under these circumstances.[12-14]

According to Lallana and DeAngelis,[25] the present recommendation is to include whole brain irradiation of 45 Gy without a boost. The eyes are not included in the port unless ocular involvement is present. The eyes receive approximately 36–40 Gy of radiation if ocular involvement is present.

Chemotherapy

In designing chemotherapy (ChT) regimens for PCNSLs, Freilich and DeAngelis[17] have enumerated the factors that must be considered. In systemic lymphomas, drug combinations are more effective than a single agent ChT. ChT must be administered before RT if its efficacy is to be assessed since PCNSLs usually respond very well to RT and the lesions often disappear. Preradiation ChT reduces the enhanced neurotoxicity of adding ChT to RT.[6] In PCNSLs, the blood-brain barrier needs to be overcome and the disease is widespread. Use of agents in high doses to enable them to penetrate the blood-brain barrier, the use of intrathecal therapy to deliver drug to the leptomeningeal tumour and the use of osmotic agents to disrupt the blood-brain barrier are methods for an efficacious drug delivery in PCNSLs.[8,12,13]

Commonly Used Drugs to Treat PCNSL

Methotrexate (MTX)I is the drug of choice for the initial treatment of PCNSLs. It inhibits dihydrofolate reductase, an essential coenzyme for folate reduction. Reduced folate is an essential coenzyme in the synthesis of purine and thymidine. This drug is poorly lipid soluble and, therefore, blood-brain barrier penetrance is poor. High dose MTX greater than 1 g/m^2 penetrates into the brain and CSF but therapeutic levels are only established in CSF at levels greater than 3 g/m^2. The latter is not sustainable for greater than 12 hours. The high doses are followed by leucovorin rescue. An Ommaya reservoir may deliver MTX into the CSF and achieve a sustained therapeutic level for 48 hours. Rapid infusion over 2–3 hours achieves a significantly higher CSF level than infusion over 24 hours, often obviating the need for intrathecal administration. MTX administration prior to RT may be protective against neurotoxicity. It is also nephrotoxic in high doses and should not be given if the creatinine clearance is below 60 mL/min. Intrathecal MTX may still be given when renal clearance is impaired.

Vincristine, Doxorubicin and Bleomycin are effective but do not cross the blood-brain barrier.

Procarbazine and Nitrosoureas (e.g. CCNU, lomustine) are lipophilic agents that cross the blood-brain barrier.

Cytarabine (ara-C) is a pyrimidine analogue that inhibits DNA synthesis by competitively inhibiting DNA polymerase with resultant inhibition of DNA chain elongation and template function. It may cross the blood-brain barrier and is also useful for ocular and leptomeningeal lymphomas. It may cause dementia and reversible cerebellar ataxia.

Alkylating agents, such as thio-TEPA, nitrogen mustards such as cyclophasphamide and ifosfamide, temozolamide or epipodophyllotoxin teniposide, a topoisomerase II inhibitor, are also used.[20]

Drugs available for subarachnoid application include MTX (12 mg twice weekly), cytosine arabinoside (30–50 mg once or twice weekly) and thio-TEPA (12 mg).

Systemic Lymphoma Protocols

The drugs used for treatment of systemic lymphomas, like CHOP (cyclophosphamide, doxorubicin, vincristine and prednisone), CHOD (dexamethasone instead of prednisone) or MACOP-B (methotrexate, doxorubicin, cyclophospamide, vincristine, prednisone and bleomycin), for 3–4 cycles, followed by cranial irradiation may show a median survival between 8.5 and 14 months.[22, 23,36,41] The poor results may be due to the inability of the non-lipophilic drugs to cross the blood-brain barrier. The development of leukoencephalopathy and drug resistance may also play a role in treatment failure.[8,12,13]

Methotrexate Based Protocols

The recent protocol recommended is to use high dose (3.5 g/m^2) systemic MTX together with intrathecal MTX (12 g per dose) administered via an Ommaya reservoir followed by cranial irradiation (4500 cGy) and high dose ara-C (3 g/m^2). A higher median survival of approximately 42 months was seen. Dementia and ataxia were seen in patients older than 50 years but not in those less than that age.

The blood-brain barrier may be overcome by administering intra-arterial mannitol before ChT administration while avoiding cranial irradiation. Neuwelt et al.[31] used intra-arterial MTX (2.5 g) with intravenous cyclophosphamide, oral procarbazine and oral dexamethasone. The carotid and vertebrobasilar systems were used for drug administration and the treatment was given at monthly intervals for 12 months. There was a median survival of 44.5 months. The complications included infarction, arterial dissection, seizures and neuropsychological changes.

High dose intravenous MTX (3.5 g/m^2) followed by RT may also be given to overcome the blood-brain barrier with a good response and a median survival of 33 months.[18,21] PCV has also been tried with a good response.

In elderly patients, ChT may be administered without RT to avoid neurotoxicity. However, RT is eventually required in many patients due to a variable response. The patients with delayed RT died mostly of progressive disease, while those elderly patients who received RT after ChT died due to neurotoxicity.[21] In an effort to limit neurotoxicity in PCNSLs, a single trial of high dose ChT (MTX) with autologous stem cell rescue has been tried with a favourable response.[1,39]

In patients who have already received RT, high dose MTX and ara-C are avoided and, instead, 4–6 cycles of PCV are administered. Patients who relapse after the initial RT are given high dose MTX, as the recurrent disease carries a poor prognosis.[24]

Ocular lymphomas respond to RT and ara-C. Other drugs penetrate the vitreous poorly and the effect of MTX has not been established.

Despite combination therapy, 40–60% of patients eventually relapse. During recurrence, combination ChT

may be tried, based on the drugs previously received by the patients. Several systemic and intrathecal drugs used at relapse include procarbazine, lomustine and vincristine (PCV) combination, thiotepa, ara-C, ifosfamide, carboplatin and etoposide.[28] Intrathecal therapy with an Ommaya reservoir or a lumbar puncture may be tried in patients with leptomeningeal disease. In bulky leptomeningeal disease, a radioisotope CSF flow study is performed before the drug is administered into the subarachnoid space. Abnormal signals signify obstruction leading to inhomogeneous distribution of drug. If the drug is retained in the ventricular system, leakage may occur around the catheter resulting in localised necrotising leukoencephalopathy. Whole brain RT is an effective option for those patients not eligible for the toxic regimens and craniospinal RT for meningeal relapse that has failed to resolve with intrathecal and/or systemic ChT. The prognosis, however, is poor.

Among the newer therapies, rituximab, an anti-CD20 antibody that has an excellent activity against systemic follicular and diffuse large cell lymphoma may be used in PCNSLs, as an adjunct to MTX, as approximately 90% of PCNSLs express CD20 antigen. Temozolamide has a reasonable tolerance, minimal nephrotoxicity and penetrates the intact blood-brain barrier. Thus, it may be used in patients unable to receive high dose MTX because of poor performance status or renal insufficiency or as a good salvage regimen at relapse. In recurrent PCNSLs, high dose busulfan and thiotepa and autologous stem cell transplantation has also been tried. It may be useful in patients with a good performance status. Slow release drug formulations are also being used, such as cytosine arabinoside encapsulated in microsopic gelfoam particles that can be administered every 2 weeks.

In patients with immunocompromise, RT remains the primary treatment of PCNSLs. Patients with CD4 counts greater than or equal to 200/mm^3, a good performance status and no active co-morbid conditions may respond to additional ChT (often 3 cycles of PCV). Other cytotoxic drugs, such as zidovudine or gancyclovir (directed against EBV stimulated growth), must be avoided during ChT, unless there is recovery of blood counts. The response to RT is poor in immunocompromised patients with a median survival following RT alone being 2–5 months that increases to 16–28 months with combined treatment.[13,16]

THE INDIAN SCENARIO

Two large neurooncology (AIIMS, New Delhi and NIMHANS, Bangalore) units[35] together assessed the trend of incidence of PCNSL in India. PCNSLs constituted 0.95% of all intracranial neoplasms. This hospital based study did not reveal any increase in incidence of PCNSLs in India over the past 24 years. The association of PCNSLs with HIV/AIDS has been low in India, possibly due to early death in AIDS on account of opportunistic infections.

There are two audits from our centre, i.e. Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow. A combined modality approach, i.e. surgical resection and cranial RT (40–52 Gy + boost 10–16 Gy) was given along with chemotherapy. The median survival of 13 and 17 months suggests that the combined modality approach should be adopted, which includes surgery, RT and CT.[32,33] Another audit from Southern India using a similar combined modality approach reported a median survival of 19 months.[34] High dose methotrexate has not been tried in any of these centres.

All these retrospective audits reflect the need for more aggressive treatment to improve the outcomes.

The incidence of PCNSLs is showing a rising trend and they usually respond to multimodality ChT and RT based schedule. CNS dissemination, an intact blood-brain barrier, leptomeningeal and ocular involvement are factors that require consideration. In immunocompromised individuals, the prognosis is poor due to a more aggressive disease and, often, the presence of coexisting infections.[5]

177 Intracranial Melanomas and Other Tumours

Bhawani S Sharma, Sumit Sinha

INTRODUCTION

Primary melanomas rarely affect the central nervous system. Intracranial melanomas derive from the proliferation of melanocytic elements normally present in the leptomeninges, which can assume neoplastic patterns. Melanin containing cells can develop melanoblastic activity, ranging between histologically benign and malignant patterns. These neoplasms are largely confined to the subarachnoid space with perivascular extension into brain parenchyma, depending on anaplastic features and the invasive potential of different clones.

The pigmented tumours of the CNS can be classified into:

- Primary pigmented lesions: Neoplasms derived from leptomeningeal melanocytes are uncommon lesions that present in localised or diffuse forms.[6] Localised lesions present sporadically as meningeal masses and range from well-differentiated melanocytomas to malignant, potentially disseminating melanomas.[17,33] The diffuse lesions (melanomatosis) generally occur in the setting of various dermatologic syndromes—Neurocutaneous melanosis syndrome and Nevus of Ota.[4,27]
- Metastasis: The CNS can be commonly affected by metastasis from a cutaneous melanoma. Among all the primary cancers, cutaneous melanomas have the highest propensity to metastasise to the brain, and in most of the reports is the third most common cause of metastatic brain tumours.[30]
- Primary CNS tumours with melanotic elements:
  - Meningiomas
  - Medulloblastomas
  - Astrocytoma
  - Acoustic neuromas
  - Pituitary tumours
  - Choroid plexus papillomas.

PRIMARY PIGMENTED LESIONS

Localised Melanocytic Neoplasms—Benign Melanocytomas and Malignant Melanomas

The term 'meningeal melanocytoma' was first proposed for 'pigmented meningioma' by Limas and Tio in 1972, on the basis of their ultrastructural characteristics: the presence of polar cytoplasmic processes, few zonula adherens and the presence of premelanosomes and melanosomes in the cells, to describe a tumour that had some of the histological characteristics of meningioma.[17] Since then, very few cases of intracranial and intraspinal meningeal melanocytomas have been described in the literature. Their epidemiological characteristics, natural history and response to treatment remain poorly understood.[18,22,23]

Melanocytes are derived from the neural crest during early embryonic development and are widely distributed throughout the normal leptomeninges. Meningeal melanocytomas probably arise from these cells, a hypothesis that appears to be confirmed by the reports of various authors.[37,39] Melanocytes occur in the highest concentration ventrolateral to the medulla oblongata, which accounts for the propensity of these lesions to occur in the cerebellopontine angle. The highest concentration of melanocytes in the spinal leptomeninges is found in the upper cervical levels, but spinal meningeal melanocytomas are not confined to the cervical region and have been described as far as the thoracolumbar junction. Both intracranial and intraspinal meningeal melanocytomas frequently arise in proximity to the cranial and spinal nerves, as they exit the brainstem and spinal cord.

Brat et al.[5] classified primary melanocytic neoplasms into: (a) low-grade well differentiated melanocytomas having an excellent prognosis; (b) intermediate or indeterminate differentiation category and (c) high-grade aggressive melanomas with cellular anaplasia and necrosis with unfavourable outcome (but better than metastatic melanoma). However, a clear distinction between them is not defined in the literature.[18,28,38,39]

Clinical Presentation

Meningeal melanocytomas are more common in females, with a female to male ratio of 2.2:1. The mean age at presentation is in the early fifth decade. The onset of symptoms is insidious over a period of several months to years.

Intracranial meningeal melanocytomas usually present with signs and symptoms of an expanding mass in the posterior fossa, sometimes compounded by obstructive hydrocephalus and cerebellar dysfunction. The tumour may grow to a significant size and the patient may present with single or multiple cranial nerve palsies.

Differential Diagnosis

Intracranial meningeal melanocytomas are rare lesions and the differential diagnosis includes pigmented meningiomas, melanotic schwannomas and primary or secondary malignant melanoma.[38] Radiological studies are of limited value in the diagnosis of the lesion and in differentiating them from other pigmented lesions and accurate diagnosis requires histological and immunohistochemical confirmation and also electron microscopy (Table 1).

The pre-operative diagnosis in meningeal melanocytomas is usually meningioma, because both the tumours have a long duration of symptoms, appearance of a dural-based extra-axial large mass, features of tight cellular nests or whorls with similar imaging features. The dark colour of the tumour pre-operatively and the presence of melanin in the tumour cells at frozen section suggest a diagnosis of melanocytoma. Electron microscopy is required to rule out meningioma, which shows many intermingling cell processes, not lined by the external lamina but joined by well-developed desmosomes, unlike the ultrastructure of meningeal melanocytes where the cell processes are surrounded by a single profile of external lamina. Electron microscopic demonstration of melanosomes and the presence of melanocytic antigens by immunohistochemistry are currently the only ways to differentiate between a pigmented meningioma and a melanocytic neoplasm.

Melanotic schwannomas contain spindle and epithelial cells with oval nuclei and cytoplasmic pseudoinclusions, in contrast to melanocytomas that show a tight nesting or a fascicular pattern of spindle cells. The schwannoma cells are individually surrounded by a basement membrane, especially at stromal surfaces, while melanocytomas show encirclement of nests or fascicles and not of individual cells. Ultrastructurally, only schwannomas contain electron dense accumulations of pericellular basal lamina.[8]

The differentiation between meningeal melanocytoma and primary or metastatic malignant melanoma[36] can be difficult. However, features suggestive of meningeal melanocytoma are duration of symptoms of more than one year, a radiological similarity to meningioma, uniform cytological features with abundant spindle cells and a low mitotic rate.[24]

Radiological Features

Meningeal melanocytomas may be confused with meningiomas because of their similar behaviour: they are solitary, attached to the dura and may be locally invasive. These tumours may be difficult to differentiate from acoustic neuromas, as they are commonly found in the posterior fossa and cerebellopontine angle.

On CT scan, they appear as well circumscribed, dural based iso- to high-density masses that enhance homogeneously on contrast, similar to meningiomas. Tumour calcification and hyperostosis of the adjacent bone are rare. The degree of melanisation strongly influences the CT pattern. There is usually sparing of the internal auditory canal and lack of haemorrhage.[22]

The MR imaging appearance of these rare tumours is not uniform and depends on the degree of melanisation, with more melanin causing greater shortening of T1 and T2 relaxation times. Thus, MR imaging of intracranial meningeal melanocytomas is not a very reliable or specific technique for the diagnosis of this rare tumour. On MR examination, they are isointense to hyperintense on T1-weighted images and isointense to hypointense on T2-weighted images with intense homogeneous contrast enhancement.[3,37]

Table 1: Differential diagnosis of localised pigmented tumours of meninges

	Meningioma	*Schwannoma*	*Melanocytoma*	*Melanoma*
IMMUNOHISTOCHEMISTRY				
Vimentin	+	+	+	-
S-100 Protein	-	+	+	+
HMB-45	-	-	+	++
Keratin	+	-	-	-
EMA	+	-	-	-
Leu-7	-	+	-	-
ULTRASTRUCTURE				
Basal Membrane	-	+	-	
Desmosomes	+	-	-	
Premelanosomes	-	-	+	
Long spacing collagen	-	+	-	
Prominent nucleoli	-	+	+	

Histopathology

On gross examination, these tumours are dark brown or black, heavily pigmented, and well-demarcated lesions that are firmly attached to the underlying leptomeninges. A meningioma may mimic this gross appearance if large amounts of haemosiderin are present within the lesion, as a result of previous episodes of haemorrhage.[35] Microscopically, the low-grade lesions have architectural and cytological features different from the high-grade aggressive tumours. The most specific feature of melanocytoma is the presence of melanocytes in tight nests with heavily pigmented cells at their periphery. Such a feature is not encountered in melanomas or in intermediate grade lesions. At high magnification, low-grade lesions reveal remarkably uniform oval or bean shaped nuclei with small regular, eosinophilic nucleoli, and the mitotic indices are low. The clinically aggressive melanomas differ from low-grade lesions in that they are highly cellular tumours with high nuclear to cytoplasmic ratio, increased mitotic activity, nuclear atypia and more basophilic in nature.

Immunohistochemistry can differentiate melanocytoma from other pigmented leptomeningeal lesions and must be done to arrive at a definitive diagnosis. It reveals a positive reaction to vimentin antibodies, S-100 protein and antimelanoma antibody (HMB-45) with absent response to epithelial Markers—EMA, NSE, GFAP and cytokeratin. Vimentin is rarely present in malignant melanoma; while meningioma cells lack the presence of HMB-45 and S-100 protein.[18,29,35]

Management

Most of the reports in literature indicate that the extent of surgical resection is the most important determinant of outcome and support the view that long-term patient survival is enhanced by complete tumour resection.[18,22,38,39] This may be impossible in up to half of the cases because of the large size of the tumour associated with vital structures, hypervascularity of the tumour and unfavourable tumour location. The role of radiotherapy in the management of these tumours is controversial;[7,23,39] however, it is worth considering for those patients with symptomatic residual, progressive or recurrent tumours not amenable for further resection.[13,23,34] According to some reports in the literature, adequate control of tumour re-growth can be achieved after partial resection, with the use of post-operative gamma knife therapy.[16] However, more cases with a longer follow-up period will help to define the adequate treatment protocol of these rare tumours.

Prognosis

Meningeal melanocytomas have a much better prognosis as compared to their malignant counterparts. These patients have a relatively good prognosis, with most of the patients surviving at least several years after the diagnosis. However, these tumours do locally recur. Despite various treatments including surgery and radiotherapy, there is a 71% recurrence rate at 5 years.

Diffuse Melanocytic Neoplasms

Neurocutaneous Melanosis

Neurocutaneous melanosis (NCM) is a rare congenital syndrome first described by Rokitansky in 1861. Van Bogaert, in 1948, named this condition as neurocutaneous melanosis. The criterion for the diagnosis of this syndrome are: (1) one or more congenital giant hairy nevi, multiple pigmented nevi or marked generalised brown cutaneous pigmentation that is unduly large (more than 20 cm); (2) there is no malignant melanoma transformation of the involved skin area; (3) diffuse thickening and brownish black melanin pigmentation of CNS pia mater, with no evidence of primary malignant melanoma in any organ other than the CNS. An autopsy or extensive surgical biopsy is essential to establish a correct diagnosis.[11,32] NCM is considered a phakomatosis because it is thought to arise from congenital dysplasia of the neuroectodermal melanocytic precursor. The disease affects both the sexes equally and occurs more frequently in Whites. The neurological symptoms usually appear within the first two years of life. Only a few cases have been reported in the second and third decades of life.

The cutaneous lesions of NCM are congenital melanocytic nevi. Most of the patients have giant nevi found in a 'bathing trunk' or lumbosacral distribution. The risk of malignant transformation of giant pigmented nevi ranges from 2 to 42% in various series.[25] Malignancy can occur at any age, but it occurs mostly during the first decade of life. It is not clear what percentage of patients with giant or multiple congenital melanocytic nevi could potentially develop NCM, but children with lesions in the head, neck or posterior midline seem to run an increased risk of leptomeningeal melanosis and should closely be monitored for the development of neurological symptoms.[15] Leptomeningeal pigmentation was present in over 85% of the cases analysed by Fox et al. and the areas most commonly affected were the pons, medulla, cerebellum, cerebral peduncles, interpeduncular fossa and the inferior surfaces of the frontal, temporal and occipital lobes.[11]

The clinical features are usually the result of raised intracranial pressure, vomiting, seizures, headache, increased head circumference or photophobia. The patient may develop ataxia with inability to walk, and show psychiatric symptoms with disease progression. Raised intracranial pressure is due to the presence of an abnormal mass of melanotic cells in the meninges or the presence of hydrocephalus. The majority of these lesions undergo malignant changes and show evidence of leptomeningeal melanoma.[14]

NCM must be differentiated from melanotic neuroectodermal tumour of the cranium of infancy and from melanotic nerve sheath tumour. MNET is a benign pigmented tumour arising from the neural crest cells and

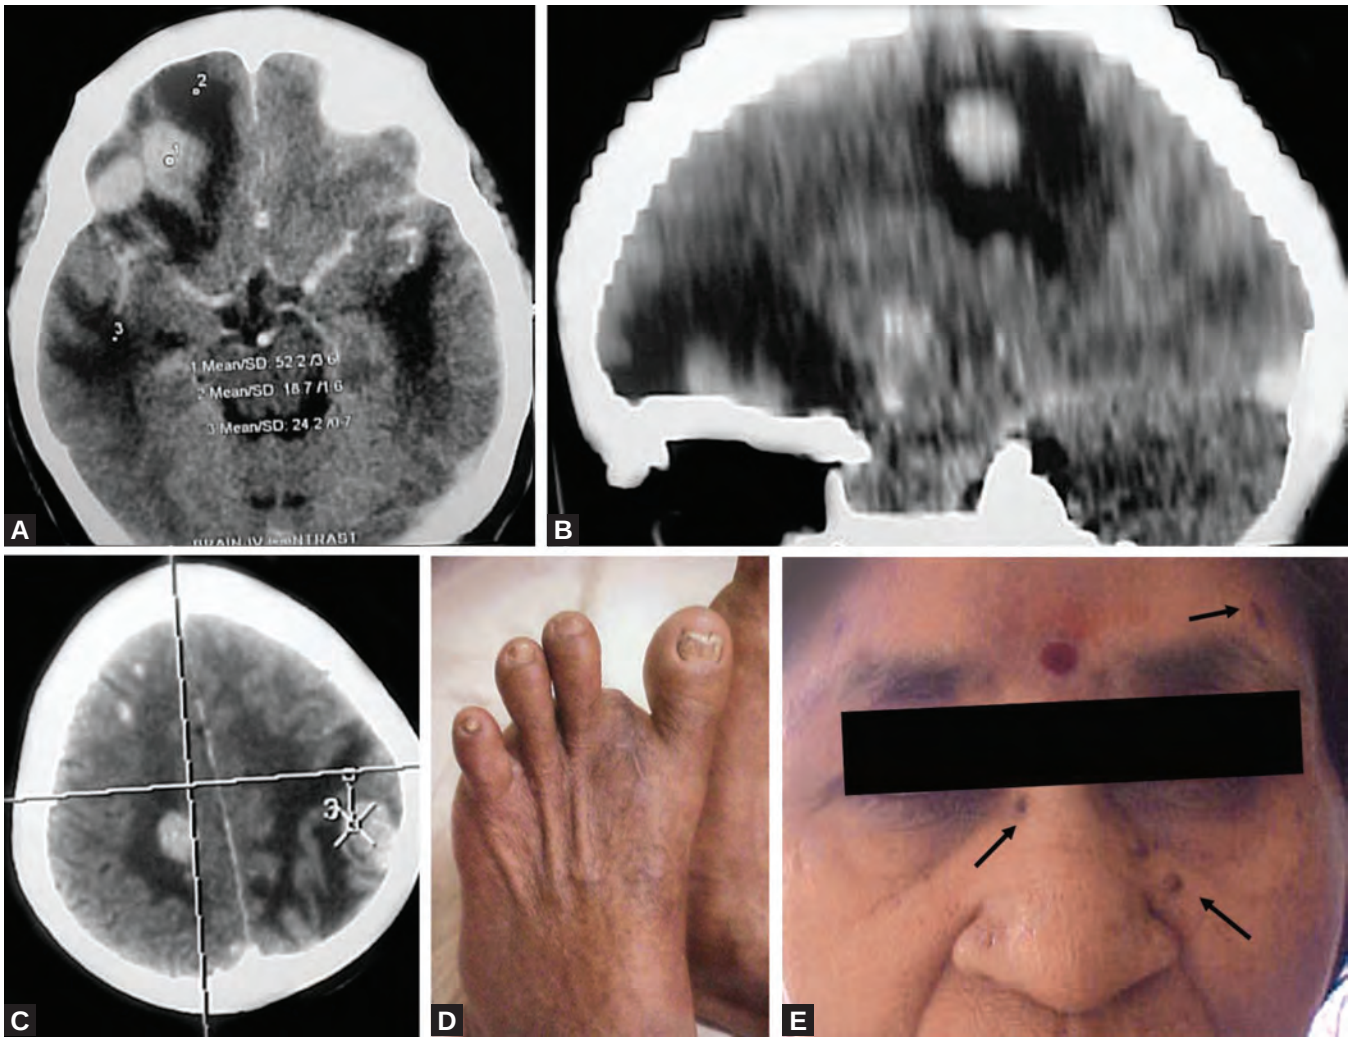
mostly occurs at the anterior fontanelle. They have an excellent prognosis with an early, complete excision and radiotherapy is reserved for incompletely resected lesions. Melanotic nerve sheath tumours are slow growing benign plexiform melanin containing neurofibromas found in young adults, which do not metastasise.

Secondary Malignant Melanoma

Melanoma has the highest tendency to metastasise to the brain among all the primary cancers. In many reports, it is the third most common cause of cerebral metastasis after breast and lung. Malignant melanomas commonly metastasise to lung and liver; however, the reported incidence of cerebral metastasis in patients with melanoma ranges from 6 to 43% in clinical series[1,2] and 12 to 74% in autopsy series.[9,33] Most of them are solitary but multiple metastases are not uncommon. Seventy-five percent of the patients with malignant melanoma with metastatic disease have intracranial involvement with the frontal and parietal lobes being the most common sites (Figs 1A to E). There is also a high incidence of extracerebral metastasis at the time of diagnosis of cerebral involvement. The time interval from the diagnosis of the primary lesion to cerebral metastasis varies from 6 to 60 months.

The clinical features depend on the site of cerebral involvement. Cerebral metastases carry the worst prognosis of all the visceral metastasis in patients with melanoma and are the cause of death in more than 50% of patients dying of malignant melanoma.

Various studies in the literature[20,31] have found an association between the development of brain metastasis and the following factors: (1) male gender; (2) head and neck primary lesions; (3) deeply invasive primary lesions; (4) primary lesions located on the mucosal surfaces; (5) ulcerated primary lesions; (6) lesions with a large diameter; (7) acral lentigenous and nodular histological types and (8) the presence of lymph nodes or visceral metastasis at the time of diagnosis. Thus,



Figs 1A to E: (A and C) Contrast CT axial and (B) sagittal reconstruction of the brain showing multiple enhancing lesions in the brain involving right basifrontal, right posterior frontal and left parietal regions in a patient who had undergone surgical amputation of (D) left second toe due a lesion, HPE of which was malignant melanoma and (E) pointed by black arrows also had evidence of multiple new naevi over the face and other parts of the body

patients with these clinical profiles should be followed more closely for the development of metastatic disease and would be candidates for prophylactic therapy.

Malignant melanomas have a characteristic appearance on CT and MRI and are classified according to their size into less than 1 cm, 1–4 cm and more than 4 cm. They are usually seen at the grey-white junction of the cerebrum and are slightly hyperdense with moderate contrast enhancement. Most of these lesions show moderate perilesional oedema and occasionally show a leptomeningeal spread. On MRI, T1 and T2 shortening is seen due to the presence of melanin.

The overall prognosis of patients with cerebral metastasis from melanoma remains dismal, regardless of the therapeutic intervention. The poor prognostic factors are the presence of more than one cerebral metastasis and disease in multiple sites, including the brain. The median survival, reported in the literature for surgically treated patients with brain metastasis from melanoma, ranges from 5 to 22 months, which compares favourably with 2–4 months median survival range for patients treated with whole brain radiotherapy alone, and the 2 weeks to 2 months median survival reported for patients treated with palliative therapy alone. Surgical treatment has also been evaluated for the treatment of cerebral metastasis from melanoma. Some studies have shown promising results following surgery with median survivals ranging from 5 to 10 months, although in most of these studies patients presented with a solitary metastasis.[40,41]

Several studies in the literature have identified a subset of patients with brain metastasis from melanoma who are expected to survive longer and they recommended the following guidelines for surgical therapy.[31]

Indications

- Single brain metastasis accessible to safe and complete resection without any other visceral metastasis
- Multiple brain metastasis with symptomatic or life threatening brain lesion accessible to safe and complete resection and no other visceral metastasis
- Single brain metastasis accessible to safe and complete resection and one other visceral metastasis accessible to complete resection or responding to systemic therapy
- Multiple brain metastasis all accessible to safe and complete resection and one other visceral metastasis accessible to complete resection or responding to systemic therapy
- Single symptomatic or life threatening brain metastasis accessible to safe and complete resection and one other untreatable visceral metastasis
- Multiple brain metastasis with a symptomatic or life threatening brain lesion accessible to safe and complete resection and one other untreatable visceral metastasis

Contraindications

- Brain metastasis not accessible to safe and complete resection
- More than one visceral metastasis in addition to the brain lesion
- Radiological or pathological evidence of leptomeningeal spread of tumour
- Surgical procedure likely to be life threatening

Malignant melanoma is relatively radioresistant. The use of radiotherapy in treating melanoma metastasis has given conflicting results; with some studies showing an increase in survival[19] and others showing no improvement.[12] Over the past decade, stereotactic radiosurgery has been found to provide control of cerebral metastasis from melanoma. Radbill et al. have supported the use of Gamma-knife radiosurgery in the initial treatment of melanoma brain metastasis, with the number and location of the lesions having significant prognostic value with respect to survival.[10,26] Mori et al. have reported that radiosurgery is effective therapy for the control of malignant melanoma metastasis. They did not find any notable benefit in combining WBRT with stereotactic radiosurgery in these patients.[21]

Other Pigmented CNS Lesions

Melanotic Medulloblastoma

These tumours show a typical histological appearance with pseudoepithelial-pigmented structures that are immunoreactive for S100 protein and vimentin. The treatment of choice is complete surgical excision and post-operative radiotherapy for any residual tumour.

Melanotic Cerebral Astrocytoma

These tumours clinically present with complex partial seizures as most of these lesions are located in the temporal lobe. Histologically, these tumours are benign and resemble pleomorphic xanthoastrocytomas, except for the presence of pigmentation. They are composed of two different regions: one consists of spindle shaped and pleomorphic cells with a foamy or vacuolated cytoplasm, while the other consists of fairly uniform spindle cells, many of which contain dark brown intracytoplasmic pigment, often with areas of desmoplasia. The features suggestive of malignancy, such as mitotic figures, necrosis and endothelial proliferation, are not found in these tumours. Immunohistochemically, the tumour cells in both the regions are positive for glial fibrillary acidic protein. On ultrastructural examination of the pigmented region, the presence of melanosomal melanin is found.

Melanotic Choroid Plexus Papilloma

These tumours show histological immunophenotypic and ultrastructural features of neoplastic choroid plexus epithelium. The pigment consists of lipofuchsin and

neuromelanin and autocatalytic peroxidation of lipofuchsin is thought to be the putative mechanism for melanogenesis.

178 Benign Intracranial Tension

Nigel Peter Symss, Ravi Ramamurthi

The term benign intracranial hypertension (BIH) refers to a condition of increased intracranial pressure (ICP) in which the ventricles are not dilated and the cerebrospinal fluid (CSF) is normal. The patients present with symptoms and signs of increased ICP usually without any focal neurological deficit. Thorough investigations fail to reveal a space occupying lesion or any other specific cause for the raised ICP. Quincke, in 1897,[75] described this condition as a *serous meningitis*, and Nonne, in 1914, used the term *pseudotumour cerebri* (PTC) which is descriptive and was acceptable to many neurosurgeons. Symonds, in 1931,[94] first drew attention to a syndrome in which infection of the ear was followed by intracranial hypertension without any evidence of intracranial abscess or infection. This was described as *otitic hydrocephalus*. In 1936, Davidoff described cases of serous meningitis[23] and, in 1937, Dandy[21] reported on 22 cases of PTC. Since then, the condition of BIH has been recognised frequently. Evidence gathered over the years suggests that this condition is not a single clinical entity, but a syndrome resulting from a variety of causes.[11,33]

Although the term BIH has been accepted by common usage, it must be remembered that the condition is not always benign and may result in blindness or death in some patients, unless vigorously treated. The term idiopathic intracranial hypertension may be more suitable.

PATHOPHYSIOLOGY

The factors that may contribute to BIH are cerebral oedema, reduced CSF resorption, increased CSF production, increased cerebral blood volume and increased venous pressure.[86] The basic pathology is either an excess of accumulation of CSF in the intracranial subarachnoid space or an increase in the bulk of the brain parenchyma. In either case, the ventricles do not dilate and the biochemistry of the CSF remains normal. Thus, two main groups may be recognised, those with obstruction to the exit of the CSF from the cranial cavity and those without.

Absorption of CSF may be interfered with when there is thrombosis of the dural sinuses or the cerebral veins or an obstruction in the arachnoid villi. This may be caused by head injury, intracranial infections or thrombotic lesions. Mild injuries to the head with minimal bleeding in the subarachnoid space, as also mild infections, may block CSF absorption. More severe infections may lead to thrombosis of the major veins or sinuses. In these cases, the back pressure builds up initially in the subarachnoid space and then gets communicated to the ventricular system. Hence, although the ventricular pressure rises, the ventricles do not dilate; in fact they are often narrow, as the pressure in the subarachnoid space is already increased. The subarachnoid space often contains an excess of CSF. This group falls under the definition of communicating hydrocephalus and not BIH. CSF is thought to flow continuously from the site of production in the ventricles into interconnected spaces, i.e. cisterns and subarachnoid spaces (SASs). Since the SAS of the optic nerve is defined by a cul-de-sac anatomy, it is not evident how local CSF might recycle from that region to the general SAS. The concept of free communication of CSF has recently been challenged by the description of a concentration gradient of beta-trace protein, a lipocalin-like prostaglandin d-synthetase (L-PGDS), between the spinal CSF and that in the SAS of the optic nerve, indicating diminished local clearance or local overproduction of L-PGDS here. Computed cisternography, with a contrast agent in three patients with idiopathic intracranial hypertension and asymmetric papilloedema, demonstrated a lack of contrast-loaded CSF in the SAS of the optic nerve, despite it being present in the intracranial SAS, thus suggesting compartmentalisation of the SAS of the optic nerve. The concept of an optic nerve compartment syndrome is further supported by a concentration gradient of brain-derived L-PGDS between the spinal CSF and the CSF from the optic nerve SAS in the same patient.[54,59]

In the group without CSF obstruction are included conditions that cause fluid retention with electrolyte disturbances, resulting in cerebral oedema. Brain water self-diffusion was studied by Sorenson et al.,[90] who used the MR imaging technique of single spin echo pulse sequence with pulsed magnetic field gradients of different magnitudes. In BIH there were abnormal diffusion images, indicating increased water diffusion in the periventricular region or in the whole brain. A convective transependymal flow of water with increased outflow resistance resulted in interstitial brain oedema and intracellular brain water accumulation. CSF outflow resistance has been confirmed by lumbar steady state infusion tests[58] and by radioisotope cisternography.[72]

Greitz,[40] used gated MR imaging techniques and radionuclide cisternography in healthy volunteers and in patients with communicating hydrocephalus, BIH and venous vasculitis and suggested that the systolic expansion of the intracerebral arteries expels the CSF into a compliant spinal subarachnoid space, providing an alternating pressure gradient. The major portion of the CSF is transported to the bloodstream via the paravascular and extracellular spaces of the nervous system and not through pacchionian granulations. Greitz[40] suggested that an increase in pressure in the venous system is likely to be the cause of increased ICP in BIH.

Vasopressin has been implicated in the causation of BIH. Elevated vasopressin levels in the CSF of patients with BIH have been reported.[44] Whether the increased level of vasopressin is the cause or the result of increased ICP is disputed.

Kesler et al.[53] in a group of 33 women with BIH and the same number of women matched for age, body mass index, vascular risk factors and medications, found a significant ($p = 0.038$) increment in fibrinogen concentrations in the patients (341 ± 60.8 mg/dl) as opposed to the controls (307.9 ± 64.8). The same increment was noted for the aggregation of red blood cells (aggregation parameter of 8.7 ± 4.9 in patients vs 5.9 ± 3.2 in the controls, $p = 0.001$) was noted. Being associated with capillary slow flow, their findings might be relevant for the aetiopathogenesis of this disease.[53]

Global elevation of cerebral blood flow measurements has been noted in BIH.[41] By monitoring epidural ICP and middle cerebral blood flows simultaneously, Lundar and Nornes[58] also found a labile cerebral vasomotor state in BIH. Bateman found in patients with a clinical diagnosis of BIH and standard MRI with venography, there was cerebral hyperaemia suggesting a derangement of autoregulation.[8]

BIH is rarely seen in very young children or in old people. It is possible that the resistance to ventricular dilatation in the presence of decreased CSF absorption may be related to the volume and the state of maturity of the brain.[15,82] In elderly patients the ventricles may show minimal enlargement.

INFANTILE PRESENTATION OF BIH

These infants present with an enlarging head and a full fontanelle. The cranial sutures show separation. Apart from these, the infants do not show any abnormality and the milestones are normal. CT shows mild enlargement of the ventricles with enlarged SASs. The prognosis is good as the disease is self-limiting.[89] Similar to patients with BIH, children with hydrocephalus show a significant elevation in collateral venous flow, indicating that the same venous pathophysiological process may be operating in both conditions. Whether or not the ventricles dilate may depend on the differences in brain compliance between adults and children.[7]

AETIOLOGY

Many conditions and agents lead to the development of BIH. Hypervitaminosis,[30] hypoparathyroidism, prolonged steroid therapy, chronic adrenal insufficiency, severe anaemia and pregnancy may cause BIH.[55] Hypervitaminosis is known to produce hydrocephalus.[39,63,70] Higher levels of weight gain and BMI are associated with greater risk of BIH. Even non-obese patients (BMI < 30) are at greater risk for BIH in the setting of moderate weight gain. Vision-specific and overall health-related quality of life (HRQOL) is affected to a greater extent in BIH than in other neuro-ophthalmological disorders.[22]

Increased incidence of this condition in middle aged, obese, females and its association with pregnancy, menarche and menstrual dysfunction suggest a possible endocrinal aetiology.[36-38] Finsterer et al., for the first time, described the association of PTC, optic nerve demyelination, polycystic ovarian syndrome (PCOS), other endocrinological abnormalities, thrombophilia due to a factor V and prothrombin mutation in a 20-year-old obese lady. A causal relationship between these abnormalities remains elusive.[32] Familial occurrence has been reported in a mother and son who were both obese.[80] Simultaneous occurrence of BIH in male heterozygous twins has been reported.[95] Godefroid et al. reported a case of Gitelman syndrome (GS) in a dizygotic twin who, at 12 years of age, presented with growth delay, metabolic alkalosis, hypomagnesaemia and hypokalaemia with inappropriate kaliuresis and idiopathic intracranial hypertension with bilateral papilloedema. The patient, her twin sister and her mother also presented with cerebral cavernous malformations. Mutation analysis showed that the proband is a compound heterozygote for two mutations in SLC12A3: a substitution of serine by leucine at amino acid position 555 (p.Ser555Leu) and a novel guanine to cytosine transition at the 5′ splice site of intron 22 (c.2633+1G>C), providing the molecular diagnosis of GS. These mutations were not detected in 200 normal chromosomes and co-segregated within the family. Analysis of complementary DNA showed that the heterozygous nucleotide change c.2633+1G>C caused the appearance of two RNA molecules, one normal transcript and one skipping the entire exon 22 (r.2521_2634del). Supplementation with potassium and magnesium improved clinical symptoms and resulted in catch-up growth, but vision remained impaired. They found three similar associations of Bartter syndrome/GS with PTC in the literature, suggesting that electrolyte abnormalities and secondary aldosteronism may have a role in idiopathic intracranial hypertension.[35]

A defect in endogenous corticotrophin metabolism or of its release has been implicated as a cause of BIH. Patients with BIH did not show a response to metyrapone. The test became normal when clinical remission occurred. The use of oral contraceptives and the consequent water and sodium retention may cause BIH. BIH may also follow antibiotic therapy with tetracycline,[5,55] ampicillin,

Familial Mediterranean fever
Chronic respiratory insufficiency

amphotericin B,[47] minocycline[26] and/or ciprofloxacin.[101] The aetiology of BIH also includes administration of eltroxin or growth hormone,[61,66] danazol[81] or of chemicals like cytosine arabinoside[29] and benzene hexachloride (Lindane)[98] (Table 1).

Peng et al. found ALZ-50 immunoreactivity to be elevated in the CSF of BIH patients; either the normal tau protein or its phosphorylated variant may be useful as a biomarker for the diagnosis of BIH. Since the ALZ-50 monoclonal antibody was generated against brain homogenate from Alzheimer's disease (AD) patients, their study suggests a possible link between BIH and AD.[73]

Cerebral and dural AVMs[79] may cause BIH. Myeloma,[100] typhoid,[67] sarcoidosis,[78] systemic lupus erythematosis[19,71] and Lyme disease (Borrebia infection)[12] may also cause BIH. The occurrence of BIH in a two-year-old female with HIV seropositivity has been reported.[96] Inferior tonsillar displacement (ITD) exists pre-surgically in a significant percentage of PTC patients and this subset of patients may actually represent a secondary form of PTC and may benefit from correction of ITD to restore normal ICP.[6]

CLINICAL DESCRIPTION

The condition is characteristically described in middle aged females who are usually obese. However, it affects all ages and both sexes. Ramamurthi,[77] reported on 75 patients of whom 49 were males and 26 females. Chatterjee and Chatterjee,[18] reported a higher incidence in males. The signs and symptoms are those of increased ICP with headache, vomiting and papilloedema. Headaches in BIH can be excruciating in some patients. They are usually pulsatile and the increasing intensity during sleep may waken the patient. Pain along the trigeminal or occipital nerve root distribution and retrocular pain often occur in BIH, unlike in other headaches.[99] There are no localising neurological signs. Some authors have reported varying incidence of diplopia, vertigo, tinnitus and ataxia,[18] and various cranial nerve palsies. Agarwal et al.[2] and Chari and Rao[17] reported cases of BIH with no papilloedema, unilateral papilloedema and III and VI nerve involvement. Bruce et al.[14] reported two patients with confirmed BIH, presenting with headache, diplopia and papilloedema. The first patient had bilateral sixth nerve palsies and a partial right third nerve palsy, which resolved rapidly after a CSF shunting procedure. The second patient had alternating skew deviation and upbeat nystagmus. Both cases had normal brain magnetic resonance imaging (MRI) and magnetic resonance venography (MRV) and normal CSF contents, ruling out a secondary cause of intracranial hypertension. They concluded that these exceptional vertical and horizontal ophthalmopareses in the setting of BIH may be related directly to very elevated CSF pressures and may be secondary to altered CSF flow in the posterior fossa.[14]

Pituitary deficiency and empty sella syndrome may occur in BIH.[25,76] Patients with chronic BIH may develop a secondary empty sella syndrome, characterised by extension of the subarachnoid space through an incompetent diaphragma sellae into the sella turcica.[10] There may be a history of ear infection in some cases. The EEG may show non-specific changes. Mani and Townsend,[62] reported that the EEG in the majority of patients appeared slightly abnormal and burst activity was a common feature. It is essential to exclude an intracranial lesion before diagnosing BIH. Imaging studies show a normal or narrowed ventricular system. Visual evoked potentials are useful in determining the state of visual function and in following up patients. Optical coherence tomography (OCT) shows increased peripapillary retinal nerve fibre layer (RNFL) and macular thickness in PTC and may be a useful clinical tool in children.[27] Heckmann et al., in their study, found laser scanning tomography (LST) measurements to be useful for evaluating the degree of papilloedema in patients with BIH and corresponded well with clinical data and measurements of CSF opening pressure. They concluded that, if a diagnosis of BIH is established, LST measurements may replace repeated CSF opening pressure measurements in follow-up monitoring.[46] Transcranial Doppler (TCD) parameters have no useful unique features for monitoring BIH patients.[43] Acquired choroidal folds and optic nerve subarachnoid space enlargement may be signs of BIH and their appearance depend on the level of ICP. They can be identified by OCT, fluorescein angiography and ocular fundus

photography. Nevertheless, the diagnosis should be confirmed by lumbar puncture.[56] Flavoprotein autofluorescence (FA) values averaged 60% greater in the more affected eyes of women with pseudotumour cerebri, but not between eyes of healthy women (control subjects), demonstrating the clinical utility of FA in the early detection and monitoring of retinal and optic nerve diseases.[28]

CT AND MR STUDIES

The diagnosis of BIH is one of exclusion and based on a series of diagnostic negatives. CT and MR help to exclude other possible causes of raised ICP. The scans are normal before and after contrast enhancement. In some patients, the subarachnoid space or the perioptic CSF space may be widened and there may be an empty sella. MR is more sensitive to exclude an intracranial lesion and to show sinus or venous thrombosis. The MR of patients with BIH shows a higher water index in the white matter, suggesting the presence of a low degree of white matter oedema.[68]

Agid and Farb, in a double blind controlled study, found that flattening of the posterior aspect of the globe is the only sign on cross-sectional imaging and, if present, strongly suggest the diagnosis of BIH. In addition, evaluation of extra-luminal and intra-luminal narrowing of the transverse and sigmoid dural sinuses, with contrast-enhanced MRV using a simple grading system, provides a highly sensitive and specific test for identifying patients with BIH.[4]

Vaphiades et al. analysed cranial and orbital MRI scans from 20 patients with BIH and 20 control subjects and found six neuroimaging signs to predict elevated ICP in these patients: flattening of the posterior sclera; optic nerve enhancement; perioptic subarachnoid space distension; optic nerve vertical tortuosity; empty sella and intraocular protrusion.[97]

The venous phase during angiography may reveal a block in a major venous sinus in an occasional case. Isotope cisternography may show abnormality of CSF absorption through the arachnoid villi in some cases,[9,72] while in many it may be normal.[50]

Pulsatile tinnitus, hearing loss and a feeling of fullness in the ear may be complained of by some patients. Brainstem auditory evoked response may show bilateral prolongation of peak latencies, which return to normal after treatment.[87,88] CSF pressure measurements are high and the composition of the CSF is normal.

DIFFERENTIAL DIAGNOSIS

In tropical countries, one should exclude cysticercosis, which may simulate BIH. The CT scan and MR are both diagnostic in cysticercosis; MR is more sensitive and may show the cysts even when the CT scan is negative.[85] Mild residual arachnoiditis following tuberculous meningitis usually causes hydrocephalus, but rarely may mimic the clinical picture of BIH. Toxic and lead encephalopathies may simulate BIH. Pseudopapilloedema[48] with headaches can be differentiated from BIH by careful ophthalmological examination, including fluorescein angiography and delineation of the blind spot. Bilateral disc drusen is an important differential diagnosis of PTC.[74]

TREATMENT

The aim of treatment is to relieve headaches and specially to prevent loss of vision. Conservative therapy is useful in most cases, but surgery is necessary when vision is threatened. Hence, a careful watch is necessary to detect deterioration in acuity of vision or in the visual fields. Visual evoked potentials and repeated quantitative perimetry are helpful in assessing the progress and in helping to decide on surgical treatment.[92,93]

Any detectable cause for BIH, e.g. hypervitaminosis, antibiotics or anaemia, requires suitable corrective measures. In other cases it is necessary to reduce the ICP. This may be done for a few days by intravenous mannitol or diuretics like furosemide. Dexamethasone, 12 mg a day, is administered for a few days in resistant cases. When the response is satisfactory, this may be followed by oral glycerol for some weeks. Topiramate seems to be effective in the treatment of BIH, weight reduction and the reduction of CSF formation being the possible mechanism of action.[16,31]

In many cases, it will be necessary to do frequent lumbar punctures to lower the ICP. Barbiturate augmented hypothermia has been used to reduce ICP.[57,84] In cases where the pressure is very high, the patient is ill or the vision is threatened, surgical therapy is indicated. Lumboperitoneal shunt is favoured by many surgeons, but has drawbacks like backache and persistent root pains. Cisternal shunting has been found useful.[51] Recent reports have shown promising short-term to medium-term results in patients with refractory idiopathic intracranial hypertension (BIH), treated using the stereotactic ventriculoperitoneal shunting (SVPS) technique. However, the long-term clinical efficacy of this technique remains questionable.[1]

Before appropriate shunts were available, subtemporal decompression has been done successfully on many patients and is still preferred by some surgeons to avoid problems associated with shunts.

Recently, endoluminal venous sinus stenting has been proposed as an effective and safe alternative treatment. It was performed under intravenous heparin administration and anti-platelet therapy was administered for 3 months post-treatment.[64,65]

OPTIC NERVE SHEATH DECOMPRESSION

Patients with BIH and progressive visual impairment have been shown to benefit from optic nerve sheath decompression.[3,13,34,49,83] It is desirable to perform the operation as soon as it is obvious that medical therapy is not effective in preventing progressive visual deterioration.[52] This operation is also known to provide relief from intractable headache.[20,83] Demonstration of

retrobulbar optic nerve sheath enlargement by CT or orbital echography is essential before making a decision to operate.

A variety of surgical approaches have been described for optic nerve sheath decompression.[24,34,49] However, the medial approach of Galbraith and Sullivan[34] remains the most frequently employed technique. The procedure is safe, with few complications. Gupta et al. found endoscopic endonasal optic nerve fenestration a safe, minimally invasive and extremely effective procedure for the management of BIH, with a 94.5% success rate and minimal morbidity.[42] Bariatric surgery and weight loss has been advocated for obese patients with BIH and stable visual symptoms to avoid shunt placement or optic nerve sheath fenestration.[57,69]

RESULTS

In the majority of cases, conservative treatment is beneficial. Risk factors identified for a bad visual outcome are the presence of atrophy of the optic discs, visual loss and marked field defects, delay in treatment, patients older than forty years and the presence of systemic hypertension.[93] In a long-term follow-up of cases, good prognosis has been reported after prolonged treatment.[60,102] Rarely, a few of the cases may turn out to have a tumour on investigations at a later date. Recurrence of BIH has been reported after a few years, especially in obese women whose obesity has not been corrected.[91] Long-term observation is advisable. Corneal contact lens-associated ophthalmodynamometry can be helpful for the monitoring of patients with intracranial idiopathic hypertension.[45]

179 Tumours of the Cranial Vault

Narayanan R, Ravi Ramamurthi

The diagnosis and treatment of tumours of the skull come under the purview of the neurosurgeon, as they have the expertise in dealing with the cranial contents. Compared to the neurosurgical literature which consists of series of individual cases, more extensive reports of such tumours are found in the radiological journals. Vandenberg and Coley,[125] estimated that primary skull tumours accounted for 0.8% of all bone tumours.

The skull bones are affected by lesions similar to those seen in the other bony structures such as benign or malignant neoplasms or metastatic deposits, congenital dysplasias, metabolic disorders and haemopoietic diseases. Lesions that are primarily intracranial may involve the skull secondarily, and similarly, tumours arising in the skull bones can spread inside, producing raised intracranial pressure and focal neurological deficits. Malignant conditions from the paranasal sinuses, nasopharynx and orbit may spread to the base of skull and produce cranial nerve palsies.

ANATOMICAL CONSIDERATIONS

The vault of the skull is made up of membrane bones, whereas the base is of cartilaginous origin. This influences the type of pathological lesions that may develop in different parts of the skull. The deeper periosteum of the skull bones (the endosteum) is firmly incorporated with the dura mater. The dura forms an effective barrier against the intracranial spread of lesions of the skull. Dural lesions, however, often invade the inner table of the skull.

Classification

Tumours of the skull can be primary or secondary.

A. Primary tumours:

1. Benign
   - Osteoma
   - Haemangioma
   - Giant cell tumour
   - Dermoid
   - Epidermoid
   - Chondroma
   - Lipoma
   - Aneurysmal bone cyst
   - Ossifying fibroma
   - Cavernous haemangioma of the skull
   - Myxomas

2. Malignant
   - Chondrosarcoma
   - Osteogenic sarcoma
   - Fibrosarcoma
   - Carcinoma of the temporal bone
   - Fibrous histiocytoma[25]
   - Chordoma
   - Reticulum cell sarcoma
   - Angiosarcoma
   - Malignant sweat gland tumour
   - Benign osteoblastoma
   - Orbital rhabdomyosarcomas
   - Bone penetrating
   - Marjolin's ulcer of scalp
   - Ewing's sarcoma

B. Secondary tumours:

1. Contiguous spread
   - Meningioma
   - Glomus jugulare tumour
   - Nasopharyngeal tumours
   - Carcinoma of the paranasal air sinuses
   - Sinonasal melanoma
   - Nasal basal cell carcinoma

2. Haematogenous
   - Secondary metastases
   - Lymphoma
   - Leukaemic deposits

C. Conditions simulating skull tumours:

- Osteomyelitis
- Cephalhaematoma
- Leptomeningeal cyst
- Vascular disorders
- Vascular impression
- Sinus pericranii
- Histiocytosis X
- Pacchionian granulations
- Hyperostosis frontalis interna
- Sarcoidosis
- Paget's disease
- Fibrous dysplasia
- Hyperparathyroidism
- Mucocoele
- Neuroectodermal dysplasia
- Haemolytic anaemias
- Petrous apex cholesterol granuloma.

DIAGNOSTIC EVALUATION

The common presenting symptoms are swelling, deformity, disfigurement and local pain. A specific neurological deficit may also be found. Many skull tumours are detected incidentally on radiographical examination done for other reasons. The usual diagnostic procedures include plain films of the skull, computerised tomography, magnetic resonance imaging and cerebral angiography. Radionuclide bone scanning is occasionally done to detect metastases in bones from other primary malignancies.[63]

Plain Skull Films

After the invention of computerised tomography, the importance of plain X-ray films has declined. Routine views and tangential or edge-to-edge views are taken to detect the location, extent and the degree of involvement of the tables and diploe, and also to know whether the lesion is sclerotic, lytic or mixed (Figs 1A and B). When both the tables are involved, the lesions appear more lucent (punched out). Examination of the margins of the radiographic abnormality gives valuable information.[36,37,44]

Sharply defined and sclerotic edges indicate that the process is a slowly expanding one, permitting enough time for the adjacent bone to react by condensation and thus, the process is more likely to be benign. Irregular, poorly defined margins suggest a more aggressive process, either malignant or inflammatory.[67,124]

Computed Tomography

Computed tomography (CT) provides more accurate information regarding the extent of involvement of the skull bones as well as the soft tissues, both within and outside the skull. It is necessary to scan the bones of the skull as well as the soft tissues, using the appropriate settings on the CT machine[65,77,117] (Figs 2A and B). Such studies are also to be done after intravenous contrast infusion, to assess the degree of invasion of the dural venous sinuses, brain and extracranial soft tissues.

Magnetic Resonance Imaging

Signal intensity in magnetic resonance (MR) depends primarily on the concentration of mobile protons (hydrogen nuclei) in the tissue being imaged. As compact cortical bone lacks in unbound protons, the inner and outer tables of the skull appear as a signal void in the MR image. The diploe has abundant fat and hence images well, so also the pathological lesions arising in the diploe. Lesions at the base of the skull are better imaged by MR than CT, as the latter produces bone artefacts. Neoplasms have greater water content and hence are imaged with sharp contrast from the surrounding structures. The possibility of histological differentiation by MR is limited.

Cerebral Angiography

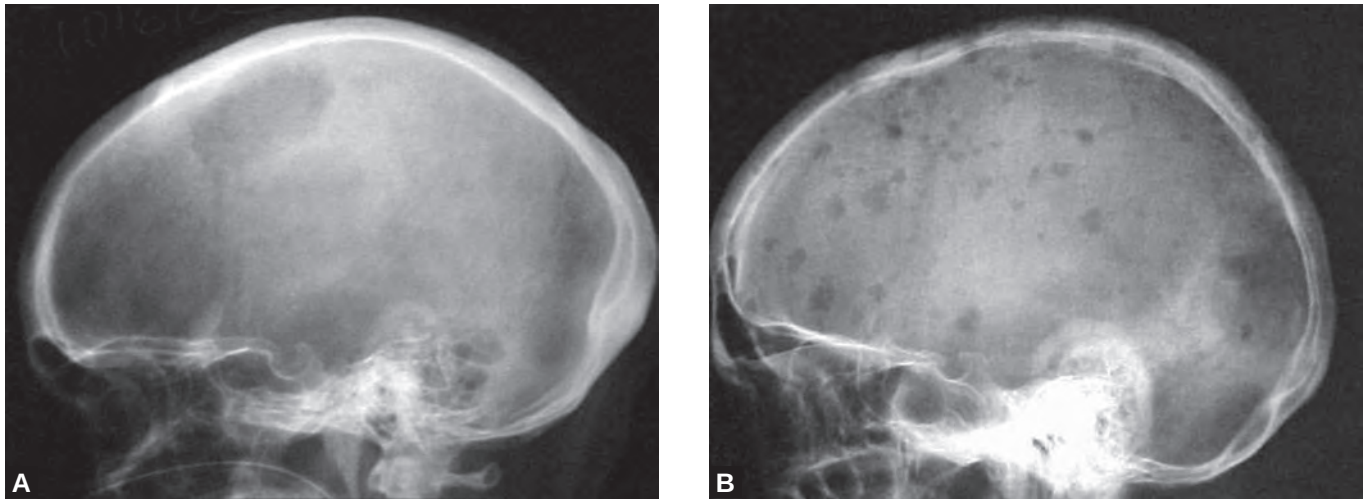
The indications for cerebral angiographic studies have become limited after the advent of CT. Assessment of possible intracranial extension when the CT and MR are not clear and the mapping out of the vascular supply of the neoplasm, before surgery, are some of the indications. Selective external and internal carotid studies are useful.

MANAGEMENT

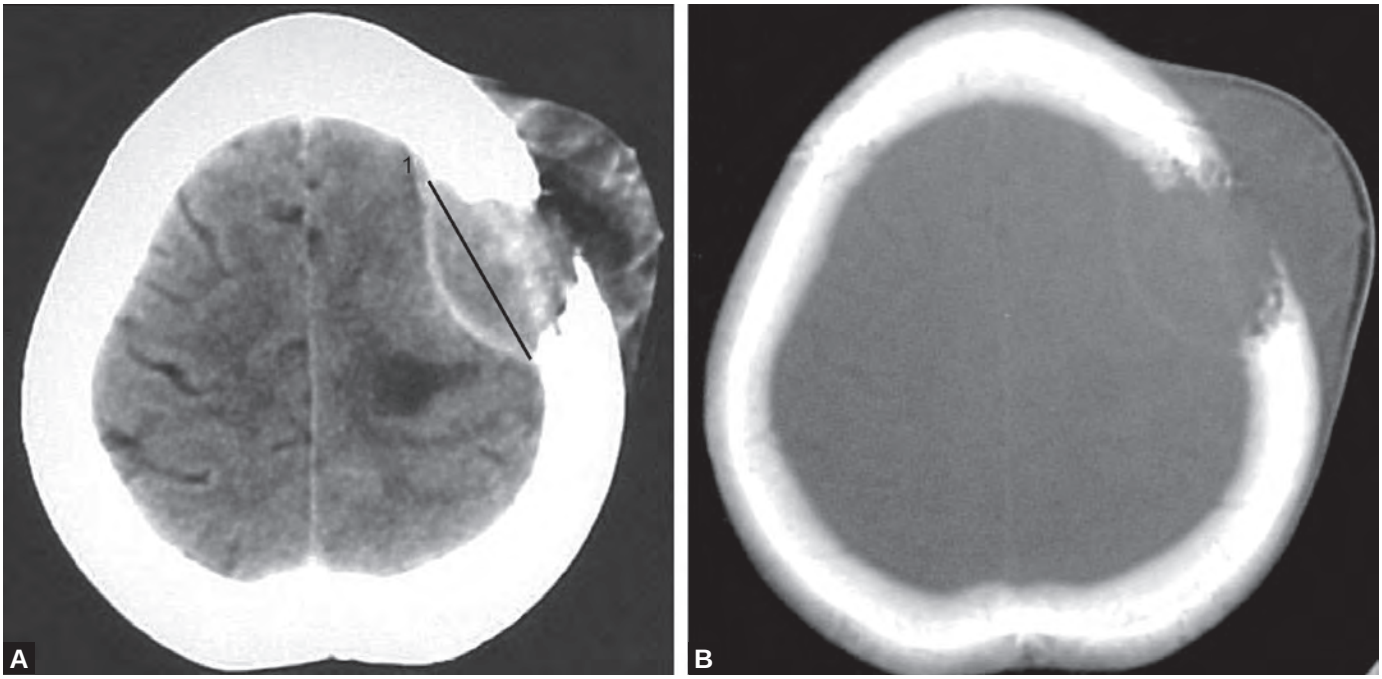
In principle, the treatment of neoplasms of the skull is similar to that of bone tumours elsewhere. The close proximity of the brain and other vital structures necessitates certain modifications in the therapy. Surgery, radiotherapy and chemotherapy are the modalities of treatment available and are often used in combination.

Operative Treatment

This depends on the suspected nature of the lesion, its location, single or multiple and whether neurological deficits are already present or are likely to result. A suspicious skull lesion, in the absence of any other demonstrable primary process, calls for a biopsy to determine the line of therapy. A needle biopsy may be adequate in some cases. In hard non-penetrable lesions, an open biopsy is done through an incision made at the circumference of the lesion, taking an adequate amount of tissue. The incision used for the biopsy should not interfere with any later scalp flap that may become necessary to excise the tumour.



Figs 1A and B: (A) X-ray skull lateral view showing osteolytic lesion in the frontoparietal region. (B) X-ray skull lateral view showing multiple osteolytic lesions, predominantly in the frontal and parietal bones



Figs 2A and B: CT scan bone cuts in the same patient, as in Fig. 1A, showing osteolytic lesion with soft tissue swelling

Primary tumours of the skull are excised completely whenever possible. This is especially important if the lesion produces neurological symptoms, causes cosmetic deformity or becomes infected. Cranioplasty may be done at the same sitting or at a later date. One must be prepared for full scale intracranial dissection, including dural grafting procedures. Modern imaging techniques give adequate warning to the surgeon to be prepared for such steps. Skull base lesions need special operative exposures and may need the co-operation of otorhinolaryngologists and plastic surgeons.[62,89,97] There has been remarkable progress in the treatment of these lesions with the advent of the speciality of skull base surgery. Lesions earlier considered inoperable are now being totally excised with good results.

Radiation Therapy

When deciding on radiation therapy, careful planning is necessary, taking into consideration the radiation sensitivities of adjacent normal structures such as the brain and eyes. In general, tissue response to radiation depends not only on the total dose but also the manner in which it is delivered. Multiple small fractionated doses per day spread out over a longer time, give a greater tumour killing response with less damage to normal structures.[88] Generally, the required dose is 55 Gray (Gy) or 5,500 rads in 30 fractions over 6 weeks utilising megavoltage photon radiation.[19,79,86]

Radiation damage to skull bones is uncommon with therapeutic doses; there is a 1% chance of delayed malignancy (sarcoma) in the irradiated bone.[14] Higher energy photon or electron beam therapy is the ideal treatment and can be tailored to the tumour volume by computerised techniques.

Adjuvant therapies, like the use of hyperthermia and hypoxic cell sensitisers, are being tried.[23,95] Palliative radiation to reduce the size of the mass may be advised, depending on the expected survival time and the probability of late adverse reactions.

Chemotherapy

Chemotherapy alone is useful in a few conditions like Hodgkin's disease, acute childhood lymphocytic leukaemia and testicular carcinoma.[30]

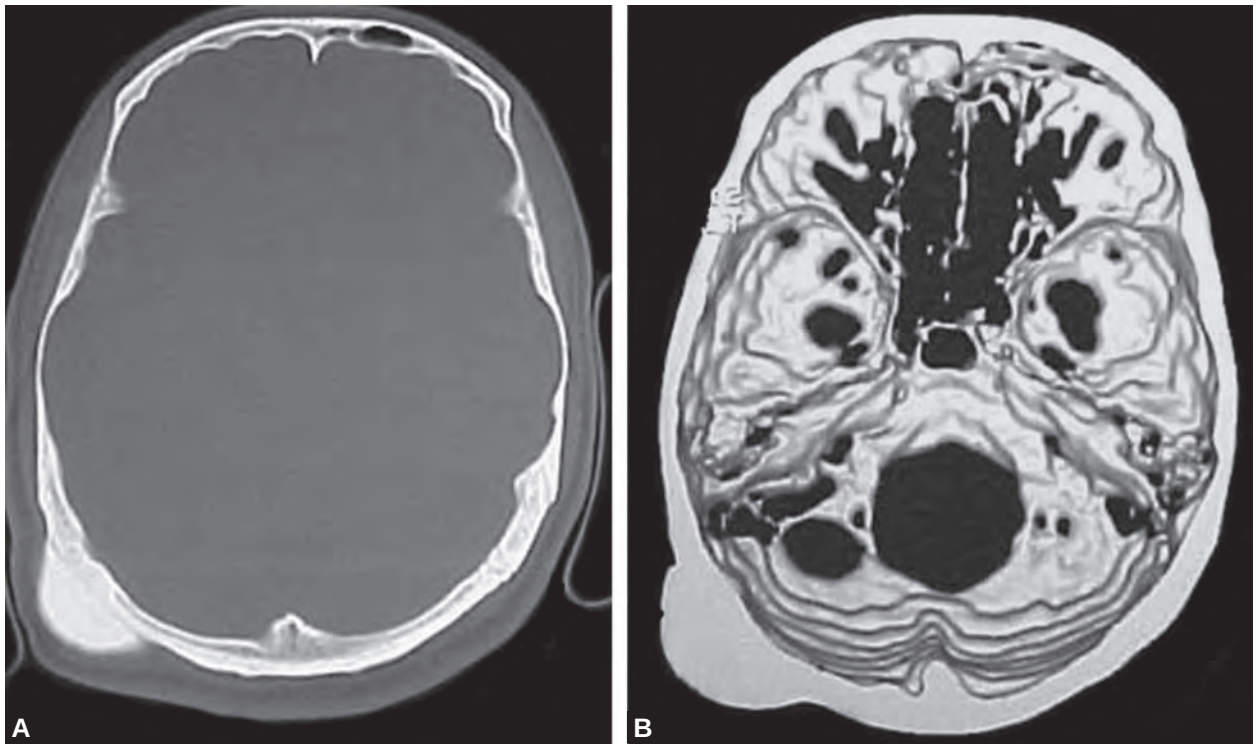
PRIMARY TUMOURS OF THE SKULL[91]

Benign Tumours

Osteoma

Osteomas are the most common of the benign neoplasms of the skull and facial bones. Bagchi,[4] reported osteomas to account for 32% of 31 skull tumours encountered by him. Usually solitary lesions are seen in the frontal region. They arise from membranous bone and proliferate into dense cortical bone or spongy cancellous bone. They commonly occur in the frontal sinus and in the mastoid air cells.[110] These slow growing tumours form an outward excrescence which is hard and painless and are usually noted while combing the hair. A compact osteoma may become hard like ivory. The attachment to the skull may be narrow or broad. Rarely, an osteoma may extend intracranially and cause seizures.

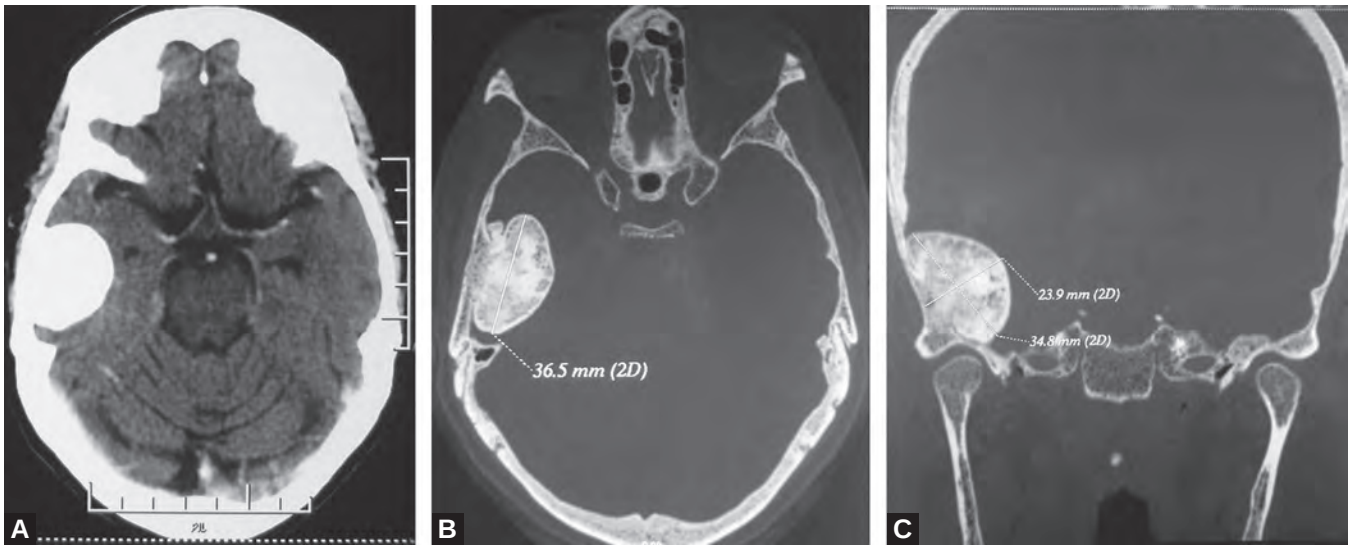
In plain X-rays, an osteoma is seen as a solid homogeneous bony shadow. There are no increased vascular channels. Tangential projections reveal the base and the



Figs 3A and B: CT bone cuts and reconstruction showing osteoma of the right occipital region

absence of involvement of the diploe and inner table. When the inner table is involved, differentiation from a meningioma becomes necessary. CT gives the precise diagnosis (Figs 3A and B and 4A to C). Multiple osteomas of the calvaria and mandible with soft tissue tumours of the skin and colonic polyposis form the triad of Gardner's syndrome.[22] Microscopically, the tumour is a nucleus of osteoid tissue in a background of osteoblastic connective tissue and is completely enclosed by reactive bone. Histological differentiation from fibrous dysplasia is difficult; but the presence of smooth, homogeneous and sharply defined sclerotic nodules is unusual in fibrous dysplasia.

Osteomas are surgically curable. The indications for removal are rapid growth, pain, obstruction to sinus outlets and noticeable deformity. Small osteomas of the outer table may be resected easily without destruction of the inner table. As these lesions are very hard, it is wiser to removed them by cutting around their base through the cancellous tissue. A large lesion needs removal of the entire bone as a flap and the defect is closed by cranioplasty. After excising the bone flap, the osteoma



Figs 4A to C: CT scan of the brain with bone cuts showing osteoma of the left temporal bone growing intracranially

can be excised from the flap and the flap can be used to close the defect primarily.[64]

Haemangiomas

Haemangiomas constitute about 7% of all skull tumours.[124] About two-thirds of haemangiomas of bone occur in the skull or the vertebral column. They arise from the vascular elements of the diploe, mainly in the vault of the skull and to a lesser extent in the roof of the orbit or petrous temporal bone. They are slow growing and may reach a large size. They are painless and the presence of a swelling is the chief complaint. The swelling is hard, but may be soft in some places. The skull is involved by erosion and the margins are imperceptible. Dilated veins may be present. In haemangiomas of the orbit, proptosis, blindness or extraocular palsies may be seen. Haemangioma of the petrous bone may present with deafness and cranial nerve palsies.

The plain X-rays show a swelling with a typical honeycombed or sunburst appearance. The diploe is enlarged and both tables of the skull bulge, outer more than the inner. Rarely, intracranial extension is seen.[104] The trabeculae are seen vertically oriented. The edges are well defined and a thin margin of bony condensation may be evident. CT images with 'bone window' show the hypodense matrix with discrete, thickened, sclerotic and widely separated trabeculae. Despite the vascular nature of the lesion, contrast enhancement is an exception rather than the rule. Carotid angiography shows enlargement of the external carotid artery branches.[104] Rarely, there may be an internal carotid supply to these tumours.[2] Calvarial haemangioma at a cranioplasty site presenting as scalp swelling has been reported by Kang et al.[60] which required total surgical removal along with cranioplasty.

Treatment is usually by en bloc excision or wide curettage. The tumour appears as a blue domed hard mass under the pericranium. Sometimes, the dural surface may bleed profusely in which case circumferential incision of the dura and resuturing will help. Radiotherapy is advisable in situations where excision is not feasible. Doses up to 30 Gy (3,000 rads), in 3 weeks, may be required.[88]

Giant Cell Tumours (Osteoclastoma)

Giant cell tumours arise from the cartilaginous bone in the sphenoid, mastoid or occipital areas.[104,105] They are extremely rare in the bones of the vault, as osteoclasts are usually not present in membrane bones. Their pathogenesis is unknown, although trauma and haemorrhage may precede their occurrence.

Osteoclastoma of the skull presents as a painless bony swelling and radiographs show evidence of rarefaction or destruction of bone. Excision is the treatment of choice; but it is often incomplete and needs supplementary radiotherapy to ensure freedom from recurrence. Occasionally, malignant changes have been reported after surgery and radiotherapy.[80] Considering the aggressive nature and potential malignancy of these lesions, careful long-term clinical and imaging follow-up is recommended.

Epidermoid and Dermoid Tumours

These tumours of developmental origin are derived from epithelial cell rests ectopically included in the bone during development. They are commonly seen in or near the midline at the vertex, the frontal or occipital regions or in the temporal bone. A posterior fossa dermoid associated with symptomatic syringomyelia has been reported.[121] However, they may occur anywhere in the calvarium. They originate in the diploe and enlarge in both directions expanding and thinning both the tables by continuous growth pressure. The bone at the edges of the lesion gets sclerosed. The lesion may break through the egg shell thin tables and expand under the scalp or extradurally. The swelling under the scalp is firm, rubbery and non-tender. Sometimes, a tract may extend through the inner table and dura to end in an intradural lesion. A lesion in the midline, especially over the torcula, may involve the venous sinuses.[81] Very large intracranial extensions may exist with surprisingly normal intracranial pressure and with no neurological deficits.[47] These are described as giant intradiploic epidermoids.[16,107] The larger lesions, especially epidermoids, tend to get infected and osteomyelitis may result.

Plain radiographs show a clear cut area of radiolucency in the skull with sclerosed margins, resembling an enlarged emissary foramen. Tangential views show expansion of the tables.[33,123] CT accurately delineates the bony defect and the size, location and extension of the soft tissue mass outside and inside the skull and dura. The lesion appears hypodense relative to the adjacent brain, due to contained keratinised debris and cholesterin.[68,129] They do not enhance with contrast, but adjacent compressed brain shows marginal enhancement. On MR, these lesions appear hyperintense in T2-weighted images and most often hypointense in T1-weighted images.

Treatment is by surgery. Pure extracranial lesions can be excised en bloc. A careful search must be made for any intradiploic or intracranial extension along a thin track which, if present, needs to be excised. While dealing with midline lesions, the surgeon must be prepared to do an extensive craniotomy and venous sinus repair, if necessary.[81]

Chondroma

These arise mainly in the cartilaginous bones of the base of the skull. They commonly occur between the ages of 20 and 40 years. The common sites are the paranasal sinuses and the sphenoethmoidal and spheno-occipital synchondroses. Depending on the site of origin, they may extend into the sellar or parasellar region, producing visual and ocular nerve palsies or endocrine dysfunction. The posterior lesions may compress the brainstem and involve the lower cranial nerves.[75] Radiographically, a chondroma appears as a lytic lesion at the base of the skull with fairly sharp margins. Areas of stippled calcification may be seen in more than 60%.[74,85,113] CT reveals well marginated bone destruction and an associated homogeneous, isodense and lobulated soft tissue mass with interspersed

calcification. Contrast enhancement is infrequent and when present is minimal. Differentiation from metastasis is based on the sharpness of the bony margin and the presence of calcification. Other lesions to be differentiated are chordoma and meningioma.[1,2,3,32,40,49,52,56,57,71,96,108,119]

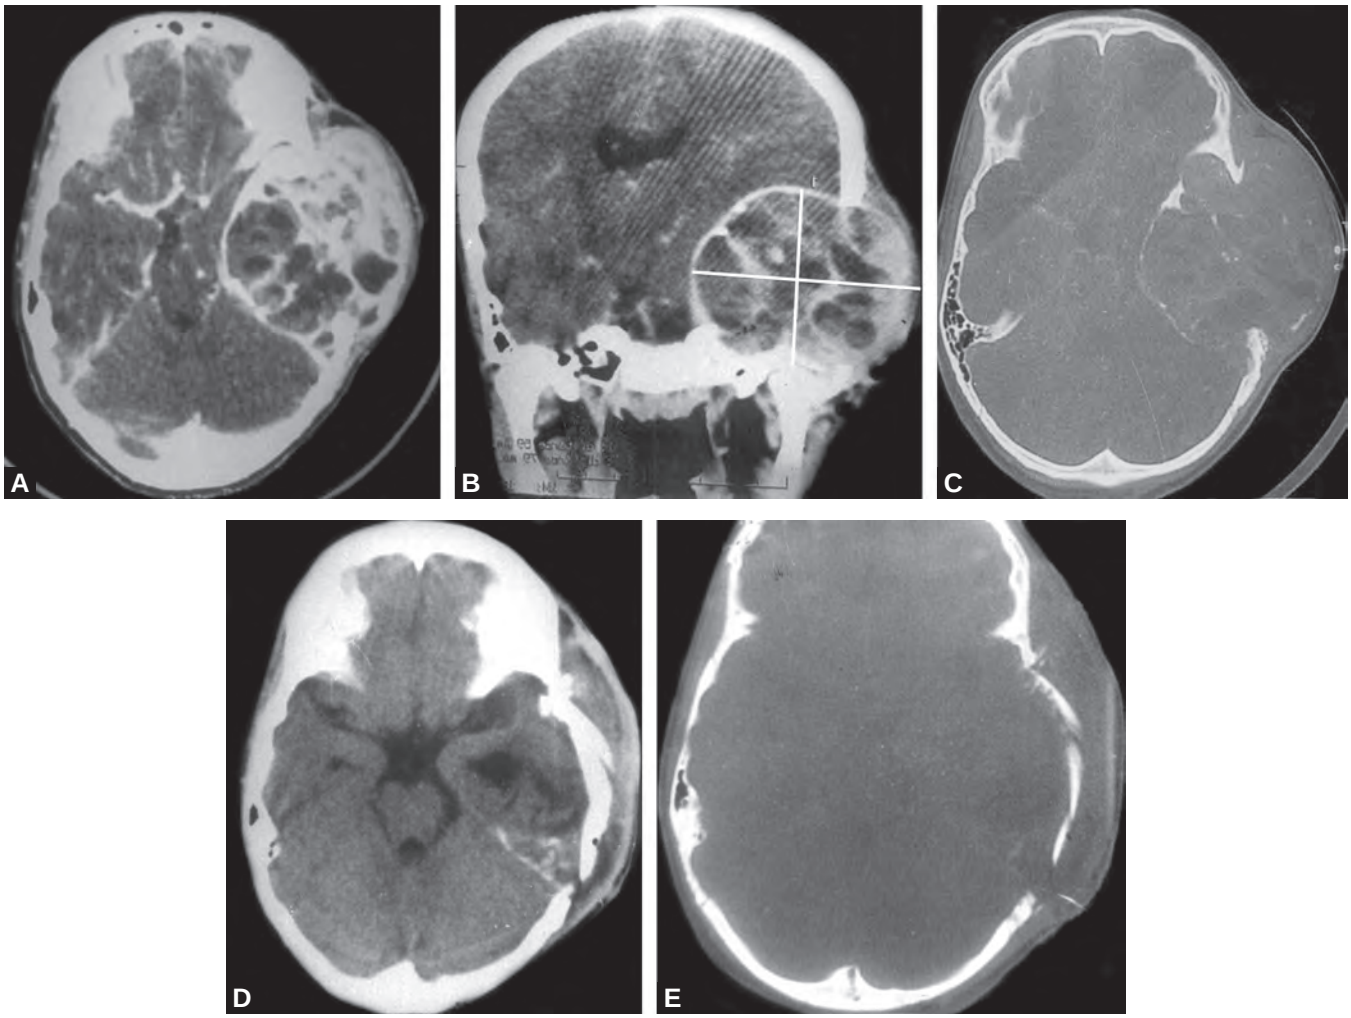
Sarcomatous changes occur in 1–2% of these tumours, more frequently in individuals with Maffucci's syndrome (multiple enchondromas and multiple subcutaneous haemangiomas).[8,72] Rapid growth indicates a malignant change. Histologically, malignancy is deduced by the presence of atypical cartilage cell nuclei in the actively growing peripheral portions of the neoplasm.[73] The treatment of a chondroma is total removal wherever possible. Most often, only partial removal is possible, especially at the skull base. Decompression of neural structures by such partial removal is often beneficial.[38]

Other Benign Tumours

Calvarial lipomas: They are rare. They present as painless, benign and slowly progressive lesions, often an incidental finding. These lesions appear hyperintense on both T1- and T2-weighted images. On CT scan, evidence of mixed bony destruction and proliferation are reported. Gross and histological features are like lipomas elsewhere. They are cured by excision.

Cavernous haemangioma of the skull: Despite their low incidence, cavernous haemangiomas must be included in the differential diagnosis of slow-growing osteolytic lesions located in the skull. The elective treatment of these tumours includes a complete resection by craniectomy, with safe bony margins. A large cranial cavernous haemangioma can be treated using embolisation and craniotomy with preservation of the outer cranial table.[18]

Aneurysmal bone cyst: It is a multiloculated expanding cystic tumour with a rich vascular network in the walls.[76] The encircling inner and outer tables are eroded to form thin bony shells. Some cysts show a central core of haemangioma and repeated haemorrhage may be the cause of the cystic expansion of the skull tables.[13] These lesions may either become symptomatic or enlarge during pregnancy.[21] On CT, the contents of the cyst may be of high or low density, depending on the protein content of the fluid (Figs 5A to E). The superficial temporal and



Figs 5A to E: (A to C) CT scan of the brain axial coronal and bone cuts showing aneurysmal bone cyst of the temporal bone. (D and E) Post-operative CT scan with bone windows of a patient with temporal aneurysmal bone cyst

middle meningeal arteries supply the tumour and this is made out well on selective external carotid angiography.

Ossifying fibromas or benign osteoblastoma: It is a rare tumour and has been described as a giant osteoid osteoma by Dahlin et al.[28] It is a solitary vascular tumour, predominantly osteolytic in character, with varying degrees of calcification and new bone formation. Treatment is by local excision.[103]

Osteoblastomas: They are occasionally seen in the base of the skull, but rarely in the vault. Most frequently, they occur in the midline in the clivus.[114,115] Depending on the site of origin, they produce signs of pressure on the optic nerves, the pituitary, the hypothalamus, the brainstem and the other cranial nerves. Radiologically, islands of erosion with normal bone in between are seen in the region of the clivus and sella. A suitable skull base approach enables excision of as much of the lesion as possible to ensure decompression of neural structures and the pituitary gland. Radiotherapy can be given post-operatively. A long-life span is usually expected. Malignant transformation after treatment has been occasionally reported.[80]

Myxomas: They are rare benign tumours arising from mesenchymal tissues throughout the body. Involvement of the skull base with intracranial extension has been reported but is extremely rare. It requires surgical excision. Despite radical surgery, the tumour may recur requiring re-surgery. The differential diagnosis frequently includes chondrosarcomas, chordoma, metastatic tumours of the skull, haemangiopericytoma, meningioma and other neoplasms of the dura and skull base in this location.[112]

Malignant Tumours

Chondrosarcoma and Osteogenic Sarcomas

They are the two primary malignant tumours of the skull and both are rare. Chondrosarcoma is a tumour of adult life, usually occurring as a malignant transformation in a benign chondroma. Chondrosarcomas form 0.1% of all intracranial tumours and 6% of skull base lesions. The common site is the base of the skull, in or around the sella, the cerebellopontine angle or the frontoethmoidal air sinuses.[5] They grow for a long time and produce pain, deformity and cranial nerve palsies in the advanced stages. Roentgenograms show destruction of bone with irregular poorly defined margins.[85] In more than 50% of cases, stippled calcification is seen, a fact used to differentiate these lesions from metastatic carcinoma, lymphoma and myeloma.[5] CT demonstrates an irregular destructive process with a soft tissue mass that is homogeneous and hyperdense. Areas of calcification are seen within the mass in more than 60% of cases. On contrast infusion, irregular and heterogeneous enhancement of moderate intensity is noted within the tumour.[46] They are locally invasive and tend to recur. Radical resection with supplemental radiation therapy is the treatment of choice. The five-year survival rate is usually in the range of 60–70%. Systemic chemotherapy is ineffective.[17,30,83]

Osteogenic Sarcoma

This rare tumour occurs usually in the vault and accounts for about 2% of all primary osteogenic sarcomas. It usually occurs in young persons, between the ages of 15 and 25 years. A second modest peak occurs in older patients with advanced Paget's disease of the skull.[29,106] Occasional cases have been reported as a late complication many years after radiotherapy to the calvarium.[7,45,59]

Osteogenic sarcomas grow rapidly and hence the history is quite brief. Pain and local swelling are the common symptoms. Early metastases to the lungs and other bones usually occur. On the plain radiographs they appear as a large lytic area with poorly defined margins.[33,42] Radiating bony spicules, in the form of sun rays, may be seen in some cases at the edge of the tumour. The calvarium is thickened at the advancing edge of the tumour due to subperiosteal extensions. CT shows irregular and prominent new bone formation within a large heterogeneous extradural mass showing irregular contrast enhancement.[6]

These tumours are extremely vascular and are sometimes referred to as bony aneurysms. Histological features are extremely variable with foci of new bone formation, necrosis, haemorrhage, telangiectasia and a frank sarcomatous stroma.[73] The reported incidence of osteogenic sarcoma in Paget's disease varies between 1% and 10%.[36,127] Radiographically, there is rapidly progressive lysis within the thickened and irregularly dense bone.[41,127] The usual treatment is complete excision followed by high doses of irradiation of 60–70 Gy (6,000–7,000 rads) post-operatively.[30] Adjuvant chemotherapy with methotrexate and leucovorin in high dose is administered. With this combination, a five year survival of 50% and even a cure may be achieved in some patients even with metastatic disease.

Fibrosarcoma

Fibrosarcoma may arise from the periosteum of the skull or from the dura. It presents as a rapidly growing painful tumour. In the early stages, X-rays show only a thinning of the outer table by an overlying soft tissue mass. In the later stages, there are large areas of complete destruction of both tables. The margins are irregular. The differential diagnosis is from other lytic tumours. Carcinomas are usually smaller and multiple. Meningiomas rarely cause an extracranial mass and other symptoms are likely to occur earlier. Osteogenic sarcoma without new bone formation at the periphery may cause difficulty in diagnosis on plain X-rays. Microscopic examination of a fibrosarcoma shows only a sarcomatous stroma without any new bone formation.

Fibrosarcomas are treated by radical resection, followed by high doses of post-operative radiation; 60–70 Gy (6,000–7,000 rads) in 6–7 weeks. Chemotherapy has

not been found to be advantageous. A five-year survival rate of 3% has been reported.

Ameloblastic Fibrosarcoma

It is a malignant odontogenic tumour that rarely affects the skull base and surrounding regions. This is due to a malignant transformation of a benign ameloblastic fibroma. The ameloblastic fibrosarcoma can extend from the site of origin to the orbit, anterior or middle cranial fossa, infratemporal fossa or to the cavernous sinus. Progressive proptosis with complete monocular vision loss was the presenting symptom. Multidisciplinary skull base approach, resection of all tumour except that in the cavernous sinus is recommended.[48]

Malignant Fibrous Histiocytoma

This is a pleomorphic sarcoma arising in the deep soft tissue of the extremities. It has also been found to arise from the bones and rarely from the skull. Hatashita et al.,[53] reported seven cases in the skull bones out of 177 such cases in the entire skeletal system. The frontal, temporal and occipital bones were seen to be involved, and there was a lesion in the clivus forming a retropharyngeal mass.[24,26,34] Metastases occur in the mediastinum, thoracic vertebrae and lungs. CT shows a large mass of low density with patchy enhancement, extending on the inner and the outer surfaces of the cranial bone with patchy enhancement. MR shows a bulky tumour with mottled enhancement with contrast.[109] Sometimes, local scalp tenderness and a skull defect in the plain film in the corresponding area may be present for several months, before the tumour becomes obvious.

The gross appearance and conventional histological examination do not show any specific features. There is a highly cellular pleomorphic picture consisting of spindle shaped cells of fibroblastic and histiocytic origin arranged in a spongiform pattern. The exact diagnosis can be made only by immunohistochemical methods to demonstrate intracytoplasmic granules, with staining of alpha-1 antichymotrypsin and alpha-1 antitrypsin. Eight to twelve months survival has been reported.[122]

Chordoma

See chapter on "Chordoma".

Ewing's Sarcoma

It is rarely seen as a primary lesion in the skull.[78] The most common site for primary Ewing's sarcoma of the cranium is the temporal bone followed by the frontal, parietal and occipital bones. The sphenoid and ethmoid are less commonly involved.[116] The patient usually complains of intermittent pain, more at night. The swelling appears later and may fluctuate in size, with increasing pain during periods of enlargement. Anaemia, leucocytosis and fever are common. The lesions are often multicentric in origin involving the tibia, ribs and vertebrae. Metastasis may occur in the liver.[82]

On plain X-rays, the lesion appears as an irregular area of bone destruction with poorly defined margins and an overlying soft tissue mass. A minor periosteal reaction may be present. CT and MR help to delineate the extent of bony involvement and the soft tissue mass, both extracranial and intracranial and will also demonstrate a diploic lesion. The venous phase of carotid angiography demonstrates depression of the superior sagittal sinus.

The lesion is composed of compact strikingly uniform cells with indistinct borders and large prominent nuclei. Differentiating this tumour from reticulum cell sarcoma and from neuroblastoma with skeletal metastases is difficult, but is very important to assess the prognosis.[78,130] Diagnosis can be confirmed by either immunohistochemistry or chromosomal abnormalities. Chromosomal abnormalities (translocation 11;22) can be detected by karyotyping and RT PCR.[17] Ewing's sarcoma is initially quite radiosensitive, so that radiation therapy with systemic chemotherapy is the treatment of choice. Recurrences are common and the prognosis is not good with any kind of treatment.

Other Malignant Tumours

Reticulum cell sarcoma is rare tumour of the skull. It appears as a lytic lesion and the diagnosis is made on histology. En bloc excision followed by radiotherapy has produced clinical cures. Angiosarcoma is occasionally seen in the skull as a soft, painful, rapidly enlarging tumour which may invade the adjacent scalp and dura. It is seen as a poorly demarcated osteolytic lesion in plain X-rays. Distant metastases are common. Microscopically, it consists of highly vascular channels, marked anaplasia and moderate mitotic activity. Wide en bloc excision followed by radiotherapy is recommended.

TUMOURS INVOLVING THE SKULL BY DIRECT EXTENSION

Meningiomas[27] may produce varying degrees of incidental bony changes in the overlying skull and may also invade the skull bone itself. The tumour may extend into the diploe and sometimes break through the outer table to form a subcutaneous palpable tumour. Such bony involvement may occur in the vault, the cribriform plate, the sphenoidal ridge or in the planum sphenoidale. While convexity meningiomas are large tumours, the dural involvement in basal lesions is often en plaque. These features and the bony involvement are seen well in CT scans. The bone involved by meningiomas can be highly vascular with tortuous arteries and large venous channels.

The bony changes caused by basal lesions may resemble those of fibrous dysplasia. The latter is usually bilateral, occurs at a younger age and angiography does not show enlarged external carotid artery branches. Sometimes, meningiomas may fail to produce a blastic response and may destroy the bone, giving an appearance very much like a metastasis in the plain skiagrams. Bone infiltrated by meningiomas is highly vascular.

Great care is needed in turning the bone flap which may have to be excised. Cranioplasty may be needed if the involved skull bone is excised. Sometimes, meningiomas remain completely intradiploic, expanding the two tables resulting in a doughnut like lesion in the plain skiagram. Total excision with repair of the bone defect gives good results.[99] Recurrent craniofacial meningiomas can usually be managed by using a lateral cranial base approach. A radical resection may prevent further recurrence with an acceptable quality of life.

Glomus Jugulare Tumour

See chapter "Jugular Foramen Lesions".

Nasopharyngeal Tumours

Benign tumours invading the base of skull are commonly angiofibroma and squamous cell papilloma. These tumours usually become symptomatic long before they invade the base of skull. When skull involvement is minimal, they can be removed through the nasopharynx. If there is marked intracranial extension, a combined approach will be necessary to ensure complete excision.

The incidence of nasopharyngeal carcinomas is low, being about 0.01% of all cancers. They are either epidermoid carcinomas or lymphoepitheliomas. The latter seems to be more prevalent among Mongoloid races. The tumour originates from the nasopharyngeal epithelium and invades the base of the skull through the foramina and also metastasises to the regional lymph nodes. Usually they are detected late, after intracranial extension has occurred. Almost all the cranial nerves may get involved.[39] Hard lymph node enlargement high in the neck may be the first symptom. Quite late in the disease, dysphagia, nasal obstruction and epistaxis may occur.

The diagnosis is made by local inspection and palpation of the nasopharynx and from evidence of erosion of the base of the skull in plain X-ray films. CT reveals the bony erosion and the soft tissue mass both intracranially and extracranially and the displacement of neural structures. SPECT is superior to CT in detecting early bone involvement by showing markedly increased focal radiotracer uptake in regions of bone involvement.[111] Differentiation from other similar lesions, e.g. chemodectoma or chondrosarcoma, is difficult and a biopsy is necessary. Nasopharyngeal carcinoma is primarily managed by radiation therapy with curative doses of 60–70 Gy (6,000–7,000 rads) delivered over a period of 6–7 weeks. Intensity modulated radiotherapy is being increasingly used in recent days along with chemotherapy for treating nasopharyngeal carcinoma. Better prognosis is seen in younger patients and those without lymph node metastasis at presentation.[50]

Oncocytic Schneiderian Papilloma

Epithelial cells of cylindrical cell papilloma are oncocytes, which arise from the sinonasal respiratory epithelium, hence the term oncocytic Schneiderian papilloma. This is a rare benign neoplasm of the nose and paranasal sinuses. Lesions arising from the nasoethmoidal space can extend to the anterior skull base through bone dehiscence with intradural invasion and orbital space involvement (Figs 6A to D). The clinical behaviour is comparable to inverted papillomas for local recurrence and malignancy co-existence. Surgical excision is the treatment of choice.[9]

Sinonasal Mucosal Melanoma

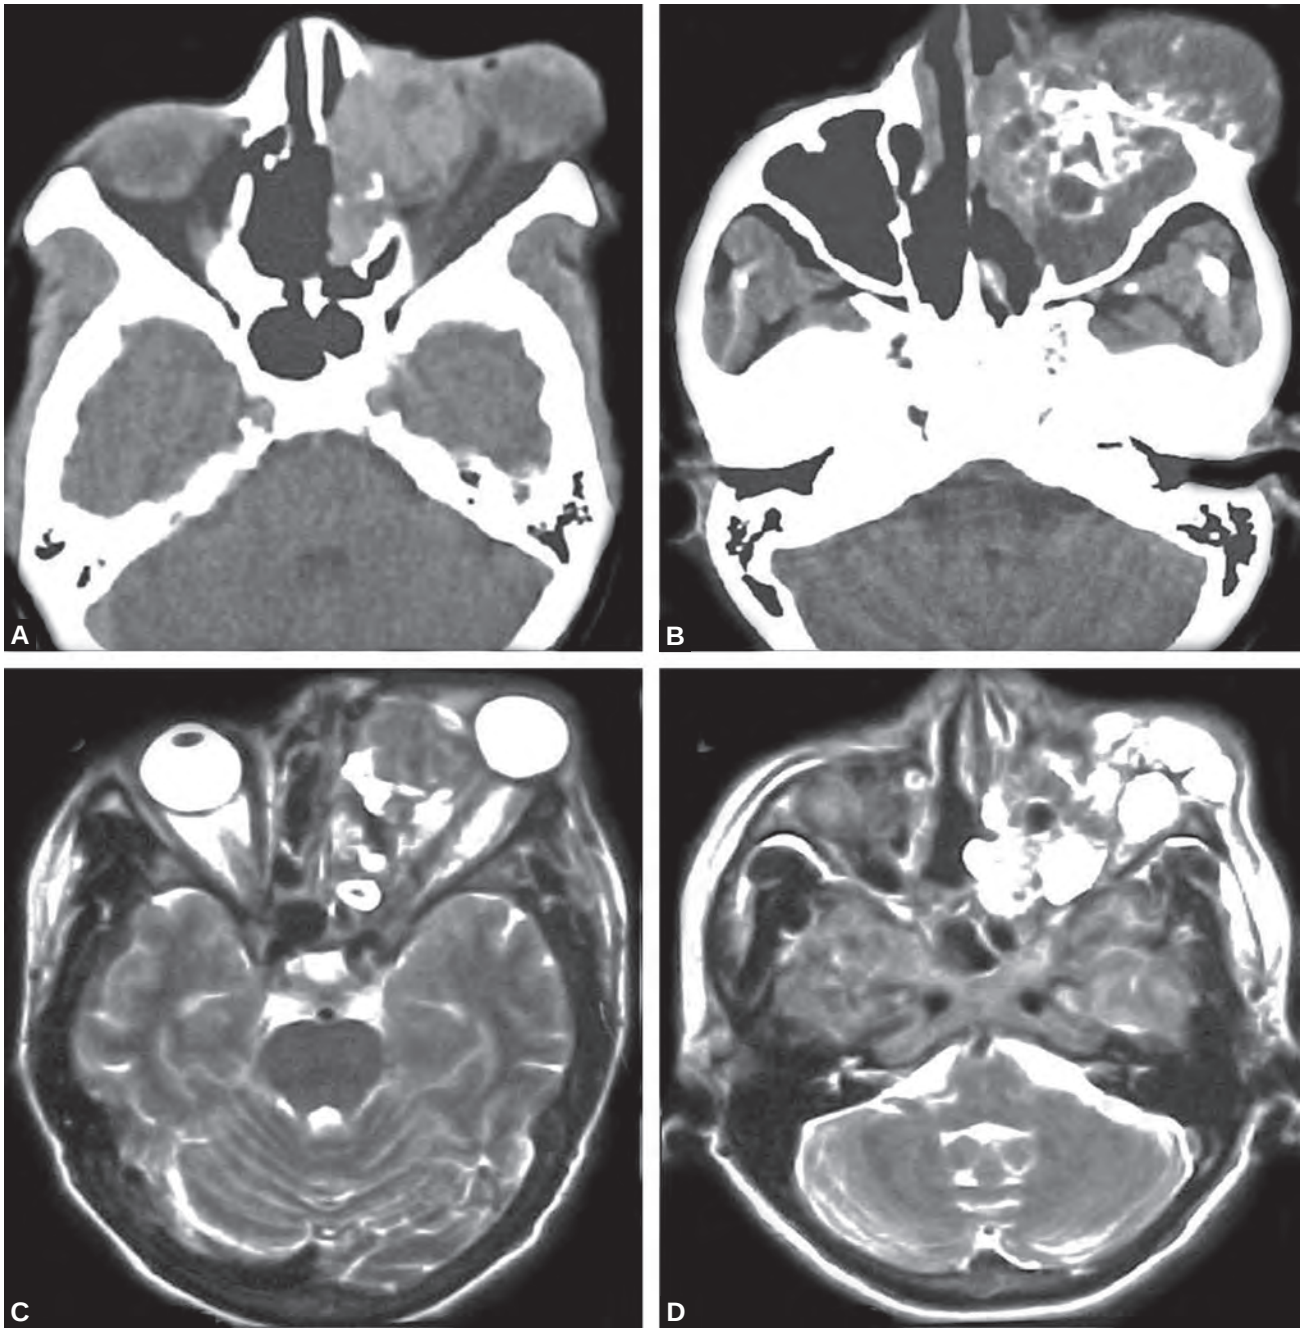
The most common presenting symptoms are epistaxis and facial pressure, mass lesion and obstruction. The most common anatomic locations are the maxillary sinus and nasal cavity. Seventy-two per cent of tumours extend to the skull base, frontal sinus, orbit or cranium. Tumour size ranging from 0.5 to 5.0 cm requires medial maxillectomy and an appropriate approach to the skull base is required to excise the tumour extending to the skull base. Chemotherapy with alpha interferon along with radiotherapy is an effective treatment.[90]

Carcinoma of the Paranasal Air Sinuses

These tumours involve the frontal, ethmoidal or the sphenoidal air sinuses and arise from the sinus epithelium. They invade the bony septae and adjacent walls and also the base of skull. Headache, epistaxis, rhinorrhoea, nasal obstruction and anosmia are the chief complaints. These tumours are best imaged by CT in the coronal plane and better still by MR.[98] Differentiation must be made from metastatic carcinoma, lymphoma, myeloma, osteosarcoma, chondrosarcoma and esthesioneuroblastoma.[12] Survival depends on the histopathological type of the tumour. Squamous cell carcinoma has the worst outcome, whereas adenocarcinoma and glandular carcinoma have better outcome and low recurrence after treatment. Patients with undifferentiated carcinoma exhibited an intermediate survival. Meta-analysis by Dulguerov et al. confirmed that surgery alone or surgery with radiotherapy has better local control and cure rates than with radiotherapy alone. Patients with skull base extension have a worse prognosis. In patients with high nasal and ethmoid carcinoma, craniofacial resection by combined cranial and transfacial approaches has become a routine procedure in a few institutions.[17]

Malignant Sweat Gland Tumour (Hidradenocarcinoma)

Malignant sweat gland tumours are rare neoplasms with high recurrence and metastasis rates. Nearly 50% of dural based hidradenocarcinoma have local brain invasion. The pathogenesis of these tumours is thought to be from ectopic sweat gland cells entrapped in the dura mater, as there is no scalp or skull bone involvement at presentation. Magnetic resonance imaging reveals a heterogeneous intense dural-based lesion in both T1- and T2-weighted images.[69]



Figs 6A to D: CT scan and MRI of a patient suffering from papilloma, arising from the paranasal sinuses, with extension into the orbit, causing proptosis

Orbital Rhabdomyosarcomas

Orbital rhabdomyosarcomas, being the most common primary orbital malignancy in children, form 8% of all childhood malignancies. They have a propensity for local spread to the skull base and parameningeal spread often resulting in a worse prognosis. MRI shows the extent of the lesion while CT scan shows bony erosion. In patients with limited disease, multimodality treatment including surgery, chemotherapy and radiotherapy need to be given to improve the outcome and quality of life. In patients with extensive skull base involvement metastatic workup needs to be done and a decision has to be taken on an individual basis.[120]

Haematogenous Metastasis

The usual primary sites for skull metastases are the breast, the lungs, the prostate, the thyroid and the kidneys. The skull metastases are osteoblastic when the primary is in the prostate, breast or gastrointestinal tract or osteolytic when they arise from carcinoma of the lung, uterus, thyroid, pancreas and kidney or from malignant melanoma.[33,123] Since the close attachment of the dura mater to the cranial bones, malignant deposits in the skull may invade the dura.

Osteolytic metastases to the skull are typically seen in plain X-ray films as multiple radiolucent areas with poorly defined margins. The size and degree of

radiolucency is variable and it is estimated that more than 50% demineralisation must occur before a lesion could become radiographically evident.[63] The larger lesions are quite typical in appearance, but lesions less than 5 mm and confined to the diploe are very much like multiple myeloma. Osteomyelitis of the skull may also have a similar radiographic appearance, but bone destruction appears later in the disease and clinical manifestations of severe pain, a soft tender swelling and constitutional symptoms occur earlier.

Osteoblastic metastases appear radiographically as multiple, poorly marginated areas of slightly increased density. On CT, the bone shows slight thickening. In some cases, mixed lucent and sclerotic areas appear, e.g. metastases from carcinoma of the breast. Although metastases can affect any part of the skull, they are found to be common in the vault. In the base, the common sites are the dorsum sellae and the clivus, where the radiographical appearance may be mistaken for demineralisation due to chronic raised intracranial pressure.

Conventional radiographs are positive only in 60% of cases of calvarial metastases and CT in 85%.[122] It is important to view the images at "bone window" setting and intravenous contrast infusion is necessary to show extradural and scalp extension[101] (Figs 7A to D). Although radionuclide bone scanning is more sensitive, it lacks the specificity and anatomical configuration. Biopsy of the skull lesions may be needed to establish a diagnosis. A complete excision of the lesion can be done and the treatment correlated with that of the primary disease. Local palliative radiation may be useful to relieve pain and symptoms of nerve compression at the base of the skull.

Lymphoma

Involvement of bone is a common late feature in disseminated lymphomas and occurs in 10–15% in Hodgkin's and 7–25% in non-Hodgkin's lymphoma.[55] Skull radiography shows areas of osteolysis and it is not uncommon to find an admixture of sclerotic areas also. CT shows the lesions at the stage of diploic permeation and also delineates extradural and scalp extension.[55] The more aggressive lymphosarcoma and reticulum cell sarcoma rarely involve the skull. Treatment consists of local radiotherapy 30–40 Gy (3,000–4,000 rads) over 3–4 weeks, with chemotherapy for wide spread disease.

Leukaemia

Leukaemia in childhood manifests with skeletal pain, anaemia and fever. Calvarial lesions are uncommon and, when they occur, they appear as ill-defined areas of rarefaction with peripheral new bone formation similar to a neuroblastoma.[33] Low dosage radiation may give rise to symptomatic resolution. Chemotherapy of the systemic disease produces a more effective remission.

Myeloma

Multiple myeloma is the most common primary malignancy of the skeletal system. It affects males more commonly and occurs between the ages of 40–60 years. The skull is a common site for these lesions. Pain, weight loss, palpable tumours, anaemia, hypercalcaemia, hyperglobulinaemia and Bence Jones proteinuria are the usual features. Biopsy of the lesion or bone marrow biopsy will usually clinch the diagnosis. Skull radiography usually shows multiple punched out areas of bone destruction of different sizes and density. Less commonly, a solitary tumour about 2–3 cm in diameter may occur. In more than 80% of cases the solitary type lesion eventually becomes multiple.[66] Solitary plasmacytomas are treated with radiotherapy in curative doses of 50 Gy spread over 5 weeks. Multiple myeloma is treated with chemotherapy, melphalan and prednisone being the most commonly used drugs. Frequently, skull involvement is treated palliatively with radiation doses of 30 Gy in 2 weeks.[30,88]

Neuroblastoma

It is a common tumour of childhood. Skull metastases often precede detection of the primary adrenal tumour. Typically, the child presents with periorbital ecchymosis and an associated abdominal mass. Diffuse nodular lucencies are seen in radiographs.[33] The lesions are highly vascular and they lift up the periosteum, thus producing radial bone speculation extending into the soft tissues. A similar spread occurs on the inner aspect of the skull and the cranial sutures get invaded producing diastasis of sutures.[20] Although the dura often resists the spread of the lesion, spontaneous intratumoural haemorrhage may rupture through the dura into the brain parenchyma (Figs 8A and B). CT is useful in detecting the gross thickening of the skull, the extent of the intracranial mass and also complications like haemorrhage and compression of dural venous sinuses.

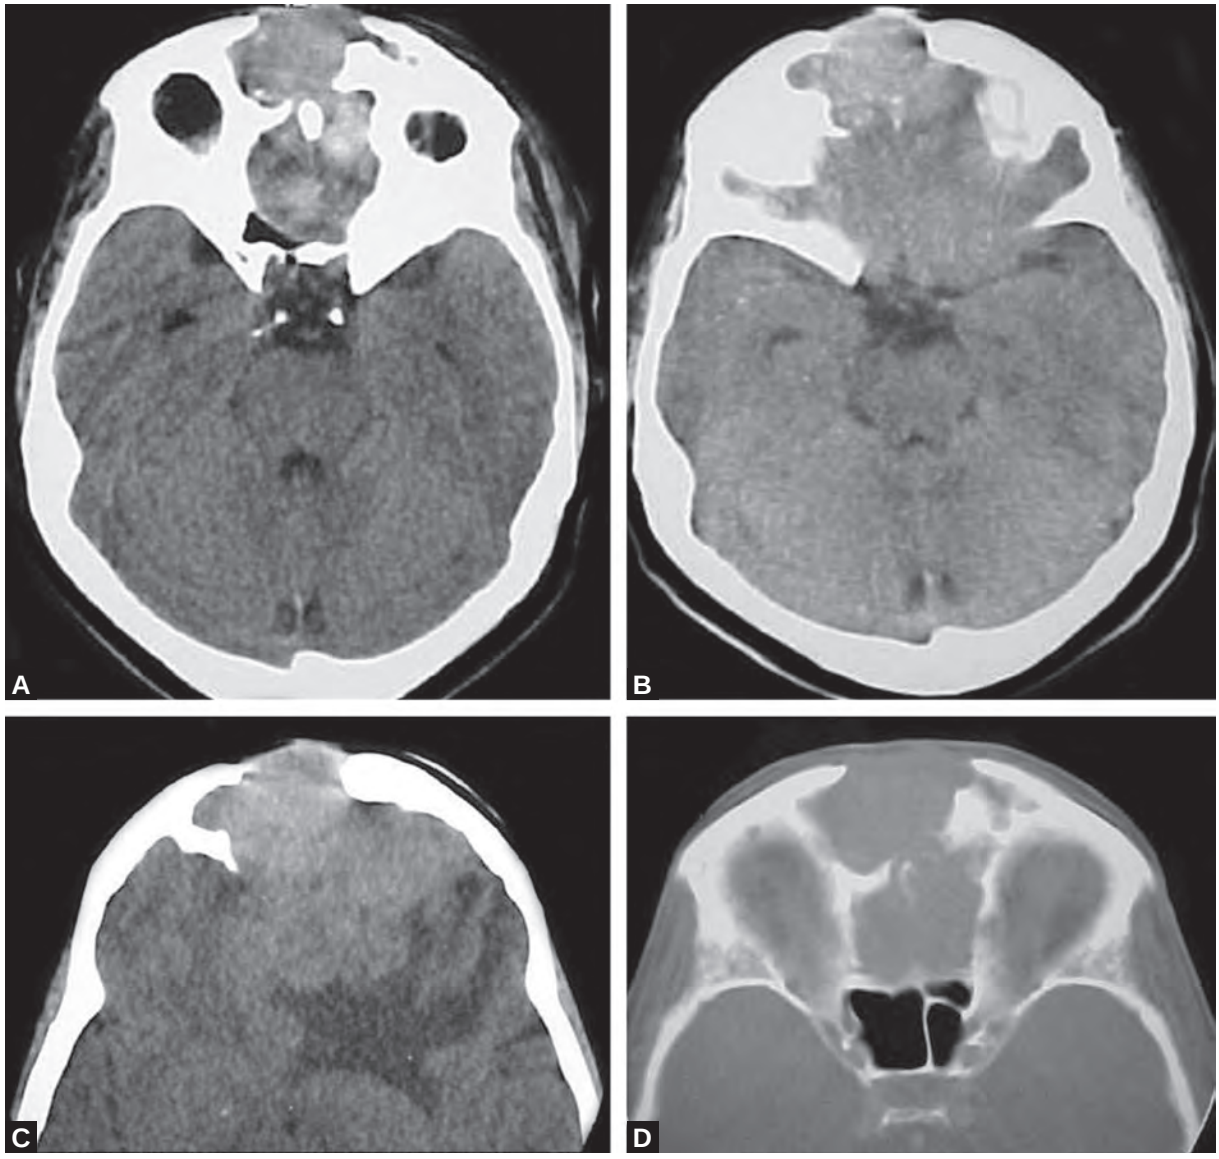
Spontaneous resolution of a neuroblastoma into more benign forms has been known to occur occasionally, as the patient matures; but involvement of the skull suggests a poor prognosis. Local irradiation and systemic chemotherapy are the treatment of choice.

CONDITIONS SIMULATING SKULL NEOPLASMS

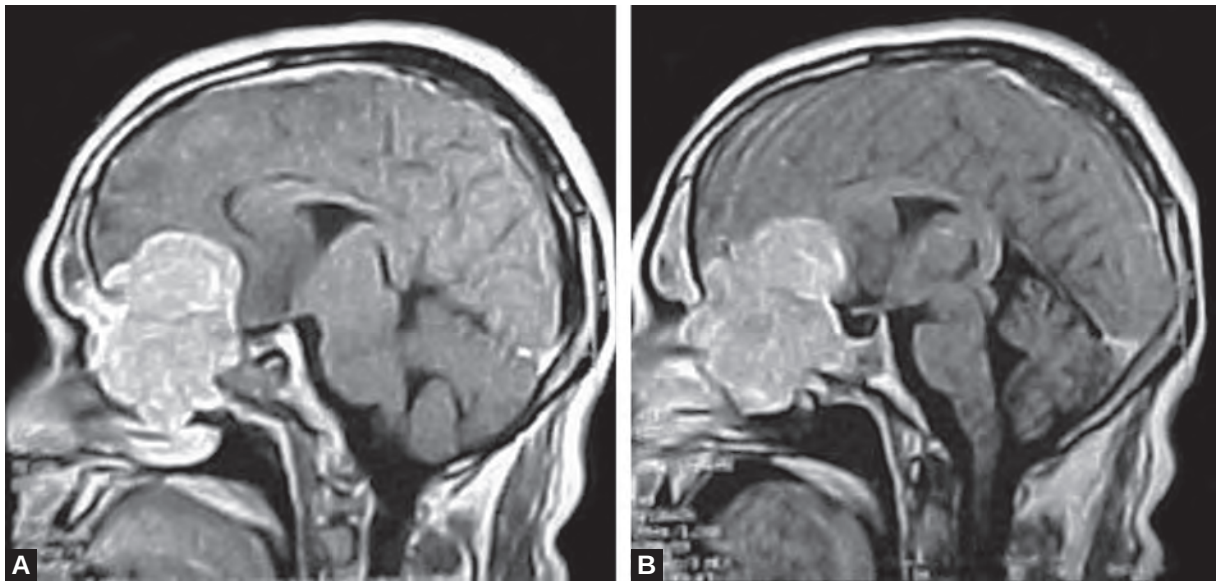
It is not uncommon to find lucent defects in plain films that are clinically insignificant and not neoplastic. On the contrary, in many neoplasms of the skull, in the early stages, symptoms are either absent or of non-specific nature. Therefore, it is important to understand and recognise the conditions which may simulate neoplasms.

Osteomyelitis

Radiological changes appear long after the onset of clinical signs and symptoms.[33,123] In the plain films, multiple nodular areas of lucencies appear in the outer table or



Figs 7A to D: CT scan of the brain with bone cuts showing osteolytic metastatic lesion in the frontal region in a patient who was treated for breast carcinoma



Figs 8A and B: Contrast MRI of the brain showing contrast enhancing lesion involving the anterior skull base and causing erosion with extension to the sinuses and intracranially. Transnasal biopsy done; HPE: Neuroblastoma

diploe.[123] CT demonstrates these early lesions clearly. In young children, the sutures usually limit the process, but in adults contiguous spread to adjacent bones is common. In course of time, the nodular lucencies condense into a large defect and visible and palpable oedema of the scalp (Pott's puffy tumour) occurs. Inward spread leads to an extradural empyema or granuloma. CT shows this as a biconvex extradural hyperdense mass with marked peripheral contrast enhancement. Poorly defined sclerosis occurs at the edges of the bone. Practically no subperiosteal new bone formation occurs. Sequestrum formation is uncommon, as the skull is very vascular. Their radiological appearance may remain stable or endosteal regeneration may continue to occur in healed osteomyelitis.

Tuberculosis, syphilis and other low grade chronic infections appear on radiographs as irregular, poorly defined areas of sclerosis. Sometimes, a central area of lysis may be present. Soft tissue thickening may be minimal or absent.

Traumatic Conditions

Cephal Haematoma

In the newborn, it results from birth injury due to forceps delivery and is commonly seen in the parietal bone and is limited by the sutures.[35] Initially, the X-rays show a soft tissue shadow overlying the bone. About a week later, calcific edges are seen arising from the sutural areas and these gradually project into the soft tissues of the scalp, resulting in a shell-like calcification completely bridging the mass.[123] Simultaneously, there is gradual resorption of the inner table with progressive remodelling. Rarely, a deformity persists with a radiographic appearance not unlike fibrous dysplasia or epidermoid tumour.[16] A review of previous skull radiographs and clinical history should aid in the differential diagnosis.

Leptomeningeal Cyst (Growing Fracture of the Skull)

A linear fracture of the skull in infants may be associated with a laceration of the dura and the brain pulsations may herniate a pouch of arachnoid, which may enlarge and widen the fracture and form a cystic collection under the scalp. Varying degrees of pressure atrophy of the brain occurs, resulting in a subdural cystic collection. The plain films show an area of lucency in the skull with scalloped margins and a soft tissue shadow outside the skull.[92] CT shows the intracranial porencephalic cyst and atrophic changes in the ventricles. Occasionally, these cysts cause expansion between the tables of the skull bone, producing an intraosseous leptomeningeal cyst.[54] This condition requires surgery and the results are often rewarding if the surgical principles are strictly followed.[118]

Vascular Diseases

Vascular Impressions in the Skull

Normal vascular structures and vascular tumours of the scalp, dura and brain produce impressions on the skull and may simulate the radiographic appearances of skull tumours. Pacchionian granulations produce focal thinning of the inner table with slightly lobulated margins. Venous lakes are wider and they invade the inner table with sloping margins. The arachnoid granulations occasionally involve the outer table also. They are commonly seen in the parietal parasagittal regions and in the occipital squama and occasionally, more laterally.

Sinus Pericranii

It is a congenital defect involving the skull, containing abnormal emissary veins which connect an intracranial venous sinus, commonly the superior sagittal sinus in the frontal region with a cluster of veins or a venous angioma in the extracranial space. Typically, the veins bulge as a swelling in the recumbent posture and disappear in the erect posture.[92] A cluster of smooth sharply marginated circular defects in the midline of the frontal region, seen in plain skiagrams, should suggest the diagnosis.

Histiocytosis X

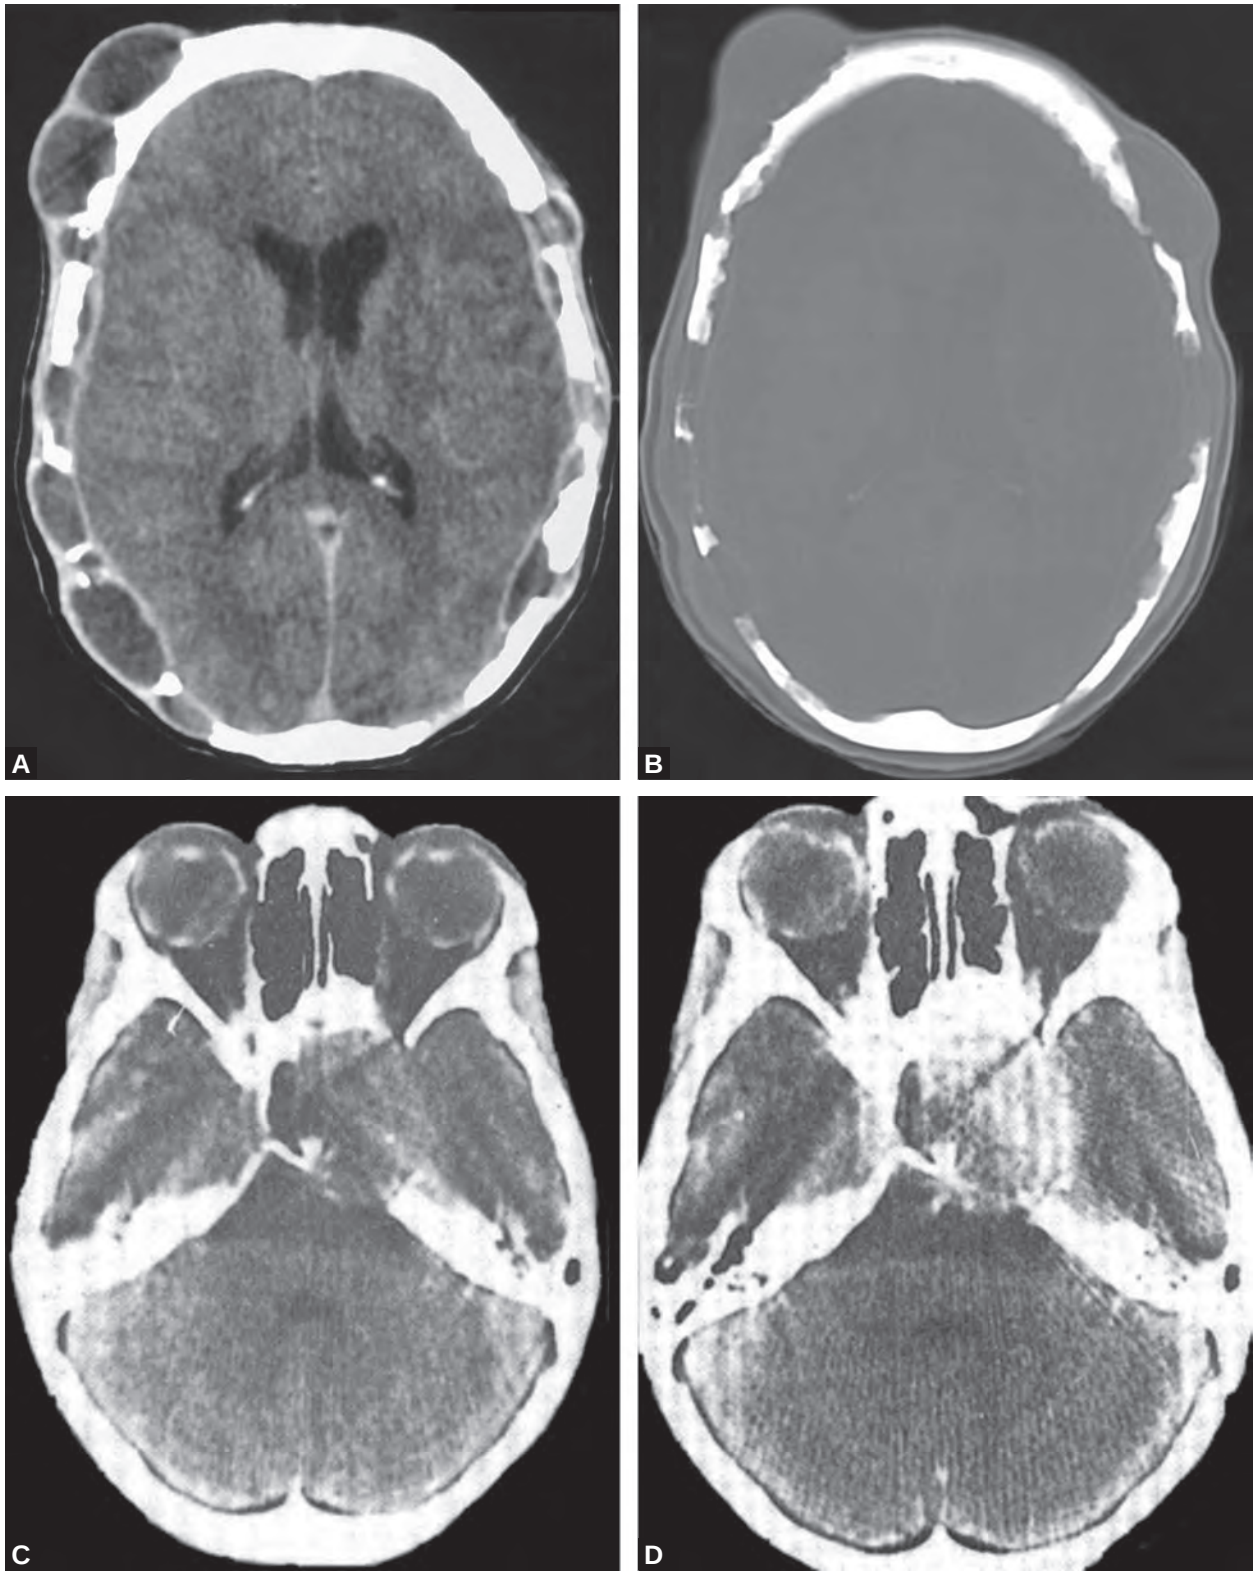
This disease complex comprises of Hand-Schuller-Christian syndrome which has associated diabetes insipidus, Letterer-Siwe disease and eosinophilic granuloma.[73,74] The first two occur in young children as multiple recurrent areas of skull involvement. Eosinophilic granuloma occurs as a solitary non-recurring lesion in older children and young adults. Co-existence of psoriatic arthritis and eosinophilic granuloma has been observed and an autoimmune mechanism is thought to be an aetiological factor.

Eosinophilic granuloma is manifested by local tenderness and pain. Skull radiographs show an irregular area of rarefaction without any sclerosis. Tangential views of the skull and the CT scan show the edges of the lesion to be bevelled, due to differential involvement of the outer and inner tables.[33,123] Sclerosis is, however, seen at the time of healing of the lesion. The solitary lucent lesion may be difficult to differentiate from myeloma or a metastatic deposit. Hence, it is important to establish a diagnosis by complete excision and histopathological examination. Radiation therapy in small doses, 10 Gy (1,000 rads) over 1 week is curative.

The multiple recurrent type of lesion seen in younger children often involves the frontal bone and spreads extensively, showing clear cut but irregular edges described as "map like" or "geographic skull" (Figs 9A and B). Soft tissue masses may become palpable, when the outer table gets perforated. Orbital involvement produces proptosis. The facial bones and paranasal sinuses eventually get involved[33,123] (Figs 9C and D). Other parts of the skeleton are involved simultaneously. Following diagnostic biopsy, systemic chemotherapy with prednisone, vincristine and cyclophosphamide is usually given. Local radiation is given as palliation.[30]

Sarcoidosis

This is another condition which destroys multiple areas of bone. Skull involvement is rare and is seen as multiple punched out areas of bone rarefaction.[94] The growth of such lesions is very slow and may remain unchanged for several years.



Figs 9A to D: (A and B) CT scan of the brain with bone cuts of a patient with histiocytosis X showing multiple osteolytic lesions with beveled edges and soft tissue swellings. (C and D) Plain and contrast axial CT scan of a child with histiocytosis X showing an enhancing lesion in the sella and the right para sellar region

Osteitis Deformans (Paget's Disease)

This disease was first described by Sir James Paget in 1877. The aetiology is still not known. The patients are usually of middle age, men being more frequently affected than women. The disease is multicentric, affecting the pelvis, the femora, the vertebral column and more commonly the skull.[31,93] It starts as a diffuse mottled thickening of bone in the frontal or occipital area or as irregular patches or lysis which give the appearance of a geographical skull when viewed on radiographs. After some months or years, patchy sclerosis develops, gradually progressing to produce gross thickening of the skull.

The new bone is soft and the involvement of the base of skull leads to invagination. The skull loses its three tabled architecture in the late stages (Figs 10A and B). Differential diagnosis includes fibrous dysplasia of mixed type, mixed blastic and lytic metastases and healing stage of hyperparathyroidism. Widespread involvement of the vault and the base, gross thickening and distortion of the normal bony architecture and the much older age of the patients help in differentiation.[39,123]

Pain and asymmetric enlargement of the skull and deafness and blindness due to foraminal involvement may occur. Involvement of the axial skeleton may produce an ape-like appearance. When there is widespread bony involvement, the level of serum alkaline phosphatase is considerably raised. Except for neural decompression, this condition usually does not need treatment. Osteogenic sarcoma may occur as an infrequent sequel.[127]

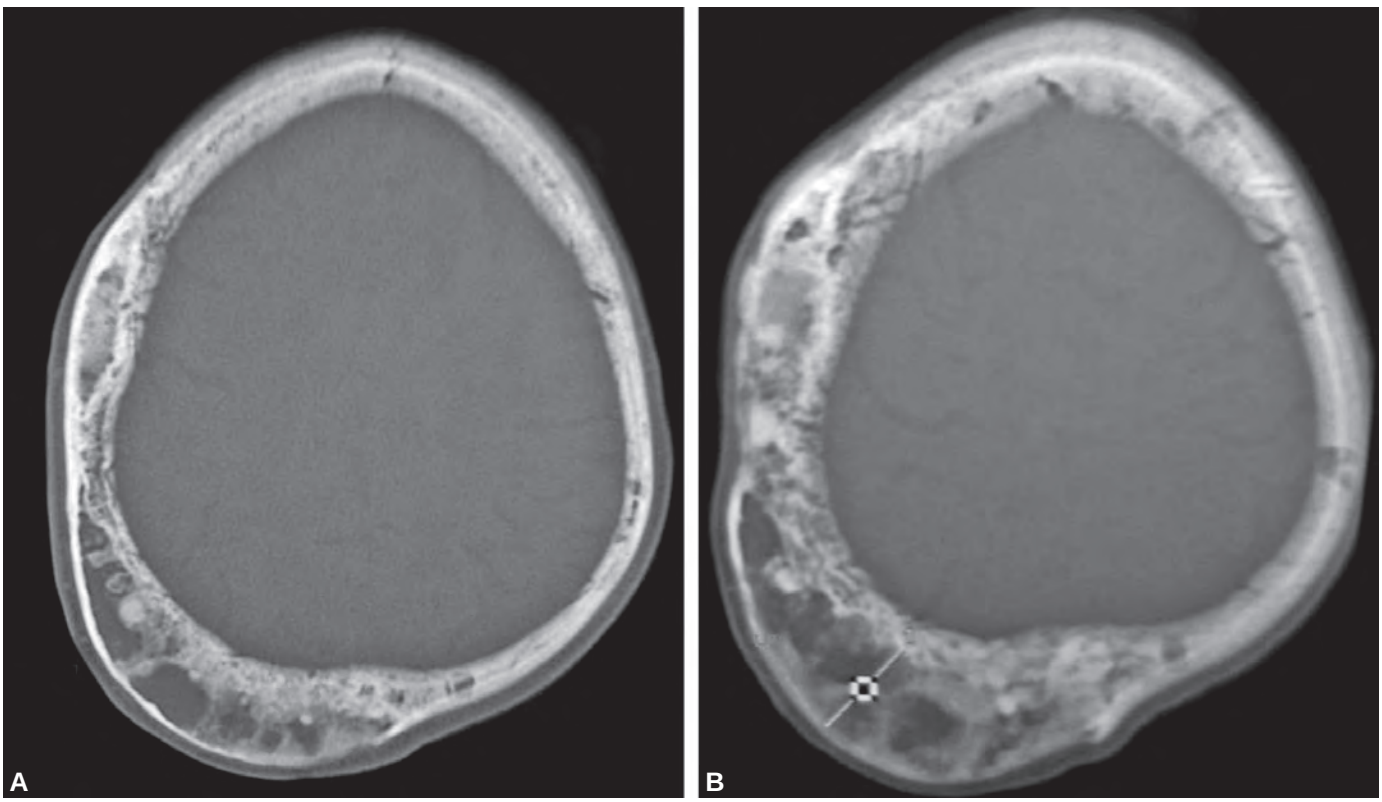
Fibrous Dysplasia

It is a benign disorder of bone commonly seen from childhood to the third decade. Normal bone is replaced by fibrous connective tissue with varying degrees of osseous metaplasia. The skull alone may be involved, but usually other parts of the skeleton are also affected.[84] The radiographic pattern may be cystic, sclerotic or mixed.[70] The cystic type mainly affects the cranial vault. It is seen in plain films or CT as a focal homogeneous widening of the diploic layer with gross thinning of the outer table and relatively less involvement of the inner table. The margins of the lesion are ill defined and gradually taper into the surrounding of the skull.

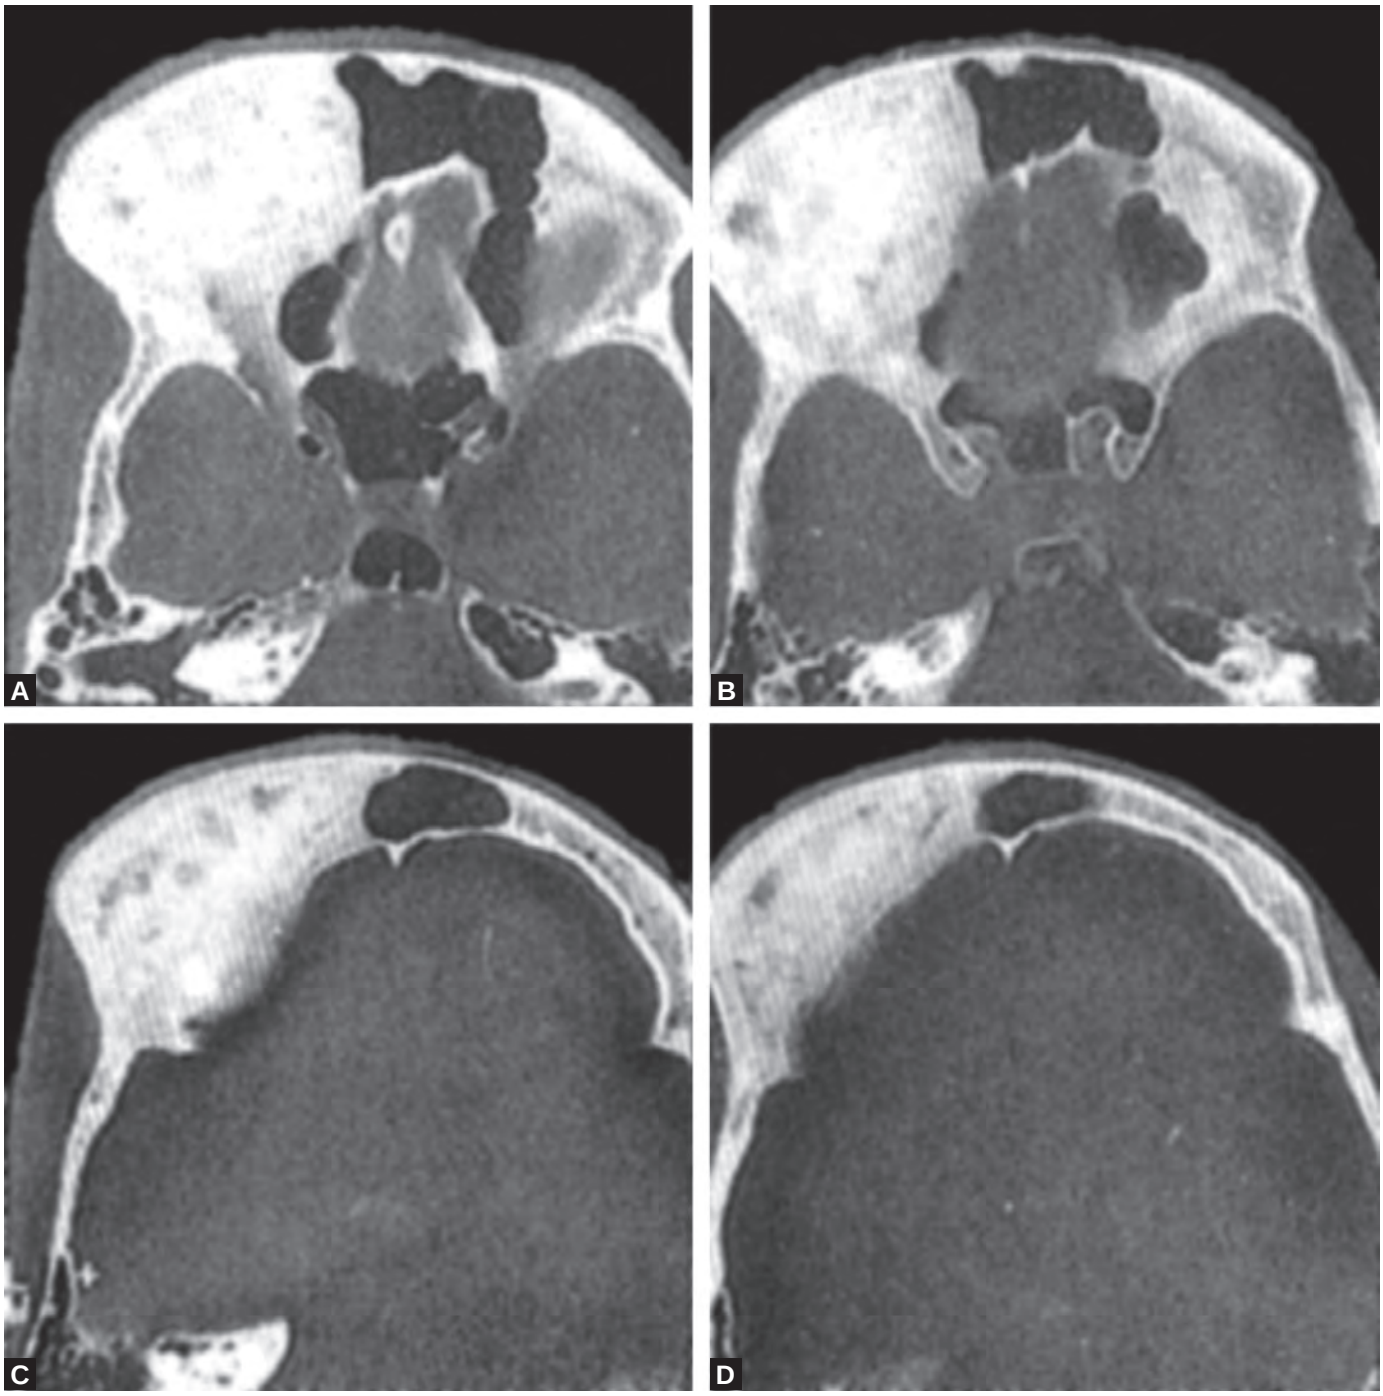
The sclerotic variety involves the skull base and facial bones, causing diffuse bilateral thickening of the floor of the anterior and middle cranial fossae. Despite gross involvement of the bones of the base of skull, neural structures are rarely compressed. The optic nerve may be compressed when the optic foramen is involved. When unilateral, the bone thickening may be difficult to differentiate from the hyperostosis due to a meningioma (Figs 11A to D).

The mixed type is least common and it involves the vault of the skull more often. The diploe is widened and the outer table is thinned. There are patches of lucent and dense areas as in Paget's disease, but they are more sharply defined and well localised.

Histologically, fibrous dysplasia appears as multiple areas of fibrous tissue contained within islands of bone with evidence of both blastic and clastic activity. The condition tends to stabilise at a certain stage with few instances of progression after adolescence.[70,84] Usually, no treatment is advised except in the case of orbital compression or neural involvement. Sarcomatous change rarely occurs. If active enlargement or local inflammation occurs, excision and cranioplasty is advised. It is important to remember that the involved bone may be vascular and one must be prepared to encounter considerable blood loss during the operative procedure. When it is localised some authors call it ossifying fibroma.[126]



Figs 10A and B: CT bone cuts in a patient with Paget's disease



Figs 11A to D: Axial CT scan bone windows showing the thickened bone in a patient with fibrous dysplasia

Hyperparathyroidism

This metabolic abnormality of calcium and phosphorus is characterised by elevated blood calcium and lowered blood phosphorus, and there is increased loss of both ions from the body. Bony changes generally occur. In the skull, wide areas of granular osteoporosis occur. These may coalesce to form large areas of lysis forming "Brown Tumours" (osteitis fibrosa cystica).[15,33] During the healing process, patchy areas of sclerosis occur superimposed on the diffuse granular osteoporosis. Patients with secondary hyperparathyroidism due to renal failure may also show such patchy sclerosis.[128]

Mucocoele

This condition occurs in any one of the paranasal air sinuses, frontal, frontoethmoidal or sphenoidal sinuses in that order. As a result of obstruction to the outflow tract, the mucoid secretions collect in the sinus cavity and gradually enlarge, thinning out the walls of the sinus. In the case of the frontal sinus, a small osteoma at the frontonasal duct may be the obstructing agent.[100] The anterior wall bulges out forming a visible swelling on the forehead (Figs 12 and 13A to D). The posterior wall may also bulge and compress the dura. Sometimes the mucocoele may burst through the dura. Ethmoidal sinus mucocoele may occur alone or in conjunction

with frontal sinus mucocoele. It produces proptosis. Mucocoeles of the sphenoidal sinus are rare and they erode into the sella and parasellar regions, the optic foramen and the superior orbital fissure. In certain instances, with spontaneous drainage, regression of the mucocoele and later recurrence of the swelling may occur. When infected, it may form a pyocoele.

Plain skiagram shows enlargement and opacification of the sinus and a soft tissue swelling. A sphenoidal lesion may erode the optic foramen and enlarge the superior orbital fissure.[11] The floor of the sella may bulge upwards and appear eroded. The location and extent of the lesion are seen well on the CT. The cystic contents, however, appear denser than the usual cysts in the cranium, due to the high protein content of the fluid.[87] Treatment consists of complete excision of the mucocoele, along with all the sinus lining and obliteration of the cavity. Where the skull defect is large, it is better to close it with autogenous bone graft than with acrylic material, as the mucocoele is often potentially infected. Even if it is not infected, care must be taken not to spill the contents into the subarachnoid space as this may result in chemical meningitis. Mucocoeles of the sphenoidal sinus are better treated through the transnasal route.

Neuroectodermal Dysplasias

Skull bone involvement in neurofibromatosis is common and may manifest as a deficiency in the orbital wall due to the local erosive effect of an overlying tumour, or as a sharply marginated round or oval defect in the lesser wing of the sphenoid or in the region of the lambdoid suture due to bone dysplasia.[10,36,58,61] The lesions may rarely mimic skull neoplasms and a CT scan clearly shows the margins of the lesion and the absence of a soft tissue mass.

Osteosclerotic nodules may be seen on plain films in cases of tuberose sclerosis.[37] These may be mistaken for the peripherally located calcified glial nodules which are so typical of this disease. CT clearly defines the location and nature of the process.

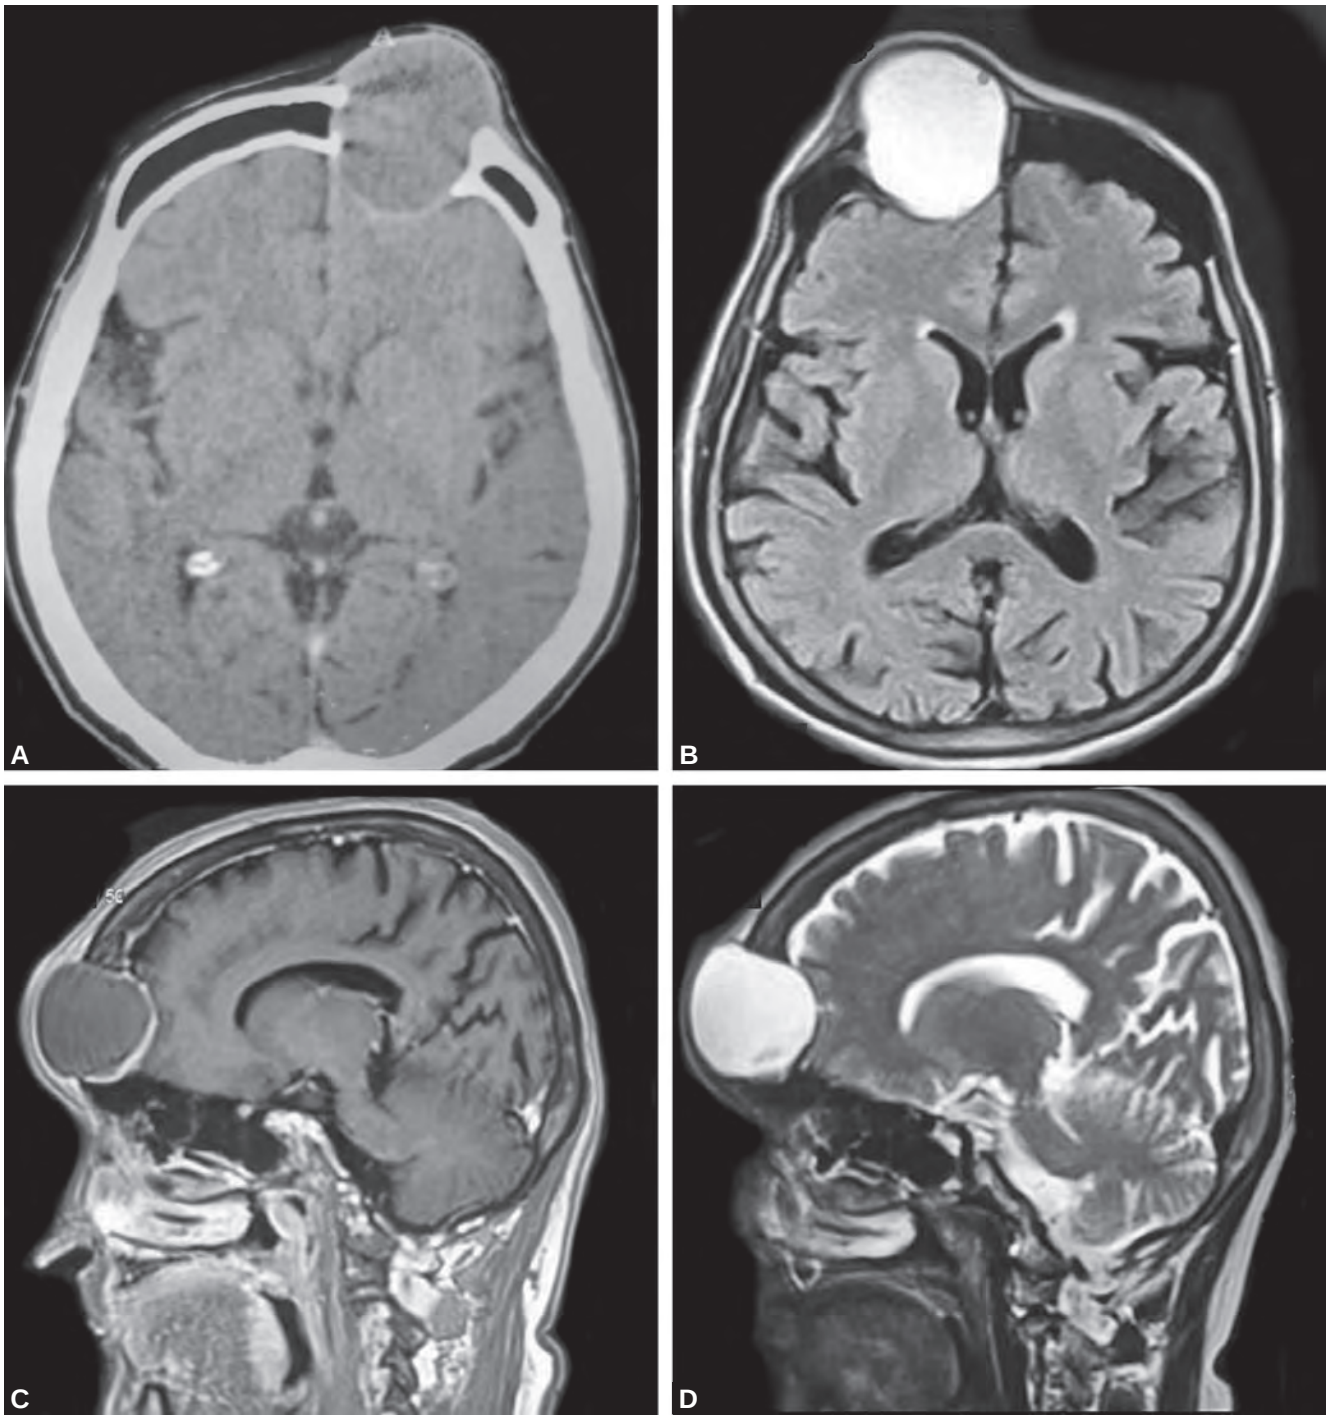
Haemolytic Anaemias

In infants with severe anaemia, the cranial diploe provide a major source of red blood cell production. The abnormalities are marked in thalassaemia or Cooley's Mediterranean anaemia. The diploe widens with resultant atrophy of the outer table. The trabeculae of the diploe assume a radial striated pattern and are seen perpendicular to the inner table which remains intact. The occipital bone inferior to the internal occipital protuberance is spared, as marrow is absent at this site. The tremendous enlargement of the marrow prevents pneumatisation of the air sinuses. Similar changes have been observed in chronic iron deficiency anaemia and in infants with congenital cyanotic heart disease.[102]

Hyperostosis Frontalis Interna

This is an idiopathic benign condition seen in the skiagrams of middle aged and elderly women. There is

Fig. 12: Coronal CT scan showing frontal mucocoele



Figs 13A to D: (A) CT scan of the brain showing frontal mucocoele. (B to D) MRI axial T2, sagittal T1, T2 showing frontal mucocoele

diffuse hypertrophy of the inner table, commonly seen in the frontal bone, but sparing the midline. It is not of any clinical significance. When it occurs on one side, the differentiation from meningeal hyperostosis of the inner table becomes difficult. CT will help to elucidate the condition.

Petrous Apex Cholesterol Granuloma

Cholesterol granuloma produces symptoms of trigeminal, facial and abducens nerve palsy and may not affect the auditory nerve. CT shows a non-enhancing, smooth-walled, expansile isodense lesion at the petrous apex with bilaterally well pneumatised mastoids. Asymptomatic patients can be observed till the condition becomes symptomatic. Drainage and permanent ventilation are the goals of treatment in symptomatic patients. Those with good hearing can be treated by the infralabyrinthine approach. The infratemporal fossa approach is advocated in patients with extensive disease and internal carotid artery involvement. Complete removal is indicated in selected cases where placement of a drainage tube is not feasible.[43,51]

180 Clival Chordomas

Chandranath Sen

INTRODUCTION

Chordomas are rare primary malignant bone tumours that arise in the axial skeleton. They are believed to originate from remnants of embryologic notochordal cell rests and thus manifest epithelial as well as mesenchymal features.[27,35] Although chordomas are found throughout the axial skeleton, they are much more frequent at either end. It has been reported that 25–39% of chordomas arise in the clivus.[7,10,14,25,43] They are slightly more prevalent in males and can be found at any age, but the mean age incidence is 40 years. The incidence of chordomas in the clival location is 1/2,000,000 per year.[5,25]

These tumours are generally slow growing but are locally aggressive, due to the fact that the clinical course of a patient is typically punctuated by multiple local recurrences. Metastases are uncommon. Local recurrence is usually the cause of the patient's death.

NATURAL HISTORY

Untreated skull-base chordoma has a dismal outlook for survival. A Swedish epidemiological study reported that the survival of untreated chordomas at the skull base from the time of diagnosis is 6–28 months.[10] Among the 15 patients with skull-base chordomas, Dahlin reported only 2 surviving beyond 5 years after surgery and radiation.[7] Forsyth et al. reported on 51 patients treated with surgical debulking and radiation at the Mayo Clinic, between 1960 and 1984.[12] Overall, 5-year survival was 51% and 10-year survival was 35%. Patients who were younger than 40 years of age had a better survival with aggressive surgery and radiation. In a Scottish epidemiological study, O'Neill et al. found a mean 7.7 year survival of patients with clival chordomas.[29] McMaster et al. conducted a large US epidemiological study and reported 5-year survival of chordoma at 67.6% and it dropped to 13.1% by 20 years.[25] Although metastases have been reported in up to 43% of patients studied, most large surgical series that were reviewed indicate a much lower rate.[15,23]

PATHOLOGICAL FEATURES

These tumours are characterised by a lobular growth pattern of tumour cells that are arranged in clusters, chords and strands. The cells are large and contain abundant eosinophilic cytoplasm. Many of them contain large clear vacuoles and hence the name, "physaliferous". The nuclei may vary from small and hyperchromatic to large and vesicular. They are usually surrounded by a myxoid matrix. Three variants have been described on the basis of the histology: conventional chordoma, chondroid chordoma and dedifferentiated chordoma. Chondroid chordomas contain conventional chordomas surrounded by neoplastic hyaline cartilage occupying up to 75% of the tumour area.[2] The dedifferentiated tumours have tumour cells arranged in irregular nests in a collagenous fibrous stroma and resemble a poorly differentiated carcinoma. Immunohistochemistry is essential in confirming a diagnosis of chordoma. They stain positively for cytokeratin, epithelial membrane antigen, S-100 protein and vimentin.

CLINICAL FEATURES

The clinical features depend on the anatomical location of the lesion. Chordomas are classified as upper, middle, lower or craniovertebral junction and the symptoms and signs depend on the spread of the lesion. They have also been classified as basisphenoidal and basioccipital, depending on whether they arise above or below the spheno-occipital synchondrosis. Diplopia due to abducens paralysis is the most common symptom. The other clinical features that may be present are visual loss, pituitary endocrinopathy, chiasmal syndrome, cavernous sinus syndrome, nasopharyngeal mass, multiple cranial nerve involvement, brainstem signs, cerebellopontine angle involvement, hydrocephalus and lower cranial nerve palsies.[32]

IMAGING FEATURES

MRI and CT scans are the most important imaging studies for evaluating chordomas at the skull base. On the MRI scans, they usually appear as lobulated masses arising from the clivus. They manifest low signal intensity on T1-weighted images and have high signal intensity on T2-weighted images. They do enhance with the administration of gadolinium, but this occurs to a variable degree.[26] They can vary greatly in size and distribution. They often extend intracranially as well as extracranially into adjacent anatomical areas and also, sometimes,

intradurally. On CT images, they appear isointense on the non-contrast studies. There is irregular bone destruction at its site of origin, which may be in the midline of the clivus or eccentrically located. The tumour may also show areas of calcification. Differentiating chordomas from chondrosarcomas is often difficult due to the identical imaging appearance. Chondrosarcomas usually arise eccentrically at the petroclival synchondrosis.

PRINCIPLES OF SURGICAL MANAGEMENT

Radical surgical excision is the primary treatment of choice. Neoplastic location at the clivus, however, poses limitations to this goal. The tumour is often located in close proximity to many critical neurovascular structures and at a considerable depth from the surface. The tumours often reach a relatively large size by the time they are diagnosed and thus have a propensity to involve many contiguous anatomical areas such as the cavernous sinuses, retropharyngeal space, the occipital condyle and its articulation with C1. There may be substantial intradural extension with variable degrees of brainstem compression. The internal carotid arteries and the vertebrobasilar system are often intimately involved by the tumour. Not a single surgical approach provides access to all the regions of the skull base.

Thus, a variety of surgical approaches have been described. Since these are primarily extradural tumours, the surgical approaches are directed to this area. A single surgical approach may not be enough to achieve a radical excision. Depending on the size and anatomical extensions of the tumour, a combination of more than one approach may be needed, either at the same or separate sittings.[13]

The surgical approaches to this area are broadly divided into anterior midline and lateral approaches (Table 1).

Anterior midline approaches:

- Extended subfrontal
- Trans-sphenoidal[20,22]
- Endonasal endoscopic with image guidance[18,33]
- Transfacial
- Transoral[8]
- Transmandibular circumglossal retropharyngea[l9]

Lateral approaches:

- Frontotemporal with orbitozygomatic osteotomy
- Preauricular subtemporal and infratemporal[37,38]
- Presigmoid combined supratentorial and infratentorial
- Extreme lateral transcondylar.[34,39]

It is important for the surgeon to be familiar with all of these approaches. Each approach has its advantages and disadvantages. Each approach often permits access to a very specific area and thus requires detailed planning based on the imaging studies and the clinical status of the patient. Because of the location of major arterial and venous structures and also the passage of many cranial nerves, the approaches need to be carefully selected and tailored to the specific tumour in a patient. This is important in order to minimise the exposure and unnecessary manipulation of these structures. The surgical procedure usually involves three components: (1) surgical approach; (2) tumour resection and (3) reconstruction of the skull base. Each of these components has to be carefully planned and executed to ensure a successful outcome. Since these operations are complex and involve access through facial, pharyngeal and temporal bone structures, close collaboration with an otolaryngologist is very helpful.[21,22,24]

Table 1: Surgical approaches

	Approach	*Areas exposed*
Anterior midline approaches	Trans-sphenoidal	Sphenoid sinus, upper clivus
	Transoral	Lower clivus, foramen magnum, C1, C2
	Le Fort maxillotomy	Middle clivus with lateral extensions
	Mandibulotomy and glossotomy	Lower clivus, foramen magnum and upper 3 vertebrae
	Extended subfrontal (transnasal)	Sphenoid sinus, middle and lower clivus
	Endoscopic endonasal	Entire midline clivus from sella and upper clivus, down to foramen magnum
Lateral approaches	Frontotemporal, orbitozygomatic (anterior transpetrosal)	Upper clivus, parasellar
	Presigmoid transpetrosal (retrolabyrinthine or ranslabyrinthine)	Midclivus
	Subtemporal and preauricular infratemporal	
	Extreme lateral transcondylar	Lower clivus, jugular foramen, C1, C2

Surgical Approach

Based on the imaging studies, the location of the main tumour bulk is determined. The surgeon must determine the most efficient approach to this area that would provide direct access and then establish adequate visualisation and control of critical adjacent structures and thus allow radical tumour removal. Although tumour

removal is done in a piece-meal fashion, all the soft portions of the tumour, the surrounding bone and involved dura need to be removed. The incisions, bone exposures and removal are performed, also keeping in mind that an additional procedure may be needed if the entire tumour cannot be removed by this approach. Also, in the future, if there is tumour recurrence, additional surgery may be needed. These options should be kept open at this time. It is also important to note that the initial operation is usually the best opportunity that will ever exist for achieving a radical tumour removal.

Tumour Resection

These tumours are usually soft and gelatinous in consistency and can easily be removed by suction and curettage. They usually push soft tissue boundaries but have an indistinct border with the bone, which is the clivus in this area. Actual invasion of the arteries and cranial nerves is unusual, but the course of these structures can be markedly altered by the tumour. The cranial nerves may also get severely attenuated by the chronic tumour compression, to the extent that they may be difficult to identify and preserve. These tumours can also be compartmentalised by fibrous septae and may also extend in between the layers of the dura.

These extensions may be difficult to identify and can result in portions of tumour being left behind. It is, therefore, important to remove the tumour in a systematic manner starting in one area and then progressing to other areas, moving along certain landmarks that have been determined on the imaging studies. This strategy not only allows the possibility of radical tumour removal but also is beneficial for planning the radiation therapy. If any tumour is left behind, it is best to have this remnant in a localised area instead of being scattered throughout the surgical bed. This allows the radiation to be aimed at a specific area rather than spread out over a large area. Occasionally, the tumour may be vascular and fibrous or contain portions of calcification. Special precautions have to be exercised here, so that inadvertent injury to nearby structures is avoided. Although intra-operative stereotactic navigation and image guidance can be helpful, it is not a substitute for thorough anatomical knowledge.[40,41]

Reconstruction of the Skull Base and Potential Complications

After removal of these tumours, there is often communication into the pneumatic sinuses at the skull base, nasopharynx, the temporal bone, etc. There may also be a substantial dural defect that will need to be covered. The facial skeleton may have been disassembled for the approach. All these factors predispose to the development of cerebrospinal fluid fistulae and post-operative infections. Reconstruction is also aimed at the function and appearance of the patient. It is, therefore, extremely important to devote special attention and effort in reconstruction and closure of the wound. Much of this is already planned out at the time of the surgical approach and review of the pre-operative imaging studies.

If there is a dural defect, it should either be closed primarily or a dural graft should be used. Watertight closure is often not possible and, therefore, soft tissue layers are a helpful adjunct. This is in the form of free-fat graft or rotation flaps such as the pericranial flap, the temporalis muscle flap and the temporo-parietal fascial flap. Free-fat graft is preferred to free-muscle graft, since it is easily visible in the post-operative imaging studies. If the reconstruction is performed in a systematic manner, future recurrence of the tumour can be detected more readily in the subsequent MRI studies.

Bony reconstruction of the clivus or the central skull base is not necessary, provided a secure layered soft-tissue reconstruction has been performed. Loss of bone around the orbit will need to be reconstructed in order to prevent enophthalmos. Loss of bone from the external surface should be reconstructed to restore the contour and appearance of the patient. Usually, commercially available titanium mesh and plating systems are excellent for this purpose. Cerebrospinal fluid diversion by a lumbar spinal drain or an external ventriculostomy is often used during the early post-operative phase.

RADIATION TREATMENT

Historically, radiation has been used throughout the management of chordomas. Catton et al. in a series of 48 patients with cranial and spinal chordomas had a 100% failure rate with a median survival of 62 months using doses of 40–60 Gy.[3] Pearlman and Friedman showed that doses less than 40 Gy are inadequate and proposed that doses higher than 70 Gy were needed to control the tumour.[31] The optic nerves, chiasm, the brainstem and the pituitary gland represent limitations to such doses when the tumour is in proximity to these structures.

Although megavoltage fractionated photon radiation, as well as stereotactic radiosurgery has been used for the treatment of these tumours, the largest body of data exists for proton beam therapy.[16,19] The "Bragg Peak" effect allows a high dose to be delivered to the precise target site with no exit dose, making it an attractive modality for chordomas. Proton-beam irradiation seems to add to the length of survival of the chordoma patient. Its benefit is clearly seen in patients with residual tumour, but its effect on the patients with no obvious residual tumour is not definitely shown. The volume and distribution of the tumour are critical for the dose planning, as well as efficacy of the treatment.[17,28] The proton radiation data are quite encouraging with an excellent effect on tumour control. Fagundes et al. studied the patterns of disease recurrence after proton-beam treatment.[11] These investigators found only 1% lymph node metastasis and a 6% distant metastatic progression in their series. Surgical pathway seeding occurred in only 5% of cases. Local recurrence is by far the leading reason for failure of treatment in chordomas. This could be explained on the basis of undetected microscopic tumour that may have escaped the full radiation

dose or a biologically aggressive tumour. They found that the mean time to local failure was 24 months, which is in keeping with our findings in the present series.

It is important for the surgeon to plan the surgery in a way that the tumour is removed in a systematic fashion, such that the residual tumour, if any, is of a small volume and confined to a small region, to be ideally suited for the proton-beam therapy. In my personal experience of treating 71 patients, 56% of the patients who are alive without evidence of tumour recurrence have not received any form of radiation therapy. Among the 19 patients who have died, 14 patients (74%) received radiation after their surgery. Although most of the patients received proton-beam radiation, they represented a mixed group treated with a variety of radiation modalities. In actual practice, the use of radiation has varied amongst the authors. Al-Mefty[1] has advocated using proton therapy routinely after surgery, while Sekhar[36] and Crockard[5] have reserved use of radiation only when there was residual tumour identified in the post-operative scans.

CONTEMPORARY CASE SERIES AND SURVIVAL

We have treated 65 patients harbouring histologically proven clival chordomas between 1991 and 2005. Of these documented cases, 47 patients had typical chordomas, 8 patients had chondroid chordomas and 10 patients had dedifferentiated chordomas. There were 45 patients with tumours in the clivus and 20 patients with tumours at the craniovertebral junction (lower clivus, C1 and C2). The male to female ratio of patients was 1.8:1. The mean age of the patients at the first operation was 40.7 years (range 7–78 years). Forty-two patients were operated upon primarily and 23 patients had had prior surgery elsewhere. Considering both initial and recurrent operations 80 operations were performed by us on this group of 65 patients. The median time to follow-up from our first operation was 53 months (range 3–174 months).

Survival was significantly not influenced by age, sex or location of the tumour. It was, however, influenced by the degree of resection. The 5-year survival was 90% with radical resection compared to 52% with incomplete resection. Radical resection of tumour (no visible tumour in post-operative scans) was achieved in 59% and incomplete removal in 41%. Factors influencing the degree of resection achieved at surgery included tumour location (clivus vs CVJ), prior surgery, surgical approach (anterior, lateral or combined) and single- or double-staged operation. None of these showed a statistically significant association with degree of resection in our experience. It should be noted that the decision to use an anterior, lateral or combined approach and also whether to perform the operation in a single- or double-stage manner was made based on the size and distribution of the tumour.

Pre-operative tumour volume and the number of anatomical areas that were involved by the tumour had a statistically significant, inverse relationship to the likelihood of achieving radical resection. The median length of follow-up of the patients in the present series was 53 months. In this time, 19 (29%) patients have died from the tumour. Twenty-five patients (38%) are alive without evidence of residual disease and the remaining 21 patients (32%) are alive with residual tumour. We achieved radical resection in 38 patients (58%) at our initial operation, 33 of these (87%) are alive with 25 of those (66%) without recurrent tumour at the time of our writing. Thirteen (48%) of the 27 patients who had incomplete tumour resection are alive. Tumour recurrence has a poor prognosis.[11] There were 14 patients who had tumour recurrence after radical resection (37%), while 15 patients with incomplete tumour resection (55%) had regrowth of the tumour. Four patients developed local seeding of tumour and one patient had distant metastasis. Three other patients had both local seeding as well as distant metastases. Radical resection thus had a significantly favourable effect on the overall survival as well as the recurrence rate.

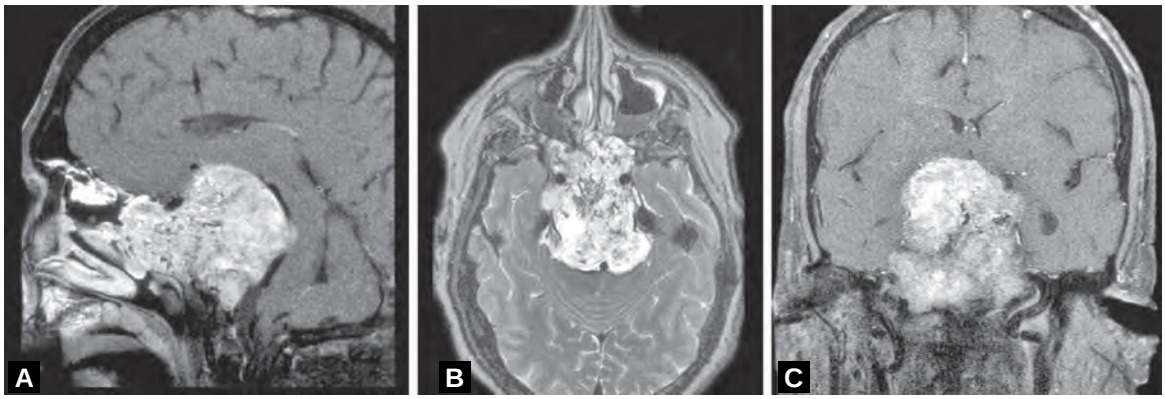
Tzortzidis reported their findings of treating 74 patients by skull base surgical techniques.[43] In his cohort, 32% of patients survived without evidence of disease at a mean follow-up of 96 months, after a gross total resection achieved in 71.6% patients. At follow-up, 50% of the group was alive with residual tumour and 17% had died.

Colli and Al-Mefty classified the degree of tumour resection as more than 90% tumour resection ("radical", "subtotal") and less than 90% resection ("partial").[4] Radical resection was achieved in 45.3% of chordomas. At five years, the recurrence free survival (RFS) was 65.9% for subtotal resection or better, compared to 23.1% for patients with partial resection. In this report, 17% (9 patients) of their chordoma patients died in the post-operative follow-up period (mean 49 months). Also in this follow-up period, 6 patients died in 3 years or less after their first operation, while 3 others died at 7, 8 and 10 years after the first operation. These data suggest a difference in the tumour biology in individual patients.

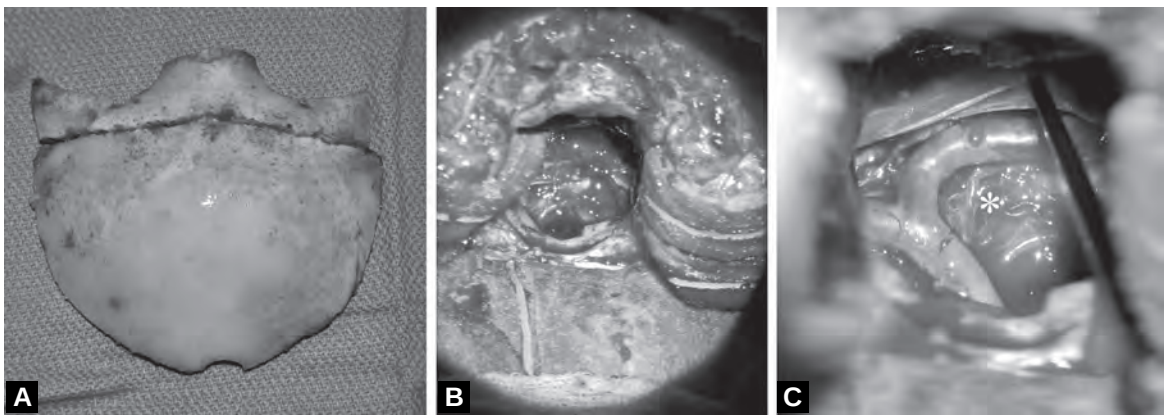
Crockard et al. reported a 4.2% surgical mortality in 42 patients with clival chordomas.[5] Tumour resection was classified as complete excision (i.e. no post-operative evidence of residual tumour), radical (i.e. more than 90% tumour removed), partial (i.e. 50–90% tumour removed) and biopsy (i.e. less than 50% tumour removed). Of the 32 patients who had radical or better tumour resection, 100% survived at 5 years. In the subgroup of patients who had less than radical tumour removal (10 patients), all received post-operative radiation therapy and had a 65% survival at 5 years. The greatest incidence of mortality was within 40 months after the operation. The overall survival for the entire group was 77% at 10 years. Pamir et al. treated 26 patients with a mean follow-up of 48.5 months.[30] In this study, about 25% of patients had radical tumour resection, 57.7% patients experienced recurrence of tumour and there was 23% mortality from tumour progression.

ILLUSTRATIVE CASES

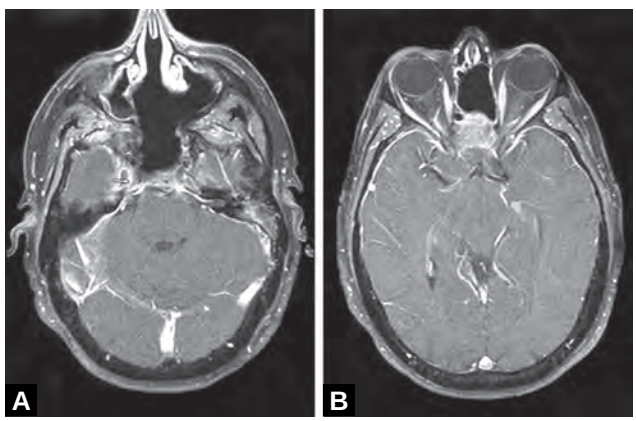
1. JD: This 43-year-old man had presented with difficulty in walking, vertigo and right sided weakness and numbness. MRI scan showed a large tumour (Figs 1A to C) at the skull base producing hydrocephalus. A ventriculoperitoneal shunt and a transnasal biopsy were done at another institution and he was then referred to us. The first operation was done through an extended subfrontal approach combined with an endonasal endoscopic approach. The optic canals were fully unroofed, in order to allow manipulation of the optic nerves while removing the tumour (Figs 2A to C). Reconstruction of the skull base was performed using a pericranial flap and autologous fat graft. After his operation, he lost hearing in his left ear. Five months later, he had surgery through a purely endoscopic endonasal approach to remove some residual tumour. He is being monitored with MRI scans on an annual basis (Figs 3A and B).
2. PB: This 11-year-old boy presented with gradual onset of left sided hemiparesis. MRI showed a large clival tumour with severe brainstem compression



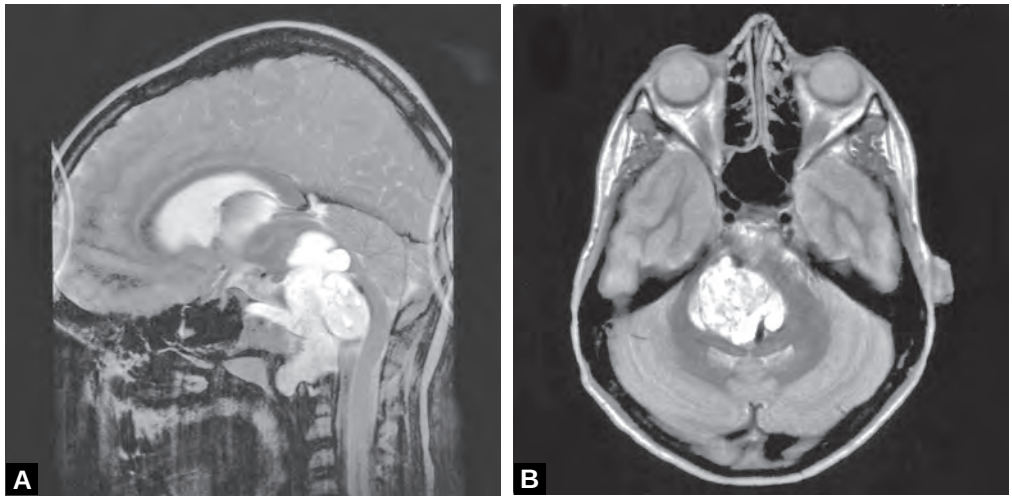
Figs 1A to C: MRI scan of 43-year-old man showing a large clival chordoma at the skull base



Figs 2A to C: (A) Bone flap of an extended subfrontal approach. (B) Operative view of extended subfrontal approach. (C) Endoscopic view showing basilar artery bifurcation and the tumour posterior to the vessels



Figs 3A and B: Post-operative MRI scans



Figs 4A and B: MRI scans showing a large clival tumour with severe brainstem compression

(Figs 4A and B), and the CT scans showed areas of bone destruction in the clivus (Fig. 5). He underwent surgery through a right-sided subtemporal and preauricular infratemporal approach. This approach consisted of an extradural subtemporal exposure and unroofing with translocation of the entire petrous segment of the internal carotid artery, in order to provide an approach to the clivus. A substantial amount of the tumour was found to be intradural. After removal of the soft portion of the tumour, the clival bone was drilled away in the affected areas. The post-operative MRI scans suggested some residual tumour and he underwent proton beam radiation (Figs 6A to D). He had temporary 6th nerve palsy immediately after surgery but recovered fully and remains functioning normally at 7 years post-operatively without any recurrence (Figs 7A and B). He does have hypopituitarism from the radiation treatment.

3. RS: This 37-year-old man suffered from severe occipital headaches. He had no neurological deficits. MRI scans showed a midline mass with bone destruction in the clivus (Figs 8A to C). The tumour was removed by a purely endoscopic endonasal approach using intra-operative navigation (Fig. 9). The tumour had invaded the dura and the tumour along with the involved bone and dura was removed (Fig. 10). The skull base was reconstructed using fascia lata and fat graft. He developed cerebrospinal fluid rhinorrhoea and required re-exploration and repair. He remains normal and has not received any post-operative radiation.
4. RR: This 16-year-old boy had developed tingling and numbness involving both upper extremities. MRI scans showed a large tumour involving the lower clivus and the craniocervical junction (Figs 11A and B). It intimately involved the vertebral artery on the right side and extended intracranially as well as extracranially. The tumour was approached through a right sided extreme lateral transcondylar approach (Figs 12A and B). The tumour was removed including the involved bone and dura (Figs 13A and B). Since the occipital condyle was also removed, he had an occipito-cervical fusion with titanium rods performed the following day[42] (Fig. 14). A few months after this he was treated with proton-beam radiation receiving 79.4 CGE.

181 Trans-facial Transmaxillary Approaches to Anterior Skull Base

Sojan Ipe, Bobby Jose

INTRODUCTION

With the evolution of skull base surgery, transfacial approaches have gained popularity for the surgical resection of lesions located anterior to the neurocranium because of the anteroinferior anatomic relationship of the facial viscerocranium to the cranial base. The intimate relationship of the anterior and midskull base to the facial structures as well as the cranium requires mobilisation of one of these, for approaching pathology in this region. The term transfacial is used to describe any procedure that mobilises the midface skeleton, through a facial skin incision irrespective of the extent of midface disassembly employed. The nasal bone, maxilla and zygoma may be mobilised alone or in combination unilaterally or bilaterally and either as an osteoplastic flap or as free bone fragments.

The surgical disarticulation of the craniofacial skeleton can be used to gain access to otherwise inaccessible sites in the skull base. These approaches allow access to the anterior and middle cranial fossa, cavernous sinus, clivus, craniovertebral junction, upper cervical vertebrae up to the level of C4, infratemporal and pterygopalatine fossa, nasopharynx, paranasal sinuses and the orbit.

The facts to be considered, while selecting an approach, should be the ease of approach, the consequences due to alterations in the affected as well as the surrounding normal structures due to the operative approach and the post-operative patient quality of life. In selecting the transfacial approaches, the variable consequences, such as post-operative swelling of the facial tissue which is short-term and self-limiting, are more desirable than a similar swelling in the neural tissue which may be fatal or debilitating.

HISTORY

The first report of bilateral horizontal maxillotomy was by Von Langenbeck in 1859.[33] He also reported a case where he used this technique to remove fibroids of the pterygopalatine fossa.[34] Later, in 1867, Cheever used the approach for removal of a nasopharyngeal tumour.[7,20] In 1893, Lanz described division of the maxilla in the midline in addition to the horizontal maxillotomy.[10,18] In 1901, Le Fort classified the variants of fractures of the maxilla. Subsequently, Martin Wassmund performed a Le Fort I osteotomy for correction of congenital malocclusion in 1927 and the operation was reported in his textbook of 1935.[10,20] Paul Tessier,[31] in his landmark paper, demonstrated that intracranial and extracranial exposures could be combined without undue risk of infection. He also showed that the facial bones can be stripped of periosteum, osteotomised and would still survive. Numerous other reports followed this in the otolaryngological and maxillofacial literature in the use of the transmaxillary approach for removal of various nasopharyngeal tumours and correction of deformity. The approach gained popularity in neurosurgical circles after the applications of this were rediscovered following the advent of skull base surgery in the late 1980s. These principles have proven valuable for achieving wide exposure of the skull base through facial routes, which allowed complete resection of tumours previously considered unresectable.[8,33]

INDICATIONS

The basic principles of anterior skull base surgery are as follows:

- Identify the epicentre of the mass.
- Take the shortest route from the skin to the target lesion.
- Bypass the vital structures essential for satisfactory functional outcome.
- Use pre-existing spaces in the face and the skull bones.
- Plan reconstruction depending upon the approach.
- Reconstruct aesthetically with best cosmetic end result.
- Maintain compartmentalisation—segregate neurocranium and viscerocranium.
- Evaluation of tumour biology and appropriate pretreatment to downgrade the tumour.

The transfacial transmaxillary approach is useful for a variety of lesions from the paranasal sinuses to the clivus. It can be extended with mandible splitting procedures, to reach up to the upper cervical spine. This approach is ideal for lesions arising from the paranasal sinuses with or without intracranial extension, anterior skull base lesions, extradural lesions of the upper and middle third of the clivus such as clival chordoma and chondrosarcoma. Other potential lesions that can be treated with this approach are fibrous dysplasia, inverting

papilloma, osteoma and ossifying fibroma.[19] It can also be used for the removal of small to moderately sized nasopharyngeal lesions, such as juvenile angiofibromas, with limited lateral extension, esthesioneuroblastoma (olfactory neuroblastoma), adenocarcinoma and adenoid cystic carcinoma.[4,5,26,28,30,32] Many of these tumours to a greater or lesser degree are malignant. Inverting papilloma is an example of a tumour that is locally invasive, does not metastasise but must be resected aggressively to avoid recurrence. Esthesioneuroblastoma varies from a very sluggish to highly aggressive tumour. Most tumours of nasal or paranasal sinus origin are squamous cell or adenocarcinoma of the maxillary or ethmoid sinuses. Transfacial approaches also provide access to the deformed skull base in patients with basilar invagination and marked neuraxial compression.[13,27] There are reports of this approach being used for treating vertebrobasilar junction aneurysms,[2,9,21] but, with the advent of interventional treatment for such lesions, surgery is almost never done considering the risk factors of the surgery. This approach has also been used for intradural lesions in this region. We use the anterior transfacial approaches mainly for extradural lesions and extradural lesions that have transgressed the dura secondarily. Combined craniofacial resections are recommended when there is tumour extension beyond the anterior skull base and if there is frank intradural extension of the tumour. Purely intradural lesions, such as basal meningiomas, are also approached by combining this with transcranial approaches for the ease of repair of the dural defect and thus to avoid potential complications. The transmaxillary approach has the advantage of being an extradural anterior inferior midline approach with a relatively low risk of injury to the cranial nerves and the major blood vessels.[19] Also, for extensive lesions, these transfacial approaches can be combined with other intracranial approaches simultaneously or staged.[11,12]

The advantages[15] of the transfacial approaches are the following:

- Facial anatomy has developed from embryonic fusion of nasofrontal, maxillary and mandibular processes. Normally the fusion takes place in the midline or in the paramedian region, thus logically presenting the optimal lines of separation of facial units for surgical approaches and facilitating the least traumatic displacement.
- The primary blood supply to the facial units is through the external carotid system which also has a lateral to medial direction of flow, thus ensuring viability of displaced surgical units.
- The midface contains multiple hollow anatomical spaces (oronasal cavity, nasopharynx and paranasal sinuses) that facilitate the ease of surgical access to the central skull base.
- Displacement of facial units for approach to the central skull base offers much greater tolerance to the post-operative surgical swelling, as opposed to similar displacement of the contents of the neurocranium.
- Re-establishment of the normal anatomy, following repositioning of the reconstructive phase of surgery, leads to good functional as well as aesthetic results.

The disadvantages[15] of transfacial approaches are the following:

- Contamination of the surgical wound with oropharyngeal bacterial flora.
- The need for facial incisions with subsequent scar formation.
- Emotional consideration of the patient related to surgical facial disassembly.
- The potential need for supplementary airway management like post-operative endotracheal intubation, temporary tracheotomy, etc.

SURGICAL ANATOMY[1,23,25]

The cranium is sub-divided into the cranial vault and the cranial base which consists of the floor of the cranial cavity intracranially and the inferior surface of the skull extracranially and the facial skeleton which includes the orbital cavities, the nasal fossae and the jaws. The base of the cranial cavity is divided into three distinct fossae—the anterior, middle and posterior.

The floor of the anterior cranial fossa is at a higher level than the others. The anterior cranial fossa occupies less than the anterior one-third of base of the skull.

Skeletal surface landmarks of the face are sometimes palpable. It is important to have an idea of the surface relationship of the underlying structures to plan the transfacial approach. The superciliary arches are palpable above the orbit with a horizontal ridge in the midline called the glabella. The supraorbital margin lies beneath the upper margin of the eyebrow. The supraorbital notch is palpable 2 fingers breadth from the midline at the junction of the rounded medial 1/3rd and the sharp lateral 2/3rds of the supraorbital margin, which at times may be converted into a foramen. It is worth noting that the supraorbital, infraorbital and the mental foramina all lie approximately in the same vertical plane (Fig. 1). The median mental tubercle of the mandible is palpable. The mental foramen lies below the premolar tooth, 2 fingers breadth lateral to the mental tubercle and midway between the upper and lower borders of the mandible. A vertical line drawn from the supraorbital notch to the base of the mandible passing over the canine fossa crosses the infraorbital foramen 5 mm below the infraorbital margin and a finger breadth from the side of the nose. The canine fossa is posterior to the canine eminence overlying the root of the canine tooth.

The relevant osteological details alone will be discussed here. For a detailed account of the anatomy, the reader is advised to refer to specialised anatomical textbooks. The superciliary arch is a rounded curved elevation situated just above the medial part of each orbit. The glabella is the horizontal median elevation connecting the two superciliary arches. The nasion is the median

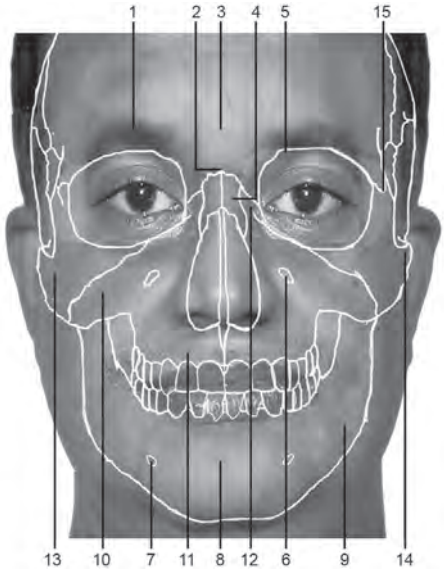

Fig. 1: Surface landmarks: (1) Superciliary arch; (2) Nasion; (3) Glabella; (4) Nasal bone; (5) Supraorbital notch; (6) Infraorbital foramen; (7) Mental foramen; (8) Mental tubercle; (9) Mandible; (10) Maxilla; (11) Alveolar process; (12) Frontal process of maxilla; (13) Zygomatic bone; (14) Zygomatic arch and (15) Fronto-zygomatic suture

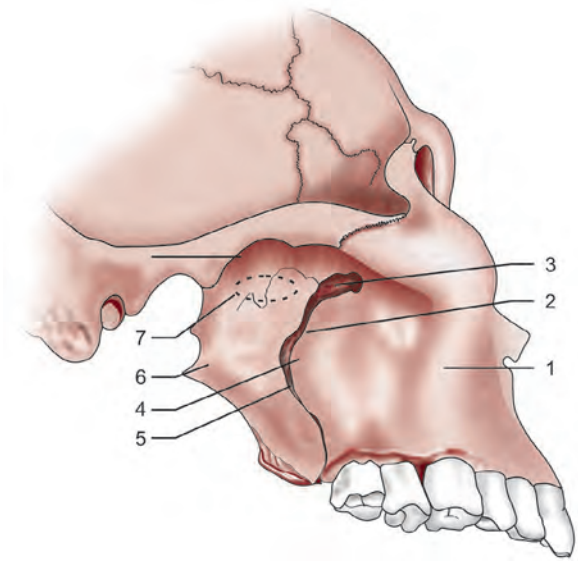

Fig. 2: Right inferiolateral view: (1) Zygomatic crest; (2) Pterygopalatine fossa; (3) Inferior orbital fissure; (4) Maxillary tuberosity; (5) Pterygomaxillary fissure; (6) Lateral pterygoid plate and (7) Infratemporal fossa

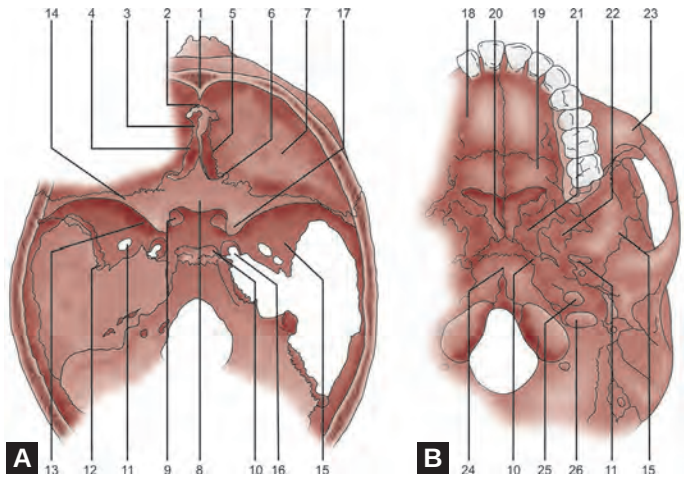
point of the root of the nose where the internasal suture meets with the frontonasal suture below the glabella.

The central part of the face is mainly occupied by the maxillary bones and the anterior nasal aperture. Each maxilla contributes to the upper jaw, the bridge of the nose, the floor of the orbit, the nasal aperture and the bone of the cheek. The maxilla has a body and four processes. The body encloses the maxillary sinus. The anterior aspect of the maxilla has the following landmarks: the alveolar process is socketted for the maxillary teeth, the frontal process projects posterosuperiorly between the nasal and the lacrimal bones, connecting the frontal bone and the nasal bone (Fig. 1). The lateral surface of the frontal process gives attachment to the medial palpebral ligament and the zygomatic process connects to the zygomatic bone. The infraorbital foramen contains the infraorbital nerves and vessels. The lateral aspect of the maxilla has the zygomatic crest between the lateral pointing zygomatic process superiorly and the second molar inferiorly. The posterior convexity of the maxillary body is the maxillary tuberosity which forms the anterior wall of the infratemporal fossa (Fig. 2). The superior aspect of the maxilla forms the nasal floor medially and the greater part of the orbital floor laterally.

The palatine process, which forms a large part of the nasal floor and the hard palate, arises as a horizontal plate from the body of the maxilla at the boundary between the body and the alveolar process. The hard palate is formed by the paired palatine processes of the maxilla and the horizontal plates of the palatine bones posteriorly (Figs 3A and B). The pterygomaxillary suture defines the connection between the maxilla and the lateral pterygoid plate of the sphenoid bone.

The piriform apertures contain the nasal septum, which is formed by the cartilaginous septum anteroinferiorly, by the vomer posteroinferiorly and by the perpendicular plate of the ethmoid bone superior to both these structures. The lateral wall of each nasal cavity supports the curved bony plates of the nasal conchae. The pterygoid process of the sphenoid bone consists



Figs 3A and B: (A) Interior of the base of skull and (B) Inferior view: (1) Frontal crest; (2) Foramen caecum; (3) Crista galli; (4) Cribriform plate; (5) Anterior ethmoidal foramen; (6) Posterior ethmoidal foramen; (7) Orbital plate of frontal bone; (8) Jugum sphenoidale; (9) Carotid groove; (10) Foramen lacerum; (11) Foramen ovale; (12) Foramen spinosum; (13) Foramen rotundum; (14) Lesser wing of sphenoid; (15) Greater wing of sphenoid; (16) Posterior clinoid process; (17) Anterior clinoid process; (18) Palatine process of maxilla; (19) Horizontal plate of palatine bone; (20) Insertion of vomer on sphenoid; (21) Medial pterygoid plate; (22) Lateral pterygoid plate; (23) Zygoma; (24) Clivus; (25) Carotid canal and (26) Jugular foramen

of the lateral and medial pterygoid plates and extends inferiorly on each side of the sphenoid (Fig. 3B). The foramen lacerum is immediately posterior to the medial pterygoid plate and its upper half houses the internal carotid artery. The internal carotid artery limits the lateral exposure in this area. The anterior margin of the pterygoid process is adjacent to the horizontal plate of the palatine bone. The lateral pterygoid plate forms the posterior aspect of the pterygomaxillary fissure, adjacent to the maxillary tuberosity (Fig. 2). The maxilla, thus, forms the anterior wall of the pterygopalatine fossa as well as that of the infratemporal fossa.

The anterior cranial fossa is formed at the front and sides by the frontal bone while its floor is formed in the median plane anteriorly by the cribriform plate and the crista galli of the ethmoid bone and posteriorly by the superior surface of the anterior part of the body of the sphenoid (Fig. 3A). On either side, the floor is formed by the orbital plate of the frontal bone and the lesser wing of the sphenoid posteriorly. The medial end of the lesser wing forms the anterior clinoid process. The inferior surface is related to the roofs of the orbits on each side and the roof of the nasal cavity.

The cribriform plate spreads across the midline between the orbital plates of the frontal bones and is depressed below them, forming part of the roof of the nasal cavity. The olfactory nerves pass from the nasal mucosa to the olfactory bulb through numerous foramina in the cribriform plate. The anterior margin articulates with the frontal bone at the frontoethmoidal suture, which is marked in the median plane by the foramen caecum. The cribriform plate has the crista galli anteriorly, which projects upwards like a tooth and provides attachment to the falx cerebri. The lateral margins articulate with the orbital plate of the frontal bone and the suture has the anterior ethmoidal canal which transmits the anterior ethmoidal nerve and vessels. The nerve then passes into the roof of the nose by the side of the crista galli via a foramen. The posterior margin articulates with the jugum sphenoidale and the posterolateral corners present the posterior ethmoidal canals, which transmit the posterior ethmoidal vessels.

Jugum sphenoidale separates the anterior cranial fossa from the sphenoid sinuses. The orbital plate of the frontal bone separates the anterior cranial fossa from the orbit and supports the orbital surface of the frontal lobe. The medial margin covers the labyrinth of the ethmoid and the posterior margin articulates with the lesser wing of the sphenoid.

PRE-OPERATIVE EVALUATION

The patient is evaluated with high resolution CT scan and MRI to define the anatomical extent of the lesion. Angiography may be done in selected cases. Some cases may benefit with pre-operative embolisation. Adjuvant pre-operative chemotherapy and\or radiotherapy may be planned in some cases to down size the tumour. The decision on the approach is based on the anatomical site and the extent of the lesion, experience and familiarity of the surgeon, and the age and overall prognosis of the patient and the presumptive biological characteristics of the lesion. The dental hygiene of the patient should be evaluated and any infection should be treated to avoid post-operative complications. A dental splint is fabricated to reproduce normal occlusion after surgery, depending on the type of osteotomy planned. Culture of the nasal and throat flora should be obtained pre-operatively. Appropriate antibiotics should be started with the induction of anaesthesia, to be continued post-operatively.

ANAESTHESIA

The airway is maintained either with orotracheal intubation or with tracheotomy. We prefer orotracheal intubation and have not anytime encountered excessive swelling of the orofacial tissues compromising the airway in the post-operative period. Arterial and central venous pressure lines and a precordial stethoscope to detect venous air embolism are desirable. Hypotensive anaesthesia is not mandatory. A spinal drain may be used if dural breach is expected.

PATIENT POSITIONING

The patient is positioned supine with the head resting on a head ring or rigid fixation as per the surgeon's preference. Then complete preparation of the face and neck is performed with povidone iodine solution and the oropharynx is irrigated with appropriately diluted solution, the area is then draped. In addition, the lateral thigh is prepared and draped as a fascia lata donor site.

OPERATIVE TECHNIQUE

The transfacial approach relies on the principle that the facial anatomy can be divided into composite units along key neurovascular units and aesthetic lines.[15] These individual units merge into larger composite units without compromising their individual function. Although there are numerous terminologies for the various transfacial approaches, all are based on the general principle of disassembling the face along these units depending on the location and extent of the lesion.

Classification of Transfacial Transmaxillary Approaches

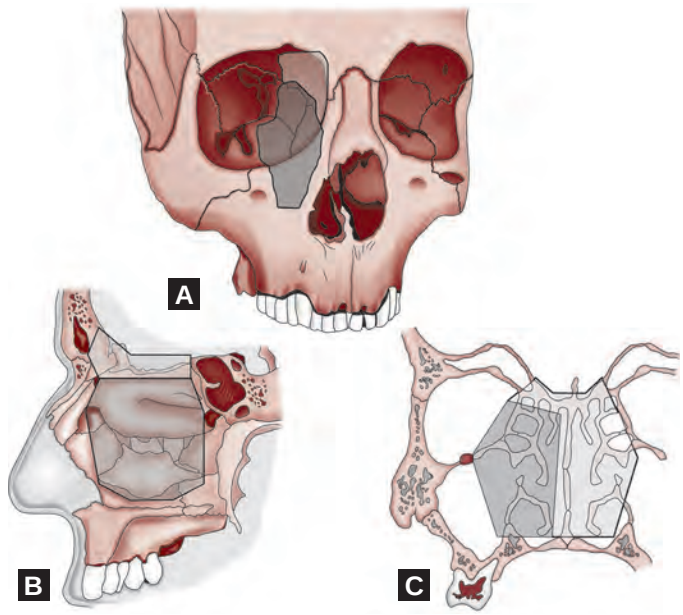
I. Medial
   1. Medial maxillectomy[29]
   2. Medial mini-facial translocation[15]

II. Lateral
   1. Total maxillectomy[22]
   2. Standard facial translocation[15]
   3. Extended osteoplastic maxillotomy[6]

III. Combined (Medial and Lateral)[15]
   1. Medial extended facial translocation (Le Fort I)
   2. Medial and inferior extended facial translocation

IV. Bilateral
   1. Bilateral facial translocation[15]
   2. Extended transfacial subcranial[24]
   3. Facial degloving[16]
   4. Transmaxillary approaches of Beals and Joganic[3]

This classification was based on the extent of bone removal and the limits of anatomical exposure gained by each approach. Several approaches have been described by different authors, from which we have selected certain standard procedures described in the literature, which will help the reader to understand the various concepts. The choice of employing the appropriate approach for an anterior skull base tumour is dependent on patient factors such as age, general health of the patient, tumour characteristics, extent of involvement, nature of growth (whether benign or malignant) and the surgeon's personal preference and experience.



Figs 4A to C: Medial maxillectomy extent of excision

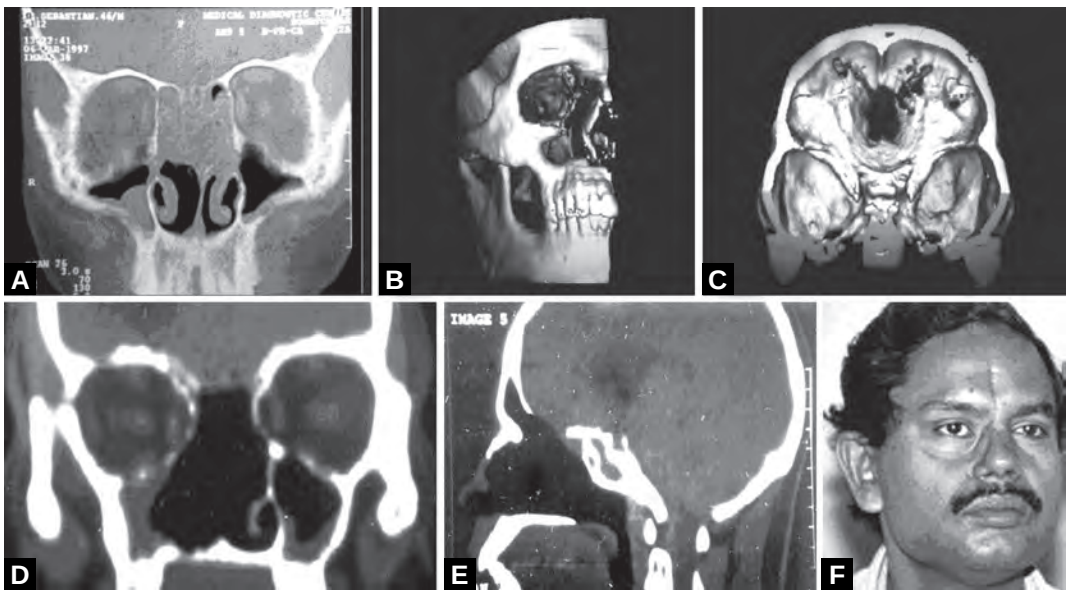
Medial

Medial Maxillectomy

The technique of medial maxillectomy, as described by Sessions and Larson in 1977,[29] requires excision of the medial maxillary sinus wall and turbinates, ethmoids and lamina papyracea, lacrimal bone and the orbital wall medial to the infraorbital nerve [Figs 4A to C (shaded areas in views)]. This procedure is an extension of the lateral rhinotomy approach made in the side of the nose for surgical exposure.

Medial maxillectomy is indicated for benign and malignant neoplasms limited to the nasal walls, medial wall of the maxillary sinus and adjacent ethmoid sinus. When a component of the neoplasm extends intracranially, the medial maxillectomy can be combined with a frontal craniotomy to allow en bloc craniofacial resection of the lesion.[17] A number of modifications of medial maxillectomy are possible including the medial orbital rim, in combination with frontal sinusotomy for lesions of the ethmoid roof extending to involve the anterior cranial base [Figs 4A to C (shaded areas with lighter tone)]. Under magnification, the entire median aspect of the floor of the anterior cranial fossa can be removed with the infiltrating tumour mass (Figs 5A to F).

Medial maxillectomy approach gives better physical quality of life index (PQLI) after surgery, early feeding with good dental occlusion and early mobilisation and



Figs 5A to F: (A to C) Clinical example of modified medial maxillectomy employed to excise a squamous cell carcinoma filling the upper nasal cavity and infiltrating the floor of the anterior cranial fossa. (D to F) 18 months follow-up CT scan showing the extent of bone removal and the cosmetic end result

rehabilitation of the patient. It minimises intracranial complications that would occur with combined transcranial approaches such as brain retraction related contusions of the frontal lobes, intracranial haematomas, dural tears, CSF leaks, pneumocephalus and meningitis.

Medial Mini-Facial Translocation[15]

This approach is designed to reach the medial orbit, sphenoid and ethmoid sinus and inferior clivus as described by Janecka (Figs 6A and B). The port of entry is through the displaced ipsilateral nasal bone and the nasal process of the maxilla with attached medial canthal ligament, lacrimal duct and skin. The skin incision is made along the lateral aspect of the nose and the inferior aspect of the eyebrow with a triangular design at the level of the medial canthal ligament. The lateral extent of the osteotomy is just medial to the infraorbital nerve. The entire unit can be displaced laterally for surgical exposure.

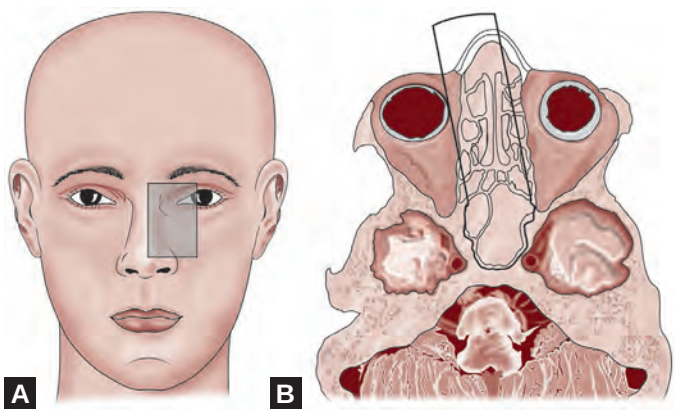
Lateral

Total Maxillectomy

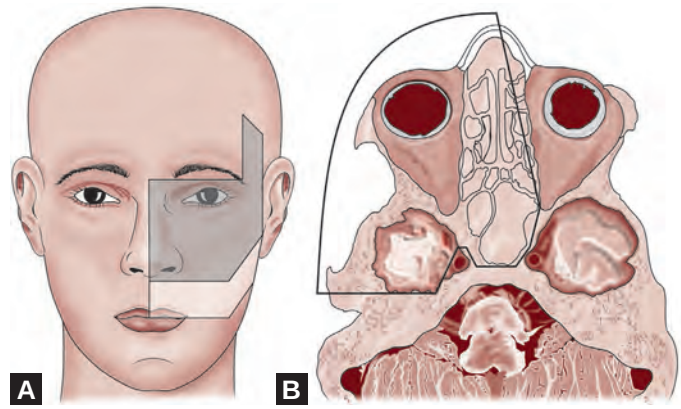
Classical total maxillectomy procedures are described in plastic surgery,[22] which gives clear cut details of this procedure which becomes part of the extended procedures described by others. The classical Weber-Ferguson-Longmire skin incision and the soft tissue dissection involved in exposing the anterior surface of the maxilla have to be followed. An in depth understanding of this step is important before learning various levels of osteotomies involved in the extended procedures.

Standard Facial Translocation

With this technique of translocation, good exposure of the anterolateral skull base is achieved, especially when the infratemporal fossa is involved as well. This was originally described by Janecka.[15] The ipsilateral facial skin including the lower eyelid is displaced laterally and inferiorly with the underlying maxilla, with or without the hard palate (Figs 7A and B). The nasal incision may extend inferiorly to include an upper lip split. The superior incision continues from the nose to the inferior fornix of the lower eyelid through the lateral canthus horizontally to the preauricular area. Osteotomies correlate to Le Fort I-II or the mid-palatal lines when the entire maxilla is being displaced.



Figs 6A and B: (A) Basic plan for medial mini-facial translocation. (B) Axial outline of surgical view

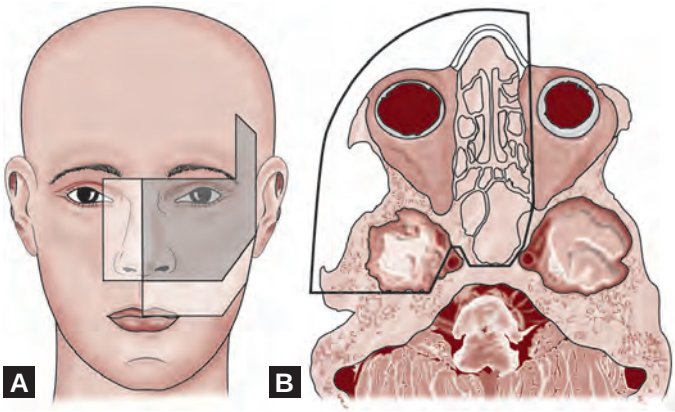


Figs 7A and B: (A) Basic plan of standard facial translocation with palatal extension shown in the lightly shaded area. (B) Axial outline of surgical view

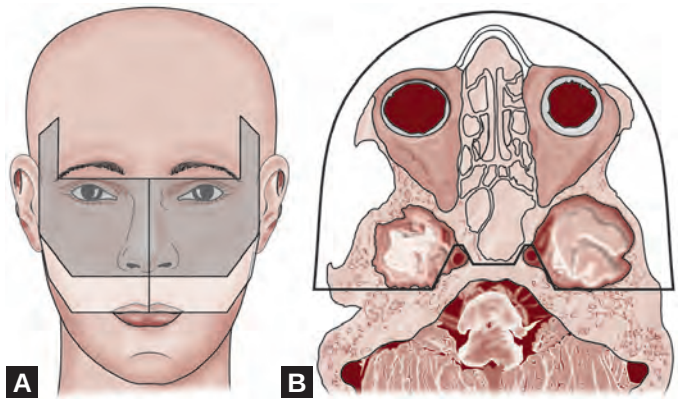
Extended Osteoplastic Maxillotomy

This technique, originally described by Catalano,[6] provides wide, direct exposure of the lateral and/or central skull base. It is indicated for benign or malignant lesions that involve two or more of the following anatomic areas: pterygopalatine fossa; sphenoid sinus; nasopharynx; infratemporal fossa; cavernous sinus and/or floor of the middle fossa and clivus. The maxillofacial skeleton is exposed via a Weber-Ferguson incision. Osteotomies in the maxilla and zygoma disengage the maxilla from the facial skeleton. The maxilla is mobilised on the skin and the soft tissues of the ipsilateral cheek, thereby maintaining its blood supply. Due to this osteoplastic technique, the untoward effects of adjuvant radiation therapy and/or chemotherapy are minimal. By varying the position of the facial osteotomies, this approach is very flexible. Medial positioning of the anterior osteotomy of the maxilla determines the extent of exposure of the nasopharynx and the positioning of the lateral osteotomy determines the extent of exposure of the infratemporal fossa. Pterional or temporal craniotomy can be combined to gain access to the corresponding cranial cavity. Miniplate fixation of the maxilla and the zygoma re-establishes the contour of the facial skeleton functionally and cosmetically.

Catalano's technique of osteoplastic maxillotomy has many similarities to the techniques described by Janecka et al.[14] and Wei et al.[35] The basis of osteoplastic maxillotomy is the pedicled osteoplastic unit, comprised of vascularised bone, muscle, skin and mucosa, whose design can be tailored to the desired skull base exposure.



Figs 8A and B: (A) Scheme. (B) Axial extent of the exposure



Figs 10A and B: (A) Scheme. (B) Axial extent of the bilateral facial translocation

Combined (Medial and Lateral)

Medial Extended Facial Translocation (Le Fort I)[15]

This approach incorporates the standard translocation unit of Janecka plus the nose and the medial one-half of the opposite face up to the infraorbital nerve. It can be rotated at the Le Fort I level or include the ipsilateral palate and upper lip split (Figs 8A and B). The skin incisions are similar to the standard technique, except that the paranasal incision is made on the contralateral side. The surgical exposure involves the ipsilateral infratemporal fossa and central and paracentral skull base bilaterally. The entire clivus, optic nerves, precavernous internal carotid arteries and nasopharynx are accessible. Reconstruction is with the temporalis muscle flap. Occlusion plane is re-established with an orthognathic splint.

Medial and Inferior Extended Facial Translocation[15]

This exposure is the same as the medial extended facial translocation with an inferior extension by a mandibular split (Fig. 9). The lower lip incision is performed in a zigzag fashion to conform to the tension lines of the skin. Mandibular osteotomy is performed just medial to the mental foramen. Prior to osteotomy, it is wise to select an appropriate miniplate for eventual fixation, contour it to the mandible and create drill holes. This assists in post-operative re-establishment of normal occlusion. This inferior extension adds a significant inferior cranial as well as upper cervical surgical access.

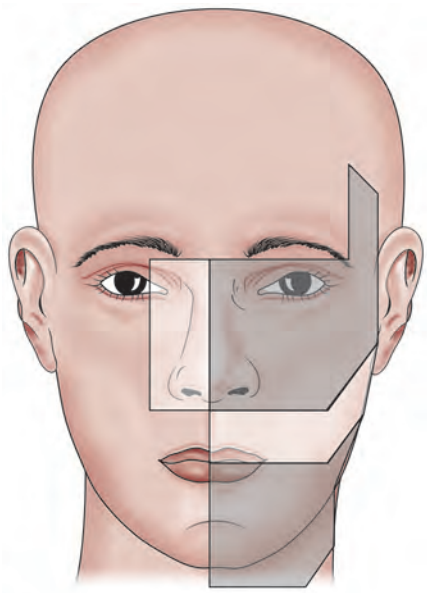


Fig. 9: Scheme of medial and inferior extended facial translocation

Bilateral

Bilateral Facial Translocation[15]

This approach combines complete right and left standard facial translocation units of Janecka with or without palatal split (Figs 10A and B). The exposure incorporates both infratemporal fossae and the central and the entire paracentral skull base. Both distal cervical internal carotid arteries and the clivus are in view. The palatal split permits a reach to the level of C2-3 and an added mandibular split adds a vertical reach to C3-4. The surgical defect is repaired with a single temporalis flap.

Extended Transfacial Subcranial Approach[24]

Raveh, in 1993, described an en bloc bifrontal craniotomy including the supraorbital ridges and the nasal bones. He proposed the extended subcranial approach to the anterior skull base, which is an extended exposure of the anterior, middle and posterior planes of the anterior fossa. With only one operating field, this technique provides a wider angle of approach to the skull base. The other advantage of this method is that only minimum retraction of the frontal lobes is required. The perfect fit of the free bone flap and the fact that there is no facial incision ensure a satisfactory cosmetic result.

The first step of the procedure is designing a bicoronal flap. The pericranial flap is taken down, and care is taken not to injure the supraorbital pedicle with the nerve and vessels. A pneumatic tool or a chisel should be used to remove the nerve from its channel. A meticulous dissection is made entering the orbit and both orbits are dissected medially, superiorly and laterally. The anterior ethmoid artery is ligated and the flap is cut down to the

tip of the nasal bone. The lacrimal duct is taken out of its bony channel.

The next step of the procedure is to decide what type of osteotomy is needed. The type A would include the anterior frontal sinus wall along with the nasal bones. The type B osteotomy involves taking off the posterior frontal sinus wall just anterior to the crista galli. Before doing this, however, a radical ethmoidectomy is performed. In the type B osteotomy, after both orbits have been dissected, the anterior ethmoidal arteries ligated, and radical ethmoidectomies have been performed bilaterally, the whole fronto-naso-orbital segment is taken out and this will include the posterior frontal sinus wall as well. If the tumour is unilateral, it is possible to preserve the olfactory filaments on the contralateral side. This is very rare, but can be done in some cases, since anosmia is the major inconvenience of the procedure. There is a large defect at the end of this procedure. The posterior sinus wall and the entire area that is left after the resection of the tumour need to be reconstructed. This is done with very large and generous pieces of fascia lata. The first layer of fascia lata is sutured to the edges of the resected dura and a second layer of fascia lata is introduced under the edges of the bone. Telecanthus is prevented by bilateral fixation. A thread is passed through the medial canthal ligament and fixed on the contralateral side. After the reconstruction of the skull base, the last step of the procedure is the application of the naso-frontal-orbital segment in its original anatomic place and its fixation by titanium plates. The plates were formed pre-operatively in order to replace the bone in its original anatomical position at the end of the operation. With the subcranial approach, a medial maxillectomy can be done to only a limited extent. When the tumour is above the inferior turbinates, the subcranial approach alone is sufficient, but if it reaches the inferior walls of the maxilla, a transfacial approach or a formal maxillectomy will be needed in addition.

Facial Degloving[16]

This is performed to prevent surgical incision on the face. First, a midface degloving procedure is done and then the regular osteotomies as per requirements are done for excision of the lesion. For the degloving procedure, the medial palpebral ligament is first dissected and wired after making a small incision near the medial angle of both eyes. These wires are tied under the nasal skin at the end of the surgery.

Bilateral circumferential mucosal incisions are made in the nares. A transfixation incision is connected bilaterally with intercartilaginous, pyriform and nasal floor incisions. The soft tissues of the nasal dorsum are separated from the upper lateral cartilages and nasal bones through the intercartilaginous incisions bilaterally in a subperiosteal plane. All fibrous attachments between the septum and the skin of the nasal tip area are divided. Thus, the nasal tip including the lower lateral nasal cartilage is separated. Extension of the incision circumferentially within the nasal vestibule at the skin mucosal junction completes the release of the nasal soft tissue at the pyriform aperture. A sublabial incision is made 4–5 mm above the labiogingival sulcus. It may extend up to or beyond the first molar tooth on both sides. The skin and soft tissue of the face is then dissected in the subperiosteal plane, sparing each infraorbital nerve. Facial soft tissues including lip, cheeks, nasal tips and alae, columella and nasal skin are then reflected superiorly. The elevation is extended as high as the infraorbital rim and the glabella as per the requirement. Then the necessary nasomaxillary and Le Fort I osteotomies, as required, are performed.

Transmaxillary Approaches of Beals and Joganic[3]

The system is based on selecting the most appropriate angle and exposure to the anatomic site of the tumour. Six levels of exposures are described. The upper three approaches are transfrontal approaches incorporating a supraorbital bar, either alone or with nasal and medial orbital walls; and further extended by including the lateral orbital walls.

The lower three levels of approaches provide exposure to the midline skull base through the maxilla. The transnasomaxillary approach (level IV) achieves a wide exposure of the entire central skull base but requires a Weber-Ferguson incision and a Le Fort II osteotomy. The level V transmaxillary approach requires a midfacial degloving and a Le Fort I osteotomy. It is mainly indicated for extradural lesions of the upper two-thirds of the clivus. Level VI is a transpalatal approach (Fig. 11).

Level IV: Transnasomaxillary approach: This approach can be used for nasopharyngeal lesions or for large clival lesions that extend in any direction. This technique requires a modified Weber-Ferguson incision, which extends across the radix and along the subciliary margin of the opposite lower lid. The nasomaxillary area is exposed and a Le Fort II osteotomy is performed. The osteotomy skirts along the infraorbital

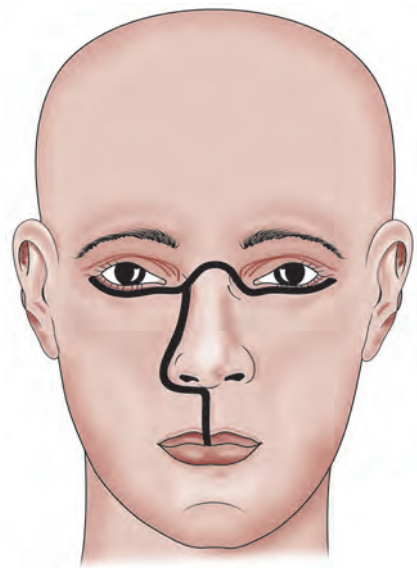

Fig. 11: Modified Weber-Fergusons incision

foramen anteriorly and along the nasolacrimal canal at the medial aspect of the inferior orbital rim (Figs 12A and B). The fragment is split at the nasal process of the maxilla on one side and the palate is split at the midline. The nasal complex remains on any one side of the fragment, depending on the best angle for exposure of the tumour and is retracted with it.

Level V: Transmaxillary approach: This exposure is ideally suited for moderately sized nasopharyngeal lesions as well as for clival lesions with superior or inferior extensions. An intraoral approach using an upper buccal sulcus incision is used as for midface degloving. Le Fort I osteotomy is performed along with a midline split (Figs 13A and B) and each half is retracted. After tumour resection, reassembly is done using an interdental splint.

Level VI: Transpalatal approach: This approach gives access to the lower clival region. A midline incision is made from one side of the uvula towards the incisive foramen. A separate incision is made in the upper labial sulcus and the floor of the nasal mucosa is lifted from the palatal surface and then the osteotomies are performed (Figs 14A and B).

POST-OPERATIVE MANAGEMENT

Most patients are extubated immediately after surgery. Only rarely tracheotomy is necessary, especially in patients with palatal splitting procedures. Suction drains are kept in the operative bed. Parenteral antibiotics are continued until all the drains are removed and then oral antibiotics are continued for a week. A short course of steroids is also administered to minimise soft tissue inflammation. Tube feeding can be started after 24 hrs, once bowel activity returns. The patient is maintained on tube feeding for 5 days and then oral intake is resumed. If a spinal drain is in place, it is removed after 3–4 days. CT scan is performed after 24 hours to ascertain immediate post-surgical changes.

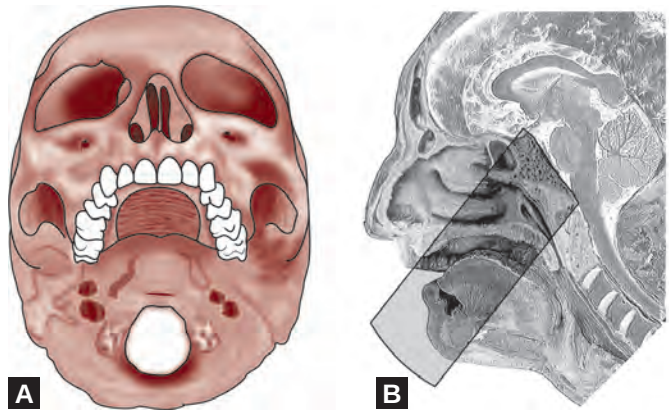

Figs 14A and B: (A) Scheme for level VI transpalatal approach. (B) The sagittal extent of surgical view

COMPLICATIONS

Complications fall in three main categories: (1) bleeding; (2) infection and (3) wound healing and can be quite hazardous.

Venous bleeding is often encountered, which can be quite bothersome and may be controlled with bone wax or with gelfoam. Inadvertent injury to the vertebral or the carotid artery may be fatal and repair should be attempted after application of temporary clips.

Infection is often due to the presence of non-vascularised tissue or post-surgical dead space or due to inadequate dural repair leading to CSF leak and meningitis. Wound healing problems are more common in patients who had previous surgery or radiotherapy.

Attention to certain details, such as the assurance of the displaced tissue viability, judicial use of electrocautery, detailed and thorough knowledge of the vascular anatomy along with judicious use of vascularised flaps, lessens the potential for complications.

Above all, in planning and treating by the transfacial approach, the surgeon has to keep in mind that the post-procedure quality of life should not be worse than the natural course of the disease.

182 Approaches to the Lateral Skull Base

Atul Goel, Muzumdar D

INTRODUCTION

Lateral approaches to clival, petroclival and posterior cavernous sinus tumours have been used for a long time. Advances in skull base surgery have resulted in development and refinements in these approaches.[2,6,7,21,23,27,47,52,55,58,63,72,73,78,81,87,90,93,94,96] With the availability of modern radiology, in most cases, the histological nature of the lesion can be made out frequently. The surgery is, therefore, undertaken with the aim of radical excision and decompression of the region, helping in the alleviation of symptoms and aiming for a cure. To achieve this goal, the planning and execution of the surgery should be meticulous and should take advantage of the advancing technology in radiology, neurophysiology, operative instrumentation and neurointensive care. Wherever necessary, a combined effort of a neurosurgeon and an otolaryngologist could prove to be helpful.

IDEAL APPROACH

It is necessary to consider various issues while selecting an ideal approach for a particular tumour. The ideal approach has the following features:

- The working distance between the surgeon and the tumour should possibly be the minimum. The direction of the approach selected should therefore be such that the tumour is closest to the surface. Temporal bone drilling could be done on some occasions only to reduce the operating distance.
- The approach should be quick to perform. The time factor is of less consideration when safety of the patient and radicality of tumour excision could be compromised. If by reduction of bone work and limitation of the exposure safe excision can be performed, such an approach could be selected. The bone work can be extended after the tumour is exposed and its nature assessed.
- The approach should be least difficult. Manoeuvres, like exposure and mobilisation of the petrous carotid artery, unroofing and mobilisation of the sigmoid sinus, transposition of the facial nerve, are difficult and potentially dangerous and time consuming procedures and should be avoided as much as possible. Such endeavours could be done in desperate cases and only after adequate assessment of the nature of the tumour.
- The exposure should be low which could avoid retraction of brain. The exposure should be wide enough such that the entire lesion can be excised in one single operative field. The exposure should provide access to the base of the tumour so that in cases of meningiomas, the tumour could be devascularised early in the operation. The exposure should be such that the tumour and the normal surrounding structures are exposed in the same field so that dissection under vision is possible.
- As far as possible, an approach through a potentially infective field should be avoided.
- Reconstruction should be easy, safe and with a vascularised pedicle graft.

SURGICAL CONSIDERATIONS

The following important characters of the tumour determine the nature of approach:

1. *Size of the tumour, its relationship to arteries and nerves, and to the adjacent bone*: The larger size of the tumour, the more difficult is the surgery and consequently the outcome can be affected. The vertical height of the tumour in relationship to the petrous bone and tentorium is also an important consideration. In cases of large tumours, the approach itself may not extremely be wide, as the tumour makes space for itself and, when the initial intratumoural debulking is started, more working space can be obtained around the area.
2. *Nature of the tumour*: In most cases the arterial displacements, as a result of growth of the tumour, differentiate meningiomas from other tumours. A trigeminal neurinoma displaces the intracavernous carotid medially, while chordomas and chondrosarcomas displace the internal carotid artery at the petrous apex anteriorly. Soft tumours, like the chordomas and pituitary tumours, displace the artery but only rarely narrow its lumen. On the other hand, firmer tumours, like meningiomas, rarely encase the artery and when they do, they frequently narrow its lumen. Such and other characters help in histologically classifying the tumours and thus assist in deciding the route of approach and the extent of resectability and for prognosticating the ultimate outcome.
3. *Consistency of the tumour*: On the basis of radiological imaging and presenting clinical features a reasonable idea

regarding the consistency of the tumour can be made. Long-standing symptoms and symptomatic involvement of adjacent nerves suggest the presence of a firm tumour. Signal characters on T1- and T2-weighted MR images help in diagnosing the nature of the tumour. These characteristics determine to a considerable extent the ease of surgical resection and the extent of exposure that may be necessary to resect the lesion. The consistency of the tumour and its vascularity are important variables on which the course of surgery depends. Encasement of the vessels signals difficulties in resection. Narrowing of the encased vessels suggests the firm nature of the tumour. Resection of such tumours could be a formidable surgical problem.

4. *Vascularity of the lesion*: Vascularity of the lesion can be observed on angiography. Multiple punctate spots in the tumour on MRI also suggest high vascularity. More vascular the lesion, the larger is the exposure that is necessary.

5. *Presence of arachnoidal plane of dissection around the tumour*: It can be determined on MRI scanning. Such information can critically be important. The presence of arachnoidal lakes around the tumour should carefully be analysed.

6. *Patient related factors like age, presence of other major illnesses*: It can also guide towards the extent of the surgery that would be necessary.

Operative Technique

The direction of the approach should be towards the base or site of the attachment of the tumour in an attempt to devascularise it early. In larger tumours, frequently, approaching the base may be difficult due to the presence of the tumour bulk and the stretched adjoining nerves and vessels. In the majority of cases, intratumoural debulking near the base, devascularising the lesion by coagulating at the site of attachment to the dura, followed by further debulking and later removal of the thin residual shell by carefully separating the adjacent structures under vision can lead to successful resection of the lesion. In cases where the tumour has encased a particular major vessel, the first aim is to either isolate the parent artery early in the operation, or debulk the tumour with the primary aim to isolate the parent artery and the tumour encased vessel. Once the artery is isolated and dissected the rest of the clear plane of cleavage between the artery and the tumour can be made out and the dissection can proceed in that plane. In case the arachnoidal plane is lost, one should consider the risks of further dissection vis-à-vis problems of leaving residual tumour behind. Extensive dissection around arteries is wrought with risks of vascular occlusion by laceration or thrombosis. It is usually safer to avoid prolonged dissection of the tumour from the arteries. Tumoural coagulation should be avoided as such a procedure makes the tumour firmer and resection more difficult. A combination of sharp and blunt dissection with the help of bipolar cautery (with irrigation) and graded suction is necessary in the proximity of major arterial channels. Traction over the tumour should be avoided during the entire operation. Leaving tumour residue remote from the site of attachment and origin is safer than leaving tumour in the region of attachment (or origin), as regards possibility of recurrence. In selected cases, lumbar puncture and drainage of CSF is an important pre-operative adjuvant to help relaxation of the brain and to permit safe and adequate exposure of the lesion. In subtemporal approaches, retraction of the temporal lobe is much easier and safer when CSF drainage is performed. CSF drainage could always be considered when a bulging brain restricts manipulation. For this reason a complete lateral position is better than a supine position with head turned to the other side. The lumbar drainage of CSF can be done with ease whenever it is indicated in this position. CSF drainage for facilitating retraction of the brain should be avoided prior to craniotomy in cases of large tumours where herniation may occur.

Bone Work

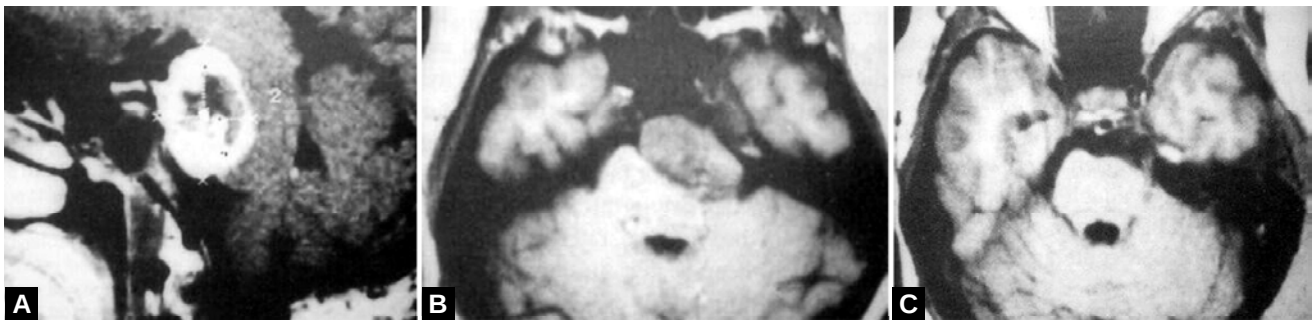
Drilling of the petrous bone to obtain basal and wider exposure is frequently necessary. However, such a procedure should be done only when it is absolutely necessary. The drilling should be minimal and only at sites where it is necessary to expand the exposure. In more difficult lesions, extensive temporal bone drilling may be required.

SURGICAL APPROACHES TO LATERAL SKULL BASE

Anterior Subtemporal Approaches

Anterior subtemporal approach is indicated when a majority of the tumour is in the middle fossa in the region of the cavernous sinus. Basal extension of the anterior subtemporal approach is frequently necessary to avoid retraction of the temporal pole.

Anterior extension of the temporal craniotomy can be done by removal of the posterior part of the lateral and, whenever indicated, the superior wall of the orbit. Removal of the orbital rim is seldom necessary but can be done in complex cases. The inferior extension of the conventional temporal craniotomy can be done by caudal displacement of the temporalis muscle facilitated by zygomatic osteotomy. The zygomatic arch can even be cut and displaced inferiorly by leaving the attachment to the masseteric fascia intact. The infratemporal muscles are dissected off from the base of the middle fossa bone by sharp subperiosteal dissection. The middle fossa basal bone is removed to expose the superior orbital fissure, foramen rotundum and foramen ovale. These manoeuvres provide an inferior angle of approach to the basal middle fossa structures. The horizontal portion of



Figs 1A to C: (A) Contrast-enhanced MRI shows a large clival meningioma. (B) Transverse cut showing the tumour indenting into the pons. (C) Post-operative scan showing complete resection of the tumour. Basal extension of the subtemporal craniotomy was used to resect the tumour. Resection of the rest of the petrous bone was not necessary

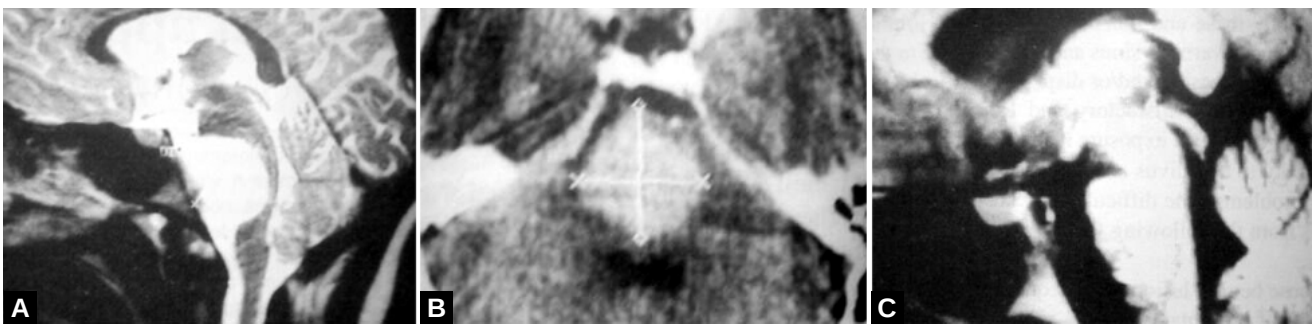
the intrapetrous carotid artery can be exposed. Exposure of the entire intrapetrous carotid artery (horizontal segment, genu and the vertical segment of the carotid artery) can be done. However, exposure of the vertical segment (a procedure which is seldom necessary) can be done more easily after resection of the condyle of the temporomandibular joint. The Eustachian tube and the tenser tympani muscle are in the way during the exposure of the genu of the carotid artery. After the exposure of the horizontal segment of the intrapetrous segment of the carotid artery, the petrous apex can be drilled safely and more radically to expose the upper clivus. Familiarity with the anatomy is crucial to perform petrous apex drilling. Arcuate eminence, greater superficial petrosal nerve (GSPN), lateral border of the Gasserian ganglion, third trigeminal nerve division and foramen ovale and spinosum are important landmarks of the petrous apex. The GSPN lies superior to the internal carotid artery in the petrous apex. Drilling in Kawase's triangle and widening of the exposure according to the requirements can crucially expand the exposure at the petrous apex.

Combined approaches, which involve utilisation of a posterior fossa craniotomy as well, with or without sigmoid sinus ligation, are seldom necessary. Inferior temporal gyrus resection and anterior temporal polectomy can help in expanding the superior exposure. Such a corticectomy is safer than resorting to prolonged retraction of the temporal lobe.

Transtemporal Approaches

The petrous bone has been considered an obstructing 'hump' by neurosurgeons, during the approach to clival or petroclival lesions. In the various recently described skull base surgical approaches, the petrous part of the temporal bone has been 'exploited' to enhance the exposure to deep seated lesions which were difficult to excise by the conventional neurosurgical approaches. Transpetrous approaches not only provide better exposure of the tumour in the cerebellopontine angle and petroclival regions, but also expose the intrapetrous extensions of the tumour and cranial nerves in healthy areas, so that their function can be better preserved. However, petrous bone drilling should highly be calculative and precise. Indiscriminate or overenthusiastic drilling of this important bone should be avoided. In some instances, it may be better to expose the lesion, analyse its consistency and vascularity before starting the petrous bone drilling procedure.

Most of the lesions situated in the petroclival region can be approached and safely resected by conventional neurosurgical operations, like the subtemporal and retrosigmoid, or combined subtemporal and retrosigmoid approaches. However, some tumours are hidden behind bony protuberances and in the angle of the petrous bone and the clivus (Figs 1 to 6) and various 'transpetrosal' approaches have been adopted (Figs 7 and 8).



Figs 2A to C: (A) T2-weighted MRI shows a large hyperintense midclival tumour deeply indenting the pons. (B) Contrast-enhanced CT scan shows the large tumour involving the pons. (C) Post-operative MRI showing complete resection of the tumour

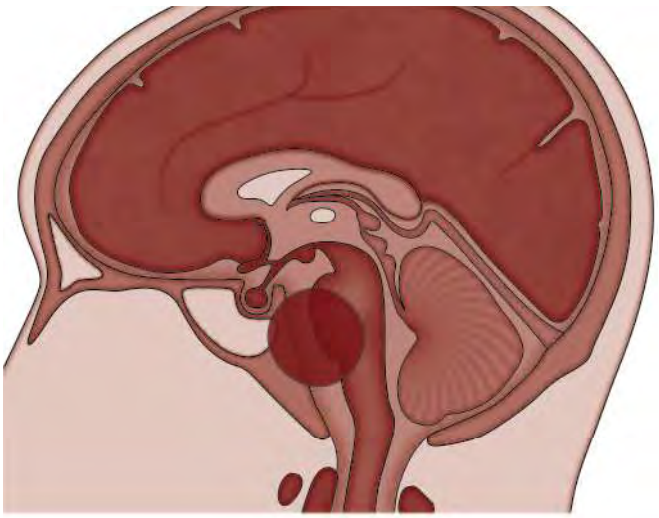

Fig. 7: Schematic drawing showing the midclival tumour. Apart from other parameters, the sight of the tumour in relationship to the clivus is important in determining the approach to the tumour and to determine the extent of exposure necessary

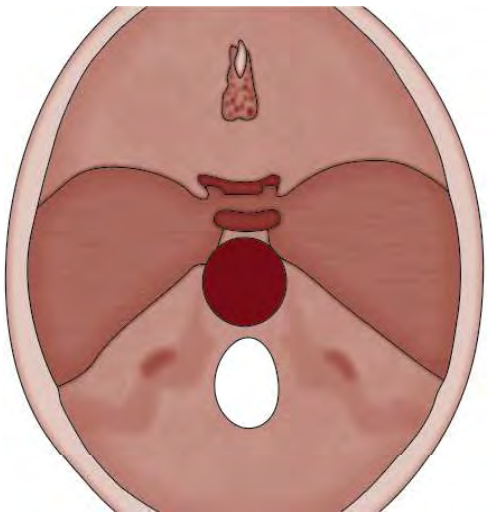

Fig 8: Transverse view of the midclival tumour. The lesion is located in front of the brainstem. The site of the tumour, relationship to the brainstem and pressure or absence of the arachnoid planes will determine the extent of the bone drilling necessary for a particular case

Spetzler et al.[90] summarised 'neurosurgical' approaches through the temporal bone into three groups:

Group 1: Approach preserving hearing.

Group 2: Approach where hearing is sacrificed.

Group 3: Approach that involves transposition of the facial nerve.

The petrous bone is situated at an angle of 40 degrees from the horizontal plane. On the other hand, the external ear canal is almost transversely placed. These angles should carefully be taken into account when one is planning the operation and more importantly while positioning the patient. The line drawn along the external ear canal meets the petroclival region and the approach along this line is the shortest from the surface. The petrous bone contains the vestibulocochlear apparatus and the facial nerve. At the anterior end of the bone lies the intrapetrous carotid artery and at the posterolateral end lies the sigmoid sinus. Apart from these structures, from the neurosurgical standpoint and for simplifying the study of the approaches, the rest of the petrous bone is described to be made up of packing material.

Petrous Apex

The Gasserian ganglion is situated in a shallow groove of the Meckel's dural cave at the petrous apex. The GSPN lies on the anterior face of the petrous apex. This nerve forms an important landmark for surgery in this region, as it is relatively easily identified and isolated during an extradural operation due to its location in a long shallow groove. GSPN originates from the geniculate ganglion and becomes extradural after its exit from the petrous bone through a small opening called facial hiatus. In some cases, the geniculate ganglion itself is without a bony cover and lies in an extradural location. Often there is another orifice situated slightly anteriorly and medially called the accessory hiatus from where emerges the lesser petrosal nerve. During surgery, which involves extensive manipulation in the region of the petrous apex, it is sometimes advisable to section the GSPN early in the operation as traction on this nerve may result in facial nerve palsy. There is a small branch of the middle meningeal artery, which courses along the GSPN supplying the facial nerve and geniculate ganglion. The horizontal portion of the intrapetrous carotid artery lies parallel and underneath the GSPN. The tensor tympani muscle and the Eustachian tube are located in small grooves on the anteromedial aspect of the inferior surface of the petrous bone. The Eustachian tube is osteocartilaginous in nature and about 35 mm in its length. It connects the middle ear cavity to the pharynx.

The intrapetrous carotid artery lies in the carotid canal and has been divided into three segments: (1) the vertical segment; (2) genu and (3) the horizontal segment. In its entire intrapetrous course, the artery is covered by a 'periosteal' sheath in which are enmeshed a large number of sympathetic nerve fibres. The carotid artery enters into the carotid canal after its cervical course. There is a firm fibrous ring at the site of the entry of the artery into the canal, which fixes the artery at this point. The temporomandibular joint is lateral to the vertical segment of the carotid artery. The genu of the intrapetrous carotid artery has a close relationship to the middle ear cavity. Anteriorly, the tenser tympani muscle and Eustachian tube travel in close proximity to the genu. Sometimes, the Eustachian tube and the tenser tympani muscle lie directly over the genu of the intrapetrous carotid artery, without any intervening bone. The horizontal segment of the carotid artery lies parallel to the GSPN. Posteriorly, this segment is in close relationship to the basal turn of the cochlea.

Mobilisation of the Intrapetrous Carotid Artery

Sometimes this difficult and precise procedure may be necessary to widen the exposure through the petrous apex and occasionally the segment of the artery needs to be exposed for the purpose of bypass graft, particularly whilst dealing with intracavernous tumours or lesions. Exposure of the horizontal segment of the carotid artery is frequently necessary for the purpose of proximal control of the artery during cavernous sinus surgery. The medial end of the horizontal segment of the artery lies under the Gasserian ganglion at the site where it gives off the third division of the nerve, which traverses through the foramen ovale. A very thin film of bone under the Gasserian ganglion covers the artery and sometimes the bony divide is absent and the ganglion lies directly over the artery, separated from it by a layer of fibrous connective tissue. It is easier to begin isolation of the artery from the medial side where the thin bone can be gently removed. The drilling can then continue laterally. The GSPN can be saved when only the horizontal segment of the artery needs to be exposed. Complete anterior mobilisation of the carotid artery is necessary for obtaining a wide anterior exposure through the petrous apex for lesions located in the mid or lower clivus region. This procedure necessarily involves sectioning of the Eustachian tube and tenser tympani muscle. Whenever there is a need to section the Eustachian tube or when it is accidentally opened, it should be denuded of mucosa, packed firmly with fat and later stitched to prevent cerebrospinal fluid (CSF) leakage. As the artery is firmly fixed by a thick fibrous ring at the site of its entry into the petrous bone, the ring has to be sectioned before satisfactory mobilisation of the artery is possible. The temporomandibular joint lies laterally to the vertical segment of the artery. The condyle of the joint can be either inferiorly displaced or sectioned to expose this part of the artery. Sectioning of the condyle is easier and the procedure is less painful to the patient in the post-operative phase.

The superior petrosal sinus lies in a shallow groove on the petrous ridge. The leaves of the tentorium are attached to the petrous ridge and divide to enclose the superior petrosal sinus. The superior petrosal sinus either courses over the root of the fifth nerve or rarely divides to enclose it. The superior petrosal sinus drains in close proximity to the junction of the transverse and the sigmoid sinus. The 'vein of Labbe' drains a large part of the temporal lobe of the brain into the transverse sinus. This vein needs to be preserved as sectioning it has been reported to result in temporal lobe haemorrhagic infarcts. The dissection of the vein from the arachnoid and from the surface of the temporal lobe can result in the relaxation and mobilisation of the vein, which can assist in enhancing the room for retraction of the temporal lobe. The sigmoid sinus marks the posterolateral limit of the petrous bone. More often, the right side sinus drains into the right jugular vein and the right atrium is larger than the left. Various presigmoid approaches have been described. Often the exposure obtained by this route can be restricted and there arises the need for posterior mobilisation of the sigmoid sinus to enhance the exposure. The mobilisation of the sinus is a technically challenging manoeuvre and should be done slowly and carefully. There can be profuse bleeding and sometimes sacrifice of the sinus may be necessary. For mobilisation of the sigmoid sinus, a long segment or the entire vertical length of the sinus needs to be exposed. The presigmoid dura (dura of the posterior fossa), retrosigmoid dura, tentorium and superior petrosal sinus also have to be adequately exposed. Sigmoid sinus unroofing is more difficult in the elderly due to dural adhesions to the bone. The sinus wall is very thin at the site of the bend from the transverse to the sigmoid sinus. The endolymphatic sac is sectioned during the process of cutting the presigmoid dura for posterior mobilisation of the sigmoid sinus. The superior petrosal sinus is isolated, clipped and sectioned. Sectioning of the superior petrosal sinus is safe as there is a large alternative channel for venous drainage from the basilar venous plexus. This procedure has never been reported to result in problems related to venous infarction. Ligation of the sigmoid sinus to enhance the exposure is seldom used in modern neurosurgery. However, the non-dominant sigmoid sinus can be ligated after confirming the adequacy of flow in the contralateral sinus. The sinus can also be sectioned after application of proximal and distal temporary clips. The sinus can then be repaired by application of sutures to the walls circumferentially at the end of the procedure to maintain the blood flow. The dominant sigmoid sinus should not be ligated.

Facial Nerve

This nerve has the longest intraosseous course (28–30 mm) of all the cranial nerves. With the various acute bends during its course the shape of the nerve resembles that of a 'Z'. There are three segments of the facial nerve in the bone. The labyrinthine segment is the one with which a neurosurgeon is familiar due to its proximity to the more commonly encountered lesion—the acoustic neurinoma. This segment is in close relationship with the superior semicircular canal, which presents on the superior surface of the petrous bone, as a well-defined bony elevation called the arcuate eminence. The labyrinthine segment of the facial nerve ends in the geniculate ganglion from where arise the greater and lesser superficial petrosal nerves. The tympanic segment of the facial nerve begins as an acute bend after the geniculate ganglion and is in close proximity to the middle ear cavity. Only a thin shell of bone covers the segment of the nerve in relationship to the middle ear cavity. The mastoid segment of the facial nerve lies firmly fixed in a bony canal. Some air cells may surround the nerve in this segment. The nerve exits from the stylomastoid foramen and the stylomastoid branch of the external carotid artery supplying the facial nerve enters through

the foramen. The digastric muscle groove forms an important landmark for the identification and isolation of the facial nerve.

Mobilisation of the Facial Nerve

During any transtemporal approach the facial nerve must adequately be protected. The intraosseous facial nerve rarely needs to be mobilised as it forms an obstructing band in any transpetrous approach. However, such mobilisation is wrought with the dangers of affecting the functional integrity of this important nerve and should be done only as a 'last resort'. Segments of the facial nerve can be unroofed and mobilised for enhancing the exposure. The mastoid segment of the facial nerve can be selectively mobilised for the exposure of the region in a glomus jugulare tumour. Some transpetrous approaches involve decompression and complete mobilisation of the facial nerve. The unroofing of the facial nerve is more difficult in the region of the geniculate ganglion due to the relationship with the thick bones of the semicircular canals and the cochlea and the relative thinness of the nerve (bottleneck of the nerve) in this region. The labyrinthine segment of the nerve is accompanied by three other nerves (cochlear, superior and inferior vestibular nerves); thus rendering the dissection of the facial nerve relatively safe. The mastoid segment of the facial nerve is also difficult to unroof due to its relatively long course in the firm surrounding bone. Any attempt towards mobilisation of the facial nerve involves tedious dissection. Mobilisation necessarily involves sacrifice of blood vessels supplying the nerve. There is an inherent risk of precipitating a partial paresis after mobilisation of the nerve. The temporomandibular joint is directly anterior to the external ear canal. The glenoid fossa bulges in the middle fossa floor. The posterior end of the root of the zygomatic arch divides to form the external landmark of the condyle.

Approaches Preserving Hearing

The petrous apex and the mastoid bone are two major areas deprived of neural or vascular structures. The presigmoid-retrolabyrinthine-transmastoid approach has been used to approach petroclival lesions. However, on some occasions the labyrinth forms an obstructing bulge in the field, restricting the exposure and resulting in a posteriorly and inferiorly directed approach. Injury to the labyrinth often results in an immediate hearing loss. Some authors have recently suggested the use of partial labyrinthectomy to widen the exposure from the presigmoid route. Such a procedure has been shown not to affect hearing. Superior projection of the jugular bulb (high jugular bulb) can also limit the exposure obtained by the transmastoid (or translabyrinthine) approach. Posterior mobilisation of the sigmoid sinus can be used to enhance the exposure. The presigmoid transmastoid exposure is combined with the subtemporal exposure for widening the exposure.

Kawase described a triangle (named after him) in the petrous apex lateral to the root of the trigeminal and medial to the internal auditory meatus.[55] This part of the petrous bone can be drilled in a middle fossa approach providing a crucial window to lesions located in the region of the mid clivus. The exposure can be enhanced underneath the Gasserian ganglion. The cochlea is the lateral limit, while the horizontal segment of the petrous carotid artery is the medial limit. The exposure can be increased by the anterior displacement of the carotid artery or by drilling the cochlea.

Approaches Involving Sacrifice of Hearing

The presigmoid translabyrinthine approach is an anterior extension of the presigmoid retrolabyrinthine approach. The approach involves removal of the semicircular canals, thus enhancing the exposure. The facial nerve comes in the way during this approach while exposing petroclival region tumours. The transcochlear approach is the anterior extension of the translabyrinthine approach.

Approaches Involving Mobilisation of the Facial Nerve

Elaborate transpetrous approaches have been described for petroclival lesions some of which involve mobilisation of the facial nerve. Approaches involving extensive resection of the petrous bone with or without translocation of the facial nerve include transcochlear and total petrosectomy approaches.[82,90,97] The total petrosectomy approach has been described by Sekhar et al.[90] The approach involves unroofing of the entire facial nerve and its posterior mobilisation. The petrous carotid artery is displaced anteriorly. The unroofing of the entire petrous segment of the facial nerve is a time consuming procedure and involves a high possibility of jeopardising facial nerve function. The transcochlear approach can be modified and segments of the facial nerve can be mobilised.

Extended Middle Fossa Approach[27]

The author has found the approach relatively quick, safe for the facial nerve and results in an extensive manoeuvrable exposure. It involves unroofing and depression of the external ear canal, removal of the glenoid cavity of the temporomandibular joint, exentration of the middle ear ossicles, posterior mobilisation of the labyrinthine and tympanic segments of the facial nerve and drilling of the petrous bone from an entirely lateral perspective. An extensive and low exposure of the petroclival region, posterior aspect of the cavernous sinus, upper and mid clivus and the cerebellopontine angle is obtained. The anterior surface of the brainstem up to the pontomedullary junction is exposed with minimal

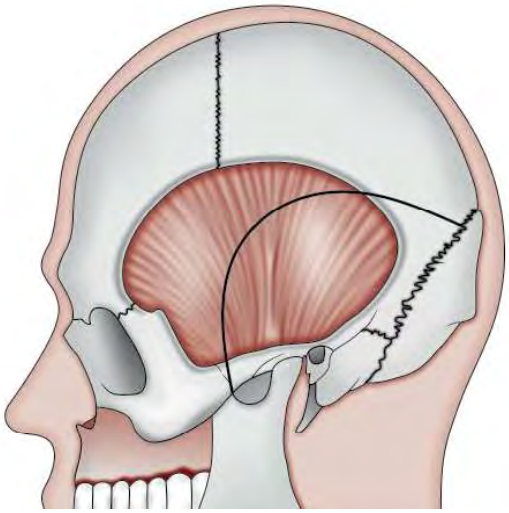

Fig 9: Line drawing showing the scalp incision. The incision starts anterior to the tragus and then traverses superiorly over the middle of the zygomatic arch and then posteriorly in the occipital region. The centre of the operative activity is in the line of the external ear canal

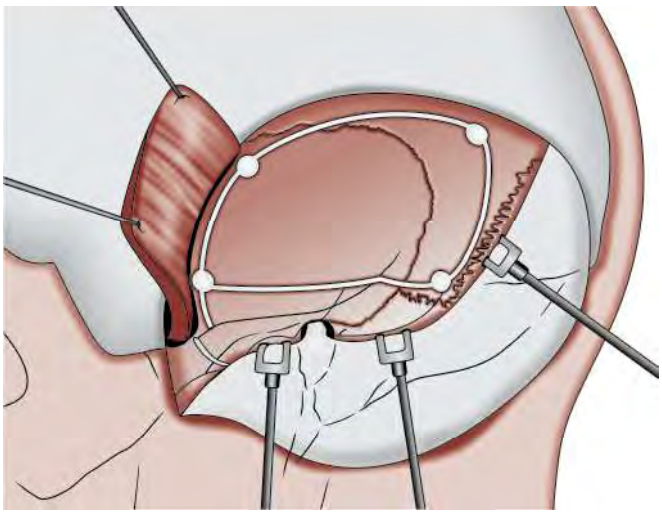

Fig. 10: The root of the zygomatic arch, roof of the external ear canal and the superior half of the mastoid bone are exposed. The part of the temporalis muscle exposed is reflected anteriorly. The sites for burr holes and the craniotomy are seen

or no retraction of the temporal brain (Figs 9 to 27). The vein of Labbe and the sigmoid sinus drainage are unhampered. Anterior and posterior extension of the exposure is possible. Only a limited mastoidectomy and labyrinthectomy, necessary to facilitate exposure and mobilisation of the facial nerve, is required. The dome of the jugular bulb sets the inferior limit of the exposure. Hearing is sacrificed.

Operative Technique

The patient is placed in a lateral position. Under continuous external lumbar CSF drainage, a low temporal craniotomy with the base centred on the external ear canal is performed (Figs 9 to 13). This is followed by unroofing of the superior half of the bony external auditory canal and removal of the glenoid fossa and the root of the zygomatic bone, taking care to preserve the meniscus of the joint (if a larger exposure is necessary, the external ear canal may be exenterated and closed and the mandibular condyle resected).[23,80,90] Drilling of air cells in the upper and middle half of the mastoid bone remaining anterior to the sigmoid sinus and wide opening of the antrum is carried out. The external ear canal is depressed inferiorly with the tympanic membrane after removing the ossicles of the middle ear, thus preserving the sterility of the field. The dura is elevated off the petrous bone and the GSPN and the foramen of the middle meningeal artery are identified.

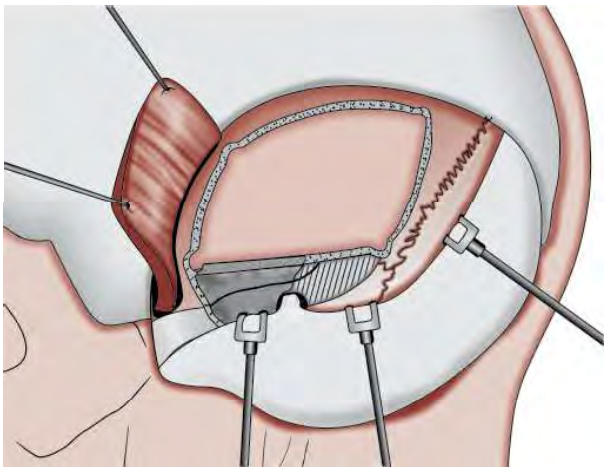

Fig. 11: Low temporal craniotomy. The roots of the zygomatic arch and the glenoid fossa are preferably removed in one piece with the help of an electric saw. The shaded angled lines depict the area of mastoid bone and the roof of the external ear canal that can be removed with the help of an electric drill. Note that the centre of the basal exposure is on the external ear canal

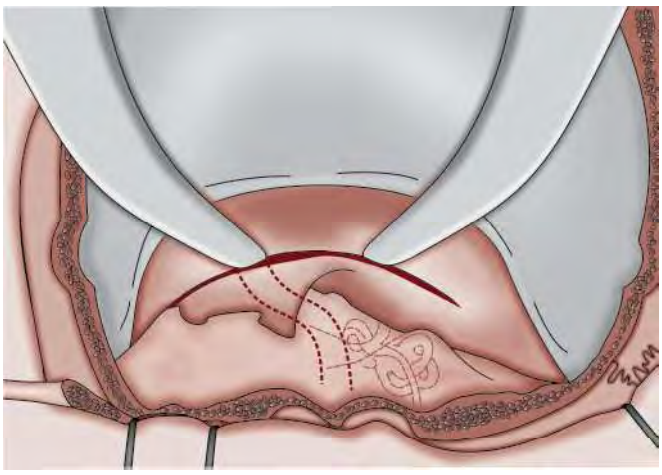

Fig. 12: The condyle and the superior half of the external ear canal are unroofed and the superior half of the mastoid air cells has been drilled to obtain a basal exposure. Elevation of the middle fossa dura and exposure of the Gasserian ganglion, foramen spinosum, foramen ovale, foramen rotundum and the anterior face of the petrous bone

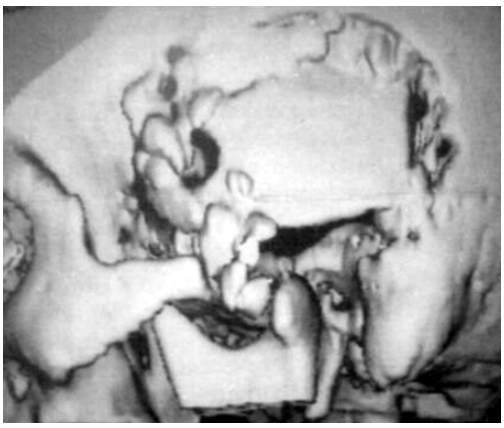

Fig. 13: Post-operative three-dimensional CT image showing removal of the posterior aspect of the zygomatic arch, roof of the condyle and the external ear and the superior part of the mastoid air cells. The basal exposure available to the petrous apex can be appreciated

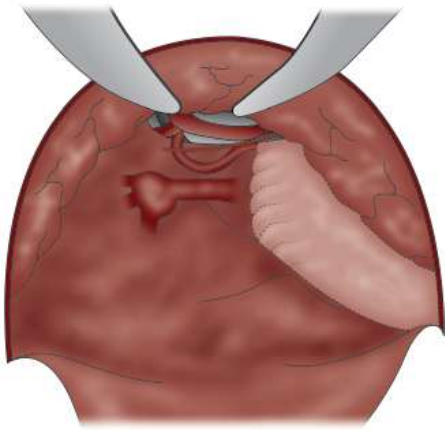

Fig. 14: After the basal bone work, the dura is opened, the temporal lobe is retracted and the edge of the tentorium and the brainstem are exposed

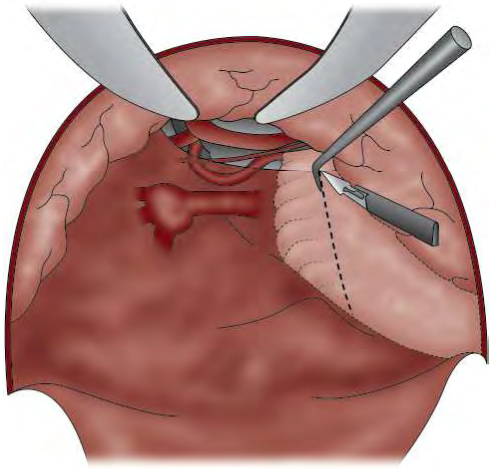

Fig. 15: Tentorial dural flap is being made. A blunt hook is used to elevate the tentorium. The hook and the knife are being used (as described in the text) to make the tentorial incision

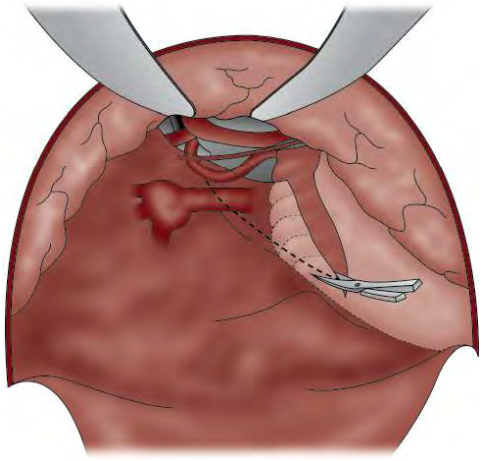

Fig. 16: The tentorial incision has been completed and the tentorial dural flap is elevated. The tentorial flap can be resected by cutting along the superior pertrosal sinus or can be rotated anteriorly over the middle fossa floor. Brainstem, cerebellum, superior cerebellar artery, posterior cerebral artery, petrosal vein and cranial nerves third to eighth are exposed widely

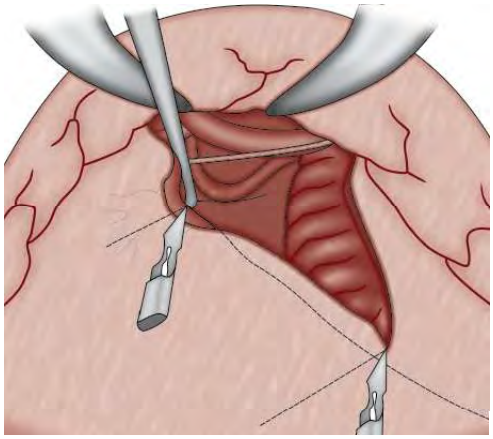

Fig. 17: Drawing showing the incision over the roof of Meckel's cave (after application of haemostatic clip to the superior petrosal sinus). An incision of the middle fossa dura can also be made, a procedure, which connects the extradural with intradural compartments

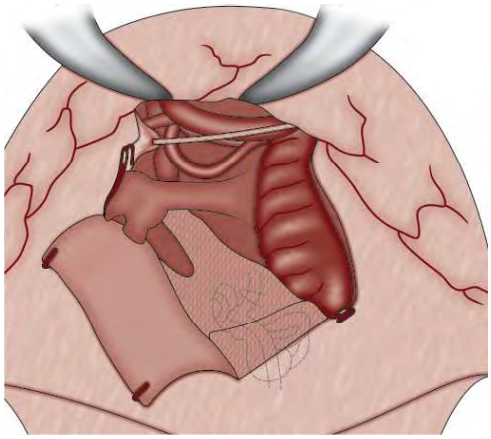

Fig. 18: The superior petrosal sinus is clipped with the help of two sets of clips, one over Meckel's cave and the other laterally in the region of the arcuate eminence. The fifth nerve root, posterior half of the Gasserian ganglion and the cerebellopontine angle are now exposed

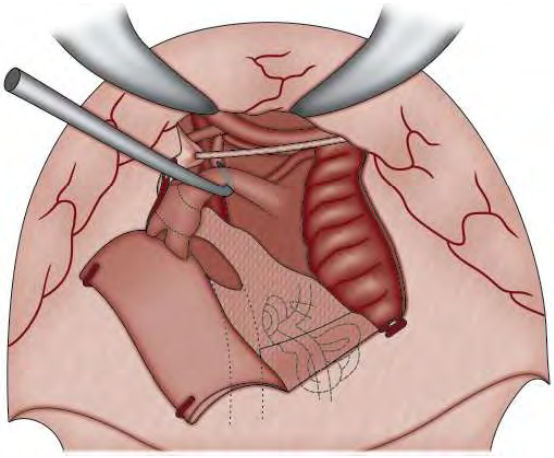

Fig. 19: The root of the fifth nerve can be lifted superiorly (after its adequate mobilisation in the region of Meckel's cave dura) to expose part of the brainstem and basilar artery

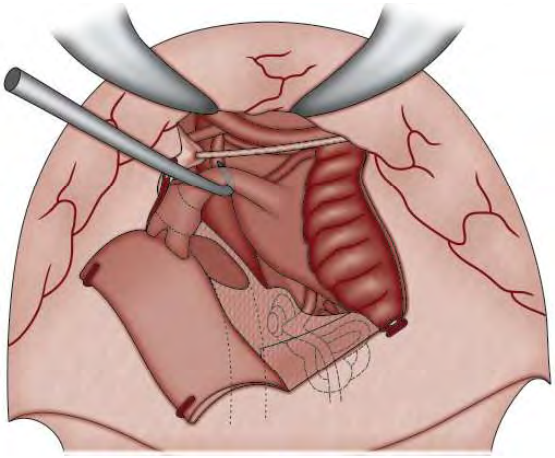

Fig. 20: The petrous apex posterior to the course of the carotid artery (horizontal petrous and precavernous sinus segment) and medial to the cochea is resected to enhance the exposure of the brainstem

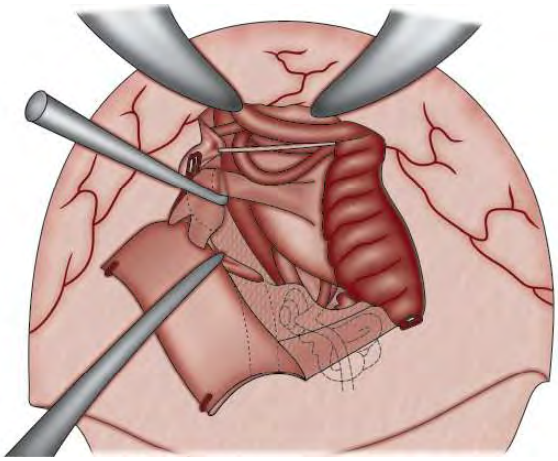

Fig. 21: The petrous carotid artery is depressed anteriorly to expose an additional segment of the petrous apex, which can be drilled to improve the exposure

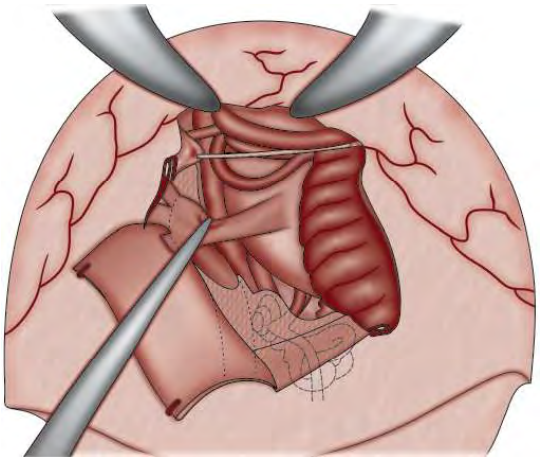

Fig. 22: The fifth nerve root and the Gasserian ganglion can be depressed inferiorly to expose the petroclival region bone, which can be drilled

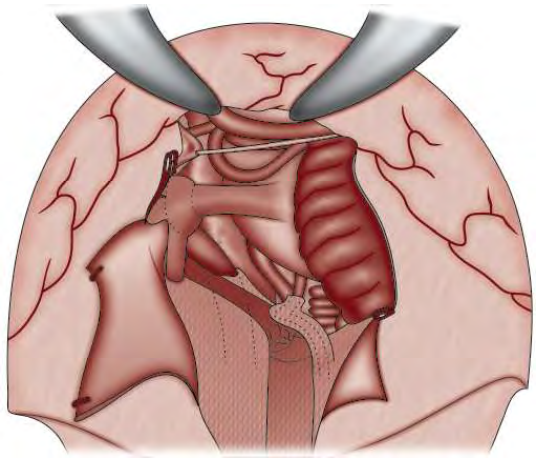

Fig. 23: Bony unroofing of the horizontal segment of the petrous carotid artery. The bone medial to the labyrinthine segment of the seventh cranial nerve (in its course in the internal auditory canal up to the geniculate ganglion) is removed, including the cochlea and the labyrinth in the bone drilling. The exposure is thus widened. Such bone drilling also exposes the lateral aspect of the cerebellopontine angle

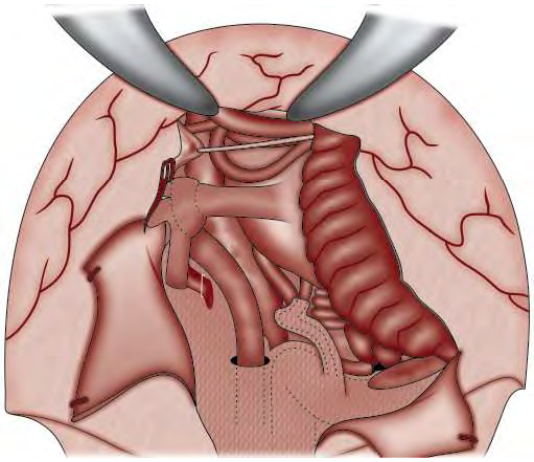

Fig. 24: Further drilling of the petrous bone. The Eustachian tube is sectioned and clipped, and the middle ear contents are exenterated and removed. The vertical segment, genu and the horizontal segments of the intrapetrous carotid artery are unroofed of the bony cover. The tympanic segment of the facial nerve is also unroofed of the bony cover

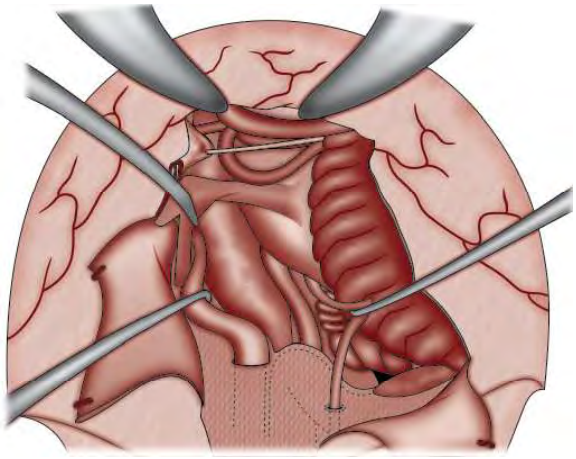

Fig. 25: The entire intrapetrous carotid artery is mobilised anteriorly, the tympanic and labyrinthine segments of the facial nerve are mobilised posteriorly and the petrous bone is resected entirely in a lateral perspective. The mastoid segment of the facial nerve is not yet unroofed. A large portion of the brainstem is now exposed. The inferior limit of the exposure is set by the dome of the jugular bulb

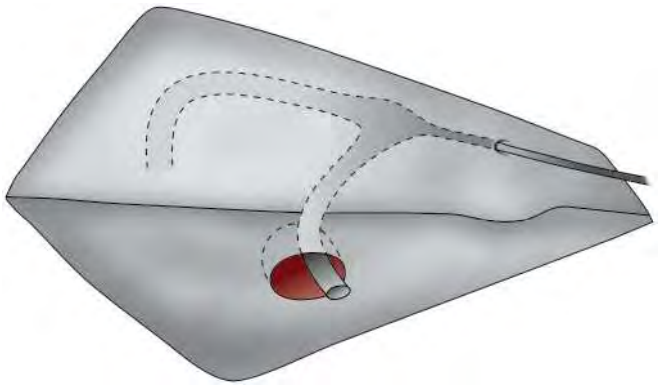

Fig. 26: Simplified figure depicting the winding course of the seventh nerve. Number 1 is the labyrinthine segment; number 2 is the tympanic segment and number 3 is the mastoid segment of the facial nerve. The nerve lies in a bony canal

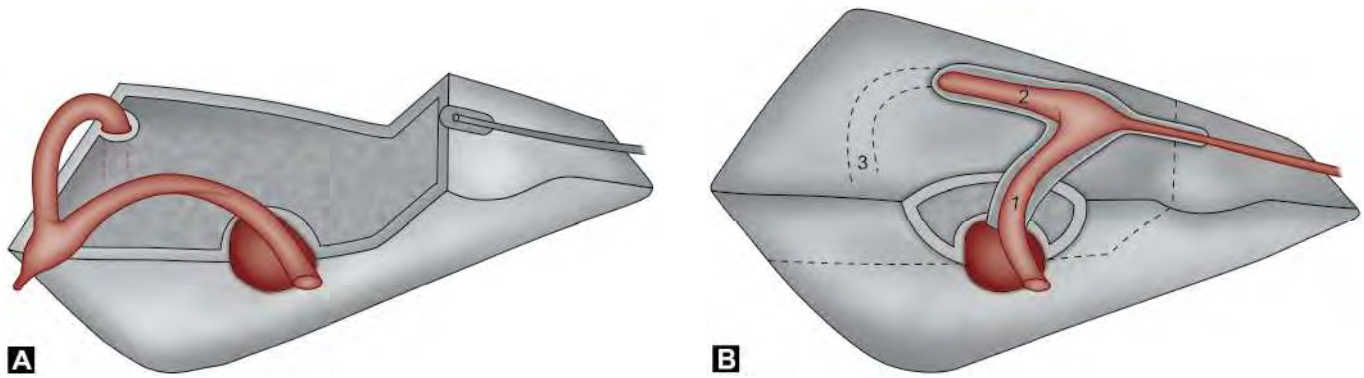
The middle meningeal artery is coagulated and cut. The GSPN is followed laterally and the geniculate ganglion is unroofed of its thin bony cover (Figs 26 and 27). Partial superior labyrinthectomy is carried out to expose the dura of the internal auditory meatus. The thin bony shell covering the tympanic segment of the facial nerve is removed by gentle drilling. The 1st and 2nd segments of the facial nerve are dissected. The facial nerve now hangs freely from the brainstem up to its external genu and is mobilised posteriorly, after sectioning the GSPN sharply (Figs 25 to 27). After the mobilisation of the nerve, radical resection of the petrous bone is carried out avoiding the petrous segment of the internal carotid situated anteromedially and jugular bulb inferiorly. The petrous carotid artery is under control and can be mobilised for obtaining further anterior exposure. The Eustachian tube is closed (Fig. 24).[79] Widening of the anterior and posterior exposure as necessary is carried out. For intradural lesions, the temporal dura is opened and the lobe retracted superiorly. The edge of the tentorium is cut parallel to the petrous ridge preserving the fourth nerve and the root of the fifth nerve. The superior petrosal sinus is clipped. An approach directed inferomedially to the upper and mid clivus, petroclival area and the posterior cavernous sinus is now available (Figs 24 and 25).

The procedure is an approach from the middle cranial fossa and occipital craniotomy is not necessary. Unroofing of the sigmoid sinus and decompression of the mastoid segments of the facial nerve and their mobilisation as required in other similar approaches can be time consuming procedures. Tears in the sigmoid sinus can complicate the operation. Facial nerve decompression in the tight bony mastoid canal can be difficult, and important blood supply to the nerve from the stylomastoid foramen may be jeopardised. These manoeuvres are avoided in this operation. The approach being relatively quick when compared to other similar approaches can be more frequently utilised. The procedure involves posterior mobilisation of the tympanic and labyrinthine segments of the facial nerve. A small branch of the middle



Figs 27A and B: (A) Partial unroofing of the labyrinthine and tympanic segments of the facial nerve. (B) The labyrinthine (1) and the tympanic segments (2) of the facial nerve which have been mobilised posteriorly after sectioning of the greater petrosal nerve. The nerve now hangs freely from the brainstem to the point of the external genu of the nerve (3)

meningeal artery, which accompanies the GSPN, rarely of critical importance in its vascular supply to the geniculate ganglion, needs to be sacrificed. The mobilisation of the facial nerve from the brainstem to the external genu provides a large area of petrous bone for resection. Since the major blood supply is preserved, its function can be retained. The approach to the clivus is directly lateral. The height of the external and middle ear is utilised to provide the critical basal exposure minimising the need for temporal lobe retraction. Clival meningiomas can be devascularised from the base early in the operation. Control of the internal carotid artery in the petrous bone can be obtained whilst dealing with lesions involving the posterior cavernous sinus. The approach is particularly useful in situations where the facial and eighth nerve functions are already compromised.

Basal Extension of Lateral Subtemporal Craniotomy

The temporal line (supramastoid ridge) forms the inferior limit while the zygomatic arch is the anterior limit of a conventional neurosurgical basal craniotomy. Zygomatic osteotomy, inferior displacement of the temporalis muscle and resection of the floor of the middle fossa have been employed to improve the basal exposure. Partial unroofing of the external ear canal has also been recommended for enhancing the inferior angle of vision.[88] Resection of the root of the zygomatic arch, including the glenoid fossa, roof of the external ear and superior third of the mastoid process, was seen to improve the basal exposure for lateral subtemporal middle fossa approaches. The enhanced exposure helps in reducing the extent of brain retraction and improves the working space for manipulation of the instruments.

Operative Technique

The scalp incision starts about 1.5 cm anterior to the tragus and about 1.5 cm inferior to the mid-point of the zygomatic arch (Fig. 9). Initially it curves superiorly and then posteriorly. The incision exposes the squamous temporal and posterior parieto-occipital bone, posterior aspect of the temporalis muscle, roots of the zygomatic arch, supramastoid crest and the base of the mastoid process (Fig. 10). The posterior aspect of the temporalis muscle is mobilised in the subperiosteal plane from the temporal bone and the sharp superior border of the zygomatic arch. The muscle is then rotated anteriorly. A low temporal craniotomy with the base centred on the external ear canal is performed (Fig. 11). The anterior and posterior roots of the zygomatic arch, the glenoid fossa and lateral half of the roof of the external ear canal are removed preferably with the help of an electric saw in one piece (Figs 12 and 13). Rongeurs may also be used. The external ear canal is protected by sharp subperiosteal separation of the canal from the bony roof. The meniscus of the temporomandibular joint is exposed but not removed. The superior third of the mastoid air cells are drilled. The mastoid antrum and the sigmoid sinus are not exposed. After the procedure the mastoid air cells are packed with bone wax, free muscle or fat graft. The posterior third of the temporalis muscle along with its fascia can be rotated to the base for strengthening the reconstruction. The bone piece harbouring the roots of the zygomatic arch, glenoid fossa and the lateral aspect of the roof of the external ear is replaced and sutured along with the craniotomy bone flap. The external auditory meatus is packed with cotton pledgets to avoid cicatricial stenosis.

Most of the described skull basal techniques employ zygomatic osteotomy, facilitating inferior displacement of the temporalis muscle. Some reports indicate the usefulness of resection of the middle fossa floor.[79] However, such approaches are anterior subtemporal and the working angle to the petrous apex is about 40–60 degree from the horizontal plane in the line of the external ear canal. The posterior subtemporal approach is performed after mastoidectomy. In such a posterior subtemporal approach, the vein of Labbe obstructs the exposure. The direct lateral approach, as described, is the shortest route to the petrous apex and has an additional advantage of ease of working in the infratentorial compartment.

The technique of extension of the temporal craniotomy, as described, improves the horizontally wide basal exposure directly in line with the petrous apex. It does not affect hearing and the function of the temporomandibular joint. The procedure is technically easy. There is no need to expose the superior bend of the sigmoid sinus, which is posterior in the line of the operative direction. This makes the exposure relatively quick and safe. The temporalis muscle is displaced anteriorly and is thus away from the operative field. Resection of the entire zygomatic arch is unnecessary. Whenever indicated, the basal exposure could further be widened both horizontally and inferiorly. The condyle of the temporomandibular joint can be removed, the external ear canal can be depressed (after it is entirely unroofed) along with the tympanic membrane (by removal of the ossicles of the middle ear) or it can be exenterated and closed, mastoidectomy could be widened and the sigmoid sinus can be displaced posteriorly, whenever indicated. The petrous bone resection can be done as much as is necessary. The external ear canal has loose fibrous connections to the bony and cartilaginous wall. It is more firmly attached to the spine of Henle, where sharp dissection may be necessary to dissect the canal. In an occasional case, where a radical transpetrous approach is being adopted, the superior half of the external ear canal can be unroofed up to the tympanic membrane and middle ear cavity. After the section of the head of the malleus, the external ear canal with the tympanic membrane can be depressed inferiorly, thus adding to inferior exposure and maintaining sterility of the surgical field.

Middle Fossa Sub-Gasserian Ganglion Approach[29]

Most of the lateral procedures described for resection of clival chordomas involve relatively complex and extensive skull basal dissection, exposure and mobilisation

of the carotid artery,[79,85] facial nerve,[23,54] sigmoid sinus[2] and temporomandibular joint.[23,79,85]

A modified lateral subtemporal, transpetrous apex and sub-Gasserian ganglion approach is suitable for clival chordomas. The approach selection is based on the typical anatomic relationship of chordomas in terms of site of origin, pattern of growth, bone destruction and neural and vascular displacements. The approach is suitable for dealing with tumour anterior and lateral to the brainstem, clival part of the tumour and its subcavernous sinus extensions. The carotid artery is under control. The approach has the advantage of being simple and relatively quick and its familiarity to general neurosurgeons. The tumour can be excised radically and extension of the anterior, posterior and inferior exposure is possible.

Operative Technique

The patient is placed in the lateral position and a continuous external drainage of CSF by lumbar subarachnoid catheter placement is established. The approach is by a subtemporal route centred on the external canal. A low temporal craniotomy is done and a basal exposure is obtained along the anterior face of the petrous bone. In cases where a large middle fossa extension of the tumour is present, zygomatic arch osteotomy can be done to elevate the temporalis muscle out of the exposure.[31]

The approach is initially intradural where the temporal lobe is elevated off the middle fossa floor. By an intradural exposure and tentorial incision, the root of the trigeminal nerve and the Gasserian ganglion are unroofed and mobilised superiorly.[26] Underneath the medial and inferior dural cover of the Gasserian ganglion is the most prominent bulge of the tumour. An incision is made along the root of the fifth nerve over the dura of Meckel's cave. It is sometimes difficult to identify the fifth nerve. Identification of the nerve after an initial tumour debulking or following the nerve along its intradural segment is advocated. The tumour is seen immediately underneath Meckel's cave. The petrous apex is drilled laterally as required, more frequently up to the medial end of the internal auditory meatus, taking care to preserve the cochlea. The internal carotid artery is identified in the petrous apex and is exposed and protected. The soft, relatively avascular and extradural nature of the tumour helps in expanding the exposure. The tumour is removed by an initial intratumoural debulking procedure that releases the stretch on the neural and vascular structures, which are then dissected free. Remaining intratumourally and debulking is the safest way to preserve the adjoining critical structures. Anterior extension of the exposure by removal of the middle fossa base, condyle of the temporomandibular joint and mobilisation of the petrous carotid artery, and lateral and inferior extension by additional drilling of the petrous bone and whenever necessary mobilisation of the labyrinthine and tympanic segments of the facial nerve is possible. The clivus is directly in the line of the exposure and can be drilled widely.

It was observed that combined intradural and extradural exposure makes dissection of the tumour from the cranial nerves and brainstem relatively safe and under direct vision. A basal temporal exposure and lumbar drainage of CSF make temporal lobe elevation off the base relatively safe. The inclusion of the intradural route for a primarily extradural tumour, although against the principles of skull base surgery, significantly increases the exposure, which is critical for the safety of the patient and radical resection of the tumour. Direct lateral and basal exposure is the shortest surgical route to the tumour located in the clivus and adjacent areas. As the tumour displaces the adjoining segments of the internal carotid artery anteriorly, the direct lateral route is more appropriate for its safety. The arteries and nerves are relatively easily dissected free from the tumour, probably because their involvement is only compressive and not invasive in nature. The petrous apex and clival bone are eroded, precavernous and cavernous segments of the internal carotid artery are displaced anteriorly and the Gasserian ganglion is elevated on the dome of the tumour in all cases. These anatomical features are utilised in developing a sub-Gasserian ganglion exposure. The tumour, being soft and relatively avascular, is removed by debulking and blunt dissection (Figs 28 and 29). The dura protects the brainstem and cranial nerves and an intact periosteal sheath protects the internal

Figs 28A to C: (A) T1-weighted MRI shows the large hypointense petroclival chordoma. (B) Post-operative CT showing resection of the tumour. Part of the petrous apex is destroyed by the tumour and part was drilled during surgery. (C) Bone window of the post-operative scan showing the petrous apex medial to the internal acoustic meatus drilled during surgery. carotid artery. Reconstruction of the region is easy and safe.

The described middle fossa approach appears to be ideal for dealing surgically with the more characteristic form of clival chordomas. This approach could be used and exposure widened depending upon the extensions of the tumour.

Infratemporal Fossa Interdural Approach[28]

A small craniectomy in the infratemporal fossa incorporating the foramen ovale can be used to resect even large trigeminal neurinomas with extensions from the posterior cranial fossa into Meckel's cave and the lateral wall of the cavernous sinus. After the bone cut the dural sheath around the mandibular nerve and Gasserian ganglion is opened. By progressive tumour debulking, the entire lesion can be exposed and safely excised. The head position and the surgeon's view of the tumour are modified to obtain a basal view. The craniectomy at this strategic site provides an avenue for control of the carotid artery at the petrous apex, avoids the need for brain retraction and permits safe and complete resection of the tumour. The approach appears to be ideal for selected cases of trigeminal neurinomas.

Operative Technique

Operative technique has been depicted in Figures 30A to G. The patient is positioned so that the head is extended and turned to the contralateral side. The right-handed surgeon stands on the right side at the level of the chest of the patient irrespective of the side of the lesion and suitably alters the angle of the rotation of the head (Fig. 30G). A linear incision is made over the zygomatic arch, which is completely resected (Figs 30A to C). The temporalis muscle is either split in the direction of the incision (Fig. 30C) or can be reflected either superiorly or inferiorly. The muscles of the infratemporal fossa are dissected from the bone by sharp subperiosteal dissection and the foramen ovale is exposed (Fig. 30D). With a microdrill, a small craniectomy, measuring approximately 3 x 3 cm is made in the infratemporal fossa, incorporating the foramen ovale (Figs 30E to G and 31). An incision is made on the lateral surface of the dural sheath of the mandibular nerve at the level of the foramen ovale and extended posteriorly to the inferior and lateral surface of the dural sheaths covering the Gasserian ganglion. Usually the tumour is palpable in the region of the ganglion. The dura over the Gasserian ganglion and the lateral wall of the cavernous sinus is reflected exposing the middle fossa part of the tumour (temporal lobe exposure and middle fossa floor durotomy is avoided). The bulk of the tumour usually dilates the dural sheaths in each case and a large exposure can be obtained. After debulking the tumour, the exposure can be further widened. A large tumour in the region of the Gasserian ganglion is seen to dilate Meckel's cave, thus providing sufficient exposure to the part anterior to the brainstem. The inner membranous dural layer separates the tumour from the venous channels of the cavernous sinus. The cavernous sinus part of the tumour can usually be resected by anterior angulation of the microscope. The tumour is followed in the posterior fossa along Meckel's cave. The operation is thus carried out in the infratentorial compartment. Tumour resection in the posterior cranial fossa can be carried out only if the tumour is small or is very soft and amenable to suction debulking and subsequent resection (Figs 31A to C).

A modification of the above-described interdural approach is suitable in some cases, particularly those with small tumours (Figs 32A and B). The patient is placed in the lateral position. Lumbar drainage of CSF is carried out. A limited subtemporal craniotomy in the line of the external ear canal is done. Zygomatic osteotomy is avoided. The temporalis muscle is displaced anteriorly. Extradural exposure of the foramen ovale is done. Dissection is done between the dural sleeves of the third division of the trigeminal nerve and the tumour is resected.

Presigmoid Approach

Presigmoid approaches are advocated to provide an anterior line of vision to the cerebellopontine angle or clival tumours. The working distance between the surgeon and the tumour can be minimised by this approach. However, there are the following various disadvantages in the approach:

1. The working space between the anterior surface of the sigmoid sinus and the external ear canal is small. The space can be extended by posterior mobilisation of the sigmoid sinus, but complete unroofing and mobilisation of the sigmoid sinus is not always an easy procedure and can sometimes lead to tears in the sinus with its attendant problems.
2. The line of vision to the tumour in the presigmoid transmastoid approach can severely be limited by the posterior semicircular canal. Partial labyrinthectomy can help in improving the exposure. Although some authors report preservation of hearing after partial labyrinthectomy, such results are difficult to achieve.
3. The line of vision by a selective presigmoid approach is in the inferior and posterior direction of the cerebellopontine angle.

Retrosigmoid Approach

In some situations, a selective retrosigmoid approach may be appropriate. Lateral extensions into the cerebellopontine angle and inferior extensions of the lesions along the clivus are indications for such an approach.

Surgical Technique

The patient is placed in a semi-sitting position with the head suitably turned. Routine precautions necessary for surgery in the sitting position are taken. A conventional retrosigmoid approach adopted for large acoustic neurinomas is used. The lateral aspect of the transverse sinus and the sigmoid sinus are exposed widely. The cisterna magna is exposed early in the operation to drain CSF and relax the brain. The initial exposure of the tumour is through a lateral supracerebellar infratentorial avenue. The nature of the tumour as regards its arachnoid planes, consistency and vascularity is assessed. The tumour is first debulked towards the site of its attachment. Once the region is significantly relaxed, the cerebellum is retracted away from the petrous bone and the exposure is then done through the cerebellopontine angle. The tumour resection is further performed using careful microsurgical dissection techniques, by working

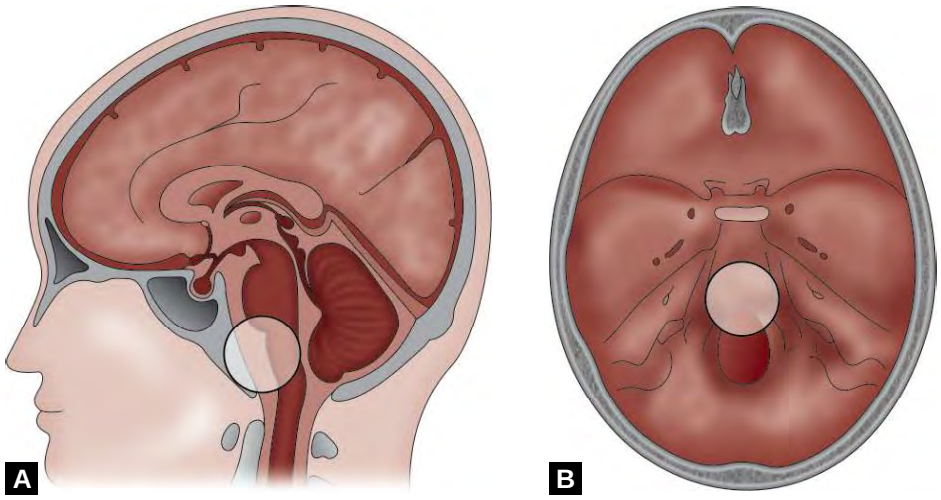

Figs 33A and B: (A) Schematic drawing showing a low clival tumour. (B) Transverse view of the low clival tumour

in both the lateral retrosigmoid and the supracerebellar infratentorial avenues. Drilling the petrous apex medial and superior to the seventh-eighth-nerve complex can access extensions of the tumour into the middle cranial fossa. A tentorial incision is performed whenever a superior angle is needed.

Transcondylar Transclival Approach

An anterior approach is rarely needed for lesions located in the pontomedullary region. An approach which involves unroofing of the jugular bulb followed by either its superior mobilisation or packing, drilling off of the condyle and continuing the drilling to resect part of the clivus provides a considerably anterior view to lesions anterior to the lower brainstem (Figs 33A and B).

Supracondylar Infrajugular Bulb Keyhole Approach to Anterior Medullary Lesions[32]

Lesions located anterior to the brainstem in the lower clival and foramen magnum region pose a formidable surgical challenge. Various lateral approaches have been suggested to widely expose anterior medullary lesions. An alternative approach is suggested, which involves resection of the subsigmoid and retrosigmoid sinus, lateral occipital squamous bone, lateral border of the foramen magnum and a small area of bone between the jugular bulb and the condyle. Exposure, manipulation or mobilisation of the extradural vertebral artery is avoided. Condylar resection is not necessary. The exposure is relatively quick and significantly anterior. After an adequate inspection of the nature of the lesion, the exposure could be widened in all directions.

Operative Technique

The patient is placed in a lateral position and the head is flexed and turned to the contralateral side (inferiorly). A low occipital and retromastoid incision is made, which extends inferiorly into the upper cervical region. The lateral rim of the foramen magnum and the occipital squama are exposed. The part of the occipital squama including the rim of the foramen magnum is carefully removed (Fig. 34). The bone removal is extended anteriorly to include the bone of the supracondylar and infrajugular bulb region. The condylar vein can sometimes result in troublesome bleeding and has to be adequately dealt with. The exposure obtained is of a key shape (Fig. 35). A dural incision is made as shown in Figure 36. The lateral edge of the cisterna magna is opened. The intradural segment of the vertebral artery is identified and its relationship to the tumour analysed. No additional exposure may be necessary if the tumour is soft and suckable. The exposure may be widened inferiorly by drilling off the condyle as necessary, preserving the hypoglossal nerve, which travels in the superior half of the condyle. The bone on the inferior aspect of the jugular bulb can widely be removed. In cases where the dura of the jugular bulb is thick, the jugular bulb can be compressed superiorly and the exposure widened (Fig. 37). In most of the cases, no significant further increase in exposure is necessary. Whenever necessary,

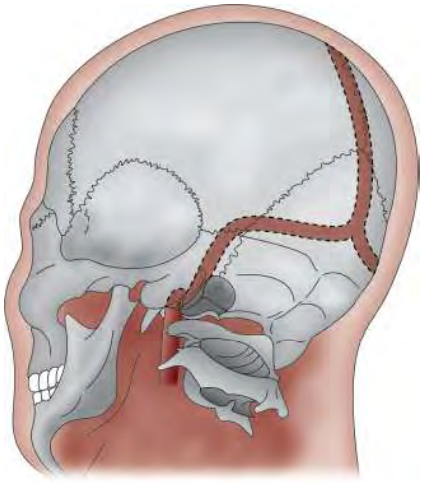

Fig. 35: The shaded area shows the site of keyhole exposure. The bone lying between the condyle and the jugular bulb is removed. Bone removal is extended posteriorly to include the anteroinferior part of the occipital squama

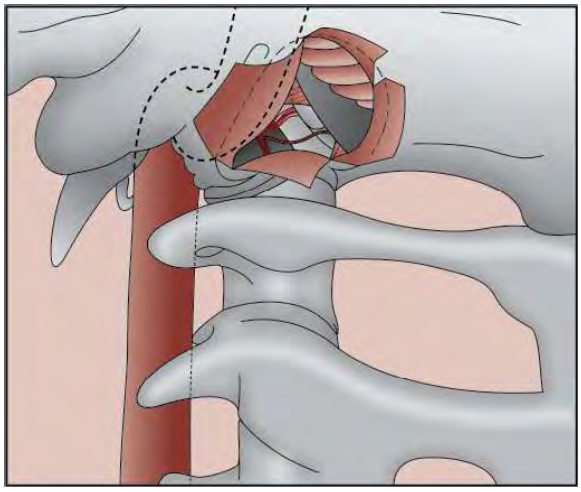

Fig. 36: The supracondylar and the infrajugular bulb area are exposed after making a cruciate dural incision and reflecting the dural flaps. A large condylar vein can sometimes cause troublesome bleeding

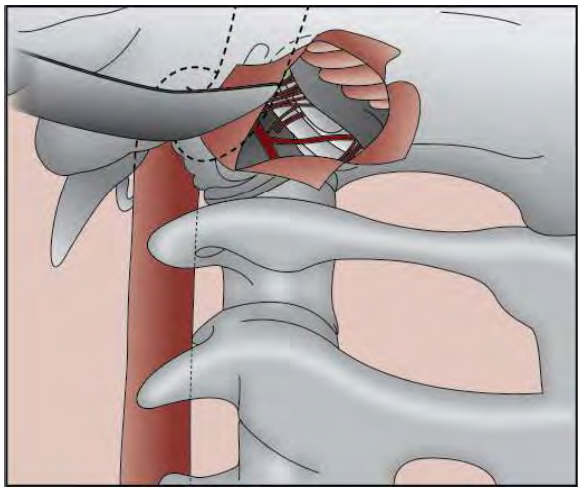

Fig. 37: The jugular bulb is being retracted superiorly to enhance the exposure. In cases where additional exposure is required the jugular bulb can be sacrificed and packed after adequate preparations

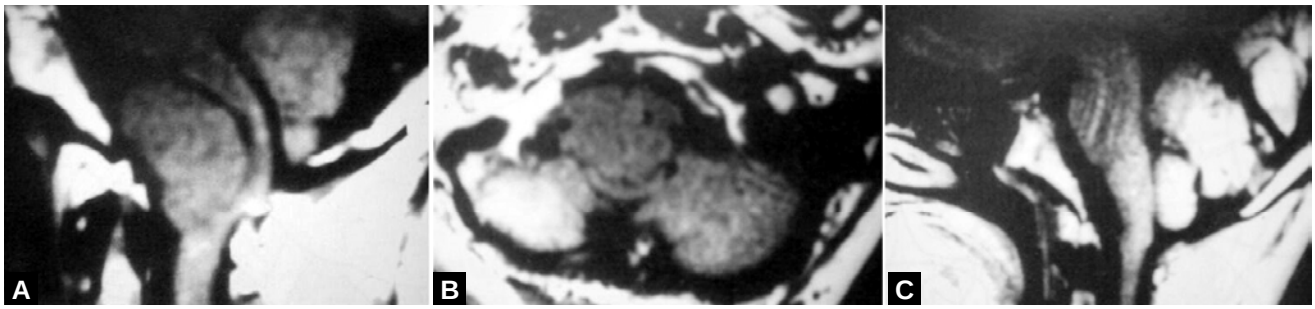
various complex manoeuvres like exposure of the extradural vertebral artery, its mobilisation, condylar resection, obliteration of the jugular bulb and other such procedures may be employed (Figs 38 to 40).

Splitting of the Temporalis Muscle[33]

There are various methods recently described to enhance the middle fossa basal exposure circumventing the obstruction to the visual field, imposed by the



Figs 38A to C: (A) T1-weighted MRI shows a large anterior medullary meningioma. (B) Transverse cut showing partial encasement of both vertebral arteries. (C) Post-operative scan showing complete resection of the tumour. A lateral suboccipital subsigmoid sinus approach was used to resect the tumour

(C) Post-operative scan shows complete resection of the tumour. A supracondylar, infrajugular bulb keyhole approach was used to resect the lesion

temporalis muscle bulk (Figs 41 and 42). Spiller has employed splitting of the temporalis muscle to improve the caudal exposure in various subtemporal approaches including the classic one described.

Anatomical and Technical Considerations

The temporalis muscle is a fan shaped muscle. The muscle arises from a large area of squamous temporal bone and adjoining frontal, parietal and occipital bones and the fibres converge towards a relatively smaller area over the coronoid process of the mandible. The muscle fibres are vertically oriented and directed towards the site of insertion. There is abundant vascular supply to the muscle through the anterior, middle and posterior sets of deep temporal arteries and a large superficial temporal artery. The nerve supply to the muscle is through deep temporal branches of the mandibular division of the trigeminal nerve. Vertical splitting of the temporalis muscle into half or one third would still preserve the main feeding vessels and the nerves. The splitting will not adversely affect the circulation and will not significantly disturb the function of the temporalis muscle. Retraction of the split segments of the temporalis muscle can be carried out after its adequate mobilisation. The zygomatic arch is anatomically inferior in relation to the middle fossa floor. In most instances, zygomatic arch osteotomy is performed principally to facilitate the inferior displacement of the temporalis muscle, as its bulk limits the basal exposure. By splitting the temporalis muscle, zygomatic arch osteotomy could be avoided in some cases (Figs 43 and 44). The split in the muscle is done directing the incision towards the coronoid process to minimise the transection of the muscle fibres. The split may predominantly be anterior or posterior depending upon the desired area of the exposure. In cases requiring exposure of the infratemporal fossa, splitting of the temporalis muscle can be performed after zygomatic osteotomy. This manoeuvre helps in obtaining a significantly improved inferior exposure of the infratemporal fossa.

The variety of vascular lesions and tumours involving the cavernous sinus, petroclival region, infratemporal and sphenopalatine fossa are treated by a basal subtemporal and infratemporal fossa approach. In most of the described approaches, the temporalis muscle is completely detached from its insertion in the temporal fossa[13,62,69,79] and its caudal displacement is facilitated by

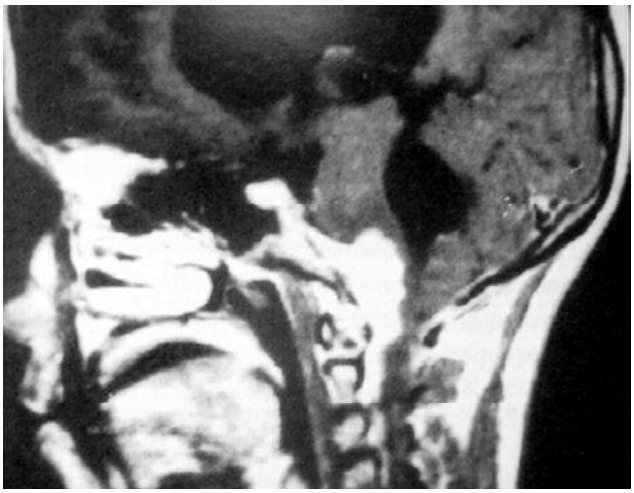


Fig. 40: Contrast-enhanced MRI shows the large premedullary lesion

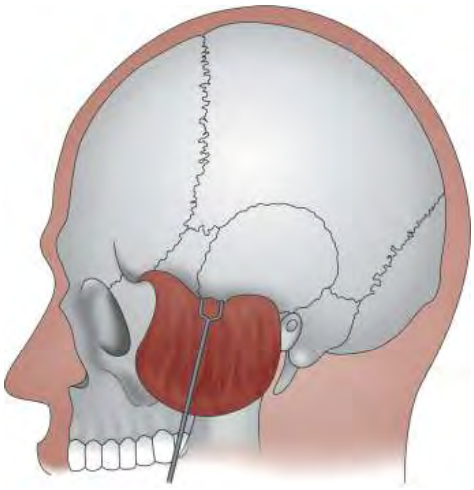

Fig. 41: The temporalis muscle is reflected inferiorly. Zygomatic osteotomy is not done. The muscle bulk limits the extent of basal exposure

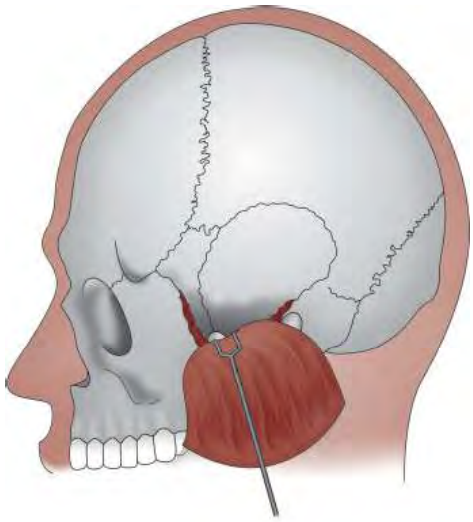

Fig. 42: Zygomatic osteotomy is done to caudally retract the muscle and obtain an improved middle fossa basal exposure

either temporary resection or mobilisation of the zygomatic arch. Al-Mefty et al. suggested superior retraction of the temporalis muscle along with its coronoid insertion.[3] Splitting of the temporalis muscle as described in this report appears to be a simple alternative to the other described procedures to obtain a basal subtemporal exposure. The obstacle to the surgical exposure imposed by the muscle bulk is minimised. In selected cases, zygomatic osteotomy is not necessary. The problems of denervation and devascularisation of the temporalis muscle are avoided.

Tentorial Dural Flap[26]

For a subtemporal transtentorial approach to the anterior part of the posterior fossa, a tentorial incision has to be made. Various methods of retraction of the edge and incisions over the tentorium have been described. The fourth nerve travels along the edge of the tentorium. The nerve is closer to the edge of the tentorium in its distal segment as it comes closer to the posterior clinoid process. In the terminal segment, the nerve travels within the fold of the tentorial dura for about 1 cm. An incision made in the tentorium about 1.5 cm posterior to the posterior clinoid process, keeping the nerve under vision by retracting the tentorial edge, is usually safe as regards the fourth nerve. The root of the fifth cranial nerve and the petrosal vein lie directly underneath the tentorium. During surgery, the location of the superior petrosal sinus cannot be adequately ascertained and an inadvertent incision into it could lead to profuse bleeding which could be difficult to control due to the inadequate space available underneath the retracted temporal lobe. Bleeding from the superior petrosal sinus occurs from both sides of the cut. Packing of the sinus, after widely opening the mouth of the sinus, with oxidised cellulose and pressure with the help of cotton patties can adequately control the bleeding. Removal of extra oxidised cellulose can then be carried out, so that it does not obstruct the operative field. Sometimes, an incision into the venous sinuses in the tentorium could lead to troublesome bleeding. The incision, travelling parallel to the superior petrosal sinus and terminating in the tentorial dural edge posterior to the entry of the fourth nerve, is the most commonly employed incision. Such an incision is appropriate in cases where a large part of the tentorium cannot be exposed due to the limited working space (Figs 15 and 16). Adequate relaxation of the brain is necessary for the described incision and eversion of the tentorial dural flap. An incision is begun at the free edge of the tentorium at the level of the posterior edge

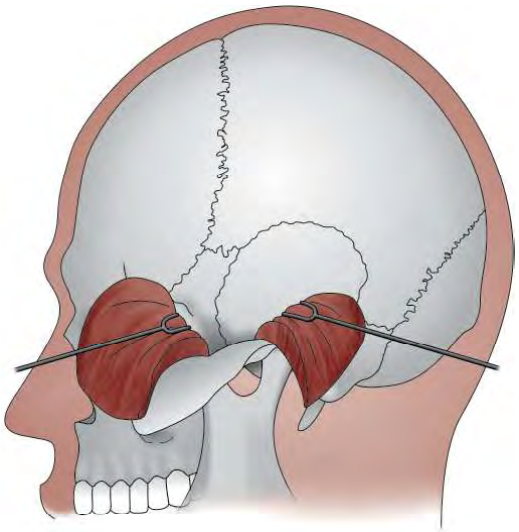

Fig. 43: Splitting of the temporalis muscle. The shaded area depicts the extent of enhancement of basal exposure

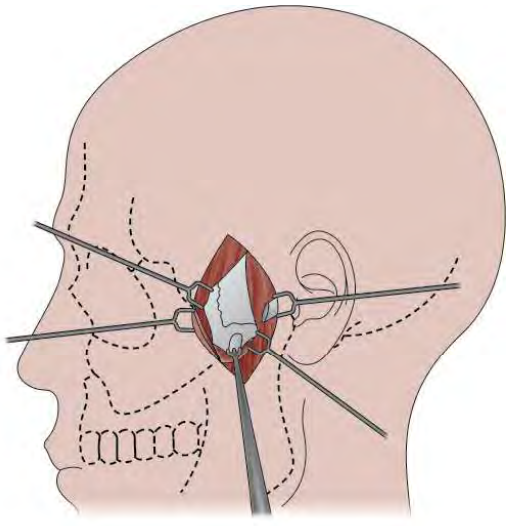

Fig. 44: Splitting of the temporalis muscle is done after zygomatic osteotomy. The infratemporal fossa muscles are retracted inferiorly. The basal exposure is enhanced by these procedures. The mandibular division of the fifth cranial nerve can be exposed extracranially

of the cerebral peduncle and is then directed anterolaterally towards the superior petrosal sinus. A triangular flap of the tentorial dura is everted over the superior petrosal sinus. The flap has the advantage of being simple and safe and provides a wide window to the infratentorial structures. In addition, the occasional troublesome bleeding from the superior petrosal sinus and the petrosal vein is avoided. The fourth and fifth cranial nerves are protected and exposed widely. The 40 degree angle of the petrous bone in relation to the transverse plane is used in making the incision over the tentorium.

Operative Technique

A blunt hook is used to elevate the tentorial edge and the number 11 scalpel is used to advance the incision anterolaterally in the tentorium. The knife cuts the tentorium onto the base of the hook, which protects underlying structures (Figs 14 and 15). The incision starts from the edge of the tentorium at approximately the posterior edge of the cerebral peduncle and traverses towards the base of the petrous pyramid and superior petrosal sinus. As the hook advances laterally, its path is obstructed by the edge of the petrous bone. In this fashion, a triangular flap of tentorium is obtained which can be everted over the superior petrosal sinus. Thus, a wide exposure of the infratentorial compartment is obtained (Fig. 16). The described incision starts much posterior to the conventional incisions, which begin or terminate just posterior to the dural entry point of the fourth nerve. Thus, it results in better protection of the fourth nerve. On eversion of this flap based on the superior petrosal sinus, a wide exposure to the infratentorial compartment is obtained. The need to make an incision on the tentorium superior to the fifth nerve and petrosal vein is avoided. As the incision is directed anterolaterally, the edge of the petrous bone obstructs the passage of the hook, which therefore helps prevent an inadvertent injury to the superior petrosal sinus. If felt necessary, the tentorium can be sutured at the termination of the surgery.

SELECTION OF APPROACHES

Petroclival Meningiomas

There are various approaches described to deal with lesions present in this location.[2,8,9,11,15,17,23,27,34,36,46,53,67,83,90,97] However, for a particular tumour, there is only one approach, which is ideal and best and can be performed. It is up to the surgeon to decide the ideal route of approach for a particular lesion. The familiarity with all the available approaches is, therefore, essential so that the best possible route could be selected.[35] Expertise in one particular route and an attempt towards performing surgery on all lesions with the same approach could sometimes lead to problems. Some modifications of the described approaches may be appropriate for a particular case to be operated upon. The issues in the decision regarding the approach should include considerations for the approach, which could be performed in the shortest time, is least difficult and safest for the patient. The exposure must be wide and it must also provide with avenues for dealing with disasters like major arterial tears, and for reconstruction of nerves and arteries whenever necessary. A secure basal reconstruction is vital to prevent CSF leakage.[25,30]

Petroclival meningiomas are described as those which arise from the dura in the region medial to the entry of the trigeminal root into Meckel's cave.[83,84] Frequently, these and other lesions situated in this region involve the cavernous sinus and extend down to the mid-clivus, encasing and/or displacing critical arteries and perforators.[38,40,42,43] For satisfactory and safe excision of these tumours, an adequate exposure is necessary. Meningiomas in proximity to the clivus are amongst the most difficult surgical problems. The difficulty in resection of these lesions stems from the following facts:

- These benign lesions are frequently of large size at the time of presentation.
- Patients present with relatively subtle neurological symptoms and signs.
- Tumours may encase vital major arteries and perforators, sacrifice of which could result in permanent neurological deficit or even death. Such an eventuality could have taken years in the natural course of tumour growth.
- Alternative methods of treatment, like radiosurgery, chemotherapy, photodynamic therapy, etc. are of no proven value in the management of these cases.
- If left alone, in all probability, the tumour will grow and lead to a slow and crippling death. Once the decision regarding surgery is made, one has to understand that in most cases the operation is not being carried out to obtain a histological confirmation regarding the nature of the lesion as such information is usually available with reasonable certainty on radiological studies. The approach to the lesion involves retraction of vital brain structures and the operation needs prolonged microsurgical dissection to isolate the lesion from vital structures. A low or basal approach that could avoid or limit retraction is necessary as prolonged and excessive retraction may not be well tolerated by the brain. A small or limited excision may be of very little help to the patient. It only means that clival lesions should be approached when the operating team is reasonably confident that a total or a radical excision could be made on the basis of their experience and level of confidence.

The extensions of the tumour and the site of its attachment into the supratentorial compartment, cavernous sinus and cerebellopontine angle are common. A variety of transpetrous and middle fossa approaches have recently been described and successfully employed for surgical resection of petroclival meningiomas. Some authors believe that the conventional retrosigmoid approach is suitable for some of these tumours.[8,73,74]

The selection of a surgical approach for petroclival meningiomas will depend on a large number of variables. The nature of tumour extensions, its relationship with the petrous bone, clivus, tentorium and cavernous sinus and the adjoining critical neural and vascular structures, generally determine the surgical approach. However, personal preferences, experience and the nature of surgical technique of tumour resection of an individual surgeon will be some crucial factors that can affect the decision making, regarding the surgical approach. The variability of extensions and relationship with adjoining structures in petroclival meningiomas, unlike a fixed location and specific extensions of tumours, like acoustic neurinoma, makes it impossible to specify that one particular surgical route is the best or the only option in all of these cases. A posterior fossa approach is generally suitable for large sized tumours, those having majority of their bulk in the posterior cranial fossa and those 'pointing' into the cerebellopontine angle. The approach is suitable for tumours having a lateral extension beyond the internal auditory canal and an inferior extension below the level of the pontomedullary junction. Smaller, superior clival tumours, tumours with predominant location in the tentorial hiatus, and those with significant extension into the supratentorial compartment or in the cavernous sinus may be suitable for an alternative basal subtemporal approach. A lateral surgical position and a basal subtemporal approach could be selected in cases where the anticipated tumour resection is expected to be a more difficult and a time-consuming process, as long operations with the patient in the sitting position can be stressful both for the patient and for the surgeon's hands.

The posterior fossa approach is far easier, safer and quicker and the exposure of the tumour is wider, as compared to the transpetrous or basal subtemporal approaches. It avoids any major arterial or venous or venous sinus handling, manipulation or sectioning, petrous bone drilling and temporal lobe retraction related problems. The authors of the earlier reports recommending a posterior cranial fossa route for these tumours also recommended a sitting surgical position for the patient.[8,15,21,89] Utilising both supracerebellar and cerebellopontine angle routes provide a circumferential exposure of the tumour. The extent of petrous bone drilling could be determined after the nature of the tumour is ascertained. This is in variation of the predetermined bone drilling necessary for all transpetrous and basal subtemporal approaches. The site of the tumour attachment is in direct line of vision and can be widely exposed. Dural and wound closure is easy and safe. The approach has the additional advantage of its familiarity to general neurosurgeons. Although it is possible to resect middle cranial fossa extension of the tumour by a posterior cranial fossa route by a limited petrous apex drilling, the exposure of this part of the tumour is cumbersome and the angle available for tumour resection is inadequate.[73,74] The control of venous haemorrhage from the superior petrosal sinus and the cavernous sinus is more difficult through the posterior fossa route. Proximal or local control of the carotid artery is not possible and control of supratentorial arterial bleeding is more difficult by the posterior cranial fossa route.

Recurrence rate of a relatively small residual tumour after a radical surgical resection has been seen to be distinctly low.[59,73,74] Due to this reason, and the possibility of disabling morbidity or even death as a result of injury to blood vessels and neural structures, various authors have stressed the need of a safe dissection and cautioned against extensive dissection around the perforators and cranial nerves.

Out of the total 84 petroclival meningiomas treated in our institution over 12 years, we found a posterior fossa approach suitable in 28 cases. After using extensive[36] and limited petrous dissection,[31,36,94] and also using a conventional posterior fossa approach for a number of years, the percentage of these tumours dealt with by a posterior fossa route have increased in the later part of the series. The tumours treated by different surgical routes in our series had varying degree of complexities and the extent of tumour resection and the overall patient outcome varied and was not comparable.

Trigeminal Schwannomas

Surgery for trigeminal schwannomas has evolved along with the evolution of skull base surgical techniques.[95] Various operative approaches have been described for the surgical resection of trigeminal neurinomas.[77,98] The anatomy of the tumour and its dural covering, anatomy of the region and anatomy of various approach routes are now better understood. Trigeminal schwannomas can now be removed by relatively small and straightforward exposures with minimum brain handling. Most recent papers show a higher percentage of tumour resection, low surgical morbidity rate and a lower rate of recurrence.[60,71,75,98] Various reports have stressed the need for radical surgery, as total resection leads to cure from the tumour and the recurrence rate for cases with partial resection is relatively higher with trigeminal schwannomas than acoustic schwannomas.[4,28,41]

On the basis of the presenting clinical features and characteristic radiological signs, a diagnosis of a trigeminal schwannoma could be made in a majority of cases. Such a diagnosis is crucially important in planning the surgical strategy for the cavernous sinus related lesion. The relationship of the dura and the adjoining structures, which is characteristic in trigeminal schwannomas, may not be for other tumours in the location. The major impediment to complete removal is an inadequate exposure.[18,71,77,79] Due to the location in the depth, close proximity to vital neural and vascular structures; the ideal surgical approach should be the shortest and most direct, it must be wide and low, avoiding the need for prolonged and excessive brain retraction. Considering

the location within the layers of the dura in the middle fossa, there is no specific need to have proximal control of the carotid artery as would probably be necessary for some other lesions in this location.[48] The layers of the dura also form a relatively thick barrier that facilitates surgery. A large proportion of these tumours are soft, necrotic and only moderately vascular. Frontotemporal craniotomy with or without orbitozygomatic osteotomy and the petrosal approaches were used in the early part of the series but were later not preferred. For small tumours in the middle fossa and those having a relatively small extension into the posterior fossa, an infratemporal fossa interdural approach as described by us was found safe, quick and provided adequate exposure.[28] Al-Mefty et al. described section of the temporalis muscle at its insertion at the coronoid process and superior displacement of the muscle.[3] The temporalis muscle can also be either split in the direction of its fibres or reflected inferiorly and later used for basal reconstruction.[31,33] The tumour is followed into the posterior fossa along the dilated Meckel's cave. The presence of atrophy of the temporalis and pterygoid muscles makes the infratemporal fossa exposure relatively easy. The Meckel's cave is exposed after drilling and widening of the foramen ovale and the tumour is resected by dissection between the layers of the dura. The direction of approach and the surgeon's position in relation to the patient can be altered, to provide a direct and low access to the lesion. The approach is interdural, avoiding the need to expose the temporal lobe and thus, limiting the extent of temporal lobe retraction to the minimum. The possibility of anatomically dissecting the layers of the dura in cases of trigeminal neurinoma has been described earlier.[19,68] Although the carotid artery at the petrous apex is not exposed, as it is usually covered by the dural sheath, it is close in the field and can be exposed relatively easily.[49] The tumour bulk widens Meckel's cave and a large window can be obtained for resection of the posterior fossa portion of the tumour. The soft nature of the tumour can be used to circumvent the disadvantage of confronting the tumour prior to exposure of the brainstem. The approach to the tumour anterior to the brainstem is entirely infratentorial. In our series, the exposure obtained by such an approach was seen to be adequate for safe and complete resection of the tumour. In none of the cases was there any need to extend the exposure for tumour removal. The entire procedure could be performed in a significantly shorter time and is cosmetically appealing.

In larger tumours located in the middle fossa, a basal lateral subtemporal exposure is suitable.[31,37,41] Extradural exposure for relatively smaller tumours and intradural exposure for larger tumours is appropriate. The approach is found to be suitable to deal with the middle fossa component or both the middle fossa and the posterior fossa component of the tumour. The basal extension of the exposure is achieved by resection of the roots of the zygomatic arch, roof of the external ear canal and superior third of the mastoid bone.[88,94] The temporalis muscle is rotated anteriorly and is thus away from the field.[31,65] The exposure is centred over the external ear canal in line with the petrous apex. The direction of the approach to the tumour is the shortest and perpendicular from the surface and avoids any neural or vascular manipulation. Inclusion of mastoidectomy in the exposure added to the advantages of the petrosal approach.[3] In tumours located in the posterior cranial fossa, a retrosigmoid exposure is satisfactory. The tumour does not involve all the fibres of the fifth nerve and some fibres were invariably spared. At least some fibres of the nerve are preserved in the majority of cases. Working within the tumour, using blunt dissection with the help of suction or cavitron ultrasonic aspirator (CUSA) and avoiding coagulation, as much as possible, probably avoids injury to these fibres. The inferolateral approach to the tumour helps in preserving the more crucial first division of the trigeminal nerve than the frontotemporal approach, which provides an anterolateral trajectory. In the posterior cranial fossa, the sixth cranial nerve and the seventh-eighth-nerve complex are most likely to be injured during the dissection and need to be protected. Superior cerebellar and posterior cerebral arteries and their branches are critically located and need to be protected. However, in the majority of cases, the dissection of the cranial nerves and vessels off the tumour is relatively simple due to the presence of a well-defined arachnoidal plane of dissection from the tumour capsule. In the subtemporal intradural approaches, protection of the 'vein of Labbe' forms a crucial part of the operation. Pre-operative lumbar drainage of CSF can be used to great advantage. In patients with large tumours, resection of the inferior temporal gyrus helps in increasing the exposure and avoidance of excessive retraction. In tumours having an extracranial extension, the infratemporal or orbital exposure is obtained depending on the extensions.

Foramen Magnum Meningiomas

Meningiomas in the region of the foramen magnum are relatively rare.[1] A large proportion of foramen magnum meningiomas are located anterior to the brainstem and have a close relationship to vital neural, vascular and bone structures. Meningiomas with en-plaque extension and extradural growth have been reported.[24,44,45,76] The clinical course is slowly progressive, leading to dysaesthesia, asymmetric motor weakness, gait ataxia and relatively less commonly, lower cranial nerve affection. Misdiagnosis due to uncommon symptoms, leading to wrong decisions and inappropriate treatment has frequently been observed with these lesions. MRI has provided a significant advancement in the diagnosis.[10] It clearly delineates the exact tumour size, location, site of dural attachment and relationship to vascular and neural structures, and provides an opportunity to assess its consistency and vascularity. Recovery after a successful tumour resection is almost instantaneous and recurrence rates have been

seen to be extremely low.[22] Injury to the brainstem, cranial nerves or vertebral artery or its branches can lead to a disastrous outcome for the patient and the family.[12,61,66] Surgery on meningiomas located in the region of the foramen magnum anterior or anterolateral to the brainstem constitutes a formidable challenge and has been evaluated by various authors over many years. Anterior transoral,[16,64] anterolateral transcervical,[57,92] extreme lateral,[86] far lateral[16] and lateral approaches[5,14,24,32,50,51,70,76] have been advocated and have been preferred over the conventional posterior approach.[39,70,76,91] Whilst there are certain obvious advantages of a lateral or an anterior approach to these lesions, a posterior approach used by various surgeons over a century also has a distinct set of advantages.[20] The meningiomas located in the region 'anterior' to the brainstem in the region of the foramen magnum are only rarely strictly anterior. Despite their varied sizes, most of these tumours point laterally on one side of the midline and the brainstem is displaced or twisted posterolaterally rather than posteriorly.

A midline skin incision and exposure of the region of the foramen magnum, occipital bone, arch of atlas and axis is far easier, safer, quicker and wider, when compared to any anterior or lateral approach. Extensive drilling of the occipital condyle,[5,56,76,86] lateral mass of the atlas[5] or anterior spinal elements[16] is not involved, avoiding the possibility of injury to the hypoglossal nerve and vertebral artery and spinal instability. The vertebral artery is easily exposed in the region of the arch of the atlas, at the site of its entry into the dura by a midline approach and proximal control is possible. Exposure of the extradural vertebral artery, its manipulation[86] and mobilisation amidst large venous plexuses necessary in some lateral approaches, involves considerable degree of effort and possible risks.[45] By a slightly larger midline skin incision and an additional retraction of muscles, a significant lateral exposure is obtained by the conventional midline posterior approach. The extent of additional bone removal necessary is determined, after ascertaining the nature of the tumour consistency, vascularity and the extent and site of dural attachment.

Additional drilling of the condyle is possible for a more lateral exposure in cases of directly anteriorly placed meningiomas. The condylar drilling is safer, as the vertebral artery and nerves are already exposed. The brainstem, cranial nerves, vertebral artery and the tumour are exposed in the same field and the dissection is carried out with all structures under vision. The exposure is improved after retracting the cerebellum and the operation can be done in the cerebellomedullary angle from a lateral perspective, employing appropriate angulation of the microscope. The exposure is wide and not 'deep', when compared to that obtained by transcervical, transoral and even lateral approaches.

Most of the meningiomas encountered are relatively soft and have moderate vascularity. They have a well-defined plane of arachnoid cleavage, which make the resection easier even with a relatively small exposure. The tumours are resected after performing an initial debulking and then by working within the planes provided by tumour growth. The tumour debulking provides additional working space for dissection. Debulking of larger tumours provides more space anterior to the brainstem, making it unnecessary to operate from a more lateral angle. The exposure of the anterolateral and anterior foramen magnum and clival dura is direct and in line of the exposure, which makes the coagulation and resection of the involved dura easily possible after tumour resection. Such a direct exposure is difficult or impossible by a strictly lateral approach and could be obtained only if the entire condyle is resected. Total and radical removal of the tumour should be attempted but, if dissection of the tumour from the vertebral artery, its branches, or any cranial nerve entails risk of damage, a small portion of the tumour can be left behind.

Clival Chordoma

Most of the lateral procedures, described for resection of clival chordomas, involve relatively complex and extensive skull basal dissection, exposure and mobilisation of the carotid artery,[85,79] facial nerve,[23,54] sigmoid sinus[2] and temporomandibular joint.[23,79,85]

A modified lateral subtemporal, transpetrous apex and sub-Gasserian ganglion approach is suitable for clival chordomas.[29] The approach selection is based on the typical anatomic relationship of chordomas in terms of site of origin, pattern of growth, bone destruction and neural and vascular displacements. The approach is suitable for dealing with tumour anterior and lateral to the brainstem, clival part of the tumour and its sub-cavernous sinus extensions. The carotid artery is under control. The approach has the advantage of being simple and relatively quick and its familiarity to general neurosurgeons. The tumour is excised radically and extension of the anterior, posterior and inferior exposure is possible.

183 Transpharyngeal Approach to the Cranio Vertebral Junction

AH Menezes

The transoral approach to the ventral craniocervical border is the most direct route for decompression of irreducible extradural pathology. These procedures encompass the transoropharyngeal, the transpalatal and the median mandibulotomy with glossotomy (Fig. 1).[9] The author's experience of 730 patients treated via the transoropharyngeal-transpalatopharyngeal route is shared with the readership. Since 1977, the procedure has evolved into a safe and direct approach with minimum morbidity and mortality.[5] The author's technique is elaborated here. Ninety-seven per cent of patients will require craniocervical stabilisation which is now carried out under the same anaesthetic as the transpharyngeal procedure.[10]

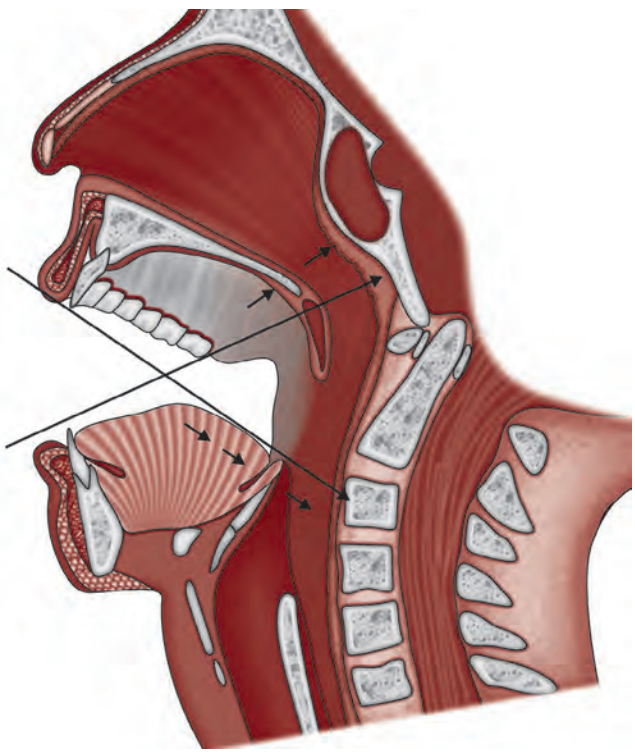

Fig. 1: Mid-sagittal line drawing of the face and neck to include the craniocervical junction. A soft palate elevation or a soft palate split with tongue depression allows exposure between the long arrows. The open areas identify the extent of exposure with removal of the distal hard palate. This brings one to the mid clivus. A midline glossotomy as indicated by the arrowheads, allows exposure to the C3-C4 vertebral body

INTRODUCTION

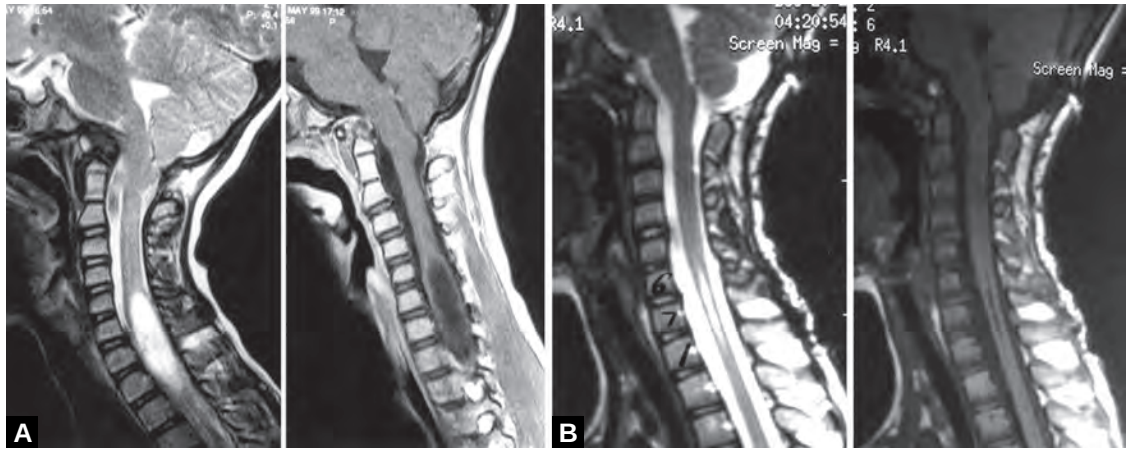
The relevant diagnostic imaging for abnormalities of the craniocervical junction consists of plain radiographs of the region which should include the skull and cervical spine. Dynamic studies with the flexed and extended position are made to assess the stability and the need for possible reduction.[8] The cervical spine radiographs should include the mandible so that the relationship of the craniovertebral border to the hard palate can be judged, including its accessibility. In patients with normal anatomy, the configuration of the clivus is normal (almost vertical). Thus, with the transoral approach, elevation of the soft palate suffices to provide anterior exposure of the craniocervical junction.[3,9] On the other hand, in patients with congenital abnormalities associated with hypoplasia of the clivus, this now tend to become horizontal. It appears as though the upper cervical spine has "ascended". Consequently, the soft and the hard palate must be sectioned.

Magnetic resonance imaging (MRI) is the mainstay of the neurodiagnostic armamentarium. The T1- and T2-weighted mid-sagittal MRI should be done in both the flexed and extended positions. This modality provides information about the neural structures, as well as their relationship to the bony abnormality and vascularity (Figs 2A and B). Magnetic resonance angiography should be performed when neurological dysfunction cannot be fully explained. In that circumstance, it is done with the patient in the rotated, flexed and extended positions, to identify vascular occlusions that can appear when the patient changes position.

Computed tomography (CT) of the craniocervical junction is an integral part of this author's assessment of the bony pathology. Conventional CT (2D CT) is further augmented by 3-dimensional CT reconstructions. This modality shows the location of the occipital condyles, the lateral atlantal masses and the axis body, as well as the lateral masses. The odontoid process is visualised and, in congenital abnormalities, it is very frequent that the odontoid process is actually smaller than in normal adults, because of segmentation abnormalities.

ASSESSMENT OF NUTRITIONAL STATUS

This issue is particularly important in patients who have had difficulty with swallowing and failure to thrive. It is also important in patients with rheumatoid arthritis,



Figs 2A and B: (A) Mid-sagittal T1- and T2-weighted MRI of craniocervical junction and cervical spine in a patient where the clivus-odontoid articulation indents into the mid medulla. Note the hindbrain herniation and the cervical syringohydromyelia. This individual will require a transpalatal approach. (B) Post-operative MRI in mid-sagittal plane of the same patient as in Figure 2A. A transpalatopharyngeal decompression of the ventral medulla has been performed. Note the reduction of the syrinx and the medullary decompression

atlantoaxial dislocation, tuberculosis and rheumatoid vertical migration of the odontoid process that compresses the brainstem.[4,7] Thus, pre-operative nutritional support is mandatory before operative intervention. Failure to do so results in wound dehiscence and non-fusion.[9]

Dental Hygiene

Dental hygiene is addressed to remove causes of bacterial contamination such as pyorrhoea, gingivitis or dental caries. This author has custom-built dental guards made so as to provide protection of the upper and lower dentition during surgery.

Assessment of Co-morbidities

Abnormalities of the lower cranial nerves can cause brainstem dysfunction. It then becomes necessary to perform pulmonary function studies and to assess for sleep apnoea. Significant loss of glossopharyngeal, vagal and hypoglossal nerve function mandates a tracheostomy before proceeding with surgery. Likewise, the cardiac status assessment is crucial.

Oropharyngeal Cultures

Oropharyngeal cultures are obtained 3–4 days before surgical intervention. The cultures must be from the oral cavity as well as from the nasal passages. In this author's experience, no antibiotics are instituted, if normal nasal flora is present. As a precaution, Nystatin rinses and Peridex gargles are performed three times a day before the procedure.

DECISION TREE FOR TREATMENT OF CRANIOCERVICAL JUNCTION ABNORMALITIES

Bony abnormalities of the craniocervical junction can be divided into those that are reducible and the irreducible categories (Flow chart 1). Stabilisation is the primary treatment for reducible craniovertebral junction lesions. Surgical decompression of the ventral cervicomedullary junction is necessary, whe n irreducible pathology is encountered. This decompression must be made in the direction in which encroachment has occurred. Thus, the transoral-transpalatopharyngeal route is utilised when a lesion is ventrally situated.[5] The other possible approaches to the craniovertebral border are the lateral extrapharyngeal and the maxillary dropdown procedures.[11] In lateral compressions, a lateral or posterolateral approach is utilised. When dorsal compression is seen, a posterior approach is made. If instability exists following any of the situations, it is mandated that the posterior fixation be made. Thus, the factors that guide the surgical approaches to lesions of the craniovertebral junction are: (1) the reducibility of the lesion; (2) the direction of the encroachment and (3) the type of lesion.

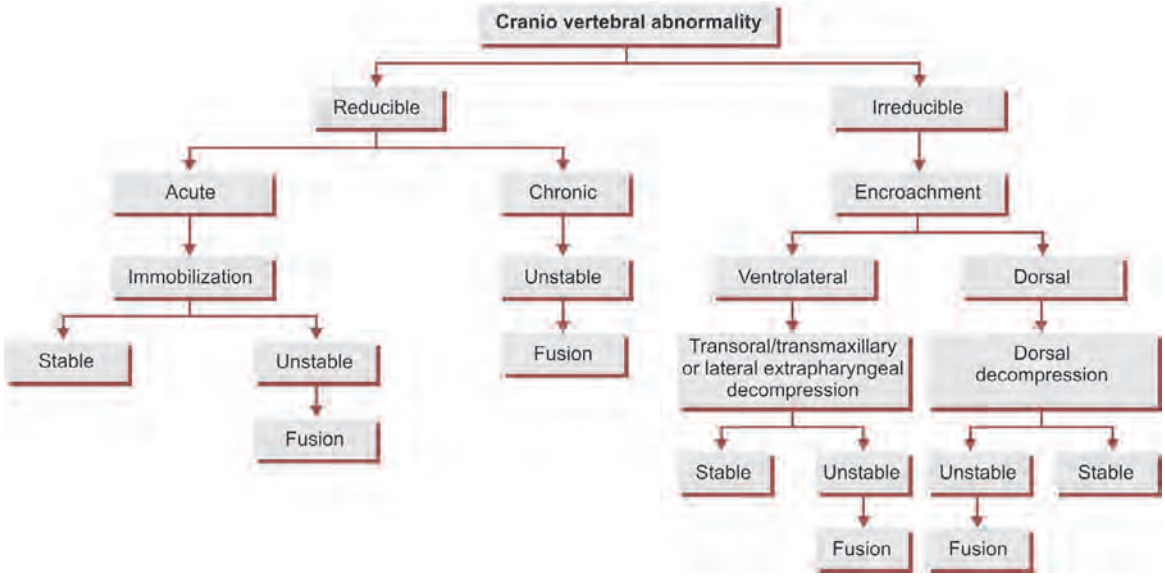
The main indication for the transoral-transpalatopharyngeal approach to the ventral cervicomedullary junction is extradural pathology and, rarely, intradural tumours.

PRE-OPERATIVE CERVICAL TRACTION

Skeletal traction is applied with an MRI compatible halo device, so as to assess the reducibility of the bony lesions. This is usually instituted 3–4 days prior to the operative procedure. Should the lesion be reducible, a dorsal fixation is all that is necessary. On the other hand, if it is irreducible, both the ventral and the dorsal procedures are carried out under the same anaesthetic. In other situations, where one knows that a grossly irreducible lesion is going to be present, the crown halo traction is placed only after the induction of general anaesthesia to stabilise the craniovertebral junction.

This author has evaluated over 5,200 patients symptomatic with craniovertebral junction abnormalities. More than 730 have undergone the ventral transoral-transpalatopharyngeal route for decompression of the

Flow chart 1: Decision tree for treatment of craniocervical junction abnormalities



cervicomedullary junction. The infection rate for this operation has been less than 1%. A dorsal occipitocervical fusion has been necessary in all individuals. Preoperative antibiotics consist of 1 gm of penicillin G started 2 hours before commencement of the transoral procedure.

A median glossotomy allows caudal exposure to the vertebral body of C4.[1,11] The lateral extent of this exposure is between the condylar canals of the hypoglossal nerve (18 mm to either side of the midline), the Eustachian tubes and the vertebral artery before it enters the intradural space. When a tumour, such as chordoma, has created the dissection, the exposure may extend as far laterally as the medial aspect of the jugular foramen. By this time, reduction of a bony lesion has already been attempted and the patient is recognised as having an irreducible ventral bony abnormality.

The ability to open the mouth and the space between the incisor teeth must be at least 3 cm. Achieving this opening is facilitated by the use of paralysing agents during the general anaesthesia.

OPERATIVE TECHNIQUE OF THE TRANSORAL-TRANSPALATOPHARYNGEAL APPROACH TO THE VENTRAL CRANIOCERVICAL BORDER

The patient is brought into the operating suite with a cervical collar in place as a precaution for the intubating manoeuvres as well as positioning. Topical oropharyngeal and nasopharyngeal analgesia is utilised and at times may be supplemented by bilateral superior laryngeal nerve blocks to facilitate fibreoptic intubation. The patient's position is guided by pre-operative dynamic studies (Fig. 3). Once the intubation is performed, the neurological status is checked in the awake patient. General anaesthesia is then administered. This author prefers not to have nasopharyngeal intubation, since it can disrupt the integrity of the high nasopharynx and obstruct the operative field.

The patient is positioned supine on the operating table with the head resting on a padded Mayfield horseshoe headrest with mild extension. Cervical traction is made at 7 lbs in the adult and 4–5 lbs in children (Fig. 4). The endotracheal tube is now secured. The nasal passages are topically anaesthetised with 4% cocaine. The laryngopharynx is occluded with a throat pack and cleansing of the oral cavity and pharynx commences.

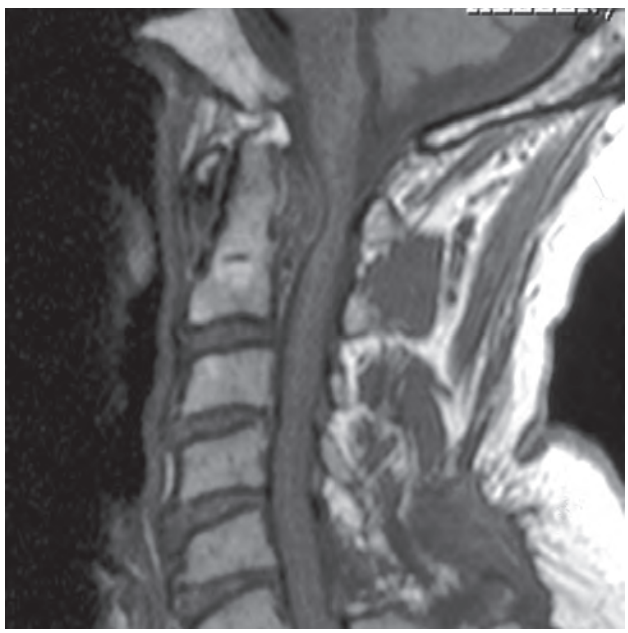


Fig. 3: Mid-sagittal T1-weighted MRI of craniocervical junction in an adult with a retro-odontoid mass, causing significant compression of the ventral cervicomedullary junction. The anatomy of the clivus and the upper cervical spine is normal. Elevation of the soft palate allows exposure from the craniocervical border to the C3 vertebral body. This patient underwent a palatal elevation and a transoral procedure

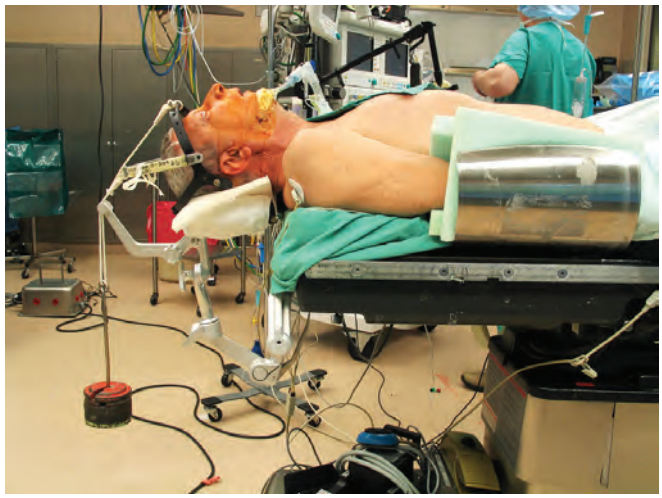

Fig. 4: The operative positioning viewed from the side. Cervical traction was applied at 7 lbs with the head resting on a horseshoe headrest and mild extension of the craniocervical junction

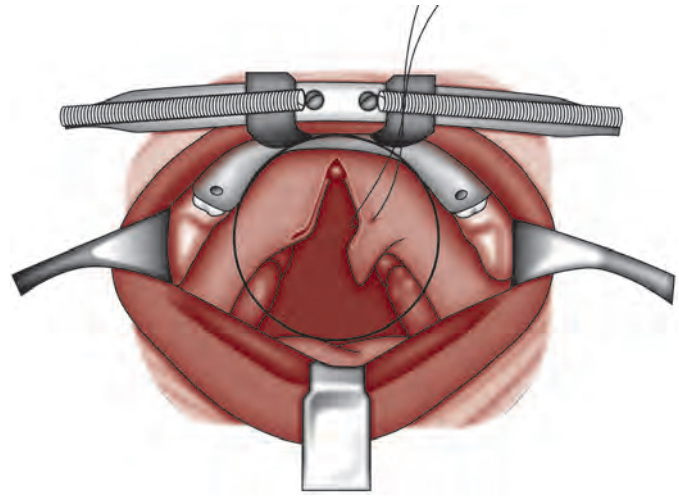

Fig. 5: Artist illustration of the transoral-transpalatopharyngeal approach. The Dingman mouth retractor is in place and the tongue blade depresses the tongue. The operative procedure through the microscope will be carried out within the circle. The soft palate has been incised

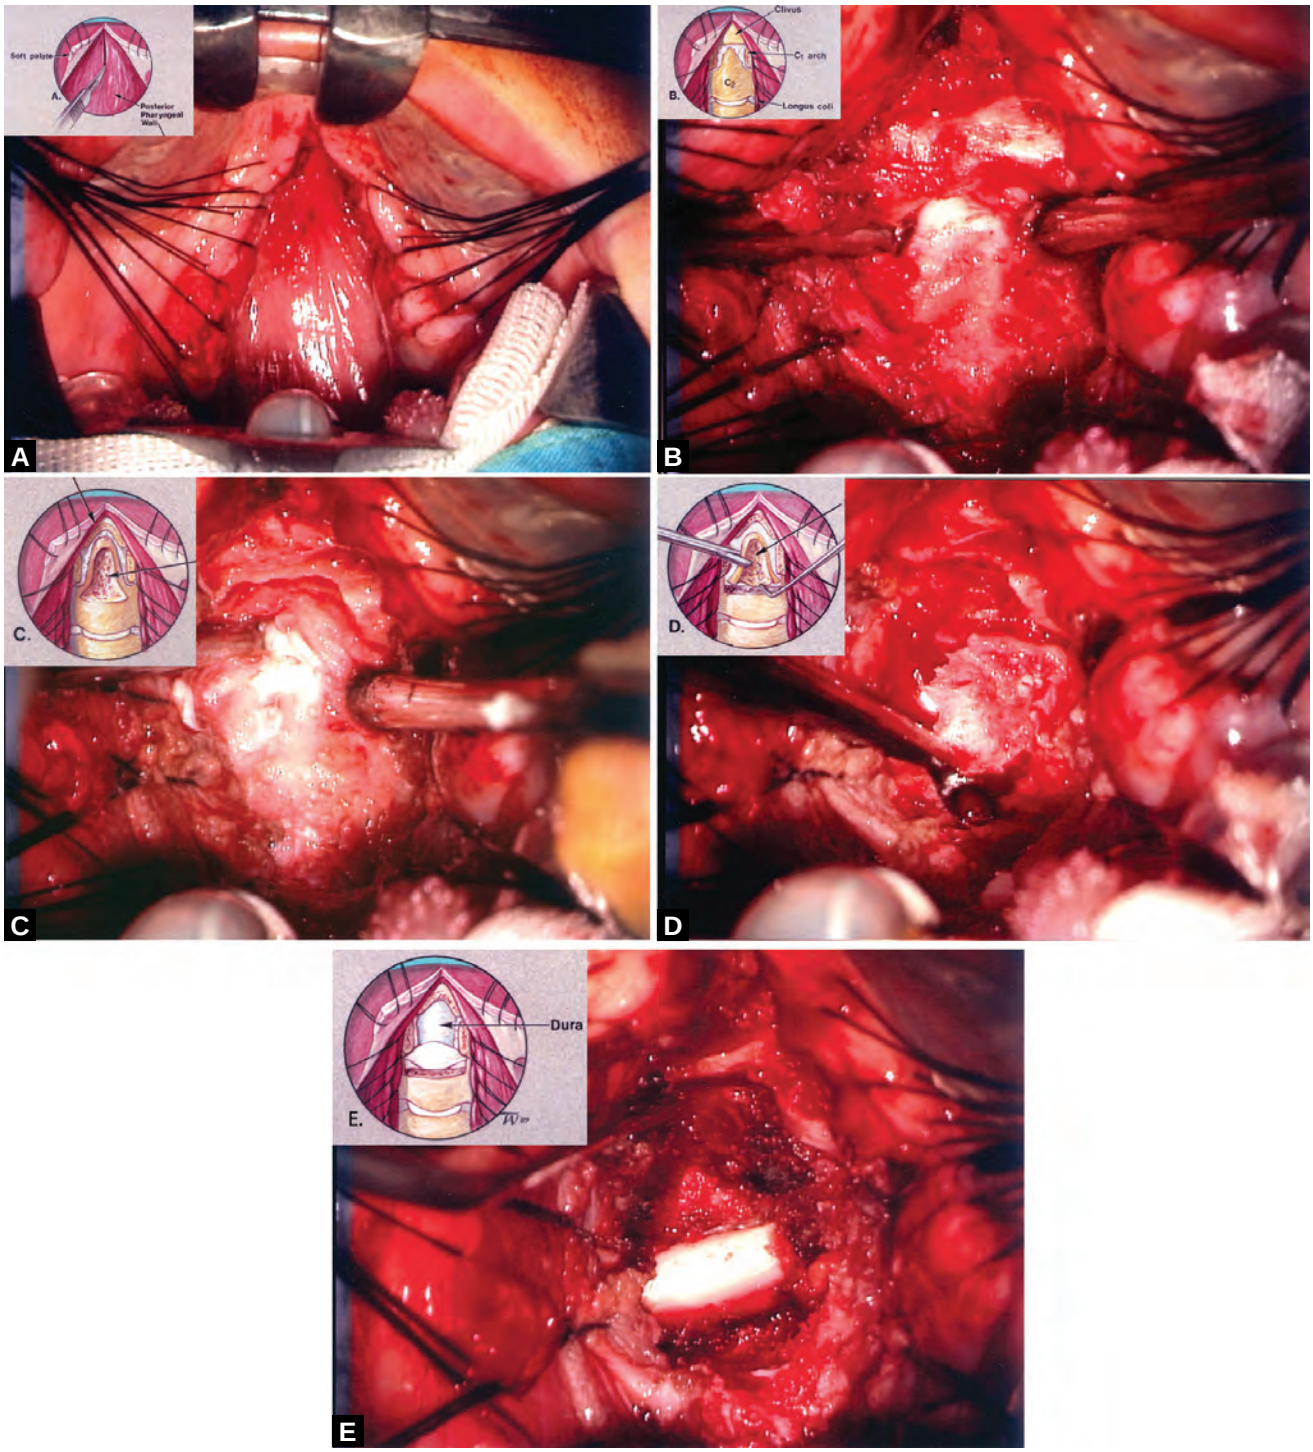
This is done with successive rinses of 10% povidone-iodine, followed by saline and then hydrogen peroxide and subsequently saline. The previously mentioned dental guards are now used over the upper and lower dentition to protect them during the operative procedure. This author prepares the right anterior abdominal wall for possible harvesting of donor external oblique aponeurosis and fat, should this be necessary, if the dura is violated during the operation. The circumoral area as well as the anterior abdominal wall are prepared and draped in a sterile fashion.

The pharyngeal exposure is accomplished with a modified Dingman mouth retractor, which has an incorporated tongue blade for automatic exposure.[6] In circumstances where the operative procedure is at the foramen magnum and above, it will be necessary to split the soft palate and at times the hard palate (Fig. 5). On the other hand, if the procedure is limited to the level of the atlas and the axis vertebra, the soft palate may be elevated by catheters attached to the soft palate via the nasal passages and secured to the soft palate on either side of the base of the uvula. The catheters are then withdrawn into the high nasopharynx to allow for exposure. A gauze pack is used to occlude the laryngopharynx. 0.5% Lidocaine solution with 1:200,000 epinephrine is injected into the median raphe of the soft palate. The microscope is now brought into the operative field for the operative dissection. The soft palate incision, when performed, starts at the base of the uvula to one side of the midline and ascends into the median raphe towards the hard palate. This author utilises stay sutures to hold apart the leaves of the soft palate and these stay sutures are attached to the Dingman mouth retractor (Fig. 6A). When exposure of the lower clivus is necessary, an extension of the midline incision is made onto the hard palate and a subperiosteal exposure of the midline hard palate is then made. The posterior pharyngeal wall is now topically anaesthetised with 2% cocaine and the midline raphe is infiltrated with 0.5% lidocaine solution with 1:200,000 epinephrine. A midline incision is then made into the posterior pharyngeal median raphe, extending from the mid clivus to the upper border of the C3 vertebra. The leaves of the posterior pharyngeal wall are now reflected laterally and folded upon themselves with stay sutures. This prevents damage to the orifices of the Eustachian tube. The prevertebral fascia with the longus colli and the longus capitis muscles are now freed so as to expose the lower clivus, the ventral surface of the atlas and the axis vertebrae (Fig. 6B). The anterior longitudinal ligament and the occipital ligaments are now, dissected free of their bony attachments. This exposes the caudal clivus, the anterior arch of the atlas, and the anterior surface of the axis body. The width of the exposure is about 3 cm. Further lateral exposure is not advised.

The anterior arch of the atlas is now removed with a high-speed drill for a width of about 20 mm. A 4 mm cutting burr is then substituted for a diamond burr using the electric drill. In situations where the odontoid process has invaginated into the posterior fossa, the inferior portion of the hard palate may require resection. This is accomplished with fine Kerrison rongeurs.

The inferior portion of the clivus is now removed by thinning of the anterior surface with the diamond burr and defining the inferior border. This now allows for separation of the circular venous sinus and the dura, as well as the tectorial membrane. It is needless to say that great care needs to be taken so as to prevent damage to the circular sinus or producing a CSF leak. The author prefers the use of fine Kerrison rongeurs for clivus resection after the thinning out has been done.

The odontoid process removal is accomplished by starting at the tip and proceeding downward. The



Figs 6A to E: (A) Stay sutures hold apart the soft palate and the posterior pharyngeal wall is now exposed. A midline incision is demarcated in the drawing to the left. (B) The longus colli and the longus capitis muscles have been retracted laterally to expose the anterior atlas arch and the base of the odontoid process underneath it. (C) The anterior arch of the atlas is now removed and a coring out of the odontoid process starts. (D) The odontoid shell is now being removed. (E) Tectorial membrane and the dura are decompressed. The odontoid removal is complete. The bright structure at the bottom of the operative procedure is the transverse portion of the cruciate ligament

odontoid process is first cored out and subsequently the lateral margins are defined using sharp curettes and rongeurs (Fig. 6C). It is essential to sharply divide the apical ligament as well as the alar ligaments with curettes. Resection of the odontoid process starts at the apex and extends into the axis body. The extent of this is dictated by pre-operative studies. Removal of the odontoid process is facilitated by the use of fine Kerrison rongeurs, as well as microcurettes and microbiopsy forceps (Fig. 6D). The removal of the pannus from behind the odontoid process and the posterior fossa is only done in a piecemeal fashion after bipolar cauterisation.

The cruciate ligament now comes into view (Fig. 6E). This author prefers to leave the cruciate ligament intact, unless it is frayed by tumour or rheumatoid arthritis. The tectorial membrane should be preserved. Cervical traction is maintained during the operation for potential, as well as inherent instability. When pannus or granulation tissue acts as a mass, this should be removed. However, once bony decompression has been accomplished, the entire removal of granulation tissue is unnecessary. This will ultimately fibrose and can aid in the healing process.

At the end of the resection, anaerobic and aerobic bacterial cultures are obtained from the depths of the wound. This author has routinely used a combination of bacitracin powder and microfibrillar collagen to layer the resection bed. The longus colli and the longus capitis muscles are now approximated in the midline with 3-0 polyglycolic sutures. A similar suture is used to bring together the pharyngeal constrictor muscles and, separately, the posterior pharyngeal mucosa.

The mucosa over the clivus is friable and delicate. There is also no muscle underneath this. In these circumstances, where the clivus is exposed, it is important to bring together the closure starting inferiorly coming up to the clivus, so that the mucosa can be brought together. A blanket of Gelfoam® is then placed over the reconstituted pharyngeal wall. At this point the throat pack is removed.

A previously tested nasogastric feeding tube is then passed via the nostril into the pharynx and thence into the oesophagus and stomach. The tube should then be secured to the ala of the nostril.

The closure of the soft palate must be made in a layered fashion. It is done by bringing together the nasal mucosa with 3-0 polyglycolic interrupted sutures. The muscle layer and the oral mucosa of the soft palate are then approximated with interrupted vertical mattress sutures. The tension in these latter sutures must be carefully assessed, so as not to be too snug. Otherwise, one will be faced with dehiscence.

A dorsal occipitocervical fusion combined with posterior fossa decompression is usually mandated and is accomplished with the same anaesthetic.[2,9]

SPECIAL CIRCUMSTANCES

Transpalatal Route

This is used routinely to treat congenital abnormalities where the clivus is foreshortened and seems to be more horizontally oriented than vertical. Removal of 1 cm of the posterior hard palate in the sagittal plane and about 8 mm to either side of the midline exposes a sufficient amount of nasopharynx and clivus. The posterior edge of the vomer is exposed. The soft palate should then be closed in a layered fashion at the end of the procedure. The author has used this exposure to get up to the mid clivus.

Median Glossotomy Combined with Transoral-Transpalatopharyngeal Approach

This procedure provides a wide caudal exposure down to the vertebral body of C4.[1,11] If combined with mandibular split, the exposure is significant along the ventral and rostral caudal dimensions. The cosmetic outcome is excellent.

Intradural Extension for Tumour and Repair of Cerebrospinal Fluid Leak

An intradural lesion at the upper cervical spine, craniocervical border or behind the clivus necessitates pre-operative recognition of the dural extension and placement of a lumbar subarachnoid drain prior to the commencement of the operation. The dural turgidity may be reduced by draining cerebrospinal fluid during the procedure. The incision in the dura is made in a cruciate fashion. The vertical component of this starts inferiorly and proceeds upwards in a rostral direction with careful cauterisation and clipping of the circular sinus at the foramen magnum. Once the intradural operation is complete, it is essential to bring the dural leaves together as much as possible. This is done with 4-0 polyglycolic sutures. It is then covered with an external oblique aponeurosis graft which is sutured to the dura. This prevents migration of the graft. Fibrin glue is now used over this. This is then backed with fat obtained from the anterior abdominal wall after which the posterior pharyngeal closure is made in the earlier described layered fashion.[7,10]

CSF tension is reduced by drainage from the lumbar subarachnoid space during and after the operative procedure. Triple antibiotic therapy consisting of methicillin, metronidazole and cefotaxime are continued for the first 5 days after operation. If no bacterial flora is present on CSF examination, the third generation cephalosporin is discontinued and the antibiotic terminated at the end of 10 days. At this point, CSF drainage is discontinued.

POST-OPERATIVE MANAGEMENT

The endotracheal tube is maintained in place for post-operative convalescence until the swelling in the oral cavity has receded. This usually stays for 3–4 days in the non-rheumatoid patient and may be longer in advanced rheumatoid arthritis. It is important to maintain caloric intake of 2,500 calories by the 3rd or 4th day. Earlier experience using intravenous parenteral hyperalimentation has led to our use of nasogastric tube feedings and has reduced our co-morbidities.

The post-operative management comprises of ventilator and respiratory care and nutrition, antibiotic regimen, pain management and immobilisation.

The vast majority of patients who have undergone the ventral procedure will leave the operating suite with an endotracheal tube in place secured to the circumoral area, intra-venous and intra-arterial lines that have been

required for intra-operative care and nasogastric feeding tube. In addition, the patient should have had a dorsal stabilisation. These individuals are then transported to the intensive care location with a soft collar in place. The halo ring that was utilised intra-operatively for traction and stabilisation is left in place if it is to be connected to a halo vest later. Otherwise this is removed.

Intra-venous penicillin G is administered for 48 hours and then discontinued. However, if wound cultures grow pathological flora, appropriate antibiotics are instituted. The Peridex and Nystatin rinses that were instituted pre-operatively now, are done at 8-hour intervals to minimise bacterial flora, especially in light of the operative procedure and prolonged intubation necessary. The dental guards are left in place to prevent inadvertent biting of the endotracheal tube. The cuffed endotracheal tube is intermittently deflated only after proper oral care is accomplished.

The tongue swelling usually recedes by the 2nd or 3rd day. The soft tissues of the retropharyngeal space are monitored with a lateral cervical radiograph. By the end of the 3rd or 4th day, when tongue swelling has receded and the pharyngeal oedema has resolved, an attempt at endotracheal extubation is made. This is carried out only with an experienced intensivist in attendance and a neurosurgeon. Prior to this, the nasogastric feedings are discontinued for at least 6 hours and the endotracheal tube cuff is deflated to detect leakage of air around the tubing. Our policy is to attempt extubation only with utilisation of a "tube exchanger", replacing the endotracheal tube. This smaller diameter exchange tube allows for satisfactory ventilation and, should it be necessary, the tube exchanger is used as a stylet for rapid reintubation.

The position of the nasogastric feeding tube placed during the operation is confirmed with appropriate chest and abdominal radiographs. It is preferable to have the feeding tube in a transpyloric location. Enteral feedings are instituted in a graduated manner at the end of 24 hours. A clear liquid oral intake is initiated by the fifth post-operative day and converted to a full liquid diet by the 10th day. By this time, the patient's caloric intake has been 2,500–3,000 calories per day. A soft diet is started at the end of the 15th day.

Post-operative immobilisation is accomplished in a soft collar until a final decision is made to either use a halo vest or an occipitocervical brace. An immediate placement of a halo vest hampers post-operative oral care as well as jeopardises extubation.

PREVENTION AND MANAGEMENT OF COMPLICATIONS

The prevention of peri-operative complications as well as delayed adverse events is described in Tables 1 and 2, respectively.

Table 1: Peri-operative complications of transoropharyngeal surgery at the craniovertebral junction; prevention and management

Complication	*Prevention/Management*
Unnecessary ventral procedure	Pre-operative reduction, if possible
Too small an oral aperture	Distance between incisors must be >25 mm May improve with administration of IV paralysing agents. May need mandible and/or tongue split or another approach
Damage to Eustachian tubes and hypoglossal nerves	Limit lateral exposure to 2 cm from midline
Inability to reach clivus for resection due to platybasia	Divide soft palate and possibly hard palate. Intra-operative fluoroscopy
Lost—cannot reach distal dens or epidural masses	Fluoroscopy. Novice may use "frameless stereotaxy". Start resection of dens from rostral end
Persistent bleeding at clivus	Bleeding from circular sinus needs fibrillar collagen/ oxidised cellulose. Else clip both leaves of dura. Pannus and arterial bleeding must be coagulated
Intra-arachnoid lodgment. CSF leakage	Pre-operative lumbar drain. Attempt dural closure. Fascia + fat + plasma glue. CSF drainage. 1 week antibiotics

Table 2: Delayed complications of transoropharyngeal surgery at the craniocervical junction; prevention and management

Complication	*Prevention/Management*
Severe tongue swelling	IV Dexamethasone; intermittent release of tongue depressor. Retain dental guards in children
Meningitis	CSF exam. Lumbar drainage. No oral intake. Antibiotics. Close CSF leak
Palatal dehiscence	Inadequate closure. Must be reclosed
Pharyngeal dehiscence	<1 week–reclosure >1 week–hyperalimentation, antibiotics
Neurological worsening	Check alignment → traction Reassess ?meningitis, ?abscess,?retained lesion. Vascular compromise ? MRI and MRA
Retropharyngeal abscess	Check for osteomyelitis and meningitis. Extrapharyngeal drainage

Contd...

Complication	*Prevention/Management*
Delayed pharyngeal bleeding	Secondary infection. Exclude osteomyelitis and vertebral artery erosion and false aneurysm MRI, CT and angiography necessary!
Velopalatine incompetence	Usually appears 4–6 months post-operative Pharyngeal retraining/prosthesis Retropharyngeal fat injection. May need pharyngeal flap
Persistent hoarseness of voice	Appears 4–6 weeks after surgery. Needs visualisation of vocal cords. Likely granulomas on cords. Needs vocal cord rest and proton pump inhibitors

184 Reconstruction of the Skull Convexity and Base

Atul Goel, Muzumdar D

INTRODUCTION

Reconstruction is an integral part of any neurosurgical operation and must adequately be planned and performed. Pre-operative planning of the reconstruction methodology and suitably altering the operating steps is crucially important for success of the surgical procedure. Adequate reconstructive procedures are necessary to provide for rigid compartmentalisation after an elaborate skull base operation.

HISTORY

The repair of skull defects paralleled the practice of trepanation from the prehistoric neolithic time (10000–7000 BC). Gold and silver pieces corresponding to the size and shape of the skull defects have been found in the graves in Peru and skull allografts (rondells, round discs) in Neolithic Celt remains. Coconut shells were used by South Sea Islanders to repair skull defects. J. van Meekren (1670) used the first bone graft in history to repair a skull defect in a Russian with a canine bone; however, he had to remove the implant under the threat of excommunication by the church. In 1821, P. von Walther performed the first human autogenic bone graft. Macewen, in 1873, re-implanted calvarial bone, after treating them with mercury bichloride and, in 1878, he was the first to transplant a human bone allograft. In 1889, Senn wrote on repair of cranial defects with antiseptic decalcified bone. Seydel transplanted a tibial autograft with attached periosteum to repair a parietal defect. Muller and Konig, in 1890, advocated a flap of scalp periosteum and outer skull table to be swung over a skull defect. Bunge (1903) first used a fresh osteoperiosteal homograft skull. Kappis (1915) used whole ribs, Brown (1917) used split ribs and Mauclaire (1914) used ilium for cranioplasty.

The use of alloplastic material for the repair of cranial defects was popularised after the availability of various plastics and metals from the end of the 19th past century. Fraenkel (1890) used celluloid, but it was later abandoned due to cellular reactions and biodegradation over a period of time. Booth and Curtis (1893) first used aluminium, followed by Gersten (1895) using gold. Many metals have been tried since then including vitallium alloy (cobalt, chromium and molybdenum) by Geib (1941); tantalum (Pudenz and Odom—1942); stainless steel mesh used by Boldrey (1944); stainless steel used by Scott, Wycis and Murtagh (1956) and titanium used by Simpson (1965) and Gordon and Blair (1974). Black (1978) reintroduced aluminium because of its malleability, radiolucency and low tissue reactivity.

Acrylic resins became available in 1937 and Zander introduced methyl methacrylate for human cranioplasty in 1940. Spence (1954) described the one stage acrylic cranioplasty, which was widely used. Galicich and Hovind (1967) incorporated stainless steel mesh within methyl methacrylate which increased its toughness. Habal and colleagues have reconstructed cranial defects with an alloplastic combination of polyurethane terphthalate filled with autogeneic cancellous bone. Plaster of Paris (calcium sulfate hemihydrate, $CaSO_4$) has been used as a bone substitute for repair of extracranial defects since 1892. It can be used in areas of infection, is absorbable, resorbs as bone grows and acts as a binder for ceramic hydroxylapatite, which is osteoconductive and bonds to adjacent bone. However, it is brittle and has low impact resistance and tensile strength. The combination of plaster of Paris and hydroxylapatite has successfully been used to close frontal sinus defects. However, the variable resorption and limited mechanical strength of hydroxylapatite make less reliable biomaterial for cranioplasty.

Reconstruction of the skull base is a formidable task due to its location and proximity to vital vascular and neural structures. However, recent advances in craniofacial and skull base surgery have allowed surgeons to safely approach these lesions. The reconstruction of the head and neck was limited to local scalp flaps and distal pedicle flaps, such as a deltopectoral flap. The temporalis, sternocleidomastoid, trapezius and pectoralis muscle flaps have also enhanced the feasibility of basal skull reconstruction. The use of locally available materials, like the galea and pericranium, are effective measures for adequate closure. The most important advance in recent times is microsurgical transplantation using free flaps. This has allowed aggressive and complete removal of basal skull tumours without the fear of inadequate reconstruction.

ANATOMICAL CONSIDERATIONS

There are various inherent problems involved in skull base reconstruction, especially the proximity of the skull

base to potentially infective spaces like the paranasal sinuses, nasal, oral and pharyngeal pathways, external ear canal and other such spaces. After the surgery, it is important to seal off the cranial cavity from these spaces to avoid ascending infections. The basal dura is relatively thin, friable and densely stuck to the bone. Approximation of the edges and watertight suturing often may not be possible, especially in areas of vessel and nerve transit. Occasionally, following a surgical procedure, the site of CSF fistula cannot be deciphered. It is pertinent, therefore, that all the potential sites of CSF leakage be recognised during the surgery and adequately taken care of. Some tumours involve the basal bone and dura, and for achieving a radical resection these structures have to be removed deliberately. Opening up of the paranasal air sinuses, middle ear cavity and Eustachian tube, can subject the patient to risks of cerebrospinal fluid fistula. Frequently, there are large dead spaces that need to be filled in after basal bone, soft tissue and tumour resection. Many skull base procedures are of long duration. Many surgeons are involved in the operation and extensive instrumentation is used. All these factors add to the risk of infection. The reconstruction begins at the end of a relatively long operation when the operative team may be exhausted and errors of omission may be made. Some prefer a plastic and reconstructive surgical team to assist in the reconstruction.

Sometimes, persistent post-surgical or traumatic cerebrospinal fluid fistula can pose a formidable surgical challenge and super-added infection can be a life threatening condition. Familiarity with various methods of reconstruction and their satisfactory performance can be gratifying. These methods should relatively be simple to perform by the operating surgeon.

SURGICAL CONSIDERATIONS

Reconstruction of Bone Defects

Reconstruction of bone defects following skull base surgery is a controversial subject. All bone defects do not require reconstruction. The size of the defect, extent of resection of the associated structures, history of previous operative procedures, endovascular and radiation treatment are important variables that determine the appropriate reconstructive procedure. The site and volume of tumour extirpation are also important determinants in the method of reconstruction. Various methods of reconstruction of basal bone have been described. Reconstruction of bone defects in the cranial base should preferably be done with the help of bone. In sterile fields, free small or large bone pieces can be used for this purpose. Ribs, iliac crest and scapular grafts have successfully been used. Acrylic and metal plates can also be used in such a situation. Autogenous tissue such as fascia lata or allografts can be used for some tumours, which require excision of the overlying dura. In situations where there is limited bone resection for access to basal tumours, the surrounding structures will collapse and obliterate the dead space. However, if the defect is very large, there is less chance of collapse of these rigid structures and these areas will require addition of bulk for adequate obliteration. Fat grafts have been used to obliterate small defects. These grafts are devoid of vascular supply upon transplantation. Moreover, up to 60–70% of the transplanted fat can get absorbed. Necrosis is also a potential problem if the mass of the graft exceeds the ability for vascularisation. Hence, fat, as a reconstructive material, should be used only for relatively small defects. In potentially infective fields, which are more frequently encountered after a skull base operation, use of a bone flap based on a vascularised pedicle is recommended.

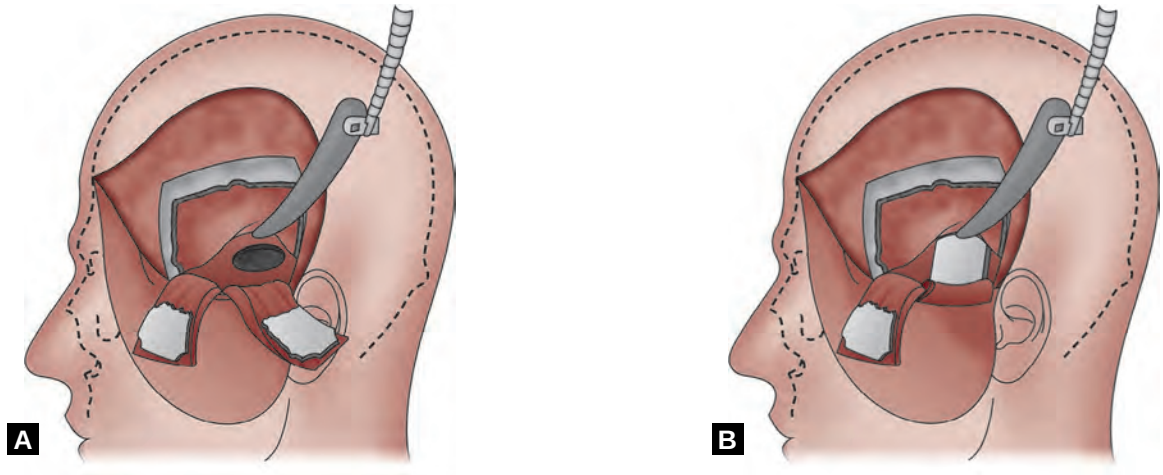
As the question of cosmesis, arthrodesis and stability are not applicable in basal reconstruction, the principle purpose of reconstructing bone defects is to avoid possible herniation of the brain matter into the aerodigestive tracts, ear, orbit or in the space resulting following resection of a large tumour or after treating a basal encephalocoele. The possibility of such an eventuality is rare and the decision regarding reconstruction of basal bone should be a calculated one. In the presence of intact basal dura even large bone defects can be tolerated without any consequence. One third to half of the orbital roof can be removed without any problem of pulsating exophthalmos. Large clival, petrous and sphenoid bone defects can safely be left unrepaired. Often it is safer not to perform bone reconstruction at the end of a long surgical procedure for the fear of infection and consequently complicating the entire surgical procedure.

Larger defects over the tegmen tympani and orbital roof should preferably be replaced with bone, as the dura in these regions is relatively thin and the region is devoid of large basal cerebrospinal fluid cisterns and consequently initially the brain pulsations can be transmitted and later the brain can herniate into these spaces. Support for brain tissue may be necessary, where large bone defects are created following the operation. Reconstruction of the bone is also carried out to support the dura and help in the provision of watertight sealing of the base and avoiding formation of cerebrospinal fluid fistulae. Protection of the brain from future injury and restoration of a reasonable appearance and quality of life are other important objectives.

Flaps

Vascularised Osteomyoplastic Flap[9]

Various experimental studies have been conducted on the use of temporalis osteomuscular flaps, as compared to calvarial free bone grafts.[1,5,7] The studies confirmed that vascularised bone flaps remain viable and are characterised by normal evolution, while free bone grafts show typical signs of necrosis and resorption. Such vascularised bone flaps based on a muscle pedicle have been used in cosmetic facial surgery and mandibular, maxillary and palatal reconstruction and mastoid

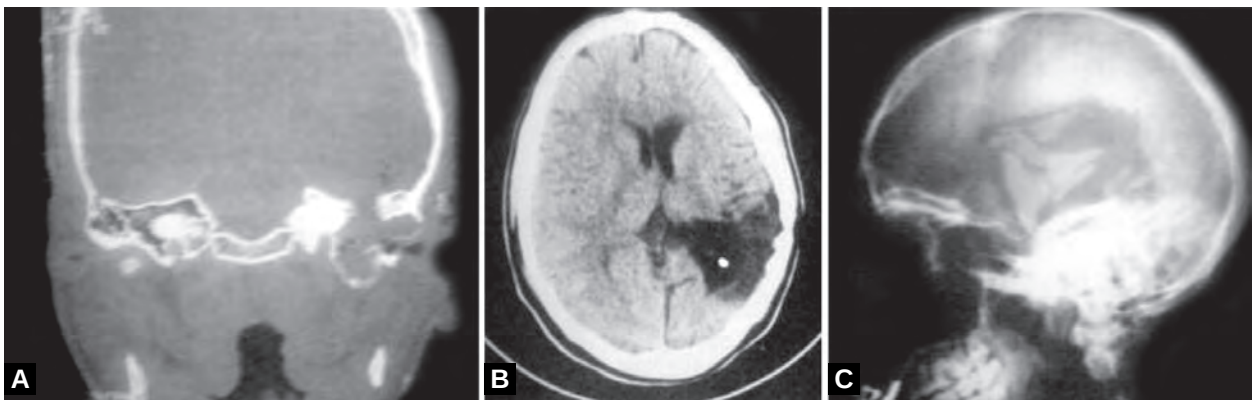


Figs 1A and B: (A) Bone defect in the middle cranial fossa on retracting the temporal brain. The temporal brain is split into two, each piece being placed on temporalis muscle pedicle. (B) The posterior piece of the temporal bone flap is rotated to fill the defect. This forms the osteomyolastic flap. The anterior piece of the temporal bone flap is replaced in the convexity

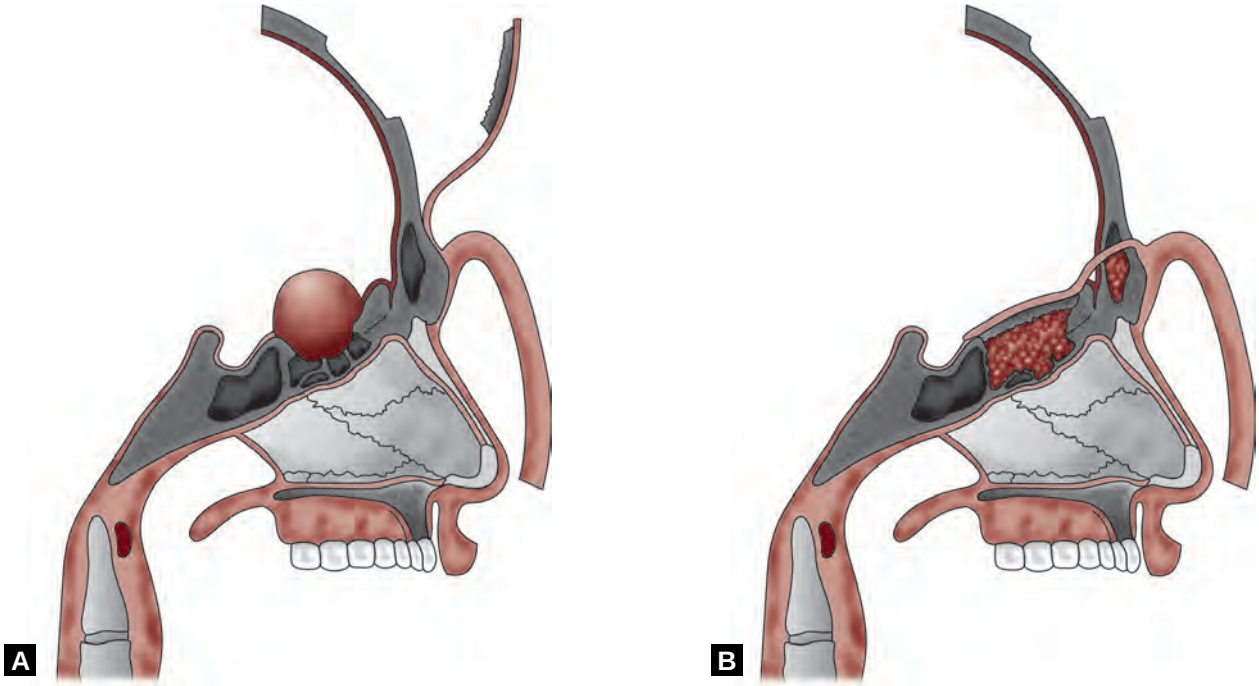
cavity obliteration.[2,4] The temporalis muscle, being in close proximity to the skull base and also the ease with which it could be rotated in various directions, can be used effectively for such an osteomyoplastic flap for skull base reconstruction (Figs 1 and 2). The temporalis muscle has an extensive blood supply to the calvarium through multiple perforators. Elevation of the bone flap with wide attachment to the muscle pedicle results in a well-vascularised flap. A vascularised bone flap can also be based on muscles of the nape of the neck. Judicious use of split cranial grafts can fill-up the resulting defects in the skull. Osteomyoplastic flaps can be used for reconstruction of middle fossa and petrous bone defects with relative ease. The fascial layers covering the temporalis muscle can be used to seal the defects in the basal dura while the muscle and bone occupy the area of bone defect. Unlike pericranial and galeal flaps, which can be raised either before or after the surgical resection, osteomyoplastic flaps, on most occasions, have to be planned and fashioned in the exposure stage of the operation. The incisions and dissection in the muscle and fascial planes are modified to avoid transection of blood supply, which could be crucial to sustain the bone flap.[13]

Pericranium Based Bone Flaps[9,10]

Pericranial and galeal flaps have been described for reconstruction of anterior cranial base and craniofacial deformities. The pericranium comprises of an outer layer of loose areolar tissue and an inner layer of osteoblasts and contains an extensive vascular network. The pericranium derives blood supply anteriorly from the supratrochlear and supraorbital arteries and laterally from the superficial temporal arteries. Pericranial layer pedicled flaps can be based on either of these vessels, and accordingly rotated anteriorly or laterally. The pericranium can sustain the calvarial flap by means of multiple small, vertical perforators. Studies have shown that calvarial flaps can safely be pedicled on the pericranial layer or



Figs 2A to C: (A) Bone window of the CT scan showing a bone defect in the tegmen. Soft tissue shadow in the petrous bone is seen. Also note air spaces in the external ear canal, petrous bone and intracranially. (B) A plain CT scan shows encephalomalacia of the parietotemporal brain and ipsilateral enlargement of the lateral ventricle. (C) Post-operative skull X-ray showing the large temporal squamous bone flap (seen end on) over the petrous bone. Bone pieces fill the bone defect created. No evidence of intracranial air is seen

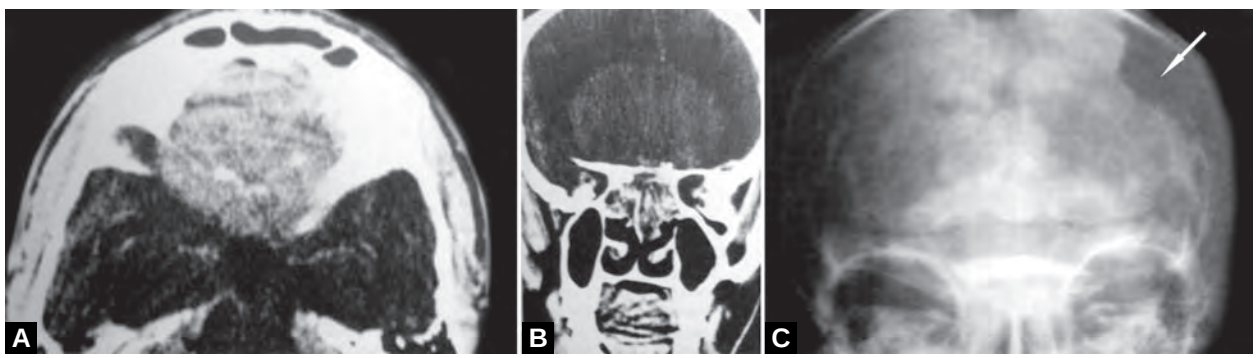


Figs 3A and B: Anterior cranial base tumour. (A) A split thickness calvarial graft pedicled on the galeopericranial layer is taken. (B) The tumour has been resected. The bone graft is placed in the resultant basal defect. Fat occupies the opened sinuses

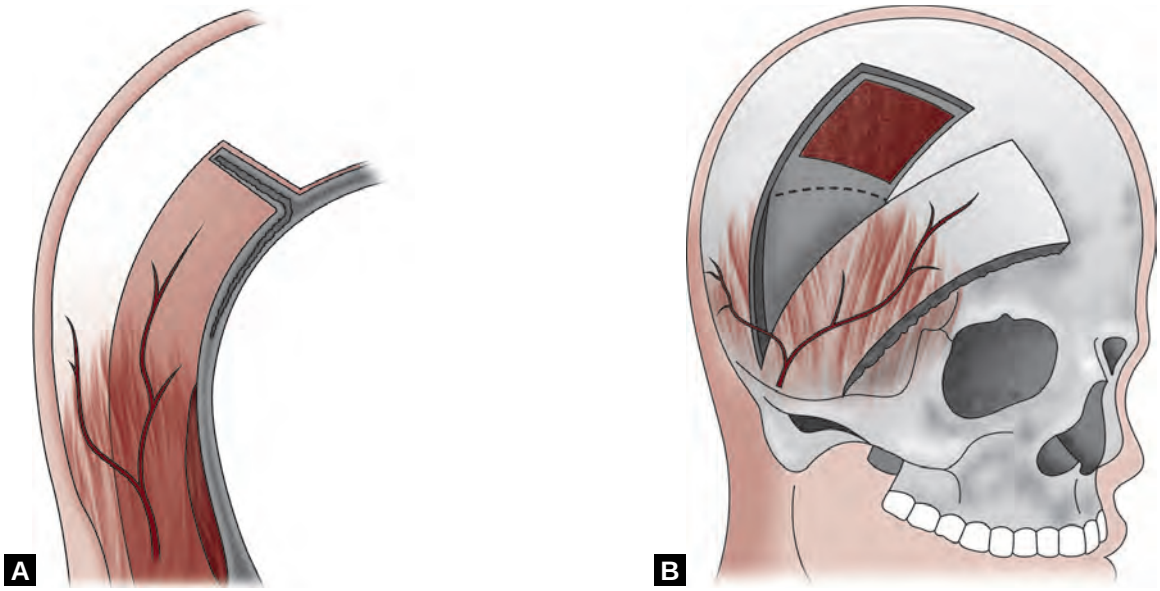
galeopericranial layer.[3,6,23,27,28] The flap can be harvested as far posteriorly as the auricular plane, giving a length of 10–12 cm. Bone flaps of the calvarium can be either of full thickness or only of the outer table. A split thickness osteo-galeopericranial flap as shown in Figures 3 and 4 can be used to reconstruct the anterior cranial fossa base. Easy availability, rotational capability, long length and close proximity to the operative area of such vascularised flaps make them ideally suited for skull base reconstruction. The bone piece can be pedicled on a large base of pericranium and can additionally be nourished by the galeal flaps. Whenever necessary, the bone flap can be turned upside down so that the bone surface is not directly exposed to the paranasal sinuses. The flap can even be sandwiched between the pericranial layers. In cases with extensive defects, an extended subgaleal fascia-pericranial temporalis flap can be first placed in the region of the defect over which the described bone flap can be placed.[12,17] Reconstruction can thus be with multiple layers of vascularised tissue. The bone piece can be fractured into two or more pieces retaining its attachment to the pericranium so that its contour can be adjusted to suit the local environment. Such vascularised flaps are more resistant to infection, tolerate radiation therapy better, are mechanically stronger, contract less and survive better in a poorly vascularised bed, when compared to free bone grafts. It is presumed that such flaps would be ideal while treating basal encephalocoeles.[20]

Long Vascular Pedicle Composite Cranial Flap[14]

The flap described is a split or full thickness cranial bone flap based on the pericranial layer, which receives its vascular nourishment from the temporalis muscle and its overlying fascial layers. The outer table of the skull bone is split, as shown in the Figure 5A, preserving the overlying pericranium. A part of the temporalis muscle



Figs 4A to C: (A) CT showing the large olfactory groove meningioma. (B) Note the involvement of the ethmoid sinuses by the tumour. (C) Post-operative skull X-ray shows that the bone flap occupies the region of the resected tumour. Arrow shows the site from where the partial-thickness split cranial graft was taken



Figs 5A and B: (A) Splitting of the cranial bone. The bone flap is being elevated along with the pericranium. The temporalis muscle and its fascial envelope form the pedicle of the flap. (B) Drawing shows how the described flap will be harvested and rotated towards the site of the bone defect. The temporalis muscle had been split vertically

(and fascial layers) along with the pericranium is elevated and rotated as required (Fig. 5B). The superficial fascial layer over the temporalis muscle is a part of the pericranial aponeurosis, whilst the deep temporal fascial layer completely invests the superficial aspect of the temporalis muscle. The temporalis muscle and its fascial envelope and the pericranium receive their blood supply from the anterior, middle and posterior deep temporal and superficial temporal arteries. Subperiosteal elevation of the temporalis muscle along with the fascial layers preserves the integrity of all the major vascular supply. The split or full thickness cranial bone based on the pericranial layer and the temporalis musculofascial layer as described, results in a viable flap with abundance of vascular supply. Vertical splitting of the temporalis muscle into half or one third would still preserve at least one or two of the main feeding vessels. This splitting would not adversely affect the circulation to the flap and could help in preservation of the function of the temporalis muscle. The skull bone is thicker superior to the temporal line, which marks the attachment of the temporalis muscle. Splitting of the skull bone is easier in the paramedian parietal bone, due to the well-formed diploic channels. The split thickness graft can be broken into pieces and can be suitably contoured, preserving the attachment of the pericranium. The long length and local availability and manoeuvrability of the flap make it versatile, with great potential for reconstruction of the skull convexity and basal defects. The other advantages of such a flap include harvesting of grafts of adequate size, ease of access within the same operative field, and no or minimal post-operative morbidity and discomfort for the patient. The described flap can be used to reconstruct cranial defects where there is poor local nourishment and potentially infective fields and areas, which are cosmetically crucial (Figs 6 and 7).

Use of Bone Dust and Debris

With the use of modern craniotomes for making burr holes, a large amount of bone dust can be obtained. The bone dust can be flattened and placed in the form of a sheet over the site of defect. Small bone chips and bone debris, which is generally available during a craniotomy, can be placed interspersed in the bone dust. This forms a template over which new bone and fibrous tissue is laid and a firm, strong and resistant barrier is formed (Fig. 8).

Reconstruction of Skull Base with Free Bone Flap

Whenever possible, bone defects should be filled up with a vascularised pedicle bone flap. However, such a vascularised bone flap is sometimes not available and in this situation a free bone flap may be required. A free bone flap should not directly be exposed to the paranasal sinuses or mucosal surfaces. Whenever such a free bone flap is placed in the skull base, it should be as small in size as possible and care should be taken that it is covered on both sides with vascularised and viable soft tissue.[18,19] Such a 'sandwich' free bone flap can be placed between muscle and fascial-pericranial layers. Post-operative collection of haematoma around the bone flap should also be avoided and whenever necessary external drains can be placed. Tenting scalp stitches can be used[8] whenever possible and indicated.

Fig. 8: The bone dust obtained after drilling one burr hole has been collected in a bowl and spread into a sheet

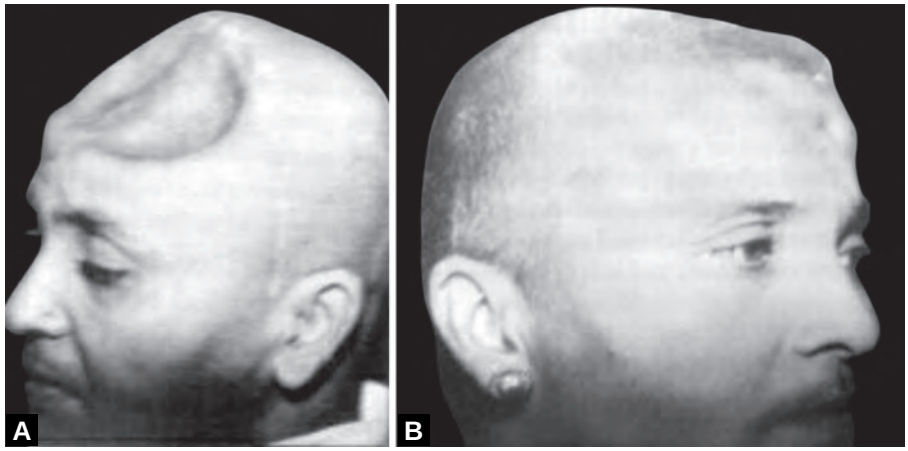
Suturing of Bone Pieces

Small bone pieces usually obtained after zygomatic and orbital osteotomy should be sutured preferably with thin wires, unbraided silk or nylon stitches. The use of miniplates, screws and an excessive volume of metal can be avoided. Placement of soft tissue in place of bone, although not consistent with the generally taught principles of reconstruction, can form a firm barrier of fibrous tissue and serve the purpose, in cases of basal bone defects. Rotation of a vascularised pedicle muscle, pericranial or fascia flap or free fat graft or muscle can be performed to occupy the area of bone defect and empty spaces.[9,10,11]

Subgaleal Preservation of Bone Flaps[15]

Convexity and basal bone flaps can be preserved in some rare situations, like brain swelling, potentially infective operative field and other such conditions, and can be replaced to the original site after a period of time. Various techniques of preservation of bone flaps have been described both inside and outside the body. The flaps have been more frequently and successfully stored in the subcutaneous plane of the abdominal wall or in the thigh (Figs 9A and B). External storage methods include deep freezing, autoclaving it while replacing, storing after radiation treatment and using antibiotic solutions.

An alternative method of preservation of the skull bone flap in the subgaleal space was found to be effective. The subgaleal plane adjacent to the site of operation is exposed widely, using blunt dissection. The bone flap is placed in this plane taking care that the curvature of the bone flap does not excessively elevate the scalp or cause tension over the scalp edges. In cases where larger bone flaps are placed in the subgaleal space, the curvature may necessitate fracturing of the bone flap in two or more pieces. The relative avascularity of the subgaleal plane helps in limiting the rate of reabsorption of the bone. The subgaleal space can be easily exposed widely, providing a large area for bone placement. Such a large and avascular space is not available elsewhere in the body. Frequently, the curvature of the bone flap matches that of the adjacent bone, which assists in the



Figs 9A and B: (A) Profile of the patient with large anterior skull base defect. The bone flap was placed in the subcutaneous fat layer of the abdomen. (B) After 18 months, the bone flap was replaced into the area of the defect resulting in satisfactory cosmetic outcome

ease of placement. The flap is placed and replaced to the original site in one operative field. As no additional incision is necessary, the procedure is quick to perform.

Use of Synthetic Material in Skull Base Reconstruction

Synthetic material is rarely required and advocated to reconstruct basal bone. Issues of biocompatibility, corrosion characteristics and metallurgic properties of the implant, its hardness and malleability and suitability of the host area to adjust to the foreign intrusion and various other factors have to be adequately analysed prior to selection of such material. Various substances including acrylic casts, plastics, glassionomer cement, silicone bars, prolene mesh and stainless steel have been used. Recently there has been a renewed interest in titanium miniplates, screws and wires. These are more commonly advocated for reconstruction of cosmetically sensitive areas such as the orbital rim, zygomatic arch and facial contour defects. Adequate reconstruction and prosthesis is necessary in patients with large and complex bone defects presenting with major functional and aesthetic disability. Adequate reconstruction is necessary and important to restore them to their accustomed way of life.

Reconstruction of Dural and Soft Tissue Defects

Fat and Free Muscle As a Packing Material

Small or large pieces of fat have been effectively used for this purpose. The fat globules get vascularised early from the surrounding tissues. Whenever free muscle is being used as packing material, it should be ground into small pieces, so that these pieces can get vascularised from the surrounding tissues. If large pieces of muscle are placed, it gets vascularised from the periphery and the central portions of the tissue can get necrosed. Such necrosed tissue can get absorbed or even pose a problem of infection. Free tissue should never be placed over free tissue, as this procedure can lead to ischaemic necrosis of the tissue most distant from the vascularised structures.

Lyophilised Dura, Gelfoam® and Fascia Lata

These dural substitutes have been used extensively and successfully for basal reconstruction. However, whenever possible, live and vascularised pedicle fascial material should be used to obtain a compact closure.

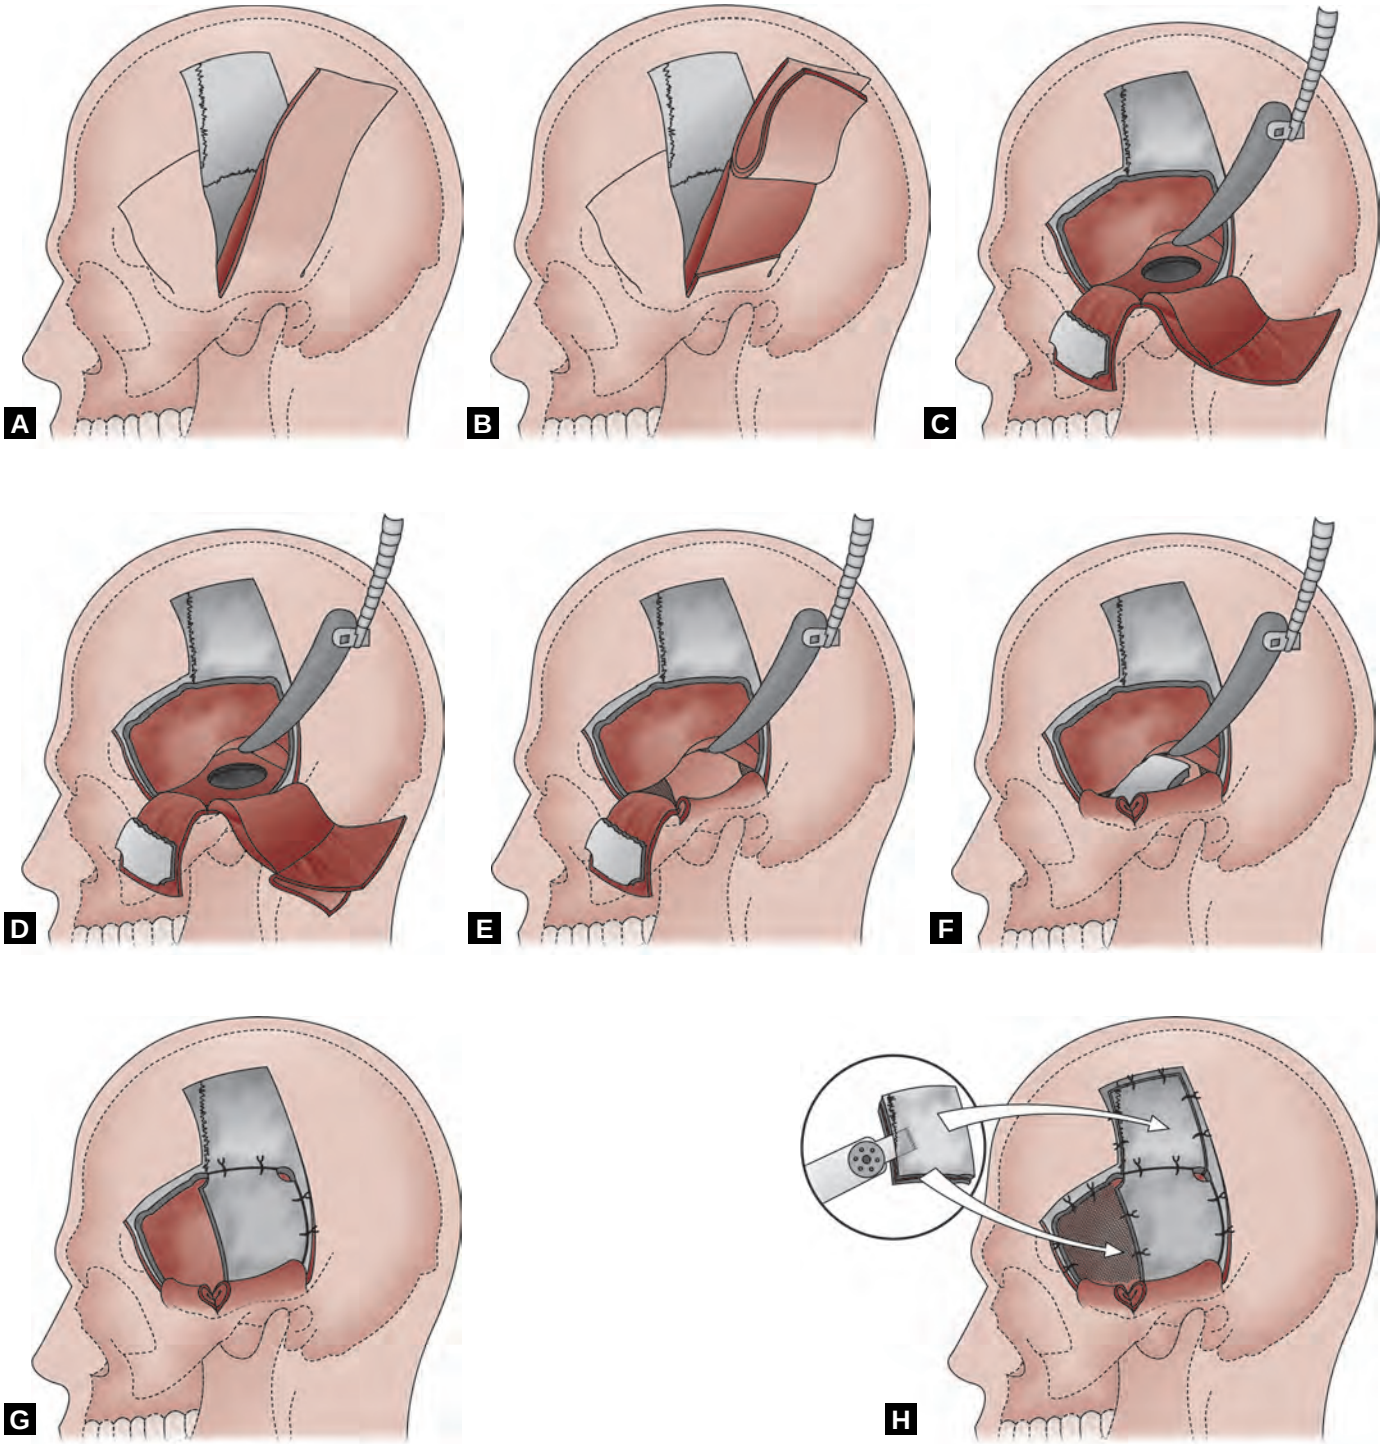
Use of Pericranial and Galeal Flaps

Pericranial and galeal flaps have extensively been used for reconstruction of basal defects. Their use is more effectively possible for reconstruction of bone and dural defects in the anterior cranial base.

Use of Rotation of Muscle Flap

Extended Vascularised Temporalis Muscle-Fascia Flap[11]

The deep layer of the temporalis fascia is everted partially over the temporalis muscle, preserving its vascularity (Figs 10A to H). A composite flap, comprising of temporalis muscle and its fascia attached along its superior border, is rotated for reconstruction of post-operative defects in the middle cranial fossa floor and mastoidectomy cavities (Fig. 10C). Partial eversion of the temporalis fascia over the muscle increases the length of the flap, while retaining its vascular pedicle. The long length vascularised pedicle flap can be used to cover defects, may be folded for bulk and may be used to carry blood supply to poorly vascularised recipient sites. The deep layer of the temporalis fascia is nourished by multiple small branches, which traverse through the muscle. Similar flaps using the thinner superficial layer of temporalis fascia have been used in craniofacial reconstruction,[3] filling up post-traumatic defects in the anterior cranial fossa and for facial reanimation.[22,24] As discussed above, the superficial temporal fascial layer is part of the pericranial aponeurosis, whilst the deep temporal fascial layer invests the superficial aspects of the temporalis muscle down to the zygomatic arch. These fascial layers have a separate arterial and venous supply and have been used as a homograft, a rotation flap or free



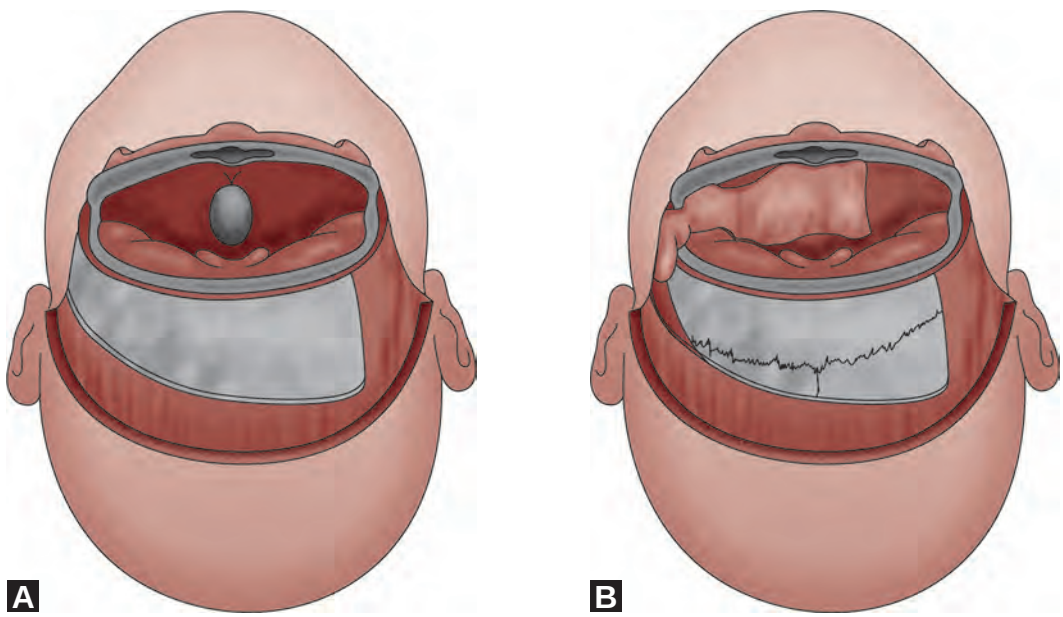
Figs 10A to H: Multilayered vascularised flap. (A) Fashioning of the flap. The temporalis muscle is split into two parts. The anterior part is used to harvest an osteomyoplastic flap (secondary flap) while in the posterior part the temporalis muscle and its fascial envelope are elevated along with the pericranial layer of the parietal bone (primary flap). This forms a long vascularised pedicled temporalis muscle-pericranial flap. (B) The deep and superficial fascial layers of the temporalis muscle are cut at the inferior aspect and rotated superiorly towards the pericranial layer. This procedure makes the distal segment of the vascularised flap relatively thick (primary flap). (C) Craniectomy. The temporal brain is retracted to expose the middle cranial fossa bone defect. The anterior half of the flap is an osteomyoplastic flap (secondary flap), while the posterior half of the flap is a long temporalis muscle-fascia-pericranial flap (primary flap). (D) The primary flap is a thick muscle fascia flap. (E) The primary flap is rotated first towards the middle fossa floor defect. (F) The secondary osteomyoplastic flap is then rotated so that it lies on the previously laid primary flap. This results in the formation of multilayer construct with vascularised pedicle falps. (G) The posterior half of the free squamous temporal bone is replaced at its original site after basal reconstruction. The anterior half of the temporal bone defect remains. (H) Parietal bone flap (from where the pericranium is harvested) is elevated and split into two halves. The temporal bone defect is reconstructed with the inner table of the bone flap (as shown in the inset) and sutured *in situ*

microvascular flap. The deep temporalis fascia is separated from the superficial by a plane of loose areolar tissue (subgaleal fascia-discussed later). The temporalis muscle and the deep layer of the fascia receive their blood supply from the anterior, middle and posterior deep temporal arteries. These vessels run between the muscle and the periosteum, and subperiosteal elevation of this fan-shaped muscle results in a viable muscle flap. The deep layer of the temporalis fascia is nourished by multiple small branches, which traverse through the muscle. Partial eversion of the deep layer of fascia with an attempt to preserve small vascular connections can result in a long vascularised flap.

Fat and free muscles have effectively been used as packing material for mastoidectomy defects. However, in some cases, particularly where there is infection in the receptor area, a vascularised pedicle graft may be necessary. Temporalis muscle can be easily rotated to cover the mastoid defects. However, the length of the muscle is not sufficient for it to be used to pack large mastoid bone defects. Also, often the thickness of the muscle restricts its rotation and it is not possible to lay it on the middle fossa base. Rotation of the muscle flap from the neck or provision of a distant muscle flap (e.g. rectus abdominis) with microvascular anastomosis, can be used in such a situation. However, an extended temporalis-muscle fascia flap provides a simple, easily manoeuvrable and locally available alternative. A similar flap can also be used for reconstruction of large defects in the middle cranial fossa base (Fig. 8).

Extended Subgaleal Fascia-Pericranial Temporalis Flap[12]

A long pericranial flap can be used to line an anterior skull base defect. The temporalis muscle is rotated along the pericranial flap and forms the vascular pedicle of the flap. Subgaleal fascia is preserved to enhance the vascularity of this long flap. Subgaleal fascia, known previously as 'loose areolar tissue layer' of the scalp and believed to be a relatively avascular zone has now been shown to have its independent and extensive blood supply entering into it at the base of the cranial vault circumferentially.[25] Casanova et al.[3] called the same layer as innominate fascia. It is a thin but well-defined trilaminar fibrous structure and discretely separable layer. The superficial temporal artery and its branches, which supply the galea, also give minute but many branches[26,27] to the subgaleal fascia, which is closely approximated to the pericranial layer. The blood supply to the subgaleal fascia is also enhanced by the vascular connections with the branches of the deep temporal arteries which supply the temporalis muscle and its fascial coverings. The pericranial layer and subgaleal fascia are continuous laterally with the superficial layer of the temporalis muscle. The pericranial layer is supplied by the perforating branches of the superficial temporal artery which traverse the subgaleal fascia and those of deep temporal arteries, which traverse through the temporalis muscle and its fascial envelope. Preservation of the subgaleal fascia and subperiosteal elevation of the temporalis muscle, along with the fascial layers, preserves the integrity of the major vascular supply to the pericranial layer. It is presumed that such a twin source of vascular supply could sustain a long length of pericranial flap. Although laterally based pericranial flaps are described for covering anterior central skull base defects, successful usage of such a flap taken beyond the midline has not been reported (Figs 11 and 12). While elevating the pericranial flap, some of the subgaleal fascia is almost always included. A specific attempt to preserve this layer by conscious and careful dissection from the galea, in an



Figs 11A and B: (A) The site from where a long subgaleal fascia pericranial flap will be harvested. (B) After rotation of the long subgaleal fascia-pericranial flap it adequately covers the site of the anterior cranial floor defect

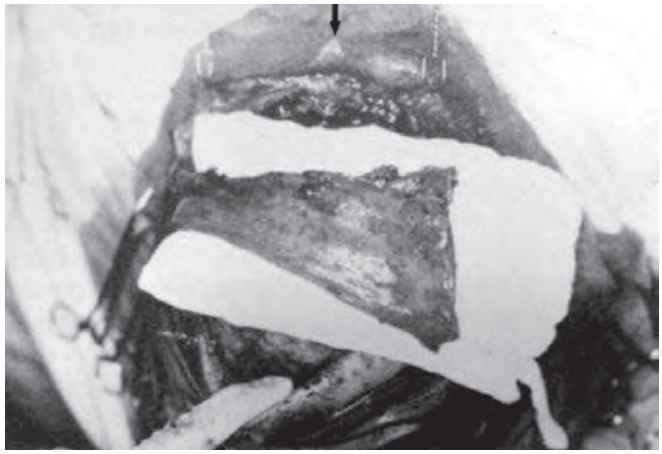


Fig. 12: Intra-operative photograph showing the extended subgaleal fascia-pericranial temporalis flap placed over the surgical mop. The exposure is basal frontal. Anteriorly, the scalp flap is everted by hooks. Posteriorly, the surgeon's index finger is retracting the scalp flap, exposing the cranial bone from where the flap is raised. Arrow indicates the midline

attempt to preserve additional vascular supply to the pericranial layer, could be critically important in long pericranial flaps, as described. Although the temporalis muscle can be used in its entirety, vertical splitting of the temporalis muscle into half or one-third would preserve at least one or two of the main feeding vessels. The described flaps can be used to reconstruct cranial defects, where there is poor local nourishment and in potentially infective fields. Relative ease of harvesting and the ability to alter the arc of rotation of this flap can be effectively used.

Temporalis Muscle and Temporoparietal Fascia

The temporalis muscle has been used for head and neck reconstruction and is a suitable muscle for lateral and anterior defects. The vascular supply to the temporalis muscle is from the internal maxillary artery. It can be used for defects in the infratemporal fossa, anterolateral skull base, orbit and maxillary regions. It is limited by its inability to reach the midline. It can be split longitudinally or rotated by subperiosteal dissection and fracturing of the coronoid process. Maintaining its muscular attachment to its insertion should preserve the venous drainage of the flap. The temporalis muscle along with its fascial coverings can be rotated along with the pericranium to form a long flap. The fascial cover of the temporalis muscle can be everted to form a thick peripheral flap. The temporalis muscle can be effectively rotated to cover middle fossa defects. The sternocleidomastoid and other muscles of the nape of the neck can be rotated superiorly to cover defects in the posterior cranial base.

Myocutaneous Flaps

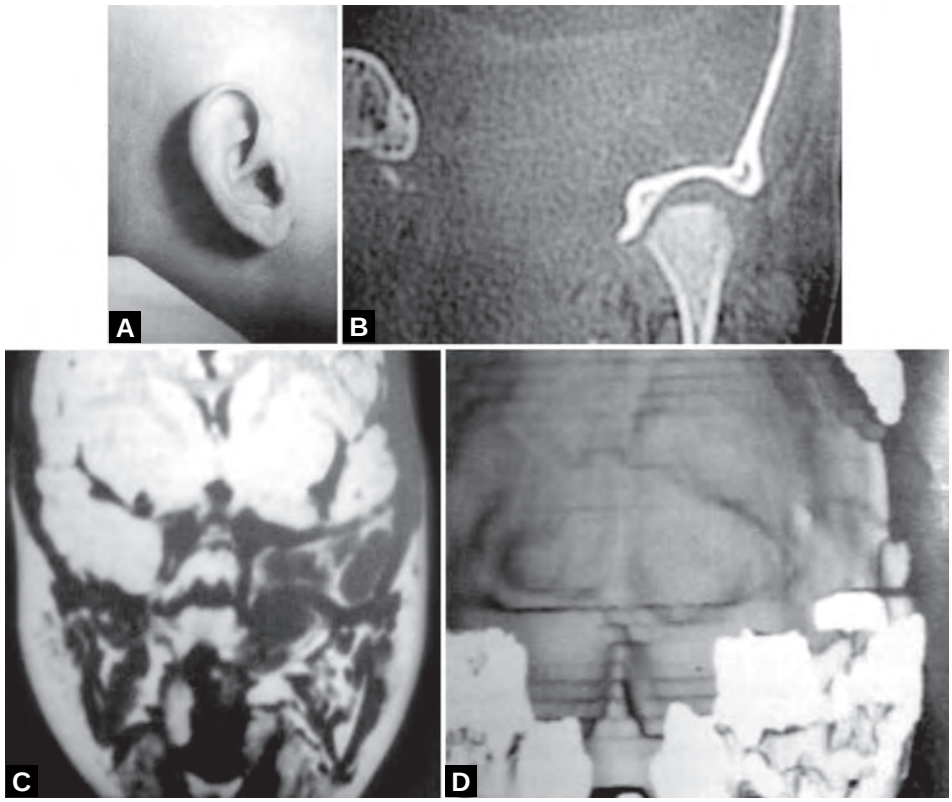
The pectoralis, latissimus and trapezius muscle can be used to raise a myocutaneous flap based on their vascular pedicles. The pectoralis muscle flap is based on the thoracoacromial vascular pedicle as it crosses under the clavicle just medial to the pectoralis minor muscle. A line, drawn from the mid portion of the clavicle to the xiphoid, delineates the path of these vessels. The clavicle can be transacted for the pedicle to gain its reach up to the cranial base. The latissimus muscle is based on the thoracodorsal vessels, which are the branches of the axillary artery. The skin paddle is designed at the anterior border of the muscle since the vascularity of the flap is safely assured at that point. The arc of rotation of the flap can be extended by transection of the humeral insertion. The pectoralis and the latissimus muscle flap have a limitation that they can deliver only a limited volume of tissue above the zygomatic arch and infraorbital rim. The trapezius flap is a versatile flap fed by the descending branch of the transverse cervical artery. The vertical part of the muscle is raised since the transverse part is required to maintain shoulder shrugging. The paravertebral perforators, which additionally supply the vertical part of the muscle, should be ligated whilst harvesting the flap. Tunnelling of the flap is avoided to prevent undue pressure on the pedicle and strangulation or kinking of the blood supply. The skin paddle is based over the muscle and can be extended past the muscle in a random manner for several centimetres. The flap is bulky and has a considerable length. Hence, it is the flap of choice for coverage over the posterior temporal fossa and the lateral and posterior skull base. It can reach up to the vertex without any difficulty.

Free Tissue Transfer/Free Flaps

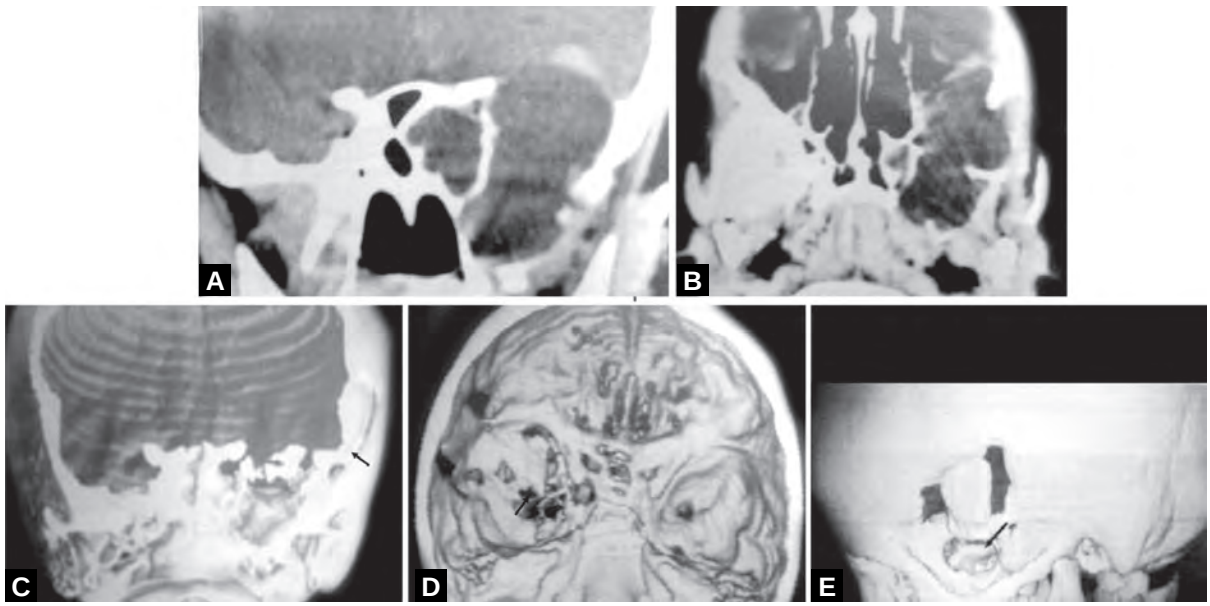
Free transfer of tissue or flaps is indicated in patients who have large geometrically complex defects of soft tissue, bone or dura following craniofacial resection, extended transtemporal bone surgery or excision of recurrent tumours. Usually they require a large volume of tissue for reconstruction. The site of defect, patient positioning for harvesting, donor morbidity, recipient vasculature and the need for an adequate pedicle length are factors to be considered. Moderate to large defects can be reconstructed using the rectus muscle or the latissimus muscle myocutaneous flap. The rectus muscle free flap is a natural choice. It is based on the deep inferior epigastric vessels which are branches from the external iliac artery and vein proximal to the inguinal ligament. The pedicle is large, usually 4–6 cm in length with an arterial diameter of 3–4 mm. The overlying skin or subcutaneous tissue provides additional bulk, if required, especially for central and irregular defects. The latissimus myocutaneous flap has less subcutaneous fat, as compared to the rectus myocutaneous flap. The radial free forearm flap is ideal for defects requiring thin tissue and enhanced vascularity. It is based on the radial artery subcutaneous perforators to the overlying forearm skin and fascia. If more bulk is required, the lower three slips of the serratus muscle can be transferred, based on the thoracodorsal vessels. Both these flaps can provide pedicle lengths of 10–12 cm.

Multilayer Reconstruction of Middle Fossa Base

Frequently there are large spaces that need to be filled after basal bone, soft tissue and tumour resection. Such spaces can be a site for haematoma or CSF loculation. Both these events may enhance the possibilities of infection and CSF fistulae (Figs 10, 13 and 14). Use of multiple layers of vascularised tissue for reconstruction not only provides a compact sealing of the defect, but by



Figs 13A to D: (A) A small swelling is seen in the external ear canal. The photograph does not clearly show the leaking CSF. (B) CT showing the large defect in the middle cranial fossa floor. (C) MRI showing the herniation of a multicystic temporal lobe into the infratemporal fossa. (D) Post-operative three dimensional CT scan showing the large defect in the petrous bone roofed almost completely by the rotated bone flap



Figs 14A to E: (A) CT showing a large defect in the middle cranial fossa floor as a result of a large epidermal cyst. (B) Axial cut showing the extent of the cyst and the bone defect. (C) Three dimensional CT, the arrow showing the rotated temporal bone flap in a multilayer construct. (D) Arrow shows the middle fossa defect covered by the temporal squamous bone flap. (E) Arrow shows the basally displaced temporal squamous bone flap

virtue of its volume helps in reducing the dead space. Two methods of multiplayer reconstruction of middle cranial base defects are shown in Fig. 10. The procedure involves use of an osteomyoplastic flap, which is placed over one of the two described types of temporalis muscle-fascia flap.

Elevation of the pericranial layer along with the temporalis muscle and fascial layers, as shown in Figures 10A and B, results in a viable flap with abundance of vascular supply. In situations where this flap is sufficiently thick, it can be used as the primary flap. Whenever the pericranial part of the flap is not very thick or for some reason cannot be harvested, a muscle-fascia flap (described earlier) can be rotated. In this method, partial eversion of the superficial and the deep layers of the temporalis fascia by cutting these two layers just above the zygomatic arch (Figs 10B to D), is performed. The peripheral part of the flap now has three fascial layers, comprising of pericranium and superficial and deep layers of temporalis fascia. This makes the distal end of the flap relatively thick. The proximal end of the flap is formed by the full thickness of the muscle. The result is a long and thick flap. This splitting would not adversely affect the circulation to the flap. The anterior or the posterior part of the split temporalis muscle can be used to harvest a vascularised pedicle osteomyoplastic flap (Figs 10A to D). This forms the secondary flap. Split or full-thickness bone can be used. The bone piece can be fractured into two or more pieces, retaining its attachment to the muscle so that its contour can be adjusted to suit the local environment. The primary flap consisting of either of the two types of muscle-fascial flap is first placed over the site of the middle fossa bone defect over which the secondary osteomyoplastic flap is placed (Fig. 10F). This forms a compact and multilayered construct of vascularised pedicle flaps. Whenever it is felt that bone replacement over the site of the defect is not essential, only soft tissue flaps could be used. The temporal bone defect resulting from basal rotation can be reconstructed with a split cranial flap, as shown in Figures 10G and H.

In most cases of middle fossa defects, a simpler method of reconstruction may suffice. However, in occasional cases with a complex defect, information about the feasibility of the described method of reconstruction may be a useful adjunct. The multilayered reconstruction, as discussed, could be performed as a radical measure, in situations where problems of CSF fistula or those related to herniation of the brain matter are anticipated or where earlier attempts at reconstruction have failed. Such a multilayered flap fashioned entirely with vascularised pedicles, by virtue of its bulk and long length can be used to cover bone defects, may be folded for bulk and may be used to carry blood supply to poorly vascularised recipient sites. In an occasional case of CSF otorrhoea, such an elaborate reconstruction could be a life saving procedure.

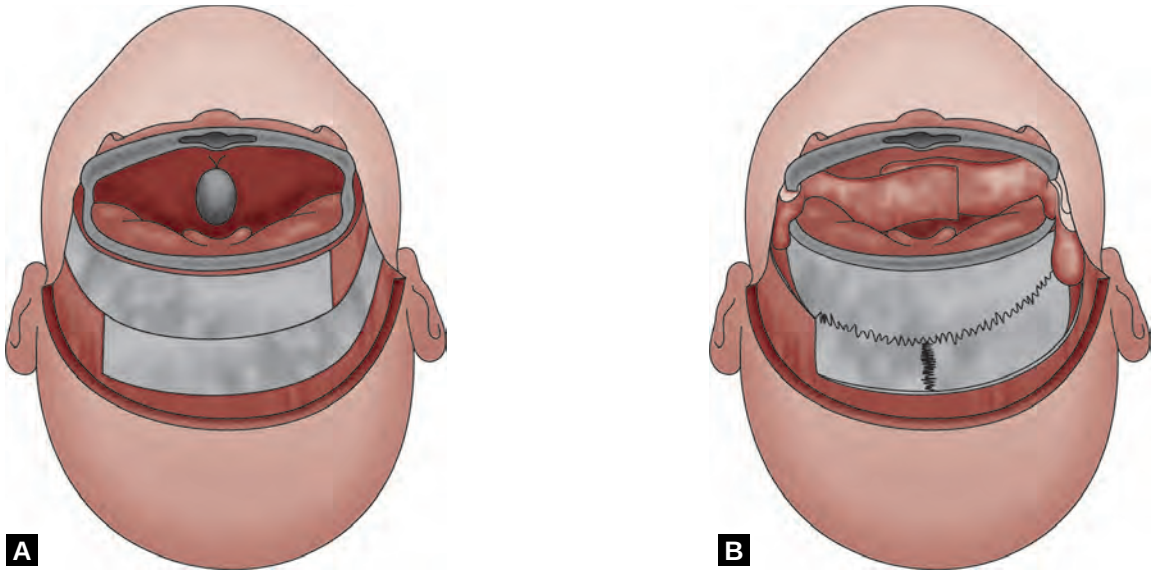
Anterior Cranial Base Reconstruction

Repair of large post-operative defects in the anterior cranial fossa is strongly recommended in the following circumstances, namely a large medial dead space, a large lateral orbital removal, thereby avoiding enophthalmos and pulsation of the eyeball, resection of the orbitofrontal rim, supraorbital margins and the frontal area for cosmetic reasons. Autogenous bone is recommended for closure of air-filled cavities of the face that have widely been opened and are predisposed to contamination. Iliac graft or split calvarial grafts have been used. Bone-dust harvested from the partial thickness burr holes behind the posterior margin of the bifrontal free flap can also be used. In reconstruction of a large portion of the anterior cranial fossa, following extensive resection of fibrous dysplasia, the dead space should be packed with cancellous bone. A cortical graft should be placed between the nasion and the clivus beneath the horizontal portion of the sellar floor, to close the ethmoidosphenoidal area. If the clivus has been removed, the graft should be placed between the floor of the sella and anterior margin of the foramen magnum or anterior arch of the atlas. Bone-dust should be packed intracranially to provide a tight closure.

Multilayer Reconstruction of the Anterior Cranial Fossa Floor[21]

Multiple combinations of flaps can be used to cover anterior cranial basal defects. Two multilayer flaps are shown in Figures 15 to 17. The flaps could comprise only of soft tissues (Fig. 15) or may include a bone piece (Fig. 16). A bicoronal incision is made and scalp flaps are reflected both anteriorly and posteriorly in the subgaleal plane. The pericranium over the frontal bosses is relatively thin and harvesting an intact pericranial flap could be difficult. Whenever such an elevation is possible, the frontal pericranium can be rotated over the defect in the anterior cranial base. Everting the posterior part of the scalp results in a wide exposure of the pericranium over the parietal or even occipital region. Harvesting a long pericranial flap, based on the temporalis muscle and its fascial cover from both sides and rotating them over the anterior cranial fossa defect, can result in a multilayer closure. The long length of the flaps can be useful in placing the flaps loosely or even double-breasting it over the defect.

Whenever it is felt that addition of bone is necessary for adequate reconstruction, a vascularised pericranial based bone flap, as described earlier, can be used. The split or full thickness bone flap can also be pedicled on a laterally based pericranial flap. A long pericranial flap is harvested from the contralateral side, as shown in Figures 15 and 16. Both these pericranial flaps (one containing bone piece) are then rotated along with the temporalis muscle and its fascial coverings. On both sides, the temporalis muscle can be split vertically to retain its function. On one side, the anterior portion of

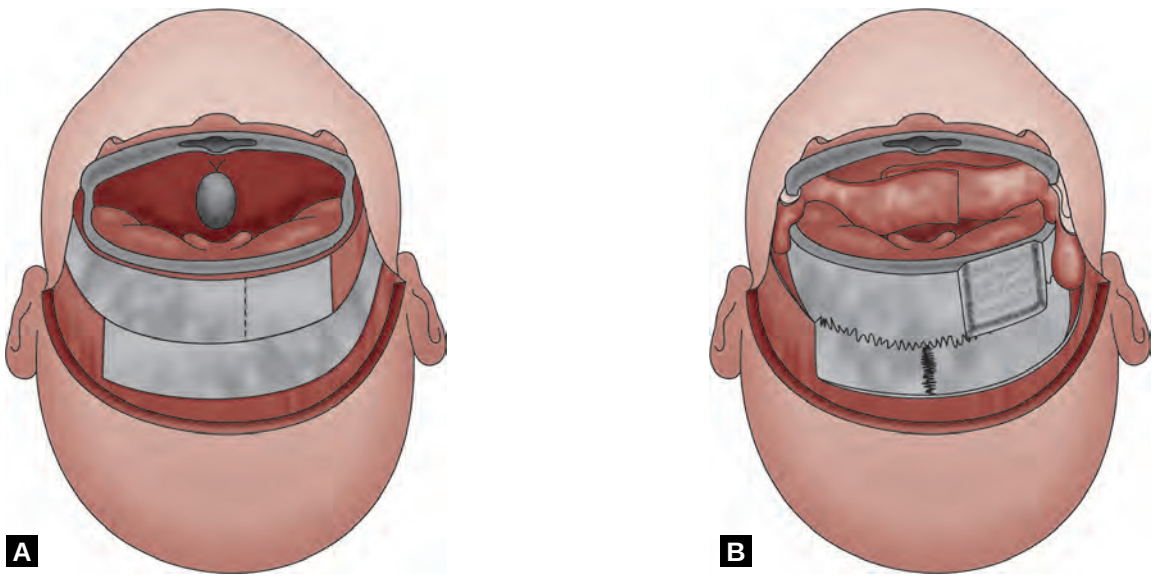


Figs 15A and B: (A) Bifrontal craniotomy. The shaded area shows the pericranial cover of the skull bone. The transverse lines show the sites of the pericranial layer incision for the purpose of harvesting the flaps. (B) The two pericranial flaps from the both sides are harvested and rotated along with the temporalis muscle towards the defect in the anterior skull base, one over the other, forming a multilayer reconstruction

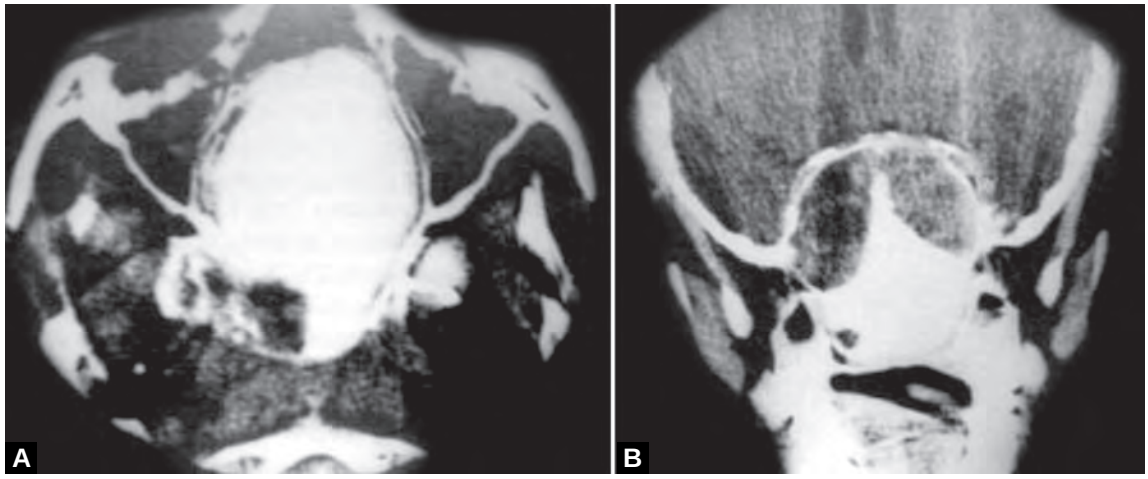
the split muscle is used as the base of the pericranial flap over the anterior parietal region, while on the other side the posterior portion of the split muscle forms the base of the pericranial flap over the posterior parietal region. A specific attempt is made to preserve the subgaleal fascia to enhance the vascularity of the designed flaps. Both these flaps are rotated anteriorly and laid down one over the other in the region of the defect in the base. The vascularised pedicle bone flap is placed superior to these flaps, so as to avoid direct exposure of the bone to the paranasal sinuses.

Use of Outer Layer of Dura As a Pedicled Flap[16]

Cranial dura is formed by two layers: (1) the outer endosteal layer and (2) the inner meningeal layer. These layers are well defined and 'separable' by manual dissection, particularly in younger individuals. Multiple small and medium sized arteries supply the dura circumferentially. The meningeal blood vessels are largely located in the endosteal layer. When preserved intact, the outer endosteal layer can be rotated and used to cover defects in the proximity. The principle advantage of using such material is that it may be used as a vascularised pedicle



Figs 16A and B: (A) The incisions over the pericranial layer. Bifrontal craniotomy is seen. Note the skull bone is split on the right side so that it can be rotated along with the pericranuim to form a vascularised pedicled bone flap. (B) Anterior cranial base multilayer reconstruction



Figs 17A and B: (A) CT showing a massive bony tumour occupying the nasopharynx, sphenoid and posterior ethmoid sinuses, which displaced the anterior cranial fossa floor including the sella, planum sphenoidale superiorly and stretched the optic nerves laterally. Multilayer reconstruction was used to repair the skull defect after tumour excision. (B) Axial view showing the large bony tumour

flap or a free graft (Fig. 18). The consistency and quality of the material matches that of the adjacent dura. Local availability and ease of rotation of this flap are the other advantages. Despite the limitations in using this flap, due to technical difficulties in separating the layers, it can be useful only in an occasional patient.

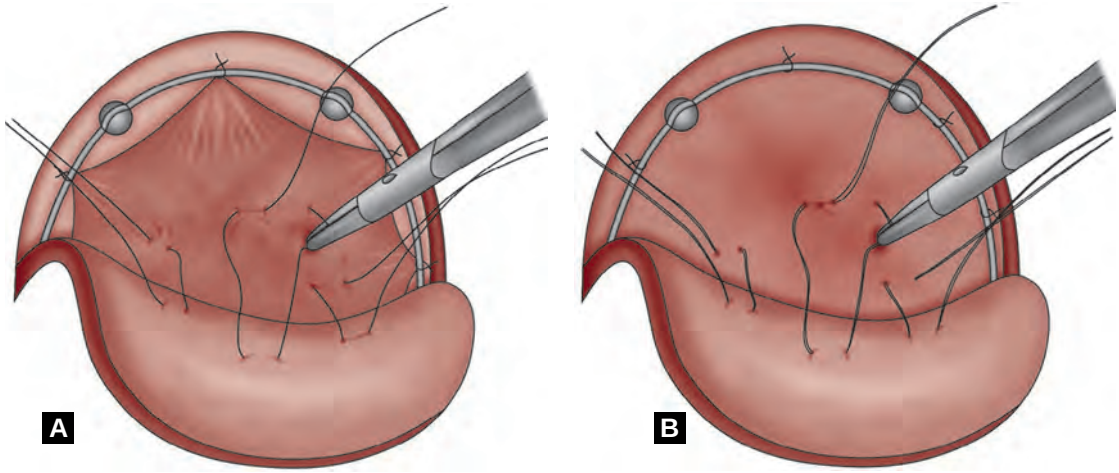
Tenting Scalp Stitches[8]

Post-operative collections underneath the scalp are common, although usually no more than a nuisance to the surgeon and the patient. However, sometimes these collections can be a source of secondary complications, such as wound breakdown and infection. Such complications are particularly relevant after a long skull base operation. The problem can occur after an osteoplastic craniotomy, when the collection develops between the galea and the pericranium or following free bone flap exposure in which case the collection is between the pericranial layer and the bone flap. Suction drains and tight head dressings are frequently used at the time of closure, to avoid this problem. Occasionally, there is a need to drain the collection and approximate the scalp layers by a large bore needle and sometimes lumbar drainage of CSF may be necessary. Suction or gravity drains often become clogged, or only approximate the layers of the scalp in a limited area. They cannot be used for long periods because of the risk of infection. Tight head dressings loosen over a period of time, can be a source of discomfort to the patient, and occasionally compromise the blood supply of the skin flap.

Fig. 18: Operative picture showing the two slit dural layers. The layer held by the stay suture is the cerebral layer, while that held by the forceps is the endosteal layer. The endosteal layer was rotated to cover the mastoid air cells

'Tenting' sutures of the dura are routine after every craniotomy. These stitches help to prevent the occurrence and expansion of extradural collections. The stitches shown in Figure 18 are similar in principle and action for the scalp. This is a simple and non-time consuming technique. The sutures help to seal surgically created space between the layers of the scalp and act as internal compression. The closer approximation of the scalp to the bone improves the vascularity of the bone, by providing an additional pathway for blood supply in the initial post-operative phase.

Technique: After adequate haemostasis, when the scalp is reflected back for closure, three to four (or more) sutures are placed between the galea and the pericranium, as shown in Figures 19A and B. The site of the sutures is carefully judged so that the scalp wound can approximate closely. It is usually easier to place the sutures at a distance of about 5 cm from the scalp incision. The greater the number of sutures placed, the more compact is the closure of the layers. It is easier to tie knots after all the sutures have traversed the layers. In case of a free bone flap, the pericranial layer is sutured to the bone flap after drilling holes in the bone. The holes used for tenting the dura in the centre of the bone flap can be used for this purpose.



Figs 19A and B: (A) Galea to pericranium stitches. (B) Galea-pericranial layer bone flap stitches. Note that the dural tenting sutures have already been placed and tied in the central bone holes

185 Orbital Tumours

Aadil S Chagla

INTRODUCTION

- Orbital tumours are rare
- They have a wide histological variance
- Benign tumours are far more common in children
- Difficult surgical challenge despite advances
- Safe access to the orbit via the cranium.

Orbital tumours arise from several locations within the orbit and have varied aetiologies. Each of these locations is associated with its own symptomatology, epidemiology, management problems and prognostic factors. However, orbital tumours may have overlapping features in the clinical presentation and imaging findings. In order to narrow down the differential diagnosis and derive an appropriate management plan, one must have a clear understanding of the gross and microsurgical anatomy of the orbit and appreciate the displacement and involvement of various intraorbital structures in relation to the tumour. One must also have a comprehensive knowledge of pathologies of different orbital tumours, in order to treat these lesions. It may be mentioned that the term tumour here is not restricted to neoplasms but includes all space-occupying lesions.

GROSS SURGICAL ANATOMY

The orbits are highly compact three-dimensional structures, which contain vital neuromuscular structures related to the eyes suspended in a sea of fat. The orbits are cone or pyramidal shaped bony cavities, each situated on either side of the root of the nose and taper posteromedially towards the cavernous sinus and optic canal. The base of the orbital 'cone' faces anteriorly and has a very strong lateral wall. The orbits protect the eyes by providing sockets for each eyeball. The orbit can be divided into four anatomical compartments: (1) bony orbit; (2) extraconal orbit; (3) intraconal orbit and (4) globe.

Bony Orbit

The skeletal framework is made up of seven bones (Fig. 1). The lateral wall is composed of the zygomatic and frontal bones anteriorly and the greater wing of the sphenoid posteriorly (Fig. 2). The medial wall consists of thin ethmoidal, nasal, frontal and lacrimal bones, a small part of the lesser wing of the sphenoid and the

Fig. 1: Cadaveric specimen of the skull showing the right orbit

tip of the maxilla. The floor is formed predominantly by the orbital process of the maxilla. The roof of the orbit is formed by the lesser wing of the sphenoid and the frontal bone (Fig. 3). If the roof is deficient, the brain

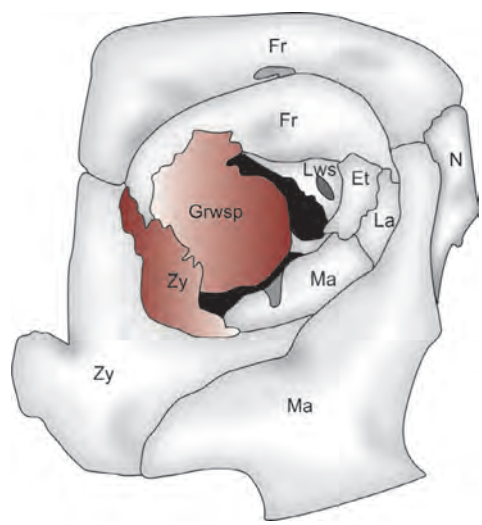

Fig. 2: Diagrammatic representation of the bony orbit showing various bones that form the orbit (Zy—Zygoma, Fr—Frontal bone, Grwsp—Greater wing of sphenoid, Et—Ethmoid, La—Lacrimal bone, Lws—Lesser wing of sphenoid, Ma—Maxilla)

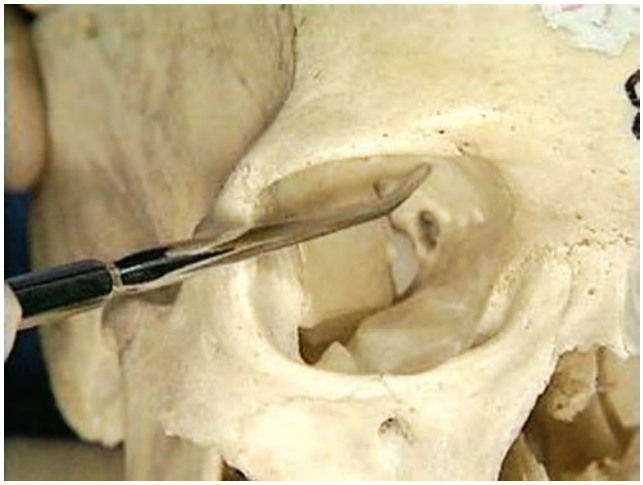

Fig. 3: Roof of the orbit; the frontal bone anteriorly and the sphenoid lesser wing posteriorly

pulsations will translate on the orbit and the pulsations will be quite evident to the clinician and the patient. The long axis of each orbit passes medially and backwards, so that their medial walls lie parallel to each other and the lateral walls are set at right angles to each other (Fig. 4).

The orbital walls are perforated by the superior orbital fissure (SOF), inferior orbital fissure (IOF), the ethmoidal foramina, the zygomaticotemporal and zygomaticofacial canals, the nasolacrimal canal and the optic canal.

The optic canal measures between 5 mm and 10 mm in length and is approximately 5 mm in height.[25] The roof of the canal is approximately 2 mm thick. The proximal opening of the canal is formed by the falciform process, a thin fold of dura overlying the optic nerve. This process is also about 5 mm long. The optic canal lies between two 'struts' or roots of the lesser wing of the sphenoid, laterally the anterior clinoid process and medially the thinner portion of the sphenoid strut. The optic nerve is approximately 30 mm in length which is 5 mm longer than the distance of the orbital apex to the posterior margin of the globe and this redundancy in the nerve allows normal movements of the globe. This laxity also allows the nerve to course around the tumour and helps preserve its function. This important anatomical fact helps protect vision and sometimes even large tumours of the orbit have little or no visual impairment.

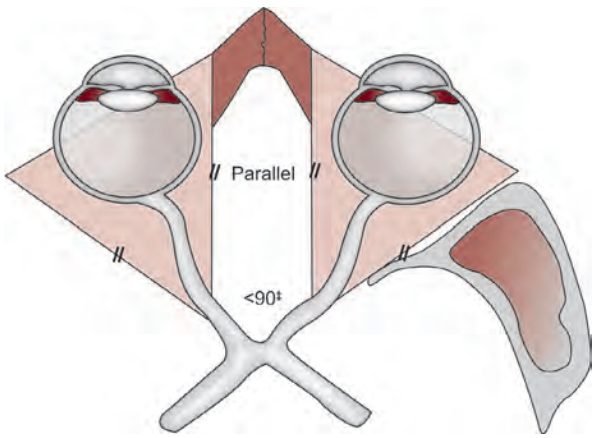

Fig. 4: The medial walls lie parallel to each other and the lateral walls are set at right angles

The SOF is bound by the lesser wing of the sphenoid bone along the superomedial margin and by the greater wing of the sphenoid on the inferolateral margin. The superior head of the lateral rectus splits this fissure into an upper part and a lower part, which is termed oculomotor foramen. The SOF is retort shaped. The bulbous end of the retort is medially placed and the thin neck directs laterally and superiorly. A fibrous ring called the annulus of Zinn surrounds the optic canal and the medial portion of the SOF. This gives rise to the four recti muscles of the orbit along with the levator palpebrae superioris and the superior oblique. These muscles pass anteriorly and attach on to the eyeball in the form of a 'cone'. The optic nerve and the ophthalmic artery enter the orbit through the optic canal. The lacrimal and frontal branches of the ophthalmic division of the trigeminal nerve, along with the trochlear nerve, enter the orbit lateral to the annulus in the SOF. The superior division of the oculomotor nerve, the nasociliary nerve (division of the ophthalmic nerve), the abducent nerve and the inferior division of the oculomotor nerve enter through the annulus (Fig. 5).

The IOF originates at the apex and extends anteroinferiorly and transmits vessels and nerves into the infratemporal and pterygopalatine fossae.

Periorbita

The periorbita is the periosteum of the orbit and separates the bony orbit from the extraconal orbit. The periosteum of the orbit lines the orbital bone from within and is continuous with the intracranial dura. The pia and arachnoid of the optic nerve are fused with the dura

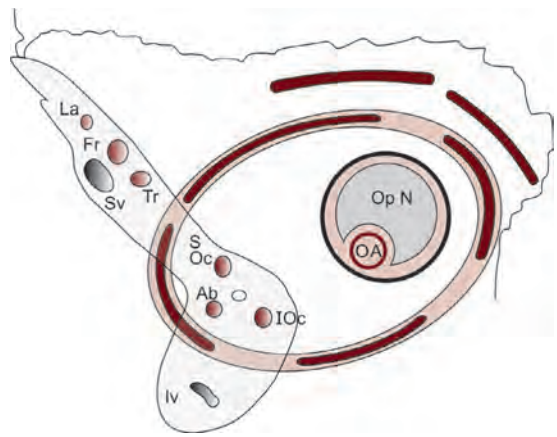

Fig. 5: Diagrammatic representation of the superior orbital fissure (SOF) (La—Lacrimal nerve, Fr—Frontal nerve, Sv—Superior ophthalmic vein, Tr—Trochlear nerve, SOc—Superior division of oculomotor nerve, Ab—Abducent nerve, Nc—Nasociliary nerve, IOc—Inferior division of oculomotor nerve, Iv—Inferior ophthalmic vein, Op N—Optic nerve, OA—Ophthalmic artery)

Fig. 6: Cadaveric specimen showing the structures of the extraconal orbit

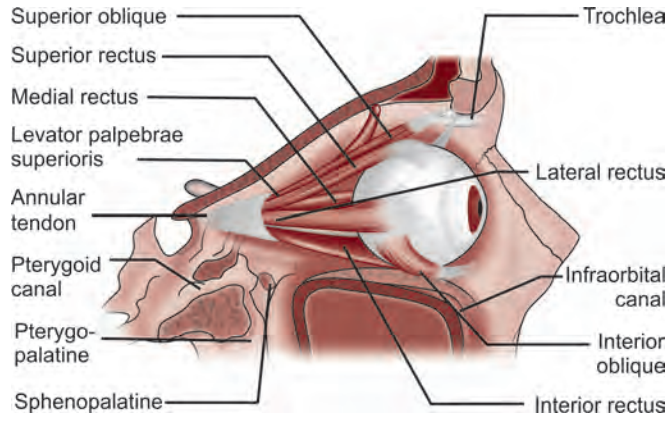

Fig. 7: Muscles forming the intraconal orbit

at the fibrous annulus of Zinn dorsomedially and ventrally. Since the dura is continuous with the periorbita at the SOF, it is difficult to eradicate tumours at the orbital apex which are adherent to the dura/periorbita without compromising neural functions.

Extraconal Orbit

The principal content of this compartment (Fig. 6) is the orbital fat. The frontal nerve and the lacrimal nerve, which pass through the SOF lie on the superior surface of the levator palpebrae superioris. The trochlear nerve is the only nerve which supplies an extraocular muscle and is extraconal in location. It enters the muscle as a series of branches quite posteriorly. This compartment also contains the lacrimal gland. It is divided into a larger orbital and a smaller palpebral part. The orbital part is encased superiorly by the lacrimal fossa and inferiorly by the aponeurosis of the levator and the lateral rectus. The palpebral part lies under the aponeurosis of the levator and over the conjunctiva of the superior fornix.

Intraconal Orbit

The orbital apex is the most posterior part of this compartment (Fig. 7) and contains the most important structures passing through it. The external ocular muscles originate from the common tendinous ring or the annulus of Zinn. The annulus encloses the optic canal and the oculomotor foramen. Various structures which enter through the optic canal include the optic nerve with its meningeal and arachnoid coverings, the ophthalmic artery and a sympathetic plexus. At first, the ophthalmic artery is below and lateral to the optic nerve. Within the orbit, it first lies between the lateral rectus and the optic nerve. It then crosses over the nerve and lies below the superior rectus muscle. As it reaches the medial wall of the orbit, it is accompanied by the nasociliary nerve. It then divides into various branches. The central retinal artery is the most important branch and is given off 5–10 mm behind the globe and enters the optic nerve from its inferomedial side.

The blood supply of the intraorbital portion of the optic nerve is from the tight vascular plexus in the pia matter. This pial network arises primarily from the arterial perforating branches from the posterior ciliary arteries, which are posterior to the entry of the central retinal artery into the optic nerve. A second contribution to the pial network is from the recurrent branches of the long and short posterior ciliary arteries. A third contribution is from the central retinal artery.[12]

The structures entering through the oculomotor foramen include the superior branch of the oculomotor nerve, abducent nerve, nasociliary nerve and the inferior branch of the oculomotor nerve, in that order. The superior division supplies the levator and superior rectus, while the inferior division crosses below the optic nerve to supply the medial and the inferior rectus. This arrangement of the nerve supply makes the approach to the optic nerve from the medial compartment extremely safe and easy. All nerves supplying the muscles enter the internal surface of the muscles at their posterior third. The ciliary ganglion lies between the lateral aspect of the optic nerve and the lateral rectus in the posterior orbit.

The optic nerve is the principal constituent of this compartment. It is 4.5–5 cm long and about 4 mm in diameter. It has four portions, namely intraocular, intraorbital, intracanalicular and intracranial.

Globe

The globe is the "raison d'être" of the orbit. All constituents of the orbit ultimately contribute to the optimal function of the globe. There is a fascial sheath, Tenon's capsule which invests the globe snugly. A third of the globe lies outside the orbit. There is a connective tissue network spanning the entire orbit. The anterior part is the Tenon's capsule which surrounds the globe. The connective tissue septa around this condense into various suspensory ligaments and also get attached to the periorbita. The orbital septum is the anatomic boundary of the anterior orbit and originates from the thick periorbita of the orbital rim called arcus marginalis. The orbital fat is held in its posterior position by this septum.

The orbital spaces are divided into: (a) sub-periosteal space; (b) the peripheral surgical space; (c) the central surgical space and (d) Tenon's space. These spaces correspond with the compartments defined above. This concept of compartmentalisation of the orbit is immensely helpful in dealing with orbital tumours and planning the surgical approaches.[22]

TYPES AND INCIDENCE OF ORBITAL TUMOURS

Orbital tumours are rare. Table 1 describes histologically proven primary orbital tumours, operated upon from 1995 to 2007 at the King Edward VII Memorial Hospital, Mumbai. The list of tumours is only of primary orbital tumours. Not included in this list are pseudo-tumours and skull base malignant tumours, such as sinonasal carcinomas and other tumours that have secondarily invaded the orbit. The most common malignant tumour in an adult population in any large series of orbital tumours is a metastatic tumour.[27] In our series, metastatic tumours are far less due to the referral pattern. The low incidence of optic nerve gliomas and capillary haemangiomas, noted in this series, is because these patients are often observed and have not undergone surgery (Table 2).

Table 1: Total number of cases operated at the King Edward VII Memorial Hospital, Mumbai, Maharashtra, India

Year	*Total number of cases*
1995 to 2007	148

CLINICAL FEATURES OF ORBITAL TUMOURS

Orbital tumours produce symptoms and signs by compression, infiltration and/or infarction of the orbital structures. Sometimes, they act as mass lesions producing only proptosis. Occasionally, they may produce limitation of eye movements. They may also produce neuro-ophthalmological symptoms and signs through their effect on:

- The optic nerve.
- The ocular motor nerves.
- The orbital branches of the ophthalmic division of the trigeminal nerve.
- The nerve supply to the iris sphincter and dilator muscles.

Proptosis

Most orbital tumours produce some degree of proptosis (Figs 8A and B). Optic sheath meningiomas may take up little room in the orbit and may produce minimal proptosis but present early with visual complaints. On the other hand, vascular tumours, which are soft in consistency and can become quite large, produce significant proptosis. Tumours located within the extraocular muscle cone, e.g. haemangioma, optic nerve glioma, meningioma, are more likely to produce axial proptosis (the eye is pushed directly forwards), while tumours outside the muscle cone, e.g. dermoid cyst, neurinoma, lacrimal gland tumour, tend to push the eye out or in a direction opposite to that of the lesion. Proptosis can also be caused by lesions outside the orbit, e.g. cavernous sinus, when the venous flow is impaired. Pulsatile proptosis may occur in vascular lesions or when the roof of the orbit or the sphenoid bone is deficient.

Optic Neuropathy

Vision is generally impaired with tumours involving the optic nerve namely optic sheath meningiomas[35,42] and optic nerve gliomas.[43] Benign tumours of the orbit, such

Figs 8A and B: Proptosis

as neurofibromas and haemangiomas tend to produce visual deficits only when they are of large size and have been symptomatic and have been present for a while.[11] Malignant lesions often produce visual deficits.

Visual field involvement may be subtle, i.e. enlargement of the blind spot and slight peripheral field constriction. The optic disc will show swelling and would appear similar to unilateral "papilloedema" from increased intracranial pressure (ICP). Hence, the term unilateral optic disc swelling is preferred and the term papilloedema restricted to disc swelling which results from raised ICP.[28]

A second form of presentation of orbital tumours is that of unilateral transient visual loss.[4,39] This may occur only in certain positions of gaze and immediately clears when the direction of gaze is changed. Either direct pressure on the optic nerve or interruption of the blood supply is the explanation for this phenomenon. Chronic compression of the intraorbital portion of the optic nerve will produce:

- Loss of vision.
- Optic disc swelling that resolves into optic atrophy.
- The appearance of optociliary shunts veins.

This is often seen in spheno-orbital meningiomas,[1,9,44] but may also occur in cases with optic nerve gliomas.[14,17]

Ocular Motor Nerve Paresis

The three ocular motor nerves enter the orbit through the SOF. Each of these nerves may be involved resulting in varying degrees of diplopia. Tumours that are located at the orbital apex may involve the ocular motor nerves early, before they are large enough to produce proptosis. The ophthalmoparesis that is produced by orbital tumours is indistinguishable from that produced by intracranial lesions. Ophthalmoplegias are most common in malignant tumours of the orbit, metastatic carcinomas or lymphomas, although optic nerve gliomas, neurinomas, haemangiomas and lymphangiomas can also produce it.

To differentiate diplopia due to oculomotor nerve paresis and muscle involvement due to mechanical restriction of ocular movement can be gauged by the following:

- Intraocular pressure increases substantially when the patient attempts to look in the direction of gaze limitation[32,34,45] The intraocular pressure measurements are performed using a pneumatic tonometer,[34] although any instrument may be used.
- Forced duction (or traction) testing can also be used to detect mechanical limitation of motion. An attempt is made to move the eye forcibly in the direction of gaze limitation. As described by Jaensch,[18] this test is performed as follows. The cornea is anaesthetised using several drops of a topical anaesthetic such as proparacaine or tetracaine hydrochloride. The conjunctiva is further anaesthetised by holding a cotton swab or cotton-tipped applicator soaked with 5–10% cocaine against it for about 30 seconds. The conjunctiva is then grasped with a fine toothed forceps near the limbus on the side opposite to the direction in which it is to be moved. The patient is instructed to try and look in the direction of limitation and an attempt is made to move the eye in that direction (i.e. opposite that in which mechanical restriction is suspected). If no resistance is encountered, the motility defect is not restrictive; however, if resistance is encountered, then mechanical restriction does exist. In some patients, particularly those who are co-operative and have substantial limitation of movement, the forced duction test can be performed simply by asking the patient to look in the direction of limitation and then attempting to move the eye, by placing a cotton-tipped applicator stick against the eye on the opposite side, just prior to the limbus.[37]

Pain

Tumours that involve the orbit are generally not painful. Neoplasms causing pain are likely to be malignant.

Inflammation causes severe pain and one can confidently predict neural infiltration at the orbital apex and cavernous sinus, when there is ophthalmoplegia and pain together.[2,29,30,38,40,41]

Pupillary Abnormalities

It is theoretically possible that patients with an orbital tumour could develop either a Horner's syndrome from damage to the oculosympathetic pathway that supplies the iris dilator muscle or a tonic pupil from damage to the ciliary ganglion or short ciliary nerves that supply the iris sphincter muscle. Such abnormalities do not occur in isolation and if they are present, they are usually masked by the oculomotor nerve palsy.

Chemosis and Bruit

Chemosis is often seen in tumours that cause obliteration of the venous outflow of the orbit. It is generally seen in inflammatory or malignant tumours and also seen in carotico-cavernous fistulae (CCF), due to the back pressure in the veins secondary to the arteriovenous shunt.

Bruit is sometimes audible on auscultation which should be routinely carried out in all patients with proptosis and suspected arteriovenous malformations (AVMs). A bruit that disappears on carotid compression is characteristic of CCF. Opto ciliary shunts and retro-ocular striae may be seen on fundus examination.[15]

INVESTIGATIONS

Plain X-ray

Plain X-rays (Fig. 9) have lost their place of importance in the pre-operative investigations of proptosis. Plain X-ray films are important to detect:

- **Bony erosions:** Bony erosions are seen on the superolateral margins of the orbit. Erosions may occur at this site which suggests a lacrimal gland neoplasm.
- **Sclerosis:** Sclerosis of the bones may suggest an intraorbital meningioma or metastatic disease. But when sclerosis is associated with an expanded bony contour, the diagnosis of fibrous dysplasia must be entertained.
- **Calcification:** Osteomas of the paranasal air sinus are extremely dense and diagnostic on plain X-ray.

Plain radiographs also demonstrate enlargement and changes in the bony wall. The optic canal may be widened in optic nerve gliomas and sometimes the posterior lateral wall is deficient in neurofibromatosis.

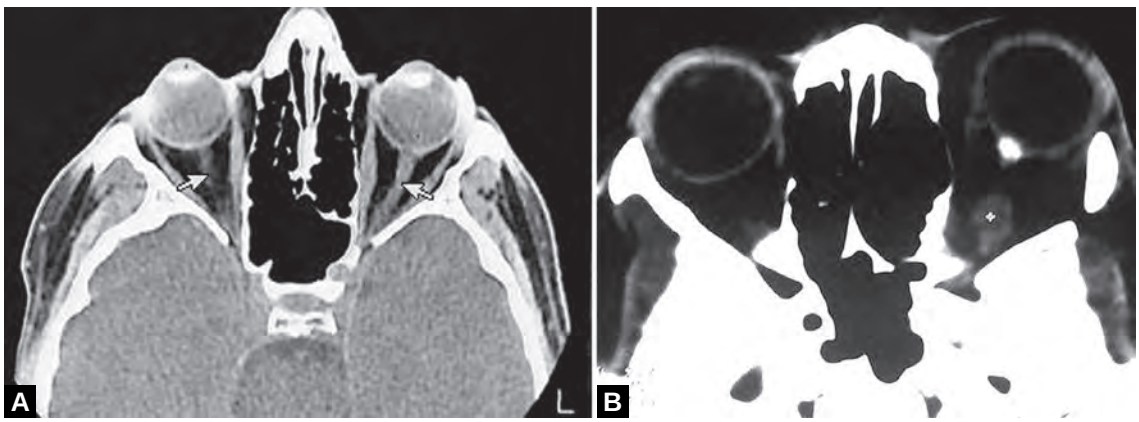
Computed Tomography Scan

With recent advances in technology, the computed tomography (CT) (Fig. 10A) images are excellent and provide a wealth of information in the diagnosis of orbital tumours. Axial scans along with coronal images help in localisation of tumours, show the bony changes, calcification and various enhancing patterns of different tumours (Fig. 10B).

High Resolution Magnetic Resonance Imaging Scan

Magnetic Resonance Imaging (MRI) is the investigation of choice for orbital tumours. It not only shows the soft tissue structures well but also gives us the most important relationships of the tumour with various structures

Fig. 9: Plain X-ray of the orbit; arrows showing the lesser wing of the sphenoid on either side



Figs 10A and B: (A) Computed tomography (CT) scan showing the optic nerves. (B) CT scan showing left optic sheath meningioma

within the orbit and most importantly the optic nerve. Gadolinium enhanced MRI also shows the varied enhancing patterns of orbital tumours. The location of the tumour in the orbit in the extraconal, in the intraorbital but outside the periorbita, inside the periorbita but extraconal and intraconal is easily delineated. Infiltration of various intraorbital structures in malignant and inflammatory conditions is also seen. Non-tumourous conditions, such as Grave's disease and inflammatory myositis, are also picked up (Figs 11A and B).

Angiography

Angiography is sometimes required when tumours are suspected to have increased vascularity in cases of:

- Meningiomas
- Haemangiopericytomas
- Retro-orbital pial or dural arteriovenous malformations (AVMs)
- Carotid cavernous fistula

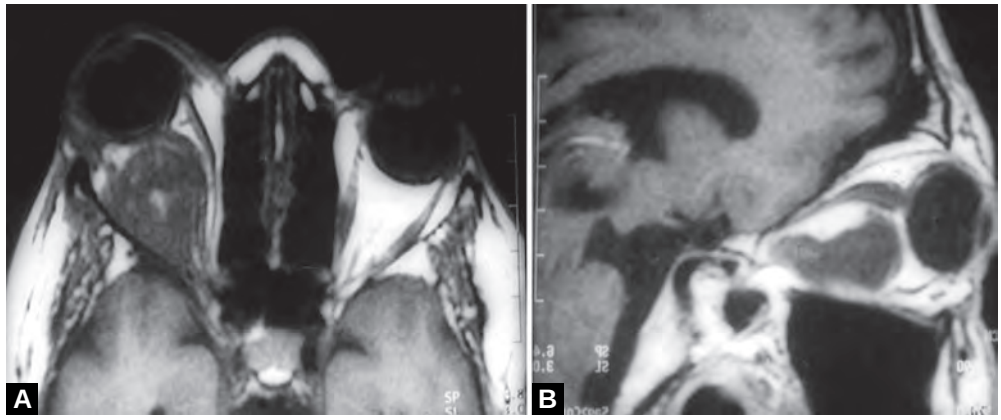
Angiography is sometimes coupled with embolisation techniques to prevent excessive blood loss during surgery. Orbital venography was a common diagnostic procedure in the past, but with more sophisticated imaging facilities available. This angiographic technique is rarely used today. It is still a good tool to diagnose and treat intraorbital varix and other developmental vascular lesions (Figs 12A and B).

Ultrasonography

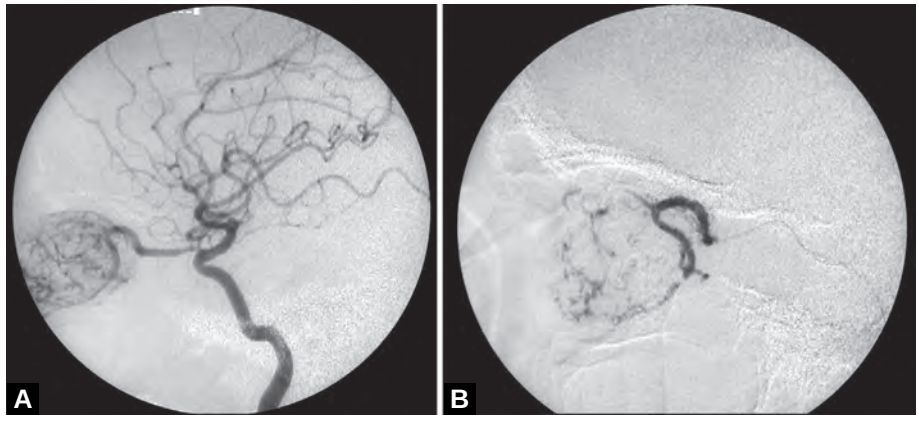
Ultrasound is particularly useful in evaluating intraocular lesions by ophthalmologists and in diseases involving the anterior portion of the retrobulbar space. At times, intra-operative ultrasound may be required to locate small tumours.

MANAGEMENT OF ORBITAL TUMOURS

The orbit is a meeting place for numerous surgical specialties, to focus their skills in order to achieve good results. The neurosurgeon, the ophthalmologist, the maxillofacial surgeon, the head and neck oncosurgeon and at times the otolaryngologist may share their knowledge and to derive the best cosmetic results the plastic surgeon too is involved in the resection of certain tumours. Orbital tumours are a difficult surgical challenge despite various advances in techniques and radio imaging. The cranium provides a safe access to the orbit and, therefore, it is imperative for neurosurgeons to have sufficient knowledge of tumours in this region.



Figs 11A and B: (A) Medial displacement of the optic nerve. (B) Superior displacement of the optic nerve



Figs 12A and B: (A) Pre-operative digital subtraction angiogram (DSA) showing vascular tumour of the orbit (haemangiopericytoma). (B) Post-embolisation DSA image on the same patient

Principles in the Treatment of Orbital Tumours

- The essence is to achieve safe "total" excision of benign tumours.
- "En bloc" excision in malignant tumours.
- Use "safe" orbital spaces to access the tumour.
- Attack the tumour from the base of the cone.
- Avoid bipolar coagulation.
- Gentle handling of the intraorbital structures.
- No fat to be sacrificed.
- Reconstruction of the walls of the orbit.

History of Surgical Approaches to the Orbit

Tumours of the orbit are of interest to various surgical specialties. Neurosurgeons too have shown great interest in orbital tumours over the years (Table 3).

Table 3: Choice of operative approach for orbital tumours

Subfrontal approach with superior orbitotomy	• Superiorly and medially placed moderate and small-sized tumours • Intraconal tumours medial to optic nerve
Fronto-orbito-zygomatic craniotomy	• Superiorly and medially placed large size tumours • All tumours with involvement of the apex
Fronto-orbito-zygomatico-temporal craniotomy	• All tumours with middle fossa extension • All tumours with infratemporal extension
Lateral orbitotomy	• Laterally placed extraconal tumours • Intraconal tumours lateral or inferior to the optic nerve

Bartisch (1583) described one of the earliest approaches to the orbit. He attempted a subtotal exenteration with preservation of the eyelids. Thomas Hope (1744) reported one of the first orbital eyeball sparing procedures. On the other hand, Foster (1948) stated that the only accepted method of treating orbital tumours was to 'iodise and temporise—irradiate and exenterate'.

Extracranial Approach

Anterior orbitotomy was first described by Hermann Knapp in 1847. It was rediscovered by Benedict in 1949. Inferior orbitotomy was described by Davis in 1940. The frontal trans-sinusoidal approach was used by Colohan in 1941. Niho described transethmoidal orbitotomy in 1961.[27]

Lateral Orbitotomy

Gustav Passavant was the first person to use the lateral approach to remove a vascular malformation in 1866. However, its name is associated with Kronlein who first described the process in great detail in 1889. Stalard rediscovered the same in 1947. Rowbotham furthered the approach in 1949. Berke improved upon it in 1953 and Krayenbuhl and Brihaye improved upon the technique in 1967 and 1968, respectively. Kennerdell and Maroon further added variations in 1976.[27]

Transcranial Approach

Durante (1887) was the first person to adopt a transcranial route for treating orbital tumours. However, it was Walter Dandy who popularised this approach (subfrontal approach) with his classical paper in 1941. Poppen was another strong proponent of this approach in 1943. This was furthered upon by Housepain in 1969 and 1978. Iliff restudied the Dandy series and concluded that surgery of orbital tumours properly lay within the province of ophthalmology. The frontolateral (without sphenoid bone resection) approach was popularised by Naffziger in 1948 and further refined by Maroon and Kennerdell in 1984. The frontotemporal (pterional) approach was described by Welti and Offret in 1943 and later by Hamby in 1964, then by Seeger in 1983 and further by Hassler and Eggert in 1985. The fronto-orbital approach was described by Tym in 1961 which was furthered upon by Brihaye in 1968 and then by Jane in 1982.[27]

Other Approaches

Rollet in 1907, Elscnig in 1927 and Golovine in 1930 advocated a transpalpebral route through the superior orbital margin.

Davis, in 1940, described an approach through an incision along the inferior orbital border to remove an optic nerve glioma. Callaham in 1948 and Vergez in 1958 used it for other pathologies.

The transconjunctival approach was introduced by Hermann Knapp in 1974.

I prefer to include lateral orbitotomy as a transcranial approach rather than an extracranial one. In fact, micro-orbitotomy should be described as a minimally invasive "cranial" access to the orbit.

Various Areas in the Orbit may be Approached in the Following Manner

Extracranial approaches are generally reserved for tumours that involve the anterior two-thirds of the orbit. Medially placed lesions may be tackled by transethmoidal, anteromedial orbitotomies, whereas lateral lesions may be tackled by an anterolateral orbitotomy. The subfrontal approach is generally used to tackle superiorly placed tumours or tumours medial to the optic nerve. The frontolateral approaches provide greater access into the orbit and are used for tumours that are superolateral in the orbit and may encroach into the orbital apex or SOF. The fronto-temporo-zygomatic approaches are used to access tumours superiorly and laterally placed in

the orbit, extending into the intracranial region involving the SOF, IOF, orbital apex and inferior orbit as well.

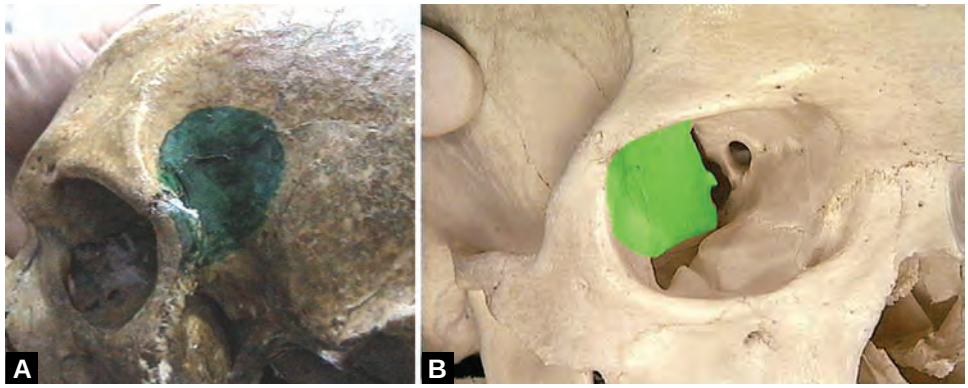
Surgical Approaches

Lateral Orbitotomy

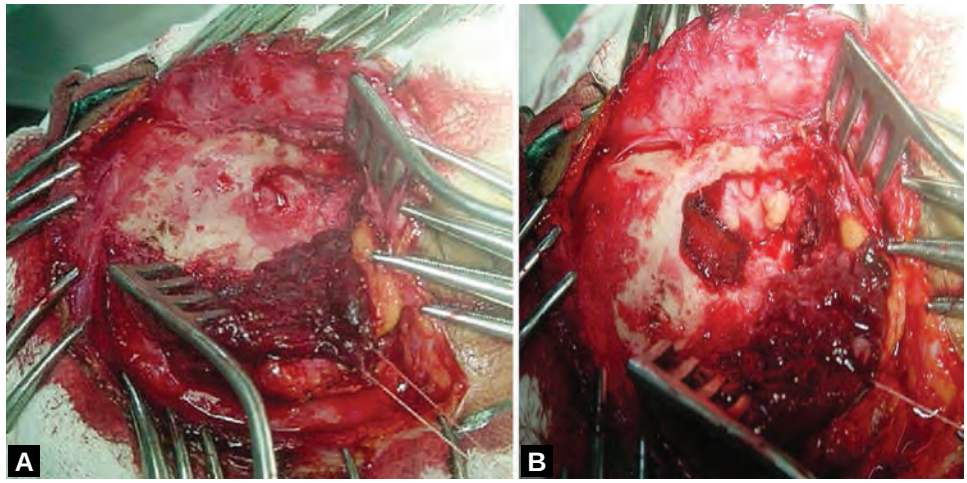
This is the most popular approach (Figs 13A and B) to orbital tumours today. A skin incision, which is curvilinear and follows the hairline, is used. As the skin flap is elevated, dissection is carried out to the lateral orbital rim, completely exposing it. The temporalis muscle is dissected off the lateral wall. A burr hole is placed in the lateral orbital wall, exposing the periorbita (Figs 14A and B). The zygomatic bone may be divided using a Gigli saw for greater exposure. At times, the zygoma may be nibbled to widen the exposure, without excising the lateral rim of the orbit. Additional exposure is achieved by removing the lateral wall of the orbit till the apex. If needed, the temporal dura can also be exposed by removing a part of the sphenoid bone. A cruciate incision is made on the exposed periorbita and periorbital fat is encountered. Extraconal tumours lie in this space and can be removed safely. If the tumour is intraconal, the lateral rectus muscle has to be identified and dissection is carried out either above or below it, as needed. Exploration of the intraconal space should be done using microneurosurgical techniques and principles to avoid injuries to vital structures. Minimal use of bipolar coagulation is recommended. After the lesion is excised, haemostasis is achieved and the periorbita closed with 3-0 Vicryl. The lateral orbital margin should be reconstructed and the temporalis muscle sutured back. It is not necessary to reconstruct the entire lateral wall. However, as there is always plenty of bone pieces and bone dust, it is easy to reconstruct the lateral wall as well. The temporalis muscle and fascia are anchored and sutured in position and the wound is closed in layers.[5,6] Figures 15A and B are pre- and post-operative images of a haemangiopericytoma excised using a microlateral orbitotomy.

Subfrontal Approach

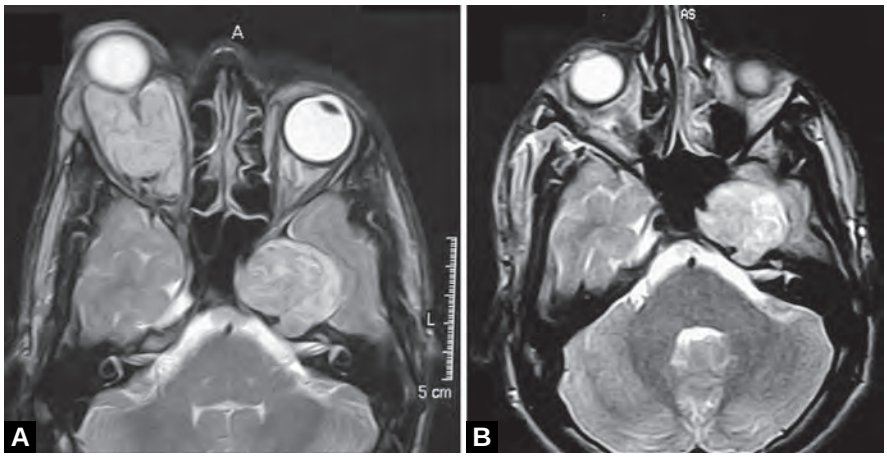
A "key hole" burr hole is placed and unifrontal craniotomy is performed (Fig. 16A). The supratrochlear nerve



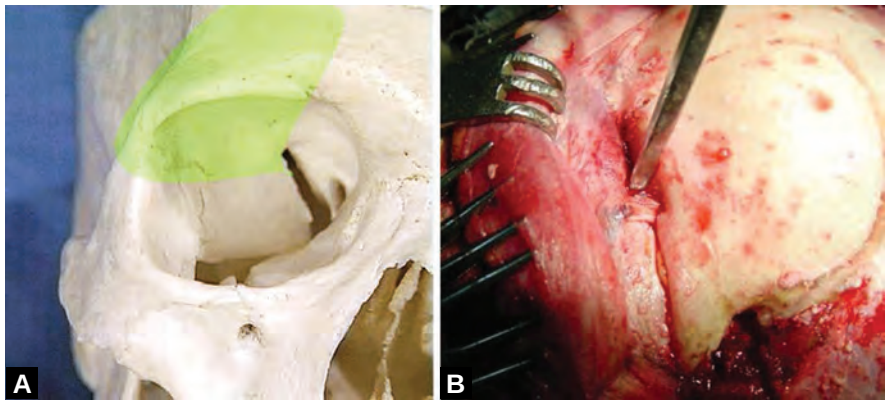
Figs 13A and B: (A) Bony exposure required for a microlateral orbitotomy. (B) Wide exposure available through the lateral wall. This diagram clearly shows that inferiorly placed tumours (that displace the optic nerve superiorly) can safely be approached from this route as well



Figs 14A and B: Intra-operative image of the exposure provided by microlateral orbitotomy (in this case the lateral rim of the orbit is preserved). The skin and subcutaneous tissue is reflected anteriorly and the temporalis muscle and fascia are seen reflected posteriorly. The orbitotomy is widened to the extent, to allow safe access to the tumour



Figs 15A and B: Examples of (A) pre-operative. (B) post-operative images of a haemangiopericytoma excised using a microlateral orbitotomy

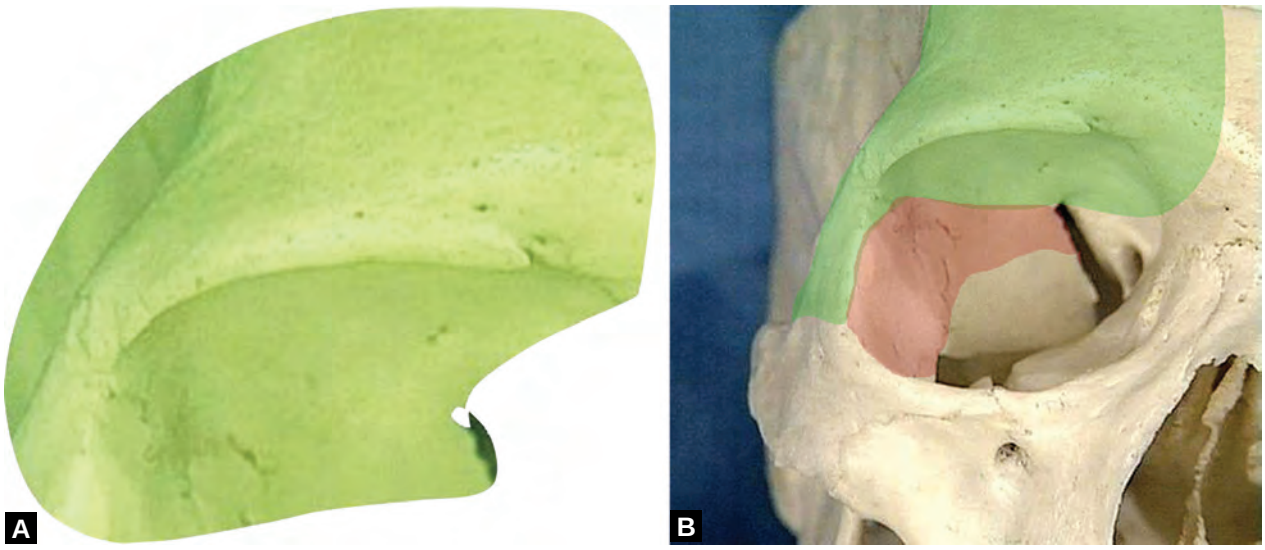


Figs 16A and B: (A) Superior orbitotomy for the subfrontal approach. (B) How to preserve the supratrochlear nerve by breaking the bony strut which anchors the nerve using a fine osteotome

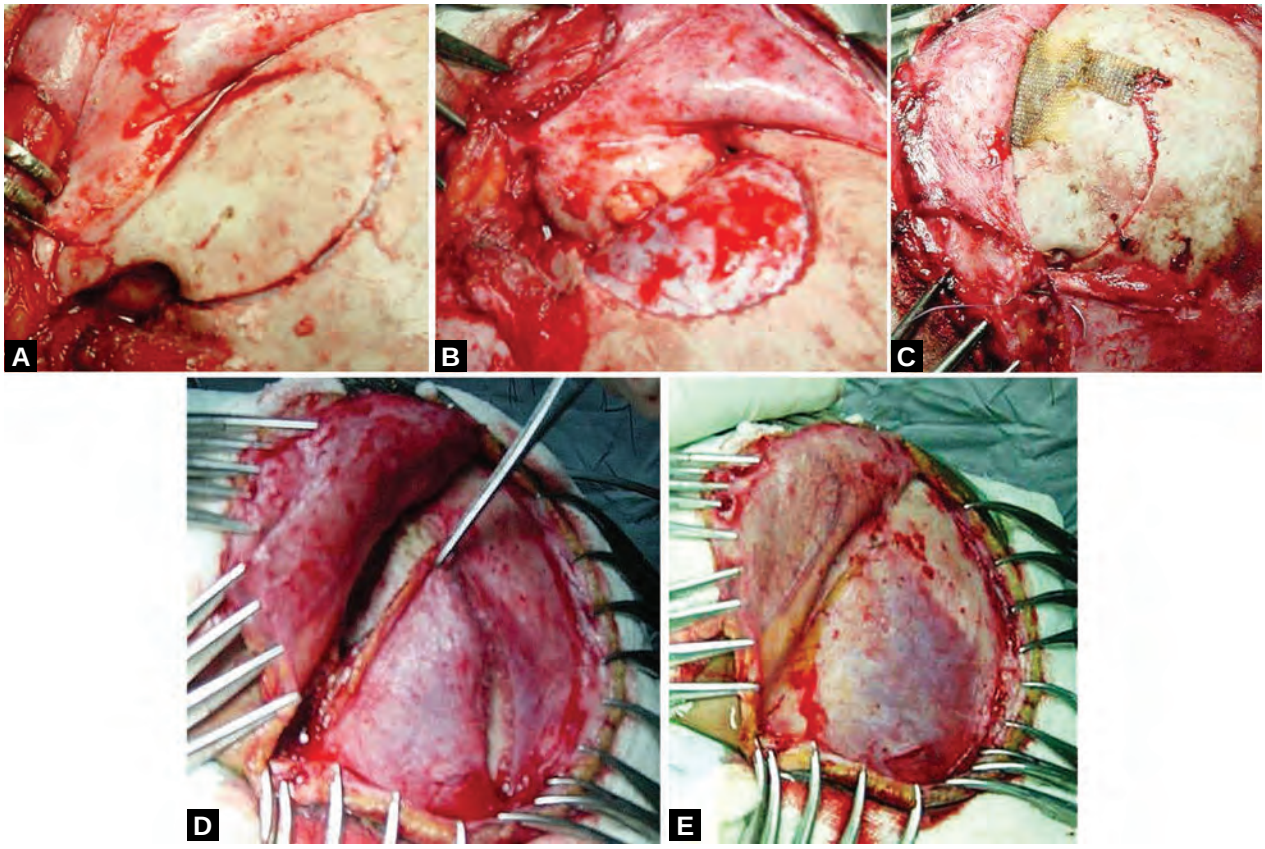
is preserved as shown (Fig. 16B). The roof of the orbit is excised, along with the bone flap. In this manner, no loss of bone occurs and the reconstruction is quick and cosmetically and functionally perfect. Orbital exploration demands a minimal backward retraction of the dura. The periorbita is cut in a cruciate manner. Once a small opening is made, the opening can be enlarged by using a roungeur. The optic canal can be unroofed using orbital micro-punches (House). The periorbita is incised in a cruciate fashion with a no.11 blade. Micro-neurosurgical techniques are used to excise the tumour. The approach to the tumour should be preferably between the superior rectus and medial rectus muscles, to avoid any injury to the branches of the oculomotor nerve. This is particularly useful for tumours of the optic nerve. A meticulous reconstruction is done after this and wound closed in layers.

Fronto-orbito-zygomatic Craniotomy

This approach (Figs 17A and B) was popularised by Maroon. A bi-coronal hairline incision is used. It starts just in front of the tragus and extends to the superior temporal line of the opposite side. The entire scalp flap and temporalis muscle are dissected subperiosteally. The supraorbital nerve is freed from the superior orbital margin. The dissection is carried out along the orbital roof to displace the periorbita away from it. Dissection is carried out laterally to clear the lateral periorbita away from the lateral orbital margin. The temporalis muscle is dissected down to the zygomaticotemporal suture. A frontal craniotomy is planned. The first burr hole is placed in the anterior most part of the lateral wall of the orbit. The other hole is made just inferior to the superior temporal line. These are connected with the craniotome cutter. The roof of the orbit and the zygoma are removed in one piece; the thin orbital roof is broken posteriorly, using an osteotome. The optic canal should be thinned with a diamond drill and then exposed with a small curette. The periorbita is excised in a cruciate fashion. The approach to the tumour should be preferably between the superior rectus and medial rectus muscles, to avoid any injury to the branches of the oculomotor nerve. This is particularly useful for tumours of the optic nerve.[7] A meticulous reconstruction is done after this and wound closed in layers (Figs 18A to E).



Figs 17A and B: Diagrammatic representations of the superolateral approach also called the orbitozygomatic craniotomy



Figs 18A to E: (A) Operative photograph showing the craniotomy, roof of the orbit and the inferior cut on the zygoma, all removed in one piece. (B) Exposure after the bone flap is removed. (C) Bone flap anchored and bone dust and oxidised cellulose placed to produce the best cosmetic results. (D) Temporalis muscle and fascia repositioned. (E) Sutured

Fronto-temporal-orbito-zygomatic Craniotomy

It is similar to the above procedure however the temporal burr hole is also placed posteriorly so that after the craniotomy the temporal dura is also exposed (Fig. 19). The sphenoid ridge and the lesser wing of the sphenoid are removed to expose the SOF and the middle fossa skull base (Figs 20A and B).

Fig. 19: Bony exposure on a cadaveric skull

DIFFERENT ORBITAL TUMOURS

Neurofibroma

Neurofibromas (Figs 21A and B) of the orbit are common tumours which occur in the latter half of the second decade to the fourth decade of life. Multiple neurofibromas occur in the younger age group and may also have a diffuse or plexiform appearance and may be a part of Neurofibromatosis Type I. The tumour is seen in both sexes with a slight pre-prominence in the female sex.

These tumours have an excellent plane of cleavage and are distinct from the surrounding orbital tissue. There are a few, however, which are adherent to the posterior aspect of the globe, tumours which are of long standing duration and larger tumours. Unless the tumour is totally excised, there is always a possibility of recurrence and at times the recurrence may be cystic. Recurrent tumours are difficult to excise completely, making it a difficult management problem. These tumours often arise from sensory twigs of the ophthalmic division within the orbit. These tumours are intraconal and often can be tackled using the microlateral orbitotomy. The plexiform variety of tumours are more diffuse and spread extraconal and at times outside the orbit as well, making it difficult to excise the tumour completely. These tumours, however, pursue a more indolent course.

Meningioma

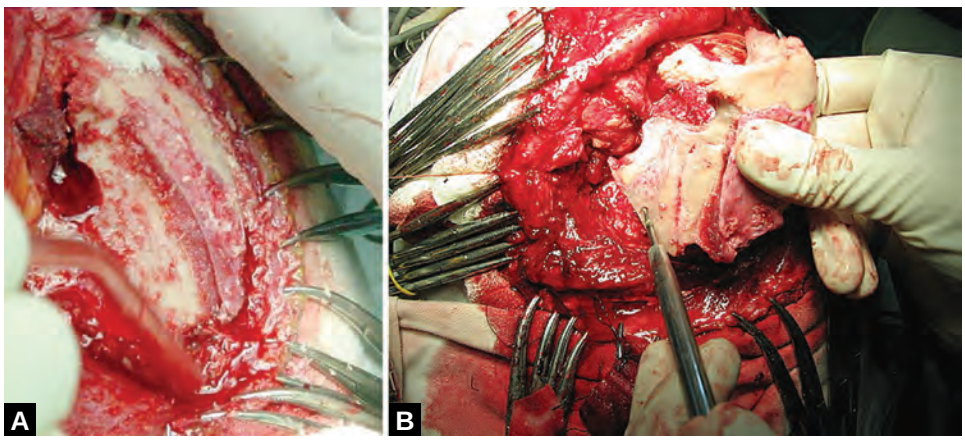
There are three types of meningiomas that involve the orbit:

(1) Optic sheath meningioma (Fig. 10B).
(2) Tumours arising from the arachnoid cap cells involving the periorbita or the dura around the orbital fissure or optic canal (Figs 22A and B).
(3) Meningiomatosis that involves the dura extensively in and around the orbit (Fig. 22C).

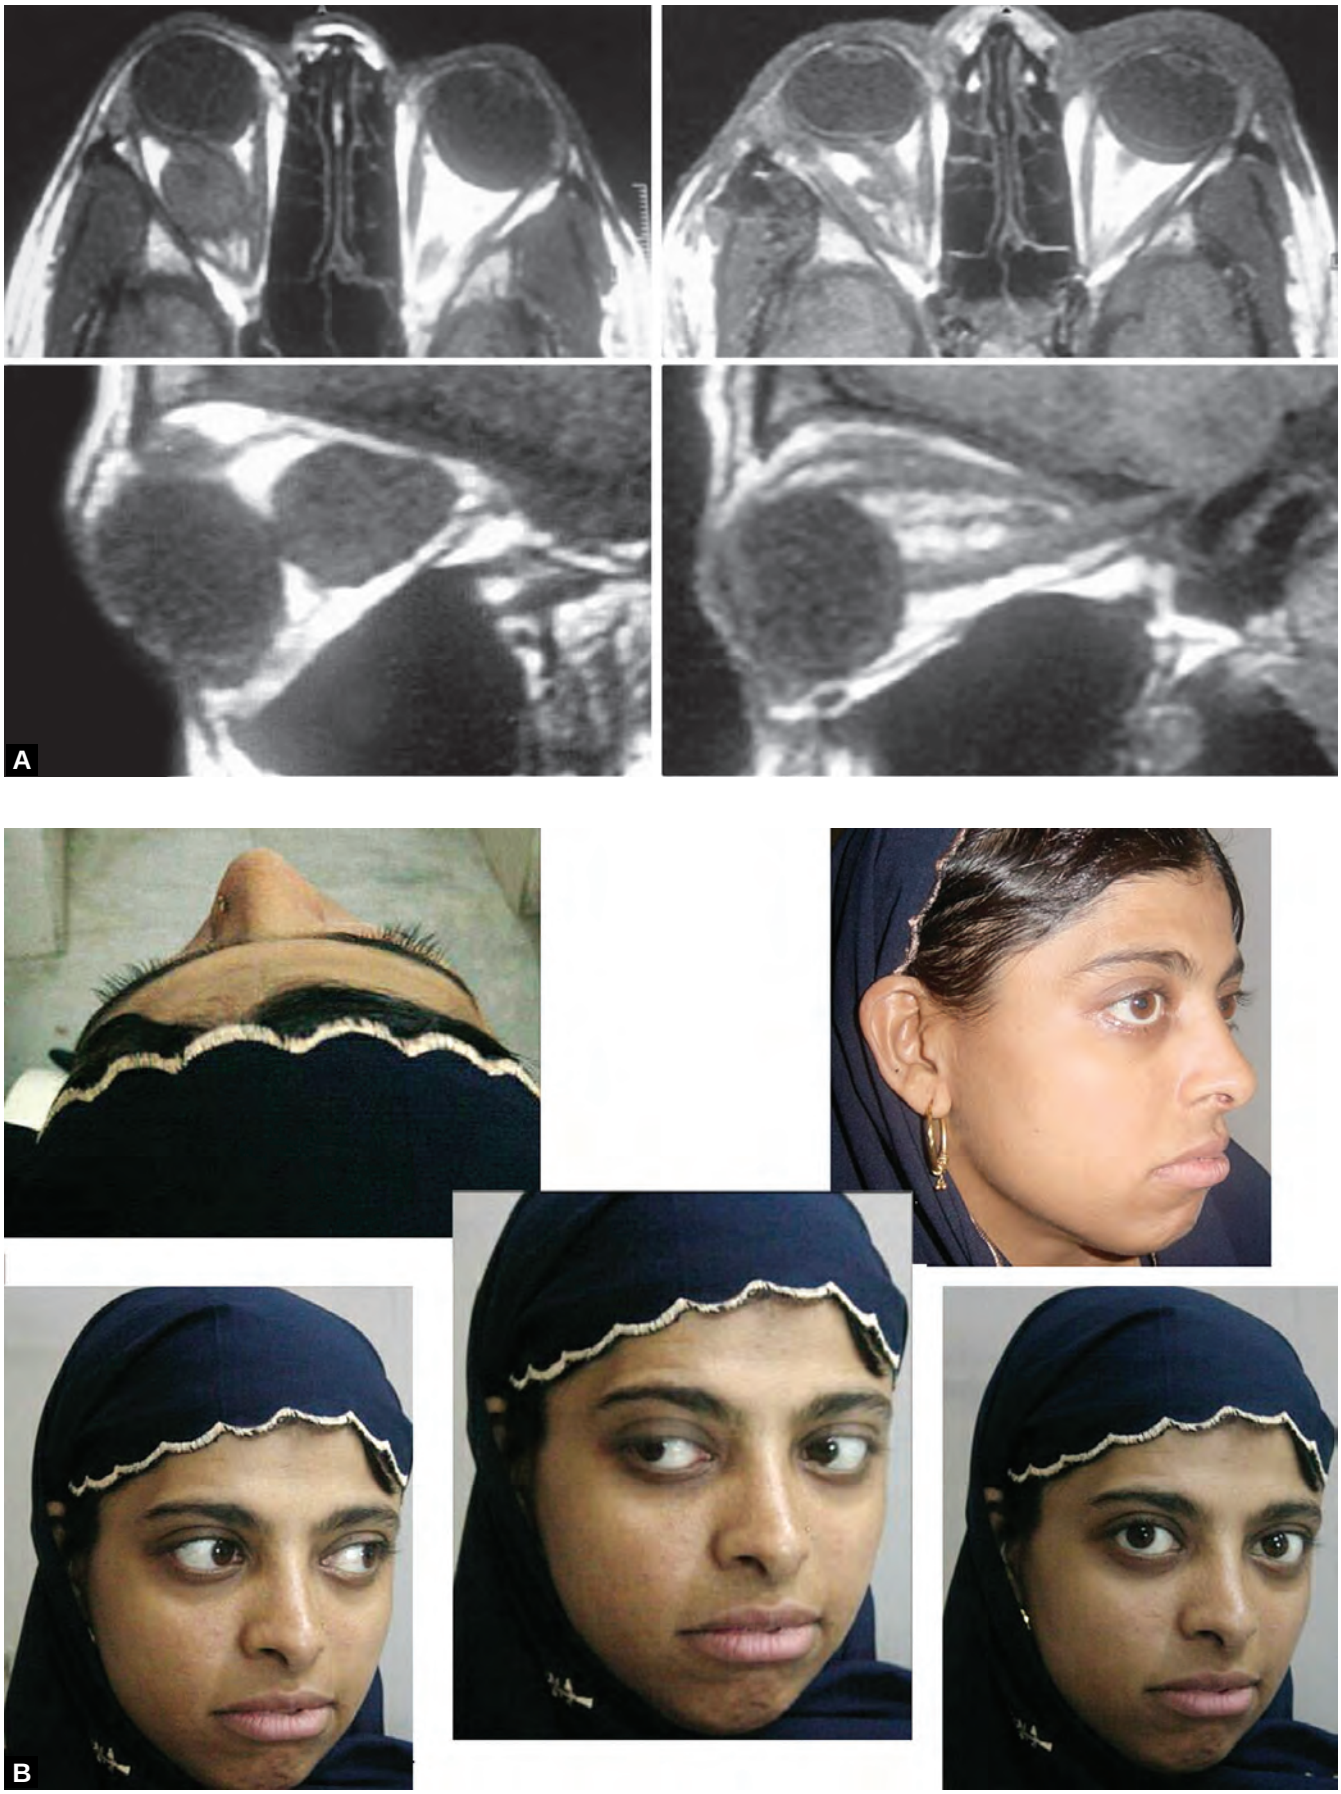
(1) Optic sheath meningiomas comprise about 5–7% of primary orbital tumours.[33] Our incidence is higher due to the referral pattern, 6 out of 21 meningiomas (28.5%). Optic sheath meningiomas are either:
   a. within the optic nerve sheath encircling the optic nerve.
   b. within as well as outside of the optic sheath, causing an exophytic growth adjacent to the optic nerve.
   c. purely exophytic growth of tumour outside the optic nerve sheath.[26]

Although these tumours are benign tumours and generally are meningothelial, transitional or fibromatous in their histological types, they produce profound visual loss, as these tumours are firm and they may encircle the optic nerve. There are some tumours that have exophytic extensions and are favourable for surgery. However, most of them are difficult to excise completely. They occur around the latter half of the third and fourth decades of life. In addition to the above symptoms, impaired movement of the globe, disc swelling or optic atrophy with shunt vessels and an afferent papillary defect may occur.[1]

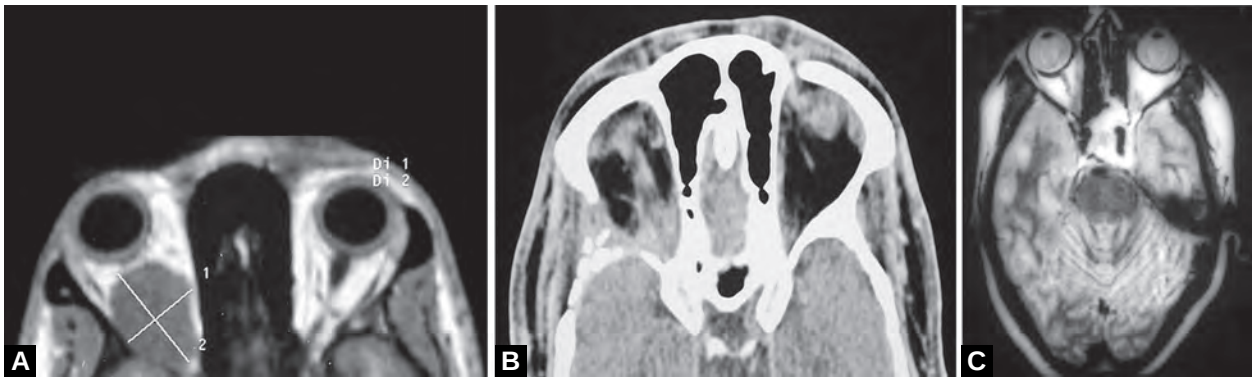
As these tumours are firm, although friable and well encapsulated, dissection sometimes is tedious at the orbital apex. At times, the dura of the optic sheath is infiltrated with tumour densely stuck to the periosteum



Figs 20A and B: Intra-operative images of the same technique



Figs 21A and B: Pre-operative and post-operative MRI of neurofibroma. (B) Three months post-operative clinical images of neurofibroma patient



Figs 22A to C: (A) Tumour arising from the arachnoid cap cells involving the periorbita or the dura around the orbital fissure or optic canal. (B) Intracranial as well as (C) Intraorbital meningioma

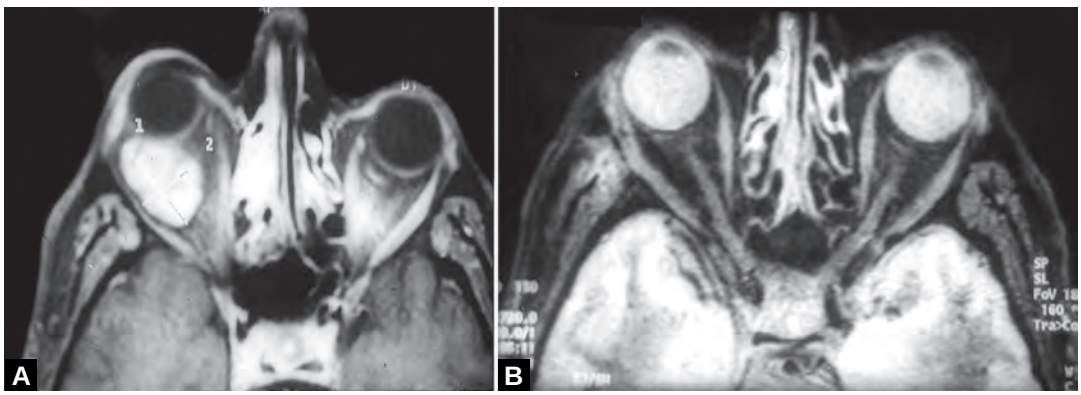
of the bone at the orbital apex, optic canal and orbital fissure. Optic sheath meningiomas are vascular and derive their blood supply from the ophthalmic artery as well. There remains considerable controversy regarding management of these lesions.[1,42] When the vision is well preserved it may be best to follow these tumours as some of them have long indolent courses. Radiotherapy proponents have claimed excellent results in control of these tumours.[36]

(2) Orbital meningiomas not arising from the optic sheath pose less surgical challenges in terms of compromised visual function. However, these tumours are generally close to the optic fissures and tend to produce oculomotor deficits. It is safer, therefore, to leave a small cuff of tumour at the orbital apex, if there is no compromise of oculomotor nerve function pre-operatively. These tumours are firm to hard and have indolent courses and can be closely observed. The unpredictable and relatively slow growth rate of a meningioma allows the surgeon to practice sub-total removal and decompression, in order to preserve vision and oculomotor function.[21,20,27]

(3) Meningiomas with a more diffuse dural involvement are most common in women and may be associated with tumours spread intradurally to involve the planum sphenoidale, tuberculum sella and the sellar region. These tumours need to be excised early so that they may cause compromise of vision on the opposite side as well. The surgical approach often entails a wide fronto-temporal-zygomatic craniotomy. The bone flap also comprises of the roof of the orbit taken as one piece. The exophytic variety may produce proptosis with relatively less visual deterioration. When the tumour is within the optic sheath, even small tumours produce dense visual impairment. Early disc swelling is recognised. If the vision is completely lost at the time of presentation, radical excision of the tumour is feasible and the aim is to prevent intradural spread of tumour and correct the proptosis. If the patient's eye movements are intact, using microsurgical techniques it is possible to preserve the same after surgery. Total excision of these tumours is difficult; in order to preserve oculomotor function it may be advisable to leave a cuff of tumour at the apex of the cone, so as to prevent handling of the nerves and muscles, as they crowd together at the orbital apex.

Cavernous Haemangioma

These are among the common benign tumours in adults involving the orbit (Figs 23A and B). They are often intraconal; however, some of them may have extraconal



Figs 23A and B: (A) Pre-scans. (B) Post-scans of a cavernous haemangioma

extensions as well. They present with painless proptosis with remarkably well preserved vision and normal eye movements, in spite of their huge size. They occur from the second to the fourth decades of life and have a female pre-ponderance.[13]

These tumours are well encapsulated. They have variable consistency and although they bleed at surgery, the bleeding is never difficult to control. They have a typical bluish hue, due to the stagnant blood filled cavernous spaces. At times, they may also show micro calcification. These tumours have the best prognosis following surgery and are often tackled by microlateral orbitotomy.

Lymphangioma

These tumours are similar to haemangiomas; however, they are far more extensive and infiltrative and often involve the intraconal and extraconal spaces simultaneously. Total eradication of tumour is difficult. If microneurosurgical principles are adhered to and no aggressive surgical options are undertaken, remarkable clinical results can be achieved. These tumours pursue a relatively benign course.

Optic Nerve Glioma

Optic nerve gliomas arise from the anterior visual pathway and may involve the optic nerve, chiasm or tract (Figs 24 and 25). They generally manifest in the latter half of the first decade or second decade of life. They are often associated with neurofibromatosis. Most of these tumours have an indolent course; however, there are some tumours that are aggressive in nature. Tumours that are associated with neurofibromatosis have a more indolent course.[16] They are common with neurofibromatosis type I (NF 1).

Tumours involving the optic nerve present with blindness and proptosis.[19] The typical imaging finding shows enlargement of the optic foramina. These tumours progress and grow intracranially and can involve the chiasm. The general principle of management is close observation and regular follow-up. Tumours that demonstrate progression are excised when the vision is completely compromised. It is important to cut the optic nerve beyond the tumour to prevent the spread of the tumour into the chiasm. Tumours that involve the chiasm are generally biopsied and given radiotherapy. Although western literature favours chemotherapy, most of the patients we deal with are in the age group of 10 years and over (paediatric age group) and can tolerate radiotherapy better than chemotherapy. The surgical approach for these tumours would often entail a frontotemporal craniotomy coupled with a subfrontal approach to the orbit.

The histology of these tumours shows a predominantly fibrillar pattern with microcystic changes sometimes. Rosenthal fibres are commonly seen. As the tumour enlarges, reactive proliferation of the meninges occurs, contributing to the increased size of the tumour.[43]

Lacrimal Gland Tumours

Lacrimal gland tumours make-up 35% of lesions involving the lacrimal gland and the rest being inflammatory lesions. The most common tumour is the benign mixed tumour which accounts for approximately 50–60%. The malignant mixed tumours account for 5–10%, adenoid cystic carcinomas for 20–30% and other carcinomas for about 5–10%.[8,23,31] Microlateral orbitotomies may suffice for benign tumours, however, "en bloc" resection of malignant tumours is required.

Fibrous Dysplasia

These are not actually tumours; however, these are lesions of childhood and adolescence which can cause significant deformity of the orbit, frontal, zygomatic, ethmoid or sphenoid bones. The fibrous dysplasias are generally of two varieties:

(1) The mono-osteotic variety where only one bone is involved.
(2) The polyosteotic where many bones in the orbit are involved.

They produce unsightly proptosis and distortion of the face. Often, the patient has no other complaints besides cosmesis. However, there are times when the optic nerve is compressed in its canal and surgery becomes mandatory. Surgical removal of the roof of the canal and the optic struts provide relief of compression.

Fig. 24: Optic nerve glioma

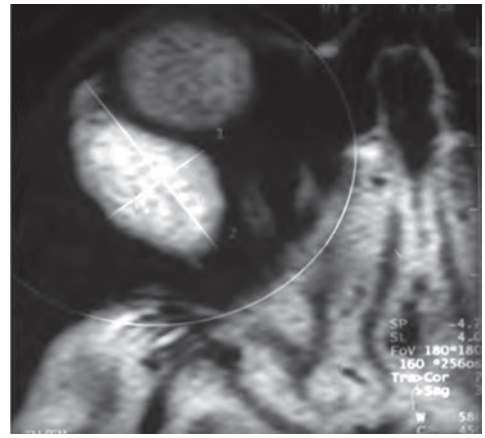


Fig. 25: Dermoid and epidermoid cyst

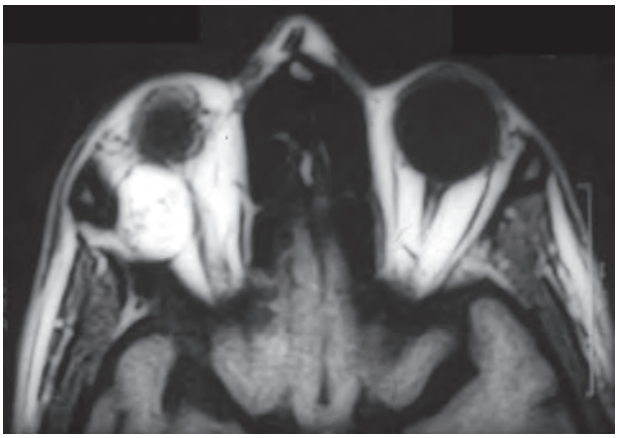

Fig. 26: Simple reconstruction using a metal plate contoured to the shape of the rim of the orbit and screwed into the buttress of the maxilla

Dermoid and Epidermoid Cysts

Dermoids (Fig. 26) are the most frequent developmental cysts. They are found usually in the latter half of the first decade or first half of the second decade. However, as they are slow growing and innocuous in their presentation, they can be encountered in late adult age. They are usually located at the lateral canthus and are almost always extraconal and extraperiosteal in location. These tumours may sometimes cause scalloping of the bone due to prolonged and slow growth and may produce radiolucent bone defects with well corticated margins on X-ray or CT scans. They usually are painless, generally produce cosmetic disfigurement of the face and cause little or hardly any displacement of the globe. They can be completely excised by various approaches; a lateral orbitotomy would suffice in most cases.

Osteoma

These are commonly found in the frontal or ethmoid sinuses. They are hard lesions which displace the globe laterally and produce a bulge superior to the medial canthus. These are usually present in the second decade of life. They may also have intracranial extensions. Depending on the location and the extent, transcranial or extracranial approaches may be used. The excision is greatly simplified by using high speed pen drills. It is important to excise the entire osteoma or else recurrences are known.

Mucocoele

This is a cystic collection of obstructed mucous lined by the mucous membrane, arising either from the frontal or from ethmoidal air sinus and, occasionally, from a pneumatised roof of the orbit. The blockage may be secondary to chronic inflammation, scarring due to trauma or surgery and at times polyps or bony tumours (Osteoma). The radiology shows "ballooning" of the sinus walls, producing a characteristic "eggshell" appearance. Patients can present with proptosis, pain, visual discomfort, headache and, at times, a palpable mass. Often a transcranial approach would provide a better cosmetic result, however, direct eyebrow incision with excision of the mucocoele by using an anterior approach may also be used.

Metastatic Tumours

Neuroblastoma and Ewing's tumours are common in childhood and may metastasise to the orbit. These malignant tumours of the orbit have a short history with ecchymosis, pain and swelling. The most common malignant tumour of the orbit in an adult is a metastatic tumour and common primary sites are testicular tumours, breast, lung and some skin tumours. When malignant tumours are suspected, a fine needle aspiration biopsy is preferred so that the treatment protocol may be planned.[21] "En Bloc" resection must be performed whenever surgery is indicated.

Vascular Lesions

CCF: The fistula causes increased venous pressure in the veins of the orbit, particularly the superior ophthalmic vein. This leads to increased orbital volume and produces proptosis. At times, muscle thickening is also seen due to the increased venous pressure. All these features are reversible on treatment of CCF, which is now only performed by the interventional neuroradiologist.

Venous Varix

It is a congenital condition where a venous pouch is present in the orbit and any increase in venous pressure produces exophthalmos. Valsalva manoeuvre, dependency of the head and straining tend to fill the venous pouch and produce the characteristic symptoms. Today, such lesions are treated by the neurointerventional team.

Arteriovenous Malformations

AVMs may be located within the orbit and are diagnosed with a bruit audible over the eye and verified by characteristic scan and angiogram findings.

Intraorbital Ophthalmic Artery Aneurysms

These are extremely rare. More commonly, the aneurysms from the cavernous and clinoidal segments of the internal carotid artery encroach upon the orbit and orbital structures.

Pseudotumours

Inflammatory pseudotumours of the orbit are far more frequent than specific granulomas, such as tubercular or cysticercus. They represent a heterogeneous group.[3,24] At times, they have extensive spread of disease with involvement of the paranasal air sinuses. They have the following characteristics: there is a dense tissue reaction due to mobilisation of chronic inflammatory cells,

vascular proliferation and hyperplasia of connective tissue forming an indurated orbital mass, which often surrounds the optic nerve and also incorporates one or more extraocular muscles. There is absence of any aetiologic agent and, at times, histological verification may be required to rule out:

- Specific granulomas
- Hodgkin's lymphoma
- Lupus erythematosus among other diseases[10]

Besides the MRI and CT findings the per-operative gross features are also quite pathognomonic. The treatment of choice is dexamethasone which is given over a period of 3–6 weeks in tapering doses.

RESULTS

Remarkable results can be achieved using microsurgical techniques. As a rule, results, such as the case shown in Figures 21A and B, are what we can achieve using the techniques described above. The only patients who have worsened in vision were two cases of optic sheath meningioma, as described earlier. At times, reconstruction of the lateral rim of the orbit may be necessary and implants may be needed. Figure 27 shows a simple reconstruction using a metal plate contoured to the shape of the rim of the orbit and screwed into the buttress of the maxilla. An 'en bloc' excision for an adenoid cystic carcinoma (cylindroma) had been carried out, prior to the reconstruction at the same operation. Complications are uncommon if the above techniques and general microneurosurgical principles are meticulously followed.

The key to successful orbital surgery is a proper knowledge and understanding of the surgical anatomy, proper selection of the approach for a given patient and pathology; adequate exposure to allow safe tumour excision. To conclude, excellent results are possible using standard microsurgical techniques.

Stereotaxy

Ravi Ramamurthi

186 Stereotaxy: General Principles

Ravi Ramamurthi, Vikram M

The ability to reach any desired depth of the brain and to stimulate or make lesions in predetermined areas has been a notable advancement in modern neurosurgery. The development of stereotaxic surgery has given this capacity to the surgeon to operate in the depth of the brain, without undue mortality or morbidity. It has led to advancement in knowledge about the functioning of the deep areas of the human brain and has helped to provide relief in diverse types of neurological disabilities, apart from the diagnosis of deep-seated lesions.

Although the idea of reaching the deep structures in various areas of the brain is more than a century old, its real development for human use has been only after World War II. At the end of the 19th century, Sir Victor Horsley,[15] with the help of his physicist Mr Clarke, devised an apparatus, which could be fixed on the head of animals, to enable him to introduce a probe into a desired area of the brain. At the conclusion of the experiment, the animal was sacrificed and the brain examined to confirm the correct placement of the probe. Only 50 years later the technique of stereotaxic placement of lesions was introduced for human neurosurgery, by the efforts of Spiegel and Wycis in Philadelphia, who modified the Horsley-Clarke apparatus for human use[43] (Fig. 1). For therapeutic purposes in the human, an extreme degree of accuracy was essential and this could not be achieved by calculation from external landmarks commonly used in animal experiments. The idea of using internal landmarks in the centre of the brain increased the accuracy of the placement of the electrode. The nearer these landmarks are to the target aimed at, the greater is the accuracy. The foramen of Monro and the pineal gland were used initially as guides but the variability of the pineal shadow and of the width of the foramen of Monro reduced the degree of accuracy. The anterior and posterior commissures of the brain, as outlined by air or contrast studies or recently by special CT or MR, have been found to be more accurate. Most of the measurements in stereotaxic terminology refer to the line connecting the anterior and posterior commissures in the midline and these calculations ensure anatomical accuracy of the placement. When the technique is used for other indications with other targets to be reached, the landmarks will naturally vary, e.g. tip of the temporal horn for amygdalotomy, anterior horns of the lateral ventricle for cingulotomy and the fourth ventricle for dentatectomy.

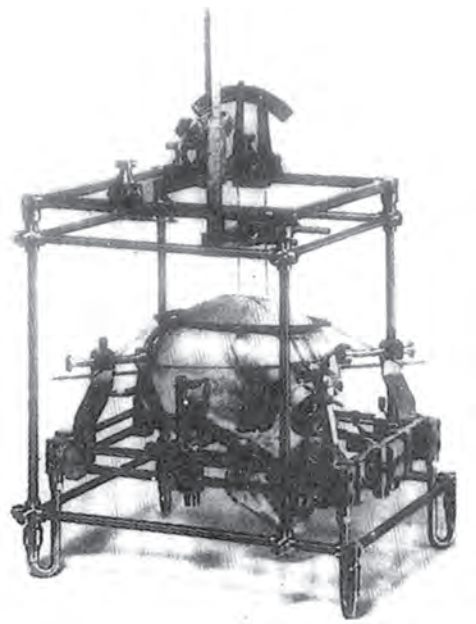

Fig. 1: Spiegel and Wycis stereotaxy apparatus

The modern techniques that are being used in stereotaxic surgery ensure a safe degree of accuracy for therapeutic purposes. Generally, there is a close correlation between the planned site of the lesion and the actual site, in the brains of Parkinson's patients examined postmortem. For finer neuropsychological determinations, a greater degree of accuracy would be desirable and necessary. One limiting factor in achieving such extreme accuracy is the variation seen in different human brains. This difference is not only seen between the sexes but also in different individuals belonging to the same ethnic group. This variation makes electrical stimulation studies necessary as a method of accurate localisation of the target. Recording of the electrical activity from the deep structures, as also a study of the evoked potentials, further help in the accurate localisation and assessment of the target. After such physiological studies, the desired area of the brain could be destroyed by heat, cold, wire loop, alcohol, wax, etc. It is also possible to focus an energy beam into a desired area of the brain, after making the necessary calculations.[25] The latter obviates the need for open surgery in the form of burr holes. This energy beam at a lower intensity can be used as a stimulus for neurophysiological studies and later, at a higher intensity, for making a lesion.

An important achievement of stereotaxic surgery, in the early years, has been the treatment of involuntary movements, chiefly Parkinsonism. Deliberate placement of a lesion initially in the globus pallidus and later in the thalamus[13] led to marked amelioration of symptoms in patients suffering from Parkinson's disease. The success attending this procedure encouraged further advancement in the science of stereotaxic surgery and the scope of such surgery has been widened to include other involuntary movements like dystonia, hemiballismus and choreoathetosis. The other condition for which the technique has been utilised with success is the relief of intractable pain. A few centres, notably in Japan and the Madras group,[20,21] have advanced the study further and have included cerebral palsy and behaviour disorders in the realm of stereotaxic surgery.[33,35,36] Further progress has included surgery for epilepsy and for some well defined psychotic conditions. The stereotactic technique can also be used in many other situations, e.g. clipping a deep aneurysm, introducing radioactive seeds into a pituitary adenoma or pineal tumours, biopsy of deep seated tumours, removal of deep lying foreign bodies, radiosurgery and draining of cysts and haematomas. Thus, stereotaxic surgery has increased our ability to give relief to patients, simultaneously providing a tool for neurophysiological investigations on the structures in the depth of the brain.

Apparently, there seems to be great scope for these forms of surgery, especially as more and more of the functions of the deep-lying nuclei in the human brain are unravelled. In addition to giving us an idea of the function of each area of the brain, stereotaxic surgery would also help us to know more about the association of functions between various areas of the brain and to understand how the human brain works as an integrated whole.

PRINCIPLES AND TECHNIQUES

Numerous apparatuses and guides are now available to approach accurately the desired target in the brain. All ensure a good degree of accuracy, whilst some provide ease and variety of manoeuvrability.

All the instruments use internal landmarks as guides from which one can determine the exact location of the target. During the past three decades, many stereotactic instruments, which are CT compatible, have been introduced. These instruments, while accurate enough for biopsy, do not provide enough accuracy to locate physiological targets in the depths of the brain. Special CT images are needed or the CT scan has to be done with positive contrast ventriculography, to provide clear delineation of the internal landmarks. MR compatible machines provide accurate visualisation of the needed landmarks in the centre of the brain. When such machines are not available, stereotaxic surgery can still be done accurately with air or non-ionic water-soluble contrast X-ray studies. The position of the anterior and posterior commissures and the midline of the brain, which are the common landmarks used, are determined by contrast studies.

Air may be introduced into the ventricles through a lumbar puncture (pneumoencephalography) or through a burr hole (ventriculography). Some workers introduce a water-soluble positive contrast medium into the ventricular system through a burr hole, so as to get a better definition of the third ventricle. In the sagittal and the horizontal planes of reference, the line joining the anterior and posterior commissures is used as the guide. The target point is calculated as so many millimetres above or below the inter-commissural line and as so many millimetres in front of or behind the midpoint of the same line. In the coronal plane, the site of the target is calculated with reference to the midline of the brain, as determined by the centre of the third ventricle demonstrated in the AP view. Although the commissures and the ventricles can be well demonstrated both by ventriculography as well as by PEG, the latter may induce some error in calculation, if air enters the subarachnoid space as this tends to displace the deep brain structures. Such difficulties were encountered in about 14% of cases by Schmidt et al.[41]

To reach accurately the predetermined subcortical target, calculations are necessary which enable one to adjust the direction and the depth of the electrode in relation to the constant reference points. The aim is to get the calculations accurate for each individual brain. In the CT and MR guided machines, once the target is defined, the calculations are made by the computer. In the older technique, it was necessary to use measurements to obviate the centrifugal enlargement of the X-ray pictures obtained by a near X-ray tube with divergent beams.

To fix the measurements of the required anatomical target points in each brain is difficult. Hence, model brain charts are prepared, taking the average of measurements taken from a large number of brains. Racial differences have been identified in brain measurements and separate charts have been prepared from Japanese brains. In general, the experience of more than 1,700 stereotactic operations done at The Institute of Neurology, Madras confirm the belief that Indian brain measurements are similar to European measurements. Kalyanaraman and Ramamurthi[18] found that the length of the third ventricle in patients of Parkinsonism, operated upon in Edinburgh and Madras, did not differ significantly, whereas there was a difference in the measurements of the width of the ventricle, the size being smaller in the Madras population. No autopsy-based accurate measurements are available as yet for Indian brains. Using the average or the model brain chart and calculating for X-ray magnification, the x, y and z co-ordinates are determined to fix the target accurately and also to determine the angle of inclination of the electrode.

There are two types of stereotactic apparatuses that are commonly used; in one type (Spiegel and Wycis)

horizontal co-ordinates are used and in the other polar co-ordinates are used (Leksell, Talairach, Riechert, Sugita and the Brown Todd-Wells apparatus, Cosman-Roberts-Wells apparatus).

In the linear type, the measurement of the target is taken in three planes and then the electrode is introduced in one of the three planes. Adjustment is possible for the needle (electrode) only in the three planes. It is not possible to incline the needle (electrode), as calculations for angle are not included. Hence, to reach different targets, the burr hole has to be made at different sites. In the apparatus that utilises polar co-ordinates, the needle (electrode) can be tilted to the required angle to reach the target. Thus, through one burr hole, different structures can be reached.

Cooper used an instrument which he called a guide. In this apparatus, movement of the needle in various planes is possible. Under X-ray control the needle is advanced to the desired target, the position of the needle being checked by repeated X-rays. Guiot and Gillingham, Bertrand, Narabayashi, Sano, Mackinley, Sehgal and Patil have devised their own machines. The principles used in these apparatuses include those explained above.

STIMULATION AND DEPTH RECORDING

In stereotactic surgery aimed at physiological targets, achievement of anatomical accuracy alone is not enough to ensure a good result. Tasker et al.[45] in a review, found deviations in a significant number of patients between the intended target and the target decided upon by anatomical calculations. Hence, a physiological check is essential to test the accuracy of placement of the electrode. In Parkinsonism, when the proper site is stimulated, there may be an arrest of the tremor for a few seconds. Depending on the frequency of the stimulus, the tremors may also get accentuated. If the tip of the electrode happens to be in the motor part of the internal capsule, motor phenomena resulting from stimulation would indicate that the electrode is not correctly placed. In such a case, it can be withdrawn and reinserted correctly. In temporal lobe epilepsy, a seizure may be induced by stimulation of the target.[47] Stimulation of the amygdala may cause apnoea, or sympathomimetic effects may be obtained from the hypothalamus[3,38] or from the lateral thalamus.[34] This stimulation serves as a method of physiological control. This is the most popular method of physiological localisation. The stimulation is performed at the tip of radiofrequency lesioning electrodes. Stimulation is performed at low current levels (less than 1 mA) and low frequency (2–5 Hz) and the current is increased until an effect is seen. The current is then reduced to sub-threshold levels and the frequency increased until a response is seen. Monopolar stimulation results in greater current spread than bipolar stimulation; the optimal probe is a 1.1 mm bipolar concentric electrode with 0.5 mm pole separation.[45]

Recording of evoked potentials from the nuclei during stimulation of the target is another way of identifying and delimiting the target. The modern technique of using the averaging computer to analyse the evoked potentials has increased the value of such studies. Similarly, evoked potentials recorded from the target on stimulation of peripheral structures are also useful in determining the accuracy of placement. The target in the depth may also be localised by recording the impedance of various areas of the brain.[24]

It is also possible to record the electrical discharges from these deep areas of the brain and the information utilised for locating the various nuclei. Such depth recording is especially useful in surgery for epilepsy. Microelectrodes may be used to record the response from single cells or from a small group of cells to peripheral stimuli (evoked responses). Some groups of cells in the thalamus and subthalamic nucleus fire in unison with the tremor of the limbs, while others precede the muscle contraction. A study of such activity contributes to the accuracy of placement[21] and adds to our understanding of the functioning of those nuclear groups.[4,10,19]

METHODS OF MAKING THE LESION

Temporary Lesions

Once the correct target is decided upon, it is necessary to make a lesion which will be permanent but circumscribed. Before making a permanent lesion, a temporary lesion may be made to enable one to know whether the correct target has been reached and whether benefit will accrue from placing the lesion in the particular area. The original technique of Cooper of inflating a balloon at the tip of the needle was one such procedure. In the techniques that use electrodes, similar temporary lesions can be made by heating the electrode tip to about 40°C for about 20–30 seconds to a level when function would be interrupted. If the placement is satisfactory, then the electrode is heated to coagulation levels. Similarly, when using cold as the lesion-making agent, the cryoprobe can be cooled to about 0°C for 30 seconds to make a temporary lesion, which may later be made permanent by cooling to minus 80°C.

Chemical Lesions

Chemicals have been used for many years to produce lesions during stereotaxic procedures. Alcohol or a mixture of alcohol with myodil or cellulose or bees wax has commonly been used. The danger of these chemicals seeping along the various tissue planes is always present. One can also not be absolutely sure about the shape of the lesion and its direction of spread.

Electrolytic Lesions

By using a diathermy current and coagulating the tissues, precise radiofrequency lesions can be made in the various deep nuclei. Special arrangements have to

be made in the diathermy machine, to make sure that there is no sudden voltage change which would make the lesion inconsistent. With the help of a thermocouple fixed to the tip of the electrode, the temperature at the tip may be increased to the desired level (62.5°C for 2 minutes) so that a constant lesion could be made.[48,50] Radio-frequency lesion-makers are available and help to create a predictable lesion. The optimum size of the lesion is 100–150 mm.[11,49]

Cold Lesions (Cryogenic Lesions)

By using vacuum-insulated probes conducting liquid nitrogen gas, the tip of the probe may be cooled to minus 80°C.[9] After the accuracy of the probe placement has been confirmed by a temporary lesion, by cooling the tip of the probe to 0°C, the temperature of the tip is brought down to minus 80°C and kept down at that level for 3 minutes. This usually produces a frozen lesion about 8 mm in diameter. The size of the lesion depends on the temperature of the tip and the duration of cooling and can be accurately monitored.[27] The tip of the probe is warmed to 20°C before being withdrawn. The temporary post-operative disturbances are minimal when cold lesions are used.

Mechanical Lesions

Mechanical lesion-makers are useful, as one can be sure of the exact extent of the lesion. Small wire leucotomes have been used successfully in may centres.[5] When the needle is in the correct position, the wire is protruded to the required extent (2–4 mm). The leucotome is turned around 45 degrees on each side. The wire is now withdrawn into the leucotome, the direction of the leucotome rotated to 90 degrees and the process is repeated. Such a procedure prevents accidental tearing of any blood vessel that may lie near the tip of the needle.

Lesions can be made by using radioactive substances like radioactive gold or yttrium. It is also possible to make the lesion by using high-energy proton beams. The use of the proton beam obviates the need for a burr hole. The high speed accelerator is so adjusted that the concentration of the protons would be at the target area whose co-ordinates are calculated in the usual manner. Tym and Weynad[46] have used external alpha particle radiation to create lesions. Leksell's group has used gamma rays from a radiocobalt source to make functional lesions.[26]

STEREOTAXIC BIOPSY

Before making a permanent lesion and after one is satisfied regarding the accuracy of placement of the electrodes, it is possible to take a small biopsy from the area of the lesion[11] to study the morphology of the site of the lesion. Histochemical and electron microscopic studies of such biopsy specimens add to our knowledge of the pathological anatomy of the diseased area.

Biopsy Instrumentation

A variety of instruments are available that include cup forceps, spiral needle, side-cutting aspirator, and needle core device. The needle core device is a 14-gauge cannula with a stylet for entry. A core is aspirated at the target site but greatly depends on lesion texture. The side-cutting aspirator is a modification of the needle coring device. It provides a 1.5 × {times} 10 mm cylindrical specimen, but the result also depends on lesion consistency. The cup forceps provides about 1.5 mm specimens and depends less on lesion characteristics. It also provides some assessment of tissue firmness as judged by resistance to palpation of the lesion with the probe tip.

POST-OPERATIVE STUDY OF THE SITE OF THE LESION

As the procedure of stereotaxic surgery is an accurate neurophysiological exercise, it is essential to have an idea of where exactly the lesion has been placed and to correlate it with the results. Only thus can further knowledge be gained. After the permanent lesion is made, to mark the site of the lesion, a small stainless steel ball or an MR compatible radio-opaque marker is introduced through a cannula and pushed into the area of the lesion. By studying the position of the marker on the X-rays, it is possible to chart accurately the site of the lesion on anatomical charts of the brain.[39,40,45] In case myodil wax is used as in amygdalotomy, the insertion of the radio-opaque marker is not necessary.

ASPIRATION OF CYSTS AND HAEMATOMAS

Using stereotactic localisation, a number of cysts, neoplastic and non-neoplastic may be biopsied for diagnosis and then drain them to relieve compression on the brain. When a predominantly cystic craniopharyngioma is encountered in the third ventricle, stereotactic biopsy of the enhancing margin for diagnosis, followed by placement of a catheter into the cyst attached to a large Ommaya reservoir for serial aspirations, is a surgical option. The cyst wall commonly is very thick and resists puncture by conventional biopsy probes, which may result in deviation of the catheter around the cyst wall. To prevent this, the blunt probe is advanced to the wall of the cyst and a sharp inner cannula is used to puncture the cyst wall. The outer probe is then advanced over the inner probe into the cyst cavity. An alternative treatment for recurrent cystic craniopharyngiomas is the use of beta-emitting radioisotopes. Phosphorus-32 is a pure beta emitter with penetration of several millimetres that has shown efficacy in treating cystic tumours,[22,29] provided the cyst wall is competent before isotope instillation; as leakage of isotope into surrounding cisterns may be disastrous. A computed tomography scan with contrast injected into the cyst is sufficient to demonstrate competence. Colloid cysts are amenable to similar

surgical aspiration and, as with craniopharyngiomas, a sharp probe may be needed to puncture the cyst.[12]

A stereotactically guided Archimedes screw-type device has been advocated to evacuate organised deep brain haematomas,[1,7] as well endoscopes may be used to irrigate and evacuate haematomas. Catheter reservoirs may be implanted into the haematoma, followed with streptokinase or tissue plasminogen activator injections to lyse the clot with periodic aspiration.

STEREOTACTIC CRANIOTOMY

Image-guided stereotaxis can be used to guide the surgeon to deep-seated or small tumours that need to be resected. Vascular lesions, such as cavernous malformations and small arteriovenous malformations, can be localised and removed as well. Use of an arc-centred system, such as the Cosman-Roberts-Wells system, allows the surgeon to tailor the incision and bone flap to the lesion, as the pointing device can be rotated out of the field while the craniotomy is performed. After the dura is opened, the probe can be used to guide or create a corridor to the lesion. Tumour-brain interfaces can be detected more easily by correlating the intra-operative position with the stereotactic co-ordinates.

CHRONIC IMPLANTATION

Instead of making an acute lesion, fine electrodes can be left in the desired target in the brain (chronic electrodes) and periodic stimulation and recording may be done. As indicated, small incremental lesions could be made. Such chronic implanted electrodes have to be made of special alloy or stainless steel to diminish tissue reaction.[23,37] Similarly, a chemode can be inserted into a desired area and chemical agents may be delivered to focal areas in the depth of the brain for the relief of seizures, pain, abnormal movements or behaviour disorders.[32]

STEREOTACTIC ANGIOGRAPHY

There are several applications for stereotactic angiography: vessels to be avoided during biopsy or implantation procedures can be visualised, localisation of arteriovenous malformations for radiosurgery or open procedures can be done and specific cortical gyri and sulci can be identified by the positions of cortical arteries and veins.[44] The angiogram is performed with the patient in the stereotactic head frame in the lateral and anteroposterior projections. The referencing system consists of nine points on a radiolucent plate that fits on the four sides surrounding the patient's head. Each film contains 18 points that are related by the degree of separation between them and the divergence of the X-ray beams. Structures located between the two plates can be described in stereotactic space after the appropriate computer programme transformations.

Fig. 2: Leksell's stereotaxy apparatus

TECHNIQUE USING THE LEKSELL'S APPARATUS

The Leksell's apparatus (Fig. 2) has a square frame with opaque markings that help in calculating the co-ordinates. On this, a semicircular frame with an electrode carrier is fitted, so that the electrode may be introduced into the target from any angle. This is one of the simplest and most accurate stereotactic apparatuses and the technique is easily learnt. The apparatus can be modified suitably for further sophisticated use.

The Leksell frame may also be used for spinal stereotactic surgery, but the technical difficulties are too many. Hence, it is better to use a specially made spinal stereotaxic apparatus to make lesions in the upper cervical cord and the brainstem[14] (details about the BRW frame are given in the chapter "Stereotaxy for Brain Tumours").

COSMAN-ROBERTS-WELLS SYSTEM

The head ring, localiser ring and phantom frame of the Cosman-Roberts-Wells system are identical to those of the Brown-Roberts-Wells system. The difference rests in the design of the arc guidance frame. An arc-centred frame similar to those of the Todd-Wells and Leksell systems is used. The four angles of movement and the need for separate entry point calculation are avoided. Anteroposterior, lateral and vertical co-ordinates are accounted for in the arc, placing the lesion in the centre of the sphere with a fixed radius. Consequently, the depth of the probe is fixed and the target is always accessed, regardless of the choice of entry point. The design of the frame allows removal of the arc ring from its base for a 90 degree transposition before placement onto the head ring. This allows a lateral trajectory to the head, useful for acquisition of temporal lobe lesions. Posterior fossa targets can be reached by angling the posterior portion of the head ring inferiorly. This allows a nearly horizontal approach to biopsy infratentorial lesions. The simplicity, flexibility and accuracy of the Cosman-Roberts-Wells frame have made it the preferred stereotactic system.

PHANTOM INSTRUMENTS

Some stereotactic instruments, like Riechert's and Sugita, use the principle of phantom apparatus; the calculations and the adjustments are all made in the phantom set-up

from which they are directly transferred to the frame on the patient's head.

TWO MACHINE STEREOTAXY

It is possible to approach various regions on both sides of the brain by using two stereotaxic apparatuses simultaneously. However, there are instruments available now which facilitate the introduction of electrodes into both halves of the brain. With this technique, it is possible to record and stimulate from one hemisphere while recording from the opposite side. This helps in further understanding of the deep neural mechanisms.[17] However, the CRW system allows lesioning on multiple sites, on either side of the brain in the same sitting without removal of the frame and recalculations, as the system is arc centred.

Simultaneous bilateral lesions in the thalamus have been described by Kalyanaraman and Ramamurthi.[16] It is found that such lesions can be made without lasting side-effects in younger patients, but these are better avoided in the older ones. Making simultaneous lesions in the amygdaloid nucleus for behaviour disorders is a common practice.

Although stereotaxic surgery was initially performed only in adults, it is possible to operate on young children. This becomes necessary for cerebral palsy as well as for behaviour disorders. The Madras group has operated upon patients as young as three years of age.[2]

STEREOTACTIC EXTERNAL BEAM RADIATION THERAPY

General Concepts

Ideal radiation therapy would subject the lesion to very high levels of ionising radiation sparing all normal tissue. This ideal can be approximated with the use of interstitial brachytherapy or external beam radiation (teletherapy). With the advent of computed tomography-guided stereotaxis, radiation may be targeted and focused onto lesions within the brain at a much higher dose than is possible with conventional radiotherapy.

Three methods can deliver this type of radiation. The Gamma knife uses fixed cobalt-60 sources that emit gamma rays (photons) to a focal point 403 mm away.[25,30] A collimator helmet with various diameters is used to alter the volume of radiation emitted. The stereotactic device allows accurate targeting from imaging and places the target at the focal point of the converging gamma rays. The second system that uses photons as an energy source is a modification of the standard linear accelerator (Linac).[6,8,51] Secondary collimators are fitted to the head of the machine, which rotates with intersecting arcs to produce a high concentration of radiation at the isocentre. A stereotactic frame is used to place the target at the isocentre. The last method uses collimated beams of charged heavy particles, such as protons (hydrogen ions) or helium ions.[28] Charged particles have several properties that make them ideal for radiotherapy. They penetrate through matter with a low initial dose, followed by a very high dose at the end of the range of the beam (the Bragg peak), which is well defined for each particle.[18] Immediately after the Bragg peak, the dose steeply falls off. The shape of the radiation field is controlled by specially designed collimators. The width and depth of the Bragg peak can also be modified with tissue compensation techniques. Only a few beams of radiation are required because of the unique physical qualities of charged particles. This mode of therapy is restricted to a few research centres because of the expense required in setting up and running a cyclotron to generate the charged particles.

Clinical Applications

Stereotactic radiosurgery has found its greatest application in the treatment of small, deep-seated arteriovenous malformations, small benign tumours of the cerebellopontine angle and metastatic disease.[42] Obliteration of arteriovenous malformations after radiosurgery is a result of radiation-induced vascular injury, resulting in the thrombosis of vessels and ultimately of the nidus. This effect is delayed, often not seen for as long as 2 years. Although surgical resection is still the mainstay of therapy for acoustic neuromas, stereotactic radiosurgery is gaining popularity, especially in elderly patients with medical illnesses that preclude surgery. Growth arrest of the tumour is seen in most cases, but long-term follow-up is lacking. Tumour shrinkage from radiosurgery usually is minimal, although central necrosis may be seen. The risk of developing a delayed facial neuropathy is 33%, but some degree of recovery is seen in most cases.[31] Following Kelly's development of the technology that made volumetric sterotactic guidance for tumour resection, the targets are being defined as a volume in space rather than a point in space. The stereotactic arc holds a cylindrical retractor aimed at the centre of rotation, which is used to direct the surgeon's view line along the same trajectory as the computer reconstruction. Similar techniques were used for volumetric reconstruction to guide craniotomy, tumour resection and endoscopy.

FRAMELESS STEREOTAXY

With the introduction of computers, frameless stereotactic systems have been developed. These are based on the co-registration of an instrument or a pointer relative to the patient's anatomy, as demonstrated by CT or MRI scans. They are more useful as a guide during craniotomy and are not accurate enough for functional neurosurgical procedures. The first commercial frameless system was developed using a multi-articulated arm attached to the operating table or head holder. With advances in the system, there is no longer a need to use the multi-articulated arm. The use of ultrasonography, light emitting diodes, or video "machine vision" to

localise hand held pointers or instruments in stereotactic space has made them more user friendly.

SPINAL STEREOTAXIC SURGERY

The principles of cranial stereotaxic surgery can be extended to the spinal cord, thus facilitating the placing of accurate small lesions in the various tracts. A simple electrode carrier to make a spinal cord lesion in animals was devised by Clarke in 1920.[14]

As cordotomy after laminectomy carries a good amount of risk for debilitated patients, the technique of percutaneous cordotomy was developed. Spinal stereotaxic surgery is a further step in this direction.

A special stereotaxic frame suitable for spinal surgery was devised by Hitchcock.[14] The midline is found in relation to the AP view of the frame, using co-ordinates based on either the odontoid process or the third and fourth ventricle. By suitable adjustments of the frame, the spinal target in the lateral view can be related to the radio-opaque markings on the horizontal and vertical bars. The vertical and horizontal bars are then rearranged, so they lie within the plane of the target, at the desired laterality from the midline and at the required depth below the frame. An electrode carrier fitted with a Vernier scale is attached to the vertical bars, thus permitting the movement of the electrode tip by 0.1 mm distances. This technique can be used for various types of tractotomy in the medulla and for cordotomy in the upper cervical cord.

187 Stereotaxy: Brain Tumours

Murali Mohan S, Ravi Ramamurthi

INTRODUCTION

The fundamentals of stereotactic surgery lie in the understanding of the brain as a three-dimensional structure and the application of the Cartesian co-ordinate system to define a specific region of interest. Any geometric volume can be divided by three imaginary intersecting spatial planes, orthogonal to each other, based on the Cartesian co-ordinate system. The brain is considered as a geometric volume and can thus be defined in the horizontal, frontal and sagittal planes. With reference to the centre point of intersection of these orthogonal planes, any point within the brain can further be defined by precise numerical values termed as co-ordinates. From its conception in the late 19th century, the concept of stereotaxy has evolved from frame-based applications to frameless stereotaxy. Further, the concept has been utilised in the field of radiation therapy to administer a high dose of concentrated radiation to a precise target, termed as stereotactic radiosurgery. In recent times, the addition of stereotactic techniques to endoscopy has added to precision and safety of the procedure.

Classically, stereotactic surgeries are performed using a stereotactic frame, the popular frames are the Leksell, Brown-Roberts-Wells, Patil and Cosman-Roberts-Wells frame. The basic principle of nearly all current stereotactic equipment is firm fixation of the stereotactic apparatus to the patient's skull vault with metal pins. Once the head frame is attached under local anaesthesia, the patient is shifted to obtain magnetic resonance (MR) or computed tomography (CT) images with the reference frame in place. The patient is then returned to the operation theatre, where the procedure is performed. Frame-based fiducials and target points are entered into a computer that calculates the entry points and trajectory.

In the frameless stereotactic technique, the surgeon can navigate through the spine and cranium with image guidance. The CT or MR images of the surgical field are imported into the computer software. A digitising camera senses the position of the surgeon's instruments in space and indicates the position of the instrument on the image displayed on the computer monitor in real time by referencing the co-ordinate system of the brain with a parallel co-ordinate system of the three-dimensional image data of the patient that is recorded earlier. The spatial accuracy of frameless stereotaxy has been further enhanced with the introduction of intra-operative MR imaging (MRI) that provides real-time images to document the residual lesion and to assess brain shift during surgery as the operation proceeds.

Frameless stereotaxy and stereotactic radiosurgery have been dealt with in detail in other chapters. This chapter deals with the application of stereotaxy for brain tumours using the stereotactic frame. Stereotactic techniques, though commonly used in functional neurosurgery, have been widely utilised for brain tumour surgeries mainly biopsy and aspiration of critically located masses or combined with craniotomy for excision of lesions.[32,33,51]

STEREOTACTIC BIOPSY

Stereotactic biopsy is the most common stereotactic neurosurgical procedure performed. Considerable experience has accumulated all over the world with different systems. An obvious limitation of stereotactic biopsy is the small amount of tissue obtained. Several studies have shown good diagnostic yield using combined cytological and histological techniques.[12,17,24,50]

Stereotactic biopsies are generally performed for the following intracranial masses:

- Suspected malignant intraparenchymal tumours in eloquent areas
- Deep-seated lesions
- Multiple lesions
- Patients reluctant for open surgery.

Stereotactic biopsies are avoided in the following conditions:

- Extra-axial lesions
- Superficial (grey-white junction) lesions
- Suspected vascular malformations/vascular lesions.

Stereotactic brainstem biopsy sampling needs special mention. It was first reported by Gleason and his colleagues in 1978 in a series of eight adult patients.[28] Proponents of this procedure claimed that stereotactic biopsies of brainstem lesions were safe, had a high diagnostic yield, and carried low morbidity and mortality rates.[65,70,75] It has also been reported that brainstem tumours were better managed once a definitive tissue diagnosis had been established.[42] More recently, however, with the improved resolution of MRI it has

been recommended that diffuse pontine lesions do not need to undergo routine biopsy sampling and that the procedures should be reserved for patients with a focal mass lesion.[1,14,59,72] Because of the increasing diagnostic capabilities of neuroimaging modalities, the role of stereotactic biopsy sampling for brainstem masses has been refined. In patients in whom a biopsy procedure is indicated, it remains a safe option with excellent diagnostic and prognostic value. Currently the use of biopsy sampling is reserved for a specific subset of patients, particularly those with the following:

- A focal, enhancing, peripontine mass in the midbrain, medulla or peduncle
- A posteriorly exophytic tumour protruding into the fourth ventricle
- A tumour exhibiting an uncharacteristic MRI pattern and is probably non-glial
- Focal, enhancing (especially ring-enhancing) lesions (to identify patients with benign non-neoplastic lesions)
- Clinical or neuroimaging evidence of disease progression in tectal masses.[1,18,58,60]

Procedure

The majority of operations are done under local anaesthesia. General anaesthesia is used only for children and uncooperative adults. Shaving of the head is not necessary. The sites where the pins are to be fixed are cleaned with povidone-iodine topical solution. The head ring is then fixed to the head with the help of pins, after infiltrating the sites with 2% lignocaine. In fully conscious, co-operative patients, the head ring is fixed in the sitting position. While fixing, care is taken to make sure that the likely target is not in the plane of the head ring or the pins so that pin/head ring artifacts do not interfere with the target selection. Then, the patient is transferred to the CT/MR scan table.

The patient is given intravenous contrast medium for the contrast CT scan. Usual slice thickness of CT scan of 8–10 mm is taken. However, for smaller lesions scans are obtained at 1–2 mm thickness. The target chosen is from a contrast-enhancing region, in an area away from ventricular or cisternal spaces. Once the target is chosen, the co-ordinates are obtained from the CT scan monitor depending upon the stereotactic system used. The patient is then shifted to the operation theatre. After sterile cleaning and draping, the stereotactic arc is attached to the head frame and using the co-ordinates the entry point is marked. Local anaesthetic agent is then infiltrated to the area. A burr hole or a craniostomy is done using a twist drill. Once the drill has gone through the bone, care is taken to just puncture the dura without damaging the brain. Care is taken to prevent excess cerebrospinal fluid (CSF) drainage as it may result in shift of the brain and hence the target. Then the arc system is placed over the head ring and co-ordinates are adjusted in such a way that the probe can enter perpendicularly through the centre of the burr hole. The probe is then guided in up to the predetermined depth. The sleeve is withdrawn. About 3–4 bits of tissue are obtained using a biopsy forceps introduced through the outer sheath. The tissue smear is made immediately. If the consistency of the tissue precludes a smear preparation, more than one target is biopsied. In case of cystic lesions, care is taken to obtain the biopsy sample prior to decompressing the cyst. There are several types of biopsy instruments:

- Cup forceps
- Spiral needles
- Side-cutting instruments
- Needle core devices.

Spiral needles and Sedan-type side-cutting instruments have a higher risk for morbidity.[6]

Although stereotactic biopsy is a safe, efficient and valuable procedure. It has a morbidity rate ranging from 0.9 to 15% and mortality rate between 0% and 4.2% in reported series (Table 1). After the stereotactic procedure, a plain CT scan is done after 4 hours to rule out haematoma at the biopsy site or along the course of the probe tract. The site of the biopsy can also be made out by the presence of a dot of air in most of the cases. The relief of pressure effects following decompression of cystic lesions can also be demonstrated by the post-procedure CT scan.

Stereotactic brain biopsies can be performed using frameless stereotaxy, which provides several advantages.[19] The MRI or CT can be obtained any time before the procedure. This flexibility is convenient for scheduling of operation and avoids issues related to transporting the patient after the frame has been fixed. The image guidance workstations can be configured to view the trajectory in which the biopsy needle will travel. The risk of injuring an artery or vein can be minimised by selecting an appropriate entry point and trajectory. The ability to change biopsy targets in the operation theatre is yet another benefit of frameless image guidance. If non-diagnostic tissue is obtained, the target can easily be readjusted without reimaging or arithmetic calculations. This advantage is lacking during a conventional stereotactic biopsy. One potential drawback to using frameless stereotaxy for biopsy is the lack of a rigid frame to serve as a structural support for the biopsy needle. The freehand image-guided advancement of the biopsy needle can increase movement of the needle and decrease accuracy.

Results

Several series of stereotactic biopsies have reported a positive yield between 90% and 96%.[5,15,37,44,45,53,71,75] The non-specific diagnostic biopsies could be classified into two categories:

1. Negative biopsy in which the tissue obtained failed to indicate the nature of the lesion.
2. Inconclusive biopsy in which a representative tissue was obtained, but the definitive diagnosis could not be made.[61]

Linskey et al.[54]	2009	106	4	4	0

Although experience of the pathologist is the most important factor in the diagnostic yield, the small size of the samples is the major disadvantage of stereotactic biopsy.[27,74] Because it is a two-step procedure that includes interpretation of smear preparations intraoperatively and paraffin preparations post-operatively, there could be some discrepancies between the results of smear and paraffin preparations. In the literature, discordance between smear and paraffin preparations has been reported as ranging from 5 to 38.46%. The presence of massive necrosis and the absence of a diagnostic histological component in the small biopsies were the reported causes of the discordance in those studies.[12,15,27,54] Ostertag et al.[54] reported 5% discrepancy between the diagnosis from the smear preparation and the subsequent histological diagnosis. In cases where only necrosis is detected in smear, the pathologist should acquire additional samples. If the presence of only necrosis persists, the case must be deferred for the paraffin preparations to evaluate the other samples taken for paraffin section. If the only finding is necrosis in the final paraffin sections, rebiopsy or resective surgery must be offered.[6]

The quality of the smears is one of the most important factors in evaluating the cytological details. Improper quality causes difficulties in diagnosis of a glial tumour versus metastasis and gliosis and in the diagnosis between tumours having cytological similarities such as pineocytoma and oligodendroglioma.[6]

The specific method of tissue biopsy likely plays a key role in determining diagnostic accuracy and yield. Earlier series appear to be relatively evenly divided between the use of biopsy forceps or a side-cutting biopsy needle, while many report using both and other surgeons still use needle aspiration techniques.[3,9,25,30,54,62,73] More recent series tend to favour a side-cutting needle exclusively, which has the advantage of preserving a core of intact cross-sectional tissue architecture which facilitates histological interpretation.[25,68,78]

Linskey and Owen[56] used a relatively aggressive biopsy technique which would minimise sampling error and increase the likelihood of an accurate diagnosis. Multiple sections were taken with the side-cutting needle at serial depths along the track to obtain ''geologic core'' with a single needle trajectory, providing samples of normal brain, lesion edge and central contents. The utility of this approach is reflected in the accurate grading of all but one of the gliomas in their series, and in the low number (three) of necrosis—only results in glioblastoma multiforme biopsies. In another series of 407 cases of intracranial masses, there were 19 (4.87%) negative biopsies and three (0.76%) inconclusive biopsies, thus giving a total of 5.64% of non-diagnostic biopsies.[61] Stereotactic biopsy has also been shown to have a high specificity. The diagnostic yield in CT-guided stereotactic biopsy of gliomas is highest at the enhancing margin.[29] The CT morphology of intracranial masses does not seem to influence the positive yield, although a negative biopsy may be more likely with hypodense non-enhancing masses than with enhancing masses. Similarly, an increase in operator experience in stereotactic biopsies does not seem to correlate with a significant increase in positive biopsies.[61] The mortality after stereotactic biopsy has been variously reported as 0.6–2.6%.[44,52,54] Ranjan et al.[61] in their series of 407 patients (this includes all the non-neoplastic lesions as well) who underwent biopsy and aspiration, had two deaths due to procedure related complications. In both there was bleeding at the biopsy and aspiration site. The procedure related morbidity has been reported to be between 1% and 5.9%. Various authors[25,49] have reported that brainstem, pineal and deep-seated lesions are associated with increased

morbidity. Shastri-Hurst et al.[66] have noted the finding of blood intra-operatively in seven cases out of 203 cases as having a positive predictive value of 57% for post-operative deterioration but a sensitivity of only 30%. In Linskey's series,[56] 19% of patients who had persistent intra-operative bleeding which persisted beyond two needle irrigations had significant haemorrhage in the post-operative scan. In general, a morbidity rate of less than 4% (temporary or permanent neurologic deficit) has been reported in various large series (Table 1), hence an aggressive sampling technique can be employed without compromising patient safety. McGirt et al.[49] found that increasing the number of biopsy samples did not independently impact morbidity if the samples were collected along a single needle trajectory.

STEREOTACTIC ASPIRATION

Primary and metastatic brain tumours often have associated cystic components. Conventionally, the presence of a single, large and cystic brain tumour has been regarded as an indication for surgery.[26] Yoshida and Morii advocated surgical treatment for patients with large cystic lesions, providing rapid relief of neurological symptoms caused by mass effect.[79] However, if the lesion is deep within the brain or located adjacent to eloquent areas, surgical procedures may result in severe neurologic deficits. In addition, surgical procedures are not effective or safe for patients in poor general condition or those with multiple lesions. Stereotactic cyst aspiration with or without Ommaya reservoir insertion is a safe and effective alternative procedure in these patients. Possible complications include haemorrhage, focal neurosurgical deficits, seizures and infection.[77]

In cystic lesions, the most dependent portion is chosen as the target and the wall of the cyst is targeted for biopsy. If possible, the biopsy of the wall is obtained before aspirating the cyst, because decompression of the cyst would change the position of the biopsy target. A cannula with a stylet is inserted through the probe holder and at the appropriate depth the sylet is removed and gentle suction applied through the cannula. In cases where a large amount of fluid is aspirated from a cystic lesion, care is taken to prevent entry of air into the cavity. Stereotactic implantation of an intracystic catheter with an Ommaya reservoir placed in the subgaleal space can be used to instil therapeutic agents and to perform frequent aspirations where necessary.[63]

In metastatic tumours located in the eloquent areas or in deep locations with a large cystic volume, it is difficult to remove the tumour completely or subject them for radiosurgery. Because the volume of the lesion is the limiting factor for radiosurgery given that it correlates with the risk of radionecrosis and the cystic component of a metastatic lesion is unresponsive to radiation, the therapeutic effect of gamma knife radio-surgery (GKRS) is reduced. In such situations, stereotactic cyst aspiration followed by radiosurgery could be the better treatment modality than surgical resection. Stereotactic cyst aspiration with or without Ommaya reservoir insertion and GKRS can be performed with a single frame application on the same day in large cystic brain metastases that do not appear suitable for radiosurgery alone.[80]

In order to avoid invasive procedures (transfrontal, transcallosal) in the surgical treatment of colloid cysts the stereotactic aspiration technique was introduced by Bosch, Rahn and Backlund in 1978.[10] Colloid cyst of the third ventricle can be aspirated obviating the need for open surgery. A high incidence of early recurrence was reported by various authors.[48,67] Stereotactic partial cyst wall disruption and content aspiration was then suggested to limit recurrence of colloid cysts, thus offering an advantage over simple stereotactic aspiration alone.[43] The major factor that is predictive of difficulties during percutaneous procedures concerns the high viscosity of the cyst's content, which is correlated with the hyperdensity of the cyst noted in CT scans.[40,46] T2-weighted sequences are useful for predicting the difficulty of aspiration of colloid cysts during percutaneous procedures by stereotactic aspiration. A significant correlation between low signal on T2-weighted fast spin-echo sequences and viscosity (and therefore hard or impossible-to-evacuate) of cysts has been reported by EL Khoury et al.[13] However, with conflicting reports in the literature, it has been suggested that radical removal by open or stereotactically guided microsurgery is the method of choice since stereotactic aspiration fails to offer a radical or permanent treatment for colloid cysts of the third ventricle. Stereotactically placed precise and limited craniotomy, a small cortical opening (10–20 mm), a precise trajectory to the foramen of Monro and standard microsurgical resection has been reported as safe and effective management of patients with colloid cysts.[8,21,41]

In unresectable craniopharyngiomas, the goal of treatment is tumour control and improved length of survival, while maintaining quality of life. The most commonly used alternative treatments have been a biopsy, cyst drainage, or planned partial resection, followed by radiotherapy. One of the typical characteristics of craniopharyngiomas is the presence of a cyst within the tumour. Recurrent collection of fluid in cystic craniopharyngiomas can be periodically aspirated. The aspirated fluid is of prognostic significance as well. Instillation of antineoplastic agents into the tumour, including beta-emitting radionuclides, bleomycin and IFNα into the cyst is an effective option. Bleomycin has been used for intracystic treatment of craniopharyngiomas, both initially and at the time of recurrence. In general, bleomycin has been used for temporary tumour control with the expectation that other therapies, such as resection or radiotherapy, will be required for longer term tumour control. Bleomycin is usually injected into the craniopharyngioma cyst via a subgaleal Ommaya reservoir attached to a catheter, with its tip located in the cyst. One of the concerns with the transventricular route is that there may be toxic effects from spillage of the cyst

contents into the ventricular system. As an alternative to bleomycin, intracystic IFNα has been used for patients with craniopharyngiomas. It is similar to bleomycin in that it provides short-term control of a predominantly cystic tumour and delays more definitive treatment aimed at longer term control. Unlike bleomycin, IFNα does not appear to have any significant major toxicity, even if it spills into the subarachnoid space.[23,31,69]

STEREOTACTIC BRACHYTHERAPY

In conventional external beam radiation therapy (EBRT) for cerebral tumours, the total radiation dose is limited by the potential for damage to the overlying brain. Stereotactic brachytherapy, the temporary or permanent implantation of radioisotopes into brain tumours, is one method of overcoming the limitation of conventional teletherapy. Another advantage is that this mode of therapy can also be employed in recurrent tumours which already have received the maximum tolerated dose of EBRT.[16] For solid tumours, 125 or 1921r sources are most commonly used.[7] The most often used dose rate is of the order of 40–60 rads/hour. At these levels, interstitial irradiation is supposed to achieve a therapeutic ratio superior to conventional teletherapy.[16] For cystic tumours such as craniopharyngioma, 90 Yt or 32P has been used. The beta-emitting radionuclides are instilled after stereotactic puncture of the cyst and the appropriate dose is calculated on the basis of the size of the cyst. The goals of intracavitary radiotherapy are reduction of the cyst and long-term control of the tumour, in many respects similar to the goals of EBRT. Regardless of the beta-emitting radionuclide used, intracavitary radiotherapy reduces the size of the cyst in 50–100% of cases, according to different case series.[11,36,57]

Iodine-125 interstitial irradiation has been used for gliomas, pinealomas, brainstem tumours, recurrent meningiomas, solid craniopharyngiomas and metastases. Due to financial reasons, gamma knife and Linac are not available widely in many countries and neurosurgical institutes. In the absence of the above mentioned radiosurgical methods, brachytherapy is an alternative solution in the treatment of different types of inoperable or recurrent brain tumours. One of the negative aspects of intracavitary radiotherapy is the difficulty in accessing the radioisotopes and the complexity of the process for instillation of such materials into the cyst.

STEREOTACTIC CRANIOTOMY

The stereotactic system can be effectively combined with conventional neurosurgical craniotomies for treating smaller lesions located in deeper or eloquent areas and helps in reducing morbidity. Stereotactic and computer-assisted techniques have revolutionised the diagnosis and treatment of many brain disorders, enabling the surgeon to adopt the least traumatic approach. These stereotactic methods were initially introduced by Kelly, using a frame-based stereotactic system.[37] Frame-based systems are designed to mechanically constrain instrumentation to a direct path to tumour tissue. Stereotactic craniotomy is most useful for small, deep-seated lesions where reliance on surface anatomic landmarks can be misleading. Furthermore, for convexity lesions, stereotactic guidance can allow for smaller, more localised craniotomies than would be possible with the use of surface landmarks. Normally for this procedure seven targets are chosen—lesion centre, lateral edge, medial edge, posterior edge, anterior edge—these five are calculated from the same axial slice, and the superior edge and inferior edge—these are calculated from slices showing the upper and lower limits of the lesion. The calculation of multiple target co-ordinates enables a more accurate planning of the craniotomy as well as aiding in volumetric excision. The initial procedure is similar to stereotactic biopsy. It can be carried out under conscious sedation (awake craniotomy) or under general anaesthesia. The posterior, anterior, superior and inferior edges of the lesion are marked out on the skin using the sterile pointer—this procedure outlines the lesion. Generally the centre target is used to plan the trajectory. Once the outlining is over, the arc is swung away and craniotomy performed. Before opening the dura, the arc is swung back and the trajectory confirmed. Further surgery is the standard procedure of tumour excision. In deep-seated lesions the sterile pointer may be passed directly into the target and locked in position. This will act as a guide to the target, with dissection being carried around the pointer. There is inevitably some movement of the brain on performing a craniotomy, even under stereotactic conditions, and this will affect the accuracy.[22,34,51,64]

STEREOTACTIC ENDOSCOPY

Cerebral endoscopy has been used to approach an intracerebral tumour for visualisation, irrigation, tumour cyst wall puncture, aspiration and biopsy.[2,4,5] The use of endoscopy for the management of intraventricular brain tumours has evolved from simply treating the associated hydrocephalus, to sampling of tumour tissue, to tumour resection. Planning the entry point and trajectory is often the most crucial aspect of the surgical procedure; this step can be guided by stereotaxy. An entry site must be selected that provides a direct, linear route to the cyst to accomplish two distinct goals:

1. One is to minimise any torque on the cortical or intraventricular neural tissue.
2. The second is to allow direct, inline access to the distal edge of the cyst wall; the edge abutting the CSF-containing cistern into which the cyst will be fenestrated.[47]

The application of stereotactic techniques to endoscopy enhances both precision and safety. The custom made modifications in the endoscope can provide multiple capabilities to bring about such functions.[2,38,39] Stereotactic endoscopy has the advantage of control over depth penetration and precise trajectory to deep-seated lesions under direct vision.

In colloid cysts stereotactic aspiration may at times be unsuccessful due to the viscosity of the intracystic colloid and the displacement of the cyst away from the aspiration needle. The CT/MR-guided stereotactic endoscopic technique gives the opportunity to fenestrate the cyst wall under direct visual control. After CT-guided stereotactic puncture of the right lateral ventricle with the foramen of Monro as the target, a steerable endoscope is introduced and the foramen of Monro is passed. The wall of the cyst is fenestrated and coagulated by means of monopolar (or laser) coagulation. Continuous rinsing is mandatory to preserve clear vision.[20]

Stereotactic endoscopic resection of intra-axial brain tumours using an endoscopic system consisting of a stereotactic guiding tube and a fine endoscope was reported by Otsuki et al.[55] The stereotactically inserted guiding tube acts in the place of brain retractors to expose deep-seated pathological lesions, which are then visualised by means of a fine endoscope. The lesion was then treated by various microsurgical techniques such as laser vaporisation. This system was reported to be particularly useful for removing small intra-axial tumours in deep or eloquent areas which are difficult to resect using ordinary surgical techniques. Johnathan et al.[35] developed a minimally invasive microsurgical technique for intraventricular surgery using parallel endoscopy to visualise the lesion. Surgical resection was performed via an 11.5 mm transparent conduit (neuroendoport) deployed under stereotactic guidance, termed as stereotactically guided endoscopic port (SEP) surgery. They reported that this technique was not limited by the vascularity, friability or size of the lesions. They concluded that SEP surgery for colloid cysts and intraventricular tumours was a safe and effective alternative to conventional microsurgical resection.

188 Involuntary Movements: Anatomy and Pathophysiology

Srinivasan AV

INTRODUCTION

The extrapyramidal system (EPS) is more of a functional concept derived primarily from the study of patients with neurological disease than an anatomical or physiological entity. The term "extrapyramidal" was first used by Wilson while describing Wilson's disease.

Extrapyramidal disorders lead to a category of neurologic illnesses now more often referred to as movement disorders. Such a disturbance may cause excessive movements—Huntington's disease (HD) or a poverty of movements—Parkinson's disease (PD), or a disturbance of tone, posture or other manifestations.[1]

The EPS is phylogenetically old. Much of its functions are confined to modulation of the pyramidal system rather than by direct projection to the spinal cord. The term basal ganglia (BG) is given to the grey nuclear masses that are located subcortically and are derived from the telencephalic ganglionic hill of the embryo.[4]

These ganglia consist of the caudate nucleus (CN), putamen, globus pallidum, claustrum and amygdaloid nuclear complex. In addition, the related structures, i.e. substantia nigra (SN), subthalamic nucleus (STN) and red nucleus (RN) are also included.[13] The CN and putamen are functionally related as also the SN and globus pallidum.

The caudate, putamen and pallidum are known as corpus striatum. The caudate and putamen are together called neostriatum and the phylogenetically older globus pallidus (GP) or pallidum carries the name paleostriatum. For purposes of discussion, striatum refers to the neostriatum. The putamen and GP are commonly spoken of as one unit using the term lentiform nucleus or lenticular nucleus with the putamen lateral to the GP, which lies like a wedge between the internal and external capsules.[9]

The putamen develops from the telecephalon while the pallidum develops from the diencephalon. The caudate and putamen are identical histologically. They contain few large and many small neurons with the small cells predominating in the ratio of 20:1. The dendrites may be spiny or aspiny.[13]

The most common cell type in the striatum is small and spiny and contains GABAergic neurons along with either substance P (SP) or enkephalin (ENK). The small spiny neurons are the primary source of striatal efferents. The small aspiny neurons are cholinergic.[5]

The microstructure of the striatum consists of a matrix and striosomes. In the CN the matrix contains cholinergic neurons while the striosomes primarily contain SP neurons (D1 dopamine receptors) and ENK neurons (D2 dopamine receptors).

The striosome—matrix is not evident in the putamen as in the caudate and consists mostly of matrix. The cholinergic neurons of the matrix are facilitatory to the projection neurons and are inhibited by dopamine.[4]

The GP is medial to the putamen and separated by the external medullary lamina. Internally, the GP is divided by the internal medullary lamina into a lateral part [globus pallidus externa (GPe)] and a medial part [globus pallidus interna (GPi)].[13]

The GP contains only about 5% as many cells as the striatum and all are large neurons. Neurons throughout the GP use primarily gamma-aminobutyric acid (GABA) as a neurotransmitter and less use Ach. The associated neuropeptide is SP in the GPi and ENK in the GPe.[4]

The SN consists of the substantia nigra compacta (SNc) which contains large melanin containing dopaminergic neurons and substantia nigra reticulata (SNr) which contains large, multipolar, non-pigmented GABAergic neurons similar to those in the GPi.[5] The SNr is closely related functionally to GPi.

Other important structures involved in the extrapyramidal motor control system include the thalamus, RN, the brainstem reticular formation, the inferior olivary nucleus in the medulla, zona incerta, the pedunculopontine nucleus (PPN), and the grey matter of the quadrigeminal plate.[10,13]

The PPN is a cholinergic nucleus that lies caudal to the SN in the brainstem tegmentum, partially buried in the superior cerebellar peduncle. It receives afferents from GPi and sends cholinergic projections to the dopaminergic neurons in the SNc. This may be involved in locomotion, and dysfunction of the PPN may be important in the pathophysiology of the locomotor and postural disturbances of Parkinsonism.

The BG have rich connections with one another and also with brainstem structures, the cerebral cortex and with lower centres. In essence, the cerebral cortex projects to the striatum which in turn projects to the GP and SNr; efferents go to the thalamus, which projects back to the cerebral cortex primarily to the motor areas.

MAJOR BASAL GANGLIA PATHWAYS

Connections of the Basal Ganglia

The BG is part of a complex network of neuronal circuits organised in parallel to integrate activity from different cortical regions.[7,13]

Striatal Afferents

Striatum forms the main input zone of the BG.

Corticostriate fibres: The major inputs to CN are from the entire ipsilateral neocortex which is arranged somatotopically. The head of the CN receives afferents from the frontal lobe, the body from the parietal and occipital lobes and the tail from the temporal lobe.

The putamen (mainly medium spiny neurons) receives projections from areas 4 and 6, the parietal lobe and perirolandic motor areas.

Thalamostriate fibres: The striatum receives afferents from the dorsomedial and ventral anterior nucleus of the thalamus.[13]

Nigrostriate fibres: The SNc sends fibres to the striatum which liberate dopamine at their terminals and are inhibitory in function.[6]

Brainstem striatal fibres: Brainstem raphe nuclei from the locus ceruleus also send ascending fibres to the striatum.[7,13]

Striatal Efferents

The primary efferent fibres project to the GPi. They have GABA as their neurotransmitter. The CN also sends fibres to the putamen and to the thalamus.[4]

Striatonigral fibres: Fibres pass from the CN and putamen to the SN. Some of the fibres use GABA or Ach as the neurotransmitter while others use SP.[3]

Pallidal Afferent

Striatopallidal fibres: The principle afferents to GP are from the CN and putamen. They have GABA as their neurotransmitter.

There are also afferents from STN, thalamus, SNc and from areas 6 and 4.

Pallidal Efferent

The pallidal efferents are the principal outflow of the BG. They are:

- Fasciculus lenticularis
- Ansa lenticularis
- Pallidotegmental fibres which arise from GPi
- Pallidosubthalamic fibres which arise from GPe.

Both the ansa lenticularis and fasciculus lenticularis have the same origin, the GPi, the same destination, the thalamus; the difference is that the fasciculus penetrates through and the ansa curves around the internal capsule.

Pallidofugal fibres are often discussed in terms of their relationships to the "fields of Forel".

Pallidofugal fibres stream into the prerubral field (lies just rostral to the RN, Forel fields H) and as they ascend towards the thalamus, they divide into a dorsal stream (consist of the lenticular fasciculus, Forel field H2) and ventral stream (consist of the thalamic fasciculus, Forel field H).[1,4]

Subthalamic Nucleus

The connection to STN is the only pallidal efferent to arise from GPE, all others arise from GPi. The STN sends back fibres to GPe and to GPi through the subthalamic fasciculus.

Substantia Nigra

Afferents: This includes:

- Striatonigral fibres: SNr receives fibres from the striatum, Gp and STN

Efferents: This includes:

- Nigrostriatal fibres
- Nigrothalamic fibres
- Nigrotectal fibres: It connects SN with the ipsilateral superior colliculus and is concerned with the control of eye movements. There are also connections between SN and PPN and reticular formation.[4]

FUNCTIONAL ORGANISATION OF THE BASAL GANGLIA AND OTHER PATHWAYS

Afferent projections to the striatum arise from all areas of the cerebral cortex, the intralaminar nuclei of the thalamus, mesencephalic SN, and from the locus ceruleus and raphe nuclei. There is also a projection from the cerebral cortex to the STN. The major efferent projections are from the GPi and SNr to the thalamus and brainstem nuclei such as PPN. The GPi and SNr project to ventral anterior and ventrolateral thalamic nuclei. The GPi also projects to the centromedian thalamic nuclei and the SNr projects to the mediodorsal thalamic nuclei and superior colliculus. The ventral anterior and ventrolateral thalamic nuclei then project to the motor and premotor cortex. This circuit is somatotopically organised throughout the loop so that the leg is represented dorsally, the face ventrally and the arm in between. Movement related neurons are found mainly in the posterolateral region of BG.

The BG have dense internuclear connections exemplified by the box and line circuit diagrams that have become entrenched in the literature. Five parallel and separate closed circuits through the BG have been proposed. These are the motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal and limbic loops. It is now generally agreed that these loops form three major divisions—sensorimotor, associative, and limbic, that are related to motor, cognitive and emotional functions, respectively.[9]

The functions of the sensorimotor striatum are subserved mainly by the putamen, which derives its afferent cortical inputs from both motor cortices. Sensorimotor pathways are somatotopically organised and the pathway ultimately terminates in the premotor and primary

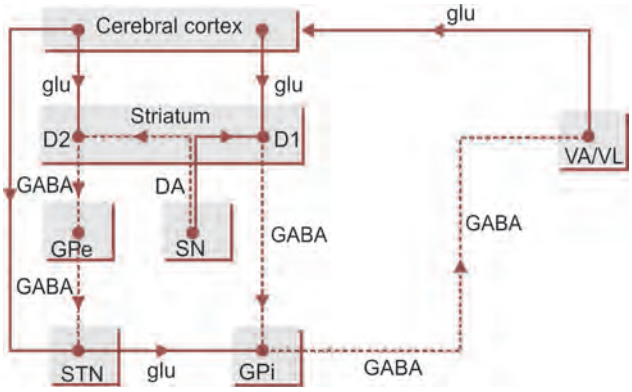

Fig. 1: Modified schematic drawing of the internuclear connections of the basal ganglia, including (A) direct and indirect pathways and depicting (B) the direct pathway. (See figure 2 for a depiction of the indirect pathway). Excitatory pathways in solid lines, inhibitory pathways in dotted lines. GPe = external segment of the globus pallidus; SN = substantia nigra; STN = subthalamic nucleus; GPi = internal segment of the globus pallidus; VA/VL = ventral anterior/ventrolateral thalamic nuclei; glu = glutamate; GABA = γ-aminobutyric acid; D2 = dopamine D receptor; D1 = dopamine D receptor; DA = dopamine

motor cortices and the supplementary motor area. Cognitive functions are managed by the associative striatum. In this pathway, the dorsal CN receives afferent input from the homolateral frontal, parietal, temporal and occipital cortices. Projections from this pathway ultimately terminate in the prefrontal cortex. The limbic striatum subserves emotional and motivational functions. Its input derives from the cingulate, temporal, and orbitofrontal cortices, the hippocampus, and the amygdala. It comprises mainly the ventral striatum with ultimate projections to the anterior cingulate and medial orbitofrontal cortices. Whether these divisions are interconnected or organised in parallel remains a topic of debate.[13]

Within each BG circuit lies an additional level of complexity. Each circuit contains two pathways by which striatal activity is translated into pallidal output. These two pathways are named the direct and indirect pathways, depending on whether striatal outflow connects directly with the GPi or first traverses the GPe and STN (Fig. 1). The direct and indirect pathways have opposite effects on outflow neurons of the GPi and SNr. A closer look at the motor circuit illustrates this principle.

In the motor direct pathway, excitatory neurons from the cerebral cortex synapse on putaminal neurons, which in turn send inhibitory projections to the GPi and its homologue, the SNr. The GPi/SNr sends an inhibitory outflow to the thalamus. Activity in the direct pathway disinhibits the thalamus, facilitating the excitatory thalamocortical pathway and enhancing activity in its target, the motor cortices. Thus, the direct pathway constitutes part of an excitatory cortical-cortical circuit that functions to maintain ongoing motor activity.

In the indirect pathway, excitatory axons from the cerebral cortex synapse on putaminal neurons. These neurons send inhibitory projections to the GPe. The GPe sends an inhibitory projection to the STN. The net effect of these projections is disinhibition of the STN. The STN in turn has an excitatory projection to the GPi. Activity in the indirect pathway thus excites the GPi/SNr, which in turn inhibits the thalamocortical pathway.[1,4,9,13]

Thus, the net effect of increased activity in the indirect pathway is cortical inhibition. The striatum also receives a robust afferent input from the SNc. This projection, from the SNc, an important modifier of striatal activity, facilitates activity in the direct pathway and inhibits activity in the indirect pathway, thus promoting cortical excitation through both pathways.

In addition to these pathways there are other closed loop circuits, which seem designed to modulate and regulate the excitability of the BG themselves.[9,13] Several circuits may be recognised which are as follows:

- The centromedian/parafascicular (CM-Pf) thalamic nuclei striatum GPi CM-Pf circuit, which is probably a positive feedback loop leading to increased neuronal activity
- The CM-Pf STN GPi CM-Pf circuit, which is probably a negative loop leading to reduced neuronal activity
- The STN GPe STN circuit, which is an excitatory-inhibitory loop with "autostabilising" characteristics
- The STN-GPe/GPi dual projection, which is an "open" but inter-connected loop by which the STN might induce excitation and inhibition of the same GPi neurons within less than 5 ms
- The primary motor cortex (area 4) STN GPi motor thalamus area 4 loop, which is perfectly suited to provide inhibitory feedback signalling to the cortex and probably very relevant for the termination of movement.

The dopaminergic system innervates all BG nuclei and probably exerts a powerful modulatory control of the above-summarised circuits. The mesencephalic dopaminergic system stems from three main cellular groups known as areas A8, A9 and A10. Mesencephalic dopaminergic neurons are now divided according to their topographical distribution and chemical characteristics.[13] Neurons in the dorsal tier of the SN mesencephalic region (including some SN cells, VTA, and retro rubral area) are loosely spaced and are positive for calbindin D. These neurons project mainly to the limbic and associative areas of the striatum. On the other hand, cells from the ventral region of the SN mesencephalic region, which are calbindin D negative but rich in dopamine transporter, give rise to the major dopaminergic projection to the motor regions of the BG.[7,13]

Two different types of axonal projections have been recently distinguished:

1. Neurons with a long axon travelling directly to the striatum and emitting no collaterals, which mainly innervate specific zones of the striatum known as "patches" or striosomes.

2. Neurons producing axons that are profusely arborised and mainly innervate extrastriatal nuclei such as the GPe, GPi, STN and even the thalamus. The latter type of cells in the ventrolateral tier of the SN, which appear arranged in columns penetrating into the SNr, seems to be the first to degenerate in PD.[4,11]

Disorders of the BG result in prominent motor dysfunction, though not generally in frank weakness. The absence of direct primary or secondary sensory input and the lack of a major descending pathway below the level of the brainstem suggest that the BG moderates rather than controls movement. In the simplest sense, the direct and indirect pathways have opposite effects on the cerebral cortex. The direct pathway is important in initiation and maintenance of movement and the indirect pathway helps with suppression of extraneous movement.[7] From this model of BG connectivity, hypotheses about the motor function of the BG have been proposed. One hypothesis is that the relative activities of the direct and indirect pathways serve to balance the facilitation and inhibition of the same population of thalamocortical neurons, thus controlling the scale of movement. A second hypothesis proposes that direct pathway mediated facilitation and indirect pathway mediated inhibition of different populations of thalamocortical neurons serve to focus movement in an organisation reminiscent of centre surround inhibition. These hypotheses related activity in the direct and indirect pathways mainly to rates of firing in the STN and GPi.[7,12,13] Thus, death of neurons in the SNc decreases activity in the direct pathway and increases activity in the indirect pathway (Fig. 2). These changes cause an increased rate of firing of subthalamic and GPi neurons with excessive inhibition of thalamocortical pathways and produce the behavioural manifestations of bradykinesia in PD. On the other hand, selective loss of indirect pathway neurons, as in HD, interferes with suppression of involuntary movements.[12] Choreic involuntary movements are the usual result. Direct electrophysiological recordings of the STN and GP during stereotactic functional neurosurgical procedures confirm that the GPi and STN are overly active in patients with PD. The activity of these nuclei returns toward normal with effective pharmacotherapy, and chorea is associated with lower firing rates of neurons in these nuclei. Unfortunately, this model does not completely explain some important features of movement disorders. For example, bradykinesia and chorea coexist in HD and in treated PD.[2,8] Thalamic lesions that might be expected to worsen Parkinsonism by reducing excitatory activity do not do so. Pallidal lesions that might be expected to worsen chorea by decreasing inhibition in thalamocortical pathways instead are dramatically effective at reducing chorea. The model is even more problematic when applied to dystonia. It has been suggested that, in dystonia, there is overactivity of both the direct and indirect pathways. Yet, intra-operative recordings in dystonia show low rates and abnormal patterns of neuronal activity in the GPI.[2,8,14] A simple change in firing rate of the STN or GPi is thus insufficient to explain the underlying physiology of dystonia. It is likely that disordered patterns and synchrony of pallidal firing as well as changes in sensorimotor integration and the control of spinal and brainstem reflexes are important.

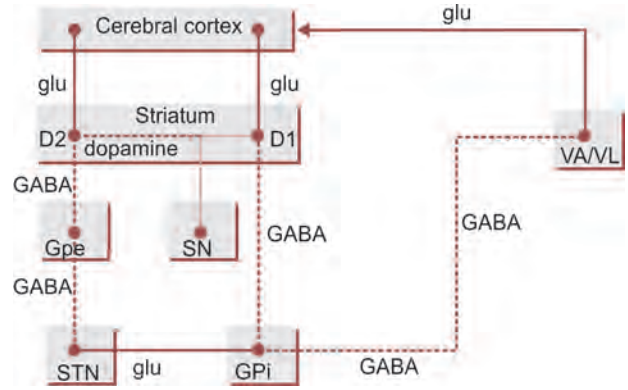

Fig. 2: Modified schematic drawing of the functional activities of the direct and indirect pathways in Parkinson's disease. Reduced dopaminergic facilitation of the direct pathway and inhibition of the indirect pathway due to death of dopaminergic neurons causes increased firing and increased inhibition of thalamocortical pathways, causing reduced inhibition in thalamocortical pathways with the production of excessive or involuntary movements

190 Surgery for Movement Disorders

Paresh K Doshi, Animesh Upadhyay

INTRODUCTION

Movement disorders, such as Parkinson's disease (PD), tremor and dystonia, are among the most common neurological conditions, and affect millions of patients. Although medication is the mainstay of therapy for movement disorders, neurosurgery has played an important role in their management for the past 60 years. Surgery is now a viable and safe option for patients with medically intractable PD, essential tremor and dystonia.

HISTORY OF MOVEMENT DISORDER SURGERY IN INDIA

Stereotactic surgery started in India as early as 1960. Balasubramaniam and Ramamurthi performed chemopallidectomy using Cooper's balloon in 1962.[18] From 1964 they used the Leksell's apparatus to perform thermal lesions for movement disorders.[5] Kalyanaraman performed bilateral simultaneous thalamotomies in patients with various movement disorders using two different stereotactic apparatus (Sehgal frame and Leksell frame). They observed that the complication rate was acceptable and no greater than staged procedures in patients with advanced PD. In patients with bilateral intention tremors this formed a good surgical option as it avoided two hospitalisations.[32]

Another area of interest was cerebral palsy. Following the work of Narabayashi,[56] Balasubramaniam and his colleagues operated upon a large number of cerebral palsy patients. As their experience evolved they chose different targets depending on the predominant symptom complex. For rigidity they made a lesion in the area below the ventrolateral nucleus (VL); for dyskinesias they used a variety of targets including the ventralis intermedius nucleus (Vim), the centromedian nucleus (CM) and the dentate nucleus of the cerebellum. As most of these surgeries were done under general anaesthesia verification of the electrode placement by stimulation as done in PD was not possible. Stimulation was still done to exclude electrode placement in the corticospinal tract.[33] They later on introduced stereotactic dentatectomy for patients with predominant spasticity. They found that VL and sub-VL lesions were effective for rigidity, whereas for patients with a mix of rigidity and spasticity these lesions had to be supplemented by dentatectomy. Patients with sensory induced involuntary movements benefited from centromedian thalamotomy.[3]

For severe hyperkinetic disorders, Kanaka found hypothalamotomy to play a distinct role in their management. She observed that it works because the area destroyed forms part of the limbic system. It seemed to be more on the "effector" side. It does not cause any morbidity. However, in the management of hyperkinetic behaviour disorders the first target to be destroyed used to be the amygdaloid nucleus. If this operation failed hypothalamotomy was performed.[4]

HISTORY OF MOVEMENT DISORDER SURGERY—WORLD (EXCLUDING INDIA)

Various surgical approaches, such as resection, lesioning, stimulation and others, have been used to treat patients with movement disorders. Craniotomies were performed for the resection of the motor cortex,[17] cerebral peduncles,[81,82] and a variety of subcortical lesioning procedures.[70] Irving Cooper[19] first reported the effects of ligation of the anterior choroidal artery for PD in 1953. Six patients were treated with eight ligations, which resulted in significant alleviation of rest tremor, rigidity and contralateral cogwheeling. It was not until the introduction of stereotaxis by Spiegel et al.[69] in 1947, and later by Leksell[46] in 1949, that a more accurate, less invasive and more consistent placement of lesions in various subcortical locations became feasible. The development of stereotaxy led to a variety of lesioning procedures of the basal ganglia and the thalamus for the treatment of rigidity and tremor in the 1950s and 1960s. The motor thalamus and the pallidal targets in the ventral and posterior portions of the globus pallidus internus (GPi) as well as the pallidal projections were considered to be the most effective targets. However, it was the advent of L-dopa in the mid-1960s and its significant clinical benefits that led to a dramatic decrease in surgery for PD. For the next 20 years, surgery for movement disorders was predominantly limited to thalamotomy[2] for the treatment of tremor and pallidotomy and thalamotomy for dystonia.[50,59]

It was not until the late 1980s that there was a re-emergence of interest in the neurosurgical treatment for PD due to the increasing realisation of the limitations of PD medications and the side effects of L-dopa. This led

to a resurgence of lesioning surgeries such as pallidotomies for PD. The initial Leksell[72] target of pallidal lesions for treatment of PD was modified and repopularised by Laitinen et al.[42,43]

Original analytical descriptions of thalamic nuclei and circuitry by Hassler,[29] Hassler et al.[28] and Macchi and Jones[52] and basal ganglia circuitry by Delong et al.[21,22] also served as a foundational substrate for newer targets for therapeutic interventions using stereotactic techniques. The ability of electrical impulses to modify functional outcome in certain brain regions was identified more than 200 years ago, in 1809, by Rolando.[25] The use of electrical stimulation to understand and map the function of the human brain and its circuitry became commonplace in the 20th century.[15,16] Early explorations by Hassler et al. revealed that acute low-frequency stimulation during stereotactic exploration for ablation of the pallidum could augment tremor, whereas high-frequency stimulation at 25–100 Hz had the opposite effect.[15] These observations paved the way for the future development of chronic electrical stimulation therapies for the management of movement disorders. The first systematic use of chronic deep brain stimulation (DBS) for the treatment of movement disorders is attributed to Bechtereva et al.[6] from Russia. Beginning in 1967, they reported benefits with chronic DBS of the thalamus, striatum and pallidum. But it was not until the 1980s that Brice and McLellan,[11] Blond and Siegfried,[10] Siegfried and Shulman[66] and Benabid et al.[9] published reports of the use of chronic electrical stimulation or DBS for the treatment of movement disorders, thus ushering in a new era of functional neurosurgery for movement disorders. DBS has similar efficacy as that reported with various lesioning procedures (e.g. pallidotomy and thalamotomy). However, the superior safety profile of DBS relative to lesioning procedures, particularly bilateral thalamotomy and pallidotomy, has made it the procedure of choice in countries where access to this technology is available. DBS, with its inherent features of reversibility and adjustability, has gained popularity and emerged as the neurosurgical standard of care for movement disorders, such as PD, dystonia and essential tremor, over the past 20 years.[1]

Movement disorders can be classified according to the predominant motor manifestations (Table 1). For this chapter we have reviewed the therapies for more common movement disorders, i.e. tremors and various forms of dystonias. Surgical treatment for PD is reviewed elsewhere.

Spinocerebellar degeneration

Table 2: Tremor classification and treatment

Tremors classification
Parkinson's disease
Essential tremor
Post-traumatic and Post-hemiplegic tremors
Tremors from multiple sclerosis
• STN is the target of choice for PD tremor
• Vim nucleus of thalamus is the target of choice for other tremors
• Thalamotomy for unilateral cases/thalamic stimulation for unilateral or bilateral cases
• Bilateral thalamotomy has high morbidity
• More than 90% success rate in relieving tremors by either procedure
• Major morbidity is less than 5%

TREMORS

Tremor is an unintentional (involuntary), rhythmical alternating movement that may affect the muscles of any part of the body. Tremor is caused by the rapid alternating contraction and relaxation of muscles (Table 2).

The thalamus is involved in the genesis of various types of tremors. It functions as a relay nucleus in the cortico-basal ganglia-thalamocortical loop in Parkinsonian tremor, the premotor cortex and cerebellar thalamic connections in cerebellar types of tremors, and the premotor cortex and connections with the triangle of Mollaret[27] in essential tremor and brainstem tremor, or Holmes tremor.[23] Although part of the motor thalamus [ventralis oralis posterior (Vop) and ventralis intermedius] is considered as the target of choice for tremor relief by stereotactic neurosurgery[67] recently, tremor suppression in PD was also demonstrated after surgery of the globus pallidus[51,54] and subthalamic nucleus (STN).[37,63] Tremor can be objectively evaluated using –NIH essential tremor consortium diagnostic criteria for essential tremor[12] and Fahn-Tolosa-Martin tremor rating scale for tremor outcome.[71] Good control of tremor is defined as more than 66% control; moderate is 33–66% and poor outcome is defined as tremor control less than 33%.

The most common types of tremor amenable to stereotactic neurosurgery are PD tremor, essential tremor, tremors due to multiple sclerosis (MS), stroke and post-traumatic tremor. The Vim nucleus of the thalamus, as defined by Hassler, is the currently preferred target for tremor suppression (Fig. 1). Thalamotomy or thalamic stimulation can be offered for unilateral tremor. However, bilateral thalamotomy carries a significant risk of morbidity of speech and cognition and hence is not

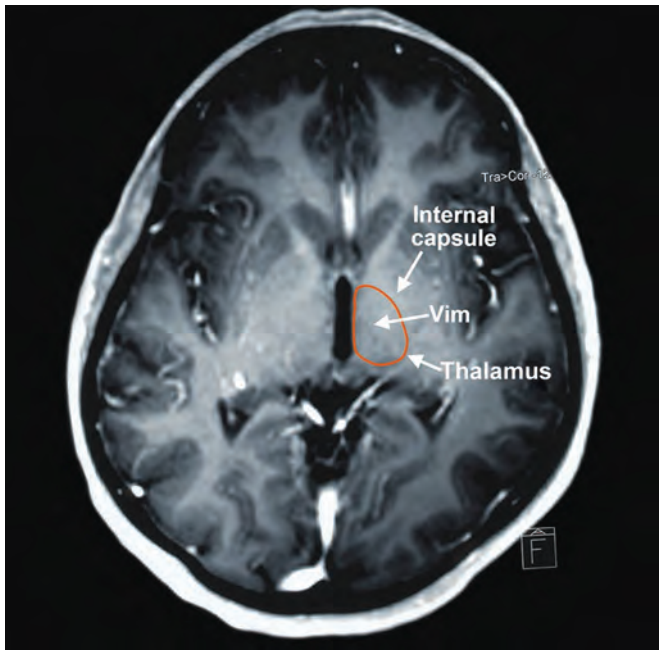

Fig. 1: MRI at the level of AC-PC showing different thalamic nuclei including Vim

currently practiced. The results of thalamotomy and thalamic stimulation are dependent on the type of tremor aetiology and are discussed separately.

Parkinsonian Tremor

Unilateral thalamotomy results in a permanent significant improvement of Parkinsonian tremor in approximately 80% of the patients. Permanent morbidity is 4–47% and mortality is below 1%.[31,34,55,64,77] In 1991, Benabid and his co-workers reported tremor suppression in 88% in 26 patients undergoing thalamic stimulation with very low morbidity, making bilateral surgery possible.[8] These findings were confirmed in a multicentre European study.[47] Lozano and associates described an improvement of tremor after unilateral pallidotomy in patients with advanced PD.[51]

Pallidal and STN stimulation may give both striking and lasting suppression of Parkinsonian tremor. Permanent adverse events are less frequent and less severe with these targets after bilateral stimulation as compared to the thalamic target. Another advantage of this procedure is simultaneous reduction in rigidity and dyskinesia with improvement in bradykinesia. These procedures have replaced thalamic surgery in patients with advanced PD even with severe tremor. STN is the target of choice for advanced PD, including patients with severe tremor. We prefer to perform bilateral surgeries (especially DBS) in PD patients as we feel that PD is a bilateral disease and will eventually need bilateral control to improve quality of life. However, there are some exceptions, for example, in a small proportion of Parkinsonian patients with a long history of tremor and a slight bradykinesia, well-controlled by medication, a unilateral STN stimulation can be considered. Patients who cannot afford DBS can also be offered STN lesioning with good outcome.

We have performed nine thalamotomies, one thalamic stimulation, one unilateral subthalamic stimulation and three bilateral subthalamic stimulation for pure PD tremors. Of the patients undergoing thalamic surgery, six had good control of tremors whereas four had moderate control. However, all patients undergoing subthalamic surgeries had good tremor control.

Essential Tremor

Essential tremor is also known as familial tremor as it runs in families. It is characterised by tremors on action or posturing. There are no tremors at rest. Usually, they remain under control for long years up to 10–15 years. When the tremors become severe, the patient can be considered for surgical intervention.

The number of patients referred for surgery is rather small as compared to PD. Vim nucleus of the thalamus is the preferred target by most workers. A permanent satisfying tremor relief was demonstrated in the contralateral extremities of 68.7% and 95% for coagulation and stimulation.[68] Schurman demonstrated that, after 2 years follow-up, thalamotomy and thalamic stimulation were equally effective in tremor suppression, but thalamic stimulation had considerably less adverse effects and made bilateral surgery possible.[64,65]

We have performed one thalamotomy and five bilateral thalamic stimulations for essential tremor. Of this, four patients had good control whereas one patient has moderate control of tremor and the other has poor tremor control. We have not been able to evaluate the cause of these failures as they have been lost to follow-up. It could be possible that reprogramming using a different set of stimulation parameters may achieve better tremor control.

Post-Traumatic and Post-Hemiplegic Tremor

These tremors are mainly postural and action tremor. They are more violent in nature as compared to the essential or Parkinsonian tremors. They manifest following recovery from the original cerebral insult and can be of considerable disability to the patient. Pharmacotherapy is generally not effective. The surgical target for their treatment is once again the Vim nucleus. Various workers, for the treatment of this disabling tremor,[83] have performed thalamic stimulation or thalamotomy. The results have been variable as far as tremor control was concerned, but they all reported significant improvement in the quality of daily living.

We have performed six thalamotomies and one thalamic stimulation for this indication. Five patients had good tremor control and two had moderate control.

Multiple Sclerosis Tremors

Of the various disabilities from MS, tremor also forms one important component. The tremors are coarse and

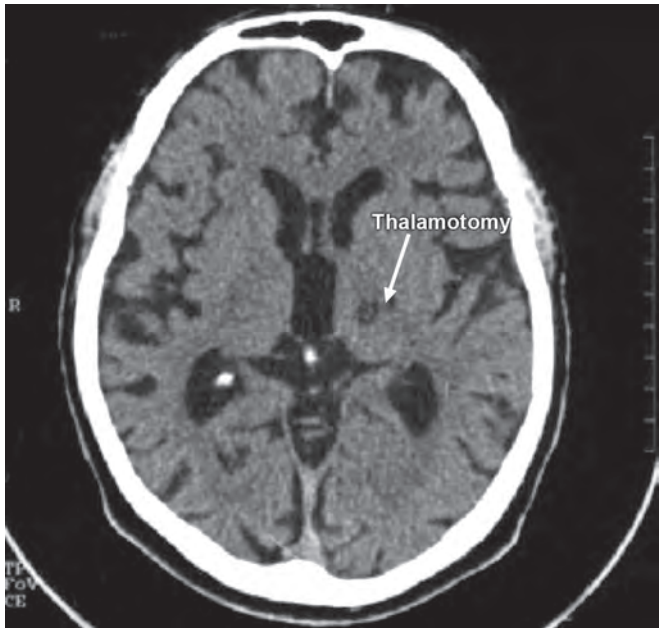

Fig. 2: Left sided thalamotomy for essential tremor (arrow)

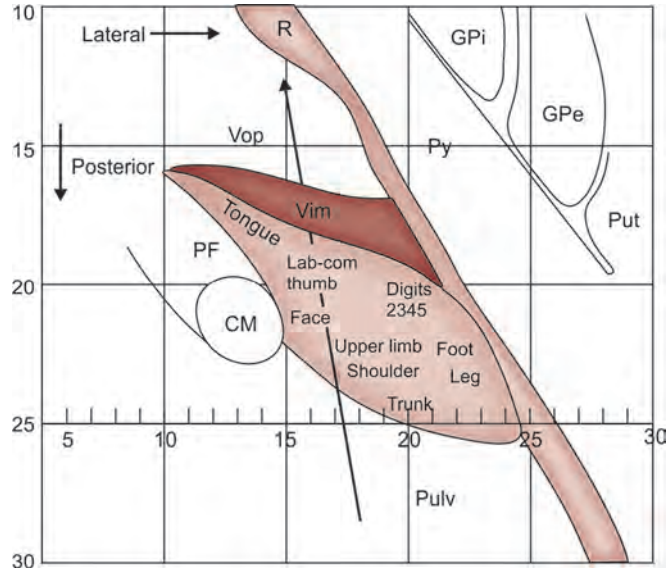

Fig. 3: Somatotopic organisation of Vim target (marked in red)

have a large amplitude proximal component. They are also associated with neck tremors or dysarthria. These tremors are very difficult to control, especially the proximal component. Besides, they also have very low side effect thresholds precluding use of higher stimulation parameters.[49,83] We have performed one surgery for MS tremors with only partial improvement.

The Vim Target

The Vim nucleus is the common lesioning and DBS target used for the treatment of tremors (Figs 1 to 3).[7,57] In the somatotopic organisation of the Vim nucleus the face area lies medially, followed by the upper extremity laterally and the lower extremity is the most lateral situated close to the internal capsule (Fig. 3). The Vim nucleus of the thalamus has neurons that fire in synchronous bursts with the tremor frequency and are called tremor cells (TCs). The TCs are believed by some to act as tremorigenic pacemakers.[38] The DBS target for tremor control is the electrophysiologically defined Vim. This electrophysiologically defined motor thalamus (Vim) has TCs and kinesthetic cells, and it lies immediately anterior to the cutaneous receptive cells, which lie in the sensory thalamus.[1] The somatosensory relay nucleus ventralis caudalis (VC) of the thalamus lies immediately posterior to Vim. The VC has specific neurons that respond to tactile stimulation in small, receptive fields. The Vop nucleus lies immediately anterior to the Vim. The internal capsule lies lateral to the Vim. The Vop receives afferents from pallidal neurons and the Vim receives afferents from the cerebellar neurons (cerebellothalamic fibres). There is some degree of overlap and interdigitation between these two nuclei.[38] Vim is not visible as a separate nucleus on routine MRI sequences. We base our targeting on CT scan. As we use a CRW stereotactic system, which is gantry independent, we can align the anterior commissure (AC) and posterior commissure (PC) on the same plane. We base our target 2/10–3/10 anterior to PC and ½ of AC-PC length. We thereafter examine its relationship to the internal capsule. Microelectrode recordings (MER) are used to identify TCs and stimulation-based responses to finally find the target. Usually tremor control is seen on the operating table itself. If the tremors are not controlled alternative trajectories are explored depending on the MER and stimulation responses.

DYSTONIA

Dystonia is defined as an involuntary movement disorder characterised by repetitive, patterned or sustained muscle contractions causing twisting movements or abnormal postures.

Dystonia is classified as primary or secondary. Primary dystonia is the classical familial dystonia described by Oppenheim. It is also known as dystonia musculorum deformans (DMD). DMD is a disease of young people, with most cases commencing in childhood (Age: 0–12 years), although some do not appear till the age of 10 years; adult onset is rare.[53] Primary idiopathic dystonia refers to dystonia with no discernible aetiological factor responsible for its onset. Patients with primary idiopathic dystonia have normal imaging findings, cerebrospinal fluid composition and laboratory test examinations. A subset of patients with primary dystonia have a DYT-1 mutation on chromosome 9q,[44] whereas others are sporadic cases. Secondary dystonia occurs due to a variety of disorders ranging from hereditary neurological syndromes, like Wilson's disease and Huntington's disease, to perinatal cerebral injury causing cerebral palsy or later on in life secondary to head

trauma, brainstem lesions or brain tumours. Tardive dyskinesia is another subset of dystonia that results from super-sensitivity of the post-synaptic dopamine striatal receptors due to long-term administration of dopamine receptor blocking agents such as neuroleptics.[35] The most common drugs implicated are metoclopramide, olanzapine and risperidone. Risperidone appears to have fewer dystonic effects, only clozapine has been shown to have a lower risk of tardive dyskinesia than older antipsychotics. These are commonly used to treat psychiatric conditions. Another form of dystonia that is amenable to surgical treatment is a focal dystonia known as Writer's cramp. This is a task specific dystonia. Patients develop abnormal posturing during performance of a particular task like writing, playing a musical instrument, drawing, etc. whereas they are completely normal during rest and with other activities.

Dystonia can also be classified according to the affected body part. In focal dystonia, a single region of the body is affected, such as in blepharospasm (eyes), cervical dystonia/torticollis (neck) and spasmodic dysphonia or laryngeal dystonia.[39] In segmental dystonia, two or more adjacent body parts are affected, such as cranial-cervical dystonia, or brachial dystonia. Generalised dystonia refers to dystonia involving most body parts. Currently accepted clinical rating scales for dystonia include physicians global dystonia rating scale (PGDS), The Burke-Fahn-Marsden (BFM)[14] scale, and the unified dystonia rating scale (UDRS). We use the BFM score for our pre-operative and post-operative work up.

Primary, generalised dystonia of DYT-1-positive[44] or non-DYT-1 types, as well as patients with idiopathic cervical dystonia can obtain the best motor benefits with bilateral GPi DBS.[79] Patients with juvenile-onset idiopathic dystonia whose age of onset is older than 5 years and who do not have multiple orthopaedic deformities also have a good response to surgery.[60] Appendicular symptoms (e.g. those affecting the limbs) appear to respond better than axial symptoms. With regard to focal dystonia, ideal surgical candidates are those with cervical dystonia.[45] The results of DBS for secondary dystonia are inconsistent. In general, DBS for secondary dystonia is less effective than for primary generalised dystonia, particularly in those patients with an identifiable structural brain abnormality. The only exception is tardive dystonia, which has been reported to respond well to surgery in a small number of patients[24] (Table 3).

Table 3: Classification of dystonia

Dystonia
Primary/Secondary
• Usually for hemidystonia or generalised dystonia
• GPi is the target of choice
• Pallidotomy in hemidystonia/pallidal stimulation for hemidystonia or generalised dystonia
• Results are variable

Indications for Surgical Treatment of Dystonia

It is difficult to define surgical indications for dystonia; the clinical picture varies enormously and there are many different causes. Surgery does not alter the progress of dystonia or the underlying neurological deficits. Thus, not withstanding how successful the surgery is, the eventual outcome is determined by the subsequent disease progress and the underlying neurological deficit. Selection of suitable candidates for dystonia surgery is extremely crucial. Patients with primary generalised dystonia, also those who are DYT1 gene positive, are the best surgical candidates. Primary dystonia of sporadic variety also benefits from surgery. Secondary dystonia, especially hemi-dystonia, which has been stabilised, can be offered a surgical option. Patients whose progress has halted and have been stable for the last 6 months or more could also be offered surgical treatment. Severe pain from dystonia also forms one of the indications for surgical intervention. It is important to exclude the primary dystonias that are responsive to medical treatment with trihexyphenidyl hydrochloride or Levodopa.

Surgical Options in Dystonia

The GPi is currently the most common target for treating dystonia[76] although, earlier, the thalamus (Voa, ventrolateral)[73] and subthalamus have been used. The GPi DBS target is the posteroventrolateral GPi, which is the predominant motor territory of the nucleus (Fig. 4). The Gpi is well-visualised on MRI (inversion recovery and T2 sequences) and we routinely use MRI to define the surgical target and identify the internal capsule and the optic tracts (Figs 5 and 6). The globus pallidus is divided into two anatomic segments: (1) internal (GPi) and (2) external (GPe). Although these segments are separated

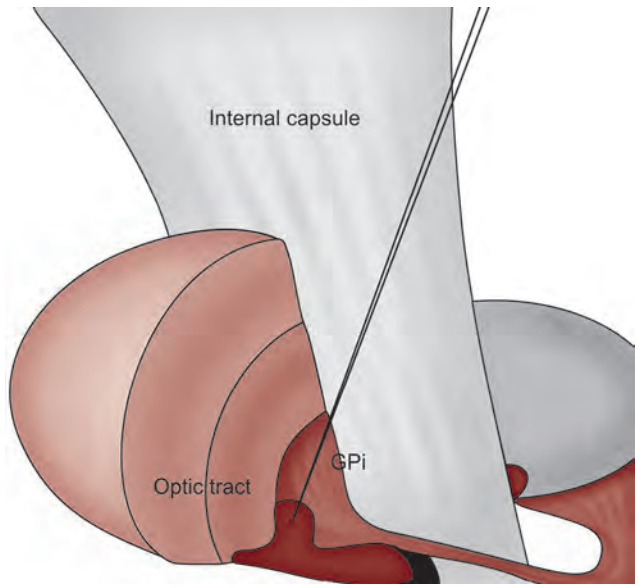

Fig. 4: GPi target and its relationship with optic tract

Fig. 5: IR coronal MRI showing GPi lesion (note the relationship to the optic tract)

by the medial medullary lamina, the pallidal neurons from each segment are similar and, for the most part, morphologically indistinguishable. The GPi is bound laterally and dorsally by the GPe. Medially the GPi is bound by the internal capsule. Ventrally it is close to the optic tracts. The therapeutic sensorimotor territory of the GPi is ventral and posterior, and the somatotopy places the face and arm posterior and ventral, and the leg central and more dorsal.[74] Pallidal stimulation is a better alternative to pallidotomy. This has the advantage of being completely reversible and chances of

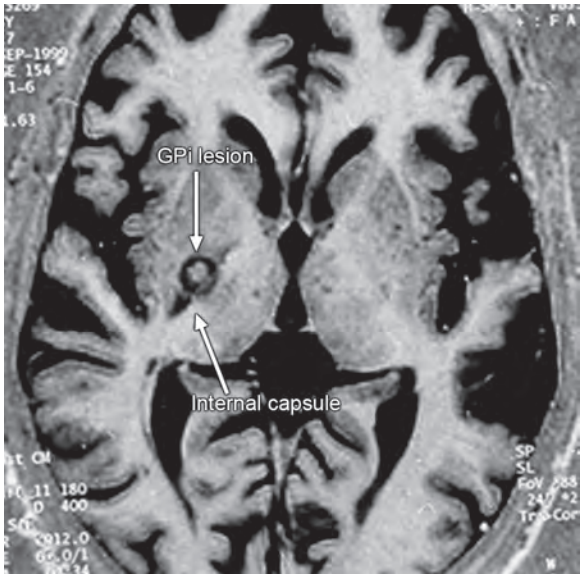

Fig. 6: IR axial MRI showing GPi lesion (note the relationship with internal capsule)

cognitive deficits are much less. Bilateral pallidotomy does carry a risk of cognitive impairment[26,50] and hence in bilateral cases only pallidal stimulation should be performed. However, pallidotomy is a useful adjunct for treating focal and unilateral dystonias.

Results

Results of pallidotomy or pallidal stimulation are both comparable. However, pallidal stimulation offers an added advantage of post-operative titration. The current requirements for the stimulation are considerably high and hence it affects the battery life used for the pulse generator. Typically the battery lasts for 5–6 years, if it is used to stimulate for PD. However, with the currently available batteries they would require to be replaced within 3 years or less, if used for stimulation of the pallidum for dystonia. It may take months for the full effect of pallidal stimulation to develop. Mild improvement in "mobile" dystonia is often seen within the first few hours after the initial programming of the stimulators and is a good predictor for continuing improvement.[40]

There are several case reports about dramatic improvement of generalised dystonia after bilateral pallidotomy.[30,41,48,51,58] The most striking effect was the clear benefit of axial dystonia without side effects, such as hypophonia, known to be associated with bilateral pallidal lesioning in PD. It has been reported that the BFM DRS scores improve approximately by 80%.[20,75,80]

For secondary generalised dystonia, reported results are highly variable, ranging from no benefit at all to significant improvement in some cases. However, the numbers are too small to give any meaningful comment about predictive factors.[78]

DBS offers a therapeutically viable option for patients with severe, primary dystonia and also for a small subset of patients with secondary dystonia. The key to favourable responses after DBS in patients with dystonia is proper patient selection. Patients who are refractory to all conservative measures, including medication trials (anticholinergics, baclofen, benzodiazepines or other muscle relaxants) and botulinum toxin injections are potential candidates.

We have performed six unilateral pallidotomies and nine bilateral GPi stimulations for dystonia. Good response was found in 6, moderate benefit was found in 5, poor in 1, 2 cases were explanted and 1 abandoned. There was no major visual or motor deficit. The explanation was done because of delayed infection in one due to poor hygiene and the second one due to self inflicted injury post-operatively leading to infection.

COMPLICATIONS

Complications of pallidotomy and thalamotomy are uncommon. Both procedures are designed to create defined lesions in deeply seated and critically located brain nuclei. Haemorrhage is the primary concern in both procedures. Since the electrode is small and no tissue is

removed during such procedures, the haemorrhage rate is low (Table 4). The second common complication is infection. Minor infection presenting as inflammation can be conservatively managed with antibiotics; however, if there is an implant, any evidence of discharge or pus formation warrants removal of the implant. If the infection is at the pacemaker site, the pacemaker and the connecting extension needs to be removed. If it is at the burr hole site the intracranial electrodes have to be removed. We had to explant the system completely in two patients developing infection, one due to poor hygiene and another due to self mutilation.

Pallidotomy Complications

Neurologic deficits may be produced by the lesion itself. The most common neurologic deficits after pallidotomy include visual field deficit, hemiparesis and dysarthria. Such symptoms are usually temporary. The close approximation of the globus pallidus interna to the internal capsule and optic tract are the basis for these deficits. Radiofrequency lesion generation causes focal tissue necrosis surrounded by a zone of oedema. This peripheral oedema may cause transient deficits. The mainstays of complication avoidance for pallidotomy surgery are appropriate patient selection and target planning, the use of test lesions and visual evoked potential monitoring, physiologic evaluation, careful intra-operative neurologic examinations and judicious lesion generation. Attention to each of these steps reduces complications of pallidotomy procedures; each is addressed subsequently. We had no lesion related complications in pallidotomy for dystonia.

Thalamotomy Complications

Common complications following thalamic surgery include dysarthria and pyramidal and cognitive deficits. Bilateral thalamotomies have the highest risk of these complications followed by unilateral lesioning and then stimulation procedures. Bilateral thalamotomies are rather contraindicated in present day functional neurosurgery. Putzke et al.[62] reported on the outcomes of 22 patients with head, voice or trunk tremor undergoing bilateral, staged, DBS thalamic implants. Bilateral stimulation was more effective than unilateral stimulation in alleviating axial tremors; however, as for bilateral thalamotomies, the rate of neurological complications was higher in patients who underwent bilateral stimulation. Dysarthria was observed in 27% of patients with bilateral stimulation, whereas none of those undergoing unilateral stimulation experienced the same problem. Likewise, disequilibrium was more common during bilateral stimulation. These stimulation settings varied minimally during this period, further corroborating the stability of the effects. Although staged bilateral procedures are often preferred for axial symptoms, they may not be safer than simultaneous implantation procedures.[61] Thalamotomy results were comparable to thalamic stimulation as per Pahwa et al. and tremor suppression was very similar in both groups. Complications, particularly intracerebral haemorrhages, were more common among patients with thalamotomies (35% vs 0%). Likewise, cognitive deterioration and hemiparesis occurred respectively, in 29% and 12% of patients who had undergone thalamotomies, but in none of those with thalamic stimulation. Although thalamic stimulation is chronically effective for most patients,[13] reductions in efficacy during longer-term follow-up periods have been reported.[36]

SURGERY FOR MOVEMENT DISORDERS: FUTURE DIRECTIONS

The field of functional neurosurgery has witnessed a renaissance over the past 20 years. This development has been fuelled by progress in understanding the

neurobiology of movement disorders, surgical technical advancements, therapeutic device developments and innovative approaches. The growth in our understanding of the neural circuitry of the disease has determined and refined our surgical targets. This increased understanding of the neurobiology of movement disorders will guide the discovery of additional targets for surgical exploration and translational clinical research. The evolution of stereotactic surgical tools and techniques is facilitating safe and minimally invasive approaches that enable neurosurgeons to target various brain structures with reliable accuracy. This, coupled with rapid advances in imaging technology, will play an important role in improving our capability to visualise brain structures and function with unparalleled resolution. At present, DBS is the standard therapy of choice for movement disorder patients who are medically intractable and meet the surgical selection criteria. DBS has a proven safety and efficacy profile and long-term outcomes have been demonstrated by prospective, randomised studies. Technological advances in DBS systems have already resulted in improvement and will continue to do so. The next generation DBS systems will be smaller and rechargeable, with current steering features and built-in sensing capabilities. A number of clinical trials are under way to explore the utility of gene therapy and cell transplantation and stem cell approaches with promising preliminary outcomes. In the near future, these technologies will provide additional options for neurosurgical management of movement disorders.

191 Gamma Knife Radiosurgery

Manish Singh Sharma, BS Sharma

The introduction of gamma knife radiosurgery (GKS) in the mid 20th century has heralded a quiet revolution which has changed the way neurosurgery is practiced, at levels which perhaps could not be contemplated as early as two decades ago. Gamma knife is actually a misnomer. There is no knife. It is a platform used to deliver highly focused beams of gamma radiation onto an immobilised intracranial target within a frame, using the age-old principles of stereotaxy.

HISTORY

The gamma knife was the brainchild of Dr Lars Leksell, the Swedish neurosurgeon, who succeeded Professor Herbert Olivecrona as the Chairman of the Department of Neurosurgery at the Karolinska Institute in Stockholm. The first procedure was performed in October 1967 for a patient with a craniophayngioma, previously treated with intracavitary radiation with yttrium 90 at the private hospital Sophiahemmet in Stockholm. A single lesion using a maximum dose of 20 Gy was created. Success in the form of tumour necrosis was documented on autopsy 4 months later when the patient expired due to shunt obstruction.[2] In 1970, Steiner and Backlund treated the first intracranial arteriovenous malformation (AVM) with astounding success.[58] Since then, the platform has evolved from a model U (University) to B, C, 4C and a revolutionary new platform called Perfexion™. Initially devised to treat benign tumours, movement disorders and intractable pain with gammathalamotomy, the scope of GKS has seen a radical diversification. It is now considered the most accurate and reliable means of delivering radiation to precisely delineated intracranial targets, without exposing the normal brain tissue around the lesion.

MEDICAL PHYSICS

The Leksell Gamma Knife™ (LGK) contains 201 cobalt-60 sources of approximately 30 curies (1.11 TBq) each, placed in a heavily shielded assembly. A combination of helmets with pores (collimators) focuses the gamma rays into the centre of a circular array where the patient's head is placed. Gamma rays are ionising rays in that they have the capability to generate secondary electrons, by removing outer shell electrons from atoms, thus creating a positive ion. This is made possible by the fact that the energy of the gamma ray exceeds the binding energy of the outer shell electron. This binding energy depends on the proximity of the electron shell to the nucleus and the number of protons within the same. In biological tissues, this varies from 13.6 eV for hydrogen atoms to 4 KeV for the calcium atom.

Co-60 is produced in nuclear reactors by adding a neutron to the naturally occurring isotope Co-59. This decays as follows:

Co-60 $\rightarrow$ Ni-60 + β radiation $\rightarrow$ Co-59 + 2 γ rays (1.17 MeV + 1.33 MeV)

The half-life of Co-60 is about 5.26 years which means that the radioactivity of the source becomes half its original activity in this span of time. Sources can be used up to a maximum of 10 years before they need to be reloaded and the spent source disposed. The danger in waiting this long lies in the fact that the treatment time gets prolonged and the unwanted scatter radiation to which the patient is exposed increases. The advantage of Co-60 is its relatively high radioactivity for a small volume (specific activity), ruggedness, reliability and output stability. The disadvantages are that the radiation is always 'on' unlike Linear Accelerators (LINAC), the half-life is relatively short and the sources need to be reloaded.

There are two basic principles in radiosurgery:

1. *Conformity:* This implies that the isodose at which the radiation is prescribed (prescription isodose) should hug the margin of the tumour target as closely as possible. Conformity is achieved in GK by using multiple isocentres ("shots"), changing the position of the isocentres, adjusting the beam diameter (by using 4, 8, 14 and 18 mm collimators), adjusting the weight of the beams (which determines the time spent by the patient within the gantry) and finally by beam blocking (by plugging specific pores with the collimator helmet).
2. *Selectivity:* This implies precise targeting of the lesion with a rapid dose fall-off, thus avoiding radiation damage to adjacent normal tissue. This is influenced by the size of the collimator, the beam penumbra (distance between the 80% and 20% isodose lines), mechanical stability of the treating machine and the number of radiation fields. Multiple shots with small sized collimators is likely to improve the selectivity of a given radiation dose plan (Fig. 1).

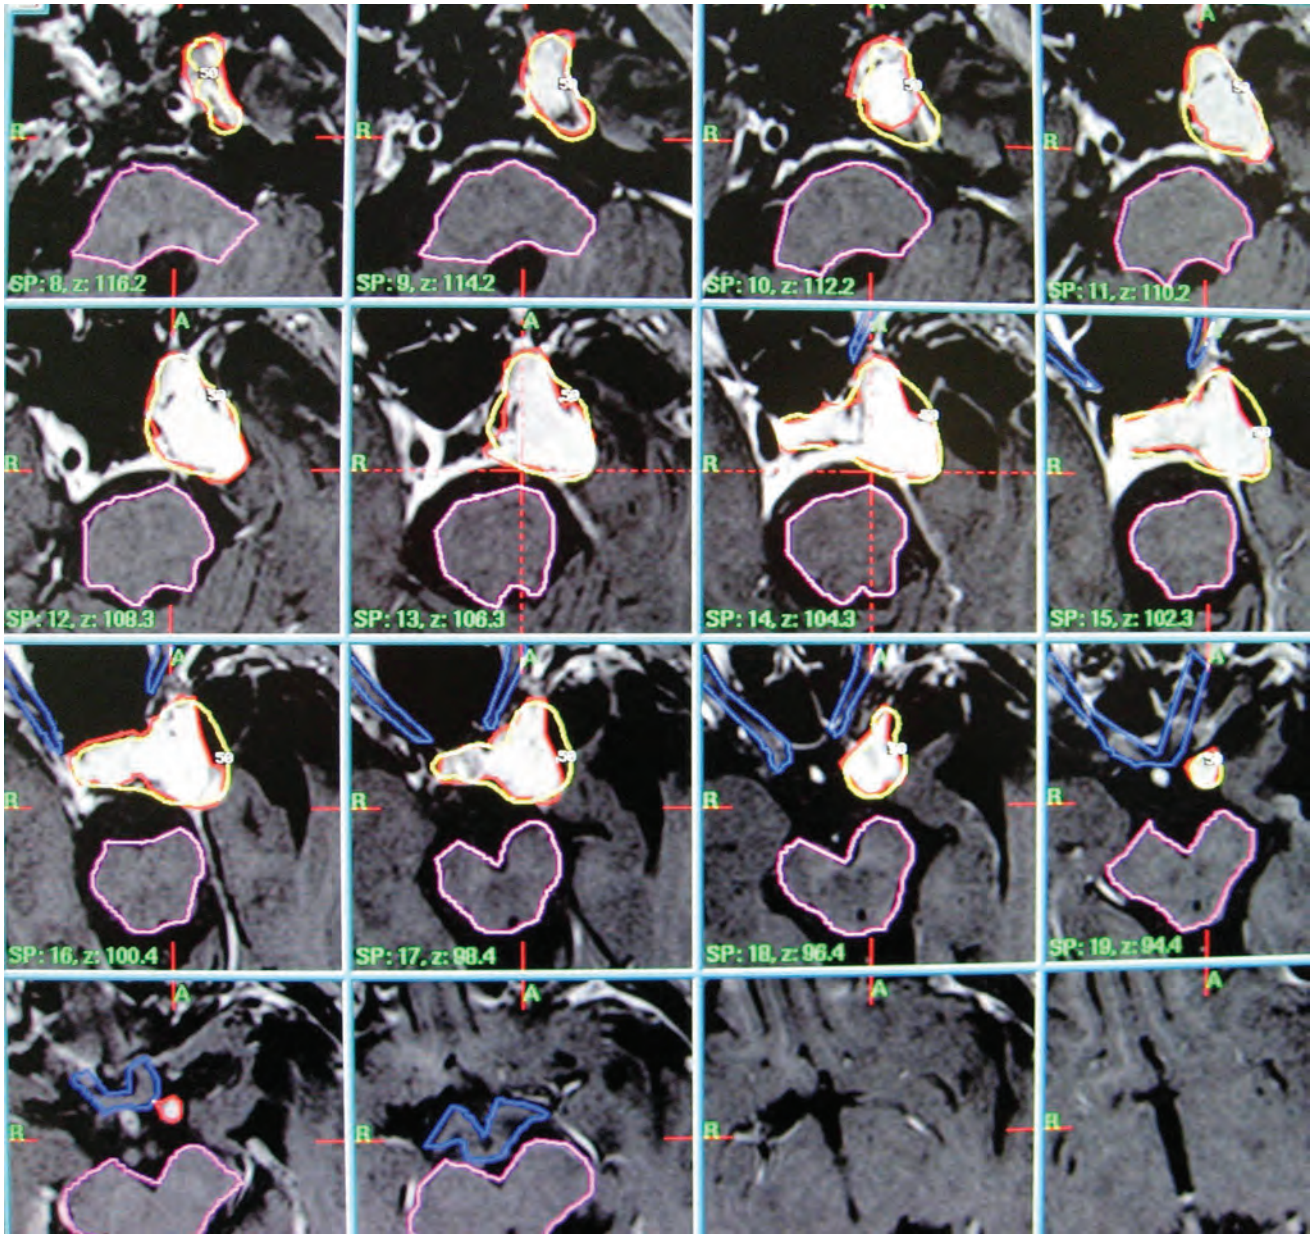

Fig. 1: Planning for a residual left cavernous sinus meningioma. The meningioma is depicted in red, the brainstem in pink and the optic pathways in blue. The radiation isodose seen in yellow is applied as closely as possible to the tumour margin to ensure conformity and selectivity

Dose-Volume Histogram

These measurements can be used to compare and contrast multiple dose plans by indicating the radiation doses received by a specific volume of target tissue at a particular isodose. Most users target 90–100% of the lesion at the 50% isodose line.

Conformity Indices

These are objective measures of the fitness of a particular plan. The simplest conformity index (CI) is related to the prescription isodose volume (PV) and the target volume (TV) by the following equation:

CI = PV/TV

Ideally CI should be 1. Practically, any value less than 2 is satisfactory. There is a fundamental flaw in this index, in that it does not measure the degree of overlap between the two volumes, the PV may actually completely miss the target and yet be 1. To overcome this lacuna, Paddick et al. proposed the following ratio: Conformity = PV/TV × % target coverage.

Thus, the plan is penalised for poor overlapping.[45]

RADIOBIOLOGY

GKS is better classified as a form of stereotactic radiosurgery (SRS), which has been defined as the precise destruction of a chosen target containing healthy and/or pathological cells, without significant concomitant or late radiation damage to adjacent tissues.[26,29] SRS involves the delivery of high dose single fractions of radiation, as opposed to multiple smaller doses (fractionation) in

stereotactic radiotherapy (SRT), which is used to treat larger volumes.

SRS is by necessity highly accurate and the system has an inherently steep dose fall-off (selectivity), which enables the precise and focused delivery of a single fraction of high dose radiation. This overcomes the so-called 'radiation resistance' of benign tumours which are late responders and in whom fractionation has no value.

GKS has been performed mostly for benign tumours. As these patients generally have normal survival and rarely require salvage surgery, little tissue is available to study its *in vivo* effects. Animal experiments using athymic nude mice with subrenal allografts of human vestibular schwannomas (VSs) and meningiomas, indicates that tumour size reduction may be due to neoplastic cell death and a decrease in vascularity.[27] Tsuzuki et al.[63] postulated that apoptosis my play a central role in controlling the growth of tumours after GKRS. Tumour volume was rapidly reduced in lymphomas and in some benign tumours, characterised by strong positive immunohistochemical staining for PCNA and Bcl-2. They hypothesised that targets with a large proportion of proliferating cells may undergo DNA damage, enter the cell cycle and then undergo apoptotic cell death without necrosis or inflammation.

GKS in AVMs seems to cause a proliferative vasculopathy and endothelial cell injury, leading to vessel wall thickening, hyalinisation and luminal closure.[51] Activated myofibroblasts too may add to the obliteration of AVMs.[59] In the standard recommended doses, GKS does not seem to affect normal brain vessels, not even tiny perforators. Perhaps it is only abnormal angiogenesis that may be selectively affected by high dose single fraction GKS.[27]

Gamma radiation changes may be characterised as:

1. *Acute:* This entails sharply demarcated parenchymal coagulative necrosis with apoptosis and an acute inflammatory reaction. Blood vessels show endothelial destruction and fibrinoid changes in the walls.
2. *Subacute:* In this stage, macrophages replace polymorphonuclear cells. Granulation tissue and reactive gliosis sets in as does proliferative vasculopathy with luminal narrowing.
3. *Chronic:* Necrosis is replaced by scar tissue, lymphocytic infiltrates, hyaline change and calcification. Subendothelial cell proliferation is seen in vessel walls with hyalinisation and subtotal/total luminal obliteration.[60]

DOSE SELECTION

This is the final phase of treatment planning. The dose to be administered depends on the actual or anticipated histopathology based on the imaging, the proximity and radiation safety tolerance limits of adjoining normal structures and the anticipated lifespan of the patient. It is useful to consult risk prediction curves, especially in AVMs, to balance the therapeutic advantage of dose escalation versus the risk of developing an adverse radiation reaction. Flickinger et al.[9] postulated an integrated logistic formula to estimate the risks of brain necrosis from radiosurgery, in order to limit the risk to less than 3%. Using a multivariate analysis, they found that radiation change correlated significantly with only one variable, the total volume of AVM plus normal tissue receiving greater than 12 Gy of radiation (the 12 Gy volume).

GKS uses marginal doses between 12 and 25 Gy for the most benign and malignant tumours prescribed at the 50% isodose. Maximum doses up to 90 Gy have been used to treat trigeminal neuralgia (TGN). Although Steiner et al.[8,57] reported that doses more than 180 Gy may be required for gammathalomotomy, 130–140 Gy may be adequate. Just to put this in perspective, a whole body exposure of 6–10 Gy of gamma radiation will produce a 100% fatality in untreated humans within 14 days (LD 100/14). GKRS enables the safe delivery of up to 15 times this dose because of its high specificity and conformity.

The following tables indicate standard prescription doses to the margin of the lesion and the radiation safety tolerance limit of crucial adjoining structures, as practiced in our centre (Tables 1 and 2).

Table 1: Commonly recommended dose prescriptions

Diagnosis	*Prescription dose (Gy) at the 50% isodose*
AVM	20–25 Gy
AVF	20–25 Gy
Ac. Neuroma	12–14 Gy
Meningioma	12–14 Gy
Pit. adenoma	12 Gy
Functional pituitary	25–35 Gy
Craniopharyngioma	12–14 Gy
Neurofibroma	12–14 Gy
Metastasis	20–25 Gy
Glomus jugulare	16–25 Gy
Malignant glioma	20–25 Gy
Haemangioblastoma	20–25 Gy
Trigeminal neuralgia	70–90 Gy
Cavernoma	14–20 Gy

Table 2: Radiation tolerance limits

Critical structure	*Radiation tolerance limit (Gy)*
Brainstem	12 Gy
Visual pathways	8–10 Gy
Cranial nerves	8–12 Gy
Eye lens	< 1.5 Gy

PROCEDURE

GKRS requires a close liaison between the radiation oncologist, the medical physicist, the neuroradiologist, the nursing staff, technicians and the neurosurgeon.

Fig. 2: Frame application under local anaesthesia. We place the MRI indicator box on the frame during fixation so as to avoid any subsequent collision with the skull

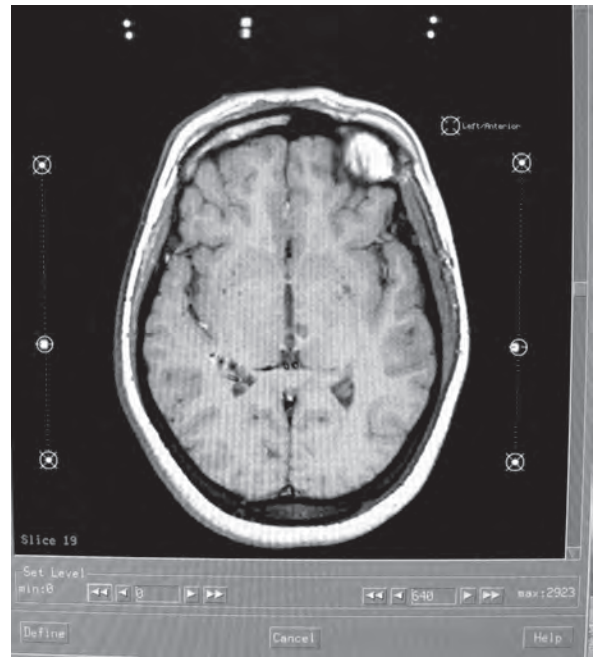

Fig. 3: Image definition. The fiducials are recognised by the software as is the orientation

Every centre has its own stylised protocol, right from frame fixation under general/local anaesthesia to imaging sequences to target delineation prior to radiation delivery and dose prescription. A brief description is provided below.

Basic Principles

Prior to beginning GKRS, the patient's head is immobilised in a frame which has posts and screws which provide secure skeletal fixation and rigid immobilisation. The frame also houses a marker box with columns for copper sulphate solution which can be picked up on axial MRI images as round fiducials in each cut (Fig. 2). These fiducials are used to define the images in proprietary software and transpose CT/MRI co-ordinates into Cartesian co-ordinates, based on the gradations present on the Leksell frame (Fig. 3). Thus, the principles of stereotaxy very much apply here and instead of delivering a needle into the required depth, the frame is used to guide stereotactic radiation beams with the isocentre of the arc being the centre of the tumour. The software also generates a 3D reconstruction of the skull which is used to calculate the distance of the lesion from the scalp. This helps determine attenuation of radiation with distance. Combined with the rate of radiation available for that day as per the half-life and days since installation of the Cobalt source, the software calculates the time duration for which radiation therapy will be given at each isocentre. The software also gives the isocentre (x, y and z) co-ordinates for each shot and the patient's head and frame are positioned in such a manner, as to place the tumour in the centre of a secondary collimator with a pore size varying between 4, 8, 14 and 18 mm, which further focuses the gamma rays onto the exact centre of the target for the particular shot (Fig. 4). As the individual beams carry less radiation, the remaining brain receives a low dose of radiation, which is below the safety tolerance threshold. Several shots are used to plan a compound conformal radiation isodose, which should ideally cover about 90% of the lesion at least. Dose-volume histograms (DVHs) are then calculated to determine whether the safety tolerance limits of vital structures, such as the brainstem, optic pathways and/or adjoining cranial nerves, are not exceeded. In eccentrically placed tumours, collisions are looked for between the skull and the frame and/or posts and screws, as determined by the software and the 3D skull reconstructions. After checking all these variables, a plan is selected

Fig. 4: The Leksell Gamma Knife Unit B. The collimators are seen in the inset

and the patient is then transferred to the GKS gantry for administering radiation.

Specific Steps

Frame Fixation

Care is taken to place the frame in such a manner as to position the tumour in its centre as far as feasible. For example, if the patient has a left parieto-occipital lesion, the frame is placed as far back and to the left as dictated by the size of the patient's head, which can prove to be a major limitation in well built patients with eccentrically placed lesions. Sometimes, the presence of collisions may make radiation delivery impossible and patients with the above characteristics must be warned beforehand that radiation delivery may need to be aborted and the frame removed because of technical limitations. The frame can be placed under local anaesthesia or under a general anaesthetic, especially in children less than 7 years of age. When anticipating a need for a general anaesthetic or heavy sedation, it is advisable to place the face plate of the frame in such a manner so as not to obstruct the airway or prevent possible endotracheal intubation.

Imaging

MRI with contrast is best used for evaluating brain tumours. Routine T1- and T2-weighted (T1WI and T2WI) sequences are run in thin 2 mm contiguous sections, either in the axial and/or coronal planes through the region of interest. Fat saturation may be added for base of skull lesions and in post-operative patients with pituitary adenomas with nasal packing performed at the time of surgery. Most centres now use 3D volume acquisition (MPGR or SPGR) sequences which are less time consuming and thus produce less motion artifacts. T2WI may be of superior benefit in treating patients with AVMs. Heavily T2-weighted images are of benefit (CISS) in visualising the trigeminal nerve in the treatment of neuralgic pain. Occasionally, CT and MRI fusion can be carried out for small intracanalicular acoustic neuromas, as CT scans can be acquired at 1 mm intervals and thus may halve the error of image acquisition. Positron emission tomography (PET) fusion is a capability of the 4C and Perfexion™ softwares which can help target the metabolically active part of residual tumours, especially those which have received prior radiation. Angiograms are performed with simultaneous vertebral and carotid injections (if need be) and images acquired in the anteroposterior and lateral projections in the capillary phase.

Cross-Registration

MRI and/or CT images are then defined by the software after feeding them into the computer by scanning, through a PACS/Ethernet system or via a CD/DVD. Fiducials are recognised as is orientation and images are accepted only after the error is within permissible limits. The software generates its own coronal and sagittal reconstructions based on the axial imaging. This helps planning. The shape of the skull is also generated based on manual depth readings, provided by a bubble placed on the patient's frame.

Planning

This is the most crucial part of the procedure. Images are viewed on a convenient workspace on the computer and the target is defined using a marker function. A matrix is then placed around the target to produce a snug fit. The matrix contains 136,789 arbitrary points which are used to calculate the radiation dose. Adjoining vital structures such as the optic pathway and the brainstem too are delineated (segmented). Multiple isocentres are then placed to encompass at least 90% of the tumour with minimal spillage onto normal structures (Fig. 1). The dose is finally prescribed in consultation with the radiation oncologist based on proximity to adjoining vital structures and the actual or anticipated histopathology. A final check is made to ensure that the software does not anticipate any collisions before transferring the patient into the radiation suite.

Manual/Automatic Positioning

The older GKS platforms use mandatory manual changing of secondary collimators and the patient's head position while partial and complete roboticisation is a feature of the 4C and Perfexion™ systems, respectively. This is as crucial as planning because the sub-millimetric accuracy of the software can easily be negated by a manual error in reading the Vernier caliper scale used to fix the frame in the x, y and z axes. The Perfexion™ system has 192 C0-60 sources and three inbuilt mobile collimators (4, 8 and 16 mm), which eliminates the need to manually change helmets. Thus, the operating time is reduced, as is the capacity for human error. The chances of collision too are reduced, as the distance between the frame and the inner collimator is also increased. Thus, it makes treatment of multiple targets, especially polar metastases, less time consuming, more accurate and feasible within a single sitting itself. After the treatment is over, the frame is removed and the patient can be discharged home.

ADVANTAGES OF GAMMA KNIFE RADIOSURGERY

Gamma Knife is superior to conventional surgery in that it has the accuracy of a knife, especially when conventional surgery may be risky or lesions may be considered inoperable (Fig. 5). It is extremely precise as it is guided by thin slice stereotactic MRI and CT scans. The mechanical precision of the unit has been estimated at between 0.25 mm and 0.3 mm. It is safe as the radiation falloff is steep and the exposure of normal brain is minimised. It has also been designed primarily as a neurosurgical tool to be used in consultation with the radiation oncologist and the medical physicist. This is advantageous in

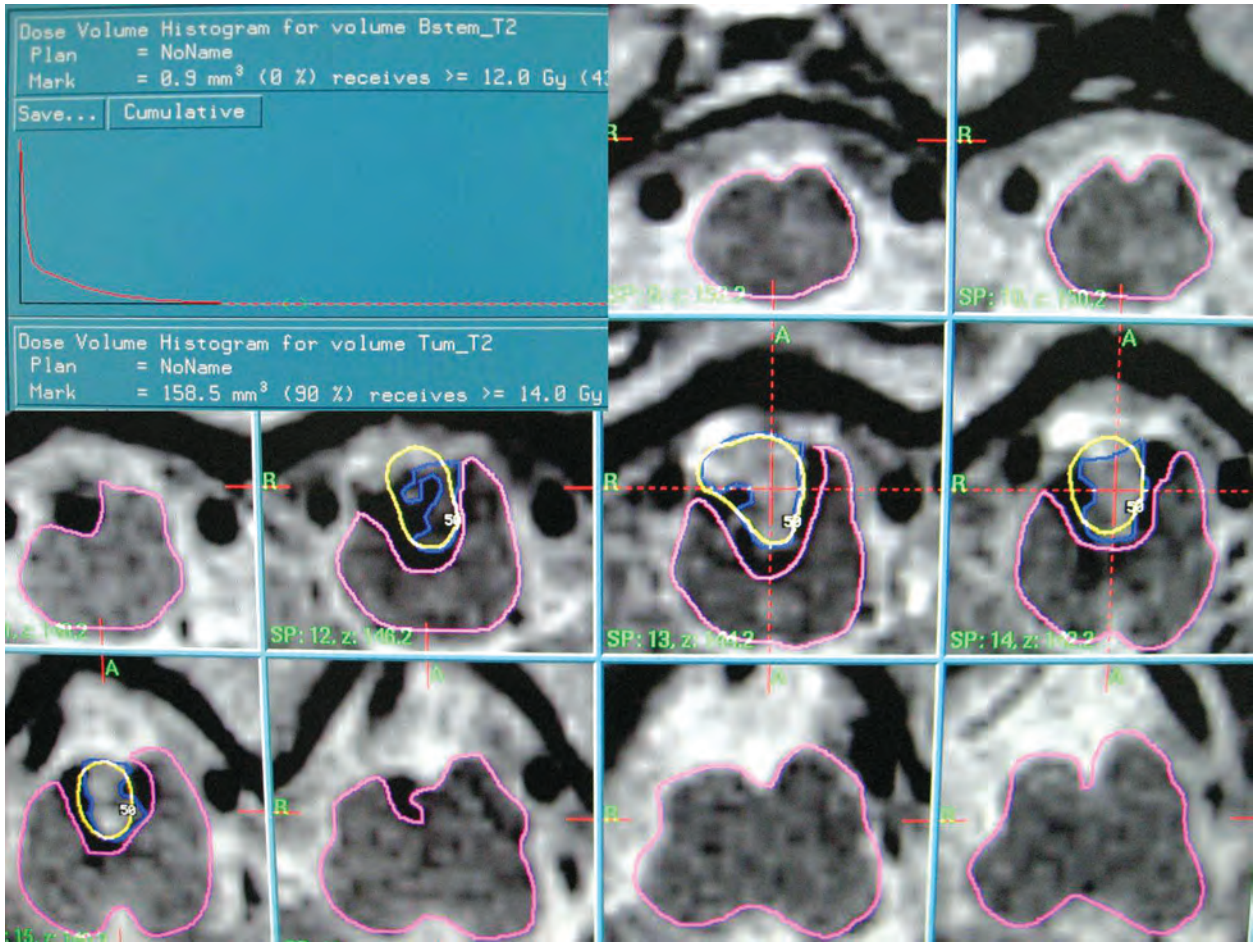

Fig. 5: Treatment planning for an intra-medullary cavernoma (T2-weighted MR axial images). Surgery was considered very high risk and consent was taken for GKS, as the patient had two previous bleeds (see text for rationale). The haemosiderin ring was excluded and the brainstem exposure was below 12 Gy (see Dose volume histogram in the inset). The brainstem is segmented in pink, the cavernoma in blue; the yellow line marks the 14 Gy 50% isodose line

that the neurosurgeon retains a primary and direct role in planning either primary or adjuvant therapy for a variety of benign, malignant and functional neurological disorders.

Current Uses

Although the GK platform was originally used in Stockholm for treating functional disorders of the brain, its scope has now drastically widened and evolved to include a variety of benign lesions such as pituitary adenomas, acoustic neuromas, meningiomas, schwannomas, haemangioblastomas, chordomas, chondrosarcomas, glomus jugulare (GJ),[52] posterior third ventricular tumours, pilocytic astrocytomas, gangliogliomas and craniopharyngiomas. Malignant lesions, such as haemangiopericytomas, malignant gliomas, endolymphatic sac tumours and metastases, may also benefit because of the excellent local control that may be provided by GKS.

AVM therapy has possibly been the most significantly revolutionised by the introduction of GKS. Three-year obliteration rates may approach 90% with minimal side effects (Figs 6A to D). This is all the more remarkable because most of these lesions are inaccessible to surgery and not amenable to embolisation.

A growing indication for GKRS is now multiple metastases—the most common indication in the West where detection and locoregional control rates are high. In our centre, AVMs remain the primary indication for GKS followed by VSs.

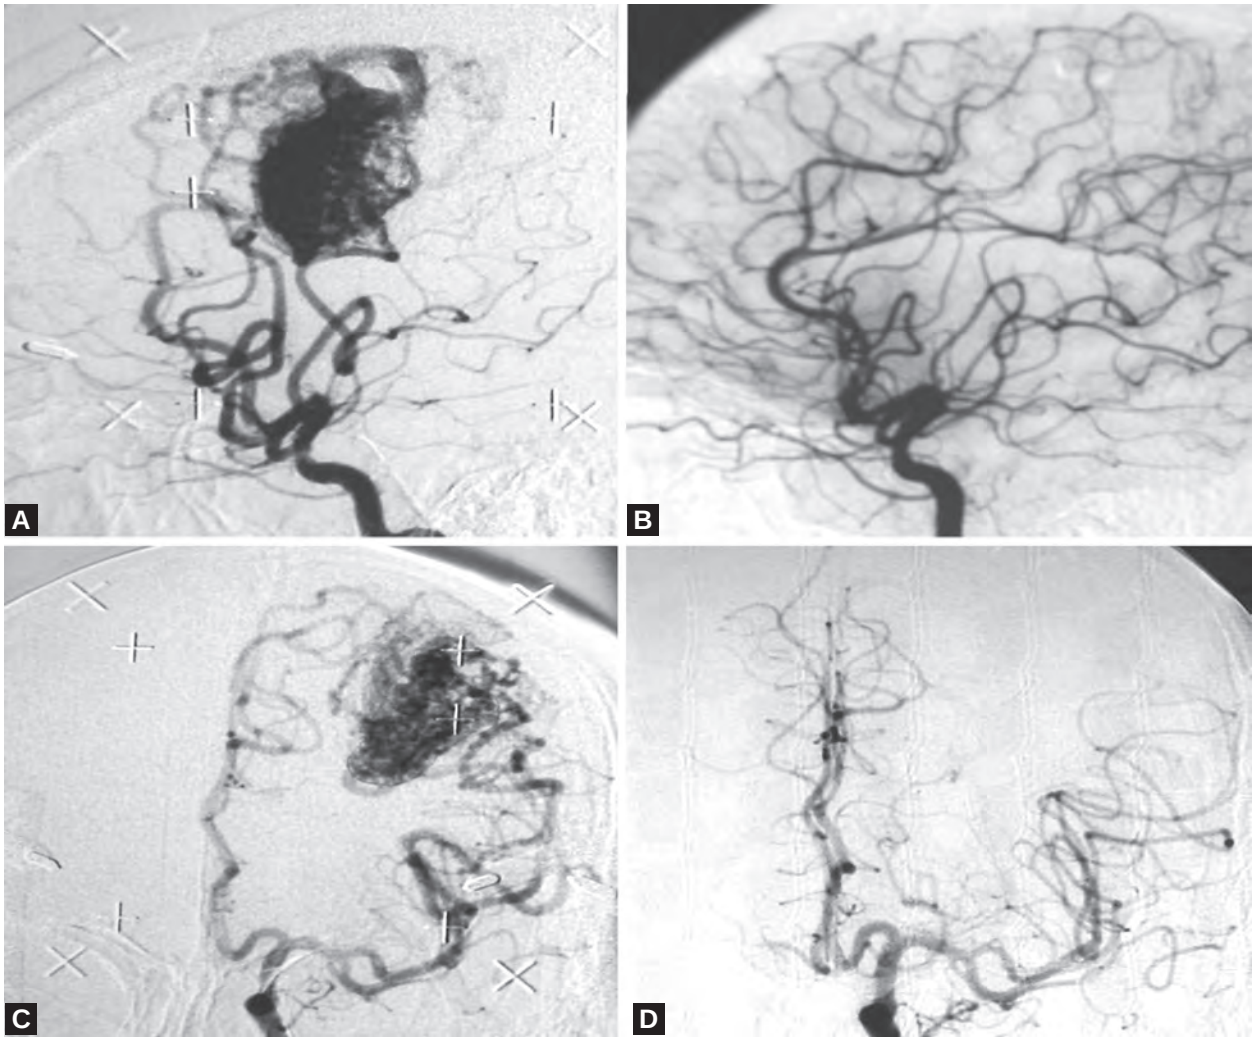
Standard limitations for administering GKS are:

- Tumour diameter exceeding 3 cm.
- Tumour volume greater than 19 cc.

These limits are only indicative and depend largely on the proximity of critical neural structures such as the optic pathways and the brainstem.

Review of Literature

Gamma knife has been used as a key word in 5,211 peer-reviewed articles indexed by Pubmed till date. As more and more follow-up MRI scans of patients accumulate from a greater number of centres around the world, the extent of both clinical and radiological follow-up has now begun to outstrip those available in surgical literature. The significant advantage of GKS remains its association with a demonstrable improvement in a



Figs 6A to D: Angiograms documenting AVM obliteration three years post-GKS. The images on the left are stereotactic, the fiducials can be seen on the plates

patient's quality of life.[6,41,42,46,47,48] Moreover, the same standardised machine is available throughout the world. Thus, results do no longer depend upon the skill and experience of the operating surgeon but on the available technology and the quality of imaging.

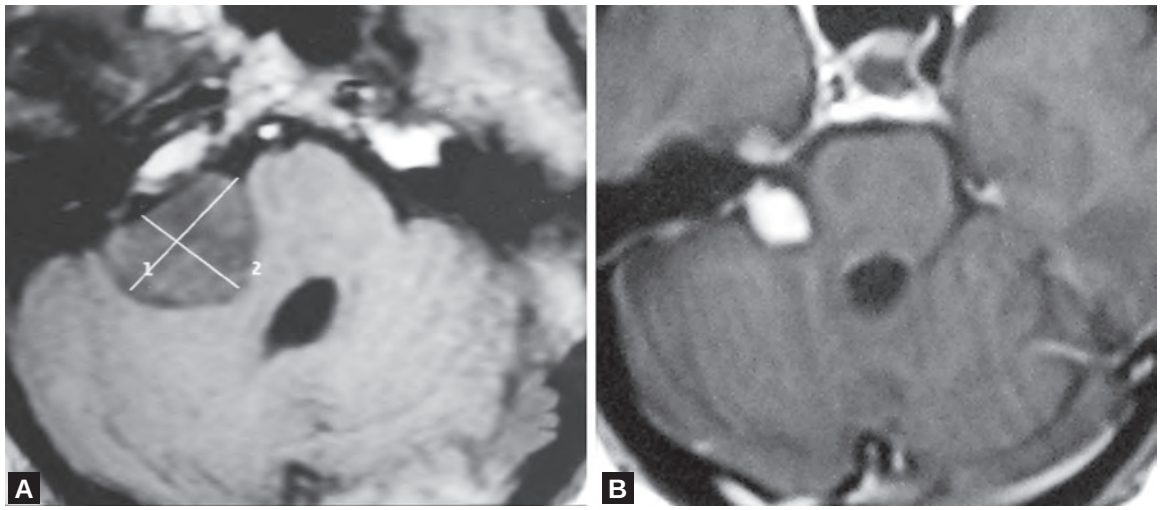
GUIDELINES AND SUCCESS RATES

We have attempted to compile the results of some of the largest available series of patients to date to provide an idea of the effectiveness and complication rates associated with GKS in the following conditions.

Vestibular Schwannomas

GKS has now become the standard of care in the treatment of VS, if it is less than 3 cm in size. Tumour control rates reported by the Pittsburgh group approached 97% at 10 years in their 15 year experience of 829 cases (mean tumour volume 2.5 cc). Hearing preservation was possible in up to 90% of intracanalicular tumours. Complications included a 3% risk of trigeminal neuropathy and a 1% risk of facial palsy. Pollock et al.[34] in a prospective study from the Mayo clinic reported 82 patients with unilateral, un-operated schwannomas less than 3 cm undergoing surgical resection (n = 36) or radiosurgery (n = 46). At a mean follow-up of 42 months, normal facial movement and serviceable hearing was more frequently seen in the radiosurgical group at 3 months ($p < 0.001$), one year ($p < 0.001$) and at the last follow-up examination ($p < 0.01$) compared with the surgical resection group. They concluded that pending an unacceptable rate of recurrence in later follow-up, radiosurgery should be considered the best management strategy for VS less than 3 cm in size.[46] Figures 7A and B depicts the reduction in size after 6 years of a large VS given 12 Gy of radiation.

In bilateral VS, GKS does appear to be safe, although results are not as favourable as for sporadic tumours. In the largest series so far, 74 VS (mean tumour volume 5.7 cc) were studied in 62 patients in whom ipsilateral serviceable hearing was present in 35%. The mean marginal dose was 14 Gy and the median follow-up was 53 months. Actuarial control rates were 85% and 81% at 5 and 15 years, respectively. The actuarial serviceable



Figs 7A and B: Reduction in size of a large VS demonstrated six years after GKS. It is to be noted that acoustic neuromas with a mass effect on the pons can also be successfully treated with GKS, although with a slightly lower control rate

hearing preservation rate was 73% at 1 year and 48% at 5 years after radiosurgery. The rates of facial and trigeminal neuropathy were recorded at 8% and 4%, respectively.[36]

Meningiomas

Kondziolka et al.[36] reported their 18 year experience in 972 patients with 1,045 intracranial meningiomas of whom 49% had undergone a previous resection. The overall control rate was 93% at 10 years follow-up. Delayed resection after radiosurgery was necessary in 51 patients (5%) at a mean of 35 months. The overall morbidity rate was 7.7%. Mindermann et al.[39] reported that tumour control rates approached 95%, 92% and 100% in patients with parasagittal or convexity meningiomas, skull base and posterior fossa meningiomas, respectively. They also observed that neurological deficits tend to resolve in deep tumours following GKS.

Pituitary Adenomas

Non-functioning Tumours

Liscak et al.[30] over a period of 10 years treated 140 patients with non-secreting pituitary adenomas (median volume 3.45 cc) of whom 85% had had previous surgery. The median marginal dose was 20 Gy (range; 12–35 Gy) while the median follow-up was 60 months. Tumour control rates were 100%; 89% of treated adenomas decreased in size showing a median volume reduction of 61%. There was no visual impairment or ocular motor paresis after radiosurgery. Pituitary hormone deficiency occurred in two patients. They also concluded that contact between a non-secreting pituitary adenoma and the optic pathway is not an absolute contraindication for GKS.

Cushing's Disease

Jagannathan et al.[22] studied 90 patients over 15 years with adrenocoticotropic pituitary adenomas (89 were previously operated upon) with a mean endocrine follow-up of 45 months (range 12–132 months). The mean marginal dose was 23 Gy (median 25 Gy). Normal 24-hour urinary free cortisol levels were achieved in 49 patients (54%) after an average of 13 months post-procedure (range 2–67 months). A decrease in tumour size occurred in 80%, while tumour growth was recorded in 6% of patients. Twenty per cent of patients experienced a relapse after initial remission at a mean interval of 27 months. Redo GKS was associated with a remission rate of 43%. New hormone deficiencies developed in 22% of all patients, while 5.6% of all patients developed new onset visual deficits or ocular motor paresis.

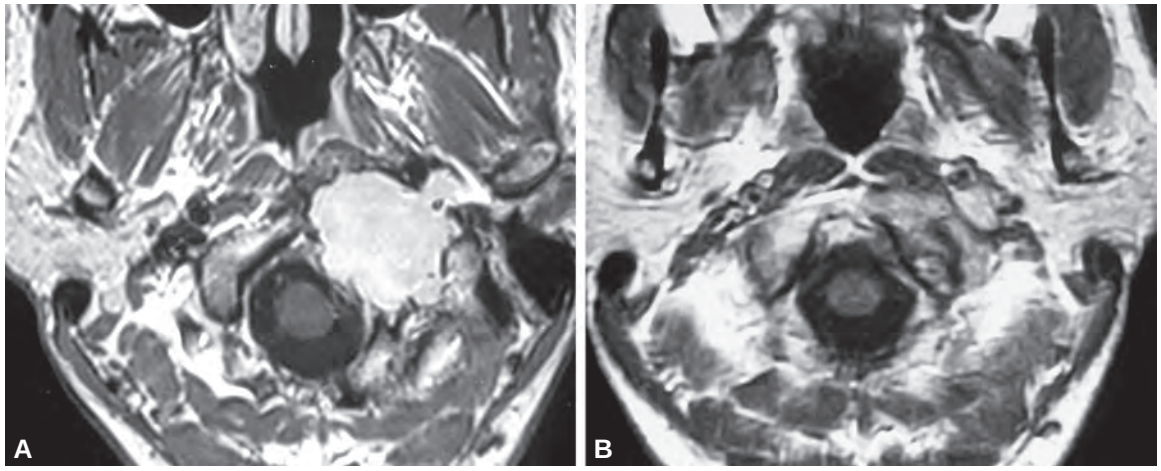
Acromegaly

Jezkova et al.[23] studied 96 acromegalic patients (median tumour size 1,350 mm^3) over a mean follow-up period of 53.7 months of whom 24 received primary GKS. Thirteen patients needed a second sitting; fifty per cent of the patients achieved mean GH less than 2.5 ug/l within 42 months, normalised their IGF-I within 54 months and achieved GH suppression in the oral glucose tolerance test with normal IGF-I within 66 months. The effectiveness of GKS depended on initial GH and IGF-I serum levels and not on the size of the adenoma. Hypopituitarism occurred only at doses exceeding 15 Gy. Patients with primary neurosurgery followed by GKS had better outcomes than those with GKS alone.

The choice of therapy for functioning pituitary adenomas still remains open surgery, as the prescription dose in GKS is limited by the proximity of the tumour to the optic pathways.

Chordomas and Chondrosarcomas

Hasegawa et al.[16] studied 37 patients; 27 chordomas, 7 chondrosarcomas and 3 radiologically diagnosed chordomas treated with GKS. The mean tumour volume was 20 cc, the mean marginal dose was 14 Gy and the mean



Figs 8A and B: Twenty-two months follow-up contrast MR axial images revealing significant reduction in the size of a glomus jugulare treated primarily with GKS at the level of the C1 lateral mass

follow-up period was 59 months post-procedure. The actuarial 5-year and 10-year local tumour control rates were 76 and 67%, respectively, and 100% for patients with low-grade chondrosarcomas. Tumour volumes less than 20 cc significantly affected tumour control. Only one patient developed facial numbness. They recommended treating patients with a generous margin with prescription doses exceeding 15 Gy to achieve best long-term tumour control.

Glomus Jugulare

GKS has revolutionised the treatment of this rare tumour with primary therapy being offered on presumptive radiology. In a study from our centre, 24 patients with GJ underwent 25 procedures, 15 patients received primary GKS. Mean tumour size was 8.7 cc (range 1.1–17.2 cc); 93.1% coverage was achieved using a mean prescription dose of 16.4 Gy (range 12–25 Gy) at a mean isodose of 49.5% (range 45–50%). At a median interval of 24 months follow-up, six patients had improved clinically while a single patient developed transient TGN. Tumour control was 100% with MRI scans recording a decrease in size in 70% of all patients. Our data indicated that 83% of patients who underwent primary GKS had tumour regression on MRI, as opposed to 50% of patients who underwent GKS after an open procedure. Eighty per cent of patients developed a Grade V/VI House and Brackman facial palsy after surgery and the average volume of residual tumour was 9.2 cc. For large tumours, we have now begun fractionating GKS by targeting the intradural and extradural tumour segments separately in different sittings. Figures 8A and B reveals dramatic tumour reduction 22 months after GKS at the level of the C1 lateral mass.

Haemangioblastomas

Matsunaga et al.[37] in a study of 22 patients with 67 tumours (mean volume 1.69 cc) who received a mean marginal dose of 14.0 Gy had a tumour control rate of 83.6% at a mean follow-up of 63 months. The only factor adversely affecting tumour control was the presence of a cystic component. Wang et al.[64] found that a prescription dose exceeding 18 Gy resulted in a total absence of tumour cells within 48 months. In their series of 35 patients followed-up for a mean of 66 months, tumour control rates were 71% at the end of 5 years (mean prescription dose was 17.2 Gy).

Gliomas

Pilocytic Astrocytomas

Hadjipanayis et al.[4] studied 37 patients with biopsy proven recurrent or unresectable pilocytic astrocytomas, of which 18 involved the brainstem. Tumour volumes varied from 0.42 to 25 cm^3. The median prescription dose was 15 Gy. Complete tumour resolution was demonstrated in 10 patients, reduced tumour volume in 8, stable tumour volume in 7, and delayed tumour progression in 12.[13] GKS may be the only modality available in such cases. In another study from Karolinska institute involving 16 patients in whom GKS was used to treat residual tumours with a prescription dose of 10–12 Gy, tumour control was achieved in all patients at a mean clinical follow-up time of 8.5 years and a mean radiological follow-up time of 5.9 years.

Low-Grade Gliomas

In a study of 12 histologically proven cases of recurrent or unresectable World Health Organization (WHO) grade II fibrillary astrocytomas, Hadjipanayis et al.[14] found that GKS using a median prescription dose of 16 Gy to volumes ranging 1.2–45.1 cc resulted in complete tumour resolution in one patient, reduced tumour volume in four patients, stable tumour volume in three patients and delayed tumour progression in four patients of whom three patients presented with an increase in cyst size alone. All patients were alive at a

median follow-up of 52 months after radiosurgery and 103 months after diagnosis.

Malignant Gliomas

GKS offers effective treatment as a salvage therapy for patients with small recurrent glioblastoma multiforme (GBM). In a study of 32 patients with 36 treated lesions, who had previously undergone neurosurgical resection and fractionated external beam radiotherapy (EBRT), it was found that the median overall survival after SRS was 10 months, with a progression-free survival of 7 months. The median interval between primary irradiation and re-irradiation was 10 months. The median prescription dose was 15 Gy delivered at the 80% isodose. No concomitant chemotherapy was given. No acute or long-term toxicity was observed.[5] Nwokedi et al.[44] studied 64 GBM patients treated with EBRT alone (Group 1) or those who received both EBRT plus a GKS boost (Group 2). GKS was administered to most patients within six weeks of the completion of EBRT. The median EBRT dose was 59.7 Gy and the median GKS boost was 17.1 Gy. The median survival was 13 months in Group 1 versus 25 months in Group 2. The addition of a GKS boost was a significant predictor of overall survival. Hsieh et al.[20] further concluded that adjuvant GKS performed at tumour progression seemed to increase median survival to 16.7 months compared with 10 months when performed after tumour resection.

Metastases

The magnitude of this problem can easily be assessed by the fact that cerebral metastases occur in 15–30% of cancer patients during their lifespan. Brain metastases can be dealt with surgery, GKS/SRS, whole brain irradiation (WBI) or combinations thereof.

Current Recommendations

Aoyama et al.[1] presented the first multi-institutional, prospective, randomised comparison of WBI plus SRS versus SRS alone for 1–4 cerebral metastases less than 3 cm in diameter and found that the median survival and the 1-year actuarial survival rate were 7.5 months and 38.5% in the WBI + SRS group and 8.0 months and 28.4% for SRS alone. The one year brain tumour recurrence rate was 46.8% in the WBI + SRS group and 76.4% for the SRS alone group. There were no significant differences in cognition between the two groups. Thus, WBI did not confer a survival advantage whereas its omission upfront increased the chances of intracranial relapse. Conversely, a trial comparing WBI + SRS versus WBI alone for 2–4 metastases less than 2.5 cm found that the rate of local failure at 1 year was 100% after WBI alone but only 8% in patients who had boost SRS. Patients who received WBI alone lived a median of 7.5 months, while those who received WBI + SRS lived 11 months. Survival was dependant on the extent of extracranial disease.[28] This lack of significant survival benefit but improved local control has also been supported by a Cochrane database meta-analysis.[62]

For single metastases, current recommendations suggest that surgery followed by WBI may improve functionally independent survival but not overall survival and may reduce the proportion of deaths due to neurological causes, without increasing the risk of an adverse outcome as compared to WBI alone.[15,40] Although there is no data to confirm or repudiate the effectiveness of SRS as a single modality of therapy or compare surgery with SRS as the initial modality of therapy, the addition of SRS to WBI confers a significant survival advantage.[31,56]

These do not apply to patients with metastatic lymphoma, small-cell lung cancer, germ-cell tumour, leukaemia or sarcoma.

Vascular

Arteriovenous Malformations

Steiner revolutionised AVM management by demonstrating AVM obliteration without open surgery in the 1970s.[58] Since then, historically, AVMs have formed the bulk of cases for whom GKS is done. In one of the largest published series, Liscak et al.[31] analysed 330 patients with AVMs with a median volume of 3.9 cc. Repeat radiosurgery was performed on 76 patients after angiography failed to demonstrate obliteration after 3 years. AVM obliteration was achieved in 74% of patients after the first round of radiosurgery and in 69% after the second, with the overall chance of cure being 92%. Smaller volume AVMs and the application of a higher radiation dose resulted in a higher chance of obliteration. The risk of re-bleeding was 2.1% annually until full obliteration. The risk of permanent morbidity was 3.4%. In a study from our centre, 103 children (mean age 13.9 years) with a mean follow-up of 26.4 months were studied (57 had Spetzler-Martin Grade I or II, and 46 had Grades III–V). The mean volume of the AVMs was 2.4 cc and the mean marginal dose was 24.4 Gy. Complete obliteration of the AVM was documented in 87% of patients with a 4 year angiographic follow-up. The three-year actuarial rate of nidus obliteration was 66%. Three patients (2.9%) experienced bleeding during the latency period and symptomatic radiation-induced oedema was noted in four patients (3.8%). A significantly higher incidence of radiation oedema was noted in patients with AVM volumes greater than 3 cc and in patients with Spetzler-Martin Grade IV and V AVMs.[24]

Cavernomas

There is a great deal of controversy regarding the role of GKS in cavernous malformations. This is because these lesions are angiographically occult and MR scans reveal persisting blood products; thus, it is very difficult to assess whether these have been obliterated post GKS. Hence, an analysis of bleeding rates may perhaps verify the efficacy of GKS in the same. Hasegawa

et al.[17] examined the long-term haemorrhage rate after radiosurgery for 82 patients with symptomatic cavernous malformations in the brainstem or diencephalon, in which surgery was deemed to be very high risk. They found that the annual haemorrhage rate was 12.3% per year for the first 2 years after radiosurgery, followed by 0.76% per year thereafter. When compared to the natural history of these lesions (annual bleed rate of 0.6% per annum in previously unruptured cases, 4.5% per annum in patients with a single previous bleed and a 30% per annum bleed rate in patients with greater than two bleeds), GKS may confer a greater than 30 fold reduction in the baseline risk of symptomatic bleeding.[25] Liscak et al.[32] also studied 112 patients with cavernous haemangiomas, treated with a median prescription dose of 16 Gy with GKS of which 107 patients were followed for a median of 48 months. They observed that the re-bleeding rate was 1.6% while it was 2% prior to radiosurgery. A transient morbidity rate of 20.5% and a permanent morbidity rate of 4.5% were also observed. Before radiosurgery, 39% of patients suffered from epilepsy and this improved in 45% of them. Re-bleeding was more frequent with a prescription dose below 13 Gy.

Functional

Trigeminal Neuralgia

TGN was one of the first indications for GKS. However, microvascular decompression provides more effective pain control over longer periods of time. GKS should be reserved for patients who are not optimal surgical candidates and have TGN refractory to medical treatment. Sheehan et al.[54] reported the results of GKS in 151 cases of TGN, wherein the trigeminal nerve was targeted 2–4 mm anterior to the pons with 50–90 Gy of radiation. Around 90%, 77% and 70% of patients experienced some improvement in pain at 1-, 2- and 3-year follow-up, respectively, with 27% of patients suffering a relapse and 9% developing new onset facial numbness. Although these results have been validated by a large number of series, our experience, though limited, suggests that only about 50% of patients have some improvement in pain relief after this procedure.[10,12] It is our experience that GKS is possibly a good second line treatment option for patients with typical TGN. It is the procedure of choice for patients with TGN secondary to multiple sclerosis.

Movement Disorders and Epilepsy Surgery

Although SRS is the only non-invasive form of treatment for functional disorders, these contribute only a small percentage of treated patients. The drawbacks in using GKS is that only anatomical targeting is possible, this is an ablative procedure and very high doses (up to 150 Gy) are utilised, making shielding of adjacent neural structures impossible. Radiosurgical treatment for epilepsy and certain psychiatric illnesses is performed in several centres as part of strict research protocols.[11] Radiosurgical pallidotomy or medial thalamotomy has been associated with a 50% risk of complications and is no longer recommended. However, radiosurgical ventrolateral thalamotomy for the treatment of tremor in patients with Parkinson's disease, multiple sclerosis and essential tremor may be indicated in patients with advanced age, at high risk for surgery or those on anticoagulation.[7] A promising new application of GKS is the delivery of a high-dose of 160 Gy to the pituitary stalk, using an 8 mm or two 4 mm collimators in patients with intractable pain related to bone metastasis. A prospective multicentre study proved the efficacy and the safety of this treatment in nine patients, all of whom reported pain resolution without significant complications. Pain relief was observed within several days and this effect was prolonged until the day that they died.[18]

COMPLICATIONS AND SIDE EFFECTS

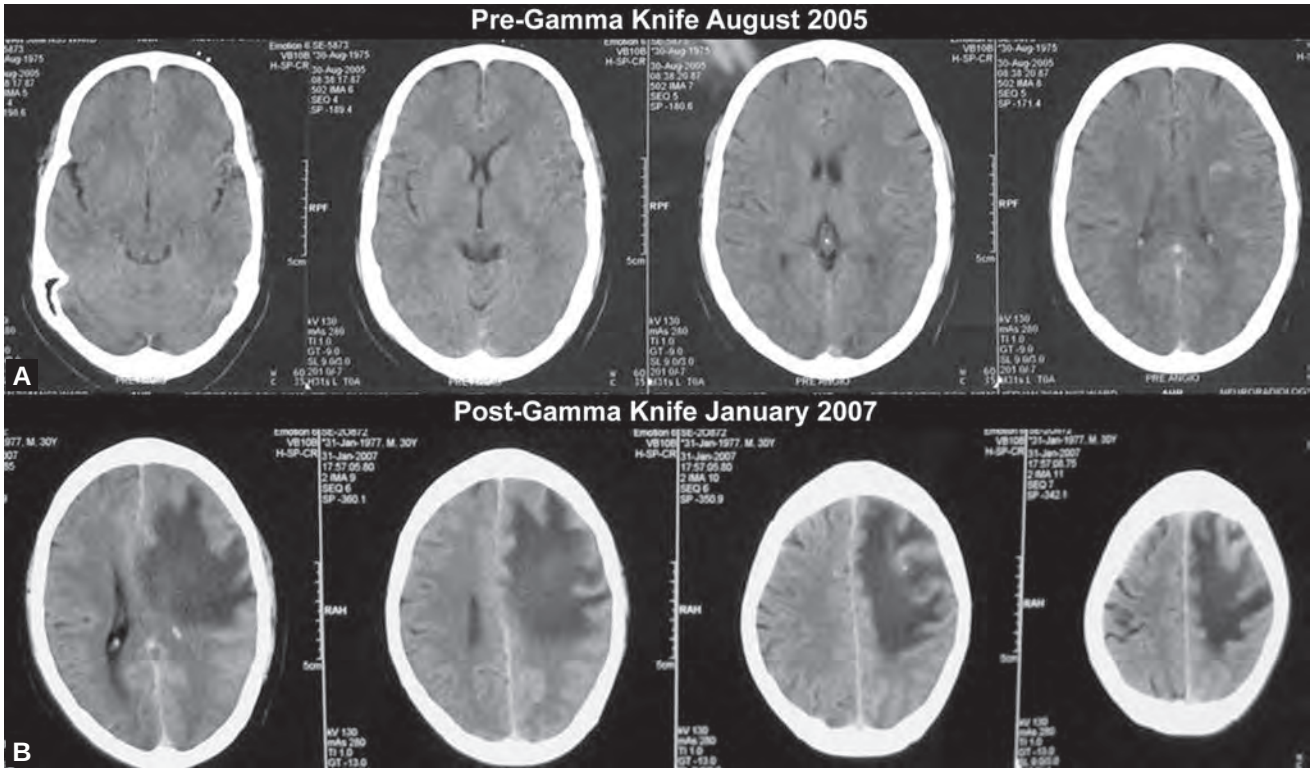
GKS has caught the imagination of the lay population and the neurosurgical community because of its ability to treat lesions with a very high conventional surgical risk of morbidity and mortality, with exact precision and a very low risk of complications. Principal among these are:

Acute Complications: Post Gamma Knife Headache a New Syndrome?

Although conventional wisdom dictates that the overall risk of adverse effects that a patient undergoing GKS has to contend with is about 2–4%, a study from our centre revealed that 12.7% of patients had immediate (less than 24 hours) complications, while 11.3% of all patients developed acute (24 hours–3 months) complications such as headache, nausea/vomiting, vertigo and seizures. None of these were severe. The incidence of perilesional oedema on follow-up radiology was 9.8% and correlated significantly with a maximum target diameter more than 25 mm and prescribed dose more than 20 Gy.[35] St George et al.[55] found that the incidence of headache following GKS was greater than 50% in a cohort of 47 patients followed-up for two weeks. Rozen et al.[49] have tried to identify a stereotypic "post-gamma knife (PGK) headache", but these complaints have never been severe nor are the mechanisms of induction clear. It has to be stressed that early complications are, with few exceptions, never severe.

Radiation Myelitis

Radiation changes can or do occur in the normal adjacent brain parenchyma due to a number of complex reasons which are not altogether understood. Flickinger et al.[57] used an integrated logistic formula to study the effect of dose and location on adverse radiation imaging effects (ARIE), after GKS for AVMs and found that the entire volume under the 12 Gy line correlated significantly with the same. Thus, the anticipated risk should be plotted against the estimated chances of AVM occlusion before prescribing the final dose. Care should be taken to avoid



Figs 9A and B: Serial axial CT scans revealing post-GKS radiation changes in the region of the left sensorimotor cortex of the patient whose angiograms confirmed AVM obliteration in Figure 6

exceeding the conventional tolerance doses of the optic pathways, cranial nerves and the brainstem. When MR changes do develop, these are often asymptomatic or else produce transient neurological deficits, which can be dealt with a prolonged course of steroids and free radical scavengers. Only rarely have patients required a decompressive craniectomy for the same. Figures 9A and B illustrates the ARIE which developed prior to the successful obliteration of the large motor strip AVM depicted in Figure 6. The patient had developed dysphasia and hemiparesis, which resolved over six months with steroids and decongestants.

ARIE may be most devastating in the compact cross-section of the brainstem. A collaborative study from our centre has shown that patients with benign intra-brainstem gliomas, cavernomas and AVMs run an 18.7% risk of developing an ARIE at a median prescription dose of 15 Gy delivered at the 50% isodose. Exposure of the brainstem at volumes as low as 0.1 cc to doses greater than 12 Gy resulted in ARIE. Four of these patients developed new neurological deficits which were all transient. The presence of an ARIE in this study was linked significantly to the development of new neurological deficits and age below 40 years. ARIE, thus, was actually a favourable prognostic marker to predict recovery from a new neurological deficit.[53]

Cyst Formation

Despite a favourable outcome after GKS, cysts may sometimes form at the target site which may produce a mass effect and require surgery, especially in AVMs and VS. Izawa et al.[21] studied 12 such patients with delayed cyst formation in the vicinity of the AVM after an average period of 6.7 years, following GKS which had shown complete angiographic obliteration. Eight of these patients subsequently required surgery. Cyst formation after GKS for VS may produce hydrocephalus and acute neurological deterioration warranting monitoring with serial MR scans.[19]

Hydrocephalus

Hydrocephalus has also been reported following GKS for VS, whether a causative relationship exists is highly debatable, as these may occur as a consequence of the natural history of the disease process.[61] Following fractionated SRT, however, Sawamura[50] reported an 11% incidence of hydrocephalus in a series of 101 patients who received 40–50 Gy administered in 20–25 fractions over a 5–6 week period. The mean size of tumours associated with this change was 25.5 mm and was significantly higher than the rest of the cohort.

Second Malignancy

Perhaps the most dreaded complication associated with the use of GKS, especially for benign lesions, is the risk of inducing a second malignancy. Twenty such cases have been reported thus far, 10 tumours developed *de novo* of which eight were malignant. Fourteen patients had VS of whom eight had neurofibromatosis-2.[3]

As nearly 400,000 patients have undergone GKS thus far, the incidence of brain cancer in this cohort is about 5 per 100,000. This should be compared with the overall age-adjusted incidence rates for brain cancer in the United States, which was reported to be 6.4 cases for every 100,000 persons in the year 2002.[65]

PLATFORMS DELIVERING STEREOTACTIC RADIOSURGERY

Leksell Gamma Knife™

The Leksell Gamma Knife™ (Elekta instruments AB, Stockholm, Sweden) has patented most of the widely used GKS platforms using either 201 (models B and C) or 180 (Perfexion) Co-60 radiation sources. Most available research in GKS emanates from this technology. These platforms remain some of the most expensive single pieces of medical equipment that a hospital could invest in.

Rotating Gamma System

A more recent entrant in this field is a Rotating gamma system (RGS) developed by OUR International Inc. Shenzen, China. This uses 30 Co-60 sources contained in a revolving hemispherical shell with six groups of five collimator holes, which provide varying radiation beams. The advantages lie in that helmets need not be changed manually and the chances of collisions are low.

LINAC Based Radiosurgery

Great interest has recently been focused on the Cyberknife® (Accuray Inc., Sunnyvale, California, USA) which utilises a 6 MeV Linear accelerator (LINAC) attached to a robotic manipulator which is mobile in six different axes. The robot guides the LINAC which aims the beam at the target. Unlike GKS, a rigid stereotactic frame is not used, target localisation is achieved by a mask or by fiducials. Two orthogonal X-ray cameras and an optical tracking system are used to track the patient's movements. An integrated X-ray image processing system then compares the actual real time images with those acquired previously and stored in a database to determine the shift. This information is then conveyed to the robot which makes the necessary corrections before radiation delivery. The accuracy of this system is 0.7 mm. CT is the primary modality of imaging. Treatment is often over multiple days and can be fractionated. The advantage lies in that this system can be used to target extracranial targets too.

Charged Particle Radiosurgery

Proton beam radiation using either the Bragg-peak to make these charged particles stop within the target or the plateau-beam to deposit particle energy remains, theoretically, the most attractive option of delivering intracranial radiation, as spillage is minimal due to a sharp dose fall-off as the charged particle rapidly loses energy. This facility, however, requires sufficient space to accommodate a cyclotron, significant maintenance overheads, continuous quality control and installation costs to the tune of Rs 160 crore. Only two facilities exist in the United States (Massachusetts General Hospital and Loma Linda University, California) and none in India.[43]

EVOLVING INDICATIONS AND FUTURE TRENDS

Despite the volume of clinical material documenting the efficacy of GKS in the host of benign, malignant and functional disorders detailed above, there is still a paucity of histopathological data to convincingly document the biological response of normal and/or pathological tissue to the effect of high dose single fraction delivery of stereotactic radiation. The development of an animal model will go a long way in our understanding of the radiosurgical dose response. The other areas of advancement are likely to be in the extension of the stereotactic space available for targeting polar lesions, advances in imaging and segmentation of target structures and normal tracts and in peri-operative pharmacological treatment, to protect normal tissue and sensitise target cells.

The Perfexion™ platform may significantly enhance our capability to treat lesions in the cervical spine, paranasal sinuses, the oral cavity and even the neck. Ophthalmic indications for using GKS now include uveal melanomas, haemangioblastomas, ocular metastases, macular degeneration and even glaucoma.[33]

Integration of Magneto-Encephalography (MEG) into planning may offer epilepsy surgery programs a truly non-invasive means of specifically targeting seizure foci, while minimising the risk of radiation myelitis. Integration of Positron-emission Technology (PET) too can help us treat malignant disease with greater specificity.

Future research needs to be directed towards the development of radiosensitisers, injected during the pre-GKS angiograms that would allow us to target larger AVMs with a lower prescription dose to increase obliteration rates, while reducing the risks of radiation damage to adjacent normal structures. Similarly, the use of hypothetical neuroprotective agents during GKS for malignant disease may help us escalate the prescription dose to enhance the tumour kill capability, without increasing the risk of adverse radiation effects.

GKS remains a most valuable tool for the neurosurgeon, both in the primary therapy of neurological disease and as an adjuvant to conventional surgery. Its scope and indications have crystallised over the last two decades and are likely to broaden with the further passage of time. This represents the next phase of modern neurosurgery and arguably ranks as its most important innovation since the introduction of the operating microscope.

192 Psychosurgery

Ramamurthi B, V Balasubramaniam, Ravi Ramamurthi, Santosh Mohan Rao K

The increase in our knowledge of the functions of the human brain, especially in the realm of cognition has now made it possible to make discrete lesions in selected areas of the brain and achieve amelioration in predominantly psychiatric illnesses. This field of surgery may be termed psychosurgery or functional neurosurgery. The WHO defines psychosurgery as; "the selective surgical removal or destruction of nerve pathways for the purpose of influencing behaviour".[11,47] Another definition of psychosurgery is as follows: "Any surgical procedure that attempts to alter, through manipulation of neural tissue a thought or thought process that is associated with a psychiatric disorder categorised in DSM-IV and that is not caused by any known structural lesion".[25] The WHO also mentions depression as the 4th largest group in the global burden of disease. Surgical procedures on the brain to control restless or aggressive behaviour have been included under the term *sedative neurosurgery*.[89,90]

HISTORY OF PSYCHOSURGERY

Observations on excavated skulls have shown well circumscribed defects, which suggest some form of a procedure on the skull of a living person, presumably an attempt at 'letting the devil out' of a 'mental' patient. After these early attempts, psychosurgery was abandoned due to ignorance regarding psychiatric diseases which were held to arise from various extraneous and non-human influences and due to many superstitions that clouded psychiatric illnesses and their management. Ancient India had specialised in the science of the mind and its control. Yoga and the universal acceptance of a tolerant attitude helped minimise psychological stresses. But in ancient Indian works on medicine, psychiatric illnesses were still attributed to extracorporeal influences. With increasing and better scientific study of psychiatrically ill patients, early 20th century saw a more rational approach to the problem of mental illnesses.

Franz Gall's phrenology tried to localise brain functions, based on external calvarial landmarks. Paul Broca ushered in the era of cerebral localisation. In 1891, Gottlieb Burckhardt, a Swiss psychiatrist, drilled holes in the heads of 6 severely agitated psychiatric patients and extracted parts of their frontal lobes. Three patients' outcomes were deemed "successful". Burckhardt's report gives us an insight into the desperation with regard to mental illnesses in those times. The concept of *primum non nocere (first do no harm) had given way to Melius anceps remedium quam nullum (better an unknown cure than no cure at all).* He was forced by his colleagues to abandon further such endeavours. In the late 1800s, Fredrich Goltz did temporal lobectomies in dogs and observed that the animals became more calm and tame than non-operated ones.[45,48]

The functional basis of psychosurgery was laid down by Fulton[28] who, in 1935, published his observations on frontal lobectomy in two chimpanzees. But Fulton also cautioned that, "….turning to questions involving perception, learning, memory and other higher intellectual functions, objective data are far more difficult to obtain in humans". Fulton and Carlyle Jacobson observed behavioural changes in chimpanzees after frontal lobe ablation and concluded that such procedures could decrease anxiety states in chimpanzees.[47] In 1936, Egaz Moniz and Almeda Lima published their experience with prefrontal lobotomy in humans. Moniz himself remarked, "We are certain that these experiments shall stir up keen discussions in the medical, psychiatric, psychological, philosophical, social and other fields. We expect that and hope at the same time that this discussion shall promote the progress of science and above all, the benefit of mental patients".[64]

That Moniz received the Nobel Prize for Medicine in 1949, is proof of the desperate situation prevailing in the field of therapy for mental illnesses.

Prior to psychosurgery there was no treatment for mental patients. Therapeutic nihilism was the philosophy of treatment, i.e. patients were allowed by default to languish according to the natural history of the disease. In the 1930s, somatic therapies, like ECT and others, were introduced. Walter Freeman, a neuropsychiatrist of the organicist school of psychiatry, popularised psychosurgery in the USA by publishing his work in the style of pulp-fiction thus abandoning scientific protocol. Moniz's procedure, the frontal leucotomy, was modified by Freeman and Watts as a prefrontal lobotomy. Freeman later devised the transorbital prefrontal lobotomy with an ice pick leukotome. Freeman with an ice pick severed psychosurgery's final ties with its roots, those of neurosurgery itself. His practice did not follow scientific principles and gradually a public campaign of misinformation was mounted against psychosurgery as

a form of mind control and this led to its near disappearance from the field of neurosurgery.[47] Govindaswamy and Rao[30] published, in 1944, the first series of leucotomies in India and Whitty et al.,[101] in 1952, in the United Kingdom. The results of prefrontal leucotomy were so remarkable that a large number of operations were performed. Although many patients benefited, in some instances the patients deteriorated and became dull and apathetic with alterations in personality and this led to dissatisfaction with the long-term results. The discovery of chlorpromazine in 1945 heralded the fall of psychosurgery. In 1947, Spiegel and Wycis started stereotatic dorsomedial thalamotomy and this formed the basis of subsequent stereotactic procedures in psychosurgery.[4,47] In 1949, Scoville[92] devised and modified leucotomies in the hope of diminishing the unsatisfactory side effects of the classical leucotomy. Ramamurthi, working in the United Kingdom, in 1949, had performed open orbital undercutting operations with satisfactory results.[41] In 1947, Fulton warned against the widespread use of leucotomy and hoped that neurosurgeons will not allow their zeal to outrun their knowledge of function. He also suggested that operations on the cingulate gyrus could be done as a *"limited" leucotomy.*

Hugh Cairns in London and Le Beau in Paris took up this suggestion and started removal of a portion of the anterior cingulate gyrus under direct vision. Reporting on 37 cases, Lewin[52] found that after cingulate resection, there were no ill effects on the personality of the patients and the complication rate was low. It may be mentioned here that Miller[63] in a ten year follow-up of patients who underwent leucotomy (lobotomy) for mental illness, between 1948 and 1952, found that 61% were working and rehabilitated in the community. In 1967, the Harvard Neurosurgeon H Thomas Ballantyne Jr ushered in the era of modern stereotactic psychosurgical procedures with air ventriculography for localisation and thermocoagulation for lesion making. He also deserves credit for making psychosurgery truly multidisciplinary with the involvement of psychiatrists and neurologists and also for the use of questionnaires for documentation of the outcome in patients undergoing various psychosurgical procedures.[40] *"It has all been done before"* remarked Holmes in the BMJ.[36] Readers of psychosurgery are requested to acquaint themselves with the achievements of the *Madras school of psychosurgery* pioneered by Profs. B. Ramamurthi, V. Balasubramaniam, S. Kalyanaraman, T. S. Kanaka, Jagannathan et al. through the 1960s and the 1970s. Several anatomical targets were selected and approached stereotactically, via various trajectories. Balasubramaniam and Ramamurthi reported on the largest clinical series of patients to date who were submitted to stereotactic amygdalotomy.[49] Prof. Lars Leksell pioneered the use of the gamma knife in lesion making in psychosurgery. The contributions of Norman Geschwind, Luria and Muriel Lezak, in the parallel fields of neuropsychology and cognitive neurology, also deserve mention in mankind's effort to unravel the mystery of the human brain. Early attempts at controlling aggressive behaviour disorders by ablation of the frontal or temporal lobe were not uniformly successful and also led to undesirable results. The understanding of the various behavioural mechanisms was hampered by the fact that the part of the brain which controlled behaviour was labelled the rhinencephalon or olfactory brain and was considered vestigeal in man. The breakthrough came when Bard[15] and Cannon[22] following Woodworth and Sherrington[104] established that the 'sham rage' phenomenon arose from the region of the hypothalamus.

LIMBIC SYSTEM ANATOMY—NEWER PERSPECTIVES

The functional anatomy of the limbic system has undergone a sea change with advances in neurobiology and neurosciences. The earliest concept of *networking* was provided by Prof. Niewenhuys in 1936[53] when he considered the LS to be comprised of five concentric C-shaped circuits which were as follows:

1. Stria medullaris thalami, habenular nuclei and habenulointerpeduncular tract.
2. Amygdalae and stria terminalis.
3. Fimbriae and fornix.
4. Hippocampus with extension over the corpus callosum and the septal nuclei.
5. Parahippocampal gyrus and cingulum.

Another classification is the division of the limbic system into limbic areas comprising the amygdala, parahippocampal gyrus, hippocampus, septum, hypothalamus, limbic thalamus, insula and paralimbic areas comprising the anterior temporal pole and the orbitofrontal cortex.

Papez suggested a circuit for human emotion in 1937 which was as follows: Cingulate gyrus → Hippocampus → Fornix → Mammillary bodies (Hypothalamus) → Anterior thalamic nuclei → Cingulate gyrus.

To this circuit, MacLean in 1952 added the septal area, nucleus accumbens, orbitofrontal cortex, anterior temporal cortex, DM thalamic nucleus and amygdala.[57]
Goldenberg in 1988[30] suggested three limbic sub-circuits:

1. *Medial limbic circuit:* This is the classical Papez circuit.
2. *Basolateral circuit:* Orbitofrontal cortex and anterior temporal cortex → amygdala → magnocellular DM nucleus of thalamus (fronto-thalamic fibres).
3. *Defence reaction circuit*: Comprising the hypothalamus, stria terminalis and amygdala.

It has been postulated that interruption of any of these pathways can block inputs to frontal lobes and relieve psychiatric symptoms by affecting one of the primary functions of the frontal lobes namely, cognition.[84]

Mega et al.[61] classified psychiatric disorders into three groups localised to specific anatomical structures and circuits. Limbic system disorders were classified based on the increased, decreased and distortional activity of the circuits.

Concept of Thalamocortical Dysrhythmias[97]

This brings the concept of mental disorders down to disturbances in single cell physiology using MEG. These are a group of disorders characterised by localised and protracted low frequency spontaneous recurrent activity of the thalamocortical system and this underlies certain chronic psychotic, affective and anxiety disorders, including obsessive compulsive disorders (OCD). The re-establishment of normal oscillation could be achieved with anteromedial pallidal and centrolateral thalamic lesions. These were based on the studies of Spiegel and Wycis who targeted the MD thalamic nucleus for psychosis.[79]

The features of thalamocortical dysrhythmias (TCD) are as follows:

- Hyperpolarisation through disfacilitation and/or over-inhibition of thalamic relay and/or reticular cells by the disease source. Psychosis is therefore attributed to corticothalamic disfacilitation and a striatal anomaly providing thalamic over-inhibition. Chronic dysfunction of the cognitive network triggers neurotic disorders.
- Hyperpolarised state is due to a source of calcium T channel de-inactivation, causing production of low threshold Ca^{2+} spike (LTS) bursts by thalamic or reticular neurons.[106]
- Neurons in such a state have a slow rhythmicity of thalamic cortical loops. They are locked up in theta rhythm low frequency domain by ionic currents. Recurrent divergent corticothalamic and reticulothalamic projections cause coherent diffusion of frequency to various cortical areas.
- The proposed existence of activation of higher frequencies, i.e. beta and gamma cortical domains due to asymmetrical corticocortical GABAergic collateral inhibitions. This is similar to the edge effect due to lateral inhibition in the retina.

The essential feature is that resonant oscillatory thalamocortical properties are required for the generation of normal hemispheric function.

The concept of thalamocortical slow burn, i.e. progressive cortical and thalamic atrophy, due to self-destruction by calcium triggered apoptosis, further reinforces the concept of TCD. The above concept is important, as it provides a neuroanatomical target for psychosis, which was previously considered as a contraindication to psychosurgery. The concept of thalamocortical dysrhythmia will be of importance in the near future, as psychiatrists are gradually understanding that schizophrenia, OCD, depression, etc. are different manifestations of dysfunction in the same or related anatomical circuits.

The targets selected by researchers of TCD are:

- *Centrolateral nucleus of the thalamus* which is located by the co-ordinates: 2 mm posterior to the posterior commissure, mediolaterally 6 mm lateral to the lateral border of the 3rd ventricle, dorsoventrally at the inter-commissural plane. It is reached by an anteroposterior angle of 60 degrees and mediolateral angle of 5–10 degrees. The size of the lesion must be 4 mm in diameter and 12–14 mm in length.
- *Anteromedial paralimbic thalamic nucleus* which is located by the co-ordinates: anteroposteriorly 4 mm posterior to the anterior commissure, mediolaterally 12 mm lateral to the lateral border of the lateral ventricle, dorsoventrally 2 mm ventral to the intercommissural plane. It is reached by an a-p angle of 55 degrees and a mediolateral angle of 20 degrees. The lesion size must be 4 mm in diameter and 6 mm in length.

The authors employed the above targets in patients with psychotic hallucinations/delusions, OCD, major depression, BPD, anxiety states and impulse control disorders (ICDs) and had good results. The sample size was however small, comprising 11 patients.

Note: *The targets are based on documented magnetoencephalography (MEG) data. They do not imply a reduction of functional thalamocortical loops and are based on regulation towards normalisation of the dysrhythmic thalamocortical oscillation.*

Figure 1 shows the schematic diagram of (highly simplified) connections of limbic system.

The amygdala was excluded in the concept of the behavioural brain initially. During the past two decades, however, it has become increasingly obvious that the amygdala plays a pivotal role in the production of behavioural patterns through its connections to the cortex, the limbic system, the hypothalamus[88] and thalamus. The circuit that Papez proposed is essentially on the medial side of the hemisphere aligned parallel to the sagittal plane. In 1937, Papez remarked that "the cingulate gyrus is the seat of dynamic vigilance by which emotional experiences are endowed with an emotional consciousness".[62] Livingston[55] proposed another limbic circuit at right angles to the plane of the Papez circuit and termed it the basolateral circuit, consisting of the orbito-insular-temporal connections. The median circuit of Papez connects to the anterior thalamic nucleus, while the basolateral circuit connects to the dorsomedian nucleus. The basolateral circuit reaches the thalamus without the interposition of a hypothalamic midbrain relay. Livingston[55] also suggested that normal behaviour may be the result of a balance between the basolateral and the median circuits.

The behavioural brain may be conceived as having a central core of executive structures with extensions and distant connections. The amygdala, the hypothalamus and the periaqueductal grey form the central core. The inferior orbital cortex is connected to the amygdala by the uncinate fasciculus and functions as a frontal extension of this system.[66]

The cingulum is connected to the limbic nuclei of the thalamus and is more concerned with emotional 'feeling' (a purely subjective phenomenon) than with emotional behaviour. The dorsomedian nucleus of the thalamus, by virtue of its connections with the cingulum

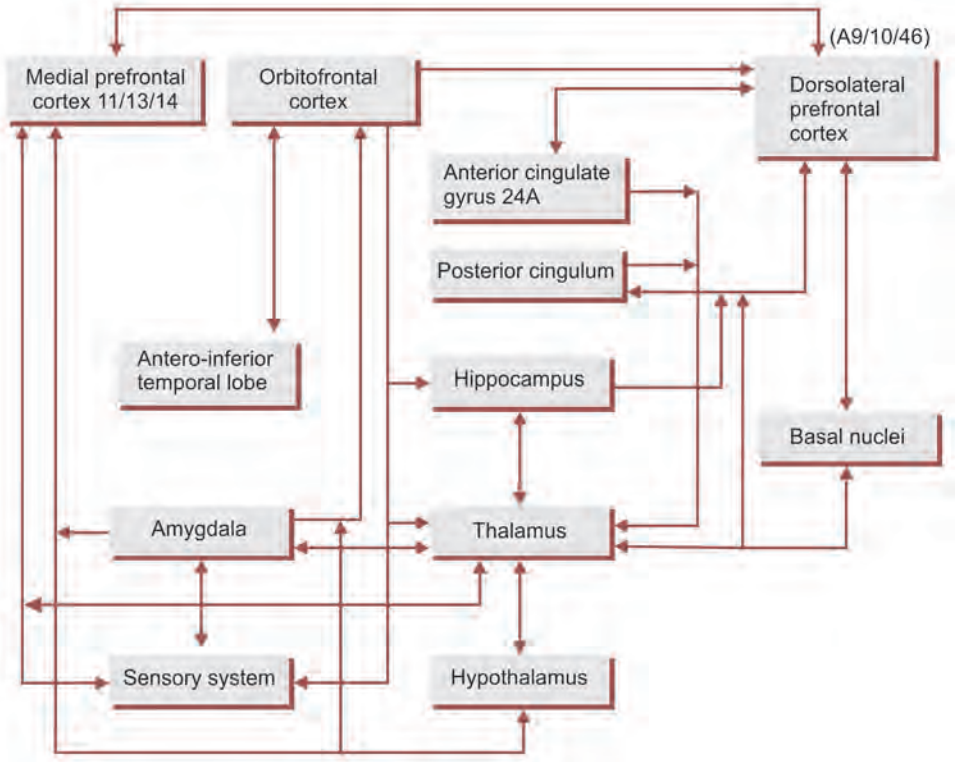

Fig. 1: Affect regulation circuit—cognition and emotion

and hypothalamus, forms an integral part of the behavioural brain on the 'affect' side. The anterior third of the internal medullary lamina of the thalamus connects to the hypothalamus and is involved in the modification of behaviour. Figure 2 shows connections of the cingulated gyrus.

The close proximity of the olfactory brain and the behavioural brain and their interconnections was not only an anatomical accident but also represents an important stage in functional evolution of humans from lower animals, in whom olfactory sensations were major determinants of behaviour. Thus, in man also, the olfactory and non-olfactory parts are closely interrelated at many levels, including the amygdala.

Amygdala

The amygdaloid nucleus has a dual origin. It develops partly from the primitive olfactostriatum and partly from the hypopallium. It has been identified in cyclostomes and tail less amphibians. As we go up the evolutionary scale, it undergoes an increase in size, until it reaches a maximum size of 1200 cumm in man. It becomes very complex in man and the terminology used to describe the amygdaloid nuclei is a little confusing because the same descriptive terms used for lower animals have been applied to man, without taking into consideration the changes in the position of the amygdaloid nuclei. The amygdaloid primordium lies on the floor of the temporal horn. As the temporal horn changes in form, the amygdala is carried medially and also rotates until, eventually (in man), it lies on the anterosuperior wall,

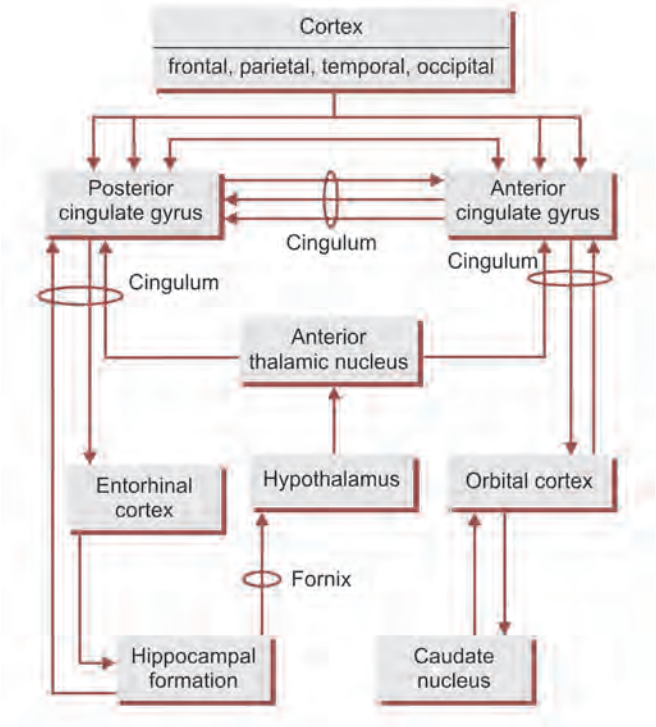

Fig. 2: Connections of the cingulate gyrus

exactly opposite the inferolateral bulge of the hippocampus. It is this shift that causes some confusion when terms, like corticomedial and basolateral, are used. The amygdaloid nucleus lies in close approximation to the superomedial wall of the temporal horn. The tail of the caudate nucleus, as it runs forwards, seems to end in the

amygdala. In sagittal sections, the centre of the amygdaloid nucleus is about 4.5 mm in front of the most anterior point of the temporal horn; its long axis lies along the roof of the temporal horn. In the coronal plane, it is related to the medial margin of the temporal horn.

Structure of the Amygdala

Broadly speaking, the amygdala can be divided into the *basolateral* (which is non-olfactory) and *corticomedial* (which is olfactory) parts. The basolateral part is further divided into a basal and a lateral nucleus; similarly the corticomedial is divided into a medial and a cortical part. The main sub-divisions have different afferent and efferent connections.

In addition to the study of cytoarchitecture by Nissl and Golgi stains, efforts at understanding the structural organisation of the amygdala include a consideration of its chemoarchitecture. On the basis of acetylcholinesterase stains, monoamine oxidase stains and dithizone and Timm stains, various divisions have been proposed. Most of these studies also confirm the broad division of the amygdala into a corticomedial and a basolateral part.

Connections of the Amygdala

The amygdala connects many nuclear groups and structures. For some of them, both electrophysiological and anatomical evidence is available. A few of these connections, however, still need anatomical verification, although there is abundant electrophysiological proof, e.g. the amygdalo-hippocampal pathway. The connections of the amygdala are to the temporal lobe, the hypothalamus, the thalamus and the frontal lobe. All these connections are predominantly unidirectional circuits. The important fasciculi of the amygdala are as follows:

A. Amygdalo-temporal connections: The amygdaloid nucleus connects to the temporal pole by the amygdalo-polar bundle. It is this bundle that is the main link between the amygdala and the inferior orbital cortex.[39]
B. The Amygdalo-hypothalamic pathways: The amygdalo-hypothalamic pathway is the most important link in this system. Originally, the amygdalo-hypothalamic pathway was probably a single entity, but subsequently it was separated into a dorsal and a ventral part, by the development of the basal ganglia and the internal capsule. The dorsal amygdalo-hypothalamic pathway is the older of the two and is referred to as the stria terminalis. It is a bi-directional pathway, although its main flow is to the amygdala. It runs along the roof of the temporal horn posteriorly and then turns superiorly to reach the anterior commissure. Here, it divides into two main components known as the precommissural and the postcommissural components.

The precommissural component ends mainly in the septal nuclei and also connects to the hypothalamus. The postcommissural component ends mainly in the hypothalamic nuclei. The ventral amygdalo-hypothalamic pathway is more important functionally. Arising mainly from the basolateral part of the amygdala, it runs medially and superiorly to reach the level of the anterior commissure where it splits into two. One division enters the hypothalamic nuclei particularly the posteroventral medial nuclear group. The other turns superiorly and ends in the subcallosal gyrus and the septal nuclei.

C. The Amygdalo-thalamic bundle: This is a distinct band that arises from the basolateral part and for a certain distance is part of the inferior thalamic peduncle. It eventually ends in the dorsomedian nucleus of the thalamus.
D. The uncinate fasciculus: This arises partly from the temporal pole and partly from the amygdala and ramifies after reaching the inferior orbital cortex, which is considered to be a frontal extension of the limbic system. The internal medullary lamina, which is the thalamic extension of the reticular system, contains in its anterior one-third nuclei which form part of the behavioural brain. Their connections with the amygdala have not been deciphered as yet. However, considerable electrophysiological evidence exists to show that the hippocampus projects to the amygdala, but anatomical studies have not been demonstrated.
E. The olfactory connections of the amygdala: They are practically confined to the corticomedial group of nuclei. The olfactory tract divides into three bands:
    i. The intermediate fibres end in the anterior perforated substance, which is encircled by the lateral and medial bands.
    ii. The medial tract passes deep to the cortex and ends in the region of the subcallosal gyrus.
    iii. The lateral goes to the corticomedial group.
F. The term extended amygdala includes the central and medial amygdaloid nuclei, various divisions of the bed nucleus of the stria terminalis, the interconnecting cell populations along the course of the stria terminalis dorsally and the caudal part of the ventral striatum and populations of neurons in the subpallidal region of the basal forebrain (previously called the substantia innominata). The extended amygdala has a high degree of internal associative connections. It has been considered to be a separate anatomical-functional unit. It must be emphasised that only the "non-cortical-like" central and medial nuclei of the amygdaloid complex and not the "cortical like" basal and lateral amygdaloid nuclei are included in the concept of the extended amygdala. This unit has rich afferent projections from the association cortex, basolateral amygdala and hippocampal formation and has efferents to the basal nuclei,[107] hypothalamus and various brainstem nuclei. Heimer et al. suggest that a functional derangement of the extended amygdala leads to a constellation of motor, affective, endocrine and autonomic symptoms.[62]

Figure 3 shows the connections of amygdala.

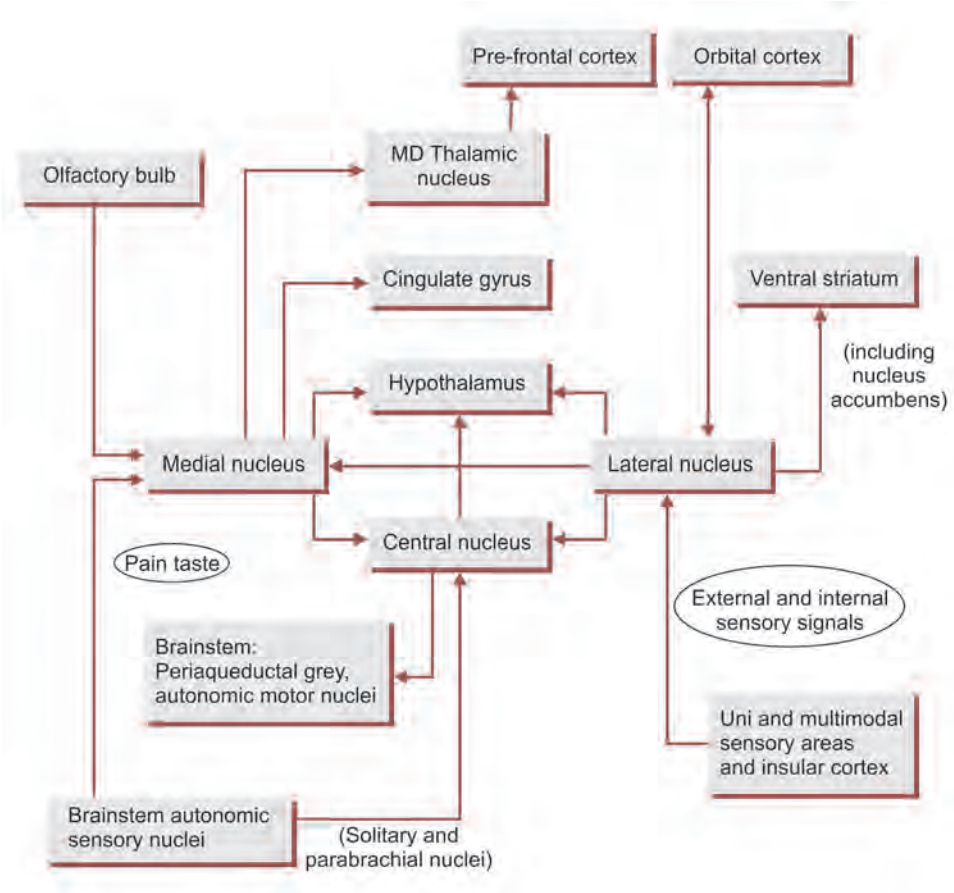

Fig. 3: Major connections of amygdala

Nucleus Accumbens

The nucleus accumbens is an enigma that has long been thought to be one of the main crossroads between the limbic (hippocampus and amygdala) and the motor systems, the focal point of an expression of motivational and emotional processes into motor behaviour. The shell of the nucleus accumbens is in reality a transition zone between the amygdala and the striatum. The ventral tegmental area (VTA) has a modulatory effect on this limbic-motor interface. Derangements of this meso-limbic dopamine system at the level of the nucleus accumbens has been implicated in specific aspects of drug addiction, schizophrenia and other affective disorders. The antipsychotic effects of neuroleptic drugs are mainly mediated through the shell of the nucleus accumbens.[62]

HYPOTHALAMUS

The hypothalamus was the first structure to be recognised as associated with behavioural mechanisms. Cannon,[22] in 1929, demonstrated that the hypothalamus was responsible for rage reactions, and Bard[15] localised the 'rage centre' in the hypothalamus. One of the nuclear groups in cats, which on stimulation gives rise to a rage reaction, is the periforniceal nucleus. The nucleus that corresponds in man to the feline periforniceal nucleus is the ventromedial nucleus. A few facts about the anatomy of the hypothalamus as pertaining only to the behavioural system are described here.

Two important fibre tracts course through the hypothalamus:

1. The median forebrain bundle connecting the various areas of the limbic system and the mesencephalon.
2. The fornix, an efferent pathway from the hippocampus to the mamillary body, consisting of many fibres to the hypothalamic nuclei.

The afferent connections of the hypothalamus are:

- The amygdala-hypothalamic pathways that have already been described,
- Fronto-hypothalamic fibres and
- Fibres from the ventral anterior nucleus of the thalamus to the hypothalamus.

The efferent connections are many, the more prominent one being the dorsal longitudinal fasciculus of Schultz. This runs from the medial hypothalamic zone up to beyond the mesencephalic tegmentum.

Physiology

Stimulation of the amygdala in cats is known to cause a rage reaction. By means of such stimulation studies, Ursin and Kaada[31] were able to show that certain parts of the amygdala controlled the fighting reaction and certain areas controlled the flight reaction. Removal of the amygdala has been shown to tame some naturally

ferocious animals, such as the Australian marsupial known as the Tasmanian devil. Electrical stimulation of the amygdala in humans does not produce rage or anger, although this has been reported in certain studies.[31,44,96]

For the purposes of behavioural physiology, the hypothalamus can be divided into two zones: the medial-ergotrophic and the lateral-trophotrophic zones, the former corresponding to the dynamogenic and the latter to the adynamogenic zones of Hess.[35] Most of the amygdaloid connections end in the medially situated ergotrophic zone. Stimulation of this zone (particularly near the periforniceal nucleus) produces sham rage. The psychovisceral phenomena of emotions are autonomic in nature, whether they are concerned with flight or fight and hence the hypothalamus can be presumed functionally to be the chief effector centre of the behavioural brain.

With the increasing telencephalic control of the diencephalon, the areas concerned with behaviour get represented in the amygdala and the limbic system (the behavioural brain).[34,99] If one compares the behavioural brain to the motor system, one can distinguish an upper level and a lower level. The upper level is represented by the amygdaloid nucleus and its connections with the limbic system and the thalamus. The amygdala acts as the higher centre by receiving inputs from various regions and levels, like the viscera, the endocrine organs and from the hippocampus. The lower level is represented by the hypothalamus and the periaqueductal grey, which are the common efferent pathways for all behavioural impulses akin to the final common pathway in the anterior horn cells for motor phenomena.

The internal medullary lamina helps to reinforce the amygdalo-hypothalamic influences and can be considered a reinforcing centre like the cerebellum in the motor system, if one might extend the analogy.

Early Psychosurgery

The procedures in vogue were: (1) operations on the frontal lobe; (2) cingulumotomy (cingulotomy) and (3) sedative neurosurgery.

The psychosurgery procedures that were used subsequently were further improvements of the above procedures.

Choice of Target

To understand the rationale behind target selection, one needs to understand the following concepts. Interoceptive and exteroceptive stimuli impinge on the frontal lobe wherein, by means of conceptual thought, the proper response is decided upon.[5] This response is 'driven by' two pathways: (a) directly to the hypothalamus from where the resultant action may come through and (b) more often through the cingulum, the amygdala and the thalamus and indirectly to the hypothalamus. At all stages this response is modified by the memory records coming in from the hippocampus. Thus, there is a reverberating circuit within the system which according to Papez can "add emotional colouring to the psychiatric process".

In cases where the thought processes are disturbed or chaotic, surgery has to be directed to the frontal lobe and hence a leucotomy is indicated. When the drive is strong and uninhibited, an interruption of the cingulum is indicated. But when the disturbances consist of wandering, aggressive or destructive behaviour, one has to target the amygdala or the hypothalamus.

In spite of nearly seven decades of work, there is no unanimity about the fibres that are to be divided in a leucotomy. In the earlier days it was perhaps correct to speak of quadrantic, bimedial or inferomedial cuts. Many of them were in alignment to the lesser wing of the sphenoid. With the increasing knowledge of the connections of the frontal lobe, one has to name the tracts involved, if scientific accuracy is to be achieved.

Freeman and Watts[27] claimed that in the most restricted leucotomy, the fronto-hypothalamic fibres were divided. In the bigger cuts, more of the fronto-thalamic connections were divided, which was why one observed a retrograde degeneration in the thalamus of certain patient groups. Knight[46] suggested that the usefulness of this procedure was due to the interruption of fibres of the orbital fasciculus, lying beneath the caudate nucleus (subcaudate tractotomy or basofrontal tractotomy). He believed that in basofrontal tractotomy, one divides the centripetal and centrifugal fibres of the amygdaloid nucleus, the fronto-hypothalamic connections, some connections of the median forebrain bundle and the diagonal band of Broca.[20]

CLASSIFICATION OF PSYCHIATRIC DISORDERS[3]—AN OUTLINE

Before proceeding to a full fledged discussion on the treatment of mental disorders, it would be appropriate to familiarise ourselves with the psychiatric classification of diseases.

The first psychiatric classification of mental disorders appeared in the international classification of diseases-6 (ICD-6) just after WWII. The American Psychiatric Association published the Diagnostic and statistical manual-I for classification of psychiatric diseases in 1952 which was based on ICD-6. Since then, there have been several revisions—the present one being ICD-10 and DSM-IV TR. The aim is to establish definite scientific criteria for diagnosis and research in psychiatry. It is strictly not to be used by unqualified personnel.

Most mental disorders are categorised into mild, moderate, severe, in partial remission, in full remission and as past history of mental illness. There are five axes in DSM-IV TR namely:

Axis I: That comprises clinical disorders and other conditions that may be a focus of clinical attention

Axis II: Personality disorders, mental retardation

Axis III: General medical conditions
Axis IV: Psychosocial and environmental problems
Axis V: Global assessment of function

Personality disorders are classified into three clusters: (*DSM-IV TR pp. 685-721).*

Cluster A: Which comprises paranoid, schizoid and schizotypal disorders.

Cluster B: Under which come antisocial, borderline, histrionic and narcissistic personality disorders.

Cluster C: Which includes avoidant, dependent, obsessive disorders and personality disorders not otherwise specified.

Each mental illness is diagnosed with definitive criteria and has multiple subsets. However, it must be remembered that: "The concept of mental disorders like many other concepts in medicine and science lack a consistent operating definition that covers all situations."

AN OVERVIEW OF THE COMMON PSYCHIATRIC MALADIES AMENABLE TO PSYCHOSURGERY (NEUROANATOMY AND CLINICAL FEATURES)[91]

Obsessive Compulsive Disorder (OCD)

It afflicts about 2–3% of the general population. It starts in childhood/adolescence and is characterised by recurrent thoughts, images, feelings or behaviours that persist after the patient's attempts to eliminate them and which are accompanied by marked and often overwhelming anxiety. The mainstay of treatment is selective serotonin re-uptake inhibitors (SSRIs) with clomipramine as a 2nd line drug.

The main side effects of these medications are weight gain, sexual dysfunction and sedation. Tardive dyskinesias and dystonias can also occur. Behavioural therapy is useful in 70–80% but has a poor compliance, as many feel the distress exposure which is a part of the therapy annoying. Ten per cent of all cases of OCD are refractory to all medical/behaviour therapies. It is in this subgroup of patients that psychosurgery has a role to play.

Neuropathologic Circuitry

In OCD, the circuitry involved is the *cortico-striato-thalamocortical circuitry (CSTC).*[1,2]

The orbitofrontal cortex, anterior cingulated cortex and the caudate nucleus are central to the pathogenesis of OCD. The relative imbalance favouring the direct versus the indirect paths within this circuitry, leads to overactivity, i.e. amplification within the orbitofrontal cortex and the anterior cingulated cortex including the caudate nucleus and thalamus resonant with failed striato-thalamic inhibition, i.e. filtration within this same circuitry. This model *(striatal topography)* can be extended to explain Tourette's syndrome and trichotillomania and body dysmorphic disorder as well.[46] In OCD there is a deficit at recruiting the striatum in the service of thalamic gating.[81] Therefore, in OCD, interruption of the reciprocal projections between the orbitofrontal cortex and the thalamus would theoretically decrease the reverberating (amplified) activity in the orbitofrontal cortex-caudate nucleus CSTC and thereby decrease OCD symptoms.

Intractable OCD[82] which comprises 10% of all OCD cases is defined as:

Failure of treatment despite:

- maximum doses of 5 or more than 5 SSRI for 10 weeks with augmented doses of buspirone hydrochloride and lithium carbonate
- Yale-Brown obsessive compulsive score more than 20
- Global assessment of function score (GAF) less than 50

"Both Parkinson's disease and obsessive compulsive disorder share the same cortico-basal ganglia-thalamic circuits and both should be considered as tremors. In PD, it is a motor tremor while in OCD, it is a limbic thought tremor."[40]

Depression

Major Depression (MD) is characterised by apathy, anhedonia, appetite and weight disturbances, sleep disruptions, psychomotor abnormalities, fatigue, guilt, suicidal ideas and behaviour, delirium, hallucinations and catatonia. It affects 2.6–5.5% of males and 6–11.8% of females.

The *circuitry* involved in major depression is as follows:

1. *Dorsal component*: Anterior, dorsal and lateral prefrontal cortex, dorsal anterior cingulated cortex, parietal cortex and pre-motor cortex (Cognitive circuit).
2. *Ventral component*: Paralimbic cortex, subgenual anterior cingulated cortex, orbitofrontal cortex, anterior insular cortex (Affective circuit).
3. The hypothalamic-pituitary-adrenal pathways are also associated with behaviour.

Major depression, therefore, is due to hypoactivity of the dorsal circuit and hyperactivity of the ventral circuit.[91]

Deactivation of the subgenual anterior cingulated cortex or disruption of interconnections among elements of the ventral component is a plausible mode of therapeutic action by anterior capsulotomy. The pregenual anterior cingulate cortex has the capacity to facilitate restoration of the dynamic equilibrium between compartments, via its inhibitory influence over dorsal and ventral elements. Thus amygdala hyperactivity and hippocampal insufficiency play an important role in the pathogenesis of depression major. Hyperactive amygdala innervation is seen in patients with major depression. The amygdala is assessed by the response to pictures of human faces with various emotional expressions. Right amygdala dysfunction results in failure to habituate to threat related stimuli in anxiety disorders.[80]

Sexual Disorders and Drug Addiction

Abnormal and compulsive sexual drives are very difficult to treat. Such drives may be directed against the opposite sex, the same sex or against children. Medical

therapy with oestrogen has been tried. Surgical therapy with castration has been suggested, but is not always useful and is also unethical. In such cases, stereotactic lesions in the region of the tuber cinereum seem to confer good benefit without any appreciable disturbance of other aspects of hypothalamic functions. Careful assessment of this type of surgery is necessary.

IMAGING IN PSYCHIATRY

Radiology, of late, has aided us tremendously in our understanding of mental illnesses. MRI, fMRI, SPECT and PET are the main modalities of imaging in neuropsychiatry. *Morphometric MRI* is able to detect subtle volumetric abnormalities in the striatum in OCD.[38,69] Decreased caudate nucleus volume is also reported in OCD.[85] Decreased putaminal and lenticular size is seen in trichotillomania and Tourette syndrome.[67] MRS showed a decrease in striatal NAA but normal NAA in the lenticulum in OCD.[16] fMRI in post-traumatic stress shows stimulation of the anterior cingulate cortex and other anterior paralimbic regions. In symptomatic OCD, there is recruitment of the caudate nucleus and the anterolateral orbitofrontal cortex. Pre-treatment neuroimaging is used to test the hypotheses regarding the prediction of response to treatment. Increased activity in the orbitofrontal cortex suggests a better treatment response to behaviour therapy versus pharmacotherapy (and also predicts the usefulness of SSRI therapy) in OCD.[21] Emotional state and presenting symptoms at the time of injection are important determinants in brain perfusion in SPECT but less critical in PET. SPECT study during symptom provocation is better than resting SPECT for studying the pathophysiological mechanism of OCD. Presurgical CMR (with PET) within the posterior cingulated gyrus predicts the outcome after cingulotomy.[78]

To summarise, the SPECT studies in OCD are as follows: there is increased perfusion in the anterior cingulate gyrus, left basal nuclei and orbitofrontal cortex. A decrease in rCBF in the above structures results in symptomatic improvement.[55]

MRI studies in depression are done by cortical parcellation methods. In depression, decreased volume of the subgenual cortex and the orbitofrontal cortex are noted.[18,19] This finding corresponds with the post-mortem brain studies done in patients who had depression major, wherein glial cell loss was seen in the subgenual cortex, dorsolateral prefrontal cortex and the orbitofrontal cortex.[72]

It has thus been concluded that the severity of major depression is inversely proportional to orbitofrontal cortex function.[77] Baseline pregenual anterior cingulated cortex level of activity predicts the response to antidepressants. The greater the activity, the better the response to therapy is.

Indications for Surgery

There are no universal guidelines for surgery. The indications are decided by the local hospital committees (e.g. The Cingulotomy Committee of the Massachusetts General Hospital). The criteria[82] are as follows:

- The patient must fulfil the DSM IV or WHO criteria for OCD/major affective criteria/anxiety.
- The duration of the illness must be 5 or more than 5 years duration and has been documented to be refractory to all therapy available.
- The disease must be shown to cause substantial suffering and significant impairment to the patient's psychosocial function.
- Prognosis without relief of symptoms is shown to be very poor.
- The patients and the family must be willing to participate in pre-operative evaluation and long-term post-operative rehabilitation.
- The referring physician must demonstrate a commitment to pre-operative and long-term post-operative care of the patient.
- The patient has a Y-BOCS score over 20 (for OCD), BDI over 30 (for depression major) and GAF under 50.

The contraindications are as follows:[23]

- Age less than 18 years or more than 65 years.
- Concurrent complicating DSM IV-Axis I disorders (organic brain syndromes/substance abuse).
- Complicating Axis II cluster A or B disorders (personality disorders).
- Complicating Axis III disorders (brain tumour, atrophy).
- Medical conditions which would increase the risk of surgical/imaging complications.

Indications for surgery described in another study,[37] had slight differences such as:

- Duration of disease should be more than 3 years.
- Substantial suffering as evidenced by various rating systems.
- Current and up to date treatment options have been tried systematically for 3 years without appreciable effect on symptoms or have to be discontinued because of intolerable side effects.

Contraindications to surgery were the same. But the patients were kept off medications for 4 weeks before obtaining a baseline SPECT image prior to surgery and also after surgery.

In both studies there were certain essential features, like all patients were thoroughly assessed pre-operatively with various psychiatric rating scales and were reviewed by an institutional board comprising two psychiatrists, one neurologist and one neurosurgeon. In all cases it had to be made clear that the surgery was only to relieve the patient's suffering and restore normal function. All patients who were undergoing psychosurgery must be able to give informed consent, which is usually possible in cases of OCD and depression where insight is retained. This was enforced by the Medical Ethics

Committee of North America to prevent the chaos of the Freeman era from recurring.

PROCEDURES USED IN MODERN PSYCHOSURGERY

Modern psychosurgery has seven standard procedures[29] in its armamentarium to help combat mental illness. (Deep brain stimulation has been approved by the FDA for obsessive compulsive disorder, depression major epilepsy and Parkinson's disease.) They are:

1. Cingulotomy
2. Subcaudate tractotomy
3. Anterior capsulotomy
4. Limbic leucotomy
5. Amygdalotomy
6. Hypothalamotomy
7. Thalamotomy

Cingulotomy

The goal of cingulotomy is to cut the anterior supracallosal fibres of the cingulate gyrus and interrupt a major component in the medial limbic circuit. The conceptual thought processes arising in the frontal region reach the hypothalamus through the cingulum, the amygdala and the thalamus. This results in the desired action being exhibited for the benefit of the subject. When this process gets exaggerated and out of control, thoughts revolve in the mind of the patient leading to an obsession, as well as to the performance of compulsive acts. In such cases, dividing the cingulum bundle breaks the vicious cycle.

The cingulum as a target was conceived by the experiments of Jacobsen in lower animals and Fulton in primates. In 1949–1951 Fulton proposed lesions in the anterior cingulate gyrus in the Papez circuit. Fulton suggested cingulotomy as a form of restricted leucotomy. Freeman and Watts, in 1942, noticed an overall decrease in the tension of patients who undergo cingulotomy. The first open cingulotomy was done by Scoville. Others attribute it to Cairns.[101] Whittey, in 1952, excised anterior supracallosal fibres of the cingulate gyrus, as treatment for depression. Foltz and White undertook stereotactic cingulotomy for intractable pain. Ballantine and Giriunas practiced modern stereotactic cingulotomy in patients with psychiatric illnesses.[25]

Indications for Cingulotomy:

- Unipolar disorder
- Depressive component of bipolar disorder
- OCD
- Generalised anxiety disorder
- Chronic pain syndrome
- Drug addiction

It has been advocated even for aggressive behaviour.[98] It was found that after cingulumotomy for painful conditions, it was possible to withdraw the pain killing drugs without serious side effects. There were no withdrawal symptoms. It was thus only logical to conclude the benefit of cingulumotomy for drug addiction. This procedure not only relieves the persistent preoccupation of the patient with the idea of consuming the drug, but also relieves him of the drug habit, without having to suffer the withdrawal symptoms. The abolition of these symptoms was demonstrated in animals by Foltz and White.[26] Cingulumotomy primarily for drug addiction has been practised and popularised by Balasubramaniam et al.,[5] Ballantine et al.[13] and Foltz and White.[26]

Anatomical Considerations

The cingulum bundle runs anteroposteriorly in the cingulate gyrus, forms an essential part of the Papez circuit and is a major integrating force in the limbic system. It contains fibres that run from the frontal lobes to the hippocampus and also has connections to the anterior and dorsomedial nuclei of the thalamus and the hypothalamus. As the hypothalamic connections are the pathways through which the autonomic disturbances are mediated, the lesion must be made at the point where these fibres join the cingulum (i.e. in the plane of the foramen of Monro).

Technique of Cingulotomy (As was Used by Profs. Balasubramaniam V and Ramamurthi B)

The anterior horns of the lateral ventricles are visualised in the lateral and AP views by pneumoencephalography. This technique continues to be useful even after the advent of MR guided stereotactic surgery. The usual level of the target is 9 mm above the upper margin of the anterior horn in the plane of the foramen of Monro. In the AP view, the lesion is made 9 mm from the midline. In the air studies, the subcallosal cistern gives an idea regarding the thickness of the corpus callosum. But in cases of doubt or when it is necessary to know the thickness of the corpus callosum, angiography may be done with the stereotactic frame in position.[5] The position of the anterior cerebral artery and its branches gives one an idea about the thickness of the corpus callosum and that of the cingulated gyrus.[5] Usually, such elaborate estimation is not necessary. With MR guided stereotactic techniques, the landmarks mentioned above can be identified and the lesion placed precisely at the desired target. In patients being operated upon under local analgesia, stimulation may produce either sudden relief or a feeling of tension. As soon as the lesion is made, the patient may experience a change for the better in his mental status. The lesion is made with diathermy coagulation, a cryogenic probe or oil wax. Thermal lesions are better avoided, because of the proximity of the anterior cerebral vessels.

Results

The results of cingulumotomy for OCD are good and the complications are few (Table 1). In 573 procedures performed on 400 patients, Ballantine[14] reported two hemiplegias and no death. Post-operative psychological assessment revealed no deterioration in personality or

Table 1: Various cingulumotomy studies

Author	*Target*	*Imaging and probe*	*Results*
1. Balasubramaniam V	9 mm above upper margin of anterior horn in the plane of the foramen of Monro AP: 9 mm from midline. The ACA was a guide.	Pneumoencephalogram diathermy coagulation	n = 154 17% well 50% improved
2. Cosgrove, Rauch	Three separate lesions encompassing the cingulum from the ventricle roof to cingulate sulcus. 2–2.5 cm in ant. CG (2–5 cm above lat ventricle roof). 7 mm from the midline, 20–25 mm Posterior to the tip of the frontal horn. The lesion size 15–20 mm in height and 10 mm in diameter.	MRI Thermocoagulation (Radionics) 85 deg for 90 seconds.	n = 18, > 35% imp

mental skills. Of 154 patients followed-up by Ballantine,[12] 17% were well and 58% had significantly improved. Our results of cingulumotomy on 37 patients with obsessive neurosis were similar.[74] Based on a 25 year follow-up of patients operated upon in Boston, Jenike et al.[37] concluded, in 1991, that cingulumotomy is a potentially effective treatment for patients with severe and disabling obsessive compulsive disorder.

For drug addiction the results depend on many factors. One of the most important is the personality type of the addict (psychopathic or non-psychopathic) and the nature of the drug abuse. In the case of alcohol, the results are uncertain because the alcohol habit up to a point is socially accepted in daily life. Cingulumotomy often helps established addiction, but it is not a safeguard against future addiction.

Long-term experience has shown that the effects of limited operations on the frontal lobe and those of cingulumotomy are similar. But in our experience, there seem to be preferential sites for different types of psychiatric illnesses like depression and obsessive neuroses. At times, the two procedures may have to be combined or repeated one after the other to obtain maximum benefit. Stereotaxic cingulumotomy does not produce any appreciable or demonstrable deficit. In the series of Ballantine,[13] Foltz and White[26] and Balasubramaniam et al.,[5] the subjects did not have post-surgical deficits.

An important feature of Cosgrove's study was that the lesioning was done in 2–3 stages. When the patient did not improve the next lesion was made, the time interval being as long as 1 year. It was subsequently noticed that creating one large lesion and following-up the patient revealed the same benefit as a staged procedure.

Transient complications of cingulumotomy were headache, nausea, urinary difficulties and seizures. It is, however, believed that cingulotomy causes fewer side effects and cognitive disturbances compared with other psychosurgical procedures and is therefore used more frequently on the American side of the Atlantic.

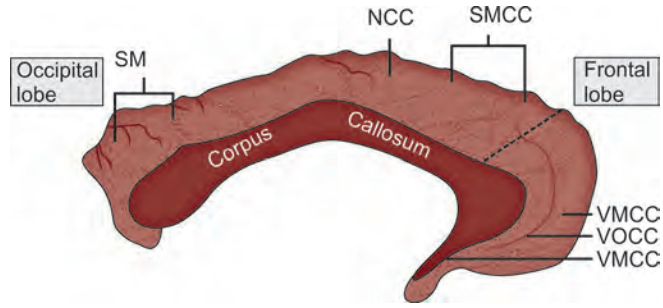

Fig. 4: Divisions of cingulated gyrus

Figure 4 shows the cingulum and its subdivisions.

Subcaudate Tractotomy

The aim of the procedure is to lesion the substantia innominata of Reichert in the area inferior to the caudate nucleus head, whereby white matter tracts between the orbitofrontal cortex and the subcortical structures (thalamus, hypothalamus, amygdala) are interrupted. This disrupts the basolateral circuit and cortico-striato-thalamic pathways. In this area, the diagonal band of Broca, anterior commissure and medial forebrain bundle traverse with cholinergic inputs from the entorhinal cortex, pyriform cortex and hypothalamus. Secondary degeneration of the dorsomedial nucleus of the thalamus occurs. The connections in this area generate endocrine, autonomic and somatomotor responses to emotional and motivational states, leading to increasing primary sensory stimuli. Scoville did the first open orbital undercutting. Knight (1964) did the first stereotactic tractotomy originally with Yttrium 90 radioactive beads.[25]

Indications

1. Major depression (most common indication).
2. Chronic pain.
3. OCD (2nd most common indication).
4. Anxiety.
5. Bipolar disorder.

It has been observed that in patients who have depression major with sudden midlife onset or in the peripartum period and, also have a positive family history of psychiatric disorder or if they have a history of having responded to ECT in the past, there is a very good response to SST.

Target

The earlier operations were done through a coronal burr hole and were open procedures. The stereotactic landmarks in the earlier era with pneumoencephalography for basofrontal-tractotomy were 0.5 cm in front of the plane of the tuberculum sellae, 1 cm above the orbital roof and 1 cm from the midline.[47] The lesions were made by radiofrequency current or oilwax. Knight[47] created localised lesions with Yttrium 90 seeds and found that the majority of patients improved.

The target co-ordinates for stereotactic tractotomy using an MRI based system[58] are as follows: three lesions are made of about 8 mm diameter each bilaterally in the same coronal plane, 15 mm anterior to the base of the anterior clinoid process.

1st lesion: 6 mm lateral to the midline and 10 mm superior to the floor of the anterior cranial fossa.

2nd lesion: 6 mm lateral to the midline and 15 mm superior to the floor of the anterior cranial fossa.

3rd lesion: 14 mm lateral to midline and 10 mm superior to the anterior fossa.

Results

The results of basofrontal tractotomy depend on: (a) the type of disease (schizo-affect, schizophrenia etc.); (b) the duration of the illness; (c) the type of operation and (d) the post-operative rehabilitation. When all these factors are taken into consideration and the results assessed, it is clear that basofrontal tractotomy has a distinct place in the management of selected psychiatric disorders. Bartlett et al.,[17] reported 68% recovery from depression, 63% from anxiety states and 53% recovery from obsession in cases who had basofrontal (subcaudate) tractotomy. In our series of 42 cases of basofrontal tractotomy for severe depression, 72% showed recovery. In some cases, the results are not immediately apparent, but progressive improvement occurs over a few weeks.[41] Response to medications which were previously ineffective is augmented after tractotomy,[56] while in others the benefits are transient. The latter cases may require a second procedure, depending on their predominant residual psychiatric complaint. The addition of a lesion in the cingulum often helps these patients. Poor results are seen in primary psychosis and substance abuse (Table 2).

Transient Complications Seen in Patients

These complications are: headache, confusion, transient disinhibition and somnolence for about a week. These patients had no decrease in general intelligence, speed, attention and frontal lobe cognitive tasks. They were assessed 1 week prior to surgery, and 2 weeks and 6 months after surgery and were found to have insignificant long-term side effects.[42] In a series of 42 cases, Balasubramaniam and Ramamurthi had no deaths and one case had post-operative epilepsy, with none having deterioration following basofrontal tractotomy.

Anterior Capsulotomy

Anterior capsulotomy as a procedure was discovered by serendipity. Post-mortem studies on patients having undergone frontal lobotomy revealed degeneration betwixt the mediodorsal thalamic nuclei through the anterior limb of the internal capsule. It was first devised as a technique by Talairach et al. in 1949. In 1950, Lars Leksell of the Karolinska Institute in Sweden invented the gamma knife and used it for anterior capsulotomy.

The rationale behind anterior capsulotomy is as follows: By lesioning the anterior limb of the internal capsule, anterior capsulotomy interrupts the connections between the orbitofrontal cortex and the midline thalamic nuclei, thus disrupting part of the basolateral limbic circuit and cortico-striato-thalamic pathways. Anatomical studies have confirmed that the anterior limb of the internal capsule has anterior thalamic radiations (fibres connecting the frontal lobe with the medial and anterior thalamic nuclei) and prefrontal

Table 2: Various studies in patients who have undergone SST[21]

Author and year	*Number of patients*	*Results*
1. Goktype (1975)	n = 208	68% became independent 62.5% of the above had anxiety disorder 50% in OCD.
2. Strom-Olsen-Carlisle (1971)	n = 150	55% became independent 36% had anxiety, 50% had OCD.
3. Lovett et al. (1989)	n = 15 (unipolar disorders)	10 patients had decrease in symptoms 5 patients had decrease in frequency of episodes
4. Bridges, Bartlett et al. (1994)	n = 1300	40–60% returned to normal lives Suicide rates dropped to 1% in the surgical group.

Table 3: Various clinical series in patients who have undergone anterior capsulotomy

Author and year	*Patients*	*Outcome*
1. Leksell et al. (1956)	n = 116 gamma knife	For various reasons therefore no comparison
2. Leksell (1961)	n = not specified	50% OCD pts improved, 48% major affective disorders improved. Poor results were seen in schizophrenics. Overall success in OCD 60%
3. Burgley (1971)	n = 35 OCD pts	71% improved at 35 months (20 pts returned to Society).

corticopontine fibres.[25] Electrical stimulation of the anterior limb of the internal capsule results in a generalised sense of well-being with decreased anxiety and tension. Extrapyramidal responses, like tremors in the contralateral limbs, also occur. Disruption of the pathological CSTC circuitry at the level of the orbitofrontal cortex-caudate nucleus/reciprocal orbitofrontal corticothalamic connections underlies the therapeutic effects of anterior capsulotomy. Anterior capsulotomy is more popular on the continental side of the Atlantic.

Target

The target co-ordinates for anterior capsulotomy are as follows: The target height is 20 mm that spans the anterior limb of the internal capsule bilaterally. Radiofrequency probes are used for lesioning at 80–85°C for 45 secs. The inferior target is 2–4 cm lateral to the anterior tip of the lateral ventricle and the superior target is 1 cm superior to the inferior target site. The target used by Lars Leksell for his capsulotomy was as follows: Anterior 1/3rd of the anterior limb of the internal capsule, 5 cm behind the frontal horn tip and 20 mm lateral to the midline at the intercommissural plane. The technique used routinely involved the use of thermocoagulation and was also called thermocapsulotomy, in contrast to Leksell's gamma knife capsulotomy (Table 3).

Kullbey found no difference in outcomes between capsulotomy and cingulumotomy.

Side Effects

Transient deterioration in mental status was seen more in the patients undergoing capsulotomy, compared with those who underwent cingulumotomy.[50] Other rare but longer lasting complications include haematomas, nocturnal incontinence, mild frontal syndrome, aggressiveness, memory deficits and weight gain. "Slovenliness" has been described after capsulotomy. Gamma knife capsulotomy results are as good as conventional stereotactic capsulotomy.

Limbic Leucotomy

The total isolation of the frontal lobe from the rest of the brain, as was practised by Moniz, is unnecessary and harmful. The fibres that are to be divided are included in the inferomedial quadrantic leucotomy. Cuts that run laterally involve the uncinate fasciculus and result in some of the undesirable effects of leucotomy. Freeman and Watts[27] also claimed that in transorbital leucotomy only the fronto-hypothalamic connections are divided.

This procedure combines anterior cingulumotomy and subcaudate tractotomy, although the lesions for subcaudate tractotomy are more anteriorly placed. Kelley (1973) introduced limbic leucotomy, so as to combine the benefits of two procedures. He had an 84% improvement rate. Brown introduced *multitarget limbic leucotomy* wherein the amygdala are bilaterally lesioned too. Richardson used brain stimulation techniques for target localisation in the substantia innominata during limbic leucotomy. The lesion was only done if ANS changes like apnoea/blood pressure changes were seen during stimulation.[83] Long-term side effects, although rare, are transient like headache, confusion, lethargy, sphincter disturbances and preseveration.

Limbic Leucotomy is the Procedure of Choice in the Treatment of Intractable OCD[26]

Cosgrove and Rauch, after comparison, find that although therapeutically all procedures are equally effective, cingulumotomy is the safest.[24] Recently, limbic leucotomy has also shown to be of benefit in self-mutilation disorders and Tourette's syndrome.

Comparing the surgical results in OCD and major depression, it was found that limbic leucotomy was most effective.

Effectiveness in OCD (Percentage of Improvement): 56% cingulumotomy, 50% tractotomy, 61% limbic leucotomy, 67% capsulotomy.

Effectiveness in major depression: 65% cingulumotomy, 68% subcaudate tractotomy, 78% limbic leucotomy, 55% capsulotomy.[24]

Dorsomedian Thalamotomy

The aim and effectiveness of leucotomy lies in the division of the fronto-thalamic and hypothalamic connections. These can also be achieved by eliminating the thalamic end station of these limbic relay systems, namely the dorsomedian nucleus, as was demonstrated by Speigel and Wycis in 1950.[93] The results are comparable with those of leucotomy.

Amygdalotomy

Aetiology of Behaviour Disturbance

A disturbance of the delicate balance between various neuronal circuits in the hypothalamo-limbic system

results in abnormal behaviour patterns. While such disturbances may occur temporarily from injury, drugs, toxins, etc. more lasting trouble results from epileptic disorders and encephalitis. Post-epileptic behavioural disorders may occur in a patient who has a long history of tonic-clonic seizures. The behavioural disorder often sets in some time after adequate control of the seizures by anticonvulsant medication. Such a combination is often seen in association with temporal lobe epilepsy. Post-encephalitic behavioural disorders may follow immediately or some months after an attack of encephalitis. The Japanese B virus is the most prevalent type in India. This type of behaviour disorder is often associated with varying degrees of mental subnormality, ranging from minimal cerebral dysfunction to severe mental retardation. The other aetiological factors include trauma, meningitis, vascular disorders and schizophrenia. In these cases the behaviour disorder occurs without epilepsy.

Selection of Cases

The subjects for whom sedative neurosurgery is recommended are carefully chosen. Surgery is indicated when adequate drug or psychiatric therapy have not helped, even after a prolonged trial. A change of environment may sometimes help to modify the behaviour and this can be advised when feasible. When all conservative measures have failed, surgery is advised. Once surgical therapy has been decided upon, it is better to do it early to give relief to the patients as well as to the long-suffering parents and relatives.

Selection of Targets

Amygdalotomy or hypothalamotomy is effective in aggressive, violent behaviour, in low rage threshold and self-mutilation. Restlessness or hyperkinesis sans violence is difficult to treat. In these cases thalamolaminotomy combined with amygdalotomy gives better results than either of these procedures alone. Amygdalotomy is preferred as the first step by some,[8,32,65] since it is the 'higher centre' and is strategically located. In amygdalotomy, the lesion usually involves the entire nucleus, although the part directly concerned with behaviour is the basolateral part.

Stereotactic hypothalamotomy was first performed by Spiegel and Wycis[87,94] in a schizophrenic patient. Sano et al., reported on a series of 22 cases, in 1966,[89] and 51 cases in 1970.[86] The lesion in the hypothalamus is placed in the medial or ergotrophic zone, after elicitation of sympathomimetic effects on stimulation. This area corresponds to the posterior part of the ventromedial nucleus. Modern stereotactic amygdalotomy was commenced by Lee (1998) with MRI.

EEG may be normal, may show generalised paroxysmal dysrhythmia, diffuse disturbance or evidence of unilateral or bilateral temporal lobe dysfunction.[95] EEG is not helpful in the selection of cases for surgery, as there are frequent discrepancies between EEG findings, the clinical picture and the response to surgery.

Unilateral or Bilateral Operations

Unilateral amygdalotomy or hypothalamotomy may be done if the behavioural disturbances are of moderate severity but most cases require bilateral amygdalotomy or hypothalamotomy. Operations for behavioural (or emotional) disorders have generally to be done on both sides, since there is no laterality demonstrable in emotion or behaviour. One condition in which a strictly unilateral procedure (either amygdalotomy or hypothalamotomy) gives good relief is the behaviour disorder associated with infantile hemiplegia. These patients, who were once candidates for hemispherectomy, are considerably benefited by unilateral sedative neurosurgery.

One-stage or Two-stages

Bilateral amygdalotomy may be done in two successive stages. Bilateral one-stage amygdalotomy can be done safely and is not accompanied by extra deficits attributable solely to the bilaterality of the procedure. Bilateral hypothalamotomy is done only in successive stages.[6]

Amygdala First or Hypothalamus First

Some surgeons prefer hypothalamotomy as the procedure of choice,[86,89,90] while others prefer amygdalotomy as the first step,[7,33,65] due to the following reasons:

- The amygdala is considered to be the 'higher' centre.
- Bilateral amygdalotomy is a one stage operation, whereas hypothalamotomy has to be done in two stages.
- Eliminating the amygdala is perhaps more logical, as in many cases of behaviour disorders there is likely to be a defect in the amygdala; full proof for this is however lacking.

In patients in whom bilateral amygdalotomy does not succeed, hypothalamotomy is performed. Hypothalamotomy done after amygdalotomy has been termed *secondary hypothalamotomy* and in such cases, unilateral lesions in the hypothalamus are usually effective.[7] In severely retarded violent children, it is preferable to perform hypothalamotomy as the first procedure *(primary hypothalamotomy).*

The following are the types of abnormal behaviour patterns amenable to amygdalotomy and hypothalamotomy:

- *Hyperkinesis (restlessness and wandering tendency)*: Hyperkinesis is the term used to describe a tendency to keep moving aimlessly. This may be within or outside the house. In severe cases, the patient may exhibit a tendency to wander away from the house for some hours or days.
- *Destructive and violent tendencies*: These may be continuous or intermittent and may arise with or without provocation. Articles and objects within reach are broken and destroyed. The patient, for no obvious

reason, may suddenly throw objects at people nearby or attack them with heavy objects. The basis for this type of behaviour disorder is not clear. It cannot be equated with predatory aggression or even agnostic behaviour. At times the aggression suddenly bursts out after a period of augmentation. It is only in these cases that the aggressive act may be considered as the culmination of 'anger'. Patients with a low threshold for rage explode into a catastrophic rage reaction over trivialities. This is similar to the aggressive acts of the paranoid schizophrenic.

- *Pyromania*: A few patients have an obsessive desire to set fire to objects inanimate or animate. They derive pleasure and immense self-satisfaction from these acts of arson.
- *Self-destruction*: Some of the patients exhibit a marked tendency to hurt themselves. Instead of destroying external objects these patients tend to mutilate themselves and one of the most common ways is biting. Callous ulcers may be produced on the forearms by the constant biting. These patients seem oblivious to the pain produced by the biting. Similarly, some patients exhibit persistent head banging which would alarm any onlooker. The patients who indulge in self-mutilation do not attack others. The self-mutilation of the lips seen in Rett's syndrome is a different entity and is not considered here.

Assessment

The history of the disorder and the account given by the relatives are important in the assessment of a patient with behavioural disorder. It is difficult to quantitate aggression, violence or self-destruction. Hyperkinesis and restlessness may be measured, but accurate rating scales have not been worked out since many variables are involved. Narabayashi[65] used a room divided into blocks; the number of blocks the patient traverses over a fixed time period gives an insight into the intensity of the restlessness. *Clinical examination* is often difficult but may be possible during quiescent periods. Usually there is no neurological deficit, but occasionally, infantile hemiplegia with asymmetry of the limbs may be seen. Mental deficiency may often be obvious as also are the signs of self-mutilation or epileptic injuries.

Surgical Technique for Amygdalotomy (As Used by Balasubramaniam and Ramamurthi)

1. *Determining the Co-ordinates*: Under general anaesthesia, with the patient supine, bilateral coronal burr holes are made. A temporal or a posterior route may also be chosen.[59] The tip of the temporal horns are visualised by installing water soluble contrast medium through the burr holes, after the Leksell's stereotactic frame is fixed. In this position the dye clearly visualises the temporal horn in the AP and lateral X-rays. Use of CT/MR makes this step dispensable. The co-ordinates are calculated from the tip of the temporal horn. The centre of the amygdala lies 4 mm in front of and 4 mm above the anterior most point of the temporal horn. In the coronal plane this is 3 mm medial to the medial margin of the temporal horn.
2. *Depth Recording*: Recording of the electrical activity of the amygdala is not essential for localisation of the target, but is useful to get an idea of the rhythm of the amygdala and to find out if there are any abnormal discharges. In some patients, the amygdala shows spindle activity of about 25 microvolts at 12–15 cis. Narabayashi[65] has described injury potentials, consisting of small amplitude waves of 40–50 cis for 10–30 seconds. In an abnormal amygdala, there may be spike discharges or a flat record.
3. *Verification of Electrode Placement*: When an electrode reaches the target, three types of electrical activity may be recorded:
   a. High voltage spikes of transient duration; these are injury potentials
   b. High voltage fast activity
   c. Low voltage longer lasting waves occurring in spindles, the amygdala spindle.[5]

These patterns may not be elicited in every case. In some cases, typical spikes suggestive of focal epilepsy may be recorded.

Depth EEG is not always a reliable method of verifying the correctness of electrode placement, as our knowledge of the electrical activity of the amygdala is incomplete. Elicitation of evoked potentials from the amygdala, when the patient inhales ether, is more reliable.[65]

Stimulation of the target serves as a good method of verification. The stimulation, with a current of 2–3 volts at 50–60 c/s for 2–5 seconds, usually results in apnoea. Sometimes, vasopressor effects, dilatation of the pupils and increase in gastric acid secretion are also observed.[73] In some cases, despite correct anatomical localisation, the stimulation effects are not obvious. The explanation proffered is that the amygdala is diseased and cannot, therefore, function normally.[5]

4. *Making the Lesion:* The lesion in the amygdala can be made by diathermy coagulation, myodil wax injection or by the loop. The results do not depend on the paraphernalia used for lesioning, but do depend on the volume of the lesion made. The lesion must be at least 1 cc in volume for effects to be discerned.
5. *Post-operative Complications:* Complications can occur even in the best of hands despite meticulous planning and technique. These are seen in 2–3% of the patients undergoing the procedure. Usually all these complications are transient and revert back to normal in 3–4 weeks.

They are as follows:

1. Injury to the neighbouring structures:
   a. When the electrode placement is too deep and medial, the crus may be injured causing hemiparesis. Delayed hemiparesis has been noted to

occur 2–3 days after surgery; the cause for this is not clear, but is probably due to delayed white matter oedema.
   b. The subcortical white matter fibres may be injured by too many insertions of the electrode thereby causing hemiparesis.
   c. Dysphasia may occur if the electrode tract passes through the superior temporal gyrus.
   d. Injury to the optic tract, which lies medial to the amygdala, may produce a homonymous hemianopia.
2. Post-operative haematemesis may rarely occur and is due to an acute stress phenomenon. This is because of the connections of the amygdala with the hypothalamus.
3. Pulmonary oedema, although rare, can occur.
4. Loss of memory may occur if the lesion placement is too far posterior bilaterally. The Kluver-Bucy syndrome (or its equivalent in humans as described by Terzian and Ore)[43] has not been seen.
5. Transient hyperphagia and hypersexuality have been noted (two cases out of 260).[6]
6. Face processing impairments occur after partial bilateral amygdalotomy, especially for new faces. The patient is unable to interpret social signals from the face.[105]

Results

In 1963, the first large series of patients treated by amygdalotomy was published by Narabayashi et al.[65] who reported improvement in 51 out of 60 patients. Heimburger[33] reported that 17 out of 25 cases improved after amygdalotomy. Balasubramaniam et al.[25] reported on 44 cases with good results in 59% of the patients. In a report on 205 cases by the same group in 1973, improvement was seen in 65% of cases. Kiloh et al.[43] found 50% of 18 patients operated upon to show improvement a year after operation; in seven out of these nine patients, the improvement was maintained for periods ranging from 2–6 years (Table 4).

Table 4: Tabulation of the results of various clinical series in amygdalotomy

Author and year	*Patients*	*Imaging*	*Target*	*Results*
1. Narabayashi (1963)[65] (for severe behaviour and hyperactivity)	n = 60	Pneumography	Lateral group nucleus. Depth electrode recording with olfactory stimuli	85% improved
2. Chitanondh (1966)[23] (for olfactory fits, schizophrenia with olfactory hallucination and post-trauma personality disorder with olfactory hallucinations).	n = 7	(LA) — contrast ventriculogram amygdalography (EEG) Mechanical block with beeswax.	Medial ½ of amygdala	100% on EEG
3. Heimburger (1966)[32]	n = 25	pneumoventriculogram	2 cm lateral to midline, 1 cm below intercom line 45% posterior to AC along i-c-line in ant-med angle	35% cured, 45% improved.
4. Balasubramaniam, Ramamurthi (1960–70) For aggressiveness	n = 603	Leksell stereo-iophendylate ventriculography, intra-operative EEG, depth elec stim.	481 bilateral amygdalotomy 122 unilateral amygdalotomy.[8-10, 76] 0.5–2 V at 50 cyc/sec for 1 min, Diathermy coagulation 200 cc lesion. Total lesion size 2800 cc more than amygdala volume.	39% good, 37% improved
5. Hitchcock and Cairns (1973) For hyperactive destructive rebellious disorder with history of epilepsy[35]	n = 18	Physiological localisation.	Bilateral stereo amygdalotomy transtemporal route. Safest anatomical target with physiological localisation 3 x 1.8 cm depth elec stim, 1–10 V, 50–100 Hz, Medial group of nuclei.	27.7% imp
6. Lee (1998)[51] For intractable aggressiveness	n = 2	MRI, mod Todd-Wells Schaltenbrand and Warren atlas	EMG of facial muscles and skin conduction RF lesion, 3 separate lesion 3 mm apart b/l the largest 10 mm	100%

Hypothalamotomy (Surgical Technique as Described by the Senior Author)

Determining the Co-ordinates

After fixing the stereotactic frame, with the patient in the sitting position, a lumbar air study is performed and AP and lateral X-rays of the skull are taken. The co-ordinates for the target are calculated with reference to the anterior and posterior commissures and the lateral wall of the third ventricle. Sano et al.[86] used a target which lies in the triangle formed by the anterior border of the mamillary body, the mid-commissural line and the rostral end of the *aqueduct (the ergotropic triangle).* The chosen point lies 3 mm inferior to and 1 mm anterior to the mid-commissural point and is also 3–6 mm from the lateral wall of the third ventricle. A more anterior target, 6.5 mm in front of the mid-commissural point, 5 mm below the CA-CP line and 3–6 mm from the lateral wall of the third ventricle, has been found by Balasubramaniam and Kanaka[7] to be more useful than the conventional targets.

Depth Recording

Depth recording from the hypothalamus is not essential for surgery, as it does not provide useful information for localisation. Microelectrode recording and eliciting evoked potentials by peripheral painful stimulation may yield fruitful results.

Verification of Electrode Placement

Stimulation of the target and eliciting the required sympathomimetic responses is an essential step. The parameters of stimulation are 1–3 volts at 50 c/s for 10–30 seconds. If the original point chosen does not give the required response, adjacent points are stimulated to select the ideal site for the lesion. The stimulation effects are sympathomimetic in nature. They consist of dilatation of the pupils, ocular movement, tachypnoea, tachycardia and rise of blood pressure.

Pupillary dilatation is obtained on stimulation from a wide area. The ipsilateral pupil usually dilates more than the contralateral one. In most cases, medial or medial and downwards eye movements are seen. At times there may be some nystagmoid jerks.

In the series of Sano,[86] tachypnoea has been the most common finding. Apnoea was first noted by Balasubramaniam.[6] Both the afore mentioned are sympathetic responses. When the electrode is moved laterally, bradypnoea may be elicited. Tachycardia is a common result of stimulation. Sometimes there are minor degrees of arrhythmias like extra systoles. There may be a rise of systolic blood pressure. Movement of the neck to the side of stimulation or to the opposite side may occur.[86] There is an increase in circulating ketosteroids because the stimulation is similar to acute stress. The eosinophil count also falls. Sano[86] has reported a rise in non-esterified fatty acids. Increased gastric acid secretion has also been reported.[73] Electrical stimulation of the ergotrophic area results in desynchronisation of the EEG with production of theta waves in the hippocampus or diffuse irregular delta waves of high voltage.[86]

Making the Lesion

The lesion is made by diathermy coagulation. When coagulation is done by diathermy, a non-magnetic pellet is introduced into the site of the lesion. Post-operative X-rays were taken for the purposes of mapping out the site of the lesion on a standard brain atlas.

Post-operative Complications

These are rare and include:

- Transient diabetes insipidus
- Haematemesis may occur if the lesion is too far anterior
- Haemorrhagic pulmonary oedema is a recognised complication following hypothalamic destruction in animals, but rare after human hypothalamotomy and
- Ballistic movements have been reported presumably due to injury to the body of Luys.

Thalamolaminotomy[71,90]

Since this part is also connected with the limbic system, stimulation may produce apnoea. The lesion can be made either with wax or diathermy. Both sides can be done at one sitting. There has been no noteworthy complication after this operation.

Results of Hypothalamotomy and Other Sedative Neurosurgical Procedures

The results of hypothalamotomy in a large number of cases have been reported by Sano,[86] where 95% of patients showed improvement. In the series of Balasubramaniam and Kanaka,[6] 68.5% of patients had improved. In most cases the improvement is seen within a few days after the operation and consists of a reduction or abolition of aggressiveness. The fearless and restless child becomes obedient and quiet. In some cases there is an absence of the rage reaction to frustrating situations. Some patients exhibit a welcome placidity while in the hospital, but relapse into violence at home. These patients require progressive rehabilitation in a special institution. Sano et al. (1962) reported a series of 43 patients who underwent posterior hypothalamotomy for violent, restless behaviour. He used a bipolar needle electrode 0.8 mm in diameter and 0.5 mm being the inter bipolar distance. The imaging technique was pneumoencephalography. The lesions are made in the posterior medial hypothalamus 1 mm to 2 mm posterior to the midpoint of the intercommissural line, 2–4 mm below the intercommissural line and 2 mm lateral to the lateral wall of the 3rd ventricle. Bilateral lesions were made and improvement was seen in 7 days. Around 30.2% of patients had excellent results while 65.1% were good. 1 patient died due to aspiration.[89,90]

In addition to the abolition of aggression, a positive gain may also be observed such as a co-operative attitude hitherto unnoticed and also the emergence of a sense of responsibility, especially when insight improves. Another disability which may regress after sedative neurosurgery is the tendency for generalised convulsions. Although, the primary aim of amygdalotomy or hypothalamotomy is the control of behavioural problems, it has been observed that in many cases seizures, when present, are decreased in intensity and frequency. Aggressive destructive behaviour presenting as a major component of schizophrenia is also benefited by amygdalotomy. Vaernet and Madsen[100] reported disappearance or marked reduction of aggressive episodes in 11 out of 12 patients, on whom bilateral amygdalotomy was done. In about 30% of cases of amygdalotomy, the improvement disappears after some time and the patient reverts to his pre-operative state. This may happen even though the lesions had been of adequate size and were accurately placed. Such patients need hypothalamotomy. The results often depend on the aetiology of the condition. If the original cerebral damage is not extensive, the results of sedative neurosurgery are better. Thus, behavioural disorders following epilepsy do much better than post-encephalitic cases where the brain damage may be widespread. Patients with primary mental retardation respond the least to surgery.

The experience so far shows that sedative neurosurgery is a useful procedure in alleviating aggressive behaviour disorders. Wise patient selection yields good results without damaging the patient's personality. An established useful procedure in surgery should not be abandoned due to irrelevant and unscientific reasons.

OUTCOME MEASUREMENTS IN PSYCHOSURGERY

Evaluation of psychosurgery patients has come a long way from Walter Freeman's 'experience' to modern scientific questionnaires and outcome scores. There are several disease specific scores such as Yale-Brown Obsessive Compulsive score (Y-BOCS) for OCD, Hamilton depression rating (HA-DRS) and the Beck depression inventory (BDI) for depression and the Hamilton Anxiety Rating Scale (HA-ARS) for anxiety. Other tests used in neuropsychological evaluation of the patient are—the Wechsler Adult Intelligence score and its Korean modification (WAIS and K-WAIS), Hopkin's Verbal Language Test (HVLT), Rry-Osterrieth complex figure test, Wisconsin Card Sorting Test, Stroop test, tests of verbal imaging, Mini Mental State Examination (Folstein's and the Korean versions), etc. These scores help to aid in the diagnosis and also in the quantification of disease severity.

The post-operative assessment which was used previously is as follows:

The pre-operative and post-operative assessment of behavioural disorders is based on clinical impression in most cases. The results may be graded under the following five categories:[25]

1. There is no need for drugs. The patient is able to mingle easily with others.
2. Very much docile and given only to occasional outbursts.
3. Manageable when given drugs, although not leading a useful life.
4. Transient improvement followed by relapse.
5. No change.

The assessment is arrived at by direct observation and by interrogation of the relatives, nurses and attending doctors. The same type of assessment is used for amygdalotomy, hypothalamotomy and the other procedures of sedative neurosurgery.

To assess the outcomes of psychosurgical procedures, the *Pippard post-operative rating* scale[70] is presently used which is as follows:

- Very much improved
- Much improved
- Slightly improved
- Unchanged
- Worse

The *clinical global improvement (CGI)* may also be used which is an improvised version of the above score:

- Very much improved
- Much improved
- Slightly improved
- Unchanged
- Slightly worse
- Much worse
- Very much worse

NEWER MODALITIES OF TREATMENT IN PSYCHOSURGERY

Vagal Nerve Stimulation

Cervical VNS as a treatment modality was approved by the FDA in 1997. The implant used has only one manufacturer (Cyberonics, Houston, Texas). The vagal nerve nucleus (nucleus of the tractus solitarius) projects to the limbic system, higher cortex, parabrachial nuclei and the locus coeruleus which in turn project to the thalamus, amygdala, hypothalamus, insula and orbitofrontal cortex. In 1938, Bailey and Bremner observed synchronous activity by VNS in cats. The response obtained is a slow wave response in the anterior rhinal sulcus and amygdala in awake cats through corticospinal pathways. Zabara realised the relationship between VNS and anticonvulsant effects.[108] In 1988, the first FDA trial for VNS was done for drug resistant epilepsy. The number of patients who developed hoarseness was 0.7%. VNS for epilepsy has been recommended to be as effective and safe (Class I evidence). VNS acts in two ways. It increases NTS GABA which in turn is responsible for the antiseizure activity. VNS also increases 5-HIAA, HVA and DA which is responsible for the mood stabilising action

of VNS. As VNS has only been recently commissioned as a treatment modality there have been few studies. The one of interest is the "D-01" study which compares the efficacy of VNS to ECT (the gold standard of treatment of depression). There were 60 patients in the study and 36.5% patients had a reversal of their clinical condition after 10 weeks of VNS. Of these, 15% of the patients had full remission of their disease. 1 mA or more current strengths bring about better responses. Another interesting feature is that VNS seems to be effective only in the long-term and this has been proven by blood oxygen level dependent MRI (BOLD-MRI). There have been several other applications for pulsed electrical signals awaiting approval by governments the world over. These include: movement disorders, eating disorders (obesity), anxiety, dementia, Alzheimer's disease, chronic pain, migraine, cardiac arrest, post-traumatic stress and bilateral diaphragmatic VNS for morbid obesity. The battery life of a VNS unit is about 8–10 years. Another very important feature of VNS is that whole body MRI is contradicted in patients with *VNS.*[54]

Transcranial Magnetic Stimulation (TMS)

Transcranial Magnetic Stimulation (TMS) is a non-invasive method of cortical stimulation by creating a powerful transient magnetic field. It is a research tool and is still not approved by the FDA for therapeutic purposes. The principle behind TMS involves the use of a powerful handheld magnet to create a time varying magnetic field, so that a localised pulsed magnetic field over the head surface depolarises underlying superficial neurons. High intensity current is rapidly turned on and off in an electromagnetic coil through discharge of capacitors. This generates brief but very powerful magnetic fields, which is different from the 'magnetic fields used in alternative therapy'. TMS acts solely through production of electric currents in the cortex. Repetitive and rhythmic TMS is called *rTMS.* If the frequency is more than 1 Hz, it is known as *fast rTMS* with current frequencies up to 25–30 Hz. Increasing the frequency in TMS increases the seizure risk. The frequency of TMS is slow, compared with that of DBS (where stimulation frequencies progress up to 150 Hz.). There is limited depth penetration and the amount of electricity needed to cause changes in the cortex varies from person-to-person. An important parameter to be defined in TMS is that of the motor threshold. *Motor threshold* is defined as the minimal amount of electricity needed to produce movement in the contralateral thumb, when the coil is placed optimally over the primary motor cortex. This can be determined either by an observer or by EMG. *Paired pulsed TMS* has immediate effect within seconds. It comprises of applying two TMS pulses to the same region with varying interpulse intervals and intensities. This can be used to assess the stimulatory and inhibitory systems of the brain at rest in individuals with different disorders. Speech arrest can easily be accomplished by TMS and is due to a "virtual lesion" in the speech centre. There are safety issues regarding the use of TMS. The TMS safety table is calculated using a surrogate end point—for seizure; it is the spread of TMS induced motor evoked potential (MEP) beyond the target area of stimulation. This is applicable only to the motor cortex. A past history of seizures puts one at an increased risk of seizures during TMS. There is, however, no decrease in cognitive performance in patients undergoing TMS when compared with patients receiving ECT, although rTMS is similar to ECT but functions at subconvulsant levels. The heating of metallic cochlear implants and pacemaker inactivation during TMS is another hurdle preventing its clinical use. TMS has been found to correlate with fMRI findings in the determination of eloquent cortex. TMS has been found to increase dopamine levels in the pre-frontal cortex. It provides insights into the methods of drug action, e.g. lamotrigine was found to augment the effects of TMS in the limbic region. TMS has been found to be beneficial in the treatment of drug resistant depression.[68] TMS has been found to be better than sham studies in meta-analyses.[60] It could be used in future to prevent relapse and also treat mania. An interesting observation is that TMS over the supplementary motor area worsens Parkinson's disease, although this finding has been greatly contested. TMS is being evaluated as a therapy for writer's cramp, Tourette's syndrome and OCD. Schizophrenia with hallucinations and anxiety disorders may also be amenable to TMS, although some reports suggest that prolonged TMS aggravates the auditory symptoms of schizophrenia.

There are several newer therapies which are emerging as neurobiology and other neuroscience fields grow at an astronomical pace. It would be wise to remember Sir William Osler who said: *"…..We, the doctors are so fallible, ever beset with the common and fatal facility of reaching conclusions from superficial observations, and constantly misled by the ease with which our minds fall into the rut of one or two experiences", while dealing with newer treatment modalities all of whom promise to be in the field of mental disorders.*[103]

ETHICS OF FUNCTIONAL NEUROSURGERY[75]

Psychosurgery has had its crescendo and decrescendo periods orchestrated by human emotions rather than by rational thought. The anti-psychosurgery campaigns by self-styled pundits resulted in misconceptions about the procedures used to this day. It was viewed as a form of 'mind control' and even spawned the popular science fiction of a whole generation. But to look at the brighter side of the argument, the smear campaigns forced practitioners of psychosurgical procedures to develop a high degree of accuracy where everything was based on reason and rational scientific thought with no room for abstract concepts. It has become necessary to state the case for functional neurosurgery, although in countries with a different background, this may appear to be stressing the obvious.

Efforts of the scientists and medical men to improve the lot of their fellow beings have always met with initial opposition from a society which has not yet adjusted itself to a new idea. The objection to neurosurgical procedures to improve those with severe mental illnesses, unfortunately, evokes a public resistance, the fires being ignited and stoked by those ignorant of scientific facts. Such a resistance which is expressed openly and sometimes violently in the developed countries has retarded or even stopped the progress of psychosurgery in these countries. The ingrained ancient concepts of the mind being separate from the body and of its inviolability and sanctity still seem to be a drag on an unbiased approach to the problem of the afflicted.

The medical profession has taken upon itself the task of alleviating many ills and afflictions of the body. Similarly, it is its duty to help, by all possible means at its disposal, the mentally afflicted, since mental diseases are also basically due to an underlying brain disorder, chemical or organic. Consequently, success in restoring the mental balance of a person and returning him to society is as much the aim of surgeons and physicians as their declared and accepted ambition to treat bodily ailments like hypertension, diabetes or cancer. The dichotomy of approach to a mental problem as opposed to a physical problem clouds judgement and thus prevents relief from being given to the mentally ill, who desperately require help to return to normal life, by whatever means available. To deny them this is to deny the role of medicine as a provider of relief and succour to the ill. Precise neurosurgical procedures in appropriate cases enable the patient to return to society without any alteration in his basic personality.[102]

The fact that the operations are on the brain, 'the seat of the mind' and the confusion between the soul and the mind in some aspects of Western thought, seem to have raised a furore over psychosurgical procedures. Luckily, in the Orient, such a mix-up is not seen, the mind being associated only with the physical body at a much lower level than the soul. Reports from centres in the world, where such procedures are practiced and also where there is good patient follow-up subsequently, have shown that with precise and well-planned procedures in properly selected patients, the results can be extremely encouraging with no deleterious effect on personality.

The field of psychosurgery has moved from ablation to neuromodulation and palliation. The lessons of history are to be learnt for the ethical conduct and regulation of neuropsychological research. It is a field, which, although is fascinating, must be tread upon with caution. The fears have to dispel as the benefits outweigh the risks. In conclusion, we must remember that: *"...to be afraid of our technology is to be afraid of ourselves. It is essential that we protect ourselves here, as everywhere, from arrogance and insensitivity. The answer is not to prohibit technology but to insist that it always be subservient to the transcending values of human worth and dignity".*[105]

APPENDIX 1: THE YALE-BROWN OBSESSIVE COMPULSIVE SCALE (Y-BOCS)

The Severity Rating Test

Obsession Rating Scale (Item Range of Severity)

1. Time spent on obsessions:
   0 hr/day
   1 0–1 hr/day
   2 1–3 hr/day
   3 3–8 hr/day
   4 more than 8 hr per day
2. Interference from obsessions:
   0 none
   1 mild
   2 definite but manageable
   3 substantial impairment
   4 incapacitating
3. Distress from obsessions score:
   0 none
   1 little
   2 moderate but manageable
   3 severe
   4 near, constant and disabling
4. Resistance from obsessions score:
   0 always resists
   1 much resistance
   2 some resistance
   3 often yields
   4 completely yields
5. Control over obsessions:
   Control
   Much control
   Some control
   Little control
   No control

Compulsion Rating Scale

1. Time spent on compulsions:
   0 hr/day
   1 0–1 hr/day
   2 1–3 hr/day
   3 3–8 hr/day
   4 more than 8 hr/day
2. Interference from compulsions:
   0 none
   1 mild
   2 definite but manageable
   3 substantial impairment
   4 incapacitating
3. Distress from compulsions:
   0 none
   1 little
   2 moderate but manageable
   3 severe
   4 near, constant and disabling

4. Resistance to compulsions:
   0 always resists
   1 much resistance
   2 some resistance
   3 often yields
   4 completely yields
5. Control over compulsions:
   0 complete control
   1 much control
   2 some control
   3 little control
   4 no control

   Total score = 0–7 Subclinical OCD
   8–15 mild OCD
   16–23 moderate
   24–31 severe
   32–40 extreme

APPENDIX 2: ITEM HAMILTON RATING SCALE FOR DEPRESSION

1. Depression mood (sadness, blues, weepy)
   Have you been down or depressed this past week? How often have you felt this way and for how long?
   0 absent
   1 indicated only on questioning
   2 spontaneously reported verbally
   3 communicated non-verbally (facial expressions, posture, voice, weeping tendency)
   4 patient reports virtually only these feeling states in spontaneous verbal and non-verbal communication

   Note the length of time if depressed mood is present. Do not enter it in the score.
2. Feelings of guilt: (self-criticism, self-reproach)
   In the past week, have you felt guilty about something you have done, or that you have let others down?
   0 absent
   1 self-reproach (letting people down)
   2 ideas of guilt or ruminating about past errors and sinful deeds
   3 present illness is a punishment. Delusions of guilt
   4 hears accusatory or denunciatory voices and/or experiences threatening visual hallucinations
3. Interest, pleasure, level of activities (work and activities)
   Are you productive at work and at home as usual? Have you felt interested in doing the things that usually interest you?
   0 no difficulty
   1 fatigue, weakness or thoughts/feelings of incapacity (related to work, activities, hobbies)
   2 loss of interest (directly reported or indirectly through listlessness, indecision and vacillation)
   3 Decrease in actual time spent in activities or decrease in productivity
   4 Stopped working due to current illness
4. Tension, nervousness (psychological anxiety)
   Have you been feeling more tense or nervous than usual this past week? Have you been worrying a lot?
   0 no difficulty
   1 subjective tension and irritability
   2 worrying about minor matters
   3 apprehensive attitude apparent in speech or face
   4 stopped working due to current illness
5. Physical symptoms of anxiety:

In this past week, have you had any of these symptoms?
   GI—dry mouth, gas, indigestion, diarrhoea, cramps, belching
   CVS—palpitations, headaches
   RS—Hyperventilation, sighing
   Having to urinate frequently
   Seating
   Have much of these things been bothering you in the past week?
   Note: Don't rate, if these are clearly due to medication.
   0 absent
   1 mild
   2 moderate
   3 severe
   4 incapacitating
6. Energy level
   How has your energy level been this past week? Have you felt tired? Have you had any aches or pains or felt any heaviness in your limbs, back or head?
   0 none
   1 heaviness in limbs, back or head (backache, headache muscle aches: loss of energy and fatigability)
   2 any clear cut symptom rates two points.
7. Suicide (ideation, thoughts, plans, attempts)
   Have you thought that life is not worth living or you'd better be dead? Have you thought of hurting or killing yourself? Have you done anything to hurt yourself?
   0 absent
   1 feels life is not worth living
   2 wishes to be dead (or any thoughts of possible death to self)
   3 suicidal ideas or gestures
   4 attempts at suicide (any serious attempt rates 4 points)

Total score =……..

HAMD-7 score less than or equal to 3 indicates full remission.

HAMD-7 score greater than or equal to 4 indicates non/partial response.

193 Neural Transplantation and Stem Cell

PN Tandon

The nearly absent ability of the neurons to regenerate or multiply has prompted neuroscientists to search for the means to replace the damaged or dead cells. The failed attempts using adult tissue initiated nearly a century ago ultimately brought a ray of hope, when developing foetal neurons were used for transplantation in the 1970s. The initial excitement was tempered by limited success and ethical issues, but these efforts unequivocally established the feasibility of successful neural transplantation, provided appropriate tissue was available. The ability to derive embryonic stem cells with their totipotent potentials by Thomson in 1998 rekindled the interest in their use for replacement therapy for damaged brain tissue. The present review surveys the current status of this promising field of stem cell research, especially in respect to their therapeutic potentials for purposes of neural transplantation. A brief account is provided of the ongoing Indian efforts in this direction.

HISTORICAL BACKGROUND

While attempts at neural transplantation for repair of damaged/diseased brain started a century ago,[84] the real enthusiasm was stimulated after the pioneering work of Das and Altman (1972),[20] Bjorklund and colleagues,[9–12] Olson (1970)[61] and Lund and Hauschka (1976).[51] These studies heralded an explosion of investigations, which established that use of foetal-neural tissue provides a reliable method of achieving a successful graft in an adult host. Investigators all over the world initiated experiments dealing with various aspects of neuronal grafting, as a strategy to replace damaged areas of the brain in the late 1970s. It has been unequivocally demonstrated that such grafts "take", grow, develop at least limited two-way connections with the host brain, produce appropriate neurotransmitters, and to a variable extent restore functional deficits, resulting from disease or damage to the host brain (Tandon 1992).[3] Furthermore, these grafts have been found to induce "trophic" effects on the host nervous system. These results in experimental animals were so tantalising that for once the neurosurgeons jumped straight from the "rat-to-man" without even waiting for the results of the studies in higher primates. The first neural transplants in humans were performed in Sweden by Backlund and his colleagues in 1982 and 1983.[3] In 1984-85, a multidisciplinary group was established at the All India Institute of Medical Sciences, New Delhi, India to study the neurobiological and behavioural consequences of the neural transplants in rats and in rhesus monkeys. Donor tissue was obtained from 16 days to 17 days old rat foetuses. This was transplanted as a "plug" and not as a dissociated cell suspension. Successful transplantation could be achieved in 80–85% of adult rats. Recognising the limitations of transferring information gathered from rat to man, it was decided to study the fate of foetal neural transplants in sub-human primates. Rhesus monkeys were utilised for this purpose. Following a number of trials, ultimately successful transplants were observed in the caudate nucleus in two monkeys.[52] These studies revealed that the foetal-neural transplant in rhesus monkey is successful in 20–30% cases only. At 3–4 months after transplantation most of the grafts had resorbed completely, leaving behind a necrotic cavity heavily infiltrated by lymphocytes and macrophages.

However, in the rodent model, the transplanted neurons matured, differentiated and developed phenotypic characteristics, comparable to the normal adult nigral neurons. Electron microscopy revealed characteristic sub-cellular organelles and synapses. Golgi stain clearly demonstrated the growth and branching of neuronal processes up to 1–3 mm. While initially the dendritic pattern closely resembled that of the age-matched control, with passage of time the processes were found to be wavy and with restricted centrifugal spread. Some of these neurons migrated into the surrounding brain. Neuronal processes could be demonstrated to cross the graft-host interface in either direction. Immunohistochemistry confirmed that these neurons and their processes were positive for tyrosine hydroxylase (TH), implying their capacity to produce the appropriate neurotransmitter: dopamine. This remained so for the first 3–4 months after the implant. Most investigators did not study the fate of these grafts beyond this period. The unique observations of our study were those related to morphological details in long-term surviving grafts. At varying intervals, we observed changes compatible with premature aging leading to neuronal loss. These changes were characterised by the appearance of clear spaces, membrane bound vacuoles, paucity of organelles, especially rough endoplasmic reticulum and increasing accumulation of lipofuscin granules in the cytoplasm. Such changes continued to increase in frequency and severity with further passage of time, so

that at the end of 18 months and 2 years, the majority of the surviving neurons were so affected. [33] While it is impossible to demonstrate the development of intricate circuitry between the graft and the host, a number of observations would indicate that such circuitry, at best, can only be very partial. Thus, the majority of neuronal processes were no longer than 1–3 mm. In a large structure like the striatum, these could probably develop contacts with the host neurons in the immediate vicinity only. In spite of the tremendous enthusiasm generated by the reports of the beneficial effect of adrenal medullary transplants in the head of the caudate nucleus of patients of Parkinson's disease by Backlund et al. (1985)[3] and Madrazo et al. (1987),[52] it was generally accepted that the neurobiological basis of the observed clinical effects was not clear. Peterson et al. (1989)[69] could not find any surviving cells at autopsy of a Parkinson's disease patient treated with adrenal to brain transplant. It is, therefore, obvious that in spite of claims to the contrary by Madrazo et al. (1991),[53] there is now a general consensus that there is hardly any place for the use of adrenal chromaffin cell transplant in cases of Parkinson's disease. The clinical trials so far conducted have provided enough evidence, that at least for patients of Parkinson's disease, there can be mild to moderate improvement in their motor function, although it may be temporary. Nevertheless, it is also obvious that translation of findings of animal experiments to human beings is not without its limitations and pitfalls. The legal and ethical issues, implicit in the use of human foetuses for therapy, need to be carefully assessed and deliberated upon. These considerations alone would necessitate search for alternate sources for transplantable cells, cultured, cryopreserved or genetically modified. There are already leads in this direction.[45]

Long before embryonic stem cells were demonstrated to give rise to all types of brain cells, an extensive experience had already accumulated in respect to the use of foetal neural tissue, obviously containing neural progenitor cells or even stem cells for repair or replacement of damaged brain.[3,9–12,45] Similarly, stable clones of neural stem cells (NSCs) isolated from human foetal telencephalon were shown to replace neurons and respond to development clues, when transplanted in new born mouse brain.[28] There has been rapid success in devising *in vitro* protocols for differentiating human ES cells to neuroepithelial cells. Progress has already been made to guide these neural precursors further to more specialised neural cells, such as spinal motor neurons or dopamine-producing neurons (or various types of glia). However, some of the *in vitro* produced neuronal types such as dopamine neurons do not possess all the phenotypes of their *in vivo* counterparts, which may contribute to the limited success of these cells in repairing the injured or diseased brain or spinal cord. Hence, efficient generation of neural subtypes with correct phenotypes remains a challenge, although major hurdles still lie ahead in applying the human ES cell-derived neural cells clinically.

In February 2001, only 15 months after the publication of two seminal papers by Thompson, and Snyder and McKay in Science on isolation of human embryonic stem cells (ESC), the author published a General Article—"Neural Stem cell research: A revolution in the making" in Current Science.[24] A decade after the Science papers, the prediction made in 2001, has been validated beyond imagination by the voluminous literature that has already accumulated, the number of specialised centres, departments, laboratories established globally, the scientific conferences held and the socio-political, ethical implications debated all over the world and even a large number of clinical trials initiated. Unlike research on the human genome, owing to the prompt initiatives taken by the Department of Biotechnology, research in the field was promoted early in the country. Several state-of-art facilities have been created, both for basic research and its translation into clinical practice.

At the same time, the conclusion arrived at in the 2001 paper[24] "… it could be safely stated that NSC research needs to be pursued with vigour for it to be of clinical use. While there is a lot of hope one should not be carried away by the hype and prematurely raise the expectations among those most in need of it" has continued to be echoed even today by a large number of distinguished researchers from all over the world. This has prompted a prestigious journal like Philosophical Transactions of the Royal Society to devote a complete issue in January 2008[54] on the subject of "Stem Cells and Brain Repair". I could do no better than to quote Magnus and colleagues from Stem Cell Section, Laboratory of Neurosciences, National Institute on Aging, NIH and Children's Research Centre, Michigan, "Stem Cells, although difficult to define, hold great promise as tools for understanding development and as therapeutic agents. However, as with any new field, uncritical enthusiasm can outstrip reality. We have listed nine common myths that we believe affect our approach to evaluating stem cells for therapy".[54]

Having followed the subject keenly during the past decade, having observed the interest it has generated among colleagues, both basic scientists and clinicians and concerned about the inadequate knowledge, often verging on gross misconceptions amongst some of them, has prompted this review of the existing knowledge on the subject primarily restricted to aspects of interest for neuroscientists.

Grafting cells for therapeutic purposes has been ongoing for a long time in the case of bone marrow or skin transplantation. But now we are faced with the exciting prospect that cells with large differentiation potential, that are maintained *in vitro* in normal proliferation state, could provide a variety of cell types for transplantation and therefore help cure disease for which there is as yet no other treatment.[45]

The first experimental demonstration that stem cells exist goes back to the early 1960s when the haematopoietic system was shown to harbour single cells responsible

for the renewal of the circulating blood.[85] Historically, it was EB Wilson who, in 1925, introduced the term stem cells in his description of the development of the *Ascaris* worm. Pioneering work of Weissman and his colleagues on the biology of haematopoietic stem and progenitor cells[24,58], the purification and characterisation of mouse haematopoietic cells,[78] clonal analysis of haematopoietic stem cell differentiation *in vivo*,[76] as also the isolation of a candidate human haematopoietic stem cell population[6] helped a great deal in understanding the basic biology of haematopoietic stem cells, which has important lessons for stem cell biology in general.[94]

EMBRYONIC STEM CELLS

The discovery of the embryonic stem cell constitutes one of the greatest achievements of modern biotechnologies. It was observed that at the blastocyst stage each embryonic cell is essentially as totipotent as the egg itself. Already, in 1980, Evans and Kaufman[23] established culture of pluripotent cells from mouse embryo. However, it was only in 1998 when Thompson et al. published that they had been able to derive embryonic stem cell lines (ES) from human embryo that the technology attracted global attention.[83] In the same year, it was shown that germ cells isolated from gonads of older human embryos can also give rise to permanent lines of embryonic stem cells endowed with properties that are very close to those of embryonic stem cells derived from the inner cell mass at the blastocyst stage. The stem cells that result from germ cell proliferation are designated EG cells in order to distinguish them from the classical ES cells.[75]

DEFINITIONS

Stem Cells

Cells able to reproduce themselves throughout the life span of the animal and are able to give rise to differentiated cells. They have the ability to divide for indefinite periods in culture and give rise to specialised cells.

Embryonal Stem Cells

Cells derived from embryo—pro-implantation or post-implantation—prior to their differentiation into specific cell types.

Totipotent Cells

Cells which have the potential to differentiate into derivatives of all three embryonic germ layers, i.e. ectoderm, mesoderm and endoderm. In addition, they can also specialise into extraembryonic membranes and tissues.

Pluripotent Cells

Cells which can give rise to different types of cells representing derivatives of two different germ layers, e.g. skin (ectoderm) and muscle (mesoderm).

Neural Stem Cells

Cells which can generate neural tissue, either both neuron and glia (astrocytes, oligodendrocytes) or one of them. The term is also used for stem cells derived from embryonic or adult nervous system, which normally differentiate into nervous tissue. These cells remain undifferentiated for long periods of time while retaining the potential to differentiate into nervous tissue.

Progenitor Cells

Cells with a more restricted potential than a stem cell and are generally destined to give rise to a specific cell type.

A vast amount of new information has accumulated on human stem cell biology. The generation of human embryonic, foetal and adult stem cell lines has been standardised. It is proposed that the cells obtained from these different sources could contribute different but, perhaps, equally important properties of therapeutic relevance. Three fundamentally different stem cell strategies could lead to a cure of neurodegenerative diseases. Stem cells could deliver bioactive proteins or peptides to modify or biomodulate the disease process. At the opposite end of the spectrum, stem cells could generate exact neuronal or glial cells lost in disease affected systems. Although fully restoring a degenerated neural network is a worthy, yet lofty goal, disease symptoms could be alleviated by introducing stem cell-derived neurons ectopically, to modulate an affected network.[63]

Stem cells from different sources have unique attributes that will differentially affect their suitability for use in therapeutic strategies.

SOURCES OF STEM CELLS

Human embryonic stem cells, derived from the blastocyst inner cell mass of excess embryos generated by *in vitro* fertilisation, can provide an unlimited source of cells for transplantation and can be directed into neural precursors which can generate neurons, oligodendrocytes and glia both in culture and *in vivo*.[41,81,99] Perrier et al. in 2004,[67] demonstrated *in vitro* and *in vivo* differentiation of human embryonic stem cells into dopamine neurons. It may be mentioned that, over the years, culture conditions that rely on the use of various cytokines and growth factors have made it possible to induce the differentiation of a high proportion of ES cells into selected cell types, such as neurons, pancreatic islet cells, cardiomyocytes, etc.[46]

The ease with which hESCs can be expanded in culture as normal diploid cells is a significant advantage over foetal and adult stem cells that require immortalisation via mutation or proto-oncogene introduction, to escape eventual senescence. Cultured hESC grow very efficiently and maintain pluripotency, but the potential risk of developing malignant transformation cannot be ruled out in the current stage of knowledge.

Foetal neural stem cells harvested from the postmortem human foetal brain maintain a normal karyotype for a significant number of passages in culture and can produce a large number of neurons and astrocytes.[80] These posses a relatively high proliferative capacity and yet do not generate tumour, following transplant. These are really mostly progenitor cells and not true ESCs. Seth at National Brain Research Centre, Manesar, Haryana, India has established a foetal brain derived cell culture system, to obtain CNS stem/progenitor cells. These could be selectively differentiated to astrocytes and neurons, by providing appropriate growth factors and defined media conditions. Development of such a cell culture system has to a great extent eliminated the need for a constant supply of foetal material which raises some ethical concerns.

Adult Neural Stem Cells

Contrary to the earlier belief, neural stem cells persist throughout life, not just in the two now well-known sites of adult neurogenesis, e.g. the subventricular zone and hippocampus but also at other sites.[29,30,40] It has been claimed that adult neural stem cells can be harvested from brain tissue, postmortem or through biopsy and expanded in culture both in rodents and humans. These cells exhibit genetic stability over many passages and differentiate into neurons, astrocytes and oligodendrocytes, under suitable culture conditions.[65,71] Lie et al. described the existence of progenitor cells with neurogenic potential in the adult substantia nigra.[49] Young and Black have provided a detailed review of adult stem cells. However, their proliferative capacity is somewhat limited.[98]

Non-Neural Adult Stem Cells

A number of recent studies have challenged the traditional view that stem cells present in somatic tissues are restricted to producing that tissue's cell types. The first such observation was in respect to bone-marrow derived stem cells (BHMSC), which could develop into liver cells,[68] muscle,[34,44] bone[27,60,64] and neural tissue.[14,32,55,92] Woodbury et al. claimed that adult rat and human bone marrow stromal cell differentiate into neurons.[72] Zhao et al. demonstrated neural differentiation and functional recovery after transplanting human bone marrow stem cells into the ischaemic brain of rats.[37] Sanchez et al. observed expression of neural markers in human umbilical cord blood.[73]

Recently there has been great excitement about the possibility of generating neural progenitor cells from such diverse sources as mesenchymal cells derived from skin,[38] bone-marrow[18] or adipose tissue.[42,87] It may be mentioned that a reproducible technique to convert them into authentic CNS cells has not yet been accomplished.

Recently, evidence has been presented that stem cells identified in organs other than the haematopoietic system (HSC) and skin thought to be responsible for the generation of mature differentiation cells of one organ, such as HSC, may have the ability to differentiate across lineage and contribute to tissues other than haematopoietic cells, including neuronal tissue.[37,39,72,73,85] Such apparent lineage switch has been termed stem cell plasticity. This had led to much sensationalism as evident from such titles of reports as, "Blood to bone" or "Bone to Brain", etc. However, many questions remain as to the validity of a number of these studies, in a large part owing to loose criteria, which have been used to describe 'neural differentiation'.[90]

Fernandez et al. have demonstrated that cultures of multipotent precursors can be grown from dermis of neonatal and adult mammalian skin.[25,26] The skin derived precursors (SKPs) display multi-lineage differentiation potential, producing both neural and mesodermal progeny *in vitro*. The presence of such cells in human skin obtained from the scalp had already been demonstrated by Toma et al.[86] More recent work using skin from other sites has now been verified to be identical to the findings in rodents.

According to Toma et al., analysis of expanded human SKPs demonstrated that they maintain their differentiative abilities for at least one year in culture. They have a potential similar to embryonic neural crest derived precursors.[87]

However, differentiation of SKPs under neurogenic conditions resulted in the production of cells that fulfill most, but not yet all criteria for neuronal differentiation.[48] They believed that SKP-derived neurons are probably peripheral in nature, since they express peripherin and proteins characteristic of a catacholaminergic phenotype and almost all of them are positive for p75 NTR, a hallmark of peripheral neurons.

One type of stem cell that definitely differentiates into mature terminally differentiated and functional neural cells *in vitro* is NSC.[66,74,77,97] Criteria used to define differentiation of NSCs to mature neural cells should be used as the gold standard to gauge whether somatic stem cells of non-neuronal origin, such as HSCs or mesenchymal stem cells (MSCs), can give rise to neural progeny. Authors describe a series of criteria like expression of these markers should occur in a temporal sequence consistent with development and that the differentiated cells should display function characteristics consistent with neurons and glia, such as voltage-gated sodium channels, depolarising response to neurotransmitters and release of neurotransmitters on depolarisation, as has been demonstrated for ES derived neurons *in vitro*.[48] Other caveats exist that need to be kept in mind when assessing the ability of non-neural stem cells to generate neurons or glial cells. However, more recent studies have demonstrated that at least MSC's generated neural progeny have functional characteristics consistent with neurons.[21,95] Pluchino et al. using syngeneic culture derived adult NSCs in an animal model of multiple sclerosis, demonstrated promotion of multifocal remyelination.[70]

It needs to be kept in mind that the functional benefit following transplantation of such cells may not be due to integration of donor neural cells but due to trophic effects elaborated by the donor cells that promote endogenous neural cells to repair the deficit.[16,50,97]

Induced Pluripotent Stem Cells

In November 2007, two groups headed by James Thompson at the University of Wisconsin – Madison and Shinya Yamanaka and his post-doctoral fellow Kazutoshu Takahasi at Kyoto University, Japan, described methods to re-program adult human cells from skin to a pluripotent state, using genetic engineering techniques. These cells, called induced pluripotent stem cells (iPS) were found to be similar to human embryonic stem (ES) cells in morphology, proliferation, surface antigens, gene expression, epigenetic status of pluripotent cell-specific genes and telomerase activity. Furthermore, these cells could differentiate into cell types of the three germ layers.[82] This technique could help generate patient and disease specific cells, which cannot be generated from ES cells. The problem related to the epigenetic transformation of the somatic cells has recently been elaborated.[56] In addition, excellent reviews on the subject are available.[36,96] Soon after, George Daley of Harvard Medical School in Boston confirmed these findings and also demonstrated that iPS cells could be generated from a wide variety of adult cells. Attempts are underway to improve the current 1% efficiency of transformation of somatic cells to embryonic stem cell-like state using the four genes—oct 4, sox2, klf4 and cmyc—by using some other combination of genes. Reprogramming protocols that exclude cancer-associated gene c-myc have been developed.[17] However, at the moment, iPS cells remain a research tool and not a potential therapeutic agent.[13] David Cyranoski quoting a number of other investigators in the field pointed out that the greatest challenge still exists: the generation of high-purity, clinically relevant cell populations.[19] It takes a couple of months to establish a cell line, several more to expand it, more still to differentiate the iPS colonies into cell types required, a few more to expand those and then a good half-year of testing to ensure that the cells do not form tumours. In addition, to produce and use custom-made cells "would take a ridiculous amount of money". Attempts are already on to establish a library of therapy-ready cell lines from donated placental and cord-blood tissue.

Zhang [100] has provided detailed accounts and comparison of methods for neuroepithelial differentiation from human ES cells. Ideally, the method should be simple, efficient, chemically defined, scalable and reproducible and the end product should be an enriched or purified homogeneous neural progenitor population.

Neuroepithelial cells produced from human ES cells using different methods may appear similar in morphology and expression of certain neural precursor markers. However, they, in fact, differ significantly from each other, depending upon the culture conditions. Carefully designed strategies will be needed, in order to direct ES cells to the vast array of neuronal subtypes that are harboured in the primate forebrain. In order for neuroepithelial cells to make a decision between a dopaminergic, serotonergic or GABAergic neuronal fate, the neuroepithelial cells have to be able to 'sense' the nuances within the set of morphogens (e.g. the amount, sequence, isoform, etc.) and/or additional signals.

In vitro, like during development, human ES cell-derived neuroepithelial cells produce neurons first followed by astrocytes and oligodendrocytes. There appears to be a significant progress in producing oligodendrocytes from hES cells.

The ability to differentiate into versatile neuronal subtypes in a neurogenic environment places human ES cell-derived neuroepithelial cells as a useful source of cells for neural replacement therapy in multiple neurological disorders. Recognising the therapeutic potentials of stem cells, a number of public and private organisations like International Stem Cell initiative, UK Stem Cell Bank, ES Cell International in Singapore, Cellartis in Sweden and Millipore in USA have developed ES cell lines to be made available to researchers.[13] However, due to their restricted migration and differentiation in the adult brain regions, it may require further specification of the neuroepithelial cells to a more restricted fate, in order to achieve targeted differentiation.

Despite significant progress in an efficient differentiation of neuroepithelial cells (70–90%) and a few neural subtypes, such as dopamine neurons (approximately 30%), spinal motor neurons (approximately 20%) and oligodendrocytes more than 90%, protocols for generating many neuronal subtypes have to be established.

Demonstration of functional integration of human (ES derived) neural cells in the brain is still awaited (our experience with foetal neural transplant-lessons learnt are probably valid for ES derived cells also).[22] While functional improvement occurs, it is obvious that intricate integration in host circuitry was not unequivocally observed. The functional improvement could be partially attributed to a protective role of the graft on endogenous neurons. Under most circumstances, neural transplant acts as a local chemical replacement, rather than due to integration in the host circuitry. As a consequence, the release of neurotransmitters is uncontrolled. This may be the reason for dyskinesia observed in patients who received foetal neural transplants, as reported by Olanow et al.[59]

NINE MYTHS ABOUT STEM CELLS

In a review, Magnus et al. have listed nine common myths that affect our approach to evaluating stem cells for therapy.[54]

Myth 1: Stem Cells are Immortal

This idea is based on reliable observations in the haematopoietic system. This has lead to the assumption of the

same ability for extensive self-renewal to other stem cells also. However, several reports challenge these assumptions. It has been suggested that NSCs cannot divide in culture more than 12 passages without undergoing dramatic changes.[15,57]

Mesenchymal stem cells appear to have a limited self-renewal potential and generally cannot be expanded indefinitely.[39] Even *in vivo* stem cells age and cannot be assumed to have a lifespan which is greater than that of an individual. Bailey et al. have reported that ageing leads to a substantial mutational load within the NSC compartment, a change that is likely to affect the function of these cells.[4] Taken together, these results argue that not all stem cells have a lifespan that is extensive and that not all stem cells maintain their karyotypic integrity over the prolonged time period required for expansion and differentiation.

Myth 2: Asymmetric Divisions are Required to Define Stem Cell

This does not appear to be strictly true on either theoretical or practical grounds. Several alternate models can be proposed. In many systems, particularly haematopoietic and neural systems, stem cells undergoing asymmetric division best fit the available data both *in vitro* and *in vivo*. However, even in these systems, it is unclear whether asymmetric divisions are obligatory.

Myth 3: Adult Stem Cells are like Foetal Cells, only Better

This is, however, not true. More detailed analysis of foetal and adult stem cell populations harvested from the same tissue has suggested that changes occur. Like somatic cells during normal process of ageing, adult stem cells show similar signs of ageing. These findings raise concerns about the potential for reactivating endogenous NSCs within the aged brain or the use of adult NSCs in transplantation.

Stem cells isolated at different stages of development display different properties. Overall, we note functional differences between foetal and adult stem cells, which preclude the assumption that stem cells from different ages will act alike. Indeed, decreased survival and migration of adult compared with newborn neural progenitors is seen, when they are transplanted into a chick embryo. In general, neural replacement in the adult system is mainly successful in areas of ongoing neurogenesis, like the hippocampus and the olfactory bulb.

Myth 4: Cells Similar to Embryonic Stem Cells Exist in Adult Tissue

ES cells are unique among all stem cell populations and have a well defined core-identity. According to the authors, none of the adult pluripotent cells (APCs) share the key features of ES cells. APCs do not appear to express ES cell markers, do not form teratomas and when injected into blastocysts do not develop reliable germ lines. These authors do not believe that available data allow any adult-derived stem cell population to be reasonably classified as "Es-like".

Myth 5: Stem Cells are more Plastic than Other Cells

It appears that bone marrow contains a population of pluripotent cells that can differentiate into a variety of cells lineage including astrocytes, oligodendrocytes and neurons.[1,43] In different injury model systems, these cells were found to be integrated into the brain parenchyma and, in part, were associated with a functional improvement.[35] On the other hand, it has been shown that both mouse and human NSCs transplanted into the bone marrow of irradiated mice will generate cells of the haematopoietic lineage.[62] Galli et al. demonstrated the skeletal myogenic potential of human and mouse neural stem cells.[31] However, the most convincing demonstration of trans-differentiation suggests that such events are rare.[91] For example, when several million cells were infused into the venous circulation, at best a few hundred trans-differentiated cells could be identified.[47]

It is not to argue that trans-differentiation does not occur or that it has not been convincingly demonstrated by numerous researchers. But it is a myth to assume that stem cells trans-differentiate in a robust and reliable fashion.

Myth 6: The most Primitive Stem Cell for a Tissue or Organ is the Best Stem Cell to Use

Authors believe that the available data do not support such a conclusion. In the nervous system, there is a limited role for stem cells in adults. In general, an intermediate or restricted blast or progenitor cell will often repair such tissue. Several ES cell biologists have suggested using (differentiated) dopaminergic cells derived from ES cells, rather than NSCs for therapy.

Myth 7: Stem Cells can Home and Migrate to Sites of Injury

This concept has largely been developed in the haematopoietic system. Reviewing the existing data, it is observed that the turnout and survival of transplanted stem cells is so low, even given the relatively large number of transplanted cells. The authors predict that, depending on the tissue, homing of stem cells will be difficult and survival will be limited.

Myth 8: Stem Cells do not Provoke an Immune Response

Numerous studies have challenged this view, by showing that a potent immune reaction can and does occur even in the CNS.[2] Rejection of neural allografts and xenografts were observed in several studies. However, there is evidence to indicate that MSCs do not elicit an immune

response. Today, it is difficult to say if histocompatibility in stem cells is as critical as it is in bone marrow or organ transplant or is an irrelevant issue. However, the lack of available relevant evidence highlights the importance of additional experiments to clarify the issue.

Myth 9: Therapy will be Straight-forward and will Mimic Strategies used in Bone Marrow Therapy

The oldest and arguably the best characterised stem cell is the HSC. It is also, thus far, the only clinically useful stem cell. Current strategies for cell replacement therapy appear to model this strategy. This belief has led to so much excitement that several clinical studies have been initiated utilising bone marrow derived 'stem cells' for a variety of clinical conditions, as diverse as congestive cardiac failure, cardiac infarct, stroke and spinal cord injury. It is hard to understand conceptually how stem cells in other systems could adopt the "HSC strategy" notwithstanding a report by Englund et al. [22] It is difficult to imagine that in a solid tissue like the brain or spinal cord how the issues of targeting, migration and connectivity will be overcome, which are not faced by HSCs in the bone marrow. Luskin, already in 1993, pointed out restricted proliferation and migration of post-natally generated neurons derived from the forebrain subventricular zone. In these systems, the most primitive stem cell may not be as appropriate to transplant as a more differentiated cell. Notwithstanding all the hopes generated in respect to therapeutic uses of stem cells, the above observations make it obvious that their routine clinical use has still a long way to go.

OTHER USES OF STEM CELLS

Human ES cell-generated neural cells provide a tool for screening pharmaceuticals that may have therapeutic values in neurological disorders, as also for toxicity screening and possibly drug discovery. The availability of human ES cells with natural diseases,[89] via somatic nuclear transfer or through genetic alterations in laboratories, will provide not only disease-specific neural cells for drug screening but also a tool to unveil some fundamental pathological processes underlying individual neurological disorders.

EXPANSION OF HAEMATOPOIETIC STEM CELLS

The number of HSC, that one can isolate from mobilised blood or from umbilical cord or from bone marrow limits the full application of HSC transplantation in man. Attempts to expand HSC with the known cytokines, stem cells factor, steel factor (SLF), thrombopoietic (TPO), interleukins 1, 3, 6, 11 plus or minus the myeloerythroid cytokines and erythropoietin have never resulted in a significant expansion of HSC. However, cytokines, such as GCSF and SLF can increase the number of HSC in the blood, especially if administered for several days following a cytoxan pulse.

Weissman reported that "We and others have attempted to reproduce the demonstration of production of critical neurons from marrow or haematopoietic stem cells precursors and have failed".[93] Nevertheless, these experiments have led to extensive clinical trials in humans[8,62,79] primarily for myocardial regeneration and more recently for patients with stroke. Unfortunately the claims made in this regard have not been universally accepted.[5,7] Using strict criteria, the author concluded "We do not believe there is sufficient evidence for any of the transplant claims of trans-differentiation. In fact, most, if not all, reports of donor markers in unexpected tissues are the result of cell fusions and the rarity of cell fusions makes it questionable that such events are regeneration rather than reflect the functions of post-injury phagocyte cells".

In addition to haematopoietic stem cells, the following stem cells have been prospectively isolated to homogeneity: Peripheral nervous system stem cells, central nervous system stem cells,[88] skin, as well as the mesenchymal stem cell.[37]

In the case of human CNS stem cells, extensive experiments of transplanting them into the lateral ventricle, into the brain or into the spinal cord of SCID mice have shown that they contributed in a robust way to engraftment of the neurogenerative cells. These robust regenerations stand in contrast to microglial contributions and the rare Purkinje cell fusion derived from bone marrow and haematopoietic stem cells.

STEM CELL RESEARCH IN INDIA

Soon after the publication of the paper in Current Science,[24] as Chairman of the Medical Biotechnology Task Force of DBT, a meeting was called to take stock of the interest in the field among biomedical scientists in the country and to prompt them to initiate studies in this emerging field, by providing research grants. This had progressively emerged as a major national effort primarily steered by DBT. The key components of the strategy are: Creation of centres of excellence (CoE), virtual network of centres, generation of adequate human embryonic stem cell (hESC) lines, human resources development through training, short and long-term overseas fellowships, study the biology of all types of adult stem cells and in parallel evaluate its safety and efficacy in animal models and clinical research on myocardial infraction and stroke for safety and efficacy. Over 30 institutions, hospitals and industry are involved in SCR in the country. The government has invested about 8.0 million US$ for SCR in the last 2 years. Draft guidelines for SCR in the country have been formulated and the same are currently being placed for public debate. The major ongoing programmes include among others: Establishment of hESC lines, use of limbal stem cells to repair damaged cornea, isolation, purification and characterisation of haematopoietic, mesenchymal and liver stem cells and differentiation of stem

cells into neural, cardiac β cell lineages. Studies have been supported to explore the potential applications of adult stem cells in stroke, cardiac, pancreatic, spinal cord injury, use of lectins for haematopoietic stem cell preservation, etc. Reliance Life Sciences, Mumbai has characterised several stem cell lines including two neuronal cell lines, dopamine producing neurons and neurons for patients of stroke. One cell line has been deposited in the National Centre for Cell Science (NCCS), Pune. Interaction between clinicians and basic scientists already exists in several centres in India, such as the Christian Medical College, Vellore; LV Prasad Eye Institute (LVPEI), Hyderabad, National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore and All India Institute of Medical Sciences (AIIMS), New Delhi. Limbal stem cells are being routinely used at LVPEI, Hyderabad and AIIMS to repair corneal surface disorders caused by limbal stem cell deficiency. At CMC, Vellore, a technology has been established for collection, isolation and purification of HSC for haploidentical haematopoietic stem cell transplantation. The first haploidentical haematopoietic transplantation was carried out at CMC, Vellore, in April 2003. A phase I multi-centric clinical trial and a pilot study using bone marrow mononuclear cells have been initiated in the country for myocardial infarction and stroke, respectively. A 'CMC-DBT Centre for Stem Cell Research' has been created at CMC, Vellore. Clean room facilities for SCR are being established at SGPGIMS, Lucknow: KEM Hospital, Mumbai and LVPEI, Hyderabad. Dedicated short-term and long-term overseas fellowship programmes have been initiated by the Government of India for providing training to 25 fellows every year in niche areas including stem cells. A stem cell bank may be a useful repository for all types of stem cells, i.e. cord blood. In India, some companies have started establishing the repositories of cord blood banking. Reliance Life Sciences, Mumbai has a repository of 3000 cord blood samples. These samples have been processed and tested for infectious disease and stored at -196°C. Life Cell is a Chennai-based company and has a licence agreement and knowledge-sharing tie-up with Cyro-Cell International, USA. They have a repository of 1000 cord blood samples and are offering to preserve stem cells for 30 years. There is no controversy in the research involving stem cells derived from adult tissues and umbilical cord blood. These have been summarised in Table 1. The crux of the debate centres around derivation of the embryonic stem cells which require the destruction of an embryo. Draft guidelines for SCRF in India have been formulated jointly by the Department of Biotechnology, Ministry of Science and Technology and Indian Council of Medical Research. The same is currently being placed for public debate (Sharma, A; Personal Communication). National Brain Research Centre, Manesar has actively pursued basic science investigations on both commercial ES cells and neural precursor cells derived from human abortuses.

Neural progenitor cells: Based on promises of initial transplantation experiments in experimental and clinical studies, stem cell therapy promises hope for patients and caregivers for several neurodegenerative diseases. However, the pre-requisite of a purified, continuous and sufficient population of well-characterised human neural precursor cells (hNPCs) with ability to differentiate into glial cells and neurons remains the biggest hurdle. Several investigators claim success in isolation of purified population of hNPCs, but the procedure is typically difficult with ill-defined protocols. A detailed description of protocols for isolation, expansion and differentiation of hNPCs as well as characterisation of glial and neuronal cells differentiated from hNPCs is largely unavailable. Seth and his team at National Brain Research Centre, Manesar have designed a standardised 3 week protocol that describes an ethically approved stepwise process for isolation, maintenance, expansion, differentiation and characterisation of undifferentiated as well as differentiated hNPCs from human foetal brain samples collected from abortus material. They have studied the kinetics of cell specific and physiologically relevant markers in differentiating cells (unpublished work). The neuronal cells differentiated from hNPCs cultures established by them express markers, like neuron specific markers, intermediary filament and immature neuronal cell marker Tuj-1 and microtubule associated protein-2 (MAP-2), and the mature neuronal cell marker, human specific enolase, neprilysin, polysialic acid neural cell adhesion molecule (PSA-NCAM) and N-methyl-D-aspartate receptor (NMDA-R). The astrocytes derived from hNPCs express the astrocytic marker, glial fibrillary acidic protein (GFAP) and another astrocytic marker S-100 beta, further confirming the identity of astrocytes. Several batches of astrocytes were found to express a functional astrocytic marker, Glutamate transporter-1 (Glut-1). Their work has yielded a unique resource in the country of human neural stem cells that can be used for various basic and transplantation studies.

Intrinsic factors that control the commitment to neuronal lineage and that play a role in neuronal differentiation and cell type specification are largely controlled by transcription factors that contain the basic helix-loop–helix (bHLH) motif. Proneural bHLH factors are involved in the commitment of a multipotent neuroepithelial progenitor cell to the neuronal lineage. These include the neurogenins and Mash. Terminal neuronal differentiation further involves a second class of bHLH factors, known as neuronal differentiation factors. This includes NeuroD, NDRF and Nex. Expression of neuronal differentiation factors results in cell cycle arrest and differentiation of neurons in culture. The pattern of expression of neural differentiation genes *in vivo* is overlapping but not identical. In fact, some of these genes are expressed in specific subsets of neurons and suggests an additional important function of these factors, that they may be involved in specifying neuronal cell type. Knock-out mice have been generated in order to

Table 1: Institutes, hospitals and industries which involved a stem cell research

Embryonic stem cell research	• National Institute for Research in Reproductive Health, Mumbai • National Centre for Biological Sciences, Bangaluru • National Centre for Cell Sciences, Pune • National Brain Research Centre, Manesar • Rajiv Gandhi Centre for Biotechnology, Thiruvananthapuram • Centre for Human Genetics, Bangaluru • Jawaharlal Nehru Centre for Advanced Scientific Research, Bangaluru

study whether these differentiation factors are involved in the specification of neuronal subtype. At NBRC, studies are underway to elucidate the function of proneural and neural differentiation bHLH genes using ES cells as a model system for studying neuronal differentiation.

The embryonic stem cell (ESC) is the 'mother' of all other cells. Adult stem cells may be derived from the bone marrow, peripheral blood, tissues, muscles, cardiac tissues, cartilage, brain tissues, etc. MSCs are present in many tissues of adult cells. MSCs may be isolated from various sources from normal healthy volunteer donors and manufactured under strict cGMP conditions. Stem cells may also be isolated from the umbilical cord blood. Much like the bone marrow, cord blood is one of the richest sources of stem cells. Any disease in which there is tissue degeneration may be a potential candidate for stem cell therapies, including conditions and disabilities as Parkinson's and Alzheimer's disease, spinal cord

injury, stroke, burns, heart disease, type 1 diabetes, osteoarthritis, rheumatoid arthritis, liver diseases, retinal degeneration, limb ischaemia, hair cell regeneration, etc. Extensive basic research is required for standardisation of methods for the isolation of embryonic and adult stem cells from various sources. Future prospects for embryonic stem cell research include the following: generation of therapeutic grade cell lines; identification of human embryonic stem cells (hESC) growth factors; controlled differentiation, i.e. generation of specific cell population; study of fundamental changes in cell cycle control that occurs during embryonic stem cells differentiation; maintenance of stem cell in undifferentiated stage; regulation of differentiation of ESC; pluripotency and differentiation of established cell lines; standardisation of animal free defined culture condition; developmental potential of human versus mouse ESC; standardisation in use of specific stem cells to specific organ systems, etc. (Sharma 2006; Personal communication).

Use of *ex-vivo* expanded stem cells has been identified as a new drug as per FDA, USA, i.e. investigational new drug (IND). This would require information about the source, number, purity, appropriate stage, optimum condition and criteria for harvesting stem cells; also standardisation of doses in terms of concentration and number of stem cells for each application and minimal manipulation of cells for clinical use. Good animal models are required to address the issues of safety and efficacy before attempting clinical applications of stem cells.

The basic requirements for clinical trial are: adequate infrastructure, i.e. Good Manufacturing Practices (GMP), clinical grade reagents, trained manpower, proper documentation, Standard Operating Procedures (SOPs), quality control, etc.

ACKNOWLEDGEMENT

The author acknowledges the help provided by Dr (Mrs) Alka Sharma of the Department of Biotechnology, Government of India, Dr Pankaj Seth and Dr Shyamala Mani of National Brain Research Centre, Manesar, Haryana, India in preparation of this review.

Pain

AK Singh

194 Pain: Anatomy and Physiology

Ravi Ramamurthi, Santosh Mohan Rao K

"Nothing begins and nothing ends,
That is not paid with a moan,
For we are born in others' pain,
And perish in our own."

Francis Thompson

INTRODUCTION

"Where life ranks highest, there it can suffer most. Human life has among its privileges that of a pre-eminence of pain." Sherrington (1940).[83]

Since time immemorial, the most important goal of medical science is the relief of pain in all its various manifestations. In modern times, neurosurgery has made substantial contributions towards achieving this easier said than done task. This has been made possible due to:

- A better understanding of the physiology and pharmacology of pain perception and conduction
- Advances in neurobiology and allied neurosciences in providing new insights into the functioning of the nervous system.
- Newer and safer neurosurgical techniques like stereotaxy, percutaneous, intraspinal and intracere bral stimulation and suppression techniques
- Development of newer technologies and devices proving true the quote; "Today's science fiction is tomorrow's scientific fact."

DEFINITIONS OF PAIN

The word pain is derived from the Latin word "paena" which is synonymous with "dolor" and not easily defined. The Oxford English Dictionary defines pain as 'suffering or distress of body or mind". The Greek philosopher Aristotle (303-322 BC) described pain as an agony of the soul of mind. Spinoza (1632–1677) defined pain as a form of focal sorrow. Tagore, through his various verses, expressed pain as a form of psychic agony.[42] Sherrington defined pain as, "the physical adjunct of an imperative protective reflex.'' Pain is defined as an "unpleasant sensory and emotional experience with actual or potential tissue damage or which can be described in terms of such damage" (International Subcommittee on Taxonomy 1979). This was re-stated in 1986 by Morsky and was accepted by the International Association for the Study of Pain. The definition runs thus; "Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or as described in terms of such degree". Wall in 1985 defined pain as: "a state akin to hunger and thirst in which action is imperative. Behaviour must be changed to prevent further damage including psychological damage".[26]

The sensation of pain is protective in nature and essential for the well-being of the organism. It urges the sufferer to seek measures for relief from the disturbing influence by suitable means. Diseases that have pain as an early symptom have a greater chance of attention than, for example, a malignant lesion which may progress to an advanced stage without any pain being apparent. The real problem arises when pain becomes persistent and demands continuous attention. In such cases, the phenomenon of pain seems to be purposeless and instead of being protective becomes a means of destroying the organism. Neurosurgical relief of pain is required mostly in such cases where there is persistent and purposeless pain.

In case of chronic persistent pain, the psychology of the individual gets deeply involved in the pain phenomenon and the problem of pain transcends the anatomical pathway of conduction and physiology and extends in to the higher realms of cerebral physiology and neuropsychology. It has been observed that even after complete destruction of the pain conducting pathways, a subject may still complain of pain, which is certainly of psychogenic origin. The description by people of the severity of pain varies according to their personal concept, intelligence, vocabulary and psychic background. Some persons are born without the sensation of pain. In such patients there may be an absence of the peripheral sensory receptors or a deficiency in the conducting mechanism. The patient may feel other sensations but may not appreciate pain. Such patients do not have the protective measures when the various parts of the body are subjected to the ordinary trauma of everyday life. A

greater intensity of ordinary stimuli such as heat, cold, touch and pressure can induce a subjective sensation of pain. As the intensity of any stimulus increases, one can differentiate two stages: metaesthesia which is just uncomfortable and algaesthesia which could indicate pain.[47]

Perception of pain is variable in different individuals and in the same individual at different times and thus, it is difficult to assess the severity of pain objectively. Physiologists have attempted to assess the degree of pain from polygraphic recordings of psychogalvanic reflexes like tachycardia, cutaneous pallor and hypotension. Methods have been devised to assess objectively or qualitatively the intensity of pain by a special mechanical pressure apparatus, like an algometer or by chemical means, e.g. the blister base being stimulated by chemical solutions of different strengths.[46] "Pain" itself cannot be measured, but the stimulus leading to the pain can serve as an analogue of the pain. Thus, the stimulus leading to an experimental pain equal to the intensity of a pathological pain can serve as an analogue of the intensity of the latter.[45] Pioneering work in the first decade of the 20th century by Foerster,[25] Spiller and Martin[87] and Schueller,[81] served to initiate the surgical science of amelioration of intractable pain.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The human sensory nervous system carries information from the external and internal environment to the brain which is responsible for the ultimate perception and appreciation of pain. Particular areas are especially involved in different facets of sensation like appreciation, memories of sensations and their emotional significance.

Peripheral Receptors

There are a variety of sensory receptors, usually known after the names of those who initially described them, namely, Meissner, Ruffini, Merkel, Krause, Pacini, Golgi, Mazzoni, etc. The histological peculiarities and the specificity of these receptors are now known. It is now becoming increasingly clear that these receptors are much less specialised in function than previously assumed. Weddell[98] and his group proposed that the various cutaneous sensations do not arise from the selective activation of specific receptors, but from the selective activation between the various types of stimuli, the differentiation depending on the spatiotemporal pattern of excitation of non-specific sensory endings.[52] In large parts of the body surface specific end organs are altogether absent, except those in relation to hair follicles.[98] The cutaneous plexus of naked axoplasmic filaments have not only a large part to play in pain reception, but also seem to identify a wide variety of stimuli. The cornea has only fine small fibres and yet these fibres carry touch, as well as pain and temperature sensation.[6] Neurophysiological research work on mammals has shown the existence of pain receptors (nociceptors) of different types in different structures.[76] There is no doubt as to the presence of nerve endings which respond only to painful or tissue damaging stimuli and are therefore to be identified as pain receptors or nociceptors.

In the appreciation of sensation, the specificity of the receptors as well as spatiotemporal summation of stimuli plays an important role. This is further modified by the phenomenon of modulation in receptor activity. The receptor sensitivity is under the influence of environmental stimuli, the state of the tissue, as well as feedback information from other levels of the nervous system, all of which can alter the receptor response to stimuli. The receptors are divided into high threshold nociceptors,[38,41,74,75] mechanical nociceptors, polymodal nociceptors[9,32] and muscle[72] (Table 2) and visceral nociceptors.[41] These connect with the fine medullated or unmyelinated fibres in the peripheral nerves.

Lewis[53] described, in 1935, the occurrence of hyperalgia at the site of the noxious stimuli and the surrounding area and attributed it to the production of pain producing chemicals from the injured tissue. Tissue damage releases H+, K+, 5-HT, histamine, prostaglandins, bradykinin, and substance-P and these cause pain. Calcitonin gene related peptide (CGRP), vasoactive intestinal peptide (VIP) and somatostatin are also released by C-fibre stimulation.[70] Prostaglandins potentiate the role of inflammation and pain and enhance the effects of other inflammatory substances. Corticosteroids, by blocking the formation of arachidonic acid (precursor of prostaglandin) from membrane phospholipids, reduce pain and the inflammatory response. Aspirin and indomethacin relieve pain by inhibiting cyto-oxygenase, an essential enzyme in the cycle of production of prostaglandins. Substance P, present in the peripheral terminals of unmyelinated fibres, has a role in the initiation of pain. Capsaicin is used in the study of secondary hyperalgesia. It selectively activates nociceptors and causes a large zone of hyperalgesia when topically applied. Capsaicin hyperalgesia closely resembles thermal injury/laceration.[84]

There are four peripheral mechanisms of pain generation and transmission:[85]

- Tissue receptors
- Generated potentials (voltage and ligand gated channels)
- Membrane receptors (NMDA, AMPA, GABA, etc.)
- Signal modulators (NMDA agonists, etc.).

Sensory Nerve Fibres

The Bell-Magendie law segregated motor and sensory functions in a nerve. We, however, know that is not exactly true. Some sensory fibres also pass through the ventral root. Thirty per cent of ANS fibres in the ventral root are unmyelinated. These ventral root fibres take two pathways: they either turn back and enter via the dorsal root (DR) and the dorsal root ganglion (DRG) or they continue through the ventral root and traverse the grey matter and terminate in the superficial layers of the dorsal horn.[70]

The sensory nerve fibres travel proximally in the peripheral nerves towards the spinal cord, form the first relay in the bipolar cells of the dorsal root ganglia and they enter the spinal cord in the posterior roots. The cells in the dorsal root ganglia are of two types: large A cells and small B cells. The A cells give rise to large myelinated axons and the B cells to small (A delta) myelinated axons and non-myelinated axons (C fibres) (Table 1). The pain impulses travel in the small myelinated fibres (A delta) and in non-myelinated fibres (C fibres). This has been confirmed by single fibre recordings in animals[16] and by percutaneous microneurography.[94] Conduction in A delta and C fibres is blocked early during the injection of local anaesthetics, whereas the bigger fibres get blocked early in ischaemia. The conduction along A delta fibres leads to discrete localisation of the pain, whereas C fibre stimulation leads to a diffuse and longer lasting uncomfortable sensation resembling pain. It has been proposed that this differential conduction of pain may be the cause of the double pain, e.g. when the skin is pricked there is an immediate pricking sensation (first pain) followed after a short interval by an unpleasant sensation (the second pain).

Phylogenetically the C fibres belong to a primitive afferent system relatively complete in itself with a large spectrum of sensibilities. C fibres are polymodal nocipceptors which respond to various noxious stimuli, including thermal, mechanical and chemical stimuli.[32] This has been overlaid during development by an independent system of fast fibres (A) connecting to the newer parts of the brain.[11]

Table 1: Erlanger and Gasser classification of nerve fibres

Cutaneous sensory fibres	*Description*	*Diameter (μm)*	*Mean conduction velocity (MCV)/ms*
A-beta	Mechanoreceptor (low threshold)	8 (5-15)	50 (40-70)
A-delta	Mechanothermal nociceptor (Type I). Hair mechano-receptor (low threshold). A-fibre mechano-, heat- and nociceptor (AMH). Chemosensitive AMH (type II)	<3 (1-4)	15 (2-40)
B	Pre-ganglionic sympathetic	3 (1-3)	7 (3-15)
C	Mechano-, heat-, chemical nociceptive	1 (0.5-1.5)	1 (0.5-2)
C	Post-ganglionic sympathetic	1 (0.5-1.5)	1 (0.5-2)

Table 2: Lloyd Hunt classification of muscle sensory endings

Type	*Description*	*Diameter*	*Mean conduction velocity (MCV)/ms*
Ia	Primary muscle spindle	15 (12-14)	100 (70-120)
Ib	Golgi tendon apparatus		
II	Secondary muscle spindle, Spray (Ruffini) endings, Lamellated (Paciniform) endings	9 (4-12)	55 (25-70)
III	Mechanoreceptor	3 (1-4)	11 (10-25)
IV	Mechano-, chemical nociception, thermoreceptors	1 (0.5-1.5)	1 (0.5-2)

Sensory perception on the skin surface is not compartmental. There are overlapping areas supplied by adjacent sensory nerves. After surgical section of a single posterior root, the analgesic effects are negligible. To produce loss of sensation of pain in a predetermined part of the body, it is essential to cut several posterior roots above and below the appropriate segmental level. The possibility of the existence of some sensory fibres in the anterior spinal root (motor) has been suggested by physiologists. Obviously, these sensory fibres cannot be divided without jeopardising motor function.

Nociceptors

Pain sensitive fibres are called nociceptors. There are two types of pain receptors namely, unimodal nociceptor subserving only one sensation and polymodal nociceptor subserving chemical, mechanical and thermal nociception.[2] A delta and C fibres comprise the various nociceptors.

C Polymodal Nociceptor[70]

These are very important in nociception. Ninety five per cent of sensory C-fibres in the human skin are constituted by C Polymodal Nociceptors (CPNs). They respond to intense mechanical stimulation (more than 1g), thermal stimulation (threshold 38 degree C) and chemical stimuli. CPN activation thresholds are similar to high threshold mechanoreceptors (HTM), although CPNs demonstrate a graded sensitivity to thermal stimuli from 38–49 degree C (45–51 degree C is the maximum sensitivity range). They are further characterised by prolonged discharge with slow adaptation. They are associated with release of histamine, KCl, etc.

A-delta fibres: These are lightly myelinated. They respond to intense noxious mechanical stimuli and are not activated by noxious thermal/chemical stimuli, although intense cold

or repeated chemical stimuli sensitise them. They have multiple discrete receptor fields (less than 1 sq. mm) over the body and face. The active threshold is 5–1000 times more than the low threshold mechanoreceptors (LTM). The high threshold mechanoreceptors (HTMs) are initially quiet, but with repetitive stimulation are characterised by a slow background firing pattern.

Myelinated mechanothermal nociceptors (MMTN) are basically A-delta fibres. They have a thermal stimulation range of 40–46 degree C (45–53 degree C maximum sensitivity). They also are stimulated by mechanical stimuli and are involved in the genesis of first/fast pain.

Cold nociceptors: These respond to intense cold and noxi ous stimuli (A-delta or C fibres). They are insensitive to mechanical stimuli.

Visceral Pain

Pain sensation from the viscera is generally more diffuse. This is due to the high proportion of small C fibres in the visceral nerves and the existence of extensive ramifications between the nerves. In addition, afferent impulses from a given visceral area enter the central nervous system via many DRs. The visceral afferent fibres run in the autonomic nerves but are not a part of the autonomic nervous system. This explains the value of sympathectomy in some types of visceral pain and pain of vascular origin. The *convergence theory* wherein somatic and visceral afferents converge on the same spinothalamic neurons and the *facilitation theory* wherein collateral connections for visceral afferents to dorsal horn neurons receiving pain impulses from somatic stimulation facilitate pain have both been used to explain referred pain which occurs in visceral pain.[28]

ORGANISATION OF THE SPINAL CORD

The spinal grey matter has been organised into 10 laminae. These were initially studied in the cat by Rexed. That human beings too possess a similar laminar arrangement was proved by the work of Truex and Taylor[4,59,93] (Fig. 1).

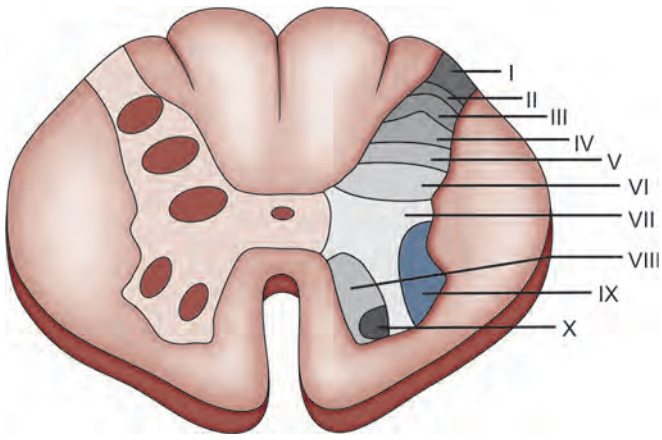

Fig. 1: Cross-section of the spinal cord showing laminar arrangement of spinal grey matter

Lamina I

The grey matter is situated at the margin of the dorsal horn. There is a marginal plexus which constitutes a hori zontal group of fibres. Larger elements of this lamina constitute the *marginal cells of Waldeyer* which respond to mechanical or thermal nociceptive information released secondary to tissue destruction and contributes elements to the contralateral spinothalamic tract.

Lamina II (Substantia Gelatinosa of Rolando)

This exists throughout the spinal cord with a narrow outer zone and a broader inner zone. Afferents to the SGR come from the tract of Lissauer, posterior column and adjacent parts of the lateral funiculus of the spinal cord. Nociceptive special neuronal soma is in lamina I and in the outer Lamina II. Innocuous mechanical stimuli occur in the inner zone of lamina II. Lamina II is a closed system with no axonal contributions to the other relay systems. The SGR neurons project to Lissauer's tract and fasciculus proprius. Lamina II primarily serves to influence the neurons in the deeper laminae and has a modulatory function.

Laminae I and II have a high concentration of substance P which is synthesised in the DRG and then transported into the terminals of the DR fibres. Substance P stimulates nociceptive impulse transmission. Both these regions have high concentration of opiate receptors. After dorsal root rhizotomy, there is a significant decrease in the number of opiate receptors in the deafferenated spinal segments.

In the substantia gelatinosa of Rolando (Lamina II) and in Lamina I, there are a group of neurons which are interposed between the first order and second order afferent neurons. These interneurons play an important role in regulating the afferent impulses, resulting in segmental control of input and output. The output pattern of the cells is modified not only by the peripheral input, but also by the facilitatory or inhibitory action of central tonically active descending systems.[76] A barrage of impulses via the large myelinated fibres produces inhibition of small cells and C fibres.[24] Counter irritation to modify pain and therapeutic transcutaneous nerve stimulation (TENS) reduce the firing of dorsal horn cells, inhibiting segmental as well as descending control. Descending control of dorsal horn cells is well known. Stimulation of the periaqueductal grey or the nucleus raphe magnus results in prolonged analgesia.[103]

Laminae III-V

These are vertically oriented with larger neurons and dendrites which arborise dorsally into laminae I and II. Afferent input consists of myelinated axons. The laminae are mostly comprised of interneurons and receive low threshold mechanoreceptor input. There are 2 types of projection neurons here namely, dorsal columns and spinocerebellar tract. Lamina IV has the thickest layer of large neurons external to lamina II. The grey matter

of laminae III and IV comprise the principal sensory nucleus/nucleus proprius. Large diameter primary afferents terminate here. Lamina V is a broad zone across the neck of the dorsal horn. The output depends on the degree of convergence of large and small fibre input—low threshold, wide dynamic range (WDR) or nociceptive specialised neurons. Hyperalgesia is primarily due to unmasking of low threshold inputs to nociceptive neurons.

Laminae VI and VII

Lamina VI is across the base of the dorsal horn and in the cervical and lumbar region. It has group I muscle afferents to the medial lamina VI terminating in the lateral zone. Lamina VII (zona intermedia) is situated between the anterior and posterior horns. The size and the boundaries of the laminae vary according to the level of the spinal cord. They have well defined cell groups, including the dorsal nucleus of Clarke (nucleus thoracicus). Lamina VII also serves as the origin for the uncrossed dorsal spinocerebellar tract and intermedio lateral and intermediomedial nuclei and tract.

Laminae VIII-X

These occupy the ventral horn of the grey matter. They also contribute to the gamma efferents to the muscle spindle. Lamina X is around the central canal and processes nociceptive input from visceral afferents and spinothalamic projection neurons.

A brief synopsis of the above is as follows:

Lamina I-VI: Dorsal grey, Lamina II-SGR, III and IV-nucleus proprius, V-formatio reticularis, VI-limb enlargements (brachial and lumbar), VII-nucleus thoracicus, intermedio-medial and intermedio-lateral columns which include the inhibitory interneurons of Renshaw, VIII-base of ventral column, IX-somata of motor neurons (alpha and gamma), VIII-X: Dorsal grey, X-spinal grey commissures.

PAIN PATHWAYS IN THE SPINAL CORD

The following tracts (Figs 2A and B) have been studied in great detail by horseradish peroxidase labelling and antibodies:[101]

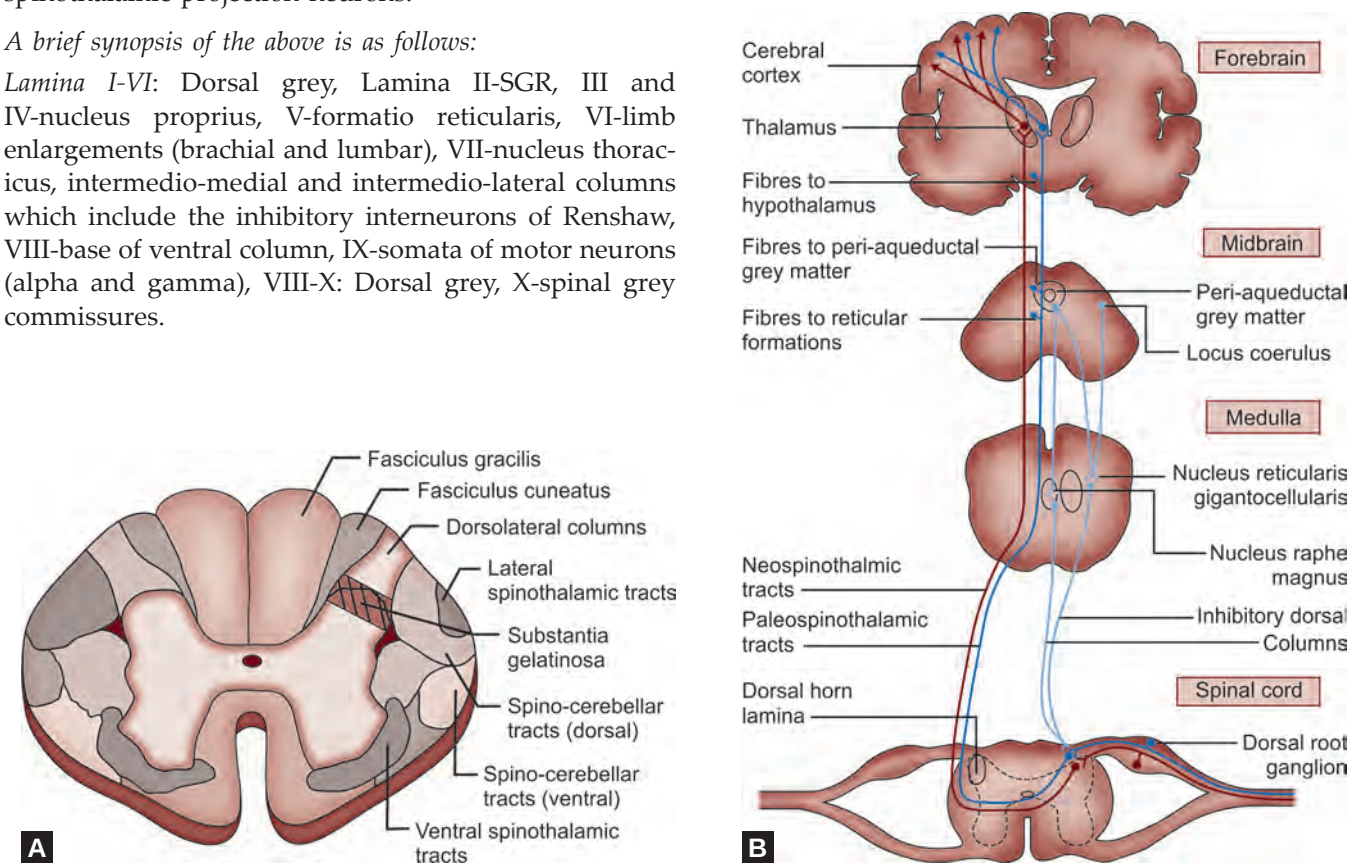
Dorsolateral Tract of Lissauer

This tract is situated laterally and caps the dorsal horn. It has A-delta and C-fibres and is concerned with nociception. Fibres from the lateral division of the dorsal root bifurcate into ascending and descending branches that give off a number of collaterals. These terminate in the SGR with interneuronal synapses.

The tract of Lissauer (TL) is situated dorsolateral to the dorsal horn and consists of:

Medial part: Here the small afferents enter and bifurcate to reach the dorsal horn, either directly or through ascending/descending pathways. This part transmits excitatory effects of each DR to the adjacent segments. The medial division contains large medullated fibres which carry proprioceptive stimuli from the muscles.

Lateral part: Through this part, a large number of long endogenous propriospinal fibres interconnect at different levels of the SGR. These convey the inhibitory influence of the SGR into the neighbouring metameres. The small medullated fibres and the fine unmyelinated fibres conveying pain sensibility pass through the lateral division and end in the area of the substantia gelatinosa of Rolando (SGR) encasing the posterior horn.



Figs 2A and B: Pain pathways. (A) Cross-section showing spinal tracts. (B) Spinal supraspinal pathways of pain

Spinothalamic Tract

The spinothalamic tract (STT), spinoreticular tract (SRT) and spinomesencephalic tract (SMT) together constitute the spinal lemniscus and may be considered to be a single path. The origin is from laminae I and V-X. The fibres from laminae I-V go to the ventralis posterior nucleus of the thalamus and those from laminae VI-IX project to the ventralis posteromedial nucleus. In the brainstem, as it is nearing the thalamus, the spinothalamic tract divides into:

A large lateral neospinothalamic tract, which terminates in the ventroposterior lateral nucleus along with the quintothalamic tract (trigeminothalamic) fibres and

A small medial portion which terminates in the most rostral part of the ascending reticular activating system (ARAS) and in the central nuclei of the thalamus (the so-called non-specific thalamus).

The Vpm and Vpl nuclei then project to the somatosensory cortex and these fibres are called the neospinothalamic tract (neo-STT). Second order fibres from the deeper laminae project to the reticular formation, pons, mesencephalon, periaqueductal grey and hypothalamus and thence to the medial and intralaminar thalamic nuclei. These constitute the paleospinothalamic tract (paleo-STT) of Mehler[61] and project to the limbic forebrain. The paleospinothalamic tract in lower vertebrates represents the only true connection to the thalamus. The neo-STT is highly organised somatotopically, while the medial paleo-STT is not. The fibres in the STT are arranged from lateral to medial (sacral, lumbar, thoracic, cervical).[3,49] Bishop[11] and Mehler[61] proposed that the neospinothalamic tract becomes more prominent and the paleospinothalamic tract less prominent in higher mammals. Anterolateral cordotomy interrupts the SRT and SMT together with the STT.

In the cervical cord, the disposition of the tract is as follows: sacral, lumbar, thoracic, cervical from outside inwards. At different levels of the spinal cord, the depth of the incision required to interrupt the spinothalamic fibres during an anterolateral cordotomy must vary to obtain optimal effect. Hyndman and Van Epps[40] regarded the lamination of the spinothalamic fibres as having a postero anterior distribution, rather than an onion peel arrangement. Hitchcock[36] supported this view as he observed that a 3 mm incision often produces as complete and lasting analgesia as the 4–5 mm incision. This fact is of importance, as too deep an incision would inevitably injure the visceral fibres.[35] There are 3 types of spinothalamic neurons namely, low threshold neurons which are mechanoreceptors in lamina VI and VII, high threshold neurons which are nociceptors in lamina I and wide dynamic range neurons from lamina IV and V, involved in mechanoreception and nociception.[2]

Magoun[57] described the two systems of central pain pathways as lemniscal and extra lemniscal systems. It may also be noted that the afferent responses evoked in the thalamus through the lemniscal system are somatotopic, i.e. spatially organised, whereas those in the extra lemniscal system are also capable of evoking various reflex effects both in the somatic and the autonomic systems, e.g. the peripheral results of arousal and alarm reactions.

Spinoreticular Tract

This is triggered by arousal and is influenced by emotional and affective aspects of pain and somatic autonomic reflexes.[13] The fibres originate from lamina VII and VIII and are in the anterolateral quadrant of the cord. It projects ipsilaterally and contralaterally but mostly to the contralateral side in the lumbar region. It terminates bilaterally in the medullary reticular formation, the nucleus subceruleus and the raphe magnus nucleus. From here, fibres proceed to the medial thalamic nuclei.

Spinomesencephalic Tract

It is similar to the spinoreticular tract. The fibres originate from laminae I and V. These fibres are 1–5 μm in thickness and conduct at 7m/s. Sixty per cent to 75% project to the contralateral brainstem, where these fibres diverge from those of the STT and SRT and turn dorsomedially into the midbrain. Most of the fibres terminate in the mesencephalic reticular formation (RF), periaqueductal grey and rostrally in the medial and ventrobasal thalamus. These fibres serve a discriminative function and also a role in autonomic reflexes. Ascending impulses activate supraspinal descending inhibitory pathways.

Spino-Cervical Tract

This originates in laminae III and V and subserves non-noxious tactile stimuli.[13] It lies in the ipsilateral dorsal funiculus and extends up to the lateral cervical nucleus; a small group of cells in the upper cervical cord lying lateral to the dorsal horn. Fibres from the spino-cervical tract (SCT) project to the contralateral thalamus. It is an inconsistent pathway in humans and has a yet unclear role in nociception.

Dorsolateral Posterior Synaptic Pathway

Laminae III and IV of the dorsal horn give rise to dorsolateral posterior synaptic pathway (DLPSP). This carries noxious and non-noxious stimuli. Less than 10% respond to noxious input. Somatotopic arrangement exists in this pathway. This tract plays a role in pain modulation.

Propriospinal Multisynaptic Ascending System

Propriospinal Multisynaptic Ascending System (PMAS) originates in the deep dorsal column in lamina X, with input from nociceptors and midline structures. It projects to the brainstem reticular formation and medial and intralaminar thalamic nuclei. Selective ablation of this path is considered to be effective in the treatment of bilateral visceral pain, without the potential problems associated with commissural (extralemniscal) myelotomy.[33]

Dorsal Root Entry Zone[86]

The dorsal root entry zone (DREZ) is an entity including the 1 mm central part of the dorsal rootlet, the posterior medial part of the tract of Lissauer and the most dorsal layers (I-V) of the dorsal root where afferents synapse with cells of the spino-reticulo-thalamic pathway. Each DR divides into 4–10 rootlets according to metameres and is 0.25–1.5 cm in diameter, according to the cord level. Each rootlet is a functional entity, i.e. a miniature root. In each dorsal rootlet and in its corresponding DREZ, there is a spatial segregation of afferent fibres according to their size and destination. The fine fibres re-group in the lateral region of the DREZ.

The tract of Lissauer (TL) is situated dorsolateral to the dorsal horn and consists of two parts as described above.

Most fine nociceptive afferents enter the dorsal horn through the medial part and then through the dorsal aspect of the SG. Ramon y Cajal's recurrent collateral vessels of large lemniscal fibres enter the dorsal horn through the ventromedial aspect of the SG. Because dendrites of the spino-reticulo-thalamic tract (SRT) cells make synaptic connections with primary afferent fibres inside the SG layers, it is assumed that the SG has a segmental modulatory effect on nociception. When large lemniscal afferents in the peripheral nerve/dorsal root are stimulated, there is a decrease in the inhibitory control of the dorsal horn which can cause excessive firing of the dorsal horn neurons. This is the origin of de-afferenation pain. Micro-DREZotomy (MDT) involves preferential destruction of the nociceptive fibres in the lateral bundle of the dorsal rootlets, as well as the excitatory medial part of the LT. Descending control of dorsal horn cells is well known. Stimulation of the periaqueductal grey or the nucleus raphe magnus results in prolonged analgesia.[103]

Trigeminal Nerve and its Nuclei

A special reference is made here to the trigeminal system as it subserves the pain of the face and as tic doloureux is so commonly seen in clinical practice (Table 3).[34]

There are two patterns of trigeminal somatotopic organisation within the descending trigeminal tract and the nucleus caudalis. The first is that of concentric rings with the middle part of the face being subserved by the trigeminal nucleus in the rostral medulla. The caudal end of the face is subserved by the spinal nucleus at the caudal end of the medulla. The second pattern is that arranged along the three divisions of the trigeminal nerve V1,V2,V3.[31]

The Thalamus (Table 4)

The spinothalamic tract enters the posterior part of the ventral lateral nucleus (VpL). The pain fibres from the face travel as a separate bundle called the quintothalamic tract and terminate in the posteroventromedial (VpM) nucleus of the thalamus. According to Glees,[30] the termination of the medial fillet lies between those of the spinothalamic and quintothalamic tracts. Other fibres carrying pain sensation enter the interlaminar nucleus and many of them terminate in the centromedian and parafascicular nucleus, which comprise the nucleus parafascicularis (the paleosensory system). The dorsomedian nucleus of the thalamus, through its connections with the VA nucleus and the limbic system, plays a part in the emotional reaction to pain.

The thalamus has been divided into:[13]

- *Medial paleothalamus* which comprises the medial and intralaminar nuclei. It has no somatotopy. The role of these nuclei in pain processing is primarily related to the emotional and motor reaction associated with aversive behaviour, rather than discriminative sensory function.

Table 3: Nuclei of trigeminal nerve

No	*Nucleus*	*Location*	*Distribution*	*Function*
1.	Nucleus motoricus trigeminus	Midpons (lateral reticular formation)	Special visceral efferents (SVA), branchial muscles of mastication from branchial arch I.	Motor supply to masseter, temporalis, pterygoids, tensor tympani, tensor palatine, mylohyoid and the anterior belly of digastrics.
2.	Nucleus mesencephalicus trigeminus	Rostrally from the primary nucleus to the superior colliculus of the mesencephalon	General sensory afferents (GSA), proprioception from organs of mastication.	Force of bite controlled.
3.	Nucleus sensiblis principlis trigemini	From the tegmentum of the midpons at the trigeminal root entry zone.	General somatic afferents (GSA), exteroceptive	Tactile facial sensation.
4.	Nucleus tractus spinalis trigeminus	From the midpons at the level of the trigeminal root entry zone caudally to C2.	Exteroceptive	Pain and temperature sensation of the face.

- *Neothalamus* which receives fibres from laminae VI-VIII of the dorsal horn through multiple ascending systems and the brainstem RF. The neothalamus comprises the VpL and VpM nuclei and has a high degree of somatotopic organisation. VpL receives the neoSTT via the medial lemniscus and the VpM receives the spinal-trigeminal system via the ventral tegmental tract (VTT).

Summary of the Neurophysiology of the Thalamus[89]

The thalamic lesion sites for pain relief have been classified as follows:[90]

- Thalamic nuclei of the limbic system and their radiation
- Hypothalamus
- Thalamic nuclei of the frontal association system and their radiation
- Spino-thalamic relay nuclei for the medial lemniscus and the spino-quintothalamic tract and their radiations
- Intralaminar nuclei.

NEUROPHARMACOLOGY OF PAIN

An understanding of the neurochemical mechanisms involved in sensory conduction and pain helps to understand the basis of pharmacological therapy.

Substance P is an important neurotransmitter concerned with transmission of nociceptive stimuli. Substance P also contributes to the inflammatory response and nerve sensitisation. Recent studies have shown calcitonin gene related polypeptide (CGRP) to exist with substance P in the primary afferent neurons.[37] Its role may be neuromodulation rather than neurotransmission. Other substances are serotonin and norepinephrine which mainly act as neurotransmitters of the descending pathways from the nucleus raphe magnus and locus ceruleus, respectively. The other important modulators are endogenous opiates which are present in the substantia gelatinosa, lamina V, nucleus raphe magnus and periaqueductal grey (PAG).

Peptides like substance P, VIP, somatostatin, chole cystokinin and angiotensin are present in the dorsal horn.[32] Substance P is present in 20% of the cells of the dorsal root ganglion (DRG), mainly in the small cells. Noxious peripheral stimuli result in the production of substance P, which probably acts more as a neuromodulator than a neurotransmitter.[51]

Opiate receptors are found in laminae I and II of the dorsal horn, the medial raphe nucleus, the periaqueductal grey, the locus ceruleus and the hypothalamus. Endorphins are found near these receptors. Seven different endorphins have been identified with varying receptor specificity.[50] The descending control of dorsal horn activity is an opiate dependent mechanism. The periaqueductal grey projects to the raphe nucleus which projects to the dorsal horn.[7] The neurotransmitters involved in these projections are serotonin and norepinephrine.

Table 4: Nuclei of the thalamus

No.	*Nucleus*	*Stimulation*	*Miscellaneous recording*	*Applications*
1.	Ventrocaudal (Vc)	Paraesthesia	Tactile neuron	Lesion and chronic stimulation for pain relief
2.	Parvocellular ventrocaudal (Vcpc/VMpc)	Warm, cool, painful effects and paraesthesiae	Nociception, thermoception	Pain relief lesions
3.	Anterior ventral oral (Voa)	None recognised	Voluntary cells	Dyskinesia
4.	Posterior ventral oral (Vop)	Motor "on" effects	Voluntary cells	Functional dyskinesias
5.	Ventralis intermediate (Vim)	Paraesthesiae, vestibular, sensorimotor effects.	Kinesthetic and deep sensory nuclei	Lesioning and chronic stimulation for tremor and dyskinesia control
6.	Anterior nucleus (A)	None-recognised	None-recognised	Lesions for relief of psychiatric disease
7.	Parafascicular (Pf)	None	Nociception	Pain relief
8.	Periventricular grey (PVG) medial parafascicular	Acute pain relief, satiety centre.	None	Chronic stimulation for pain relief
9.	Interlaminar (IL)	None/pain/burning sensations.	Nociception	Pain relief
10.	Pulvinar (Pu)	None-recognised	Vision	Pain and spasticity relief
11.	Dorsomedian nucleus (DM)	None-recognised	Firing cells	Psychiatric disease treatment
12.	Centromedian nucleus (CM)	None, pain	None-recognised	Lesion for pain relief and also for treatment of movement disorders

Substance P is also present in this projection to the dorsal horn. The opiates have mu 1 and 2, delta 1 and 2 and kappa 1, 2 and 3 as receptors.[97] When cloning of opiate receptors was attempted, an orphan opioid like receptor (ORL) was deciphered. The agonist of this receptor was nociceptin and the antagonist was nocistatin. These are under investigation.[28]

The endogenous analgesic system:[60] This consists of the peri aqueductal grey (PAG), nucleus raphe magnus (NRM), parabrachial region, midbrain medullary RF, dorsal raphe nucleus, cuneiform nucleus, medial reticular formation, nucleus of trigeminal spinal tract and SGR; the first four being the most important. The pathway on receiving painful stimuli stimulates the release of endorphins which serve as pain modulators. Low intensity electric stimulation of the raphe nuclei cause analgesia mediated by norepinephrine and serotonin (5-HT). Analgesic action of the system of endogenous opioids is blocked by the depletion of 5-HT levels and NE.[23,29]

Towards the Understanding of Pain—Pain Models

The Biophysical Model of Pain

This states that pain behaviour is only the outermost manifestation of nociceptive inputs filled through each individual patient's pain perception and suffering.[55]

The Gate Control Theory of Pain

One of the functions attributed to the interneurons is that of a gate control system modulating the afferent input (Gate control theory of Melzack and Wall).[62] The theory was first stated in 1965 by Wall and Melzack and was then re-stated by Wall in 1978 and 1983 to embrace the criticism about the role of the SGR, extent of pre-synaptic inhibition in nociceptive afferents in the dorsal horn and the known fact of stimulus specificity of nerve fibres. Simply stated the theory runs thus—information about the presence of injury is transmitted to the CNS by peripheral nerves. Cutaneous small diameter fibres (A delta and C fibres) respond only to injury, while others with lower thresholds increase their discharge frequency if stimuli reach noxious thresholds. Cells in the spinal cord/trigeminal nucleus which are excited by these injury signals are also facilitated or inhibited by other nerve fibres which carry information about innocuous events. A descending control system originating in the brain modulates the excitability of cells which transmit information about the injury. The brain receives by way of the gate control system, injury signals, descending signals and other types of afferents.

The gate control theory was based on certain observations from experimental physiology. It was noted that, in cats, when the spinal cord was transected, neurons in lamina V responded to noxious stimuli which led one to speculate about a tonic inhibition of nociceptive responses in the spinal cord by a descending pathway.[96] Stimulation produced analgesia associated with (in animals) inhibition of nociceptive reflexes like the tail flick reflex (by intra-spinal neurons). Stimulation of analgesia producing brainstem loci selectively inhibits nociceptive response cells in the dorsal horn of the SC.[27] Monoamine receptor antagonists could antagonise this inhibition by bulbospinous monoaminergic pathways. Discrete lesions in the dorsolateral funiculus (DLPS) also inhibit the effects of SPA on behavioural response to pain.[5] The gate control theory has also been refuted by many who have questioned the overstated role of the SGR cells.[66,92]

This theory of gating, although modified later, is generally still applicable to many levels of the nervous system. The interneurons have an inhibitory effect on the afferent fibre terminals. This inhibition is increased by activity in the large diameter fibres and decreased by activity in the small diameter fibres. The balance of activity between the two sets of fibres influences the interneurons, to control the afferent input into the central nervous system. The descending pathways from the cortex and the brainstem also exert an inhibitory influence on the gate control system. Thus, the role of the interneurons is to help in the convergence, interaction and control of afferent influences. It is probable that such neural switches or gates exist all along the sensory system.[76] But for such control, the bombardment of the central nervous system by innumerable sensory stimuli will be intolerable.

"The busy line effect" wherein antidromic conduction interferes with the impulse propagation of noxious stimuli has also been implicated in the gate theory.[39]

The technical details of the gate control theory are as follows (Fig. 3):

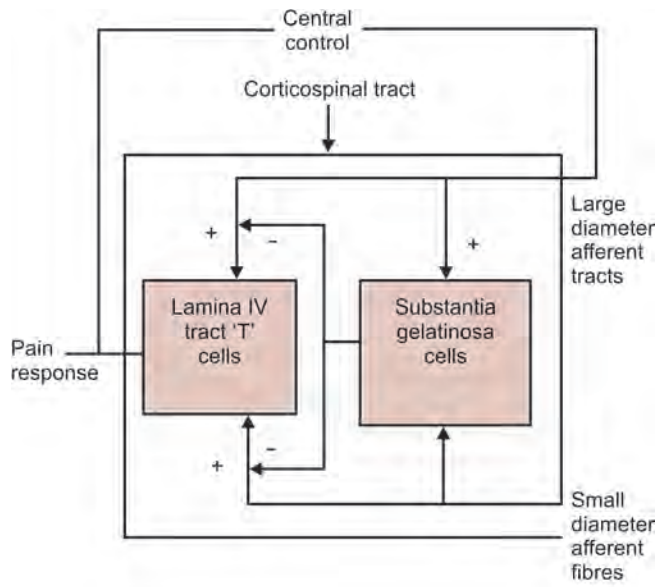


Fig. 3: Sensory gate control circuit (Melzack and Wall)

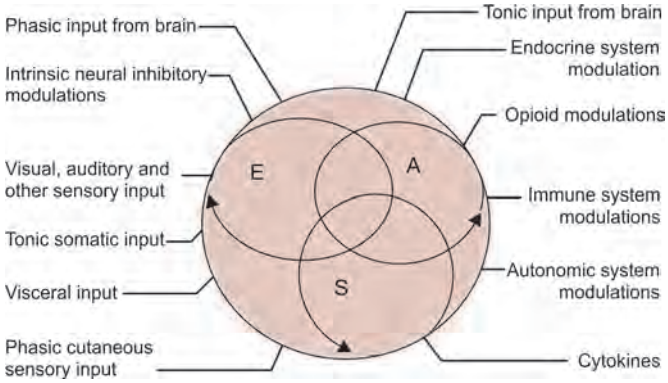

Fig. 4: The neuromatrix theory of pain

- Ongoing activity preceding a state is caused by tonic, slowly adapting fibres that tend to keep the gate open.
- Peripheral stimulation activates both small and large fibres. Discharge of large fibres will initially cause the tract cells (T cells) to fire by the direct route and then partly close the gate in Lamina II. This facilitates pre-synaptic inhibition.
- Balance between large and small fibre activation will determine the state of the gate. If the stimulus is prolonged, large fibres will adapt which will result in a relative increase in small fibre activity and cause the gate to open. The gate functions and there is an increase in T cell activity. However, if large fibre activity is increased by a proper stimulus (vibration) the gate will then close and the T cell activity will decrease.

Neuromatrix Theory of Pain[63]

Neuromatrix theory of pain (Fig. 4) states that the body-self neuromatrix comprises a widely distributed neural network that includes somatosensory, limbic and thalamic cortical components. There are 3 parallel networks which account for the dimensions of pain experience namely, S-sensory discriminative, A-affective motivational and E-evaluative-cognitive.

The synaptic architecture of the neuromatrix is determined by genetic and sensory influences. The neurosignatory output of the neuromatrix results in a pattern of nerve impulses of varying temporal and spatial dimensions and is produced by neural programs genetically built into the neuromatrix and which determines the quality and other properties of pain experience and behaviour. Multiple inputs that act on the neuromatrix programs and contribute to output neurosystems include:

- Sensory inputs from the somatic receptors
- Visual and other sensory inputs that influence cognitive interpretation of the situation
- Phasic and tonic cognitive and emotional inputs from other brain areas
- Intrinsic neural inhibitory modulation inherent in all brain function
- Activity of the body's stress regulation systems including cytological as well as endocrine, autonomic, immunologic and opioid systems.

CHRONIC PAIN SYNDROMES

While generally pain is beneficial as a warning to the organism, continuous and chronic pain with all its variations seems to serve no biological purpose. The onset and continuance of chronic pain appears to arise from the intrinsic complexity of the peripheral sensory and pain conducting systems, the peripheral nerves, the dorsal root ganglion, the dorsal horn, the ascending tracts and the higher brain centres. In chronic pain syndromes (CPS), the complaints are usually stated in affected terms like—excruciating, throbbing, stabbing, etc. and have no dermatomal pattern.

Pain in Peripheral Nerve Lesions

In peripheral nerve injuries, long-lasting discharges occur in the small sensory fibres and not in the large sensory or motor fibres.[1] It was suggested that cross connections between sensory and motor fibres in an injured nerve (ephaptic transmission) leads to perpetuation of pain as seen in causalgia. Further work has not confirmed the presence of such connections either by light or electron microscopy.[65,88] The persisting pain has been attributed to the possible formation of small injury neuromas inside the nerve,[79] where the axonal sprouts are sensitive to physical and chemical stimulation. Spontaneous and evoked afferent activity has been noted from the affected area. Adrenergic receptors have been shown to develop on the axonal sprouts at the site of the injury. While catecholamines increase the afferent activity, local anaesthetics abolish these. Even in minor localised injuries, it has been suggested that focal demyelination may lead to spontaneous impulse generation and mechanical sensitivity.[17] This abnormal physiology gets reflected also in DRG cells. Microneurography studies in humans have confirmed that mechanical sensiti vity and ectopic discharges occur at the sites of nerve damage.[69] Neurotrophins, Protein Kinase-C, 5-HT and NO are involved in neuropathic pain.

During regeneration after nerve injury, recovery is only partial even after carefully performed surgery. The patients often suffer from paraesthesiae in the affected part, and also spontaneous pain, allodynia and hyperpathia. These abnormal sensory phenomena arise from many factors. The possibilities are: 1) conduction in sensitive fibres that have not yet made a receptor connection in the periphery, 2) death of DRG cells affecting the larger cells more than the smaller cells and increasing small fibre input into the cord, 3) functional connection between fibres serving high threshold and low threshold receptors and 4) impaired inhibition in the spinal cord.[20,54,62,79]

Root pain: Root pains are referred to discrete areas, can be intense and usually there is no sensory loss. Pressure

on the posterior nerve roots often causes changes in the DRG, because of its close proximity to the affected area and cell death can occur in the DRG. Prolonged pressure causes demyelination in the nerve roots leading to ectopic discharges and mechanosensibility. In long standing cases, the radiating pain may disappear leaving an area of sensory loss with hyperaesthesia or hyperalgesia.

Post-herpetic neuralgia is a painful syndrome characterised by anaesthesia, paraesthesia, hyperpathia and allodynia in the affected area. The virus of herpes zoster causes damage to the peripheral nerve, the DRG, the dorsal root and the dorsal columns.[22]

Cerebral Areas for Pain Perception

Cerebral discrimination and assessment of all varieties of sensations including pain is essential for highly deve loped organisms, especially man, so that the response may be adequate and appropriate. This is a function shared by many areas of the cortex. Cephalad to the thalamus, the impression of pain sensation is carried by multiple pathways to the sensorimotor cortex, the parietal lobe, the limbic system and the temporal and frontal lobes. These areas are concerned with the appreciation and assessment of pain, including the memory of pain, its significance and the reaction to the pain. Ablation of these areas does not produce objective impairment of pain or of touch sensation. The parts of the cerebral hemispheres concerned with the sensation of pain have been mapped out by various physiologists. Foerster,[25] in 1927, was one of the earliest to study the effects of electrical stimulation of the sensory areas of the cerebral cortex. Penfield and Boldrey,[73] found that on stimulation of the cortex, the subjects felt paraesthesia instead of pain. The cortical areas concerned have been studied by eliciting evoked potentials. These studies show that there is basically a fixed pattern of cortical representation but this often becomes labile during stimulation, reflecting the great plasticity of sensory representation at the cortical level.

Fibres from the posteroventral nucleus of the thalamus proceed to the sensorimotor cortex. Although the majority ends in the post-Rolandic sensory area, many of them can be traced to the motor strip also. The sensory cortex is concerned with the primary appreciation of sensation. Lesions in this area which include the parietal lobe may cause spontaneous hemibody pain and dysaesthesia which may be indistinguishable from thalamic pain except for its paroxysmal nature, resembling an epileptic discharge. Its pathogenesis is dependent on complex paleothalamic interrelationships.[78]

In addition to the direct thalamocortical sensory fibres, many fibres concerned with sensation travel to the parietal operculum to end in the second sensory area. The second somatic sensory area[10,74] situated near the parietal operculum is the most primitive area for appreciation of pain from the phylogenetic point of view. It is to this area that the unmyelinated fibres ultimately project. The other complex routes for pain assessment are to the limbic system, to the temporal lobes (for memory storage and comparison) and to the frontal lobes (for final assessment and judgement) and back to the limbic system, viz. the claustrum, the amygdala and the orbital cortex (for emotional colouring). The connections to the limbic system are important as they are involved in the motivational and affective determinants of pain.[19]

Mechanisms of Central Pain[4,70]

- Selective destruction of neo-STT
- Irritation of the sensory pathways
- Irritation of sympathetic pathways
- Hypothalamic disturbances
- Loss of nociceptive inhibitory influences
- Activation of secondary pathways
- Activation of non-specific pathways related to the paleospinothalamic system
- Abnormal findings of de-afferenation
- Hyperactivity in de-afferenated reticulo-thalamic pathway.

Thalamic Pain Syndromes (Dejerine and Roussy)

The following are the various types of thalamic pain syndromes which have been described in Table 5.[2]

Congenital Indifference to Pain (Pain Asymbolia)

This condition is a good model for study of the mechanism of pain appreciation. The disorder, a definite clinical entity, differs from insensitivity to pain resulting from drugs, surgical pain relieving procedures or hysteria. The patient perceives the painful stimulus, but this is not accompanied by discomfort or suffering. Careful anatomical studies of the nervous system of such individuals have not shown any specific abnormality. Magee[56] reported a decrease in the number of

Table 5: Thalamic pain syndromes

Type	*Central pain*	*Vibration, touch and joint sensations*	*Pain and temperature sensations*	*Somatosensory evoked potentials (SSEP)*
I (analgetic)	Absent	Lost	Lost	Absent
II	Present	Lost	Present	Absent
III	Present	Present	Present	Decreased
IV (pure algetic type)	Present	Present	Present	Normal

myelinated fibres, whether this finding has any direct significance to the problem of congenital indifference to pain is uncertain. The demonstration of a localised anatomical lesion in such cases will prove to be a great advance in the surgery of pain, as it may then be possible to place a small stereotaxic lesion in the concerned area which will relieve the patient of the unpleasantness of pain without altering his personality. Osuntokun et al.[71] reported the occurrence of congenital indifference to pain associated with auditory imperception in two siblings. They support the suggestion made by Boyd and Nie,[14] that there may not be any specific underlying defect in pain asymbolia which may be dependent upon lack of established cerebral dominance.

Congenital analgesia may occur as a developmental defect and may be associated with anhydrosis, vasomotor instability and hyporeflexia. A defect in neural crest differentiation has been suggested as the underlying embryonic abnormality.[15]

Summary of Physiological Principles

The physiological principles on which surgical procedures for pain relief are based are:

- Pain is a sensory modality
- It has definite pathways of conduction in the spinal cord and the brain with definite neurochemical basis
- The mechanisms of pain conduction and perception are different from pain appreciation, the latter being confined to the higher brain levels.

Physiology of pain has come a long way from the "doctrine of specific nerve energies" of Muller in the 1830s to the law of specific projection. The Weber-Fechner law states that the magnitude of any sensation felt is proportional to the log of the stimulus intensity. There are also two types of pain; an initial fast/mild pain mediated by A delta fibres through glutamate and a slow secondary pain mediated by substance P through C fibre endings.[28]

Knowledge accumulated from recent neurophysiological studies in animals and in man tends to suggest that the above orthodox concepts are too simple. The current efforts in research on pain have highlighted the following facts which need careful consideration:

Definition and assessment: The idea of "pain" itself requires better definition and better classification with a more objective assessment. This sensation of pain, "discomfort", "ache" and so on needs to be differentiated into various subgroups with properly assessed significance, e.g. metaesthesia, algaesthesia, paraesthesia and anaesthesia.

The Periphery: a) The specific end organs do not need necessarily to have special functions, b) it is not always possible to relate specific fibres to certain modalities of sensation. No particular fibre type is exclusively related to any particular class of stimulus, c) the unmyelinated fibre network in the skin may carry sensations other than pain, d) being a network, a single stimulus in this system will activate a number of fibres.

In the spinal cord: The spinothalamic tract is not a bundle of fibres which arises from one group of nerve cells and ends in another distant group. Although admittedly there are large numbers of long fibres in the spinothalamic tract, the majority of them is short fibres with multiple synapses and forms a multisynaptic afferent system.[68] This system has an inbuilt capacity for temporal and spatial summation as well as for inhibition. This arrangement of the fibre system would also imply that even a well planned section of the spinothalamic tract does not necessarily cut off permanently all the pathways of pain in the spinal cord.

In the brain: All fibres of the spinothalamic tract do not reach the thalamus, but the majority of them proceed bilaterally to various cell groups in the medulla and the brainstem and communicate with the reticular system. Stimuli conducted both by the large and small fibre systems come into the mesencephalic tegmentum and stimuli intense enough to be noxious are summated into a prolonged central response. In the thalamus, there is more than one area concerned with pain, with the neospinothalamic tract going to the posterior regions, while the old fibre system reaches the interlaminar nuclei, including the centrum median nucleus and the nucleus parafascicularis.

The response of the central nervous system to any noxious stimulus is modified by numerous central and peripheral influences on the neuronal pool of which the spinothalamic tract forms a part. The perception of pain is associated with reverberations and feedback among these cell groups.

Inhibition: Neurons have been seen to receive myelinated as well as unmyelinated fibres at the secondary sensory neuronal level. Stimulation of one group of fibres might selectively inhibit the passage of impulses along another pathway. This is seen when stimulation of one area of the brain selectively inhibits impulses in other pathways and this may also be a possible explanation for yogic control of pain and acupuncture analgesia.

Experimental stimulation of some areas of the brain (the caudate nucleus, septal, preoptic region or medial geniculate) raises the threshold of pain, while stimulation of other areas may reduce the threshold (central tegmental tract, ventral posteromedial nuclear group in the thalamus or the periaqueductal grey).[80] These studies confirm the already well-known experience of pain being suppressed in some extreme situations of pleasure or excitement only to become evident a little later.

These facts help to explain the successes and failures of neurosurgery for pain. By and large, the surgical procedures based on the presently accepted "orthodox" knowledge do give benefit and have proved their usefulness in the large majority of cases.

The above physiological considerations suggest the following mechanisms of chronic pain:[48]

Physiological Classification of Pain[91]

- Stimulation of peripheral nociceptors (e.g. Carcinomatous deposits in the long bones)
- Direct stimulation of nerve trunks, plexi and roots (e.g. Carcinoma in the L-S plexus)
- Impulses related to neural injury (neuropathic pain/sciatica)
- Central re-organisation pain (allodynia, hyperpathia, peripheral neuropathy, sympathetically mediated pain).

A special type of pain is "mirror pain" seen post-cordotomy, occasionally due to unmasking of cord pathways subserving pain.

Mechanisms of Chronic Pain

1. Nociceptive
   a. Somatic
   b. Visceral
2. Neuropathic
   a. Deafferentation
   b. Peripheral
3. Sympathetic
4. Psychogenic
   a. Without a coexisting organic lesion
   b. With an organic lesion.

CHRONIC REGIONAL PAIN SYNDROME

Chronic regional pain syndrome (CRPS) was first described by Paget in 1862. The syndrome was re-defined in 1995.

There are three types (*Stanton Hues, 'International Association for the study of Pain –IASP 1995*):

Chronic regional pain syndrome (Type I) (Reflex sympathetic dystrophy):

The features are as follows:

- The syndrome develops after an initial noxious event
- Spontaneous pain/allodynia/hyperalgesia not limited to the territory of a single peripheral nerve and is disproportionate to the exciting event
- There is evidence of oedema/shiny skin and abnormal blood flow with abnormal sudomotor activity in the region of the inciting event
- Exclusion of any condition that would account for the above dysfunction.

Chronic regional pain syndrome type II (Causalgia)

- This develops after a nerve injury
- Spontaneous pain/allodynia/hyperalgesia occurs and is not necessarily limited to the territory of the injured nerve
- There is evidence of oedema/shiny skin and abnormal blood flow with abnormal sudomotor activity in the region of the inciting event
- Exclusion of any condition that would account for the above dysfunction.

There are three stages in causalgia:

- Pain/oedema and wasting
- Cold skin with trophic changes
- Atrophy.

Chronic regional pain syndrome type III: Not Otherwise Specified

Pathophysiology of Chronic Regional Pain Syndrome

There are several theories of CRPS:

- Vicious circle of Leriche (1939) and Livingstone in 1943.
- Walker and Nielsen (1948) attributed the pain due to action of the sympathetic nervous system. Patients undergoing pregnancy sympathectomy had electrodes placed along the sympathetic chain. Activation of the sympathetic ganglia post-operatively blocked the pain. This was confirmed by White and Sweet in 1969.
- Pain in CRPS is relieved by local anaesthetic sympathetic blockade/sympatholytic procedure like the regional application of guanethidine/IV phentolamine.
- Pain may re-initiate/exacerbate by the application of an alpha adrenoceptor agonist, either iontophoretically or by injection of a limb with pain and hyperalgesia.
- Guanethidine elicits pain when injected IV in the affected extremities. Represents a response to NE released from the post-ganglionic tissue.

Coupling of sympathetic afferents and efferents results in abnormal afferent impulses generated by the sympathetic nervous system. This explains why RSD is abolished by sympathetic block.

The following explains the mechanism of this coupling:

- Direct chemical coupling between NE terminals and primary afferents through an alpha 2 receptor that produces excitation/sensitisation of afferent fibres
- Coupling occurs in traumatised neurons (no experimental proof exists)
- Coupling in DRG to large diameter afferent fibres and possibly unmyelinated fibres
- Indirect coupling in microvascular beds/non-neural cells proximate to afferent receptors (hypothetical)
- Indirect coupling with post-ganglionic NE axon terminals serving as mediators in the sensitivity of nociceptive afferents (involving NE and others like prostaglandins)
- Ephaptic coupling between sympathetic and afferent fibres.[43]

Diagnostic Criteria for Chronic Regional Pain Syndrome

Clinical Signs and Symptoms

- Burning pain
- Hyperpathia/allodynia
- Temperature or colour changes
- Oedema
- Hair changes/nail changes.

Lab Results

- Thermometry/thermography
- Bone radiography
- Three phase bone scan
- Quantitative sweat test
- Response to sympathetic blockade.

Interpretation

- More than 6 points present—probable RSD
- 3–5 points present—Possible RSD
- Less than 3 points present—Unlikely to be RSD.

Table 6: RSD probability scoring system

Parameter	*Definitive RSD*	*Probable RSD*	*Possible RSD*	*Not RSD SMP*
A. Allodynia • Touch (a) • Pressure (b) • Movement (c)	3/3	2/3	1/3	0/3
B. Vasomotor • History • Examination Swelling: • History (a) • Examination (b)	4/4	Greater than or equal to 2/4	Less than or equal to 1/4	0/4

Scores

- 7–definitive RSD
- 4–6-probable RSD
- 2–3-possible RSD
- 0-not RSD.

Clinical Correlates in Pain

The symptomatology of pain is easily remembered by the mnemonic "PQRST" wherein P, Q, R, S and T stand for palliative/provocative factors, quality of pain (burning, shooting or stabbing), radiation of pain, spatial distribution and temporal aspect, respectively.

The definitions of certain terms used in pain are as follows:[18]

- *Allodynia*: Increased sensibility to pain, pain in response to a stimulus which is not normally painful.
- *Alloaesthesia*: Perception of a sensory stimulus at a site other than where it was delivered. Kinetic alloaesthesia is feeling something other than at the site of stimulation.
- *Analgesia (alganaesthesia)*: Abnormal sensitivity to pain.
- *Anaesthesia*: Absence of all sensations.
- *Dysaesthesia*: Unpleasant/painfully abnormal perverted sensation—spontaneously or caused by normally non-painful stimuli, e.g.: burning response to touch, other accompanying paraesthesiae.
- *Hypalgesia*: Decrease in pain sensibility.
- *Hyperalgesia*: Increase in pain sensibility or pain in response to a stimulus not normally painful.
- *Paraesthesiae*: Abnormal spontaneous sensations experienced in the absence of specific stimulation (feelings of hot, cold, numbness, burning, itching, etc.).

Hyperalgesia

There are two types of hyperalgesia. Primary at the site of injury and is due to mechanical and thermal stimuli. The injured area and the test stimulation area must coincide. Secondary hyperalgesia occurs in the areas surrounding the injury site and therefore, does not coincide with the site of stimulus.[64,102] Primary hyperalgesia results from sensitisation of peripheral nociceptors (leftward shift of stimulus response function) and is characterised by decreased threshold, augmented responses to suprathreshold stimuli and ongoing spontaneous activity. Primary hyperalgesia can be further divided into mechanical and thermal hyperalgesia: mechanical hyperalgesia comprises stroking hyperalgesia (allodynia) and punctuate hyperalgesia (tested with von Frey's probes). Hyperalgesia also occurs due to loss of central inhibition. NGF is involved in inflammatory hyperalgesia and BDNF is involved in alleviated hyperalgesia.[2]

Secondary hyperalgesia: This occurs in the area surrounding the primary zone. Enhanced pain response occurs only in response to mechanical stimulation. Spreading sensitivity occurs with secondary hyperalgesia, predominantly by the release of substance P. Secondary hyperalgesia differs from flare, in that it is larger than the zone of flare and does not cross the anatomical midline. Flare can occur without induction of hyperalgesia. Peripheral sensitisation does not occur with secondary hyperalgesia.

Grading of Pain

There is an old Portuguese proverb which runs thus; "*The wearer knows best where the shoe hurts*." In no other field of medicine other than pain is this true. The results have to be quantified and the outcomes scored only on the basis of the patient's assessment of his condition. To quantify pain, several scales have been developed which are enumerated below:

Unidimensional scales (Verbal rating scale): This rates pain as none, mild, moderate, severe.

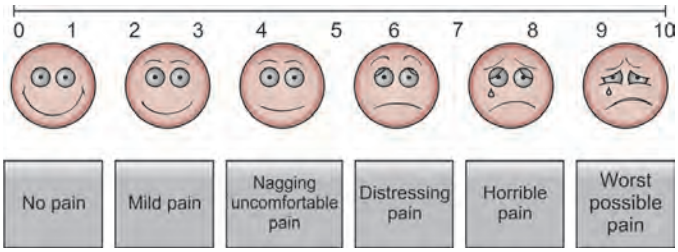

Fig. 5: Visual analogue scale for pain

Visual analogue scale (VAS): Continuous/intermittent pain. This is a 10 cm unmarked line where the pain is graded from:—no pain to worst pain (Fig. 5).

Colour red analogue: This includes a pictographic representation of the patient's emotional state of mind in relation to the pain.

Berman, Tagg et al. (1996) put forth a system of pain grading to standardise quantification of pain:[8]

Severe: Continuous disturbance of daily life or of work or study/sleep. (Visual analogue scale 9–10).

Significant: The patient is able to sleep but he cannot work/study/engage in hobbies due to pain (VAS 7–8).

Moderate: The patient is able to work; sometimes severe pain which results in the patient taking time off (VAS 4–7).

Mild: Patient aware of pain but can pursue a normal life (VAS 0–3).

Psychological Issues in Pain Management

"Each person carries his own doctor inside him. They come to us not knowing the Truth. We are our best when we give the doctor who resides within each patient a chance to go to work."

Dr Albert Schweitzer

Nowhere in medicine do the afore-quoted words ring more true than in the management of pain. Pain is intricately connected with the limbic system and is influenced by the mental state of the patient. Understanding the patient's personality and mental make-up will go a long way in helping us treat our patients.

Several personality disorders have been noticed in patients with chronic pain.[82] These are:

- Narcissistic and histrionic personality disorders
- Depressive personality disorder
- Compulsive personality disorder
- Borderline personality disorder.

The following are the indications for a psychological consultation in clinical practice, while treating a patient with chronic pain.[21] These are:

- Diagnosis and clinical signs do not fit with each other
- Three or more Waddell signs (vide infra)
- Markedly unusual reaction with or without medicine or treatment
- Emotional instability
- Personality crisis
- Suspicion of poor/inadequate/inappropriate coping, fears, beliefs, distress, expectation and/or attitude.

Waddell, et al.[95] in 1980 described five categories of signs to define the non-organic component of pain:

- *Tenderness tests*: Superficial and diffuse tenderness and/or non-anatomic tenderness
- *Simulation tests*: These are based on movements which produce pain, without actually causing that movement, such as axial loading and pain on simulated rotation
- *Distraction tests*: Positive tests are rechecked when the patient's attention is distracted, such as a straight leg raise test
- *Regional disturbances*: Regional weakness or sensory changes which deviate from accepted neuroanatomy
- *Overreaction*: Subjective signs regarding the patient's demeanor and reaction to testing.

Three or more of the above signs are positively correlated with non-organic pain.

Psychological tests and questionnaires in the assessment of chronic pain:

Function	*Examples*
1. Pain (qualitative)	McGill pain questionnaire, Numerical rating scale, Visual analogue scale, Verbal rating scale, Pain diaries, North American Spinal Society questionnaire.
2. Mood and personality overall function	Minnesota multiphasic Personality inventory 2 (MMPI 2), Beck depression inventory, Illinois behavioural questionnaire (IBQ), Personality assessment inventory (PAI).
3. Pain beliefs and coping	Multidimensional pain inventory: Coping strategy questionnaire, pain relief efficacy ruestionnaire, Pain self-efficacy questionnaire, Survey of pain attributes; Sickness impact profile (SIP).
4. Level of function/ Perception of disability	Multidimensional pain inventory, Oswestry disability questionnaire, Sickness impact profile, Short Form Health Survey (SF-36), Pain disability index, Roland-Morris disability scale.
5. Cognitive function	MMSE, Microcognitive neuropsychological tests

Risk factors for poor surgical outcome identification in presurgical psychological screening interviews:[12]

Risk factor	*Risk of treatment failure*
• Pending legal action related to injury	high risk

- Worker's compensation — high risk
- Job dissatisfaction (Moderate/extensive) — moderate/high risk
- Heavy job demands (frequent lifting of > 50 pounds) — high risk
- Substance abuse:
  - Pre-injury — moderate risk
  - Current/untreated — high risk
- Reinforcement of disability by family — moderate to high risk
- Marital dissatisfaction — moderate risk
- Physical/sexual abuse
  - Pre-injury — moderate risk
  - Current — high risk
- Pre-injury psychological problems
  - Out patient department — moderate risk
  - In-patient — high risk

Predictors of poor outcome in the management of chronic pain:[67]

These were initially listed as contradictions to spinal stimulation but can be used in a wider perspective. They are:

- Active psychosis
- Active suicidality
- Active homicidality
- Untreated depression major
- Somatisation disorder
- Alcohol/drug dependency
- Compensation resolution
- Lack of social support
- Cognitive deficits.

Cognitive behavioural therapy may produce benefits by decreasing peripheral nociceptive activity, enhancing descending inhibition of pain transmission or directly altering pain transmission in the CNS.

Alternative and Complementary Treatment in Pain

> *"For all the happiness mankind can gain,*
> *Is not in pleasure, but in rest from pain."*
>
> ***Dryden***

To achieve pain relief, man has turned to all sources for a remedy. Western science in the early days scoffed at the traditional wisdom of the orient. The approach to health in the orient is holistic. The dawn of the 21st century has seen a renewed interest in these traditional systems. Many of these concepts are now being tested with the solid scientific and reasoning methods which modern science has to offer and have proved their worth. Now, every textbook in the field of modern medicine has a separate section dedicated to these alternative therapies. The American Academy of Neurologists also recommends some of these as treatment options in chronic pain.

"To believe with certainty, we must begin by doubting" remarked King Stanlislos I of Poland and nowhere has this been proved to be more true than in the treatment of pain in medicine.

The following is a brief synopsis of these alternative treatments. The reader is advised to refer to standard books on the subject for further reading:

Acupuncture:[99] Acupuncture is based primarily on traditional Chinese medicine which is derived from the Taoist philosophy that the human body is in a state of dynamic interaction with nature—the environment/universe which in turn is in a state of continuous change. Changes arise from an inherent dynamism of cyclical patterns and are constant. "Huang Di Nei Ying" or the "Yellow emperor's inner classic" is the Bible of Chinese medicine. There are 12 major and two collateral meridians with intermediate nomenclatures. Classic acupuncture points usually are situated at points of low resistance to electricity. They are found near major nerve bundles. There are different types of needles in acupuncture, each stimulating a particular opioid receptor type. Studies have shown acupuncture is akin to PAG stimulation and causes release of endorphins.[44,58]

There are other types of acupuncture such as, auricular acupuncture developed by Dr Paul Nogin of France and the *Koryo hand therapy* wherein the pressure points are applied to describe points on the pinna and the palm, respectively, each having its own homunculus.

QiGong

Qi in traditional Chinese medicine is described as the vital energy that protects and nourishes organs. QiGong is the science that ensures the normal flow of Qi. Studies have shown that QiGong for intervertebral discs stimulate the autonomic nervous system and cause pain relief.

Tai-Chi

It is a set of slow, free flowing exercises useful in pain prevention. It was founded by Bodhidharma.

Traditional Indian Systems of Medicine[100]

Ayurveda is holistic medicine and aims at prevention. The system of Yoga teaches about *Nadis* which are akin to nerve plexi. The pranayama (breath control) of yoga aids in stress relief. The concepts of energy flow from the tail through the spine (*Sushumma*), together with coiled and intertwined energy channels (*Ida* and *Pingala*) are described in great detail. The points of intersection of these energy channels are called *chakras*. Pingala stimulates the sympathetic nervous system and Ida stimulates the parasympathetic nervous system. The concept of the spinal gate mechanism was known and was extensively used.

Biostimulation

Laser biostimulation is based on the fact that light stimulates pain at low frequency and inhibits pain at high frequencies.

Magnetic biostimulation is based on the principle that a magnetic field through ions would generate

heat (Hall effect) and this heat would then generate an action potential (Lorentz force). The WHO has recently approved the use of 2 Tesla magnets for this purpose.

Other forms of treatment such as *chiropractice* (mobilisation and manipulation) of painful joints and *aroma therapy* have also been used in the treatment of chronic pain.

Multidisciplinary Approach to the Management of Chronic Pain

As seen above, when dealing with a subject as complex as pain, it would be wise to use all available treatment modalities based on proven scientific principles, rather than be prejudiced against any of them. The complexity of the issue has led doctors to coin the term "multidisciplinary approach to pain management". The organisation of such a team approach has been outlined by Rawl:[77]

Truly, the subject of pain which has been perceived with awe and dread by humans since time immemorial is still an enigma to us. It is intricately connected with behaviour and represents one of the last frontiers which neuroscience has to conquer.

195 Surgery for Intractable Pain

Nigel Peter Symss

TREATMENT

Intractable pain of multiple aetiologies remains a substantial problem for many patients presenting in the clinical setting. Recent years have seen the introduction of powerful pain relieving drugs and their use has been extended to chronic pain syndromes where the cause of the pain cannot be eliminated. Treatment of chronic intractable pain needs a multidisciplinary approach. With the advent of newer analgesic and antidepressant drugs, the first line of treatment is medical. If the pain is not ameliorated with these drugs, anaesthetic procedures to block the pain pathways or neuroaugmentative or neuroabalative procedures can be offered.

DRUGS

At present there are no drugs which effectively ameliorate the chronic pain of non-cancerous origin. Improved pain relief can be achieved and adverse effects minimised by multimodal analgesic combinations. Substantial evidence supports combining analgesics for the management of pain and, in some instances, they have a heterogeneous pharmacologic sparing effect. Fixed-dose combination analgesics with demonstrated efficacy and safety are useful for pain management. One also has to take care of anxiety and depression which are common in these patients.

Non-Narcotic Analgesic Drugs

Acetaminophen (Official Generic Name: Paracetamol)

It is an antipyretic analgesic with no effect on the platelet function or inflammatory cascade. It acts centrally, inhibiting prostaglandin function.[11] Due to its lack of significant inhibition of peripheral cyclo-oxygenase (COX), it does not promote bleeding, thus making it safe to use in the peri-operative period. Taken within the prescribed dose range, it is safe. The main safety concern is dose-related hepatic toxicity. Overdose is treated with N-acetylcystine.[87]

Salicylates

Aspirin is an antipyretic, anti-inflammatory, analgesic agent. It is quite effective and its action may be central, blocking prostaglandin synthesis. It is the prototypical non-steroidal anti-inflammatory drug (NSAID), being a non-selective COX inhibitor at usual analgesic doses, although it may somewhat selectively inhibit COX-1 at doses typically used to reduce platelet aggregation therapeutically.[130] It is used in a dosage of 500–1000 mg/q 4–6 hourly, with a maximum daily dose of less than 4,000 mg. Gastrointestinal side effects are common. It predisposes to haemorrhage even in low doses; while gastrointestinal bleed is common, intracranial haemorrhage is well documented.

Non-Steroidal Anti-inflammatory Drugs

These types of non-opioid analgesics are frequently used as first-line analgesics. They lack significant abuse potential and do not induce the development of analgesic tolerance. These drugs act by inhibiting the biosynthesis of prostaglandins at various stages, through inhibition of the COX enzymes, thus reducing the inflammatory process. There are two similar, but distinct, isoforms of COX identified: (1) COX-1 and (2) COX-2. Several drugs are now available that selectively, more accurately and preferentially inhibit COX-2, which is responsible for inflammatory processes and pain relief. They too have side effects on the gastrointestinal system.[55] The commonly used drugs are indomethacin (25–50 mg/q 8 hrs), diclofenac (50 mg/q 6 hrs), ibuprofen (200–400 mg/q 4–6 hrs) and naproxen (250 mg/q 6 hrs). Their use depends on their being tolerated by the patient. The COX-2 selective non-steroidal anti-inflammatory drugs are etodolac, meloxicam, celecoxib, rofecoxib, etoricoxib, valdecoxib and lumiracoxib.

Phenothiazines

Phenothiazines block dopamine and epinephrine postsynaptically and have a strong atropine like action. Commonly used phenothiazines are chlorpromazine 50 mg/q 8 hourly, thioridazine 50 mg/q 8 hourly and fluphenazine 2 mg/q 12 hourly. Combinations of tricyclic drugs, which are mood elevators, with phenothiazines have been found to be useful in the management of postherpetic neuralgia and intractable cancer pain.[55]

Phenytoin

Phenytoin has a direct effect on both axonal conduction and synaptic transmission.[44,150,169-171] It is found useful in many pain syndromes such as trigeminal neuralgia,

post-herpetic neuralgia,[51] glossopharyngeal neuralgia[123] and diabetic neuropathy.[29]

Carbamazepine

It may act at the level of central synapses.[38] It is found effective in treating patients with trigeminal neuralgia and some forms of neuropathic pain.[139] It is effective at serum levels between 8 μmg/ml and 12 μmg/ml. The dosages of these drugs have to be individualised for effective response.

Oxcarbazepine

Oxcarbazepine is the 10-keto analogue of carbamazepine, but has a distinct pharmacokinetic profile. In contrast to the oxidative metabolism of carbamazepine, oxcarbazepine is rapidly reduced to its active metabolite, 10,11-dihydro-10-hydroxy-carbamazepine. Direct comparison of oxcarbazepine and carbamazepine has shown no difference in efficacy between these two agents in terms of reducing seizure frequency in patients with partial epilepsy with or without secondary generalisation, or with tonic-clonic seizures. Limited data indicate that oxcarbazepine may be a useful alternative to carbamazepine in the management of trigeminal neuralgia.[46] Zakrzewska et al. found an overall serum therapeutic concentration range of 50–110 mumol/l of 10-OH-carbazepine corresponding to a daily effective dose range of 1200–2400 mg (14.6–35.6 mg/kg body weight) oxcarbazepine. Onset of the effect was observed within 24 hours in all cases.[177]

Gabapentin

Gabapentin resembles gamma-aminobutyric acid (GABA), and was initially marketed as an adjunctive anticonvulsant. However, it was found to be an effective analgesic for conditions where neuropathic pain was a significant contributor, such as post-herpetic neuralgia.[119] Its advantages are that it is not metabolised, so there is no concern regarding accumulation of active metabolites. Gabapentin is not a GABA agonist, nor is it metabolised into GABA. It is cleared renally, and needs to be used cautiously in the presence of renal dysfunction. Gabapentin absorption is mediated by a saturable transporter system located in the upper gastrointestinal tract, indicating a short window of absorption. It has a dose dependent oral bioavailability. A dose of 400 mg is approximately 25% less bioavailable than of a dose of 100 mg. Above 800 mg per dose, there is little additional absorption of gabapentin. The recommended maximum daily dose is approximately 3,600 mg.

Benzodiazepines

They increase both pre- and post-synaptic inhibition. The effect appears to be caused by facilitation of the inhibitory neurotransmitter GABA.[85] Clonazepam is effective in the management of chronic neuropathic pain and in patients with nerve or plexus injury.[110,151] The commonly used benzodiazepines are diazepam, alprazolam, chlordiazepoxide and flurazepam.

Tricyclic Antidepressants

They probably act by facilitation of monoamine transmission by inhibition of serotonin and norepinephrine reuptake at the synapse. They may also potentiate the descending analgesic pathways. They are effective in neuropathic pain, especially post-herpetic neuralgia and diabetic neuropathy.[154,159] They also inhibit the encephalin hydrolyzing activity, thus increasing the level of encephalin in the CNS.[63] The commonly used tricyclic antidepressants are amitriptyline (75–300 mg/day), imipramine (150–300 mg/day) and doxepin (150–300 mg/day).

Pregabalin

Pregabalin is a potent ligand for the alpha-2-delta subunit of voltage-gated calcium channels in the central nervous system that exhibits potent anticonvulsant, analgesic and anxiolytic activity in a range of animal models. Pregabalin has been advocated for the treatment of neuropathic pain associated with diabetic peripheral neuropathy and post-herpetic neuralgia. Most patients with chronic lumbosacral radiculopathy have also been found to respond well to pregabalin therapy. Pregabalin is rapidly absorbed following oral administration, with peak plasma concentrations occurring between 0.7 hour and 1.3 hours. Pregabalin oral bioavailability is approximately 90% and is independent of dose and frequency of administration. Food reduces the rate of pregabalin absorption, resulting in lower and delayed maximum plasma concentrations. However, the extent of drug absorption is unaffected, suggesting that pregabalin may be administered without regard to meals. Pregabalin elimination half-life is approximately 6 hours and steady state is achieved within 1–2 days of repeated administration. Corrected for oral bioavailability, pregabalin plasma clearance is essentially equivalent to renal clearance, indicating it undergoes negligible non-renal elimination. Pregabalin is eliminated renally; thereby renal function affects its pharmacokinetics. It is not subject to hepatic metabolism and does not induce or inhibit liver enzymes such as the cytochrome P450 system. An effective starting dose of 150 mg/day is advocated in clinical practice.[16]

Narcotics

Narcotics should be reserved only for the management of chronic pain due to cancer.[68,160,161] Patients usually develop tolerance and may require increasingly higher doses. If a narcotic is used for non-malignant pain it should be for short periods only. Morphine, codeine and thebaine are naturally occurring opioids isolated from opium poppy. Fentanyl, meperidine and methadone are synthetic opioids. Oxycodone, hydromorphone and hydrocodone are semisynthetic opioids made by chemically modifying thebaine.

Opioids in Cancer Pain

About 70% of patients with advanced cancer experience moderate to severe pain, necessitating the use of opioid medication for pain relief. According to the WHO in 1986, the worldwide daily cancer pain prevalence is a staggering 4 million patients and the yearly worldwide prevalanec is 19 million patients. Effective analgesia can be achieved in 70–80% of these patients with opioid adjuvant medications. Opioids are the main stay in the treatment of moderate to severe cancer pain of all causes. The WHO advocates the following three step approaches:

Step 1 for mild pain involves 24 hour coverage with acetaminophen or NSAID medication. When these medications fail to provide adequate analgesia or when pain is moderate at onset, a "weak" opioid, such as codeine or oxycodone, is appropriate (step 2). A strong opioid (step 3) is indicated for the patient in whom relief of pain is inadequate with step 1 or 2 or when the pain is severe at onset. Some of the common drugs used in step 3 are morphine, hydromorphine, levorphanol tartarate, methadone hydrochloride and fentanyl.

To begin with, the oral route is preferred because of the ease of administration and good oral bioavailability of most opioids. Orally administrated morphine sulfate immediate release (MSIR) is generally considered the first-line drug in severe cancer pain. Treatment generally begins with a low dose. Mean starting doses of MSIR are 10–30 mgm 4 hourly throughout the day and night. "As needed" dosing is inappropriate and should be avoided and a constant plasma level required for good analgesia is achieved by 'round the clock' administration. There is no "standard" opioid dose and therapy should be highly individualised and dose titrated until analgesia is achieved or side effects are unmanageable.

Adverse effects of opioids include sedation, nausea, constipation, respiratory depression or myoclonus. Generally no narcotic is universally better or worse with respect to others. Most opioid side effects are manageable. Constipation, to which tolerance rarely develops, is avoided by the use of stool softeners or bowel stimulation.

Tolerance to respiratory depression develops rapidly. Severe respiratory depression may necessitate mechanical ventilation and the use of the opioid antagonist naloxone hydrochloride. Tolerance also develops to opioid induced sedation but, if it is incomplete, a trial of a stimulant like methylphenidate hydrochloride or dextroamphitamine 5 gm. bd may be used.

Nausea during opioid administration may be produced by different mechanisms. Nausea due to direct stimulation of the chemoreceptor trigger zone of the medulla occurs constantly is unrelated to food intake and is best relieved by a phenothiazine. Nausea which is worse after eating is due to reduced gastric motility and decreased gastric secretions and this responds to metaclopromide. Nausea due to sensitisation of the vestibular apparatus occurs with changes in the position of the head, and responds to treatment with scopolamine or meclizine. Myoclonus, especially common with meperidine occurs during sleep and responds to clonazepam or change of opioid. Thus, most opioid side effects are manageable either by waiting for tolerance to develop or by symptomatic treatment.

Approximately 5–10% of patients with cancer related pain will have inadequate control of pain with oral medication and at sometime during the course of their illness these patients require other interventional techniques for relief of pain. Parenteral administration of opioids by intravenous or subcutaneous administration has the advantage of rapid pain relief, ease of adjustment of dosage, constant plasma levels and fewer side effects and is also useful in patients with gastrointestinal dysfunction.

Continuous infusion by long-term central venous catheter or by portable ambulatory infusion pumps which are presently available is suitable for some patients. Patient controlled analgesia has also proved to be useful in selected patients with cancer related pain. This is especially suitable for patients with fluctuating pain or incident pain (as pain precipitated by movement) and allows for rapid adjustment of analgesic level to the degree of pain.

Spinal Delivery of Opioids

Injection of morphine or fentanyl in the spinal epidural or subarachnoid space, when parenteral administration fails, provides intense analgesia with lesser side effects. The injection can be as a bolus or continuous infusion with a pump system. For long-term spinal analgesia access to the epidural or intrathecal space by an indwelling catheter system is possible, but appropriate test doses of an opioid should be administered to ensure that the patient's pain will respond to spinal analgesia without excessive or intolerable side effects.

Intraspinal narcotic therapy has the advantage of delivery of low doses near the site of action in the spinal cord. Yaksh[172,173] demonstrated the long lasting efficacy of intrathecally administered opioid alkaloids and peptides. Their action is antagonised in a dose dependent fashion by systemic or intrathecal naloxone. The onset of analgesic activity is dependent on lipid solubility; agonists, such as mepiridine, being highly lipid soluble, have a rapid onset of action, and agents, such as morphine, have a slower rate of onset, but longer lasting effect. An intraspinal implanted morphine infusion pump can be used to deliver continuous low dose morphine to effectively control intractable pain due to malignancy.[107] The dose of morphine can be significantly reduced and with 0.5–1 mg of lumbar intrathecal morphine, analgesia may be achieved for 8–30 hours. In spite of these advances, relief from intractable chronic pain may continue to elude therapy. There are many conditions of chronic or recurrent pain in patients with long or normal life expectation, where medical therapy is ineffective because of inadequacy of the drugs, reactions to the drug or fear of addiction. In these cases neurosurgical relief of pain is indicated.

Anaesthetic Measures

The use of reversible nerve blocks or lysis of neural tissue by appropriate agents is efficacious both in the diagnosis and management of certain painful states. Reversible nerve blocks result in temporary interruption of nociceptive transmission and can be achieved by percutaneous injection of a local anaesthetic, which results in temporary abolition of pain. More permanent nerve blocks can be achieved by destruction of neural tissue, by the use of chemicals such as alcohol or phenol or by physical methods such as heat or cold. Chemical neurolysis can also be achieved by intraspinal delivery of the agent (epidural, subdural or subarachnoid).

Peripheral Nerve Block

This can be achieved by using phenol or alcohol. The nerve to be blocked has to be confirmed first by using a local anaesthetic agent. An RF lesion can also be used to destroy the nerve. This is commonly used for intercostal block and trigeminal neuralgia.

Autonomic nerve blocks are also used to relieve pain. The commonly used targets are the paravertebral sympathetic chain, the coeliac plexus and the stellate ganglion. The relief of pain following sympathetic blockade may be because of 'cross talk' between sympathetic efferents and unmyelinated afferents, the sympathetic efferents interacting with cutaneous afferents to produce contacts between sensory efferents and tiny cutaneous afferents within the skin, or excessive sympathetic outflow resulting in change in vascular permeability and an elevation in extracellular substances that produce pain.

Spinal Neurolysis (Subarachnoid, Subdural and Epidural)

Subarachnoid neurolysis is one of the most common methods used. The duration of pain relief is directly related to the amount of nerve fibre destruction. The major drawback of this procedure is the risk of destruction of other structures coming in contact with the neurolytic agent. There is gradual regeneration of pain fibres following chemical neurolysis. Hence the pain will recur after varying periods.

The agents commonly used are phenol (5–8%) in glycerine (0.5–1 ml), absolute alcohol (1–2 ml) and chlorocresol (parachlorometacresol (1 in 50) in glycerine (0.5–1 ml). The drugs should be given slowly. Phenol and chlorocresol are gradually released from glycerine, limiting their spread. Phenol and chlorocresol in glycerine are hyperbaric solutions while absolute alcohol is hypobaric. This should be kept in mind while positioning the patient for injection.

Injection of cold or hypertonic saline into the subarachnoid space[56] helps to relieve pain in many cases. The effect on the roots is more due to the ions than to the low temperature of the fluid. After repeated perfusion of cold saline in the lumbosacral region Tsubokawa[158] showed that conduction is blocked in the A delta and C fibres and that afferent depolarisation in the dorsal column is altered. As mentioned earlier, adoption of these techniques is still prevalent in many countries.

The main complication with these procedures is the risk of injury to other nerves resulting in motor weakness and sphincter disturbances. Epidural neurolysis has the advantage of less risk of spread intracranially and less chance of motor and sphincter disturbances. Subdural neurolysis is not an easy procedure and is used in intractable neck and shoulder pain.

SURGICAL PROCEDURES

The management of chronic pain by neurosurgical techniques is not new. The surgical manoeuvres described are directed at various sites in the pain pathway ranging from the most proximal to the most central components of the central nervous system, i.e. from the peripheral nerves to the cerebral cortex and subcortical areas. On the basis of the sites of operative intervention, they can be classified as:

1. The peripheral and cranial nerves: peripheral neurectomy
2. The posterior roots:
   a. Section (Rhizotomy) in:
      i. the spinal canal
      ii. the middle cranial fossa
      iii. the posterior cranial fossa
   b. Intrathecal injections for blocking the posterior roots, chemical rhizotomy using phenol, alcohol, glycerol or cold saline
3. The sympathetic chain: sympathectomy
4. The spinal cord:
   a. dorsal root entry zone (DREZ) lesions
   b. spinothalamic tractotomy, open or percutaneous
   c. commissural myelotomy
5. The medulla:
   a. medullary spinothalamic tractotomy
   b. trigeminal tractotomy
6. The mesencephalon: mesencephalic spinothalamic tractotomy
7. The thalamus:
   Stereotaxic thalamotomy (chemical, thermal, cryogenic or gamma rays): posteroventrolateral nucleus, centrum median, dorsomedian, pulvinar
8. The hypothalamus: posterior median hypothalamotomy
9. The sensory cortex: ablation of the sensory cortex
10. The frontal lobes:
    a. prefrontal leucotomy or lobotomy
    b. cingulumotomy
    c. basofrontal tractotomy
    d. fornix section
11. Pituitary ablation
12. Non-destructive procedures:
    a. transcutaneous nerve stimulation
    b. acupuncture
    c. dorsal column stimulation (DCS)
    d. periaqueductal grey stimulation
    e. thalamic stimulation
    f. spinal and intraventricular morphine.

Peripheral Neurectomy

Peripheral neurectomy is one the oldest surgical procedures decribed for the relief of pain, and is performed on the cranial or peripheral nerves. Severe forms of pain may sometimes be well localised in the area of distribution of a peripheral nerve, permitting local sensory denervation by section or avulsion of the nerve. In the case of purely sensory nerves such a procedure is simple, but in mixed nerves careful consideration is necessary before deciding on a nerve section; although, in pain due to malignant neoplastic diseases with a short life expectancy, one may perhaps ignore the resulting motor disability.

The common indications for peripheral neurectomy are supraorbital or infraorbital neuralgias, inferior alveolar neuralgia, and painful stump neuromas. The other indications are meralgia paraesthetica, malignant invasion of the chest wall, selected cases of post-herpetic neuralgia, causalgia, painful arthtritis and phantom limb. Radiofrequency or cryogenic techniques can be used to make lesions. The procedure is also useful in some cases of peripheral vascular disease of the lower limbs with incapacitating rest pain, where the cutaneous nerves can be divided with benefit. As the peripheral nerves tend to regenerate after simple division, a section of the nerve is removed during surgery. Although neurectomy is useful in many instances, there is always a risk of development of neuropathic pain. As some peripheral nerves contain both motor and sensory fibres, division can cause sensory loss, weakness and atrophy.

Cerovic et al. analysed the remission period after repetitive neuroexeresis of the same neural branch, to calculate "predicted" remission, and to evaluate the benefits of repetitive neuroexeresis. They found the remission time after repetitive neurectomy decreases, and there is no point in repeating the surgery on the same neural branch more than three times.[23]

Posterior Root

Section (Rhizotomy)

In 1898, Sherrington[138] demonstrated that in monkeys each part of the distal extremities was supplied by three overlapping sensory spinal roots and, in 1889, Abbe[1] and Bennett[17] independently performed spinal rhizotomy. Posterior root section or posterior rhizotomy implies section of the posterior root of a peripheral or cranial nerve for relief of pain. In the spinal canal, the section is made between the cord and the posterior root ganglion. It is a useful operation which can be selectively done to cover a number of dermatomes without any involvement of the motor fibres. Considering sensory overlapping in continuous dermatomes it is necessary to cut at least two posterior roots above and below the area of pain. The results of rhizotomy may not be long lasting in many cases. The sensory supply of muscles and bones (myotomes and sclerotomes) does not conform to the overlying cutaneous sensory arrangement in all parts of the body. Hence, in disease involving bones and muscles, rhizotomy, to be useful, must include the concerned roots, also in addition to those supplying the dermatome.

In cases of thoracic pain due to tumour infiltration of the chest wall or pleura or other causes, posterior rhizotomy is helpful. In some cases of post-herpetic neuralgia, as also thoracic radiculopathy, pain may be relieved by such an operation.[67] Sensory rhizotomy is also useful in patients with chronic pain in the lower extremity resulting from repeated disc surgery. The posterior roots can be sectioned intradurally after laminectomy. In the thoracic region an interlaminar approach may be adopted. Extradural spinal sensory rhizotomy has been advocated by Scoville[128] as a useful and simple procedure where the dorsal root in its dural sleeve is exposed by "one bite with the rongeur" in the lower edge of the lamina just caudal to the transverse process. Trans-spinal ganglionectomy (removal of the posterior root ganglion) has been advocated by Smith[143] for relief of intercostal pain. In cases of malignant disease of the head and neck, pain can be relieved by section of the upper cervical and lower cranial nerve roots. Rhizotomy is also useful in occipital neuralgia and in coccydynia where bilateral sacrococcygeal root section helps.[4]

The drawback of rhizotomy is the possible development of deafferentation pain syndrome in some cases. Rhizotomy is also not useful for benign peripheral neuropathic pain.[126,153]

Selective Rhizotomy (Rhiziditomy)

Sindou et al.[141] proposed selective destruction of rootlets which carry the small afferent fibres. These are grouped on the ventrolateral part of the posterior root before they re-enter the cord. The technique has been found useful in the treatment of malignant lesions involving the brachial and pelvic plexuses.

Percutaneous Radiofrequency Rhizotomy

Interruption of nerve root function by the percutaneous route using radiofrequency current is now preferred over the previous techniques mentioned; this has proved to be effective and safe and has been performed for relief of pain as well as of flexor spasms.

Dorsal Root Entry Zone Lesions

Nashold[100] advocated lesions in the spinal cord at the zone of entry of the dorsal roots in the substantia gelatinosa, either by thermocoagulation or by laser. The procedure is based on the concept that deafferentiation in the root or peripheral nerve lesions leads to loss of control and inhibition in the neurons of the dorsal horn and a DREZ lesion helps to restore the balance. The lesion probably involves Lissauer's tract and the deeper layers of the dorsal horn.[126] Ramer et al. studied the ability of intrathecal neurotrophin-3 (NT3) to promote axonal regeneration across the DREZ and functional recovery

in adult rats. Quantitative electron microscopy showed good penetration of CNS tissue by regenerating sensory axons treated with NT3 at 1 and 2 weeks post-rhizotomy. Light and electron microscopical anterograde tracing experiments showed that these axons re-entered appropriate and ectopic laminae of the dorsal horn, where they formed vesicle-filled synaptic buttons.[114]

They found recovery depended on NT3-mediated sensory regeneration: preventing regeneration by root excision prevented recovery, and concluded NT3 treatment allows sensory axons to overcome inhibition present at the DREZ and may thus serve to promote functional recovery following dorsal root avulsions in humans.[114] DREZ lesions have been found useful in brachial plexus avulsions, phantom pain,[22] painful paraplegia and some cases of post-herpetic neuralgia.[18]

Chemical Rhizotomy

It is done using phenol, alcohol, glycerol or cold saline. Percutaneous transovale trigeminal rhizotomy by injecting glycerol into the retrogasserian cistern of Meckel's cave is a useful treatment modality for tic douloureux. The major advantage of glycerol rhizotomy is significant reduction in post-operative facial deafferentation and its sequelae when compared to differential thermal rhizotomy performed by graded radio-frequency-induced lesions.

Sympathectomy for Visceral Pain

The fibres carrying pain sensation from the viscera and blood vessels travel along the sympathetic system and interruption of the system at the appropriate level gives relief from specific types of visceral pain. Paravertebral injection of procaine may relieve intractable visceral pain for short periods; this may be followed by surgical section of the sympathetic chain for more lasting effects. Resection of the upper four thoracic ganglia relieves precordial pain of cardiac origin. Alcohol block of the coeliac plexus helps to control pancreatic pain. Resection of the splanchnic nerves and the lower thoracic sympathetic ganglia relieves upper abdominal visceral pain and if, along with these, the lumbar sympathetic ganglia are also resected, pain from the kidneys is abolished. Presacral neurectomy has been found to be of benefit in severe dysmenorrhoea, as well as in pain due to lesions of the urinary bladder and other pelvic viscera. Sympathetic denervation of limbs relieves vascular pain[74] and the pain of phantom limb in some cases. Sympathectomy is the treatment of choice for cases of causalgia. Unilateral thoracoscopic sympathectomy induces adequate and lasting relief of pain caused by benign as well as malignant diseases originating from the pancreatic region, chronic pain from upper gastrointestinal tract diseases and portal vein thrombosis. The sympathetic chain and splanchnic branches are divided from level IV to X-XI, with all patients reporting substantial relief of pain post-operatively.[83]

Operations on the Spinal Cord

Cordotomy is one of the treatment choices in pain caused by malignancies localised unilaterally to the extremities as well as the thorax and the abdomen.

Spinothalamic Tractotomy-Anterolateral Cordotomy

Section of the lateral spinothalamic tract in the spinal cord was first suggested, in 1910, by Schueller, who coined the term 'Chordotomie', in 1911. The next year, Spiller also suggested the same procedure and it was first performed in the USA by Martin.[147]

Schueller[127] developed the idea of cordotomy for the relief of intractable pain after extensive animal experiments and suggested that anterolateral cordotomy could lead to immense relief from intractable pain due to malignant disease of the lower half of the body.

In anterolateral cordotomy the pain carrying fibres in the anterolateral quadrant of the cord are divided. The level of choice for this operation is the upper thoracic (the 2nd thoracic level) and the upper cervical region (between the first and the second cervical segments). Open cordotomy is seldom performed nowadays although it was a popular procedure four decades ago.

Percutaneous Cervical Cordotomy

Percutaneous cervical cordotomy (PCC) was described, in 1963, by Mullan et al.,[96] who introduced a strontium needle into the cord and destroyed the anterolateral region by irradiation. In later operations, the destruction was made by radiofrequency current instead of by irradiation.[98,121] An anterior approach to the lower cervical cord has been described for percutaneous cordotomy.[40,42,80] It is claimed that this approach is safer, as it leads one directly to the anterolateral part of the cord and the incidence of respiratory complications are minimal. Hardy et al.[50] emphasised the benign postoperative course with the use of the operating microscope via the anterior route.

Crul et al. determined whether there is still a place for PCC in actual clinical practice with its wide spectrum of pain therapies. All their patients had severe unilateral pain due to cancer, resistant to opioids and co-analgesics. Following PCC, mean pain intensity was reduced from numeric rating scale (NRS) 7.2 to 1.1. Initially, following PCC, a good result (NRS < 3) was obtained in 95% of patients. At the end of life, a good result was still present in 69% of patients. Complications were minimal and subsided within 3–4 days. Thereby, PCC remains a valuable treatment option in patients with treatment-resistant cancer pain and still deserves a place in the treatment of terminal cancer patients with severe unilateral neuropathic or incidence pain.[26] CT-guided percutaneous cordotomy is an option in specially selected cases with malignancy with intractable pain. The target of computed tomography (CT)-guided percutaneous cordotomy is the lateral spinothalamic tract located in

the anterolateral region of the spinal cord at the C1-C2 level. Kanpolat et al. performed CT-guided percutaneous cordotomies in 207 patients mostly suffering from intractable pain related to malignancy. The patients' pain scores and Karnofsky Performance Scale scores were evaluated pre- and post-operatively. The initial success rate of CT-guided percutaneous cordotomy was 92.5%, and was higher in the malignancy group. Bilateral selective percutaneous cordotomy was successfully performed in 12 cases.[69] CT-guided bilateral high-level percutaneous cordotomy can be used in the treatment of intractable upper trunk pain in patients with cancer without pulmonary dysfunction.[15]

Autopsy examination of cervical cords occasionally show lesions in areas away from the spinothalamic tract even after carefully performed percutaneous cordotomies.[93] Hitchcock[56,57] introduced stereotactic spinal surgery for greater precision. Hitchcock[57] mentions that Clarke of Horsely-Clarke fame had developed a spinal stereotactic apparatus in 1921, in addition to the well-known cranial apparatus. With his apparatus Hitchcock was able to stimulate and record from the tracts in the spinal cord and was able to site his lesions accurately. By the stereotactic technique the complications can be lessened and the benefits extended to more seriously ill patients.[152]

Despite the drawbacks of the level of analgesia lowering after a few weeks and of the possibility of limb, bladder or respiratory weakness, the procedure of cordotomy (thoracic or cervical) continues to be a useful procedure, giving benefit to the majority of patients operated upon, specially to those suffering from pain due to malignancy. Cordotomy is not effective in deafferentation syndrome.

Complications: While unilateral cordotomy spares bladder function, bilateral cordotomy most often results in its impairment. However, the bladder function returns to normal in most patients after varying intervals. There may also be post-operative weakness of muscles of the lower extremities. After a thorough study of 106 cases patients who underwent open cordotomy with full follow-up including autopsy, McKissock[88] concluded that cordotomy offers complete relief of pain in half the patients, and a good result in a further quarter. Lipton[81] reviewing 300 cordotomies found complete relief in 76% and partial relief in 8%. In the immediate post-operative period 40% of patients had lower limb weakness. There is a 20% risk of serious weakness of the arm or leg and permanent disturbance of sphincter control after successful bilateral operations. To minimise such complications, bilateral cordotomy is performed at different levels, e.g. either at the upper and lower limits of the same exposure or at the first thoracic and the first cervical level in two separate sittings.

Impairment of respiratory function may occur after bilateral cervical cordotomy due to interference with the motor fibres to the diaphragm that lies between the anterior horn and the cervical fibres of the spinothalamic tract. There is reduction in tidal volume. This respiratory difficulty is seen chiefly when the patient falls asleep and so to say 'forgets to breathe'. This is usually transitory.[97] It is not possible to predict which case will develop this complication, even by extensive pre-operative pulmonary function tests.[122] Krieger and Rosomoff[73] suggest that this respiratory dysfunction is due to damage to the ascending reticular fibres in the ventrolateral segment of the spinal cord, in view of the fact that the apnoea occurs only during sleep, it is reversible by arousal and there is no evidence of motor changes. Respiratory paralysis was the cause of death in seven out of nine patients who died in a series of 400 patients treated by percutaneous cordotomy.[54] Severe hyponatraemia and hypochloraemia have been reported following bilateral cervical cordotomy.[82] This has been ascribed to extensive vasoparesis, increased vascular and cellular permeability and consequent dilution of the extracellular space. In the series of Lahuerta et al.,[75] pain relief was reported by 64% of patients, with a mortality of 6% due to respiratory problems.

Commissural Myelotomy

Commissural myelotomy (CM) was introduced to overcome some of the limitations of bilateral cordotomies in the treatment of bilateral pain syndromes. CM disrupts pain-conducting fibres as well as a polysynaptic pain pathway that runs through the centre of the spinal cord. The thin fibres which enter the spinal cord through the zone of Rolando and cross over to the opposite side may be severed at the site of crossing by splitting the cord in the midline. This results in bilateral relief of pain at the segmental level corresponding to the site of incision. The idea formulated first by Greenfield, in 1926, was implemented by Armour,[5] in 1927, and later by Putnam,[111] in 1934. The operation has been used for relief of pain in the upper abdomen and pelvis and also for pain in the upper limbs, chest and neck. The most common side effect is transient diffuse dysaesthesia which improves over days or weeks.[21] The procedure may also produce sphincter or motor dysfunction. It is a common observation that pain relief is not limited to areas rendered analgesic to pin pricks. Sourek[144] suggested that the myelotomy destroys the slow conducting anterolateral system and a fast conducting mediodorsal system. In the modern operation of CM, the cord is divided in the posterior midline with an additional lateral extension of the incisions.[76]

Stereotactic CM avoids major surgical exposure unsuited for ill patients. Hitchcock[58] found more extensive areas of analgesia after cervicomedullary stereotactic myelotomy. In this method, after visualising the cord by myelography, steel, gold or tungsten wires are placed inside the cord stereotactically and electrolytic lesions are made to destroy the commissure. Tasker[153] in a review found the analgesia to be transient.

Medullary and Mesencephalic Tractotomy

Patients complaining of severe pain in the head, face, neck and shoulders due to malignancy cannot be helped

even by high cervical cordotomy. In such cases the spinothalamic tract may be divided in the medulla or the midbrain. Mesencephalic tractotomy is most effective for nociceptive cancer pain, and the aim is to interrupt the lateral spinothalamic and spinoreticular tracts at the level of the superior or inferior colliculus while preserving the medial lemniscus.[20]

For the treatment of trigeminal neuralgia Sjoquist[142] described, in 1938, the method of cutting the spinal tract of the trigeminal nerve in the medulla. Walker, in 1942, devised a method of severing the spinothalamic tract in the midbrain (mesencephalic tractotomy). This resulted in analgesia and thermoanaesthesia of the opposite half of the body, but often the relief was incomplete and short lasting and sequelae like ataxia and dysaesthesia frequently incapacitated the patient.[164]

Stereotaxic coagulation of the dorsolateral tegmentum of the mesencephalon at the level of the posterior commissure was developed, in 1948, by Spiegel and Wycis.[145] A number of publications report significant relief of pain by this method, especially in central dysaesthesia and phantom pain,[104,117,146] but undesirable ocular and motor deficits may occur.[157]

Gioia et al.[43] believe that the creation of minute bilateral lesions stereotactically in the reticular activating system would modify the reception of peripheral sensory stimuli and relieve pain. With that intent, they produced thermal lesions stereotactically at the midcommissural level, 5 mm lateral to the posterior part of the third ventricle and obtained good results in ten patients.

Nashold et al.[101] improved the results by adopting stimulation techniques and by combining mesencephalotomy with a lesion in the thalamus. Stimulation causes pain referred to the limbs, to the trunk or head and neck area, thus helping in better siting of the lesions. In Nashold's series, patients with deafferentation pain due to a brachial plexus lesion benefited the most. The mortality was about 3%. Tasker[153] found better relief with nociceptive pain than deafferentation pain. Scadding[126] concludes that nowadays this operation is rarely a procedure of first choice.

Thalamus: Stereotaxic Thalamotomy

Currently, ablative stereotactic procedures for relief of chronic pain have limited application except in a few patients, because of the low rate of success achieved, relatively short duration of pain relief and associated complications. The advent of newer non-destructive techniques such as electrical stimulation of deep brain structures, chronic intraspinal and intra-ventricular administration of opiates with lower chances of complications and the reversible nature of the effect have further reduced the need for ablative stereotactic procedures.

Lesions can be made in the thalamus for the relief of intractable pain, but the results may not always be good or constant. Heat, cold (cryo) or chemical lesions may be produced stereotactically at predetermined foci. Gamma rays have also been used for this purpose.[148] In 1949, Hacaen et al.[48] made a lesion in the post-eromedial nucleus of the thalamus with resulting abolition of pain and loss of temperature sensation on the opposite side of the body. Spiegel and Wycis[146] reported a number of cases of pain treated by mesencephalic lesions and by lesions in the post-eroventrolateral nucleus and in the dorsomedian nucleus. Lesions made in the PVL nucleus of the thalamus have not been uniformly successful. A dissociated sensory loss may result and the pain recurred in about 50% of cases.[118] Ramamurthi and Kalayanaraman[113] reported success with lesions in the post-eroventromedial nucleus of the thalamus for intractable pain in facial and pharyngeal malignancies. The area of maximum pain response is determined by stimulation studies using a bipolar probe of 1 mm diameter. Pain relief was reported with no demonstrable sensory deficit. The lesions were made in the termination of the quintothalamic tract which is most medially situated. The operation seems to work in pain due to malignancies and not in other types of facial pain.

On the contrary, lesions made in the termination of the palaeospinoreticular tract in the internal medullary lamina including the centrum medianum nucleus seem to offer more lasting pain relief.[49] Mitchell and Kaelber[92] and Sano et al.[124,125] demonstrated in cats the effectiveness of destruction of the centrum-medianum-parafascicularis-subparafascicularis complex in the abolition of reaction to painful stimuli. The extent of destruction necessary varied with the intensity of pain stimulus. If the pain is well localised and lateralised, lesions in the contralateral thalamus would suffice. However, if the pain is diffuse or bilateral, a bilateral lesion would be required.[162] Askensay et al.[6] recommended combining mesencephalic reticulotomy with a centrum median lesion, as the benefits from the latter are often short lived. Tasker[153] reviewing the results of many authors found pain relief for nociceptive pain in up to 57%, but with a recurrence rate of 50%.

Lesions in the dorsomedian nucleus interfere with pain appreciation and not with pain perception and act more like a selective leucotomy. If there is a psychological inadequacy, a lesion in the dorsomedian nucleus is useful.[117] Lesions have also been made in the medial and lateral pulvinar nuclei for intractable pain. Siegfried[140] found only 25% of patients having relief for four weeks. Medial thalamotomy is one of the first stereotactic operations to have been used for neurogenic pain, and has a low complication rate with no risk of the development of iatrogenic neurogenic pain. It represents selective local relief for all types of pain, without causing somatosensorial deficit. Balas et al. performed 39 post-eromedial thalamotomies in patients with persistent intractable pain due to various disorders. Half of their patients operated on had relief of pain after thalamotomy. In 84% of their cases this relief occurred on the second day. They found post-eromedial stereotactic thalamotomy under MR guidance can provide safe, effective treatment for

persistent, intractable pain.[7] Young et al. treated 20 patients who suffered persistent intractable pain from a variety of disorders by medial thalamotomy with the Leksell Gamma Knife. The lesions were directed at the intralaminar nuclei, the lateral portion of the medial dorsal nucleus, the centromedian and the parafascicular nuclei. Lesions were made with radiation doses from 140 Gy to 180 Gy using a 4-mm beam collimator helmet and either a single isocentre (1 patient), two isocentres (17 patients) or three isocentres (2 patients). Two-thirds of the patients experienced either excellent or good pain relief in a follow-up period between 1 month and 22 months. One patient died due to radiation necrosis following a bilateral thalamotomy. Medial thalamotomy with the Gamma Knife produces thalamic lesions which are reliable in size, shape and location with a low complication rate and offers a minimally invasive, cost effective treatment for certain selected patients with chronic intractable pain.[174-176]

Hypothalamotomy

This was suggested by Sano[125] Nashold[103] suggested implantation of chronic electrodes in various parts of the brain in intractable pain. Stimulation studies are conducted later on to determine the best site for the lesion which is by thermocoagulation.

Sensory Cortex Ablation

It has been observed during stimulation experiments on the human sensory cortex that pain occurring in a 'phantom limb' could be explained by a cortical sensory projection from the missing limb. In this type of painful condition, the sensory cortex is subpially ablated under local anaesthesia. The precise area of ablation is determined by electrical stimulation during surgery. It is disappointing that after initial success from such operations the end results are temporary.

Frontal Lobes

Frontal lobotomy or prefrontal leucotomy can be performed to give relief to patients suffering from intractable pain when other measures have failed. The frontal lobe fibres which are severed in such an operation have no relation to pain pathways; still the operation proves effective on many occasions, as the patient is relieved from the psychic apprehension of pain. Fibres project from the dorsomedian nucleus of the thalamus to areas 9, 10, 11 and 12 of the anterior portion of the frontal cortex as well as to areas 13 and 14 of the supraorbital cortex, while fibres from the anterior nucleus run to area 24 in the cingulate gyrus. Interruption of these fibres or the corresponding cortical areas suppresses awareness of suffering and the reactive expression of pain. These operations do not raise the sensory threshold for pain.[167]

Operations on the frontal lobe have been performed for relief of pain chiefly on patients in the terminal stages of malignancy. These operations carried with them definite risks of psychological disturbance and were performed only on those patients with a short life expectancy. Scarff[129] advocated, in 1948, a unilateral frontal leucotomy and found that while the patient had good relief from suffering, personality change was absent or minimal. Gutterman and Shenkin[47] have reported on the usefulness of saline injections into the frontal lobe for relief of intractable pain. Specific and limited operations on the frontal lobe can now be performed by dividing only the fibres in the inferior quadrant of the frontal lobe, those arising from the orbital cortex (subcaudate tractotomy). This may be done either as an open operation or by the stereotactic technique. Personality disturbances are minimal after these operations. Operations on the frontal lobe should be performed only when other methods have not given relief and when the life expectancy is very short.[32,57,167]

Cingulumotomy

Stereotactic coagulation of the rostral part of the cingulum bundle gives relief from chronic pain. The results are often short-lived (for a few months) and are similar to an open operation. Foltz and White,[36] Ballantine et al.,[10] Paillace et al.[109] and Balasubramaniam et al.[8] found cingulumotomy useful for pain relief. The operation is based on the knowledge that the cingulum consists of multisynaptic pathways connecting the medial frontal cortex, the anterior thalamic nuclei and the rostral midline and intralaminar nuclei with the hippocampal formation. In painful conditions, this system becomes overactive and hypersensitive so that the emotional status of the patient becomes dominant in his reaction to an evaluation of the pain. In such cases, where the emotional factors are marked, transection of the cingulum gives benefit by a volumetric reduction effect that interferes with the involved feedback mechanisms.[37] The operation is simple and does not leave behind an apathetic person or any obvious psychological defect.[8] Paillace et al.[109] reported some impairment of cognitive function (non-verbal) after cingulumotomy, but the overriding significance of verbal behaviour in man masks these minor deficits. Patient selection for cingulumotomy must be based on assessment of the cause of pain and the overall personality of the patient.

Hypophysectomy

Hypophysectomy has been efficacious in reliably relieving pain due to secondaries from carcinoma of the breast and the prostate. Endocrine manipulative measures, such as oopherectomy and adrenalectomy were found to have a beneficial effect in advanced carcinoma of the breast with metastasis, by tumour regression and pain relief. The addition of hypophysectomy to the armamentarium of the surgeon dealing with advanced carcinoma of the breast and prostate was possible, following the popularisation of the trans-sphenoidal microsurgical

approach which reduced the morbidity and mortality of the transcranial approach.

Hypophysectomy can be performed by various means such as stereotactic radiofrequency or cryogenic destruction, chemical destruction by use of absolute alcohol through the transnasal trans-sphenoidal route or the trans-sphenoidal microsurgical approach. The most reliable complete destruction of the pituitary gland is achieved by direct surgical exposure (trans-sphenoidal), but involves slightly more morbidity than the percutaneous stereotactic methods. In patients with metastases from carcinoma of the breast or prostrate, significant relief of pain is noticed.[94] Pain relief with equal efficacy has also been reported in other malignancies not related to endocrine function.[156] The mechanism of pain relief is not clear and an endocrine effect (endorphin) and a neurogenic mechanism have been postulated. There is still no agreement as to the relationship of the extent of pituitary destruction, hypopituitarism and the extent and duration of pain relief.

In general, pain relief occurs in 80% of patients with pain due to disseminated malignancies, usually lasts for 3–6 months, although in some it may last for 1 year or more. Currently, hypophysectomy is considered a useful procedure for relieving terminal disseminated cancer pain when other less invasive measures have failed. Hypophysectomy by stereo radiosurgery, radiofrequency coagulation or by chemical agents carries the least risk.

Intracranial Neurostimulation for Pain Control

First employed in 1954, intracranial neurostimulation represents one of the earliest uses of neurostimulation for the treatment of chronic pain refractory to medical therapy. Currently, there are two kinds of intracranial neurostimulation which are commonly used to control pain: (1) motor cortex stimulation (MCS) and (2) deep brain stimulation (DBS), which have proven effective for treating a number of neuropathic and nociceptive pain states not responsive to other therapies. Intracranial neurostimulation for pain relief is most frequently delivered by stimulating the motor cortex, the sensory thalamus (ST), or the periaqueductal and periventricular grey matter. The increasing use of intracranial neurostimulation for the treatment of chronic pain, especially for pain not responsive to other neuromodulation techniques, reflects the efficacy and relative safety of these intracranial procedures.

Motor Cortex Stimulation for Neuropathic Pain Syndromes

The unique lack of stimulation-induced perceptual experience with MCS makes it uniquely suited for double blind studies of its effectiveness. MCS has emerged as a promising technique for the management of pain in patients with difficult neuropathic and central pain conditions. Although MCS has proven most successful for patients with trigeminal neuropathic/deafferentation pain and central post-stroke pain, other conditions are now emerging as potential targets for this therapy. Based on previous as well as ongoing work, it would appear that the future of MCS is indeed bright. With the ongoing work in this area, investigators will be able to develop a better understanding of the mechanisms underlying this modality and be able to further refine the technique of MCS. It is also possible that with the use of non-invasive tools, such as transcranial magnetic stimulation, practitioners will be able to predict with accuracy which patients are likely to respond favourably to MCS.[108] Lefaucheur et al. reported their results of the first randomised controlled trial using chronic MCS. Sixteen patients were included with pain origin as follows: trigeminal neuralgia (n = 4), brachial plexus lesion (n = 4), neurofibromatosis type-1 (n = 3), upper limb amputation (n = 2), herpes zoster ophthalmicus (n = 1), atypical orofacial pain secondary to dental extraction (n = 1) and traumatic nerve trunk transection in a lower limb (n = 1). A quadripolar lead was implanted, under radiological and electrophysiological guidance, for epidural cortical stimulation. Clinical assessment was performed up to 1 year after implantation and was based on the following evaluations: visual analogue scale (VAS), brief pain inventory, McGill Pain questionnaire, sickness impact profile and medication quantification scale. At final examination, the mean rate of pain relief on VAS scores was 48% (individual results ranging from 0% to 95%) and MCS efficacy was considered as good or satisfactory in 60% of the patients. Their results suggest that the indications for MCS might be extended to various types of refractory, chronic peripheral pain beyond trigeminal neuropathic pain.[77]

Deep Brain Stimulation

Prospective randomised clinical trials to confirm the efficacy of these intracranial therapies have not been published. DBS may be employed for a number of nociceptive and neuropathic pain states, including cluster headaches, chronic low back pain, failed back surgery syndrome, peripheral neuropathic pain, facial deafferentation pain and pain secondary to brachial plexus avulsion.[78]

To better understand its efficacy, Bittar et al. performed a meta-analysis of DBS for pain relief. Databases were searched using key words DBS, ST, periventricular grey and pain. Stimulation sites included the periventricular/periaqueductal grey matter (PVG/PAG), internal capsule (IC) and ST. The long-term pain alleviation rate was highest with DBS of the PVG/PAG (79%), or the PVG/PAG plus ST/IC (87%). Stimulation of the ST alone was less effective (58% long-term success). DBS was more effective for nociceptive than deafferentation pain (63% vs 47% long-term success; $p < 0.01$). Long-term success was attained in over 80% of patients with intractable low back pain (failed back surgery) following successful trial stimulation. They found higher success rates were

seen with phantom limb pain and neuropathies. They conclude that DBS is frequently effective when used in well-selected patients.[19,115]

Afferent Stimulation for Abolition of Pain

The skin and peripheral nerves could be electrically stimulated to obtain relief of pain [transcutaneous electrical nerve stimulation (TENS)].[84,91,131] The principle on which it is based is the fact that when the larger diameter myelinated afferent cutaneous fibres or their extensions into the dorsal column are stimulated, there is a diminution in the activity in the dorsal horns induced by stimulation of the smaller or unmyelinated fibres. This is based on the gate control theory of pain proposed by Melzack and Wall.[89]

Acupuncture techniques are generally based on the above principle. The stimulation is of high frequency and low intensity just sufficient to cause tingling. Endorphin levels in the CSF show an increase during TENS. The indications for TENS are many and include a wide variety of nociceptive, deafferentation and neuropathic pains.[169]

TENS has been useful in both acute and chronic painful states. It has been used in acute painful states of postoperative pain or pain due to musculoskeletal injury. In chronic pain of various causes as the failed back, sympathetic dystrophies and post-herpetic neuralgia, it has been found useful in relieving pain. It has no use in the treatment of central pain as in the deafferent state.This procedure has the advantage of being non-invasive and can be used for long-term stimulation at home by the patient. The efficacy of TENS tends to decrease over time and many patients show a decline in response after 1 year of use. There is no significant morbidity due to the procedure. Pigmentation and skin hypervascularity may occur in areas of chronic stimulation.

Dorsal Column Stimulation

Chronic intractable pain can also be relieved by intermittent stimulation of the dorsal column. Surface electrodes were applied to the dorsal columns by Shealy et al.[132,133] and Sweet and Wepsic[149,150] for the treatment of intractable pain and encouraging results were obtained. Stimulation of the dorsal column may also be done by direct implantation of electrodes into the dorsal column with subsequent electrical self-stimulation to relieve the pain.[102] About 50% of patients get good relief. The results are expected to be better, if well defined objective criteria for patient selection could be established. Direct implantation carries with it the risk of morbidity like transient paresis of the leg, CSF leak, root pains and delayed intraspinal haemorrhage. There is also the problem of long-term tolerance of the tissues to the implant. The best results have been obtained using multipolar electrodes, with epidural placement above the level of the pain segments. When the pain is localised and stimulation induced paraesthesias completely overlap the pain segments, the results are better.The main indications for DCS are pain due to the failed back syndrome, post-amputation pain, incomplete plexus lesions, peripheral nerve lesions, sympathetic reflex dystrophy and rest pain in peripheral vascular disease. It is contraindicated in pain due to complete transverse lesions of the cord, cancer pain, deafferentation pain due to spinal root avulsion and post-herpetic neuralgia.

In carefully selected patients, pain relief is seen in 60% of patients early and over a long-term 40% of patients have pain relief. A positive stimulation test predicts a 70% chance of benefit from implantation while a negative result reduces the chance to 25%. Hence, it is essential to perform trial stimulation at exactly the same level as the final implantation for optimal results.

Focal Brain Stimulation

Relief of chronic pain may also be achieved by precise focal electrical stimulation of brain centres.[2,52,45,116] Stimulation of the IC was utilised for the successful suppression of chronic pain by Adams et al.,[3] who suggested that the pain suppression was due to the stimulation of parietal corticofugal inhibitory fibres.

Stimulation of the periaqueductal grey has been reported with 50% good results by Richardson and Akil[116] and Hosobuchi et al.[62] The procedure is more useful in nociceptive pain and not in deafferenation pain. Meyerson[91] recommends the procedure for patients with malignancy with a life expectancy of 6 months. Thalamic stimulation of the ventrobasal nuclei has also been tried and found effective in deafferentation pain and anaesthesia dolorosa.[61] Levy et al.[79] found that 48% of 628 patients obtained relief from ventrobasal thalamic stimulation. The mechanism of pain relief by stimulation of VPM and VPL is not clear, and it is thought to be due to activation of an inhibitory system independent of the endogeneous opioid system.

The surgical procedure involves placement of platinum flexible electrodes into the appropriate target area using CT/MR guided stereotaxy or positive contrast ventriculography. Physiological parameters, especially the response to electrical stimulation help in accurate placement of the electrodes. The lead wires are brought out of the scalp and temporary electrical stimulation is done for about a week to determine the efficacy of stimulation. If pain relief is good, then the electrodes are internalised for permanent placement and are connected to a programmable battery powered pulse generator.

Extensive clinical experience has shown that the procedure is efficacious in pain relief in around 60% of the patients.[174] Relief of nociceptive pain is higher at 80%, while deafferentation/central pain relief is about 50%.

As with any surgical procedure for pain relief, efficacy diminishes with time and long-term success rates are lesser. The most common complications of the procedure are technical malfunction of the apparatus and infection (5-20%). The risk of permanent neurological morbidity and haemorrhage is around 5%. The drawbacks of the

procedure are the expense involved and the required technical expertise being limited to a few centres.

Chemodes, which are fine tubes through which a defined chemical agent may be delivered into the brain, may also be used for this purpose. Mark et al.[86] used a silastic brain chemode to transport an anaesthetic gas into the human thalamus to obtain pain relief. Morphine can also be injected into the III ventricle and produces very good analgesia with few side effects.

Hypnosis

Rosen[120] reported the usefulness of analgesia induced during a hypnotic trance in patients with intractable pain, especially in phantom limb pain. Hypnotic suggestion has been tried to cure chronic pain unrelieved by previous cordotomy. It is obvious that the relationship between damaged tissues, conscious awareness of pain and the reaction to pain is little understood.

From the large variety of procedures used in different parts of the nervous system, it is clear that patients with intractable pain present a variety of anatomical, physiological and psychological problems. 'They are often difficult to mange, but generally are grateful for even unsuccessful efforts to relieve them. Success, especially when not entirely expected, continues to inspire us and failure, especially when unexplained, to challenge us'.[163]

Outcome Assessment

Quality of life (QOL) is probably the most useful and important measure of outcome that is generally collected. The standard QOL measure has been the SF-36. A 36-item short-form (SF-36) was constructed by Ware et al. to survey health status in the Medical Outcomes Study. The SF-36 was designed for use in clinical practice and research, health policy evaluations and general population surveys. The SF-36 includes one multi-item scale that assesses eight health concepts: (1) limitations in physical activities because of health problems; (2) limitations in social activities because of physical or emotional problems; (3) limitations in usual role activities because of physical health problems; (4) bodily pain; (5) general mental health (psychological distress and well-being); (6) limitations in usual role activities because of emotional problems; (7) vitality (energy and fatigue) and (8) general health perceptions. The survey was constructed for self-administration by persons 14 years of age and older, and for administration by a trained interviewer in person or by telephone.[165]

In 1993, Ware and Sherbourne published a new short-form health survey, the MOS 36-Item Short-Form Health Survey (SF-36), consisting of 36 items included in long-form measures developed for the Medical Outcomes Study. The SF-36 items and scoring rules are distributed by MOS Trust, Inc. Strict adherence to item wording and scoring recommendations is required in order to use the SF-36 trademark. The RAND 36-Item Health Survey 1.0 (distributed by RAND) includes the same items as those in the SF-36, but the recommended scoring algorithm is somewhat different from that of the SF-36. Scoring differences and new T-scores are presented for the 8 multi-item scales and two-factor analytically derived physical and mental health composite scores.[52]

CHRONIC PAIN SYNDROMES

Deafferentation Pain Syndromes

Pain is commonly due to tissue injury, but can also result from damage to peripheral or central somatosensory pathways. Neuropathic pain which follows damage to peripheral or central somatosensory pathways is termed deafferentation pain.[178] This chronic pain may then be referred to the deafferented regions of the body surface. Neuropathic pain is defined as the pain which arises as a result of damage to the somatosensory pathways that transmit pain.[85] Neuropathic pain after trauma tends to be delayed in onset, severe in intensity and resistant to treatment.

Pain following brachial plexus avulsion, phantom limb pain, amputation stump pain and pain occurring after neurosurgical ablative procedures are examples of deafferentation pain and may be due to changes in central somatosensory pathways, as in the dorsal horn.

Clinical Syndromes of Deafferentation Pain

The clinical syndromes of pain following deafferentation include pain associated with both peripheral and CNS damage.

Peripheral Nerve and Root

Some common examples of painful peripheral neuropathy include those due to diabetes, chronic alcoholism, amyloidosis and neurotoxins. Pain is due to deafferentation of the dorsal horn. Herpes zoster afflicts the roots to cause neuropathic pain with deafferentation of the cord segments. Trigeminal and other cephalic neuralgias and arachnoiditis are other examples of deafferentation pain due to root involvement.

Spinal Cord

Traumatic cord injury interrupts the central connections of nociceptive neurons in the spinal cord. Demyelination, necrotizing myelitis, spinal cord injury, syringomyelia, spinal cord AVMs and tumours are other causes of deafferentation pain due to cord involvement.

Brainstem

Common examples of pain due to deafferentation of the brainstem are those due to vascular occlusions, surgical procedures or demyelination.

Thalamus

The thalamic syndrome of Dejerine and Roussy is usually due to vascular injury (ischaemia or haemorrhage) to the ventroposterolateral (VPL) and ventroposteromedial

(VPM) nuclei of the thalamus and it is characterised by persistent, spontaneous burning pain.

Cortex

Large subcortical parietal lesions interrupting the thalamocortical sensory pathways may produce pain similar to thalamic pain.[35]

Treatment

The treatment of deafferentation pain is difficult, and the pain is intractable. Anticonvulsants, like phenytoin, carbamazepine, clonazepam and valproic acid, have been reported to be effective in relieving pain due to diabetic neuropathy, post-herpetic neuralgia, phantom limb pain and trigeminal neuralgia. Anticonvulsants may inhibit abnormal spontaneous activity of other damaged neurons. Steroids and NSAIDs may be useful, especially as adjunctive drugs.[14] Opiates are of limited efficacy in the management of deafferentation pain. TENS may be useful in some patients with brachial plexus avulsions, post-herpetic neuralgia (PHC), phantom limb pain and spinal cord injury. Generally, ablative neurosurgical procedures do not result in lasting relief in deafferentation pain. However, DREZ lesions have been shown to be effective in pain relief in conditions like brachial plexus avulsion, phantom limb pain, post-herpetic neuralgia (PHN), etc.[99]

Phantom Limb and Stump Pain

Stump pain is the pain in the residual limb after amputation, and phantom limb pain is a referred pain in the absent amputated limb. Long-term control of these pain syndromes is difficult and up to 80% of amputees are known to experience significant stump or phantom limb pain.[137] The underlying mechanisms of pain are poorly understood, and the most commonly used treatment regimens are ineffective at one year follow-up.

Acute Pain Following Amputation

Most patients undergoing amputation experience acute stump pain as a result of surgery and nearly all amputees experience phantom limb feelings after amputation. Such patients are frequently distraught if they have not been prepared about phantom limb sensation or pain. Stump pain is usually severe immediately after amputation and subsides with healing. Persistent post-operative pain or worsening pain may indicate an inadequate blood supply interfering with proper healing or may be due to post-operative infection.[135] The optimal treatment of acute post-ampuptation phantom pain includes patience, stress control and relaxation training.

Mechanisms of Pain in Chronic Stump and Phantom Limb Pain

Phantom limb pain has previously been ascribed to psychological mechanisms, peripheral nerve and CNS transmission mechanisms or centrally generated reverberating circuits. Evidence suggests that each major variation of phantom limb and stump pain may have different mechanisms and that stump and phantom limb pain having similar descriptions may have similar mechanisms.[134]

The following are some of the mechanisms underlying specific pain patterns seen in phantom limb pain.

Blood Flow

Decreased blood flow in the stump has been described to be associated with persistent burning, throbbing and tingling phantom limb and stump pain. An increase in peripheral blood flow to the stump can result in decreased pain. A further proof of a vascular related mechanism for burning phantom limb pain is the short-term effectiveness of sympathetic blocks and sympathectomy that increases blood flow to the limb.

Voluntary Muscle Spasm

In some amputees, cramp like pain is present when the residual limb muscles are in spasm and is relieved when they are relaxed. Such pain may respond to biofeedback training to reduce muscle tension.[136]

Psychological Factors

Current evidence[137] does not establish a relationship between the occurrence of phantom limb pain and psychological factors, but intensity may be affected by stress and exhaustion.

Treatment

The following are some of the guidelines for treatment. Complete evaluation of an amputee involves a team approach.[72] Evaluation includes correlation of pain with diet, weather, physical/mental stress and the use of prostheses. Residual limb pain is to be treated before tackling phantom limb pain. The prosthesis should be evaluated for its fitness and its effect on gait. If trigger points are present and pain is reproduced by them local blockade may be of use. When phantom limb pain is of a burning quality and related to decrease in stump temperature, it is probably due to decreased blood flow in the residual limb and may respond to biofeedback, peripheral vasodilators or sympathetic blocks. A cramping type of pain associated with spasm would be optimally treatment by muscle tension biofeedback and muscle relaxants. When pain is neither burning nor cramp like it is more difficult to treat, but short-term treatment may be effective with TENS, active motion exercises, ultrasound at the stump, steroids and sedatives/hypnotics. Neurosurgical ablative procedures with the exception of DREZ lesions may not result in long-term effective pain relief.

POST-HERPETIC NEURALGIA

Post-herpetic neuralgia (PHN) is a common cause of severe intractable neuropathic pain. PHN is a consequence of herpes zoster which is caused by reactivation of varicella zoster virus contracted in childhood.

The virus initially causes varicella and remains dormant for many years in the trigeminal, the geniculate or the dorsal root ganglia and re-erupts in the elderly or in immunocompromised states. The resulting segmental haemorrhagic inflammatory reaction of the skin and mucous membrane is very painful before, during or after the appearance of the rash. This pain subsides with healing, but if it persists for more than 1 month it is said to be PHN.

Natural History and Epidemiology

PHN occurs in 9–14.3% of patients with herpes zoster.[60,112] Of these, a third continue to have pain at 3 months and in another third it lasts for more than one year. Both the severity and incidence of PHN are directly related to the age of the patient. Demoragas[27] found that 50% of patients with herpes zoster who were over 60 years old and 75% over 70 years of age developed PHN 1 month after the rash. The sex incidence is equal and PHN has a predilection for the thoracic dermatomes, especially T5 and T6, and the ophthalmic division of the trigeminal nerve. Pain in PHN may be both steady and paroxysmal[106] and is described by patients as burning or gnawing for the constant pain and sharp or shooting for the paroxysmal component. The pathologic changes are characterised by haemorrhagic inflammation involving the dorsal root ganglion, peripheral nerve, roots, leptomeninges and the spinal cord.[53] Both central and peripheral mechanisms may be involved in PHN; innocuous sensory stimuli from the periphery may cause hyperaesthesia, dysaesthesia and allodynia and the failure of peripheral deafferentation surgery and the limited success of DREZ lesions point to a central mechanism.

Prevention of Post-Herpetic Neuralgia

Several studies[28,30,70] have found steroid administration in the acute phase of herpes zoster to be beneficial in reducing the incidence of PHN. The bulk of evidence supports the use of moderate doses of steroids, such as prednisolone 60 mg/day at the onset of HZ, in non-immunosuppressed patients with tapering of the dose over two weeks. Some of the other measures reported successful in reducing the incidence of PHN are sympathetic blockade,[24] amantadine,[41] levodopa and benserazide[128] and intramuscular alpha-interferon.[90] Significantly, acyclovir does not reduce the incidence or severity of PHN in immuno-competent or in immuno-compromised patients.[9,12,13,33,110]

Treatment

The past 60 years have witnessed a bewildering array of medical and surgical approaches for the treatment of PHN, the sheer number of which demonstrates the difficulties in managing this disorder.

Medical Treatment

Antidepressants and neuroleptics: Woodforde et al.[168] used amitryptiline to treat depression in patients with PHN and found that all patients had good pain relief at doses of 40 mg/day initially and stepped up to 100 mg/day. Watson[166] found that pain relief with amitryptiline occurred in patients who had no depression and at doses lower than those used for treating depression.

Anticonvulsants: Carbamazepine, phenytoin and valproic acid have been shown to be of limited use in PHN.[71]

Tropical capsaicin: Capsaicin (8-methyl N-vanilyl 1-6 nonenamide) selectively stimulates and then blocks unmyelinated sensory afferents from the skin and mucous membranes.[64-66] Capsaicin is thought to act by depleting substance P. It should be used 4–5 times a day for at least 4 weeks. Burning after application may be a significant problem, but may respond to lidocaine ointment and analgesics.

Other therapies: Repeated nerve blocks, ethyl chloride spray,[155] sympathetic blocks,[25] chlorprothixene[34] and epidural injection of methyl prednisolone[39] have all been claimed to be effective. Nathan[105] found TENS useful when used for a prolonged period of time.

Surgical Treatment

Stereotactic trigeminal tractotomy[59] in ophthalmic PHN was found to be effective. Nashold[99] found DREZ lesions to give good long-term results.

PAIN IN MULTIPLE SCLEROSIS

Pain is a common feature in established multiple sclerosis (MS) and is reported to occur in up to 55% of patients.[95] It may manifest as acute, subacute and chronic pain syndromes. Acute pain syndromes are exemplified by trigeminal neuralgia, Lhermitte's phenomenon, tic like extremity pain and painful tonic seizures.

Subacute pain syndromes are seen days or weeks after the onset of MS and typical examples are retrobulbar neuritis and painful peroneal and unlar nerve palsies. Treatment of MS with steroids or immunosupressants can itself lead to subacute pain syndromes due to vertebral compression fractures, haemorrhagic cystitis, etc. Relief of pain assumes a high priority in treatment of an incurable disease like MS. It is important to realise and characterise the type of pain syndrome for effective treatment.

In patients with a mean duration of illness of more than 10 years, chronic pain is common and is almost always associated with myelopathy. Three major pain patterns are dysaesthetic extremity pain, back pain and painful leg spasms. Dysaesthetic extremity pain has been treated with tricyclic antidepressants, DCS and DBS with varying degrees of success. Chronic back pain due to spastic weakness and abnormal stresses on the paravertebral muscles may accelerate degeneration of the intervertebral disc, resulting in herniation or

degeneration of the facet joints and mechanical pain. Treatment consists of NSAIDs, physical therapy and disc removal. Painful leg spasms may respond to muscle relaxants such as baclofen, dantrolene and diazepam, or a short course of high dose steroids. A novel approach in the management of severe pain and spasticity is spinal opiate administration[31] which is effective at lower doses when compared to parenteral administration and has the advantage of being non-destructive.[173] Neurolytic procedures like dorsal rhizotomy and intrathecal phenol have been found useful, but may worsen the neurological deficit.

PAIN SYNDROMES WITH CANCER

Pain is a common presenting symptom of neurologic involvement in cancer patients. Pain syndromes due to cancer can be due to various causes and can be broadly considered in three major categories.

The first and the most important category is pain associated with direct tumour infiltration of the dura, cranial nerves, spinal cord and peripheral nerves or compression of these structures by tumour in contiguous tissues, e.g. epidural spinal cord compression and brachial plexopathy.

The second category includes pain syndromes associated with cancer therapy including surgery, chemotherapy and radiation pain. Post-chemotherapy pain syndromes include peripheral neuropathy, steroid pseudorheumatism, aseptic necrosis of bone, headache and mononeuropathy. Post-surgical pain syndrome may be due to post-mastectomy pain, post-radical neck dissection pain, post-thoractomy pain and phantom limb and stump pain. Post-radiation pain may be due to radiation fibrosis of the brachial or lumbosacral plexus, radiation myelopathy or acute herpetic and post-herpetic neuralgia.

The third category of pain syndromes in cancer are not related to either cancer or its therapy (e.g. lumbar disc disease, epidural abscess, osteoporosis). It is, therefore, important to categorise the cause of pain in cancer patients for their optimal management.

196 Trigeminal Neuralgia

Ramakrishna Easwaran

The Serpent comes
Fork tongued and unctuous
It slithers down the ganglion,
Fang flickering, nerve licking
Where and when to strike?

('Tic douloureux', a poem written by Roger Levy, a sufferer of trigeminal neuralgia)[97]

Trigeminal neuralgia is rated by patients as the worst of all pains that afflict mankind. Although tremendous progress has been made in the last three decades in alleviating the suffering caused by trigeminal neuralgia, its basic pathogenesis remains mysterious.

HISTORY

John Locke provided the first physician's description of trigeminal neuralgia when he treated the Countess of Northumberland in 1667.[66] In 1756, Nicholas André described two patients and gave the name 'tic douloureux'. The clinical description of the trigeminal neuralgic pain by John Fothergill, in 1773, can hardly be improved upon. The initial surgical procedures were essentially ablative. The first effective non-ablative surgical therapy was the introduction of microvascular decompression (MVD) by Jannetta[20] (Table 1).

Table 1: Landmarks in the treatment of trigeminal neuralgia

	Ablative		*Non-ablative*
1891:	Horsley, Taylor, Coleman—Intradural preganglionic root section	1932:	Dandy—Observation of vascular compression (proposed as cause but continued to perform root section)
1892:	Hartley, Krause—Extradural subtemporal Gasserian ganglionectomy	1952:	Taarnhoj—Surgical decompression of Gasserian ganglion (? minimal ablation) early success, high recurrence
1901:	Frazier, Spiller—Modification of Hartley-Krause operation to spare corneal sensation	1962:	Blom—Carbamazepine therapy Gardner-Vascular compression
1910:	Harris—Percutaneous alcohol ablation		
1925:	Dandy—Posterior fossa sensory root section	1967:	Jannetta—Early vascular decompression reports
1928:	Stookey—Differential middle fossa root section, dividing only the fibres of affected division	1975:	Jannetta—Microvascular decompression for trigeminal neuralgia, hemifacial spasms
1937:	Sjöqvist—trigeminal tractotomy		
1955:	Shelden—Trigeminal ganglion compression procedure	1984:	Fromm—Baclofen therapy Baker—Synergism of carbamazepine and baclofen
1971:	Leksell—Stereotactic radiation to produce Gasserian ganglion lesion	1989:	Zakrzewska—oxcarbazepine therapy[99]
1974:	Sweet, Wepsic—Radiofrequency rhizolysis, temperature monitoring, localisation by stimulation	1998:	Khan—Gabapentin, for trigeminal neuralgia in multiple sclerosis[51]
1981:	Håkanson—(Serendipitous discovery) retrogasserian glycerol injection	2007:	Obermann—Pregabalin therapy[70]
1983:	Mullan, Lichtor—percutaneous balloon compression		
1991:	Rand—Gamma knife radiosurgery		

INCIDENCE

The crude incidence rate of trigeminal neuralgia was reported to be 4.3 per 100,000 in the Rochester population based study.[50] The right side is more often involved than the left, in the ratio of 3:2. The disease is rarely bilateral (about 5% of cases), but the incidence of bilateral neuralgia in patients with multiple sclerosis is 18%.[65] Women have been reported to be more affected in most series from the West, while in Indian series men are more affected.[47,94] The maxillary (V2) division is the most common single division to be involved and nearly a third of patients have the pain in the maxillary (V2) and mandibular (V3) divisions, simultaneously (Fig. 1). There is over-representation of ophthalmic (V1) division and holotrigeminal neuralgia in the MVD series, due to selection bias. The mandibular (V3) division is similarly over-represented in many series of percutaneous ablative procedures.

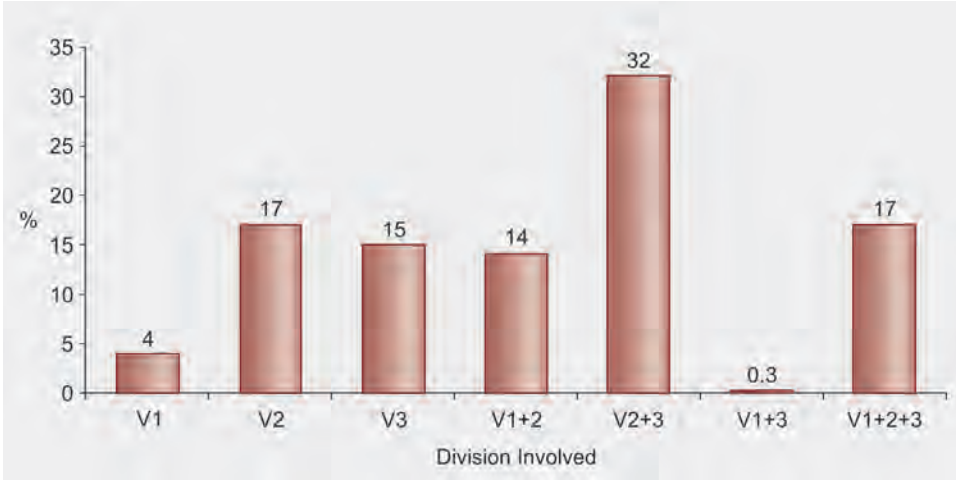

Fig. 1: Divisions involved in trigeminal neuralgia (based on data from 16 series of 8,124 cases)[94]

The age at onset is generally in the sixth decade (Fig. 2). Idiopathic trigeminal neuralgia and vascular cross compression are very rare in children.[18] The occurrence of trigeminal neuralgic pain in children should prompt a thorough search for another cause such as abscess or tumour.

CLINICAL FEATURES

Tic douloureux is diagnosed solely on the patient's history. The characteristic feature is the sudden stabbing (described as lancinating or lightening or electric shock like) pain in the distribution of one or more divisions (or branches thereof) of the trigeminal nerve, generally on one side. Each pain episode is stereotyped and it occurs as a brief spell lasting a few seconds or a minute. The onset of each spell is sudden and the intensity severe. Many such pangs of pain may be felt repeatedly in a short span of time and this leads the patient to describe the attack as going on for hours or days. Some patients describe a burning pain. The pain can occur spontaneously or may be triggered by light touch over the nasolabial fold, upper lip or tooth ('trigger zones'). Talking, smiling, eating (chewing or swallowing), contact with cold breeze or water on the face, brushing the teeth or shaving are common daily events that precipitate pain and become impossible tasks. Often the patient can give the history only by writing. The unshaved, halitotic and cachectic appearance signals unremitting prolonged spells of pain. The pain commonly starts in the teeth or gums and patients have usually had several teeth extracted before coming to the neurosurgeon. Some patients rub the face vigorously during the attack while most others guard their face from the slightest of contact. Patients learn to avoid cold drinks and fear the winter. There might be a sudden wince of the facial muscles in response to the pain and this characteristic gives the name tic douloureux. True hemifacial spasms are also seen along with trigeminal neuralgic pain and this is described as tic convulsive.[22] A single dolichoectatic vessel may be found compressing both the trigeminal and facial root entry zone in such cases. The pain may be confined to one branch of a division. The supraorbital/nasociliary (from V1), infraorbital/zygomaticotemporal (from V2) and inferior alveolar/auriculotemporal (from V3) branches may be exclusively involved.

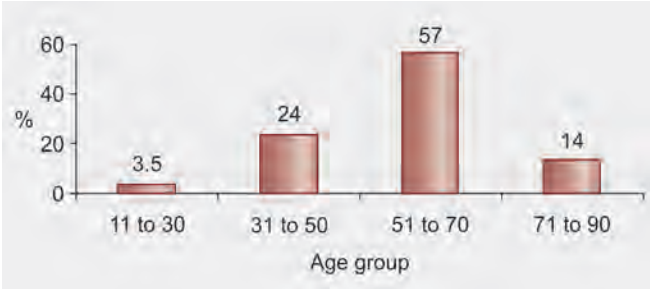

Fig. 2: Age at onset of trigeminal neuralgia (based on data from 16 series of 8,124 cases)[94]

The pain episodes are well known to spontaneously remit and patients may even be able to stop medication. The pain may cease for several months only to return with renewed vigour, increasing in severity and frequency with each episode. In due course, the attacks might cease and then start in a different division and rarely on the opposite side. Recently an attempt has been made to separate the above described 'classical' trigeminal neuralgia (TN 1) from the 'atypical' trigeminal neuralgia (TN 2). In the latter syndrome the pain is aching, throbbing or burning for more than 50% of the time and there is constant background pain but strictly confined to the anatomical distribution of the trigeminal divisions. TN 2 might represent progression of idiopathic TN 1 or it might indicate a secondary cause, such as tumour.[26] This entity of 'atypical' trigeminal neuralgia is not to be confused with atypical facial pain syndrome. 'Atypical' trigeminal neuralgia has also been treated with MVD and multiple vascular conflicts are the rule.[38] Familial trigeminal neuralgia is infrequent but well reported.[36]

Clinical examination is remarkable for the absence of physical signs. A slight sensory loss over the area of

pain may be disclosed by careful examination during the attack and is in itself not against the diagnosis of primary or idiopathic trigeminal neuralgia. Absent corneal reflex behoves a search for a cerebellopontine angle mass in a patient presenting with trigeminal neuralgia. Profound sensory loss may be due to a past ablative procedure but must lead one to suspect a secondary cause. Arterial hypertension, especially systolic hypertension, is seen more often than in age-matched controls. Good control of blood pressure alone may reduce the severity and frequency of trigeminal neuralgia. This author has had patients in whom the blood pressure was impossible to control, until the pain was relieved by MVD of the trigeminal root entry zone. Antihypertensive medication was no longer needed in some after surgery for trigeminal neuralgia. Hypertension caused by vascular cross compression on the vagal root entry zone or the ventrolateral medulla (neurogenic hypertension), its coexistence with trigeminal neuralgia or hemifacial spasm and its response to MVD of the vagus and medulla are a different issue altogether.[8]

PATHOLOGY

Trigeminal neuralgia has been classified into primary (idiopathic) and secondary varieties. The primary variety is far more common. In the secondary variety, there is a tumour, vascular malformation or cyst causing compression, stretch or distortion of the trigeminal nerve. Such cases account for 6% of all patients with trigeminal neuralgia.[60] The distinction between primary and secondary varieties was sacrosanct in the CT and pre-CT era but with the advent of MR imaging, the distinction is not as straightforward as it might seem. This is because a good degree of nerve compression by a vascular loop may be demonstrable with MR in the so-called 'idiopathic' cases. On the other hand, even in patients who have trigeminal neuralgia due to a mass lesion, the neuralgia has been reported to be due to concomitant vascular cross compression.[10] The pain gets relieved in such patients not merely with the removal of the mass but with MVD performed at the same time.[78] Epidermoid tumour in the cerebellopontine angle must be suspected in young patients and vestibular schwannoma in adults. The occurrence of trigeminal neuralgia on the contralateral side of the mass has been reported.[37,77] This is believed to be due to distortion of the brainstem, arachnoiditis or a contralateral vascular cross compression of the opposite trigeminal nerve. Unlike ipsilateral neuralgia, contralateral neuralgia generally resolves with the excision of the mass. If it does not do so, exploration of the affected nerve, MVD and partial sensory rhizotomy (PSR) might be needed.[35] Trigeminal neuralgia can be a false localising sign of raised intracranial pressure.[52] The list of lesions causing secondary trigeminal neuralgia is summarised in Table 2.

Table 2: Causes of secondary trigeminal neuralgia

Lesions causing secondary trigeminal neuralgia:
• Vestibular schwannoma[81]
• Epidermoid tumour[22,63]
• Meningioma[10]
• Petrous osteoma[79]
• Abscess[12]
• Tuberculoma[9]
• Cysticercosis[78]
• Chiari malformation[32]
• Cavernoma of V nerve[23]
• Aneurysm[91]
• Arteriovenous malformation[6]

The pathology in the idiopathic variety was not detectable before surgery until the advent of modern MR imaging in the last decade. After the widespread use of MVD, an extensive body of literature has been built up about the vascular compression on the trigeminal root. It is proposed that with age, the arteries become tortuous, elongated and rigid. This, coupled with the sagging of the brain, tends to bring the trigeminal nerve in to position of contact or compression by the vessels. The reported incidence of vascular cross compression has been as high as 96%.[42] Some, who are more rigid in their concept of what constitutes vascular cross compression, have found lower rates of such vessels during the course of posterior fossa exploration for sensory rhizotomy (11% of 57 patients).[1] Table 3 summarises the vessels implicated in the genesis of trigeminal neuralgia from an Indian study, which found compression in 98% of 58 cases.[86] These figures conform to a personal series of 98 cases of MVD.

Jannetta reported that the compression is on the rostral and anterior portion of the nerve when the pain is in the V2 or V2-3 distribution. The vascular conflict is on the caudal aspect of the root entry zone in V1 neuralgia.[43] This correlates well with the known anatomical fact of the inverted distribution of the fibres in the trigeminal root entry zone (caudal ones representing the V1 division). The degree of compression may be variable. While some vessels make only a contact, others distort and

Table 3: Vessels implicated in the genesis of trigeminal neuralgia

Findings from an Indian study of microvascular decompression[86]
• Arteries 84%
• Superior cerebellar artery or its branch 77%
• Anterior inferior cerebellar artery 2%
• Combinations of both 5%
• Veins 5%
• Combined artery and vein 9%
• No vascular compression 2%
Other reports:
• Dolichoectatic basilar/vertebral artery[85]
• Persistent trigeminal artery[17]
• Transverse pontine vein[61]

groove the nerve, even to the point of atrophy. In fact the nerve atrophy can be demonstrated in MR imaging.[27] The compression may be between two straight vessels running at an acute angle, rather than be caused by an elongated tortuous loop. The compression might be anywhere from the pontine attachment of the root up to the Meckel's cave. This was believed to be because of the variable length of the Obersteiner-Redlich zone, i.e. the junction of the central (oligodendroglial) and peripheral (Schwann cell) myelin in the trigeminal root.[41] A recent microanatomical study dispels this view and shows that the transition zone extends only one-fourth the length of the trigeminal root from the pons to the Meckel's cave.[72] Hence, some mechanism other than demyelination of the central myelin needs to be invoked to explain the trigeminal neuralgia due to more distal vascular conflicts. Additional findings such as arachnoiditis may also be seen. With modern MR imaging, it has become rare to find a small tumour as a surprise finding at surgery. Platybasia has been found to be more common in patients with tic douloureux than in controls.[49] This might alter vascular relations to favour cross compression. Reduced volume of the pontomesencephalic cistern by 13% has been reported on the symptomatic side by MR volumetry.[76] This might also contribute to crowding and promote vascular compression.

Enthusiastic espousal of the vascular compression theory must be tempered by the fact that vascular contact and compression may be seen in those who do not have trigeminal neuralgia. This has been shown in 26 out of 50 cadaver nerves.[39] It has also been shown in a recent 3 Tesla MR study of 110 persons, without trigeminal neuralgia, that 49% of the nerves made a contact with a vessel and contact with mild deviation of the nerve occurred in 15%. However, moderate or severe deviation of the nerve by the vessel was never seen in the asymptomatic person.[45]

In an ultrastructural study of trigeminal root entry zone biopsies obtained during MVD, axonopathy and axonal loss, demyelination, dysmyelination, residual myelin debris and the presence of excess collagen, including condensed collagen masses, were found.[24] Within zones of demyelination, groups of axons were often closely apposed without an intervening glial process. Pathological characteristics of nerve fibres were clearly graded with the degrees of root compression noted at operation. Remyelination has been noted and one wonders if this explains the spontaneous remission in pain.[59]

PATHOGENESIS

Gardner postulated that 'short-circuiting' between the demyelinated axons in the trigeminal root results in 'cross talk' (ephaptic transmission) leading to the paroxysms of pain.[30] The abnormal peripheral discharge has been shown by microneurographic recording during the course of radiofrequency gangliolysis.[15] Since remyelination cannot explain the immediate recovery after MVD, reversal of a conduction block caused by the compression has been invoked.[55,58] Impaired trigeminal nociceptive processing has been described in patients of trigeminal neuralgia, who have concomitant chronic facial pain. This has been proved by nociceptive blink reflex (nBR) testing and by recording pain related evoked potentials (PREP).[69] Prolonged latency and threshold elevation have been demonstrated during trigeminal evoked potential (TEP) studies in patients with the classical form of trigeminal neuralgia.[13] TEPs are altered in patients with trigeminal neuralgia secondary to tumours.[88] Arguing by the same token, an MR demonstrable vascular compression can be held as the cause of trigeminal neuralgia, if similar TEP abnormalities are seen. Trigeminal reflex elicited by electrophysiological study also helps distinguish the idiopathic and symptomatic varieties of trigeminal neuralgia.[21] Central mechanisms in the pontine nuclei or tracts may also play a part in the genesis of trigeminal neuralgia. Multiple sclerosis is the best example.

IMAGING

Trigeminal neuralgia remains a clinical diagnosis. CT scans are routinely done prior to definitive therapy for trigeminal neuralgia to exclude a secondary cause such as tumour. The mass lesion might be on the contralateral side.[37,77] CT might show dolichoectasia of the vertebrobasilar arteries and this can be confirmed by CT angiography.[85] Although dolichoectatic vertebrobasilar arteries may be present, the compression on the root may often be due to a superior cerebellar artery loop, rather than the dolichoectatic vessel. Figure 3 shows an example. MR imaging can demonstrate the neurovascular conflict and help select patients for and to plan the surgery (Fig. 4). Several MR techniques are available for imaging the artery and the nerve simultaneously. These include 3-D constructive interference in steady state (3-D CISS) and 3-D fast inflow with steady-state precession (3-D-FISP).[2] MR angiography with multiplanar reconstruction helps detail the anatomy of the arterial compression, while the veins are shown in 3-D CISS

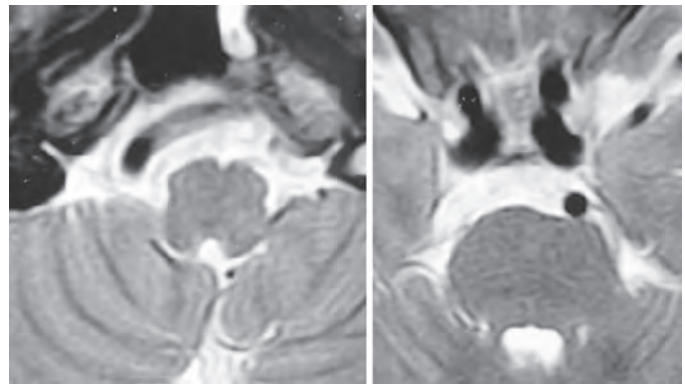

Fig. 3: Axial T2-weighted MR images of a patient with left trigeminal (V2) neuralgia although he has dolichoectasia of the carotid and vertebrobasilar arteries, the compression was on the ventral aspect of the nerve by a loop of the left superior cerebellar artery

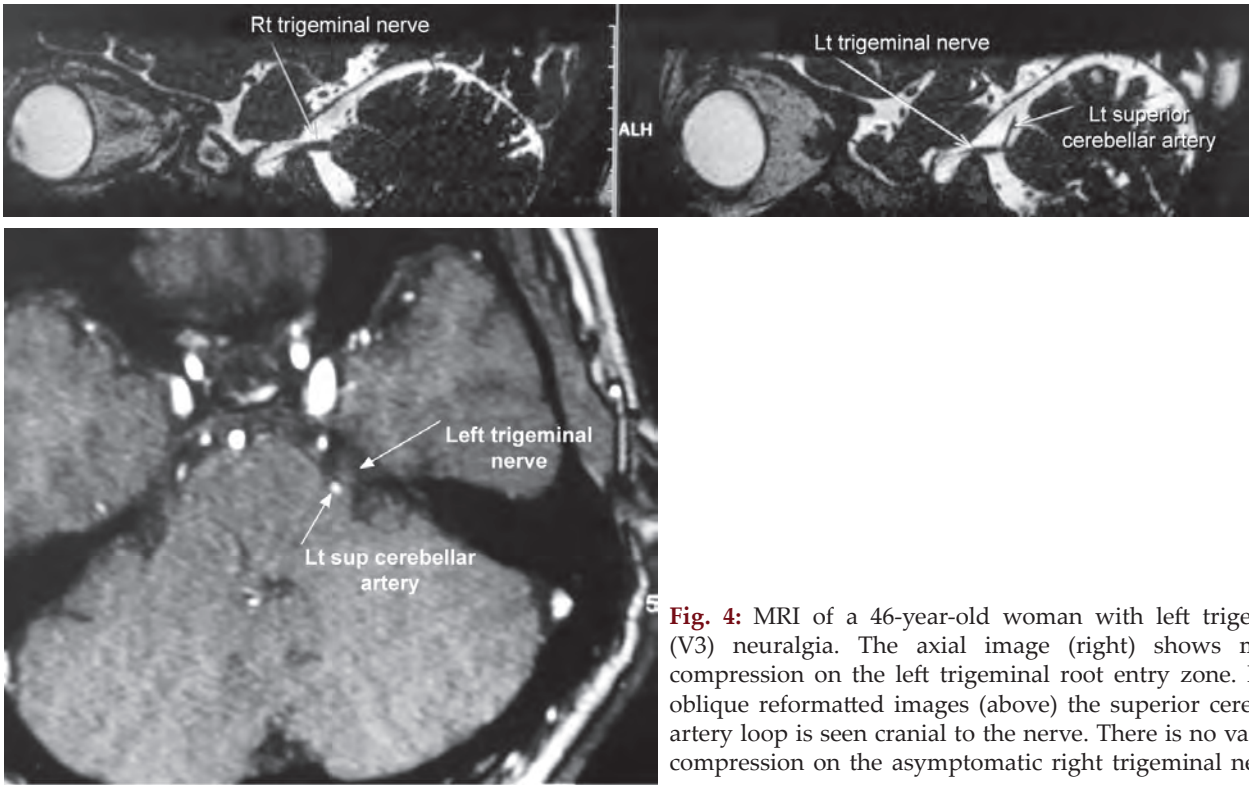

Fig. 4: MRI of a 46-year-old woman with left trigeminal (V3) neuralgia. The axial image (right) shows medial compression on the left trigeminal root entry zone. In the oblique reformatted images (above) the superior cerebellar artery loop is seen cranial to the nerve. There is no vascular compression on the asymptomatic right trigeminal nerve

imaging only. The pre-operative prediction of the site of compression and the exact vessel responsible was found correct in all 15 operated cases in one report.[96] On correlating with the surgical findings, the sensitivity of contrast enhanced MRA was 90.5% and the specificity 100% in a prospective, single blinded study.[71] Recently balanced fast-field echo (BFFE) imaging with 3-D TOF MRA and gadolinium enhanced 3-D SPGR imaging have been combined to accurately predict the neurovascular conflict.[64]

TREATMENT

Emergency Room Management

Traditional analgesics, including narcotics, make hardly any impact on the severe pain of trigeminal neuralgia. We have found a loading dose of phenytoin (15 mg/kg IV by infusion) to be of help in tiding over the crisis. Lignocaine can be used similarly.

Medical Therapy

Carbamazepine is the sheet anchor drug in managing trigeminal neuralgia.[93] The efficacy of carbamazepine has been proved in at least six placebo-controlled randomised trials.[19] The response is specific enough to use it as a 'therapeutic diagnostic test'. The dose that gives relief may be as little as 100 mg bid in some patients, while others get relief only with 1600 mg per day. The controlled release preparations used for epilepsy are not ideal for management of pain. It is ideal to keep the dose strength at a low level (200–300 mg) and increase the frequency (say 4–5 times a day). This gives sustained pain relief and helps minimise the peak dose ataxia, drowsiness and visual blurring. The patient must be told to take the drug before eating, washing, brushing or shaving. Skin rash and depression of blood counts are the most frequent reasons to switch over to another agent. The drug of choice to those intolerant of carbamazepine should be oxcarbazepine.[67] The pain generally escapes control with carbamazepine over some months or years. Drug additions at this stage improve the pain. The additional drug could be lamotrigine or baclofen.[44] Gabapentin has been used alone or in combination with trigger point block with a local anaesthetic.[57] Topiramate was found ineffective in a placebo-controlled crossover trial but only 3 patients were studied.[31] Although several non-antiepileptic drugs, like tizanidine, clomipramine, tocainide and pimozide have been tested in randomised trials, there is no conclusive evidence supporting any of them.[40] One study suggests that sumatriptan administered subcutaneously controls intractable trigeminal neuralgia.[48] Recently, injection of botulinum toxin in the face has been advocated for intractable trigeminal neuralgia, but this drug has been claimed to work for migraine, tension, headache and post-herpetic neuralgia too.[92]

Surgical Procedures

The ideal surgical procedure for trigeminal neuralgia should have a 100% initial success rate with no recurrence of pain on long-term follow-up. It should not leave the face numb and there should be no dysaesthesia or anaesthesia dolorosa. It should not be associated with

Table 4: Practical goals for procedures used to treat trigeminal neuralgia

Initial success	> 95%
Long-term recurrence	< 10%
V sensory dysfunction	
Ablative procedure	< 50%
Non-ablative procedure	< 2%
Minor complication	< 5%
Major complication/death	< 0.5%

mortality or morbidity to the neighbouring cranial nerves, brainstem and cerebellum. It should be suitable for all ages and should come at an affordable cost. The skill must not be difficult to master. It should also address the aetiology as is known now. Needless to say that such a utopian procedure does not exist. What we do have is a plethora of procedures, which are all good in parts, like a curate's egg. The problem is compounded by the master surgeons stridently championing one procedure over the other. It is too simplistic to assume that every neurosurgeon dabbling in trigeminal neuralgia surgery now and then would be able to get the same results as the experts with large operation volumes. Hence, we are forced to lower the bar and set reasonable and practical goals of treatment for trigeminal neuralgia (Table 4). Results from the literature are mere guideposts and milestones. Each surgeon must chart his/her own course, tempered by the knowledge of what he/she is good at.

Peripheral Procedures

The peripheral procedures, which were widely used earlier, have not found favour with modern neurosurgeons. These consist of trigeminal branch blocks with local anaesthetic, followed by alcohol injection or branch avulsion. Sensory loss is invariable. The pain invariably comes back within a few months in case of alcohol/glycerol block and within a year or two in case of branch avulsion.[28,29] The recurrence is due to quicker regeneration in the more peripheral sites of the trigeminal nerve, as compared to lesions made in the retrogasserian roots. Such peripheral procedures may need to be considered only in the very old and infirm patient with neuralgia restricted to one branch of a trigeminal division.

Percutaneous Retrogasserian Glycerol Rhizolysis

Glycerol, which can be harmlessly ingested by humans, is neurotoxic when injected into the nerve or around it. Percutaneous retrogasserian glycerol rhizolysis (PRGR) offers a low-cost, low-risk method of treating trigeminal neuralgia that can be easily repeated in case of recurrence.

Technique of Percutaneous Retrogasserian Glycerol Rhizolysis

The procedure can be done entirely under local anaesthesia, but it is ideal to have an anaesthetist for administering fentanyl-midazolam sedation or short intravenous propofol anaesthesia and for monitoring the patient. The Härtel technique for percutaneous needle placement through the foramen ovale is followed. The puncture is made on the skin of the cheek 2.5 cm lateral to the corner of the mouth. The needle is directed in the sagittal plane towards the pupil and in the coronal plane to a point 2.5 cm in front of the tragus on the zygomatic arch. Radiographical confirmation with anteroposterior and lateral views on C-arm image intensifier screening is essential to prevent accidental entry into the optic canal, superior orbital fissure or the carotid artery. CSF flow is seen when the needle is in the trigeminal cistern but this does not exclude subtemporal placement. Radiographical confirmation with iohexol trigeminal cisternography is desirable as it helps to visualise the retrogasserian fibres in the lateral view but it is not mandatory. More importantly it shows inappropriate positioning into the posterior fossa, middle fossa or cavernous sinus. The volume of the cistern is judged with iohexol and generally it is around 0.3 ml. About 0.15–0.3 ml of sterile 99.9% anhydrous glycerol is then injected. This viscous liquid is easier to push through a 19G spinal needle. The injection is done in the head up position. Mixing radio-opaque tantalum powder with glycerol helps in marking the trigeminal cistern permanently.[53]

Results of Percutaneous Retrogasserian Glycerol Rhizolysis

The initial complications include headache, transient cardiac dysrhythmia, hypertension, seizure, temporal lobe haematoma, other cranial nerve palsies due to spread of glycerol, oral herpes and aseptic/bacterial meningitis. The procedure fails in about 10% due to technical reasons. About 70% of patients, in whom the procedure can be completed, note a hypalgesia in the face but hypoaesthesia occurs in about 30% only. Dysaesthesia and corneal sensory loss occur in less than 2%. Anaesthesia dolorosa is not seen. The initial relief evaporates as the patient is followed-up for longer periods. The recurrence rate is about 20% at 1 year and by 4 years it might be as high as 70%.[89] The factors, which predict success of PRGR, are patients without any constant facial pain, patients with immediate facial pain during glycerol injection and patients with new trigeminal deficits after PRGR.[73]

Percutaneous Radiofrequency Thermocoagulation (PRFTC)

This procedure depends on the differential sensitivity of nerve fibres to heat damage. The myelinated touch fibres are more heat resistant than the unmyelinated pain fibres. Therefore, controlled heating using radiofrequency energy ablates the pain carrying fibres, while theoretically leaving the other sensations largely intact. The technique enables proper localisation in the 'stimulation mode' and temperature monitoring in the 'lesion mode'.

Technique of Percutaneous Radiofrequency Thermocoagulation

The anaesthetic technique is similar to that for PRGR, but PRFTC is potentially more painful than PRGR and there are greater changes in the blood pressure and pulse. The crux of the anaesthetic technique is to keep the patient pain relieved, while keeping the sensorium intact for getting patient feedback during stimulation. The needle placement technique is the same. The 20G needle is directed at the vertex of the angle between the shadows of the clivus and the petrous ridge in the lateral view of the C-arm image intensifier screening. The 7.5 mm straight electrode is the standard one passed through the needle. In the AP view, the target is 9 mm medial to the lateral border of the internal auditory meatus. The electrode tip is placed just proximal to the clivus for V3, at the clivus for V2 and projecting just beyond the clivus for V1 access, as seen in the lateral projection. Impedance monitoring is not routinely done. When the electrode is properly placed, the impedance should be 150–350 Ω. The impedance is higher if the electrode is in non-neural tissue.

Next, stimulation of the retrogasserian root is done with 100 mV square wave current at 50 Hz and 1 msec duration. This should produce a tingling paraesthesia in the distribution of the desired root. The stimulation current strength and frequency are increased in steps until the patient reports the paraesthesiae. If more than 0.5 V is needed or if there is a motor response, the electrode tip must be repositioned. Having confirmed the proper placement radiographically and by stimulation testing, the lesion is made under short anaesthesia. The size of the coagulum in the roots depends on both the current strength (in milliampere) and the duration. The lesion generator machine generally automatically selects the current strength and voltage when the operator sets the desired temperature. The usual limit is 60°C for 60–90 seconds. If the threshold for stimulation is high, a higher temperature setting is needed for lesioning. The end point is hypoalgesia (tested with a pin on the face) and not hypoaesthesia. This can of course be tested only when the patient awakens enough from the anaesthesia. If adequate numbing has not been achieved, additional lesions can be made in 5°C increments up to 80°C. If the smaller cordotomy type electrode is used, anaesthesia may not be needed and this ensures sensory testing as the lesioning proceeds. However, the cordotomy electrodes do not generally permit temperature monitoring. Corneal sensation can be protected by repeatedly testing the blink repose to light touch over the eyelid or eyelashes. Tew electrodes are smaller than the standard ones and are curved. The incidence of motor palsy, corneal anaesthesia and dysaesthesia are lower with the Tew electrode.[65]

Results of Percutaneous Radiofrequency Thermocoagulation

About 93% of patients undergoing PRFTC report immediate and excellent or good pain relief. Around 15% have recurrence of pain within 5 years and by 15 years an additional 10% have had recurrence of pain. There is an inverse relation between the degree of hypalgesia achieved during the procedure and subsequent recurrence. The sensory loss might not trouble most patients in the mandibular or maxillary division but corneal anaesthesia with neurogenic keratitis occurs in about 9% of patients. Painful dysaesthesia (20%) and anaesthesia dolorosa (1%) are other undesirable effects.[65] Masticatory weakness due to motor root involvement is seen in about 20% but it generally resolves fully in 3–6 months. The rare complications are carotid-cavernous fistula, monocular blindness and 6th nerve palsy.[25]

Percutaneous Trigeminal Balloon Compression (PTBC)

This procedure may be looked upon as a closed version of the original Shelden procedure of open trigeminal ganglion compression, reported in 1955.

Technique of Percutaneous Trigeminal Balloon Compression

In the procedure described by Mullan and Lichtor, a 14G needle is passed percutaneously up to the foramen ovale but not into it. A balloon catheter is pushed for 1 cm beyond the needle tip and is inflated to 0.5 cc for about 1–10 minutes.[68] The balloon inflates to a pear shape and this can be seen under image intensifier screening, as the inflation is done with iohexol. The shorter balloon inflation time is associated with lower rates of initial pain relief, lesser facial dysaesthesia and a higher recurrence risk. Higher inflation pressures are associated with greater incidence of transient bradycardia, severe hypertension or hypotension during the procedure. The incidence of trigeminal motor weakness is the highest with PTBC as compared to PRGR or PRFTC.

Results of Percutaneous Trigeminal Balloon Compression

In one 20-year follow-up study, all except one of 522 completed procedures had initial improvement in their pain. Recurrence rate was 19% at 5 years and 32% over 20 years. Painful dysaesthesia occurred in 4% but there was no neurogenic keratitis or anaesthesia dolorosa.[87]

Comparison of the Three Percutaneous Ablative Techniques

There are several studies of each of the percutaneous techniques but there has been no randomised study comparing the three methods so far. Morgan and Tew have analysed the results of studies since 1989 reporting 100 patients or more for each of the techniques. Table 5 is derived from their exhaustive analysis. The references to the individual studies are given in their analysis.[65] The largest reported experience is with PRFTC and this has also had the longest follow-up reports. Dense sensory loss is associated with higher rates of pain relief, less

Table 5: Comparison of the three percutaneous ablative techniques for treating trigeminal neuralgia[65]

	PRGR	*PRFTC*	*PTBC*
No. of studies	12	14	9
No. of patients	2,273	8,246	1,737
Follow-up (years)	5	7	4.3
Long-term pain relief	57%	71%	76%
Troublesome dysaesthesia	4.5%	5.5%	6%
Corneal anaesthesia	4.3%	5%	0.4%
Trigeminal motor weakness	1.1%	11%	8.4%
Cranial nerve palsy	0%	0.6%	0.6%
Minor morbidity	0.6%	0.3%	0.3%
Major morbidity/mortality	0.2%	0.1%	0.1%

recurrence rate, longer time to recur and higher rate of troublesome dysaesthesia.

Microvascular Decompression

MVD surgery has been dealt with extensively in another chapter of this textbook. Hence, only some pertinent issues and findings from recent literature are addressed here.

Table 6 summarises the indications and contraindications for MVD. Fitness rather than the age should be the determinant.[5] None of these are absolute and there is every need to tailor-make the decision to the patient.

Microvascular decompression surgery can be accomplished in a minimally invasive manner. Over the years, the size of the incision and the bony opening has diminished. Self-retaining cerebellar retractors can often be dismissed, especially when an endoscope is also used. Personal preference is not to use self-retaining retractors as far as possible, as we feel that the retraction distorts the vascular relations to the nerve. Retraction has been associated with hearing impairment and with accidental tear of the petrosal vein.[84] A contrary opinion, favouring the use of self-retaining retractor is expressed in a recent

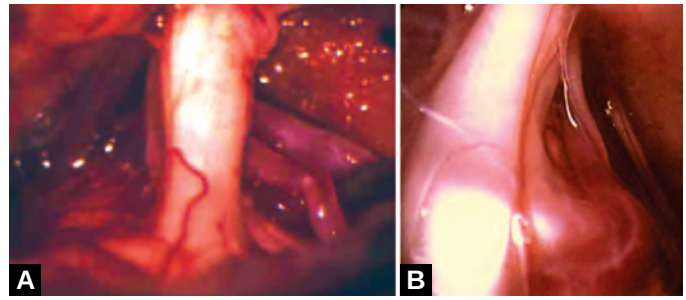
Table 6: Indications and contraindications for MVD

Indications for MVD

- Failure of medical therapy
  - Lack of initial response
  - Escape of control with medication over time
  - Unacceptable side effects of medication
- Patient fit for anaesthesia
- V1 division pain (singly or in combination)
- MR demonstrable compression/distortion by vessel
- As a primary procedure for fit patients, especially the young
- As a secondary procedure when pain recurs after a previous ablative procedure
- Tic convulsif-associated need for facial MVD
- Patient choice (those who are averse to facial sensory loss)

Contraindications for MVD

- High anaesthetic risk, medical risk
- Anaesthesia dolorosa from a previous ablative procedure
- Pain on the side of the only good hearing ear
- Very elderly patient



Figs 5A and B: Comparison of the views obtained of the left trigeminal root entry zone and the superior cerebellar artery vascular compression from microscopic. (A) and endoscopic. (B) perspectives in two different patients

article.[33] A bulge from the petrous bone (endostosis) may cover the view of the trigeminal nerve in about 4% of cases. It can be drilled away or endoscopic assistance can be used to avoid drilling.[83]

While some prefer to do the vascular mobilisation under the endoscope, others (including me) prefer to use the endoscope as a visualising tool (see Figures 5A and B for comparing the microscopic and endoscopic view of the trigeminal root entry zone and the vascular conflict). This is especially so for compression on the ventral portion of the root. In one study, of 113 endoscopically assisted MVD procedures, in 38 patients (33%), endoscopy revealed arteries that were poorly seen (25%) or not seen at all (8%) with the microscope.[90] Dolichoectatic vessels are no longer a contraindication for MVD. On exploration, a non-dolichoectatic vessel or vein may be found to be the cause of the trigeminal root entry zone compression, rather than the dolichoectatic vessel *per se*. Even if the dolichoectatic vessel were found directly distorting the root, it can be effectively encircled.[95] Use of fenestrated aneurysm clip and sling to draw a vessel away from the nerve is a recently described technique, for long and ectatic arteries that repeatedly fall back into a position of compression, despite adequate arachnoid dissection.[7] The distance between the acousticofacial bundle and the trigeminal nerve is small when the tentorial angle is steep (< 50°) and this limits the space for vascular manipulation.[80]

Every series of MVD has shown a fall in the complication rate, as experience builds up and as technical modifications are adopted.[62] The recurrence rate was higher when muscle was used as the interposing substance. Muscle was replaced by polytetrafluoroethylene (PTFE-Teflon®) pledgets. These pledgets must be fluffy and cut to the required shape and size. The pledget must be placed in contact with the vessel, rather than in close contact to the nerve. Persistent headache due to aseptic meningitis and Teflon® induced granuloma have been reported.[14,16] Transient brainstem signal intensity change on MRI after MVD has been noted.[3] The mortality for trigeminal MVD is mainly due to cerebellar injury and brainstem infarction. The petrosal vein has been coagulated and divided with no consequences in many patients, while there are reports of death due to venous infarction of

the brainstem after petrosal vein tear or intentional coagulation.[62,84] The complications of trigeminal MVD, their frequency in the author's personal series and the techniques of avoidance are listed in Table 7.

Table 7: Complications and avoidance of complications of MVD (figures from personal series)

Complications and avoidance—Trigeminal MVD	*Frequency N = 98*	*Avoidance*
New facial numbness	3%	Avoid coagulation on V nerve, irrigation during small vein coagulation, keep Teflon away from nerve
Hearing impairment	4%	Avoid excess retraction, avoid tailed cottonoids on VII-VIII nerves, BAER monitoring[75]
Vestibular syndrome	4%	Same as above, wax mastoid air cells on the way in and out
Facial paresis	3%	Same as for VIII nerve. Occurred in a delayed fashion in two patients due to? Teflon reaction, responded to steroids in 2–3 weeks
Trochlear palsy	0%	Reported in literature Avoid dissecting on tent undersurface, ensure that Teflon is not pushed too high
Abducent paresis	2%	Use low pressure suction, take care when mobilising dolichoectatic vessel
CSF leak	5%	May be from wound, ear or through nose (paradoxical rhinorrhoea). Meticulous dural closure, if needed with pericranial graft, is essential. Waxing mastoid air cells
Pseudomeningocoele	1%	Dural closure, bone replacement. May need lumbar drainage
Meningitis	2%	Peri-operative antibiotics, avoid CSF leak
Chronic operation site pain	10%	Avoid cutting greater occipital nerve during exposure, replace bone at craniectomy site
Brainstem infarct	1%	Petrosal and pontomesencephalic vein coagulation to be avoided
Cerebellar infarction or haematoma	1%	Adequate CSF drainage before retraction, intermittent release of retractor, avoid a retractor that juts out of the field too much which may be bumped accidentally
Supratentorial haematoma	1%	Avoid excessive CSF suctioning, avoid mannitol, take care when applying the pins of the head frame

The early long-term results of MVD have been well documented.[11] The best results come from centres and surgeons with a high volume of work.[46] The results are always better in those who have not undergone a previous ablative procedure. While failures may be due to missed vessels, recurrences might be due to recanalisation of veins.[56] The results from a personal series of 98 cases of trigeminal MVD are presented in Table 8. This is in keeping with the much larger series of cases.

To summarise, the advantages of MVD over the ablative procedures are the near-absence of facial sensory loss, least long-term recurrence and the best patient satisfaction in the successful cases. These must be balanced against higher cost, a slightly higher risk of neighbourhood neurological dysfunction and mortality. At the present time MVD seems to be closest to the ideal goals set in Table 4.

Partial Sensory Rhizotomy

The middle fossa rhizotomy procedures are now history. The posterior fossa procedure is done during the course of MVD operation, if no vascular compression is seen. The facial numbness is lasting and the inferior part of the nerve is spared for preserving corneal sensation. Naturally, the patients undergoing PSR are less satisfied with the outcome than those getting relieved with MVD.[98]

Radiosurgery

The latest (and the most expensive) method of treating trigeminal neuralgia is to ablate the retrogasserian cisternal part of the trigeminal nerve with gamma knife radiosurgery. Linear accelerator based radiosurgery seems to be nearly as effective.[34] The lower radiation dose (70 Gy) with a single 4 mm isocentre results in less sensory dysaesthesia. Two isocentres and an initial higher dose (90 Gy) appear to relieve pain better and faster—even this takes about 3 weeks.[4] Targeting with MRI is superior to targeting with CT.[100] Generally, some relief is reported in around 80% of patients. Troublesome sensory loss is seen in 10%.[54] A recent study reports relief in 44% and improvement in 70% at 3 years.[82] Radiosurgery has been used in patients with multiple sclerosis but they fare poorer than the idiopathic variety. In a retrospective comparison (of prospectively maintained data), it was found that posterior fossa exploration (MVD and PSR) gave better outcome than radiosurgery.[74]

CONCLUSION

From purging prescribed by Locke to gamma knife radiosurgery, we have come a long way in treating trigeminal neuralgia. It is sobering that till date no randomised controlled trial is available to compare the results of the various procedures used to treat trigeminal neuralgia (and none is in the offing). Therefore, the surgeon has to base his decisions on level 3 evidence at best and blend it with the surgeon's personal experience. It is essential

Table 8: Early and follow-up results of trigeminal MVD (personal series)

	Results of Trigeminal MVD			
	All cases	*Primary MVD*	*MVD after ablative procedure*	*Comments*
Early results	N = 98	N = 77	N = 21	
Total relief	91%	96%	77%	4 patients took a week to get relief
Partial relief, reduced medication	4%	1.3%	14%	
No relief	2%	1.3%	4.5%	1 had no compression, rhizotomy not done. 1 had vein that could not be mobilised
Disabled/death	2%	1.3%	4.5%	1 disabled from cerebellar haemorrhagic infarction, 1 petrosal vein coagulation led to brainstem infarction
Follow-up results (minimum 5 years, longest 12 years)	N = 47	N = 38	N = 9	
No recurrence	81%	84%	67%	
Recurrence, controlled with medication	13%	11%	22%	
Recurrence, not controlled with medication, needing another procedure	6%	5%	11%	

to inform the patient of the choices available, results and unwanted side effects, so as to make the patient a partner in choosing the treatment. A surgeon who is a one-trick pony should guard against the tendency to fit all his/her patients into a Procrustean bed. It is hoped that the future will allow us to raise the bar further towards the utopian ideal method of treatment alluded to earlier.

197 Glossopharyngeal and Other Cranial Neuralgia

Ravi Ramamurthi, Goutham Cugati

INTRODUCTION

Weisenberg, in 1910, was the first to describe severe pain in the distribution of the glossopharyngeal nerve.[60] The word glossopharyngeal neuralgia was coined by Harris in 1926.[17] It has a striking similarity to trigeminal neuralgia with a few exceptions.

CLINICAL FEATURES

Glossopharyngeal neuralgia is described as a paroxysmal painful condition confined to the somatosensory distribution of the IX nerve (ear, tonsillar region, larynx, posterior 1/3rd of tongue and nasopharynx) and triggered off by swallowing, coughing, laughing, speaking and yawning. The pain is described classically as lancinating and may last from a few seconds to several minutes. It can also cause an unpleasant sensation in these areas, palatal myoclonus, syncope and cardiac arrest. As is usual with paroxysmal painful syndromes, it is characterised by periods of exacerbation and remission. The period of remissions may vary from a few months to several years. The longest known remission is 20 years.[44,58] A very small percentage of patients with glossopharyngeal neuralgia occasionally become hypotensive, bradycardic, lose consciousness and have seizures associated with a paraoxysm of pain.[37] This syndrome, called vagoglossopharyngeal syncope, is due to enhanced vagal outflow. The association between glossopharyngeal neuralgia and syncope was initially described by Riley et al. in 1942.[42] The cause of seizures is thought to be due to cerebral infarction secondary to episodes of asystole.[41]

CAUSES

Glossopharyngeal neuralgia is thought to be caused by irritation of the IX cranial nerve and most of the time the source of irritation is never found. Some of the known causes producing this type of pain are:

- Vascular loop pressing over the cisternal portion of the IX nerve
- Benign and malignant lesions of the skull base
- Local infections and tumours in the throat and mouth
- Eagle's syndrome
- Infarction (Lateral medullary)
- Multiple sclerosis.

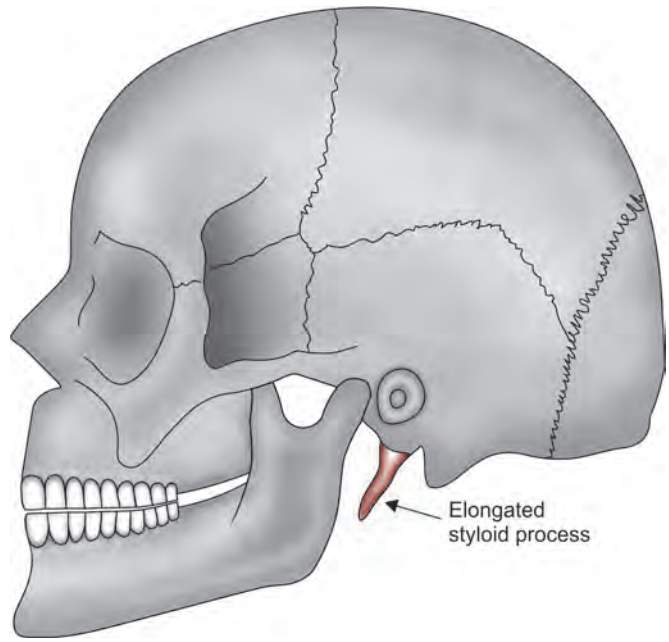

Fig. 1: Diagram of the skull showing elongated styloid process

In Eagle's syndrome, an elongated styloid process (Fig. 1) or an ossified stylohyoid ligament results in the compression of the glossopharyngeal nerve.[50] This has been described mostly as an acquired condition after trauma or a surgical procedure in the throat like tonsillectomy.[27] Chiari type I malformation presenting as glossopharyngeal neuralgia has been reported by Kanpolat et al.[25]

Although there has not been so strong an association of glossopharyngeal neuralgia and multiple sclerosis as seen with trigeminal neuralgia, there have been reports of glossopharyngeal neuralgia being seen in patients with multiple sclerosis.[24,44]

EPIDEMIOLOGY

A comparison of epidemiological and clinical features of trigeminal neuralgia and glossopharyngeal neuralgia in Rochester revealed that the overall age and sex adjusted annual incidence rates were significantly higher for trigeminal neuralgia than for glossopharyngeal neuralgia (4.7 vs 0.8 per 100,000 population).[26] The ratio of incidence of trigeminal neuralgia to glossopharyngeal neuralgia as described by Spruling and Grantham[53] is

70:1, by Brzustowicz[10] 88:1 and by Böhm and Strang[7] 100:1. Glossopharyngeal neuralgia is milder than trigeminal neuralgia, as indicated by the number of episodes, treatment and characterisation of pain. The right side is affected more often and bilateral involvement is less common in trigeminal neuralgia, as compared to glossopharyngeal neuralgia.[26]

EXAMINATION

The patient suffering from glossopharyngeal neuralgia may not have any neurological deficits. If a lesion in the skull base is the cause for the neuralgia, there may be multiple cranial nerve deficits, depending on the extent of the lesion. An enlarged styloid process may be palpable in the tonsillar fossa as in Eagle's syndrome. Digital palpation of the styloid process often reproduces pain or a foreign-body sensation.[27] A thorough ENT evaluation is required if local pathology is suspected.

DIAGNOSIS

Previously, cocaine test was used to confirm glossopharyngeal neuralgia. This was first used at the Mayo Clinic in 1925. The application of 10% cocaine solution to the throat gives relief of pain in a classical patient with glossopharyngeal neuralgia and also predicts a better outcome from surgery.[44] X-ray lateral views of the skull base and cervical spine may show an enlarged styloid process ipsilateral to the side of pain which helps to diagnose Eagle's syndrome.[27] ECG is mandatory for all patients and especially those having syncopal attacks. ECG monitoring, done during swallowing induced syncope (loop monitoring), shows cardiac asystole which is characteristic of glossopharyngeal neuralgia.[30]

MRI is an important investigation to rule out a tumour, one of the common causes of symptomatic glossopharyngeal neuralgia. Gadolinium enhanced images will pick up even small lesions and, in larger lesions, it clearly delineates the extent of the tumour. Schmitz et al.[48] and Huang et al.[21] proposed that 3D constructive interference in steady state (CISS) and 3D fast imaging with steady-state free precession (FISP) MR angiography, may be useful for evaluating neurovascular contact of the nerve root exit zone of the glossopharyngeal nerve, which is located in the supraolivary fossette. The posterior inferior cerebellar artery (PICA) is the most common offender followed by the vertebral artery, the anterior inferior cerebellar artery (AICA) and other vessels or combinations of vessels.[20,25,38,39,46] Brihaye et al.[8] and Kondo[29] have observed a tortuous and atheromatous vertebral artery as the offender in glossopharyngeal neuralgia. The AICA divides into cranial and caudal branches of which the caudal trunk is supposed to be in proximity to the nerve root entry zone. The diameter of the offending artery was also found to be greater as compared to the opposite side.[20]

Balloon occlusion test using double microcatheter technique helps to identify the vessel responsible for glossopharyngeal neuralgia. Once the microcatheter is in the desired vessel, the balloon is inflated to block the vessel which will make the pain disappear, while deflation of the balloon reproduces the pain. This test is repeated several times and the same pattern seen consistently confirms vascular compression as the aetiology. This way, patient selection for MVD can be done. This procedure may lead to complications like thromboembolism, balloon migration, premature deflation and others.[18]

TREATMENT

Medical Management

The medical management of this condition is similar to that of trigeminal neuralgia and the medications used include carbamazepine, oxcarbazepine, gabapentin, pregabalin, phenytoin and several other newer antiepileptics.[34] Antidepressants like amytriptyline have also been used in treating this condition. Neuropathic pain is generally not controlled by opioids. However, Kouzaki et al.[32] have described the usefulness of opioids in glossopharyngeal neuralgia and enumerated the possible mechanisms. Opioids control neuropathic pain by their effects on cortical brain regions and the thalamus, the descending antinociceptive pathway (via actions on the periaqueductal grey matter) and by modulating pain transmission in the spinal dorsal horn.

Surgical Management

Surgery should be advised when medical management fails to control the pain. This can be microvascular decompression in the posterior fossa or section of the glossopharyngeal roots in the neck or in the posterior fossa.[2,14,35] The supraolivary fossette, which is the most medial portion of the cerebello-ponto-medullary angle, is close to the root entry zone of the glossopharyngeal nerve and is the vulnerable location for neurovascular decompression surgery.[46] In patients with cardiac syncope, peri-operative placement of a temporary pacemaker is advocated.[15]

Microvascular Decompression

(Refer to Chapter 199 on microvascular decompression.) Glossopharyngeal nerve root section in the posterior fossa gives good results. Before surgery, if the patient is weak from malnutrition, as a result of difficulty in swallowing due to severe pain, application of a local anaesthetic to the throat before each meal would help the patient pick up strength. The glossopharyngeal nerve emerges out of the skull along with the vagus nerve roots through the jugular foramen. The glossopharyngeal roots are rostral and are identified from the vagal roots by a dural partition, which separates the fibres at their exit from the skull. This makes it easy to pick up and divide the glossopharyngeal roots. Gentle handling is necessary while isolating the nerve roots, to avoid

cardiac abnormalities and sudden changes in blood pressure. Sometimes, division of the glossopharyngeal root may give rise to an increase in blood pressure due to its connection with the carotid sinus. As the posterior auricular branch of the vagus nerve is at times involved in the pain, a few rostral fibres of the vagus nerve should also be divided.[11,14,48,55] The results of glossopharyngeal section are most gratifying. Transcranial endoscopic approach for glossopharyngeal neurotomy has also been tried with good outcome.[5]

Ferroli et al. in their series of 31 patients found vascular compression of the IX cranial nerve in all the patients.[16] It is found that the offending vessels are usually the branches of the posterior inferior cerebellar artery, vertebral and rarely AICA. There is a possibility of a hypertensive crisis, while handling the glossopharyngeal roots at the root entry zone near the brainstem.

Resurgery (MVD) in patients with recurrent glossopharyngeal neuralgia has been performed with good results. Patients who had evidence of vascular compression in their initial surgery, followed by drug resistant recurrence of pain are the ideal candidates for resurgery.[16] Recently, there has been a report of keyhole microsurgery with good outcome.[36] Gamma knife radiosurgery has been used for intractable pain with the target being the distal part of the nerve and the maximum dosage being 75 Gy. More studies are awaited to determine the optimal radiation dose and target of GKS for achieving long-term pain relief.[61]

Resection of the elongated styloid process or the ossified stylohyoid ligament will provide relief of pain in Eagle's syndrome. A lateral transcutaneous approach and resection is required.[50]

Other Ablative Procedures

Percutaneous rhizotomy of the glossopharyngeal nerve in the jugular foramen should be undertaken only by surgeons trained in this technique. The surgeon and patient have to be aware of the unavoidable sensorimotor deficits of the IX and X nerves.[51] Tractonucleotomies at the medullary level should be reserved essentially for pain of malignant origin.[51] Microwave ablation of the glossopharyngeal nerve has been tried.[57]

Complications

Post-operative complications of surgical treatment of glossopharyngeal neuralgia have been described in many series:

- Sensory and motor deficits of IX and X nerves
- Vocal cord paralysis[36]
- Cerebellar or/and brainstem infarction
- Hypertensive crisis
- CSF leak and pseudomeningocoele
- Intra-operative mortality.[57]

GENICULATE NEURALGIA

Geniculate neuralgia, also known as nervus intermedius neuralgia, is characterised by pain deep in the ear radiating to the pinna. The pain is lancinating and, unlike other typical neuralgic pains, may last for an hour or so. It is due to abnormalities of the somatosensory branch of the VII cranial nerve (nervus intermedius of Wrisburg) and the geniculate ganglion. Patients have also complained of having salivation, bitter taste, tinnitus and vertigo during the pain attacks which might reflect the central connections of the nervus intermedius.[23]

The pathology in this condition is presumed to be similar to any other neurovascular compression, where a vascular loop is causing compression over the root exit zone of the nervus intermedius.[23] Jannetta has described microvascular decompression for such patients with favourable results. Geniculate neuralgia can also be seen in Ramsay Hunt syndrome which is caused by varicella zoster virus. Rash with facial paralysis are the additional features seen in patients with Ramsay Hunt syndrome.[56]

Geniculate neuralgia may respond to carbamezapine. Operative treatment consists of MVD or section of the nervus intermedius or the geniculate ganglion. This was first done by Clark and Taylor in 1909. Rupa et al.[43] recommend a combined posterior fossa-middle fossa approach for adequate exploration and/or section of the V, IX and X cranial nerves, as well as the geniculate ganglion and nervus intermedius. Sachs[45] recommended surgery under local anaesthesia, so that the nerve may be stimulated and the patients' pain confirmed. Gamma knife is an alternative, but studies on the outcome are awaited.[23]

PERSISTENT IDIOPATHIC FACIAL PAIN

Persistent idiopathic facial pain (PIFP) refers to pain along the trigeminal nerve distribution that does not fit into the classical description of other cranial neuralgias. Previously termed as atypical facial pain, in 1924, by Frazier and Russel, there is no obvious cause and the pathophysiology is unknown.[13,54]

The International Headache Society defines PIFP as follows:[19,54]

- Pain in the face
- Pain confined at onset to a limited area on one side of the face, which is poorly localised
- Pain present throughout or for most of the day and daily
- No sensory loss or other physical signs
- No abnormalities in laboratory or imaging studies.

This entity predominantly affects adults with no sex predilection. Neurological examination is essentially normal. PIFP is a diagnosis of exclusion. Hence, the more common causes of facial pain need to be excluded with all available facilities before coming to the diagnosis of PIFP. Contrast MRI is the investigation of choice.

Treating this condition is difficult and is less effective than in other facial pain syndromes. Medications used include anticonvulsants, antidepressants, topical anaesthetic agents and narcotics. Kuhner[33] stresses that destructive trigeminal surgery has no role in the

treatment of this condition and quotes figures of more than 58% deteriorating after surgery. Multimodality approach with involvement of a psychiatrist and pain therapist is appropriate.[13,54]

TOLOSA-HUNT SYNDROME (PAINFUL OPHTHALMOPLEGIA)

This syndrome is a non-specific inflammatory process in the region of the cavernous sinus/superior orbital fissure. It is characterised by periorbital or hemicranial pain, ipsilateral ocular nerve palsies, oculosympathetic paralysis and sensory impairment in the trigeminal nerve distribution (mainly ophthalmic and occasionally maxillary division). Occasionally, there may be additional cranial nerves palsies (II, V2, VII) ipsilateral to the ophthalmoplegia. Having a relapsing and remitting course, they respond promptly to systemic corticosteroid therapy.[28]

In 1954, Tolosa[59] first reported a patient with left orbital pain, ipsilateral progressive visual loss, total left ophthalmoplegia and reduced sensation over the first division of the trigeminal nerve. Per-operatively no abnormality was found and the patient died in 3 days. Granulomatous inflammation of the carotid artery and cavernous sinus was found at post-mortem. In 1961, Hunt et al.[22] described a clinical entity similar to that of Tolosa. In 1966, Smith and Taxdal[52] named it "Tolosa-Hunt syndrome".

This syndrome affects patients of any age group and there is no sex predilection. There have been reports of bilateral involvement.[9] Orbital pain usually lasts for 2 weeks. All the three nerves supplying the external ocular muscles can be involved in various combinations. There have been reports of involvement of the optic nerve which might favour pathology around the orbital apex.[3,63] There have been reports of involvement of cranial nerves away from the orbital apex or cavernous sinus, like the mandibular or maxillary divisions of the trigeminal nerve and the facial nerve.[1,28,47]

The differential diagnosis of this condition is trauma, neoplasm or aneurysm in the region of the cavernous sinus/superior orbital fissure.[28] Contrast enhanced MRI is the investigation of choice. Coronal views may show abnormal soft tissue with contrast enhancement in the region of the cavernous sinus, the intensity of which is similar to an inflammatory process. High resolution CT can demonstrate the same, but is less sensitive. The findings on the MRI may be confused for a cavernous sinus meningioma, lymphoma or sarcoidosis. Hence, post-steroid therapy MRI showing decrease in the size of the lesion is considered diagnostic.[31,49,62] Cerebral angiogram has showed segmental narrowing of the intracavernous carotid artery, which also resolves with corticosteroid administration. Biopsy of the lesion is done as a last resort.

Corticosteroids have been used effectively for treating this condition. They dramatically decrease the periorbital pain and also shorten the natural course of the disease.[28,49] Tolosa Hunt syndrome is a diagnosis of exclusion where all the probable causes of a parasellar lesion causing painful ophthalmoplegia are ruled out.

OCCIPITAL NEURALGIA

Occipital neuralgia is caused by irritation of the greater occipital nerve, the causes being entrapment of the nerve in the trapezius muscle due to post-operative scarring or injury to the nerve. Patients may have unilateral or bilateral throbbing pain over the occipital region. Since the greater occipital nerve receives branches from the superior cervical sympathetic ganglion, the trigeminal ganglion, acoustic and vestibular nerves, it may produce additional symptoms of vomiting, nausea, vertigo and photophobia.[6,12,40] Pressure on the greater occipital nerve will produce a positive Tinnel's sign.[40]

Potentially dangerous conditions, like craniovertebral junction pathologies which may produce similar symptoms, have to be ruled out before coming to the conclusion of occipital neuralgia.[40] Nerve block will often relieve the patient of the neuralgic pain. In patients with persistent pain, nerve decompression or sectioning of the nerve stem, which causes loss of feeling in the occipital region, may be required.[4]

COSTEN'S SYNDROME

Costen's syndrome is temporomandibular joint dysfunction characterised by aching pain felt in front of the ear which is aggravated by chewing. It is due to mal-alignment of the TM joint or rarely to rheumatoid arthritis.

READER'S SYNDROME

Reader's syndrome also called the paratrigeminal syndrome is characterised by pain around the eye associated with a sympathetic paresis (ptosis and small pupil) and is usually associated with granulomatous lesions or nasopharyngeal carcinoma involving the middle fossa.

Other different varieties of pain syndromes may be encountered in practice. Some patients have a combination of the features of trigeminal neuralgia and ciliary neuralgia. The pain occurs in paroxysms and is accompanied by redness and watering of the eyes. Simultaneously, there are trigger zones in the forehead and around the eye that initiate the paroxysm. A combination of carbamezapine and ergot therapy has been found effective.

198 Microvascular Decompression

Ravi Ramamurthi, Manish Singh

For long, the treatment of conditions, like trigeminal neuralgia (TN), glossopharyngeal neuralgia and hemifacial spasm (HFS), was based on disruption of the conductivity of central and peripheral nerve pathways through various techniques. These procedures led to relief in most of the cases, but at the cost of sensory or motor loss or the possibility of recurrence. The real pathophysiology was not clear till several observers beginning with Dandy, Gardner, Rand and Jannetta showed compression of nerve elements by neighbouring vascular structures and produced good relief by eliminating such compression of the nerves by the blood vessel. Now microvascular decompression (MVD) has become an established procedure for the relief of several syndromes.

The proximity of the blood vessels to the nerves in the cerebellopontine angle makes the cranial nerves vulnerable to compression by the blood vessels. This compression is a major cause of trigeminal neuralgia (V), hemifacial spasm (VII) and glossopharyngeal neuralgia (IX). It may also cause vertigo (VIII), tinnitus (VIII), hypertension (X) and spasmodic torticollis (XI).

HISTORY

Dandy,[19,20,21] reporting on a series of 215 patients with TN, found an artery compressing the nerve in 66 cases and a vein in 30 cases. Gardner,[34] using the posterior fossa approach to treat patients with recurrence of pain following the middle cranial fossa approach, found vascular compression of the trigeminal nerve in one-third. Gardner and Miklos[32] interposed a piece of Gelfoam® between the offending artery and the trigeminal sensory root. Rand and Jannetta[47] introduced and popularised vascular decompression using microsurgical techniques. The first report from India was by Virani and Palande,[111] in 1985.

Campbell and Keedy[12] found vascular compression of the facial nerve in HFS. Dandy,[20] in 1932, treated Meniere's disease with vascular decompression of the vestibular nerve. Lille and McCraig[65] reported on improvement in hearing after decompressing the auditory nerve. Laha and Jannetta[61] reported on MVD in glossopharyngeal neuralgia. Jannetta and Gendell[45] decompressed the left lateral medulla for hypertension as did Fien and Frishman.[28] Freckmann et al.[31] and Pagni et al.[72,78] reported on successful treatment of spasmodic torticollis by MVD.

PATHOPHYSIOLOGY

It has been proposed that a number of cranial nerve dysfunction syndromes are caused by vascular cross compression of the root entry zone (REZ) of the appropriate cranial nerve. This may be a direct reflection of the ageing process[13,29,46,47,59,110] which leads to: (a) arteriosclerotic degeneration of the arteries resulting in their elongation and (b) in hind brain sag (descent) which causes abnormal contacts between the blood vessels and the lower cranial nerves.

The arteries in the posterior fossa arise anteriorly and travel posterolaterally around the brainstem and have a relatively long course. Elongation of these arteries by sagging of the brainstem may cause abnormal neurovascular contacts. The relation between the neural structures and the veins, both intrinsic and bridging veins, may also be altered. The abnormal neurovascular contact may cause hyper or hypoactivity, depending on the site of contact and the rapidity with which this contact occurs. In general, hyperactivity results when there is a gradually progressive compression at the point on the nerve where peripheral myelin (Schwann cell) changes to central myelin (oligodendroglia). This area is at the root entry zone (REZ) of the V and VII nerves and in the VIII nerve is located peripherally, near the internal auditory meatus. It had been assumed that vascular contact at the REZ was solely responsible for the dysfunction. De Ridder[22] et al. have divided the nerves into a central nervous system (CNS) segment and a peripheral nervous system (PNS) segment, separated by the REZ. They have proposed that compression on the CNS segment alone causes symptoms. The PNS part is quite resistant to compression. Sindou et al.[99] in their anatomical observations during surgery for TN, found in addition to vascular compression, that alterations were seen in the whole trigeminal nerve. In 42%, there was significant global atrophy, in 18.2% local thickening of the arachnoid adherent to the nerve, in 12.6% the nerve was severely angulated while crossing the petrous ridge and in 3.9% the nerve was compressed between the pons and the petrous bone due to the small size of the posterior fossa.

The chronic compression causes transaxonal short circuiting of the action potential in the nerve.[32,34] Segmental demyelination of A alpha and beta fibres

occurs in the region of transition and results in artificial synapses with ephaptic transmission between fibres carrying different sensations.[10,25,56] Spontaneous discharges may occur at the site of compression[33,114] and pathophysiological changes occur in the nucleus due to the chronic compression. Bannett and Jannetta[5] presented data on evoked potentials studied in patients with TN. There was increased latency and threshold consistent with V nerve compression. Patients with atypical facial pain did not have similar findings. The presence of pre-operative evoked potential abnormalities was associated with post-operative pain relief.

TRIGEMINAL NEURALGIA

Selection of Patients

The indications for MVD are failed medical therapy using carbamazepine, phenytoin or both, or when the patient has adverse reactions to medication. Fitness for anaesthesia and major surgery is vital in older patients and the usually accepted cut off point is 65–70 years of age. Older patients may also be operated upon, if found fit. Elderly patients have been operated upon and good results have been reported.[16,77]

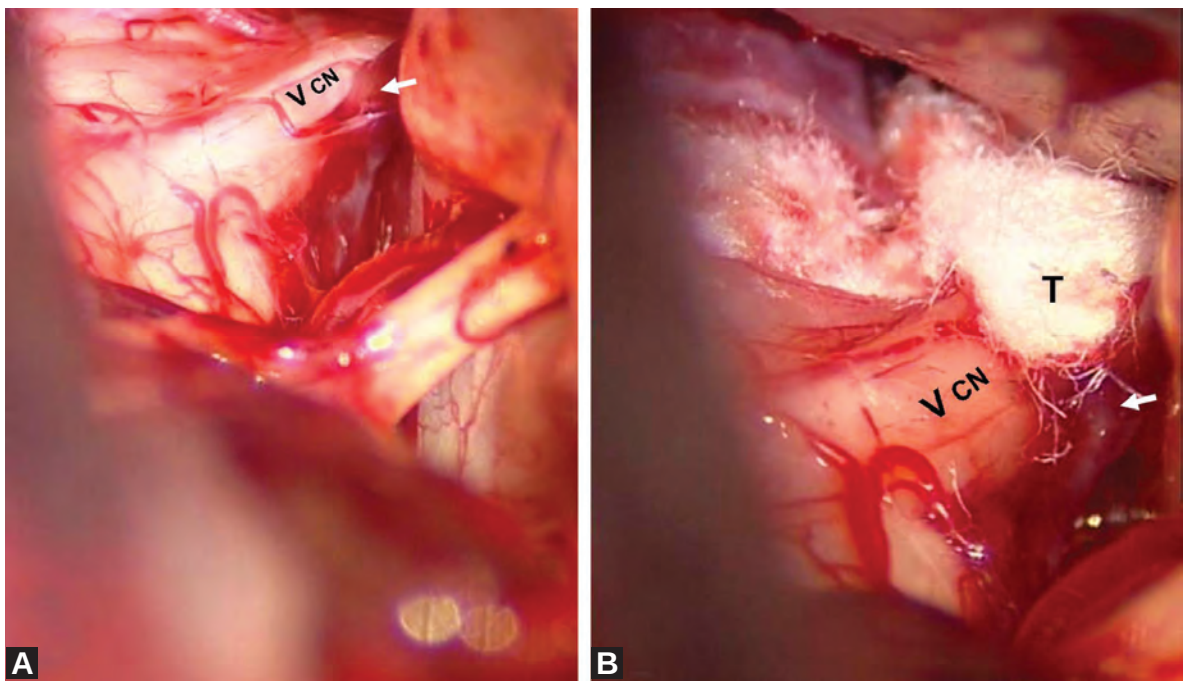
Investigations

Plain skull X-rays are done to see the configuration of the skull, especially the posterior fossa and are useful in planning the craniectomy. The size and aeration of the mastoid air cells are noted, as also of the auditory meatus and the petrous temporal bone.

CT scans and MRI are done to rule out extra-axial tumours, plaques of multiple sclerosis, ecstatic arteries and possible arteriovenous malformations. Three-dimensional time-of-flight magnetic resonance angiography (3D-TOF MRA) is useful in demonstrating cranial nerve compression, as well as in excluding other aetiologies.[14,60,94,104] A boundary imaging of fusion three dimensional (3D) magnetic resonance (MR) cisternogram/angiogram has been used for virtual assessment of the spatial relationship of the neurovascular compression at the REZ.[95] Pre-operative imaging of the neurovascular structures can be performed using constructive interference in the steady state magnetic resonance (CISS MR) imaging, which consists of 2D images. The 3D visualisation is generated after segmentation of the CISS MR imaging in combination with direct volume rendering (DVR) in the operating room.[104] Electrophysiological tests are useful in pre-operative assessment and in post-operative follow-up and include otovestibular testing, BAER and trigeminal evoked potentials.

Anatomy of the Trigeminal Nerve in the Cerebellopontine Angle

The root entry zone (REZ) of the trigeminal nerve is the first one centimetre of the nerve after it has emerged from the pons.[38] In its intradural course, the nerve emerges from the lateral part of the pons just inferomedial to the ala of the cerebellum and runs obliquely upwards, towards the petrous apex and enters Meckel's cave, leaving the posterior fossa beneath the tentorial attachment.[39] The angle of entry of the trigeminal nerve into the pons is acute and in some cases the portion near the pons may be parallel to the pons (Figs 1A and B).



Figs 1A and B: (A) Intra-operative picture of a patient with trigeminal neuralgia showing a vascular loop (white arrow) around the trigeminal nerve (V CN) in the right CP angle. (B) Teflon (T) placed between the trigeminal nerve (V CN) and the vascular loop

The number of fascicles is variable, as is the diameter of the nerve. About a hundred fascicles, which form the dorsal root and emerge from Meckel's cave, coalesce about half to one centimetre from the pons into a gelatinous mass and this mass is surrounded by pia-mater and is called the portio major. This is the "fibrous cone" described by Dandy.[18]

About 20% of the sensory fascicles do not enter the "fibrous cone" and are separate from the portio major. They enter the pons between the portio major and the motor fibres. These fibres carry a considerable part of light touch and proprioception and, therefore, complete section of the portio major gives good results without much of touch and proprioception loss.

The motor part arises as a large number of fascicles, which join together 2 or 3 mm from the pons to form two distinct structures surrounded by pia mater. The motor part courses medial to the sensory root, crosses under the Gasserion ganglion and exits through the foramen ovale.

Surgical Procedure

The positioning of the patient depends on the surgeon and the best position to use is the one with which the surgeon and the anaesthetist are more comfortable and familiar. The positions that may be used are lateral, park bench, supine with head rotated, and sitting. Janetta et al.[42] have described the steps of surgery in detail.

A vertical retromastoid incision is made about half to one centimetre medial to the mastoid notch. The incision is 5–7 cm long and one-third of this should be superior to the nuchal line. The incision is carried down to the bone and craniectomy (2.5 cm x 2.5 cm) is done, exposing the transverse sinus superiorly and the sigmoid sinus laterally. It is essential to expose the junction of the transverse and the sigmoid sinuses. The dura may be opened in any convenient fashion, but it is essential to expose the junction between the superior and the lateral surfaces of the cerebellum.

The superior petrosal vein is identified and, if absolutely necessary, it is coagulated and divided, if it prevents access to the entire length of the trigeminal nerve. The ala of the cerebellum is retracted and the trigeminal nerve comes into view. The arachnoid over the nerve is dissected using sharp dissection and the whole nerve is exposed. The IV nerve lies above and parallel to the V nerve. In lower division TN, the offending vessel is usually the superior cerebellar artery compressing the nerve superiorly or anteriorly and in upper division TN, the anterior inferior cerebellar artery is often the offending artery. The whole complex of arterial loops is gently elevated from the nerve. Various substances, like Gelfoam®, muscle or plastic prosthesis-like Ivalon and shredded Teflon felt, have been interposed between the offending vessels and the nerve (Figs 1A and B). It is preferable to use non-absorbable materials, as the others may get absorbed before the vessel is permanently repositioned. In complicated cases such as re-operations and transpositions of long ectatic arteries, fenestrated aneurysm clips can be used to maintain transposition of the culprit vessels.[3,113]

When a vein is compressing the nerve and it cannot be separated from the nerve, it should be coagulated and divided. Care should be taken to see that too many veins are not sacrificed during the procedure. If adequate decompression of the nerve is not possible, then sectioning of the portio major gives good results.

The cross compression may be due to an arterial loop, a vein or a combination of both. Other causes are tumours, AVM and aneurysm. In a few patients there may be a negative exploration. The various causes of nerve compression are given in Table 1.

Results

In about 20–40% of the patients, some pain may persist in the immediate post-operative period. If the nerve had been manipulated during surgery, the post-operative pain is absent, but if it is not manipulated the pain may persist for a period of up to 2 months. This is not a true recurrence and this pain promptly responds to phenytoin therapy. True recurrence is seen when the pain occurs with the same intensity as pre-operatively and also if the pain subsides initially to recur with the same intensity 3–4 days post-operatively. In these patients it is better to re-operate within 2 weeks. Barker

Table 1: The various causes of nerve compression

Author	*Number of cases*	*Artery %*	*Veins %*	*Artery and veins %*	*Tumours %*	*AVM aneurysm %*	*Negative %*	*Arachnoiditis %*

Klun[58] (1992)	178	79	7	7	7	--	--	--

et al.[7] reported 70% excellent results and 4% good results on long-term follow-up of 1,185 patients. The overall long-term results in various series have been reported to be excellent in about 70% and good in an additional 4–7%.[1,15,49,50,100,112] The results in atypical TN have been excellent in 35% and good in 16%.[109] The results are worse when there is purely venous compression without an arterial component.[62] When there is late recurrence that is not controllable medically, repeat MVD or other procedures may be needed for pain relief. None of the patient related factors, like sex, age of the patient at surgery, hypertension, duration of pain or previous surgery, were found to have an influence on the outcome.[100] More severe the degree of compression, the better is the outcome. Patients with neuralgia involving the ophthalmic division of the trigeminal nerve had better long-term results than those without V1 involvement. When the neuralgia involved all three nerves, the outcome was worse. Older patients had a better outcome than the younger age group.[100] The relief from MVD after a prior destructive procedure has been reported to be not as good as when a previous procedure has not been done.[6,10,11,68,81,102,103] Later reports claim that this is not so.[44,100,105,108]

The mortality and morbidity are low. Four out of 1,000 in Jannetta's series[44] and three out of 500 patients in Apfelbaum's series 1 had a fatal outcome. Klun[58] has reported a mortality of 3/220 and Bederson et al.[8] no mortality. The cranial nerves IV (2–3%), VI (1%), VII (2%) or the VIII (3%) may be affected.[1,44,58] In later series, the complication rates have come down. This is attributable to improved techniques and increasing operator experience.[67]

The cranial nerve dysfunction that may occur is usually temporary, except in the case of the VIII nerve where there is usually permanent hearing loss. Cerebellar dysfunction due to infarction or haemorrhage may occur in a small percentage of patients. Rare complications, like polytetrafluoroethylene-induced granuloma, brainstem cyst and brainstem infarction, have been reported in literature.[101,102,107]

Various imaging changes, which occur in TN in the nerve and in the pons before and after TN, have been studied by Jawahar et al.[52] The brainstem was found to be normal in all patients before surgery. Eighty-eight patients had undergone one or more MVD procedures. In 34% the nerves were normal, 30.8% demonstrated perineural scarring, 28.4% a distortion of the course of the nerve, 23.8% had a brainstem infarction and 17% a persistent vascular compression.

HEMIFACIAL SPASM

HFS is more common in women than in men and more on the left side than the right side. Two types of HFS have to be differentiated, typical and atypical. Typical HFS, seen in 90% of patients, begins in the orbicularis oculi muscle and spreads caudally to involve the rest of the face. Atypical HFS, affecting 10% of patients, starts in the buccal muscles and spreads upwards. This differentiation is of surgical importance as, in typical HFS, the offending vessel is on the anterior caudal side of the nerve or on the pons over the intrapontine part of the facial nerve. In atypical HFS the vessel compresses the rostral posterior aspect of the nerve and may be located between the facial and the auditory nerves or above the auditory nerve.

Selection of Patients

MVD for HFS is a cosmetic operation and should be undertaken only if it seriously affects the patient's social or professional life. Patients who are fit for surgery are selected, age being no bar.

Anatomy of the Facial Nerve in the Cerebellopontine Angle

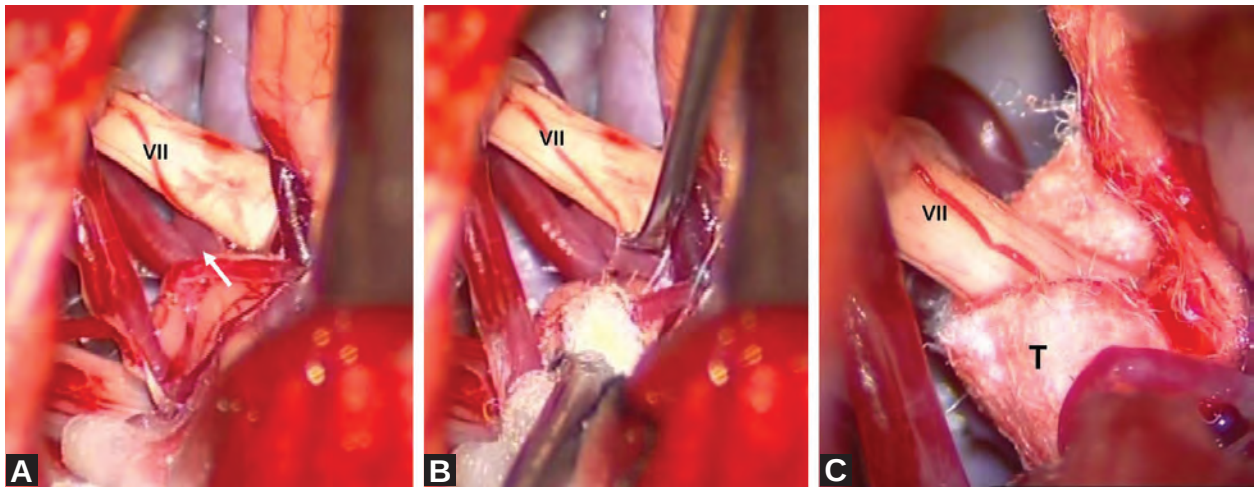
The facial nerve may be compressed either in its intrapontine or extrapontine course in the cerebellopontine angle. The junction zone between central and peripheral myelin is close to the exit of the nerve from the pons. The nerve runs superficially in the pons in a caudorostral direction starting at the pontomedullary junction. On exiting from the pons, it runs laterally in the cerebellopontine angle to enter the internal auditory meatus along with the VIII nerve and the nervous intermedius.

Surgical Technique

The anaesthesia and positioning are the same as for TN. The craniectomy is made more caudally and extends up to the sigmoid sinus laterally and the floor of the posterior cranial fossa inferiorly.

After opening the dura, the cerebellum is elevated from the floor of the posterior cranial fossa. It should not be retracted in a lateral to medial direction, to avoid injuring the VIII nerve and producing hearing loss. The IX and X cranial nerves are identified and the arachnoid over them is dissected with a sharp hook. The caudal cranial nerves are followed medially, till the flocculus is seen. The pons is then visualised as well as the choroid plexus at the lateral exit foramen of the IV ventricle. The VII nerve is thus approached from a caudal direction in typical HFS. The view of the VII nerve may be obstructed by the offending vessel, either single or multiple arteries or a vein. The dissection must be carried out all around the nerve to make sure that a second compressing vessel is not missed (Figs 2A to C). The technique and the materials used are the same as in TN. A whole range encircling method has been described by Qi which is claimed to be a safe approach, associated with high cure rate and minimises of the rate of recurrence and complications.[82]

BAER and direct monitoring of VIII nerve function during this operation have been found useful in preventing injury to the VIII nerve.[37,41,69,70,71,76] Facial muscle EMG is also useful to make sure that the compression has been relieved.[70] The lateral spread response (LSR)



Figs 2A to C: (A) Intra-operative picture of a patient with hemifacial spasm showing a vascular loop (white arrow) around the facial nerve (VII) in the left CP angle. (B) Gentle dissection being carried between the facial nerve and the vessel. (C) Teflon (T) placed around the facial nerve (VII) to prevent contact with the vascular loop

was studied in a series of 300 patients undergoing MVD for HFS by Doo-Sik Kong et al.[24] In 263 (87.7%), LSR was observed during surgery. In 230 (87.4%) of these 263, the LSR disappeared after decompression. The one year outcome was worse in patients in whom the LSR persisted following decompression.

Results

In the majority of patients the compression is by an artery. The offending arteries may be the AICA, PICA, vertebral or an ecstatic basilar artery. The anterior inferior cerebellar artery (42.6%) was found to be the main offending vessel by Yuan.[115] In 62% of patients there is a single artery, in 26% multiple arteries, 9% are compressed by an artery and a vein and it is purely venous in 2%. The remaining 1% may be due to tumour, AVM or aneurysm.[48]

In Japan, Kato et al.[55] summarised the results of long-term follow-up of 4,865 HFS patients who had undergone MVD in 23 hospitals. They found 83.7% of the patients were symptom free, there was some relief in 12.2% and the surgery failed in 4.1%. Other authors have also reported similar results.[90,115] Results of re-operation are quite good and in patients who have no response, re-operation must be considered.[27] It would be best to wait for a month before re-operation is decided upon. Nagahiro et al.[73] analysed the patterns of vascular compression in unsuccessfully treated patients. Good results are obtained with caudal compression by the AICA or PICA; however, the results were not as good in patients with compression by the vertebral artery or when the offending vessel was between the VII and VIII nerves.

The mortality is low 1/750.[48] The most common and permanent damage is ipsilateral hearing loss (3%). Transient facial weakness (5%) may also occur and in a few patients this may be permanent (2.4%).[93,115] Delayed facial palsy on an average time of occurrence of 12 days was reported to be seen in 5.4%.[84] The VI nerve may be involved temporarily.

ESSENTIAL HYPERTENSION

Experimentally, hypertension may be produced by electrical stimulation of the cortex, bilateral lesions of the anterior hypothalamus and bilateral lesions of the nucleus tractus solitarius (NTS). The cell mass, the pars commisuralis, probably forms the primary medullary centre for the baroreceptor reflex. The rostral ventrolateral medulla (RVL) is a critical area for auto-regulation and control of arterial blood pressure. At the rostral end of the inferior olivary nucleus and within the RVL, adrenergic neurons are present which contain the adrenaline synthesising enzyme phenylethanolamine N-methyl transferace (PNMT).[2,35,40,86,89] These neurons are innervated by projections from the nucleus tractus solitarius.[17,87,88] The NTS receives input from arterial baroreceptors, chemoreceptors and other cardiovascular afferent fibres.[54] Cardiovascular baroreceptor impulses from the carotid sinus travel in the X nerve and those from the aortic arch in the IX nerve. The left X nerve also carries afferent signals from mechanoreceptors in the wall of the left atrium. The RVL projects to the intermediolateral and intermediate columns of the spinal cord via fibres travelling through the principal tegmental tract. This tract is the source of tonic and reflex drive to preganglionic neurons of the intermediolateral columns of the spinal cord.[30,85,88] Lesioning the RVL leads to reduction in blood pressure and stimulation to an increase, indicating that RVL medulla carries sympathetic fibres.[17,36,86] Experimentally, in cats and baboons, pulsatile mechanical pressure using a balloon was applied to the left RVL. This pressure is similar to what happens when there is a vascular compression and led to hypertension in all the animals. They became normotensive when the compression was released. There was no hypertension in the control group.[43,97,98] In a cadaver study in 1992, Naraghi[74] found that all patients with essential hypertension had a vascular compression of the left lateral medulla. In a study of a family with autosomal dominant hypertension and brachydactyly

mapped to chromosome 12, Naraghi[75] found on MRI and MRA that all 15 affected members had vascular compression of the left medulla. None of the 12 non-affected members had a vascular compression.

A major portion of the afferent impulses from the myocardial receptors of the left ventricle and atrium are conducted by cardiac c-fibres of the left vagus nerve to the NTS.[106] Mechanical damage to these nerve fibres by vascular compression may partially block conduction in these fibres resulting in partial deafferentation of the NTS. Doba and Reiss have demonstrated in animal experiments that deafferentation or destruction of the NTS results in fulminant hypertension.[23] It has been shown that NVC of the rostral ventrolateral medulla in patients with essential hypertension is accompanied by increased central sympathetic outflow.[96]

In 1979, Janetta published his first report of MVD for hypertension.[45] The offending vessel is usually the vertebral artery or the PICA.[63] MVD is indicated for essential hypertension in a select group of patients. It is reserved for those with intractable, poorly controlled essential hypertension, while on at least three different antihypertensive medications or who have three failed attempts with different medical regimens.[63] Out of 53 patients operated upon by Janetta[63], 51 had microvascular compression of the left RVL medulla. In 42, MVD was done. On follow-up, 31 patients were normotensive, 13 of whom were on no medication, 12 on diuretics and 6 on combination medical therapy. Similar results have been reported in smaller series.[30,64] The selection of patients who will benefit from MVD for hypertension is still a difficult problem. Further studies will be required.

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia is uncommon. It is characterised by intermittent lancinating pain in the posterior part of the tongue and the pharynx. Often it radiates to the inner part of the ear. Medically refractory neuralgia has to be treated by surgery. Classically, the IX nerve and the upper rootlets of the X nerve are cut in the posterior fossa through a retromastoid approach. In 1977, Laha and Janetta[61] reported on four cases where MVD was done. The largest reported series of 217 patients is by Patel et al.[79] The immediate relief is in the range of 90–98%.[79,83] On long-term follow-up 70–76% of patients were relieved of pain. The complications are permanent hoarseness of voice and mild dysphagia (11%) and, rarely, facial palsy.[79,91] When there is associated hypertension, the MVD results in reduction in blood pressure. MVD is a safe and effective procedure in the management of glossopharyngeal neuralgia.

ENDOSCOPE IN MICROVASCULAR DECOMPRESSION

Recently, endoscopes have been used for treating neurovascular compression. Supplementing an endoscope to the microscopic procedure has demonstrated improved localisation of neurovascular conflicts and has improved the efficacy of surgery. The endoscope has superior visualisation and also minimises the risks of brain retraction.[26,51,57] Initially, the endoscope was being used to supplement the microscope. Later on, many have reported fully endoscopic vascular decompression surgeries. Of the total of 255 patients who underwent fully endoscopic vascular decompression of the trigeminal nerve, 95% had complete relief by the end of the initial 3 months, as reported by Kabil.[53] In 1994, Magnan introduced a combined microscopic and endoscopic approach to vascular decompression of the facial nerve for HFS.[66] Recent studies have reported a success rate of 92.5%.[4]

RADIOSURGERY VERSUS MICROVASCULAR DECOMPRESSION

Gamma knife radiosurgery has been used to treat neurovascular compression but the results are delayed and are not satisfactory, with complete pain relief in less than half.[9] Radiosurgery is more likely to be the final treatment for recurrent TN regardless of the initial treatment.[80,92]

MVD is an operation that has come to stay and is recognised as the surgery of choice in TN, HFS, glossopharyngeal neuralgia and in some selected cases of vertigo, tinnitus, hypertension and spasmodic torticollis. The mortality and morbidity of this procedure is low and decreases further with increasing experience of the surgeon.

Epilepsy

Ravi Ramamurthi

199 Epilepsy: Overview

Dinesh Nayak S, Radhakrishnan K

INTRODUCTION

Epilepsy is one of the most common neurological disorders worldwide and yet not very well understood by physicians and the general public alike. The word epilepsy comes from the Greek verb '*epilamvenien*', which means "*to be seized*", "*to be taken hold of*", or "*to be attacked*". Excellent descriptions of epileptic attacks or apasmara can be found in the treatise *Caraka Samhita*, written by one of ancient India's immortal physicians Caraka, who probably lived in the 2nd century BC.[78] He postulated the cause of epilepsy to be a perturbation of the three doshas, and recommended a variety of treatment protocols based on Ayurvedic principles. Although Hippocrates, as early as in 400 BC, correctly postulated epilepsy as a disease originating in the brain, which needs to be treated by drugs and diet and not by religious incantations,[36] superstitions and myths abound to this day, especially in the developing countries.

DEFINITIONS

Epilepsy is defined as a group of neurological conditions characterised by recurrent unprovoked epileptic seizures. Epilepsy is not a specific disease or even a single syndrome, but is a broad category of symptom complexes arising from a number of disordered brain functions that may themselves be secondary to a variety of pathological processes. A *syndrome* is defined as a clustering of symptoms and signs consistently occurring together and not fortuitously. *Active epilepsy* is defined as having had at least one seizure in the previous 2 years. *Chronic epilepsy* is defined as epilepsy being active 5 years after onset. *Terminal remission* means a seizure-free period of 5 years or more, lasting to the time of most recent follow-up.[35,37,65]

Modern concepts of epilepsy are largely based on Hughlings Jackson's work.[38] His definition of a seizure in the late 19th century as "sudden, rapid, excessive synchronous discharges from a group of neurons" has not been bettered, and it sums up the mechanism and the paroxysmal nature of the condition.

MAGNITUDE OF THE PROBLEM

The prevalence rate of active epilepsy from the developed world is around 5 per 1,000 population (0.5%).[65] To this number, new patients will be added every year at a rate of about 50 per 100,000, which gives an incidence rate of 0.05%. Although prevalence rates in the developing countries are reported to be 2–25 times that of the developed world, this may be related to misdiagnosis, inclusion of single seizures, acute symptomatic seizures, febrile seizures and inactive epilepsy.[22] Recent community-based surveys from India have shown prevalence rates comparable to those from developed countries.[22,55] In one of the largest community based studies from India, conducted by Sree Chitra Tirunal Institute for Medical Sciences and Technology, Trivandrum (Thiruvananthapuram), comprising 50,000 households and a population of 200,000 in central Kerala, the prevalence of active epilepsy was found to be 4.9 per 100,000.[55,58] In a meta-analysis of the prevalence data obtained from 20 community-based studies from India, the overall prevalence rate per 100,000 was found to be 5.3.[74] These figures are comparable with prevalence rates from the developed world. Increased prevalence rates in some parts of the developing countries may be attributable to regional factors like higher prevalence of infections, such as cerebral cysticercosis and hot water epilepsy.[45,66] The only incidence data on epilepsy from India, found it to be 49.3 per 100,000 population per year.[42]

Around 20–30% of patients with epilepsy continue to suffer recurrent seizures, despite optimal antiepileptic drug (AED) therapy.[57] This has an adverse impact on education, marriage, employment and quality of life. The ICMR monograph [Epilepsy in India edited by PN Tandon (1989)] provides detailed information on this aspect. The last two decades have witnessed remarkable advances in the management of such patients. Patients with medically refractory epilepsy need to be identified early in the course of the disease and referred to a comprehensive epilepsy care program for detailed diagnostic evaluation, to determine candidacy for surgical or other modes of treatment, before their quality of life is irreparably adversely affected.

BASIC MECHANISMS OF EPILEPTOGENESIS

Epileptogenesis is the result of abnormal firing of a group of neurons sufficient to produce epileptiform activity that can be recorded as electroencephalographic

(EEG) seizure activity with or without clinical findings. Such activity may be restricted to a small population of neurons, as in focal epilepsies or may involve large areas of the brain simultaneously as in generalised epilepsies. There is alteration in the balance between excitatory and inhibitory mechanisms. Epileptogenesis may either be due to increased excitation or reduced inhibition or a combination of both.[53] The three main elements in the expression of epileptogenesis are: (1) the capability of membranes of pacemaker cells to develop intrinsic burst discharges; (2) reduction of gamma aminobutyric acid (GABA) inhibition and (3) enhancement of synaptic excitation. Synchronisation of cellular activity and its spread to involve a significant number of neurons is required to produce EEG and clinical seizure activity, as well as in the generation of cellular paroxysmal depolarisation shifts.

Neurons get depolarised by entry of extracellular sodium (Na^+) into the cell to set-up the action potential, called the *sodium action potential*. Similarly, calcium (Ca^{2+}) influx also produces the *calcium action potential*. Repolarisation takes place when potassium re-enters the cell. Any factor that affects the balance of depolarisation or repolarisation can affect cellular excitability. Therefore, agents that block potassium channels (tetraethyl ammonium and barium) prolong the action potential and therefore are proepileptogenic. Blockers of Na^+ and Ca^{2+} (e.g. phenytoin, valproic acid, ethosuximide and lamotrigine) inhibit action potentials and are used in the pharmacotherapy of epilepsy.[46]

A number of neurotransmitters and their receptors mediate excitation and inhibition in the central nervous system. The amino acid glutamate is an excitatory neurotransmitter and mediates synaptic excitation. The post-synaptic excitation induced by glutamate largely depends on stimulation of receptors. Based on their physiological and pharmacological properties, glutamate receptors are organised into two classes: ionotropic and metabotropic. The ionotropic receptors are further sub-divided into two classes: those that respond to α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionic acid (AMPA) or kainic acid (KA) and those that respond to N-methyl-D-aspartate (NMDA).[80] The metabotropic glutamate receptors (mGluRs) are second messenger-coupled receptors and play a role in neuronal plasticity and epilepsy.

The inhibitory system is mainly based on the neurotransmitter Gama aminobutyric acid (GABA). The GABA receptors are divided into two subtypes: $GABA_A$ and $GABA_B$.[50] Activation of $GABA_A$ receptors open a chloride channel and results in hyperpolarisation and, therefore, inhibition. $GABA_B$ receptor is a G protein-coupled receptor that can open potassium channels or close calcium channels. This results in prolonged hyperpolarisation and therefore leads to post-synaptic inhibition. Other receptors that have been implicated in epileptogenesis are acetylcholine receptors and adenosine receptors.

One of the most important prerequisites in the development of an epileptic seizure is the manner in which excitatory neuronal populations synchronise. Usually, recurrent synaptic excitation is balanced by recurrent inhibition. Blockade of inhibition results in paroxysmal depolarisation shifts. When recurrent inhibition is affected in various pathological conditions, there is multi-synaptic excitatory-induced synchronisation of neurons leading to the generation of after discharges. The glial network is protective in nature and glial cells take up glutamate. Failure of these mechanisms can result in secondary generalisation of a focal seizure.[40]

CLASSIFICATION OF SEIZURES AND EPILEPSIES

Seizures are broadly classified into partial and generalised seizures.[15] Partial seizures indicate initial activation of a group of neurons limited to one part of the cerebral hemisphere, as evident clinically and electrographically. Depending on whether consciousness is preserved or not, partial seizures are further classified into simple partial (consciousness preserved) and complex partial (consciousness impaired). A simple partial seizure may evolve into complex partial and then secondarily generalised seizures. The manifestations of simple and complex partial seizures may be motor, sensory, autonomic and psychic. Generalised seizures are those in which the first clinical changes indicate initial involvement of both hemispheres. Consciousness may be impaired and this may be the initial manifestation. Motor manifestations are bilateral, and the ictal EEG changes are bilateral. The generalised seizures include absences, myoclonic, tonic, atonic, clonic and tonic-clonic.

Epilepsy syndrome classification is a more useful concept for the prognosis and treatment than seizure classification, because it includes elements other than seizure symptomatology and EEG. The 1989 International League Against Epilepsy (ILAE) classification[16] is based primarily on the definition of electroclinical syndromes (Table 1). They are broadly divided into localisation-related epilepsies (in which seizure semiology or findings at investigation disclose a localised origin of the seizures) and generalised epilepsies (seizures in which the first clinical changes indicate initial involvement of both hemispheres and initial ictal EEG changes are bilateral).

Table 1: Classification and coding of epilepsies and epileptic syndromes (Modified from ILAE, 1989)[16]

1. Localisation-related epilepsies and syndromes
1.1. Idiopathic localisation-related (with age-related onset) epilepsies
1.1.1. Benign childhood epilepsy with centrotemporal spikes (BECT)
1.1.2. BECT in brain-damaged children
1.1.3. Childhood epilepsy with occipital paroxysms

(Contd ....)

1.1.4. Benign frontal epilepsy of childhood
1.1.5. Benign psychomotor epilepsy of childhood
1.2. Symptomatic localisation-related epilepsies
1.2.1 Temporal lobe epilepsies
1.2.2. Frontal lobe epilepsies
1.2.3. Parietal lobe epilepsies
1.2.4. Occipital lobe epilepsies
1.2.5. Chronic progressive epilepsia partialis continua of childhood (Rasmussen's syndrome)
1.3 Cryptogenic localisation-related epilepsies
1.3.1. Temporal lobe epilepsies
1.3.2. Frontal lobe epilepsies
1.3.3. Parietal lobe epilepsies
1.3.4. Occipital lobe epilepsies
2. Generalised epilepsies and syndromes
2.1 Idiopathic generalised (with age-related onset) listed in order of age
2.1.1. Benign neonatal familial convulsions
2.1.2. Benign neonatal convulsions
2.1.3. Benign myoclonic epilepsy of infancy
2.1.4. Childhood absence epilepsy
2.1.5. Juvenile absence epilepsy
2.1.6. Juvenile myoclonic epilepsy
2.1.7. Epilepsy with generalised tonic-clonic seizures (GTCS) on awakening
2.1.8. Other generalised idiopathic epilepsies not defined above
2.1.9. Epilepsies with specific modes of seizure precipitation
2.2 Cryptogenic or symptomatic generalised epilepsies (in order of age)
2.2.1. West syndrome
2.2.2. Lennox-Gastaut syndrome
2.2.3. Epilepsy with myoclonic-astatic seizures
2.2.4. Epilepsy with myoclonic absences
2.3 Symptomatic generalised epilepsies
2.3.1. Non-specific aetiology
Early myoclonic encephalopathy
Early infantile epileptic encephalopathy with suppression burst
Other symptomatic generalised epilepsies not defined above
2.3.2. Specific syndromes
Disease in which seizures are a presenting or predominant feature
3. Epilepsies undetermined whether focal or generalised
3.1 With both generalised and focal seizures
3.1.1. Neonatal seizures
3.1.2. Severe myoclonic epilepsy in infancy
3.1.3. Epilepsy with continuous spike-waves during slow wave sleep
3.1.4 Acquired epileptic aphasia (Landau-Kleffner syndrome)
3.1.5. Other undetermined epilepsies not defined above
3.2. Without unequivocal generalised or focal features

(Contd ....)

4. Special syndromes
4.1. Situation-related seizures
4.1.1. Febrile convulsions
4.1.2. Isolated seizures or isolated status epilepticus
4.1.3. Seizures associated with acute metabolic or toxic events, such as alcohol, drugs, eclampsia, non-ketotic hyperglycaemia, and hepatic and uraemic encephalopathies
5. Differentiation between epileptic and non-epileptic events uncertain.

Localisation-related and generalised epilepsies are further divided into idiopathic, symptomatic and cryptogenic. *Idiopathic* means "arising spontaneously from" and imply normal intelligence and neurological examination. Many of the idiopathic syndromes may be genetic disorders. *Symptomatic* means there is an obvious underlying cause for the epileptic syndrome. The term cryptogenic presumes an underlying symptomatic cause but this has not been detected in these patients.

In 2001, the Classification Task Force of the ILAE proposed to use the term focal instead of partial.[27] This Task Force also proposed a diagnostic scheme for detailed characterisation of each seizure disorder. The scheme involves assessment along five axes: (1) symptoms and signs; (2) seizure types; (3) syndromes; (4) aetiology and (5) impairment. This scheme is still under development. Many times, the syndromic diagnosis can be made only retrospectively, or on long-term follow-up. The outcome of epilepsy depends on the syndromic diagnosis. Thus, four different groups can be made depending on the prognosis.[65] Syndromes with excellent prognosis consist of the benign epilepsy syndromes of childhood such as benign Rolandic epilepsy and benign occipital lobe epilepsy. Almost all these children remit as they grow older and many of them may not require AED therapy. Although childhood absence epilepsy (CAE) and juvenile myoclonic epilepsy (JME) are two forms of primary idiopathic epilepsy, they vary in the prognosis. Both are easily controlled with appropriate AED therapy. CAE enter remission during adolescence, while JME rarely remits even after several decades. There is evidence to suggest that the recurrence of seizures itself does not influence the outcome of epilepsy. Rather, it is the underlying syndrome that determines the prognosis. Although AED therapy is effective in controlling seizures, they probably do not prevent the development of chronic epilepsy. Contrary to the concept held in the early 20th century, seizures do not beget seizures in humans, and epilepsy is a self-limiting disorder in most.

GENETICS OF EPILEPSIES

There has been an explosion in the knowledge of the molecular basis of epilepsy in the last 15 years or so. Although the heritability of epilepsy was known from the time of Hippocrates, it is only in the last two decades that the biological mechanisms are beginning to be

understood.[67] The first step is to obtain a detailed family history. This is not easy, since there is considerable social stigma attached to epilepsy and history may not be forthcoming even when there is a positive family history. On the other hand, spontaneous gene mutations are well known to occur and in such cases no positive family history will be present. A single genetic defect may result in several phenotypes, while a single phenotype can be a result of several genetic mutations.

Patterns of inheritance follow two broad groups: (1) Simple Mendelian [autosomal dominant (AD), autosomal recessive (AR) and X-linked] and (2) complex (non-Mendelian). Mendelian disorders are relatively rare, cluster in families and have a high rate of penetrance (expression), so that if one carries the gene, the disorder is likely to manifest. This makes it easier to trace the abnormal gene.

Complex disorders may have several genes (multiple genotypes) involved and not everyone who carries the gene will get seizures. In clinical practice, complex modes of inheritance are more common than Mendelian disorders. Approximately 10 genes have been identified for the idiopathic generalised epilepsies within the last 15 years, all of them simple Mendelian disorders with AD transmission (Table 2). These genes involve either an ion channel (sodium and potassium) or a neurotransmitter receptor (acetylcholine and GABA). Autosomal recessive disorders are associated with multiple cerebral abnormalities as well.

Table 2: Inheritance patterns and gene localisation of some epilepsy syndromes

	Inheritance	*Identified gene*
Simple (Mendelian) inheritance idiopathic generalised epilepsies		
Benign familial neonatal convulsions	AD	Potassium channels
Benign infantile convulsions	AD	19q
Generalised epilepsy febrile seizure (GEFS) plus	AD	Sodium channels, GABA receptors
Partial		
Nocturnal frontal lobe epilepsy	AD	α4 nicotinic acetylcholine receptors
Partial epilepsy with auditory features	AD	LG 1 (leucine rich repeats)
Complex (non-Mendelian) idiopathic epilepsy syndromes		
Childhood absence epilepsy	UCL	
Juvenile absence epilepsy	UCL	
Juvenile myoclonic epilepsy	UCL	
Idiopathic generalised epilepsy	UCL	
Partial		
Benign rolandic epilepsy	UCL	
Febrile seizures	UCL	

(AD = autosomal dominant; UCL = unconfirmed chromosome localisation)

NATURAL HISTORY OF EPILEPSIES

The factors that determine the development of epilepsy, following an initial unprovoked seizure and its refractoriness to AED treatment, are largely unknown. Recent epidemiological studies have thrown light on some of these questions. Around 15% of patients will go on to develop refractory epilepsy after a first unprovoked seizure.

Initial Unprovoked Seizure

The risk of developing a second seizure after a first unprovoked seizure varies between 27 and 80%.[1,34,65] This wide variation is mainly because of selection bias in the patient population. A population-based prospective study in the United Kingdom involving 564 unselected patients with non-febrile seizures showed that 67% had recurrence within 12 months of the initial seizure and 78% had recurrence in 36 months.[34] The risk of recurrence is greatest in the first 6 months and diminishes over time. In another population-based study from Rochester, Minnesota, Annegers et al.[1] observed the risk of recurrence after an initial unprovoked seizure among a cohort of 424 residents to be 36% in one year, 48% in 2 years and 56% by 5 years. Based on these studies, it can be concluded that around 60% of persons go on to develop epilepsy after a first unprovoked seizure.

Natural History of Treated Epilepsies

The British National General Practice Study of Epilepsy investigated the remission rate of 1,091 newly diagnosed patients with epilepsy.[14] The remission rate was 87% at the end of 3 years and 71% at the end of 5 years. The majority of those who remitted did so within the first 2 years of onset of epilepsy. In a more recent prospective, long-term population-based study from Finland,[70] 144 patients with childhood onset of epilepsy were followed-up for an average of 37 years. Terminal remission was achieved in 67%. Three patterns of terminal remission were noted: early (within 1 year of seizure onset, in 31%), late (after a mean delay of 9 years, in 50%) and remitting-relapsing in 19% (terminal remission following a relapse after early or late remission). Drug resistance was observed in 19% of patients and another 14% relapsed after early or late remission and never achieved terminal remission. Thus, 70–80% of persons with newly diagnosed epilepsy will eventually achieve remission. Most of those who remit will be able to discontinue AED therapy and remain seizure-free. This goes against the common perception that epilepsy is a chronic disease and needs life-long therapy in the majority of patients.

Natural History of Untreated Epilepsies

In the developing countries, it is common to encounter *treatment gap*, which is defined as the percentage of persons with active epilepsy who have never received AED treatment. Population-based studies in the developing regions have shown the treatment gap amounts to

70–90%.[2,41,42,56] Epidemiological studies from rural areas in Karnataka,[42] West Bengal[20] and Kashmir[41] found treatment gap in 78%, 74% and 75%, respectively. The treatment gap was as high as 36% even in Kerala,[55] the most literate state in India. The treatment gap was, however, only 6% in the literate and affluent Parsi community of Mumbai.[7] This is unlike in the developed world where most patients with epilepsy would be investigated and receive AED therapy. The reasons are both medical and social, and include lack of medical services, lack of diagnosis of epilepsy, reluctance to accept the diagnosis and take "English" medicines, lack of knowledge about diagnosis and treatment and non-availability or non-affordability of medication.

In a population-based study from Equador, only 29% of epilepsy patients ever received treatment.[52] Interestingly, 46% of the untreated patients were in long-term remission. The duration of untreated epilepsy and number of seizures do not appear to influence the chances of remission. In a study from Kenya, half the patients had epilepsy for more than 5 years and 38% already had more than 100 generalised tonic-clonic seizures (GTCS) at the time of therapeutic trial.[29] Neither the duration nor the number of GTCS correlated with response to therapy. These results clearly belie the popularly held notion that chronic epilepsy will develop unless treatment is initiated early.

Chronic Epilepsy

Although the majority of patients with epilepsy do go into remission with or without treatment as discussed above, around 20–30% of patients will continue to get seizures despite appropriate treatment (pharmacoresistant epilepsy).[57] This works out to around 1 million patients in India. Fortunately, around 30% of these patients are candidates for epilepsy surgery.

Determinants of Natural History of Epilepsies

There are certain well established predictive factors for the development of pharmacoresistant epilepsy. These include onset of epilepsy in infancy, organic brain damage (mental retardation and neurological signs), seizure type (tonic, atonic and myoclonic seizures), multiple seizures, high seizure frequency, long duration of uncontrolled seizures, failure of past AED treatments and an abnormal EEG.[75] Most of these factors are especially relevant to prognosticate the outcome of epilepsy in children.

Refractory Epilepsies

Despite the fact that the majority of patients with epilepsy remit, about 20–30% of patients continue to suffer recurrent seizures despite appropriate AED therapy.[57] These unfortunate patients are a challenge to the treating team. Fortunately, about 25% of these patients are candidates for epilepsy surgery. When selected appropriately, surgical treatment results in a cure in the majority of patients.

The definition of refractory epilepsy is essentially an individual one. A rough rule would be a patient who suffers two or more disabling seizures per month and who has failed trials of two appropriate AED monotherapy trials and one polytherapy trial over a period of 2 years. Patient's expectation, degree of disability, AED toxicity, employment and education, and obtaining driving license are some of the factors that ultimately influence the decision for surgery. The natural history studies have shown that most patients who are destined to achieve seizure control will do so within the first 2 years of onset of epilepsy.

Mechanisms of Pharmacoresistance

Resistance to AEDs can be explained by two putative neurobiological mechanisms:[68] (1) removal of AEDs from the epileptogenic tissue through excessive expression of multidrug transporters and (2) reduced drug-target sensitivity in epileptogenic brain tissue. Overexpression of certain genes, like MDR 1 and MDR associated protein 1 (MRP1) in the epileptogenic tissue, can result in pharmacoresistance.[71] Therefore, pharmacoresistance may develop even before the first seizure or may develop many years after the onset of epilepsy. Pharmacoresistance may reverse in some patients.

Comprehensive Epilepsy programme

Patients with refractory epilepsy are best managed by a team of specialists within a comprehensive epilepsy programme. There are many problems encountered by patients with refractory epilepsy. Some of them include incorrect or imprecise diagnosis, inappropriate AED therapy, inadequate polypharmacy, frequent adverse effects of AED therapy, physical injuries related to seizures, psychosocial problems, educational and occupational problems, disturbed family life, economic problems and poor quality of life.[77] The team should include a neurologist with special expertise in epilepsy (epileptologist), a neurosurgeon with expertise in epilepsy surgery, a neurophysiologist, a neuroradiologist with special interest in epilepsy, a psychiatrist, a psychologist, a medical social worker and on occupational therapist. The team is usually led by the epileptologist. Although seizure control is the most important aspect in the treatment of epilepsy, it is not the sole factor and other issues, like education, employment, marriage and quality of life, are equally important in the management.

Nearly one-third to one half of patients with refractory epilepsies are potential surgical candidates. In carefully selected patients, epilepsy surgery offers the best chance of cure of epilepsy.

DIFFERENTIAL DIAGNOSIS OF EPILEPSIES

Epileptic seizures are paroxysmal in nature, with varying manifestations ranging from brief absences to the most bizarre motor phenomena as seen in some patients

with frontal lobe epilepsy. A variety of paroxysmal phenomena, which are non-epileptic, can mimic epileptic seizures. These can be sub-divided into physiologic and psychogenic non-epileptic events.

Physiological non-epileptic events include syncope, paroxysmal movement disorders, transient ischaemic cerebrovascular phenomena, non-epileptic myoclonus and sleep disorders. Psychogenic non-epileptic events include somatoform disorders, dissociative disorders, anxiety disorders and malingering. A very careful history and appropriate investigations will usually help in differentiating between true epilepsy and non-epileptic events, although in some instances, the distinction can be extremely difficult. It is not uncommon for patients with non-epileptic seizures to be treated as intractable epilepsy with multiple AEDs for years. It is important to recognise that around 20% of patients with chronic epilepsy referred to a video-EEG unit proved to be non-epileptic attacks.[8] Meticulous history and judicious use of investigations will help clarify the existence of the two seizure types.

INVESTIGATION OF EPILEPSIES

Electroencephalography

"On the paper of the electroencephalogram the brain writes out its own record in the language of electrical potentials, but it does not make its own diagnosis and in some cases it is strongly silent" (Jasper H 1954) (In Electroencephalography in Epilepsy and Functional Anatomy of the Brain. Penfield WP and Jasper HH (Eds). Boston: Little Brown & Co; 1954).

The first electroencephalogram in humans was performed by Hans Berger in 1928.[6] Since that time, EEG has played a central role in the diagnosis and management of epilepsy. The generators of the EEG signals on the scalp are not precisely known. The EEG represents summated synchronised post-synaptic potentials, which may be excitatory or inhibitory. These excitatory and inhibitory post-synaptic potentials (EPSP and IPSP) are generated from apical dendrites of neurons in the superficial cortex. The electrical fields generated from deep sources do not normally get recorded over the scalp, unless the more superficial cortical neurons get activated.

The EEG is the only test that provides information about epileptogenesis. It is important to recognise that epilepsy is essentially a clinical diagnosis. The role of the EEG in epilepsy is mainly to support the clinical diagnosis of epilepsy and to aid in the syndromic classification of epilepsy (Figs 1 and 2A to C).

The diagnostic sensitivity of a single awake EEG with photic stimulation and hyperventilation is about 50% in adults with epilepsy.[9] After four EEGs, the sensitivity increases to 92%.[64] Recording EEG during sleep increases the sensitivity considerably; a single awake plus sleep record will be positive in about 80%.[26,81]
The diagnostic specificity of the EEG depends on the proper interpretation of the EEG. Misinterpretation

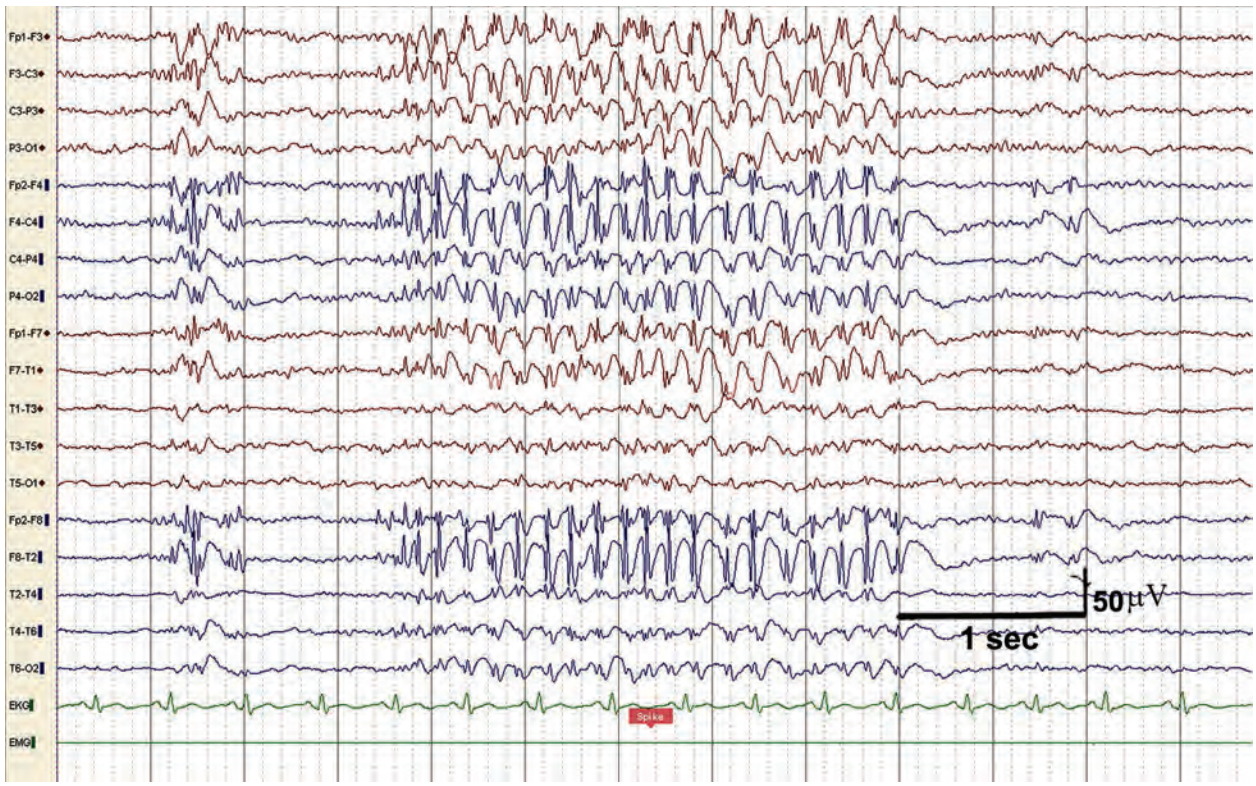

Fig. 1: EEG of a patient with juvenile myoclonic epilepsy (prototype of idiopathic generalised epilepsy syndrome), showing generalised atypical spike and wave discharges

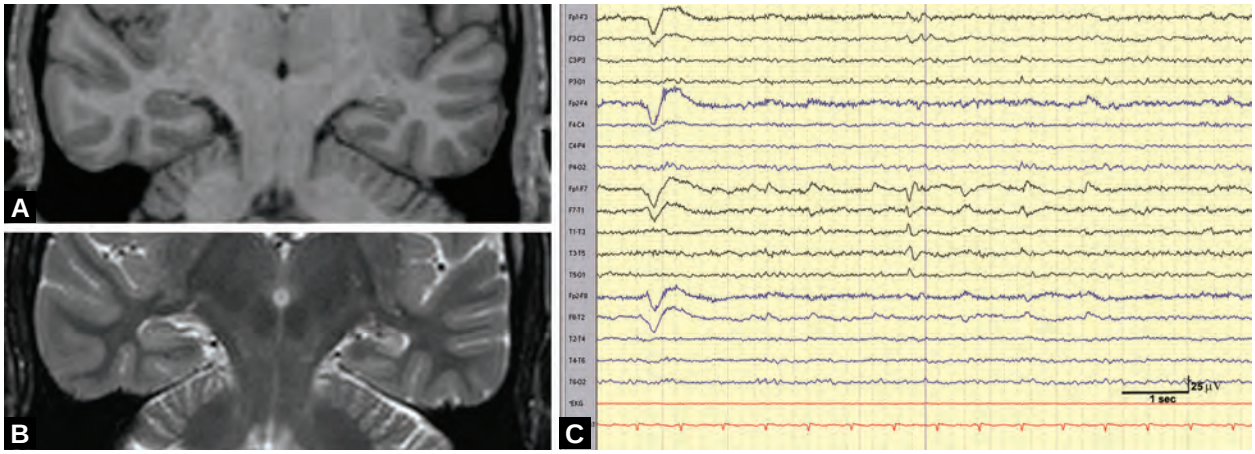


Figs 2A to C: MRI-EEG correlation in a patient with medically refractory mesial temporal lobe epilepsy, prototype of symptomatic focal epilepsy syndrome, shows. (A) Small left hippocampus on T1-weighted coronal MRI sequence. (B) Increased signal intensity on T2-weighted coronal MRI sequence. (C) Left anterior temporal spike discharges

of normal variants and artefacts can lead to a wrong diagnosis of epilepsy and unnecessary AED therapy. It is also important to understand that a normal EEG does not exclude epilepsy. As discussed above, the EEG may remain normal despite repeated EEG recordings in 5–10% of patients. Such patients usually have only simple partial seizures or mesial frontal or parietal lobe epilepsy.[43]

Most of the EEG laboratories in India now have digital EEG machines. They have several advantages over the conventional analogue paper machines[18] Digital EEG machines are paperless and have automatic event detection systems. Recording parameters can be changed *post hoc* and the EEG can be displayed in a variety of montages. Brain mapping is the topographic display of digitally quantified EEG information on a stylised head model. These tools are used extensively but do not offer any advantage over conventional reading of the EEG. In fact, they can mislead the clinician. Interpretation of the EEG must always be done in the clinical context. There must be a dialogue between the referring physician and the person doing the EEG, regarding the clinical problem and the questions the EEG is expected to answer. Specific interictal EEG abnormalities can be found in a small number of epilepsy syndromes. These include hypsarrhythmia in West syndrome, centrotemporal spikes in Benign Rolandic Epilepsy of childhood and slow spikes in Lennox-Gastaut Syndrome.[25]

Video-EEG Telemetry

Video-telemetry or video-EEG is the simultaneous and synchronous recording of clinical events on video, along with EEG. It has several advantages over the routine EEG recording.[12] Prolonged Video-EEG monitoring provides the opportunity to study interictal and ictal paroxysmal electrographic and clinical events synchronously, thereby permitting electroclinical correlation. The routine scalp EEG allows recording for a limited period of time, thereby making it less sensitive and specific than a long-term video-EEG recording. The occurrence of interictal epileptiform abnormalities in a patient with epilepsy is variable and is usually maximal during drowsiness and light sleep. During wakefulness, epileptiform discharges can be absent for several hours, hence a routine awake EEG may be normal, whereas the scope of recording these discharges is much greater during video-EEG monitoring.

Video-EEG is used to confirm seizure disorder, classify seizure type(s), distinguish epileptic seizure from non-epileptic seizure, assess seizure frequency, study precipitating factors and most importantly, to localise the ictal onset zone in patients who are evaluated for focal resective epilepsy surgery.

Interictal epileptiform abnormalities in the form of spike-waves and sharp waves can be focal, multi-focal or generalised. The distribution of these discharges helps in localising the lobe of origin. In mesial temporal lobe epilepsy (MTLE), which is the most common surgically remediable epilepsy syndrome, the epileptiform discharges are maximal at the anterior temporal electrodes, whereas in neocortical temporal lobe epilepsy, the spikes are maximal at the mid-and/or posterior temporal locations. In unilateral MTLE, the incidence of bilateral independent temporal epileptiform abnormalities is around 30% during routine scalp EEG recording, whereas it increases to around 70% during prolonged video-EEG monitoring.[28] The spikes in mesial frontal epilepsy are usually seen over the midline vertex region. Generalised spike discharges can also occur and indicate secondary bilateral synchrony.

One of most important aspects of video-EEG monitoring is the recording of clinical seizures. The semiology of seizures would help classify seizure types into generalised, complex partial seizures of temporal or extratemporal (frontal, parietal and occipital) type or simple partial seizures.

Ictal electrographic rhythms differ from interictal discharges and consist of low voltage beta activity,

rhythmic medium amplitude theta or alpha activity, rhythmic delta activity and runs of spikes or sharp waves. Electrodecremental response, either focal or diffuse in distribution can also occur, but is less specific. The rhythmic activity evolves into different frequencies and morphologies and propagates to regions remote from the origin. Ictal onset can be focal or diffuse. In temporal lobe seizures, the rhythm is typically a focal rhythmic 5–7 Hz theta activity over the temporal region, which remains lateralised for several seconds before spreading to other regions.[24] The electrographic changes usually precede the clinical onset, but may be delayed. In some, the electrographic onset is diffuse, but thereafter lateralises to one side, a phenomenon called late lateralisation pattern.[10] In some instances, the electrographic change is initially on one side, but later switches to the opposite side (switch of lateralisation).[69] This may indicate bitemporal epileptogenecity.

Frontal lobe seizures are typically hypermotor and the ictal rhythm may be obscured by myogenic and movement artefacts. In such instances, interictal abnormalities and the ictal clinical semiology may be more informative than ictal electrographic changes.[63]

Post-ictal changes can be in the form of slowing or attenuation of the background activity and can be focal, hemispheric or generalised. Focal post-ictal change is of lateralising value. The video-EEG is expensive, labour-intensive and time consuming to analyse. If used judiciously, the test is cost-effective and can result in a change in management of the patient. In a study of 324 patients who underwent long-term video-EEG monitoring at the R Madhavan Nair Centre for Comprehensive Epilepsy Care, around 30% had a change in the diagnosis and thereby a change in treatment.[13] Nearly one-third of patients could be recruited for epilepsy surgery. It must, however, be emphasised that notwithstanding the utility of video EEG, the majority of patients requiring surgery for their epilepsy can be selected on the basis of conventional EEG and clinical evaluation.

Neuroimaging

Rapid advances in neuroimaging in the last couple of decades have made available a wide array of imaging modalities to the treating team. These modalities include computed tomography (CT scan), magnetic resonance imaging (MRI), positron emission tomography (PET), interictal and ictal single photon emission computed tomography (SPECT), MR spectroscopy (MRS), T2 relaxometry and functional MRI (fMRI). The main goals of neuroimaging in persons with epilepsy, as laid out by the Commission on Neuroimaging of the ILAE,[17] are: (1) delineation of structural and functional abnormalities in the suspected epileptic zone; (2) prediction of the nature of structural pathology; (3) detection of abnormalities distant from the putative epileptogenic region (diffuse or dual pathology) and (4) identification of eloquent brain regions, such as language, memory and sensorimotor areas, and the relation of these regions to the epileptogenic lesion.

The most common imaging modalities used in epilepsy are the CT scan and MRI. The CT scan detects only gross structural lesions and a negative CT scan does not exclude subtle epileptogenic lesions. The current role of CT in epilepsy is mainly in an emergency situation and in a patient presenting with recent seizures in an area known to be endemic for cysticercosis.[32,60] The MRI is currently the best investigation to define both normal and abnormal brain structures.[24] The most common structural pathology detected on MRI in patients with focal epilepsy is mesial temporal sclerosis (MTS). Other lesions include malformation of cortical development, vascular lesions and low-grade neoplasms, and focal atrophic lesions (Figs 3A to D).

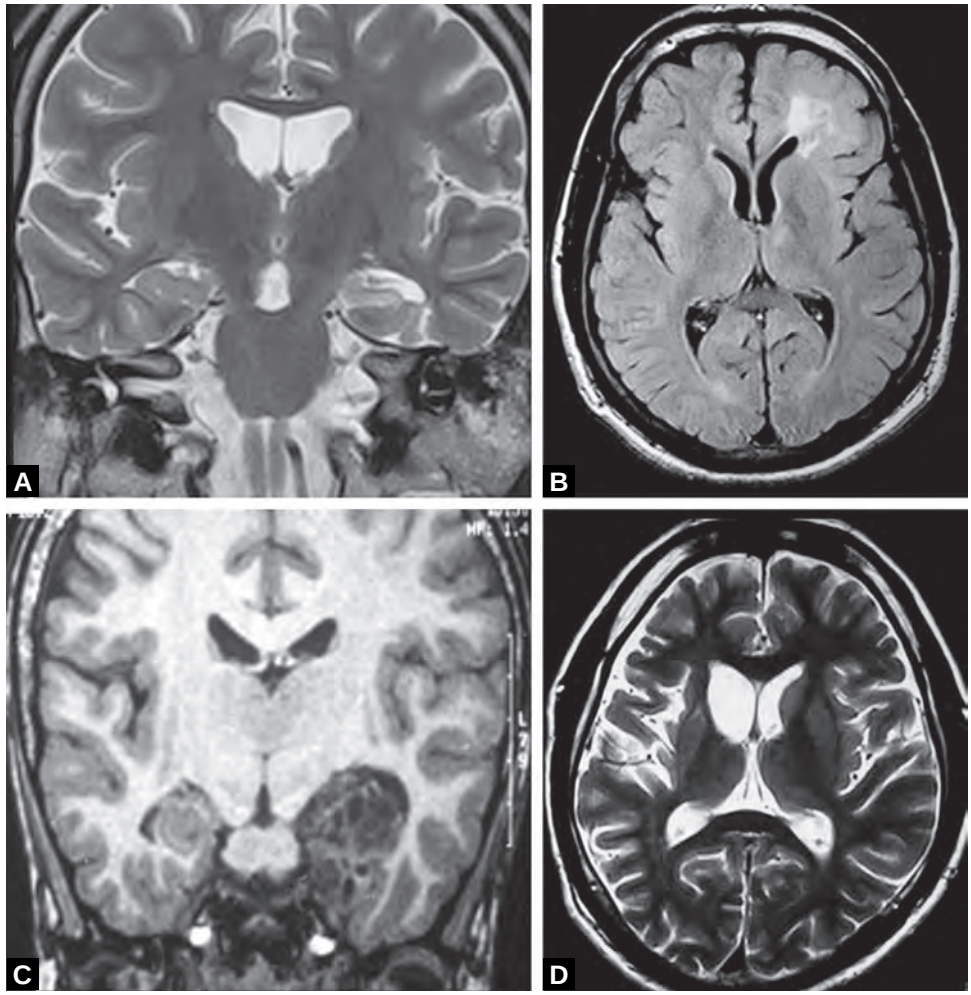
Not all patients with epilepsy need neuroimaging. Patients with primary generalised epileptic syndromes, such as childhood and juvenile absence epilepsies, juvenile myoclonic epilepsy and idiopathic benign localisation related childhood epileptic syndromes do not need neuroimaging. On the other hand, patients with refractory focal epilepsy must be investigated with MRI. It is also important to emphasise that the imaging must be done with a strict protocol laid out for epilepsy imaging.

Special imaging modalities, like PET, SPECT and fMRI, are available in selected centres in India. The PET scan is usually done in the interictal state and measures the metabolic rate of the tissue.[79] Epileptogenic tissue will usually be seen as hypometabolic.[62] The SPECT is usually done by injecting a radiotracer within a few seconds of a seizure onset. The seizure focus will show hyperperfusion, whereas interictal SPECT will show reduced perfusion.[72] By co-registration of interictal and ictal SPECT on the MRI (SISCOM), the seizure focus can be mapped with great accuracy.[49]

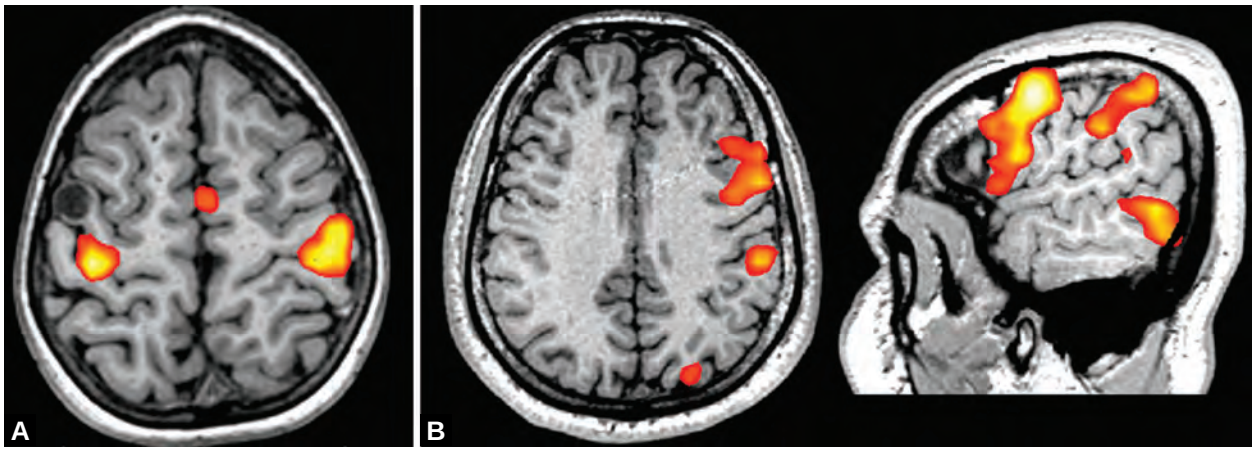
The fMRI is used to map out eloquent cortical regions using the blood oxygenation level dependent (BOLD) technique. Changes in oxyhaemoglobin levels during activation of the cortex results in a change in MRI signal. Language, sensorimotor and visual areas can be mapped out (Figs 4A and B). This technique is now being routinely used in the evaluation of patients with intractable extratemporal epilepsy with epileptogenic zones close to eloquent areas.[39]

Invasive Video-EEG Monitoring

When there is discordance between various non-invasive tests, like scalp EEG, video-EEG, MRI and functional imaging findings or in cases of focal cortical dysplasia where the epileptogenic focus is usually more widespread than the MRI abnormality, invasive monitoring is required to exactly delineate the epileptogenic focus.[83] This is achieved by means of implanting multicontact



Figs 3A to D: The MRI appearances in some surgically remediable focal epilepsy syndromes. (A) Coronal T2-weighted sequence shows increased signal intensity in the left hippocampus in a patient with mesial temporal sclerosis. (B) Axial FLAIR sequence shows left frontal lesion with thickened cortex and hyperintense signal suggestive of focal cortical dysplasia. (C) Coronal T1-weighted sequence shows hypointense mass lesion in the left hippocampus in a patient with pathologically verified ganglioglioma. (D) Axial T2-weighted sequence shows left perisylvian atrophy with increased signal and severe caudate nuclear atrophy characteristic of Rasmussen's encephalitis



Figs 4A and B: Functional MRI (fMRI) for language and motor activation. (A) Inline BOLD fMRI shows activation of both hand motor areas and supplementary motor area with bilateral finger tapping task. The lesion is just anterior to the motor hand area on the right side. (B) Inline BOLD fMRI language area mapping with verbal fluency task shows a strongly left lateralised language function

subdural grid or strip electrodes or stereotactically implanted intracerebral depth electrodes. It is very important to generate a hypothesis regarding the probable epileptogenic focus/foci, before deciding on the type of electrodes and the extent of coverage. This will avoid the danger of inadequate or inappropriate sampling of the brain, resulting in a false negative study.

Invasive monitoring carries a risk of infection, haemorrhage, weakness or even death. Around 3.5% patients will have transient morbidity, while the risk of permanent morbidity is about 0.7%.[4] Moreover, invasive monitoring is very expensive and this is a significant constraint in developing countries like India. Furthermore, the very need for invasive monitoring for localisation of seizure focus is indicative of a less favourable post-surgical outcome, when compared to those who could be selected utilising a non-invasive protocol.

NEUROPATHOLOGY OF EPILEPSIES

The six common neuropathological substrates of chronic epilepsies in adults are: (1) hippocampal sclerosis; (2) malformations of cortical development; (3) traumatic lesions and changes secondary to chronic epilepsy; (4) tumours and hamartomas; (5) infective (tuberculosis, cysticercosis, encephalitis) disorders and inflammatory lesions (Rasmussen's encephalitis) and (6) Sturge Weber syndrome and angiomas.

Hippocampal sclerosis is the most common pathologically confirmed lesion in chronic temporal lobe epilepsy (Figs 5A to D). In the last decade, advances in MRI techniques have made it possible to accurately diagnose MTS pre-operatively. Typically, there is marked loss of pyramidal neurons in the CA1 region, followed by less severe loss in the CA3 and CA4 sectors, followed by hilar and granule cells, whereas the neurons in the CA2 region are typically resistant to damage.[44]

Malformations of cortical development have long been recognised as an underlying cause of epilepsy in a proportion of adults with early or late onset disease, as well as in the paediatric age group.[76] The basic problem is a disturbance in the migration of neurons from the periventricular germinal mantle to the cortical mantle along the radially oriented glial fibres. The type of insult, its severity and time of occurrence, influence the extent, location and type of malformation, which in turn affects the degree of clinical disability. Malformations can be divided into focal and diffuse abnormalities; focal malformations include focal cortical dysplasia (Fig. 5), cerebral microdysgenesis, grey matter heterotopia, polymicrogyria, pachygyria or agyria and schizencephaly. Diffuse malformations include hemimegalencephaly, microdysgenesis, grey matter heterotopia and lissencephaly.

The two most common tumours which cause chronic epilepsy are dysembryoplastic neuroepithelial tumour (DNET)[21] and gangliogliomа[82] (Fig. 5). Other tumours include low-grade astrocytomas, oligodendroglioma, pleomorphic xanthoastrocytoma and subependymal giant cell astrocytoma.

Rasmussen's encephalitis is a rare disorder that presents in childhood or adulthood as epilepsia partialis continua and progressive hemiparesis. The disease progresses through various stages. The neuropathology is one of chronic polio-encephalitis, which is typically unilateral and characterised by neuronophagia and perivascular cuffs of lymphocytes.[51]

TREATMENT OF EPILEPSIES

The mainstay in the treatment of epilepsy is AEDs. The medical and surgical management of epilepsy will be dealt with in detail in subsequent chapters.

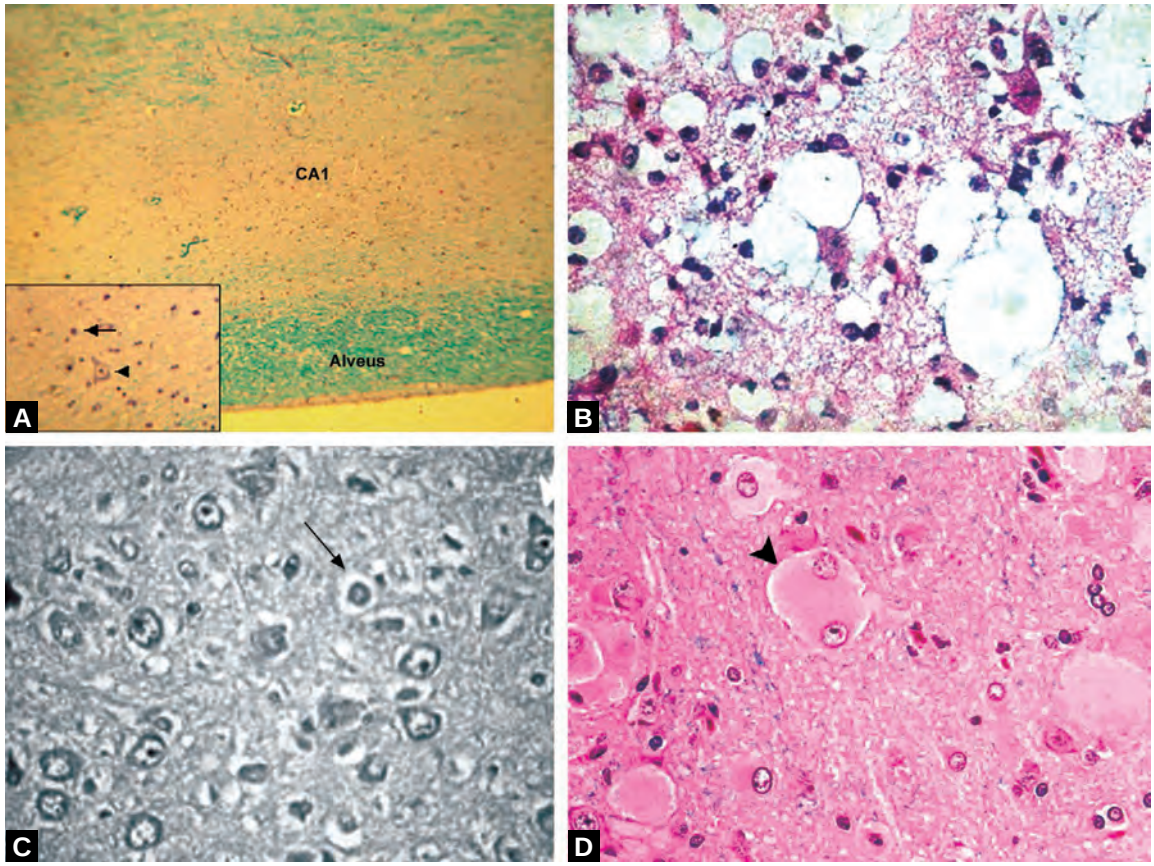
Emerging and Alternative Treatment for Epilepsy

Treatment options are limited for patients with pharmacoresistant epilepsies who are not candidates for resective surgery. In the recent years, however, two well studied options have emerged: (1) vagus nerve stimulation and (2) ketogenic diet.

Vagus Nerve Stimulation

More than 30,000 patients have been implanted with vagus nerve stimulation (VNS) since 1997, when the USFDA approved its use for adult patients with refractory epilepsy. Clinical trials have shown reduction in seizures and improvement in quality of life measures.[19,33] The device consists of a battery-powered pulse generator (Cyberonics™) which is implanted subcutaneously in the anterior chest wall below the clavicle, lead wires which are attached to the vagus nerve (the left vagus nerve is used for stimulation since the right vagus has strong cardiac innervation) and a hand-held magnetic wand which can activate or deactivate the pulse generator. The stimulation parameters are programmed by means of a personal computer or laptop. The stimulation is carried out intermittently once every 2–5 minutes (off time) for a period of 30 seconds (on time) at a current intensity of 0.25 mA, which is gradually ramped up to a maximum of 3.5 mA. Meticulous follow-up is required to adjust the duty cycle and to ensure proper functioning of the device. Optimal stimulation parameters are achieved usually within 3–4 months. The hand held magnet can be used to abort a seizure, either by the patient when he/she experiences an aura or by a family member/caretaker as soon as a seizure develops.

The mechanism of action of VNS is still not clear. The vagus nerve has extensive afferent connections in the brainstem, forebrain and hypothalamus. Animal studies have demonstrated that an intact locus ceruleus in the brainstem is essential for the efficacy of VNS. The adverse effects of VNS consist of hoarseness of voice, cough and breathlessness. Over time, these symptoms tend to subside. The battery life of newer devices is approximately 7 years.



Figs 5A to D: Histopathology of common lesions associated with refractory focal epilepsies. (A) Shows neuronal loss in the CA1 sector of the hippocampus in hippocampal sclerosis. Inset shows a neuron (arrowhead) and reactive gliosis (arrow); Luxol-fast blue-PAS stain X 150, with magnified inset. (B) DNET: photomicrograph showing characteristic microcystic spaces containing pale staining material. Some of these microcystic spaces contain well-formed neuronal cells-floating neurons. In between these, sheets of glial cells are also seen [haematoxylin and eosin (H&E stain X 200)]. (C) Photomicrograph shows admixture of neoplastic ganglion cells (white arrow) and astrocytes (dark arrow) characteristic of ganglioglioma (H&E X 200). (D) Focal cortical dysplasia: photomicrograph shows classical balloon cells (arrowhead) (H&E stain X 150)

Ketogenic Diet

The ketogenic diet has a long history and antedates the use of AEDs. With the advent of phenytoin, ketogenic diet fell out of favour. It resurfaced in the 1990s and has been found to be effective in patients who have failed multiple AEDs.[48] While on the diet, lower doses of AEDs are required, thereby reducing the potential for AED-related side effects. The diet is very high in fat and low in carbohydrate and protein at a ratio of 3:1. South Indian and North Indian versions of the ketogenic diet are available. A brief period of hospitalisation is required during the initiation of the diet. The diet is monitored by measuring urinary ketones, which must be 4+ to ensure that the diet is sufficiently ketogenic.

The exact mechanism of action is not known. It appears that the effects on the brain are multiple, with overall changes in brain phosphorylation state and altered gene expression. Many studies have shown that ketogenic diet is effective in medically refractory epilepsy in children. Adverse effects include acidosis, anorexia, dehydration, diarrhoea and symptomatic hypoglycaemia, renal stones, etc.

Yoga

The ancient Indian practice of Yoga has been shown to reduce stress and create relaxation. Studies have shown reduction in seizure frequency and a feeling of well-being.[59,61] In a recent prospective, non-randomised, open-label, add-on trial of yoga meditation protocol study, there was significant reduction of seizure frequency at 3, 6 and 12 months in 20 patients with drug-resistant chronic epilepsy.[59]

COMMUNITY AWARENESS AND ATTITUDE TOWARDS EPILEPSY

Even to this day, people with epilepsy are discriminated against because of misunderstanding and lack of knowledge and awareness throughout the world. Many studies from both the developed and the developing countries have investigated public awareness and attitudes towards epilepsy.[43] Only in recent years has the public perception about epilepsy begun to change for the good in the developed countries, whereas considerable stigma continues to be attached to epilepsy in the developing countries. In a study conducted in central Kerala,[21] 27%

respondents considered epilepsy as a mental disease, 11% would object to their children playing with a child with epilepsy, 44% would not employ a patient with epilepsy, compared with 3%, 6% and 9% in the United States.[11] These negative attitudes even in the highly literate population of Kerala towards epilepsy are not much different from less literate North Indian and Pakistani populations.[3,31] Detailed information on this subject is available in the multicentric ICMR publication "Epilepsy in India".

PROBLEMS ASSOCIATED WITH LONG-STANDING EPILEPSY

Sudden Unexplained Death in Epilepsy

People with epilepsy are 2–3 times more likely to die prematurely than those without.[5] The many causes of death among patients with epilepsy include accidents, status epilepticus, sudden unexplained death in epilepsy (SUDEP), ischaemic heart disease and various malignancies.

The SUDEP is defined as "sudden, unexpected, witnessed or unwitnessed, non-traumatic or non-drowning death in patients with epilepsy, with or without evidence of a seizure and excluding status epilepticus, in which postmortem does not reveal a toxicological or anatomical cause for death".[47] The aetiology is poorly understood but a higher incidence has been noted in patients with intractable epilepsy, thereby indicating that seizure frequency and severity are risk factors. Polytherapy may also be a risk factor but evidence is conflicting. Risk of SUDEP in someone with epilepsy in the community is 24 times higher than for someone without epilepsy.[30]

Psychiatric Disorders

Depression, anxiety and other psychosis can develop in patients with medically refractory epilepsy. Major depression can occur in around 30% of patients,[80] while the risk of developing interictal schizophrenia-like psychosis is significantly higher than in the general population.[54] Psychiatric disorders are not absolute contraindications to epilepsy surgery, but it is important to identify and stabilise the symptoms pre-operatively.

Quality of Life Outcome

There are several measures of quality of life (QOL) that assesses various domains of social, physical, psychological, vocational and economic well-being.[73] It has been shown that patients with chronic epilepsy have lower QOL scores than those without epilepsy.[23]

SUMMARY

The epilepsies are a group of disorders with diverse aetiologies and variable prognoses, with recurrent unprovoked seizures being the common feature. Syndromic diagnosis is important for choosing the appropriate treatment as well as for determining the prognosis. While nearly 80% of patients with epilepsy achieve remission with or without medication, the remaining 20% will be refractory to medical therapy, with considerable psychosocial morbidity. Around 50% of these unfortunate patients are potential candidates for epilepsy surgery, while the remaining may benefit with newer antiepileptic drugs and novel therapies, like vagal nerve stimulation and the ketogenic diet. These patients need to be evaluated in a comprehensive epilepsy centre and there are only a handful of them in India. The need of the hour is to set up such centres in various parts of the country, in order to reduce the huge medical and surgical treatment gap.

200 Epilepsy: Medical Management

Ashalatha, Radhakrishnan K

INTRODUCTION

Epilepsy affects every sphere of an individual's life, cutting across age, gender and social differences. Major areas of education, employment, marriage and social functioning are affected and the overall quality of life is hampered due to the nature of the illness and its consequences. Therefore, management of a patient with epilepsy involves much more than treatment with antiepileptic drugs (AEDs). The steps in the management of a patient with epilepsy are summarised in Table 1.

The medical treatment of seizure disorders is a complex process requiring extensive interaction and co-operation between the physician and the patient. The physician is required to have an accurate knowledge of the type of seizures and epileptic syndromes, pharmacology of AEDs and experience with their therapeutic applications. It is important that patients or a responsible member of the family in case of children and mentally challenged individuals should be informed about the nature of the disorder, fully involved in the therapeutic decision making and should be active participants in the treatment process. In addition, it is important to emphasise the vital necessity to strictly follow the instructions regarding the dose, the frequency and regularity of treatment.

An enquiry conducted between 1979 and 1983 by the Commission on AEDs of the International League Against Epilepsy (ILAE) on the availability of AEDs in 35 developing countries, including India, concluded that "older and less efficacious compounds (such as phenobarbitone) are the only AEDs available to most patients, whereas newer and more compounds are either not available or restricted to a very limited number of cases".[29] According to WHO, 3 out of 4 persons with epilepsy in the world do not receive treatment at all. The approach to pharmacological treatment of epileptic disorders has changed substantially over the last 25 years due to several factors: (a) improved knowledge of the efficacy and tolerability of AEDs;[11,16] (b) acquisition of new information through observational studies and clinical trials, which led to more rational therapeutic decisions;[1] (c) introduction of new AEDs[15,30] and (d) availability of alternate treatment options such as surgery for refractory partial epilepsy.[7,26] Recent worldwide trends in the management of patients with epilepsy emphasise the use of a single AED (monotherapy) over the previous approach of using multiple AEDs simultaneously (polytherapy).[17,25]

Health care delivery in developing regions is largely governed by the three As: availability, acceptability and affordability. The introduction of seven new AEDs (e.g. clobazam, gabapentin, lamotrigine, topiramate, oxcarbazepine, levetiracetam and zonisamide) in India over the last 10 years, in addition to better availability of already existing standard AEDs (Table 2), have provided physicians and their patients with new treatment options, but has in several ways complicated the management of epilepsy. New AEDs are expensive and are beyond the reach of the majority of the patients with epilepsy in developing countries. Despite their promise, only very few patients, who have not responded to standard AEDs, became seizure free while they were initiated on treatment with new AEDs.[10] Primary and secondary care physicians, without special training and expertise in the disorder, treat a majority of patients with epilepsy in India and other developing countries,[14] which often results in indiscriminate usage of the available AEDs.[22] In a recent study, which inquired about the user profile of AEDs in Kerala, the following pertinent observations were made: (a) polytherapy, especially with sub-optimal dosages of AEDs, is quite prevalent;

Table 1: Steps in epilepsy management

Correct diagnosis
Epilepsy education
Treatment with appropriate AEDs
Psychosocial support
Early detection of medical refractoriness

Table 2: Commonly used AEDs currently available in India

Standard AEDs	*New AEDs*
Phenobarbitone	Clobazam
Phenytoin	Gabapentin
Carbamazepine	Lamotrigine
Sodium valproate	Topiramate
Clonazepam	Oxcarbazepine
	Levetiracetam
	Pregabalin
	Zonisamide

(b) the use of relatively expensive AEDs, often in combinations, has escalated the cost of AED treatment and (c) better availability of AEDs has not been supplanted adequately by education of the treating physicians.[22]

This review provides a framework for the choice of AEDs in five clinical situations: (1) newly diagnosed epilepsy; (2) seizure recurrence on initial monotherapy; (3) seizures controlled on polytherapy; (4) seizures poorly controlled on polytherapy and (5) special clinical situations. The role of serum AED monitoring will critically be appraised. Many AEDs are available currently as extended release preparations; their therapeutic implications will be briefly discussed. A practical guide to AED withdrawal in seizure-free patients is provided. A detailed account on the management of status epilepticus, epilepsy in pregnancy and paediatric seizure disorders is beyond the scope of this review.

NEWLY DIAGNOSED EPILEPSY

It is now generally accepted that 65–70% of newly diagnosed patients with epilepsy can successfully be treated with the available AEDs.

The goal of AED therapy is to make the patient completely seizure-free without causing undesirable side effects and thereby achieve improved quality of life. Most epileptologists now agree that monotherapy is the appropriate choice in newly diagnosed epilepsy. The advantages of monotherapy are listed in Table 3.

Nearly 75% of patients with newly diagnosed epilepsy achieve one-year seizure freedom with a single appropriate AED.[17,24]

Various factors, such as seizure type, the epilepsy syndrome, age and gender of the patient, side effect profile of the AED and economic factors, influence the choice of AED for a newly diagnosed patient with epilepsy. Although, the seizure type is the principal consideration in the selection of AEDs, over the last few years, emphasis has shifted from treating the seizure type to treating the epilepsy syndrome. However, in a significant proportion of patients, the syndromic diagnosis of epilepsy may not be possible initially or may not be evident despite long-term follow-up. The choice of drug based on seizure type is given in Table 4.

It is advisable to choose the AED to 'fit the fit and fit the patient'. Valproate is the drug of choice in patients with absence epilepsy and juvenile myoclonic epilepsy. Carbamazepine is contraindicated in these groups of patients. If the patient can afford it, valproate is preferred in patients with all types of primary generalised epilepsies, although phenobarbitone, phenytoin and carbamazepine are also effective and can safely be used in some of them. Lamotrigine either alone or, if necessary, in combination with valproate is a good choice in these groups of patients. In partial epilepsies, since there is little difference in the efficacy of different AEDs, availability and affordability govern the choice.

Phenytoin and carbamazepine may worsen absence and myoclonic seizures.[19] Drug-induced drowsiness caused by clonazepam and clobazam can exacerbate absence seizures. Sedative drugs, like barbiturates and benzodiazepines, are better avoided in children as they can produce subtle cognitive and behavioural disturbances and in adults with occupations involving driving and operating dangerous machines. Phenytoin can cause coarsening of the face and hirsutism, which may be unacceptable to women. Coexistent medical problems, like porphyria, hepatic or renal diseases, will also influence the selection of AEDs. Teratogenic effects of AEDs is an important consideration in women of child bearing age and supplementation of 5 mg of folic acid is routinely recommended with all AED prescriptions for this group of patients.

The cost of the AED is an important factor, which the physicians often forget to give due consideration (Table 5). Newer AEDs escalate the cost of therapy

Table 3: Potential advantages of AED monotherapy

Fewer adverse effects
Improved compliance
No drug interaction
Improved seizure control
Less expensive
Less risk of teratogenicity

Table 4: Efficacy of AEDs according to seizure types

Seizure type	*First line drugs*	*Second line drugs*
Primary and secondarily generalised seizures,	DPH, PB, CBZ, VPA	PRM, CZP, CLB, TPM, LTG, LEV, SPS, CPS
Generalised absence seizures	VPA, ESM	LTG, CLB, CZP, LEV
Atypical absence, tonic and clonic seizures, myoclonic seizures	VPA	CZP, CLB, LTG, PB, PRM, LEV, PIR

Table 5: Cost of AED treatment

Drug	*Average daily dose (mg)*	*Daily cost (Rs)*
Phenobarbitone	90	2.08
Phenytoin	300	3.24
Carbamazepine	800	6.26
Sodium valproate	1200	11.27
Primidone	750	8.67
Clonazepam	4	8.25
Clobazam	20	12.20
Gabapentin	1600	50.33
Lamotrigine	200	24.60
Topiramate	200	33.71
Oxcarbazepine	1200	19.08
Levetiracetam	2000	50.0
Zonisamide	500	45.0

several fold, without offering a significant advantage in seizure control over the established drugs. Hence, their indiscriminate use is unrealistic in a developing country set-up. Even among first line AEDs, cost of treatment with carbamazepine and valproate is 3–4 times more than that with phenytoin or phenobarbitone.

Notwithstanding these concerns, especially regarding the routine use of such affordable drugs, like phenobarbitone, hydantoins or carbamazepine, there should be no hesitation in their use for the large number of economically disadvantaged individuals. A large multicentric study in India involving more than 3,000 patients revealed these drugs provided satisfactory therapeutic control of seizures in nearly 70% of cases without any serious adverse effect.

SEIZURE RECURRENCE ON MONOTHERAPY

What to do when the first AED fails? The first step to be taken is to review the diagnosis and treatment. Common diagnostic errors are failure to consider non-epileptic events and missing the history of myoclonic jerks in syndromes like juvenile myoclonic epilepsy. One of the most important reasons for failure of AED therapy is poor patient compliance.[13] Over one-third to one-half of persons with epilepsy are non-compliant to the extent of interfering with their optimal treatment.[15] A significant factor that may lead to non-compliance is insufficient education regarding medication regimen, treatment with multiple drugs, multiple dosing and apprehension about adverse effects of AED. Patients' education has been shown to be highly effective in improving compliance and thereby seizure control.[10]

Some patients may not achieve seizure control until their serum drug levels are higher than the conventional therapeutic range. It may be advisable to increase the dose of the AED up to maximum tolerated doses in such patients, rather than adhering to serum AED levels.

Patients who do not improve with appropriate monotherapy should be switched on to an alternate AED. A second drug is added slowly and, after reaching the optimal dosage, the first drug is gradually withdrawn. Reducing the dose of the first drug while titrating the second AED may result in an increase in seizures making the physician and the patient to prematurely conclude that the second drug is ineffective.

In patients who have failed two or more monotherapy trials, adding a second AED (duotherapy) may improve seizure control in 20–25% of patients, but is likely to result in complete seizure freedom in only 5–10% of patients.[17] If seizures are completely controlled with duotherapy, consideration should be given to withdrawing the first AED in order to minimise the adverse effects and cost of therapy. For example, over 40% of patients whose seizures were completely controlled when lamotrigine was added to valproate, phenytoin or carbamazepine, remained seizure-free when treated with lamotrigine alone.[3] In a study from South India involving 972 patients with epilepsy, with change over from polytherapy to monotherapy, frequency of side-effects decreased from 29% to 20%, seizure control increased from 29% to 45% and resulted in net saving of Rs. 750 per patient per year.[22]

CONTROLLED ON POLYTHERAPY

The advent of several new AEDs has widened the scope of AED treatment. Given the lower side effect profile of the newer AEDs, there may be a role of polytherapy in certain clinical instances, particularly when a patient develops refractory epilepsy. The term 'rational polytherapy' refers to combining AEDs with different, presumably synergistic mechanisms of action.[8] Several combinations of AEDs appear to fit the model of rational polytherapy. An example would be combining a sodium channel-blocking agent (such as phenytoin, carbamazepine or topiramate) with a GABA enhancing agent (benzodiazepines, valproate or tiagabine). For the treatment of partial epilepsies, the addition of newer AEDs to standard drugs has led to a significant decrease in seizure frequency. Use of ethosuximide and valproate or valproate and lamotrigine in patients with refractory absences or idiopathic generalised tonic-clonic seizures, respectively, are well-accepted forms of rational polytherapy.[1] However, many irrational AED combinations are used as is frequently observed during clinical practice.

Patients, whose seizures are controlled on polytherapy, should be re-evaluated periodically to determine the need for multiple AEDs. Although polytherapy may be responsible for the seizure control, it is also possible that one of the AEDs alone might be effective. Withdrawing AEDs in patients on polytherapy can result in complex drug interactions. For example, discontinuing enzyme-inducing AEDs, such as phenytoin or phenobarbitone, may increase the plasma levels of other AEDs. Conversely, stopping valproate in a patient on therapy with valproate and lamotrigine could result in sub-optimal lamotrigine levels. An increase in seizures in such a situation could be managed by increasing the dose of lamotrigine rather than by re-introducing valproate.

POORLY CONTROLLED ON POLYTHERAPY

Patients whose seizures are not controlled on multiple AEDs should have their diagnosis and treatment critically evaluated in a comprehensive epilepsy care centre. A proportion of patients with medically refractory epilepsy can be cured by surgical treatment and others might benefit from vagus nerve stimulation or ketogenic diet.[23] Surgical treatment of epilepsy should not be considered as the last resort after all combinations of AEDs have been tried. With 10 commonly used AEDs (phenobarbitone, primidone, phenytoin, carbamazepine, valproate, clonazepam, clobazam, gabapentin, lamotrigine and topiramate), there are 45 two-drug and 36 three-drug combinations to which a patient with chronic epilepsy may be exposed to; the trials with all of them will require the whole life-time of the patient to complete. In

general, patients who continue to exhibit one or more disabling seizures per month for a period of two or more years, despite supervised medical trials (6 months each), twice with monotherapy and once with polytherapy, are candidates for presurgical evaluation in a comprehensive epilepsy program.[23]

SPECIAL CLINICAL SITUATIONS

A significant change in the patient's general medical condition should prompt a re-evaluation of the AED treatment. Carbamazepine is a well-documented pro-arrhythmic drug and should be avoided in patients with cardiac disease.[12] Valproate is generally contraindicated in the setting of hepatic failure because of direct hepatotoxicity and risks of fulminant hepatic failure.[4] An increased incidence of valproate-induced pancreatitis has been described in patients with renal failure.[21] Carbamazepine and oxcarbazepine have the least potential for toxicity in renal failure. Gabapentin is the drug of choice for seizure control in patients with porphyria.[27] Patients who are contemplating pregnancy should have their AED treatment reviewed and simplified, if possible. The risk of foetal malformations increases with high dose of valproate and with polytherapy.[18]

The pharmacokinetics of many AEDs change in old age. Also the associated co-morbid conditions will affect AED clearance, leading to potential toxicities and interactions between AEDs and non-AEDs.[31] There is no drug of choice for the treatment of epilepsy in the elderly. AED therapy has to be tailored to the individual patient, weighing potential adverse effects against the benefits. Monotherapy in a low dosage is to be initiated and titration should be graded until the desired benefit is attained. The patient should be seen on a regular basis to screen for potential adverse effects.

LONG-ACTING ANTIEPILEPTIC DRUG FORMULATIONS

Successful treatment of epilepsy requires good patient compliance. It has been reported that adherence to AED treatment falls as the number of daily doses of the drug increases.[5] Maximum compliance is achieved with once-daily dosing regimens.[5] A number of extended release formulations of AEDs have been developed with the goal of providing patients with effective and well-tolerated seizure control through less frequent daily doses. The major advantages of extended release AED preparations are: (a) more stable serum levels with fewer fluctuations, thereby minimising the chance of peak dose related side effects and breakthrough seizures related to low serum AED levels and (b) improved compliance resulting in better seizure control. Several long-acting formulations of carbamazepine and valproate, which can be administered in once or twice daily doses, are currently available. To achieve equivalent serum level, 20–30% increase in the dosage will be required, while converting from conventional to extended release formulations.[6] The bio-availability of most of the locally available long-acting carbamazepine and valproate preparations are unknown.

ROLE OF SERUM ANTIEPILEPTIC DRUG LEVEL MONITORING

Since the goal of pharmacotherapy of epilepsy is to make the patient seizure-free without side effects, measuring the serum level of AEDs has a sound basis in clinical practice. If utilised selectively to address patient and drug-specific issues, serum AED monitoring helps to maximise seizure control and minimise side effects (Table 6).[9] However, plasma AED concentrations are often measured unnecessarily and interpreted incorrectly.

Because of its long half-life, saturation kinetics of its metabolism and narrow therapeutic index, phenytoin makes the soundest case for therapeutic drug level monitoring. The serum level monitoring is less dependable for carbamazepine, since its serum level shows considerable variation between patients and is markedly influenced by the presence of other enzyme-inducing AEDs. Sodium valproate has a wide therapeutic range of serum levels and has very little clinical application. The therapeutic serum levels of new AEDs have not been defined.

Timing of blood sampling for AED assay is influenced by the time taken to achieve a steady blood level, phenomenon of autoinduction and half-life of individual AEDs.[20] A reliable steady blood level of phenytoin can be obtained only after 3 weeks of its constant dose. Carbamazepine markedly induces its own metabolism (autoinduction), which is usually completed within 20–30 days of its initiation. Therefore, for both phenytoin and carbamazepine, serum AED assay should wait for at least one month of being on a constant dosage of these drugs. Once the steady state is achieved, due to the long half-life, for phenytoin, a morning sample will give the steady state serum level. With carbamazepine and sodium valproate, blood samples taken 6 hours and 4 hours after drug intake, respectively, is recommended.[20] If AED assay is being undertaken to verify a toxic side

Table 6: Indications for serum AED level monitoring

Poor response despite adequate dose: to identify unusual pharmacokinetic patterns or poor compliance
Physiological or pathological conditions known to be associated with altered pharmocokinetics (hepatic disease, renal disease, pregnancy, elderly)
Establishing drug toxicity
Minimising the problems caused by non-linear kinetics with phenytoin
Detect and minimise the problems caused by drug interactions
Detect altered bioavailability caused by changes in drug formulations

effect, blood drawn at the time of maximum symptoms will be the most relevant. Failure to educate the patient about the timing of the blood sample is a common mistake made in clinical practice.

A PRACTICAL GUIDE FOR ANTIEPILEPTIC DRUG WITHDRAWAL

Nearly two-thirds of patients with epilepsy will become seizure-free on AEDs within a few years of diagnosis and more than 60% of seizure-free patients on AED will remain seizure-free when the medication is withdrawn.[17,24] In a recent meta-analysis of over 5,000 patients, 29% had a recurrence of seizures within 2 years after initiating AED withdrawal.[2] In most patients, the relapse occurred within the first 6 months after withdrawal. A few readily available patients' attributes help in the clinical decision making for or against AED withdrawal (Table 7). Those with the lowest rate of relapse rate have no seizures for over 2 years after start of AED, a normal IQ, neurological examination and EEG and do not have JME.

The decision to withdraw or continue the AED centres on the risk or relapse and the consequence of seizure recurrence. The social consequences of relapse are smaller in children and women, as driving privileges and employment are not a concern, while adverse influence of AEDs on cognitive performance and pregnancy, respectively, are concerns. The physician's duty is to provide full information about risk of relapse and the consequences to the patient and care givers and leave the final decision to them.

Although no data is available on the optimal rate of AED withdrawal, a slow withdrawal extending not less than 2 months is recommended. A recent randomised trial, which compared a 6-week versus a 9-month withdrawal in 1333 seizure-free children showed a similar relapse rate.[28] In patients taking more than one AED, withdrawal will have to be done of one drug after the other. Sedative medications, such as phenobarbitone, primidone, clobazam and clonazepam are usually withdrawn more slowly.

CONCLUSION

The pharmacotherapy of epilepsy is more complicated now than the years past, due to better availability of already existing standard AEDs and the introduction of new AEDs. A majority of patients with recent onset epilepsy can be successfully treated with one of the standard AEDs (monotherapy). Although several factors influence AED selection, in a developing country, the cost and the seizure type are the principal ones. Long-acting AED formulations, through less frequent daily doses, improve compliance and thereby seizure control. In patients who have failed to benefit from appropriate monotherapy trials, adding a second drug results in seizure control only in a minority of patients. Patients whose seizures are not controlled on polytherapy should be re-evaluated periodically to determine the need for multiple AEDs. Patients whose seizures are not controlled on multiple AEDs should have their diagnosis and treatment critically evaluated in a comprehensive epilepsy care centre. Surgical treatment should not be considered as a last resort after all combinations of AEDs have been tried; a diagnosis of medically refractory epilepsy can be made within 2 years of supervised AED treatment. In patients who are seizure-free for 2 years or more, AED withdrawal should be considered. Those with lowest rate of relapse following AED withdrawal rate have normal IQ, neurological examination and EEG, and do not have juvenile myoclonic epilepsy. If utilised selectively to address patient and drug-specific issues, serum AED monitoring helps to maximise seizure control and minimise side effects.

Table 7: Profile of patients with high likelihood of remaining seizure-free following AED withdrawal

Normal neurological examination and normal IQ
Normal EEG prior to AED withdrawal
Epilepsy with a single seizure type
Seizure-free for > 2 years prior to AED withdrawal
No juvenile myoclonic epilepsy

201 Surgery for Epilepsy: General Principles

Bhaskara Rao Malla, Jayanti Mani

INTRODUCTION

Definitions

An epileptic seizure is a transient occurrence of signs and/or symptoms, due to an abnormal and excessive or synchronous neuronal activity in the brain. Epilepsy is a chronic condition of the brain characterised by an enduring propensity to generate recurrent unprovoked seizures and by the neurobiological, cognitive, psychological and social consequences of this condition. Epileptogenesis is the sequence of events that turns a normal neuronal network into a hyperexcitable network.[59] Epilepsy surgery is the resection or functional manipulation of part of the brain with the aim of alleviating seizures, improving the cognitive function and the quality of life.[22]

Magnitude of the Problem

Epilepsy constitutes a major public health problem in both developing and developed countries.[83,89] At any time and in any place, at least 5 out of 1,000 population have active epilepsy and to this burden, new patients will be added every year at a rate of about 5 per 10,000.[99] A majority of these people with newly diagnosed epilepsy will eventually achieve remission. However, 20–30% of patients continue to exhibit chronic recurrent seizures, despite optimal treatment with antiepileptic drugs.[82] Among these medically refractory patients, there are identifiable subgroups with surgically remediable lesional syndromes.[9] The seizures in patients with these lesional syndromes are resistant to treatment with antiepileptic drugs but have a high rate of cure following surgery.[20,88] A number of centres have reported that epilepsy surgery is not only possible in countries with limited resources, but can also be undertaken in a cost-effective way.[109] In this chapter, we elaborate on the pathological substrate, principles of pre-surgical evaluation, selection of ideal candidates, surgical treatment and post-operative outcome of patients with medically refractory epilepsy.

HISTORICAL PERSPECTIVE

The history of modern epilepsy surgery began in the late 1880s. Victor Horsley performed the first surgery for epilepsy by excising the visible frontal cortical scars in 1886.[29] Based upon autopsy studies, Hughlings Jackson reported in 1888 that a chronic seizure disorder could be the initial and only symptom of a foreign-tissue lesion such as a tumour, vascular malformation or cicatrix in the brain.[32] However, between 1900 and 1930, a number of operations were carried out in vain to control epilepsy (Table 1). Following Hans Berger's invention of the human electroencephalograph (EEG) in 1929, EEG was adopted to identify and better localise epileptiform abnormalities, particularly in the temporal lobe.[58] Wilder Penfield and his colleagues made pioneering contributions in promoting surgery for epilepsy at the Montreal Neurological Institute, Canada.

Epilepsy surgery had an early beginning in India. A sizeable number of patients with refractory epilepsy were operated upon at the Christian Medical College, Vellore, Tamil Nadu, India[1,15,18,45] and at the Institute of Neurology, Chennai, Tamil Nadu, India[66,67] in the 1950s, 1960s and the first half of the 1970s. In the mid seventies, like elsewhere in the world, epilepsy surgery took a dramatic downwards trend in India as well. There was resurgence of interest in the early 1990s. This was due to better understanding of the surgically remediable lesional epilepsy syndromes, the advent of computerised EEG and video-EEG telemetry, magnetic resonance (MR) imaging of the brain as well as application of microneurosurgical techniques for

epilepsy surgery. Incorporating these recent technological advances, Sree Chitra Tirunal Institute for Medical Sciences and Technology, Trivandrum, Kerala, India.[61,65] All India Institute of Medical Sciences, New Delhi[8,14] and a number of other institutions in India have successfully developed epilepsy surgery programs.

PHYSIOLOGY

The brain consists of neurons and neuroglia. Neurons are inherently excitable cells and are continuously electrically active. Seizures are a result of an excessive synchronised discharge of abnormal neurons. Seizures start when a small group of abnormal neurons undergo prolonged depolarisation associated with the rapid firing of repeated and synchronised action potentials. These abnormally discharging epileptic neurons recruit adjacent neurons or neurons with which they are connected into the process. Seizures may then spread to involve adjacent areas of the brain or through established anatomic pathways to other distant areas.

Cellular Mechanisms

The intracellular phenomenon that represents abnormal neuronal excitation is the "paroxysmal depolarisation shift (PDS)" in the intraneuronal electrical recording. This is a sustained depolarisation of the neuron that results in a series of action potentials within the neuron and in turn generates a series of "excitatory post-synaptic potentials" at the apical dendrite. The PDS is followed by sustained hyperpolarisation of the cell when it is relatively inexcitable. The excitatory electrical activity spreads via synaptic mechanisms in neuronal networks, to activate more and more cortical neurons and thereby generate interictal epileptiform discharges. That such abnormal discharges do not occur in the normal brain is because of highly efficient and ubiquitous inhibitory systems. An unstable relationship between excitatory and inhibitory mechanisms in the brain results in the generation and propagation of seizures. In addition to the inhibitory and excitatory synaptic mechanisms that involve gamma-aminobutyric acid (GABA) and glutamate, respectively, other non-synaptic neuronal interactions also contribute to the spread of electrical activity in neuronal networks. These include gap junctions, fluctuating extracellular ionic concentrations, especially potassium and field effects. Recently, evidence has been accumulating to establish the role played by astrocytes in this process.

Seizure Generation

Although several hypotheses have been proposed, the simplest of these is the concept of a discrete seizure focus with spreading epileptic activity and is probably best applied in lesional partial epilepsies. This hypothesis is fundamental to the feasibility of surgery as a therapeutic option for epilepsy. The second theory of distributed networks proposes the presence of multiple, spatially distinct neuronal groups that act as seizure generators that may be phase-linked through a neuronal network. The latter hypothesis explains the mechanism of primary generalised seizures to involve both cortical and sub-cortical generators. Networks represent functionally and anatomically "connected" cortical and sub-cortical brain structures and regions bilaterally. Activity in one part of the network affects activity in others, i.e. vulnerability to seizure in one part of the network is influenced by activity elsewhere in the network. The network as a whole produces clinical and electrical phenomena associated with seizures. This model could also predict the success of epilepsy surgery by hypothesising that successful epilepsy surgery requires removal of all epileptic generators.

Current theories try to explain the mechanism(s) for the abnormally increased propensity of the brain to develop excessive discharges of cerebral neurons. The early theory, according to which disruption of the normal balance between excitation and inhibition in the brain results in seizure generation, may have been an oversimplification. Cortical networks that generate oscillations, on which inhibitory neurons, neuronal communication (e.g. synaptic transmission) and intrinsic neuronal properties (e.g. ability of a neuron to maintain burst firing) are dependent, are thought to be crucial elements of seizure generation. The occurrence of epileptic activity may be an emergent property of such oscillatory networks. Transition from normal behaviour to a seizure behaviour may be caused by a number of factors, including greater spread and neuronal recruitment secondary to a combination of enhanced connectivity, enhanced excitatory transmission, a failure of inhibitory mechanisms and changes in intrinsic neuronal properties.

Seizure Classification

Epileptic seizures are broadly classified according to their site of origin and pattern of spread. In 1981, the International League Against Epilepsy (ILAE) developed an international classification of epileptic seizures that divides seizures into two major classes: (1) Partial-onset seizures and (2) Generalised-onset seizures. Partial-onset seizures begin in a focal area of the cerebral cortex, whereas generalised-onset seizures have an onset recorded simultaneously in both cerebral hemispheres. Some seizures are difficult to fit into a single class and they are considered unclassified seizures. Focal or partial seizures arise from a localised region of the cortex and have clinical manifestations that reflect the area of brain involved. Focal discharges can remain localised or they can spread to nearby cortical areas, to sub-cortical structures and/or transmit through commissural pathways, to involve the whole cortex. The latter sequence describes the secondary generalisation of focal seizures. As an example, a seizure arising from the left motor cortex may cause jerking movements of the right upper extremity.

If epileptiform discharges spread to adjacent areas and then the entire brain, a secondary generalised tonic-clonic seizure ensues. Primary generalised seizures begin with abnormal electrical discharges in both hemispheres, simultaneously. Generalised seizures involve reciprocal connections between the thalamus and the neocortex. The manifestations of such widespread epileptiform activity can range from brief impairment of consciousness (e.g. absence seizure) to generalised motor activity accompanied by loss of consciousness (e.g. generalised tonic-clonic seizure).

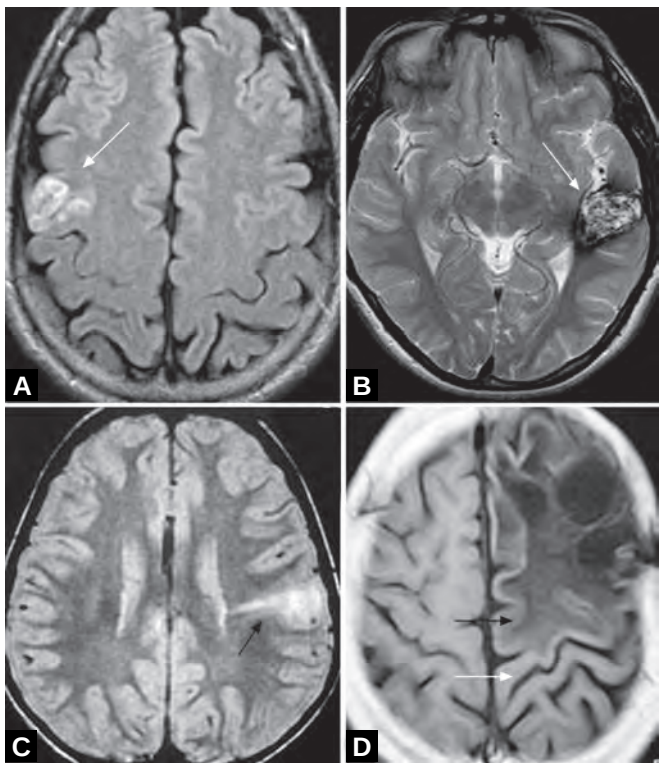
PATHOLOGY

Mesial Temporal Lobe Epilepsy

(Refer to chapter 203 on "Surgical Treatment of Temporal Lobe Epilepsy")

Neocortical Epilepsy

Whereas most temporal lobe epilepsy (TLE) is characterised by hippocampal pathology, neocortical epilepsy lacks a common pathological substrate.[7,62] A wide range of structural anomalies have been associated with chronic partial neocortical epilepsy (Figs 1A to D). These anomalies can be classified into five categories: (1) Malformative; (2) tumoural; (3) ischaemic; (4) traumatic and (5) infectious.



Figs 1A to D: Spectrum of neocortical lesions in people with epilepsy: (A) DNET involving the face motor cortex. (B) Cavernoma involving the posterior temporal neocortex. (C) Focal cortical dysplasia adjacent to the central sulcus. (D) Frontal gliosis in an operated case of tuberculoma

In a small number of patients, the non-specific substrate of gliosis is found. Most of these lesions are not believed to be epileptogenic per se; rather, the epileptogenicity is due to excitability of the surrounding cortex. Numerous mechanisms have been implicated in the epileptogenicity.[76] These include neurochemical changes, pressure effect, ischaemia and intrinsic epileptogenicity in the congenital malformative diseases.[55]

Developmental Lesions

Developmental lesions associated with chronic seizures are mainly malformations of cortical development. These abnormalities are often diffuse and, therefore, less amenable to surgery.[74] Such widespread abnormalities include pachygyria, lissencephaly, band heterotopia and subependymal heterotopia. Focal abnormalities include focal cortical dysplasia, polymicrogyria, schizencephaly, focal subcortical heterotopia and tuberous sclerosis. When a focal ictal onset zone is identified and completely resected, an excellent outcome can be achieved otherwise the overall surgical outcome in this group is sub-optimal.[54,56,102] In gelastic epilepsy and hypothalamic hamartoma, seizure remission has been achieved by hamartoma resection,[77] suggesting possible seizure origin in the hypothalamic lesion. Surgical treatment has recently been advocated for patients with intractable infantile spasms. Patients who fail treatment with antiepileptic drugs and corticosteroids and who demonstrate predominantly unilateral abnormalities on EEG, PET and MRI may be suitable for lobar or multilobar cortical resection.[16]

Developmental Tumours

The natural history of the lesions associated with intractable seizures is variable.[93] The main concern with tumours in this patient population is the possibility of tumour progression or transformation.[37] As a general rule, the glial tumours associated with intractable seizures have a rather indolent course[10,25] Given their developmental nature, gangliogliomas and dysembryoplastic neuroepitheliomas are frequently associated with cortical dysplasia.[19] This could explain the persistent seizures following some lesionectomies. In dealing with this pathology, wide resection of the gyrus involved is recommended, rather than a pure lesionectomy. If seizures persist, an invasive electrode study is indicated.

Vascular Malformations

Vascular malformations, like cavernous angiomas and arteriovenous malformations (AVMs), are increasingly being detected in patients with localisation-related epilepsy.[35]

Although the pathophysiological mechanism appears to be very focal in cavernous angiomas, several series have recorded suboptimal seizure outcome following lesionectomies. This could be due to incomplete

resection of the haemosiderin-impregnated area or the existence of dual pathology, specifically when located in the mesial temporal lobe. Arteriovenous malformations are characterised by a steal phenomenon resulting in ischaemic damage and haemorrhage in the surrounding cortex. The surgical management of AVMs with respect to seizure outcome is also controversial. Good seizure outcome has been reported following resection of AVMs and additional epileptogenic cortex identified by interictal electrocorticography.[115] On the other hand, good seizure outcome has been reported following radiosurgery for AVMs.[27] Sixty per cent of patients presenting with seizures became seizure free, following stereotactic proton beam radiation. This suggests that the epileptogenic zone is in the immediate vicinity of the vascular malformation rather than at a distance from it.

Brain Trauma

Penetrating injuries to the brain are frequently complicated by seizures.[12,101] Focal and diffuse pathological changes are noted.[108] The focal damage results in the classically described meningocerebral scar. Seizure outcome following cortical resection is excellent if the pathological changes are focal and correlate well with the semiology and electrophysiology of the seizures. A variety of pathological changes have been noted following blunt or non-penetrating injury to the brain.[34] These are axonal damage, intracerebral haematomas, ischaemic parenchymal changes and contusions, frequently involving the orbitofrontal cortex and the basal and anterior temporal lobes. The incidence of seizures following blunt injury is variable.[33] Due to the diffuse nature of closed head injury, localisation of the epileptogenic cortex is frequently difficult. Patients are considered for surgery when there is a good correlation between the electroclinical syndrome and pathological changes on MR. Wide cortical resections are recommended to ensure a good surgical outcome.

SURGICALLY REMEDIABLE LESIONAL EPILEPSY SYNDROMES

Surgically remediable syndromes (Table 2) are epileptic disorders for which: (a) the pathophysiology is understood; (b) the natural history is reasonably well known to be medically refractory or even progressive, once the major first-line antiepileptic drugs fail; (c) pre-surgical evaluation can be accomplished and (d) surgery offers an excellent chance that disabling seizures will completely be eliminated or markedly reduced.[9] The presence of a lesion in a patient with refractory partial epilepsy does not invariably indicate that the lesion is responsible for the seizures. There is a consensus at present that a comprehensive epilepsy pre-surgical evaluation should be performed in patients with a lesional epilepsy syndrome associated with pharmacoresistant seizures, to establish a relationship between the MRI-identified lesion and the site of the epileptic brain tissue.[21]

PRE-SURGICAL EVALUATION

The principle of epilepsy surgery is to identify and resect or disconnect a single identifiable epileptogenic focus without risk of neurological deficit. The rate of success of epilepsy surgery depends upon the accurate localisation of the epileptogenic zone, which is defined as the area necessary and sufficient for initiating seizures and whose removal or disconnection is necessary for abolition of seizures.[40] Since the epileptogenic zone cannot always be reliably defined pre-operatively, selection of ideal candidates for epilepsy surgery requires a multimodal evaluative approach, by careful correlation between clinical, electroencephalographical, radiological and neuropsychological data.[21] This constitutes the pre-surgical evaluation. Concordance of multimodality data for a single epileptogenic focus which can safely be removed is crucial for good surgical outcomes. The relationship between a lesion and the area generating epileptic seizures is also a concern when the lesion is poorly circumscribed and more diffuse, as in focal encephalomalacia or neuronal migration disorders.

Objectives of Pre-surgical Evaluation

It aims to accomplish the following: (a) establish the epileptic nature of the paroxysmal events; (b) identify a discrete structural abnormality, either directly with neuroimaging techniques or inferentially because of an associated functional deficit; (c) provide evidence of localised abnormal neuronal excitability of that actual or presumed structural lesion and (d) establish lack of vital function (e.g. speech and movement) in the suspect region.

Candidates for Pre-surgical Evaluation

Natural history studies have shown that most of the patients with epilepsy, who are destined to achieve satisfactory seizure control with antiepileptic drugs, will do so within two years of the onset of epilepsy.[36,82] Continuing frequent seizures during childhood and

Table 2: Surgically remediable lesional epilepsy syndromes

Atrophic scars
Rasmussen's encephalitis

early adult life can produce devastating psychosocial, educational and occupational consequences. Recurrent seizures are known to result in pathological changes locally, which enhance the tendency for refractoriness. In addition, these may produce a secondary epileptogenic focus, for example, the "mirror focus" on the opposite side. More emphasis is therefore now being placed on early referral for epilepsy surgery. As a general rule, patients with refractory epilepsy continuing to exhibit one or more disabling seizures per month for a period of two years or more, despite supervised therapeutic trials (six months each) twice with a single antiepileptic drug and once with a combination of two antiepileptic drugs, are candidates for detailed evaluation in a comprehensive epilepsy care program[62] (Table 3). Many epilepsy syndromes are well characterised and have defined prognoses, simplifying the selection process; thus, idiopathic partial and generalised epilepsies are not amenable for surgery, whereas surgery might be considered the treatment of choice for some specific surgically remediable syndromes discussed above.

Absolute contraindications to epilepsy surgery include primary generalised seizures, underlying degenerative or metabolic disorders or supervening medical illness and psychogenic seizures. Psychogenic non-epileptic seizures are frequently seen at epilepsy centres, where they represent approximately 20% of patients referred for medically refractory seizures. Relative contraindications to surgery include medication noncompliance, interictal psychosis, mental retardation and severely dysfunctional family dynamics. Establishment of refractoriness of epilepsy in an individual patient requires a complete clinical re-evaluation with a detailed medical history. All efforts should be made to establish that seizures are truly epileptic and determine the electroclinical syndrome. Unresponsiveness to antiepileptic drugs should not be due to inappropriate AED choice or wrong AED combinations, poor drug compliance, social or psychological factors.

Table 3: Indications for pre-surgical evaluation

- Persistent seizures despite appropriate pharmacological treatment (usually at least two drugs as monotherapy and one combination as polytherapy appropriate to seizure type, at adequate doses, with adequate compliance)
- Impairment of quality of life due to ongoing seizures
- Memory deficit, attention deficit, injuries, accidents due to ongoing seizures
- Severe adverse reactions of antiepileptic medications

Contraindications for epilepsy surgery

- Minor seizures that do not impair quality of life
- Primary generalised epilepsies
- Non-epileptic seizures
- Progressive medical or neurological disorder
- Active interictal psychosis or behavioural problems

Pre-surgical Evaluation

The standard pre-surgical evaluation includes non-invasive tests consisting of high resolution brain MR imaging, scalp video-EEG telemetry and neuropsychological assessment. Concordance of data obtained from these tests may be adequate to perform surgery with good results, as in the classical mesial temporal epilepsy syndrome. For patients with epileptogenic lesions located at or near the primary motor, sensory, or language cortex, several non-invasive tools of functional mapping have been developed. These include magnetoencephalography (MEG), positron emission tomography (PET), and, more recently, functional MRI.[17]

NEUROIMAGING

MRI has revolutionised the evaluation of medically intractable epileptic patients who are being considered for surgery. Now the pathologic substrates can be identified pre-operatively, which has led to a renewed interest in the surgery for neocortical epilepsy. MRI can detect almost 100% of structural lesions that are associated with epilepsy (Figs 1A to D) and can almost always detect the mesial temporal sclerosis associated with mesial TLE. The advent of high resolution MR imaging and multiplanar analysis have significantly improved the ability to visualise malformations of cortical development in patients with epilepsy.[5] Abnormalities of the gyral and sulcal pattern have been studied with various techniques, including curvilinear reformatting and volumetric analysis in patients with focal cortical dysplasia.[91] Ictal SPECT is particularly useful in non-lesional extratemporal epilepsies, often revealing discrete neocortical regions of activation, not appreciated by video-EEG monitoring or MRI.[38,92] Interictal metabolic PET imaging has been extensively utilised in pre-surgical evaluation of refractory seizures to correlate with ictal electrophysiologic and structural magnetic resonance findings.[16] Regardless of the presence of structural abnormalities, functional imaging by PET or SPECT provides complementary information. Ideally, these techniques should be used and interpreted together to improve the localisation and understanding of the epileptic brain.[95]

Non-invasive Electroencephalography

The purpose of video, EEG telemetry is to record habitual seizures, identify the seizure type and syndrome and obtain information about the electrical localisation of the seizure onset. It is also useful to rule out the rare possibility of non-epileptic events. While video-telemetry is a very useful addition to the diagnostic armamentarium for pre-surgical evaluation, a large majority of patients can still be satisfactorily evaluated for surgery without[103] this facility. Hence, this should not be considered

an absolute requirement, although no doubt a desirable one for difficult cases. The duration of recording is individualised and varies from 24 hours to 7 days, based on the number of seizures to be captured and the baseline seizure frequency in the patient. Uncomplicated cases with a single seizure type may require only one seizure to be recorded, patients with multiple seizure types or multiple interictal foci may require prolonged recording to capture all types of seizures. The semiology of the clinical seizures provides evidence for the symptomatogenic zone, while the localisation of the scalp ictal-EEG represents the ictal onset zone. In the classical lesional mesial temporal epilepsy syndromes, the ictal scalp-EEG patterns are usually typical and adequate for surgical decision making. Not uncommonly however, ictal scalp EEG may show widespread changes even in focal lesions and especially in extratemporal epilepsy. Sphenoid electrodes may help to localise the spiking and ictal onset zones in mesial TLE.[44] The interictal EEG represents the irritative zone and provides equally valuable and often localising information about the epileptogenic zone during scalp video telemetry.

Neuropsychological Assessment

Neuropsychological assessment is included as a part of the standard pre-surgical evaluation. Neuropsychological assessment is the best single means of quantifying the cognitive abilities and psychosocial status of a person.[28] The pattern of cognitive strengths and weaknesses provide evidence for the area of cerebral dysfunction, also referred to as the functional deficit zone, which may overlap with the epileptogenic zone. In addition, the neuropsychological evaluation also plays a unique role in assessing the potential risk to cognitive function after surgery. In the context of temporal lobe surgery, this involves quantification of verbal and visual memory scores prior to surgery. Frontal lobe epilepsy patients perform worse on measures of speed/attention, motor sequencing and concept formation.

Intracarotid Amobarbital (Wada) Test

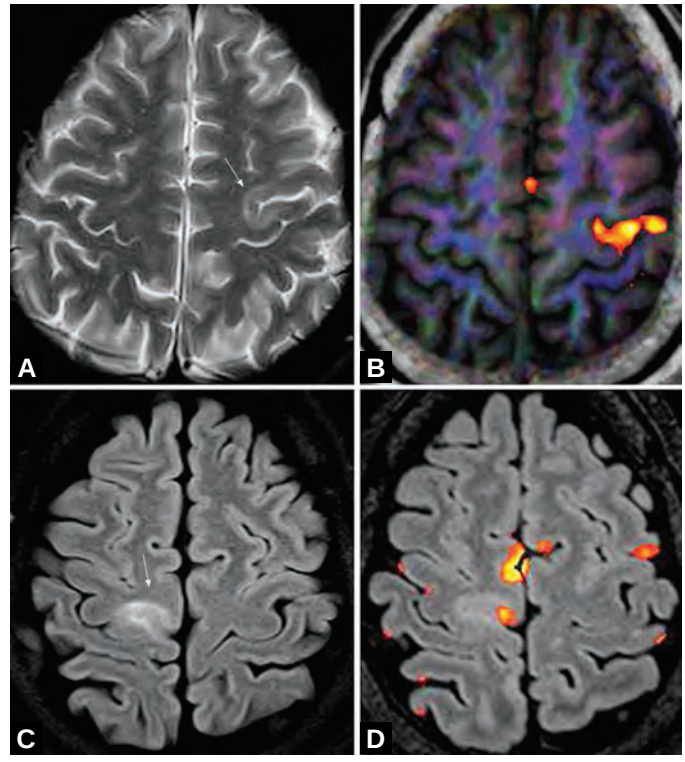
The intracarotid amobarbital (Wada) test is used to temporarily anaesthetise each hemisphere in turn by intracarotid injection of amobarbital or methohexital, in order to determine the language and memory abilities supported by the non-anaesthetised hemisphere.[107] While language assessment during the Wada test is simple and straight forward, interpretation of memory deficit is complex and requires a carefully designed protocol.[104] Recently, a non-invasive method, like the functional MRI, is gradually replacing the Wada test for the lateralisation of language and memory, due to ease of use and reproducibility.

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) is an exciting new technique that provides maps of human cortical function[17] (Figs 2A to D). Motor cortex and vision can adequately be displayed using this methodology.[31] The value of fMRI in language and memory localisation is being assessed, but requires excellent patient co-operation. Both functional MRI and magnetoencephalography (MEG) can now be used preoperatively to create functional brain maps that can be linked to several of the available frameless stereotaxy workstations.

Invasive Electroencephalography

Intracranial EEG is indicated in the setting of uncontrolled epilepsy considered for resective surgical treatment when: (a) there is likely to be a single region of seizure onset; (b) localisation of this region is insufficiently precise or impossible, based on the combination of non-invasive EEG and tests of focal functional deficit and structural abnormalities and (c) the available information from non-invasive evaluation in an individual patient allows a hypothesis about the suspected region of seizure onset to be further investigated.[40] To further define the ictal onset area, several classes of invasive electrodes have been introduced. These consist of electrodes of intermediate invasiveness, such as epidural pegs, electrodes introduced through the foramen ovale and more invasive electrodes, such as depth, subdural grid, and strip electrodes. Foramen ovale electrodes provide a definite advantage over both scalp EEG and sphenoidal electrodes. In patients with suspected TLE,



Figs 2A to D: (A and B) Focal cortical dysplasia involving the hand motor cortex with functional activation in the same area. (C and D) Leg motor cortex with functional activation in the same area, as well as in the supplementary motor cortex

foramen ovale electrodes like depth electrodes reliably pick up epileptiform activity generated in or involving the hippocampal formation. However, these have definite limitations also. Depth electrodes are inserted with stereotactic MR or CT guidance, such that the trajectory, termination point and location of each contact can be accurately predetermined. Cortical grids may be useful to stimulate and localise certain essential cortical regions, such as language and sensorimotor areas, when awake craniotomies are not possible such as in children.[46] Grids are particularly useful when both seizure onset zone and cortical function have to be mapped. With intracranial EEG, the decision to offer surgery rests primarily on the ictal EEG, a measure of the brain's excitability. If seizure onset is well localised, surgery is recommended. If it is poorly localised, or multifocal seizure onsets are detected, then resective surgery is not advised.[98]

Cortical Stimulation Mapping

In 1909, Victor Horsley reported on the function of the motor cortex based upon stimulation of the cortex in front of the central sulcus with a bipolar electrode. Fedor Krause reported[96] patients operated upon for focal epilepsy after performing brain mapping by electrical stimulation in 1912. Penfield and Jasper, in 1954, provided the most extensive maps of cortical localisation, based on a very large series of carefully recorded observations, following electrical stimulation of the cortex during surgery for epilepsy on conscious, co-operative patients.[58] When the lesion or the epileptogenic zone involves or is adjacent to eloquent cortex, functional mapping should be performed to delineate eloquent cortex and thereby permit a safe and complete resection. Mapping is usually performed when resection is contemplated in or near eloquent cortex that includes the central area (motor and sensory cortices), dominant inferior frontal cortex, dominant temporal lobe posterior to the precentral sulcus (language cortex) and the dominant parietal lobe and occipital lobe (visual and association cortex). Mapping may be done pre-operatively during invasive video-EEG telemetry and by other methods mentioned above. Stimulation mapping may also be done intra-operatively in selected cases with good patient co-operation. Direct cortical stimulation with bipolar electrode stimulators under propofol anaesthesia can be used to readily identify the motor cortex during surgery. Monopolar cortical stimulators are also used with EMG recording electrodes placed in advance in the major muscle groups. Intra-operative mapping of the language cortex is more elaborate and requires patient co-operation with awake craniotomy. Somatosensory evoked potentials (SSEPs) are utilised to demarcate the central sulcus, by the identification of phase reversals.[114] Standard anatomical landmarks will aid in the identification of the central sulcus, as well as eloquent cortex prior to neurophysiological mapping (Fig. 3).

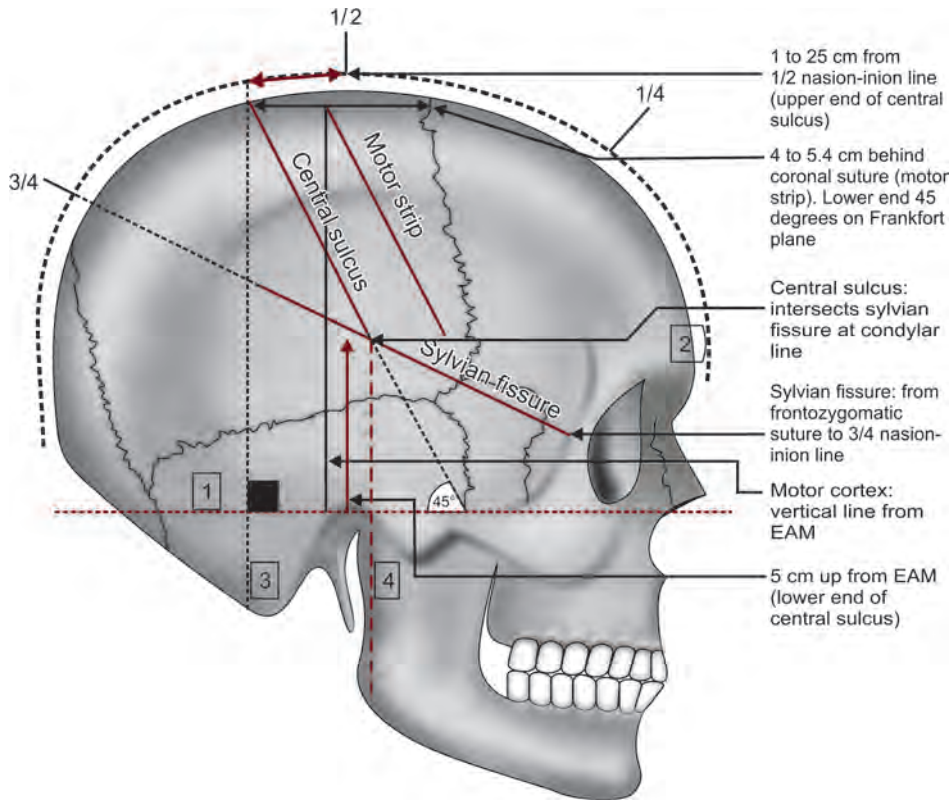


Fig. 3: Outline of the skull with anatomical landmarks to identify the central sulcus (*Reproduced with permission from Dr Sabbagh and the Pan Arab Journal of Neurosurgery*)

Awake Craniotomy

Wilder Penfield and his colleagues standardised the original technique of awake craniotomy at the Montreal Neurological Institute, Montreal, Canada. This technique has been facilitated with the introduction of propofol anaesthesia.[2] Patient co-operation and an anaesthesiologist familiar with the technique are essential. This technique provides continuous feedback, while the patient is maintained awake during resections adjacent to language, primary motor and sensory areas. An awake craniotomy is difficult to perform in children who, therefore, may require an implanted grid and extra-operative mapping of the eloquent areas.

Electrocorticography

Foerster and Altenburger introduced electrocorticography (ECoG) in 1934. It refers to intra-operative recording of EEG directly from the cortical surface. It has been used to identify the epileptogenic area and guide the extent of resection. The resection is extended to include all of the cortical areas showing active interictal spikes (so-called "spike chasing"). In addition, information regarding the presence of spikes in the rim of the resection or at a more distant location has been used for prognosticating seizure outcome after surgery.[87] It is mostly performed for extratemporal epilepsies. The major disadvantage of ECoG is its duration, limited to brief intra-operative periods and often complicated by anaesthetic effects.[42] Therefore, intra-operative ECoG is restricted to the definition of the irritative zone and thus, it has limitations for sufficiently delineating the epileptogenic zone or eloquent cortices. Residual spikes in the resection margins do not reliably predict residual epileptogenicity, nor does their absence guarantee post-operative seizure control. It is performed routinely at some centres, but the extent of resection was rarely dictated by ECoG, which depended on anatomical constraints and the feasibility of complete removal of a lesion.[3] Experience of routine ECoG is required to recognise anomalous findings. ECoG is useful particularly in intrinsically epileptogenic lesions like focal cortical dysplasia, as frequent continuous ictal-like electrographic activity can be identified in 65% of patients.[55]

Neuronavigation

One of the most significant advances in lesional epilepsy surgery has been neuronavigation.[46] Evidence suggests that seizure outcome correlates with the extent of lesion resection. In this regard, the ability of neuronavigation to optimise the surgical approach and confirm the extent of resection has been invaluable. It is particularly useful during the surgical planning and resection of hypothalamic hamartomas associated with gelastic seizures. Neuronavigation can be used to select the optimum side for the parasagittal craniotomy for corpus callosotomy, as well as to assess the completeness of callosotomy from rostrum to splenium.

SURGICAL PROCEDURES

Surgical procedures (Table 4) for epilepsy may be classified as resective procedures with an aim to stop seizures or palliative procedures that disconnect various regions of the brain to prevent seizure spread[47] (Fig. 4). While the former is employed if the pre-surgical evaluation identifies a single safely removable epileptogenic zone, the latter are employed when seizures are multiregional or overlap eloquent cortex.[60] Temporal lobe resections make up approximately two-thirds of all procedures currently performed at epilepsy surgery centres, reflecting the predominance of adult patients with intractable TLE. In paediatric epilepsy surgery centres, a greater proportion of patients undergo extratemporal, multilobar and hemispheric resections or disconnections.

Lesionectomy

Lesionectomy for epilepsy is a surgical procedure that is directed at the structural lesion, believed to be the aetiology of the seizure disorder. Complete resection of the lesion appears crucial for freedom from seizures in lesional epilepsy surgery.[19] The operative strategy may include: (1) lesionectomy, i.e. complete lesion excision, as determined by MRI, without attempting to resect the epileptogenic zone; (2) extended lesionectomy, i.e. resection of the lesion with “margins”; (3) resection of the lesion and the epileptogenic zone, as determined by ECoG; (4) resection of the epileptogenic zone alone. The most common resection strategy involves excision of the lesion with a “margin” around the lesion.[3,63] The extent of the resection may be determined by different criteria: (1) intra-operative visualisation of the tissue; (2) radiological margins determined by MRI signal abnormalities; (3) histologic margins based on intra-operative frozen section evaluation of the tissue and electrocorticographic margins based on intra-operative ECoG or a combination of these techniques. Incomplete resection can be due to poor differentiation of lesion from the normal brain. It is probable that systems that provide "image-guided surgical capabilities" or intra-operative imaging will help to solve this problem. The second cause of incomplete resection is the extension of the

structural abnormalities to a functional area; multiple subpial transections have reportedly been successful in alleviating this problem.[48]

Lobar/Cortical Resections

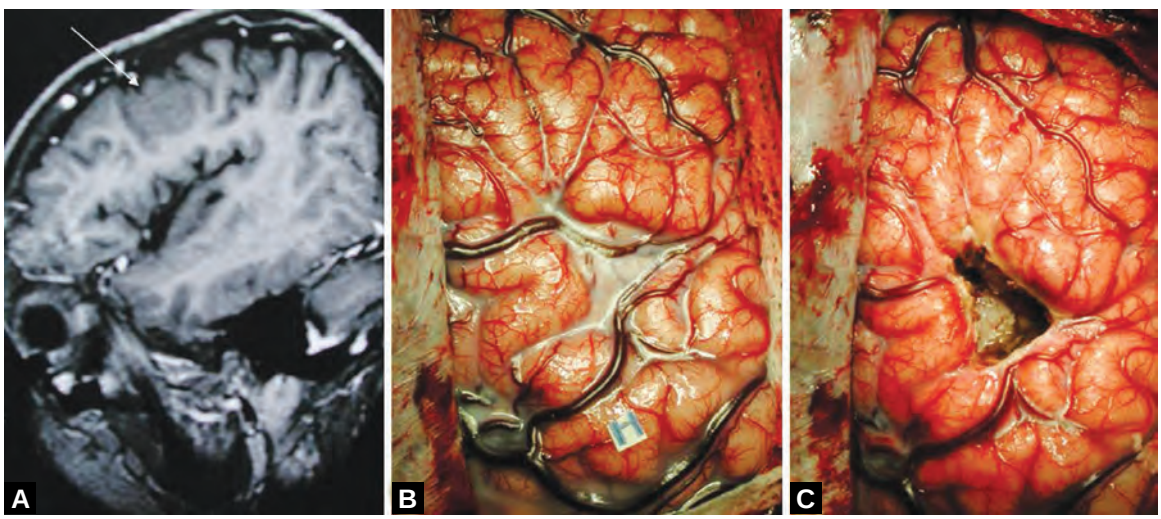
(Temporal Lobe Resections are discussed in detail in the Chapter 203)

Frontal Lobe Resections

In frontal lobe epilepsy the localisation of an ictal onset area is difficult and is facilitated when a lesion is present on imaging[69,71,72] (Figs 5A to C). When the epileptogenic zone is diffuse, a complete frontal lobectomy anterior to the precentral sulcus can be performed under general anaesthesia. The location of the central sulcus is determined using SSEPs or cortical stimulation.[52] In the dominant hemisphere, Broca's area should be identified and preserved. This is best performed under local anaesthesia or with the use of a subdural grid. Resection of the supplementary motor area leads to transient contralateral weakness and apraxia. On the non-dominant side, extensive resection of the orbitofrontal cortex can be performed. The intersection of the optic nerve and olfactory nerve is used as the posterior limit of the resection.

Central Resections

In central type epilepsy, resective surgery is performed, preferably under local anaesthesia with monitoring of motor function. A focal resection is performed if the ictal onset area is circumscribed and involves the primary face motor or sensory cortex or trunk or leg area.[39] Resection of the primary face area does not cause any significant deficit (Figs 6A to C). Resection of the hand area leads to severe disturbance in hand function. Resection of the



Figs 5A to C: (A) MR image showing focal cortical dysplasia in the premotor cortex (arrow). (B) Located with the identification of prominent overlying sulcus. (C) Resected with the aid of intraoperative monitoring and post-resection cavity

hand sensory cortex results in impaired position sense and stereognosis. Resection of the motor leg area leads to a footdrop; this usually improves and most patients can walk independently. The vascular supply of the primary motor area should not be disturbed and the geometry of the white matter tract is respected.[53]

Parietal and Occipital Resections

Seizures originating in the parietal and occipital lobes are rare.[70,110,111] Somatosensory aura, pain, vertiginous sensations, aphasia or disturbance of body image are suggestive of parietal origin of the seizures.[80] The ictal manifestations are varied and reflect the quick spread to the frontal lobe in superior parietal epilepsies and to the temporal lobe in inferior parietal cases. Interictal and ictal scalp EEG recordings are not reliable markers for parietal lobe epilepsy. In patients with occipital lobe epilepsy having hemianopsia, resective surgery carries little risk.[79] In the case of dominant hemisphere epilepsy, the speech-related cortex should be identified and spared. When a circumscribed lesion is found, lesionectomy can yield satisfactory results. In non-lesional cases, the ictal onset area should be precisely localised using invasive electrodes. These are used in addition to mapping of the calcarine cortex and speech-related cortex. With this strategy, visual deficits can be minimised.

Multilobar Resections

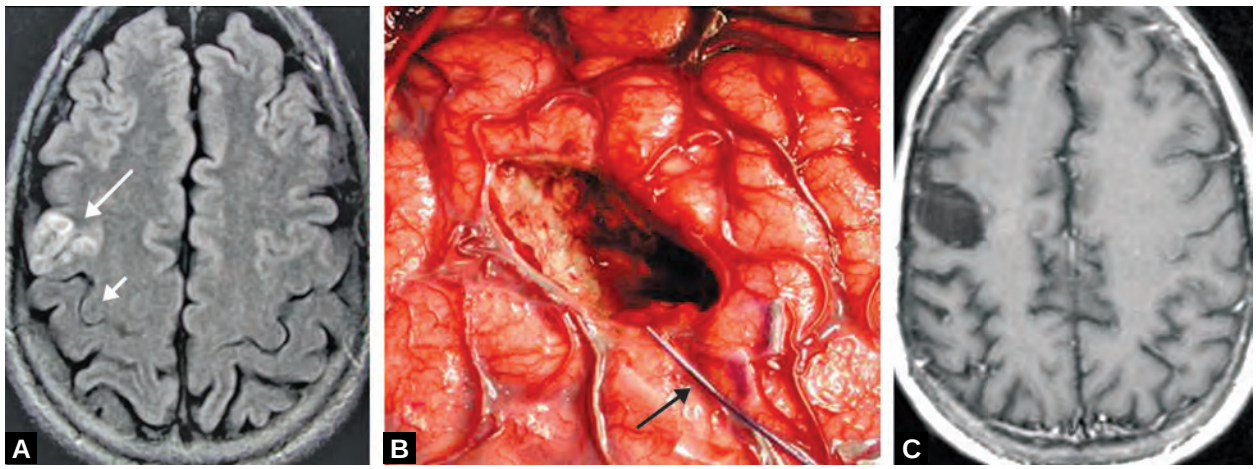
Multilobar resections are indicated for the control of pharmacologically refractory seizures, in the presence of widespread epileptogenicity involving more than one lobe in patients with preserved neurologic function. These patients have various types of lesions, including cerebral gliosis, atrophy (porencephaly), dysplasia (heterotopia, cortical dysplasia and hemimegalencephaly), Sturge-Weber syndrome or Rasmussen encephalitis. Patients with non-progressive disorders (e.g. atrophy, gliosis, dysplasia), with presence of fine-finger movements and foot-tapping are potential candidates for multilobar resections, as hemispherectomy is contraindicated in these patients.

Hemispherectomy

Hemispherectomy is generally indicated in patients with widespread unilateral EEG abnormalities, diffuse unilateral structural abnormality and clinical evidence of hemiparesis and hemianopia.[14] Three aspects of the aetiology may have an impact on the decision for and results of surgery: whether the condition is congenital or acquired, strictly unilateral or possibly bilateral, progressive or static. Congenital pathologies, such as large porencephaly resulting from in utero or perinatal insult or the Sturge-Weber syndrome, which are usually strictly unilateral, have a better prognosis with surgery than a congenital lesion, such as hemimegalencephaly, which may be associated with some degree of contralateral involvement.[112] Acquired unilateral pathology, such as Rasmussen's chronic encephalitis, has a better prognosis than infectious processes, which usually have bilateral involvement.[68] Various surgical techniques are employed to treat hemispheric epilepsy syndromes and include anatomic hemispherectomy, functional hemispherectomy, hemispherotomy and hemidecortication. Hemispherotomy may be more suitable for patients with perinatal stroke and Rasmussen syndrome, whereas a modified functional or anatomic technique may be better suited to patients with hemimegalencephaly and cortical dysplasia. The choice of technique depends in part on the patient's age, type of lesion, size of the hemisphere and lateral ventricle and the surgeon's expertise.

Corpus Callosotomy

In patients with symptomatic or cryptogenic generalised epilepsies, such as the Lennox-Gastaut syndrome, bilateral cerebral dysfunction and bilateral seizure onset, focal cortical resection is of no use. Atonic, tonic and tonic-clonic seizures may, in some patients, respond to



Figs 6A to C: (A) MR image showing DNET involving the face motor cortex (long arrow). (B) Adjacent hand area (small arrow), post-resection surgical cavity. (C) Post-operative MR image showing lesionectomy

corpus callosotomy, the rationale being interruption of the rapid secondary bilateral synchrony that underlies these seizures types.[13] The indications for corpus callosotomy are not standardised, but patients with drop attacks usually respond best. Recurrent episodes of convulsive status epilepticus are also eliminated in most cases.[43,51] A complete callosotomy is performed in those children who are developmentally retarded and who have no or very limited speech.[96] A partial callosotomy can be reserved for those children with partial speech preservation.[50]

A number of methods have been employed to assure accomplishment of the desired length of section.[4] These include physical measurement of the exposed callosum to be sectioned, identification of structural features (such as the thinning of commissure generally seen in the posterior body or the appearance of the fornices), intraoperative radiographs and, most recently, the image guidance of frameless stereotactic navigational systems. Radiosurgical corpus callosotomy may be a promising alternative treatment to open callosotomy.[57] A complete callosotomy is preferable to a partial callosotomy, in terms of long-term seizure control. However, the former may lead to debilitating functional impairments. The goal of surgery with callosal section is different from that of other epilepsy surgeries, in that it is usually palliative, rather than curative.[73]

Multiple Subpial Transections

The surgical technique of multiple subpial transections (MST) was first described by Morrell in 1969, as a means to eliminate seizure propogation in eloquent brain regions.[48] It was based on experimental studies by Kristian Kristiansen of Oslo, Norway. The technique takes into consideration the organisational anatomy of the cerebral cortex. It has been known for some time that neuronal function passes through vertical columns of the cortex, while the horizontal columns are thought to be important for the propagation of seizure activity. Multiple subpial transections disrupt the horizontal fibres that propagate seizure activity but maintain functional vertical columns.[30] The Landau-Kleffner syndrome of acquired epileptic aphasia is a rare disorder characterised by regression of language in early childhood, prominent EEG abnormalities that involve the language cortex and often, seizures.[84] In some children with impaired language who fail to respond to medical treatment, multiple subpial transection of perisylvian cortex on one side may be of benefit.[49]

Radiosurgery

Radiosurgery delivers focused radiation using stereotactic guidance to targets within the brain. Seizure reduction was documented when vascular malformations and hypothalamic hamartomas have been treated with radiotherapy.[86] For patients who are not suitable or not willing to undergo surgery, radiosurgery is an effective alternative. Stereotactic radiosurgery improves seizure outcome in the majority of patients and more than half of the patients with medically intractable partial epilepsy had an excellent seizure outcome after radiosurgery. The safety and efficacy of Gamma knife surgery in mesial TLE has been documented in a prospective study.[75] At 2 years, 65% of the patients (13 of 20) were seizure free with neither permanent neurological deficit nor neuropsychological deterioration.

Neurostimulation

Electrical stimulation to treat seizures in patients who are not suitable for resective surgery is a novel idea. Electrical stimulation is reversible. If it does not work, it can be discontinued and the electrodes can be removed. Neuronal tissue need not be destroyed or resected, except for the tissue directly along the tract of the stimulating electrodes. Stimulation can occur within seconds, enabling patients to turn the stimulator on at the beginning of a seizure. Despite these theoretical advantages, electrical stimulation is still far from being an established and effective therapeutic technique. Earlier experience with superior cerebellar stimulation utilising implanted electrodes failed the test of time.

Vagal Nerve Stimulation

Vagal nerve stimulation (VNS) is a technique that is used in patients with epilepsy that cannot be lateralised or localised. Several reports suggest that VNS can be used in both adults and children with intractable epilepsy, with varying degrees of success.[41,85] Vagus nerve stimulation is an accepted method of treatment with low morbidity and mortality, which improves seizure control in at least 30% of patients, together with concomitant improvements in QOL.

Deep Brain Stimulation

Electrical stimulation of relay nuclei may influence electrical activity in widespread regions of the brain and is useful for multifocal seizure types. Stimulation of deep brain targets in the cerebellum, caudate nucleus, diencephalon, anterior and centromedian nuclei of the thalamus, the subthalamus and mesial temporal structures, is practical.[24,105] There are indications that deep brain stimulation (DBS) improves seizure control in a group of patients previously not suitable for resective surgery and this methodology has enormous potential. Questions regarding the best target sites, best candidates for stimulation as well as the efficacy and safety of the stimulation have not yet been answered.

Stereotactic Surgery

Stereotactic lesionectomy and radiofrequency lesioning have been reported with variable safety and success rates in controlling refractory seizures.[66,67] Stereotactic

craniotomy is used for the excision of small lesions causing epilepsy and for lesions which are close to eloquent regions of the brain.[64] A major advantage of the stereotactic technique is the capability of resecting deep-seated intracranial lesions involving the functional or eloquent cortex, with a low surgical morbidity. A well-defined lesion can be resected stereotactically with much less morbidity than the conventional approach. In a series of 23 patients who underwent stereotactic lesionectomy for refractory partial seizures at the Mayo Clinic, USA, 74% had a significant seizure reduction and 56% were almost seizure free.[11] Stereotactic amygdalotomy for TLE was carried out by Ramamurthi et al. but long-term results were not encouraging.[66]

COMPLICATIONS

The general complications of any neurosurgical procedure include acute post-operative haemorrhage, retraction injury, wound infection and the usual peri-operative sequel, such as anaesthetic and medication intolerance, deep vein thrombosis and infections of the bladder, lung or intravascular lines. Whenever surgery for epilepsy is contemplated, the risks and benefits must be carefully weighed.[78] The risks of epilepsy surgery are acceptably low in the modern era, with overall mortality being less than 0.5% and morbidity less than 5%. Surgical complications include cerebral infarction, intracranial haemorrhage, intracranial infection, and direct cranial nerve or cerebral injury, possibly resulting in temporary or permanent neurologic deficits. Morbidity and mortality vary according to the patient's age and type of surgery; risks appear to be slightly higher in children compared with adults and in hemispherectomy and corpus callosotomy, compared with anterior temporal lobectomy and extratemporal resections.[6]

OUTCOME ASSESSMENT

Until recently, the outcome of epilepsy surgery was reported in terms of seizure frequency alone. Psychosocial, educational and occupational consequences of epilepsy and their treatment were rarely considered, when reporting the outcome of epilepsy surgery. Currently, a comprehensive outcome measure, emphasising the overall quality of life is practiced by a majority of the epilepsy surgery centres.[97]

Seizure Outcome

Surgery is widely accepted as an effective therapy for selected individuals with medically refractory epilepsy.[106] Numerous studies in the past 20 years have reported seizure freedom for at least 1 year in 53–84% of patients after anteromesial temporal lobe resections for mesial temporal lobe sclerosis, in 66–100% of patients with dual pathology, in 36–76% of patients with localised neocortical epilepsy and in 43–79% of patients after hemispherectomies. Careful patient selection even with non-invasive investigations can aid in obtaining a good outcome in patients with extratemporal epilepsy.[90]

A four-part classification system, called the Engel classification, categorising post-operative seizure outcome to Class I (free of disabling seizures), Class II (rare disabling seizures), Class III (worthwhile improvement) and Class IV (no worthwhile improvement) is still in widespread use today.[23] Engel has compiled seizure outcome data on more than 5,000 patients. Temporal lobe resections and lesional non-temporal lobe resections have a very high probability of success. Seizure freedom with anterior temporal lobectomy and lesionectomy are 67.9 and 66.6%, respectively. Hemispherectomies have a comparably high success rate with 67.4% seizure freedom. The seizure freedom is only 45% with neocortical and multilobar resections. Seizures completely stop in fewer than 10% of patients who undergo callosotomy. However, it can completely eliminate atonic seizures in approximately 70% of patients.[26] It is now a well-established fact that a prolonged longitudinal follow-up is essential for accurate assessment of seizure outcome, since initially seizure free patients may relapse and some patients with early post-operative seizures may become seizure-free subsequently (running-down phenomenon).[94] Reported rates for non-resective surgery have been less impressive in terms of seizure freedom; however, the benefit is more apparent when reported in terms of significant seizure reductions.

Resurgery

Seizures persist or recur in 20–60% of patients after resective surgery for intractable partial epilepsy. Re-operation is the performance of a further surgical procedure intended to relieve drug-resistant epilepsy, when a previous procedure for the same purpose has failed.[81] Overall, the outcome from resective re-operation is around 44% seizure-free and 25% not affected. However, when there is a structural lesion that has been missed or incompletely removed, the seizure-free proportion rises to 80–90%. Recurrent seizures after extratemporal resections were more likely to become persistent and intractable than seizures recurring after temporal resections.[113]

CONCLUSION

In recent decades, there has been increasing interest in the surgical treatment of patients with intractable seizures. Identification of patients with surgically remediable syndromes became easier with the application of relatively inexpensive non-invasive EEG and MRI approaches.[100] It is possible to identify ideal surgical candidates with the correlation of clinical semiology, neuroimaging and video EEG telemetry. It is essential to clearly delineate the underlying pathological substrate and resect completely to cure or control epilepsy. However, if such a resective procedure is not possible, then functional surgery should be considered. New centres can successfully

establish epilepsy surgery programs, by initially performing relatively simple and standard surgical procedures like anterior temporal lobectomy and lesionectomy. Subsequently, the programmes can be expanded to include patients with bitemporal and extratemporal epilepsy, as well as non-lesional epilepsy.

ACKNOWLEDGMENTS

We wish to thank the Kokilaben Dhirubhai Ambani Hospital and Medical Research Institute for approval to submit the chapter and Dr Poornima Shah, Dr Darshana Sanghvi, Dr Mihir Munshi and Dr Soumendranath Ray for providing the illustrations.

202 Surgery for Temporal Epilepsy

Bhaskara Rao Malla, Jayanti Mani

INTRODUCTION

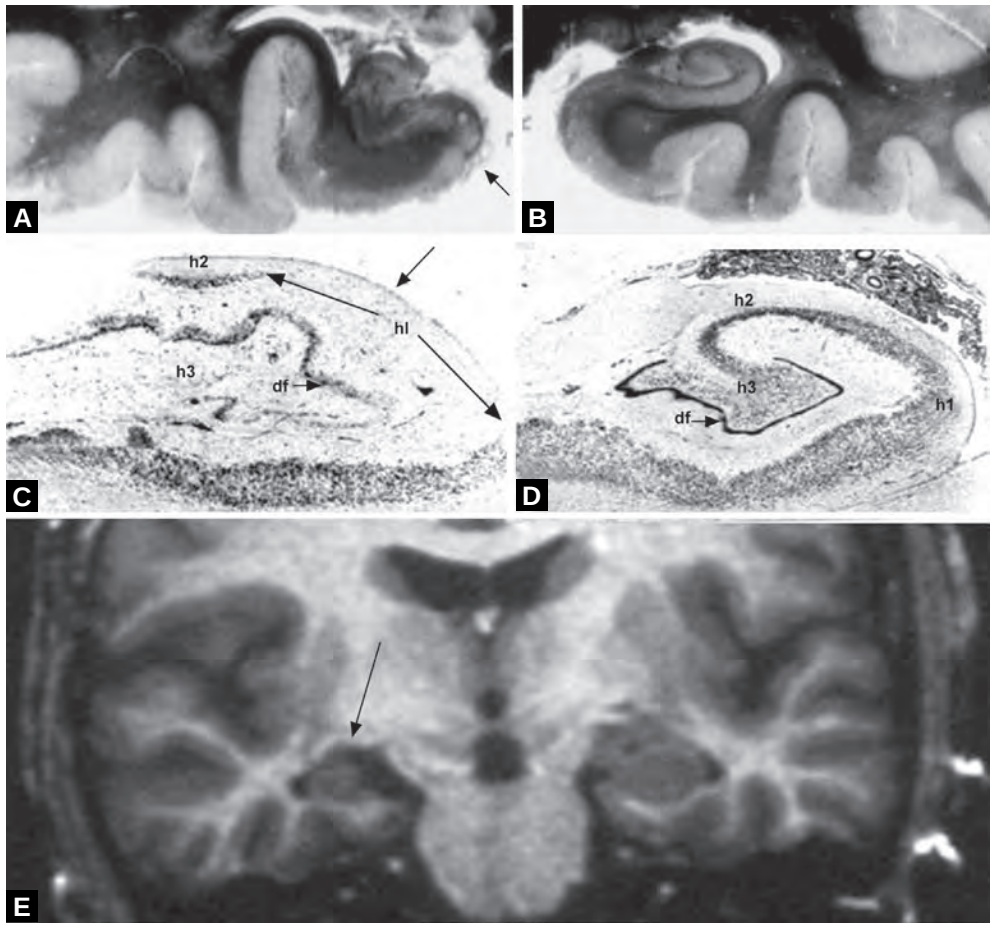
Temporal lobe epilepsy (TLE), especially mesial TLE (MTLE) is the most common form of human epilepsy. In the ICMR multicentric study involving 3,439 cases, TLE, with or without generalisation, accounted for 27.5%.[93] The pathological substrate of MTLE is usually hippocampal sclerosis, the most common epileptogenic lesion encountered in patients with medically refractory epilepsy.[23,24] The disabling seizures associated with MTLE are typically resistant to antiepileptic drugs but can be abolished in most patients by surgical treatment.[20] Anteromesial temporal resection, therefore, is the most common surgical procedure performed to treat epilepsy.[20] The benefits of surgery for TLE have been well demonstrated in terms of seizure control, cognitive function and quality of life (QOL).[85] In this chapter, we elaborate on the pre-surgical evaluation, selection of ideal candidates, surgical treatment and post-operative outcome of patients with medically refractory TLE.

HISTORICAL PERSPECTIVE

In 1825, Bouchet and Cazauvieilh[8] first described the association between epilepsy and a sclerotic hippocampus, based on gross pathological examination of brains from patients with mental alienation seizures. In the latter part of the 19th century, however, Hughlings Jackson[36] recognised the role of the temporal lobe in epilepsy, by associating the auras of taste, smell and epigastric sensations with temporal lobe lesions. With the advent of EEG Gibbs et al.[31] reported an ictal discharge pattern which they believed was characteristic of psychomotor seizures. It was Jasper and colleagues[37,38] who pointed out that inter-ictal and ictal epileptiform EEG abnormalities in psychomotor dreamy states and other phenomena now known to be limbic seizures, originated in mesial temporal structures. The first temporal neocortical resection for epilepsy was performed by Penfield in 1929[27] Bailey and Gibbs[4] were the first to perform anterior temporal lobectomy (ATL) on the basis of EEG evidence alone. Penfield and his colleagues[55–57] in a series of studies established the aetiology, pathology, clinical manifestations and treatment of this distinct entity. They elaborated the role of undue molding of the head during childbirth, resulting in mesial temporal herniation and ischaemia leading to incisural sclerosis.[17] In 1954, Penfield and Jasper[58] reported a better outcome with more complete resection of the mesial temporal structures and described the atrophic changes in the hippocampus, in the majority of the patients with epilepsy who underwent temporal lobectomy. Falconer[23] described the detailed pathology in the 'en bloc' temporal lobe resections. The term 'mesial temporal sclerosis (MTS)' was coined to include the entire spectrum of changes involving the medial temporal structures.[24] Falconer and Serafetinides[25] also highlighted the incidence of other pathologies like hamartomas as a frequent cause of TLE in these patients, in the absence of MTS.[23] In 1958, Niemeyer[51] developed a transcortical transventricular amygdalectomy and a 3 cm hippocampectomy, which was performed through a 2 cm middle temporal gyrus incision. Rasmussen and Jasper,[71] Falconer et al.[25,26] and later on Feindel and Rasmussen[28,71] and Engel and colleagues[18,21,22] made noteworthy contributions in the field. In India, both open and stereotactic procedures were performed for patients with intractable TLE at the Christian Medical College, Vellore[2,48] and at the Institute of Neurology, Madras [5,66,67] in the 1950s and 1960s. The current status of epilepsy surgery in India has been summarised in a recent publication in the Neurology India.[61]

PATHOLOGY

The most common pathology observed in nearly two-thirds of resected temporal lobes was MTS[90] (Figs 1A to E). In MTS, the hippocampal neurons were lost in the CA1 and CA3 regions and the dentate hilus.[43,60,65,105] Sommer[84] was the first to describe the neuropathological changes in Ammon's horn (*cornu ammonis, CA*) of patients with chronic epilepsy, predominantly characterised by a loss of pyramidal cells in the CA1 sector (often called the Sommer sector). Margerison and Corsellis,[47] in their study of TLE, observed two types of hippocampal sclerosis: (1) classical Ammon's horn sclerosis (with neuronal loss and gliosis in the CA1 sector and the dentate gyrus) and (2) end folium sclerosis involving the CA_3 and CA_4 sectors. Low-grade neoplasms such as ganglioglioma and dysembryoplastic neuroepithelial tumour, focal cortical dysplasia and vascular malformations comprised the rest.[63,105] In endemic areas for cysticercosis, calcified cysticercous granulomas as a cause for refractory partial epilepsy are not uncommon.[50] The spectrum of pathology in the paediatric population of



Figs 1A to E: (A and B) Gross specimen. (C and D) Photomicrographs. (E) MRI of the temporal lobes with arrows pointing towards atrophic hippocampus, suggestive of mesial temporal sclerosis (MTS)

TLE is different to adults. In a multinational report on paediatric epilepsy surgery, the most common pathology in the resected specimens was a tumour followed by cortical dysplasia and then hippocampal sclerosis. Thus, at an earlier age, developmental lesions are much common than hippocampal sclerosis.

MEDICAL REFRACTORINESS

Over 50% of patients with MTLE fail to respond to optimal medical treatment. A recent evidence-based report on the effectiveness of anteromeial temporal lobe resection has recommended that patients with disabling complex partial seizures with or without secondarily generalised seizures, who have failed appropriate trials of first-line antiepileptic drugs, should be considered for referral to an epilepsy surgery centre. Patients referred to an epilepsy surgery centre for the reasons stated above, who meet established criteria for an anteromeial temporal lobe resection and who accept the risks and benefits of this procedure over continued pharmacotherapy should be offered surgical treatment.[22]

PRE-SURGICAL EVALUATION

A non-invasive protocol for evaluation of patients with medically refractory TLE is provided in Table 1. Today, a majority of patients with TLE can be selected for surgery, based on the results of non-invasive methods such as scalp EEG, video-EEG, MRI and neuropsychological findings.[39,62,89,91,94] Concordance of MRI and scalp EEG abnormalities correlates with an excellent post-operative seizure outcome.[64] A sub-group of patients

Table 1: A non-invasive protocol for the evaluation of patients with medically refractory temporal lobe epilepsy

Review the history, past AED treatments, seizure frequency and EEGs
Medical and neurological examinations
16-channel awake and sleep scalp EEG recordings
Neuropsychological évaluation
Psycho-social evaluation
Psychiatric evaluation
Visual field testing
MRI with protocol for hippocampal volume loss and sclerosis
Long-term video-scalp EEG monitoring
Wada test in selected patients

AED—antiepileptic drug; EEG—electroencephalogram; MRI—magnetic resonance imaging

with MRI-negative TLE can also be evaluated and selected for surgery, by using clinical history and scalp-recorded inter-ictal and ictal EEG data. The attributes of these patients are antecedent history of febrile seizures, strictly unilateral anterior inter-ictal epileptiform discharges and concordant type 1 ictal EEG pattern.[92]

Non-invasive Evaluation

Seizure Semiology, Lateralisation and Localisation

Detailed study of the seizure semiology, as part of the video EEG evaluation, provides confirmation of the epileptic nature of the seizures and also provides valuable lateralising and localising information regarding seizure onset (Fig. 2). This procedure involves continuous recording of synchronous scalp EEG and video over a period of 24 hours to 7 days, with the aim of recording inter-ictal EEG and clinical seizures with corresponding ictal EEG. Medications are gradually withdrawn with the aim of recording habitual seizures.

The seizures associated with TLE consist of simple partial seizures without loss of awareness and complex partial seizures with loss of awareness. The partial seizures may secondarily generalise. In TLE, auras are reported in about 20–67% of seizures. They occur either as isolated events or as the first event that evolves into more elaborate seizures. Auras are more frequent in TLE. The epigastric or abdominal auras are considered to be typical of MTLE, although extratemporal origin of epigastric auras has also been noted. Psychic auras of fear and dèjà vu are related to the amygdala. Gustatory and olfactory auras are quite characteristic of TLE. Motionless stare with a behavioural arrest is the first evidence of the onset of seizures in a large number of patients. Oro-alimentary automatisms consisting of lip smacking, chewing and swallowing are common in TLE. Hand automatisms may be bimanual and when unilateral, they are often ipsilateral to the side of seizure onset. Contralateral arm dystonic posturing and forced contralateral version of the head and eyes are strongly lateralising features in TLE with specificity more than 90%. The latter is particularly useful when it occurs just prior to secondary generalisation of the seizures. Typically, the seizure lasts between 30 seconds and 2 minutes. Secondarily generalised tonic clonic seizures are rare in MTLE. Post-ictal phenomena, like nose wiping, spitting, coughing and vomiting, have been shown to occur in seizures from the non-dominant hemisphere, whereas post-ictal aphasia lateralises the seizure to the language dominant hemisphere. Auditory auras are seen in seizures from the lateral temporal neocortex. Early secondary generalisation and clonic phenomena involving the face and hands are also more frequent with lateral temporal epilepsy.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the neuroimaging modality of choice for patients with TLE. All patients with newly diagnosed TLE should have a high-resolution imaging with at least a 1.5-Tesla MR

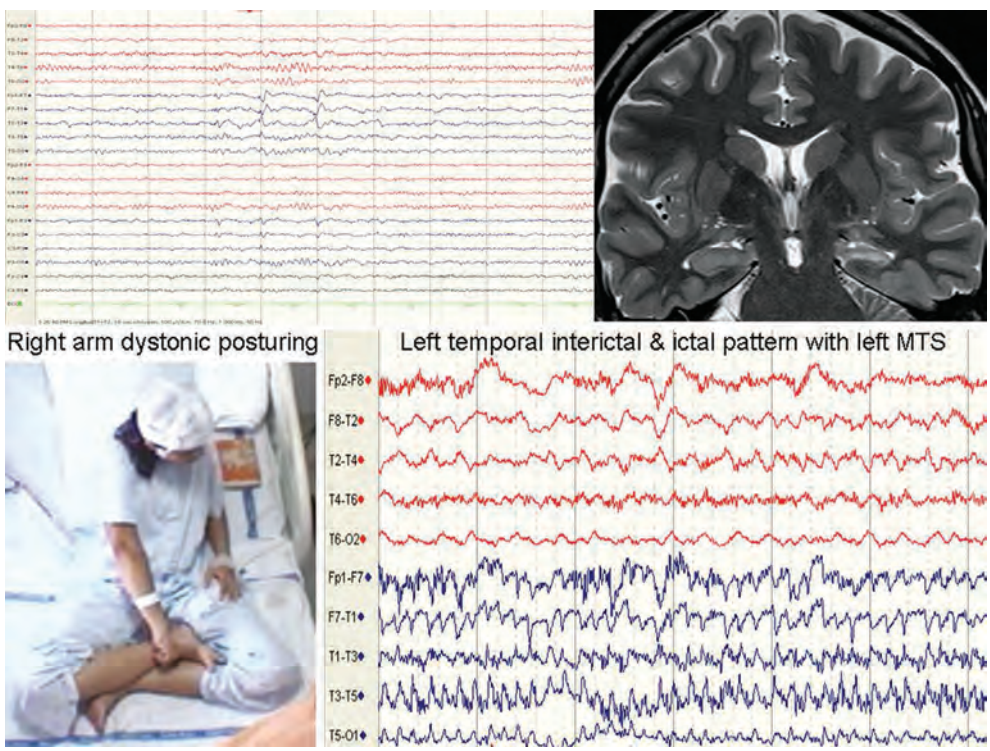


Fig. 2: Clinical, MRI and EEG correlation in a patient with medically refractory left temporal lobe epilepsy shows right arm dystonic posturing, small left hippocampus on T2-weighted coronal MRI sequence with left anterior temporal spike discharges and left temporal rhythmic theta EEG activity during a complex partial seizure

scanner, although the availability of a stronger magnet will increase the resolution. Thin coronal oblique slices through the temporal lobe, of 1.5–2 mm thickness with no gap using spoiled gradient recall images (SPGR) are recommended. Most brain MR scans do not include coronal images but, for TLE, this sequence is more informative than the axial and sagittal cuts. On MRI, decreased hippocampal size on T1-weighted images increased signal on T2-weighted and on fluid-attenuated inversion recovery (FLAIR) images characterise hippocampal sclerosis.[6,16] High-resolution MRI shows hippocampal atrophy in many patients with TLE by visual analysis alone. Hippocampal atrophy is bilateral in 10–15% of cases. Volumetry is used by some investigators to demonstrate asymmetry, although controversy exists as to the need for this quantitative technique.[10]

Neuropsychological Evaluation

The information obtained through neuropsychological testing helps in counselling patients about the potential risk of post-operative memory impairment and is also valuable in assessing progress in the follow-up period.[78] The Wada test is undertaken prior to temporal lobectomy to lateralise the distribution of language and memory function between the two hemispheres and to thereby predict the post-operative language and memory outcome.[95] While language assessment during the Wada test is simple and straight-forward, interpretation of memory deficit is complex and requires a carefully designed protocol. Inadequate memory support during the Wada test is not an absolute contraindication to ATL and should be considered within the context of the patient's basal neuropsychological functioning and the impact of the expected post-operative deterioration on one's QOL. Restricting the Wada test to patients with suspected bilateral temporal dysfunction, as evidenced by neuropsychological testing or MRI findings, may be a cost-effective approach in developing countries. In the near future, non-invasive evaluation with fMRI and PET may obviate the need of the Wada test.

Currently, the risk of severe post-operative memory decline, following unilateral ATL, can be predicted with reasonable accuracy.[32] The risk is higher when the following factors are present: (1) ATL on the language dominant side; (2) no hippocampal atrophy or sclerosis on the side of proposed resection; (3) a higher pre-operative memory performance; (4) evidence of bilateral hippocampal atrophy on pre-operative imaging; (5) seizure onset at an older age; (6) surgery performed at an older age; (7) functional assessments (e.g. Wada test) that suggest greater residual pre-operative function of the left temporal lobe and (8) left handed or ambidextrous patients. Thus, the risk would be highest for patients undergoing left temporal lobectomy with left cerebral language dominance, absence of left hippocampal atrophy/sclerosis, high baseline verbal memory, absence of unilateral left temporal lobe hypo-metabolism in the PET and the presence of high memory performance with right intracarotid amobarbitol injection, but low memory performance with left injection.

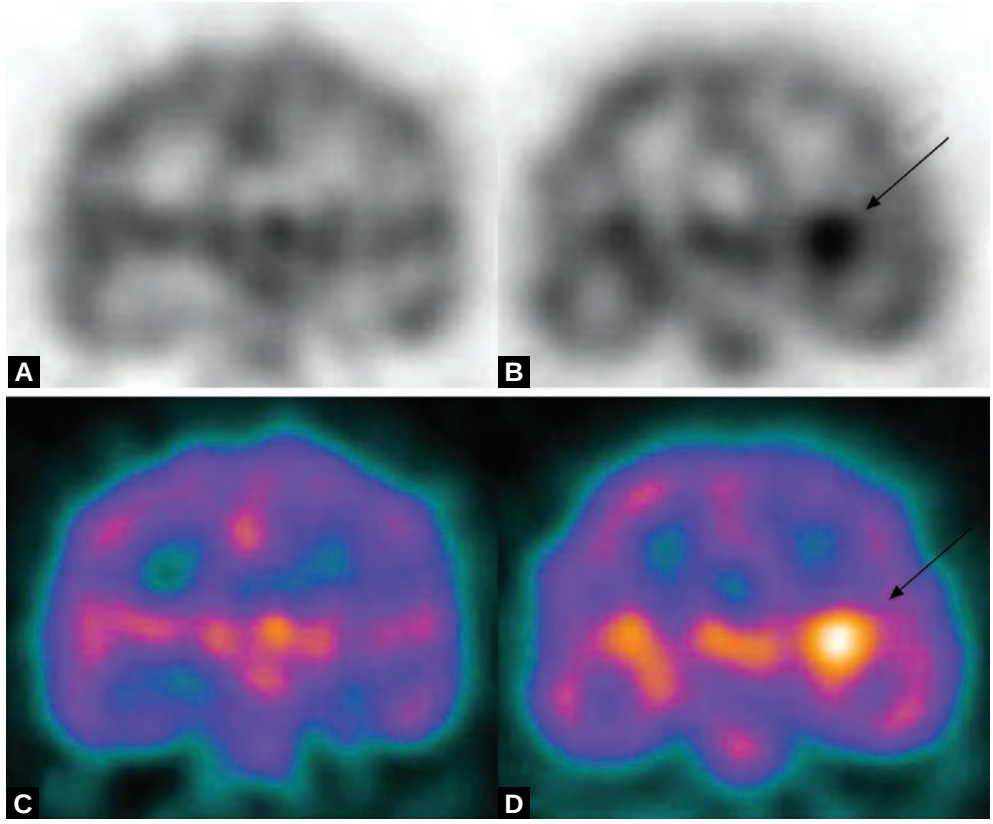
Functional Imaging in Temporal Lobe Epilepsy

Non-invasive mapping procedures, such as single photon emission computed tomography (SPECT), positron emission tomography (PET), functional MRI (fMRI), magnetic resonance spectroscopy and magneto-encephalography, may provide information complementary to that provided by EEG, video-EEG and MRI.[19] Peri-ictal SPECT studies are obtained by injecting a radiotracer during (ictal) or soon after the seizure activity (post-ictal), which necessitates electro-clinical correlation utilising continuous video-EEG monitoring.[82] Hyperperfusion of the epileptic temporal lobe occurs during the ictus and persists for up to one minute into the immediate post-ictal period. Ictal SPECT studies of temporal lobe seizures yield over 90% correct lateralisation of the epileptogenic focus[42] (Figs 3A to D). Post-ictal SPECT studies are lateralising in about 70% of temporal lobe seizures, whereas inter-ictal SPECT studies have a low yield of true positivity and an unacceptably high false positive rate.[42]

The findings of complex partial seizures of temporal lobe semiology, anterior temporal inter-ictal sharp waves arising in the mesial temporal structures, without evidence of extratemporal epileptiform activity on EEG and unilateral MTS on MR imaging without extratemporal lesions, together yield the diagnosis of MTLE (Fig. 2). Vascular lesions, such as cavernous angiomas and arteriovenous malformations, focal developmental abnormalities, hamartomas and low-grade neoplasms, may involve the medial or lateral parts of the temporal lobe (Fig. 4).[63] Due to the considerable overlap in the seizure semiology and inter-ictal and ictal EEG data between mesial and lateral TLE syndromes, the location of a lesion on MRI is the only reliable finding that helps to distinguish between these two epileptic syndromes.[99] Selecting patients with TLE for the appropriate operation begins by first using MRI to classify them into the three anatomical substrate categories noted above: (1) hippocampal atrophy (MTLE with presumed MTS); (2) lesions (LTLE) or (3) normal anatomy (CTLE). The presence of a lesion in a patient with refractory partial epilepsy does not invariably indicate that the lesion is responsible for the seizures. Patients with long standing lesions (e.g. developmental, atrophic or benign neoplastic lesions) may develop hippocampal atrophy (dual pathology) (Figs 5A to C).[12] The primary lesion, the secondary hippocampal sclerosis or both, may be responsible for the seizures.

Invasive Evaluation

Patients with TLE may require invasive monitoring, when the results of non-invasive methods such as scalp EEG, video-EEG and MRI are conflicting. In selected patients with presumed MTLE with sparse inter-ictal



Figs 3A to D: Inter-ictal and ictal SPECT images of the same patient shows hyperperfusion in the left mesial temporal region

epileptiform discharges or poorly defined ictal EEG activity, long-term monitoring utilising sphenoidal electrodes may help to localise the spiking and ictal onset zones.[3,46] Several types of intracranial recording electrodes, such as subdural strip and grid electrodes, epidural electrodes, intracerebral depth electrodes or their combination, may have to be utilised to define the site of seizure origin.[88] Exclusive use of either intracerebral or subdural electrodes may occasionally result in erroneous localisation because of insufficient sampling.[34] Patients with suspected MTLE, with bilateral temporal inter-ictal and ictal abnormalities and/or bilateral MTS, often will require bilateral depth electrode placement to the mesial temporal structures. Patients with TLE with normal MRI and equivocal SPECT and PET findings will require invasive monitoring with subdural and depth

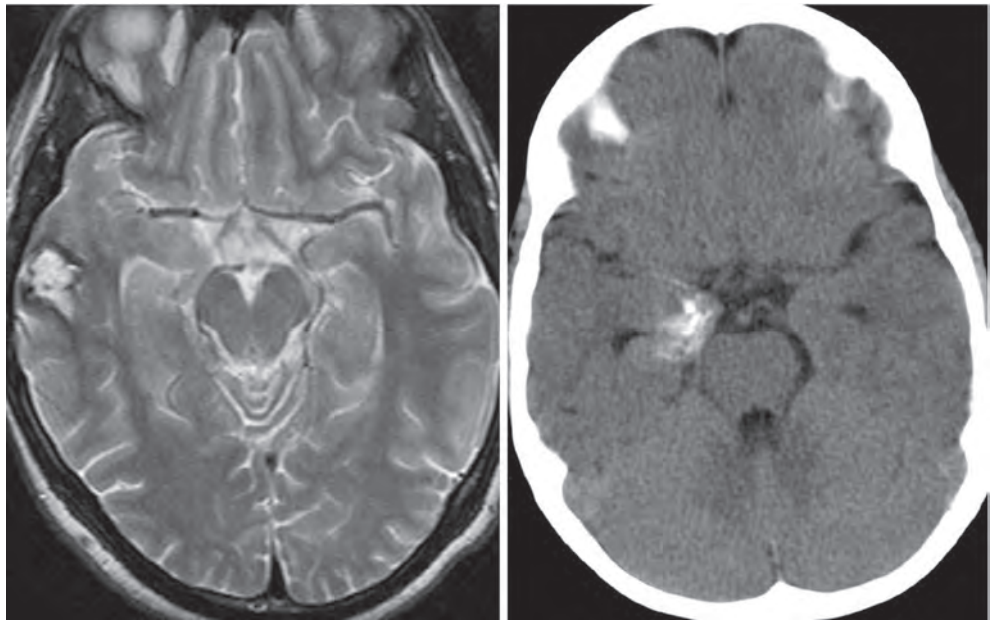


Fig. 4: MRI and CT scan of the brain show lateral neocortical and mesial temporal lesions

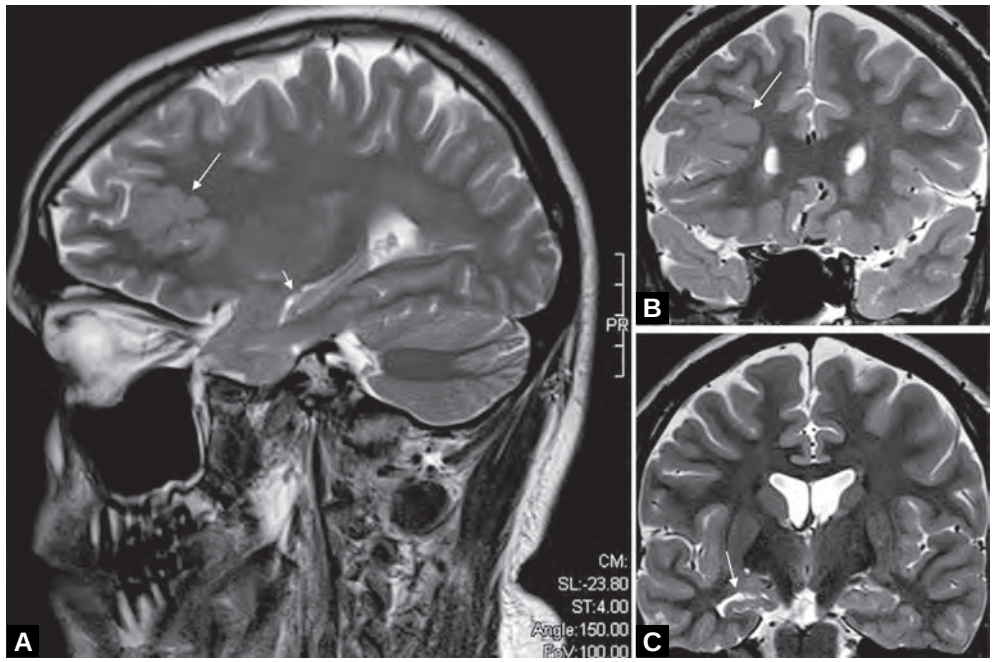


Figs 5A to C: MR images showing (A and B) frontal focal cortical dysplasia and (C) Hippocampal sclerosis suggestive of dual pathology (arrows)

electrodes to localise the zone of ictal onset.[88] Depth electrode recordings, using the Talairach's Stereo electroencephalographic (SEEG) method, may identify patients who can benefit from surgery, in spite of equivocal concordant pre-surgical investigation criteria, as well as to exclude from the selection process patients with multilobar or bilateral foci.[88] When neurosurgical procedures encroaching the neocortical sensory, motor and speech areas are planned, functional mapping using fMRI or during surgery with the patient awake or extra-operatively after placing intracranial electrodes is performed to circumscribe the area of resection, in order to avoid post-operative neurological deficits.[52]

SURGICAL TREATMENT

Surgical Approaches

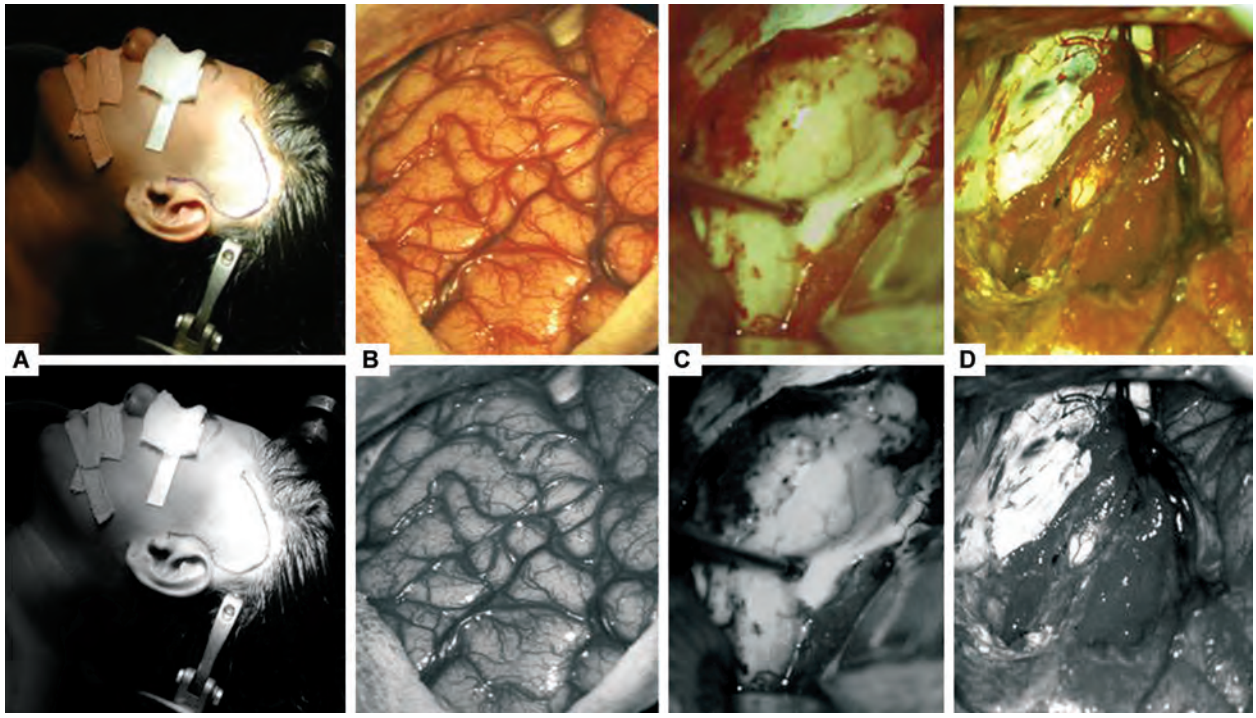
A diversity of operations has been undertaken for the management of refractory TLE (Table 2). ATL is the most common surgical procedure undertaken.[20] For patients with unilateral or predominantly unilateral seizures, most centres perform a standard ATL in which the anterior temporal neocortex, anterior hippocampus and lateral amygdala are resected.[13,28] Intra-operative electrocorticography (ECoG) and cortical stimulation are used at some centres to tailor the lateral temporal resection, according to the extent of EEG abnormality and the location of the language cortex.[52,89] Selective amygdalohippocampectomy (SAH), sparing the lateral temporal neocortex, is performed at some centres.[102] Other centres perform only lateral neocortical resections, sparing the amygdala and hippocampus. The aim of modified temporal resections is to reduce post-operative cognitive deficits.[32]

Anterior Temporal Lobectomy

Anterior temporal lobectomy is also known as standard or tailored ATL and anteromedial temporal lobectomy.[20] The procedure, as it is undertaken today, is a modification of the en bloc temporal lobectomy popularised by Falconer and Taylor.[26] Based on invasive electrophysiology and pathology, Spencer et al.[87] modified the standard resection for those patients with medial temporal ictal onset, such that all of the medial structures (amygdala, hippocampus and parahippocampal gyrus) were removed via a limited temporal pole resection. In the majority of epilepsy surgery centres, ATL (Figs 6A to D) is performed under general anaesthesia (Fig. 6A).

Table 2: Surgical techniques for the treatment of medically refractory temporal lobe epilepsy

Anterior temporal lobectomy with amygdalohippocampectomy
Standard
Tailored
Selective amygdalohippocampectomy
Transcortical-transventricular approaches
Through superior temporal gyrus
Through middle temporal gyrus
Through inferior temporal gyrus
Trans-Sylvian approach
Subtemporal approach
Selective lateral temporal (neocortical) resection
Lesionectomy
Multiple subpial transections



Figs 6A to D: Operative photographs showing: (A) Left temporal craniotomy. (B) Anterior temporal lobe.(C) Left hippocampus. (D) Anterior temporal lobectomy cavity

At a few centres, local anaesthesia is used as originally advocated by Penfield.

Anterior temporal lobectomy includes resection of the neocortex, extending up to 3.5–4.0 cm on the dominant side and 4.0–4.5 cm on the non-dominant side along the Sylvian fissure (Figs 6B and D). Lateral neocortical resection, especially the superior temporal gyrus, may have to be limited in certain cases, depending upon cerebral dominance and when large cortical branches of the middle cerebral artery or a prominent vein of Labbe are placed anteriorly. The vein of Labbe is inconstant and, when present, only indicates a posterior drainage of the Sylvian venous system. Opening the temporal horn of the lateral ventricle exposes the pes hippocampus (Fig. 6C). The amygdala and the hippocampus are always removed by a transventricular approach. En bloc resection is limited to the anterior two-thirds of the hippocampus and lateral two-thirds of the amygdala, along with the uncus and the parahippocampal gyrus by subpial dissection, using the operating microscope (Fig. 7). The medial part of the amygdala is not removed, as it abuts the striatum, anterior commissure and tail of the caudate nucleus. The hippocampal sulcus contains the artery of Ammon's horn, which is the fundamental landmark for a subependymal, subpial resection of the hippocampus. Both the hippocampal formation and the amygdala can be removed subpially. This approach minimises the coagulation, division and manipulation of the anterior choroidal artery and the branches arising from the posterior cerebral artery.

The role of ECoG during TLE surgery is uncertain. It is performed routinely at some centres, but the extent of resection was rarely dictated by ECoG, which depended on anatomical constraints and the feasibility of complete

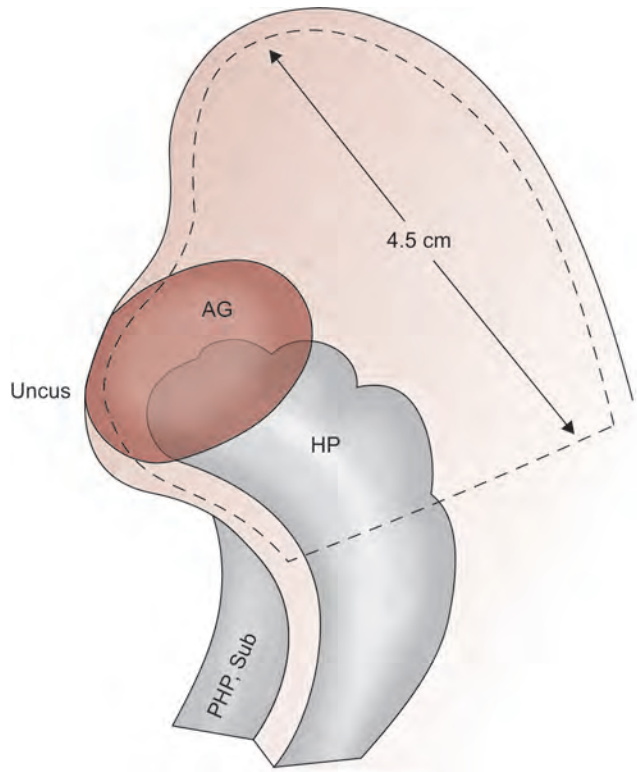


Fig. 7: Diagram illustrates the extent of resection in anterior temporal lobectomy with amygdalohippocampectomy consisting of 4 cm of anterior temporal neocortex, anterior two-thirds of the hippocampus (3 cm) and parahippocampal gyrus along with the lateral two-thirds of the amygdala and uncus (AG—amygdala, HP—hippocampus, PHG—parahippocampal gyrus)

removal of a lesion.[33] ECoG may help to tailor the extent of temporal lobe resection. However, the distributions of spikes in the pre-resection electrocorticogram (ECG) and quantity of residual spikes in the post-resection ECG, have not consistently correlated with the post-operative seizure outcome.[80]

Selective Amygdalohippocampectomy

Amygdalohippocampectomy is a selective resection of the amygdala, uncus and hippocampus posteriorly to the level of the superior colliculus. Amygdalohippocampectomy can be performed via different approaches. With this approach, the lateral temporal cortex is not resected. Since the introduction of SAH by Niemeyer,[51] several modifications of this technique have been proposed.[53,96] Wieser and Yasargil[101,102] suggested the trans-Sylvian approach. After dissection of the Sylvian fissure, the temporal ventricular horn is entered through the temporal stem in the inferior semicircular sulcus, followed by the resection of mesiotemporal structures. The dissection of the Sylvian fissure may be challenging, but a good overview of the hippocampus including the possibility of far dorsal hippocampal resection is provided. Damage or vasospasm of Sylvian veins, branches of the middle cerebral artery, anterior choroidal artery and branches of the posterior cerebral artery may result in hemiparesis or hemianopia. Olivier, at the MNI, modified and popularised the transcortical transventricular approach, which was initially done through the anterior part of the superior temporal gyrus and later through the superior temporal sulcus.[53] With the aid of neuronavigation, the ventricle is entered via the middle temporal gyrus, followed by a resection of the anterior parts of the hippocampus, then amygdala, uncus and parahippocampus. A smaller craniotomy is an advantage with neuronavigation, but the disadvantage is a more limited overview on the mesiotemporal structures. Spencer et al. described a combined approach to gain access to the posterior mesial temporal structures.[87] Other suggestions comprised the sub-temporal, zygomatic, subtemporal trans-parahippocampal, trans-Sylvian-transcisternal and even retrolabyrinthine-presigmoid approach, etc. However, all of them are being practiced by only a few, compared to the trans-Sylvian and trans-cortical approach. The sub-temporal approach is also technically complex because it entails zygomatic process removal for exposure of the floor of the middle fossa. For rare cases of tumour or cavernoma in the dominant hemisphere, this may be considered, but alternative approaches, notably awake temporal lobectomy with functional mapping, is usually preferred.[52]

In spite of technical advances, unilateral SAH has a limited place and in its present form it is probably applicable to 15–20% of patients in a centre offering a comprehensive range of surgical procedures. The indications for SAH are as follows: (1) a lesion confined to the medial temporal structures; (2) evidence of ipsilateral medial temporal onset of partial complex seizures; (3) indications that some of the patient's memory function was subserved by the operated temporal lobe, possibly more so in the dominant temporal lobe. The contraindications for SAH are as follows: (1) a lesion outside of the medial temporal structures; (2) a lesion confined to the medial temporal structures, but too large or too posterior; (3) a patient in whom neurophysiological evidence indicates a regional seizure onset within the temporal lobe; (4) a patient in whom the contralateral temporal lobe carries all or most of the recent memory function. In the last two circumstances, a temporal lobectomy would be preferred. Patients, in whom most of the memory function is carried in the temporal lobe to be operated upon and there is no evidence of a structural lesion in that temporal lobe also, are likely to have a poor result with regard to both seizure control and cognitive outcome.

The advantage of SAH over ATL lies in the fact that the former causes a smaller disruption of potentially functional temporal neocortex, while attaining the same post-operative seizure control as the latter. Different strategies for surgical approaches for TLE result in equally good outcomes. Seizure outcome is mainly dependent on the correct diagnosis and clinical factors, whereas the neuropsychological results are better after resections limited to an epileptogenic lesion and the focus.[1] A number of mechanisms may be involved in the control of seizures, including the removal of structural disease, disruption of neuronal connections and pathways and reduction in the mass of epileptogenic neurons available to participate in the seizure. The disconnection of afferent and efferent networks also helps to explain how the various temporal lobectomy approaches across the spectrum from standardised to tailored resections, may have similar outcome efficacy. There is no consensus regarding either the minimum necessary volume of resection or which structures must be resected for freedom from seizures, following TLE surgery. However, it is generally agreed that in patients with MTLE with MTS, the anterior two-thirds of the hippocampus and the lateral two-thirds of the amygdala along with the parahippocampal gyrus and uncus need to be removed to achieve seizure cure or control.

Lesional Temporal Lobe Epilepsy

In patients with various types of developmental, neoplastic or vascular lesions responsible for epilepsy, three surgical solutions are possible. First, only the lesion may be removed; second, the lesion and some portion of the medial structures may be removed to assure a margin of resection; and, finally, a formal antero-mesial temporal resection may be performed in addition to removal of the lesion.[9,63]

Stereotactic Procedures

Stereotactic procedures have been used for the surgical management of intractable epilepsy since the 1960s.[5] Stereotactic amygdalotomy was performed upon a

sizable number of patients with marked improvement in control of seizures, as well as behaviour disorder.[41,66,67] Currently, these techniques are widely used to implant electrodes in the temporal lobe, to determine the laterality and extent of the epileptogenic zone in patients with intractable TLE. Placement of depth electrodes can be performed using the orthogonal approach or an occipital approach. Both frame-based and frame-less stereotactic systems can be used for depth electrode placement. Frameless stereotaxy can be used for SAH. However, strict lesion resection guided by neuroimaging may be less efficacious in controlling seizures in the temporal lobe than in other cortical regions.[11]

Alternate Surgical Procedures

For lesions located in close proximity to eloquent areas, such as motor and speech areas, multiple subpial transection is a safe option to reduce the seizure frequency without causing morbidity.[49] Although multiple subpial transections alone seldom result in complete seizure control, transections surrounding a lesionectomy may minimise the excised volume without compromising seizure control.[35] Children with Landau-Kleffener syndrome may show substantial recovery of speech, following multiple subpial transections.[77]

The initial experience has shown safety and short-term efficacy of gamma knife surgery for MTLE,[73] but needs further confirmation of long-term efficacy. The role of deep brain stimulation to treat epilepsy is being investigated. For refractory epilepsy patients in whom resective surgical treatment is not an ideal option, neurostimulation therapies hold the promise of improving seizure control, without the adverse effects of multiple antiepileptic medications. Vagus nerve stimulation is currently an approved method of treatment for medically refractory epilepsy in adults[79] and children[45] who are not candidates for resective surgery.

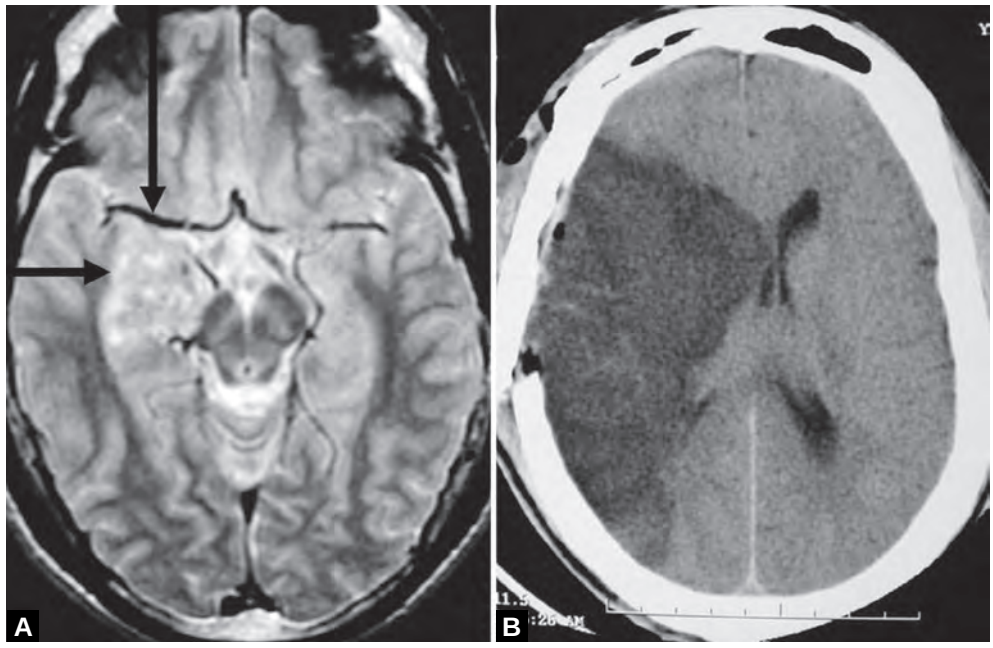
Complications

Specific complications of ATL include homonymous superior quadrantanopsia, due to involvement of either the optic tract or radiation and language deficits and manipulation hemiplegia (Figs 8A and B), due to vascular injury or spasm involving the Sylvian vessels, anterior choroidal artery branches supplying the cerebral peduncle or the perforators supplying the internal capsule.[59,74] These complications may be minimised if care is taken to avoid damage to the branches of the anterior choroidal artery and the branches of the P2 segment of the posterior cerebral artery. Disabling visual field defects are more likely to result from damage to or spasm of the vessels that supply the optic tract, than from direct injury to Meyer's loop. In the Mayo Clinic study,[68] the frequency of acute post-operative seizures was 21%. Only recurrence of habitual seizures predicted an unfavourable post-operative seizure outcome. Expanding cyst following temporal lobectomy has been reported as an unusual complication.[70]

OUTCOME ASSESSMENT

Seizure Outcome

Analysis of the pooled data from epilepsy surgery centres around the world revealed that over 70% of the patients become seizure free after temporal lobe surgery.[21] The exact type of temporal lobe resection (standard vs selective amygdalohippocampectomy) did not influence the



Figs 8A and B: MR images showing: (A) Ganglioglioma involving the anterior hippocampus (black arrows pointing the lesion and adherence of the lesion to the blood vessel). (B) Large middle cerebral artery infarct

seizure outcome.[21] The better seizure outcome in recent years compared to the past appear to be related to the advent of techniques, like digital EEG-Video monitoring and MRI, which have improved the localisation of the epileptogenic zone and thereby, the selection of ideal surgical candidates.[85]

Wiebe et al.[100] recently compared the seizure outcome in 40 patients with TLE randomly assigned to surgery, with that in 40 patients on treatment with antiepileptic drugs alone. At 1 year, the cumulative proportion of patients who were free of consciousness impairing seizures was 58% in the surgical group and 8% in the medical group; the difference was highly statistically significant ($p < 0.001$). This first randomised controlled trial conclusively established that, in refractory TLE patients, surgery is far superior to prolonged medical therapy.

In the initial series at SCTIMS,T[69] 107 patients (50.2%) were completely seizure free (including free of aura) and 166 patients (77.9%) had an Engel Class I outcome (no disabling post-operative seizures). Among the patients who had post-operative seizure recurrence, a majority had a reduction in seizure frequency. Only 6% exhibited a lack of improvement or a worsening in seizure frequency following surgery.[69] These results are similar to those reported from other major epilepsy surgery centres around the world.[7,20,64,81] It may be worth emphasising that during this period the SCTIMST protocol utilised a non-invasive pre-surgical evaluation protocol, to decide the indication for ATL and did not undertake intra-operative ECoG.

Paediatric populations coming to epilepsy surgery centres have shown similar seizure free rates as compared to the adult population. The seizure free range varied from 60 to 78% in different series and the spectrum of population. Various epilepsy centres are reporting cases with dual pathology; for instance, children with MTS and other pathology like cortical dysplasia of the temporal lobe. Surgical results in this group of patients are similar to adults with typical TLE, provided there is complete resection of the mesial temporal structures and the second pathology.

Surgical Failures

Reasons for surgical failures are not completely understood and include bitemporal, pseudo temporal, extratemporal and so-called temporal plus epilepsies, as well as insufficient resection of the mesial temporal structures.[30] It is now a well-established fact that a prolonged longitudinal follow-up is essential for accurate assessment of seizure outcome, since initially seizure free patients may relapse and some patients with early post-operative seizures may become seizure-free subsequently (running-down phenomenon).[75] In the majority of patients who exhibit seizures following ATL, seizures recur within the 1st year after surgery, often as early as in the first few weeks and months after surgery.[29,44,104] Incidence of seizure recurrence increases progressively with the length of follow-up; however, being seizure-free for 1 year after surgery is an excellent predictor of continued seizure-free outcome.[64] There are several reasons for failure of surgery.[29,30] A new area of epileptogenesis may develop at the resection edge or at another site such as the opposite medial temporal area. An error in localising the epileptogenic area during the pre-operative evaluation will result in the persistence of the focus. However, the most important reason for surgical failure is insufficient excision of the epileptogenic zone. In patients with ATL, retained mesial structures or diffuse epileptogenicity in the residual temporal lobe has been recognised as the reason for surgical failure.[30,54]

In 20 patients in whom the first surgery failed due to inadequate resection of the hippocampal formation, Olivier et al. performed a second surgery and removed the residual mesial temporal structures.[54] After the second surgery, 30% of the patients became seizure-free, 15% had a marked seizure reduction, 35% appreciated worthwhile improvement and 20% failed to achieve any significant seizure reduction.[54] Wieser and Yasargil reoperated on patients who had an initial amygdalohippocampectomy.[101] Using a standard ATL, they achieved a 50% seizure-free outcome. Sub-optimal post-operative seizure control following SAH has been found in patients in whom there is evidence of significant bitemporal or extratemporal seizure onset; patients requiring depth electrode investigation to clarify seizure lateralisation or localisation; bilaterally normal hippocampal volumes on MR imaging; pseudo temporal epilepsy and patients in whom the resection of mesial structures has been inadequate.[1] Wyler[106] reported a prospective randomised study of patients undergoing surgery for MTLE, the ictal onset being verified in each case by subdural recordings. The anteromesial temporal resection (AMTR) was compared to a more limited medial resection in this group. Complete seizure control was seen in 69% of the AMTR patients and in only 38% of the patients with a partial hippocampectomy.[106] QOL improves early after epilepsy surgery; the improvements are both statistically and clinically significant. Surgical morbidity with clinically significant permanent sequelae is 2%. In addition, successful TLE surgery appears likely to reduce the risk of seizure-related death. However, surgery remains largely under-used and overly delayed, partly because of the fear of possible surgical complications, such as verbal memory deficits and failure to control seizures.

Determinants of Post-Operative Seizure Outcome

The attributes of ideal surgical candidates for ATL with amygdalohippocampectomy are listed in Table 3. Nearly 90% of patients with unequivocal unilateral MTLE (TLE associated with MTS) achieve excellent seizure outcome, following this procedure.[15,20,40,64,69,103] By using the Seizure Frequency Scoring System, it has been demonstrated that seizure outcome remains stable after

Table 3: Ideal candidates for anterior temporal lobectomy or selective amygdalohippocampectomy

ATL.[83] The pre-operative and post-operative predictors of seizure outcome following TLE surgery are cited in Table 4. While an MRI or histopathologically verified lesion is a strong predictor of a favourable seizure outcome, a normal MRI and absence of pathology in the resected specimen are often associated with post-operative seizure recurrence.[20,64] The seizure remission is better in those patients with a complete lesion removal, when compared to those with post-operative residual lesions.[40] A number of factors predictive for good seizure control have been reported as follows: (1) clear abnormality on MR imaging; (2) absence of status epilepticus; (3) MR imaging confirmed ganglioglioma or DNT; (4) concordant lateralising memory deficit and (5) absence of dysplasia on MR imaging.[1,13,76] A syndrome of paradoxical or pseudo-TLE (PTLE) has been described, in which the seizures may be the manifestation of a complex epileptic system composed of extrahippocampal components, secondarily involving the hippocampus. This PTLE substrate does not respond as favourably to anteromedial temporal lobe resection, because the epileptogenic pathology may have been left behind.[14]

Table 4: Predictors of seizure outcome following temporal lobe epilepsy surgery

Favourable outcome
Pre-surgical factors
• MRI detected lesion
• EEG abnormalities concordant with the lesion
Post-surgical factors
• Demonstrable pathology in the surgical specimen
• Complete seizure freedom during 1st year
Unfavourable outcome
Pre-surgical factors
• Normal MRI
• Bilateral temporal EEG abnormalities
Post-surgical factors
• Absence of a detectable pathology
• Recurrence of disabling seizures during the 1st year

EEG—electroencephalogram; MRI—magnetic resonance imaging

Quality of Life Outcome

Health-related QOL describes an overall state of health that includes domains of physical, social, psychological, vocational and economic well being.[86,97] QOL scores improve after temporal lobectomy. Post-operative neuropsychological testing revealed better memory function after AH and lesionectomy compared with standard ATL.[13,32] Patients who are completely seizure free (including aura free) after surgery usually achieve an excellent QOL.[76] Work outcome was favourably influenced by pre-surgical work experience, successful post-surgical seizure control and ability to obtain further vocational skills after surgery.[72]

Economics

The mean direct recurring cost of a patient with refractory TLE continued on medical treatment at a governmental medical organisation was reported to be Rs. 6,000 per year.[69] Even with new anti-epileptic drugs, complete freedom from seizures for 1 year is not more than 10% for patients with refractory TLE.[98] A major part of the recurring direct costs of epilepsy is the cost of anti-epileptic drugs. The out-of-pocket payment for pre-surgical evaluation and TLE surgery at most of the governmental medical facilities would be about Rs. 50,000, but is likely to be double this amount in a non-governmental medical organisation. Although this amount is substantial, there is a 70% chance that the patient will be seizure-free after ATL with amygdalohippocampectomy and a 30% chance that the patient will be completely off the antiepileptic drugs within 2 years after surgery.[69] A seizure-free person could be better employed, has less psychosocial problems and more often achieves an improved QOL[72,76] Therefore surgical treatment of medically refractory TLE is a better cost-effective option than continued medical treatment.

CONCLUSION

The last two decades have witnessed remarkable advances in the evaluation and treatment of patients with refractory TLE. The improvement in the localisation of the epileptogenic zone through the advances in technology, such as digital EEG, structural and functional neuroimaging and stereotactic placement of invasive electrodes, have facilitated the selection of ideal surgical candidates and, thereby, have improved post-operative outcome. Today, surgical treatment is certainly a cost-effective option in carefully selected patients with medically refractory TLE. Developing countries should concentrate on selectively utilising the recent advances to evolve cost-effective epilepsy surgery programmes, by selecting ideal surgical candidates by utilising locally available technology and expertise, without compromising patient safety. Surgical treatment could play a major role in reducing the population of people disabled by epilepsy in the developing world.

ACKNOWLEDGEMENTS

We wish to thank the Kokilaben Dhirubhai Ambani Hospital & Medical Research Institute, Mumbai, India for approval to submit the chapter and Dr Poornima Shah, Dr Darshana Sanghvi, Dr Mihir Munshi and Dr Soumendranath Ray for providing the illustrations.

Cerebral Palsy

AK Purohit

203 Stereotaxy for Cerebral Palsy

Kanaka TS, Balasubramaniam V, Sampathkumar M

Cerebral palsy is a complex neurological syndrome involving intellectual, locomotor and postural functions. When intellectual retardation is prominent, the only method of treatment available is education at special institutions, but when the intellect is preserved and the motor aspects of the disease, like hypertonus and involuntary movements predominate, stereotaxic surgery may be helpful in relieving these features. Encouraging results with such surgery have been reported by Balasubramaniam et al.,[5,6,7] Heimburger,[24,26] Kanaka,[32,35] Krayenbuhl and Siegfried,[41] Laitinen,[42,43] Narabayashi et al.,[46,48,52] Siegfried[65] and Zervas.[74,75]

HISTORICAL ASPECTS

Ever since the description of cerebral palsy by Little in 1861, the management of this disease complex has been mainly along orthopaedic lines. However, sporadic attempts at neurosurgical treatment have been made from time to time.

Horsley[29] excised the precentral cortex, Walker[71] advocated pedunculotomy and Putnam[57] anterolateral cordotomy, in order to combat involuntary movements. These operations were done by these pioneers amidst their busy neurosurgical schedule and there was no concentrated or multidisciplinary approach towards the total problem of cerebral palsy. Narabayashi[47] was the first to approach this problem systematically.

DEFINITION

MacKeith and Polani[44] defined cerebral palsy as 'a persisting qualitative motor disorder appearing before the age of 3 years due to a non-progressive damage of the brain'. In 1964, the Little Club (a society devoted to the study of Little's Disease, in London) modified the definition as 'a permanent but not unchanging disorder of movement and posture due to a non-progressive defect or lesion in the brain in early life'. This definition does not impose an age limit. Moreover, the term 'disorder of movement and posture' is preferable to 'motor disorder'.

The World Commission[45] on cerebral palsy of the International Society for Rehabilitation of the Disabled approved of the following definition in 1969: Cerebral palsy is a persistent, but not unchanging disorder of posture and movement due to dysfunction of the brain (excluding dysfunction due to progressive disease) present before the growth and development of the brain are complete. Many other clinical features may also be present.

AETIOLOGY

The disease complex known as cerebral palsy is due to many aetiological factors the most common being trauma during birth. The birth trauma may occur due to excessive moulding of the head during delivery, resulting in multiple haemorrhages due to venous obstruction and brain distortion. Hypoxic damage can also result from placenta praevia, delayed second stage of labour, cord round the neck, neonatal aspiration or neonatal convulsions. However, cerebral palsy has often been noted in children whose delivery was uncomplicated and non-cyanotic. Towbin[70] provided evidence that in such cases the hypoxic damage occurs prior to labour and the lesion is localised in the depth of the cerebrum. Soon after birth, kernicterus can give rise to damage to the basal ganglia and result in dystonia and hypertonus. Kernicterus may also result from Rh incompatibility.

In the first few years of infancy and childhood, many diseases can damage the brain, the most common being encephalitis or 'hypertoxic state' as it is called now. The child suffers from a sudden rise of temperature and perhaps exhibits generalised seizures for 1 or 2 days. This may be followed by neurological deficits, like spasticity and mental retardation with behaviour problems. In most of these cases, special virological studies prove inconclusive.

In another group of cases, the patient develops high temperature with focal seizures. On recovery there is usually hemiplegia. In those cases, it is quite likely that the major insult is to the arteries (a form of obliterative arteritis) or to the veins (as thrombophlebitis). In some cases, a global damage also results. Investigations like angiography done months or years later are not helpful in revealing the aetiology, except in a few cases. Head injury during the first few years of life may also lead to cerebral palsy.

CLINICAL FEATURES

This condition is essentially a non-progressive one but, in an occasional case, it may be apparently progressive when a hypotonic patient becomes hypertonic or when a

hypertonic patient develops contractures or disuse atrophy of muscles due to lack of physiotherapy.

The clinical features of cerebral palsy could be classified into those due to:

1. Disorders of tone
2. Disorders of movement.

These are often in addition to varying degrees of other deficits like speech disorders, disorders of vision, cranial nerve palsies and disorders of hearing.[66] Associated seizures, mental retardation or frank behavioural abnormality may be seen in some cases. Arrest of cerebral development, early in life, results in the persistence of primitive reflexes like Moro's reflex. The tonic neck reflexes may often be elicited.

Disorders of Tone

These are of two types, viz., a. hypotonic, b. hypertonic. The hypotonic variety is seen in the classical 'floppy infant'. There is generalised absence of tone in the axial as well as in the apendicular system. In some cases, the tone returns as the child grows and the child may have hypertonicity. All these children have mental retardation.

Hypertonic cases may have spasticity, rigidity or a combination of both. This may involve one or more limbs and, often, the neck and the trunk. During passive movement of the limb, uniform hypertonus indicates rigidity and a sudden reduction of the hypertonus on continuing passive movement points to spasticity. It is not always possible to decide the type of hypertonus by clinical examination alone; surface EMG is useful in differentiation. The degree of hypertonus may vary from time to time and different observers may differ in their assessment if the examination is done at different times.

Abnormal Movements

Involuntary movements may co-exist with hypertonus and/or mental retardation. The common varieties are choreoathetosis, athetosis, torsion dystonia and intention tremor.

Athetosis refers to slow writhing movements particularly affecting the distal portions of the limbs, involving alternately the agonists and antagonists. There is always an element of hypertonus in these movements. Choreic movement is characterised by frequent jerky, quasi purposive movements predominantly of the distal parts of the limbs. The term 'choreoathetosis' is applied when the movements cannot be classified as choreic or athetotic and when there is a combination of both elements. Ballistic movements are more rapid, forceful, projectile and involve mainly the proximal parts of the limbs, rotating the limb in a wide arc. Intention tremors may also be seen in some patients.

Some children exhibit involuntary movements that are made worse by sensory stimuli like touch, noise, light or questioning. The movements may also be induced on attempts at voluntary acts. Left alone, the child is quiet and relaxed, but when the examiner asks the child to do something like putting out the tongue, the entire body goes into a severe dystonic posture.

Dystonia implies an abnormal fixity of posture due to sustained muscular contraction. When the posture continues to change, the abnormal fixity involves fresh sets of muscles, resulting in dystonic movements.

TREATMENT

Stereotaxic surgery does not replace physiotherapy. Physiotherapy, occupational therapy, education of the child and speech therapy (wherever needed) are ancillary treatments carried out pre-operatively and post-operatively.

Surgery for cerebral palsy was, earlier, confined to orthopaedic operations on muscles, tendons and selected neurectomies of peripheral nerves. Division of selected nerve roots may help in relieving localised severe muscular hypertonus.[27,56] However, all these operations give only partial relief and do not alter the central mechanisms responsible for the hypertonus.

Criteria for Selection of Cases for Stereotaxic Surgery

Patients with hypertonus and/or involuntary movements may be considered for stereotaxic surgery straight away if they are not grossly mentally retarded. For mild hypertonus, physiotherapy and orthopaedic corrective procedures may suffice. If after such a course of treatment, the hypertonus still interferes with function, stereotaxic surgery is considered. Patients with severe mental retardation, incontinence of urine and faeces, pseudobulbar signs or fixed contractures are not suitable for surgery. Patients with severe hypertonus and gross mental retardation are at times given the benefit of stereotaxic surgery mainly to ease the nursing care.

Pre-operative Assessment

In the pre-operative motor assessment, the Johnson's motor-age test and the severity index suggested by Beals[8] are of value to provide the base line to judge the degree of improvement during treatment.

Electromyographic Studies

To choose appropriate targets for making the surgical lesion it is necessary to have an accurate idea of the degree and variety of hypertonus. This information is objectively provided by surface EMG. As mentioned above, hypertonus can be of the following types: rigidity, rigidospasticity, spasticity[64] and spastorigidity.[37] Although clinically it may be easy to distinguish extremes of hypertonicity like spasticity or rigidity, surface electromyography is necessary for recognition of rigidospastic states and to have an objective assessment of the other types. EMG studies are also useful to determine the amount of hypertonicity present in cases with involuntary movements

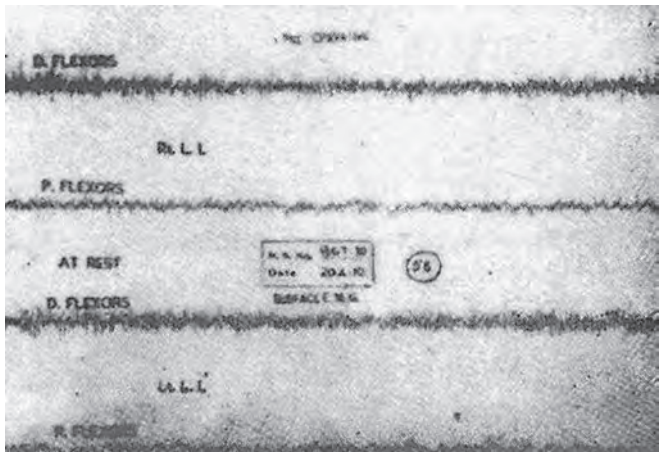

Fig. 1: Surface EMG (pre-operative) showing the continuous discharges from the muscles even during rest

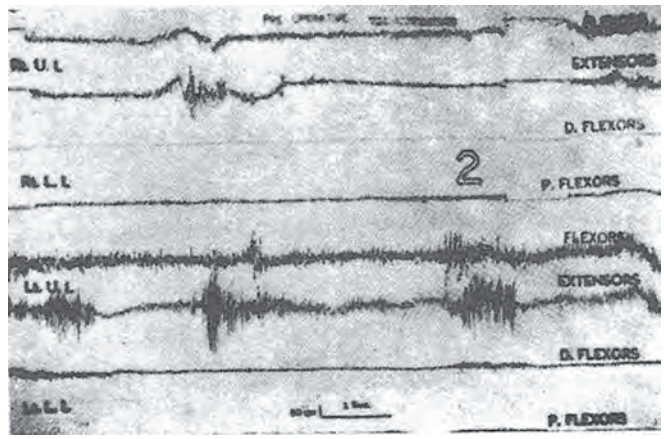

Fig. 3: Pre-operative surface EMG showing simultaneous contraction of flexors and extensors on active movement, indicating lack of reciprocation

Fig. 2: Surface EMG 1½ years after operation showing restoration of normality in the EMG

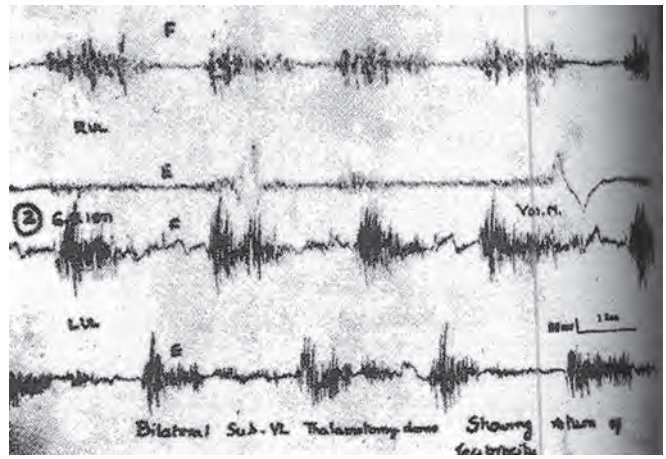

Fig. 4: Surface EMG after bilateral sub-VL thalamotomy, showing return of reciprocity

and to have comparable quantitative graphic records of the hypertonus before and after the operation (Figs 1 to 4).

Psychometric Assessment

The result of treatment of cerebral palsy depends to a large extent on the co-operation of the patient and, hence, the child should be sufficiently intelligent to follow the instructions during physiotherapy and occupational therapy. Psychometric assessment helps in decisions regarding surgery and prognosis.

The difficulties and limitation of intelligence tests in these children have been highlighted by many workers.[9,12,20,23,62,72] A definite relationship has been found between motor handicap and intelligence.[14,21,30] Tests advocated by Holt and Reynell,[28] which vary for different age-groups and degree of motor disability are more useful as they give a picture of the mental age of the patient, rather than relying totally on the psychologists' reports, based on tests meant for normal children. A much better assessment of these children can be obtained by taking into consideration the basic intelligence capacity for learning ability and willingness to co-operate with the physiotherapist, home environment and the severity of the physical handicap. This has been borne out well by the experience of the Madras Group in a large series of such patients.[36]

Timing of the Operation

Some workers prefer to postpone surgery till the child is 5 or 6 years old, treating the child in the meantime with intensive physiotherapy, but, generally, once neurosurgical treatment is considered useful, it is better to do it as early as possible even in children less than 5 years old.[36]

Early relief from hypertonicity and dyskinesias is conducive to better physiological growth of the limbs and an earlier commencement of the overall training programme of the child. Further, as many of these children may require multiple-staged operations, much time is lost if the surgical treatment is started late. The timing of surgery

is also guided by the intensity of the disability. In severe cases, stereotaxic surgery has to precede other measures.

In patients who need bilateral surgery on the thalamus, it is desirable to have an interval of at least 6 months between the two operations. This time-interval is not essential when a cerebellar lesion is to be combined with a thalamic lesion.

Pathophysiology and Choice of the Target

The disturbance of neural mechanisms in the brain of a patient with cerebral palsy is widespread and varies in each individual patient, although the resulting overall picture is one of movement and postural disturbance mixed with mental retardation. Such disturbances in the central mechanisms interfere with finely co-ordinated influences that act on the spinal motor neuron, upsetting its balanced precision, but the exact mechanisms are still controversial. Hypertonus has been ascribed by some to gamma motor neuron hyperactivity[59,60,64] and by others to hypoactivity.[22,67] The hypertonus may also be explained by central activation of the large motor neurons, through the alpha route and by gamma activation independent of muscle stretch.[3] We hypothesise that imbalance between the dynamic and static activity is responsible for various types of hypertonus seen in cerebral palsy. The choice of the target depends on the type of hypertonus of the muscle and the presence and nature of involuntary movements.

Rigidity

Rigidity is relieved by a lesion in the ventrolateral (VL) nucleus of the thalamus (Voa and Vop of Hassler). The extent and location of the lesion varies with different workers. Cooper[15] placed the lesion more posteriorly in the Vop nucleus of Hassler. Narabayashi[48,50,51] selected the VL and the area immediately below the VL nucleus abutting on the zona incerta (sub-VL thalamotomy) as, according to him, all the necessary fibres are included in a lesion at this site. We place the lesions in both the Voa and Vop and the sub VL areas and VIM.

Rigidospasticity and Spasticity

In cases with rigidospasticity and spasticity, thalamotomy alone fails to help, neither does pallidotomy influence significantly the cases with a spastic pattern.[64] In such cases, the addition of a lesion in the dentate nucleus of the cerebellum gives adequate relief. Following the work of Schneider and Crosby[61] and Heimburger,[26] we tried dentatectomy and found it useful in cases with spasticity. Nashold et al,[54] Zervas,[74,75] Krayenbuhl and Siegfried,[41] Siegfried[65] and Kanaka[35] have published favourable results with dentate lesions.

The cerebellum, as the only structure that receives the afferent influx from the annulospiral endings of the muscle spindle and from Golgi tendon organs, is of great importance in both the static and dynamic phases of muscle activity. This is seen clinically by the relief of rigidity, as well as spasticity after dentatectomy. It is of historical interest that the first successful open dentatectomy was performed for Parkinsonism by Delmas-Marsalet and Von Bogaert in 1935[19] and in 1958 by Toth.[69]

Sensory-induced Dystonia

In cases where the dystonic movements are aggravated by sensory stimuli (like a noise, flash of light or a question), a lesion in the centrum medianum (CM) nucleus in addition to the one in the VL-sub-VL area gives relief. The suggestion that the CM nucleus of the thalamus may have a critical role in movement disorders was first made by Schulman.[63] Many fibre systems converge on the CM nucleus. It receives collaterals from all sensory pathways indirectly through the connections with the reticular formation. Some fibres of the spinothalamic tract also terminate in this nucleus. Its efferents pass to the caudate and putamen, through which it probably influences the motor cortex.

Although still poorly understood, the physiologic role of the CM nucleus appears to be the integration and modulation of heterogeneous sensory and cerebellar impulses. The aggravation of the dystonia by sensory input is due to a lowering of the 'threshold for transmission from sensory to motor system'.[51] A lesion in the CM nucleus interrupts various converging fibre systems and destroys the cells of origin of the efferent neurons to the putamen, both of which may be critical in the genesis of movement disorders.[1]

In the patient with sensory-induced dystonia, it is felt that there may be an abnormality, either in the threshold or in efferent motor reaction mediated at the thalamic level to any sensory stimulus. This results in an abnormal motor response (non-purposive and uncoordinated) to a sensory stimulus. Although much of this hypothesis is still to be verified, there is no doubt about the relief obtained from CM lesions in cases of cerebral palsy with sensory-induced dystonia.[33-35,58]

Dyskinesias

In cases with various dyskinesias, a lesion in the VIM (Ventralis intermedius externus of Hassler) nucleus is helpful when combined with VL and CM lesions. These lesions were termed as "comma" lesion by Cooper.[15] On the contrary, Narabayashi[53] makes a pure VIM lesion to treat cases with involuntary movements (Figs 5 and 6).

The VIM nucleus is recognised as a distinct entity only by some workers. The nucleus receives fibres from and the impulses project to area 3-a. Hassler[22] suggested that the nucleus receives vestibular afferents. The exact function of this nucleus is not known. That it is a part of the tremerogenic zone is certain, as tremors are facilitated or produced on stimulation of this area. VIM externus lesions have been found to be of value in normotonic tremors.[34]

Fig. 5

Fig. 6

Figs 5 and 6: Pre-operative and post-operative pictures showing marked improvement in the upper limbs and the neck in a patient with severe dystonia after VL, CM and VIM lesions

Infantile Hemiplegia with Athetosis

Among the conditions, which prove recalcitrant to treatment, infantile hemiplegia with athetosis is one. In the hands of most workers, neither thalamotomy nor dentatectomy alone has given consistently good results. A combination of dentate and VIM lesions, 'dentatothalamotomy' has been found to give satisfactory results.[6,38] This suggests the existence of a servo-mechanism for correcting the position of the limbs in the dentate–VIM connections. Spinocerebellar fibres and afferents from the cerebellum probably play a role in this mechanism. Cooper et al.[15] have done pulvinotomy in such cases. Our immediate results with pulvinar lesions in selected cases are encouraging[37] (Figs 7 and 8).

To summarise: for rigidity the best results are obtained with VL and sub-VL lesions. Rigidospastic patients need thalamotomy and/or dentatectomy, depending on whether rigidity or spasticity predominates. Spasticity is relieved by dentatectomy. Sensory induced involuntary movements need CM thalamotomy for their relief. Normotonic involuntary movements are relieved by VIM lesions. Infantile hemiplegics with spasticity and

athetosis do very well with a combination of ipsilateral dentatectomy and contralateral VIM thalamotomy.

Ipsilateral Relief

About 35% of the cases show ipsilateral relief in addition to the expected results on the contralateral side.[36] This is probably due to the involvement of the uncrossed ascending fibres of the brachium conjunctivum in the lesion (Figs 9 to 12).

Location of the Target during Surgery

Since most of these operations are performed under general anaesthesia, the exact localisation of the target during surgery becomes important and at the same time

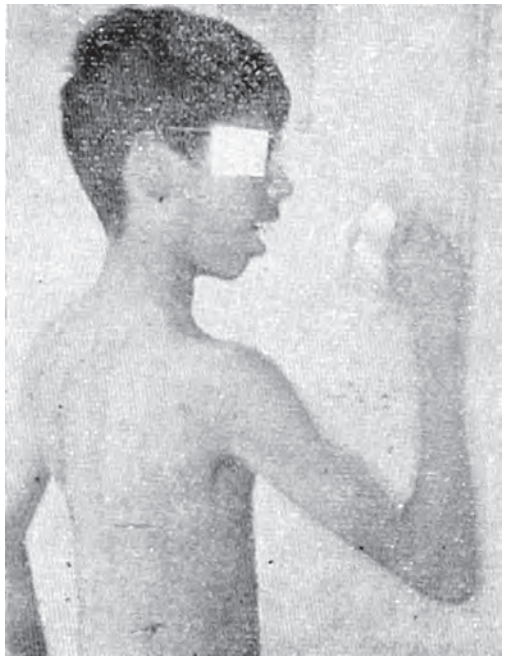

Fig. 11

Fig. 12

Figs 11 and 12: Pre-operative and post-operative pictures showing improvement in the right upper limb in the same patient

more difficult. Depth EEG may be useful in differentiating the thalamus from the white matter but it is not so informative in the recognition of individual nuclear groups. Some workers have tried to identify particular patterns of activity within specific nuclear groups.[2] However, this has not been sufficiently worked out in detail to be reliable during human surgery.

Recording of the evoked potentials from the cortex or from the concerned nucleus is a useful method. Yoshida et al.[73] used it to determine the site and size of the VL nucleus. The CM nucleus can be identified by evoked potentials on stimulation of a peripheral nerve like the ulnar nerve.[49] Balasubramaniam has suggested the "capsular delineation" method. Taking advantage of the fact that the VIM nucleus forms the medial border of the internal capsule, the position of the corticospinal tract is first determined by stimulation and noting the motor response; then the electrode is moved medially in steps of 2 mm at a time, until there is no motor response. Such a technique becomes easier with flexible electrodes that can be made to reach the desired area by necessary manipulation after the initial insertion of the probe. This method has been found useful and free from adverse effects, as most of the cases need stimulation at only two or three sites to determine the target. It is particularly useful in cases of infantile hemiplegia where there is a marked shift of the third ventricle to the atrophic side.

For localising the dentate nucleus, Heimburger[25] and the Madras group rely on calculations only. Nashold et al.[54] and Slaughter et al.[68] rely on depth electrographic analysis and stimulation responses. The calculations are made with reference to the roof of the fourth ventricle. The lesion is made 9, 13 and 17 mm from the midline.

Method of Making the Lesion

The method of making the lesion does not seem to matter as long as the lesion is big enough and is permanent. Both diathermy and oil wax lesions have given good results.

Post-operative Assessment

Post-operative assessment of cerebral palsy is limited by the fact that methods of quantification of disability are not standardised. It is better to evaluate results by comparing them with pre-operative function and in so far as is possible to determine if the improvement obtained justified the surgery having been done.[4]

Since the main purpose of surgery is to improve function of the limbs, a functional assessment would be of greater value than any other method. In this respect, the motor age test of Johnson et al.[31] has been found useful. The child is asked to perform small tasks and scores are given. The test is useful both for hypertonus as well as for involuntary movements.

A proforma has been devised taking into consideration the assessment of various specialists like the neurologist, orthopaedic surgeon and physiotherapist. Numerical estimation of improvement given by them, the patient and the parents and the objective assessment by surface EMG and motor-age determination are added together and the percentage of relief calculated.

Pre-operative and post-operative states of the patients are illustrated in the Figures 5 to 12.

To conclude, stereotaxic surgery for cerebral palsy is only one aspect of the overall management of the disabled children. Physiotherapy, education and some minimal orthopaedic procedures continue to be essential. In this context, it may be pointed out that physiotherapy in cerebral palsy is not rehabilitation, unlike in Parkinsonism where treatment results in relearning of an old skill. In cerebral palsy, new skills have to be achieved. The aim of stereotaxic surgery is only to reduce the tone and to abolish involuntary movements and, thereby, cut short the period of training and rehabilitation.

Later Additions to the Management of Cerebral Palsy

Electrical stimulation has been used for medical purposes since many centuries, but electrical stimulation of the brain gained importance in 1953 when Prof Wendel Kreig suggested the term "Neuro-prosthesis" for a device which can be implanted in the brain of a blind/deaf/motor paralysed person. His idea was implemented by Brindly and Lewin[11] who reported about the implantation of visual prosthesis in a blind nurse's visual receptor cortex. Cooper et al.[16,17] reported on the efficacy and safety of chronic stimulation of the cerebellum. Further, Delgado[18] reported that electrical stimulation of the brain by implanted electrodes can inhibit speech, movement and varieties of behaviour responses.

Chronic electrical stimulation of the brain was not used extensively as the equipment required was expensive. It has gained importance on account of its efficacy and safety.[10,13,55]

Our Experience

The electrodes consisted of platinum set in silicon. One of them was placed on the superior surface of the cerebellum, after performing an occipital craniectomy and the distal end of the electrode tunnelled to the infraclavicular region. The receiver is implanted subcutaneously in the infraclavicular region. The ends of the receiver and electrodes are coupled. Stimulation is carried out transcutaneously, using external antenna and an external stimulator (Figs 13 to 16).

At present many commercial totally implantable sets are available at huge cost. However, it was tried in an improvised way at the Institute of Neurology, Madras[39,40] (Figs 17 and 18).

Simple copper electrodes were used. Nine electrodes were introduced stereotactically into the dentate nucleus of the cerebellum. The distal ends of the electrodes are exteriorised and stimulated using Grass stimulator. The

frequency, amplitude and current used are modified depending on the patient's response to stimulation and stimulation is done for 6–8 hours a day, and at the end of 3 months a kindling effect is produced. When the interstimulation period shows beneficial effects, stimulation can be stopped.

204 Surgery for Spasticity

AK Purohit, Jagan Mohan Reddy K

INTRODUCTION

The motor pathways in the CNS may get affected directly or indirectly by various aetiological factors that may result in development of spasticity. However, these people may also have other associated motor and non-motor neurological and musculoskeletal impairments that can make the clinical picture highly complicated. This kind of picture is present, often, in cerebral palsy.

The task to relieve spasticity alone is not difficult. However, the task becomes difficult when neurological functions also have to be developed. This is the reason that there are many methods to deal with this problem, more so because ideal methods are not available for clinical use. Therefore, the team members are expected to have experience in all the available methods, so that they do not get favourably restricted and prejudiced to the only method they know of.

The selection of methods based purely on medical grounds has to be from least invasive (physical methods) through less invasive (chemicals–botulinum toxin, baclofen pump) to more invasive (ablative–rhizotomy, neurotomy) procedures. However, in practice, it is not easy to choose the methods like this. Say, physical methods that take a lot of time may not be feasible with the families having time constraint¸ whereas, the use of chemicals may not be possible where there are financial constraints (most families in the world). Therefore, the experience of the team with various methods is mandatory and, then, discussion with the family would lead to the most suitable method for that family. However, the team has to keep in mind, while deciding on the plan, that these methods are complimentary to each other and physical methods play an important role in improving neurological functional outcome.

This chapter would deal with various neuro-interventional methods to produce useful tone in people having spasticity. However, keeping in mind the patient as a whole, non-surgical and surgical management protocols will also be suggested.

MECHANISM OF GENERATION OF SPASTICITY AND BASIS OF ACTION OF VARIOUS PROCEDURES[10]

The exact mechanism of generation of spasticity and difference in spasticity generated due to brain and spinal cord pathologies is still not known.

The following are the two levels of control of muscle tone.

Suprasegmental Control

The reticular system of the brainstem plays a central role in the maintenance of normal tone. It consists of both an excitatory and an inhibitory centre. The excitatory centre is located in a diffuse area extending from the basal diencephalon, central gray and tegmentum of the midbrain and the pons and the lateral bulbar reticular formation outside the inhibitory field. The spinal projections of this system involve the ventral half of the cord and descend as the medial reticulospinal tract. This centre is supposed to be autonomous and is not under any cortical control.

The inhibitory centre is located in the caudal brainstem and is under the control of the motor cortex and to a lesser extent is also influenced by the cerebellar cortex and fastigial nucleus. The spinal projections of this system involve the dorsal half of the lateral funiculus and are conducted by the dorsal reticulospinal tract.

Normal tone consists of a balance between inhibitory effects on stretch reflexes, mediated by the dorsal reticulospinal tract and facilitatory effects on extensor tone, mediated by the medial reticulospinal tract and, to a lesser extent, by the vestibulospinal tract.

In cortical and capsular lesions, some of the drive on the inhibitory centre in the caudal brainstem is lost, resulting in spasticity. In partial spinal lesions like demyelinating disorders, there is involvement of both the pyramidal tracts and dorsal reticulospinal tracts, giving rise to severe spasticity due to the unopposed action of the medial reticulospinal and vestibulospinal tracts. In severe or complete cord lesions, there is loss of all supraspinal influences on the cord. During the period of spinal shock, the muscles remain flaccid, toneless and areflexic. After this period, there will be gradual development of hypertonia and hyper-reflexia due to the plasticity within the spinal cord, namely receptor hypersensitivity and sprouting of the axon terminals. This hypertonicity is different from the velocity dependent spasticity seen in partial cord lesions that results in virtually continuous flexor spasms.

Segmental Control

All these tracts normally inhibit the spinal myotatic monosynaptic circuit, through their influence on gamma

motor neurons that are found amongst various anterior horn cells. The gamma motor neurons, by nature, continuously discharge impulses (autogenicity) that travel through the anterior roots and peripheral nerves to reach muscle spindles located parallel to striated muscle fibres (extrafusal muscle fibres). The spindles by nature can sense the length of the muscle fibres and send the message via fibres that are located in the peripheral nerves and posterior roots. The message reaches alpha motor neurons that are found in the anterior horn cells. They in turn send the message via anterior roots to the extrafusal muscle fibres. The circuit is facilitatory in nature.

The tone in the muscles is the product of a balance between suprasegmental and segmental control mechanisms. In people with spasticity, the suprasegmental control gets altered and this results in generation of spasticity, whereas, the segmental control remains intact. However, it becomes overactive because of loss of suprasegmental inhibition. Therefore, the ideal treatment of spasticity is regeneration or implantation of damaged neural tissue that constitutes suprasegmental control. This development is yet to take place. However, the neuro-stimulation procedures performed presently on the brain or spinal cord, indeed, act by restoring suprasegmental control to some extent.[14]

Short of the ideal treatment and the limitations of neuro-stimulation procedures, scientists have worked on the overactive spinal circuit. They have been successful in reducing the electrical impulse transmission in this circuit.

TREATMENT PROTOCOL

People having spasticity due to various non-progressive causes are examined in detail. A management plan is prepared to rehabilitate the person, taking all the adverse factors into consideration. The methods are applied in the sequence of least invasive to more invasive methods. The socioeconomic and geographical constraints are also considered while planning the management. Usually, the following protocol is considered for such cases:

Physical Methods

- Physiotherapy, occupational therapy—to improve control, balance, functions and muscle tone
- Orthotic device application
- Special education
- Psychological assessment and treatment
- Speech therapy
- Ophthalmologist's consultation
- Control of seizures and other neurological problems

Management of resistant spasticity: Resistant spasticity is managed by various methods that will be discussed now in this chapter.

Selection of Cases

One of the most important steps in the success of spasticity relieving surgery is correct selection of cases. It is important to remember that the people with spasticity can have many other neurological deficits and/or musculoskeletal complications that may influence the results. The assessment of true muscle power in the presence of spasticity is also difficult. The clinician must also keep in mind that, sometimes, the spasticity can be helpful in performing some of the motor activities. The best example of helpful spasticity is paraplegia in extension. Such factors make the selection of cases for neuro-intervention a difficult task. If proper selection is not done, the surgical exercise may prove futile or even harmful.

Therefore, it is mandatory for all the members of the team to participate in the complete and careful evaluation of a case, before deciding on the necessity for neuro-intervention. During clinical examination, the following features should be noted:[60,61]

I. Non-progression of neurological deficits
II. Harmful spasticity
    1. Disabling spasticity
    2. Complications of spasticity and disfigurement
    3. Discomfort, pain and high energy consumption
III. Resistant spasticity
IV. Safety and usefulness of the procedure
V. Goals

Detection of Non-progression of Neurological Deficits

Preferably, persons having spasticity caused by non-progressive disorders are selected. There are various non-progressive disorders like cerebral palsy and injury to the central nervous system (CNS). Also, there are some diseases such as infections, vascular insult, neoplasm and lathyrism that, after treatment, may leave a person with some non-progressive neurological deficits like spasticity. Careful clinical and investigative procedures are advised to detect and differentiate these from partially treated progressive disease or incurable degenerative, metabolic and hereditary diseases. Surgical procedures are mostly indicated only for non-progressive disorders. However, if the disorder is very slowly worsening and producing harmful spasticity, certain selected procedures can be considered.

Detection of Harmful Spasticity

1. *Disabling spasticity:* Mostly, motor performance of the person is adversely affected by the presence of spasticity. However, spasticity may act as a natural inbuilt calliper and help the person to perform certain motor activities. For example, a person with spastic paraplegia in extension may be able to maintain an upright standing posture. He may be able to walk with the help of the spasticity, in spite of poor control in the lower limbs. Similarly, spastic elbow flexion is helpful in performing most of the activities of daily living. In general, in the presence of disabling spasticity, persons are unable to attain or maintain various postures or have difficulty in performing certain voluntary movements. Inadequate control in the limbs and trunk may also adversely affect motor activities.

It is a professional challenge to the team to detect that out of the two factors, spasticity and control, which one is mainly responsible for poor motor activities. For example, clinical tests like squat to stand and stand to squat can reveal the true degree of control. People who are able to perform such tests several times, by repeatedly interrupting the movements, are considered to have good control, while those who are unable to even initiate the movement are said to have poor control. Tests of similar nature can be applied to detect control of the trunk and upper limbs.

2. *Development of complications of spasticity:* Long standing spasticity can produce musculoskeletal complications like organic shortening of muscles, dislocations, etc. They may adversely affect motor activities and, therefore, the results of neuro-intervention. Such complications can also affect the appearance of the affected part.
3. *Discomfort, pain and high energy consumption:* Severe spasticity can cause discomfort and pain. Persons may get tired easily due to high-energy consumption. These factors adversely affect motor functions and performance during physiotherapy. In such cases, relief can be obtained following neuro-interventional methods, by improving functions.

Detection of Resistant Spasticity

Initially, most of the people with spasticity are advised to undergo proper physiotherapy. If necessary, anti-spasticity pharmacotherapy is also added. The patient is evaluated and treated for any nociceptive stimuli in the body like a spastic bladder, urinary tract infection, urolithiasis, chronic constipation, fissure in ano, perianal infection and bedsores. Sometimes, serial plaster of Paris cast application, temporary neural blocks, ice application and botulinum toxin injections, can also be tried to relieve spasticity. If residual spasticity persists despite all these measures for a sufficient period of time (usually 6 months), a person is said to have resistant spasticity. These measures may, in fact, either reduce the number and extent of surgical interventions or improve the person with spasticity to such an extent that surgery is not required.

Detection of Probable Safety and Usefulness of the Procedure

Surgical exposure should be safe. Therefore, in the presence of kyphoscoliosis, spondylolisthesis and poor trunk control, a laminectomy for intraspinal procedures is contraindicated. Relief of spasticity is also contraindicated in the presence of severe ataxia, dystonia and athetosis, because these neurological deficits may become more apparent after reduction in tone. Non-motivated people with spasticity may not be trainable by physiotherapy and, therefore, motor function improvement may not be possible. The presence of major and/or multiple musculoskeletal complications hamper motor performance, despite optimisation of the spastic tone. In some cases, however, improvement in motor performance may not be possible, but surgery can help in relieving pain, discomfort and improving nursing care.

Detection and Discussion of Goals

The goals of neuro-interventional methods vary from person to person and depend on the various factors mentioned above. Therefore, the expected improvement, duration of treatment and the nature of the recommended surgical procedure should be discussed with each patient and the relatives in simple words. Facility for post-operative physiotherapy and other rehabilitative therapy should also be confirmed. The whole discussion is written down when the consent is obtained.

In short, neuro-intervention for optimisation of the spastic tone is indicated only in those people who have non-progressive, harmful, resistant spasticity. The team should ascertain the safety and usefulness of the procedure and clearly discuss the goals with the person with spasticity and his relatives.

Ideal case: A well-motivated person having non-progressive, harmful, resistant spasticity with good control in the affected part and who has no musculoskeletal complications is considered as an ideal candidate for optimisation of the spastic tone by neuro-intervention, especially by ablative methods.

Neuro-interventional Procedures

Ideal Method

The ideal method to treat non-progressive harmful spasticity is regeneration or transplantation of the damaged neural tissue, prior to development of irreversible histochemical and structural changes in the neural structures and the musculoskeletal system. Some success with this procedure in movement disorders has been published, but there are no reports on spastic disorders.[3,5]

Short of regeneration or transplantation, other surgical methods can be considered; ideally, this surgical method should produce a calculated, reversible reduction in spasticity. In other words, it should produce optimum tone that is beneficial to the person, with least possible invasion and without adversely affecting the normal and potentially normal functions of the nervous system. The procedure should be safe, not too time consuming or expensive, and technically easy to perform. It should not cause geographical or any other dependency. There are various procedures in practice (Table 1) but none of them satisfy all the above mentioned criteria. However, presently, they are of tremendous help to people with spasticity.

CLASSIFICATION

The neuro-interventional procedures are classified according to the site and the nature of the neuro-intervention (Table 1).

Table 1: Classification of neuro-interventional procedures for optimisation of spastic tone

	Site	*Non-ablative*	*Ablative*
I. *Segmental* (Spinal Circuit)			
A. PNS			
1. Extra-craniospinal	Myoneural junction Peripheral nerves	— Temp. neural block Peripheral nerve stimulation	Botulinum Toxin Perm. Neural block Fasciculotomy (Neurotomy)
2. Intra-spinal	Spinal root	—	Rhizotomy
B. CNS			
Intra-spinal	Spinal cord	Intrathecal baclofen	Drezotomy Myelotomy
II. Supra-segmental			
A. CNS			
1. Intraspinal	Spinal cord	Spinal cord stimulation	—
2. Intracranial	Brain	Thalamic stimulation Cerebellar stimulation	Thalamotomy Pulvinarotomy Dentatectomy Fastigii lesions

** PNS – Peripheral nervous system, peripheral procedure, CNS – Central nervous system, central procedure, Temp.- temporary, Perm.- Permanent*

Anatomical Classification

Control Pathways

- *Suprasegmental:* The procedures that act on suprasegmental control of tone are called suprasegmental procedures. These are performed on the central nervous system (e.g. spinal cord stimulation).
- *Segmental:* The procedures that interrupt the spinal circuit responsible for the maintenance of tone are called segmental procedures. These are performed on the peripheral (e.g. fasciculotomy) or central nervous system (e.g. myelotomy).

Location

- *Central*: When surgery is performed on the brain or spinal cord.
- *Peripheral*: When surgery is performed on cranial nerves, spinal roots or peripheral nerves.

Physiological Classification

The procedures are classified into two types, depending on their effect on the nervous system.

- *Non-Ablative:* A reversible neural response is obtained without creating a lesion with the help of neurostimulation or chemical substances (e.g. spinal cord stimulation).
- *Ablative:* An irreversible lesion is created in the neural tissue (e.g. rhizotomy, fasciculotomy, etc.).

Non-ablative Segmental (Spinal Circuit) Procedures

Peripheral Procedures

Temporary peripheral (nerve) blocks: Chemical substances like bupivacaine are used on the peripheral neural structures to relieve spasticity, by reducing excessive gamma fusimotor drive. In the closed method, easily accessible nerves like the obturator, tibial, peroneal, musculocutaneous, ulnar and median nerves can be blocked by infiltration of chemical substances around the nerve. In the open method, inaccessible nerves are exposed surgically and a catheter that is connected with a reservoir for repeated injections is introduced, so as to obtain the effect of the drug for a long time. For example, a catheter can be introduced into the axilla to relieve spasticity of the upper limb. Both these procedures can also be used prior to any contemplated definitive neuro-interventional methods, so as to determine the amount of relief that can be expected and the possible motor function improvement or deterioration.

Central Procedures

Intrathecal baclofen (ITB):[4,11,30,31,40,42–47,64] Birkmayer et al. (1967) introduced oral baclofen for reduction in spasticity.[8] Penn and Kroin[53] used it intrathecally due to the poor penetration of the drug across the blood brain barrier. Baclofen is a GABA-B agonist drug that gets bound to the receptors on the superficial layers of the posterior horn. This inhibits presynaptic transmitter release, by depolarising the action potential induced calcium conductance.

Various kinds of pumps have been devised, to provide a smooth and sustained release of the drug. Under general or local anaesthesia, an intrathecal tube is passed from the back through the lumbar intervertebral space and left in the subarachnoid space. It is brought out at a convenient site on the abdomen through a subcutaneous tunnel and is connected to a reservoir that is implanted into the abdominal wall. Good and sustained reduction

in spasticity of spinal origin has been demonstrated with the use of intrathecal baclofen (ITB) in a number of studies conducted in the recent past. Spasticity of cerebral origin is also reduced, but the effect is less than in spasticity of spinal origin. Higher doses of baclofen can reduce spasticity further, but it causes weakness in the lower limbs and leads to other adverse events.[40,42]

An important positive aspect of ITB is that it is a non-ablative, reversible method and the reduction in spasticity can be titrated. ITB improves motor performance in the activities of daily living and in existing functions. However, the results do not vary much as far as lower limb functions are concerned, in comparison with much cheaper methods like selective posterior rhizotomy. The results in the spastic upper limbs are not good.

Unconsciousness to the extent of coma and respiratory failure, infection, disconnection of the tubes, geographical dependency and high expenses are the limiting factors for the use of this procedure. However, the use of better designs of the pump has lead to fewer complications. Recent reviews have shown that, even with the use of better pumps, adverse effects are common; however, they are manageable. Common adverse effects were worsening of seizures, somnolence, nausea and vomiting.[41–47]

Non-ablative Supra-segmental Procedures—Central Procedures

Neural-stimulation

Neural-stimulation for therapeutic purposes was first introduced in 1962 and, since then, has been used for pain relief and in movement disorders.[48] Later on, it was found useful for spasticity also.

1. *Spinal cord (dorsal column, posterior column) stimulation:* Cook and Weinstein[13] observed reduction in spasticity in a patient with multiple sclerosis who was being treated by spinal cord stimulation to relieve pain. The mechanism of relief of spasticity, resulting from spinal cord stimulation, is not yet clear. Stimulation of descending inhibitory pathways, blockade of nociceptive afferent influences on long loop reflexes and influence on the ascending and descending reticular systems, have been proposed.
   Electrodes are implanted in the midline posteriorly at the cervical, thoracic or lumbar epidural space by an open surgical procedure or by a closed method under fluoroscopy. The electrodes are connected to a receiver that is implanted subcutaneously in the subclavicular or sub-costal region. The frequency of stimulation is adjusted through an external spinal cord stimulator system called transmitter, which is a four electrode system using Lithium rechargeable Nickel-Cadmium batteries. Waltz[72] has reported moderate to marked overall improvement in the neurological condition of 75% of patients with cerebral palsy, head injury and spinal cord injury. Similar results have not been reproduced by other scientists. Therefore, its use has been recommended only in highly selected cases. Leakage of current, displacement of electrodes, infection, CSF leak, pain at the stimulation site, geographical dependency and high expenses, are the possible problems related to the use of this system.
2. *Thalamic stimulation:* Stimulation of the sensory relay nuclei of the thalamus has been tried for relief of spasticity.
3. *Chronic cerebellar stimulation:* This includes:
   a. Stimulation of the cerebellar cortex:[16,17,27,37,54,65] Electrodes are implanted on the posterior lobe of the cerebellum, under general anaesthesia through small bilateral craniotomies and are connected to a receiver pacemaker implanted subcutaneously in the sub-clavicular region. While some reports indicate improvement in spasticity by this technique[16,54], others did not observe any improvement. Neurotoxic effects of the stimulation have also been observed.[17,65]
   b. Dentate nuclei stimulation:[28,66,73] Schwarts et al. have reported that this procedure is effective in relieving spasticity in cerebral palsy. Spinal cord stimulation and ablative procedures are producing encouraging results and, therefore, the central neuro-stimulation procedures have not received wide acceptance. Besides the equivocal results, these implantable devices are very expensive and have not stood the test of time.

   Editors Comment: Most of these methods which are more than two decades old have not gained significant popularity suggesting their inherent limitations.

Ablative Segmental (Spinal Circuit) Procedures

Peripheral Proceduress

1. *Peripheral nerve blocks:* [12,21,35,71]Ablative peripheral neural blocks can be done on the peripheral nerves. The procedure is similar to the non-ablative technique described earlier. However, the chemicals used for this purpose are different and the effects are irreversible. They are phenol in glycerin[35,71] and alcohol.[21] The results obtained were sub-optimal and a high rate of recurrence of spasticity was noticed.
   Myoneural junction blocks:[2,15,26,70] In 1897, Von Ermengem related botulism to a toxin produced by clostridium botulinum and in 1949 Burgen showed that the toxin blocks neuromuscular transmission. In 1973, Alan Slot used botulinum toxin for the treatment of strabismus in non-human primates. In 1981, he used it for treating strabismus in humans. Tsui and Eisen used the toxin for treating cervical dystonia. Jancovic, used it for treating focal dystonias. Koman et al. first reported in 1994, the use of this toxin for patients with cerebral palsy. Bohlega studied its role in spastic paraplegics, following spinal cord injury. It was also used for treatment of spasticity in patients with multiple sclerosis and stroke.

Botulinum toxin blocks the release of acetylcholine (ACh) at the myoneural junction and, thereby, reduces spasticity. It is effective in dystonia, affecting the small muscles of the face and neck. It reduces spasticity of limb muscles also, but high doses are needed. It can be helpful in selected young children with cerebral palsy who have only focal spasticity, but quadriplegic patients having severe diffuse spasticity are not the right candidates. The drug is of no use in the presence of contractures. It can be complimentary to physical methods of treatment.

The toxin is injected at the myoneural junction. Sometimes, especially for small muscles, ENMG is required to localise the exact site of drug administration. There are no major side effects when injected into the limb muscles. However, recurrence is seen quite often. Therefore, repeated injections are required. In such cases, sometimes, antibodies against the drug can develop and then it becomes ineffective. Presently, the drug is very expensive. Recent papers and reviews have reported on the use of botulinum toxin for focal spasticity and for diffuse spasticity in young people having cerebral palsy. There is a reduction in spasticity for a short duration. However, the patients' responses were not predictable and there is no strong evidence to support or refute its use.[2] The results of long term use and functional outcome are still awaited. The functional outcome in a series of 758 children who had spasticity and received 1594 injections of botulinum toxin was studied. The functional goals were achieved fully in only 3% but, in 44% there was moderate improvement and, in 50% there was improvement.[6] Therefore, the results were compared with plaster casts. Interestingly GMFM (Gross Motor Function Measures) revealed no significant difference between the groups. It is inferred from these studies that further research on the use of the toxin to diminish spasticity and improve function is needed.[2,26]

2. *Neurotomy (neurectomy, fasciculotomy):*[18,19,20,29,32,38,62,63,69] In 1887, Lorenz first performed obturator neurotomy for relief of spastic hip adduction.[48] Intra-operative electrical stimulation of nerves was done by Gros et al. in 1977.[32] Only a few reports were available in world literature on neurotomy till 1998.[29,69] However, recently, there is an increase in the use of this procedure and many scientific papers have been published. The senior author coined the term selective motor fasciculotomy (SMF) (Fig. 1) in 1998 to give a precise picture of the procedure.[63]

Classification: This includes the following:

a. *Closed procedures*: Radiofrequency (RF) lesion[38]

b. *Open procedures*: This procedure has been classified into the following types:

i. Non-functional
   - Total neurotomy
   - Partial neurotomy

ii. Functional
   - Functional neurotomy (Selective neurotomy, Selective motor fasciculotomy)

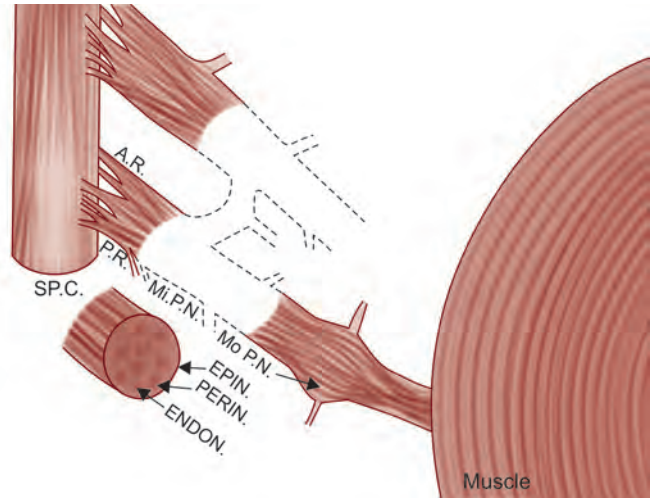

Fig. 1: Selective motor fasciculotomy: the motor peripheral nerve (MoPN) is dissected into its component fascicles. The fascicles are stimulated during selective motor fasciculotomy SpC—Spinal cord; AR—Anterior root, PR—Posterior root; MiPN—Mixed peripheral nerve; EPIN—Epineurium around a nerve fibre

In this procedure, the function of different nerve fascicles is determined by intra-operative stimulation[32] and the appropriate fascicles are divided.

Specific indications, selection criteria and goals: In general, this procedure is indicated for optimisation of focal spastic tone. However, the procedure can be performed on multiple nerves even in people with diffuse spasticity of the lower limbs when rhizotomy is contraindicated. For example, in children with diffuse spasticity of the upper limbs, this procedure is preferred to cervicothoracic rhizotomy, because a laminectomy to expose the cervicothoracic rootlets can cause cervical spinal deformity.

People with good control in the affected muscles are operated for improvement and gain in motor functions. People having only fair or poor control, may or may not improve in motor functions. However, they may get secondary benefits, like prevention of contracture, relief of discomfort and pain, improvement in the appearance of the limb and less fatigability. Fasciculotomy (SMF) of various nerves and corresponding spastic muscles has been shown in Table 2.

Procedure

In selective motor fasciculotomy procedures, the chosen nerve is exposed close to its entry into the spastic muscle say the median nerve in the cubital fossa. The component fascicles are dissected and stimulated with bipolar current, to ascertain that they are supplying the spastic muscle. The intensity of the response to the threshold current and the train stimulus is recorded. The fascicles that show hyperactive response are considered for ablation. Depending on these responses, the clinical picture

Table 2: Spastic muscles and selection of nerves for SMF

Nerves for SMF	*Spastic posture and movement*	*Spastic muscles*	*No of SMF in authors series*
Musculocutaneous	Elbow flexion	Biceps Brachii Brachialis	125
Median	Forearm pronation	Pronator teres Pronator quadrants	350
Ulnar	Wrist flexion Ulnar wrist flexion	Flexor carpi radialis Flexor carpi ulnaris	55
Obturator	Hip adduction	Adductor longus Adductor bravis Adductor magnus	130
Sciatic	Knee flexion	Hamstring muscles	40
Tibial	Ankle plantar Flexion, Toe flexion, Inversion	Gastrocnemeus, Soleus, Toe flexors	240

and the goals, the extent of ablation is determined. The fascicles are ablated by cutting them and cauterising the proximal stump by bipolar current. The number of fasciculotomies performed by the senior author has been shown in Table 2. If orthopaedic complications are present, then SMF and orthopaedic surgeries can be combined in patients having good control in the affected muscles.

Results

Following SMF, the spastic tone gets optimised right on the operation table. It is better appreciated once the operative pain subsides. The reduction in tone improves the range of movement across the joint. These movements become painless and more comfortable. However, if contracture is also present, the complete range of movement does not develop till soft tissue release surgery is also performed.

Functional improvement occurs, depending on pre-operative voluntary muscle control and motivation of the child. The presence of orthopaedic complications and previous orthopaedic surgery adversely affect the outcome. SMF improves the posture of the limb and the body. Improvement in pre-operative voluntary motor functions is observed very often following SMF. SMF of the lower limb nerves gives rise to improvement in sitting, crawling, standing and walking. Similarly, SMF of the upper limb nerves gives rise to improvement in upper limb functions related to activities of daily living and prehensile activities.

Usually, the maximum improvement is seen in the first six months. The long-term follow-up shows that spasticity does not recur and the improvement is maintained. Functional improvement is seen more often in people having spasticity in the lower limbs compared to the upper limbs. The procedure is quite useful in children who have diffuse spasticity in the upper limbs, wherein cervicothoracic rhizotomy cannot be done due to the risk of developing swan neck deformity. The procedure is quite cost effective because hardly any disposables are used and just a nerve stimulator is enough, as a special instrument that is also not an expensive tool.

Positive side effects: The procedure is found quite safe, simple and cost effective. In the upper limbs, interestingly, improvement in prehensile and shoulder movements is observed, following SMF of elbow flexors, pronators and wrist flexors. Improvement in a person's cooperation, behaviour and psychological functions also occur.

Negative side effects and complications: Paraesthesia, limb oedema, deep vein thrombosis, hypotonia, injury to vascular structures, wound gaping and infection are the possible rare complications. The senior author in his series of ten years has not faced any major problem.

3. *Rhizotomy:*[22,23,24,25,49,51,56,57,58,59,60,67] Rhizotomy means ablation of a spinal root. Depending on whether the posterior (dorsal, sensory) or the anterior (motor) root is ablated, the procedure is named accordingly. In selective rhizotomy, especially when the posterior root is selected for ablation to relieve spasticity, it is split into its component rootlets and each one is stimulated with bipolar current. The intensity of the response to the threshold current and the train stimulus is recorded. The rootlet that shows hyperactive response is considered for ablation. Depending on these responses, the clinical picture and the goals, the extent of ablation is performed. If the goals are to improve motor functions, usually under correction is preferred, because one can always reduce the spasticity further by either physical methods or extraspinal peripheral procedures like SMF, but over correction cannot be undone. Usually for this purpose 25–40% of the rootlets are ablated. Ablation is performed by sectioning the rootlet through and through. Cauterisation of the stump(s) is not required.

   In an open method, laminectomy is performed to expose the spinal roots.

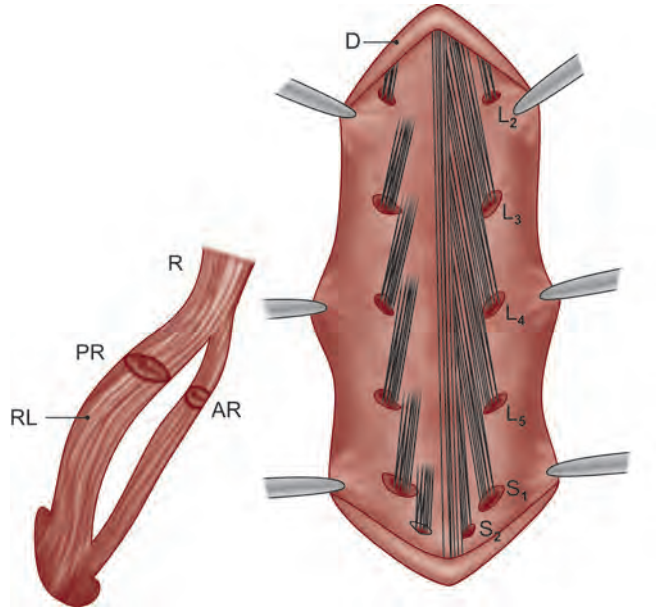

Fig. 2: Selective posterior rhizotomy: diagram on right side shows the cauda equina that has been exposed from L2 down to S2. The diagram on the left side shows dissected anterior (AR) and posterior roots (PR). Each root is composed of rootlets (RL). The posterior rootlets are dissected away from each other for stimulation during SPR R—Root

History: In an animal (cat) model of decerebrate rigidity, Sherrington, in 1888, observed relief in hypertonia, after sectioning of the posterior spinal roots.[67] Abbe[1], who first performed division of the posterior roots for relief of pain, suggested the possible use of this procedure for relief of spasticity. Otfrid Foerster first performed posterior rhizotomy in human beings for relief of spasticity.[24] Results in terms of reduction in spasticity were good, but there was widespread sensory impairment. In 1945, Munro[49] performed anterior rhizotomy in patients with spinal cord injury. This resulted in flaccid paralysis. Gros et al.[33], in 1967, introduced partial posterior root sectioning during lumbosacral rhizotomy. Based on a protocol of pre-operative mapping of spasticity and muscle functions, the rootlets responsible for function in useful muscles were spared by Privat in 1976 (Sectorial Posterior Rhizotomy).[56] In the recent past, many reports on lumbosacral rhizotomy have been published with minor modifications. In India, for the first time in 1988, WJ Peacock demonstrated selective posterior rhizotomy (Fig. 2) on cerebral palsy people at NIMS in Hyderabad. The senior author perfected and popularised the procedure and also extended the indications. He also performed for the first time, cervico-thoracic posterior rhizotomy for relief of upper limb spasticity, by using electro-stimulation technique.[59]

Indications and Specific Selection Criteria and Goals

People having diffuse spasticity in the lower or upper limbs are considered for lumbosacral or cervico-thoracic rhizotomy, respectively. In children, cervical laminectomy is preferably avoided because they are likely to develop spinal deformity.

Classification: Rhizotomies can be classified into the following types:

a. Open surgical method

i. Lumbosacral

This is done to relieve diffuse spasticity of the lower limbs. A limited T12 and L1 (Fasano's technique)[22,23] or L2 to L5 (Peacock's technique)[51,52] laminectomy and bilateral L2 to S2 SPR are performed. Improvement in motor functions has been observed in a significant number of cases. The senior author has performed Peacock's procedure on more than 225 people having cerebral palsy[58,60] and 20 others having spastic paraplegia[57] with good success.[57,60]

ii. Cervicothoracic[7,34,59]

This is done to relieve diffuse spasticity involving both the upper limbs. C5 to T1 laminectomy and bilateral C5 to T1 SPR are performed. The authors have observed improvement in motor functions including prehensility in middle-aged people having traumatic quadriparesis. The procedure was also performed in non-traumatic cases.[59]

iii. Sacral

This is indicated for spastic bladder. L5 laminectomy and partial removal of the sacrum are performed. All the sacral roots are stimulated and detrussor contractions are observed through cystometry or through some indirect methods. The goals vary from voluntary voiding to self-evacuation during socially acceptable timings.

b. Closed surgical method

Percutaneous radio frequency posterior rhizotomy[36]

Thermocoagulation of the posterior roots perhaps blocks the conduction of 'A' delta and 'C' fibres and reduces pain and spasticity. The procedure is performed under general anaesthesia in the lateral position. A skin incision, 6 cm lateral to the midline and at the level just below the site of passage of the posterior roots, responsible for carrying impulses to generate spasticity, is made. It can be considered in high-risk people with focal spasticity. A high rate of recurrence has limited its use.

c. Non-surgical method

i. Chemical rhizotomy

Intrathecal alcohol was first used by Dogliotti[21] in 1931, to relieve intractable pain. Maher used phenol in place of alcohol. Guttman used the same procedure to relieve hypertonia. Five percent phenol in glycerine, added to a water-soluble contrast medium, was also advised for this purpose. Chemical rhizotomy is indicated only in people with spasticity who are suffering from severe intractable painful spasms in the lower limbs, having no useful lumbosacral neural functions like bladder and bowel control and who have a short life expectancy, along with inability to withstand major surgery.

Results[22,23,51,52,57,58,59]

Spasticity and Spasms

Optimum reduction in hypertonicity can be achieved following SPR. However, considerable expertise is required in making a decision for ablation of a particular rootlet, as discussed earlier. The reduction in spasticity occurs immediately; however, it is well appreciated only after 3–4 days of surgery, i.e. after reduction in pain of surgical trauma. At this time, hypotonia may be present, due to electrical shock of the nerve roots that were stimulated during the surgery. SPR weakens the monosynaptic myotatic spinal reflex arc and produces quite an effective reduction in hypertonia, whereas, it produces no significant reduction in spasms, spastic patterns and mass reflexes, because they are mediated through multisynaptic pathways. Long-term follow-up reveals that no recurrence in spasticity occurs.

Motor Functions

Pre-surgical motor functions show considerable improvement within 3–9 months following SPR. New motor functions may also develop in ideal cases. The improvement is noticed in posture, balance, duration and ease of doing the activities. The awkward look also improves. Long-term follow-up reveals that the improved clinical picture is maintained.

Rhizotomy is contraindicated in the presence of significant ataxia, dystonia and athetosis. It is relatively contraindicated in the presence of multiple severe contractures, severe mental retardation, poor control in the lower limb, trunk and neck, and diseases of the spine, where laminectomy has to be performed. Relief in helpful spasticity can cause deterioration in the person's condition.

Side Effects

1. *Useful (positive) side effects*: There are many beneficial side effects, which have been observed following SPR:
   a. Improvement in upper limb function to the extent of picking of hair and threading the needle, bowel habits, swallowing and squint
   b. Clarity of speech
   c. Smooth flow and easy initiation of urination
   d. Decrease in seizures
   e. Improvement in respiratory functions and decrease in chest complications
   f. Improvement in social skills.
2. *Harmful (negative) side effects*: In a few cases troublesome post-operative numbness and paraesthesia have been observed. Usually they subside within a few days. Sometimes, mostly in adults, it may last for a few weeks to months and may require medications like carbamazepine or amitryptyline. Hypotonia can occur if an excess number of rootlets are sectioned. Rarely, touch, pain or kinaesthetic sensory impairment can occur. In the author's series of 225 cases, one child developed trophic ulcer in the foot, who walked bare footed and two others developed mild touch and kinaesthetic sensory impairment. In one case, cerebellar ataxia got worsened and in three cases neck holding worsened. All these complications were noticed in only the initial cases.
3. *Microsurgical drezotomy (MDT)—(Selective posterior rhizotomy in DREZ):* Lesions in the dorsal root entry zone (DREZ) (Fig. 3) were first used for the relief of pain. Sindou et al.[68] performed this procedure for relief of spasticity. At DREZ, the fine myelinated and unmyelinated nociceptive fibres and large 'A' alpha myotatic fibres are rearranged more centrally and laterally. During Drezotomy, these fibres are sectioned. A lesion at 45 degree into the DREZ spares the lemniscal fibres, responsible for carrying touch and kinaesthetic sensations. Although Drezotomy is being described here under the central procedures, please note it is a technique in which peripheral neural fibres are sectioned inside the cord.

   Under general anaesthesia, with only initial use of short acting muscle relaxants, the person is positioned prone. A hemi- or complete laminectomy, opposite the selected segments of the spinal cord, is performed.

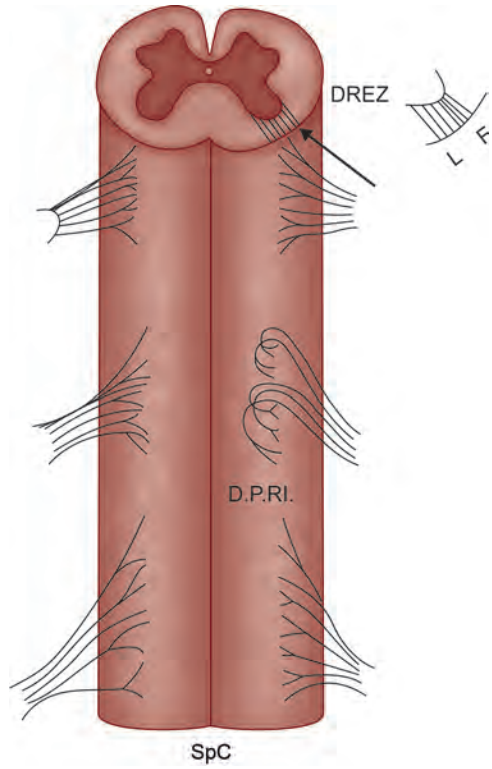

Fig. 3: Drezotomy: posterior surface of the spinal cord showing origin of posterior rootlets. One of the posterior roots rootlets have been dissected and lifted posteromedially (DPR—dissected posterior rootlets), so as to see dorsal root entry zone (Drez) clearly. The arrow is directed at 45 degrees angle into the Drez. This is the site and direction in which a lesion of the pain carrying fibres and myotatic fibres is created. The procedure spares the touch and kinaesthetic fibres

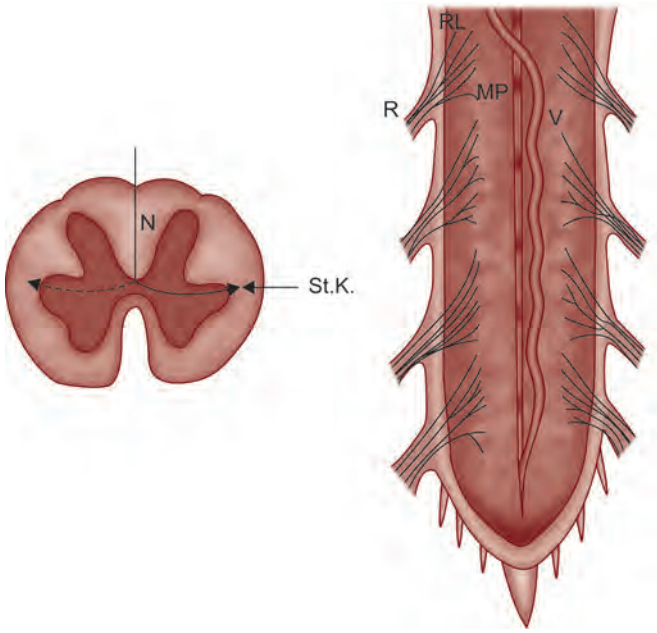

Fig. 4: Stereotactic myelotomy: longitudinal picture of posterior surface of spinal cord showing multiple black markings in the midline. These are the myelotomy puncture (MP) sites. RL—rootlets

The dura is opened and the correct site of the selected segments is confirmed by electro-stimulation of the roots/rootlets. Under magnification, the selected posterior rootlets are retracted dorsomedially from the dorsolateral sulcus, so as to reach the ventrolateral region of the DREZ. The vessels are dissected away from this site. A two mm deep incision is made at a 45 degree angle into the DREZ, with the help of a sharp knife. The area is coagulated with low intensity short duration bipolar cautery.

The procedure is indicated for adult people with spasticity, who have severe painful intractable diffuse spasticity involving one or both lower or upper limbs. The results are significantly better in people having spasticity due to pathology other than cerebral lesions. A highly significant reduction in spasticity and even painful spasms has been reported along with appreciable improvement in motor functions. Side effects like CSF leak, impairment of sensations and related complications, respiratory deterioration, urinary problems and weakness of the limbs have been observed.

4. *Longitudinal Myelotomy*: Wilhelm Bischof[9] first performed longitudinal myelotomy in 1951 and successfully relieved severe spasticity of the lower limbs. He passed the knife anterior to the attachment of the dentate ligaments on both the sides and divided the cord into anterior and posterior halves from L1 to S1 segments. The results were good in people suffering from severe frequent spasms and intractable spasticity in the lower limbs. Bischof also performed unilateral cervical myelotomy. In his technique there was a potential risk of damage to the pyramidal tracts.

Pourpre[55] modified Bischof`s technique. He opened the dorsal fissure of the spinal cord and passed a stylet knife in lateral directions. This disconnected the dorsal and ventral horns, thereby avoiding the complete interruption of corticospinal fibres.

Laitinen[39] introduced stereotactic[50] myelotomy, a more accurate and finer technique of disconnecting the ventral and dorsal horns, saving not only the corticospinal fibres but also the commissural region that transmits nociceptive and thermal fibres (Fig. 4). The incidence of spasms and of haematomyelia was less with the stereotactic procedure. The results were reported as gratifying.

Central Procedure

Refer chapter on stereotactic surgery for cerebral palsy.

205 Anaesthesia for Neurosurgery

Gupta D, Srivastava S

Anaesthetic management of neurosurgical patients is based upon an understanding of the physiology of the central nervous system (CNS) and the effects of anaesthetic agents on it. The critical homeostasis of the pathological brain may be easily disturbed by variations in cerebral blood flow (CBF), cerebral metabolic rate (CMR), cerebral perfusion pressure (CPP), CO_2 reactivity and auto-regulation due to the effects of anaesthetic drugs and techniques.

In the present chapter, a brief review of the cerebral physiology, cerebrovascular effects of the anaesthetic agents and the criteria for selecting various anaesthetic interventions, according to differing neurosurgical situations, will be addressed.

CEREBRAL PHYSIOLOGY

The brain is a converter and consumer of energy. It converts substrates supplied as metabolic fuel into usable forms of energy, which support and regulate synaptic connections, voltage dependant ion channels and synthesis, transport and packaging of neurotransmitters. The CNS receives about 15% of the resting cardiac output (750 ml/min) and consumes about 20% (170 μmol/100 g of brain/min) of oxygen required by the body at rest, whereas the weight of the brain is only 2–3% of the total body weight. The brain consumes one quarter (i.e. 31 μmol/100 g of brain/min) of the total glucose consumed by the body. Lack of substrate storage in the brain and a high metabolic rate makes the brain relatively sensitive to the effects of ischaemia. Brain metabolism can be split into two parts: the portion that drives the work of the brain, that is synaptic transmission (activation metabolism) and, the portion necessary for cellular integrity (basal metabolism), in approximately 60% and 40% of total energy consumption, respectively. The larger portion of basal metabolism is devoted to the maintenance of transmembrane ionic gradient (i.e. Na^+-K^+ pump).

CEREBRAL BLOOD FLOW AND ITS REGULATION

Average Cerebral Blood Flow (CBF) in an adult is approximately 50 ml/100 gm of brain/min. Regional blood flow varies from 20 ml/100 gm to 80 ml/100 gm of brain/min. There is approximately fourfold difference in $CMRO_2$ and CBF between cortical grey and white matter (80 ml/100g/min and 20 ml/100g/min, respectively). A rapid and precise regulatory system has evolved in the CNS, whereby instantaneous increase in the metabolic demand can be rapidly met by a local increase in CBF and substrate delivery.

METABOLIC CONTROL

Under physiological conditions, fluctuations in cerebral glucose utilisation and oxygen consumption are based upon regional electrical activity differences, matched by changes in CBF. This is known as $CMRO_2$-CBF coupling. Roy and Sherrington[41] were the first to hypothesise that the principal determinant of CBF was cerebral metabolic activity and suggested that the brain possessed an intrinsic mechanism, by which its vascular supply could vary based on local variations in functional activity. $CMRO_2$ is influenced by several factors in the neurosurgical environment, including the functional state of the nervous system, anaesthetic drugs and temperature. When the cerebral function is depressed (as in a comatose patient or during hypothermia), both CBF and substrate delivery are less than in the fully conscious state. In contrast, during a seizure, the demand for glucose and oxygen increase dramatically and must be met by an increase in CBF. In the latter situation, CBF and $CMRO_2$ change in the same direction but increase in CBF is much higher than the change in metabolic rate.

This coupling can be modified by pathophysiological processes and drugs. Clinical assessment of uncoupling may be made by measuring the arterio-jugular venous difference in oxygen content (CaO_2-$CjvO_2$). If coupling is intact, the arterio-jugular venous difference in oxygen content remains in the normal range. If CBF is inadequate to meet the CMR demand, an increased extraction of oxygen will lead to a decrease in the arterio-jugular venous difference in oxygen content. In many pathophysiological processes, the CBF-CMR coupling may be deranged selectively in focal areas, such as the area around the tumour, in subarachnoid haemorrhage (SAH) and in the region around the epileptogenic focus. Adenosine and nitric oxide are the proposed mediators of flow-metabolic coupling.[26] Adenosine increases cyclic AMP production that causes cerebral vasodilatation, whereas nitric oxide (an intercellular messenger in the peripheral circulation and in CNS) causes smooth muscle relaxation and inhibition of platelet aggregation.

AUTO-REGULATION

In the normal brain, auto-regulation refers to the ability to maintain a relatively constant CBF over a range of perfusion pressure (independent of the CBF-CMR coupling). Thus CBF is constant between an MAP of 50–150 mm of Hg (under auto-regulatory range). Above and below this range, CBF is pressure dependant (pressure passive) and varies linearly with CPP. Auto-regulation maintains the internal milieu of the CNS. It appears that change in the CPP involves a myogenic response of the vascular smooth muscles (Bayliss effect).[37] This myogenic response may consist of two separate mechanisms: one responding to the MAP changes and the other being sensitive to pulse pressure.[52]

Pathological states of the brain, pharmacological agents and physiological alterations may impair auto-regulation. Chronic hypertension shifts the auto-regulatory curve to a higher range. Intracranial tumour, head injury, brain lactic acidosis, hypercapnia and cerebral vasodilators impair auto-regulation. More recent work has shown that following trauma, auto-regulation may still be functioning.[6] In this situation, if CPP falls below the critical value of 70 mmHg, the patient will have inadequate cerebral perfusion. Auto-regulation will cause cerebral vasodilatation, leading to a rise in brain volume. This, in turn, will lead to a further rise in ICP and induce the vicious cycle described by the vasodilatation cascade, which results in cerebral ischaemia. Raising the CPP by elevating MAP can break this process, inducing the vasoconstriction cascade. Thus, maintenance of arterial blood pressure at adequate level by careful monitoring and rapid correction is of paramount importance.

CARBON DIOXIDE

Carbon dioxide is a powerful modulator of cerebral venous resistance. At normotension, there is nearly a linear response of CBF at a $PaCO_2$ between 20 mmHg and 80 mmHg (CBF changes about 2–4% for each mm Hg change in $PaCO_2$). Vasodilation by CO_2 is probably mediated by nitric oxide and cGMP pathways in adults and by prostaglandins and cAMP in neonates.[7]

Hypocapnia reduces CBF and, hence, CBV and ICP, although the CO_2 induced cerebral vasoconstriction wanes over a period of 6–10 hours.[38] Hypocapnia, however, may adversely affect cellular metabolism and shifts the oxy-haemoglobin dissociation curve to the left.[44] While hypocapnia is maintained, there is a gradual increase in CBF towards control values, which will lead to cerebral hyperaemia (over-perfusion) if the $PaCO_2$ is returned rapidly to normal levels.[36] When long-term ventilation is required, only mild hypocapnia (34–38 mmHg; 4.5–5.1 kPa) should be induced. Response of CBF towards CO_2 is attenuated below a $PaCO_2$ of 25 mm of Hg. CBF cannot be further reduced, as the ischaemic vasodilatation effect counteracts the hypocapnia induced vasoconstrictor response. Therefore, there is no advantage in inducing further hypocapnia.

OXYGEN

Low arterial oxygen tension also has profound effects on CBF. When the former falls below 50 mmHg (6.7 kPa), there is a rapid increase in CBF and cerebral blood volume.

NEUROGENIC CONTROL

Autonomic factors do not appear to control CBF, but they may modify other regulatory responses. Perivascular innervation of the cerebral resistance vessels and the specific neurotransmitters contained within the perivascular nerve fibres, also modulate vascular responses to changes in the blood pressure. The innervation of the cerebral vasculature is extensive and involves serotonergic, adrenergic and cholinergic systems of both intracranial and extracranial systems. Although acetylcholine is the most abundant perivascular neurotransmitter, other mediators in this neural response include norepinephrine, neuropeptide Y, cholecystokinin, acetylcholine, vasoactive intestinal peptide and calcitonin gene related peptide.[29] Sympathetic stimulation can shift the auto-regulatory curve to the right, thus protecting the brain against severe elevations of MAP. Stimulation of parasympathetic fibres promotes a vasodilatory reaction to ischaemia. The protective response against ischaemia however, is overshadowed by hyperaemia mediated by the same fibres.

CEREBRAL PERFUSION PRESSURE

The brain and its blood vessels are encased in the rigid cranium and subjected to surrounding pressure, i.e. ICP. Therefore, net cerebral perfusion pressure (CPP) is defined as the difference between MAP and ICP. CPP represents the blood pressure gradient across the brain's vascular bed and thus determines blood flow through the brain. MAP determines the "head of pressure" perfusing the brain.

CPP = MAP - ICP

Normal CPP is 80 mmHg, but when reduced to less than 50 mmHg, there is metabolic evidence of ischaemia and reduced electrical activity. Inadequate CPP (less than 70 mmHg) has been shown to be a major factor in poor outcome of patients with raised ICP. Assessment of CPP is vital and possible, either by measurement of both ICP and MAP or by measuring MAP and making a reasonable estimate of ICP. During anaesthesia, therefore, if ICP is raised, a fall in blood pressure must be avoided or treated quickly by volume replacement or catecholamines (whichever is relevant).

A number of studies on patients with severe head injuries have shown an increase in mortality and poor outcome when CPP falls to less than 70 mmHg for a sustained period.[28,40] Two different approaches in the management of CPP attempt to maintain adequate cerebral perfusion to meet the cerebral metabolic demand, depending upon intact auto-regulation and integrity of the blood brain barrier (BBB).

Rosner Concept or Edinburgh Concept

During head injury, when CPP is maintained within the range of 75–95 mm of Hg, auto-regulatory vasoconstriction is induced, which decreases ICP, provided cerebrovascular auto-regulation is intact.[40] Patients with a shift of the auto-regulatory curve towards the right (i.e. those in whom a higher mean arterial pressure is required to maintain the perfusion to the brain) are the most benefited by this concept (as elevation in CPP returns the pressure flow relationship into the auto-regulatory range).

Lund Concept

A group of head injured patients with defective BBB and cerebrovascular auto-regulation is benefited from a reduction in precapillary hydrostatic pressure, as well as cerebral venous constriction. This reduces CBV and thus decreases brain oedema. This concept aims at stabilisation of CPP within the range of 65–70 mm of Hg by means of proper sedation, administration of osmotic diuretics and vasopressors, and maintenance of normovolaemia.[3,4]

Continuous monitoring of jugular venous bulb oxygen saturation ($SjVO_2$) monitors the adequacy of cerebral perfusion. As CBF and the delivery of oxygen is reduced below a critical value, the brain, in order to maintain its oxygen supply, extracts more oxygen from the blood. This leads to a fall in venous oxygen saturation. More specifically, when CPP is inadequate, the $SjVO_2$ (normal range 65–75%) falls because of increased oxygen extraction. Chan[8], in a study of head-injured patients, showed that when the CPP was below 70 mmHg, there was a rapid decrease in $SjVO_2$.

INTRACRANIAL PRESSURE

The principle constituents within the skull are brain (80%), blood (12%) and CSF (8%). Normal intracranial pressure is less than 15 mm of Hg and is considered as being abnormally high when a sustained elevation greater than 20 mm of Hg occurs. Abrupt and marked increase in the ICP leads to systemic hypertension and baroreceptor mediated bradycardia (called Cushing reflex). Although this reflex is designed to increase perfusion, it eventually aggravates intracranial hypertension.

PHARMACOLOGY OF ANAESTHETIC DRUGS

Inhalational Agents

Volatile anaesthetic agents like halothane, enflurane, isoflurane, sevoflurane and desflurane cause cerebral vasodilatation with an increase in CBF. They also produce some uncoupling of the normal relationship between metabolism and blood flow. When $CMRO_2$ decreases, local blood flow falls, as there is a reduced requirement for oxygen delivery and carbon dioxide removal. The latter is the indirect effect of these agents. Volatile agents uncouple or disconnect this relationship in a dose dependent way. The overall effect on cerebrovascular tone therefore, is the sum of both the direct vasodilatory effect and any indirect residual vasoconstrictor effect. Hence, at low doses, CBF is not elevated but, at higher doses, there is an increase of CBF. An important consequence of this is that any dilatation in turn raises cerebral arterial volume and increases brain volume. A stiffer noncompliant brain raises ICP.[15]

The normal auto-regulatory mechanism is gradually abolished, as the concentration of the volatile agent is increased and CBF becomes blood pressure dependent. Thus, as MAP rises, CBF increases and cerebral vasodilation occurs. In contrast, when blood pressure falls, there is no mechanism to sustain flow by a reduction in the cerebrovascular resistance. The volatile agents also affect the CO_2-CBF relationship, causing the curve to be shifted to the left. Hypocapnia is still able to reduce CBF and, therefore, to oppose the vasodilation. However, if CO_2 is allowed to rise, there is a much more rapid increase in CBF.

Halothane

It is a moderately insoluble agent (blood gas solubility being 2.5 and the MAC, i.e. the minimal alveolar concentration at which reflex to skin incision abolishes, of 0.75%). Halothane is a potent cerebral vasodilator and in the presence of cerebral swelling, it produces a large rise in ICP. Fortunately, hyperventilating the patient for 10 min before the introduction of halothane can prevent this rise in ICP.[1] Cerebral auto-regulation is reduced at 1% inspired concentration of halothane and abolished by 2% concentration.[30] It is reasonably safe to use halothane in a hyperventilated patient up to a concentration of 0.5% in conjunction with nitrous oxide. It should be avoided, if possible, by using alternative techniques; before the duramater is opened in patients who have a raised ICP.[57] Halothane sensitises the myocardium to catecholamines making the patient more prone to developing arrhythmia, especially when adrenaline is used for local infiltration.

Enflurane

It has similar effects as halothane, but appears to be a less potent cerebral vasodilator and a more potent depressant of CMR, but it does cause cerebral seizure activity, particularly when the patient is hypocapnic.[47] Epileptic activity is harmful as it induces a massive increase in CMR, which in turn increases CBF and hence cerebral swelling. Enflurane increases ICP by increasing the rate of production of CSF and also decreasing its reabsorption.

Isoflurane (Blood Gas Solubility 1.4 and MAC 1.2%)

It is the least potent cerebral vasodilator and the most potent metabolic suppressant. It causes both respiratory and cardiovascular depression, the latter occurring

predominantly due to a fall in systemic vascular resistance.[12]

CBF and CBV are not affected by concentrations of 0.6–1.1 MAC isoflurane, but a 1.6 MAC doubles CBF. In higher concentrations, it also causes an increase in ICP. There is less impairment of auto-regulation and CO_2 reactivity when compared to halothane. There is evidence of uncoupling between the direct vasodilator effect and indirect vasoconstriction effect of isoflurane on the cerebral vasculature. Therefore, up to 1.6 MAC, the vasoconstriction effect predominantly prevents CBF from rising. As the inspired concentration rises, the direct vasodilatory effect overrides the indirect vasoconstrictor effect. However, in a damaged or pathological brain, the indirect vasoconstriction due to the depression in CMR does not occur. Therefore, small concentrations of isoflurane will cause some cerebral vasodilation. Unlike halothane, isoflurane in the concentration of 1.1% significantly increases ICP despite hyperventilation in patients with intracranial tumours, with decreased intracranial compliance.[19] Because of favourable properties and fewer side-effects, isoflurane has been recommended as the preferred drug for neuroanaesthesia.

Sevoflurane (MAC 1.7–2% and a Low Blood Gas Solubility 0.6)

It has similar properties to isoflurane on the brain, CBF, CBV and ICP.[9,43] Response to $PaCO_2$ and auto-regulation appear intact up to 1MAC. Low blood gas solubility may have an advantage for rapid awakening even after many hours of surgery. Sevoflurane is also metabolised (5%), increasing blood fluoride concentration. So far no renal complications have been reported. When sevoflurane is used with soda-lime (used for absorption of expired CO_2 in the anaesthesia machine) in a circle system, a toxic compound is produced. However, no problems have been noted due to this effect. Sevoflurane is the volatile agent of choice for induction of anaesthesia, because of its faster onset of action and non-irritant nature.

Desflurane (MAC 5–10% and Blood Gas Solubility, 0.4%)

It is also similar to isoflurane in many respects.[9] Like sevoflurane, its main advantage is in providing rapid recovery from anaesthesia. It is expensive like sevoflurane and is only economically viable if used in a sophisticated low-flow system. However, in contrast to sevoflurane, it is more irritant to the tracheobronchial tree and requires a special vapouriser, but it is not metabolised or affected by soda-lime.

Nitrous Oxide

It was believed to have minimal effect on CBF. However, in a study with human volunteers, nitrous oxide has been shown to cause a significant increase in CBF, acting synergistically with the volatile agents.[42] Nitrous oxide alters cerebral auto-regulation, the effect depending on the other anaesthetic agents it is used with. Its stand alone action impairs auto-regulation but not when added to sevoflurane 1.5 MAC.[5] Cerebral auto-regulation improves when nitrous oxide is added during propofol anaesthesia.[20] Carbon dioxide reactivity is preserved when nitrous oxide is used in combination with volatile anaesthetic agents[9,49] and also with propofol,[22] which allows manipulation of CBF during anaesthesia. This property permits the safe use of nitrous oxide in clinical practice, as the increase in blood flow resulting from its use may be nullified by hypocapnia. Recently, the effects of 50% N_2O on the frequency and extent of spike activities was investigated on electrocorticogram in eleven epileptic patients under 1.5 MAC sevoflurane, with a small dose of fentanyl. It showed that the introduction of nitrous oxide in the combination significantly decreased the spike activity, although it did not affect the extent of areas with spikes. This suggested that nitrous oxide may be carefully used during electrocorticography monitoring in epilepsy surgery.[32] Despite the fact that N_2O increases ICP in patients with intracranial tumours, it may be safely used in most neurosurgical patients, as it causes minimal cerebral swelling. N_2O allows a reduction in the concentration of potent inhalational agents, although the effect of an equipotent combination of N_2O and isoflurane on ICP and CBF may actually be worse than that of isoflurane alone.

Hypnotics

Hypnotics are agents that induce sleep. They are used for induction as well as for maintenance of anaesthesia. In general, intravenous anaesthetics decrease CBF and CMR. These agents are not cerebral vasoconstrictors. The decrease in CBF is due to decrease in CMR consequent to cerebral functional depression.

Barbiturates

They reduce CBF by direct cerebral vasoconstriction and by a reduction in metabolism. They cause dose dependent reduction in CMR and which ultimately leads to a reduction in CBV.[34] Burst suppression dose of thiopentone decreases both CBF and $CMRO_2$ to about 40% (near maximum reduction) of the awake value in humans. There is a fall in ICP, possibly because of this change in CBF and CBV. Thiopentone has multiple uses. It is used for anaesthesia, to treat raised ICP in head injured patients, as an anticonvulsant and for neuroprotection in areas of focal ischaemia.[21] Large doses of barbiturates must be used with caution in patients with raised ICP as they also cause a marked fall in blood pressure, which will lead to a fall in CPP and may delay recovery from anaesthesia. Barbiturates may also decrease production of CSF and resistance to CSF flow.

Etomidate

It resembles thiopentone in its effects on CBF and CMR. It has less cardiovascular side effects than thiopentone. The maximum reduction of CBF is more rapid than the

maximum reduction of CMR, suggesting that it has an intrinsic vasoconstrictive property. Its adverse effects include adrenocortical suppression and involuntary muscle activity. Etomidate in low concentration appears to activate seizure foci in epileptic patients and should be used cautiously in these patients.

Propofol

It is an alkylphenol, which has hypnotic properties and has a potency 1.8 times that of thiopentone. It has been prepared in intralipid and causes both respiratory and cardiovascular depression. Propofol reduces CBF, CBV, ICP and CMR in a dose related manner. The drug is rapidly metabolised in the liver and a little amount is cleared by the kidneys. Anaesthesia, when maintained by propofol infusion is followed by rapid recovery when the drug is not used for more than 3–4 hours. Prolonged use of propofol may cause systemic acidosis, progressive cardiac failure and even death in children. It should therefore be used cautiously in children.[33,48]

Propofol is a very useful agent for maintenance of anaesthesia in neurosurgical patients, particularly when nitrous oxide is to be avoided. Propofol infusions are expensive and require sophisticated infusion pumps. More recently, the concept of target controlled infusions (TCI) has been introduced, where a specially designed syringe pump using a pre-programmed algorithm injects the drug at a rate necessary to achieve the blood level set by the clinician.

Ketamine

It is a derivative of phencyclidine that induces dissociative anaesthesia. It stimulates the cardiovascular system with minimal respiratory depression. It increases $CMRO_2$, CBF and ICP in patients with intracranial decompensation. It is a non-competitive antagonist at NMDA receptors and may therefore offer protection from the adverse effects of cerebral ischaemia. Ketamine should be avoided in neurosurgical patients especially in those with raised ICP and decreased intracranial compliance.

Narcotics

Narcotics are used for their analgesic actions. Their effect over CBF, CMR and ICP are variable and depend on the background anaesthetics. In spontaneously breathing patients, narcotics will depress respiration, indirectly increasing CBF and ICP by raising $PaCO_2$; however, if ventilation is supported, then the direct effect of narcotics on CBF is minimal. With controlled ventilation and in the presence of cerebral vasodilators (like halothane), opioids produce a decrease in CBF and CMR. When given along with cerebral vasoconstrictors or when given alone, opioids have either no effect or they increase CBF and CMR. An ideal narcotic has a predictable, short lasting effect. Most of the newer opioids cause skeletal muscle rigidity when given in large doses. Seizures have been reported in some circumstances with opioid agents.

Fentanyl

It has a peak effect that starts 4 min after injection and lasts for more than 15 min. Suppression of the cardiovascular response to painful stimuli can be achieved using 1.5–2.5 mcg/kg. There is usually no change in CBF or ICP, but if a large bolus is given, a small decrease in arterial pressure can lead to a similar change in CPP. Fentanyl may accumulate in the body when used for prolonged periods and the duration of action may be up to 60 min or more. Chest rigidity may result with induction doses of fentanyl. When used in combination with droperidol, it induces neuroleptanaesthesia (Neuroleptanaesthesia is characterised by trance like immobility in an outwardly tranquil patient who is dissociated to the surroundings).

Pethidine

It is a synthetic opioid with properties similar to other narcotics, with additional atropine like effects. It can cause marked hypotension (when given rapidly), an important consideration in a patient with high ICP. The duration of action is intermediate, i.e. 2 hours with a plasma half-life of 3–4 hours. Therefore, pethidine is not an ideal agent and is not in common use in neuroanaesthesia. The usual intravenous dose is 0.5 mg/kg.

Alfentanil

It is a more recently introduced opioid, which is less potent than fentanyl, but has a very rapid onset and shorter duration. The latter is due to its rapid excretion. Alfentanil is not widely distributed in the body. As the amount of drug required to produce an adequate effective concentration is less, it is rapidly excreted. The effect on CBF and CMR are comparable with fentanyl, but when given rapidly it decreases MAP, especially in elderly patients or in patients with compromised circulation. This is especially important when ICP is also increased since the decrease of MAP decreases the CPP.

Sufentanil

It causes 29% reduction in CBF and 22% reduction in CMR. Sufentanil causes an increase in ICP, when rapidly administered.[46]

Remifentanil

It is an ultra-short acting opioid.[54] It produces rapid analgesia, and has potency similar to fentanyl. It has typical opioid effects of respiratory depression, bradycardia and skeletal muscle hypertonus. It is rapidly broken down by circulating and tissue non-specific esterases. Thus, the half-life is 10–20 min with a plasma clearance of 3–4 l/min. The recovery is rapid, and is unaffected by the dose or the length of time the drug has been given. A

bolus administered over 1 min does not cause a significant rise in ICP (2–3 mmHg), but may decrease MAP, which may lead to fall in CPP. One of the problems with remifentanil is that residual analgesia does not occur. Therefore, post-operative pain relief needs careful consideration.

The use of infusion techniques of newer narcotics (Remifentanil, etc.) with propofol, are becoming increasingly popular. With the help of ultra-short acting drugs, anaesthesia is better controlled as the rate of infusion peaks at maximum stimulation and wears off when no longer required.

Neuromuscular Blocking Drugs

Suxamethonium

It is the only depolarising muscle relaxant useful in clinical practice. It has a rapid onset of action and is the relaxant of choice for rapid intubation. It has been reported to raise ICP.[55] Therefore, it is avoided in neuroanaesthesia, until absolutely indicated (full stomach, emergency case, safe and rapid control of airway). However, some recent reports have failed to register a rise in ICP in head injured patients following suxamethonium administration.[24]

Pancuronium

It does not affect $CMRO_2$, CBF or ICP during induction of anaesthesia. It may cause arterial hypertension and tachycardia, which may make intracranial conditions difficult during surgery (but may be advantageous for circulatory support in hypotensive patients).

Vecuronium

It is an intermediate acting non-depolarising neuromuscular blocking drug. Its principal advantage is that it has negligible effects on the cardiovascular system and does not induce histamine release. A preliminary report in neurosurgical patients has confirmed that there was no observed effect on ICP or CPP.[39] Following an induction dose of 0.15 mg/kg, the time of onset for neuromuscular blockade is approximately 140 seconds, which is adequate for elective procedures. Thus, vecuronium appears to have useful properties for inducing neuromuscular blockade prior to intubation in elective cases.

Atracurium

It is an intermediate acting neuromuscular blocking drug, which has the unique property of spontaneous degradation (Hoffmann degradation) in the blood and so is preferred in patients with renal or hepatic dysfunction. Its rapid administration causes histamine release. Laudanosine, its metabolite, is potentially epileptogenic.

Mivacurium

It has a brief duration of action (10–15 min). Infusion provides stable relaxation without the risk of accumulation. It appears suitable for use in neuroanaesthesia. It causes histamine related hypotension on rapid injection.

Rocuronium

It is a steroid and serves as a relaxant with a rapid onset time, but of low potency.

Choice of Anaesthetic

The basic principles of neuroanaesthesia management include: (a) clear airway; (b) full oxygenation without hypercarbia; (c) smooth induction with no coughing or bucking; (d) careful monitoring of the patient; (e) steady well controlled maintenance of anaesthesia and (f) well controlled emergence and recovery. Based on the effects of volatile agents on the normal brain either isoflurane, sevoflurane or desflurane appear to be a better choice than halothane for patients with intracranial pathology. None of these drugs have adverse effects when mild hypocapnoea is present. Sevoflurane and desflurane have an added advantage in intracranial neurosurgery, because of faster awakening. Ketamine is probably not appropriate as a sole drug in intracranial neurosurgery. The issue of the significance of the transient rise in ICP with succinylcholine remains unaddressed. Studies in acute head-injured patients suggest that the advantages of rapid intubation, offered by succinylcholine, may offset its potential disadvantage of ICP rise. Barbiturates lower $CMRO_2$, thus offering protection during focal ischaemia. Hypothermia also protects against ischaemia. There is a growing thought that the reduction in metabolic rate, produced by barbiturates, may not be as protective as once thought.

GENERAL ANAESTHESIA: AN OVERVIEW

Pre-operative Evaluation

The American Society of Anaesthesiologist's (ASA) classification of physical status stratifies the patient's pre-existing health[58] (Table 1).

History and Physical Examination

Assessment should evaluate the history of previous surgery (problems with airway management, post-operative nausea and vomiting, coagulopathy), recent medical treatment, present medication, the presence of allergies and the family history.

Table 1: ASA Classification of physical status

1.	No organic, physiologic, biochemical or psychiatric disturbance
2.	Mild to moderate systemic disturbance
3.	Severe systemic disturbance
4.	Severe systemic disturbance that is a constant threat to life
5.	Moribund patient, likely to die with or without surgery
6.	Brain dead organ donor

The detailed neurological examination will provide the baseline status for comparison with the post-operative status. A patient with a pre-operative decreased level of consciousness may have a slow or delayed emergence from anaesthesia and may require post-operative ventilation. Patients with brainstem lesions and/or lower cranial nerve dysfunction are at increased risk of aspiration pneumonitis. Patients who have had previous motor dysfunction may develop exacerbation of focal neurological signs after sedative doses of benzodiazepines or narcotics. A patient with damaged IX-Xth nerve may present with a hoarse voice secondary to vocal cord paralysis and may be at increased risk of airway obstruction and aspiration. Finally, patients with pre-existing motor deficits may develop life-threatening arrhythmia from hyperkalaemia, secondary to succinylcholine administration.

The degree of difficulty during intubation may be predicted by the Mallampati scoring system[27] (Table 2), thyromental distances and the restriction of neck movement.

The examination is done with the patient in the sitting position with a fully open mouth.

Smoking is an important predisposing factor leading to both cardiovascular and pulmonary disease and is associated with a threefold increase in peri-operative morbidity. Cessation of smoking for 6–8 weeks is recommended for reactivation of mucociliary clearance. Even cessation of smoking for 24 hours may reduce the carboxyhaemoglobin levels and improve oxygenation.[10] The presence of reactive airway disease indicates an increased risk of bronchospasm, during airway manipulation, tracheal extubation and emergence from anaesthesia. Effect of a recent upper respiratory tract infection, in the last 2–4 weeks, places the patient at risk of peri-operative respiratory morbidity. Obesity is an important risk factor for peri-operative pulmonary complications, because it may often cause post-operative atelectasis and pneumonia.

In chronically hypertensive patients, the risk of end-organ damage must be evaluated. Patients with poorly controlled blood pressure are more susceptible to the systemic hypotensive effects of anaesthetic agents at the time of induction of anaesthesia because of constricted plasma volume. A pre-operative and intra-operative intravenous fluid loading may obviate this risk. Untreated patients may have excessive hypertension, leading to left ventricular strain and ischaemia.

A thorough cardiac workup is required in cases having coronary artery disease. An echocardiography and stress testing may be indicated in patients with symptomatic ventricular dysfunction. Electrolyte imbalance may occur because of the use of diuretics, excessive vomiting and dehydration. Concomitant drug therapy required for the treatment of raised ICP may exaggerate the cardiac related complications.

Renal disorders may lead to increased total body water, but with coexisting depleted blood volume. They are often accompanied by hypertension, electrolyte disturbances and anaemia. The volume status is often difficult to assess in renal failure and may necessitate invasive monitoring, including placement of intra-arterial and central venous pressure catheters.

Patients on anti-platelet agents, such as aspirin and clopidogrel, should have their medications stopped for a week before intracranial surgery, whereas oral anticoagulant should be switched over to heparin. Clotting factors and platelets should be made available at the time of surgery.

Patients with pan-hypopituitarism may require replacement hormone therapy. Cushing's disease may be associated with hypertension, fluid retention and diabetes mellitus. Acromegaly may present with airway problems that may need special attention at the time of intubation.

Table 2: Sampson and Young's modification of Mallampati grade

Grade I:	Soft palate, uvula, tonsillar pillar and fauces seen
Grade II:	Soft palate, uvula and fauces seen
Grade III:	Soft palate and base of uvula seen
Grade IV:	Only hard palate seen

Premedication

Neurosurgical patients with intradural pathology may require steroids prior to surgery. H_2 receptor blockers should continue on the morning of surgery to prevent stress and drug induced gastritis. All antihypertensive and cardiac medications (except ACE inhibitors) should be continued on the day of surgery. A mild sedation in the form of benzodiazepines/opioids may be given to conscious patients who do not have significantly raised ICP. None of these sedatives should be given to patients with impaired consciousness or with raised ICP, because these drugs may cause hypercapnia, hypoxia and airway obstruction. On the other hand, non-premedicated, anxious patients may have systemic hypertension, leading to increase in CBF. Therefore, it is advisable that such patients be given intravenous sedative premedication.

General Anaesthesia for Neurosurgical Procedures

Comprehensive monitoring during anaesthesia is needed for adequate assessment of a neurosurgical patient. It includes haemodynamic monitoring in the form of electrocardiogram (to see the heart rate and detect arrhythmias), arterial blood pressure (invasive or non-invasive) and central venous pressure monitoring.

The CVP catheter placement is considered to be useful when there is a risk of venous air embolism (VAE), coexisting cardiovascular disease, anticipation of substantial blood loss or with the use of ionotropic drugs. The tip of the catheter is positioned near the superior vena cava-right atrial junction and provides measurement of the intravascular volume status. Pulse oximetry measures oxygen saturation and end tidal CO_2

monitoring (capnography) measures CO_2 concentration in the expired air. The latter may be useful in detecting air embolism, as well as in assessing partial pressure of CO_2 in arterial blood and its effect on CBF. A precordial Doppler ultrasound, pulmonary artery catheter and transoesophageal echocardiography (TEE) are useful in cases with coexisting cardiac disease, as well as in cases with the risk of air embolism and operation in the sitting position.

BIS monitoring (Bispectral assay) may also be used to measure the level of hypnosis or sedation. Varieties of EEG signals are analysed and interpretation is done in the form of numerical values, called the BIS index. These numbers, derived from EEG analysis, are helpful in assessing the depth of anaesthesia. Its use has been demonstrated in reducing the doses of anaesthetic agents and in reducing the recovery time.[17] ICP and neurophysiological monitoring are an important part of the monitoring armamentarium.

The primary goals during induction are: (a) control of $PaCO_2$; (b) control of blood pressure (adequate depth of anaesthesia); (c) prevention of outflow obstruction of jugular venous blood; (d) adequate oxygenation and hyperventilation and (e) prevention of awareness. The typical scheme for smooth induction include intravenous administration of thiopentone (4–7 mg/kg), propofol (2–2.5 mg/kg) or etomidate (0.3 mg/kg) to produce hypnosis and, an opioid (fentanyl 1–2 μg/kg, sufentanil or ramifentanil), to produce analgesia to maintain strict haemodynamic control during intubation. Before giving a muscle relaxant, mask ventilation of the patient is ensured, to reduce the risk of hypoxia if intubation fails following the administration of muscle paralysing agents. For muscle relaxation, vecuronium bromide or atracurium bysilate is preferred because of minimal cerebral haemodynamic alterations. The use of succinylcholine should be reserved for patients in whom intubation difficulties are anticipated or when rapid sequence induction is absolutely unavoidable.

To achieve the morning sniffing positioning (ideal intubation position) for the intubation, a small pillow should usually be placed under the occipit to flex the neck and extend the atlanto-occipital joint. This straightens the path of vision from the upper incisor to the larynx. The curved blade is inserted toward the right side of the patient's mouth to prevent the tongue from restricting the view of the larynx. The blade tip is advanced along the tongue in front of the epiglottis to the vallecula. Then the laryngoscope is used to lift the base of the epiglottis forward to reveal the cords. Intubation is done with an appropriate sized endotracheal tube, which may be of PVC or may be armoured. Confirmation of correct placement of the endotracheal tube is made as follows: (a) the anaesthetist watches the tube pass through the cords to a position in front of the arytenoids; (b) air entry into the trachea causing bilateral, symmetrical inflation of lungs may be ascertained by auscultation; (c) the end tidal CO_2 from the expired gas during ventilation through the endotracheal tube may be assessed (it is detected continuously when the tube is in the trachea, but disappears after a few breaths when the tube is in the oesophagus) and (d) the tracheal rings may be visualised by introducing a fibreoptic bronchoscope through the endotracheal tube.

Direct laryngoscopy and intubation cause an increase in heart rate, arterial pressure and in many cases, arrhythmias. The response may be minimised by deepening of anaesthesia by an additional dose of propofol or thiopentone,[56] fentanyl 2 μg/kg, lignocaine 1–1.5 mg/kg, β blocker esmolol 150 mg or vasodilators, like sodium nitroprusside or nitroglycerine.[45]

Application of head pins during patient positioning is a painful stimulus. This can be abolished by deepening the anaesthesia (e.g. Thiopentone 1 mg/kg or Propofol 0.5 mg/kg) or by administering an analgesic (bolus of Fentanyl 1–3 mg/kg, alfentanyl 10–20 μg/kg or remifentanil 0.25–1 μg/kg) in conjunction with local anaesthetic infiltration of the pin site, to prevent undesirable CNS arousal and haemodynamic activation.

Tight Brain during Surgery

Adequate brain relaxation facilitates neurosurgery and reduces the need for excessive brain retraction. A swollen brain is prone to develop ischaemic injury. In addition, brain swelling interferes with surgery and, on occasion, may prevent the closure of the duramater. The following manoeuvres may be instituted to treat this urgent problem:

- Check ventilation. Moderate hypocapnia (target $PaCO_2$ 25–30 mmHg) will produce cerebral vasoconstriction and consequently reduce brain swelling.
- Ensure normal oxygenation.
- Control blood pressure. The target is normotension (within 10% of baseline blood pressure).
- Ensure adequate venous drainage from the brain. Neck torsion or the placement of endotracheal tube ties around the neck can impede venous drainage from the brain.
- Head elevation (30° optimum).
- Check intrathoracic pressure. Rule out pneumothorax (especially if a central line has been placed).
- Maintain adequate neuromuscular relaxation.
- Administer intravenous mannitol.
- Make sure that the concentration of the volatile anaesthetic agent is less than 0.5 MAC.
- Discontinue the administration of N_2O.
- Switch to an intravenous anaesthetic technique. A combination of propofol and opioid infusion is ideal.
- If the brain swelling does not abate, then the probability of intracranial hypertension in the post-operative period is high. Barbiturates (pentobarbital) may be administered until either the swelling is reduced or burst suppression of the EEG is attained. On rare occasions, the surgeon may elect to amputate noneloquent brain or to close the scalp without closing the dura or replacing the bone flap.

The goal of fluid therapy during neurosurgical procedures is to maintain normotension and normovolaemia. Neurosurgical patients often receive diuretics (e.g. mannitol and/or furosemide) to reduce intracranial hypertension or oedema pre-operatively. Large amounts of intravenous fluid are required to correct pre-operative dehydration and to maintain intra-operative and post-operative haemodynamics. Hyperglycaemia may increase neurological damage during cerebral ischaemia and may worsen outcome from both focal and global ischaemia.[31]

Crystalloid solutions do not contain any high molecular weight compound and have an oncotic pressure of zero. Non-glucose containing iso-osmolar 0.9% normal saline is the solution of choice for intracranial surgeries. Colloids have an oncotic pressure similar to that of plasma and both contain large molecules that are relatively impermeable to the capillary membranes. Dextran and hetastarch (hydroxyethylstarch) are dissolved in normal saline, so the osmolarity of the solution is approximately 290–310 mOsm/L. It, therefore, is suitable for use as a plasma expander.

Emergence from Anaesthesia

The emergence of the neurosurgical patient from anaesthesia may be affected by depression of the central respiratory drive, decrease in the tone of airway muscles, rise in ICP by hypoxia or hypercarbia and sympathetic stimulation, leading to systemic hypertension and further increase in ICP. The emergence should be aimed at having minimal effects on the MAP, CBF, ICP, $PaCO_2$ and temperature. Neostigmine (an anticholinesterase drug) is given to reverse neuromuscular block and anticholinergic drugs (like atropine or glycopyrrolate) are added to counteract its cardiac side effects. The extubation is facilitated by a small top-up dose of intravenous anaesthetics or analgesics and a short burst of volatile agents, to prevent coughing or bucking on the endotracheal tube, during its removal.

If the patient is not responding even after 20–30 min of cessation of all the anaesthetic agents and opioids (delayed emergence), a CT scan or MRI scan may be done to rule out intracranial bleeding, cerebral oedema, pneumocephalus or cerebral infarction. A seizure or any other metabolic disorder should also be ruled out.

ANAESTHETIC CONSIDERATIONS FOR DIFFERENT TYPES OF NEUROSURGICAL SITUATIONS

Intracranial Tumours where ICP is a Concern

Traditionally, anaesthetic agents that increase CMR or CBF result in increased CBV and ICP. However, the relationship between these agents and ICP is complex and adjuvant techniques (e.g., hyperventilation) and medications (mannitol) often mitigate the possible adverse effects.

Among the volatile agents, isoflurane, sevoflurane or desflurane would be considered as a better choice than halothane for patients with intracranial pathology. However, none of the drugs appear to have adverse effects when hypocapnia is present. Sevoflurane and desflurane appear to have advantages for intracranial neurosurgery, because of the possibility of faster awakening. The situation with nitrous oxide is probably different. A growing appreciation of the propensity of nitrous oxide to increase CBF and ICP and the fact that hypocapnia does not reduce this effect, has suggested that it may be a poor choice in patients with high ICP. Nitrous oxide is also a poor choice when closed air-filled cavities are present (e.g. pneumothorax, air embolism and pneumocephalus) because nitrous oxide diffuses into these cavities, thereby increasing the mass effect. The role of ketamine also remains controversial because of its property of increasing CBF and ICP.

The disadvantage of the transient rise in ICP brought about by succinylcholine administration in acute head-injured patients and other emergency situations is counterbalanced by its rapid action that facilitates emergency intubation.

Posterior Fossa Surgery

Additional monitoring would include end tidal CO_2, precordial Doppler and trans-oesophageal echocardiography (TEE), especially when the patient is at risk of venous air embolism (VAE), during posterior fossa surgery. Mid right atrial placement of central venous catheter is required for aspiration of air in case VAE occurs during surgery. The common positions for posterior fossa surgery are prone, park bench or sitting. Neurophysiological monitoring of brain stem auditory evoked response may be done for the assessment of VIII nerve function, during cerebellopontine angle surgery; somatosensory evoked potential monitoring for the assessment of brainstem function and, electromyography for the function of trigeminal, facial and lower cranial nerves. The neurophysiological monitoring requires adjustment of the anaesthetic technique. The depth of anaesthesia should be adjusted to an optimal level, to obtain adequate recordings. In case an EMG is being performed, then the effect of the muscle relaxant should be minimal.

While placing the patient in the sitting position, hypotension may occur, unless the patient has been adequately hydrated prior to anaesthesia. The pontomedullary area of the brain stem has the cardio-respiratory control centre. The patient may develop dysrhythmia or haemodynamic changes during dissection of the tumour. At the end of the surgery, the endotracheal tube should not be removed until the patient shows signs of reversal and evidence of airway reflex activity. Post-operative intubation and ventilation may be required in case the surgical time has been prolonged, there have been profound intra-operative haemodynamic perturbations, the patient was in altered sensorium prior to being

anaesthetised, and/or handling of the region around the respiratory centre and lower cranial nerves (IX, X, XI and XII) has been done.

Aneurysmal Subarachnoid Haemorrhage

ICP may be higher (approximately > 30 mm of Hg) in poor grade (modified Hunt and Hess grade III-IV) patients after aneurysmal SAH; on the other hand, it may be normal in grade 0-II. Following SAH, there is a reduction in CBF to 30–40% of the normal values. Global reduction in CBF is proportional to the severity of the clinical grade.[23] Auto-regulation is also impaired in proportion to the clinical grade.[53] CO_2 reactivity of the vessels is preserved, unless there is severe physiological compromise.[11] Electrolyte imbalances are a frequent occurrence. Treatment should be aimed at correcting the electrolyte abnormality, while maintaining a normal intravascular volume. In addition, hyperglycaemia often develops in patients with SAH and is associated with a poorer prognosis.[25]

ECG changes primarily involve ST segment changes or T wave inversion and occur in 40–60% of patients having SAH.[2] These ECG changes usually do not affect outcome.[59] Ventricular dysfunction occurs in 10–20% of the patients and may be more severe in poor grade patients.[35]

The anaesthetic goals of the management, during clipping of the aneurysm, are maintaining adequate CPP, preventing rebleeding and cerebral ischaemia, providing cerebral protection, and maintaining good brain relaxation. The MAP should be meticulously maintained in the higher range, especially in patients in poor Hunt and Hess grade.

Suzuki[50] advocated a combination of mannitol (500 ml of a 20% solution or 100 g), vitamin E (500 mg) and dexamethasone (50 mg), popularly called Sendai cocktail for prevention of the effects of ischaemia during temporary arterial occlusion. In addition, pharmacological metabolic suppression with thiopentone 5–6 mg/kg or etomidate 0.4–0.5 mg/kg administered before temporary occlusion, decreases CMR of the tissue distal to occlusion and increases the tolerance to ischaemia. The complications of aneurysm surgery include premature aneurysmal rupture (as high as 17.5%), delayed recovery, seizure, pneumocephalus, hypernatraemia, hyponatraemia, delayed neurological deficit and infection.[16]

Spinal Surgery

Cervical spinal pathology may be associated with restricted neck movements and may require awake fibreoptic intubation. During spinal surgery, emphasis must be placed on preventing instability and minimising blood loss and, occasionally, venous air embolism. In the prone position, proper care should be taken to facilitate ventilation and avoid venous engorgement, by avoiding excessive intra-abdominal pressure. The trans-thoracic approach may require separation of two lungs by the placement of a double lumen tube and one lung ventilation. There is a need for replacing the double lumen tube with a single lumen endotracheal tube at the end of surgery.

Paediatric Neuroanaesthesia

In children, the physiological and pharmacological response of the CNS during anaesthesia is different from that in adult patients. Newborn children have a CBF of 40–42 ml/100 gm of brain/min, which increases to 90 ml/100gm of brain/min at 6–40 months, 100 ml/100 gm of brain/min at 3–12 years of age and 50 ml/100 gm of brain/min thereafter. The metabolic rate for oxygen consumption in children is 5 ml/100 gm of brain per minute as compared to 3–3.5 ml/100 gm of brain per minute in adults. CBF is coupled to the metabolic demand and both increase immediately after birth. Auto-regulation in children occurs at a lower absolute value of MAP when compared with adults. The response of CBF to arterial CO_2 tension is similar to that in adults. Open fontanelles and cranial sutures make the intracranial space more compliant. This will lead to the masking of increase in the ICP (by tumour or haemorrhage). Therefore, due to this masking of the clinical signs and symptoms of raised ICP in children, tumours may not be detected until they are in a fairly advanced stage.

Infants less than 6 months do not show separation anxiety from parents and may not require any premedication. Children between 6 months to 6 years do not tolerate separation and are difficult to handle. The latter group of children may be premedicated with oral midazolam 0.5–0.75 mg/kg, oral fentanyl citrate 20 μg/kg and oral promethazine 0.5 mg/kg.[14]

General anaesthesia may be established by inhalation of a mixture of sevoflurane, nitrous oxide and oxygen. Alternatively, if the patient has an intravenous access, anaesthesia may be rapidly induced with sedative/hypnotic drugs, such as thiopental (5–8 mg/kg). Patients with a full stomach and difficult airway should have a rapid-sequence induction of anaesthesia with thiopental or propofol, following which muscle relaxants like succinylcholine or rocuronium should be added.

The infant's larynx is funnel shaped and narrowest at the level of the cricoid cartilage. Thus, an infant is at risk of developing subglotic obstruction, secondary to mucosal swelling after prolonged endotracheal (ET) intubation with a tight-fitting ET tube. The trachea of infants is relatively short; an ET tube can migrate into the bronchus if their head is flexed during positioning. Therefore, both lungs should be auscultated to rule out an inadvertent intubation of a main bronchus, after the final positioning of the patient. The ET tube may also kink at the base of the tongue when the head is flexed. Nasotracheal tubes are best suited for situations when the patient is to be placed prone and when post-operative mechanical ventilation is anticipated.

Normovolaemia should be maintained throughout the procedure as fluid restriction, blood loss during surgery and diuretic therapy for brain relaxation may lead to haemodynamic instability. Normal saline is commonly used as the maintenance fluid during neurosurgery, because it is mildly hyperosmolar (308 mOsml/kg).

Hydrocephalus is the most common neurosurgical problem in the paediatric population. Shunt procedures are usually not associated with significant blood loss, but exposure of a large surface area of the body during surgery may cause hypothermia.

Hydrocephalus is frequently present in patients with meningomyelocoele and they require a CSF diversion procedure before the correction of the meningomyelocoele. Congenital heart defects occur in 37% of patients with meningomyelocoele. Other associated problems include split cord malformation, abdominal wall defects, malignant hyperthermia and latex allergy.[51] Intubation in the supine position may only be possible with the meningomyelocoele sac protected in a doughnut mattress. In cases with a very large defect, intubation may be done in the lateral position. Fibre-optic intubation may help.

Craniosynostosis surgery may be associated with risk of VAE or intra-operative blood loss, requiring appropriate management.[13]

Post-operative and Intensive Care

Mechanical Ventilation

The use of mechanical ventilation in a neurosurgical patient needs to be considered carefully and should be a joint decision of the surgeon and anaesthetist. The aim of mechanical ventilation should be decided and may include either support for airway protection, ventilation (CO_2 elimination) or oxygenation. Ventilation may be inadequate due to coexisting primary lung diseases, depression of ventilatory drive or residual effect of anaesthetic drugs. Ventilatory assistance may be provided with the following modes: (a) controlled mode of ventilation (CMV, to be used in patients with no spontaneous breaths); (b) assisted/controlled mode of ventilation (AMV, in patients who initiate spontaneous breaths but cannot maintain adequate minute ventilation without support); (c) synchronised intermittent mandatory ventilation (SIMV, when ventilator breaths are delivered synchronised with the patient's breaths); (d) pressure support ventilation (PSV, that augments spontaneous breaths by pressurising the ventilator circuit to a preset value until the inspiration is terminated) and (e) pressure controlled ventilation (PCV, that delivers a pressure-limited, time cycled breath which helps in limiting lung injury). Oxygenation can be improved by applying PEEP (positive end expiratory pressure, that keeps the alveoli open at the end of expiration) or by inverse ratio ventilation (that increases the proportional time of inspiration when compared with expiration). This will lead to improved functional residual lung capacity and reduced ventilation perfusion mismatch.

During mechanical ventilation, it is mandatory to use pulse oximetry to monitor oxygen saturation, capnography to assess the end tidal CO_2 level and serial arterial blood gas monitoring to assess arterial oxygen and CO_2 concentration, pH and electrolytes.

Sedation and Analgesia

In an intensive care setting, many sedative and analgesic drugs have been administered by continuous infusion. Midazolam, a water soluble, non-analgesic benzodiazepine with a rapid onset of action, induces sleep, reduces anxiety and decreases muscle tone. The loading dose is approximately 0.1–0.2 mg/kg followed by continuous infusion of 0.05 mg/kg/hr. Propofol in a dose of 2– 4 mg/kg/hr produces satisfactory sedation without any harmful effects on CPP.

In the narcotic group, morphine in the form of intermittent boluses (2–4 mg IV) or continuous infusion (2–3 mg/hr) may be given. Synthetic opioids like fentanyl (1 mcg/kg/hr) and alfentanyl (24 mcg/kg/hr) have a limited duration of action, due to a short elimination half-life and a small volume of distribution. Haemodynamic effects are minimal and recovery from respiratory depression is rapid. Intermittent supplementation with midazolam (0.1 mg/kg) can also be used for sedation along with these agents.

Haemodynamic Management

Hypertension: It may occur following reversal with the risk of precipitating cerebral haemorrhage and myocardial ischaemia. An antihypertensive agent may be selected from amongst short acting vasodilators like sodium nitroprusside (SNP) and nitroglycerine (NTG), ganglionic receptor antagonist like trimethaphan, rapidly acting beta adrenergic blocker like esmolol or metoprolol, a longer acting vasodilator like hydralazine (10–20 mg 4–6 hourly) or calcium channel blockers. SNP infusion is started in a dose of 0.5–10 μg/kg/min. Infusion of SNP and NTG lead to rebound hypertension when the infusion is terminated. ICP and level of consciousness should be carefully monitored during SNP infusion, as rapid infusion may lead to raised ICP when intracranial compliance is reduced. Both the drugs may cause increased ICP, because cerebral capacitance vessels dilate and increase CBV. Trimethaphan has a short half-life (1–2 min.) and it seldom increases ICP in patients with reduced intracranial compliance, because ganglionic blockade spares the cerebral circulation. Esmolol in the dose of 500 μg/kg bolus and 50–200 μg/kg infusion has been used successfully in controlling hypertension after craniotomy. It can be safely used in patients with hepatic and renal disease. Its action dissipates quickly in the post-operative period. Metoprolol caused no change in ICP, CBF and $CMRO_2$, when administered to patients with increased ICP after head injury.[4]

Nefidipine, nicardipine and hydralazine are difficult to titrate and may lead to intracranial hypertension.

During hypotension, the first step is to assess the patient for hypovolaemia. Clinical assessment and invasive monitoring are used to measure the intravascular volume. Volume replacement is done with crystalloids, preferably normal saline (0.9%) and colloids. Fluid therapy is guided with CVP monitoring and pulmonary artery pressure monitoring in patients with LV dysfunction.

If there is no response to fluid therapy, ionotropic drugs are infused. If left ventricular (LV) function is good and there is peripheral vasodilatation, phenylephrine in the dose of 2–10 μg/kg/min is given. Dopamine infusion (2–20 μg/kg) is a good choice if LV contractility is not good. Noradrenaline can be added if peripheral vasodilatation exists.

Management of Disorders of Sodium Concentration

Sodium is an osmotically active, primary cation in the extracellular compartment. It contributes 90–95% of extracellular osmotic activity. Clinical disorders of sodium concentration, i.e. hypernatraemia and hyponatraemia, usually reflect alterations of body water content and not the state of sodium balance. Regulation of sodium concentration is achieved by plasma volume receptors (atrial natriuretic peptide), endocrine and renal mechanisms (ADH and aldosterone).

Hyponatraemia ($Na^+ \leq 135$)

Symptoms and signs depend on both the rate and severity of decrease in serum sodium level. Levels less then 120 mEq/L usually result in CNS symptoms like disorientation, lethargy, and coma. Acute hyponatraemia may result in brain oedema. Hyponatraemia with a normal or high osmolarity results from the presence of non-sodium solutes like glucose, mannitol, urea or toxins. The treatment requires reduction of elevated concentration of the responsible solute.

Hyponatraemia with hypo-osmolarity is associated with high total sodium like in congestive cardiac failure and renal failure. It is treated with sodium and water restriction, increase in cardiac output and increase in renal blood flow. Hyponatraemia with low total body sodium is associated with non-renal or renal loss of sodium (e.g. adrenal insufficiency). This condition is treated by restoration of blood volume, eliminating excessive sodium losses and by treatment of the adrenal insufficiency.

Euvolemic hyponatraemia is associated with a relatively normal total body sodium and extracellular volume. The syndrome of SIADH is associated with excessive release of ADH. It is treated using water restriction, loop diuretics and haemodialysis.

Neurological symptoms due to severe hyponatraemia ($Na^+ < 115$ mEq/L) and water intoxication may require aggressive therapy with hypertonic (3%) saline and intravenous furosemide. Saline, administered at the rate of 1–2ml/kg/hr increases plasma sodium by 1–2 mEq/L/hr. CNS signs and symptoms usually improve within 24–72 hours. Excessively rapid correction of hyponatraemia may result in cerebral haemorrhage, congestive heart failure and a permanent neurological condition called central pontine myelinosis or the osmotic demyelination syndrome.

Hypernatraemia

Hypernatraemia ($Na^+ > 150$ mEq/L) indicates an absolute or relative water deficit, loss of water or gain of sodium in excess of water and is always associated with hypertonicity. The clinical consequences are most serious at extremes of age[18] and in cases when there is a rapid fall in sodium level. Brain tissue dehydration produces mental lethargy and seizures. Hypernatraemia can be associated with hypervolaemia, euvolaemia or hypovolaemia and is treated accordingly. Hypernatraemia is corrected slowly due to the risk of cerebral oedema and seizures and sodium levels are reduced by not more than 1–2 mEq/hr.

After pituitary surgery, patients have high chances of developing transient or permanent diabetes insipidus (DI). Hypernatraemia secondary to diabetes insipidus is managed, depending on whether it is due to a central or nephrogenic cause. Central diabetes insipidus may require exogenous replacement of ADH with either desmopressin (DDAVP in doses of 1–4 μg every 12–24 hours subcutaneously or intranasal in five times higher dose or aqueous vasopressin 5–10 μg subcutaneously 4–6 hourly). Total body water deficit can be estimated from plasma Na by the following equation (TBW = 0.6 × body weight in Kg) – (140 ÷ actual Na^+) × 0.6 × body weight in Kg. Replacement of half the deficit should be started and further deficits should be evaluated on an hourly basis. The fluid therapy is guided by serum and urine osmolality, Na^+, K^+ and glucose levels.

Every neurosurgical procedure causes alterations in myriad dynamic physiological processes of the CNS. An active and involved anaesthesiologist achieves a favourable outcome by using an anaesthetic technique which is most appropriate for the occasion and with which he is most familiar. The choice of the anaesthetic agent and the method used can directly influence the surgical procedure and may have a significant impact on the patient's outcome.

206 Positioning in Neurosurgery

Indira Devi, Nitin Garg N, Shukla D

POSITIONING FOR NEUROSURGERY

Positioning for neurosurgical procedures is of paramount importance to the outcome of surgery. Unlike in other surgical fields, a lot of importance is given for proper positioning of the patient during surgery. A good amount of time is spent following induction of anaesthesia in positioning the patient. Every neurosurgeon takes special care to be sure that the patient's position on the operating table is ergonomical and most appropriate for the surgery that is planned. Each neurosurgeon has his own specifications, as regards the way he wants the patient to be on the operating table. Also, each patient is unique and the final position should be tailor-made for that particular patient. This may mean modification from the standard position for that surgery. It may thus vary from the recommended standard textbook description.

Proper positioning in neurosurgical procedures is:

- To provide an adequate exposure of the operative site without excessive retraction of the brain.
- To make surgery ergonomical and less tiring for the surgeon. The more comfortable the surgeon is the better are the surgical results.
- To ensure patient safety and comfort, so as to reduce the post-operative discomfort of the patient.
- To permit free access to the anaesthetist for maintaining safe anaesthesia and ability to continuously monitor the patient.
- To permit extension of the operative field if required.
- To ensure adequate venous drainage from the brain in case of cranial surgery.
- To avoid undue pressure on vital tissues, especially during spinal surgery.

A good operating table is a pre-requisite for proper positioning. It can be selected according to the preference of the surgeon and financial resources. It should keep the patient secure and should be manoeuvrable, so that minor changes while performing surgery can be undertaken easily without much delay or difficulty.

The first step in the learning of neurosurgery is to know the appropriate exposure for the surgery and the position in which this can be accessed optimally.[3] Every neurosurgeon in his initial training has been careful to ask his chief operating surgeon the minor details for positioning the patient.

The principles/steps to be followed during positioning of the patients are:

- The operative site should be easily accessible.
- The operative field should be least dependant. This makes operating on the area of interest comfortable and less stressful. The area should also have a direct line of sight. This avoids undue retraction of the brain.
- Making use of gravity to help in retracting the brain. This reduces retraction induced injury to the brain and the morbidity associated with it.
- The patient should be comfortable throughout the procedure. The pressure points, such as the malleoli and the axilla should be properly padded and protected. Any undue pressure or traction of any of the limbs should be avoided. Special care regarding the position of the upper and lower limbs should be taken. This avoids undue pain and discomfort of the patient post-operatively, as also pressure palsies of nerves. Some surgeons use appliances as G suit, to prevent venous thrombosis in the lower limbs during prolonged surgeries.
- The operative field should be at a higher position than the heart. This helps reduce venous congestion and oozing, thus providing a bloodless field. There should be no pressure on the neck vein during cranial surgery and no compression of the abdomen while the patient is in the prone position.[4]
- Proper space should be available for adjuncts, such as self-retaining retractors, CUSA, drills, operating microscope, endoscopic equipment and intraoperative monitoring. The need for these should be planned prior to surgery, so that optimal space is made available for them.
- The position of the scrub nurse is also important. It should be such as to make the transfer of instruments easy, safe and unhindered during surgery. The scrub nurse and her table should not be too close. It may interfere with the free movements of the arms of the surgeon. Too far a table hinders the smooth transfer of the instruments.
- Positioning of the patient is a dual responsibility of the surgeon and the anaesthetist. Accessibility to the anaesthetists has to be taken into consideration, while positioning. In any case, the surgeon should himself make sure that the airway is properly secured. It is

imperative to check with the anaesthesiologist that the airway pressures are within normal limits. This should be confirmed after the final positioning of the patient. High airway pressures may result in undue intra-operative complications, such as brain bulge and excessive venous oozing.[6] A reasonable guide to uncompromised airway is a two-finger breadth space between the manubrium and the chin.

- Special precautions to be taken in elderly patients: excessive rotation of the neck should be avoided as they may have spondylotic spines with compromised spinal canals.
- The head can be placed on a head-rest (horse shoe) or can be fixed with skull fixation systems (Sugita or Mayfield-Kees skull fixation systems). The horse shoe should be soft and adequately padded. Special care should be taken while positioning the patient prone to avoid undue pressure on the eyeballs. While using the skull fixation systems with pins, care should be taken to avoid the midline, the frontal sinuses, the squamous temporal bone and temporalis muscle.
- The head and neck position have significant effect on the intracranial pressure. Excessive rotation and flexion of the head and head down position result in significant raised ICP, by increasing the cerebral venous pressure by impeding the cerebral venous drainage. Patients with compromised ICP are more affected during identical manoeuvres than those with normal compliance. Although there are pharmacological means to control or reduce the ICP, proper positioning can itself significantly reduce the raised ICP. Studies have shown significantly higher ICP in the prone than in supine position. A reverse Trendelenburg position by 10 degrees itself reduces the ICP without compromising the CPP.

These are some steps to be followed for every patient. Every neurosurgeon should make his own list of important steps to be followed, while positioning the patient. The operating position for the neurosurgeon should be such that it suits him. The surgeon may prefer to operate in the standing or sitting position. A standing position provides for greater and faster mobility. The entire operative field is under vision and the surgeon may make minor adjustments, swiftly. While this is difficult in the sitting position,[5] it is more ergonomic and less tiring to operate in the sitting position. With the upper limbs supported, the muscle fatigue is less and tremors of the hands are reduced. Keeping in mind these general principles the standard positions have been described and subsequently variations of these have also been mentioned. These are divided into three groups: positioning for cranial, spinal and nerve repair procedures.

Cranial Procedures

Supine Position

The supine position with varying degrees of rotation of the head can provide adequate access to procedures for frontal, pterional, temporal, interhemispheric, trans-sphenoidal and transbasal approaches. This is one of the most commonly used positions. Various craniotomies which can be done in this position are:

- Bifrontal or unilateral frontal craniotomy
- Frontotemporal, pterional and Falconer's craniotomy
- Temporal and temporoparietal craniotomy
- Trans-sphenoidal approaches
- Frontal/frontoparietal parasagittal craniotomies
- Burr hole placements for drainage of chronic subdural haematoma and ventriculoperitoneal shunts.

Additional points to be considered while positioning the patient supine are:

- The patient should be more towards the left or the right side of the operating table, depending upon the side of the craniotomy. This makes access to the field more comfortable.
- The head should be sufficiently out of the upper edge of the operating table. This makes manoeuvrability of the head easy for positioning. This avoids obstacles and provides more working space.
- When planning frontal craniotomy when more extension is required, a sand-bag or a pillow should be placed below the shoulders. The degree of extension varies as per the procedure. Transbasal transfrontal approaches require more extension, as compared to craniotomy for frontal lobe surgery. Contralateral rotation by 10–15 degrees is useful for unilateral procedures, whereas the neutral position is preferred for bifrontal approaches.
- When planning a temporal or pterional craniotomy, the shoulder ipsilateral to the craniotomy should be elevated and supported with a sand bag. This avoids undue traction on the brachial plexus. For a pterional craniotomy, the head is extended to make the maxilla most prominent. The amount of rotation depends upon the trajectory planned. While a more anterior exposure of the Sylvian fissure requires greater rotation, a more posterior exposure of the Sylvian fissure requires more extension and less rotation.
- When planning interhemispheric procedures, the degree of flexion or extension of the head should be such that the planned site of entry should be kept highest. More posteriorly placed lesions require more flexion. The tables can also be broken midway, which further helps in bringing the posteriorly placed lesions into direct trajectory, without excessive flexion of the neck, which may compromise the venous return and complicate surgical procedures.
- For the trans-sphenoidal approach, the head should be mildly flexed and laterally rotated, so that the operating surgeon has the nostrils and the trajectory of the surgery in line with his operating position. This prevents undue bending of the surgeon over the patient and thus avoids undue exertion and discomfort.
- While doing a ventriculoperitoneal shunt through Frazier's point, the ipsilateral shoulder should be mildly elevated and the neck extended and rotated to the opposite side.

- The knees should be gently flexed with a pillow below the knees. The arms are generally placed by the side of the patient.
- Care should be taken to avoid kinking of the endotracheal tube, while putting the craniotomy drapes. As surgeons would be operating from the cranial end, the scrub nurse should not be too far away from the cranial end.

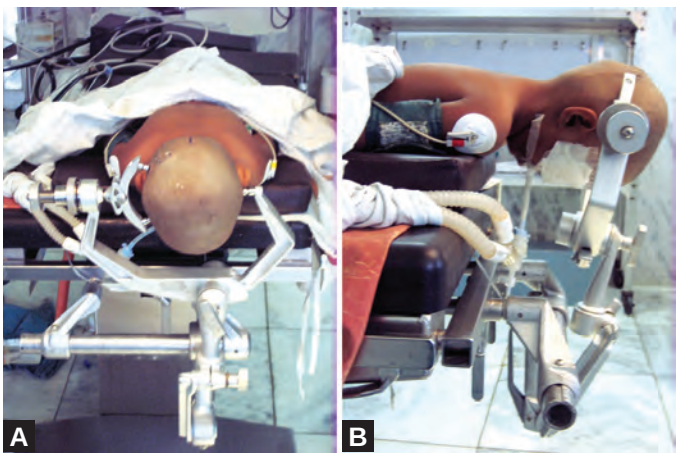
Prone Position

The prone position is used for posterior fossa procedures, such as midline/suboccipital craniectomy, posterior interhemispheric approaches, occipital, parieto-occipital craniotomies, Poppen's and Krause approach (Figs 1A and B). This position requires more care and time for positioning. Various craniotomies done in this position are:

1. Midline/paramedian suboccipital craniectomy/craniotomy.
2. Occipital/parieto-occipital craniotomy.

The patient is anaesthetised on a trolley and subsequently shifted onto the operating table. The following steps are to be followed:

- The anaesthetist usually uses a flexometallic tube for prone positions. This helps maintain better patency of the endotracheal tube and avoids kinking of the tube.
- The patient's head can be placed on a head rest or preferably fixed by three point skull fixation system. If the horse shoe is used, the rim should be soft and adequately padded to avoid a pressure sore over the face. The eyes should be padded and care should be taken to avoid compression of the eyeballs. While using the three point skull fixation, the position of the pins and frame should be such that after the final position, no part of the frame should be in contact with the face ventrally.
- Other areas such as the face, breasts, genitalia and knees should be adequately padded.



Figs 1A and B: Prone position on Mayfield clamps: (A) Patient is more towards the right end of the table. (B) Neck flexed to open the suboccipital space. The shoulders are just out to allow free movement of the neck

- The head should be brought out adequately, so as to increase the working space and avoid the obstacles due to the table and shoulders. This can be done by bringing the shoulders out adequately above the upper end of the operating table. This also helps in flexing the head at the occipitocervical junction, to open the suboccipital space.
- The patient should be more towards the right end of the operating table, to reduce the strain on the surgeon while operating.
- Adequate bolsters/pillows should be placed below the patient, so that the patient is not in direct contact with the operating table. These have to be placed over the shoulders, the thoraco-abdominal region and the pelvis. A small pillow should be placed below the leg to provide mild flexion of the knees. The abdomen should be free and there should be no restrictions in the abdominal movements.
- The extent of rotation depends upon the procedure performed. While the neutral position is maintained for suboccipital craniectomy, for a paramedian craniectomy, the patient should be rotated to the opposite side.
- The patient should be properly secured with belts or straps.

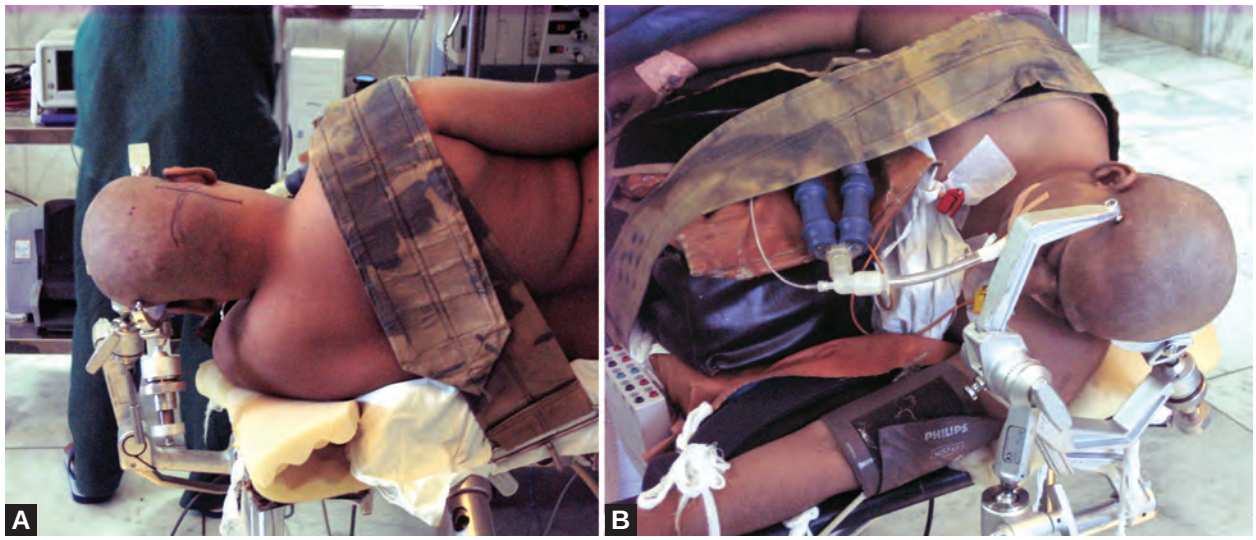
  Some modifications of the prone position are followed, as per the convenience of the surgeon. These are:

  The three-quarter position (3/4th prone): This is used by some surgeons for the parieto-occipital, vermian and supratentorial posterior interhemispheric approaches (Poppen's approach). Here, the left half of the patient is elevated by placing pillows below the bolsters on the left side of the body. This brings the right side of the body to a lower level. During Poppen's approach, this position helps in gravity dependant retraction of the right occipital lobe and the falx keeps the left occipital lobe from falling into the operative field. The upper shoulder is retracted to avoid it from obstructing the operative field. Excessive retraction may result in brachial plexus injury and should be avoided.

  Concorde position: This position is used for the infratentorial supracerebellar approach (Krause's).

Lateral Decubitus Position

This position is used for retromastoid craniectomy for cerebellopontine angle tumours and for far-lateral approaches (Figs 2A and B). Some surgeons are more comfortable in using this position for temporoparietal craniotomy and frontoparietal craniotomy for interhemispheric approaches. The patient is placed in the lateral position with the operating side up. The dependant axilla is adequately padded to avoid compression. The dependant arm is placed on an arm rest. The patient's back is brought to the edge of the operating table. The patient's head is brought out of the upper end of the operating table adequately. The upper shoulder is



Figs 2A and B: Lateral decubitus position: (A) Lateral flexion of the neck. Upper shoulder is retracted and lower shoulder is padded. Patient is towards the edge of the table. (B) Dependant arm on arm board with dependant axilla padded with sand bags and bolsters placed for support

retracted by straps, to avoid its hindering the surgeon while operating. Again, excessive retraction of the shoulders should be avoided to avoid brachial plexus injury. The body is supported by sand-bags and pillows, placed on the abdominal side of the patient and the patient is adequately strapped to secure the patient to the operating table. A pillow should be placed between the two legs with the upper leg flexed. Finally, the head has to be positioned appropriately. The head should be flexed to open the suboccipital space, laterally flexed and rotated to the opposite side, so as to bring the posterior petrous surface parallel to the trajectory of the surgery. Again, proper care of the airway and the airway pressures should be taken. It is preferable to fix the arm of the self-retaining retractor to the side opposite to where the surgeon is standing so that it doesn't interfere with the surgeon's access to the patient.

Sitting Position[2]

There has been significant decline in the use of this position due to risks such as air embolism. The current indication for the sitting position is supracerebellar infratentorial approach to the pineal region. This position gives excellent exposure to midline structures with minimal cerebellar retraction, which is facilitated by gravity. The distinct advantages are bimanual dissection as there is no need of suction because of gravity drainage of CSF and blood. Moreover, as the face is uncovered, it is directly accessible to monitor cranial nerve functions. The complications are hypotension, air embolism, tension pneumocephalus, subdural haematoma and quadriplegia. Other complications are peripheral nerve palsies (common peroneal, sciatic and recurrent laryngeal nerves), macroglossia, and haemarthrosis of the elbow. Varying incidence of air embolism in sitting or semi-sitting position has been cited by various authors. In most of these patients, the air is aspirable through central venous catheters. The tip of the CVP catheter should be at the junction of the superior vena cava and the right atrium. Presence of a patent foramen ovale is an absolute contraindication for using this position. For surgeons it is uncomfortable to operate with raised and extended arms. Monitoring for early detection and treatment of air embolism requires one of the following techniques, like trans-oesophageal Doppler, right heart catheter, fractional nitrogen extraction capnography and continuous capnography. The patient is induced in the supine position and head pins are fixed. Monitoring techniques, as intra-operative somatosensory evoked potentials,[1] have also been used, while positioning the patient to reduce the risk of iatrogenic spinal cord injury. The head end of the table is slowly elevated, over minutes, monitoring heart rate and blood pressure. Hyperventilation should be avoided at this stage, as it will further reduce cerebral blood flow. The table is flexed, the thighs elevated and knees flexed. Hyperflexion of the hips should be avoided to prevent sciatic nerve stretch. The feet should not be allowed to hang and should be secured to prevent Achilles tendon injury. The table is tilted back at the time of flexing the table to reduce haemodynamic response. Once the desirable position is attained the head may be flexed. There should be minimum two finger breadths space available between the lower jaw and the sternum. The arms are positioned in such a way that there should be no drooping of the shoulders to prevent upper trunk injury of the brachial plexus.

Spinal Procedures

Craniovertebral Junction

For transoral approaches, the supine position is used. The patient is more to the right of the operating table. The anaesthetist should be informed regarding the need of fibre-optic assisted intubation, in case there

is significant compromise of the cord and excessive movement of the spine is to be avoided. Following the transoral decompression, most of these patients require posterior fusion. While some surgeons do this as a two stage procedure, others do this at the same sitting. The patient is reversed, shifted onto a trolley and then turned prone using the same principles as followed above. Here the head should be in neutral position, so as to avoid fusion of the spine in an abnormal position. Traction has to be maintained and after final positioning, prior to inducing the patient again, the movements of the limbs should be tested. This provides an assessment of the neurological status of the patient and untoward neurological compromise that may have occurred during the positioning of the patient and decompression of the craniovertebral junction.

Cervical Spine

The supine position is used for the anterior cervical approaches for discectomies, corpectomy and fusion procedures (Fig. 3). The patient is placed supine with adequate extension of the neck. A pillow/sand-bag should be placed between the shoulder blades to extend the neck and to permit the shoulders to fall away from the operative field. The endotracheal tube should be secured properly and the patient should be more to the right edge of the operating table. This is more ergonomical, as it avoids undue bending and straining of the surgeon.

The prone position: It is used following the same principles as described above. This is used for posterior approaches to the cervical spine as for laminectomy, laminoplasty and laminotomy and foraminotomy. Care has to be taken, while turning the patient so that the neck turns along with the body. Excessive flexion or extension of the neck is avoided in an already compromised canal. It is preferable to use skull fixation for laminectomy. This provides a rigid fixation of the head and avoids unnecessary jarring movement while doing the bone work.

Thoracic Spine

The prone position is used for posterior approaches to the thoracic spine, guided by similar principles and indications outlined above.

Thoracotomy is done in the lateral decubitus position. Axillary rolls are placed below the lower axilla. The upper arm is placed on an arm rest. A pillow is placed between the legs with the upper leg flexed and the lower leg kept extended. The patient is tilted forward to about 15 degrees and strapped and secured to the operating table. The table can be flexed/broken to provide better exposure while doing a thoracotomy. However, it must be remembered to bring the table to the neutral position while doing the spinal fusion.

Lumbar and Sacral Spine

The prone position (Fig. 4) is used for posterior approaches, such as laminectomy, fenestration and discectomy, foraminotomy and posterior interbody fusion. The patient can be positioned on pillows, as described earlier or spine frames may be used. Genupectoral position is also used by some surgeons. These frames flex the spine well and the interspinous spaces are opened up, which makes access easier, especially for minimally invasive procedures, such as fenestration or endoscopic discectomies. The arms can be placed on arm boards on either side of the patient's head. Care should be taken to protect and pad the pressure points such as the eyes, breasts, genitalia and knees. The abdomen should hang free so as to decrease the intra-abdominal pressure. This decreases intra-operative venous bleeding.

Thoraco-abdominal approaches give access to D12-L1 level. The patient is positioned in the right or left lateral decubitus position, with precautions to be taken as described above. Transabdominal approaches are used for surgery at L2-L5 level. The table is flexed to open the space between the rib cage and the iliac crest. The upper leg should be flexed to relax the psoas muscle.

Fig. 3: Position for anterior cervical approach. Patient on horseshoe with neck in extension. Right hip elevated on sand bag for taking the graft

Fig. 4: Patient on Wilson's frame for lumbar discectomy. The arms are placed on an arm support

Fig. 5: Positioning for nerve repair. Note the right leg prepared for harvesting the graft. The right forearm and hand are draped for free mobility. Intercostal and musculocutaneous nerves exposed

Again, the side of the approach depends upon the surgeon's preference and the site of the pathology. A left-sided approach is preferred to avoid manipulation of the inferior vena cava and the liver. For L5-S1 access, a direct ventral approach is used. The Trendelenburg position allows the peritoneal contents to move upwards. A pillow or bolster below the sacrum can further improve the exposure.

Peripheral Nerves

Except for sciatic nerve exploration and repair, the patient is placed in the supine position for the majority of nerve repairs (Fig. 5). The involved arm/limb should be free. The site of nerve graft harvesting should also be prepared. The arm should be free for manipulation in the sterile surgical field. For repair of the upper limb nerves, the limb is placed on a side trolley and a large sand bag is placed under the ipsilateral hip, to expose the posterolateral aspect of the calf to harvest the sural nerve for a cable graft. Extent of the chest between the midclavicular line to beyond the axillary line is also prepared for the intercostals nerve harvesting (donor).

Positioning involves a conscious and concentrated effort to optimise the operating conditions for the optimal results. A thorough systemic mental check routinely reduces the chance of mistakes at various steps, thereby improving the surgical results. The importance of this initial step, in neurosurgical procedures cannot be under-estimated by any means.

207 Operation Theatre for Neurosurgery

Rahmathulla G, Ajaya Nand Jha

"Because the newer methods of treatment are good, it does not follow that the old ones were bad; for if our honourable and worshipful ancestors had not recovered from their ailments, you and I would not be here today." —Confucius

Neurosurgery is a field, which although still in its infancy, has rapidly progressed to its present form. Scientific innovations have been the driving force bringing about this metamorphosis some which initially took millennia, now take decades and in the future may take a only a few years.[14,15]

Several major milestones have marked an evolving operative environment (Fig. 1), which begins with the basic tools to allow intracranial manipulation, development of concepts regarding asepsis in an operating environment, anaesthesia and, along with this, defining the anatomical substrate and design of tools to access various locations in the CNS. The functional concepts of the various cortical areas also began to be elucidated. Subsequent to these developments, the operating theatre being used in the general surgical specialties was specifically modified to accommodate the neurosurgeon's arsenal, ranging from pneumatic instruments, various dissecting tools, electrophysiologic monitors for recording an increasing number of parameters, the operating microscope, which by itself has evolved dramatically and tools for intra-operative neuronavigation.

EVOLUTION OF THE NEUROSURGICAL OPERATING ROOM

Operating rooms have their origin from teaching amphitheatres (Fig. 2), which were used during the Renaissance period. Early pioneers performed neurosurgical procedures in an operating environment, such as Rickman Godlee (1854 to 1920) and Francesco Durante (1844 to 1934). Harvey Cushing and Walter Dandy firmly established neurosurgery as a specialty of its own and organised the operating room accordingly. They assembled combinations of aseptic and anaesthetic protocols, which were customised and laid down.

Anaesthesia was a rapidly developing branch and, as more experience was gained, became highly specialised for neurosurgical procedures. This included continuous monitoring of vital signs and blood gases, along with methods to control intracranial pressure. Development of antisepsis and asepsis brought about dramatic changes in morbidity and mortality due to infections. Mac Ewan established one of the first steam autoclaves in England and went on to perform the first craniotomy in 1879. The neurosurgical operating environment was enhanced with these rapid developments of asepsis and anaesthesia.

In the first half of the 20th century, improvements in operating instruments and better anatomical and physiological knowledge resulted in a more refined and streamlined environment. Surgical minimalism evolved following the use of magnification during surgery with the operating microscope. Theodore Kurze (1922 to 2002) used this first in 1957, many others followed suit

Fig. 1: Evolving operative environment

Fig. 2: Teaching amphitheatres

after seeing the tremendous advantages. Peter Janetta, Robert Rand, and Mahmut Gazi Yasargil established the microneurosurgical revolution.

There has been rapid progress in the past decade in the development of the 21st century operating environment. Concepts in robotics, with complex systems were applied to cardiac surgery and fields such as urology.[8,9,23] Stereotactic surgery makes use of these advances with automatic positioning that has great safety and efficacy, especially with the Leksell Gamma knife. The cyber-knife is a new frameless system, which will change volumetric controlled radiotherapy.[1]

The neurosurgical operating environment encompasses and includes even radiosurgical planning and, thus, has a completely different meaning from the conventional operating rooms, associated with the field of surgery in general. The MRI provides increasing information and we are presently at a point where we have 3T MRI's showing us clear images of the various intracranial structures, including the white matter tracts and combined with spectroscopy. With various isotopes, functional areas can also be well-defined and mapped out. Ultrafast 64-slice scanners with 300 changes per hour have the ability to reconstruct images in three-dimensions. The three-dimension flat panel angiography suite has added to the armamentarium of the surgeon, wherein all the data can be combined and interposed, so as to give the surgeon the maximum information to optimise outcome and results. We are heading to a future where we require increased accuracy, more electrophysiologic data, less invasive techniques, better imaging data and, with nanotechnology, all this may be possible in the near future.

Improved anatomic comprehension, microscopy and microneurosurgical techniques, imaging, computers and ionising radiation, along with biomedical technology and biomolecular science, have entirely reinvented neurosurgery.[2,3]

GENERAL PRINCIPLES OF PRE-OPERATIVE CARE AND OPERATING THEATRE USE-WHO GUIDELINES[12]

Infection Prevention in the Operation Theatre

Prudent use of an aseptic technique should be made to prevent infection. These are:

- Prevent open wound contamination
- Isolate the operative site from the surrounding unsterile environment
- Create and maintain a sterile field in which surgery can be performed safely.

Aseptic technique usually refers to:

- Proper patient preparation for clinical procedures
- Hand washing
- Surgical hand scrub
- Using barriers such as gloves and surgical attire
- Maintaining a sterile field
- Using a good surgical technique
- Maintaining a safe environment in the surgical procedure area.

Pre-Operative Care and Patient Preparation

Pre-Operative Processes

Assessment for infection:

- Whenever possible, identify and treat all possible infections remote to the surgical site prior to elective surgery and postpone surgery, until the remote infection has resolved.
- Adequately control blood sugar prior to surgery and avoid hyperglycaemia.
- Tobacco cessation should be encouraged, with the patient made to abstain for 30 days prior to an elective surgery.

Pre-Operative Showering

Patient to have a shower the night prior to surgery, which is shown to decrease the concentration of skin flora, but not the incidence of surgical site infections.

Pre-Operative Hair Removal

- Shaving is not recommended
- Use hair clippers and remove hair at the incision site, only if it comes in the way.

Patient Skin Preparation in the Operating Theatre

- Wash and clean around the site of the incision to remove gross contamination (Pre-scrub)
- Use an appropriate antiseptic for skin preparation
- Prepare from the operation site outwards, not coming into the area of incision and being adequately extensive, so that a drain can be placed or incision extended.

Antiseptics for Preparation of the Skin and Hands

These are commonly used for surgical hand antisepsis and skin preparation before a surgical procedure. They should never be used to disinfect inanimate objects or surfaces, such as floors or counter tops. Instruments should never be cleaned with them as micro-organisms can gradually live and multiply and cause infection.

The common antiseptics (Table 1) used in the operation theatre (OT) with their advantages and disadvantages are:

1. Alcohol (60–90% *ethyl or isopropyl*): Effective against a broad range of organisms, e.g. bacteria and mycobacteria.

Advantages

- Rapid acting
- Non-staining
- Less expensive
- Effective in reducing vegetative organisms
- Effectiveness only moderately reduced in the presence of blood or other organic material.

Table 1: Antiseptics appropriate for use in clinical procedures

Antiseptic	Uses		
	Surgical Hand Antiseptic	*Preprocedure Skin Preparation*	*Mucous Membranes, e.g. Vagina and Cervix*
Alcohol	Yes	Yes	No
Chlorhexidine gluconate with or without cetrimide	Yes	Yes	Yes, however, products contianing chlorhexidine may not be the best antiseptics to use in antiseptics to use in the genital area because of the small potential for irritation. If an iodophor is not available, product containing chlorhexidine is the best alternative
Hexachlorophene	No	No	No
Iodine, including tincture of iodine (iodine and alcohol)	No	Yes	No
Iodophors	Yes	Yes	Yes

Disadvantages

- Has a drying effect on the skin
- Cannot be used on mucous membranes
- Evaporates rapidly and makes contact time difficult to achieve
- No prolonged activity, but the reduction is so significant that it takes sometime for re-growth.

Comments

- Cannot be used over a dirty area of skin
- The surface must be dried
- 60–90% concentration is the most effective
- Very effective hand antiseptic.

2. *Chlorhexidine gluconate (4%)*: Effective against a broad range of micro-organisms but less so against gram negative bacteria and fungi and minimal against mycobacteria.

Advantage

Has a longer duration of action of 6 hours and is effective even in the presence of blood or other organic material.

Disadvantage

Effectiveness reduced in the presence of hard water, hand creams and soaps. Stains fabric brown in the presence of chlorine based disinfectants.

Comments

- Recommended for surgical hand antisepsis and skin preparation
- Should not be allowed to come in contact with the meninges, brain, eye or middle ear.

3. *Iodine compounds including tincture iodine (iodine and alcohol)*: Effective against a broad range of micro-organisms.
4. *Iodophors (solutions such as povidone iodine, e.g. betadine®)*: Iodine in a complex form making it non-toxic and non-irritating. Effective against a broad range of microbes except mycobacteria.

Advantage

Less irritating than tincture iodine and can be used on the mucous membranes.

Disadvantages

- Effectiveness reduced in the presence of blood or other organic material
- Release of the active iodine takes about 2 minutes and hence needs to be left there for a few minutes prior to the procedure
- Less persistent activity when compared with Chlorhexidine.

Comments

- Recommended for hand antisepsis and skin preparation
- Best for use in the genital area, vagina and cervix
- Need to wait several minutes for it to act optimally
- Should not be diluted.

Principles to Maximise Antibiotic Benefit Pre-Operatively

- An antibiotic to prevent infection does not substitute for good infection control practices and surgical technique.
- Antibiotics should be used in situations where an infection would be catastrophic.
- Should be safe, inexpensive and provide adequate cover against the most probable intra-operative contaminants.
- Administer the initial dose at the time of surgery.
- Maintain therapeutic serum and tissue concentrations till a few hours after surgery.
- Do not prolong antibiotic use, as there is no evidence that this practice offers an advantage. It may promote the growth of resistant bugs.

Pre-Operative Skin Preparation of Operation Theatre Personnel

Surgical hand-washing (Fig. 3) performed prior to surgery is essential and varies from 7 to 9 minutes with older hand scrubs and between 3 and 5 minutes with newer agents (Fig. 4). This prevents the growth of microbes within the warm, moist environment of the gloves. Use of an alcohol hand scrub prior to wearing gloves lowers the quantity of the skin flora so significantly, that they take several hours to grow.

Indications

- Should be done before any invasive procedure from urinary catheterisation, introducing central lines and minor/major surgeries
- All personnel should perform antisepsis.

Tips for Scrubbing

In case of allergies, a hand scrub with plain soap and water can be performed and the hands thoroughly dried. About 5–10 ml of an alcohol scrub can then be applied and the hands allowed to dry before wearing gloves.

Warm water makes antiseptics work better, but hot water damages the skin and removes protective oils.

- Keep finger nails short
- Keep the hands above the elbows before and after scrubbing
- Avoid using a hard brush during scrubbing.

Protective Clothing for Use in the Operation Theatre

These include:

- *Masks*: To be worn covering the mouth and nose
  They should not be re-used
  If moist or stained, replace with a new one
  High efficiency masks for patients with tuberculosis

Fig. 3: Area for hand scrub

- Waterproof aprons and gowns to protect personnel from contamination with blood and fluids
- Sterile drapes (Fig. 5) to create a barrier between the sterile and unsterile areas
- Scrub suits: The OT uniform over which a sterile gown and gloves are used
- Surgical caps/hood: Usually disposable
- Eye protection and face shields: For protection of staff from HIV/HBC/HCV positive patients
- Footwear: Preferably waterproof boots or shoes covering the feet
- Surgical gloves.

Steps for wearing and taking off gloves have to be followed and are available in any introductory surgical text.

Environment and Infrastructure of a Modern Neurosurgical Operating Theatre

The operating rooms have to be designed in such a way, as to minimise any risk of infection, and provide adequate space for equipment and mobility of personnel.

The highest frequency of nosocomial infections has been reported from hospitals of the Eastern Mediterranean and South-East Asian region (11.8% and 10%), respectively[11] The most frequent nosocomial infections are those of surgically infected wounds, urinary tract infections and lower respiratory tract infections. It is estimated that 20% of these infections are contracted in the OT, with irreversible damage to the patient. The economic costs of these infections are tremendous and a WHO study has shown that the overall duration of stay in the hospital for surgical wound infections was 8.2 days and, when these occur deep at the site of the procedure, carries a mortality of 77%.

Every year, in France, about 60,000–100,000 hospitalised patients contract nosocomial infections and corresponds to 6–10% of all admissions.[16] Five to ten thousand people die of hospital acquired infections. In public health terms, these figures are as alarming as those for road traffic accidents (7,800 deaths in 2002). What about India? We have no data, but we should learn from the experience of others.

Factors influencing the development of nosocomial infections are:

- The microbial agent
- Patient susceptibility
- Environmental factors
- Bacterial resistance

The operating theatre for neurosurgery is defined as a level 4 theatre, which is a high-risk zone when one considers the risk factors associated with the procedure, duration and complexity and those with the patient (age, immune status and effectiveness of antibiotic therapy). These operating rooms have to be designed to fulfil the following criteria[11] (Fig. 4):

- Minimum filtration chain
- International standards for particulate classification

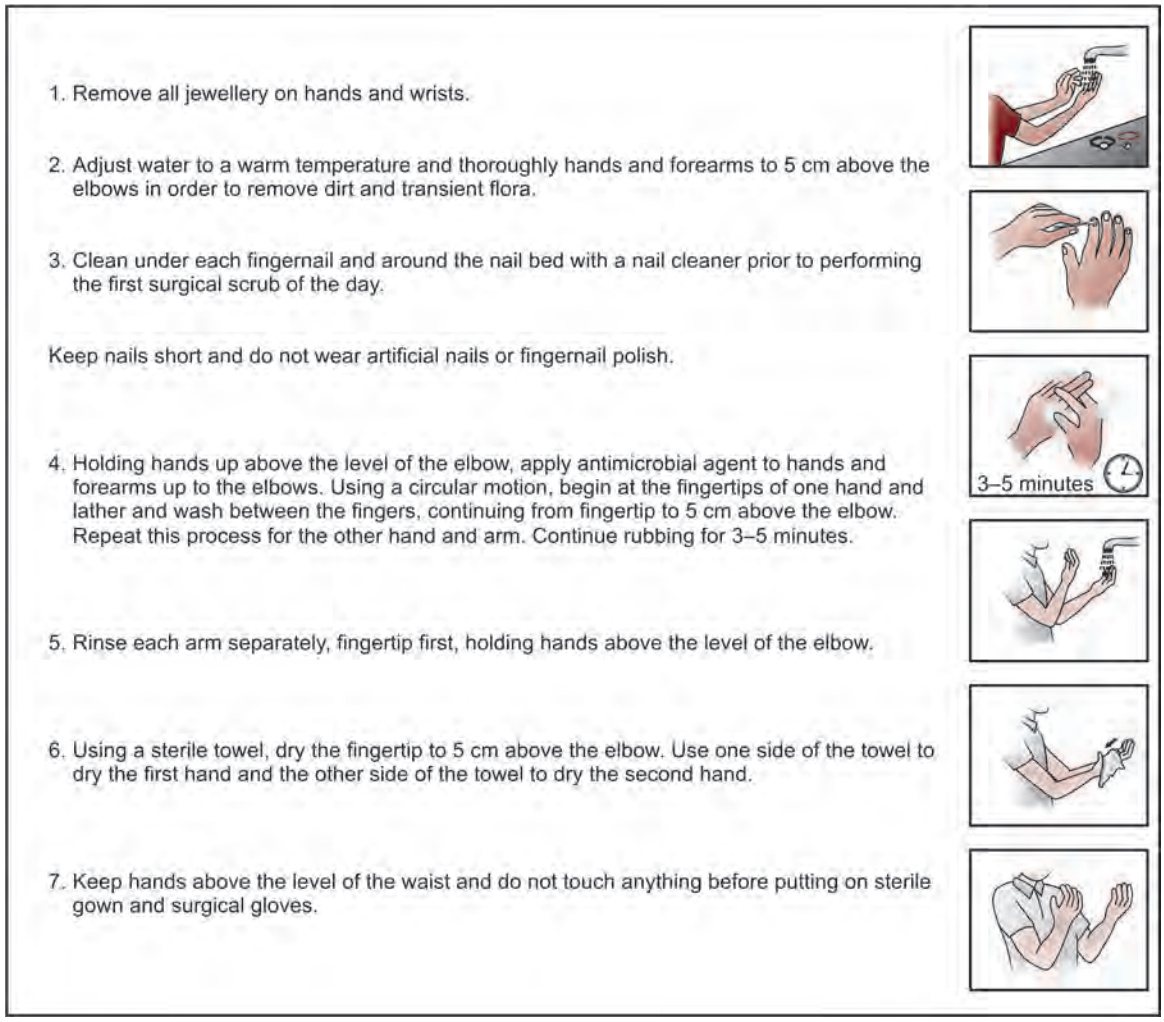

Fig. 4: Steps for a surgical hand-wash

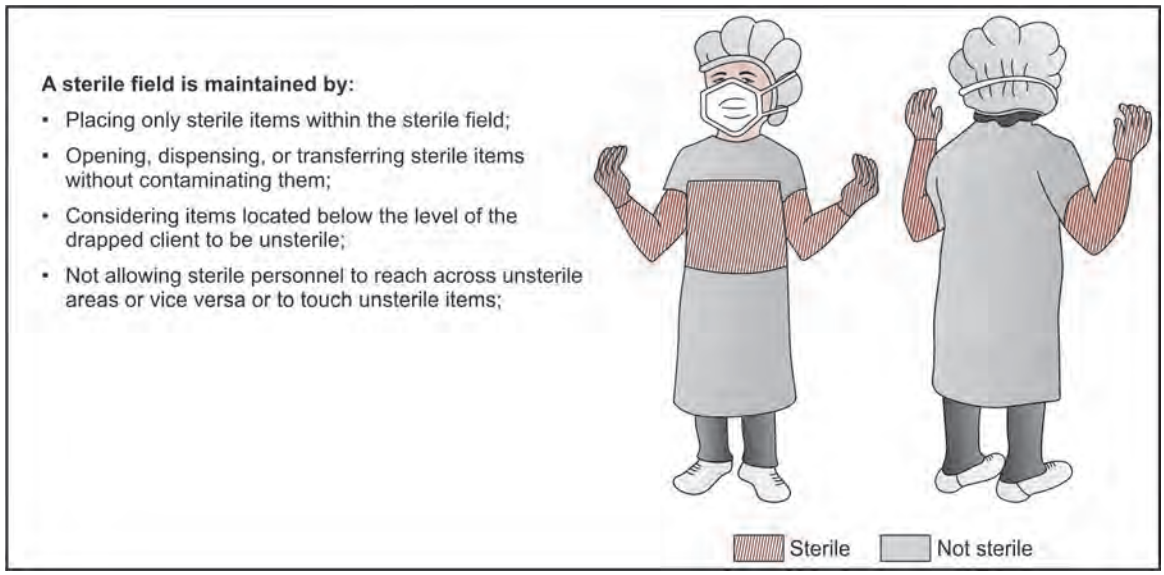

Fig. 5: Establishing and maintaining a sterile field

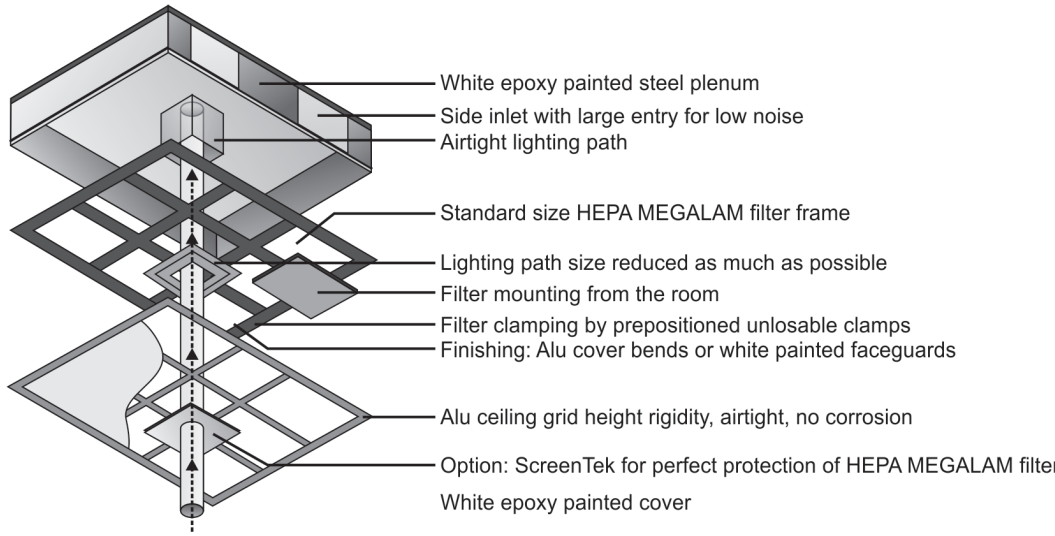

Fig. 6: Ideal ventilation system

- Particulate decontamination kinetic classification
- Use of easily decontaminable material
- Unidirectional flow
- Air exchange of the room more than 50 vol/hr
- Target bacteriological classification.

Ideal ventilation system (Fig. 6) allows frequent and efficient cleaning and disinfection.[11] Figure 7 shows the transmission cycle of infections in the OT.

Layout of the Operation Theatre

Zoned Operation Theatre

The OT should be zoned and access to this should be controlled by trained personnel. Aseptic and clean areas should be separated from the outer areas. Physical barriers may be required in order to restrict access and to maintain unidirectional movement of air in converted theatre units.

The outer zone should contain:

- A main access door
- An accessible area for waste removal
- A sluice
- Storage for medical and surgical supplies
- An entrance to the changing facilities.

The clean or semi-restricted zone:

- The sterile supplies store
- An anaesthetic room
- A recovery area
- A scrub area
- A clean corridor
- Rest rooms for the staff.

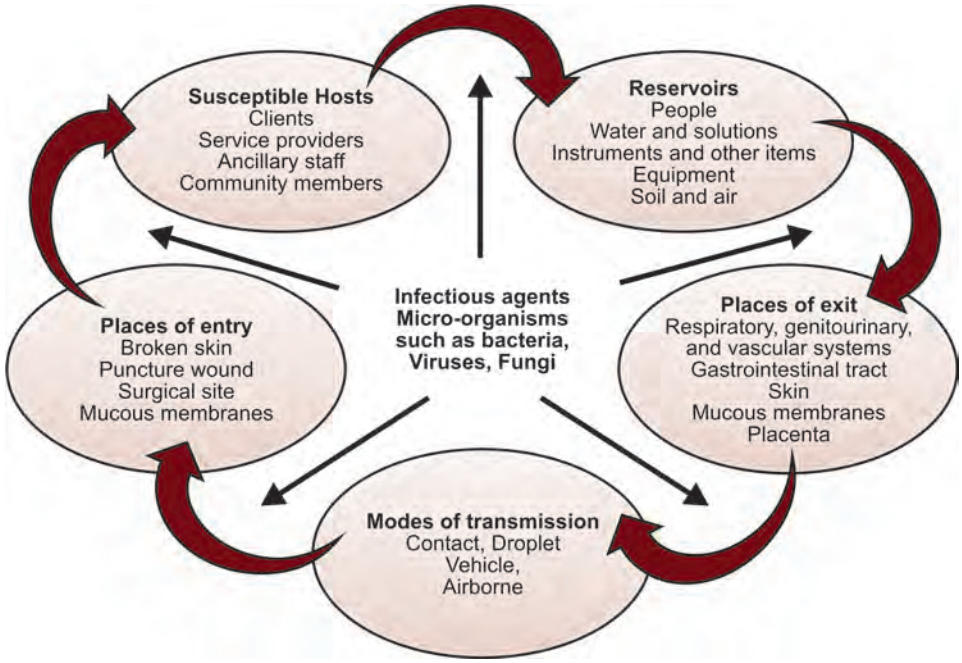

Fig. 7: Transmission cycle of infections in the OT

The staff must change into theatre clothes and shoes before entering this area, but it is not necessary to wear a mask, gloves or gown. Access from this area to the aseptic area (operating room) should be unidirectional, preferably via the scrub area. The clean zone requires exiting through the outer zone.

Aseptic or restricted area (working team only):

- The operating theatre
- The sterile preparation room.

Temperature and Humidity

Temperature and humidity play a very important role in ensuring staff and patient comfort. They must be carefully monitored and regulated. Low humidity increases the risk for electrostatic sparks.

Ideally, the OR should be 1°C cooler than the outer area, which aids in outward air movement as warmer air rises and the cooler air from within the OR moves to replace it.

Ideal Ventilation System: Air Supply and Exhaust

Positive pressure ventilation should be maintained in the corridors and areas to the operating theatre where surgical procedures are to be performed. The number of theatres supplied by air handling units (AHUs) should be consistent with their supply. The AHUs requires routine maintenance and these should not be shut off, unless undergoing servicing.

Design Features

The parameters depending on the available resources should be:

- Air changes: 15–20 air changes/hour, of which at least 3 should be fresh air from outside.
- Filtration: Prefilters with efficiency of 30%, followed by a final filter of 90%. Filters need to be changed at regular intervals.
- Air supply: Entry should be via the ceiling and exit via the floor (avoid placing furniture near the exhaust at floor level, otherwise this will impede flow).
- Doors: Should be closed except during passage of personnel and equipment.
- Traffic: Limit people going in and out of the OR as the microbial load is proportional to the number of people moving about in the theatre.
- Laminar flow and ultraclean air: This is designed to move particulate flow over the operating field in one direction. This can be designed for horizontal or vertical movement with high-efficiency particulate filters (HEPA). HEPA filters remove particles greater than 0.3 microns with 99.97% efficiency. Ultraclean air reduces the risk of surgical site infections. Appropriate use of antibiotics and good OT practices also reduce this risk and should be judiciously used in case resources for the above are not available.

There are various types of air supply:

- Plenum ventilation: Frequently used in general purpose OT's with bacterial counts at the wound site being no more than 50 to 500 CFU.
- Laminar flow ventilation (Ultraflow ventilation): Unidirectional air flow that delivers 300 changes per hour over the operating field. A bacterial count of 10 CFU or less is achieved.
- Wall mounted airconditioners: Used in some tropical countries more for comfort than anything else. The operating table receives no significant air changes and bacterial counts are unaffected.
- Freestanding air conditioners: These do not filter air and do not meet any criteria for being used in the OT.

Waste and Linen

- Minimal handling of soiled linen to avoid transmission of infections
- Body fluids to be disposed of via sluice and staff should use appropriate protective clothing and gloves
- Used linen to be contained in amperes or laundry bags and those soiled with body fluids in waterproof bags
- Other contaminated waste according to hospital and city guidelines, usually colour coded, depending on type of waste.

Environmental Cleaning and Maintenance of the OT

Simple, clear policy and guidelines, which may be set up by the institute.

Microbial Sampling

Depends on the Institute criteria for outbreak of infections and the policy is set in consultation with the Infection Control Committee (ICC). There should be an institutional Infection Control Committee (ICC). In every suite of OTs, a senior nurse should be designated to help the ICC. There should be regular monitoring of the data collected by ICC and a formal warning system established to initiate corrective measures, in the event of any unacceptable degree of contamination observed.

Theatre Sterile Services Unit

- Should have autoclaves and areas for washing and cleaning of instruments
- If available, the only services required would be to rapidly sterilise dropped equipment (134°C for 3–4 min) and for the decontamination of fibre-optics.

Neurosurgical Operating Room

We have covered the basics of operating room design, maintenance of sterility and basic sterile procedures in the operating theatre. From here on, we describe the equipment (Fig. 8) and layout of a neurosurgical operating room, which includes an introduction to the basic equipment used, followed by an introduction to the state of the art operating room (Courtesy, Max Institute of Neurosciences, Saket).

Fig. 8: The Zeiss OPMI PENTERO

Present day OT's are an integration between the neurosurgeon and his requirements, engineers and the technology to bring about best outcomes and business executives without whom this industry would not run (Fig. 9).

Theodore Kurze (1922 to 2002) of the University of South California first used the operating neurosurgical microscope in 1957. The efforts of William House in using the microscope in otological surgery inspired Kurze[13] to use it in neurosurgery. Robert Rand and Charles Drake were introduced to this by Kurze and after an initial resistance it became an invaluable tool in the neurosurgical operating room.[14,15] Peter Jannetta and Robert Rand published their series of posterior circulation aneurysms operated using the microscope and M Gazi Yasargil firmly established the micro-neurosurgical revolution.[13,27,28]

The patient has to be secure at all times, with his head suitably fixed to avoid movement. There should be no damage to the soft tissues and, at the same time, access and surgeon comfort are necessary. The basic 3-pin head holding frame is the Mayfield Kees frame and another 4-pin head holding frame is the Sugita frame.

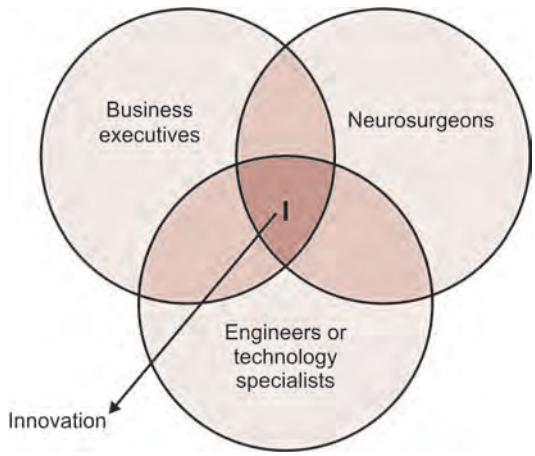

Diagram indicating that innovation is optimized when neurosurgeons, business executives, and engineers or other technology specialists are brought together to work in synergistic ways. It is often the function of venture capitalists to help integrate these individuals at the time of formation of a new venture, in addition to providing capital.

Neurosurgery 47, 169-177, 2000

Fig. 9: Integration required for innovation in the OTs

Mayfield Frame

It is a three pin fixation device, where the head is interposed between the three pins. It should be tightened by about three threads onto an adult skull as each thread is about 20 lb/in^2. The pins should preferably be over areas not covered with muscle. There are different sized pins for adult and paediatric patients.[25]

Sugita Frame

It is a 4–5 pin head holding frame, which we feel is more versatile, less cumbersome, easy to use and provides more stability. It is so designed to enable the neurosurgeon to single handedly perform any microsurgical procedure. It has an attachment for supporting the hands, as well as brain retractors of varying lengths which can be fixed onto the frame. The advantage of all the accessories centred on the frame is that with position changes of the table/head the retractors/accessories do not have to be removed, as the system moves as a unit.

The operating table should be flexible, so as to accommodate varying positions from the supine to prone, the sitting and the lateral along with a place for spine surgeries and the use of fluoroscopy.

An excellent account of positioning, microsurgical instrument (Figs 10 to 14) use and approaches is detailed in the classical 4 volume text of Professor MG Yasargil.[18,25,26] A detailed account of use of instruments and/avoidance of complications is described in Apuzzo's book on avoidance and management of complications.[4]

Brain Suite: (Integrated Operating Room with the Intra-Operative MRI)

The concept of the integrated operating room was first thought of in 1991, as a collaborative effort between GE systems and the Department of radiology and neurosurgery at Harvard. Intra-operative MR imaging is also known as 'MRT' or magnetic resonance therapy. The prototype system was installed in 1994 and was designed to perform real time imaging, while neurosurgical procedures were going on. It was first used in 1995, with the double-doughnut[6] scanner, only for intra-operative use. Just as the microscope changed the scale of dimensions of the operating field, the intra-operative MRI in the operating room has expanded the surgeons view from two-dimensions to three-dimensions. It has given the surgeon an opportunity to look beyond the exposed surface and enable clear visualisation, not only of the operational field but also operational volume.

The Erlangen concept was developed by Robert Fahlbusch with the assistance of Siemens and Carl-Zeiss.[22,24] The operating rooms and the radiofrequency shielded MRI room were different, as MR compatible

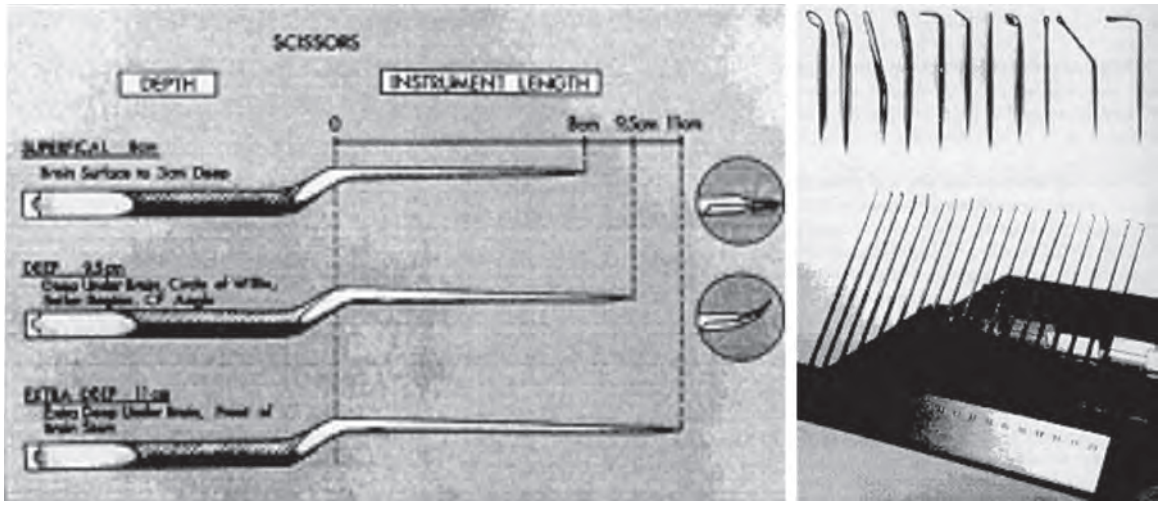

Fig. 10: Basic microsurgical instruments

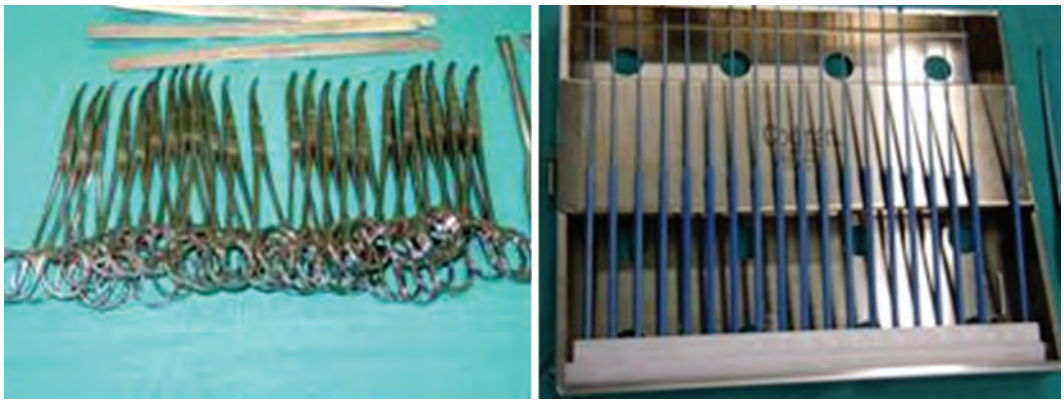

Fig. 11: Microsurgical instruments

Fig. 12: Microsurgical instruments

Fig. 13: Cavitron ultrasonic surgical asp irator (CUSA)

Fig. 14: Siemens Orbis C-arm

instruments were required for performing all aspects of microneurosurgery. The images from the MRI were transferred to navigation computers and surgery performed. The initial field strengths were 0.5 T and at present 1.5 T magnets are used intra-operatively.

The development of active shielding of superconducting magnets enabled the integration of surgery in the fringe fields with high field MRI.[20] A high field MRI may not only improve the quality of the intra-operative images, but also adds the facility of functional MRI's, diffusion weighted imaging and MR spectroscopy. Operating theatres have to be large enough to accommodate the equipment, which includes all the accessories for navigation, as well as microsurgical work. The use of ferromagnetic materials is to be avoided and non-ferromagnetic materials like aluminium, titanium and cera mics can be used. All equipment has to be compatible with MRI. Anaesthesia and monitoring equipment have also been redesigned for the operative environment.

Equipment and Theatre Set-Up

At the Max Institute of Neurosciences, Delhi, a Siemens 1.5 T MRI scanner is placed in an RF shielded room. The

Fig. 15: Anaesthesia equipment in the OT

scanner consists of a superconductive active shielded magnet with a length of 160 cm and an inner bore diameter of 60 cm, equipped with a gradient system with a field strength of up to 40 mT/m. A specially designed rotating surgical MRI table has been adapted to the scanner for intra-operative patient transportation and for imaging. The principal surgical position was at 160° with the patient's head at the 5-Gauss line. Once the rotating mechanism is locked, the height of the table, the angle of tilt, and the lateral tilt can be adjusted by remote control. The rotation of the table axis and turning the table into the axis of the scanner has to be done manually. The ventilator is MRI compatible and MRI-compatible monitoring equipment is used for maintenance of anaesthesia. The monitoring data is transferred to a remote display, which allows continuous monitoring during scanning from outside of the RF-shielded operating room, with a wireless 2.4-GHz connection. Three infusion pumps are shielded in an MRI-compatible carrier for continuous infusion of drugs. This anaesthesia equipment is located outside the 200-Gauss line.[21] Anaesthesia gas inlets and compressed air for surgical drills are integrated in the wall of the RF room (Fig. 15). Service outlets and sockets are connected to different electrical circuits, so that selected lines could be switched off from a switchboard in the MRI control room, to prevent artefacts generated by individual devices. The ceiling outlet for laminar airflow is located above the main operating area. The laminar airflow output is surrounded by a band of fluorescent lamps for optimal illumination. For scanning, the illumination could be turned off from the MRI control room. The entire operating theatre has MRI-compatible spot lighting. Two ceiling-mounted surgical lamps are installed at the main surgical position. Both the 5-Gauss and 200-Gauss lines are marked on the floor. The latter is also marked by a raised stainless steel strip as

a mechanical threshold. All equipment not completely MRI compatible, such as the navigation microscope and the height-adjustable surgeon's chair, are secured to the wall of the RF room mechanically as a safety precaution.

A modern neurosurgical OT has the space to accommodate all the equipment and personnel in a manner that allow ease, access and comfort to the operating surgeon. The instruments should be arranged in an orderly fashion so that it is easy to hand them over to the surgeon in a sequential order, as well as to sterilise them once the surgery is over. The initial requirements are that of a craniotome, with its variety of drill bits, perforators and accessories. These presently could be either pneumatic or can be an electrical craniotome, with the subsequent ones being the macro-instruments, like the dural dissectors, Penfield's instruments, knives, dural hooks, heavy and fine tooth and non-tooth forceps. The micro-instruments are required, depending on the nature of the case and these are shaped in a standard fashion, to provide ease and comfort in accessing almost any intracerebral location. The nurse should be trained and aware of the procedure. Each instrument is designed in a particular way, which is used to provide maximum comfort, steadiness, grip, flexibility and mobility.

A modern neurosurgical OT has all the above and can accommodate tools for neuronavigation such as the intra-operative MRI and the Figures 16 to 18 give us an idea of the arrangement and access with an intra-operative MRI in place.

The arrangement of the entire team is important, so that the surgeon and neuroanaesthetists do not disturb each other, and have adequate room for their monitoring and procedures. The nurses and their instrument trolley should be arranged such that there is easy access.

A trend towards bringing in neurodiagnostic imaging modalities into practice is setting in. The 1970s brought in imaging and opened up new vistas, the 1980s brought in navigation with stereotactic frames and the 1990s brought the scanner and navigation into the OT with further progress being made in the present decade.

The Future

Robotics (Fig. 19) and the introduction of more sophisticated devices seem to be incorporated in the OT of the future. The ability to incorporate sensors into operative devices for structural and physiological monitoring, design of visualisation systems for operative needs and high level simulation (rehearsal) systems using holographic and virtual reality based composites are coming.[5]

Trends toward minimalism are evident in the development of robotics such as microelectromechanical systems (MEMS), with products that have diminutive physical dimensions.[19]

Refinements in robotic devices naturally lead to the intriguing prospects of bionic integration. Bionics refers to instruments that are part biological and part machine.[7,17] Bionic devices continue to be an integral part of medical practice. Ventricular assist devices, artificial blood substitutes, and orthopaedic prostheses are all familiar examples. Subretinal implantable chips can

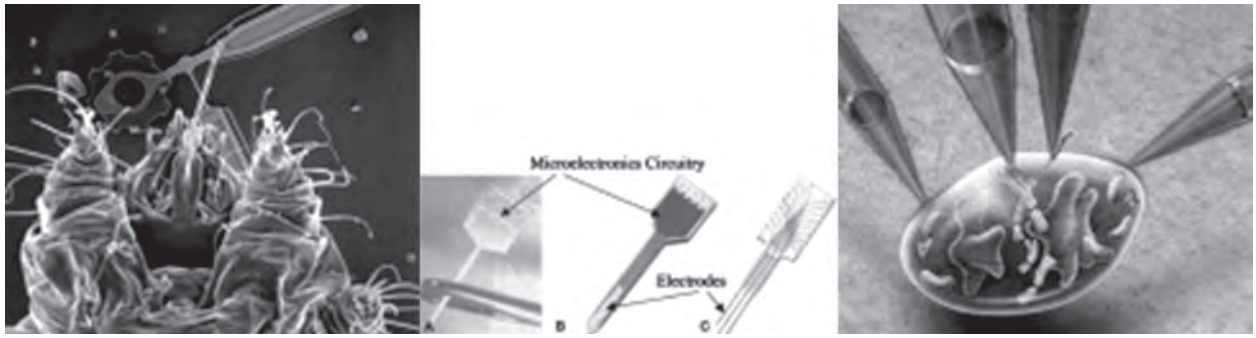

Fig. 19: Microfabrication, micromechanical technology and robotics bring surgery to the cellular level

simulate the function of the photoreceptors.[10] Cochlear implants are also being used with increasing regularity.

The ultimate operating theatre of the future will be functionally complicated with regard to the technology, but simple in use when it comes to the operating surgeon.

208 Basic Neurosurgical Instruments

Sanjay Behari, Singh RK, Lyngdoh B, Jain S, Chhabra DK

INTRODUCTION

Achieving the desired goals, reducing surgical trauma and increasing intra-operative visualisation are the key features behind every surgical technique. Microneurosurgery reduces the amount of brain retraction required and helps in precisely delineating the neurovascular structures. The use of the operating microscope has substantially improved the illumination and magnification and, consequently, the resolution of the operative field. A variety of microsurgical instruments, retractor systems, operating tables, chairs and nursing stations have been devised to improve the rate of success and reduce the risk to the patient. An adequate knowledge of these instruments and adjuncts as well as their critical properties and performance limitations must be known in order to make the best selection for each procedure.[19,27–29,32,35,41,46] The instrumentation has evolved from the stainless steel-based systems to the titanium based ones, since the latter are lighter and non-ferromagnetic, and therefore, magnetic resonance imaging (MRI) compatible. However, the titanium-based products are more expensive and more susceptible to deformation.

Several ergonomical principals guide the manufacturing of the instruments.[27–29] The instruments should be capable of being held so that the ulnar aspects of the forearm, wrist and hand may be supported. This permits accuracy of handling and prevents hand tremors. The instruments should be held in a pen-holding grip, since this is the most comfortable grip during prolonged surgeries. Straight instruments are the most precise and offer the maximum degree of freedom, but when used for working at the depth, the holding arm obscures the visualisation of their tip. Bayonet-shaped instruments of different lengths are used when operating at a depth. With round-handled instruments the tip of the instruments can be rotated easily.

HEAD FIXATION SYSTEM

Since microneurosurgery involves working with small incisions and narrow-surgical corridors, rigid head fixation is essential in order to maintain the desired head position. Even slight movement of the head during surgery may appear exaggerated when viewed under the operating microscope. Head fixation is commonly achieved using a pin-head-holder. The Mayfield's head-holder (Fig. 1) is a three-pin fixation device and the Sugita head-holder is a four-pin fixation device (Fig. 2).[38,39] These head-holders have a clamp through which sterilised pins are fixed on the skull and the whole assembly is fixed rigidly on to the operating table. Care must be taken to see that the pins are not placed at the thin temporal bones, the venous sinuses, the temporalis muscle (where a rigid fixation is not possible), the skin overlying the tubing and chamber of ventriculoperitoneal shunt systems, and the bones overlying the frontal and the mastoid air sinuses. In children, special paediatric pins are utilised. The advantages of the pin-head-holders are:

Fig. 1: Mayfield head-holder

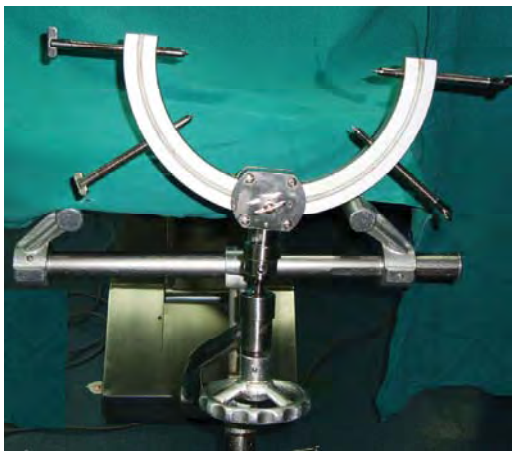

Fig. 2: Sugita head-holder

- Multiple self-retaining retractor systems with flexible arms on them can be fixed
- Arm-rests can be fixed to avoid arm-fatigue and tremors during prolonged operations
- The patient can be positioned in a variety of ways including the park-bench and the sitting positions
- Skin sores that may develop when the face rests on a padded head support for a long period can be prevented
- Electromyography of the facial muscles and somatosensory and auditory evoked potentials can be done since the electrodes may be fitted on the exposed face[28]
- Intra-operative fluoroscopy and angiography is possible with the use of head-holders made of radiolucent materials[16]
- Intra-operative MRI can be performed with the use of non-metallic graphite head-holders[13]
- When the head is rigidly fixed, registration errors while using intra-operative neuronavigation are minimised.[28]

The precautions that must be taken during fixation of the head-holder are:

- Taking care that the pins do not penetrate the inner table of the skull since they may cause cerebrospinal fluid leak, meningitis, osteomyelitis, an intracerebral abscess or, an extradural, subdural or intracerebral haematoma.
- The patient's head should not be in close contact with the head-holder as this may lead to pressure necrosis of the scalp during prolonged surgery.

OPERATING TABLE

Operating tables (Fig. 3) are electrically operated and the patient's position (during initial positioning for surgery and also during the microsurgical procedure) can be altered with ease. Thus, with a subtle change in the table position during surgery, the surgeon gets a different line of sight to the surgical field without changing the microscope's position. It is possible to move the table up and down; head down (Trendelenberg) and up (reverse Trendelenberg); and whole body rotation to the right or left.[35] There are rods on the side of the operating table that provide attachments for body support so that the patient does not move on the table if the position of the table in moved; they also provide attachment for brain retractor support rods and the neuroendoscope holder. The tables are often made of radiolucent material and intra-operative radiographs can be taken. There is a central locking system that prevents the table from inadvertently moving from its position during surgery. The height of the table is usually adjusted to the level of the surgeon's elbow to avoid excessive bending of the surgeon's body and neck.[35,38]

Fig. 3: Operating table

MICROSURGICAL OPERATING CHAIRS

The surgeon generally operates in a sitting position to reduce fatigue during prolonged surgery. The height as well as the position of the operator's position in relation to the operating table can be adjusted in the conventional chairs (Fig. 4). Sugita has devised an operating chair with side arms to support the elbows in order to avoid fatigue and tremors (Fig. 5).[38] It has an up and down movement that can be controlled by a pedal. All joints, other than that for vertical motion, are loosened when another pedal is held down so that the chair can be moved according to the surgeon's desire. The footplates in the chair can control the bipolar cautery, the movements of the operating table and the microscope, the focus of the microscope and the vertical height of the chair. The Sugita operating table, with the chair, is coupled with a remote-controlled microshifter for the horizontal plane. With the aid of this system, an object under the microscope can be kept in the centre of the microscopic field by pedal control.[38] Ohta et al.[24] have devised a freely mobile arm-rest for the microneurosurgical chair that is equipped with a ball-joint which is fixed by mechanical friction and becomes free as it is filled with compressed air after which the frictional force diminishes. As the button below the arm-rest is pressed the mechanical arm can be moved freely to the desired position. The mechanical arm is locked in position as soon as the button is released. These arm-rests can thus be moved freely and can also be fixed in the desired position.

The surgeon should sit comfortably on the electrically-operated surgical chair that has arm-rests. The foot rest is at the same height relative to the seat regardless of the height of the chair.[9] The elbows of the surgeon rest in a comfortable position.[35] Some of the surgical chairs are connected to the operating microscope and the operating table controls and the surgeon can control both the position of the table and the microscope and the magnification of the microscope by manipulating the controls that are situated in the chair close to his feet. This enables the surgeon to continue the surgical procedure without the need of asking for help in manipulating the table and without the need for taking his eyes off the operating field. At the same time, he can keep his arms engaged in the operating procedure.

Fig. 4: Conventional operating chair

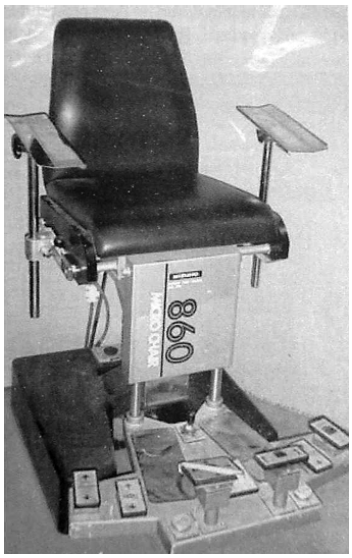

Fig. 5: Sugita operating chair

INSTRUMENT TABLE

For microsurgical procedures, an instruments table has also been devised that has various divisions, where the instruments being utilised for different sections of the operative procedures are kept in separate compartments (Fig. 6).[38] This table over-rides the operating table and is, therefore, more convenient than the one placed on the side of the table. The height of the nurse's platform is electrically changeable depending upon the patient's head position. A moving chair on the platform lessens the fatigue of the scrub nurse.

RETRACTOR SYSTEMS

Self-Retaining Brain Retractor System

A semicircular basal frame is fixed perpendicular to the head holder (Fig. 7). Screws are placed on the frame for holding conventional flexible self-retaining retractors (Leyla-Yasargil). Tapered brain retractors of three sizes (the tips being 2 mm, 4 mm and 6 mm in width) are fixed on the flexible Leyla retractors. Two holes at each end of the frame may be used to fix the hand rests and instrument holders. The angle and height of the hand rests may be adjusted to suit the surgeon. A box may be attached to each end of the basal frame to hold bipolar coagulation forceps, a suction tube or other instruments.[38,39] A smaller semicircular frame fixed on the basal frame is used for retracting the scalp flap; it also supports the plate on which surgical patties may be placed. It may occasionally also hold the self-retaining retractor.[15]

The patient's head is fixed in the desired operating position on the head holder by three or four skull pins. The patient's head may be easily rotated at any time during the operation.

Specific purpose retractor systems may be used for performing specific surgical procedures, for instance, Boyle-Davis mouth gag (Fig. 8) that opens the mouth and simultaneously keeps the tongue retracted may be used for transoral surgery; the Hardy's nasal speculum and trans-sphenoidal retractor systems (Fig. 9) that retract the nasal mucosa during trans-sphenoidal surgery; and the Cloward's self-retaining retractor system (Fig. 10) that retracts the carotid sheath and sternocleidomastoid muscle laterally and the trachea-oesophagus and strap muscles medially may be used for performing anterior cervical discectomy and corpectomy.

Fig. 6: Instrument table

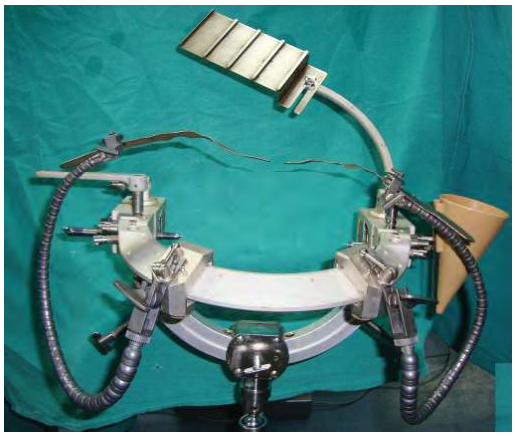

Fig. 7: Self retaining brain retractor system

Fig. 8: Boyle Davis mouth gag for transoral surgery

Fig. 9: Hardy's nasal speculum for trans-sphenoidal surgery

FIBRE OPTIC LIGHT SOURCE WITH HEADLIGHT

During the initial part of the exposure where microsurgical dissection is required, illumination may often be provided by a fibre optic headlight[2] (Fig. 11). It is lightweight and facilitates transmission of light with maximal efficiency. Several features contribute to comfort during long procedures. There are no projections, such as rivets, from the headband to obstruct the surgeon's field of view. The headband does not heat up and may be enlarged without removing the harness from the head. The focusing device is maintained in a universal movement friction lock ball joint which is adjustable in all axes. The light beam is directed from the bridge of the nose, thus avoiding shadow in deep operative fields. The fibre optic cable transmits light via fibre optic cables from a remote light source to the headlight. These cables may readily be removed from the harness.[2]

Suction

The suction tip is chosen keeping in mind both the length and the diameter (Fig. 12). For superficial procedures, a length of 8 cm is used; for most of the microsurgical procedures, a length of 10 cm is required; and for deep procedures a length of 13–15 cm is required. The diameter of the suction tube is 3 French (3 French is 1 mm outer diameter) for very small vessel and nerve anastomosis; 5–7 French for most of the neurosurgical procedures and 8 French diameter for heavy bleeding, extradural work and for rapid tumour resection.[30] A wide angle between the handle and the shaft allows the suction tube to be held in a pencil-holding grip so that the ulnar surface of the hand rests comfortably on the border of the wound and thus provides stability to the hand.[28,29,38]

The suction power may be increased by occluding, either completely or partially, the air hole at the base of the suction tube. For microdissection as well as for retraction of microstructures, the minimum power of the suction is used to prevent the entrapping of neurovascular structures. At least two suction apparatuses must be functioning during any microsurgical procedure. They should work at different power and should be colour coded to easily distinguish between the tubing. The simultaneous use of two suctions helps the surgeon in continuing his surgery even when cleaning of suction tips of one of them is taking place in case when its blockage occurs during surgery. The suction tube should be very flexible so that it is not heavy and will not hinder movement.

A malleable suction device is narrow plastic tubing with multiple perforations at one end.[37] The multiple holes allow gentle suction and prevent any tissue from

Fig. 10: Cloward self-retaining retractors

Fig. 11: Fibre optic light source with headlight

Fig. 12: Suction canula

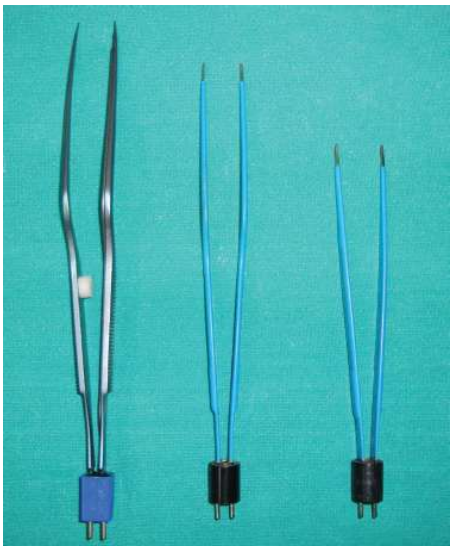

Fig. 13: Bipolar coagulation forceps

being aspirated into the suction tubing. Soft wire that is included into the tubing maintains the suction tip where it is needed. An alternative system that incorporates suction and irrigation allows constant moistening of the immediate area to prevent drying of tissues. The tubing can be fixed at the surgical field to permit microsurgical dissection in a cleaner operative field and without the need to put down an instrument in order to pick up the suction.

COAGULATION FORCEPS

Electric current passing through the tissues produces heat proportional to the distribution of the electrical power used. When heat is applied externally to blood vessels in order to achieve haemostasis, it usually produces a tissue coagulum that proceeds from outside inwards in the vessel; and, also promotes intravascular clotting within the vessel proximal to the point of application of heat. The coagulum may, however, slough off and restart bleeding; and, the heat spread from outside to within may also spread to the surrounding tissues. Thus, there was a need for an instrument that permitted coagulum formation within the vessel; and, the heat generated at the contact point would remain confined to the narrow limits close to the contact points and not spread to the surrounding tissues[18] (Fig. 13). A direct current, as is generated by a battery, introduces heat production in a straight path between the electrodes. This facilitates coagulation from inside-outside as is desired for achieving haemostasis of vessels. The coagulation, however, is poor; the direct current stimulates muscle and nerve tissue that provokes movement; and, electrolysis with marked bubble formation occurs at the negative electrode. Alternating current, as seen in the city light distribution system, further accentuates these effects when low frequency currents are used. However, when the frequency of current is greater than 100 KHz, it provokes little stimulation of muscles and nerves. A high voltage alternating current in the range of 0.5–3 MHz sustains a continuous fine arc between the active electrode and the tissues. The rapid heat produced facilitates cutting of the tissues and is also known as the "cutting current".[18]

Clark devised the first electrosurgical device with a spark generator in 1910 that was used in the operating room.[5] In 1928 Bovie developed an electrosurgical unit with a spark-gap generator that provided an output of damped irregular waveforms in a group of cycles that progressively decreased in amplitude. The multiple interruptions permitted coagulation with little cutting tendency. With a synchronous resonating circuit, it could also provide cutting ability. An electric current requires a return path. In the Bovie's monopolar machine, the current generated by the active electrode returns by the dispersive electrode also known as the ground plate. A higher current per cubic millimetre is achieved as the active electrode is very small compared to the dispersive electrode. The current flow from the active electrode to the ground plate passes through the intervening conductive tissue including blood vessels, muscles, bones, neural structures and body fluids. Heat may be generated at considerable distances from the point of coagulation. Thus, it cannot be used in delicate areas like the brainstem and the spinal cord. The machine output is also not isolated. Thus, the current may also spread to other grounding points of the patient such as metal parts of the table or the monitoring equipment. This system was used by Cushing for achieving haemostasis during his neurosurgical procedures.

Greenwood, in 1940, devised a machine that permitted the return path of the electric flow between the two-point coagulation system that formed the basis of the bipolar system.[14] In this system, the blades of the forceps were insulated from one another. One side of the forceps was attached to the active side of the current generator and the other to the ground generator. Thus, current could flow through the tissues between its blades. The ground plate of the Bovie's system was,

Fig. 14: Microscissors

therefore, not required. While in the monopolar system, the generated current from the active electrode flows to the ground, in the bipolar system, current only flows between the forceps tips. Thus, a bipolar forceps may also be used in delicate regions of the brain. Irrigation of the bipolar forceps cools the area, prevents heat from disseminating to the surrounding normal tissue while further decreasing any chance of the forceps adhering to the tissue. Malis, later on, developed a low power spark gap system that utilised winding coils and transformers to achieve optimum coagulation.[18] The modern microprocessor-controlled solid-state bipolar coagulating and cutting systems rigidly control the voltage generated at the forceps tip and prevents voltage variations with irrigation and with changes in the width of the forceps. They contribute significantly to the performance of major neurosurgical procedures, decreasing operative time and blood loss. According to Malis, the factors required for a superior bipolar generator are:

- Proper waveform
- Lowest possible generator impedance
- Isolated output so that heat does not spread
- Rigidly stabilised voltage output
- Control totally in the hands of the surgeon.[18]

Malis also introduced a self irrigating system for the bipolar forceps. In this system, sterile saline pulsed from a fine channel is added to the bipolar forceps, synchronous with the electrical output, but separately regulated in volume according to the surgeon's preference. This permits the irrigation to reach the desired area without the constant vigilance and skill of a well-trained assistant whose abilities could better be used for other duties.[18] The tip of the bipolar forceps should be clean and absolutely smooth for either coagulation or cutting. A pitted or abraded forceps surface coagulates poorly and tends to build coagulum and produce dangerous sticking. A newly developed tungsten alloy forceps tip material has a surface polish and hardness far better than one made of stainless steel, titanium, or even nickel, as well as a much higher melting point. These new forceps show no wear or change after long testing.

Char formation on the tips of bipolar cautery forceps during neurosurgical procedures is inevitable. Various methods are used to reduce the char. Frequent irrigation with saline or mannitol solution is helpful. Modification for the tips, such as Teflon coating, is available. A simple technique to help reduce char formation and facilitate cleaning during the operation is to bathe the bipolar tips in mannitol. In the instrument pouch, 25 cubic centimetres of 12.5% mannitol-saline solution is placed. When the bipolar device is not in use, the tips are submerged in the mannitol solution. Mannitol reduces the coefficient of surface tension between the char and bipolar tips. In addition, saline dissolves the char by disrupting electrostatic forces within the char. Storing the biopolar tips in a mannitol-saline solution thus reduces char adsorption.[32]

SCISSORS

Different types of scissors are used for different purposes (Fig. 14).[27–29] For excision of large tumours, Metzenbaum scissors are used. In microsurgery, curved or straight stainless steel microscissors are used. For superficial microvascular procedures such as extra-intracranial arterial anastomosis, straight handle scissors are required. For surgery in the deeper planes, the bayoneted scissors are used so that the hand holding the scissors does not obstruct the visualisation of the scissors tip. In deep cavities, it may not be possible to align the straight or curved scissors blades for the desired line of action and so angled blades are used to visualise their tips. Alligator type scissors, with a long shaft, are used for deep and narrow opening such as in trans-sphenoidal surgery. Their blades are oriented in different directions to facilitate cutting in all directions.

Forceps

For superficial operations, the jeweller's forceps may be used, but these are too short for most neurosurgical procedures. The longer straight or bayoneted forceps with a length ranging from 7 cm to 10 cm is ideal for most procedures (Fig. 15).[27] The bayoneted forceps with an angle between the shaft and the handle prevents the surgeon's hand from obscuring the surgical field. Some designs with a rounded shaft permit greater rotational movements of the forceps. The tension of the forceps or the closing force should be minimal to prevent fatigue of the surgeon's hand that may lead to tremors during the prolonged use of the forceps. However, whenever tissue planes and arachnoidal planes require to be developed, and when the bayoneted forceps is used as a dissecting instrument, considerable tension of the forceps is required. The type of tip of the forceps determines its

Fig. 15: Bayoneted and tissue forceps

Fig. 16: Microdissectors

usage. For grasping tumour tissues, a ring or a cup is required at the tip. Forceps with teeth, called the tissue forceps are used for grasping tissues including the dura. Forceps with cross serrations, known as the dressing forceps may be used for endarterectomy. Upward and downward angled tips may be used to dissect around the back of an aneurysm.[28,29]

MICRODISSECTORS AND RING CURETTES

The Penfield microdissectors and Rhoton's microdissectors are more frequently used for microneurosurgery (Fig. 16). The straight dissectors are used since rotating them will still keep their tip localised to one place, whereas the tip of a bayoneted dissector rotates through a wide arc.[35] The various microdissectors that may be used are the round, spatula or flat tip dissectors, the right angled nerve hook, the straight needled dissector, the cup shaped micro-curette or the straight or angled tear-drop dissectors. The silver dissector that has a malleable tip that can be moulded to a desired shape is also useful.[38] A hypodermic needle mounted on an artery forceps may also be used for arachnoidal dissection. Developing a cleavage by blunt dissection using a dissector should only be done in cases where only a few and fragile arachnoidal adhesions are present. Usually, sharp dissection using scissors is preferred to avoid tearing the nerves and vessels. The ball-dissector is useful for manipulating nerves and vessels. The angled dissectors are useful for separating tumour from the bone in narrow canals or to develop a plane between the tumour and its capsule.[28,29] For trans-sphenoidal surgery, ring curettes (Fig. 17) with angled handles are preferred as the field of view of the surgeon is not blocked by his hand manipulating the handle of the dissector. The blunt ring may be used to gently ease out the tumour from the lateral margins of the sella and from the supraellar regions. The tips of these curettes may have an angled ring, a straight ring or a loop with a diameter ranging from 3 to 9 mm.[27]

Needle Holders and Sutures

Suturing of blood vessels and nerves[45–47] usually require 8-0 to 10-0 nylon sutures on a variety of needles from 50 microns to 130 microns (Fig. 18). The handle of the

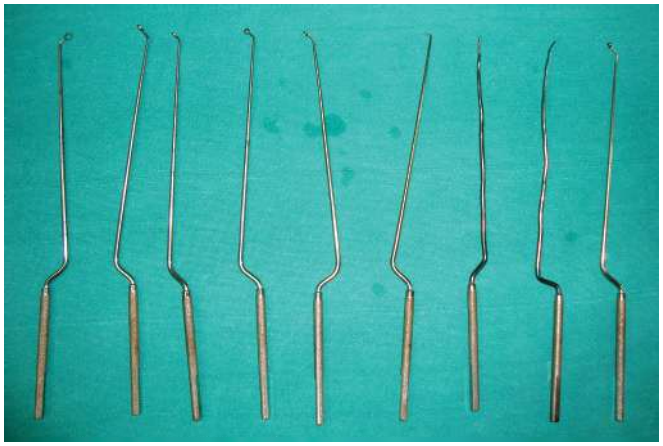

Fig. 17: Ring curettes

Fig. 18: Needle holders

Fig. 19: Cup forceps

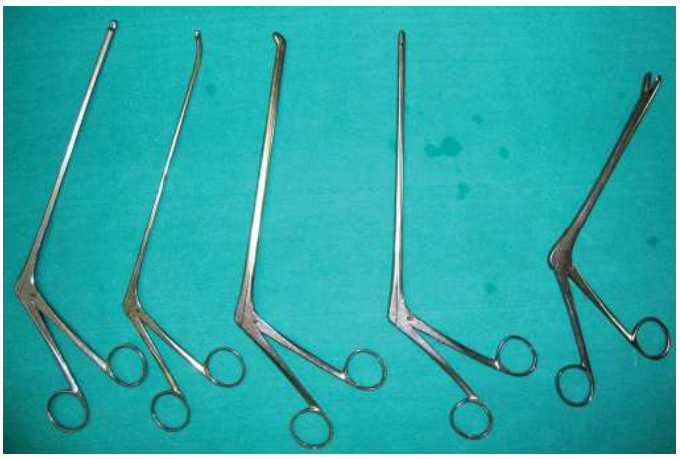

Fig. 20: Biopsy forceps

needle holders should be round so that rotating them between the thumb and the index finger is smooth. A lock or a catch in the needle holder is not preferred. This is because, releasing the lock or catch causes the tip of the needle holder to jump and be misdirected thus causing tissue damage. The straight needle holders are utilised for handling the micro-needle at the cortical surface, while bayoneted needle holders (with the bayonet shaft ranging from 8 to 11 cm) are used while working at the depth.

Cup Forceps and Biopsy Forceps

The fine cup forceps are used for grasping and removing tumours in deep and narrow exposures (Fig. 19). No traction should be applied on the tissues, otherwise the normal structures may be pulled with the tenacious tumour. The cup may be straight or angled upwards or downwards. The cup diameter ranges from 1 to 4 mm for microneurosurgical applications.[28,29] Biopsy forceps have long handles and a cup for grasping tissues at the depth of the surgical field (Fig. 20). They may be used for microsurgery at a depth like trans-sphenoidal surgery.

ANEURYSM CLIPS AND APPLICATORS

In 1910, Cushing introduced the silver clip to occlude vessels that were difficult to ligate.[7] Dandy, in 1937, clipped the neck of an internal carotid artery aneurysm using a modification of the original Cushing clip described by McKenzie.[8,22] In 1966, Scoville described a torsion bar spring aneurysm clip made of stainless steel.[34] In 1971, Mayfield and Kees reviewed the development of their spring clip for the permanent occlusion of aneurysms.[20] The most frequently used aneurysm clips have been designed by Yasargil, Rhoton, Sugita, Sundt, Spetzler and McFadden.[20,21,38,39]

Optimally the aneurysm clips must be designed to satisfy the following criteria:

- Their closing force must be sufficient to obliterate the lumen of the aneurysm against arterial pressure pulsations
- They must be non-corrosive and biocompatible
- They must not produce artifacts on MRI.[31]

The commonly available clips are made of cobalt chrome nickel and/or molybdenum alloys, e.g. Yasargil clips, Sundt clips McFadden clips, Sugita clips and Heifetz clips.[1,17] These materials are durable, biocompatible and non-ferromagnetic, yet they produce artifacts that degrade the quality of MRI scans. The newer titanium clips, while retaining the same design cause less artifacts on MRI.[17]

Dujovny et al. have classified aneurysm clips based on their design.[10,12] The alpha class having the shape of the Greek letter "alpha", have a crossed leg design. The Mayfield, Drake, McFadden, Rhoton, Sundt, Yasargil, Spetzler and Sugita clips have a similar configuration. The clip is usually a single piece except that the Yasargil, Rhoton and Sugita clips have an additional small ringlet as an alignment guide. The blades of pivot clips rotate around a central pivot with a separate coil spring providing the closing force. The Heifetz clip is a prototype of the pivot clip. The mobile fulcrum clip, of which the Scoville clip is an example, consists of an integral spring coil which acts as a fulcrum around which the blades rotate.[26,34]

Temporary clips (Fig. 21)[11,12] are used to achieve temporary vascular occlusion without damaging the vascular endothelium. They are applied to control bleeding from vessels prior to the application of the permanent clips, to isolate the aneurysm during dissection and also to test for the adequacy of occlusion of the aneurysm. The blades of a temporary clip open wider than that of a permanent clip. The permanent clips are of many shapes and sizes and their occlusion force is more than that of the temporary clips (Fig. 22).[26] For large and giant aneurysms, frequently, fenestrated clips that encircle the parent blood vessel harbouring the aneurysm are used (Fig. 23). These obliterate the neck of the aneurysm without occluding the lumen of the parent artery.[38,40] If the parent vessel or neural structures obscure direct access to the aneurysm, a fenestrated clip is especially chosen. Booster clips are often placed in order to augment the

Fig. 21: Temporary aneurysm clips

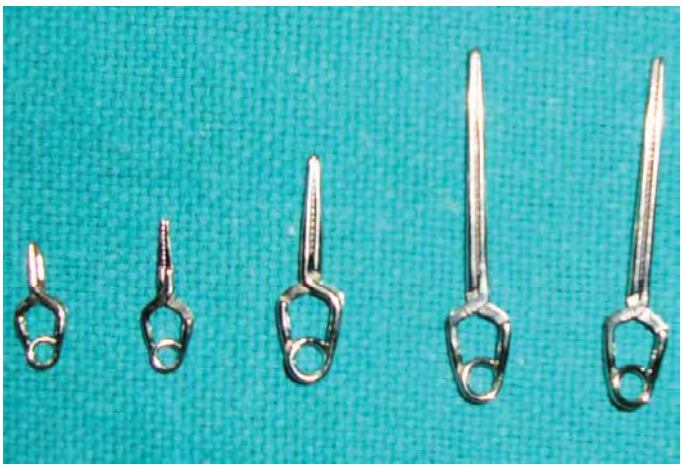

Fig. 22: Permanent aneurysm clips

primary clips. Occasionally, malleable rather than spring clips are used when dealing with broad based or fusiform aneurysms in order to perform an aneurysmorrhaphy.

If the size of the neck of the aneurysm is large compared to the lumen of the parent artery, then the clip blades must be applied parallel to the parent artery to avoid the constriction of the parent vessel or the rupture of the aneurysm base. The mechanical property of the spring clips facilitates application of greater closing force at the bottom of the blades than at the tip.[35] If an aneurysm has a hard wall or is under high pressure, it should be obliterated with the base of the clip rather than its tip.

The closing pressure is the force required to occlude the aneurysm. Besides the clip characteristics like the clip blade width, length and strength, the closing force is also determined by the blood pressure, the diameter of the aneurysms, the stiffness of the vessel wall and the geometric configuration of the aneurysm.[11,12,25] Atkinson et al. in a study of the closing pressure of the various commercially available clips found that the closing force of the aneurysm clips of average size (8–10 mm straight) were consistently satisfactory for each of the clip brands.[1] In order of decreasing strength, the clips were the Sundt, McFadden, Yasargil, Heifetz and the Sugita clips. The closing forces of the larger (20–21 mm) clips were more or less equivalent to each other. However, the closing force was often significantly less in their smaller (8–10 mm) counterparts. Thus, booster clips applied midway along the primary blade length are useful in augmenting the closing force of the larger clips.[35,42] The most important factors determining accidental clip release following its application are the incomplete crossing of the vessel diameter by the clip blades and, the degree of rigidity and thickening of the arterial wall caused by arteriosclerosis.

The clip applicators may be used for ordinary, mini and ultra large clips and may be straight or angled (Fig. 24). The Sano multipurpose clip applicator may be moulded depending upon the trajectory that the surgeon wants to adopt for clip application since it is multijointed. Another variety of Sano applicator has a small rotating socket for the clip head so that the clip may be held at any desired angle.[38,40] With the use of conventional clip applicators there is difficulty in regripping a

Fig. 23: Fenestrated aneurysm clips

Fig. 24: Aneurysm clip applicators

clip in the narrow surgical field, especially if the vessel is at an awkward angle. If improperly gripped, the clip may jump out. The newer applicators have a wider groove and grip the spring portion of the clip, thus preventing the clip from slipping during its reapplication.[38,40]

NEUROSURGICAL DRILLS

High Speed Drills

The pneumatic microsurgical drills have a vane type of motor (Fig. 25).[44] The motors have a rotor spindle placed eccentrically in its covering. Slots in the rotor spindles have vanes installed in them. These vanes move in and out of their slots to trap air while the rotor rotates within its covering in an eccentric position. A foot operated control regulates the speed of an air driven hand piece that rotates rapidly the cutting or the drilling dissecting tool attached to the end of the hand piece. The flow of compressed air both to and from the hand piece is regulated by the footswitch. Application of an operator's foot pressure on a floor level foot control, simultaneously depresses two valves which control the flow of compressed air. One valve controls the flow of compressed air from its source to the hand piece, and the other valve controls the release into the atmosphere of compressed air from the hand piece. Release of pressure on the foot control returns the two valves, utilising spring forces, to their original position cutting off the flow of compressed air both to and from the hand piece. Air entering the entrance hole pushes the rotor vane. The vane is pushed centrifugally outwards against the inner casing of the rotor housing creating a closed chamber. Thus, a small pressure chamber is created that collects air and holds it until it is released at the exhaust port. This mechanism will permit a rotation of the drill to 75,000–100,000 rpm.[44]

Fig. 25: High speed drill

The electrical drill systems with rotation speeds in the range of 90,000 rpm do not require a pneumatic gas source as the motor is driven by electricity.

The drill systems have two types of dissecting tools. The cutting tools drill the bone fast, but may cause bleeding from the soft tissues and may injure the dura. The diamond tools, on the other hand, require more time and pressure to cut the bone but may be used with much greater safety over the dura and soft neurovascular structures as they resist dissection of the soft tissues. The diamond tools also facilitate haemostasis while drilling the trabecular bone.

The drill systems have the advantage of cutting the bone rapidly and the ability to undercut the bone edge when using a large burr. They operate with virtually no torque. The tendency of the hand piece held in the surgeons hand to shift in position with changes in speed of the drill or its starting and stopping is also minimised. This makes the application of the drill safe in areas where great precision is required. Their disadvantages lie in the risk of direct mechanical and heat injury to nerve, blood vessels, and normal tissue, grabbing of cotton pledgets and in interruption of the operation for frequent irrigation and suction.

Ultrasonic Bone Curette

Ultrasonic surgical aspirators with longitudinal and torsional tip, apart from removing soft tissue tumours, may also be used to cut and scrape bone structures in skull base and spinal surgeries.[3,23] It comprises of a lightweight hand piece which is stable and easy to handle, a power supply unit with irrigation and suction, and a foot switch. Only minimal tip–bone surface pressure is needed to cut the bone. The longitudinal vibration amplitude can be varied from 120 to 365 mm at an ultrasonic frequency of 25 kHz. The tips (1.9 mm and 2.8 mm wide) operate in a scratching motion to resect bone. The irrigation fluid (cool-controlled at 20°C) can be applied from the tip with suction equipment. The ultrasonic curette is a useful instrument for procedures performed near the dura mater or other neural tissue without excessive heat production or mechanical injury. Its advantages include the lightweight of the hand piece, fine motion in scratching and cutting bone tissue, no grabbing of cotton pledgets and an easy preservation of dura and epidural venous plexus at the tips. Its disadvantages lie in less manoeuvreability because of short and fixed tips in a key-hole exposure and the possibility of injuring the neural tissue due to long duration or high energy use.

KERRISON'S PUNCHES AND RONGEURS

The bayoneted osseous punches (Kerrison's punches) (Fig. 26) have been constructed in standard sizes. The 1–5 mm sized punches are especially useful. These have a very thin small foot plate set at either a 90° or a 45° angle. The instrument can easily be slipped under the

Fig. 26: Kerrison's punches

part of the anterior clinoid process protecting the carotid artery for biting off a portion of the clinoid process. In anterior cervical disc excision, lateral dissection near the nerve root is facilitated by grasping the posterior longitudinal ligament as well as the osteophytic spurs overlying the nerve root with the osseous punch. The bayoneted punch is also helpful in lumbar microdiscectomy. The larger punches can be used to remove the portion of the ligamentum flavum in the lateral recess overlying the nerve root. In trans-sphenoidal hypophysectomy, a longer extension of the distal portion of the instrument is useful in removing the bone from the sphenoid sinus as well as from the anterior portion of the sella. In transoral odontoidectomy the bone edges can be grasped with the small osseous punches while the bayoneted curettes are used to free the odontoid from the underlying connective tissue.

The angled micro-curettes are made with either a 90° or 45° angle. The bayoneted offset allows visualisation of the cutting edges at its end under the operating microscope. These are especially useful while removing a tumour from the sella-suprasellar region in the trans-sphenoidal approach.

The single and double action rongeurs (Fig. 27) may be used to remove bone from the vertebral body and in removing the lamina during a laminectomy; for performing a craniotomy as in removing the lesser wing of the sphenoid during the frontotemporal approach; and, during skull base surgery for nibbling the bone of the calvarium and skull base.

EQUIPMENT FOR ENDOSCOPE ASSISTED MICROSURGERY

Intracranial endoscopy provides a minimal but rapid access to the target via small burr holes without brain retraction. A neuroendoscopic system that includes rigid, semiflexible, and flexible scopes, bright cold light sources, a high-resolution video camera system, effective instruments, and irrigation devices may be combined with microsurgery to improve vision, illumination and minimal invasiveness[33,36] (Figs 28 to 30). The endoscopes are usually introduced via an operating sheath initially inserted with the aid of a trocar, which permits the intra-operative exchange of different scopes without reinserting scopes through brain tissue. This avoids injury to the surrounding healthy brain. Rigid rod-lens scopes have better optical quality and wide-angle view, as well as ease of guidance and orientation and are, therefore, preferred. Rigid scopes have four different angles of view (0°, 30°, 70° and 120°). The 0° and 30° scopes are used for inspection and manipulation; the 70° and 120° scopes are used for inspection only ("looking around a corner").[4]

Instruments such as scissors, biopsy and grasping forceps, hooks and puncture needles have been manufactured that permit surgery through or assisted by an endoscope. The endoscope allows surgery with rigid instruments in a straight line, with a good tactile feedback from the tissue being manipulated and makes easy guidance of the tools possible. Bipolar as well as monopolar diathermy probes and a laser guide are used for haemostasis and dissection. Balloon catheters are used to enlarge ventriculostomies or other fenestrations. For irrigation, an irrigator may be used that controls the flow using a foot switch.[4]

Fig. 27: Rongeurs

Fig. 28: Rigid and fibre optic endoscope

Fig. 29: Light source and camera for endoscope

Lactated Ringer's solution at 36–37°C is preferable to saline as the irrigating fluid as the former prevents post-operative body temperature increase (often observed after profuse irrigation with saline). While introducing irrigating fluid into the brain, it is imperative to keep the outflow channel open to prevent dangerous increases in intracranial pressure. Xenon light sources, transmitted via fibreglass cables from the light to the endoscope provide the best illumination, because the colour temperature of xenon light resembles that of sunlight (6000 K). A mini video camera may also be attached to the endoscope via a sterile optical bridge. The documentation equipment includes a video printer and digital still recorder.

The endoscope is ideal for dealing with pathologies in the ventricular system and subarachnoid spaces; and hydrocephalus, small intraventricular lesions, and arachnoidal and parenchymal cysts may be effectively treated.[33] Even highly vascularised lesions such as cavernomas may be excised with the additional use of lasers and bipolar diathermy. During standard microsurgical procedures, the endoscopic view may provide valuable additional information ("looking around a corner") about the anatomy in the surgical field that is invisible with the microscope. The endoscopic view may be incorporated in the eye piece of the microscopic view to give a "picture in picture" image.[36] The endoscopic image reflects on a mirror in the adaptor and is projected as a part of the unilateral microscopic image by fibre optic cables to the microscope, thus allowing the surgeon to perform endoscope-assisted microsurgery without moving his eyes away from the operative field. This helps the surgeon in getting more detailed information about the neurovascular structures in the shadow of the operating field. In trans-sphenoidal pituitary surgery, the endonasal approach permits a more accurate control of tumour removal in the intrasellar space, especially in the case of larger tumours with parasellar and suprasellar growth. The combined use of endoscopes and computerised neuronavigation systems permits real-time information about the endoscope tip position and approach trajectory while performing a microsurgical procedure. The problem with endoscopic surgery is the lack of appropriate visual cues to orient oneself in three-dimensional space. This makes relatively simple anatomical regions difficult to navigate. To overcome this shortcoming, a neurostereoendoscope, that has a prismatic optical path separator mounted behind the rod-lens and captures stereoscopic three-dimensional images using dual charged-coupled devices, has been developed.

Fig. 30: Monitor for endoscope

COAXIAL MICROSURGICAL INSTRUMENTS

Keyhole microsurgical approaches involve minimal or no brain retraction. The mobility of the conventional microsurgical instruments within such narrow corridors is severely restricted and the surgical field may

Fig. 31: Coaxial microneurosurgical instruments

Fig. 32: Operating microscope

also be obscured by the relatively large size of these instruments.

The newly designed coaxial instruments contain a coaxial shaft that is made up of a coupled tube and rod rotating in opposite directions along their major axis[6] (Fig. 31) This rotational movement is achieved by compressing and releasing a spring-loaded handle. The tips of the instrument are obtained by flanging the two elements of the shaft. The length of the tips varies between 6 mm and 10 mm and the width between 2 mm and 3 mm. The instrument has all the three variations, the straight and angled tip as well as a variation of the straight one in which the distal third is curved. The instruments include microscissors and micro forceps, tumour grasping forceps as well as aneurysm clip applicators. The diameter of the shaft ranges between 2 mm and 3 mm and the length may be 90 mm, 100 mm and 130 mm. The two elements of the shaft can be disengaged by releasing a catch and be disassembled for cleaning.

The newly designed coaxial instruments possess a low-profile coaxial shaft. They are ergonomically designed with a pencil grip handle and an angled bayonet. Thus they offer a better view of the operative field and can be manipulated through narrow corridors since the bulk of the shaft of the instruments is outside the visual axis.[6]

OPERATING MICROSCOPES

Operating microscopes (Fig. 32) offer a three-dimensional magnified stereoscopic (binocular) vision in a narrow field at depth.[43] The interpupillary distance of the surgeon is maintained by the microscope, so that the images produced by the objective and eyepiece lenses of the two sides respectively are merged into a single three-dimensional image. The microscope provides a good magnification without significant aberrations. Modern microscopes have a motorised zoom system that consists of dual movable lenses which move with respect to one another so that the desired focal length may be adjusted. Field of view is the diameter of the operative field visualised when the microscope is properly focused. Size of the field of view is inversely proportional to magnification (higher the magnification, lesser is the size of field of view). At higher magnifications, the depth of field (that is the distance between proximal and the distal points in focus) also becomes very small. Therefore, at higher magnifications, the operating surgeon has to frequently adjust the microscope to the focal plane of interest to him at any given moment. This challenge may be overcome by an autofocus system that permits him/her to instantaneously focus on the region of interest. Another important feature of the microscope is that it provides good illumination at narrow depths and around corners of the surgical field without producing excessive heat. Fibre optic coaxial illumination is its property of aligning the front surface of mirrors to produce even light distribution and avoiding shadows in the operating field. The illumination, however, decreases at higher magnification. Modern microscopes have incorporated the modification of increasing the illumination in proportion to the magnification used. Automatic light collimation is the property by which an automatic shutter diaphragm increases light at higher magnification to provide appropriate illumination. In the microscopic eyepiece there is a provision for correcting the refractive errors of the surgeon and the assistant. There is a provision of instant stability in six axes without sacrificing operational flexibility. Microscopes are balanced by adjustable counterweights mounted on a stand. Electromagnetic brakes incorporated into various joints of its stand maintain stability in any desired position. Pistolgrip or mouth switch or footswitch controls for releasing the brakes allow all movements in primary axes. The controls for adjusting magnification and focal length can also either be on handles or on a pedal.

The cameras attached to modern microscopes permit recording of high definition surgical procedures. With the appropriate attachments, assistants may visualise the

same surgical field as the primary surgeon and therefore help in his surgery. Microscopes may have the capacity to incorporate neuronavigation that permits the surgeon to determine his actual position during surgery with the previously acquired three-dimensional imaging data set of the patient.[13] It can also display magnetic resonance images, angiograms, and computerised tomography scans simultaneously and combine the information intra-operatively. The simultaneous use of an endoscope with an operating microscope during surgery is facilitated by its "picture in picture" facility that permits the simultaneous display of both the microscopic and endoscopic images on the eyepiece and the microscope display panel. A blue light illumination permits visualisation of malignant gliomas in patients who have been given 5-aminolevulinic acid orally. An intra-operative angiography may be performed by detecting within the focused blood vessels intravenously injected indocyanine green. This real-time access to multiple types of imaging data facilitates spontaneous decision making of the surgeon in the operating room. Thus, a good microscope must have a clear stereoscopic view, ample homogeneous illumination, interchangeable lenses, variable magnification, well-balanced movement, coaxial illumination and provision for add on accessories.

CONCLUSIONS

Though an excellent outcome following a microneurosurgical procedure to a large extent depends on the surgeon's technical skill, an accurate diagnosis and meticulous pre-operative planning, the role of good instrumentation and their proper usage cannot be overemphasised. The microneurosurgical procedures, in an effort to lessen the operative trauma, have evolved into minimally access techniques requiring minimal or no brain retraction. Thus, a thorough knowledge of the proper usage of the newer micro-instruments and their indications and limitations is essential for improving the surgical results.

209 Navigation in Brain and Spinal Surgery

Ajaya Nand Jha, Rahmathulla G

INTRODUCTION

'Navigate' defined by the Oxford dictionary means 'to drive a ship'. The Vikings were the earliest to venture beyond their confines without instrumentation and only surface landmarks to guide them to their destinations.[1,32] Development of instruments to measure the altitude of the stars and planets and the discovery of the sextant which made it possible to measure angles, followed by the marine clock in the 18th century determined the progress of land and sea navigation.

Just as these tools were required here, a brain navigation system to reach pathology at difficult locations was developed by the pioneers of stereotaxy. 'Stereotaxic' is derived from Greek roots for 'three dimensional' (stereo) and 'system' or 'arrangement' (taxis). In Latin 'stereo + tactic' means to touch. Lesions that were located at a depth or traversed eloquent cortical areas could be safely reached without causing a permanent neurological sequel. This has been made possible with parallel advances in imaging techniques and instrumentation.

Advances in technology have improved global navigation and these principles have been utilised in parallel, along with modern instrumentation and technology to make brain and spine navigation safe.

HISTORY

Clinical localisation of a brain lesion required the precise analysis of the patient's symptoms and a detailed identification of the signs and these used to be the mainstay of a topological diagnosis. Angiography with the direct and indirect visualisation of the vascular tree[1,32] and deformation of the ventricular system on pneumocephalograms or ventriculograms were the first methods to identify lesions indirectly.[12]

Rene Descartes, a 17th century philosopher and mathematician, developed a system enabling localisation of a point in three-dimensional space using Cartesian coordinates. A few hundred years later, a brain target could be transferred to a stereotactic instrument, which guided probes and even electrodes to specific targets, when the frame was placed on the head. DN Zernov, a Russian surgeon, was the first to demonstrate a device, the encephalometer,[1] that could be fixed onto the patient's head above the sagittal suture in 1889, at the University of Moscow. A number of these instruments were made and forgotten after the Russian revolution. It was Sir Victor Horsley, a British surgeon, and RH Clarke, a British engineer (1908), who came up with a simple and enduring solution and pioneered stereotaxis.[50] They were responsible for coining the term "stereotaxis" and developing the first true frame (Fig. 1).[1] The brain was used as the geometric volume, over which, suitable reference points were defined and specially designed surgical instruments for operating on these targets were made.

In 1918, Aubrey Mussen, a Canadian physiologist, made a study of the vagus nerve in a cat and a monkey, using the Horseley and Clarke system. He later designed one for human use, but this was never used.

The modern era of stereotaxis began in 1947 when EA Spiegel and HT Wycis, in Philadelphia, made the first clinically usable stereotactic (stereoencephalotome) device for humans. This device used hollow threaded screws and could be accurately placed and replaced as necessary[1,14,32,53,54] (Fig. 2). They used positive contrast ventriculography,[11] the foramina of Monro and the pineal body to localise intracranial targets and were the first to consistently use X-rays and ventriculograms to localise the target.

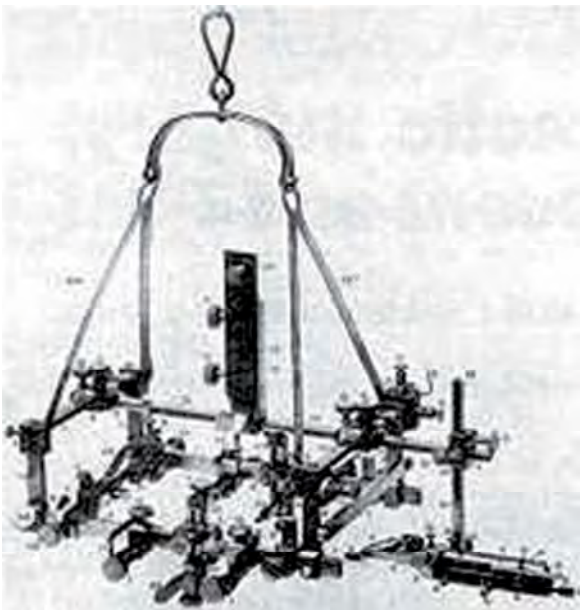

Fig. 1: Horsley and Clarke's original apparatus

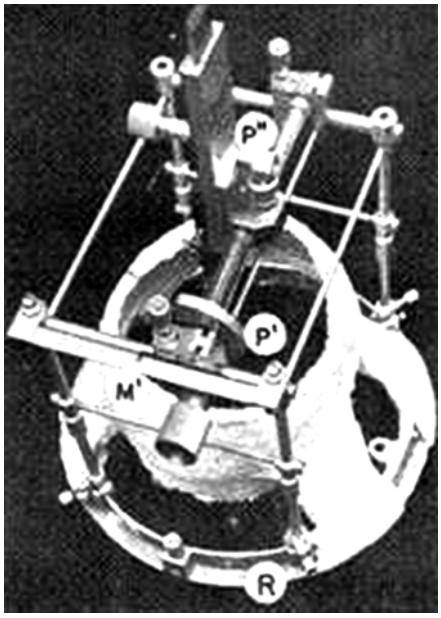

Fig. 2: Original Spiegel and Wycis instrument

Following this, there was an explosion in the number of instruments from various parts of the world: Lars Leksell (1949, Sweden), H Narayabayashi (1951, Japan), T Reichert and Wolf (1951, Germany).

Leksell devised the arc-centred frame system in 1949.[29] The simplicity of this system is the reason for its continued popularity. The fixation device was attached to the patient's skull and the pointer could be moved along the arc-quadrant to localise targets (Fig. 3).

Stereotactic atlases are an important part of the history and development of stereotactic surgery and some of the concepts behind these atlases are described here. It was important to know the distances between various landmarks and the anatomical targets and their variability in the patient population. A series of precise brain sections was made at measured intervals and contained a grid system to relate the coordinates of any point to the intracerebral landmarks. Each human brain has its own variability causing problems for the neurosurgeon and it was Spiegel and Wycis who published the first usable stereotactic atlas in 1952.[1,54] Talairach published an atlas in France with emphasis on the temporal lobes. This was extensively used to treat patients with epilepsy.[1,9,56] He also described a different plane, the anterior commissure (AC), posterior commissure (PC) line, which subsequently became the standard reference for many stereotactic surgeries (Schaltenbrand G Barley P), (Schaltenbrand G and Walker AE). Each page in a stereotactic atlas represents a brain slice taken at a measured position within the brain (Fig. 4).

The rapid development of computer software, along with technological innovations in imaging, has led to a more interactive, real time combination in the use of these atlases. The stereotactic atlas can now be superimposed on the patient's images and various target nuclei specifically located with great accuracy.[8,22] Imaging has

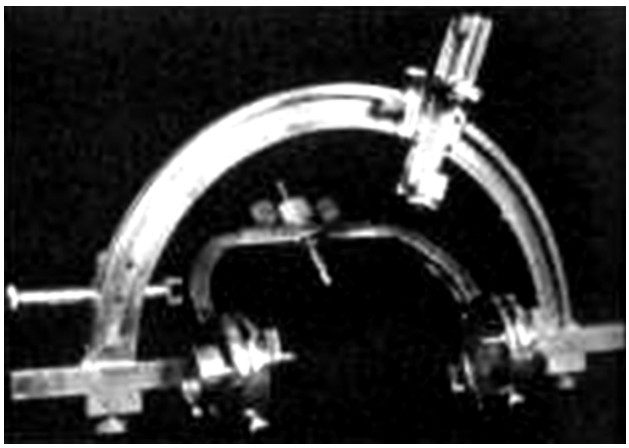

Fig. 3: Leksell's arc centred frame system

been used as a guide to the deeper structures of the nervous system and has evolved from the days of the X-rays and use of the pencil and tape.

The ultrasound was followed by the CT and then the MRI. The introduction of the CT scanner and the MRI created a revolutionary change in the way navigational systems were used. The dependence upon stereotactic atlases, which were based on normal post-mortem specimens, could only be utilised on normal persons with relatively fixed anatomy. Computers further simplified the process of including various data into the scanned images and helped calculate/manipulate the target using the coordinates.[14] This led to a shift from atlas based targeting to directly imaged targets, although not in real time.

Navigation has evolved from frame based systems to interactive image guided surgery. Real time intra-operative imaging utilising an intra-operative MRI (BRAIN SUITE) is now a reality. Using this technology to couple surgical skill with detailed anatomical images, specific targets can be identified and located, avoiding critical areas and maximising the benefits of any neurosurgical procedure. The risk of damage to the adjacent vital structures is minimised, allowing a small craniotomy to be made over the lesion. This reduces operative time, bleeding, infection and damage to vital cortex. The surgeon can maintain three-dimensional orientation of the anatomy and, when differentiation of the pathological lesion from adjacent normal brain is a problem, imaging at surgery is a boon, such as in low-grade gliomas.

GENERAL PRINCIPLES

The principle behind a navigational system is to locate a specific intracranial target point, in relation to a constant external coordinate reference system. Initially, various skull landmarks were used as a guide to locate pathological lesions and craniotomies were performed in relation to these landmarks. Lines connecting various points were used to locate the Sylvian fissure and adjacent structures (Taylor Haughton lines) and these were a guide to the surgeon.

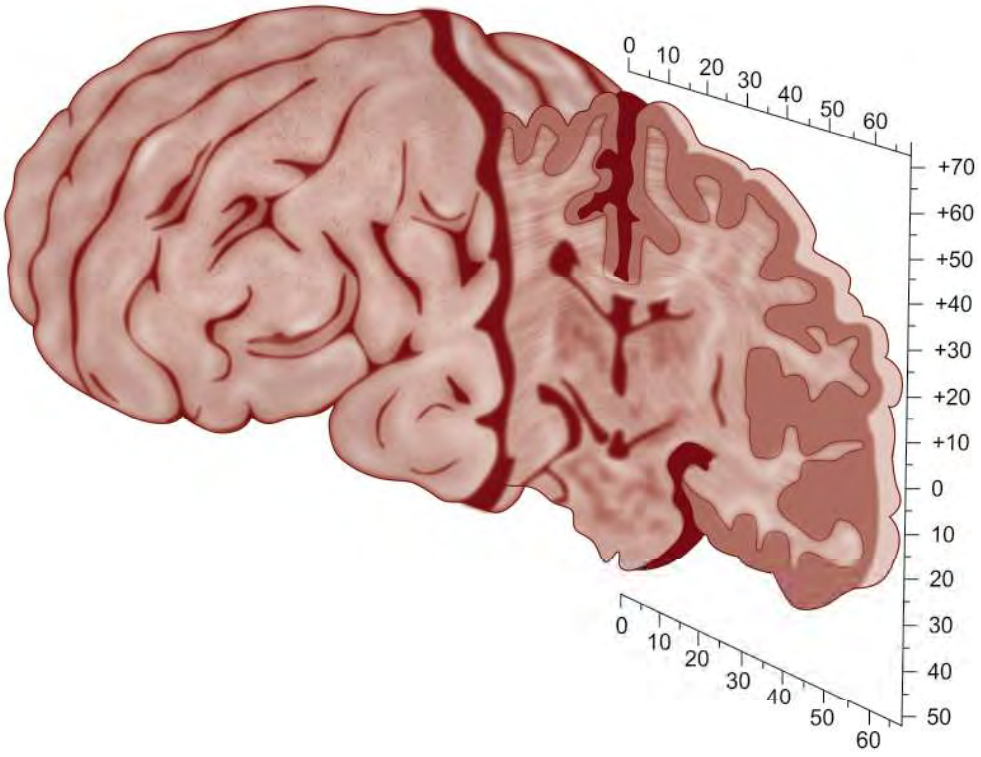

Fig. 4: Page from a stereotactic atlas

Then came the frame based system, where a base ring is attached to the patient's head, and a three-dimensional frame placed over this. The lesion is usually calculated/identified in relation to this external coordinate frame. Each intracranial point is assigned a specific location by the computer, while scanning and for the external coordinate frame as well. The target point is calculated in relation to this using imaging software.

Following this, frameless systems are now used. The external coordinate reference points consist of 'fiducial markers', either placed on the patient or by registration of surface points directly. The imaging sequences are done with the fiducial markers or the scan has to cover the entire face/surface contour, which will be used to register the patient. The location of various targets in relation to this reference system can be plotted out and probes can be used to reach the target along a particular trajectory, making procedures, such as biopsy and lesioning of nuclei in movement disorders, seem like child's play.[21,39]

ELEMENTS OF STEREOTAXIS

Geometry, reference points and surgical instruments[10,46] are the three basic elements which have evolved to produce modern stereotactic surgery.

Brain in a Geometric (Cartesian) System

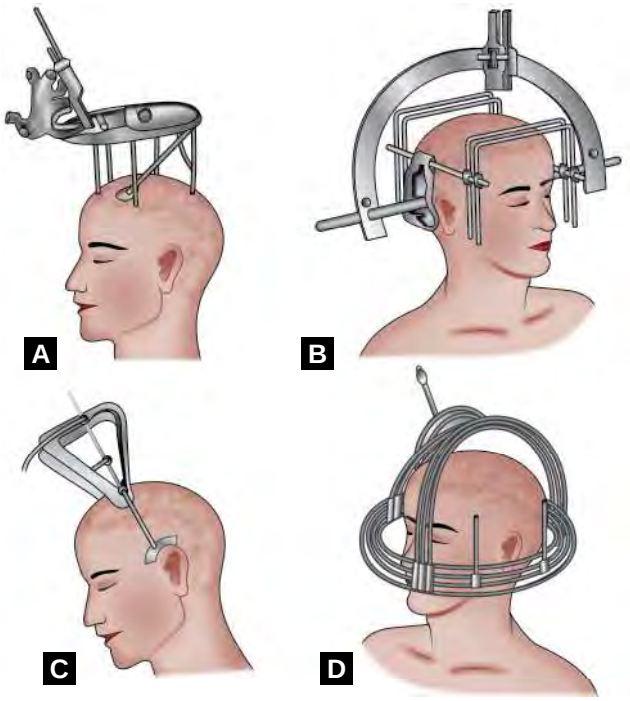
A Cartesian co-ordinate system is a three-dimensional grid with a centre point (origin) that can be used to map locations in space. The position an object occupies in space is determined by its relative position, with respect to a given point which is arbitrarily chosen as the reference point. Adding 3 orthogonal planes to intersect at this reference point which is now taken as zero point, establishes a system of reference axes (x, y, z) (Fig. 4). The location of any point in this system can be measured in relation to the zero point in all 3 axes. This concept, which is intrinsic to geometry, is being used, following the application of the Cartesian system of coordinates by Clarke.

Reference Points

Visible targets, such as tumours, are located by interfacing a stereotactic frame on the patient with CT/MRI. Targets which are not visible, like the ventrolateral thalamic nucleus, can be localised indirectly by using atlases.

Stereotactic Frame

Most frames consist of two elements, the coordinate frame and the aiming device. The frame is a rigid metallic platform attached to the skull by means of head pins, which pierce the outer table of the skull, so that no displacement can occur (Figs 5A to D). The aiming device is usually attached to this and may have a number of moving parts which bear the probe holder. This can usually be moved multi-directionally to point at a specific target in the skull. The stereotactic systems in use are either 'translation rectilinear' systems or 'arc centred' systems. In the former type, both the entry point for the surgical procedure and



Figs 5A to D: Four basic types of apparatus
(A) Translation system; e.g. Horseley and Clarke's, Talairach's and Narabayashi's
(B) Arc system; e.g. Leksell
(C) Burr hole mounted
(D) Interlocking arcs, e.g. Brown-Robert-Well's (BRW) and Cosman-Robert-Well's (CRW) frames

the target are located in relation to an external frame. The stereotactic device is attached to the frame and examples are the Horseley and Clarke system and Speigel and Wycis frames. In the latter variety of frame based systems, the target is located in relation to the frame and is always at the centre of the apparatus.[1] The Leksell and Laitinen frames are examples of such devices.

Along with this, a phantom device can be employed. The phantom reproduces the target and the surgeon can perform a simulation on this, confirming the accuracy of the points taken. The aiming arc is applied and the tip of the probe should accurately touch the target on the phantom. Frame-based systems have their benefits in that they are stable, can hold a trajectory probe and can be used in pre-operative simulation.

The limitations with these systems are that they are temporary, restrictive, sometimes complex to use and bulky, making the patient uncomfortable. Targets are limited to one trajectory at a time. Real time updates are not possible with these systems.

Applications

The various applications are:[1,10,60,62]

A. Functional
   - Movement disorders
     - Parkinson's disease[42,43]
     - Hemiballismus
     - Dystonia[43,45]
     - Choreoathetosis
     - Intention tremors
   - Intractable pain
   - Psychosurgery

B. Anatomical applications
   - Tumour localisation and biopsy[31]
   - Craniotomy guided by stereotaxy
   - Interstitial brachytherapy
   - Radiosurgery
   - Intracranial aneurysms[2,26,33]
   - Stereotactic third ventriculostomy using endoscopy
   - Epilepsy[44]—implantation of depth electrodes

Imaging prior to surgery gives the surgeon a two-dimensional idea of the lesion in relation to various bony and soft tissue landmarks. Earlier, a surgeon would localise a target based on the Taylor-Haughton lines and the corresponding set of images and place his flap in an approximate location. This could lead to a larger craniotomy, damage to vital structures, inability to localise the lesion and define the extent of the resection or the ability to locate deeper structures.

Frame-based Systems

The Cosman-Robert-Well's (CRW) frame is a common, simple and widely used system. It is ideal in situations where only specific target points have to be located, e.g. a thalamic lesion and other target nuclei for movement disorders and deep brain stimulation. The components are, however, common to most of the systems in use (Fig. 6).[41]

- A base ring, which has pins (graphite) with which it is fixed to the skull
- Over this, is fixed a localising unit, which has two vertically and one diagonally placed rod, in an array around the head. These act as the fiducial 'picket fence' pattern
- The base ring has to be fixed onto the gantry table of either the CT or MRI and the operating table. A fixation device does this
- A phantom device on which the target point and the probe should meet concurrently, to confirm the exactness of the coordinates
- During the surgery, a frame attaches to the base ring and is the interface between various instruments
- Software on the computer (stereocalculator) to compute the final target from the set of co-ordinates fed in. Usually, there are nine points starting from X1, Y1 up to X9, Y9 with x being the 9 o'clock position usually The final target is taken as X, Y. Each of these values is fed into the computer, which calculates the final target.

Various instruments are available to work on this platform and the commonly used ones are: Needle coring device, side cutting needles, spiral needle, cup forceps, interfaces for the use of endoscopic instrumentation and a microdrive for implanting deep brain stimulation electrodes.

Fig. 6: Cosman-Robert-Well's frame

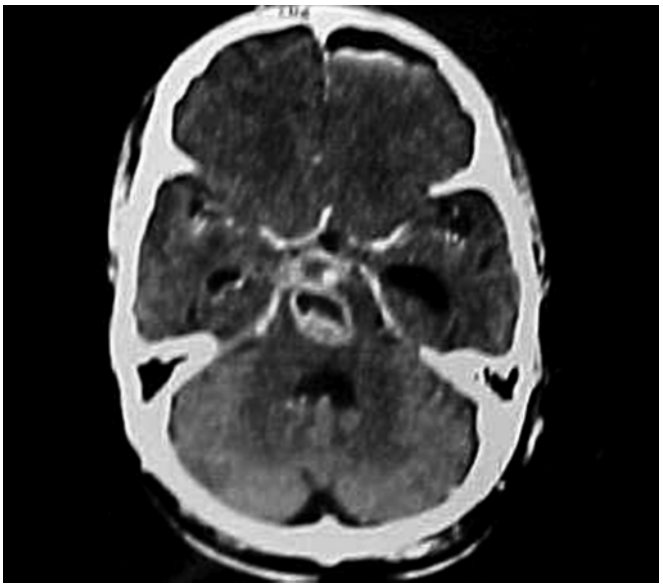


Fig. 8: Post-operative image of an aspirated cyst

The CRW frame can be used for:[43,46]

- Biopsy[31]
- Planning of craniotomy flaps overlying the surgical site
- Aspiration of a colloid cyst along with the endoscopes
- Drainage of deep seated abscesses, cysts (Figs 7 and 8)
- Brachytherapy
- Instilling chemotherapeutic agents in cystic lesions
- Lesioning of nuclei for movement disorders, such as pallidotomy and thalamotomy
- Placement of deep brain stimulating electrodes for movement disorders[43] and pain
- Depth electrode recordings (EEG) for cases of intractable non-localised epileptic foci[46]
- Radiosurgery for small well defined or remnant lesions

The limitations of these systems are that they are cumbersome and require the co-operation of the patient during frame fixation and during local anaesthesia. Fixing the frame and getting the patient scanned is time consuming as there may be other procedures being performed at the same time. The frame is bulky and may come in the way of surgery. At times, more extensive lesion resection and margin targeting may be necessary, which is not possible, unless the margins are retargeted.

Figure 9 shows the Leksell G frame with the multipurpose stereotactic arc in Figure 10. The main components of the frame are seen in Figure 11. The frame is engraved with a rectilinear coordinate scale, graduated in millimetres. The scale conforms to X, Y, Z directions

Fig. 7: CRW frame pre-operatively

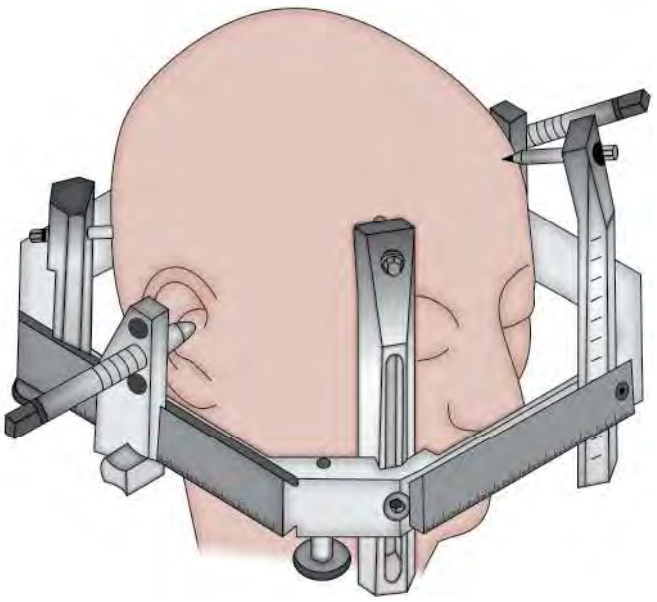

Fig. 9: Leksell stereotactic frame

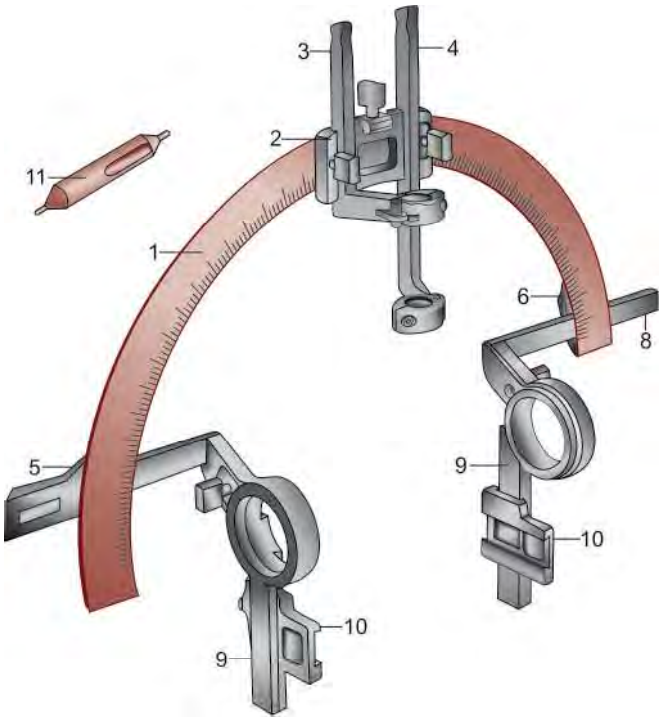

Fig. 10: Multipurpose arc

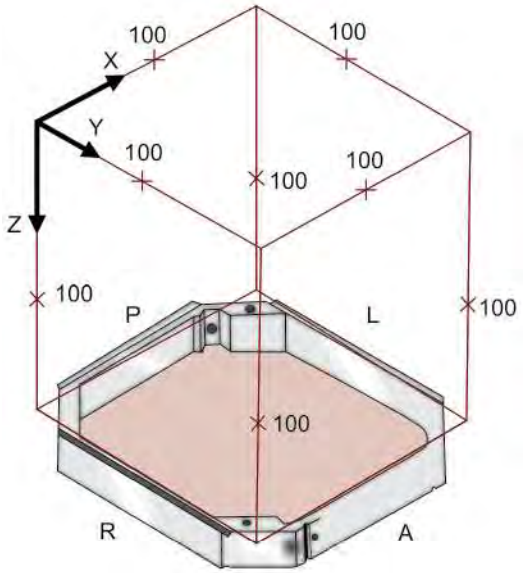

Fig. 12: Coordinate system

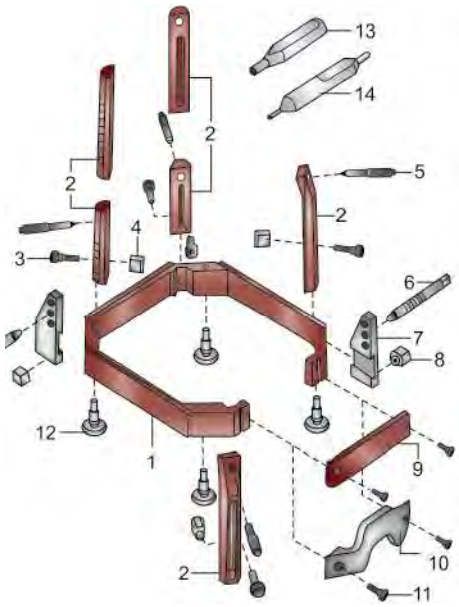

Fig. 11: Main parts of the frame

used in CT and MRI scanning. Origin (X, Y, Z = 0) is located outside the frame at a point superior, posterior and lateral to the frame on the patient's right side (Fig. 12). The frame is versatile and can be used for all stereotactic procedures, as well as target location and planning of gamma knife radiosurgery.

Stereotactic Biopsy

Technique

Stereotactic biopsy (STB) has proven to be highly accurate and safe, with least tissue invasion and proven tissue sampling.[38] The diagnostic yield is over 95%, morbidity less than 5% and mortality close to 0%. STB is often associated with a lower diagnostic yield in non-neoplastic lesions and the yield is much higher for those lesions with clear-cut margins and homogeneous character. It has a role in the diagnosis of a variety of lesions in AIDS, such as toxoplasmosis, lymphomas, focal encephalopathy and is a useful diagnostic tool in tuberculomas[31] and other infections.

Indications[7]

- Multiple intracranial masses, e.g. metastases, inflammatory lesions, lymphomas, multicentric gliomas
- Diffuse ill-defined intra-axial masses
- Deep seated intra-axial lesions which are inaccessible, such as thalamic gliomas, brainstem lesions[47]
- Lesions in eloquent locations, such as the motor or speech areas
- Unresectable invasive lesions
- Potentially radiosensitive lesions, such as germ cell tumours
- Candidates for brachytherapy and radiosurgery

Contraindications

- Suspected vascular lesions. In these cases one can employ frameless or frame based guidance for enhancing open resection

- Large lesions with significant mass effect require an open craniotomy and decompression
- Altered bleeding parameters
- Extra-axial lesions, such as meningioma
- Lesions close to the Sylvian fissure, suprasellar region and the third ventricle and most posterior fossa tumours.

Basic Steps

1. Informed consent is taken.
2. Usually performed under local anaesthesia-2% lignocaine. The scalp is infiltrated at the pin sites, prior to placing the frame. Explaining the procedure step by step is almost always all the analgesia needed.
3. The head ring is fixed onto the region of local anaesthesia with screws penetrating only the outer table of the skull.
4. Ideally, the pins are fixed in the forehead laterally and the mastoids posteriorly, to avoid muscle and the neurovascular pedicles. The target should be located within the limits of the base ring; if the lesion is in the posterior fossa the frame must be fixed at a lower level
5. A CT or MRI is done after mounting the localiser ring. Contrast is given, if required, depending on the type of lesion
6. Calculate the final position of the lesion using a stereo-calculator
7. The target coordinates on the frame system
8. Simulation on the phantom frame after entering the final coordinates and then fix the frame on the patient
9. Fix the arc system on the head frame
10. Make a small skin incision followed by the burr hole. The dura is opened in a cruciate manner and the edges coagulated
11. Adjust the probe tip to its predefined length
12. Perform a biopsy with a pair of forceps or via the needle aspiration technique
13. Send the tissue for a frozen section and paraffin staining
14. Confirm with scan/frozen section report
15. Shift the patient after removing the frame and start on oral diet if the procedure has been done under LA.

Complications

- Haemorrhage
- New neurological deficits
- Seizures
- Infection

Prevention

- Only one trajectory and one plane
- Not for vascular lesions
- Narrow instruments
- Proper choice of probe track

Stereotactic guided craniotomy uses the same principle and the steps are almost similar, except that the patient is under general anaesthesia. A craniotomy flap is marked over the site of the probe, directly overlying the target lesion. It can also be used to map out the location of the eloquent cortex. From the initial days of target localisation with frame-based systems, there has been a shift to more real time interactive imaging.

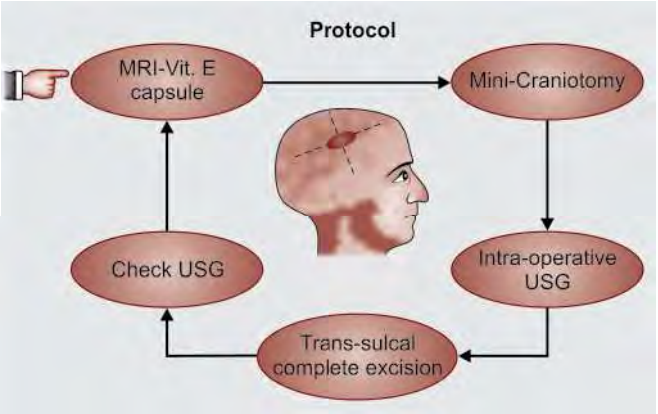

Fig. 13: Initial days of target localisation

Figure 13 depicts the earlier methods of localising targets. A marker object was placed in relation to the lesion and CT/MRI performed (Fig. 14). A mini-craniotomy was performed, based on the relation of this capsule to the underlying lesion. Once this was performed, we would then make use of the ultrasound (Fig. 15), as there would be no barrier from the intervening bone to check our location over the target. If appropriately located, a trans-sulcal approach would ideally place us over the lesion, enabling resection/biopsy, which could again be verified by an ultrasound performed at the end of the procedure.

The advantages of this were that it was accurate, cheap, safe, simple, reproducible and real-time.

The disadvantage of the intra-operative ultrasound is that the bony interface disables its use for planning

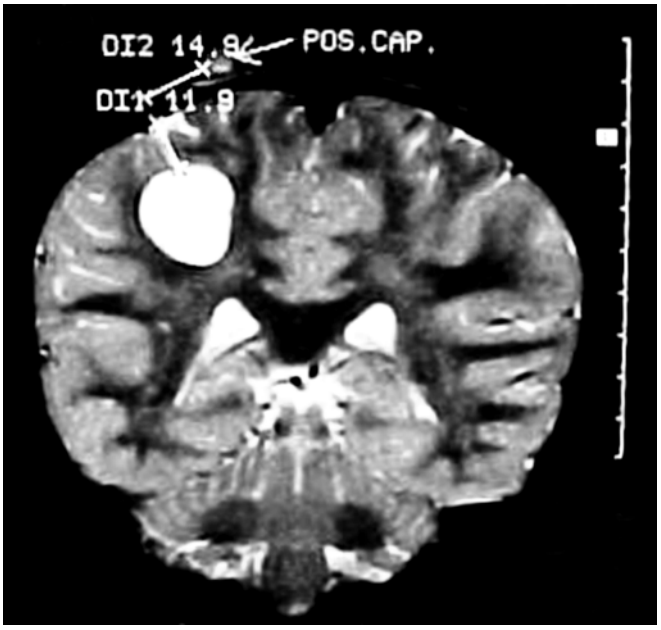

Fig. 14: Pre-operative MRI

Fig. 15: Intra-operative ultrasonography

specific craniotomy flaps. The lesion consistency should be cystic or solid, to obtain well-defined margins.

Frameless Stereotaxy (Interactive Image Guided Surgery)

Frameless stereotaxy or 'interactive image guided surgery' is a relatively new navigational modality in which there is no frame fixed on the patient's head. The basic principles had already been established in the preceding 50 years, with frame based systems, and technology evolution and implementation to stereotaxy brought about these changes. Neuronavigation is only a tool which is utilised to optimise the approach while minimising morbidity. Technology enables us to identify functional cerebral locations in relation to the lesions and approach and resect these lesions without damaging these eloquent areas.

The technological advances seen in the 1980s led to the ultimate use of these devices. These are:

- Computer software which could be utilised to manipulate data from images from either a CT/MRI
- Spatial accuracy has improved to almost 1 mm, with reasonably good speed
- Low cost equipment, in which three-dimensional digitisers could be used as pointing devices during surgery, is available

The steps in utilising these systems are almost similar:

1. Patient selection
2. Fiducial placement
3. Imaging
4. Data transfer
5. Pre-surgical viewing
6. Identification-registration of markers
7. Planning and intra-operative navigation

How one gets to the lesion, however, does not alter the basic operative technique with which the surgery is performed. These are:

- Relaxed brain—neuroanaesthesia
- Minimal dural opening
- Minimal retraction of normal brain tissue
- Trans-sulcal dissection
- Internal decompression
- Ultrasonic aspirator
- Bipolar coagulation
- Entering into the plane between the tumour and normal tissue
- Haemostasis

Patient selection is an important factor, as all cases do not require the use of navigation to locate the lesion.

Imaging

CT and MRI scans are obtained as three-dimensional volumetric databases, even though they are displayed as two-dimensional slices along an axis. The images contain within themselves a coordinate system conferred by the scanner during the acquisition, which defines a temporary address for each point in that imaging volume. To utilise these medical images, a quantitative relationship has to be established on a point-by-point basis between the information in the images and the physical space.

Surface reference markings that are usually external adhesive markers (called fiducials) are placed at various points to cover a wide area of the scalp and imaging is done with either CT or MRI. Additional contrast-enhanced studies may have to be performed, depending on the type of lesion being delineated. Fine 1–2 mm slices on the CT may also be required to increase the accuracy. These images are recorded on digital media in the DICOM format.

The fiducials are placed so that they cover a wide area, they should also be multiple, not linear and placed in relatively immobile scalp regions. Other imaging modalities such as fMRI and PET scans can also be performed if required. The present generation systems do not require external fiducials and various surface landmarks can be utilised for registration.

Once the imaging has been completed, the data is transferred to the intra-operative guidance computer. Prior to registration, the surgeon analyses the image data to decide the location, size and type of scalp flap, which would be planned. The ideal location for a burr hole and biopsy would be over a gyrus, and away from any vessels. The surgeon's plan can be recorded and used following the registration.

Patient registration is then performed. The patient's head is rigidly fixed on the table with either a Mayfield or a Sugita frame. A reference star is attached and the position of this star cannot be changed throughout the procedure (Figs 16 and 17). Registration involves placing the points in one image volume (patient's fiducials) onto the points of another volume (images taken pre-operatively). The fiducials in principle act like the picket fence target in frame-based systems and these are entered into the operating room space.

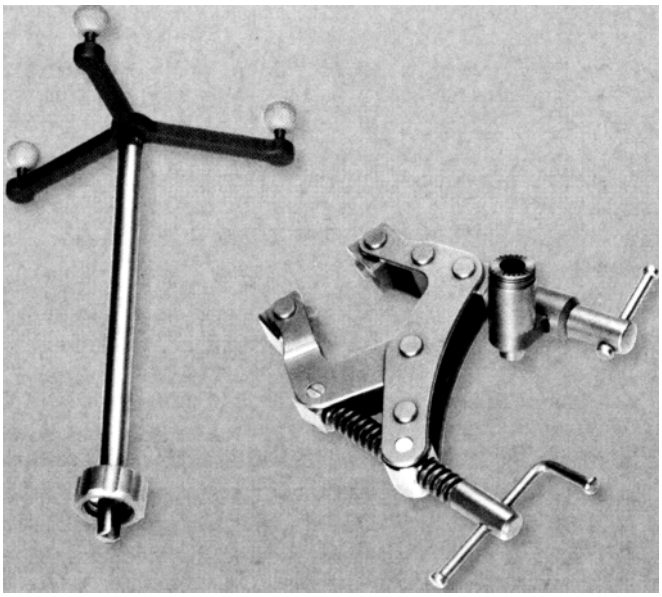

Fig. 16: Mayfield adapter with reference star

Fig. 18: Brain Lab Infrared optic triangulator
(Courtesy: Max Super Specialty Hospital, Delhi)

The different methods of registration include:

- Point-based
  - Intrinsic
  - Extrinsic
  - Non-rigid fiducials
  - Rigid fiducials or a stereotactic frame
- Curve and surface methods
- Moment and principle axis
- Correlation methods
- Interactive
- Atlas

We commonly use the point based systems or the curve and surface methods, as the others are unable to register images in physical space. Either the fiducials are brought into contact with a registration device or, in the newer machines, a laser light scans on the surface contours of various points (Z touch), which is picked up by the light emitting diode detector and correlates these points with the image dataset which has been transferred to the workstation.

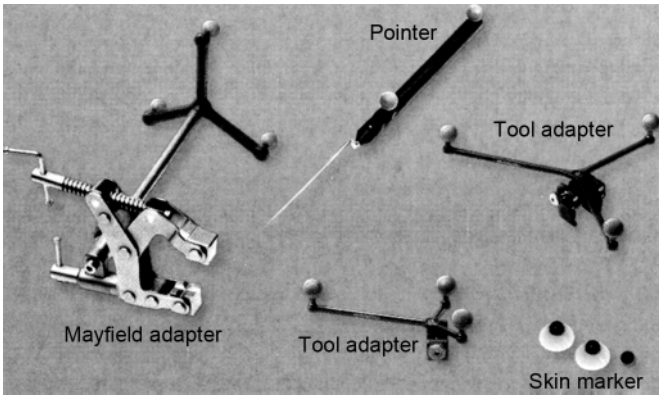

Fig. 17: Mayfield adapter

The device, which enables us to acquire these points, is known as the interactive localising device or the ILD (Fig. 17). These devices may either be linked or non-linked. Linked systems began with the stereotactic aiming arc, active robotic arms, passive articulated arms, intra-operative MRI and CT. Non-linked devices include sonic triangulators, infrared light emitting diode (LED) optic triangulation (Fig. 18), magnetic field deflection and gyroscopes.

Once the registration has been completed, the next step would be to visualise the approach and underlying structures with the help of the navigating pointer. The margins of the lesion can be defined and its relation to the scalp flap delineated. The depth of the lesion can be measured from the surface, using a virtual probe.

Disadvantages

- It is not in real-time
- Inaccuracies may occur due to brain shift
- Increased operating time
- Per-operative (pre-operative?) imaging is mandatory

Uses

- Glioma resection and localisation
- Deep seated tumour localisation
- Drainage of cysts and abscesses
- Placement of a reservoir for chemotherapy
- Surgery for epilepsy[27]
- Guidance to the ventricles

BRAIN SUITE: (INTRA-OPERATIVE MAGNETIC RESONANCE IMAGING AND REAL-TIME NEURO-NAVIGATION)

The concept of the integrated operating room was first thought of in 1991, as a collaborative effort between

GE systems and the Department of Radiology and Neurosurgery at Harvard.[1] Intraoperative MR imaging is also known as 'MRT' or magnetic resonance therapy. The prototype system was installed in 1994 and was designed to perform real time imaging, while neurosurgical procedures were going on. It was first used in 1995, with the double-doughnut scanner,[4] only for intra-operative use. Just as the microscope changed the scale of dimensions of the operating field, the intra-operative MRI in the operating room has expanded the surgeon's view from 2D to 3D. It has given the surgeon an opportunity to look beyond the exposed surface and enabled clear visualisation, not only of the operational field but also operational volume.

The Erlangen concept was developed by Robert Fahlbusch with the assistance of Siemens and Carl-Zeiss.[3,13,17,55,57] The operating room and the radiofrequency shielded MRI room were different, as MR compatible instruments were required for performing all aspects of micro-neurosurgery. The images from the MRI were transferred to navigation computers and surgery performed. The initial field strengths were 0.5 T and at present 1.5 T magnets are used intra-operatively.

The development of active shielding of superconducting magnets enables integration of surgery in the fringe fields with high field MRI.[48] A high field MRI may not only improve the quality of the intra-operative images, but also adds the ability to perform functional MRIs, diffusion weighted imaging and MR spectroscopy.[30] The operating theatre has to be large enough to accommodate the equipment, which includes all the accessories for navigation, as well as microsurgical work. The use of ferromagnetic materials is to be avoided and non-ferromagnetic materials like aluminium, titanium and ceramics can be used. All equipment has to be compatible with MRI. Anaesthesia and monitoring equipment has also been redesigned for the operative environment.[51]

Intra-operative MRI has a wide range of applications for the surgeon:

- Gliomas resection
- Pituitary tumour
- Complicated tumour resection
- Epilepsy surgery
- Intracranial cyst surgery
- Biopsy with and without a frame
- Catheter placement
- Vascular surgery
- Functional imaging
- Diffusion tensor imaging

Equipment and Theatre Set-Up

At the Max Institute of Neurosciences, Delhi, a Siemens 1.5 T MRI scanner is placed in an RF shielded room (Fig. 19). The scanner consists of a superconductive active shielded magnet with a length of 160 cm and an inner bore diameter of 60 cm, equipped with a gradient system with field strength of up to 40 mT/m. A specially designed rotating surgical MRI table has been adapted to the scanner for intra-operative patient transportation and for imaging. The principal surgical position is at 160 degree with the patient's head at the 5-Gauss line. Once the rotating mechanism is locked, the height of the table, the angle of tilt, and the lateral tilt can be adjusted by remote control. The rotation of the table axis and turning the table into the axis of the scanner has to be done manually. The ventilator is MRI compatible and MRI-compatible monitoring equipment is used for maintenance of anaesthesia. The monitoring data is transferred to a remote display, which allows continuous monitoring during scanning from outside of the RF-shielded operating room, with a wireless 2.4 GHz connection. Three infusion pumps are shielded in an MRI-compatible carrier for continuous infusion of drugs. The anaesthesia equipment is located outside the 200 Gauss line.[48] Anaesthesia gas inlets and compressed air for surgical drills are integrated in the wall of the RF room. Service outlets and sockets are connected to different electrical circuits, so that selected circuits could be switched off from a switchboard in the MRI control room, to prevent artefacts generated by individual devices. The ceiling outlet for laminar airflow is located above the main operating table. The laminar airflow output is surrounded by a band of fluorescent lamps for optimal illumination. For scanning, the illumination could be turned off from the MRI control room. The entire operating theatre has MRI-compatible spot lighting. Two ceiling-mounted surgical lamps are installed at the main surgical position. Both the 5 Gauss and 200 Gauss lines are marked on the floor. The latter also is marked by a raised stainless steel strip as a mechanical threshold. All equipment not completely MRI compatible, such as the navigation microscope and the height-adjustable surgeon's chair, are secured to the wall of the RF room mechanically as a safety precaution.

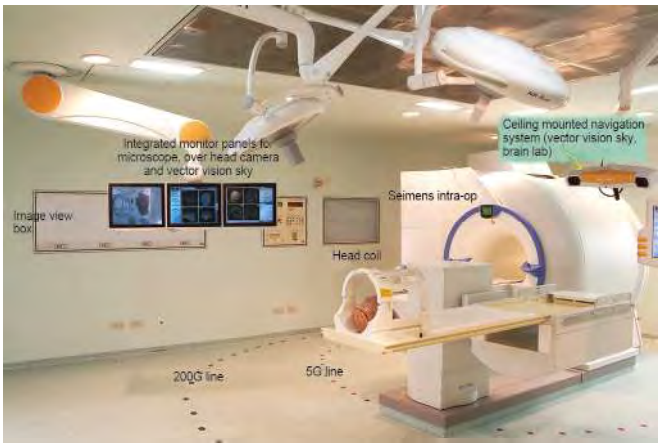

Fig. 19: Brain SUITE iMRI: At Max Institute of Neurosciences, New Delhi (Courtesy: Dr AN Jha)

Benefits of the Intra-Operative Magnetic Resonance Imaging

High field MRI has a number of advantages, such as instant real time feedback in the OR, superior image quality and

acquisition time and advanced MR sequences. Data can be incorporated into decision-making at the time of surgery.

It has the potential for unlimited research and the ability to drive new imaging techniques. Also important are the improved medical outcomes with the use of intra-operative MRI, shorter hospitalisation, and better and faster procedures with fewer complications. Certain economic and practical barriers impede the use of intra-operative MRI, but with increased volumes the cost efficacy barrier can be overcome after looking at the benefits.

MRI guided procedures are a collaborative effort between the neurosurgeons, neuroanaesthetists, radiologists, MR technologists, nurses and engineers and this collaboration is both essential for scientific growth, as well as having no glitches while performing surgery.

Future Developments of Intra-Operative Magnetic Resonance Imaging[23]

- Full patient access during the surgical procedure
- No need to move either the patient or the magnet
- Highest image quality with reduced acquisition time
- Ergonomics that incur no delays for serial or continuous scanning
- Integration of all pre-operative and intra-operative imaging data for interactive navigation
- With the introduction of high field MR systems intra-operative diffusion imaging can demonstrate early ischaemic damage during procedures and can be used to monitor vascular procedures[63]
- Diffusion MRIs can be complemented with perfusion MRIs and surgery and embolisation of AVMs will be made safer by keeping an eye on blood flow, while the blood vessels are being manipulated.
- In aneurysm surgery, 3D visualisation can help identify the position of the clips and their relation to the neck of the aneurysm.[63]

Neuronavigation

The Zeiss Opmi Pentero microscope which is floor mounted on wheels, in combination with a ceiling mounted navigation system (Vector vision sky—Brain lab) which are optimally integrated, are used. The initial sequencing protocol may be standard T1WI, T2WI and other sequences depending on what is specifically required. Functional data and magnetoencephalography, which is obtained a day or two prior to surgery, can be incorporated with the anatomical data registered in the sequences.[16,35,36] fMRI and magnetoencephalography data is used simultaneously to identify eloquent cortical areas.

iMRI Procedure

A four point head holder made of glass fibre with reinforced plastic is integrated into the common system circular head coil used for craniotomy procedures. The upper part of the head coil is sterilised using formalin tablets. Sterile adapters are fixed onto the lower part of the head coil, ensuring sterile draping. This enables variable positioning, except for the sitting position. For imaging during surgery, the head is covered with sterile drapes and the upper head coil is placed on top of the head and imaging done according to the centre protocol and requirements. The surgical strategies that can be employed during the procedure are complete resection and removal in the group of patients whose tumours are to be entirely resected,[37] further but partial removal in the group of patients in whom the tumour was unlikely to have been completely resected and in whom further resection seems to be possible, even though infiltrating and near eloquent areas.

The slice positions of every sequence are recorded to correlate images at various points during the surgery. The data for tumours is analysed to assess residual tumour volume.

Once the patient has been induced and the head fixed onto the frame, the first set of intra-operative MRI images are taken (Fig. 20). Once that is done the patient is manually shifted on the swivel operating table, to the operating position at the 5G line. The reference arc is fixed on the head fixation device and, using the laser pointer (Z-touch), surface landmark registration is performed. Once the system has registered multiple points, it verifies the accuracy and, if this is good, one can proceed with the surgery. Using the navigating pointer, the margins of the tumour can be identified (Figs 21 and 22) and the location of the scalp flap can be marked. The next steps are the routine surgical steps which include the craniotomy and dural opening. The location of the cortical incision and the surgical trajectory can all be planned at the time of surgery, with the help of the navigating tools. Two illustrative cases will be described, in one where navigation has been used during tumour resection and the other for preserving the functional speech cortical area.

Case 1: A 46-year-old male presented to our Institute in May 2006 with symptoms of memory loss for recent events, inability to concentrate on tasks, altered behaviour and inattention for about 6 months, followed by

Fig. 20: The patient being positioned in the gantry for the first set of scans.

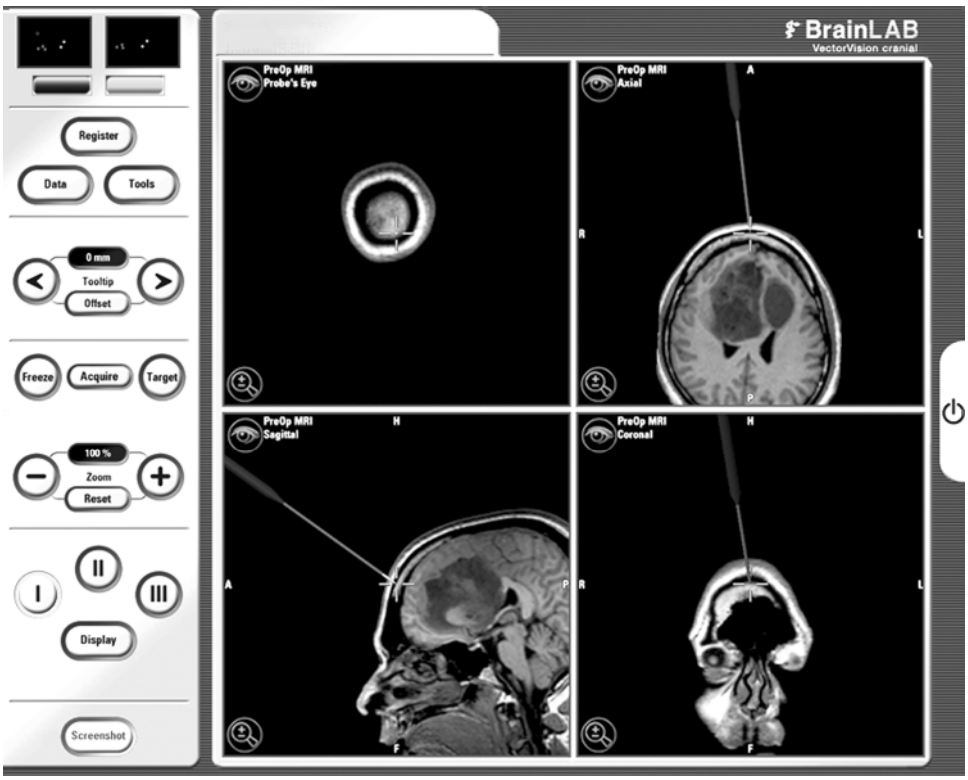

Fig. 21: Locating the margins of the skin and bone flap

urinary incontinence for 2 weeks. An MRI was done which revealed a butterfly corpus callosum glioma with the left side component being cystic and the right being solid. We decided to use intra-operative imaging and navigation to safely and accurately help us in maximising tumour resection with a minimal deficit to the patient.

The patient was induced, his head fixed onto the MRI table and the first set of intra-operative images carried

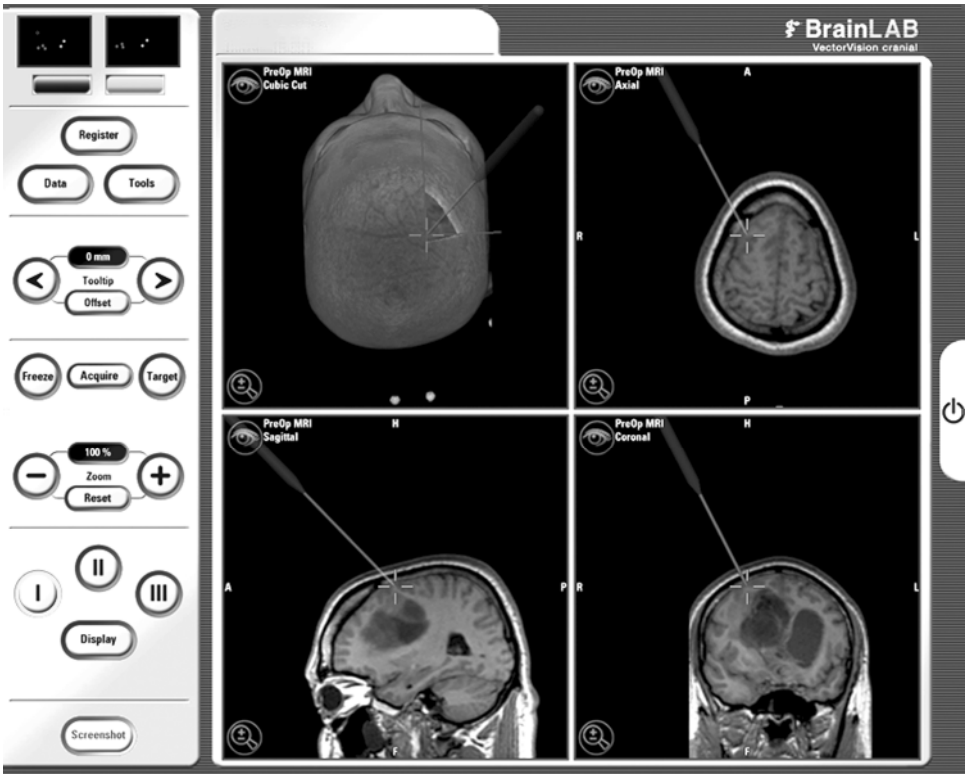

Fig. 22: Locating the margins of the skin and bone flap

out. Surface registration was then performed using the laser pointer (Z-touch) and the limits of the scalp flap marked (Figs 21 and 22). A bifrontal flap and craniotomy was performed and the tumour was approached from the right side, at its closest point to the surface, which was located with the navigation pointer. It did not have a well defined margin. It was greyish white, soft and minimally vascular and following a good decompression, an MRI was done to assess the degree of resection, as well as to acquire new sets of images so as to compensate for brain shift[15,34] (Figs 23 and 24).

The navigation tool was used to identify the trajectory into the cyst cavity and following its decompression, the second MRI revealed residual tumour (Figs 24 to 26). Further resection was then performed and to avoid damage to the ACA's the entire tumour was not chased. Closure was then performed and the final MRI revealing good tumour resection (Fig. 27) in concordance with our pre-operative plan.

Case 2: A 45-year-old gentleman was operated upon in 2000 at a Cancer Hospital for a left frontal oligodendroglioma grade 2, after which he had been followed-up with regular MRI's. His last MRI done in April 2006 revealed an increase in the size of the tumour. He had no symptoms and on examination had no deficits. His speech was intact and we decided to get a functional MRI pre-operatively and utilise these images by integrating them with the intra-operative images in order to protect the speech area during tumour resection. The intra-operative images taken were fused with the pre-operative fMRI, as shown in Figures 28 and 29.

The area in pink (Fig. 28) is the entire tumour volume and the yellow is the speech area, which is marked out by the fMRI done prior to surgery. That is the area which has to be preserved during surgery and it is very easy to get lost in tumour resection and attempt a total resection, giving the patient a permanent speech deficit. Once the images are fused we verify a good fusion by checking the overlap of the margins of the present MRI to the prior one; this is an automated process done by the computer. It selects and matches point to point targets on the images, to fuse them and the accuracy is finally checked manually by the surgeon (Fig. 28).

Once this is done the surgery is started and a craniotomy over the desired limits set out by the surgeon is performed. Using navigation, the tumour resection is begun away from the speech area as seen in Figures 29 and 30. Following a significant resection, we decided to repeat an intra-operative MRI. This was then fused on the previous data sets showing the degree of resection, remaining volume and the relation to the speech area.

The integration of the various components allows the surgeon to view the tumour, as well as speech area margins by the process of image injection. The area on which the surgeon is focusing is calculated by the navigation system and is projected onto their images as the blue circle as seen in Figure 31. Some intra-operative images are shown, as seen in Figures 32 to 36. It is difficult to identify the speech area without the help of navigation. The surgeon may be aggressive in resecting a large quantity of the tumour but cause a permanent speech deficit, making the quality of life of the patient very poor.

Neuronavigation is thus an aid to 3D visualisation of the object, entry and planning of surgical treatment. The ability to identify intra-operative swelling, brain shifts, resection margins and volumes and adjacent functional areas makes intra-operative MRI a useful adjunct to surgery. It contributes to greater tumour volume resection in gliomas.[6,49,52] The ideal treatment for low-grade gliomas is complete resection and this is an ideal modality to achieve a high cure rate.

One of the advantages of intra-operative MRI in guiding procedures, such as brain biopsy, is that it can definitively show when the biopsy needle is in the lesion, which guarantees success in obtaining a representative specimen. The ability to repeat images at close intervals enables the easy identification of bleeding.

Intra-operative MRI guided surgery is at present superior to any form of neuronavigation system, having the potential to acquire spectroscopic and angiographic data, which could lead to different surgical techniques and surgical goals. It has the ability to compensate for brain shifts, which will occur due to CSF loss, diuretics or tumour/brain being resected and is accurate. The process of updating these images enables a study of these shifts and their continuous monitoring during tumour resection. Mapping of motor and other functional areas helps in avoiding of these areas and prevent permanent neurological deficits.

Debate still exists on the degree of tumour resection necessary for low and high-grade lesions.[5,37] The recurrence of metastatic lesions is most commonly at their resection site. Could extended resections with the help of real-time intra-operative imaging reduce these recurrences? Brain swelling at the time of surgery can be immediately evaluated with immediate scanning and therapy guided towards its correction.

NAVIGATION IN SPINE SURGERY

Spine surgery also has areas where the surgeon is not completely oriented to the complex anatomy of the region and it is here that computer-aided image guidance during surgery plays a big role.[25,28] The spine surgeon's orientation to the non-visualised anatomy has taken a turn-around with crisp three-dimensional images locating the various landmarks.

Many of the surgical techniques, involving spinal surgery, require the precise spatial orientation of structures not in the visual field. In addition to this, the extent of tumour removal and reconstruction, following this by placing pedicle screws at the thoracic, lumbar and sacral spine, needs 'visualisation' of the unexposed structures.

Fluoroscopy has been the conventional guide for the surgeon in these situations, the drawback being that it gives us the trajectories in two dimensions and the surgeon has to extrapolate the third dimension and proceed. Although the lateral view (Fig. 37) may be easy to interpret, the AP view makes it difficult to estimate the depth at which one needs to work. This so called 'dead reckoning' can lead to varying degrees of inaccuracy when doing instrumentation at various spinal levels.[24] Utilising routine radiography to place pedicle screws has been shown to be unreliable at the lumbosacral level with penetration of the cortex ranging from 21% to 31%.[18,19,58]

The principles of image guided navigation for spine surgery remain the same as that for the cranial component, with regards to a number of components. The components which are common to both are the image processing workstation interfaced with an optical infrared localiser. The optical localiser can either be the source of infrared light which is reflected by the instruments back to the camera or can track infrared light, emitted by the LED. The computer workstation then utilises this information to calculate the precise location of the instrument in the surgical field, as well as the location of the specific anatomical target in relation to the instrument resting on it.

Prior to spinal fixation, a pre-operative CT scan of the various levels has to be performed. The images should be a three-dimensional volume acquisition of a continuous dataset with slices 1–2 mm thick. MRI data images may also be used and this data is transferred to the workstation via a CD format.

The application of navigation to spine surgery requires that fixed bony landmarks are utilisded as the fiducial frames of reference. Two separate registration techniques can be harnessed, while using spinal navigation.

The first would be the 'paired point registration' technique where a series of points on the CT or MRI imaging datasets are pre-selected and, on exposing the spine, fixed bony points are selected. Any intra-operative landmarks that can be easily identified, along with its corresponding radiological counterpart, are the reference points for further image-guided navigational projections. The best and easiest would be the tips of the spinous processes and the transverse process, at the levels at which instrumentation is to be performed. Alternatively, other bony landmarks, such as osteophytes or the facet joint can be used. Registration is then performed prior to any surgical decompression or manipulation (Fig. 38), thus preserving the anatomical landmarks and facilitating an easy and accurate registration process.[25] Three separate points are required for registration.

Alternatively, a second technique called 'surface mapping' can be used for registration. Here, multiple non-discreet points on the exposed and debrided surface of the spine, within the surgical field, are selected. No pre-selection of points from the imaging dataset are required and to increase the accuracy of this technique, a greater number of points are required from both the dataset and the surgical field. The positional information of these points is transferred to the workstation and this is used to create a topographic map and match it to the imaging dataset.[40] For this method, about 10–15 mins is required, whereas, for the paired point-based technique only 10–15 sec are required. This can prolong the duration of surgery.

Once the registration has been performed, a spatial relationship has been processed between the surgical space and the image space. Movement of the patient

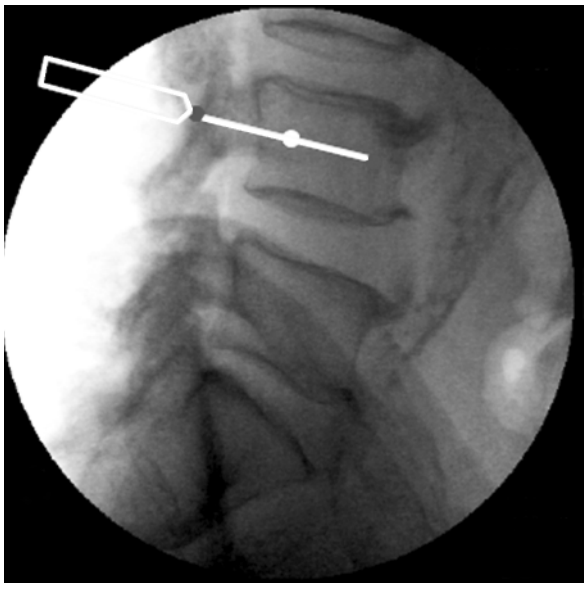

Fig. 37: Lateral view pedicle screw trajectory

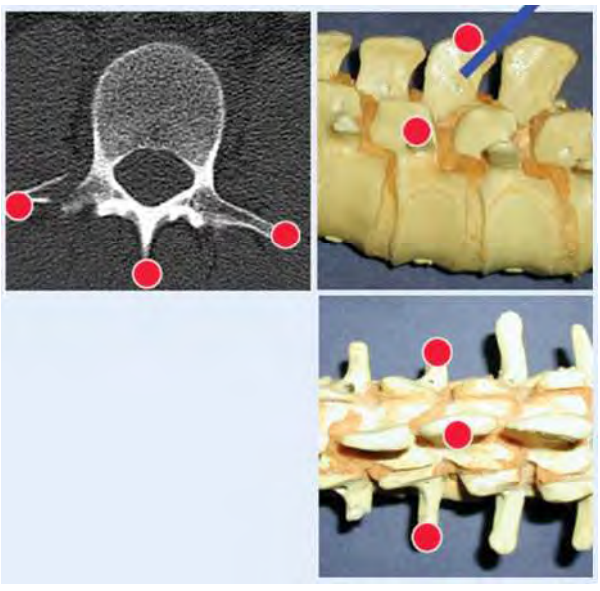

Fig. 38: Registration performed prior to any surgical decompression or manipulation

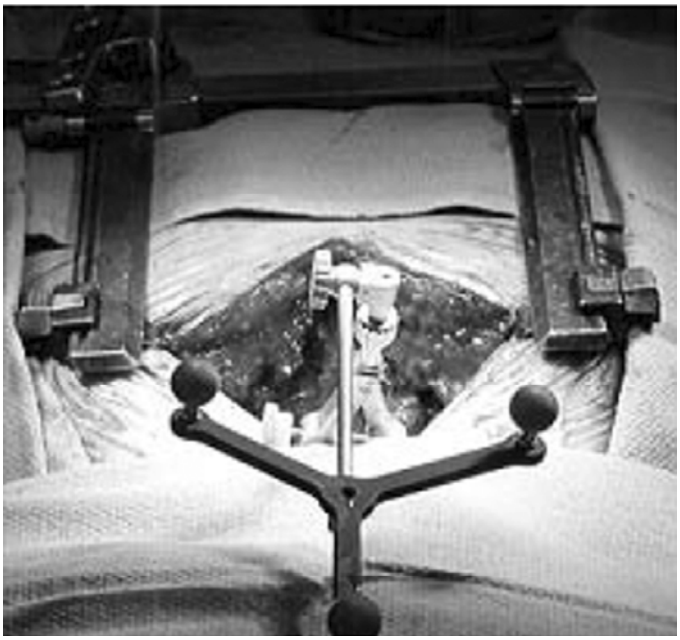

Fig. 39: LED attached to the spine

Fig. 40: Pedicle screw fixation and spinal stabilisation

following this will cause spatial distortion and navigation errors. This is usually minimised by using a spinal tracking device, consisting of separate LED or passive reflectors, which are attached to the spine (Fig. 39). This frame can be continuously tracked by the camera and any change in position will alert the navigation system, thus maintaining the accuracy of the registration and eliminating the need for redoing the entire process.

Disadvantages of the tracking device are:

- It comes in the way of the surgical field
- It should always be in the line of site of the camera
- Additional surgical time is needed for its attachment.

Sometimes, the tracking system could be avoided but absolute care has to be taken, to avoid leaning on the patient, changing the position of the table and respiration of the patient.

Clinical Applications of Spinal Navigation

- Metastatic spinal tumours can produce varying degree of spinal instability and cord compression, extending into the paraspinal region and at times encroaching upon the abdominal or thoracic spaces. Approaching the tumour through the posterior or the posterolateral route makes visualisation of its anterior limits and extent difficult and could result in damage to the adjacent soft tissue structures. Optimised excision with a minimum chance of soft tissue damage is aided by navigation
- Pedicle screw fixation and spinal stabilisation,[20, 25] for both tumour and non-neoplastic pathologies, such as spondylolisthesis is another important use (Figs 40 and 41). This prevents the chance of injury to the nerve roots and neurological damage and optimises proper screw placement.

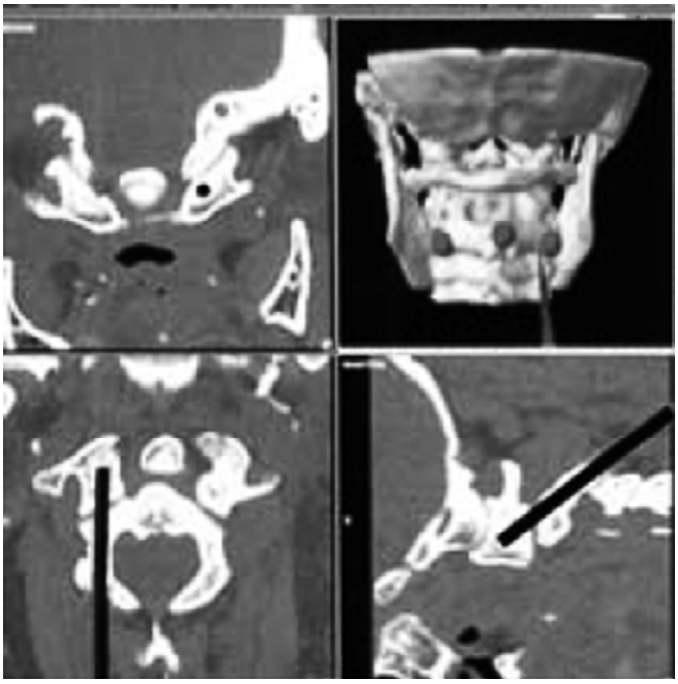

Fig. 41: Pedicle screw fixation and spinal stabilisation

- Transarticular screw fixation at C1 to 2[59] is another very important use, where navigation helps identify the position of the vertebral artery, in relation to the screws being placed and the small space being utilised.
- This can also be used for transoral decompression of the odontoid.[59]
- To fix pedicle screws at the thoracic level.[61]
- Anterior thoracolumbar decompression and fusion procedures
- Anterior screw fixation for odontoid fractures
- Cervical corpectomy and resection of cervical neoplasms via the posterior approach.

Technique

1. Standard exposure of the level to be instrumented is performed and this can be confirmed with the help of conventional fluoroscopy
2. Lateral or AP radiographs can be used to confirm this
3. The computer workstation and the camera have to be appropriately positioned, so that they can be visualised by the surgeon and optimise continuous image input to the camera
4. The infrared camera detector is usually mounted at the foot end of the table and directed rostrally, if surgery is to be performed on the dorsal or lumbosacral spine
5. In case the cervical spine is to be operated on, it would be more rostral or at the side of the table and downwards and rostral to get best image detection
6. Registration by the paired point technique with a minimum of 3 points should be done, prior to any manipulation of the bony anatomy. Pre-selected image points and the corresponding bony landmarks are selected and registered
7. The workstation calculates and gives the accuracy of registration
8. Verify the accuracy by using a probe to check bony landmarks with corresponding images, by watching the location of the cursor, as well as the line of trajectory
9. If this is accurate, proceed with surgery and, if not, re-register the points
10. Depending on the type of procedure, the pedicles, entry point of the screws, trajectory and depth, as well as depth of resection and limits can be accurately localised with the help of navigation and the surgical procedure continued as per standard techniques

For each additional level of instrumentation, re-registration of points can be performed to improve the accuracy; this is called the 'segmental technique'.

Increased precision is a great benefit in the thoracic spine, where the pedicle diameter is small and the risk of neural injury due to malposition greater and more devastating.

Trans-articular screw fixation of C1 to C2 requires passage through the pars interarticularis of C2, across the facet joint and into the C1 lateral mass.

The risks include:

- Vertebral artery injury if the screw is too lateral or anterior
- Spinal cord injury if the screw is placed too medially
- Failure to engage the lateral mass of C1 if the trajectory is too anterior.

Insertion on either side is contraindicated if the pars are too narrow. Selection of the entry site of the screw requires an understanding of the complex atlantoaxial anatomy.

The use of navigation in transoral surgery has its limitations, as readily available registration points are not present and in these cases fiducial markers may be used. Typically, two points on the mastoid processes and two points on the lateral orbital margins are taken for registration. The head is usually fixed on a three-pin head holder.

Pitfalls of Image Guided Surgery

- The registration process is critical for accuracy and best outcomes
- It is not a replacement of the surgeon's own familiarity with spinal anatomy and technique
- It merely serves to confirm estimation of the non-exposed anatomy
- System variations for intra-operative functionality should be factored in
- It takes a longer duration and OT time due to the learning curve and registration process.

210 Endoscopy in Brain Tumour Surgery

Manas Kumar Panigrahi

INTRODUCTION

Endoscopic techniques have revolutionised the practice of surgery in a number of specialties, which is evident by the impact of endoscopy in otolaryngology, laparoscopy in abdominal surgery, arthroscopy in orthopaedics and thoracoscopy in cardiothoracic surgery. The current popularity of endoscopic neurosurgery is at least in part related to its ability to permit invasive therapy with little disruption of neural structures giving rise to the term "*minimally invasive neurosurgery*".[56,59] Minimally invasive neurosurgery once relegated to the domain of science fiction is now an established discipline with an expanding role paralleling the explosive advances in endoscopic optics and miniaturisation. As the field of neuroendoscopy continues to grow, the indications for this type of intervention are being defined[14] too are its limitations. Endoscopes have been used in neurosurgery since the beginning of this century, primarily within the ventricular system to treat hydrocephalus and assortment of small tumours. Recently, the application of the endoscope outside the ventricle, in the subarachnoid space and spine, is also getting popularised. This chapter reviews the history and evolution of neuroendoscopy from the early part of the 20th century to the current state of art and its increasing utility in the management of brain tumours.

EARLY HISTORY

Max Nitze is credited with designing the first modern endoscope in 1879,[68] which was a crude device, composed of a series of lenses with an illumination source at the tip. L'Espinasse, in 1910, performed the first neurosurgical endoscopic procedure, when he performed fulguration of the choroid plexus in two infants with hydrocephalus using a cystoscope.[72] Twelve years later, in 1922, Walter Dandy described the use of an endoscope to perform choroid plexectomy; however, it was ultimately unsuccessful.

In 1923, Mixter performed the first successful endoscopic third ventriculostomy (ETV) by using a urethroscope in a 9-month-old girl with obstructive hydrocephalus. Mixter's report,[72] however, went largely unnoticed, possibly because of the cumbersome size of his instruments and the poor illumination that they offered.

In 1932, Dandy again reported the use of an endoscope for choroid plexectomy. This time the procedure was successful, but he found the results to be only comparable to those of open choroid plexectomy.[1] After Mixter's paper in 1923, there were no reports of ETV until 1935, when Scarff, described his initial results using a novel endoscope equipped with a mobile cauterising electrode, an irrigation system that prevented collapse of the ventricles, and a movable operating tip that could be used to perforate the floor of the third ventricle. He achieved dramatic results: a 3 cm decrease in head circumference 6 weeks post-operatively. However, the ventriculostomy eventually failed and the patient died. A healed scar over the ventriculostomy site was found at autopsy. Scarff noted, "This case demonstrates clearly the feasibility of the procedure, but points out also the necessity of enlarging the opening beyond a mere puncture wound."

The field of neuroendoscopy began with great promise; this new modality held the potential to allow neurosurgeons to get a magnified view of the anatomical structures within the ventricular system. In reality, however, the technology available to the pioneers of neuroendoscopy was far too primitive for these purposes.[1,72] Illumination and magnification were the major problem. Despite the numerous reports that demonstrated the potential utility of neuroendoscopy, the field never gained favour in general neurosurgical practice because of these technical limitations.

DECLINE OF NEUROENDOSCOPY—ADVENT OF VENTRICULAR SHUNTS AND MICRONEUROSURGERY

Although Fay, Grant, Putnam, Scarff and others continued to perform neuroendoscopic procedures, instrumentation limitations and significantly high morbidity and mortality curbed its use by most neurosurgeons. Furthermore, the report by Nulsen and Spitz[53] in 1952 detailing the treatment of hydrocephalus by using ventricular shunt placement marked the beginning of the era of ventricular cerebrospinal fluid (CSF) shunting and the end of the initial era of neuroendoscopy. In addition, initial success rates for CSF shunts were promising and superior to those of other available treatments.[72] Soon, ventricular shunts became commonplace in the treatment of hydrocephalus and the need for intraventricular endoscopy and ETV lessened even more.

The birth of microneurosurgery in the 1960s[32] pushed endoscopy further into the background. The microscope addressed all of the deficiencies of neuroendoscopy, allowing neurosurgeons to perform operations deep within the brain and at the base of the skull with both adequate illumination and magnification. As microneurosurgery gained popularity, the use of endoscopy waned further.

REDISCOVERY OF NEUROENDOSCOPY

During the 1960s, reports of neuroendoscopic procedures in the literature became sparse. Nevertheless, it was during this period that scientists made a number of key technological advances that would pave the way for modern neuroendoscopy.

New Lens Type

In 1966, Hopkins and Storz developed a rigid endoscope that used a new type of lens, the SELFOC lens. Conventional lenses had a uniform refractive index, so the endoscopes required the careful placement of a series of relay and field lenses to construct an appropriate image, whereas the SELFOC lens used gradient index glass that had a refractive index that varied with the radial dimension of the lens.[44] This new technology essentially obviated the need for the relay lenses while preserving light transmission and creating a wider, effective field of vision.[7]

Invention of Charged Couple Devices

In 1969, George Smith and Willard Boyle invented the first charged couple devices (CCDs) at Bell Laboratories. The CCDs are solid-state devices, usually a silicon chip, which are capable of converting optical data into electrical current. The CCDs are ideal for use in low-light environments and are readily incorporated into the system's apparatus, resulting in both improved quality of the transmitted images and decreased size of the endoscopic systems.

Fibreoptics

Fibreoptic cables were first used in the 1950s and 1960s, and refined further in the 1970s. Fibreoptics allowed the light source to be separated from the rest of the endoscope.[69] Light can be emitted from the tip of the endoscope, without significant heating, through one set of cables, while specialised, coherently arranged cables can conduct images without a loss of luminescence.

These advances, which brought together brighter light sources and cameras with improved resolution, the two key components of any endoscope, were an important part of the rediscovery of neuroendoscopy. As these new technologies were incorporated into the modern endoscope, neurosurgeons began to reconsider the field of neuroendoscopy.

Although CSF shunting procedures had revolutionised the treatment of hydrocephalus, it brought with it the frustration associated with this procedure's complications. Even in modern series, the frequency of shunt malfunction and the long-term morbidity associated with it remains high.[39] The search for a better solution to the problem of hydrocephalus led neurosurgeons to investigate new treatments and to revisit old ones that existed before ventricular shunts. With the improved imaging capability of endoscopes, interest in ETV for the treatment of obstructive hydrocephalus was renewed and currently ETV is primarily used to treat obstructive hydrocephalus caused by benign aqueductal stenosis or compressive periaqueductal mass lesions like pineal tumours and tectal gliomas.

The success of neuroendoscopy in past few decades relied heavily on the success of ETV for the treatment of obstructive hydrocephalus. Now, however, the field of neuroendoscopy has extended itself beyond just ventriculostomy procedures and is being used for the treatment of various types of neurosurgically treatable disorders like intraventricular tumours, skull base tumours, craniosynostosis, degenerative spine disease, intracranial cysts and rare subtypes of hydrocephalus.

USES IN NEURO-ONCOLOGY

The use of endoscopy for the management of brain tumours has evolved from simply treating the associated hydrocephalus, to sampling of tumour tissue, to tumour resection. Fukushima and his colleagues,[25] in 1978, were the first to report the use of neuroendoscope for biopsy procedures in intraventricular tumours. The subsequent technical development, both of endoscopes and of an increasing range of dedicated instruments have expanded the scope of neuroendoscopy in both diagnostic and therapeutic roles.

Instruments

The modern era of neuroendoscopy has been driven by technology and many neurosurgeons have contributed to advances in instruments. Harold Hopkins, an English physicist, deserves greatest credit for laying the groundwork for the modern era of neuroendoscopy by developing optical innovations.[28]

In general, there are two classes of neuroendoscopes: (1) rigid and (2) flexible. Huw Griffith of Bristol, England, pioneered rigid neuroendoscopy in 1970s. Takanori Fukushima is credited with introducing flexible neuroendoscopy.[25] Rigid endoscopes (Fig. 1) have superior optics and working channels, but lack steerability. To overcome lack of manoeuvrability, angled rod lenses (0, 30, 70 and 120 degree) have been developed to look around corners. Flexible endoscopes (Fig. 2) have better manoeuvrability at the expense of a significant reduction in the amount of light transmitted and image clarity. Table 1 enumerates the advantages and disadvantages of both scopes.[69]

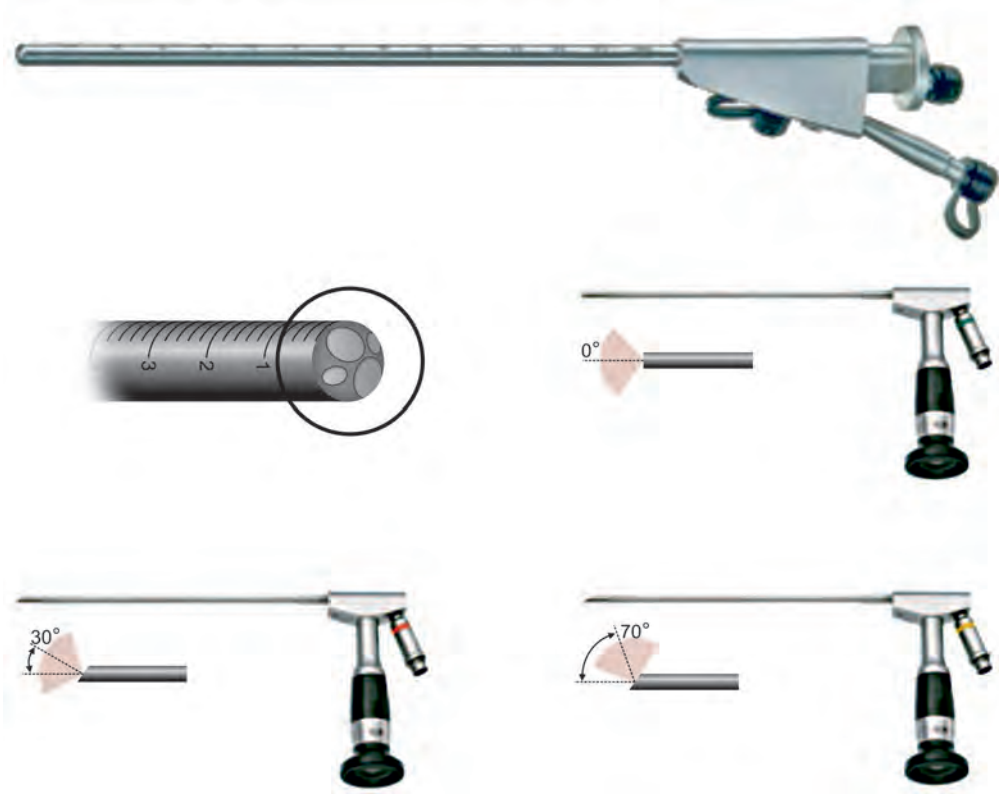

Fig. 1: Rigid endoscope 0, 30 and 70 degree

Although endoscopy can be performed with the operator looking directly through the eyepiece of the lens, it is customary to project the image on to a television monitor. This facilitates manipulation of the various microinstruments, enhances sterility and enables the entire operating team to view the procedure. The optical image is transmitted via a charged couple device microchip camera to a television monitor. Currently, two types of CCDs are in use: (1) single chip camera and (2) three-chip camera. Three chip cameras provide better picture quality; however, camera size is larger and it is expensive. Illumination is provided by a fibreoptic cable connected to a high intensity light source such as xenon. A real time record of the operation can be made on a videocassette and still photographs can be taken with a digitalised camera.

Fig. 2: Flexible endoscope

A variety of miniature instruments are required to perform therapeutic and diagnostic procedures through an endoscope.[55] These instruments can be introduced through working channels in the sheath of the endoscope. Continuous irrigation with warm lactated Ringer's solution can flow through a working channel, which aids in haemostasis in the event of minor venous bleeding and keeps the working field clear. It is essential to provide an escape port for the irrigation fluid

Table 1: Advantages and disadvantages of rigid and flexible scopes

	Rigid scopes	*Flexible scopes*
Advantage	Better image Higher resolution Wider view Better colour Better light transmission	Steerability
Disadvantage	Less manoeuvrable	Poor image Pixel granules Narrower view Less true colour Worse light Small working channel Limited selection of scopes and instruments

to prevent its accumulation in a closed system, which could lead to dangerous enlargement of the ventricles and elevation of the intracranial pressure.

The assortment of microinstruments available for procedures continues to increase. There are ingenious devices for cutting, grasping and sampling tissue. Flexible and rigid probes can be used to fenestrate membranes such as cyst walls, septum pellucidum or the floor of the third ventricle. Balloon catheters can be used to enlarge these fenestrations. Endoscope systems with multiple working channels permit the operator to use more than one instrument at the same time (Figs 3A and B).

Energy sources for endoscopic dissection include monopolar and bipolar coagulators and a number of fibreoptic lasers. Two lasers, which are most commonly used for neuroendoscopic procedures are neodymium doped yttrium aluminium garnet (Nd:YAG) laser and potassium titanyl phosphate (KTP) laser because of their ability to work through water and transmit through the miniature fibreoptic cables. CO_2 laser, commonly used in conjunction with operating microscopes, is not effective in endoscopic ventricular surgery because the CO_2 beam has a very long wavelength and is not transmissible through fluid. As Nd:YAG laser emits invisible light; it is aimed with a visible helium-neon pilot beam. Light emitted by the Nd:YAG laser is absorbed preferentially by pigmented tissue. Tissue that is poorly pigmented, such as ventricular wall and the whitish septum pellucidum, often require a high power setting for fenestration. The KTP laser emits visible green light and, therefore, a pilot-aiming beam is not necessary. The KTP laser produces less thermal injury than the Nd:YAG and can be a useful dissecting tool.

Neuroendoscopy can be done either free hand or using a rigid holder. The most commonly used holders are the pneumatic holder produced by Aesculap or Leyla retractor arms. Table 2 describes the advantages and disadvantages of the scope holder.[69]

Table 2: Advantages and disadvantages of the scope holder

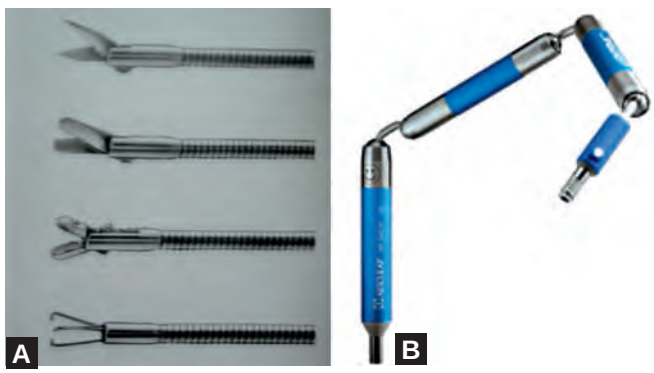
	Free hand	*Rigid holder*
Advantages	(1) More freedom of movement particularly when configuration needs to be frequently or continuously changed, e.g. tumour removal	(1) Surgeon can use both hands (2) Minimises accidental movements and tremor
Disadvantages	(1) More fatigue for surgeon (2) Risk of accidental movements	(1) More static (2) Inconvenient when frequent repositioning is needed

IMAGE-GUIDED ENDOSCOPY

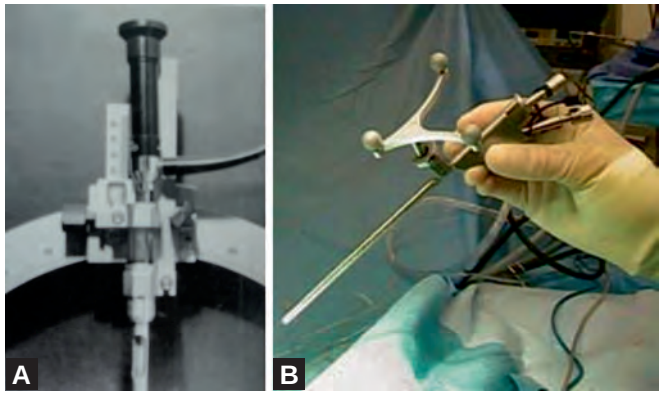
It may be difficult to cannulate the ventricle with freehand techniques to approach an intra-ventricular lesion endoscopically in the absence of hydrocephalus. Similarly, if the ventricles become loculated the endoscopist can easily get lost moving from one cyst compartment to another. In such cases, it is helpful to use the endoscope in combination with some type of guidance system which tracks the endoscope in three dimensions. A guidance system is also worthwhile for some endoscopic procedures conducted in the cerebral parenchyma or at the skull base.

Standard intra-operative C arm fluoroscopy can, on occasion, help to monitor the position of the tip of the endoscope. Ultrasound can provide more information about the location of the endoscope relative to intracranial structures.[42] In infants, an ultrasound probe can be placed directly on the open anterior fontanelle. In older patients, the probe can be placed at a burr hole or a small craniotomy. Small probes have been developed specifically for ultrasound-guided neuroendoscopy.

Stereotactic guidance systems can be combined with both rigid and flexible neuroendoscopes.[5,30] Standard frame based stereotaxy can be used to guide an endoscope to the proximity of a lesion within a small ventricle. The direct view provided by the endoscope lens offers little information as the instrument passes through the substance of the brain. It is helpful only after the ventricle has been entered and one can work within the large CSF space. Stereotaxy guides the endoscope to a ventricle in much the same way that special instruments guide a pilot to a runway in bad weather. Once the pilot gets close enough to the airfield, only he or she can use visual clues to aid in landing the plane. Another advantage of stereotactic guidance is that the frame can serve as a mount to support the endoscope. A limitation is that frame-based stereotaxy is not easily applicable to infants and young children and it is cumbersome and non-intuitive. Furthermore, when the time devoted to frame application and imaging studies is considered, frame stereotaxy may actually lengthen the overall procedure (Figs 4 and B).



Figs 3A and B: (A) Endoscopic microinstruments. (B) Unitrac (Aesculap) pneumatic endoscope holder



Figs 4A and B: (A) Endoscope mounted on stereotactic frame. (B) Frameless stereotaxy guided endoscopy

Recently, frameless stereotaxy has been used to guide the neuroendoscope.[19] The principle of frameless stereotaxy is to define a three-dimensional co-ordinate space for a pre-operative imaging modality and translate this to the three-dimensional co-ordinate space of the operative field. In frameless stereotaxy, a variety of three-dimensional digitisers have been substituted for the frame. These include articulated mechanical arms, sonic or optical digitisers and electromagnetic systems.[62] One limitation is the problem of brain shift, particularly following drainage of significant volumes of CSF or cyst fluid. Moreover, its use is restricted to using rigid endoscopes and the digitiser uses the same working endoscope port so that it must be removed to place instruments into this port.

Management of Ventricular Tumours and Cysts

Endoscopy can be used in tumour management for the following various purposes:

- Ventriculoscopy: inspection of ventricular walls for seedling and CSF sampling
- Relief of tumour associated hydrocephalus by ETV
- Tumour biopsy
- Tumour resection
- Endoscopy-assisted microneurosurgery

Ventriculoscopy

The prognosis of some primary intracranial tumours is dependent on the presence or absence of ependymal spread of tumour. Patients with primitive neuroectodermal tumours, for example, fall into the high-risk group rather than the low-risk group if there is evidence of spinal or ventricular ependymal seedling. Although MRI is reliable in the detection of ependymal tumour spread in most cases, some patients may have ependymal spread without radiological evidence.[22] Ventriculoscopy can be more sensitive than MRI with little added morbidity. Through a frontal or parietal burr hole, one can access the lateral ventricle, examine the surface, document any findings with colour photography, and even biopsy suspicious areas. This takes substantially less time than needed for an MRI examination. Furthermore, if present, definitive treatment of CSF obstruction can be achieved by either third ventriculostomy or tumour resection at the same sitting.

Endoscopic Third Ventriculostomy: Management of Tumour Associated Hydrocephalus

The risk of shunt complications and shunt failure is well documented and shunt-free outcome in management of hydrocephalus is always welcome, especially so in a patient with a tumour, in whom adjuvant therapy is proposed. Chemotherapy and neutropaenia are worrying enough without the additional concerns of the foreign body of a shunt.

An early report of successful ETV in children with posterior fossa tumours was from Chumas et al. in 1995.[16] DC MacArthur et al. (2002) found ETV successful as a long-term means of CSF diversion in 83% cases (55/66 cases) of tumour-related hydrocephalus.[46] Ray et al. (2005) achieved 69.8% (27/43) overall long-term success rate for ETV in similar patients with mean follow-up of 2 years.[60] However, Goh and Abbott (2000) described a similar series of 63 patients undergoing ETV as part of treatment of tumour-related hydrocephalus with rather different results; a disappointing 31 of their 63 (49%) required shunting over a mean follow-up period of 11.4 months. This compared unfavourably with their 15/43 (35%) rate for requirement of shunt following failed ETV in non-tumoural hydrocephalus, the difference just achieving statistical significance.[27]

Success rate of ETV for tumour-related hydrocephalus varies from 23 to 100% depending on the institution, definition of failure (resolution of clinical symptoms and radiological findings or shunt independence), indication and origin of hydrocephalus and follow-up period.[37,58,65]

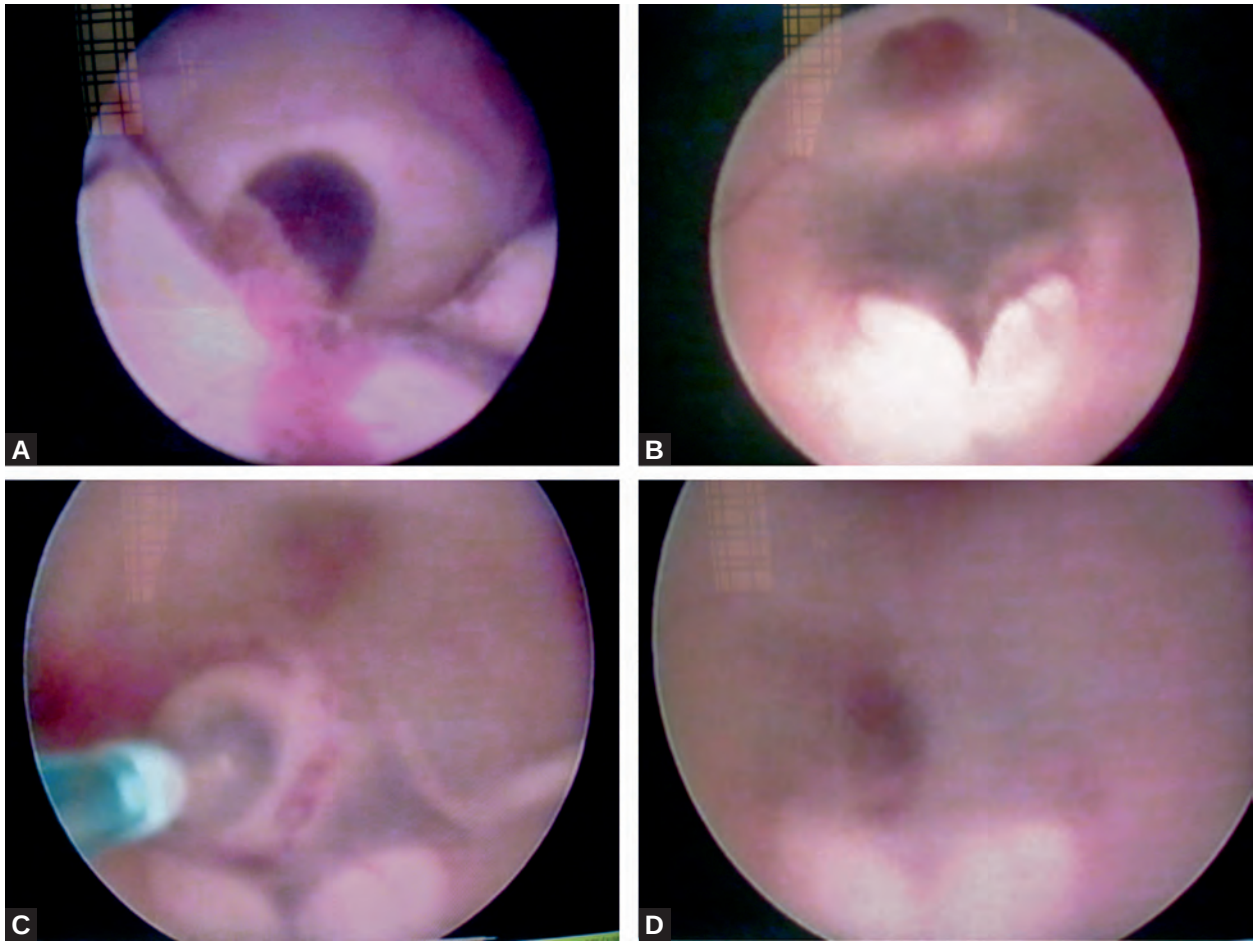
Ray et al.[60] found 100% success rate for ETV, when obstruction was at or around the aqueduct of Sylvius such as midbrain/tectal tumour, pineal region tumours or third ventricular tumour. Table 3 shows the relationship of the level of obstruction and success rate in the series of Ray et al. Hopf et al.[31] and Scarrow et al.[67] also found high success rates with ETV in patients with a space occupying lesion in the midbrain and pineal region. High success rate for such patients is due to open subarachnoid spaces and intact CSF absorption pathways. Despite these outstanding results, in a certain number of patients with ideal indications, the procedure may fail due to undetectable deficiency of CSF absorption at the level of the arachnoid villi or blockade of CSF flow from the third ventricle to the prepontine cistern by Lilliquist's membrane. Buxton et al.[12] stated that in order to achieve successful ETV not only must the floor of the third ventricle be opened but also Liliequist's membrane.

Posterior fossa and thalamic tumour associated hydrocephalus yielded a less favourable outcome following ETV. Other series have also found low success rate (0–63%) for such tumours.[12,31,37,67]

Table 3: Origin of hydrocephalus in 43 patients who underwent ETV[60]

Tumour location	*No. of pts.*	*No. of successful pts.*	*Success (%)*	*No. of procedure failed*	*No. of procedure abandoned*
Midbrain	4	4	100	0	0
Posterior fossa	9	4	44	5	0
Brainstem	14	11	79	3	0
Thalamus	6	4	67	0	2
Pineal	3	3	100	0	0
Third ventricle	2	2	100	0	0
Others	5	4	80	1	0
Total	43	32	74	9	2

Management of hydrocephalus associated with posterior fossa tumours has been a long-standing controversy. In the past, some authors advocated placement of a ventricular shunt before definitive resection because this decreased morbidity and mortality associated with tumour resection.[3,45,61] Currently, however, early surgery and the use of corticosteroids have brought down the morbidity and mortality with no need for pre-craniotomy shunt.[20,23] Use of ETV in patients with posterior fossa tumour has been reported before or after tumour resection and their successful outcome has been between 50% and 85%.[11,65,67] Some authors advocate ETV prior to resection in all cases. However, it was determined that only 15.5% of patients who undergo early and aggressive surgery require CSF diversion. Based on this finding, Ray et al. supported early surgery rather than early ETV followed by surgery and suggested ETV only for symptomatic patients after resection (Figs 5A to D).



Figs 5A to D: Steps of third ventriculostomy

There are a few precautions to be taken when performing ETV for hydrocephalus secondary to a tumour.[15]

1. In patients with tumours localised around the third ventricle, the ETV can be more challenging because of possible deformation of the third ventricle or tumour layering over the third ventricle floor, e.g. a pontine glioma may distort the floor of the third ventricle and displace the basilar artery forward so that the safe zone to penetrate the floor is narrowed. Only the blunt technique to create the stoma should be used in such cases.
2. If hydrocephalus resulting from tumour is of relatively acute onset, then floor of the third ventricle is often opaque and non-attenuated. This makes blind penetration more difficult and hazardous. It invariably requires a sharper technique without visualisation of the underlying neurovascular structures.
3. If ETV is to be performed simultaneously with tumour biopsy or resection, ETV is performed before tumour manipulation because of the expectation of some intraventricular haemorrhage and reduced image resolution after attempted tumour resection. With respect to an entry site, a trajectory is used that approximates a compromise between the two ideal trajectories for each procedure. The trajectory from a pre-coronal burr hole to the floor of the third ventricle is different from the path to the posterior third ventricle, although both must traverse the foramen of Monro. Using a rigid endoscope introduced through a standard pre-coronal burr hole is an ideal trajectory through the foramen of Monro for ETV but may require dangerous stretching of the periforaminal structures to look back at the pineal region. Pre-operative MRI may be used to solve this problem. By moving the burr hole more anteriorly one can gain access to both the anterior and the posterior third ventricle. This entry site is typically located 2–3 cm anterior to the coronal suture on the non-dominant side.

The ETV is a reasonable option to treat the secondary hydrocephalus before definitive treatment of the primary tumour. A CSF sample can be taken at the time of surgery and one can also explore the ventricle and take biopsies, if necessary. Importantly, ETV may be the definitive treatment if the obstruction is caused by a tumour that does not require removal such as a tectal plate tumour. The situations in which bilateral ventricular enlargement exists due to a tumour situated in the anterior third ventricle at the foramen of Monro, an endoscopic septostomy can eliminate the need for biventricular catheters or for CSF shunting altogether.

Secondary ETVs performed to relieve recurrent symptomatic hydrocephalus due to shunt malfunction were also found to be successful by Cinalli et al.[17] It has been suggested, however, that prior radiotherapy might have an adverse effect on outcome following ETV.[38]

Neuroendoscopic Biopsy

Endoscopic biopsy is well recognised as an acceptable or preferred technique for tumour sampling in patients with an intraventricular or paraventricular brain lesion.[25,26,46,50,58,63] There are definite advantages of endoscopic biopsy over stereotactic needle biopsy like:

- Direct visualisation of the tumour allows more accurate and safer sampling. A region for biopsy can be chosen under endoscopic vision, and vessels can be avoided.
- The specimen obtained is larger and not subjected to as much mechanical artefact. It does not need to be sucked through a needle or manipulated.
- Any resultant bleeding can be controlled by either coagulation or packing under direct visualisation.
- If the tumour is relatively avascular, it may be removed totally by endoscopic techniques.
- Other procedures can be performed at the same operation (e.g. ETV, septostomy).

Endoscopic biopsy of third ventricular tumours was first reported by Fukushima in 1973,[25] who used a flexible steerable ventriculofibreoscope that he had designed. Out of 37 patients whom he studied he took biopsy in 11 patients without any serious complications, but he was able to make a successful diagnosis in 6 only. In 4 cases of cystic tumour, he was able to perform endoscopic puncture and evacuation of the cyst. He chose not to take biopsy samples of pineal tumours because of concern about bleeding (Fig. 6).

Subsequently, both rigid and flexible endoscopes have been used to take samples from tumours in and around the third ventricle. Rigid endoscope has the advantage of superior optics of the rod lens system and working channels, which helps in obtaining a larger and better biopsy specimen. The flexible endoscope on the other hand facilitates work at more than one target site within the ventricular system via a single entry point and with less risk of injuring the brain in the course of manipulation. If there is difficulty in reaching the

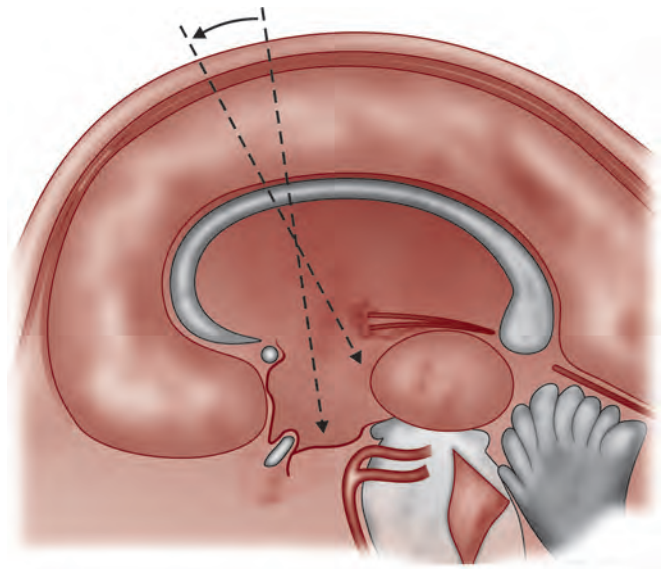


Fig. 6: Entry point for pineal tumour biopsy

posterior third ventricular lesion with a rigid endoscope one can substitute angled lenses or use a flexible endoscope for biopsy. Enrique Ferrer described a mother-daughter technique[4] in which rigid endoscope is used to perform the ETV and then a small flexible endoscope is introduced through either the rigid endoscope sheath or one of the working channels to perform tumour biopsy. Some authors have described use of stereotactic guidance. Apuzzo et al.[15] introduced a rigid endoscope through a stereotactic frame to visualise and sample a third ventricular craniopharyngioma and an ependymoma and to aspirate a colloid cyst without complications. Hellwig et al.[30] have reported using a flexible steerable endoscope in conjunction with a stereotactic frame to take biopsy samples of 22 midline cerebral tumours without any complications and a 100% success rate.

Recently, Veto et al.[24] reported a biportal technique for performing ETV and posterior third ventricle tumour biopsy. This method uses a standard coronal burr hole for ETV and a second anterior forehead burr hole for tumour biopsy. The use of two endoscopes allows independent visual control of each procedure, ensuring safe passage of each endoscope through the foramen of Monro as it is monitored by the other endoscope. A disadvantage of this technique is that it necessitates a second burr hole and corticectomy. Whereas multiple portals have become standard in laparoscopic procedures, they have a different significance in neurosurgery, because each corticectomy carries a small but real risk of injury to neural tissue. It's preferable to use a single high-resolution endoscope to perform both ETV and biopsy through a single burr hole.

Many factors including the surgical technique, the tumour type and the experience of the pathologist can influence the success of a diagnostic tumour biopsy procedure. Earlier series showed a diagnostic yield ranging from 52 to 63%. Recently, however, Pople et al.[58] and Souweidane et al.[50] have achieved a success rate of 90% and 96% respectively with 0% mortality and minimal morbidity. A small working channel and biopsy forceps size obviously significantly limits biopsy size. Paraventricular tumours tend to be subependymal and taking a biopsy not from the surface, but from the deeper tissues after incising the ependyma with the cutting diathermy can increase the yield of very small tissue samples. Diagnostic yield is most dependent on the ability to sample tissue rather than the histological interpretation.[50,63]

Surgical planning is critical for successful endoscopic tumour procedures. The most critical aspect is selecting an entry site that offers the most direct intraventricular, linear route to the target. This principle avoids undue torque on the cortical and intraventricular surface. A relatively anterior entry site with reference to the coronal suture is most important for lesions situated in the posterior third ventricle or pineal region.

With respect to laterality, most entries should be on the non-dominant side. The exceptions to this recommendation are the following: (1) hypothalamic lesions, which are best targeted using a contralateral approach and (2) in a situation in which there is significant ventricular asymmetry in which case the preference is to enter the side with greater ventricular size. Following entry into the ventricular compartment, normal anatomical landmarks including the choroid plexus, venous tributaries and the septum pellucidum are used to establish appropriate orientation. Inspection of the ependymal surface of the ventricle is performed to assess any metastatic components of the disease. Once the lesion is identified, cupped biopsy forceps are used for tissue sampling. The sites for this procedure are chosen based on an avascular pattern and the appearance of the tumour surface. Given the limited sample size, coagulation of the tumour surface prior to tissue sample is intentionally avoided to guard against any thermal artefact. Bleeding of tumour after biopsy can be controlled mostly with irrigation alone. If bipolar and monopolar instruments are available, they can be used, but they are often ineffective. Patience and copious irrigation are the keys. If the tumour appears highly vascular, however, it is recommended that endoscopic biopsy should not be carried out.

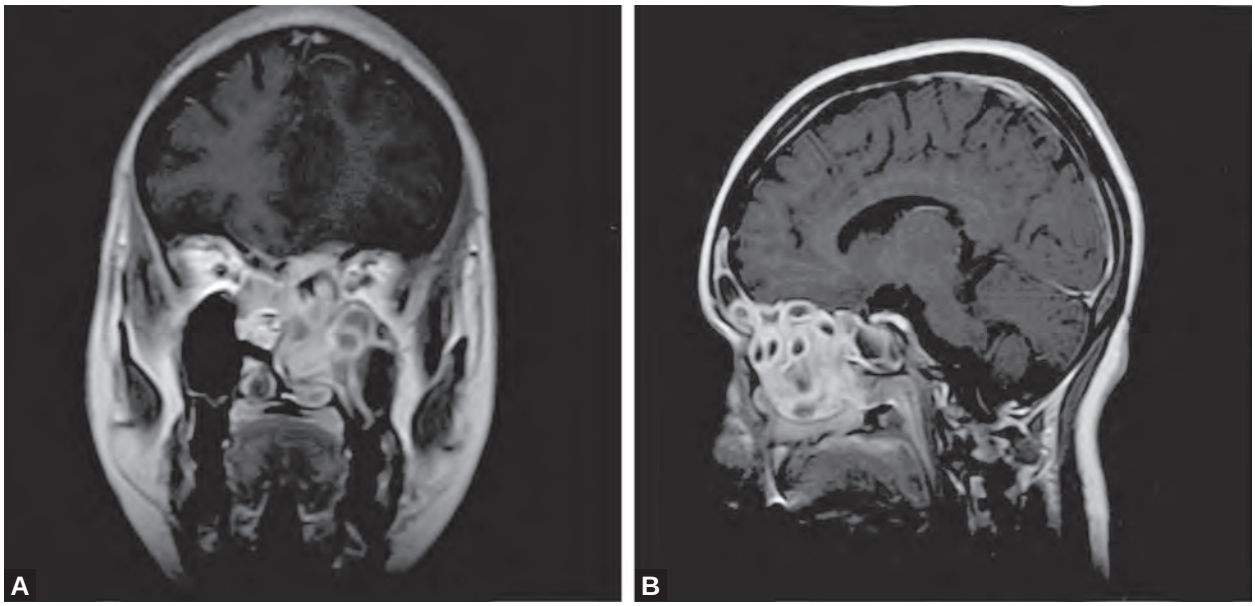
Case: A 19 years female presented with history of repeated blocking of nose and nasal discharge. An MRI was suggestive of enhancing lesion involving sphenoidal, ethmoidal sinus and nasal cavity. Malignant lesion was suspected. Patient underwent endoscopic biopsy and decompression. Histopathology confirmed it to be aspergilloma. Patient was given full course of antifungal and was totally cured (Figs 7A and B).

Endoscopic Fenestrations of Intracranial Cysts

Intracranial cystic lesions, like arachnoid cysts, tumour-associated cysts (craniopharyngioma), porencephalic cysts, multiloculated hydrocephalus,[42] septum pellucidum cysts and pineal cysts, are amenable to endoscopic management.

Arachnoid cysts are intra-arachnoid CSF containing lesions that are not in direct communication with the ventricular system. They constitute 1% of intracranial masses. Arachnoid cysts arise from a gradual expansion of clefts, or duplication in or adjacent to normal arachnoidal cisterns. The cysts expand when CSF pulsation which are concordant with the cardiac cycle become entrapped between the leaflets of the membrane. In contrast to these developmentally acquired cysts, a separate category of acquired arachnoid cysts exists, in which the pathological entity develops secondary to trauma, surgery or infection. Arachnoid cysts occur in multiple locations throughout the intracranial compartment. The commonest site is the middle cranial fossa.

Planning the trajectory is often the most crucial aspect of this surgical procedure. An entry site must be selected that provides a direct, linear route to the cyst to accomplish two distinct goals. One is to minimise any



Figs 7A and B: Lesion involving paranasal sinuses

torque on the cortical or intraventricular neural tissue. The second is to allow direct inline access to the distal edge of the cyst wall; the edge abutting the CSF containing cistern into which the cyst will be fenestrated.[33] After thorough inspection of the cystic space and selection of the target site, bipolar diathermy instrument is used both to attenuate the tissue and to provide a blunt instrument with which to perforate the cyst wall. Fenestration can be further enlarged using a combination of a balloon catheter and sharp scissors. This creation of a fenestration between the cyst and the basal cisterns is called a cystocisternotomy.

Middle Fossa Cyst

This is the most common site for intracranial arachnoid cyst (50–60%). There is still substantial support for the use of open or "Keyhole approach" craniotomy in this particular location compared with other intracranial regions, where endoscopy has been more uniformly adopted. Proponents of craniotomy point to the larger working space it affords leading to better haemostasis; however, in other case series investigators have suggested equal success rates for neuroendoscopic management of middle fossa cysts. A burr hole is made on the coronal suture approximately 5 cm lateral to midline to avoid vessels of the Sylvian fissure and to allow an optimal trajectory to the medial edge of the cyst and the adjacent cistern.

Suprasellar Cysts

These are rare lesions (5–12% of all arachnoid cysts). A variety of interesting symptomatology has been attributed to a large cyst in this region besides hydrocephalus and its associated spectrum of symptoms. Visual impairment, endocrinopathies and head bobbing may all be observed. Several authors have advocated the use of endoscopy for the management of cysts in this region. The first endoscopic fenestration of a suprasellar arachnoid cyst was reported in 1990 by Peirre-Kahn et al. using monopolar coagulation to puncture the cyst.[57] In 1992, Caemert et al. modified the approach using an Nd:YAG laser to open the cyst widely to communicate it with both the lateral ventricle and basal cisterns.[13]

The entry site is roughly at the coronal suture, 1–2 cm off the midline. Through the foramen of Monro, the blue apical dome of the arachnoid cyst with numerous fine vessels on the surface is typically seen. Ventriculocytostomy is done using bipolar diathermy and sharp dissection. Resection of the membrane at this rostral extent is not required. The endoscope is then advanced to the basal cyst membrane, where a cystocisternostomy is performed without the use of any energy source, using blunt biopsy forceps between the cranial nerves exiting the brainstem.

The MRI (T2 weighted and FLAIR sequences) is an excellent tool through which to judge the success of CSF flow through fenestrations and overall cyst volume reduction post-operatively.

Caemaert et al.[13] reported an interesting endoscopic observation about the pathophysiology of suprasellar arachnoid cysts. These investigators noted the presence of a slit valve mechanism between the cyst and the basal cisterns. A similar observation was reported by Schroeder and Gaab, who watched the arachnoid adjacent to the basilar artery open and close with each arterial pulsation, and by Santamarta et al.[66] who demonstrated cine MRI and endoscopic evidence for a slit valve mechanism. This slit valve mechanism may be related to the genesis of cyst enlargement.

Stereotaxy can also be of great help in fenestrations of deep-seated cystic lesions. Abdullah and Caemaert described favourable results in treating three cystic

craniopharyngiomas using stereotactic endoscopic technique.[2] By using frameless stereotaxy systems one moves from navigating by dead reckoning based on surface landmarks to image based navigation where the tip of the scope or a second instrument channel can be seen on CT or MRI.

Endoscopic Resection of Intraventricular Tumours

Tumours with following characteristics are ideally suited for endoscopic resection:

1. Moderate to low vascularity
2. Soft consistency
3. Less than 2 cm in diameter[26]
4. Associated secondary hydrocephalus
5. Histologically low grade
6. Situated in lateral ventricle/third ventricle

Clearly colloid cyst represents the ideal intraventricular tumour that can be completely resected via the endoscopic approach. Most of the experience with endoscopic tumour resection in the literature specifically addresses the removal of colloid cysts. Fourth ventricle tumours are rarely suitable for an endoscopic resection because of the limited space available. Table 4 shows the entry point for tumours in different locations.

Colloid Cyst

Colloid Cysts have been approached endoscopically for longer than 25 years. Successful aspiration and partial resection of colloid cysts were reported by Powell et al. in 1983[59] and Auer et al.[8] in 1988 respectively. In 1994, Lewis et al.[43] compared endoscopic resection of colloid cysts using the flexible endoscope with microsurgical excision. In those patients who were treated endoscopically, they found significantly reduced operative time, duration of hospitalisation and length of time before returning to work.

Endoscopic surgery should be considered as the first line surgical modality for the treatment of colloid cysts as it offers the advantages of direct tumour visualisation while being a minimally invasive technique.[56] Rigid endoscopes are superior to flexible endoscopes in colloid cyst surgery due to high definition image and magnification and availability of multiple viewing angles that allow one to look around the corners and behind obstructions. In most patients, a single portal endoscopic approach is sufficient for tumour removal. The disadvantage is that the surgical instruments are passed in the same line of sight as the endoscope; movement of the instruments is dependent on movement of the video image. Three-dimensional appreciation of the operative field is lost. However, precise three-dimensional clues can be gained by continuously repositioning the endoscope within the ventricle. By incorporating a second adjacent portal the endoscopic instruments can be manipulated independent of the endoscope and consequently one achieves more of a panoramic feel for the surgery gaining additional degrees of freedom with the surgical tools.

The main technical factor that affects colloid cyst removal is the density of the cyst contents. This can best be estimated using non-contrast CT. Hypodense or isodense contents are usually fairly liquid and can be removed through the small apertures of the endoscope without difficulty. A small suction catheter attached to a 10 or 20 ml syringe may help in this regard. Hyperdense cysts may have more tenacious contents, which can prove more difficult to remove with the endoscope. Cup forceps may need to be used to remove the contents of these denser cysts piecemeal. On MRI, high signal on T1-weighted imaging correlated with higher cholesterol content, thicker consistency, and more difficult removal.

The foramen of Monro, in the presence of a colloid cyst, is usually expanded. The cyst is attached to the roof of the anterior third ventricle, and its anterolateral surface usually bulges into or through the visible part of the foramen. The cyst wall can be opened with fibre-optic laser or bipolar coagulation and the cyst contents can be emptied. The cyst wall can be shrunk down with a laser/bipolar and a large portion of cyst wall can be removed with grasping forceps and micro scissors. One must avoid excessive traction on the cyst capsule. Too much traction is unnecessary and dangerous, since bleeding from partially avulsed vessels from the roof of the third ventricle may be difficult to control. Every effort is made to preserve all normal structures in removing a colloid cyst. Generally, this can be accomplished; however, three structures may be sacrificed, if necessary, to provide widened access to the tumour, in descending order of preference: choroid plexus, the thalamostriate vein and the ipsilateral fornix. The first structure is sacrificed with impunity, but sacrifice of the latter two should only be considered if all other options have been exhausted. Total or near total resection of colloid cysts should be the goal for all patients. Only in situations in which a nubbin of tissue cannot be separated from neural or vascular structures should it be coagulated and left *in situ*.[73]

Limitations of the endoscopic approach are the difficulty of working when the foramen of Monro is small and when the cyst is lying posteriorly.[18] Such cases can be recognised pre-operatively on MRI and they should be probably best managed via standard microsurgery.

Table 4: The entry point for tumours in different locations

Tumour location		Entry point
Lateral ventricle—Frontal horn		2–3 cm parasagittal, coronal to 2 cm pre-coronal
	Body	2–3 cm parasagittal, coronal to 2 cm pre-coronal
	Trigone	2–3 cm parasagittal, 4–6 cm pre-coronal
Foramen of Monro		3–5 cm parasagittal, 2–4 cm pre-coronal
Third ventricle—Anterior		1–2 cm parasagittal, coronal
	Posterior	1–2 cm parasagittal, 4–6 cm pre-coronal

Overall complication rate is very low. Reported complications include injury to the fornix, epilepsy and short-term memory problems.

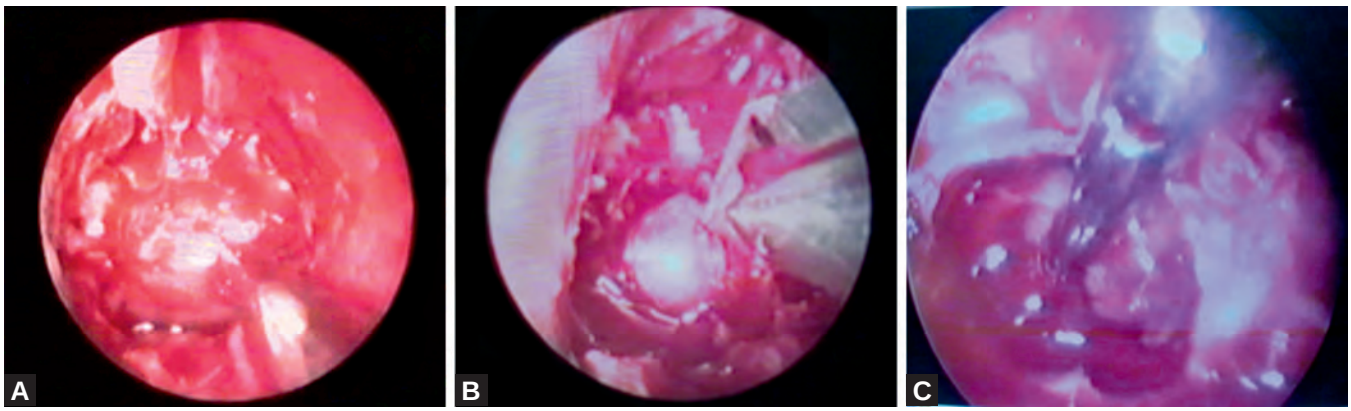
Endoscopy-Assisted Microneurosurgery

During the last century evolution of neurosurgical techniques has occurred with the aim to reduce the pre-, intra- and post-operative traumatisation of patients undergoing diagnostic and therapeutic neurosurgical procedures. The results of this ongoing process can be observed in today's microneurosurgery, which uses sophisticated microscopes, microinstruments, neuronavigation and stereotactic techniques. The improvement in diagnostic imaging enables not only precise localisation of lesions but also the accurate determination of topographical relations of specific lesions to individual anatomic variations of intracranial structures. This parallel improvement in diagnostic and surgical techniques gave rise to concept of "keyhole microneurosurgery".[9] Keyhole surgery does not imply that the craniotomy has the size of a keyhole but that the choice of the correct individual craniotomy has a key function to enter a particular area and to work there with minimum of traumatisation. By choosing the correct keyhole approach to a specific lesion, it becomes possible to dramatically reduce the size of the craniotomy, and the dura opening and less brain retraction that contributes to improved post-operative results.

However, a keyhole approaches have a few shortcomings like narrow viewing angles, reduction of light intensity in the operating field and the necessity for almost coaxial control of the microinstruments. Advantages of endoscopes like increased light intensity while approaching an object, clear depiction of exposed (patho) anatomic structures and extended viewing angle (fisheye effect) to inspect hidden but important anatomical structures without applying additional retraction, can be used to overcome the above mentioned shortcomings of keyhole approaches. This gave rise to the concept of endoscopy-assisted microneurosurgery. Apuzzo et al.[6] were the first to apply neuroendoscopic techniques to craniotomy. In 1977, they reported using side viewing angled rod lenses to assess the adequacy of aneurysm clip placement and assist visualisation during both subfrontal and trans-sphenoidal pituitary surgery.

Depending on the precise location of the lesion, a small craniotomy is fashioned and the initial exposure of the deep structures is done under the operating microscope. The solid rod endoscope lens is introduced into the craniotomy exposure and guided into position under the direction of the operating microscope. Deep structures can be seen through the endoscope with minimal or no brain retraction. The endoscope can be used free-hand or mounted to the operating table and standard microsurgical instruments are introduced into the field adjacent to the lesion. The endoscope and microscope complement one another and can be brought in and out of the field during various stages of the procedure. By alternating the use of endoscope with the operating microscope, one can improve the visualisation of the deep anatomy during craniotomy. It is prudent to inspect the position of the endoscope frequently during the dissection to maintain overview of the entire operative field and avoid complications of injuring the surrounding structures by the endoscope itself. The use of a picture in picture device allows the operator to view both the images on one screen. Taneda et al.[70] developed a display system that permits the surgeon to watch the endoscopic image through one of the ocular lenses of the surgical microscope.

The introduction of the endoscope has to revolutionised the approach to certain tumour types by allowing safe and radical removal. These techniques are particularly applicable to a wide range of troublesome tumours including sellar tumours like pituitary tumours, craniopharyngioma and Rathke's cleft cysts; clival chordomas, pineal tumours, intraparenchymal tumours near the brainstem or cranial base; acoustic neuromas and anteriorly or centrally located posterior fossa tumours (Figs 8A to C).



Figs 8A to C: An endoscopic view showing. (A) Sellar floor. (B) Dura being cut. (C) Tumour removed

The endoscope has allowed a conceptual change in the approach to low grade or benign tumours like craniopharyngioma. In the past some surgeons have discouraged radical debulking of the hypothalamic portion of these tumours because of the unacceptable side effects attended by damage to this vital structure. In fact poor visualisation is what limits adequate and safe removal of tumour. With the endoscope the occult parts of the tumour can be removed under vision making this part of the tumour as accessible as the directly visualised portion. Because the prognosis for a number of tumours depends on the adequacy of tumour removal the use of the endoscope in this fashion to obtain the best removal possible and to document that removal is highly recommended.

Endoscopic Pituitary Surgery

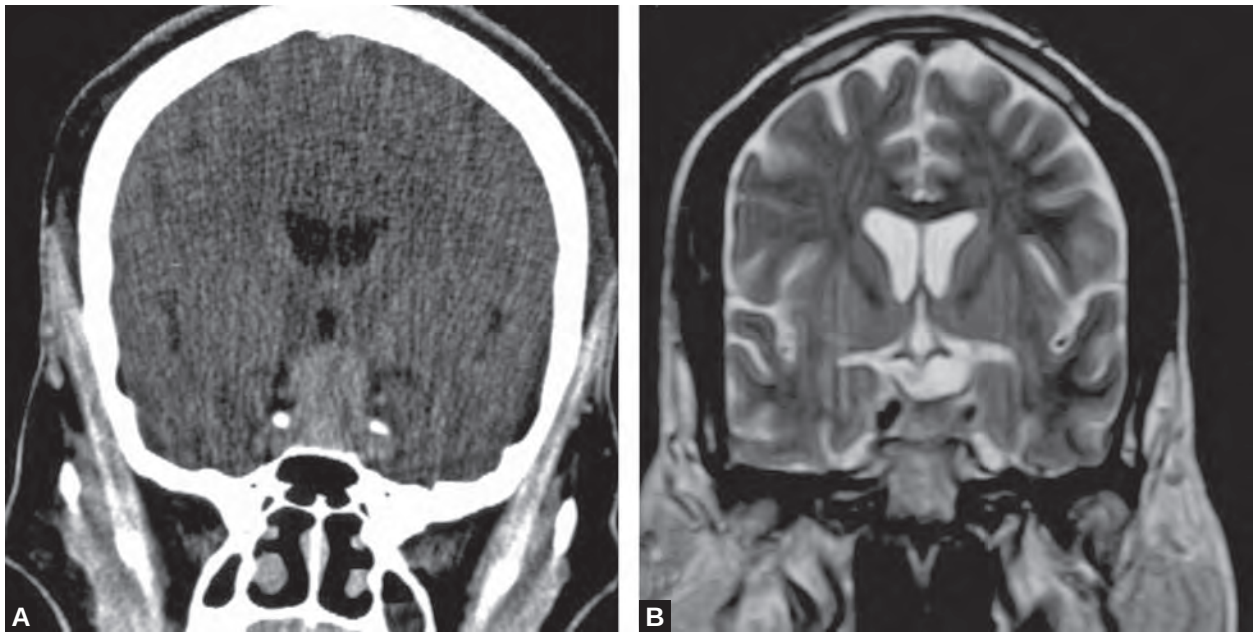
The earliest trans-sphenoidal surgeries by Schloffer, Von Eiselsberg and Kocher required an external rhinotomy incision. Hirsch and Halstead introduced endonasal sublabial approaches in 1920 respectively. These initial procedures were not trans-septal and required some degree of middle or inferior turbinectomy, ethmoidectomy and septectomy. These extensive exposures were required in order to provide both illumination and room for the use of operative instruments[36] (Figs 9A and B).

By 1914, Cushing had reported a less traumatic trans-sphenoidal technique using a sublabial trans-septal approach. The primary obstacle to trans-sphenoidal approach remained illumination and visualisation of the operative field until the later 1960s, when Hardy popularised the use of the operating microscope. Its excellent magnification and illumination capabilities facilitated the effective removal of large and small tumours alike without significant anatomical disruption. Since then, progressive modification of the microscopic approach has been done. Sublabial approach has been largely replaced by pure endonasal microscopic approaches. Endonasal microscopic trans-sphenoidal approach has several variations including the trans-septal submucosal technique, the septal pushover and the direct sphenoidotomy.

More recently, the endoscope has been introduced to trans-sphenoidal surgery and has gained significant popularity. Endoscope assisted trans-sphenoidal operation refers to the microscopic procedure in which the endoscope is used as an adjunct to the microscopic removal of a tumour. The manner in which the endoscope is used adjunctively, however, can vary significantly. The endoscope may simply be used to perform an anterior sphenoidotomy prior to inserting the nasal speculum and using the microscope. It may also be used during the microscopic tumour resection to inspect for areas of tumour residue out of the line of sight of the microscope. Pure endoscopic trans-sphenoidal surgery refers to the removal of tumour without the use of the operative microscope.

Although the endoscope assisted trans-sphenoidal approach had been reported by others, the pure endoscopic trans-sphenoidal approach was introduced and popularised in late 1990s by Jho and Carrau from the University of Pittsburgh Medical Center.[35]

Endoscopic sphenoidotomy is performed by using 0 or 30 degree rigid rod endoscopes. The endoscope is held in the left hand while supporting it superiorly against the soft tissue of the nares. Instruments are passed beside the endoscope and not through a working channel. Learning to work with the endoscope and instruments one above another provides the surgeon



Figs 9 and B: Pre-operative and post-operative images of pituitary tumour

with a significant amount of working space as compared to their side by side use. The safety of the approach described requires that the surgeon identify the posterior middle turbinate and the ostium of the sphenoidal sinus located in the sphenoethmoidal recess between the septum and the superior turbinate. Routine partial middle turbinectomy is not advocated, except for those with an unusually small nose and nasal cavity, because it is mostly unnecessary in the adult patient and leads to crusting and delayed epistaxis. Care must be taken to identify normal intra-sphenoidal anatomical landmarks and to be cognisant of the positions of the optic nerves and carotid arteries at all times. Angled endoscopes allow the surgeon added panoramic visualisation.

Entry to the sphenoid sinus can also be accomplished directly through the anterior wall of the sphenoid or via the ethmoidal bulla and sinus, if the anatomy of the nasal cavity, previous nasal surgery or other limitations hinders access to the sphenoidal ostium. The technique can also be performed trans-septally, analogous to the microscopic approach.

Although surgery can be performed through a single nostril, which acts as a portal for the endoscope and the surgical instruments, the dual-portal technique allows superior manoeuvrability, flexibility and efficiency over a single portal approach. Using the three-hand technique, as advocated by Kassam,[40] the advantages of the endoscope can be realised. This manoeuvre requires co-operation between the endoscopist and the surgeon. The endoscopist can move in during the tumour resection and focus closely on areas of interest. As instruments are moved in and out of the nose, the endoscope operator can follow the instruments, ensuring that they do not injure the nasal mucosa.

The endoscopic approach should be individualised to the patient and assessed pre-operatively by studying the computerised tomography and magnetic resonance imaging and ultimately by endoscopic assessment at the time of operation. The endoscopic approach can also be used as an adjunct to the microscopic approach in inspecting the operative site for residual disease. Using the endoscope in this way can be particularly helpful in advancing surgeons along the learning curve in endoscopy.

The endoscopic pituitary surgery technique has evolved over time due to acquisition of new instruments and a persistent quest for improved exposure and resection. Initially it was tried to recapitulate the microscopic adenomectomy by adopting a mononostril approach with the endoscope holder. However, with experience, it has been found that holder on the contrary tends to negate the advantages of the endoscopes. The surgeon can obtain a pseudo-depth perception from the dynamic movement of the endoscope relative to operative instruments. Placing the endoscope in a fixed position likens the technique of a microscopic adenomectomy during which the surgeon has wide-angle view but has limited depth perception and zoom views. Also if the endoscope becomes occluded by blood beyond the cleaning ability of the irrigation system it must be removed from the holder cleaned and then brought back into the field. These interruptions tend to disrupt flow of the operation significantly and in situation of significant bleeding can be disconcerting. Moreover downward drift of the endoscope because of the weight of the attached camera is a common problem.

De Divitiis et al.[21] have expanded the scope of this approach to include other lesions of the sellar and parasellar region. The bilateral endonasal endoscopic approach now allows for visualisation of tumours at the anterior skull base up to the crista galli and down to the level of C-2.

Microscopic Adenomectomy versus Pure Endoscopic Adenomectomy

Microscopic Adenomectomy

Advantages:

- Familiarity to neurosurgeons
- Three-dimensional view with easily manipulated zoom and focus
- Easy maintenance of the appropriate trajectory to the sella once it is defined
- Nasal speculum used for microscopic surgery protects the nasal mucosa from injury by instruments
- Microscope being out of the surgical field, the view does not suffer from red out when bleeding fills the surgical field and it does not obstruct the entry or manoeuvring of instruments into or out of it.

Disadvantages:

- Field of view is narrow and visualisation is limited by line of sight. The surgeon cannot see around corners wither towards the cavernous sinus or the suprasellar space and optic chiasm.
- Sinonasal complications due to sublabial or trans-septal approaches like anosmia, alveolar numbness, saddle nose deformity and nasal septum perforations. Post-operative nasal packing may cause facial pain and headache. However, minimally invasive approaches of the septal pushover and direct sphenoidotomy do not require nasal packing and are associated with fewer sinonasal complications.

Pure Endoscopic Adenomectomy

Advantages:

- Provides panoramic views of areas outside of a microscopes line of sight and allows dynamic, magnified inspection of areas of interest. Visualisation of the carotid protuberance is rarely possible with the operating microscope, and confirmation of their precise location does at least improve surgeon's comfort. During trans-diaphragmatic dissection, the optic chiasm can be seen and chiasmal decompression, which is often the goal of surgery, can be confirmed

- Wide views of the nasal anatomy allow the surgeon to discern the appropriate level of entry into the sphenoid sinus more easily (either by visualising the sphenoid ostia or the level of superior turbinate. This obviates the use of intra-operative video fluoroscopy
- No nasal packing unless significant CSF leak, which decreases patients discomfort and affects patients satisfaction
- Fewer nasosinal complications like saddle nose deformity, alveolar numbness septal perforations
- No alar incision is required, as in microscopic direct sphenoidotomy.

Disadvantages:

- Less familiar
- A facile endoscopist must stay throughout the entire operation while using three hand technique
- Limited zoom facility: To obtain magnification endoscope is brought closer to the region of interest requiring frequent refocus manoeuvres that are not as easily performed as with the microscope
- Endoscope gives two-dimensional views. Depth perception is provided by the dynamic interaction between surgical instruments and the endoscope. It is possible in the learning phase to dissect into the posterior pituitary, cavernous sinus and diaphragm over aggressively and cause more complications
- Because instruments enter the field out of the line of sight of the endoscope and because no nasal speculum is used the nasal mucosa along the septum and the medial wall of the middle turbinate can be injured in the course of the operation
- Posterior septal branches of the sphenopalatine artery are also at greater risk than during trans-septal microscopic approaches because in trans-septal approach mucosa containing this vessel are elevated from the sphenoid rostrum and are thereby protected. The direct sphenoidotomy places these vessels at greater risk of damage and of early post-operative epistaxis.

It is perhaps an overstatement to assert that the endoscope is less invasive than the microscope. The endoscopic approach may seem so to the patient initially because there is no nasal packing but endoscopic approach disturbs and removes more anatomical structures than the various standard microscopic approaches. The sphenoidotomy is larger so that the endoscope does not impede the necessary manoeuvring of the operative instruments. To achieve the same manoeuvrability for the operative instruments as in the microscopic adenomectomy a binasal technique is used that requires a posterior partial septectomy. Although not routine a partial middle turbinectomy is also performed at times, an action never necessary when performing a microscopic adenomectomy. All these manoeuvres are undertaken in an effort to provide an exposure that allows the surgeon to use both instruments and the endoscope.

Thus, the choice to use the endoscopic in lieu of microscopic technique should not be in the pursuit of a less invasive approach but because of the advantages provided by the endoscopic procedure.

Endoscopy Assisted Surgery for Skull Base Lesions

There has been recent interest in the use of the neuroendoscope to assist with "traditional" skull base microsurgery. Cranial base approaches have resulted in improved surgery at the cranial base by removing or displacing soft tissue and bone. The hope is that in selected situation a less invasive approach combined with the increased visualisation afforded by the endoscope will be an effective surgical alternative or adjunct. Early experiences seem promising in this regard.

The concept of using endoscopes to visualise the anatomy of the posterior fossa is not new. In 1917, Doyen described a technique for trigeminal root neurectomy under endoscopic guidance via an occipital craniotomy. Since then, published experience with posterior fossa endoscopy has been scarce. Isolated reports detailing endoscopic exploration of the posterior fossa for diagnostic purposes and for selective trigeminal nerve root sectioning were published in the 1970s, but only during the past decade has interest in the application of endoscopic imaging to this region been renewed. In 1992, O'Donoghue and O'Flynn described and classified the endoscopic anatomy of the CPA.[54] Since then, a number of neurotologists have presented their experiences with CPA endoscopy, particularly as an imaging modality in acoustic neuroma surgery.[10,34,41,48,49,64,71] A recently published atlas specifically details the endoscopic surgical anatomy of the cranial nerves at the posterior skull base.[47] Grotenhuis has reported techniques for endoscope-assisted craniotomy both supratentorially and in the posterior fossa.[29] The future of neuroendoscopy in skull base surgery will involve its use both as the primary surgical approach and as an adjunct to the microscope.

Cranial base endoscopic surgery presents unique challenges not encountered within the ventricular system, e.g.:

- Unlike with intraventricular endoscopy there is the lack of significant true or expandable space through which one can manipulate multiple instruments
- One must navigate around the lattice of nerves and arteries not present within the ventricles
- Instruments are usually not passed through working channels of the endoscope or portals as they are during intraventricular surgery, but rather must be passed alongside the telescope.

Pre-requisites to make full use of this subarachnoid space are correct positioning of the patient's head to support gravity-related self retraction of the cerebrum or cerebellum, careful release of CSF from the cisterns and, if applicable, from the ventricular system at an early stage of the procedure, and cautious debulking of the tumour. With these simple methods in most cases adequate subarachnoid working space for one endoscope and two additional instruments can be created without

significant application of retraction and traumatisation of surrounding brain substance.

Endoscope is well suited for dealing with deep midline tumours like craniopharyngiomas and epidermoid tumours, lesions of the posterior fossa and cerebellopontine angle (Figs 10A and B, 11A and B). It is a very useful adjunct in surgery of acoustic schwannoma. Other indications include microvascular decompression of the cranial nerves, vestibular neurectomy and an assortment of intrinsic and extrinsic lesion involving the brainstem.

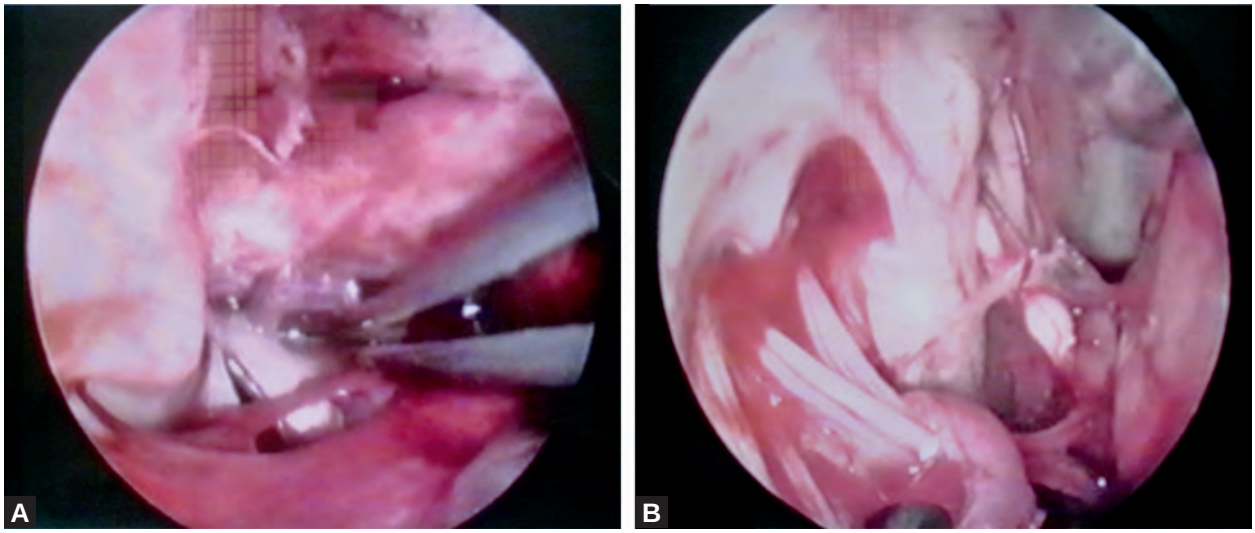
Advantages of endoscopy in surgery for vestibular schwannoma are:

- Improves visualisation of bony, neural and vascular relationships while minimising retraction
- When one is attempting to preserve hearing, it is critical that the intraosseous endolymphatic sac and posterior semicircular canal are not violated when the posterior wall of the IAC is removed. The main use of endoscope is to visualise the lateral end of the IAC, which helps the surgeon to minimise the drilling of the petrous bone with lower risk of entering the posterior semicircular canal and the vestibule
- Inspection of the IAC with angled endoscopes for residual remnants. It can also minimise the bony removal of posterior lip of the canal while achieving excellent visualisation of the fundus
- Angulated endoscope is also very useful when directed into the opposite direction, i.e. towards the brainstem and even anterior to it to the prepontine area. It is particularly useful in patients with far prepontine extension of epidermoid tumours
- Direct identification of violated air cells within the temporal bone. Identifying and sealing these with bone wax may reduce post-operative CSF leakage rate.

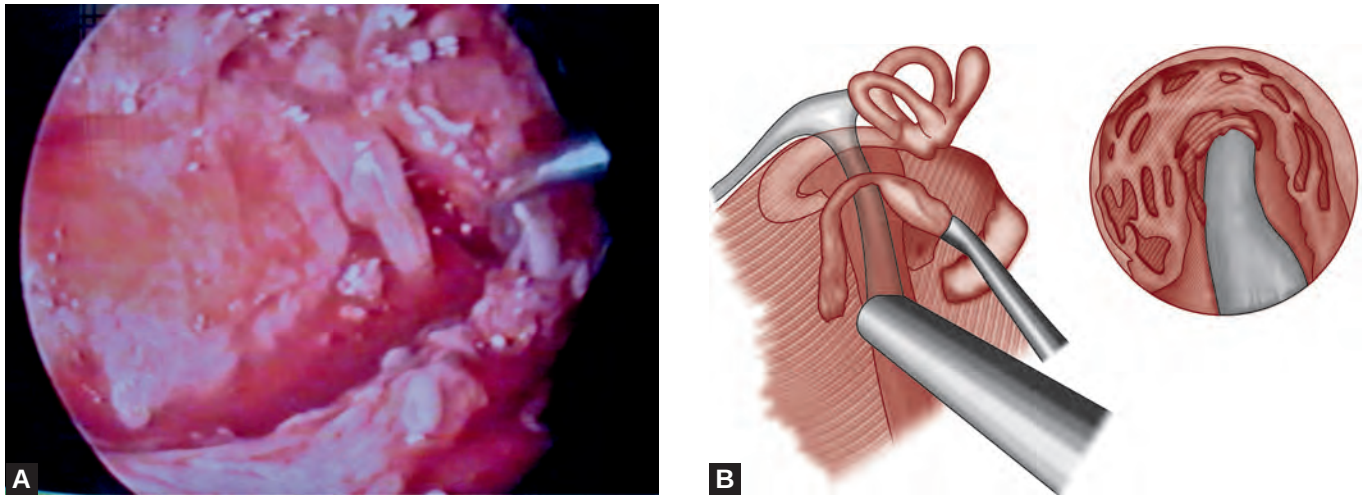
Nebil et al.[52] reported that the use of endoscopes does not appear to increase the hearing preservation rate, but is very helpful in complete tumour removal in the posterior fossa approach.

Robot-Assisted Neuroendoscopy

With the ongoing development of computer assisted surgery the appearance of robotic devices is the next step for precise conversion of the pre-operative surgical plan derived from the navigation system into surgical action. The precision of motion, the submillimetre resolution and the repetitive accuracy of a robotic tool are unavailable with other techniques. In 1992, Benabid et al. reported the first application of robotic device for stereotactic procedures including placement of electrodes for deep brain stimulation. With the Evolution 1 precision robot (Universal Robot Systems, Schwerin, Germany) a new neurosurgical tool has become available for the precise steering of instruments within the cranium.[51] It allows highly precise and reproducible positioning of any rigid instruments with an accuracy of 50 μm. All motion of the robot immediately stops if a deviation between the nominal position and the commanded position of the precision robot is detected. The universal instrument interface allows the flexible attachment of endoscopes, guiding instruments and drill instruments, and permits their exact robotic positioning with six degrees of freedom. Attached to the instrument interface is a force torque sensor, which monitors the forces applied to the patient and presents tissue damage by stopping robotic motion if these forces exceed predefined values. The advantage of using the robot as a holding and positioning device for the endoscope is the possibility of performing very smooth and slow motions in critical regions. Compared with free hand endoscopy targeting of small vessels for coagulation is easier, faster and more precise with the use of a robotic device. Neuronavigation may enhance the accuracy and safety of robot assisted endoscopic procedures particularly among patients with pathological ventricular anatomy, small ventricles or large cystic lesions. However, Robot has few limitations. It has a limited range of



Figs 10A and B: Endoscopic cerebellopontine angle view. (A) Vascular loop in front of VII nerve. (B) Lower cranial nerves and VII-VIII complex entering IAM



Figs 11A and B: (A) Endoscopic view of VII nerve separated from the tumour and entering IAM. (B) Schematic diagram showing exposed air cells

motion. Therefore, robot cannot be used for endoscopic procedures for which a larger range of motion is necessary, e.g. ventriculostomy with fenestration of a cyst, both targets can be reached via a single transcortical approach but the distance exceeds the range of motion of the precision robot.

CONCLUSION

Neuroendoscopy has a rich history that dates back to the early decades of the twentieth century. Applications for neuroendoscopy are rapidly expanding from management of pure intraventricular pathology only to endoscopic assisted microneurosurgery for pathology in the subarachnoid space. In the future, one can expect routine use of the endoscope for management of a multitude of neurosurgically treatable pathological conditions, either as the primary surgical approach or as an adjunct. However, microscope will never replace the headlight and loupes nor will endoscope ever replace the microscope. It will simply move us one step closer in our perpetual quest for minimally invasive and maximally effective surgery, with the ultimate goal of providing better care for our patients. The continued evolution of this modality will rely on new technological advances, improved understanding of endoscopically demonstrated neurosurgical anatomy, discovery of novel applications, and the training of neurosurgeons in neuroendoscopic procedures.

211 Orthotics

PK Sethi

INTRODUCTION

Galen (131–201 AD) was the first to use the term "scoliosis, kyphosis and lordosis". He advocated chest strapping, breathing exercises and singeing for the scoliosis. Ambrose Pare (1510–1590 AD) is considered the pioneer of the art of brace making and designed metal corsets and leather splints. During the early part of the 18th century Heister is credited with making the first spinal orthosis. The latter half of 20th century saw the development of various types of spinal orthoses. During this period, Schmidt and Blount developed the Milwaukee brace.

FUNCTIONS

Similar to the basic functions of an orthosis, which are correction, protection, stabilisation and immobilisation; spinal orthoses have corrective and protective functions. They support and thus stabilise the spine, as well as immobilise and thus rest the spine. Following surgery or injury, the spinal orthosis protect the cord and nerve roots, and carry out the functions that intrinsic structures of the spine and the muscles normally achieve. Many a time, the orthosis is designed to prevent a particular movement. For scoliosis and kyphosis it has a corrective role.[20]

BIOMECHANICS

The spine can be considered mechanically as a series of semi-rigid bodies (vertebrae) separated by viscoelastic linkages (discs and ligaments).[9]

Movements of the Spine

Measurement of joint motion is of considerable importance in determining the degree of deformity, in prescribing an orthosis and measuring the progress during treatment. This applies to the spine as well. The data on Indian subjects is not available. The average range of motion available from various studies are described below:[2,3]

The *Cervical Spine* is the most mobile part of the spine. It has flexion, extension, lateral flexion, rotation and gliding (translatory) movements (Table 1) at different levels. Females show slightly greater movement than males.[17]

The *Thoracic and Lumbar Spines* have similar movements as that of the cervical spine like flexion, extension, lateral flexion and rotation (Table 1). Above the age of 50 years, the range of motion gradually starts reducing and by the age of 80 years the range reduces by 10 degree.

Balanced Horizontal Forces

Horizontal forces provide efficient bending movement for correction of lateral curvature and immobilisation of the spine. This can be expressed as three-point loading system (Fig. 1), where the arrows represent the magnitude and direction of the forces (Fig. 1).[20]

Three forces are applied along the length of the spine, two in one direction and one in the opposite direction. Since the system is in equilibrium, the sum of the forces and sum of the bending movement they create remains zero. The sum of forces at B and C has to be equal to the

Table 1: Motion of cervical, thoracic and lumbar spine (in degrees)

Movement	*Cervical*	*Thoracic*	*Lumbar*	*Total*
Flexion	60	15	40	55
Extension	80	15	25	40
Lateral Flexion (Rt.)	45	15	20	35
Lateral Flexion (Lt.)	45	15	20	35
Rotation (Rt.)	75	40	5	45
Rotation (Lt.)	75	40	5	45

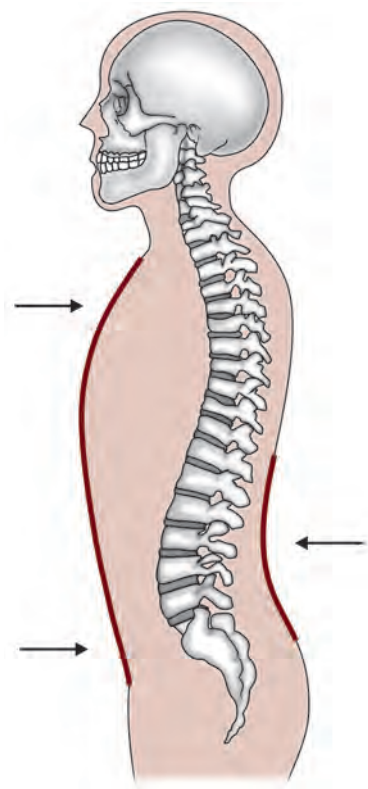

Fig. 1: Three point pressure system in correcting the spine

force at A (B + C = A). In order to have the same skin pressure, the size of the skin pad should be proportional to the pressure applied through it. By placing the force at the apex of the curvature, the correctional efficiency becomes maximal.

Fluid Compression

Pascal's law states that fluids in a closed chamber behave like solids and the pressure applied at any point is transmitted equally in all directions. This principle is utilised in supporting the spine by compressing the abdominal cavity by a tightly applied corset or abdominal support. This increases the intra-abdominal cavity pressure and produces a distracting force, thereby effectively distracting the lumbar spine.

Traction

By applying traction alone it is possible to achieve a certain amount of immobilisation and stability of the spine even if there is lateral instability.

Sleeve Principle

It is caging the patient between two semicircular fixation points, one above and the other below. Between these two semicircular fixation points there are various uprights. The uprights may be in front, at the sides of the patient, posterior or paraspinous. These uprights serve as a sleeve, splint or distracter.[20]

Skeletal Fixation

This is the most effective method of applying reliable control on the spine. Halo traction and halo pelvic fixation devices are the examples.

After the diagnosis is made the clinician decides the specific goals to be achieved, whether to support, immobilise or correct the spine and what degree of freedom is to be controlled, to what extent and in which manner.

NOMENCLATURE

Spinal orthoses can be grouped as orthoses, corsets, belts and braces. They are best described using generic names; referring to the anatomical level they are capable of controlling and treating.[6]

CO = Cervical Orthosis
HCTO = Head Cervico Thoracic Orthosis (SOMI)
TLO = Thoraco-Lumbar Orthosis
LSO = Lumbo-Sacral Orthosis
TLSO = Thoraco-Lumbo-Sacral Orthosis
CTLSO = Cervical Thoraco-Lumbo-Sacral Orthosis

Based on the effectiveness of the control applied by the orthosis, they are also grouped as minimum control, intermediate control and most effective control orthosis.

Corset and Belts

Corsets

Corsets are flexible orthoses made of fabrics with vertical stays (Fig. 2). They are adjustable by means of laces, hooks and elastic abdominal straps. They are effective for management of pain due to muscle strain by relieving the activity of spinal and abdominal muscles. However, long-term use of corsets may lead to atrophy of these muscles. Therefore, corsets should be used only for the duration necessary and not for a long term for psychological support. Corsets have vertical channels where spring steel strips or plastic strips can be placed to stiffen the corset.[16]

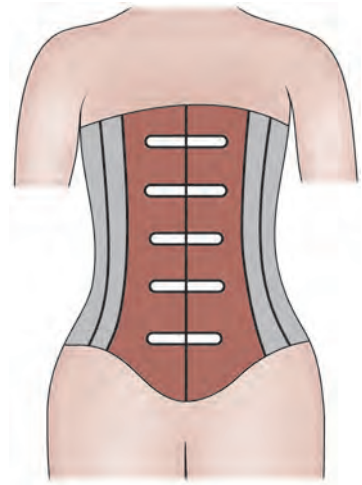

Fig. 2: Corset

Belts

Sacroiliac belt is a 5–10 cm wide belt encircling the pelvis between the iliac crest and the greater trochanter and helps in stabilising the sacroiliac joints. An abdominal belt is a 10 cm wide belt and is worn by weight lifters to prevent collapse of the vertebrae.

Orthoses

Cervical Orthoses

There are three types of cervical orthoses: (1) collars; (2) poster devices and (3) custom made. Collars restrict excessive movements, especially flexion of the cervical spine, through a feedback system and acts as a reminder to restrict movement. They have negligible control on rotation. Poster cervical orthoses provide more control and provide more rigid immobilisation because of mandibular and occipital pads, and sternal and thoracic pads. Custom-made cervical orthoses are made to relieve the weight of the head on the cervical spine.

Soft cervical collars: These are most commonly used collars and are made of foam, wrapped around the neck and are comfortable, although may not be effective in restricting the movements of the cervical spine (Fig. 3). The therapeutic rationale is that it restricts motion, reduces body heat loss and keeps the neck warm and thereby relieves muscle spasm. It maintains the head directly over the centre of gravity and reduces the cervical lordosis, which opens the intervertebral foramen and reduces nerve root pressure.

Philadelphia collar: This is a soft type of collar and provides better support due to the width of the collar that surrounds the neck. It also has anterior and posterior stiffeners to provide additional support (Fig. 4).[10]

Hard cervical collars: These are made of rigid material like low-density polyethylene. They reduce cervical movements better in the sagittal plane than a soft collar. However, they provide little control on lateral flexion and rotation, and may be of fixed or adjustable width (Fig. 5).

Fig. 3: Soft collar

Fig. 4: Philadelphia collar

Fig. 5: Hard collar

Four-post cervical collar: This is a flexion extension control orthosis (Fig. 6). Anteriorly there is a chin support and a sternal support and two turnbuckle uprights. Posteriorly there is an occipital support thoracic plate connected together with two turnbuckle uprights. The uprights are adjustable in height and made of aluminium. A traction force is applied between the cervical and the shoulder rings, which restricts flexion and extension and thus maintains the specific position as required. Lateral flexion and rotation are also restricted. The weight of the head is bypassed from the cervical spine. However, since there is no direct support to the spine, inter-segmental movements are possible.[8]

Sternal occipital mandibular immobiliser (SOMI) orthosis [head cervico thoracic orthosis (HCTO)] is commercially available and consists of a sternal plate, shoulder strips, mandibular pad, occipital pads and support bars. It has good control on flexion but allows a little extension and rotation (Fig. 7).

Halo cervico thoracic orthosis: It consists of a halo ring fixed to the skull with pins, chest jacket and connections between them (Fig. 8). This provides the most effective control on cervical movements. It allows inter-segmental movements; still this is the best option for fractures of the cervical spine.[7]

Minerva Jacket provides total control of movements including inter-segmental control. They are individually made moulded appliances and restrict flexion, extension, lateral bending, as well as rotation and, the weight of the head is relieved from the cervical spine (Fig. 9).

Thoraco-Lumbar Orthoses

The thoraco-lumbar orthosis (TLO) is the most prescribed orthoses covering the dorsal and lumbar spine. It consists of two posterior paraspinal uprights extending up to the interscapular region. Uprights are attached to the full front abdominal corset. An interscapular band holds the uprights and serves as an attachment for axillary straps, which pass under the axilla coming over the shoulder and attached to the upper end of the uprights posteriorly with the help of a buckle or Velcro fasteners (Fig. 10). It controls flexion and extension of the thoraco-lumbar spine, but does not prevent lateral flexion and rotation.[13]

Lumbo-Sacral Orthoses (LSO)

Lumbo-sacral flexion and extension control orthosis (LSO): It consists of two posterior paraspinal uprights attached inferiorly to a pelvic band and superiorly to a thoracic band. It is a three-point pressure system consisting of a posteriorly directed force from the abdominal support and an anteriorly directed force from the pelvic and thoracic bands. This orthosis provides only flexion and extension control.

Lumbo-sacral flexion, extension and lateral control orthosis (LSO): This is one of the most commonly prescribed spinal orthoses. Lateral uprights are incorporated in the above LSO to which the abdominal support is attached as shown in Figure 11. This restricts lateral flexion. Oblique bars, when incorporated, provide structural integrity and may control rotation to some extent.

Thoraco-Lumbo-Sacral Orthoses

Thoraco-lumbo-sacral flexion-extension control orthosis (TLSO) (Taylor): When TLO is extended to the pelvic region it becomes TLSO. It consists of two posterior paraspinal uprights attached inferiorly to a pelvic band. A

Fig. 10: Thoraco-lumbar orthoses

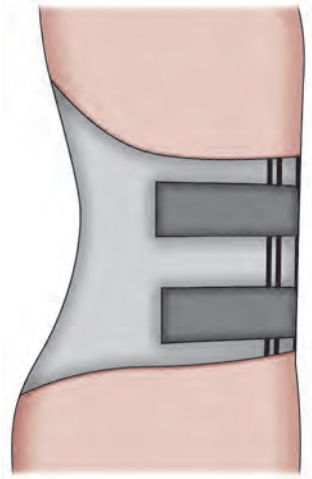

Fig. 11: Lumbo-sacral flexion, extension and lateral control orthoses (LSO)

interscapular band holds the uprights and serves as an attachment for axillary straps. It is a flexion and extension control orthosis, and commonly known as Taylor's brace (Fig. 12). It provides three-point pressure, posteriorly from the axillary pad and pelvic straps, and anteriorly from the posterior uprights at the thoraco-lumbar region.[15]

Jewett's Orthosis is a prefabricated TLSO, available in various sizes and consists of anterior and lateral frames with sternal and pubic pads and a posterior midline thoraco-lumbar pad (Fig. 13). It prevents flexion with the help of posteriorly directed forces at the sternal and pubic pads and anteriorly directed force by the posterior midline pad. Lateral strips help in preventing lateral flexion. It does not support the spine.

Anterior spinal hyperextension orthosis: Anterior spinal hyperextension (ASH) orthosis also known as cruciform anterior spinal hyperextension (CASH) orthosis is also a prefabricated TLSO. This consists of two strips at right angles to each other forming a cruciform frame. The vertical strip has sternal and pubic pads and the two lateral ends of the abdominal strip are connected with a lumbo-sacral belt having a lumbo-sacral pad (Fig. 14). The function of this orthosis is similar to that of Jewett's brace. It allows extension and lateral bending but prevents flexion. It does not support the spine.

Thoraco-lumbo-sacral flexion-extension and lateral control orthosis (TLSO) (Knight- Taylor): Two lateral uprights are added between the lateral margins of the pelvic and the thoracic bands similar to that of lateral control orthoses (LSO). An abdominal corset is fastened from the lateral uprights. These lateral uprights prevent lateral flexion, but do not control rotatory movements.

Thoraco-lumbo-sacral flexion, lateral and rotary control orthosis (TLSO) (Cow Horn): It is similar to that of Thoraco-Lumbo-Sacral Flexion-Extension and Lateral Control Orthoses (TLSO). For rotary control the thoracic band is extended anteriorly and superiorly up to the infra-clavicular region with rounded and well padded ends (Fig. 15).

Cervical Thoraco-Lumbo-Sacral Orthoses

This is a commonly prescribed orthoses for the management of spinal deformities. This can correct the curves up to 40–45 degree during the growth period. However, this is contraindicated where bony maturity has been completed. Spinal curvatures are taken care of by adding the pads over the convexity of the curvatures as well as on humps.

Fig. 12: Thoraco-lumbo-sacral flexion and lateral control orthoses

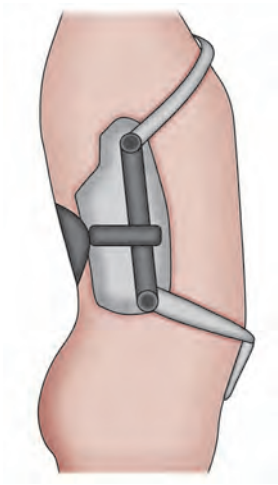

Fig. 13: Jewett's orthosis

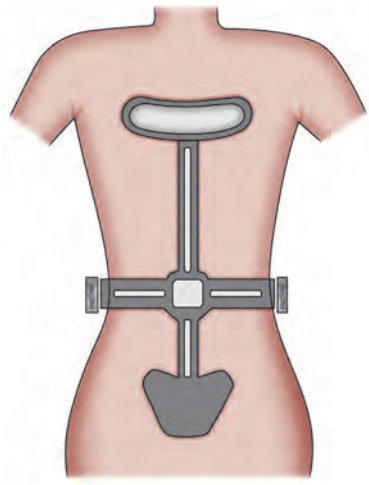

Fig. 14: ASH brace

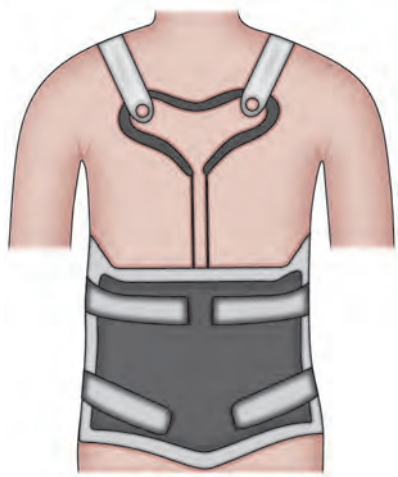

Fig. 15: Thoraco-lumbo-sacral flexion, lateral and rotatory control orthosis (TLSO)

Milwaukee Orthosis (CTLSO): It is a posteriorly open orthosis used to control and correct spinal curvatures like scoliosis and lordosis. It is like an exoskeleton and consists of a pelvic girdle, head support, one anterior and two posterior uprights and corrective pads (Fig. 16).[1]

Pelvic girdle (pelvic support) is a moulded leather construction, which has a posterior opening. It provides the foundation for the entire orthosis and also provides increased intra-abdominal cavity pressure, thus providing a distraction force on the spine.

The head support provides reaction points to encourage distraction and serves as an attachment for the uprights. It consists of a neck ring, throat piece and occipital pads (Fig. 16). The neck ring provides attachment to the throat piece and occipital pads. The throat piece falls short of the mandible and is attached to the anterior upright. The occipital pads are left and right pads and are almost right angled, attached to the posterior uprights. The horizontal portion is well padded and supports the occipital protuberances.

Uprights: The anterior upright extends vertically upwards from the pelvic girdle to the throat support and remains in the midline. The posterior uprights extend from the pelvic girdle upwards to the occipital pads on either side of the midline 8–12 cm away from each other. The uprights are contoured along the body curvatures but remain 1–2 cm away from the body. They are adjustable, transmit forces between the pelvic and the head supports and also serve as attachments for the pads.

Pads are cushioned sheet metal or plastic pieces of size proportional to the forces they have to apply over the apex of the deformities. The thoracic pads apply force directed medially, superiorly and anteriorly to the vertebral column through the ribs. Straps and pads also limit the movements of the patients inside the upright by acting as a reminder to the patient. The patient thus moves inside and stretches to reduce the scoliotic curve. This also reduces the rib hump. The lumbar pads provide an anteriorly directed force towards the transverse process, and thus de-rotate the spine.

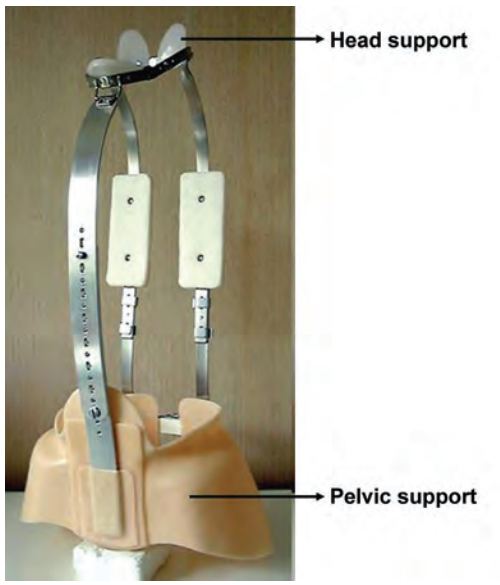

Fig. 16: Milwaukee orthosis

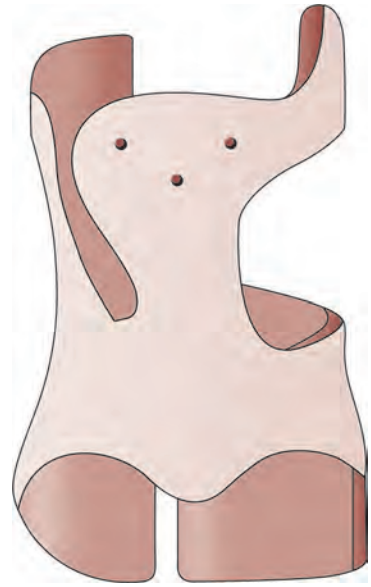

Fig. 17: Boston orthosis

Two kyphosis pads are placed one above and one below the apex of the kyphotic hump from the posterior uprights. The sternal pad is well padded and fixed to the anterior upright below the sternal notch. This encourages voluntary extension of the upper thoracic and cervical spine and also helps in relieving the uncomfortable pressure of the throat piece.

Boston Orthosis, Miami Orthosis and Under Arm Plastic Body Jacket

The TLS metallic uprights are replaced by plastic materials, hence they provide a better cosmetic appearance and therefore, more acceptable to the patients. They are custom fabricated (Fig. 17).

Casts: They are moulded orthosis and can apply force at any level and are used for severe degree of curves. Patients can be ambulatory but it restricts breathing and pressure sores can develop if not managed well.

Turnbuckle and Hinged Orthosis

This is a plastic jacket with a hinge and turnbuckles. When firmly worn, it is effective in correcting scoliosis.

17Halo Head Cervico Thoraco-Lumbo-Orthosis (HCTLO)

This provides the most effective control on cervical movements. It provides a distraction force and is used pre- and post-operatively following cervical spinal surgery.

MECHANISM OF ACTION

The results of wearing a spinal orthosis are due the forces the orthosis applies to the body and the reactionary forces the body applies against the orthosis. The location, direction and magnitude of these forces depend upon the design of the orthoses, the tightness with which it is worn and the patients efforts to move inside the orthoses. All spinal orthoses produce three basic effects: (i) reduce trunk movements; (ii) improve skeletal alignment and (iii) increase intra-cavity pressure.[12]

Reduced trunk movement is essential for bony injury healing and to give rest to the part and, thus improve the healing of the soft tissues. Skeletal alignment is an important factor in improving spinal function. Increase in intra-cavity pressure indirectly applies a distracting force on the spinal column, thus relieving the weight of the body on the vertebrae and improving the alignment.

Effectiveness of the orthoses is based on proper fit, alignment, location, material, and to their relationship with skeletal and other body landmarks. The metallic bands act as a base for the orthosis and keep the orthosis in correct position, whereas the uprights and straps help in applying the corrective forces in the right direction and hold the pads in the right place.

ORTHOTIC MANAGEMENT OF SPECIFIC PROBLEMS

Low Back Pain

Around 80–85% of the population suffers from low back pain at some time or the other in their life. Low backache, lumbo-sacral strain, sciatica, sciatic radiculitis and intervertebral disc prolapse all are included in this group. They can be caused by a number of entities like muscle weakness, skeletal instability, degenerative disc disease, osteoarthritis of facet joints or acute injury.

Muscle weakness enhances instability and encourages disc degeneration, which leads to herniation of the disc and sciatic radiculitis. This may also cause spondylosis or spur formation. Degenerative disc disease also leads to spondylolisthesis and may lead to facet joint arthritis with back pain and may lead to sciatica by root compression.

The orthosis would reduce the pain and encourage healing by trunk support and restricting the movements of the spine. When the spine is in flexion, weight transmission is through the vertebral bodies and thus reduces muscle activity. This changed posture combined with increased intra-cavity pressure relieves the pain. Patients with disc herniation will be more comfortable with LSO which maintains or increases hyperextension (lumbar lordosis) by increasing intervertebral body space and closing the facet joints. Prescription of spinal orthoses is based upon the therapeutic requirement that varies with the severity of the symptoms.

Minimal Symptoms (Mild)

In the absence of physical findings orthosis need not be provided and exercises are the best option. Analgesics may be given. If there is no improvement, a corset should be provided.

Less Severe Symptoms (Sub-acute)

Patients with moderate pain with few physical findings are provided semi-rigid orthosis (corset) to permit ambulation.

Severe Symptoms (Acute)

Spinal muscle spasm, severe sciatica, inability to walk or sit and progressive neurological deficit all need bed rest as well as rigid spinal support.

Corset is indicated in sub-acute patients especially the obese and elderly. It is more acceptable than rigid orthoses. Rigid orthoses are used when a corset does not relieve the symptoms. They are used for a severe long-term deteriorating clinical pattern and are more effective in limiting spinal motion, as also being useful in arthritis and in realigning the spine. However, it should be used for a limited period. An early start of isometric exercises of spinal and abdominal muscles within the orthosis is effective in all disorders.

For discogenic pathologies including herniation, multiple level disc bulging and degenerative disc disease the lumbar spine is set in full extension. In patients with spondylolisthesis, lumbar stenosis or facet syndrome the lumbar spine is immobilised in flexion.

Spinal Deformities

Scoliosis

Scoliosis is defined as an appreciable lateral curvature of the spine usually with rotational elements.[4] This may either be non-structural where the curvature can be corrected by change of posture or structural, which is characterised by asymmetrical side bending, fixed rotation and alterations in vertebral anatomy (Figs 18A to D).[14]

Curve progression is idiopathic and is sometimes explained using Euler's theory of elastic buckling of a slender column. Buckling load of a straight slender elastic column is a function of its flexibility, length and end support system. This relationship is described as:

$$F = C \times A^2 / L^2$$

(F is buckling load; C is constant (Pie x E/4); A is cross-sectional area of column and L is the length)[19]

In a child the weight of the upper trunk and arm may not exceed the buckling force of the spine and therefore any existing curve may not increase. Increase in the child's height greatly increases his capacity to bear the axial load by the spine. A 10% increase in height results in about 20% increase in buckling load.

The mechanism of action of spinal orthosis in correction of deformity is through end point control, transverse loading and curve correction.[11]

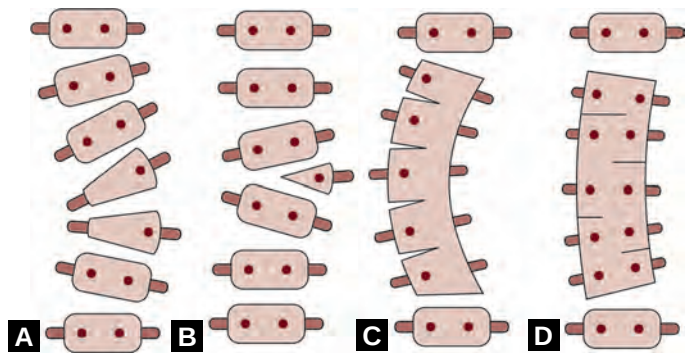
Endpoint Control

This denotes the mechanical constraints provided by an orthosis on the spine. It is done by fixing the orthosis rigidly to the base of the spine and fixing the upper end by means of a hinge. This increases the critical load value to eight times, i.e. it would require a load of 8 times to produce the scoliosis. Similarly, rigid fixation of the upper end will increase the critical load to 16 times.[18]

Transverse control is provided by all orthoses through a transversely directed force to the scoliotic spine. This is done by the load directed at the apex and two forces on either end, directed in opposite directions. However, long-term maintenance is essential.

Curve Correction

This is achieved by a three-point pressure system where one force is applied at the apex to correct the deformity and two forces are applied above and below the apex in opposite directions to produce the counter pressure and stabilisation of the spine. Up to 20 degree of curvature the patient should be kept under observation. If the deformity increases beyond 20 degree, an orthosis is indicated. Surgery followed by orthosis is indicated if the angulation is above 40 degree.



Figs 18A to D: Vertebral structural abnormality in scoliosis. (A) Wedge vertebrae partial unilateral failure of formation. (B) Hemivertebrae complete unilateral failure of formation. (C) Congenital bar unilateral failure of segmentation and (D) Block vertebrae bilateral failure of segmentation

Orthotic management of scoliosis is best done by providing a spinal orthosis TLO, LSO, TLSO or CTLSO (Milwaukee orthosis) depending on the site of the deformity, and degree and flexibility of the deformity. Other factors that should be considered are aetiology, progression of deformity and age of the patient. An elderly patient may not be able to tolerate a rigid orthosis; he should be provided a corset.

Kyphosis

Kyphosis is defined as a sagittal plane curvature of the spine with a posteriorly directed curvature. This can be generalised, angular and knuckle. They are due to deforming spinal arthropathy (Scheuermann's disease), fracture spine or collapse of the vertebrae (Tuberculosis). Kyphosis is managed by treating the cause and by applying the corrective pads below and above the apex of the deformity at an early stage.[5]

Lordosis

One of the commonest causes is obesity, when there is excessive adipose tissue over the lower abdomen. This shifts the centre of gravity anteriorly away from the spine, resulting in lordosis. An abdominal corset will improve the condition.[19]

Spinal Surgery

Pre-Operative

An orthosis, which immobilises the spine like lumbosacral flexion, extension and lateral (F E and L) control orthosis, if provided pre-operatively, can give a clue and predict the role of surgical immobilisation. It means that if such an orthosis relieves the symptoms and symptoms re-appear on removing this orthosis, it is a clear indication that surgical stabilisation would be beneficial and will offer a reasonable chance of success.

Post-Operative

Post-operative spinal support is indicated to prevent stress on the fusion from the normal physiological demand and permits transportation without causing stress over the surgical fusion. However, long-term use produces muscle atrophy and may lead to fibrosis.

Disc Surgery without Fusion

Orthosis for 4–6 weeks following surgery is a common practice to support and distract the spine by increasing the intra-abdominal cavity pressure. Corsets are found to be adequate for this purpose.

Fractures

To classify spinal fractures, the spine has been subdivided into three load bearing columns. (1) The anterior longitudinal ligament, anterior annulus fibrosus and the anterior part of the vertebral body form the anterior column. (2) The middle column is formed by the posterior longitudinal ligament, posterior annulus fibrosus and posterior wall of the vertebral body. (3) The posterior column is formed by the posterior arch, supra and infra spinous ligaments and the ligamentum flavum.

Facet joint injury increases flexion and extension of the spine. In a fully disrupted facet joint, flexion and lateral bending increases twofold, whereas axial rotation increases about ten times. Compression fracture involves failure of the anterior column with the middle column being totally intact. Burst fracture involves both the anterior and the middle column. Seat belt type of injury leads to failure of the middle and posterior columns. Fracture dislocation injury represents failure of all the three columns. Substantial instability appears if two columns are disrupted, whereas three-column injury renders the segment completely unstable.

Mechanisms of Action of Spinal Orthoses

The orthosis for spinal injury protects the spinal cord from loads and stress caused by angulation and translational deformity and provides biomechanical stability. Spinal orthoses either can be used as a substitute for operative treatment or post-operatively to provide stability to the spine.

Orthoses for Thoraco-Lumbar Injury

Anterior column compression and anterior with middle column burst fractures are best treated by bivalve TLSO in hyperextension. It reduces the segmental angle, unloads the fracture and pushes the fractured segments in an anterior direction. This stabilises the injury, reduces the segmental motion and thus allows healing.

For posterior and middle column injury, the same mechanism of action takes place and spinal extension closes the fracture and thus helps bony union. Injuries, like severe burst injury and three-column instabilities, due to fracture dislocation cannot be treated by orthoses alone. Since there is always a risk of progression of injury, surgery is the treatment of choice.

Transverse process fracture is essentially a soft tissue injury and heals quickly. Trunk support similar to that of uncomplicated fracture is the usual orthotic requirement.

Osteoporosis and Multiple Vertebral Compression Fractures

Flexible external support (corset) reduces pain by reducing movements and by increase of intra-thoraco-abdominal pressure, which in turn reduces the vertebral body compressive pressure. A corset also helps in early mobilisation and reduces weakness and disability.

For elderly patients, a flexible orthosis is suitable whereas, in younger patients, a rigid orthosis is more suitable. The deformity resulting from multiple fracture episodes cannot be prevented by bracing, and, on the other hand, excessive pressure by the orthosis to prevent the deformity may cause rib fractures.

Inflammatory Spinal Arthritis

Various inflammatory conditions, like rheumatoid arthritis, ankylosing spondylitis and Still's disease, do need bracing with the aim to relieve pain and prevent deformity. Orthotic management must restrict flexion. The orthoses used are with thoracic band extensions and subclavicular pads for restriction flexion. This does not affect the respiratory function. Extension exercises should be continued.

Juvenile Spinal Osteochondritis (Scheuermann's Disease)

This is a short-term deforming spinal arthropathy. Three-point flexion control spinal orthosis (Lumbo-sacral flexion control) and Milwaukee brace are useful.

Infectious Disorders of Spine

Osteomyelitis and Tuberculosis

Motion control is the major requirement. Large body casts have been replaced with orthosis, which control the movements. Size of the bracing is determined by the spinal level to be immobilised. The TLSO with flexion, extension and lateral control orthosis is the most prescribed orthosis.

Tumours of the Spine

Spinal support is of great benefit as an adjuvant to radiotherapy and chemotherapy. Flexion extension control orthosis are recommended to prevent deformity in children. In adults corsets with flexible stays are adequate. In the presence of neurological deficit or major instability a wider plastic moulded orthosis with an anterior wide fabric corset is given to provide better support and weight distribution. Head and neck supports may also be given.

Paralytic Disorders

Poliomyelitis and Dystrophies Involving the Trunk

Trunk support or regional pressure system applied by control orthosis is required. For the control of deformities, pads are incorporated in the orthosis.

Paraplegia

In paraplegia with absence of pelvic control and balance, spinal orthoses are counterproductive. The spinal brace with HKAFO on both the legs may allow a few paraplegics to move only a short distance. However, a corset will permit the patient to sit in a chair/wheelchair to perform the activities of daily living. In case the diaphragm is also affected, the wheelchair may be provided with special supports to control the spine and prevent collapse, which can be accomplished by ASH (CASH) brace.

Spina Bifida

With a neurological deficit the trunk needs to be supported depending upon the amount and level of weakness, instability and age of the patient. The spinal orthosis is modified for each patient and is used when there is a trunk weakness or paralysis with room to avoid pressure on the posterior mass.

Spondylolisthesis

Congenital (Developmental) Spondylolisthesis

Support is needed to realign the spine by using a three-point pressure system. Lumbo-sacral extension and lateral control orthosis will improve the lumbar lordosis and correct the pelvic tilt.

Degenerative Spondylolisthesis

This may lead to osteoarthritis of the posterior joints. Motion control is essentially required, especially if root compression is present. Lumbo-sacral corset is adequate.

Cervical Conditions

Sprains

A firm collar during the day and soft collar during the night is indicated which reduces neck movements and encourages healing. In severe cases where simple collar is unable to control symptoms, cervical spinal orthosis with posts is provided which controls the position of the spine and also relieves the weight of the head. It must be discarded as early as possible lest weakness and atrophy of muscles ensue.

Torticolis

Post appliance is provided for acute torticolis resulting from injury. This would maintain the corrected position pre-operatively as well as post-operatively.

Cervical Spondylosis and Cervical Spondylitis

They are degenerative disc lesions. Orthotic restrictions of movements improve the symptoms and permit irritative lesions to become quiescent. Soft cervical collar during the night and firm collar during the day will be a good combination. Sometimes, increased motion control and weight relief is required for severe pain by post appliances, which also reduce the shearing force.

Fracture Dislocation

The orthotic requirement is determined by the stability of the fracture, state of the nervous system, and state of cervical spinal fusion (if performed). Cervical spinal orthoses with posts will be useful to control the movements, keep the head in the desired position and relieve the weight of the head.

In unstable fractures or where the fracture or dislocation has been reduced, skeletal traction (Halo) needs to be applied, which can be mounted on a body cast. A moulded cervical collar can replace this. Maximum

support is needed for fusion of the upper cervical and cervico-occipital segments. Posterior and posterolateral fusions also need thorough external support by a moulded Minerva jacket.

Single level anterior fusion and locked interbody fusion following disc excision can be managed by simple hard and soft collars. For complete fusion, complete immobilisation with weight relief is indicated.

Minor injuries which have no or low-risk of progression, or have marginal instability that does not require surgery, do require orthosis to provide stability and prevent further progression of injury and deformity.

Post-Operative Orthosis

The aim of post-operative orthoses stabilisation is to protect the surgical correction from large loads created by movements till bony consolidation takes place. The orthosis must control the motion in which the surgical construction is most vulnerable to failure. Most commonly these motions are flexion and torsion (axial rotation). The TLSO with adequate anterior height up to the sternum resists forward bending and is quite suitable; however, it should not be allowed to provide hyperextension.

Post-Operative TLSO

The post-operative TLSO should provide a firm support at the sacrum. The upper margin should be above the most superior portion of spinal fusion. For lumbar spinal fusion, it should be up to the xiphoid process or below the breast line that can provide the immobilisation up to T11 level. For surgical procedures up to T4 the TLSO should be up to the sternal notch. For procedures up to T2 level the trim line should come up to the shoulders to reduce upper thoracic motion caused by shoulder joint movements. For procedures extending up to T1 or lower or mid cervical region, SOMI brace should be used to prevent cervical movements. In procedures in the cervical region it is motion control that is more important than flexion control alone. For lumbo-sacral fusion the TLSO must have thigh extension to provide support at the lumbo-sacral region.

POSITIVE EFFECTS OF SPINAL ORTHOSES

There are three positive effects of spinal orthosis: (1) trunk support, (2) motion control and (3) realignment. It is not possible to segregate these functions since all the orthoses have all these functions although one may be more than the other. These functions are achieved by increasing the intra-cavity pressure, containment of torso inside the orthosis providing the regional pressure and a three-point pressure system, which specifically improve alignment. These effectively reduce the functional demand on the spinal musculature as well as vertical loading on the spine. One should distinguish between motion control and trunk support by the ASH brace or SOMI (HCTO) brace, which restricts forward flexion of the spine without supporting the spine.

NEGATIVE EFFECTS OF SPINAL ORTHOSES

It is essential to be aware of the negative effects of spinal orthoses and their effects on the management of spinal conditions.

Weakness and Atrophy

Restricted spinal motion due to orthoses reduces muscular activity. Weakness and atrophy can be prevented by exercises, especially isometric, to the extent that the patient can tolerate within the orthosis.

Contracture

Prolonged immobilisation leads to progressive fibrosis of muscles, ligaments and fascia. It is therefore better to prevent this by a rehabilitation programme from the very beginning.

Psychological Dependence

This usually follows after prolonged use of orthosis. The patient feels secure with an orthosis even when it is no more required and may be due to the fear of recurrence. Over treatment must be avoided, especially when a third party is responsible for the cost of treatment.

Aggravation of Symptoms

Spinal orthosis by virtue of providing rest will improve the symptoms even when wrongly diagnosed. Thus the disease may continue to progress and may lead to a difficult situation. Frequent review of the patient will be helpful.

Hazards of orthotic use can be due to various reasons, namely wrong diagnosis, wrong prescription, wrong donning and prolonged use even when not required. Hazards can also be due to wrong manufacturing and poor finish having sharp margins and edges. The effects can be injury, swelling, ulceration, pressure sore or increased symptoms.

An understanding of the pathology and pathophysiology of the disorder and accurate assessment of orthosis both positive and negative is essential to finally select an orthosis most suitable for a patient.

CHECKOUT OF SPINAL ORTHOSIS

Checkout procedure is actually a systematic evaluation of orthosis and to ascertain that the orthosis is satisfactory and to modify it if required. The critical evaluation pertains to fit, comfort, function and appearance. The patient should be able to don and doff the orthosis easily. Check all the components of the orthosis and their function such as rotatory, flexion and extension as well as lateral flexion control. The patient should be

comfortable when sitting and standing while wearing the orthosis. Patients should be examined immediately after doffing the orthosis for signs of any undue pressure or injury, especially over the bony prominences.

PAEDIATRIC SPINAL ORTHOSES

In a child, the weight of the upper trunk and arm should not exceed the buckling force of the spine in order to prevent an increase in the existing curve. With height growth and weight gain, it increases more than the buckling load and this will lead to increase in the scoliosis even if the child does not gain in height. Increase in height of the child greatly increases his capacity to bear the axial load by the spine. Commonest causes of injury in children are falls, road traffic accidents and sports injuries.

Cervical Spine

Cervical spine immobilised with cervico thoracic orthosis (CTO) four-post cervical collar is one of the best choices.

Thoracic Spine

The Milwaukee brace is often used for thoracic injuries especially above T8.

Thoraco-Lumbar injuries from T11 to L2 are generally unstable and are best treated by custom moulded bivalve thoraco-lumbo-sacral orthosis.

Lumbar spinal injuries are not well immobilised by external orthosis. Halo pelvic traction can provide adequate fixation.

LONG-TERM USE OF ORTHOSES

This is aimed to promote bony healing and prevention of deformity, which can occur at or below the level of injury. It improves sitting balance, frees the upper extremities, slows rates of spinal deformity and may avoid the need for surgery in children.

RECENT ADVANCES

With the advent of newer materials, plastic is now replacing the metallic frame of the orthosis. There also have been improvements in reinforcing these orthosis with glass fibre or carbon fibre. Carbon fibre reinforced spinal orthoses are rigid and as strong as steel. The plastic moulded frames are pre-fabricated and provide adequate support even if they are flexible. Their flexibility is useful and can take the shape of the contours of the body.

Pneumatic cervical spinal orthosis is also a new concept where the orthosis is inflated after wrapping it around the neck and is considered to be more useful in transporting patients with a cervical spine injury.

BRACE CARE

DOs:

- The brace should be kept clean and dry with the help of mild soap.
- It should be worn over a vest or T-shirt.
- The instructions must be followed about wearing the brace.
- It should be worn snugly and tightly.

DON'Ts:

- The brace should not be removed or discarded unless advised.
- It should not be adjusted or modified unless advised.
- It should not be cut, filed or damaged.
- No additional padding should be added or removed by the patient himself.
- One should not engage in any physical activity that causes excessive pain.

ACKNOWLEDGEMENT

The assistance provided by Brigadier H L Kakria, VSM, Commandant of the Armed Forces Artificial Limb Centre, in preparing this chapter, is hereby sincerely acknowledged.

212 Principles of Physiotherapy

Sangeetha Ranganath

INTRODUCTION

Neurological rehabilitation has come a long way from passive movements, training of patients in compensatory strategies, and attempting to control secondary dysfunctions due to imbalanced muscle activity, to task specific, well defined, training methods aimed at improving function. This shift in therapeutic methods can be attributed to a better understanding of how the central nervous system is reorganised after injury and training.

Recovery involves changes in synaptic plasticity of the brain in response to motor learning. The basis for learning, memory and retrieval of information in the injured brain is the same as the normal brain, but with a lesser component of intact neural pathways.

Early gains may be got due to resolution of oedema and inflammatory processes. Once this stage has passed, the therapist has to rely on training, skill development, motivation, feedback and working memory systems to induce physiological and morphological plasticity, which can translate into functional recovery. Re-organisation also occurs in bilateral networks and hence the sensorimotor structures of the uninjured hemispheres also adapt and contribute to recovery.

Research has shown that there is a neural proliferative response to injury. This proliferation, migration, and extension of neuronal processes can probably be potentiated by the right approach to rehabilitation.

Neuroplasticity is the ability of the nervous system to modify its structural and functional organisation post-injury or surgery. Collateral sprouting of new synaptic connections, unmasking of previously redundant pathways and release from inhibition facilitate reorganisation of cortical maps. This may account for considerable recovery as this plasticity can be influenced by proper external stimuli.

In learning, the brain records patterns of synaptic connections that define an event or object, related events, the body's exploration of the environment, the body's reaction to the event, etc. in both "motor and perceptual schemas".

Computational neuroscience has enabled us to understand how complex movement and behaviour can emerge from the interaction of the thousands of neurons that are linked together in neural networks and that these form the essential units of cortical function. These networks have an enormous storage capacity of sequential knowledge.

Hence, it is important for the therapist to bear in mind that rehabilitation strategies should be task specific, intensive and progressive in their demands, and repeated at regular intervals to encourage activity-dependant plasticity in the brain.

Physiotherapy administered to patients can be divided into two parts:

1. Physiotherapy in intensive care
2. Functional rehabilitation.

PHYSIOTHERAPY IN INTENSIVE CARE

Physiotherapy should be seen as an integral part of the multidisciplinary team in the intensive care unit (ICU). Care has to be taken while administering physiotherapy for the intubated patient. The haemodynamic and metabolic status of the patient has to be carefully monitored. There can be an increase in the heart rate, blood pressure, intracranial pressure, increased oxygen consumption, increased carbon dioxide output, etc. as part of an exercise like response and an increased sympathetic output during multimodality physiotherapy.

A number of modalities are at the disposal of the therapist. A holistic assessment of pulmonary, neurological and musculoskeletal conditions need to be made by the therapist and appropriate treatment administered.

It is important that the programme of the therapy should be planned in consultation with the other members of the ICU team and the concerned neurosurgeon.

Treatment Techniques

An important component of physiotherapy in the ICU deals with respiration. This entails:

- Positioning: Includes side lying, postural drainage, getting the patient upright, etc.

All this helps to increase lung volumes and reduce the work of breathing; enhances mucociliary clearance, especially if the respiratory system is depressed. Getting the patient upright as soon as he is physiologically stable not only helps the respiratory system but also keeps the skin intact, prevents pressure sores, helps early mobilisation so the patient moves towards functional recovery soon.

- Percussion and vibration: Manually vibrating, clapping, shaking or compressing the chest wall during expiration is believed to increase the clearance of airway secretions
- Suction: To remove secretions by suctioning if a tracheostomy has been done for the patient
- Manual hyperventilation: Involves the use of a manual resuscitator bag. The lungs are inflated with a large tidal volume via the bag. Manual hyperventilation is used to prevent pulmonary collapse, improve oxygenation and lung compliance and increase movement of secretions towards the central airways, in patients on the ventilator or with a tracheostomy
- Mobilisation and limb exercises: Can be passive, active assisted, or active depending on the level of sensorium of the patient. It would include limb exercises, turning, sitting up, standing, transfer from bed to chair, etc.

FUNCTIONAL REHABILITATION

Sensory Stimulation and Arousal Therapy

This should begin as soon as the patient is medically stable. Various sensory modalities can be used like auditory, tactile, visual, olfactory, etc.

- Auditory stimuli like familiar family voices and names, music, ringing bells and so on
- Visual stimuli like family photographs, flash cards, bright colours, etc.
- Olfactory stimuli like fragrances, coffee and food
- Taste of swabs of familiar flavours, sugar, salt, etc.
- Tactile stimuli like temperature (warm and cold), touch (feel of different fabrics), pressure, etc.

Though the efficacy of sensory arousal is not fully clear, care must be taken to administer the stimulus in a way that it benefits the patient. Over stimulation and bombarding the nervous system with too much stimuli at the same time can be disturbing to the patient, and too routine a stimulus can lead to habituation.

A patient's (with head injuries or following major brain surgery) level of arousal could range from no response to confused, agitated, automatic, purposeful and appropriate. A positive approach from the start can contribute greatly to the success of the treatment. It would be wise to remember that the patient is not merely a "head injury" or a "hemiplegic", but a human being and should be treated well, with dignity and respect. The therapist may misjudge the extent of sensorial impairment, and therefore, must always be careful on casual comments about the patient's prognosis, etc. Another important factor is that "brain damage" is a family affair. Hence, all persons at home and in the environment have to be involved if the patient has to integrate back into home and family.

Every patient who has suffered a brain lesion will "feel differently" from the way he did prior to the lesion even if his sensations are seemingly normal. It is not just loss of motor control, altered tone, balance, gait, etc. that have to be assessed, but also a thorough sensory analysis has to be done. The neurological therapist has to deal with various perceptual, cognitive and behavioural issues. Patients can have visuo-spatial defects that involve neglect of certain parts of one side of the body and the world around them. He can also have problems analysing and remembering visual information, recognition of objects, judging form and distances, problems with perception of the environment and with awareness of the body in space and so on.

All this can influence the rehabilitation and recovery, and so have to be considered carefully. After a good sensory and motor assessment (can use motor assessment scale, or stroke rehabilitation assessment of movement) the next step is to move on to motor training.

There are many theories of motor control and motor recovery. Hence there are various approaches to motor training, like the neurodevelopmental theory, motor relearning model by Carr and Shepherd that the neurotherapist can use. Perhaps the various approaches are not mutually exclusive, but can be combined at different stages of recovery.

The activities can be broken down into various components starting with activities in bed, grasping, reaching out, segmental rolling and attempting to sit. The therapist can then progress to sitting balance, active trunk control, weight bearing on arms and activities while sitting. The next step is to train the patient in standing (with full support if needed), balance and walking.

There is mounting evidence to show that we learn what we practice. This has been proven at behavioural, biomechanical and biological levels. Hence, any motor learning model has to be task and context specific. It cannot for example be assumed that successfully flexing and extending the elbow in bed will automatically translate into feeding activity while sitting. This is because any activity involves a sequence of muscle activation patterns, not a muscle contracting in isolation. Hence, there is importance of task oriented activity in training. The same principle holds true for lower limb training, standing, walking or any other activity.

Constraint Induced Therapy

It is found that over a period of time patients develop a learnt non-use of the affected limb in addition to the deficit that they have. So strapping the normal arm for example, for several hours during the day enables, or rather forces the patient to attempt the use of his affected arm for various activities. This has found to produce good results.

Soft Tissue Flexibility

Alteration in tone or spasticity does have its role in causing motor dysfunction. But now there is evidence to show that changes in soft tissue length and muscle itself will limit segmental movement. It is typical for

paralysed limbs to remain motionless for long periods of time in one position. This causes changes in the properties of muscle fibres and connective tissues. Muscles persistently held in the shortened position develop length-associated changes. The clinical resistance to passive stretch is now considered to also be due to a reduced compliance of muscles. Hence, it is critical to start early task oriented mobilisation to maintain a sufficiently flexible musculoskeletal system.

There has been an attempt here to point out a growing shift in rehabilitative strategies, from passive movements and exercises in bed to a more dynamic approach involving activities of daily living. Hence, rehabilitation should be planned to maximise regaining of motor competence and integrate the patient back into his environment as early as possible.
