Intracerebral haematomas may co-exist with compound depressed fractures and may be revealed while the fracture is being treated. Some of them clinically simulate acute extradural or subdural haemorrhage or may be associated with them.[16] Others may present subacutely some days after the head injury with signs of increasing ICP. In subacute cases, CT scan is of great help in the diagnosis and localisation, as well as in detecting associated surface haematomas. The majority of acute cases are fatal if the haemorrhage does not stop. Kristiansen and Tandon[18] found (before the CT era) intracerebral haematomas in a series of 146 cases of post-traumatic intracranial haematomas of which only 50% could be saved. When encapsulated, the haematomas can be evacuated with benefit, through suitably placed burrholes.[25] Stereotactic evacuation can be done. In surface haematomas, if burrhole aspiration is not effective, the localised haematoma can be removed by a craniotomy. Tandon recommends that all patients with sizeable intracerebral haematoma require a large trephine or a formal craniotomy to achieve satisfactory

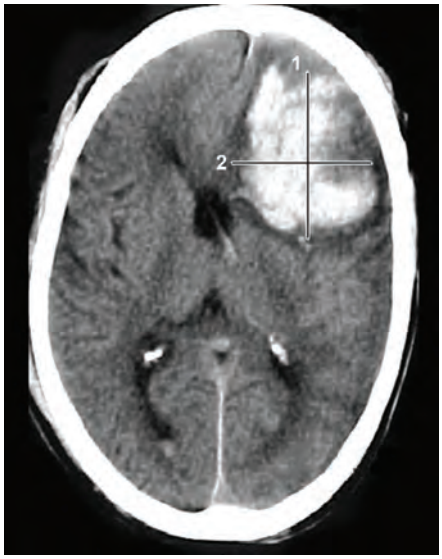

Fig. 1: CT scan of the brain showing post-traumatic haematoma in the frontal lobe

Fig. 2: CT scan of the brain showing post-traumatic haematoma in the temporal lobe

evacuation and decompression.[28,29] Small haematomas do not need surgical relief. Endoscopic evacuation of the intracerebral hematoma can also be done.

Delayed Intracerebral Haemorrhage

A delayed haematoma is one that is seen on a repeat CT scan within 24–48 hours of the injury, and was not present on the initial scan. A circumscribed haematoma may occur sometime after the original accident during the process of repair of the lacerated brain. This is due to bleeding from the necrosed blood vessels into the lacerated area. Originally described in 1891 by Bollinger[3] as "late traumatic apoplexy", this rare syndrome is interesting not merely as regards the time factor but also because of the "apoplectic" onset of symptoms.[11] Mertol et al.[20] found the average interval between the trauma and the delayed haemorrhage to be about 24 hours. Its pathogenesis is not clear.[1] The fact that these cases occur usually in the older age group may indicate that this may be a complication of a pre-existing vascular pathology such as atherosclerosis. There is renewed interest in delayed injury which is now known as the "concept of secondary autodestruction" as an area of research.[12] A probable explanation seems to be that the bleeding occurs slowly into a softened area of traumatized brain, the "apoplexy" occurring when a critical point is reached. During the intervening period the patient appears well and presents a picture resembling a chronic subdural haematoma. The diagnosis is difficult as the symptoms and signs, both focal and general, tend to wax and wane, and then all of a sudden the patient gets into the final state of coma. Clinical awareness of this possibility is important and when patients do not rapidly improve or continue to be ill, CT studies are to be repeated. The prognosis is poor even when the haematoma is evacuated by aspiration through a burrhole. Three of eight patients with delayed ICH seen by Mertol et al.[20] expired. Nineteen percent of patients with severe head injuries who deteriorated neurologically after admission to the hospital had large delayed intracerebral haematomas as reported by Clifton et al.[8]

In the course of an acutely enlarging space-occupying lesion, such as an intracerebral haematoma/contusion in the human or an extradural inflated balloon (a simulated lesion) in the experimental animal, four stages of evolution may be distinguished.

a. Stage of initial compression
b. Stage of venous congestion, oedema, anoxia and neuronal irritation
c. Stage of arterial obstruction, anaemia and neuronal paralysis
d. Stage of irreversible neuronal failure and death.

Stage of Initial Compression

Initially the rise in ICP due to an increasing mass lesion is compensated by the displacement of CSF, blood and brain itself. However, once these mechanisms prove to be inadequate, venous congestion leads to stasis of blood and an increase in tissue CO_2 and oedema. Clinically the signs are those of neuronal irritation, epileptic fits, constricted pupils and general irritability, with headache of increasing severity and vomiting. The patient may be drowsy or confused and boisterous. There is a distinct shift from orientation to confusion. There is no significant rise in the systolic blood pressure as yet. The deformed and displaced brain irritates the ipsilateral third nerve and then the contralateral third nerve followed by their paralysis resulting in sequential changes in the pupils. These changes herald temporal lobe herniation into the tentorial hiatus and compression of the upper brainstem.

Compression of the long tracts results in ipsilateral and then contralateral hemiplegia. With rapidly collecting haematomas, the brainstem is pushed and the contralateral cerebral peduncle is compressed against the free margin of the tentorium (Kernohan's notch) leading to an ipsilateral hemiplegia. Thus, the haematoma may be on the same side as the hemiplegia (Kernohan's phenomenon).

Stage of Anaemia and Neuronal Paralysis

At this stage, the ICP is raised high enough to cause a critical reduction in cerebral blood flow. This leads to abolition of vasomotor tone and further autoregulation of the cerebral circulation is not possible. The vasoparalysis results in the volume of the blood in the vessels passively following the changes in the arterial blood pressure, and haemorrhages may occur in the brain. The patient drifts into unconsciousness, the pulse pressure rises and the respiratory rate first becomes slow and then rapid. When both the cerebral peduncles get compressed, the patient goes into extensor rigidity that comes on as extensor spasms spontaneously or on stimulation. At this stage both pupils are dilated and nonreacting. As the ICP rises further, the lower brainstem begins to suffer. The patient may hyperventilate washing out the CO_2 and manifest Cheyne-Stokes periodic breathing. The respiratory centre gets deafferented and induces apneustic type of breathing. The autonomic nervous system is in disarray and there could be excessive secretions from the salivary and other glands, which trickle down the throat, making the respiration gurgling and noisy.

Stage of Irreversible Neuronal Failure

The blood pressure begins to fall and respiratory arrest and death supervene. Experimental studies have shown that the earlier the ICP is restored to normalcy by the removal of the acute compressing lesion, the greater are the chances that oedema and other tissue changes in the brain will get reversed. Irreversibility sets in between the second and the third stages, a transition which is marked by the onset of unconsciousness.

One would expect to note this orderly sequence of events in every case but for the following four important modifying factors:

Distribution of ICP: The increasing ICP is not uniformly distributed over the entire brain, the greatest pressure being exerted nearest the lesion with the zone of increased pressure successively spreading to the opposite side and then over the entire brain. Hence, in practise, a combination of symptoms of neuronal irritation and paralysis may occur simultaneously, as for example, a constricted pupil on one side and a dilated pupil on the opposite side.

Skull not a smooth sphere: This fact and the division of the cranial cavity into compartments lead to variations in the degree of ICP from area to area and to displacement of structures through anatomical openings. This results in the clinical picture of "coning" under the falx, through the tentorial hiatus and through the foramen magnum.

The rapidity and progress of compression: These influence the brain response. If the progress of space occupation is spread over weeks or months as in neoplasms or in a chronic subdural haematoma, several other compensatory mechanisms come into play and the clinical picture becomes different.[9] High blood pressure, for example, is not a usual feature even in large tumours of the brain though the ICP may be high.

Associated brain injuries: These modify all the processes enumerated so far making the clinical picture more complicated and more rapid in progress, the changes varying with the site and degree of injury.

CLINICAL FEATURES

Conscious Level

With the exception of penetrating injuries, like gunshot wounds, it is almost impossible for severe brain damage to occur without an alteration in the level of consciousness. No one dies of a damaged brain in a conscious state; a period of coma always precedes a fatal outcome. Thus, alteration in the level of consciousness is an important clinical entity. Its relationship to the time of injury and its progress with time and therapy give valuable information regarding the diagnosis.[18]

During the first two or three hours after a non-fatal head injury, the primary neuronal injury is the main, if not the only active lesion. One may assume that complicating epiphenomena take a little time to establish themselves. This assumption, though not always true, helps as a working clinical hypothesis. Unconsciousness, which supervenes immediately after the injury but clears in a few minutes, is usually explained as concussional. If such unconsciousness persists, it indicates the severity of the underlying primary neuronal damage. On the contrary, if the loss of consciousness occurs some time after the accident, the obvious conclusion is that the primary neuronal injury was not severe enough to render the victim unconscious and that this delayed loss after the "lucid interval" is due to the onset of the epiphenomena. The state of consciousness at the time of onset of the epiphenomena has a definite significance. The greater the depth of unconsciousness at the onset, the grosser is the primary neuronal damage.

Early Detection

In patients with intracerebral haematomas, perilesional swelling and enlargement of bleeding is the rule rather than the exception. Thereby, to achieve a low mortality rate, the development of the classical picture of severe compression has to be prevented by early recognition of rising ICP and prompt intervention.

Are there any clinical signs or symptoms of raised ICP which are earlier in their onset than changes in the level of consciousness? Any such pointers would be of immense value, because the most favourable time to initiate surgical or medical therapy is before unconsciousness sets in. In this context, apart from guidance from CT findings, many neurosurgeons advocate routine ICP monitoring to detect a rise in ICP before clinical signs become obvious.

Headache, which does not subside on routine analgesic administration, persistent vomiting and convulsions, especially in non-epileptics, must arouse suspicion, though they could be explained on other grounds. The earliest alterations in consciousness are subtle and must be looked for; inattention, lack of the usual alertness, and a delayed response to routine demands are extremely suggestive even though the patient may give satisfactory answers to specific questions. There is no clinical feature really pathognomonic of extradural, subdural or intracerebral haemorrhage. A direct injury, a fracture line across the vascular markings and a boggy swelling of the scalp indicate the possibility of extradural haemorrhage.

Careful neurological examination reveals subtle signs like an extensor plantar response and hyperreflexia on one side or diplopia. Involuntary micturition in a conscious adult with head injury is always a definite indication of raised ICP. Restlessness not subsiding easily may indicate the onset of cerebral compression. These various features either singly or in combination constitute grounds enough to get a CT done.

The most frequent clinical event that prompts the surgeon to operate is the deterioration in the level of consciousness. This may be with or without a lucid interval. Pupillary asymmetry and onset of hemiplegia and convulsions are events that appear later. Thus, their presence in a conscious patient requires careful assessment to exclude local injury or contusion. Changes in vital signs, like blood pressure, pulse rate except when slow, or respiration, hardly ever provide an indication for surgery. They are more useful in the assessment of the total injury to the body.

Volumetric Measurement of Intracerebral Haematoma[6]

Volumetric measurement on traumatic brain injury is calculated by the ellipsoid method (ABC method) (previously described for AVM) or by the direct estimation

method using a grid as described by Cavalieri et al. The ABC method described by Kothari et al.[17] has been proposed as a means of measuring ICH volume.

The first step is to identify the CT slice with the largest area of haemorrhage. The variables are given as follows: (A) the largest diameter; (B) largest diameter perpendicular to A on the same slice; (C) the total number of 10 mm slices. Compare each slice with the first slice. The haemorrhage is scored as follows: If it is more than 75% compared with slice 1, the slice is counted as 1, if the ICH is 25–75% of the maximum size count the slice as 0.5 and if the slice is less than 25% the slice is not counted. The total gives the value of the variable C. The volume is then calculated by the formula ABC/2.

REGIONAL CEREBRAL BLOOD FLOW (rCBF) MEASUREMENT

Chieregato et al.[7] evaluated regional cerebral blood flow (rCBF) by means of xenon-enhanced computerised tomography (XeCT) in 29 traumatic intracerebral haematomas, from 22 patients with severe head injury [Glasgow coma scale (GCS) < or = 8]. The rCBF was measured in three different regions of interest: The haemorrhagic core, the peri-haematoma oedematous low-density area, and a 1-cm rim of peri-haematoma normal appearing brain tissue, surrounding the oedematous low-density area. They found a centrifugal improvement of rCBF as well as a decrease in the rates of CBF levels below 18 ml/100 g/min from the core to the periphery ($p < 0.0001$), which persisted over time. Ischaemic rCBF values were detected in the peri-haematoma low-density area only in 24% of the traumatic haematomas. The time course of rCBF levels showed a reduced flow in the first 24 hours, with a recovery of flow from day 2 to day 4, followed by another reduced flow ($p <$ or $= 0.0001$) both in the peri-haematoma oedematous low-density area and in the non-lesioned tissue. Their findings suggest that the only area with persistent ischaemic values was the haemorrhagic core, and the low rCBF levels seen in the peri-haematoma low-density area can be ascribed partially to ischaemia, which can possibly recover over time. Their results could encourage a surgical approach based on an early evacuation of the haemorrhagic core with preservation of the surrounding oedematous tissue.[7]

GUIDELINES FOR THE TREATMENT OF TRAUMATIC ICH[5]

1. Patients with parenchymal mass lesions and signs of progressive neurological deterioration with reference to the lesion, those who develop medically refractory-raised ICP or those who show signs of significant mass effect on CT have to be managed surgically.
2. Patients with GCS 6–8 with frontal or temporal contusions more than 20 cc in volume associated with a midline shift of 5 mm or more, with cisternal compression on CT scan and with a lesional volume more than 50 cc are to be managed surgically.
3. Patients with parenchymal mass lesions who do not show signs of neurological compromise, who have a controlled ICP and with no significant mass effect on CT scan may be managed conservatively with intensive care unit (ICU) monitoring and serial imaging.

Treatment Strategies-Timing and Methods

Intracerebral haematomas generally do not require surgical evacuation unless there is significant mass effect or intracranial hypertension resulting in a poor GCS. They resorb in about 4–6 weeks by macrophage phagocytosis and gliosis.

1. Craniotomy and evacuation of the mass lesion is recommended for patients with the surgical indications listed above. A bifrontal craniotomy sometimes may have to be performed in cases of bifrontal haematoma as the procedure provides a larger area of decompression, through which the underlying haematoma and haemorrhagic tissue can be easily visualised and evacuated. For temporal lobe lesions, one requires temporal craniotomy. Ventricular drainage may be necessary when there is associated intraventricular haemorrhage causing hydrocephalus.
2. Bifrontal decompressive craniectomy within 48 hours of injury is a treatment option for patients with diffuse, medically refractive post-traumatic cerebral oedema and the resultant intracranial hypertension. Two studies showed better outcomes when the procedure was performed before irreversible ischaemic brain damage resulted.[15,24]
3. For temporal lobe lesions—contusion, laceration, haematomas, a temporal craniotomy and removal of the damaged tissue is the treatment of choice. In case the haematoma is circumscribed, it could be removed through a cortical incision. In cases with a more diffuse lesion, an anterior temporal lobectomy may be required.[28]
4. Decompressive procedures, including subtemporal decompression, temporal lobectomy and hemispheric decompressive craniectomy, are treatment options for patients with refractory intracranial hypertension with diffuse parenchymal injury with clinical and radiological evidence of impending transtentorial herniation.

To summarise, traumatic ICH of volume more than 50 cc or in any patient with traumatic ICH in whom there is progressive neurological deterioration, mass effect on CT, refractory raised ICP and with a shift of more than 5 mm, surgery is recommended.

OUTCOME

It is believed by many neurosurgeons that in addition to age and neurological status, the CT patterns of traumatic intracerebral haemorrhages are related to outcome. Wong et al.[31] analysed prospectively and collected data of patients with traumatic intracerebral haematomas. Logistic regression analysis showed that

age and GCS score/GCS motor component score were significant factors for inpatient mortality, one-year mortality and one year outcome. There was an association between temporal haematomas and inpatient mortality, subdural haematomas and inpatient mortality, and bilateral haematomas and unfavourable one year outcome. They concluded in patients with severe head injury, a traumatic haematoma of more than 50 ml was associated with higher inpatient mortality, and in addition to age and GCS score, the CT patterns of bilateral haematomas, temporal haematomas and associated subdural haematomas were suggestive of poor outcome or mortality.[31]

PREVENTION OF TRAUMATIC ICH

No discussion on traumatic ICH is complete without a note on prevention and the programs which have been implemented to lessen the sufferings of people affected by trauma. Neurosurgeons generally cry themselves hoarse about road safety, as they more than any other specialty in medicine see more often than not lives and families marred by trauma. Towards the goal of trauma prevention, the efforts of the World Health Organization (WHO) and the Accident Trauma and Life Support (ATLS) programs are to be lauded.

The ATLS was born through the untiring efforts of Dr JK Styner in 1978. Having suffered a family tragedy following a flight accident in 1977, he realised that the treatment of trauma could be made more efficient if the doctors were systematically trained. He patterned the ATLS on the already existing advanced cardiac life support (ACLS), which had made inroads into emergency cardiac care and was paying rich dividends. The first ATLS prototype program was started in conjunction with the Southeast Nerbraska Emergency Medical Services in 1978. The American College of Surgeons (ACS) committee on trauma (COT) adopted it in 1979 and ever since it has grown in stature and efficiency and is today considered the *sine qua non* in a trauma unit. It has brought about a uniformity world over in the treatment of the injured.[4]

The Essential Trauma Care Project (EsTC project) is a collaborative effort of the WHO together with the International Association for Trauma Surgery and Intensive Care (IATSIC), an integrated society as a part of International Society of Surgery. They have issued guidelines for essential trauma care.[21] The WHO also provides details about trauma care and recent advances on its website www.essential traumacare.org. They have stated in their guidelines what are known as "Rights of the injured"; in which head and spinal injury treatment find a special mention.[22]

The Indian Academy of Traumatology was among the first to implement these guidelines in 2003 even when it was in its nascent stages. This was done after a meeting in Gujarat. In 2005, the first National Consultation Meeting on Trauma System Development in India was held under the auspices of the WHO. The guidelines recommend 4 levels of trauma care with Level 1 being tertiary care hospitals with teaching programs in trauma and allied fields and with 24 hours service and the fourth level being the rural hospitals. But we in India indeed have "miles to go before we sleep" before quality trauma care on par with the Occident is available for all.

39 Traumatic Brainstem Haematomas

Ashok Kumar Mahapatra, Deepak Agrawal

Traumatic brainstem haemorrhage is a rare condition. Prior to the availability of the CT scan, it was practically impossible to establish the diagnosis of brainstem haematoma (BSH) antemortem. Prior to the CT, diagnosis was suspected based on clinical findings like decerebrate rigidity and an inter-nuclear ophthalmoplegia. However, these findings can also be present due to functional disturbances, and it is not always necessary to have anatomical changes in the brainstem.[16,25,31] With the advent of CT scan, it has become possible to visualise and diagnose BSH in head-injured patients within 4–8 hours. This chapter highlights some aspects of traumatic BSH.

HISTORY

The occurrence of haemorrhages in the brainstem in cases of craniocerebral injuries was well documented by Duret in 1878. These came to be known as Duret haemorrhages.[20] Interestingly, Duret described most of them in the medulla while these generally affect the midbrain and pons. During the following years, Bollinger (1891), Attwater (1911), Martland and Beling (1929), Jefferson (1921), Bann-Worth (1935) and others discussed the various aspects of the problem. There was difference of opinion regarding the pathogenesis, the clinicopathological correlation and even about the site of the haemorrhages. For more details refer to Tandon (1964).[31]

INCIDENCE

The incidence of brainstem haemorrhage is difficult to determine. Tandon in 1964 reported 69 cases of brainstem haemorrhage among 132 autopsy cases of head injury.[31] Mahapatra et al.[16] had reported seven cases of BSH among 62 decerebrating head-injured patients. Tsai et al.[32] in 1986 reported brainstem lesions in 67 patients among 1,600 injured patients. However, the data also included indirect evidence of brainstem involvement such as obliteration of prepontine and perimesencephalic cisterns. Thus, only 19 patients in their study had brainstem injury and 12 of them had evidence of haemorrhage on the CT scan. Zuccarello et al.[37] in 1983 reported primary brainstem haemorrhage in 36 patients among 1,000 cases of head injury in whom CT scans were performed. In a study of 2,500 patients with head injuries, only 48 were found to have BSH.[19] With the advent of CT scan, the incidence of BSH has dramatically increased. Kalyanaraman and Ramamurthi[13] reported brainstem haematomas in 4.6% of all head-injured patients.

MECHANISM OF INJURY

Since Duret first described this condition in 1878, there are several pathological studies describing the details of mechanism, location and pathogenesis of BSH[6,15,25,34] (Fig. 1). Acceleration and deceleration injuries involve the brainstem to varying degrees, depending upon several factors. Mechanical effects of stretching and distortion further aggravate the damage due to vascular injury. Involvement of the brainstem can occur due to several mechanisms: (a) damage to the brainstem by direct force of impact; (b) due to flexion and distortion and (c) vascular involvement. Primary damage is also possible due to brain movement when the brainstem gets lacerated or contused by the tentorial edge.[11,25,31] While acute flexion is the most frequent cause, rarely hyperextension injury to the head can also give rise to brainstem damage.[15] Generally, primary brainstem injury can be in the form of: (a) laceration; (b) contusion and (c) BSH (Table 1). Frequently, brainstem injury is associated with injuries elsewhere in the brain. Isolated brainstem injury/haematoma occurs rarely.[3,11,15,17,22,25,31] Very rarely, traumatic brainstem transection has been reported.[10]

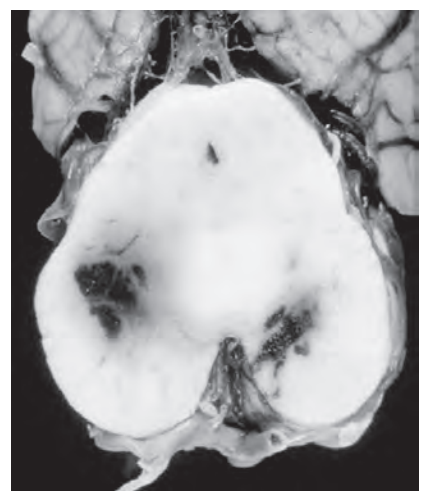

Fig. 1: Brainstem haematoma seen in bilateral paramedian location in diffuse axonal injury

Table 1: Pathology of traumatic brainstem lesions

(A)	Primary pathology
	(i) Laceration
	(ii) Contusion
	(iii) Primary brainstem haematoma
	(iv) Transection of brainstem
(B)	Secondary pathology
	(i) Oedema
	(ii) Ischaemia
	(iii) Infarction
	(iv) Secondary haemorrhage
(C)	Combination of primary and secondary pathology

Secondary damage to the brainstem occurs more frequently as compared to primary damage. Transtentorial herniation is the most frequent cause of brainstem damage. Secondary brainstem haemorrhage is more frequent in the tegmentum of the midbrain and the pons.[6,10,22,27,36] Multiple subependymal punctate haemorrhages may also occur secondary to transtentorial herniation. Secondary haemorrhages are often bilateral and paramedian in location.[5,7,15,25,27,36] Necrosis may occur in distorted areas. Secondary medullary lesions are also seen due to longitudinal buckling of the medulla. Frequently, both primary and secondary damage in the brainstem might coexist. Lesions, like ischaemic necrosis, small haemorrhages, microhaemorrhages and degeneration of axons, showing retraction bulbs can also be seen.

Subthalamic lesions are prone to microhaemorrhages and necrosis. Primary lesions are less common in the tegmentum. In the medulla, there is selective necrosis of the inferior olivary nucleus and vestibular nuclei.[25,27,31]

CLINICAL PRESENTATION

Patients with BSH are usually unconscious or in altered sensorium (Table 2). However, only on the basis of unconsciousness, a clinical diagnosis cannot be made. Rarely, patients may have GCS more than nine.[17,27,31] In our study, out of 70 patients 15 had no response to pain on admission and 35 (50%) were decerebrating. Tandon[31] reported that only two-thirds of cases were comatose from injury to death, while the remaining were unconscious. He also reported a lucid interval in 21% and no initial unconsciousness in 9% of patients. Mahapatra et al.[17] in 1990 reported five patients who were conscious at the time of admission. In a series reported by Tandon,[31] 7% of patients were conscious at the time of admission.

Table 2: Conscious state in brainstem haematoma (AIIMS experience)

Responses	*No.*
No response	15
Decerebrating	35
GCS 5–8	15
GCS ≥ 9	5
Total	70

Decerebrate rigidity is commonly observed in patients with BSH.[2,17,27,37] However, decerebrate rigidity can occur in the absence of a brainstem lesion. Rarely, patients present with hypotonicity.[27]

Other clinical findings which are typical of brainstem lesions are respiratory abnormalities, pupillary changes and temperature changes. Varieties of respiratory abnormalities have been reported depending on the site of the lesion. It could be classical Cheyne-Stokes breathing, hyperventilation or shallow breathing. Some patients rapidly deteriorate to brain death with respiratory arrest. Disturbances of temperature regulation lead to hyperpyrexia. In the past, hyperthermia was considered pathognomonic of pontine haematoma. Surprisingly, however, Tandon[31] reported hypothermia in 35% patients with brainstem haemorrhage, as compared to a 48% incidence of hyperthermia in patients with non-haemorrhagic brainstem involvement.

Pupillary abnormalities are well described in brainstem haemorrhage.[4,31,32] Fixed dilated pupils were frequently observed by Tsai et al.[32] Tandon[31] described the classical presentation of bilateral non-reacting pupils in patients with brainstem haemorrhage. Nevertheless, he found, in the same study, 26 normally reacting pupils and 65 patients clinically manifesting signs of brainstem dysfunction who on autopsy did not have brainstem haemorrhage. He also found that the so-called 'pin-point pupils' are very rarely observed in patients with BSH. Thus, pupillary changes are non-specific and not diagnostic of brainstem injury.

Disturbance of conjugated eye movement is more frequent. This is basically due to involvement of the medial longitudinal fasciculus (MLF). The disconjugate movement and abnormal oculocephalic or doll's eye movement are characteristic findings of brainstem damage.[12,21,29,32,34]

Cold Caloric Response (Vestibulo-Ocular Reflex)

Cold caloric response is an important test for assessing brainstem integrity.[12,16,17,18,29,30] Its utility in predicting the outcome in severe head injury is well established.[12,16,18,23,30] It is a simple bedside test. The head is raised by 30 degrees and the external auditory meatus is irrigated with ice-cold saline or water which stimulates the semicircular canals. The stimulus is carried by the vestibular nerve to the vestibular nuclei which are connected to the MLF, and 3rd and 6th nerve nuclei in the brainstem. Thus, by stimulating the vestibular nuclei, there is conjugate deviation of the eyes with nystagmus in normal individuals. Depending upon the site of brainstem involvement and the degree of damage, there may be absent or abnormal response of varying degrees[12,30] (Table 3). A complete absence of caloric response is indicative of a grave prognosis.[17,18] The study must be repeated several times to assess improvement or deterioration of brainstem function and is more predictive and reliable as compared to brainstem auditory evoked response.[4]

Brainstem Auditory Evoked Response

Brainstem auditory evoked response (BAER) is a reliable study assessing auditory nerve and brainstem function. BAER is frequently used as a prognostic test in severe head injury. Patients with normal BAER have a good prognosis and, on the contrary, patients with repeatedly absent BAER either die or remain vegetative. Only a few studies have reported the usefulness of BAER in BSH.[17,18,24,28,35] Sancesario et al.[28] reported BAER findings in six patients with BSH and found that abnormality of wave IV and V as well as delay in I–V interpeak latency is the most frequent finding. Tsutsui et al.[35] reported BAER in one patient with BSH, prior to and following haematoma evacuation. BAER normalised following surgery and preceded clinical improvement. Mahapatra et al.[17] emphasised the role of BAER in 70 patients with traumatic BSH. Patients with repeatedly absent BAER had a poor prognosis. On the contrary, improvement in BAER findings or normal BAER were associated with a favourable outcome (Figs 2 and 3).

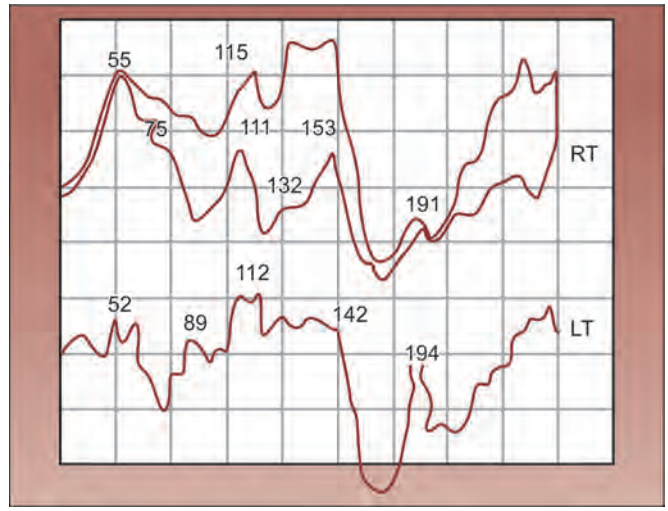

Fig. 2: BAER in a 13-year-old boy with brainstem haematoma shows normal wave pattern. The child had good outcome

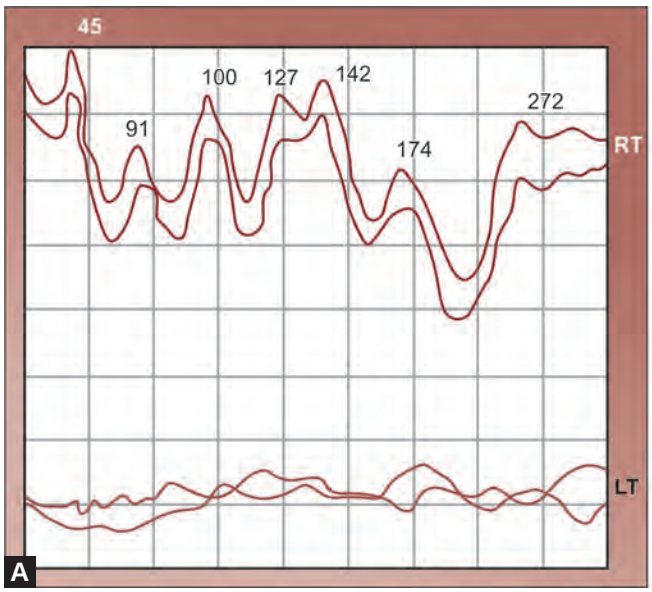
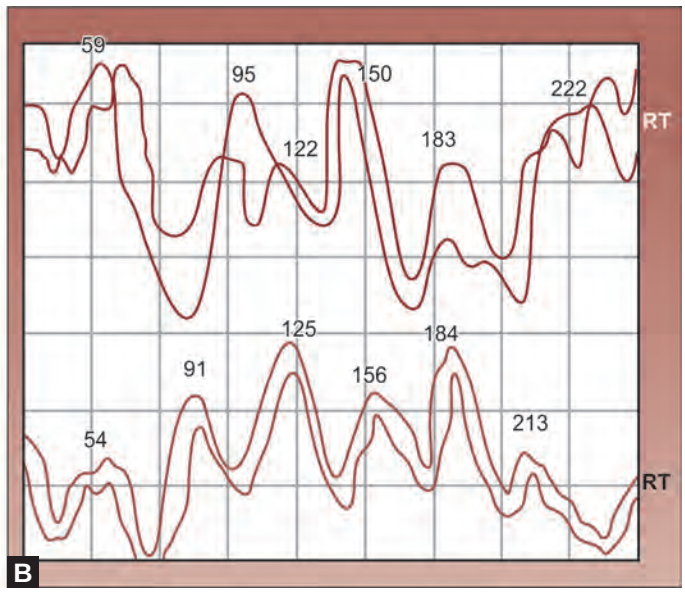
RADIOLOGY

CT scan (Tables 4A and B) is a reliable imaging modality for post-traumatic intracranial pathology, because of its ability to demonstrate the extent, sites and nature of injury. Hence, today CT is the primary diagnostic method in patients with head injuries (Fig. 4). There are several reports dealing with findings in BSH.[17,24,28,32,33,35,37] CT scan not only shows the haematoma but it also shows the obliteration of the basal cisterns and the presence of blood in the prepontine or perimesencephalic cistern17 (Fig. 5). Tasi et al.[32] studied direct and indirect evidence of brainstem injury. Direct evidence was the presence of a haematoma. Among 67 patients diagnosed as brainstem injury, only 12 had haematoma, and 55 were diagnosed on indirect evidence. They also described unifocal or multifocal haematoma. The haematomas may be hyperdense, isodense or hypodense, depending on the extent of haemorrhage and oedema.

Mahapatra et al.[17] described their findings in 70 patients. Thirty-four patients had midline haematoma and 36 had a laterally placed haematoma. In 45 patients, haematomas were situated in the midbrain and in 25





Figs 3A and B: (A) BAER findings in a patient with brainstem haematoma show no wave on the left side. (B) BAER repeated one week later shows bilateral normal waves. Patient had good recovery

* Required surgery

patients the haematoma was in the pons. Surprisingly, there was no case of medullary haematoma (Table 4A). CT scan also demonstrated a remote haematoma in the brain in a significant number of patients.[17,32] The study reported from our department[17] showed associated focal abnormalities in 25 patients with 16 requiring surgery (Table 4B).

TREATMENT

There is no specific treatment for BSH. However, associated pathology may need surgery[17,32] depending on the size of the haematoma and the mass effect. Overall, 20% of patients with brainstem haemorrhage may have sizable haematomas elsewhere in the brain needing surgery.

As the patients with BSH are very sick and remain unconscious for long periods, they need longer intensive care management and ventilatory support. Nursing care, management of pulmonary problems and tracheostomy care need special mention. Moderate hypothermia and control of hyperpyrexia, if present, are important factors in survival. Hypothermia may enhance the chance of survival.[9]

Outcome in Patients with Traumatic BSH

Outcome of patients with traumatic BSH was considered to be grave two decades ago. With the availability of CT, diagnosis and follow-up of these patients has become possible and more reports are available regarding long-term outcome and quality of survival of these patients.[1,4,8,9,17,22,28,32,35,37]

Mahapatra et al.[17] had reported survival in more than 50% of cases studied. Among the 70 patients analysed, 38 survived and 22 patients had a good recovery. Six patients each were severely disabled or remained vegetative (Table 5). Stewart et al.[8] developed a prognostic model for head injuries and found brainstem haematoma to be an important variable in the prognostication. Age, associated skull fracture and other injuries were also significant factors for prognostication. Young patients had a good outcome. In a series reported by Tsai et al.,[32] mortality rate was 67% in patients with secondary brainstem injury. In another study the same authors reported 27% mortality in patients with transtentorial herniation, but without brainstem involvement, and 61% had mild to moderate deficits. The survival rate in transtentorial herniation alone was 73%. Of the 19 patients with primary brainstem injury only 5 patients survived. Thus, in their study, patients with primary BSH had a survival rate of 25%.

Other significant factors which help in predicting the outcome are cold caloric responses and brainstem auditory

Table 5: BAER and outcome experience in 32 patients at AIIMS

BAER findings	*No deficit*	*Mild deficit*	*Severe deficit*	*Vegetative*	*Dead*
Normal (8)	4	3	1	–	–
Abnormal (16)	4	6	5	–	1
Absent (8)	–	–	–	1	7
Total	8	9	6	1	8

evoked potentials.[4,17,18,30,35] Absent cold caloric response in patients with brainstem haemorrhage carries a grave prognosis.[17,18,30] Similarly, when repeated BAER recordings fail to show waveform or absence of wave III, IV and V, it denotes a poor outcome.[17,28,35] Presence of traumatic basal subarachnoid haemorrhage[26] in association with brainstem injury also carries a poor prognosis.

CONCLUSION

Traumatic BSH is not as rare a condition as was believed earlier. With the availability of CT scan more cases are being diagnosed to have BSH. The common sites for BSH are the pons or midbrain. Around 25% of patients are conscious at admission and 50% of patients are admitted in a decerebrating state. In more than 30% of patients, there are associated haematomas elsewhere in the brain. Caloric responses and BAER are two good prognostic tests. Repeated normal cold caloric response or BAER is indicative of a good prognosis. Survival ranges from 30 to 50%, and 25% may have good outcome.

40 Complications and Sequelae of Head Injuries

Khosla VK, Gupta SK, Mukherjee KK, Chhabra R

INTRODUCTION

Head injury (HI) can account for a great deal of chronic disability. Common physical defects after HI include cranial nerve palsies, such as anosmia, oculomotor paresis, visual field defects, and motor disorders, resulting from cortical or brainstem lesions. The other more disabling effects of head injury include a group of syndromes for which there may not be a demonstrable pathological basis. Problems, such as cognitive incapacitation or personality change far outstrip the physical sequelae. These psychological deficits act as obstacles in rehabilitation and as a source of long-term disability. Decline in employment is more likely to be associated with mental than physical factors. These post-traumatic sequelae include:

- Post-traumatic amnesia
- Post-concussion syndrome
- Neurobehavioural sequelae
- Post-traumatic epilepsy
- Infections: Meningitis, osteomyelitis, abscess
- Post-traumatic CSF fistulae and pneumocephalus
- Normal pressure hydrocephalus
- Metabolic abnormalities[15]
- Vascular abnormalities like coagulopathies, carotid cavernous fistula, delayed intracerebral haematomas and others.

This chapter deals with the initial four post-traumatic sequelae in detail. Other conditions are dealt with in detail separately.

POST-TRAUMATIC AMNESIA

The length of post-traumatic amnesia (PTA) is defined as the time from the moment of injury to the time of resumption of normal continuous memory. It ends at the time from which the patient can later give a clear and consecutive account of what is happening around him. When the duration of PTA is noted, there may be two end-points—the first recollection after the accident or the first recollection after which the patient has continuous memory. The latter is the accepted end-point for PTA.

Usually, the termination is abrupt, except in patients with severe head injuries where memory impairment is likely to persist. The amnesic phase may last from several minutes to several weeks, yet finally ends sharply with the return of normal continuous memory. In a few exceptional cases, brief islands of memory emerge before the continuity of memory is restored. Behaviour during the PTA period varies from apparent normality to impaired memory and mental confusion. PTA includes any period of unconsciousness or overt confusion and, in addition, a further period during which outward behaviour has appeared to return to normal. The general behaviour may be surprisingly intact, so that one can be easily misled into thinking that full recovery has occurred. It is, thus, only in retrospect that the true duration of PTA can be determined with certainty.[86] In the majority of cases, the purely amnesic phase follows the clearing of overt signs of confusion or impairment of consciousness, but it may occasionally follow immediately after the injury and may be the only deficit.

The duration of retrograde amnesia (RA) is measured as the time between the moment of injury and the last clear memory from before the injury, which the patient can recall. In road traffic accidents, the journey may be typically recalled up to the accident point. Usually, RA is much shorter than PTA, although the reverse may occasionally be seen. Mostly, RA lasts for only a few seconds or minutes. Longer RA is usually seen in severe injuries and may be of many days or weeks duration. In mild injuries, there may be no RA and full details of the injury can be recalled up to the moment of loss of consciousness. With long RA, the amnesia is most dense for events immediately preceding the injury. RA, as determined shortly after injury, may be misleading, as it may shrink with time.

The duration of amnesia is taken as a guide to the severity of injury and prognosis. PTA is more valid and useful than RA in this regard.[85] In general, the duration of PTA may be related to the time likely to elapse before the patient can return to work. Broadly, in closed head injuries, a patient with PTA less than 1 hour will usually return to work within a month, with a PTA less than 1 day within 2 months and with a PTA less than 1 week within 4 months. PTA more than 1 week will be followed by disability of more than 1 year. The duration of PTA shows close correlation with objective evidence of damage to brain tissue, such as motor disorder, dysphasia, anosmia or memory impairment. The mean duration of PTA is significantly increased in patients who show post-traumatic personality changes. In penetrating

injuries, there is a tendency for the PTA to be very short or even absent in up to 50% of cases.[86]

Evaluation of Post-Traumatic Amnesia

Anterograde amnesia is evaluated by testing of impaired episodic memory for events that occur within a specific spatio-temporal context, which is reflected by difficulty in recalling events in the hospital environment and recount events in the news or in the patient's life. Traditional methods of assessing retrograde amnesia asked the patient to describe and date the last event in memory before the injury. More recently, lists of information in the public domain or an autobiographical memory questionnaire are used to assess retrograde memory loss. The sequence of recovery of orientation is person, place and time in about 70% of patients.[60] Serial administration of a brief bedside test, such as the Galveston Orientation and Amnesia Test (GOAT) can depict an early cognitive recovery curve that is related to long-term neurobehavioural outcome. Monitoring the resolution of PTA is useful for acute clinical management.

POST-TRAUMATIC (POST-CONCUSSION) SYNDROME

The post-traumatic syndrome is a constellation of symptoms that usually occur after a mild head injury. Historically it was called "shell shock".[52] Diagnosis may be made when symptoms resulting from concussion last for more than 3 months after the injury.[64] In late, persistent, or prolonged PCS (PPCS), symptoms last for over 6 months[31] or by other standards, three.[12] The patients frequently have few, if any, abnormalities on neurological examination; therefore, many of the patients are treated by physicians in other specialties. However, neurosurgeons are best able to evaluate these patients to recommend treatment and to perform the necessary research to determine the pathophysiology. Although much energy and considerable resources are devoted to the management of severe head injuries, it is evident that patients with mild head injury also constitute a significant problem in terms of socio-economic impact. Although the post-traumatic syndrome can occur in a patient who survives a head injury of any severity, it is far more common in those with mild brain injuries.

The incidence of post-traumatic syndrome varies from 24 to 84%[14,19,21,24,26] and its duration is usually 1–6 months.[40] Rutherford and associates studied head injury patients at 6 weeks and 1 year after injury and found that several factors are associated with a higher incidence of symptoms: (1) female sex; (2) headaches or abnormal central nervous system signs at 24 hours and (3) fall from a height.[87] However, the post-traumatic syndrome does not seem to be as prevalent in the paediatric population compared with groups of older patients.[43] Litigation and compensation seemed to play a minor role in the percentage that failed to return to work.[80] However, other studies contradict this, with one report claiming that litigation doubles the rate of complaints at a year.[87]

Pathophysiology

A paucity of information exists regarding the pathophysiology of the post-traumatic syndrome. Most of the current understanding is inferred on the basis of data from animal studies. Traditionally, diffuse axonal injury was believed to occur at the moment of impact and that this led to physical disruption and permanent damage; however, studies indicate that a sequence of events occurs that culminates in axonal fragmentation.[72] Because the axon does not necessarily sustain physical tearing initially and because the intra-axonal events progress over several hours, it is possible to arrest the process. The reason for the involvement of the brainstem in these very mild injuries is uncertain, as is the type of damage to the axons. Many neurosurgeons now think that many, if not most, symptoms result from microscopic structural changes. The fact that only a few axonal projections in any group or fibre tract are interrupted may be of functional importance. Loss of only a portion of the fibres in a tract may result in synaptic modulation, which alters the probability of certain responses.[2,3]

Many secondary injury events which include damage to the blood-brain barrier, release of factors that cause inflammation, free radical overload, excessive release of the neurotransmitters like glutamate (excitotoxicity), influx of calcium and sodium ions into neurons and dysfunction of mitochondria occur which injure the brain's white matter axons which may separate from their cell bodies and lead to cell death.[75]

There is, in addition, some early evidence of volume transmission through the extracellular space that may occur in combination with the usual synaptic transmission of information.[2,3] For example, a mismatch between the location of the transmitter release and receptors frequently occurs. Receptor up or down regulation may occur following brain insults, and such alterations of extra-synaptic receptors have been proposed as possible causes of alterations in vigilance, diaschisis, sleep and so forth. Volume transmission alterations may also be associated with neuronal damage with potassium ion or glutamate release into the extracellular fluid.[94] Hayes and co-workers have proposed that activation of an inhibitory system, such as the cholinergic system in the rostral pons, may cause behavioural suppression rather than interference with an activating system in the brain. More research is required to evaluate these potential injury mechanisms.[42]

Clinical Profile and Evaluation

The usual clinical profile of a patient with post-traumatic syndrome is that of mild head injury, minor or no significant abnormalities on neurological examination, and one or more of the following subjective complaints: Headache, dizziness, emotional lability, sleep

abnormalities, poor concentration, memory difficulties, personality changes, anxiety or depression.

Post-traumatic headaches are characterised by their variability. They range from mild to excruciatingly severe, steady to intermittent, throbbing to dull, burning to pressure-like and generalised to localised. Common causative factors are change in posture, stress, fatigue and effort.[16] Temporary respite can be usually obtained by rest or simple analgesics. The characteristics of the headache do not seem to be related to the length of persistence of the headache after the injury. Headaches lasting longer than 2 months are commonly accompanied by dizziness, anxiety, fatigability and impaired concentration. Prolonged headaches occur more often in patients with neurotic symptoms before injury, occupational difficulties, pending litigation, immediate emotional reaction to the injury and scalp laceration. Prolonged headaches occurred infrequently after very mild head injuries and recreational accidents.[16] Headaches persisting after head injury may also be due to tension in neck muscles, whiplash injuries, occipital neuralgia, migraine, depression, intracranial hypotension, injury to paranasal sinuses, scalp neuritis, hysteria, etc.

Post-traumatic dizziness is intermittent, with each episode lasting a few minutes usually.[39] A change in posture commonly initiates the attack, but stress is occasionally also a precipitating factor. The severity and frequency of attacks are largely variable. The symptoms usually subside with recumbence and with the eyes closed. Dizziness persisting longer than 2 months is associated with neurosis, anxiety, fatigability, impaired memory, occupational difficulties, pending litigation, retrograde amnesia, disorientation and definite loss of consciousness. True vertigo is much less common.

There is a marked and continuing decline in the percentage of patients displaying one or more post-concussional symptoms from 73% at 2 days to 24% at 3 months. Only about 1% of patients are still symptomatic after a year.[62]

Early after-injury organic contributions to the symptomatology have been suggested while non-organic factors appear to be operative when patients are still complaining of symptoms after 3–6 months. When persisting beyond a year, the evidence becomes overwhelming that such long-lasting post-concussion symptoms rest principally on psychogenic mechanisms.

Cognitive-behavioural factors, such as social stresses, personal resources and coping processes are influential over the entire time course of the syndrome.

Evaluation of a head injury patient with symptoms of post-traumatic syndrome should begin with a detailed history of the events surrounding the mechanism of injury.

Evaluation of pre-existing conditions, such as alcohol or drug dependency, psychiatric illness or endocrinological disorders, should be undertaken. The issue of ongoing or future litigation should be discussed to assess the potential for personal restitution in the situation. A thorough neurological evaluation should be performed by a neurosurgeon; cranial nerve examination should include testing for anosmia, visual acuity and field testing and a hearing evaluation. The neck and suboccipital area should be examined for muscle spasm, which may be responsible for the complaint of headache. Serial examinations should be undertaken at intervals to assess the consistency of findings and because many symptoms may dissipate with time.

Radiological evaluation should include a review of the studies obtained during the initial hospital stay, with careful attention to abnormalities that may have been overlooked initially. Follow-up computed tomography may show such lesions as chronic subdural haematoma, cortical atrophy (particularly in the frontal lobes) or hydrocephalus. Magnetic resonance imaging expands the diagnostic possibilities by demonstrating oedema, resolving contusions, effusions or evidence of diffuse axonal injury. PET scans showed reduction in glucose use by the brain and changes in cerebral blood flow have been found to exist for as long as 3 years after a concussion in studies using single photon emission computed tomography (SPECT).[41] Electroencephalography may be indicated, particularly in patients who have had seizure activity at some point in their clinical course.

Evoked potential studies, such as brainstem auditory evoked response analysis or visual evoked response analysis, afford yet another method for demonstrating evidence of underlying organic dysfunction. Although abnormal evoked potentials are indicative of altered brainstem function, their studies do not show a causal relationship between the test results and the subjective complaints of patients.[84]

Psychological testing is added to assess whether a patient has experienced memory alterations, personality changes, task-oriented difficulties and similar dysfunction. The Stroop Color Test and the 2 and 7 Processing Speed Test (which both detect deficits in speed of mental processing) can predict the development of cognitive problems from PCS.[41] The Minnesota Multiphasic Personality Inventory profile can identify characteristics of anxiety, somatisation and conversion mechanisms.[34] Other tests like Rivermead Postconcussion Symptoms Questionnaire[67], Hopkins Verbal Learning A test and the Digit Span Forward[41] examination are also helpful in assessing the psychological status of the patient. The Glasgow Outcome Scale is an accepted standard by which levels of recovery after head injury can be classified, whereas the Levels of Cognitive Function Scale have been adopted by the clinical departments of many rehabilitation centres for classifying patients, to plan their treatments and to track their progress throughout recovery.[107] It appears likely that the symptom complex of the post-traumatic syndrome is multi-factorial. There is accumulating evidence that neural changes actually accompany the injury. Most patients with minor head injuries have one or more of the above complaints early after their injuries. Patients' complaints lessen with time

and most patients are asymptomatic by 3 months; however, a minority may have persistent complaints at 1 year or beyond.[14,59,96] Rutherford and associates found that about one-third of patients had only one symptom, while another third had two symptoms. The remaining third had more than two symptoms.[87] Patients with post-concussion syndrome frequently manifest memory problems.

Some symptoms reported in a delayed fashion include irritability, sleeplessness, failure of concentration or memory and sensitivity to alcohol.[87] Most likely, new deficits are not added, but rather the recognition of the deficits is delayed. Initially, the patients and the family are preoccupied with the immediate events of the injury and it is only after the patient's return to a more normal environment that one notices the inability to handle the stresses of everyday life. Most patients improve with time, and Levin and associates thought that a single uncomplicated mild head injury would rarely result in permanent cognitive impairment.[59] Others have suggested that 3–7% of patients may have some permanent sequelae.[19] Rimel et al. observed that at 3 months after injury, about one-third of patients will not have returned to work.[80] These authors stated three reasons for persistence of problems: organic damage; psychological problems and secondary gain. Previous head injury increases the likelihood that another minor injury will result in post-concussion symptoms.

Treatment

Treatment of post-traumatic syndrome mandates recognition of the interplay of both organic and psychological factors.[103] Education of the family and patients about the condition and its outcome alleviates a great deal of apprehension and perhaps speeds improvement. Rehabilitation is intended to help the patient develop a sequence of adaptive behaviours that increase personal independence. This includes learning behavioural skills appropriate for independent daily living, such as use of public amenities, food, shopping and driving. As a result of the change in employment status of the patient, financial difficulties may complicate the rehabilitation period. Vocational difficulties may also affect marital relationships.

Many of the rehabilitative efforts for post-traumatic syndrome patients are directed at improving memory and attention.[103] Even acupuncture has been studied in patients with post-concussion headaches and many patients who have been treated by this modality have responded with favourable results.[26,103] Both physical and psychological factors are important in persistent post-traumatic headache and dizziness.[16] Mild analgesics, medicines for vertigo and dizziness, antidepressants or anti-anxiety drugs may be helpful. Fortunately, the post-concussion syndrome almost always resolves with the passage of time. In some cases, cessation of symptoms occurs only after the settlement of litigation.

NEUROBEHAVIOURAL SEQUELAE

Neurobehavioural sequelae refer to the cognitive and behavioural effects of brain injury. The range of mental sequelae is very broad and embraces most that can be found in psychiatric symptomatology.

There are a number of aetiological factors, which may contribute to post-traumatic neurobehavioural sequelae.[62] These are listed below:

- Mental constitution
- Pre-morbid personality
- Emotional impact of injury
- Circumstances, setting and repercussions of injury
- Iatrogenic factors
- Environmental factors
- Compensation and litigation
- Response to intellectual impairment
- Epilepsy after injury
- Amount and location of brain damage.

The different post-traumatic psychiatric sequelae can be broadly discussed under the following headings:

(a) Cognitive impairment
(b) Personality change
(c) Psychosis
(d) Neurotic disability
(e) Memory impairment.

Cognitive Impairment

This is the direct result of damage to the brain at the time of injury. The severity of post-traumatic cognitive disturbance depends on the degree of diffuse axonal injury, as well as the volume and location of focal injuries.[92] These cognitive impairments are due to cholinergic deficits following head injury.[8] A single, uncomplicated, minor head injury produces no permanent neurobehavioural sequelae in most of the patients, provided they do not have a pre-existing neuropsychiatric disorder.[59] Severe head injuries, especially with post-traumatic amnesia (PTA) more than 24 hours, are likely to be followed by persisting cognitive impairment. With penetrating injuries, the length of PTA is less reliable. Chance of intellectual impairment is higher with advanced age and with damage to the dominant hemisphere.[78,100]

Generalised Intellectual Impairment

After a closed head injury, the impairment of intellect is usually global. Marked dementia is usually accompanied by severe neurological disability and the patient may be in a persistent vegetative state.[48] Short of this state, the patient may be lethargic and apathetic, with incontinence and dysarthria. All intellectual processes are severely affected and recognition of relatives may be impaired. Emotional lability, with episodes of uncontrolled weeping or laughing, and outbursts of aggressive behaviour may also be there. The final level of incapacitation is characterised by mental slowing, impairment of memory, apathy and impaired abstract thinking. Loss of libido and paranoid behaviour are common. At the other

end, there may be only a very minimal degree of intellectual impairment, which may be apparent only when the patient resumes his job.[62] Between these extremes, all grades of intellectual impairment are seen. Complaints of forgetfulness and impaired concentration may be difficult to assess and may be attributable to depression, preoccupation or anxiety. There may be deficits in selective attention, vigilance and information processing. Such problems appear to be common even after minor head injury.[97] There may even be difficulty in maintaining their train of thoughts.[76]

Focal Cognitive Impairment

This is more likely to develop following penetrating head injury. Psychometric tests reveal disorders of memory, language and visuospatial competence. Deficits in sustained attention and mental speed may prove to be a great handicap.[69] Selective impairment of memory may persist despite excellent restitution of other intellectual functions. Localised damage to the diencephalon or medial temporal lobe may result in a post-traumatic Korsakoff syndrome.[62]

Dominant hemisphere injury may cause language difficulties such as impaired comprehension, speech production, reading, writing or spelling. There may be reduced verbal fluency, impaired arithmetical function or dyspraxia. Non-dominant hemisphere damage may result in visuospatial agnostic defects and disturbances of topographical orientation. Disturbances of body image, dressing apraxia and anosognosia may be marked in the early stages, but rarely persist in the absence of gross intellectual derangement.

Newcombe, studying men with focal injuries due to high velocity missiles, was able to demonstrate highly selective impairment in language, visual perception and spatial orientation persisting 20 years after injury, without any evidence of generalised intellectual deterioration.[68]

Recovery of Intellectual Function

Even after severe head injuries, some patients may slowly show improvement over time, so that a firm prognosis should not be attempted until 2–3 years after the trauma.

Most substantial improvement occurs during the 1st year, maximally usually within the first 6 months. Psychometric testing has shown that different components of cognitive function tend to plateau at different periods. Verbal test of the Wechsler Adult Intelligence Scale tended to approach those of a non-injured control group after 1 year, whereas recovery on performance subsets continued for about 3 years.[63] The slower restitution on performance tests depends upon their complex nature, requiring a synthesis of numerous capacities, such as perception, attention, learning and psychomotor speed. Surprising examples of apparent long-continued cognitive improvement have been recorded.[65] This is probably a measure of the plasticity of the human brain, i.e. re-education of the intact brain tissue to take over new functions. An additional factor may be that a part of dementia seen in the early phase of recovery is more apparent than real. This may be because of coincident affective disorder, which may be easily missed in the early phases or there may be marked motivational defect, which may be a result of dopaminergic under activity.[11] Later in recovery, psychological processes of readjustment and adaptation will play back powerfully to improve motivation.

Personality Change

This implies an alteration in the patient's habitual attitudes and patterns of behaviour, so that his reactions to events and to people are different from what they were before. Head injured patients are particularly prone to damage of the neocortical portions of the limbic system; frontopolar, orbitofrontal and temporal regions.[5] This may explain why behavioural problems are often out of proportion to the severity of neurological deficits.

Personality Change with Brain Damage

The personality changes, which accompany intellectual impairment, may be only a loss of refinement or lessened vitality of behaviour. With more severe dementia, there will be slowing, impairment in motivation, loss of libido and withdrawal of interest in surrounding events and people.

Frontal lobe lesions remain the best known examples of effects of regional cerebral damage on personality. These include lack of foresight, tact and concern, inability to plan ahead or judge the consequences of actions and a euphoric disposition. This leads to antisocial conduct, disinhibition, amorous advances and sexual innuendoes in conversation. Bilateral frontal lobe lesions, especially of the orbital parts, lead to the most severe changes. A combination of disabling euphoria and disinhibition associated with intense irritability is termed as "frontolimbic dementia".[82] Occasionally, patients could be said to have shown improvement in personality, being less prone to worry and becoming more outgoing and social.

Hypothalamic and basal brain injuries may be characterised by sluggishness and apathy, fluctuations of mood, sudden outbursts of irritability, disturbances of appetite, thirst and sleep rhythm, and varied sexual pathologies.[45]

Personality Change without Brain Damage

These include fluctuating depression, morbid anxiety, obsessional traits and persistent irritability. Often they represent an intensification of previous personality traits. In some cases, they conform to the picture of post-traumatic stress disorders (PTSD), with intrusive thoughts concerning the accident and avoidance of situations related to it.[66] The patient may dwell on the circumstances of injury or relive it in terrifying dreams. There may be marked startle response and phobic avoidance of situations, which bring the accident to the mind.

PTSD can be a long lasting source of chronic disability. Head injury may have profound sequelae in terms of career, marriage and lifestyle.[62]

Psychoses

Psychotic episodes may develop later in association with post-traumatic epilepsy (PTE).[47] The problem is more complex when schizophrenic, paranoid or affective psychosis develops in head injured patients. The causal role of injury may be far from clear, especially if considerable time has elapsed between the trauma and the onset of illness.

Brain disturbance may itself contribute directly to such developments or may act merely as a precipitant in someone already predisposed. The generally accepted view is that a constitutional predisposition to the psychosis is a major factor in most cases of schizophrenia or affective psychosis following head injury.

All forms of schizophrenia have been reported following head injury—hebephrenic, paranoid and catatonic.[30] The incidence of schizophrenia-like-psychosis after head injury is certainly greater than chance expectation and trauma may be often of direct aetiological significance, rather than merely a precipitating factor. The various factors which help in distinguishing TBI psychosis from schizophrenia include a later age of onset, less premorbid psychiatric disturbance, brief duration, a less common family history, better response to neuroleptics, less need for maintenance medication and a better prognosis.[88]

Paranoid disturbances may be the cause of much distress and disturbance after head injury. Ideas of persecution or of marital infidelity are prominent.[1]

Affective psychoses may be seen in all degrees of severity, both in the presence and in the absence of objective signs of brain injury, even after minimal trauma. Factors related to brain injury may be operative in both major depression and mania. Hypothalamic damage might play a part in lasting bipolar affective disorders.[45] Manic psychosis after head injury is much less common than major depression.[1]

Neuroses/Neurotic Disability

The post-traumatic neuroses represent the most common of the psychiatric sequelae of head injury.[73] These include a number of emotional disorders: minor depression; states of tension and anxiety; neurasthenic reactions; conversion hysteria and obsessional neurosis. Patients with post-traumatic stress disorders are increasingly being reported.[62] Severe neurosis is chiefly found in subjects prone to neurotic reactions generally, and post-traumatic neurotics, when compared to non-organic neurotics, have shown the same range of complaints and a similar degree of vulnerability. There is little to suggest that organic factors play a part over the years. There is a conspicuous lack of relationship between the severity of injury and severity of neurotic disability and neurotic symptoms are rare in the presence of marked intellectual or neurological disabilities.[62]

Depression in these patients is characteristic of neurotic depression. Anorexia, insomnia and early morning waking are rarely marked. The depression often fluctuates in severity and may be responsive to a change of activity and surroundings. Complaints of difficulty in concentration, lack of normal interest and minor forgetfulness may be marked. Anxiety may coexist with depression or occur alone. Persistent states of anxiety and tension tend to be seen after accidents of especially frightening nature.

A neurasthenic reaction may incapacitate the patient for months or years after the trauma. The patient complains that he is always tired, feels weak and lacking in energy. Fatigue, both mental and physical, is readily precipitated by effort and there is marked curtailment of activity.

Irritability is among the most common of the emotional consequences of injury. The patient is short-tempered, snappy and stricter in matters of discipline. It may be difficult to decide how far this represents an affective disturbance or personality damage due to brain damage. Hysterical symptoms are prominent among head injured patients during war.[6]

The dissociative states include fits, fugues, amnesia, motor paralysis, anaesthesia, disturbances of speech, sight or hearing. Obsessive compulsive symptoms may emerge in susceptible individuals. Typically, the patient is tense and ruminative, focussing his doubt, indecision and compulsive preoccupation on the injured head.[6] Compulsive disorders tend to occur after reasonably severe rather than mild head injuries.[44]

Memory Impairment

About one-half of survivors of severe closed head injury exhibit residual antero-grade memory deficit, as reflected by impaired learning and retention of new information.[86] Episodic memory for events with a specific spatiotemporal context is the most intensively studied form of memory in head-injured patients.[57] Tests involving verbal memory for word lists revealed that head-injured patients recalled about 50% fewer words. Recall declined with more severe impairment of consciousness in patients with at least one non-reactive pupil. However, verbal memory was unrelated to the Glasgow Coma Scale (GCS) in patients whose pupils reacted normally to light. Impaired recall of geometric designs was also related to the GCS and pupillary reactivity.[57]

Improvement in memory after severe closed head injury occurs primarily during the first 6 months on measures of verbal learning and memory and on visual recognition memory; whereas further gains are negligible.[56] Memory generally recovers to the normal range within 1–3 months after mild closed head injury. Moderate and severe closed head-injury groups exhibit impaired verbal and visual memory despite their relatively normal intellectual levels. The disproportionate impairment of memory was greater in the severely

injured patients than in the group with moderate head injury.[58] Patients will have difficulty with multitasking. Declarative memory for events is more affected than the implicit memory. Working memory and prospective memory (remembering to pay one's bills) are impaired, particularly after damage to the frontal lobes. Functional magnetic resonance imaging shows altered patterns of activation of the brain during memory tasks in patients with TBI.[76]

Although the neuroanatomic substrate for procedural learning is not well understood, the cerebellum and basal ganglia have been implicated.[27] To investigate procedural learning after closed head injury, Ewert et al. administered mirror reading, maze learning and visual tracking tests to patients.[32] Latencies of head-injured patients for reading words presented in mirror orientation decreased across the three sessions during post-traumatic amnesia, a pattern reflecting acquisition of this skill that was confirmed for maze learning and visuomotor tracking. Further increments in performance were obtained after resolution of PTA, suggesting transfer of training effects. In contrast, the patients' declarative memory for the proceedings of each session was grossly impaired. The potential for procedural learning demonstrated during post-traumatic amnesia could be exploited in rehabilitation to emphasise skill learning.

Neurobehavioural Sequelae in Children

The after effects of head injury in children differ from those in adults in certain important respects. There are several factors involved:

- Neural apparatus is more resilient to damage.
- Conversely, certain functions are more vulnerable during development.
- Compensation motive is absent.
- Cognitive and emotional aftermaths hamper school work.[62]

The overall incidence of sequelae is lower in children than in adults.[13] This may be due to the greater pliability of the skull and intracranial structures. In addition, the powers of restitution and compensation seem to be greater in the young nervous system.[100] Profound intellectual disability appears to be rare, following head trauma in children. More commonly, the child is observed to have setbacks only temporarily and recovers in the months that follow. However, while they persist, such factors can hamper education to a serious degree. Visuospatial and visuomotor skills tend to be more severely affected than verbal skills.[24] Recovery, sometimes, can extend up to 4–5 years.[54]

Among focal defects, dysphasia has been most closely investigated. A change in cerebral dominance is possible after unilateral brain injury in early life and this plasticity appears to persist to some degree in later childhood. A particular feature of childhood dysphasia is, often, the quantitative reduction of spoken and written language, extending even to gesture activities.[4] Spontaneous speech is sparse and the child must be strongly encouraged to reply to questions.

Behaviour disturbances are probably the most common and most disruptive of the head injury sequelae in children. They consist of hyperkinesis (restless overactivity), impulsive disobedience at home and at school, and explosive outbursts of anger and irritability. Marked delinquency may appear by way of stealing, cruelty and destructiveness.[13] The child may appear to be dominated by instinctual and emotional impulses, as though he has lost the inhibiting and restraining influences normally acquired during development. Sometimes, self-control is gradually re-established, as the child matures and hyperkinesis usually wanes as the child grows older. Neurotic disturbances are, by contrast, rare in children.

Boxing Injuries

Serious sequelae appear to follow repeated mild head injuries, each in itself leading to no more than brief concussion. The mechanisms of such a cumulative effect are unknown, although the findings of beta-amyloid deposition in the brain may be a pointer towards the pathophysiologic process.[62]

The picture of "punch-drunkenness" in retired boxers is widely recognised. In its fully developed form, the syndrome consists of cerebellar, pyramidal and extrapyramidal features, along with a varying degree of intellectual deterioration. Severe examples date mostly from boxing careers before World War II when medical control over boxing was less rigorous.[81] In mild examples, there is dysarthria, facial immobility, poverty and slowness of movement. At its most severe, there is disabling ataxia, dysequilibrium, festinant gait, tremors of the hands and head, and spasticity or rigidity of the limbs.

The prevalence of the syndrome increases with increasing exposure to boxing strongly upholding a causal relationship. The majority of cases remain static, once boxing is discontinued. In a few cases, there has been undoubted improvement after retirement from the ring.[81]

In addition to the neurological disability, there may be intellectual and personality changes indicative of dementia. There may be severe memory impairment, apathy, irritability, marked disinhibition and profoundly slowed thinking. The main psychiatric disturbances reported include a chronic amnesic state, progressive dementia, morbid jealousy and rage reactions.[51]

More recent studies have concentrated on "modern era" boxers who have fought under present medical controls. Evidence from brain imaging and psychometry is that, chronic as well as acute brain damage is still prone to occur. Cerebral atrophy has been found to antedate the development of overt signs of brain damage; and sometimes show association with the number of bouts fought rather than with the number of knockouts, suggesting a cumulative effect of multiple sub concussive blows to the head.[22] It is hoped that the introduction of new safety measures will diminish the risk of long-term boxing.[20]

Cerebral atrophy is commonly revealed on CT scanning, with dilatation of the ventricles, sulcal shrinkage and, sometimes, obvious cerebellar atrophy. A characteristic finding is perforation of the septum pellucidum. The EEG may be abnormal with flattening of the record, diminution of the alpha rhythm or diffuse slow waves.

At autopsy, cerebral atrophy and ventricular enlargement are obvious and ragged holes may be seen in the septum pellucidum. The most obvious abnormalities are in the deep midline structures, with tearing of the septal region and atrophy of the fornices. Severe gliosis is seen in these regions and also in the hypothalamus and thalamus. The cerebellum also shows gliosis and loss of Purkinje cells. In the substantia nigra, there is loss of pigmented neurons similar to that seen in Parkinson's disease.[28]

The cerebral cortex shows extensive loss of neurons, many of those surviving showing neurofibrillary degeneration of the Alzheimer type. The clinical features are probably related to damage to two main areas of the brain—the upper brainstem and the hippocampal-limbic system.[51]

In the occasional cases of severe and progressive dementia, it is hard to discount the possibility of coincident Alzheimer's disease. All cases with substantial neurofibrillary tangle formation showed extensive immunoreactive deposits of beta protein.[83] It is possible that frequent disruptions of the blood-brain barrier may allow leakage of beta-protein precursors from the serum into the brain.

Pathology of Traumatic Brain Injury

Evidence of neuronal and glial cell death and traumatic axonal injury contributing to the overall pathology of traumatic brain injury (TBI) in both humans and animals have been identified. Apoptotic and necrotic neurons were identified within contusions in the acute post-traumatic period and in regions remote from the site of impact in the days and weeks after trauma, while degenerating oligodendrocytes and astrocytes have been observed within injured white matter tracts.

It is generally accepted that a shift in the balance between pro-apoptotic and anti-apoptotic protein factors towards the expression of proteins that promote death may be one mechanism underlying apoptotic cell death. The effect of TBI on cellular expression of survival promoting-proteins, such as Bcl-2, Bcl-xL and extracellular signal-regulated kinases and death-inducing proteins such as Bax, c-Jun N-terminal kinase, tumour-suppressor gene, p53 and the calpain and caspase families of proteases have been studied.[79]

Treatment of Neurobehavioural Sequelae

Rehabilitation should be planned and supervised with care from the early stages of recovery. Fortunately, the majority of patients with mild head injuries make satisfactory progress without a great deal of specialised attention.[62] The initial convalescent period is usually undertaken in the hospital. Physical activities are beneficial, provided certain limits are imposed and the value of early mobilisation is recognised. Graduated exercises and games help to restore the patients' physical self-confidence and the morale is improved by opportunities for social interaction.[61] Usually, little is needed in the early phase by way of psychotherapy, but the value of doctor-patient relationship should not be overlooked. An appropriate period of time away from work will need to be advised, after taking into account the severity of injury, its complications and the patient's personality and the stresses of the work to which he will return to.

The main neurological sequelae, which require evaluation are locomotion, upper extremity function and impairment of communication. Visual acuity and visual field defects must also be assessed. Physiotherapy, occupational therapy and speech therapy have a role. The rehabilitation of cognitive functions presents a special therapeutic challenge.[69] Full psychometric assessment is the first step and serves both to highlight areas of deficit and areas of preserved function on which to capitalise. An optimistic and positive approach is required to instil enthusiasm, with ready allowance for fatigue and tolerance of shortcomings. The therapeutic program must be graded, with goals at any stage that are realisable, rational and acceptable to the patient.[53]

Emphasis should be placed upon:

- Re-education,
- Compensatory method, and
- Substitution, when a function is damaged irreparably.[92]

An important requirement is to separate primary defects, attributable directly to brain injury from the coping mechanisms adopted by the patient.[69] In the retraining of memory, it can be valuable to teach the use of visual imagery, verbal coding or other mnemonic systems.

Successful results have been described with a 5–10-week course of "attention training"[95] In this, a variety of tasks, including specially designed computer programs, were used to concentrate on five aspects of attention: focused; sustained and relative attention; alternating attention as needed for mental flexibility and divided attention which is required for simultaneous responses to multiple tasks.

Personality changes following brain damage are notoriously difficult to modify. Psychotherapy should aim at helping the patient to achieve some insight when this is lacking. A measure of control may sometimes be achieved in such matters as disinhibition, impulsiveness or emotional outbursts, although progress is usually limited. A valuable development is the application of behavioural modification techniques to brain-injured persons, with the aim of reducing disruptive behaviour and encouraging more constructive involvement in the rehabilitation process.

Tranquilizing drugs such as diazepam may help in tension and anxiety, and antidepressants should be tried if indicated. Low dose chlorpromazine is beneficial in patients with frontal lobe damage. Dopamine agonists, such as bromocriptine and lisuride have been found to be useful in patients with severe passivity and anergy.[9] There may be a place for a cautious trial of stimulating agents, such as methylphenidate or amphetamine in patients whose sluggishness and anergia are due to hypothalamic damage. Anti-convulsants are of doubtful value in preventing outbursts of aggression.[62]

Psychoses, which develop after head injury, require the same psychiatric management as the equivalent illnesses, which occur in other settings. For neurotic complications, the mainstay of treatment is psychotherapy and attention to the social problems that exist. Antidepressants and minor tranquilisers may be helpful. Post-traumatic stress disorder may require a cognitive-behavioural approach and phobic conditions will often respond to behaviour therapy.

Speedy resolution of litigation is to be desired, certainly in cases where brain damage does not play an identifiable part. Return to work should also be secured at the earliest possible opportunity.[62]

It is clearly advantageous to have centres for the rehabilitation of the more severely disabled patients. This need is widely recognised, but facilities are not equally widely available. Head-injured patients often present a combination of physical handicap with disturbances of intellect, mood and behaviour. Properly organised rehabilitation units allow a multidisciplinary approach, both in evaluation and in supervision of treatment with neurologists, psychiatrists and orthopaedicians, along with physiotherapists, psychologists, occupational therapists, speech therapists and social workers.

An essential part of the rehabilitation lies in the help and guidance offered when the time comes for preparation for return to work. Conditions usually to be avoided include shift or night work, noisy or oppressive conditions, high frequency vibration, working at heights or with moving machinery and work, which must be carried out under pressure of time.

Female patients more often need to be institutionalised, perhaps because a wife can more easily assume the major care of a disabled husband than vice-versa. Success can often be achieved by intensive rehabilitation, even among severely injured and behaviourally disturbed patients who would normally be considered to have a poor prognosis.[17] A designated case manager should be in a position to establish a continuous link among the various service providers, build up knowledge of what is available locally and coordinate input to the patient and the family.

Consideration of the sequelae of head injury is incomplete without mention of the broad effects on the quality of the patient's life and that of his family. Leisure and social activities are often profoundly disrupted. Family relationships can come under considerable strain.[37,71] Lack of comprehension of the patients' behaviour and its origins can lead to unhelpful responses on the part of those around. Anger may arise from a suspicion that the patient is not making proper effort or guilt that disappointing progress reflects the carer's own inadequacy.[37] The problems most frequently encountered by the family concerned are the patient's slowness, irritability, poor memory and emotional changes. Physical disability was less commonly a problem. Emotional lability and outbursts of pathological laughter were especially embarrassing features.[101]

POST-TRAUMATIC EPILEPSY

Definition

Post-traumatic epilepsy can be of two types: (a) One occurring within 7 days after injury is labelled as early PTE and (b) seizures occurring more than 1 week after head trauma are categorised as late PTE. Within the early epilepsy group, seizures occurring within the first 24 hours are labelled as immediate seizures.[98]

Incidence

The incidence of early epilepsy varies from 2.5 to 7%.[7,49] Young children, under the age of 5 years, have early seizures in about 7–9% of patients.[49] Late PTE ranges from 5 to 7%[7] being much higher in soldiers with missile wounds (34–53%).[90] Young children are more prone to early seizure and adolescents and adults to late seizures.[9]

Pathophysiology

The cascade of structural and physiological changes leading to PTE is still not well understood. The following different mechanisms may be responsible at different time intervals.[104]

- Direct neuronal impact
- Membrane depolarisation
- Acetylcholine release
- Temporary loss of inhibitory control from the mesencephalic reticular system
- Cerebral contusion and oedema with interference in cation transport
- Hyperexcitability of recovering neurons[93]
- Meningocerebral cicatrix and glial scar
- Dendritic depolarisation and post-synaptic hypersensitivity
- Genetic factors.

Even a single episode of experimental closed head trauma induces long-lasting alterations in the hippocampus. These persisting structural and functional alterations in inhibitory and excitatory circuits are likely to influence the development of hyper-excitable foci in post-traumatic limbic circuits.[91] The histopathological examination of brain tissue after trauma reveals reactive gliosis, neuronal and oligodendroglial loss, axonal retraction balls, Wallerian degeneration, neuroglial scar

formation and cystic white matter changes.[55,102] The deposition of iron liberated from haemoglobin may be an important causative factor.[33,48,89] Iron and other compounds have been found to affect intracellular calcium oscillation.

Pre-treatment of animals with antioxidants alpha tocopherol and selenium prevents seizures, suggesting that the initiation and the propagation of lipid preoxidation, especially of the arachidonic acid cascade, may play an important role in epileptogenesis.[25,36,105] The activation of the arachidonic acid cascade leads to formation of diacylglycerol and inositol triphosphate. This leads to elevation of intracellular calcium, which appears to be involved in excitotoxic damage to neurons. Neuronal death and reactive gliosis can lead to the formation of a glial scar, which becomes the epicentre of the hyper excitable focus.[106] The epileptogenic focus has been demonstrated to have biochemical defects in metabolism of acetylcholine, glutamic acid, gamma amino butyric acid and potassium. The epileptogenesis after chronic cortical injury could result from alterations of intrinsic membrane properties of pyramidal neurons, together with enhanced NMDA synaptic conductances.[18]

ApoE-ε4 allele and haptoglobin Hp2-2 allele may be a genetic risk factor in post-traumatic epilepsy.[29] Inhibitory GABAergic neurons were particularly more sensitive to cortical deafferentation than excitatory ones, leading to a progressively increasing ratio between excitation and inhibition towards excitation, which potentially explains the increased propensity to seizures.[10]

Early Post-Traumatic Epilepsy

The risk of early PTE is related to the type and severity of brain injury. It is much higher in patients with more severe injuries. Subdural haematomas and depressed skull fractures are major independent predictors of early seizures (24–27%).[49,99] In another study, subdural and intracerebral haematomas were associated with 30–36% incidence of early seizures,[48] while extradural haematoma, frontal and parietal depressed fractures, PTA more than 24 hours and focal neurological deficits were associated with an early seizure incidence of 9–13%.[23,48,49] Early seizures occur more frequently in children less than 5 years of age.[41]

About one third of early PTE occurs within the first hour, one third between 1 and 24 hours, and the rest between 1 and 7 days after injury, with adults having their first seizures somewhat later than children.[49]

Focal seizures account for most of all early seizures (from 50 to 80%), with the remaining being primarily generalised tonic clonic (25–50%). Most early focal seizures are focal motor seizures; being more frequent after missile injuries.[49,74] A generalised seizure occurring within a few moments of trauma is called immediate epilepsy.[98] This usually follows a mild injury. Immediate concussive convulsions are thought to be a brief traumatic functional decerebration that results from loss of cortical inhibition.[77] Patients with isolated concussive convulsions have no evidence of structural brain injury. The long-term outcome for these patients is universally good, with no long-term neurologic sequelae nor increased incidence of early or late PTE. It requires no specific therapy and anti-epileptic medication is not indicated.[77]

The main significance of early PTE is an indication of an increased risk for development of late PTE, being approximately 25%.[49] About 10% of adults and 22% of children under 5 years of age, with early seizures, go into status epilepticus.[50,74] Early seizures can lead to depression of consciousness and increased risk of aspiration pneumonitis.

Late Post-Traumatic Epilepsy

The highest risk factor for late PTE is missile wounds.[89,90] In blunt head injury, the main risk factors are haematomas, depressed fractures, focal signs and early seizures. Low GCS, subdural haematomas and cortical contusion, each provide independent additional risk of late seizures. About one-fifth of patients with epidural haematomas and almost one-half of those with subdural or intracerebral haematomas develop late PTE.[48] A patient with mild head injury, but having early seizures has a 25% chance of late PTE, while mild head injury without loss of consciousness and without early epilepsy has only a 1–2 % incidence of late seizures.[49] The frequency of late seizures varies within a wide range, from only a single seizure to so many that no effort is made to keep a count.

Seizure risk is initially greater. Eighteen per cent of epilepsy cases in the Vietnam Head Injury Study developed their seizure within one month and 57% developed seizures by 1 year.[90] Seizure risk remains elevated for many years, however. 60–70% of late PTE is generalised, with or without focal onset.[74]

Prophylaxis and Treatment

Natural cessation of PTE is likely to occur in patients with a low frequency of seizures, in those in whom fits started early and in those who have an early remission for more than a year.

An attack of seizures occurring within a few minutes after a head injury (immediate epilepsy) may not require any anticonvulsant medication. There is a lack of consensus on the usefulness of prophylaxis with anticonvulsants for the prevention of late PTE.[38,46] Considering the data available, prophylactic administration of phenytoin to prevent either early or late PTE is not recommended.[46] However, there are many reports, which conclude that phenytoin reduces the risk of early seizures by 67–73%.[70,99] If an early seizure occurs, intravenous phenytoin should be given with a loading dose of 18 mg/kg/minute, followed by a maintenance dose of 5–7 mg/kg/day. Prophylactic phenytoin can be stopped after about 1–2 weeks.

No prophylaxis should be given for late PTE. If a late seizure occurs, an anti-epileptic drug (e.g. phenytoin, carbamezapine or valproate) may be administered. The duration of treatment for late PTE follows the principles of treatment of all late seizures and is usually 2 years.

Resection of the epileptogenic focus is rarely required to control post-traumatic seizure intractable to medical management. Late PTE tends to diminish with time and surgery should not be performed for at least 2 years after the injury. When there are multiple epileptic foci or the focus cannot be localised and drug therapy is not effective, vagus nerve stimulation is another option for treating PTE.[35]

41 Cranioplasty

Ramesh Kumar Sharma, Mathuriya SN

INTRODUCTION

Cranioplasty is defined as the restoration of a defect in the cranial bone or correction of a deformity of the bone that may happen after trauma as in depressed fracture. The replacement of a bone flap after a craniotomy would also be a cranioplasty. There is a feeling that cranioplasty connotes repairing the defect after a gap of sometime using material other than the original bone. However, we shall include any reconstruction of the skull defect/deformity under cranioplasty. The technique of cranioplasty is a fine mix of art and surgical science. The cranium has a well-defined topography and regions with specific contours. Some areas are hidden under the hair and some areas, like the frontal regions, are easily seen. An aesthetically pleasing result necessitates that we must have the proper contours of the calvarium restored while filling up the "holes" in the cranium. There has been an attempt to reconstruct the cranium from times immemorial and there are instances of its being reconstructed as early as 3000 BC by Peruvians using Gold/Gourds.[19] The first attempt to use bone for cranial reconstruction was made as far back as 1670 by Van Meekren[2] who repaired a cranial bone defect of a Russian soldier using bone from a dog. As the patient was excommunicated as a result of this procedure, Van Meekren removed the graft 2 years later so that the patient could return to his church.

AETIOLOGY OF THE CRANIAL DEFECT

The main cause of defects of the cranial and facial bones is trauma. Penetrating head injuries at times necessitate removal of bone (craniectomy). At times it may not be possible to replace the osteoplastic craniotomy flap due to either brain oedema or infection. The replaced bone flap may become infected and may need to be removed. Other causes are surgical bone excision for tumours (osteomas, meningiomas, haemangiomas, eosinophilic granulomas, epidermoids, metastases, fibrous dysplasia, chondromas, sarcomas, aneurysmal bone cysts); for infections (osteomyelitis, infected cranial flaps); for radionecrosis and electrical lesions of the skull and for congenital cranial and craniofacial anomalies (encephalocoeles, congenital parietal defects).

CRANIOPLASTIC MATERIAL

An enormous range of materials has been employed for the repair of cranial defects. These have included an autograft from the same individual, allograft from another individual of the same species, xenograft from other species and bone substitutes from outside the realm of living tissue. Whenever possible, the use of autografts is the most preferable, although this is sometimes impractical because of insufficient amount or their unmalleable property. The ideal substitute material should be strong, lightweight, malleable, thermally non-conductive, sterilisable, easily secured, inert, radiolucent, non-magnetic, aesthetically good, readily available and inexpensive. Needless to say, the search for such a material continues. The history of cranioplasty is filled with the introduction of the "ideal replacement" only to have its use abandoned for various reasons.

PRESERVATION OF AUTOGRAFTS

There are times when the surgeon cannot replace the bone flap after craniotomy. Various methods have been used in an effort to preserve the bone and maintain its sterility without losing its osteogenic potential. Boiling of the bone was suggested by Westermann (1916),[24] but this results in increased tendency for infection and bone resorption.[16] Other older preservation methods have included storing in alcohol or formalin and then boiling before implantation. It has become clear that boiling lessens the osteogenic potential of the flap and makes it prone to bone resorption and infection. Autoclaving bone flaps may also predispose them to similar complications, but this has not been a uniform experience. Autoclaved bone flaps, in some institutions, have been observed to heal without necrosis or resorption.[15]

Storing the bone flap in the abdominal wall until it was required for the cranioplasty was first described by Kreider (1920).[10] This technique is not widely used today, because it necessitates another operation and produces an unsightly scar and there is little evidence for better osteogenic potential of the bone. It is known that bone removed from its blood supply and replaced in fresh tissue dies, with the exception of a layer of superficial cells less than a millimetre in depth. Nevertheless, this method has its contemporary proponents.[13]

NEED FOR RECONSTRUCTION

Reconstruction of the cranial vault is often needed for protective and cosmetic reasons. The goals are to protect the brain and restore the normal contour with as few complications as possible. Other controversial goals are eliminating headache and apprehension and avoiding cere bral palsy, decreasing vibration and motion intolerance, and overcoming fatigue, insecurity and post-traumatic epilepsy.[5,22]

CRITICAL SIZE OF DEFECT THAT REQUIRES CRANIOPLASTY

It is commonly accepted that the fundamental indications for cranioplasty are bone defects larger than 2 cm situated on the cerebral convexity and bone defects of the glabrous frontal region. Defects below the temporal and occipital muscles and those in very elderly patients are not usually considered to require repair. Moreover, in children under 6 years of age in whom the dura is not damaged, regeneration of a portion of the skull may be observed. Thus, it is necessary to wait at least a year after craniectomy in a child before deciding whether reconstruction is necessary.

ANATOMY OF THE DEFECT

The defect may either be very small or be quite extensive. These may be classified into Type I, where the size may be less than 5 cm^2 or Type IV, where the size may be greater than 50 cm^2. Very small defects may not be reconstructed as far as protective function is concerned, but may need reconstruction if these are situated in frontal areas, especially the supraorbital and non-hair bearing forehead region. The frontal region has been divided into three regions:

1. Supraorbital
2. Prehairline
3. Within the hairline

Even small defects in zone 1 and 2 look unaesthetic and should be corrected (Figs 1 and 2).

The defect may be situated anteriorly in the frontal area, midway in the calvarium in the parietal area or posteriorly in the occipital area. The frontal defects may either be within the hairline or be in the visible forehead. Parietal area defects of less than 5 cm^2 may not require any reconstruction. Likewise, a small defect in the temporal region may not require reconstruction. In the occipital area, defects of moderate size may also not need any reconstruction as the thick musculature provides protection. In short, the need for reconstruction is dictated both by the size of the defect and the location of the defect (Fig. 3).

TIMING OF RECONSTRUCTION

A significant reduction in incidence of infection has been noted when sometime is allowed to elapse between the initial injury or infection and the subsequent reconstruction. It is generally believed that the interval between complex or contaminated wounds and definitive cranioplasty should be between 3 months and 6 months. Rish and his co-workers[17] reviewed 491 cranioplasties and concluded that it was necessary to wait at least a year after penetrating or complex head injuries to ensure a good outcome. If the frontal sinus has been opened, it may be prudent to perform cranioplasty after about a year. Similarly, in the presence of an infected open wound, one should allow the wound to heal and then embark on cranioplasty after about a year or so. However, if adequate vascularised tissue is available, immediate reconstruction is possible. It is important to separate the aerodigestive tract from the extradural space by the use of a vascularised flap like frontogaleal flap. If the conditions are favourable, a primary cranioplasty is always advisable.

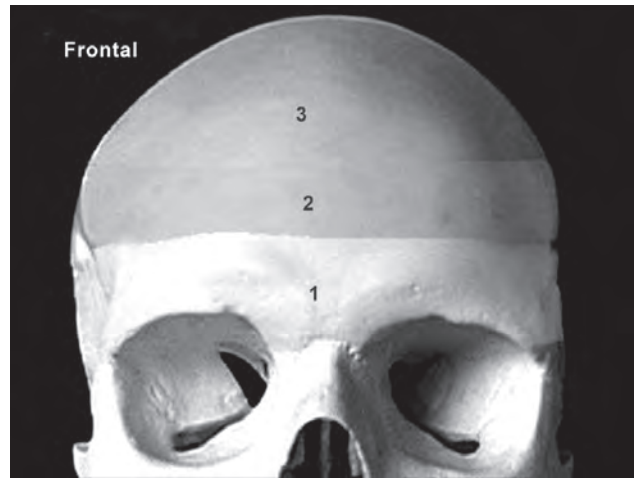

Fig. 1: The frontal region is divided into. (1) supraorbital. (2) Prehairline. (3) Within hairline

IMPORTANCE OF ADEQUATE SKIN COVER

Before undertaking cranioplasty, it is important to ascertain that there are no compromised areas in the scalp. If the scalp has unstable areas these need to be revised. The cranioplasty can be accomplished through existing scars and, if need be, additional incisions can also be made. It is very important to ascertain that there is sufficient skin available in the scalp; it is more so in large defects of long standing duration. The scalp tends to sag inside the defect and might be stretched once cranioplasty is done. This tight envelop can lead to exposure of the grafts/implants in the post-operative period (Fig. 4). If there is deficiency of tissue, it should be corrected before cranioplasty is contemplated. Smaller defects can be adjusted with local flaps, but larger defects will necessitate import of tissue from distant areas. Very large defects may require free tissue transfer (Fig. 5).

CHOICE OF MATERIAL FOR CRANIOPLASTY

There is almost unanimous agreement that autogenous calvarium possesses far better characteristics and quality

Fig. 2: Even small defects can be cosmetically disturbing in region 1 and 2

than any other currently available alloplastic materials. Calvarial autograft is the most "natural" material of all because not only does it possess all the ideal qualities for cranioplasty but it is also vital and has excellent biologic properties. It has good growth potential and resistance to infection. There can be no doubt that fresh autologous bone is the most suitable material for reconstruction of cranial defects in view of its perfect histocompatibility, optimal mechanical properties and good integration of the graft with the adjacent bone, as well as the possibility of partial or total revitalisation of the graft itself. Autologous bone also ensures the best possible physiologic and cosmetic results (in theory at least). In fact, autologous bone grafts usually display bone regeneration processes and there is a low incidence of infection.[1,4]

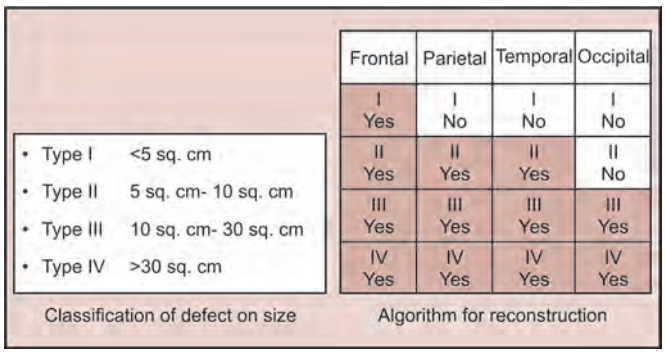

Fig. 3: Classification of defects and algorithm for reconstruction needs

The source of autologous bone can be the calvarium itself, ribs or iliac bone. The cranium is the preferred donor site for harvesting bone graft for cranioplasty. The donor area is in the vicinity of the defect and a large amount of bone can be harvested. The patient experiences much less pain at the donor site as compared to other donor sites like ribs and iliac bone. It has been consistently highlighted that the pain in the iliac crest and chest donor site often exceeds that of the primary procedure on the skull or face. In harvesting the ribs there is a possibility of injuring the pleura.

The cranium provides a large area for bone grafting. The bone can be harvested from an area which matches with the contour requirement of the defect. It requires training to obtain a cranial bone graft; however, the skill

Fig. 4: Large defect in the frontal region of long standing duration. The envelop seemed tight after reconstruction; the underlying bones got exposed in the post-operative period and urgent cover had to be given with radial forearm flap for salvage of reconstruction

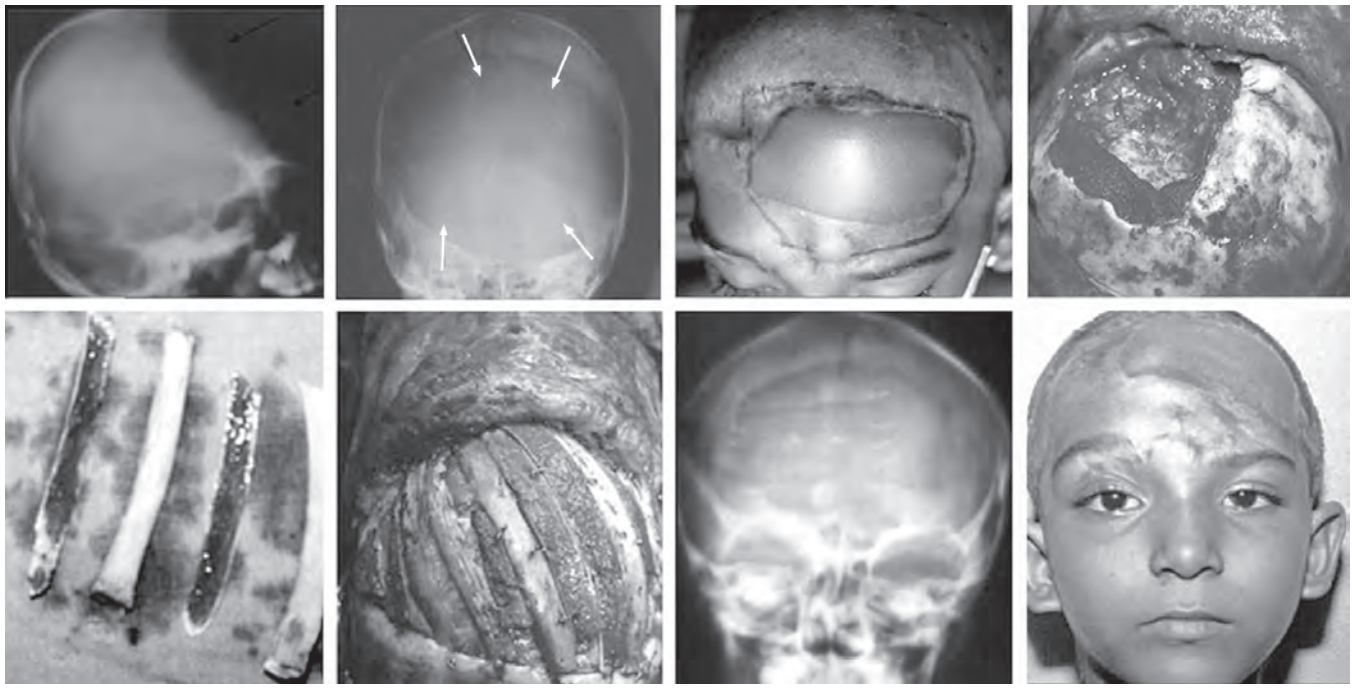

Fig. 5: Large defect in a child with skin loss. The skin defect was first resurfaced with radial forearm flap. The bony reconstruction was done using split ribs and cranial bone graft. The bones have been fixed with interosseous wires

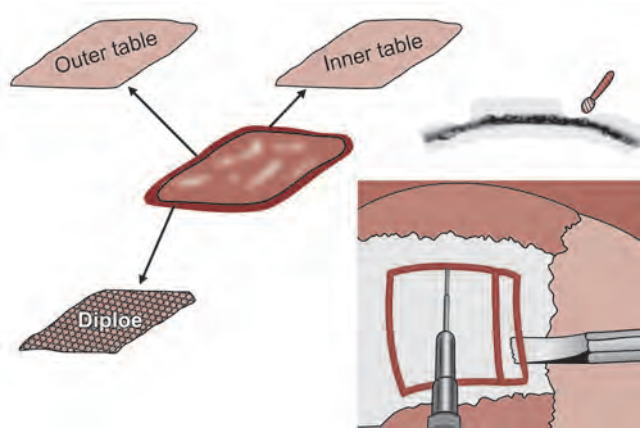

Fig. 6: The skull consists of outer and inner tables with diploe in between. The split cranial bone graft is harvested by creating a plane at the level of diploe with a burr. An osteotome has been used to harvest the cranial bone graft

is easily acquired. This may be done with a hammer and osteotome or even with a Gigli saw. The bone is generally, harvested from the non-dominant parietal area as it is technically easy and the thickness of the bone is adequate. It may be difficult to harvest split bone graft in very old and young patients as the dipole is not well-developed. A full thickness cranial bone graft may be harvested from the skull, and it can be split on a side table. More commonly, the bone is harvested as a split graft *in situ* (Fig. 6).

The cranium provides grafts of different contours to meet any reconstructive need. The graft may be oriented in any direction as dictated by the reconstructive need. The split graft can be harvested across the midline and suture areas. The template of the defect can be made and placed in an appropriate area of the calvarium to provide matching grafts (Fig. 7). With a little practise, a split cranial bone graft can be harvested even in children as young as 6 months to 1-year-old (Fig. 8).

If the need for bone graft is more than 50 cm^2 additional bones may be procured from other sources like ribs and iliac bone. The rib may be split into two for increasing the surface area. The volume loss in membranous bone[11] like the cranium is much less as compared to endochondral bone. The cranium can provide large areas of bone graft and, if it is harvested as a split table bone graft, there is no donor site morbidity. The operative site is the same so no further incision is required. It has been observed that there is little pain at the calvarial bone graft site as compared to other sites like ribs or iliac bone. Moreover, the site of the bone graft harvest can be chosen depending upon the contour requirement of the recipient site. Although some site the morbidity involved in harvesting cranial bone, it has been documented that with proper training, plastic surgeons can harvest bone grafts easily and comfortably with minimal morbidity.[9]

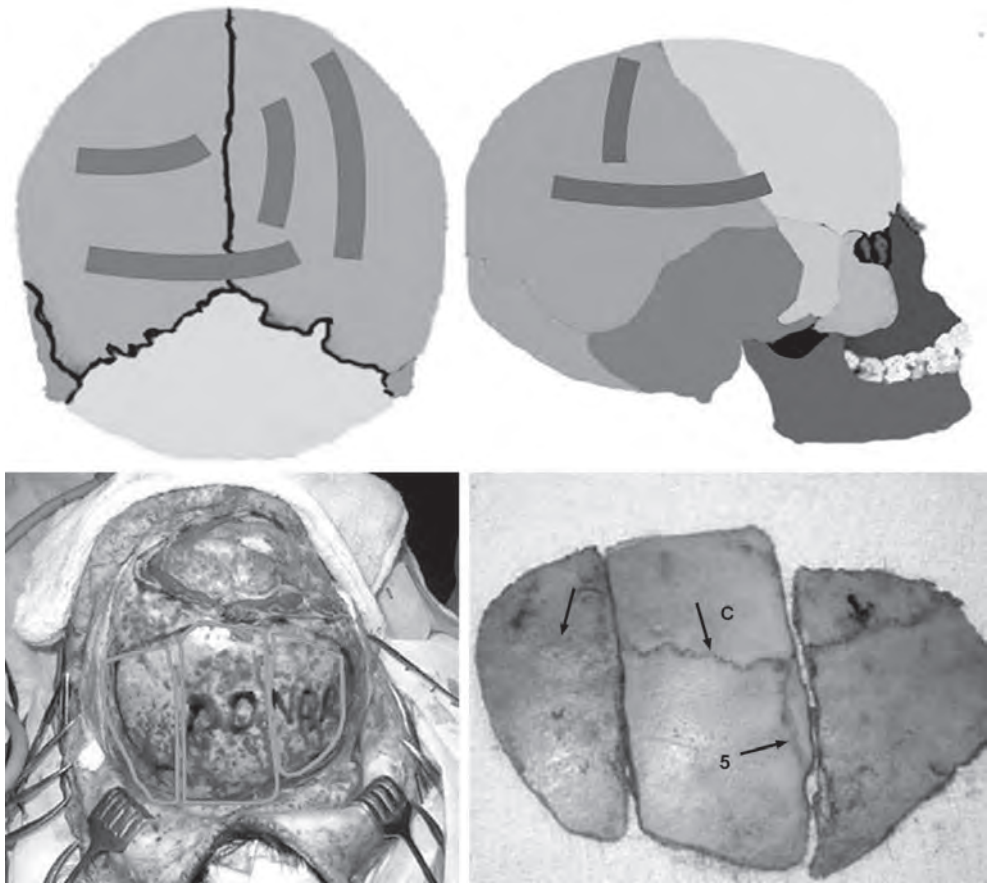

Fig. 7: The bone grafts can be harvested from the parietal region. The orientation of donor site depends upon the contour requirement at the recipient site. The graft can extend even beyond the midline or sutures

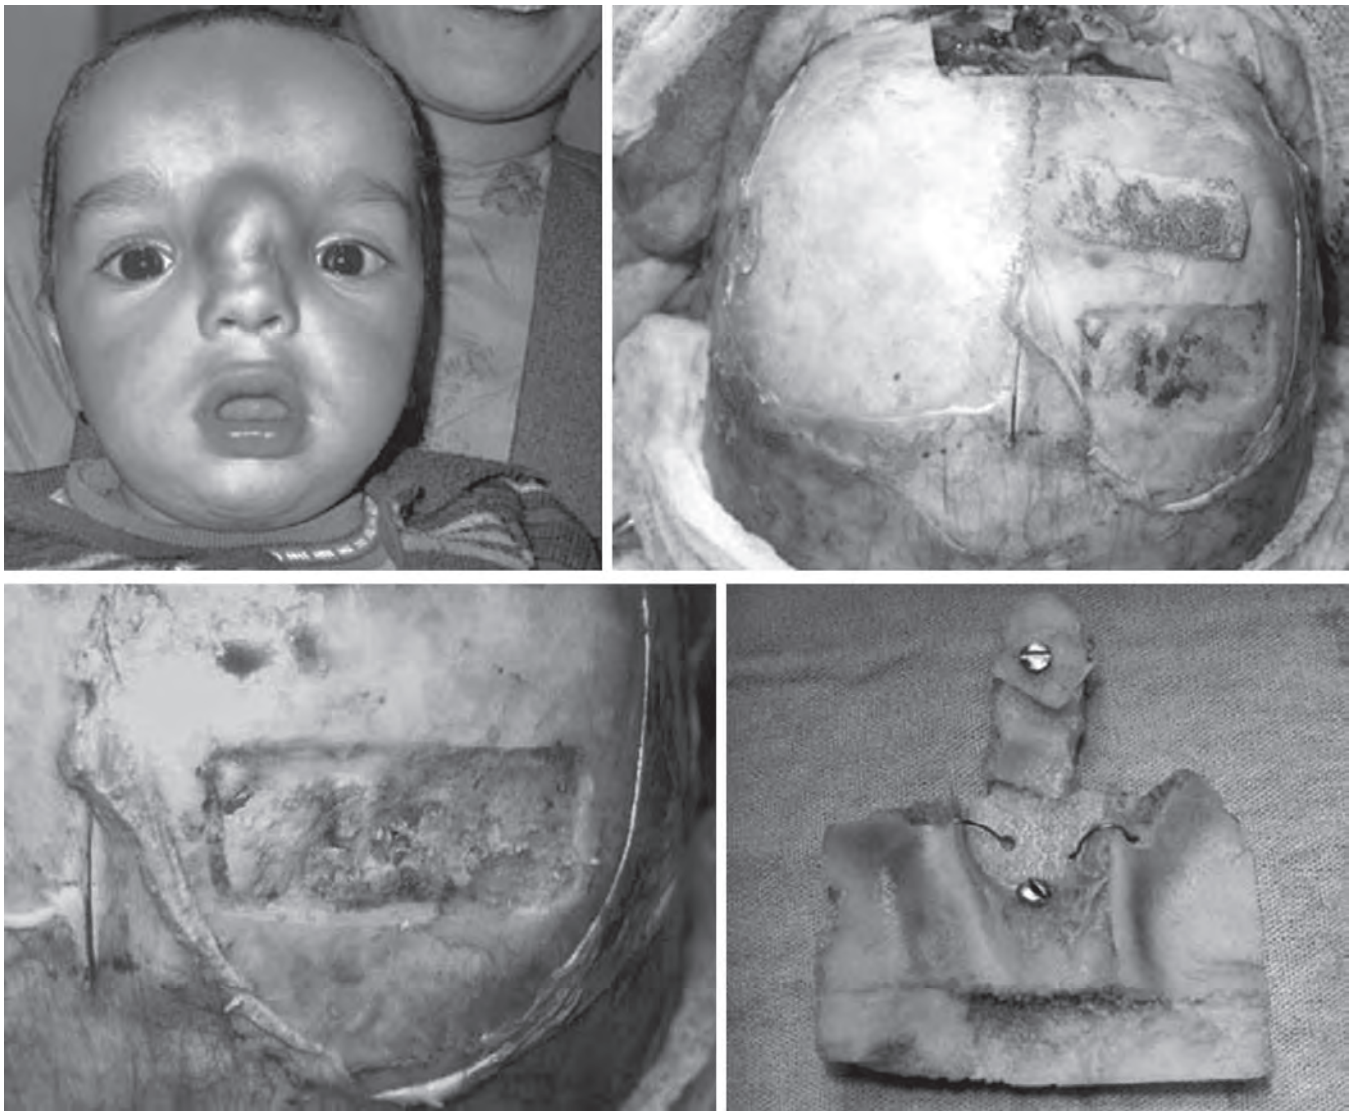

Fig. 8: The split cranial bone graft can be harvested even in small children. In this child aged 13 months, the bone graft has been used to reconstruct the encephalocoele defect. The bone graft has also been used to augment the nasal dorsum. Lag screws have been used for fixation

Autologous bone grafts from other sites can cause significant donor site morbidity, can prolong operative time, are limited in the quantity available for reconstruction and are difficult to contour.[14]

ALLOPLASTIC MATERIAL

Alloplastic material has the advantage of malleability, easy accessibility and durability. However, it has many inherent disadvantages. These include high-risk of infection, foreign body reaction, fibrous and capsular contracture of surrounding tissue and lack of incorporation in the cranium. There is also the danger of deeper migration of the implants. In experimental studies where alloplastic implants were removed, it was noted that the underlying recipient bone underwent transformation to a trabecular architecture with decreased bone density.[7] This may particularly be troublesome, if an alloplastic implant has to be removed following infection or dislodgement, which would result in greater deformity than was initially present.

The use of alloplastic implants for cranial reconstruction has a long history with numerous materials used with varying degrees of success. Currently, three different alloplastic alternatives are widely used: (1) methylmethacrylate (PMMA); (2) hydroxyapatite (HA) and (3) metal. Each has its own advantages and indications in contemporary cranioplasty. When employed with good surgical technique and in the appropriate patient, each material can lead to good clinical outcomes.

PMMA offers an inexpensive method. It is easily adapted and contoured intra-operatively to cover a defect of any size and provides great impact resistance. It does not integrate into the surrounding tissues and is reserved for use in adult and older patients. Custom preformed hard tissue replacement (HTR) implants, a modified porous PMMA material, provide a very accurate and rapid method for large full-thickness cranial defects. It requires pre-operative preparation utilising a 3D craniofacial model.

Hydroxyl apatite has excellent tissue compatibility and the advantage of being osteoactive, radiolucent and readily available. Osteoactivity is the ability of the biomaterial to be replaced with bone formation either through osteoinduction or osteoconduction. In addition, it is biocompatible and does not produce a chronic inflammatory response.[8] Unlike most other alloplasts that are inert, these materials are bioactive (capable of osteoconduction) and have the potential to develop tissue in-growth and integration into the recipient site after placement. These materials are not osteoinductive by themselves but they do provide a physical substrate onto which new bone from adjacent surfaces may be deposited and potentially guided into areas occupied by the material.

Nova Bone (Porex Surgical, College Park, GA) is a synthetic bioactive glass particulate consisting of 45% silica dioxide, 45% sodium oxide, 5% calcium and 5% phosphate, which is believed to be bioactive towards the production of new bone within the biomaterial. Most biomaterials, including bioactive glasses, are osteoconductive, serving as a biocompatible interface along which bone cells migrate. In addition, bioactive glasses are osteoproductive, which is defined as the process whereby a bioactive surface is colonised by osteogenic stem cells from the defect environment as a result of surgical intervention.[25]

A recent review of the experience with HA-cement cranioplasties revealed a high infection rate. During removal of these implants, all were loose and fractured. Forty per cent of these patients had a history of minor trauma at the site of cranioplasty before experiencing infection. Minor trauma may fracture HA cranioplasties and result in infection.[12]

Porous polyethylene (Medpor; Porex Surgical, College Park, GA) is commonly used for facial augmentation and to restore continuity to craniofacial skeletal defects.[3] Polyethylene resins are straight-chain aliphatic hydrocarbons that are inert and promote little tissue reactivity. Unlike bone grafts, porous polyethylene shows little evidence of implant degradation. Like HTR, this is a porous (100–250 mm) biomaterial that permits bone and soft tissue in-growth when placed on facial skeletal defects. There are reports of sufficient soft tissue in-growth with sufficient vascularity to allow skin grafts to be placed directly over the implant.[23]

Demineralised bone is another alternative for reconstruction of the craniofacial skeleton. Salyer and associates have studied the use of cortical demineralised perforated bone for reconstructions (produced by Pacific Coast Tissue Bank) in animal models and in the clinical setting.[18] Although all of the biomaterials discussed in this article seem to maintain their volume overtime, porosity of the biomaterial may be a significant factor in determining bone in-growth into the implant. Methyl methacrylate is non-porous, and no bone in-growth is expected. Cement paste implants tend to contain micropores, and experimental and clinical evidence indicates that there is less long-term bone in-growth into these biomaterials than in implants with macroporous architecture. Biomaterials presently reviewed that have a macroporous architecture and have demonstrated bone in-growth in clinical or experimental studies include ceramic and granular forms of HA, HTR polymer, porous polyethylene (Medpor), bioactive glasses (Nova Bone) and demineralised bone paste. Prefabricated biomaterials and those that set as a cement are not designed to change dimension overtime and are, therefore, best-suited for cranial vault reconstruction after completion of skull growth.[6,26] The most commonly used biomaterials in cranioplasty are HAs especially for contour irregularities and touch up surgeries following cranioplasty (Fig. 9).

Fig. 9: Hydoxyapatite granules have been used for correction of contour defects in this patient who had undergone plagiocephaly correction in childhood

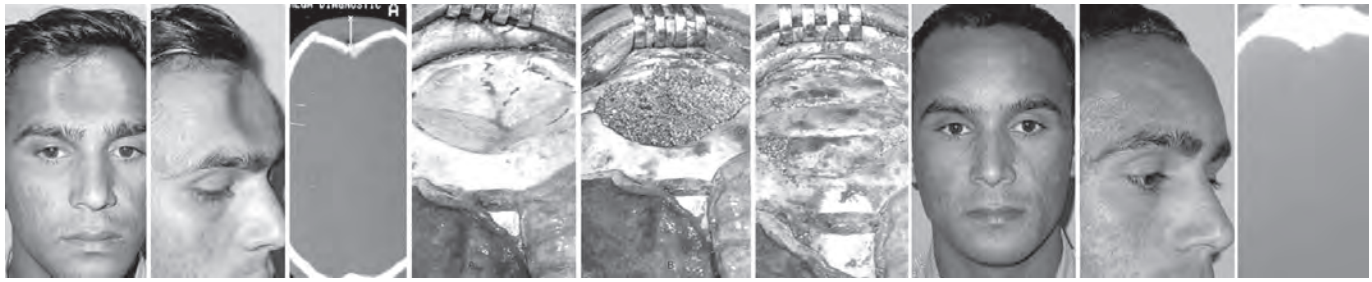

Fig. 10: Use of autogenous cranial bone graft and hydroxyapatite granules in correction of contour deformities of depressed fracture frontal bone. The granules fill up the depression and act like a paste in which bone grafts can be "set" as in a masonry job

A combination of autogenous bone and bioactive materials can be quite handy in the management of difficult contour irregularities, especially for a depressed fracture of the frontal region[21] (Fig. 10).

Metal (Ti) mesh is an historic method of cranioplasty that provides a rapid method for re-establishing an outer cranial cover. Its role today is more limited but is still selectively used in the older cranial defect patients where implantation times are shorter.

FIXATION

It is mandatory to properly fix the bone flap after bone flap craniotomy; an improperly fixed flap has a tendency to drift downwards because of the effect of gravity and pull of the temporalis muscle and leads to significant cosmetic and functional disability.[20]

A variety of techniques are available for fixation of the bone grafts. The edges of the cranial defect should be refashioned and the bone grafts should firmly be in contact with the defect edges. The fixation can be achieved quite satisfactorily with plates and screws (Fig. 11), but these need to be removed if they cause problems. The bone graft could also be pegged into the potential space between the outer and the inner table. The use of stainless steel wire is another way of fixation. The use of currently available absorbable plates may come in handy in future (Fig. 12).

CASE EXAMPLES

The following case reports will highlight the various aspects of cranioplasty:

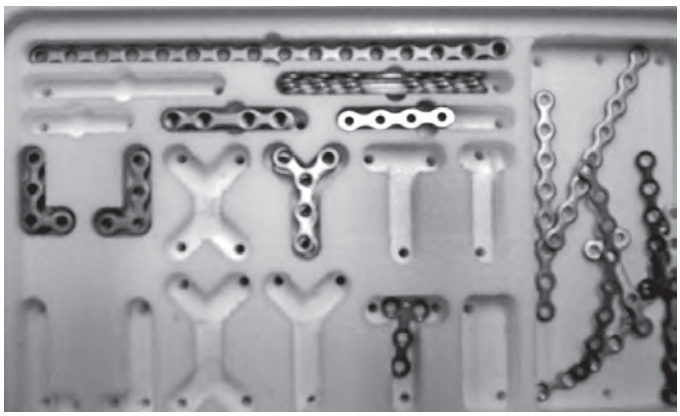

Fig. 11: Titanium plating set

Case 1: Small Defect Frontal Region (Burr Holes)

This young lady had a visible contour defect in the frontal region following frontal craniotomy for head injury many years ago. There were four burr hole defects and these were managed with autogenous split cranial bone grafts that were fixed with the help of lag screws (see Fig. 2). The post-operative appearance is quite pleasing.

Case 2: Sliding Bone Flap

The patient had undergone a right pterional craniotomy for clipping of a right anterior communicating artery aneurysm 8 months earlier. She presented with a slit-like deformity over the forehead running almost vertically over the centre of the right eyebrow. There was a palpable 2 cm wide gap between the edges of the bone. The two bony margins were at different levels leading to a contour deformity. CT scan with 3D reconstruction demonstrated that the pterional bone flap had migrated posteroinferiorly leading to a defect in the region of the forehead due to the over-riding of the bone edges posteriorly (Fig. 13). This was corrected by approaching the defect through a coronal incision. The bone flap that had malunited inferiorly was refractured and moved anterosuperiorly. This left a bone defect in the posteroinferior part and was corrected by using strips of split cranial bone graft taken from the adjacent area. The fixation

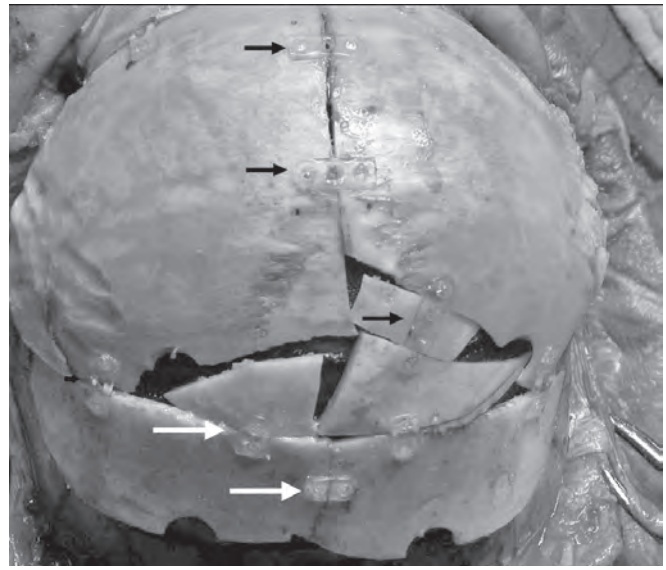

Fig. 12: Absorbable plates are very useful in growing skeleton

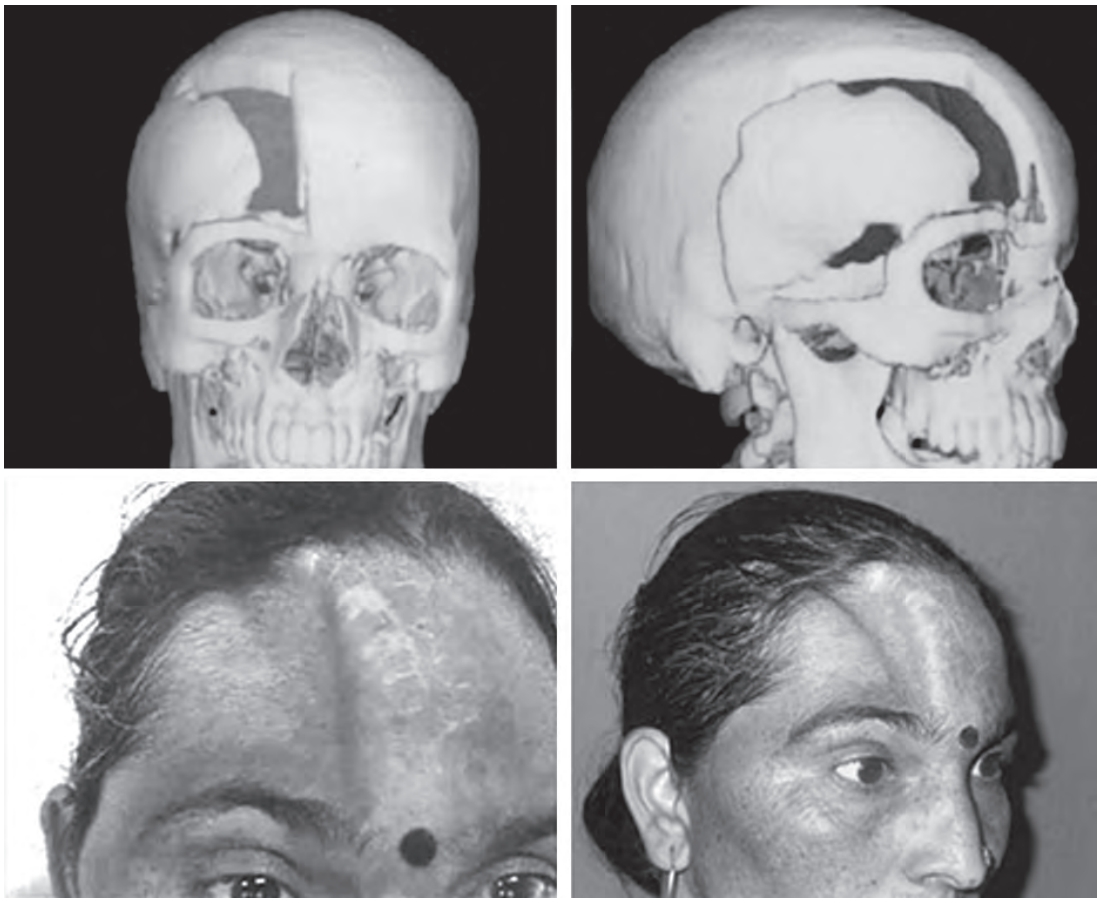

Fig. 13: Improperly fixed osteoplastic bone flaps tend to get pulled down by the temporalis muscle and can lead to significant cosmetic defects

of the bone flap and bone grafts was done using miniplates and screws. The post-operative appearance after 3 months is shown in Figure 14.

Case 3: Large Defect with Skin Deficiency

This patient had a post-craniectomy defect in the frontal region for 3 years. The reconstruction was done using autogenous split cranial bone graft. The skin envelop had, however, become tight and this resulted in exposure of the reconstructed region. This necessitated an immediate flap cover with a radial forearm flap for salvaging the reconstruction.[16] One must be very careful in assessing the adequacy of the overlying skin cover before undertaking bony reconstruction. Any shortage of skin has to be addressed before any reconstruction of the skeletal defect is undertaken. This is best exemplified in the patient shown in Figure 5.

Case 4: Large Defect in the Frontoparietal Region

This girl had a post-traumatic defect in the frontoparietal region. The donor site was selected adjacent to the defect and three large pieces of autogenous split cranial bone

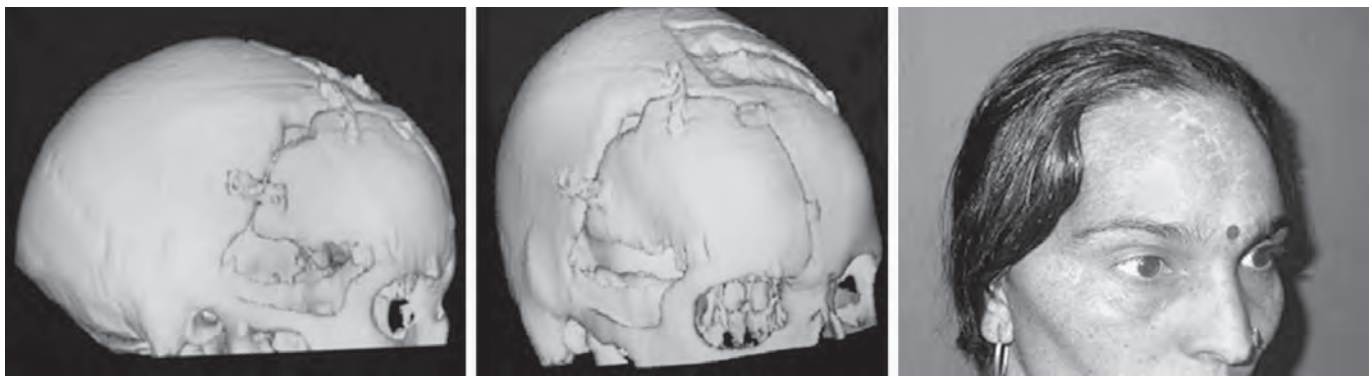

Fig. 14: Result of correction of sliding bone flap of Figure 13. The bones have been secured with titanium screws and plates

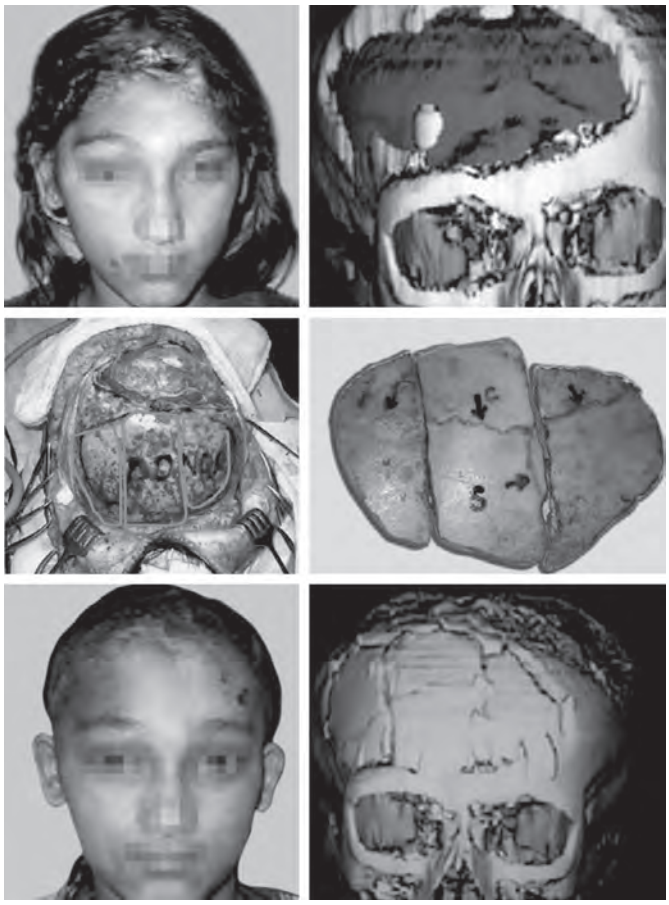

Fig. 15: Large defect in the frontoparietal region reconstructed with autogenous split cranial bone graft. Please note the grafts have been harvested across the suture lines. Three large pieces of bone were used for reconstruction

grafts were used for reconstruction of the bony defect (Fig. 15).

Case 5: Depressed Frontal Bone Fracture, Use of Autogenous Bone and HA

The patient had a depressed fracture of the frontal bone 2 years earlier. He had significant contour deformity in the forehead area. There were no neurological sign/symptoms. The contour correction was done with the help of HA granules and split cranial bone grafts. The granules were used to fill up the "crater" and cranial bone graft pieces were "set" in the mixture as a mason would do with bricks (see Fig. 10). The post-operative contour was quite satisfactory.

42 Maxillofacial Injuries

Arun Kumar Singh, Upadhyay DN

INTRODUCTION

The incidence of maxillofacial injuries is on the rise owing to increase in automobile accidents. Better roads and faster vehicles have contributed their bit in the waxing trend seen in the occurrence of these injuries. Exact incidence figures for India are not available owing to a lack of a registry system.

Other causes of maxillofacial injuries include assaults, battery, domestic violence, fall from a height and gunshot or explosive injuries (war time and peace time both).

GENERAL PRINCIPLES

A vast majority of facial injuries occur due to automobile accidents, assault and fall from a height, bringing these patients under the purview of polytrauma. As always, managing polytrauma starts with ABC (airway, breathing and circulation). The patient has to be evaluated in toto, ruling out major and life-threatening injuries. Undiagnosed head injuries, blunt abdominal trauma and open chest wounds/haemo/pnuemothorax wounds and spinal injuries are the major causes of fatality in polytrauma patients. Such concomitant injuries have to be evaluated and managed primarily before one can proceed further with the management of facial injuries.

Facial injuries, however grotesque they may look, are not life threatening, except if the airway is compromised due to bleeding in the air passages, oedema or aspiration.

Evaluation of the polytraumatised patient should include a quick recording of the vital parameters, a systematic survey of the other organ systems and ensuring proper ventilatory and circulatory support. A rapid haemogram and plain X-rays of the chest, abdomen and cervical spine will avert many a diagnostic disaster and save many lives. Continued blood loss is indicated by a labile blood pressure, a thready pulse and a dyspnoeic, irritable patient. A Glasgow coma scale (GCS) score should be established, cervical spine injury excluded and the chest and abdomen examined thoroughly to rule out injuries in these areas. Continued nasopharyngeal bleed cannot only exsanguinate the patient but can also lead to respiratory compromise. A nasal pack or interdental stabilisation of the facial fractures can often arrest the bleeding at a dramatic speed. Continued bleeding even after these measures should force one to think of embolisation/ligation of the external carotid vessels and/or superficial temporal vessels.

In rare cases the nasal/pharyngeal bleed is often refractory to even ligation of the carotid vessels and may be due to laceration of the dural venous sinuses or internal carotid vessels. These will require a thorough evaluation for head injury/arteriography with arterial embolisation, but death from haemorrhage is frequent in these cases.

CLINICAL EVALUATION OF FACIAL INJURIES

A careful history and a thorough clinical examination form the basis for the diagnosis of almost all facial injuries. Facial injury presentation can range from superficial lacerations to very ghastly wounds with skeletal disarray. A careful examination in all the cases, however, will stand the surgeon in good stead as very minor wounds or laceration can be an indicator of an underlying skeletal injury. Minor cuts, abrasions or contusions should not be taken lightly and as much time should be devoted to their examination as to other injuries. Bone injuries are often suggested by overlying soft tissue swelling and distortion of facial features. A haematoma in the region of the eye should prompt one to think of a fracture in the region of the orbit or the zygoma. A blunting of the cheek bone prominence is a clear indicator of fracture zygoma. Nasal bleed may be the only indicator of a fracture of the maxilla, while fracture of the mandible may be indicated by an inability to clench the teeth or open the jaw. An orderly examination of all the facial structures should be done according to an individualised scheme, progressing either from superior to inferior or vice versa.

IMAGING

Most patients who present to the emergency department with facial injury will be required to undergo a "Facial trauma series", which consists of plain X-rays (PA view, Lateral view, Caldwell view and Water's view). However, plain X-rays do not give the extent of information required for the planning of surgery in terms of displacement. Also X-rays are particularly deficient at showing injury to areas like the floor of the orbit. In all patients with severe facial trauma a CT scan must be

performed. A 3D reconstruction should be done which is helpful in planning the surgery and show the fracture line and their displacements in great detail.

A panoramic view of the mandible supplements the information got on a CT and, therefore, must be requested. With newer CT software it is possible to image great details of the mandibular and dental anatomy (DentaScan).

SOFT TISSUE INJURIES

The face is blessed with a very good vascularity of the soft tissues and bones ensuring very good results if proper attention to certain details is paid during the primary care. The maxim—"first chance is the best chance"—holds especially true for the management of facial soft tissue injuries. There are certain fundamental principles of facial wound management which, if adhered to, give highly gratifying results.

The first and the foremost of these principles are a thorough cleaning and lavage of the wound. Facial wounds, depending on the mechanism of the injury, are often very dirty and have dirt and grit smeared into them. During the first surgery, the wound needs to be thoroughly cleaned with copious amounts of saline and needs to be freed of all the dirt and grit, with a wire brush if needed (however revolting it may sound). Contused and avulsed facial tissues need special consideration and need to be debrided conservatively. Facial tissues, owing to the excellent vascularity, often survive major avulsions even if attached to a minor skin pedicle. All that needs to be done sometimes is to reposition the tissues back into their place. This can be more difficult than it sounds, because the mechanism of facial injuries are often such that they lead to widespread disarray of the tissues and "putting the pieces of the jigsaw puzzle together" may be an uphill task (Figs 1A and B).

Thumb rules in facial soft tissue injuries are:

- Debride conservatively
- Clean thoroughly
- Reposition nicely
- Wait patiently

A word of caution;—seemingly harmless facial injuries—can have concomitant bony injury or injury to the facial nerve or the duct of the parotid gland. Be sure to rule them out before embarking on any definitive treatment.

Figs 1A and B: (A) Soft tissue laceration, fracture of zygoma. Branch of facial nerve identified and saved. Repair of all structures by aligning soft tissue landmarks. (B) Result tafter fixation of fracture

FRACTURE OF THE MANDIBLE

The mandible is one of the most common bones to be fractured in the face, due to its prominence in the face. The mandible is injured most commonly due to direct trauma to the face. Mandibular fractures typically result in some degree of malocclusion; therefore, a complaint by the patient of a change in their occlusal status after injury is a reliable indicator of fracture mandible (Fig. 2).

Mandibular fractures are almost always compound into the mouth as the mucoperiosteum on the inner aspect of the mandible is closely adherent and gets torn during any fracture leading to the compounding of the fracture into the oral cavity.

Fracture mandible can be classified in various ways depending on the arrangement of teeth around the fracture site, the direction of the fracture line and the region of the fracture. The goal of treatment of mandibular fractures is to not only restore the aesthetics of the face but also to restore the occlusion.

Mandibular fracture can occur in the subcondylar area (commonest), body, angle, parasymphysis area, symphyseal area, alveolar process and coronoid process (Fig. 3). Again, depending on the direction of the fracture line, a mandibular fracture can be either favourable or unfavourable. An unfavourable fracture is one in which the action of muscles acting on the mandible is such that it pulls the fracture fragments apart. A favourable fracture, on the other hand, is pulled together by the action of the local muscles. The fracture can be favourable or unfavourable either in the vertical plane or in the horizontal plane.

Symptoms of fracture mandible are:

- Malocclusion
- Pain
- Swelling

Fig. 2: Segmental compound fracture of mandible, showing malocclusion and gingival tear

Fig. 3: Common sites for fracture mandible

- Bleeding from the oral cavity
- Trismus

Signs of fracture mandible are:

- Crepitus
- Intraoral haematoma
- Gingival tear
- Anaesthesia/Hypoaesthesia lower lip
- Deviation of jaw on opening the mouth
- Loose teeth
- Difficulty in opening or closing the jaws
- Open bite
- Abnormal mobility

Investigations

- Plain X-rays mandible AP and oblique views
- Ortho pantomogram
- CT scan

Management

If a fracture in the mandible is suspected at one place, one should be wary of another fracture opposite the first fracture (much the same way as a coup-contrecoup injury in the brain). Typical areas to look for (and easily missed) are the subcondylar areas.

Fracture mandible can be managed in a number of ways, both operative and non-operative. Non-operative treatment is preferred in patients at extremes of age (edentulous arch and high operative risk) or in co-operative patients with stable fracture or in polytrauma patients with other life-threatening injuries which must be attended to first.

Non-operative treatments include:

- Soft diet only
- Interdental fixation with dental wires
- Maxillomandibular fixation with arch bars
- Splints for fracture stabilisation (Cap splint, Gunning splint).

Operative treatment includes open reduction of the fracture fragment and either internal or external fixation. Internal fixation can be achieved by means of dental wires or mini-plates and screws. External fixation can be achieved by means of rigid pin and frame devices which come in various shapes and sizes.

MAXILLARY FRACTURES

In a patient with multiple injuries the maxilla is almost invariably involved along with the mandible. The maxilla occupies an important position in the mid-face and articulates with the nasal bones anteriorly, the frontal bone superiorly, the pterygoid plates posteriorly, the temporal bone laterally, and also forms part of the floor of the orbit superiorly. It houses the all important antrum of the maxillary sinus which is the biggest of all the sinuses and the most prone to trauma and infection. Maxillary fracture is also, like mandibular fractures, almost always compound into the maxillary sinus due to the delicate mucosa there being torn by the trauma of the fracture. This leads to bleeding into the antrum which may or may not manifest as nasal bleed externally.

Maxillary fracture, like the mandibular fractures, almost always leads to malocclusion, the maxilla being part of the upper, tooth bearing arch. The similarity does not stop there. Entrapment of the infraorbital nerve in the fracture fragments may lead to loss of sensation or hypoaesthesia in the upper lip and lateral nose (compare Mental N. entrapment in mandible fracture).

Maxillary fractures have classically been classified along the Le Fort lines (Le Fort I, II and III) (Figs 4A and B). Le Fort lines are the lines of inherent weakness in the maxilla along which fracture lines run. The Le Fort fractures are those which tend to separate the maxilla from the skull base and they are classified according to their position. The Le Fort fractures must extend up to the pterygoid plates for them to be complete and cause a complete dysjunction. In practice, however, the classical fracture lines are rarely seen due to the complex mechanism of injuries that cause these fractures. They, however, serve as important yardsticks to classify, plan and prognosticate maxillary injuries.

The Le Fort I fracture classically passes through the maxilla transversely between the tooth apices and the infraorbital rim. The Le Fort II (or the Pyramidal fracture) extends through the nose and the infraorbital rim in a pyramidal fashion, separating a triangular segment of the face from the skull base. The Le Fort III fracture

Figs 4A and B: Le Fort I (in green), II (in red) and III (in blue) fractures of maxilla

Figs 5A and B: Malocclusion and long face

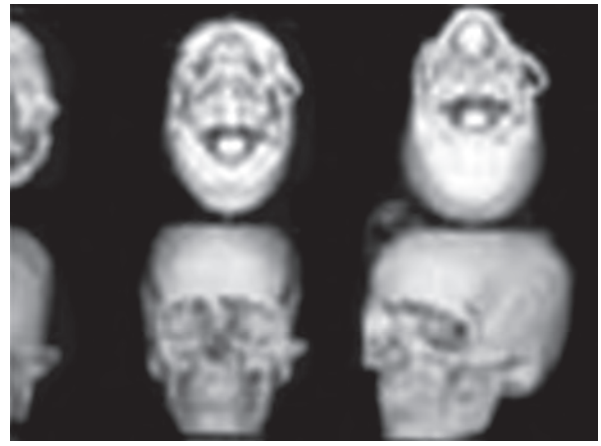

Fig. 6: Three-dimensional CT—zygomatic fracture with dislocation

is also called craniofacial dysjunction and in this the fracture line passes through the nasal bones, the zygomaticofrontal suture and the zygomatic arch and results in the face being separated from the skull (hence the name!) (Figs 5A and B).

Maxillary fractures will usually present as a combination of injuries on the two sides of the face. They are nearly always comminuted due to the thin plate of fragile bone in the area of the antrum and almost always compound into the antrum.

Maxillary injuries can be treated in a variety of ways including interdental wiring, arch bar fixation with maxillary mandibular fixation, transpalatal wiring and miniplate and screw fixation.

The surgical approach to the fractures can also be many. The Le Fort I injury is best approached through an intraoral, upper buccal sulcus incision. The Le Fort II fracture can be approached through a lower eyelid incision, a transconjunctival incision, and upper buccal sulcus incision or a local laceration.

The Le Fort III fracture can be approached via a combination of incisions—upper buccal sulcus and coronal.

While fixing the maxillary fractures it is important to keep in mind to fix the nasofrontal, zygomaticomaxillary and zygomaticofrontal buttresses.

FRACTURES OF THE ZYGOMA

The zygoma, also known as the cheek bone, is a pyramidal structure and articulates with the maxilla, the frontal bone and the temporal bone and also forms part of the floor of the orbit. Swelling in the malar area and hypoaesthesia in the distribution of the infraorbital nerve are prime indicators of fracture of the zygoma, although the swelling in the malar area often masks the zygomatic displacement except to the careful eye.

Injuries to the zygoma are often associated with injuries to the orbital area as the zygoma itself forms part of the lateral part of the orbital floor. These injuries are often together known as orbitozygomatic injuries (Fig. 6). These may be associated with ophthalmologic symptoms like diplopia and a downward tilt to the lateral canthus and merit a careful ophthalmologic examination.

Zygomatic fractures are also often compound into the antrum as the zygoma forms the lateral part of the antrum and may lead to bleeding inside the antrum, manifesting as ipsilateral epistaxis. An injury to the zygomatic arch may be the cause of trismus due to impingement of the fractured segment on the coronoid process of the maxilla.

Solitary, undisplaced fractures of the zygoma may be treated conservatively with rest and soft diet, but fracture of two of the three major articulations of the zygoma (to the maxilla, frontal bone and temporal bone) along with complicating factors, like displacement or rotation, are indications for operative treatment.

The signs and symptoms indicating an injury to the zygoma have been tabulated as under:

- Swelling and ecchymosis in the malar area
- Conjunctival haematoma
- Pain/anaesthesia over cheek/upper lip
- Nasal bleed
- Difficulty in opening the mouth/trismus
- Diplopia
- Downward tilt to the lateral canthal area

Fractures of the zygoma have been classified by Knight and North according to their displacement and the presence or absence of comminution, the discussion of which is beyond the scope of this chapter.

As already alluded to zygomatic fractures (solitary, undisplaced) and undisplaced arch fractures are treated conservatively. The zygoma has three very strong articulations with adjacent bones (maxilla, frontal bone and temporal bone) and unless two or more of these are disrupted the chances of rotational component to the displacement are minimal. Displaced zygomatic fractures, fractures with disruption of two or more buttresses, rotated fractures, fractures of the arch impinging on the coronoid and fractures with an orbital component leading to diplopia are indications for operative treatment with closed or open reduction and fixation of the fracture.

Fig. 7: Plating of orbital rim through subciliary approach

Figs 8A and B: Telescoping injury of the face. The naso-pyramid goes between the orbits into the ethmoids. May be associated with CSF rhinorrhoea. Early treatment is essential as malunion is specially difficult to treat

The zygomatic fracture lines can be approached through a variety of approaches including the intraoral, lower eyelid (Fig. 7) and temporal approach (Gillies). Fixation of two out of three buttresses ensures prevention of re-rotation of the injured zygoma.

NASAL FRACTURES

Nasal fractures occur as a result of direct violence to the nose (frontal or lateral). The diagnosis of a nasal fracture is usually straight-forward and is mainly clinical. History of trauma to the nose along with a deviated nose and/or oedema and intranasal bleed are indicators of nasal fracture. X-rays are needed only for confirming the diagnosis and for documentation purposes and usually consist of a plain X-ray lateral view of the face (soft-tissue). Nasal fractures are classified according to the extent of injury to the bony-cartilaginous pyramid (Stranc classification).

Emergency treatment of nasal fractures is usually straight-forward and consists of reduction of the fractured fragments and splintage (internal and external). Nasal packing in the acute situation helps in control of bleeding as well as provides support to the nasal splint that is placed outside. Although this can theoretically be done up to 2–3 weeks after trauma, excessive oedema and increasing union of the thin, soft, membranous bones of the face renders reduction difficult and a bloody procedure, if treatment is delayed. Later than 3 weeks, bony union of the fractured fragments renders simple reduction impractical and the treatment then consists of osteotomies and anatomical reduction of the deviated framework, akin to a formal, complete rhinoplasty.

NASO-ORBITO-ETHMOID/FRONTO-ORBITO-ETHMOID FRACTURES

The naso-orbito-ethmoid region includes the medial part of the orbits, the nasal bones and the nasofrontal area. The typical findings in case of a naso-orbito-ethmoidal (NOE) fracture are a depressed nasal area with loss of nasal support and telecanthus due to fracture of the bone bearing the medial canthi (Figs 8A and B). A depressed middle third of the face (dish face or pan face) is a diagnostic sign of a middle third fracture involving the nasoethmoidal area. The orbits are almost always involved in any frontal trauma involving the nasoethmoidal region and leading to a dish face. The supraorbital margins, owing to their prominence, are especially prone to frontal trauma. Besides fracture of the orbital margins, there can occur, fractures of the orbital walls, most commonly the floor. A frontal impact over the globe can also cause immense pressure to build up within the bony orbit in a short span of time leading to fracture of the weak areas of the orbit namely the medial wall (the lamina papyracea) or the floor. Fracture of the floor of the orbit can lead to orbital fat herniation (leading to decrease in orbital volume and enopthalmos), extra-ocular muscle entrapment and diplopia. Minor changes in the orbital volume are well tolerated by the globe and are not visible to the casual eye, but an enophthalmos of greater than 2 mm requires surgical reduction and repair of the orbital floor. Herniated fat can necrose and can get infected due to communication with the antrum leading to pan-ophthalmitis and loss of vision and, therefore, orbital injuries require careful evaluation and emergency treatment.

A CT scan of the face is the best radiological tool for visualising the floor of the orbit and the medial wall and also for calculating the loss of orbital volume and for documentation of herniated fat for medical records (Fig. 9).

The orbital floor can be approached via a number of routes, the most common of them being the 'Subciliary stair-step' incision which has the least incidence of post-operative ectropion and gives adequate exposure of the bony orbit. Another approach is the transconjunctival approach which uses an incision 4–6 mm below the lid margin.

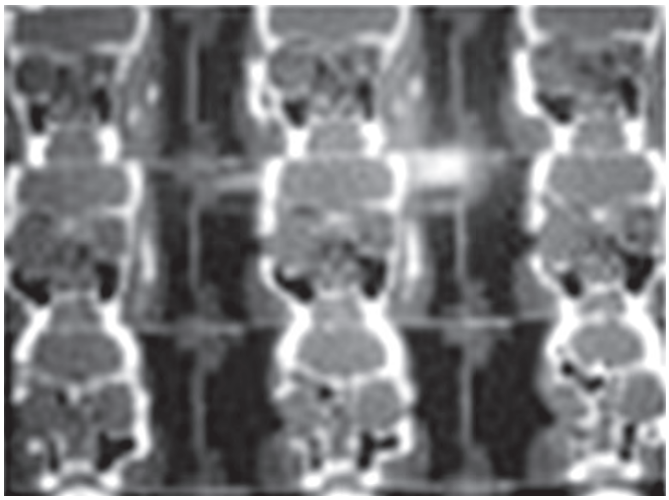

Fig. 9: Blow out fracture, herniation of contents into the maxillary antrum, incarceration of inferior rectus in the orbital floor

The orbital floor can be repaired by either autogenous or prosthetic materials. Various schools of thought favour either a bone graft or prosthetic plate for floor reconstructions. Both these materials have their pros and cons. If autologous tissue is chosen it is usually a cortical bone plate from the outer table of the skull or the iliac crest area. Prosthetic materials include polypropylene mesh, polyethylene plate or Medpore implants.

This type of injury is frequently associated with CSF rhinorrhoea. This should be carefully looked for since the associated nasal bleed or the nasopharyngeal route taken by the CSF leak may obscure its detection. The nature of management and timing of surgery would need to be decided (see chapter on "CSF Rhinorrhoea").

PAN-FACIAL FRACTURES

Pan-facial fractures are particularly tricky as most of the bones of the face are involved in the trauma. The face is conveniently divided into upper, middle and lower thirds. Any injury encompassing two or more of these regions may be classified as a pan-facial injury. Typically, in a pan-facial injury the major bones of the face are fractured leaving one with no stable platform to reduce the bones onto. These are usually the result of high speed frontal collisions or assault. Such patients have to be closely evaluated for other life-threatening injuries such as head injuries, major vessel ruptures, thoracic injuries, tracheal fractures, abdominal trauma and spinal injuries. Pan-facial fractures look particularly ghastly but are amenable to treatment and give good results, if the principles are kept in mind.

As in all facial injuries the ABC have to be secured first and then one must come to a thorough evaluation of the face. Clinical examination (inspection, palpation) must be supplemented by radiological survey. Besides the facial X-ray series, a CT scan of the face, preferably with 3D reconstruction, is a necessity.

Principles of fracture fixation remain the same as mentioned in other sections. For pan-facial fractures, however, the difficulty lies in assessing the normal contour or occlusion as all the major bones are traumatised.

One must remember to proceed either from above, below or vice versa reducing the unstable fragments over a stable bone which can serve as the reference or scaffolding to build the facial skeleton on. Comminuted fractures may require wide exposure and interfragmentary wiring or external fixation in major trauma. Patients usually will need secondary looks at revising the results (augmenting the nose, zygoma, etc.) after healing has occurred and the results of the first attempt are clear.

PAEDIATRIC FACIAL INJURIES

While managing paediatric injuries one must keep in mind that the facial skeleton is not yet mature and has a lot of growth left in it. While this may be an advantage in certain cases, in others it may be detrimental to the results in the long-term.

The facial tissues in children are blessed with a superb vascularity and, therefore, one has to be very conservative in soft tissue debridement or even in discarding small fragments of bone. Pieces of bone may show amazing take up and future growth even if they are attached by a flimsy soft tissue or a piece of periosteum.

Some surgeons now prefer resorbable plates and screws in paediatric injuries so as not to retard the growth potential of the paediatric skeleton with hardware.

Children's bones are also very soft and pliable leading to good moulding while fixing the fracture, but also necessitating gentle handling.

Facial scars in children tend to remain hard and red for a longer time than in adults but the results are far superior in terms of cosmesis. Also, due to the growth potential of the paediatric skeleton, minor discrepancies in fracture fixation can adjust themselves over a period of time so that the final result is good.

43 Traumatic CSF Fistulae

Ravi Ramamurthi, Amit Kapoor

CEREBROSPINAL FLUID RHINORRHOEA

Leakage of cerebrospinal fluid (CSF) through the nose following trauma has been reported to occur in 1–2% of head injuries admitted to hospital.[31,38] In 70%, the leak occurs within 48 hours of the injury. The leak will clinically be obvious in 98% within 3 months. The leak ceases spontaneously in 70% during the first 7 days. In most cases the leak will stop within 6 months. In a small group, after the initial arrest, the rhinorrhoea may recur a few weeks, months or even years after the original trauma.[32,44] In such cases the dural defect gets temporarily sealed by blood clot, brain, or a spicule of bone or by direct adherence of the sinus mucosa to the arachnoid. When such local factors resolve, or when there is an increase in intracranial pressure (ICP) due to post-traumatic hydrocephalus, a free pathway is opened up from the subarachnoid space to the exterior and a delayed CSF leak occurs. In some cases a leptomeningeal cyst may form, from which the leak may occur.[19] Rao[48] postulated that the mechanism of onset of late CSF rhinorrhoea is similar to that of growing fractures in children. The interposition of a piece of dura and arachnoid and possibly a bit of brain tissue trapped into the bony gap is the primary defect. The pulsations of the brain enlarge the bony and dural defect leading to a recurrence of the leak. If such interposition of the meninges into the bony gap does not occur in the immediate post-trauma period, the fistula heals spontaneously.

CSF fistulas may also be classified as low pressure or high pressure. This distinction is relevant for management, as when the CSF pressure is high as in associated hydrocephalus, the ICP has to be reduced by appropriate surgical intervention.

Pathophysiology

The CSF rhinorrhoea may be unilateral or bilateral. When unilateral, it need not necessarily be on the same side as the fracture and dural tear. The severity of the leak is also not always proportional to the size of the dural tear. Usually the leak is through a dural tear which is associated with a fracture of the anterior cranial fossa involving a paranasal air sinus or the cribriform plate of the ethmoid. Samii and Draf[51] are of the opinion that most leaks occur in the adjacent ethmoid roof. The next common sites for the fistula are fractures of the posterior wall of the frontal sinus and those involving the sphenoid sinus (tuberculum sella and anterior wall of the sella rather than the planum sphenoidale). Rarely, fluid leaking through a fracture of the middle cranial fossa into the eustachian tube may flow into the nose during forward bending of the head, i.e. paradoxical CSF rhinorrhoea.[8] A minor injury causing profuse rhinorrhoea through a large fistulous tract is due to the rupture of an associated encephalocoele projecting through a congenital defect in the cribriform plate.[42]

Diagnosis

A detailed history should be obtained in patients who do not have an obvious profuse leak. A salty taste in the back of the throat and salty fluid running down the back of the throat should be asked for. When the fluid is blood tinged, the fluid should be allowed to drip onto a piece of cloth. A ring of blood with an outer ring of fluid suggests the presence of CSF (ring sign). The fluid should be collected and sent for glucose and B2 transferrin estimation. Glucose levels above 30 mg% are indicative of CSF though it may be lower when there is meningitis. This test is more useful when it is negative as it may rule out CSF rhinorrhoea. B2 transferrin is present in CSF and vitreous fluid. It is absent in tears, nasal discharge, saliva and serum.[18,50]

Allergic rhinitis with sudden leak of clear fluid from the nostrils can be differentiated by: (1) the use of sterile cotton pledgets in the nose and soaking them later in water which is examined for glucose, (2) application of decongestant nasal drops and then attempting to provoke the rhinorrhoea by changes in the position of the head, (3) failure of nasal fluid to stain or stiffen a handkerchief and (4) the presence of eosinophils in the nasal discharge of allergic rhinitis.

Headache may be complained of and may be due to high or low ICP. Low pressure occurs when there is a profuse leak of CSF. High pressure headache is often relieved when there is fresh leak of CSF brought about by the high pressure. Meningitis may be the presenting symptom in about 20% of patients in the acute stage.[39,60] The risk of meningitis in delayed cases is 57%.[30,34,36,38,47] The most common organism is *Pneumococcus* and the mortality is around 10%.[24]

Associated symptoms help in locating the site of the leak. Anosmia would indicate a fistula near the

cribriform plate, whereas a leak through the sphenoid sinus may be suspected if there are signs of injury to the neighbouring structures, viz. visual field disturbance, diabetes insipidus or a carotid cavernous fistula. Retention of the sense of smell, demonstration of an ipsilateral middle fossa fracture and the absence of an anterior fossa fracture would throw strong suspicion on the Eustachian tube being involved in the rhinorrhoea.

Investigations

Searching for the site of the fistula during surgery can at times be time consuming and frustrating[45] and every effort must be made to locate the site by clinical and radiological means.

Plain X-rays of the skull, lateral, AP, basal and paranasal sinus views may be helpful in diagnosis, but may not always demonstrate the defect. Tomograms are useful in confirming suspected fracture sites. Radiological demonstration of a fracture involving a paranasal air sinus is strong supporting evidence that the nasal discharge is CSF. Occasionally, plain X-rays of the skull may show pneumocephalus, the air having gained access into the cranium through a fistula. Plain lateral films of the skull in the sitting position may show air in the chiasmatic cistern and a fluid level in the sphenoid sinus.

Computerised Tomography Scan

Fine 1–1.5 mm cuts in the coronal and axial planes should be done from the anterior cranial fossa base up to the sella and a fracture can be made out in about 50%[14] (Figs 1 and 2). On intravenous contrast administration there may be enhancement of the adjacent brain. Hydrocephalus can also be made out.

When the fracture site is not obvious on the plain CT scan, cisternography using water soluble non-ionic contrast, like iohexol or metrizamide, has to be done. When there is an active leak the site of leak can be made out 76–100% of the time.[2,10,46] In inactive leaks the site of leak can be made out in 60%. CT cisternography cannot differentiate between small ethmoid bones and leaking contrast as they both appear white. Bone can be separated from the contrast medium by using dual energy CT scanning.

Fig. 1: CT bone cuts coronal views showing injury to the cribriform plate

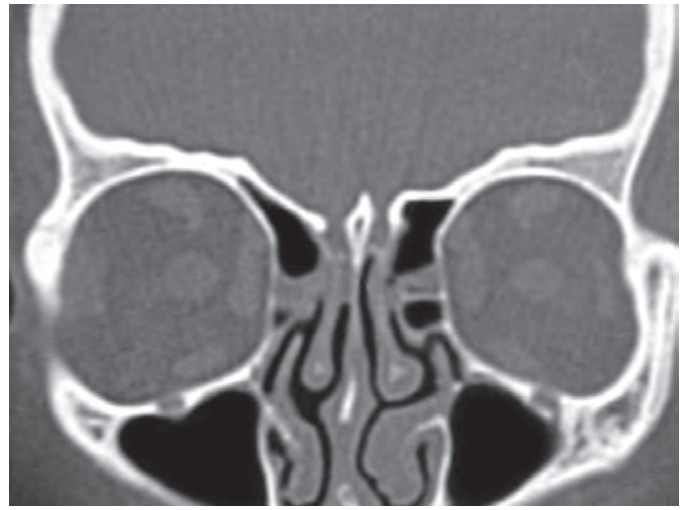

Fig. 2: CT bone cuts coronal views showing bilateral cribriform plate defect in a patient who presented with delayed post-traumatic CSF leak

Radionuclide Cisternography

Isotope studies are useful especially when the leak is minimal or intermittent.[3,12,28,55] The isotopes in common use are technetium-99 and DTPA. Cotton pledgets are placed in the appropriate areas of suspected leak like the roof of the anterior and posterior nares, sphenoethmoidal recess, the posterior floor of the nose and the middle meatus. The isotope is then injected by a lumbar puncture and counts are taken at various time intervals from the different cotton pledgets. In active rhinorrhoea, the site of leak can be located in 70% and in only 28% in inactive leaks.[17]

Magnetic Resonance Imaging

The usefulness of magnetic resonance imaging in finding the site of leak better than the other methods has been doubted.[5,22,25] One report found that magnetic resonance (MR) cisternography was superior to CT cisternography.[15] MR cisternography was done using T2-weighted sequences, a 3D PSIF (time-inversed fast imaging with steady-state precession, FISP) and a 3D constructive interference steady-state sequence. The sensitivity in detecting the site of leak was 92% as compared to 72% with CT cisternography.

Treatment

The patient is given prophylactic antibiotics and is cautioned not to sniff or blow his nose. The usefulness of prophylactic antibiotics has been questioned. There was found to be no difference in incidence or morbidity of meningitis when antibiotics were not given.[33,53] In a meta-analysis which included six series over a period

of 25 years, it was found that meningitis occurred in 10% of patients who were not on antibiotics and in 2.5% of those who were on antibiotics.[4] When the leak lasted for more than 7–10 days, the risk of meningitis increased 8–10 fold. Choi and Spann[9] reported that the incidence of meningitis was greater in patients receiving prophylactic antibiotics. The risk of producing resistant strains was higher with antibiotic prophylaxis.[53] The routine use of prophylactic antibiotics in patients with CSF fistulae in closed head injuries is not recommended.

The nose or ear may be covered with a light dressing, but the orifice should not be plugged tightly. A course of acetazolamide and oral glycerol for a week may be helpful. A period of one or two weeks is allowed to give a chance for the fistula to close on its own. In the presence of associated fractures of the face and extensive facial soft tissue, injury operative intervention cannot be delayed for too long. Repair of the CSF fistula, if required in such cases, should be performed after any surgical manipulations needed to correct mandibular or facial fractures.

Indications for Surgery

A persistent CSF fistula needs surgical closure because of the ever present risk of meningitis and brain abscess. The accepted indications for surgery are: (1) profuse rhinorrhoea; (2) delayed onset or recurrence of rhinorrhoea; (3) the presence of an intracranial aerocoele; (4) associated faciomaxillary injuries; (5) radiological demonstration of a spicule of bone projecting into the brain and (6) history of an attack of meningitis. Lewin[38] recommends that every case of CSF fistula must surgically be closed, on the argument that the temporary sealing of the leak may breakdown at any time by normal changes in ICP, as happens in straining, coughing, etc. Once meningitis sets in, it may be antibiotic-resistant or so virulent that it may prove fatal, and in surviving patients post-meningitic epilepsy is likely to occur. But even such advocates of aggressive surgery would prefer to wait for about 10 days after the injury to allow brain oedema to subside.[30] It may be mentioned that when cases of traumatic CSF fistula report for the first time with symptoms of meningitis, it is often seen that the CSF leak has stopped and does not recur after the meningitis has been controlled. However, Tandon[54] advises surgical closure of the fistula once meningitis has occurred.

Operative technique: The operative repair of CSF fistulae may be performed through an intracranial or extracranial approach.

Intracranial approach: The intracranial operation was described by Dandy,[11] Cushing and Cairns.[6] The currently used technique was first described by Taylor, as reported by Eden.[16] In case the fracture and the rhinorrhoea are on the same side, a unilateral frontal flap may be sufficient for exploration. Rhinorrhoea through either both nostrils or doubtful localisation of the site of leak dictates bilateral exploration. Good general anaesthesia with measures to relax the brain (intravenous mannitol, hyperventilation and/or lumbar drainage) is essential. This of course is not necessary, if profuse CSF leak has been present pre-operatively. An associated aerocoele is tapped to reduce the ICP.

The defect may be approached intradurally, extradurally or both ways. The most suitable plan is to look for the fistulous tract intradurally first. The protrusion through or adherence of the brain to the dural margins of the tract indicates the site of the fistula. After releasing this, the fistula is approached extradurally. A probe inserted into the fistula from inside the dura helps in identification of the tract extradurally. The dura is found adherent to the fracture line at the site of the fistulous tract. The site of the leak, along with a minimum margin of 1 cm of dura all round, is fully exposed.

Fascia lata or pericranium may be used to close the dural defect. It is advisable to place two flaps of fascia lata over the defect, one extradurally and the other intradurally. Fibrin glue can be used to promote adhesion of the graft. The use of cyanoacrylate adhesive for the dural defect[37,40,57] and methyl methacrylate for the bone defect[56] has been advocated. Sometimes, even extensive exposure may fail to disclose the site of the fistula. Ray and Bergland[49] recommended that nasal air insufflation during craniotomy may reveal the site of the leak. If the site is still unidentifiable they recommend covering the cribriform area and packing the sphenoid sinus. Mohanty and Tandon have described the steps of transcranial repair in detail.[43]

The patients are given antibiotics for at least 2 weeks post-operatively and are cautioned to avoid straining of any sort for 4 months. The intracranial route is advantageous[27] in that the surgeon has direct visualisation of the dural defect.[7] It allows inspection and treatment of any associated brain injury[29] and is necessary in the presence of intracranial haemorrhage[41] and in compound fractures. The disadvantages of the intracranial route include: (a) difficulty in reaching and dealing with sphenoidal sinus fistulas and (b) the risk of anosmia following the procedure.

Extracranial approach: The extracranial transnasal approach successfully used to repair CSF fistulae was first reported by Dohlman.[13] This has been followed by other surgeons who have successfully used the extracranial approach to treat CSF rhinorrhoea.[7,27,29,41] The approaches use mucoperiosteal or mucosal flaps, fascia lata or abdominal fat and fascia.[51] The endoscopic approach has become universally accepted and is the method of choice.[23,35,52] The advantages of the extracranial approach are: (a) it does not generally result in anosmia; (b) it produces the best exposure of the sphenoid, parasellar and posterior ethmoid regions, the posterior wall of the frontal sinus, cribriform plate and fovea ethmoidalis and (c) it produces less morbidity than the intracranial procedure. The disadvantages of the extracranial approach are: (1) it does not allow visualisation of the associated cerebral injury and (2) in the presence of comminuted fractures

of the skull base, the extracranial approach does not allow sufficient debridement to delineate the extensive dural tears which may be present.

A CSF diversionary procedure (lumboperitoneal shunt) is necessary when there is raised ICP without hydrocephalus, as measured by lumbar manometry or intracranial ICP monitoring.[21] A ventriculoperitoneal shunt should be done when there is hydrocephalus. It is wise to do the diversionary procedure after the CSF leak site has been identified and repaired. If the shunt is done first, the site of leak may be difficult to locate.

CEREBROSPINAL FLUID OTORRHOEA

This is rarer than rhinorrhoea, but in one series,[31] the incidence was equal in the immediate post-traumatic period. CSF otorrhoea occurs when there is a fracture of the petrous temporal bone along with injury to the tympanic membrane. The fracture can be longitudinal or transverse to the long axis. The incidence in longitudinal fractures is 29% and in transverse fractures 44%.[26] Ghorayeb and Rafie reported a 23% incidence in temporal bone fractures.[20] The dural tear in these cases is usually found on the anterior surface of the petrous ridge in relation to the tegmen tympani. The CSF leaks through the external auditory meatus only if there is an injury or a perforation of the tympanum. Otherwise, the fluid reaches the pharynx through the ear. Such patients complain of deafness after the injury and examination with an auroscope shows a fluid level behind the tympanic membrane. The leak in CSF otorrhoea is usually more profuse than in rhinorrhoea, but has a much greater tendency to cease spontaneously. The tear tends to heal permanently and rarely surgical repair is required. The leak can surgically be repaired by a mastoidectomy. If necessary, the mastoid cavity, middle ear cleft and the Eustachian tube may be obliterated. A limited craniotomy may also be done along with the mastoidectomy.[1] The dural defect after definition can be packed with fat and fascia. A pedicled temporalis muscle flap can be rotated.

Sudden arrest of CSF otorrhoea may be an indication of natural healing but may also be the first sign of the onset of meningitis. As CSF otorrhoea is caused by a fracture of the middle cranial fossa, the same injury may also result in an extradural haemorrhage. When such a combination exists, the CSF leak partly compensates for the rise in ICP, and masks the signs of the haematoma which may reach a large and fatal size before recognition, unless the neurosurgical team is alert to its possibility.

TRAUMATIC PNEUMOCEPHALUS

Following a head injury, air may enter the intracranial cavity through a tear in the dura and a fracture of the skull. This is most often preceded by a CSF leak which may be missed if heavily bloodstained. Occasionally, pneumocephalus may also occur in well-established CSF rhinorrhoea. Air may enter the cranial cavity immediately after the head injury or after a few days, and may be found in the ventricles, in the subarachnoid space or subdurally. In the usual course of events, the air gets absorbed without producing any symptoms. However, if there is a ball valve action which allows the entry of air, but prevents its exit, a condition of tension pneumocephalus may develop. Walker[59] states that Chiari was able to demonstrate what was probably the first reported authentic case of traumatic pneumocephalus.

Some patients present with no symptoms, the pneumocephalus being diagnosed accidentally during routine imaging. In other cases the patients may report with headache and irritability. There may also be vomiting and convulsions.[58] This clinical picture may appear immediately after the head injury or some time later. Infection may occur, leading to meningitis or brain abscess.

Treatment

If there is a tension, pneumocephalus or a trapped subdural aerocoele causing headache and vomiting, tapping and release of the air is essential. In most cases the air gets absorbed by itself. If it persists or recurs or is accompanied by a CSF fistula, then a repair of the fistulous tract is indicated after careful assessment of the patient and after accurate localisation of the tract.

44 Missile Injuries of the Brain

Harjinder S Bhatoe

Missile injuries of the brain (CMI) have traditionally been viewed with pessimism due their supposedly poor outcome. While their incidence is rising all over the world, due to rise in ethnic armed struggle and militancy and terrorist related violence, civilian injuries are also showin g a rise due to easy availability of firearms.[23] There has been improved understanding of these injuries due to the pioneering work of Horsley, Cushing and more recently by experience in the Korean and Vietnam wars. Missile ballistics is now understood better and CT has revolutionised the evaluation and prognostication of these injuries. Multi- and univariate analysis of various factors influencing the likely outcome has been attempted and the Glasgow Coma Scale score has remained the most reliable predictor of the outcome. Surgical techniques have been standardised and post-operative monitoring is better. Outcome of such injuries, both during war or war-like situations and in civilian gunshot wounds has shown improvement and there has been rethinking on the problem of retained intracranial fragments. A better understanding of pathology and adherence to basic neurosurgical principles of definitive surgical management will ensure saving of more lives and improved neurological preservation. Nevertheless, mortality due to these injuries remains high a fact to be borne in mind by all those who attend on the victims of craniocerebral missile injuries.

HISTORICAL PERSPECTIVE

Penetrating wounds of the head have challenged physicians since medieval ages. Within a few hundred years of the Mongols' bringing gunpowder to Europe from China in the fourteenth century, a firearm (Spanish musket) was invented which could propel a projectile at 1,000 ft/sec and could inflict previously unimaginable wounds.[53] There was little attempt to treat these injuries over the next three centuries and until the turn of the twentieth century, missile injuries of the brain were considered to be almost universally fatal. Modern management of these injuries began with the experimental studies of Sir Victor Horsley,[30] in which he described the hydrodynamic nature of CMIs and cessation of respiration with rise in intracranial pressure. This was followed by application of antiseptic techniques to combat neurosurgery in the Anglo-Boer war (1899–1902). Management was further advanced and standardised by Harvey Cushing during his wartime service in France during the First World War, which resulted in a decrease in mortality from 54 to 28%.[18]

The literature on missile wounds sustained during war is more extensive than on peacetime injuries. Each war has furthered experience in this regard. World War I proved the efficacy of definitive surgical intervention. The Spanish Civil War showed that the blast effect was a significant component of craniofacial injury. During World War II, initial dural repair and antibiotic medication showed distinct improvement in outcome.[37] The Korean War confirmed the effectiveness of prompt evacuation of the patient to a neurosurgical centre, often by helicopters from the battle site, followed by definitive neurosurgical intervention. This resulted in improved survival and reduced infection.[38] The civil disturbances in Belfast took place close to a neurosurgical centre and the natural history of penetrating injury could be studied from the moment of injury.[10,41] During the Israeli expedition into Lebanon, all the victims of head injuries were brought to a single institution and for the first time, the place of CT scan in combat neurosurgery was established and a less aggressive debridement could be followed.[9] Finally, after the Vietnam conflict, the Vietnam Head Injury Study (VHIS) involving the US Army, Navy, Air Force and American Red Cross followed up the head injury survivors of war for 18 years and elicited valuable data.[40] Significantly, during the Gulf War (1991), there were only two cases of missile injuries of the brain among the American troops.[11] From India, Bajpayee[4] reported on missile injuries of the brain sustained during the 1971 Indo-Pakistan war. Experiences with civilian gunshot wounds too have been reported.[14,19,39,43] Experiences in management of low velocity missile injuries (LVMIs) to the brain during low intensity military conflicts and anti-militancy operations have recently been analysed.[8,20] Experiences with CMIs during OP VIJAY (Kargil) have been analysed and the role of conservative debridement and meticulous dural closure has been firmly established.[49] The management principles have been successfully extrapolated to the management of civilian casualties.

APPLIED BALLISTICS

Missiles

Projectiles travelling at less than 2,000 ft/sec fall into the category of low velocity missiles, while those travelling

above this speed are high velocity missiles. There is a distinct difference in the pattern of injury and the outcome of low velocity missile injuries (LVMIs) and of high velocity missile injuries (HVMIs). Most handguns and revolvers use heavy bullets weighing about 0.5 oz and have muzzle velocities ranging from 550 ft/sec to 900 ft/sec. In contrast, most rifles and small arms (rifles, stenguns, machine-guns, etc.) used in war use light bullets, having muzzle velocities averaging 3,000 ft/sec. High velocity missiles, as they reach the limit of their range become low velocity (spent bullet) and may inflict less severe wounds, as compared to that within their effective range. The handgun ammunition can achieve muzzle velocity of 1,200 ft/sec effective over a short distance. Pieces of shrapnel from exploding devices may have a velocity of 600 ft/sec, unlike rifled bullets; however, they rapidly lose energy due to their irregular shape and non-aerodynamic nature. The commonly observed CNS missile injuries are inflicted by one of the following missiles:

- The 7.62 mm bullet: This can be fired by the AK-47 assault rifle (Kalashnikov), self loading rifle (SLR), light machine gun or medium machine gun (LMG/MMG). The bullet weighs 150 grams and has a muzzle velocity of more than 2,000 ft/sec.
- The 5.56 mm bullet fired from the Indian Small Arms System (INSAS), M-16 rifle. The bullet weighs 55 grams and has a muzzle velocity of more than 3,000 ft/sec.
- Low velocity missiles fired from a variety of firearms, viz. revolvers, shotguns, handguns, 12 bore single/double barrel guns and country made weapons (katta, tamancha, etc. as prevalent in parts of Bihar and Uttar Pradesh).
- Fragments of exploding devices: The variety of exploding devices reflects the ingenuity of the minds that assemble them, often in innocuous looking forms. They may be made to look like toys, transistors, cassette players, etc. which are often detonated by handling or by remote access. A domestic LPG cylinder placed on its top often makes an innocuous looking but deadly combination for explosion. Other familiar sources of missiles are the HE 36 mm grenade, rockets and exploding artillery/mortar shells. Fragments of exploding devices initially travel at high speeds of over 3,000 ft/sec and then rapidly lose speed because of their volume, weight, irregular shape and become low velocity at distances of 10 metres or more.
- Glass fragments, nails, etc. may rarely act as missiles.[42,55]

Energy Transfer

A bullet is stable in its flight through the atmosphere, but becomes less stable on entering the tissues, when it tends to yaw, deform and tumble due to resistance offered by the tissues, thus releasing kinetic energy (KE). Injury to the tissues by a missile is a function of energy release over time and of the volume and location of tissue disruption. The amount of kinetic energy contained in the missile is defined by the formula $E = -1/2mv^2$, where m is the mass of the missile and v its velocity. Since energy contained in the missile varies directly with the square of its velocity, the latter is relatively more important in determining the energy transfer by the missile than the mass. The amount of tissue damage caused by a missile may be correlated with the amount of energy deposited within the tissues by the missile. The energy transferred can be expressed by the equation:

$E_t = E_{en} - E_{ex}$, where E_t = missile energy transferred, E_{en} = energy of entry at the time of impact, and E_{ex} = energy contained in the missile at the time of its exit from the tissues. If the missile exits, only part of its kinetic energy will be deposited within the tissues. The same amount of energy may be deposited by a missile of a smaller mass with a high velocity or a greater mass missile with low velocity. The amount of energy transfer to the brain is the difference of the energies of the missiles at entry into and exit from the skull. If the missile does not exit from the skull, the energy transferred is the energy contained in the missile at the moment of impact. Thus, lower the residual velocity, greater the energy liberated.[29]

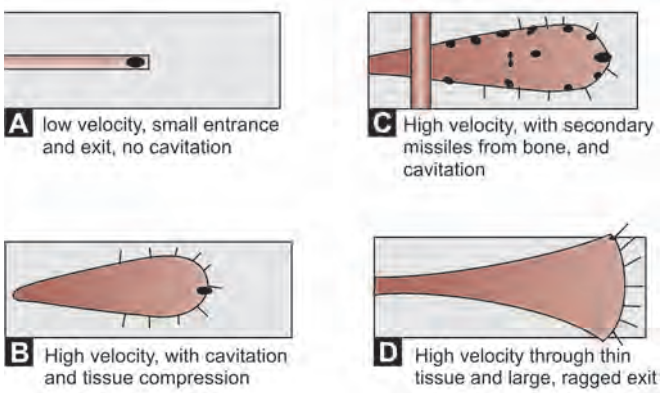
The extent and degree of damage in wounds are proportional to the amount of KE of the missile dissipated in the wound. The injury produced by the missile is increased by factors causing it to give up more of its energy intracranially. A missile that yaws will give up more of its energy. Similarly, a hollow point bullet that shatters upon impact will tend to give up more KE to the brain and is more destructive than bullets that do not shatter. Likewise, shotgun injuries caused by multiple pellets at close range, each with a relatively small amount of KE are extremely destructive; each of these pellets acts as an independent missile invested with KE according to its mass and velocity. Other factors that determine KE transfer by a missile are the resistance offered by the tissues and the tendency of the bullet to deform and increase the area, with which it impacts the brain with a consequent increase in energy transfer to the tissues. Bullets with a flat front and expansion on impact (dumdum bullets) present a large surface area to the tissues to transfer energy. A rifled bullet fired at low velocity, spinning with its long axis parallel to the trajectory may pass cleanly through the tissue and exit retaining much of its KE it had on impact. A high velocity rifle bullet of the same calibre, will more likely strike with its long axis at a slight angle to its trajectory[6] and as a consequence of this and its great velocity, deforms and may even disintegrate in the tissues. The much greater tissue resistance to this high velocity deformed and 'tilted' missile and its fragments leads to release of an enormous amount of KE. The tissue damage is proportionately greater. Transfer of energy is greatest in dense tissues with high water content. Thus, wounds of the brain (and those of liver, kidney, muscle and bone)

are more destructive than wounds of less dense tissue, such as lung or fat.

PHYSICAL EFFECTS OF MISSILE WOUNDING

Missile wounding can be understood in terms of physical interactions between the missile and the tissues through which it passes. The primary destructive effects of a missile interacting with tissues are caused by two mechanisms:

- *Crushing action of the missile*: There is fracture of the skull, laceration and fragmentation of brain tissue and injury to vascular structures.
- *Pressure waves and cavitation (Figs 1A to D)*: Besides the direct crushing action, a missile moving in water or tissue medium generates distinctive types of pressure waves within the medium it transits:
  a. *Juxta-missile pressure*: Extremely high pressures (thousands of atmospheres) are generated immediately in front of and at right angles to a moving missile, owing to the flow of medium (through which the missile is travelling) around the missile.
  b. *Longitudinal shock wave*: When a missile strikes animal tissues, a high-pressure compression front or shock wave is formed which moves spherically away from the point of impact. It is doubtful whether these shock waves result in any energy transfer to cause tissue damage.[28]
  c. *Pressure waves from KE transfer (Cavitation)*: Cavitation was first recognised as a pathological phenomenon in missile injuries by Woodruff.[54] At the same time, Sir Victor Horsley[30] demonstrated experimentally the cavitation in missile injuries of the brain by firing into clay models of brain. When a high velocity missile passes through tissues, KE is transferred to adjacent tissue elements, which are propelled radially, creating a large subatmospheric temporary cavity directly behind the missile. When the elastic limit of this outwardly displaced tissue is reached, it falls inward whence it was displaced. This cycle may be repeated several times before the deranged tissue comes to rest around the permanent track created by the missile. The oscillatory, outward and inward rush of tissue created a long lasting (milliseconds) lower amplitude (20–30 atmospheres) pressure wave, which propagates throughout the medium. It has been considered that these lower amplitude, longer lasting pressure waves are the cause of damage to the tissues at a distance from the site of actual missile injury. Kinetic energy deposited by a missile is partitioned between that which directly crushes tissues in its path and that which displaces tissues adjacent to the missile track. The latter is less destructive than the former owing to the elastic properties of the displaced tissue, which may be deformed without being irrevocably destroyed.[12,16]



Figs 1A to D: Passage of low and high velocity missiles through animal tissues

PATHOPHYSIOLOGY

The pathophysiology of CMI remains a complicated and poorly understood aspect of neurotrauma, although some deductions arrived at from head injury management can be applied to it. Absence of specific data and scant literature on experimental studies (unlike that seen in closed head injuries) are major limiting factors in further understanding of the pathophysiology of CMI.

Effect on ICP and Cerebral Perfusion

Experimental studies have revealed an instantaneous rise in ICP immediately after tissue penetration, due to shock waves lasting 15–25 microseconds; the magnitude of rise is determined by the amount of KE of the missile and can reach up to 80 kg/cm^2.[29] Such a rise in ICP may produce instant brainstem compression and internal brain herniations, resulting in death or decerebration, while there may be no demonstrable significant mass effect.[32] Such acutely raised ICP may be the cause of instant death in humans following CMI. Experimental studies have demonstrated a second rise in ICP to 60–100 mm Hg within two to five minutes of injury and a rapid rise in mean arterial blood pressure (MABP); MABP shows a subsequent fall and a low MABP with persistently raised ICP results in poor cerebral perfusion, decerebration and higher mortality.[12,17,34] Transcranial Doppler studies in patients with CMI have shown vasospasm in 37% cases; these patients have poor survival, as compared to those without vasospasm.[33]

Mechanism of Brain Injury

Immediate rise of ICP due to a shock wave lasting 15–25 microseconds may be transmitted to the brainstem and this factor along with internal brain herniations may lead to instantaneous death, especially if the missile is a high-velocity one.[32] As the missile penetrates the brain, cerebral parenchyma in its path is crushed and spread apart, creating a permanent cavity that is slightly larger than the diameter of the missile. Formation of a temporary cavity, which may be 30 times the diameter of the

missile (depending on the KE of the missile) stretches and tears the brain parenchyma. KE transfer to the brain may be cumulative with injuries from multiple pellets, secondary missiles or from internal ricochet and injuries remote to the observed missile track are quite common.

Contusion and haemorrhage may occur in areas distant from the missile track. Laceration of major vessels may produce large parenchymal haematomas, extending considerable distances from the site of the track. Patients who have no intracranial missile penetration may develop neurological deficit as a result of blast wave. They may suffer fracture of the skull as well. White matter oedema has been observed in experimental CMI in primates,[3] with widespread swelling of perivascular astrocytes within 30 minutes of injury.[2] Oedema has been observed in minutes in patients with CMI who died subsequently.

Experimental studies on cats have shown the early-stage changes in the cerebral microcirculation after a craniocerebral missile wound. The blood flow in the microvessels may increase progressively in the areas of concussion, contusion and laceration, induce reperfusion injury following ischaemia and hypoxia of the brain tissue resulting from a microcirculation disorder caused by the wound.[52]

EVALUATION AND INITIAL MANAGEMENT

Rapid neurological deterioration after missile injury to the brain can occur due to primary and secondary factors. Because the morbidity and mortality are significantly influenced by the patient's neurological status before reaching neurosurgical care, efforts should be made to minimise the time taken for transportation to a well-equipped neurosurgical centre.[31] Upon arrival in the emergency room the patient is completely evaluated after ensuring an adequate airway and haemodynamic stability. All external bleeding should be controlled and a search for abdominal, thoracic and extremity injury is made and their appropriate treatment is planned. The head is shaven completely and extruded brain matter or CSF leak, boggy scalp swelling, eye injury (indicating oculocerebral injury), bleeding or CSF leak from nose or ears, subcutaneous emphysema over the face and neck and pulsations in the carotids in the neck are carefully looked for. The mouth and oropharynx are cleared by suction and examined for bone fragments, splinters and brain matter.

A detailed neurological evaluation, as practical in the prevailing circumstances, is carried out, which will be the baseline for all subsequent evaluations. Rapid examination of sensorium by Glasgow Coma Scale (GCS) is done. Pupils and visual status and ocular movements are noted and facial paresis, focal motor deficit, etc. are looked for. An enlarging intracranial mass lesion should be suspected when there is progressive loss of brainstem function in a pattern consistent with herniation or if the brainstem examination is dramatically better than the overall GCS score.[25]

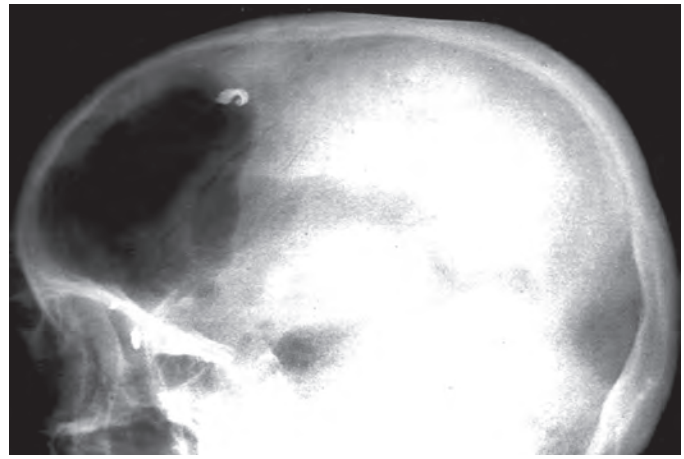


Fig. 2: Skull X-ray showing intracranial splinter with pneumocephalus and air ventriculogram

Imaging

Skull Radiograph

Skull radiographs are done routinely in all the patients. The most common finding is the presence of intracranial radio-opaque foreign bodies (Fig. 2). Their location and distribution can give an idea about the direction of the missile track and the structures likely to have been injured. Communited fractures, depressed fractures, stellate and linear fractures can be observed. Skull radiographs are superior to CT in delineating certain fractures, such as horizontal linear fractures and fractures in the same plane as axial CT slices that can be missed on CT. Another important finding is the presence of pneumocephalus and rarely an air ventriculogram if the ventricle has been entered. Other findings that may be present are opacification of paranasal sinuses and contralateral shift of calcified midline structures, if any.

Skull radiographs may also be done after CT, when trying to locate a single intracranial foreign body, which is suspected to have changed its position and in patients with post-operative neurological deterioration, when it may show a treatable lesion like pneumocephalus.

Computed Tomography

CT is the imaging procedure of choice for evaluation of these injuries, which can diagnose as well as prognosticate the injuries. Usually, a depressed comminuted fracture with in driven fragments is seen in LVMIs. On the other hand, HVMIs may result in extensive skull fracturing remote from the impact site. The parenchymal laceration is seen as a conical track with the base of the cone at the entrance site. Haemorrhage into the track outlines it as a high attenuating track (Fig. 3). However, the shape of the track is variable, according to the missile yaw and energy transfer to the tissues as mentioned earlier. CT will also show the ricocheted missile tract, intracranial haemorrhage, in driven radio-opaque material, pneumocephalus, cerebral oedema

Fig. 3: CT brain showing the missile track

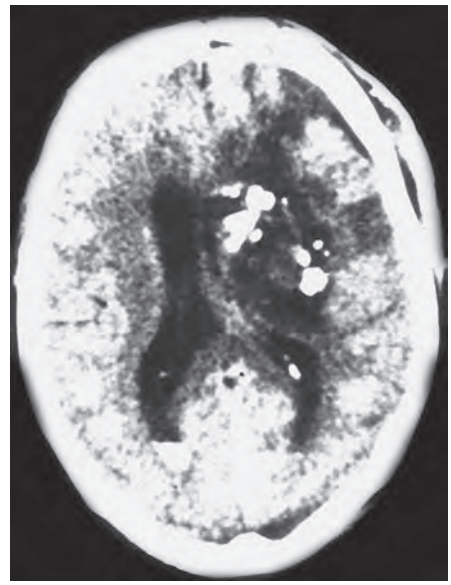

Fig. 4: CT brain showing intracerebral splinter, oedema and intraventricular haemorrhage

and brain contusion (Figs 4, 5A and B). Besides being the most important diagnostic imaging modality, CT is also valuable in prognostication of CMIs. Patients with multilobar injury, subarachnoid haemorrhage and cerebral infarction carry a worse prognosis, as compared to those with localised damage. CT is also valuable in serial evaluation of CMI patients, especially in the event of neurological deterioration.

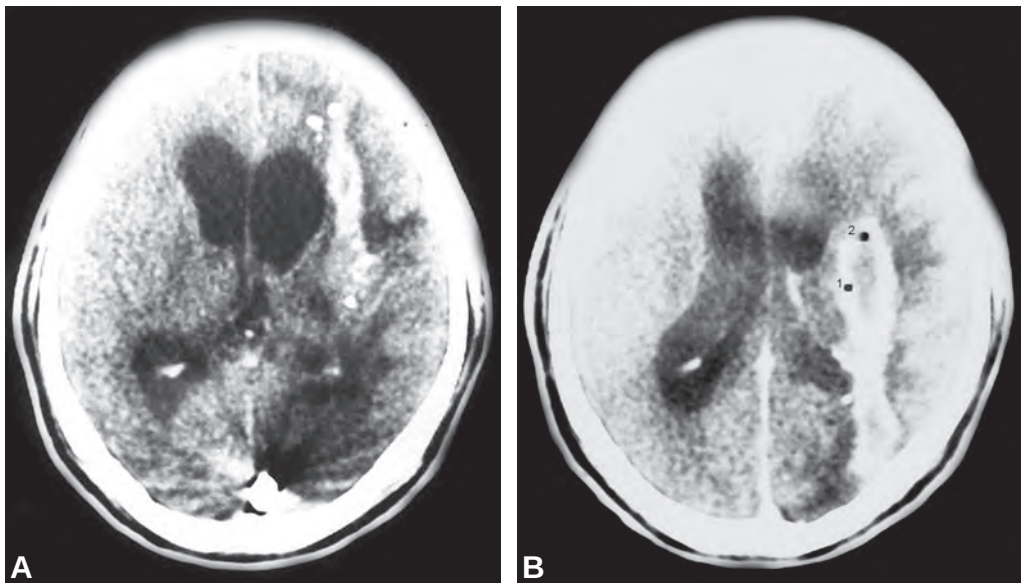
Carotid Angiography

Evaluation of CMI with carotid angiography in the acute phase is no more necessary. Angiography is, however, valuable in evaluation of certain sequelae of CMI like traumatic aneurysms, arteriovenous fistulae, etc.

OPERATIVE MANAGEMENT

The aim of surgical management in missile injuries of the brain is to improve the quality of survival by reducing the raised intracranial pressure and prevention of infection in as many patients as possible. The principles of surgery enunciated by various authors are:

a. The mass lesion consisting of intracranial haematoma and non-viable brain tissue along the path of the missile must be evacuated.
b. The missile and bone fragments, wherever feasible, must be removed, but without enhancing the pre-existing neurological deficit. The brain is usually swollen and retraction can be hazardous. Therefore, one should avoid digging into the brain to retrieve the elusive missile.



Figs 5A and B: CT brain showing intracranial splinters and haemorrhagic missile track

c. Dura and scalp must be closed over the brain in a watertight fashion.
d. Post-operative elevation of intracranial pressure should be minimised and adjunctive therapy (vide infra) should be instituted aggressively.

Availability of adequate anaesthesia support during and after surgery, good fibreoptic illumination, suction and bipolar cautery are mandatory prerequisites for optimum management.

The choice of approach is between debridement via small craniectomies[27] and large bone flaps centred over the wound of entrance.[26] The latter allows greater control of haemorrhage and better decompression[4] and lower infection rate.[44,45] Craniectomy should be wide enough to allow access to normal dura from all sides. Recent military data[9,21,50] indicate that an aggressive approach is not always necessary and efforts should be made to preserve as much neural tissue as possible. After debridement, missile and bone fragments should be retrieved, only if they are accessible without producing any further neurological damage. Exit wounds, if present, are also debrided and the dura is closed with pericranial graft, temporalis fascia or fascia lata.

Orbito-cranial injuries and fronto-orbito-maxillary injuries are usually associated with compound fracture of the skull base, resulting in profuse CSF rhinorrhoea and orbitorrhoea. Such injuries may not be accompanied by alteration in sensorium but are potentially dangerous due to their communication with the oral cavity or air sinuses. These injuries have to be recognised and repair of the dural defect (usually by bifrontal craniotomy) to stop the CSF leak should be carried out at the earliest. Pericranial flaps, mashed muscle and fascia lata are extremely useful in dealing with these CSF leaks.

Gunshot injuries to the paranasal sinuses and orbit are uncommon. Their severity depends on the missile track in the tissues. Such injuries can involve the orbit, paranasal sinuses or brain. Functional endoscopic sinus surgery is the most appropriate technique for removing projectiles.[5] Penetrating orbitocranial non-missile intracranial injuries caused by metallic foreign bodies are very rare among the civilian population. After careful radiological evaluation of the shape and position of the foreign object, a combined right frontal craniotomy and supraorbital osteotomy can be performed, in order to achieve safe removal of the metal bar.[41] Neuronavigation techniques have been utilised as a component of the surgical strategy for secondary removal of retained missile fragments.[47]

PROBLEM OF RETAINED INTRACRANIAL FRAGMENTS

It may not be possible to extricate all the metallic fragments lodged within the brain, due to the unpredictable trajectory of the missile and accompanying factors like brain swelling. Attempts to aggressively remove these missiles may aggravate neurological injury due to retraction, haemorrhage, etc. The problems to be kept in mind while dealing with retained fragments are:

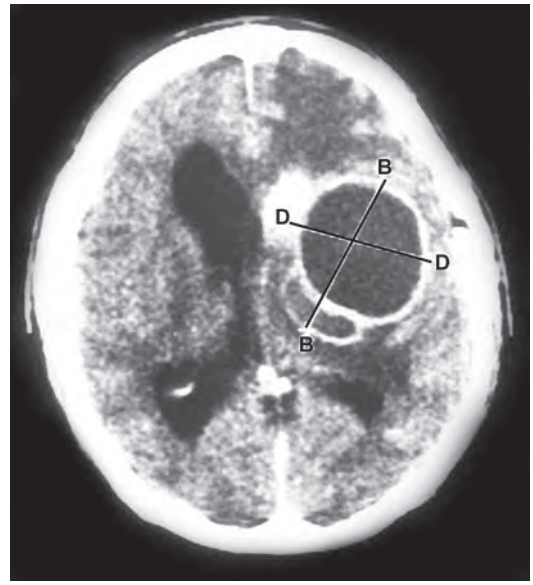


Fig. 6: CT brain showing retained intracranial splinters with cerebral abscess

Infection (Fig. 6)

In the past, military neurosurgeons believed that it was imperative to remove all the bone and metallic pieces. Re-operation was advocated if retained fragments were evident after initial debridement.[27,36] Retained fragments were believed to be fraught with intracranial suppurative complications.[38] Martin and Campbell[35] recorded an infection rate of 16% based on their World War II experience. Over 40% of their patients with retained fragments became infected. Re-operation in such patients was associated with increased neurological deficit.

Recent reports have advocated a more conservative approach. Brandvold et al.[9] while treating Israeli soldiers during their expedition into Lebanon, reported that 60% of the survivors had retained fragments and none of them developed suppurative complications. In the wartime experience of Bajpayee,[4] 22 patients out of 63 treated for missile brain injuries had retained intracranial missiles; two of these 22 developed brain abscess and two developed recurrent meningitis. In a recent series of patients with retained intracranial splinters in low intensity military conflicts,[7,8] there were suppurative complications in only four out of 37 cases with retained fragments; all the four had either orbitocranial injury or breach of paranasal sinuses. They had recurrent episodes of pyogenic meningitis; two of these developed brain abscesses and two developed hydrocephalus, requiring ventriculoperitoneal shunt (Fig. 7). Intraventricular fragments may be associated with meningitis and ventriculitis (Fig. 8). Metallic foreign body in the cavernous sinus causing delayed formation of brain abscess after missile injury has been reported.[48] It is now evident that the extent of brain damage as evident on initial CT is of

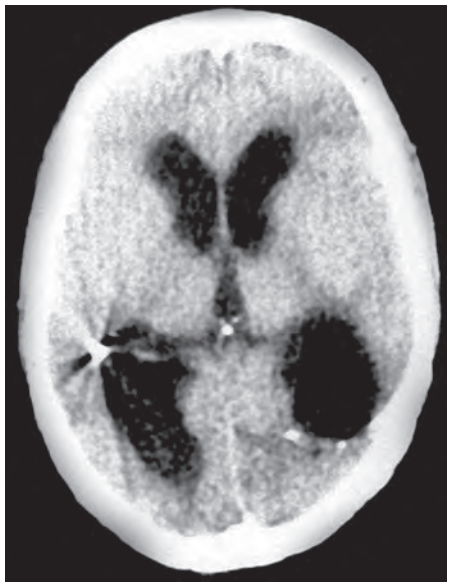

Fig. 7: CT brain showing intraventricular splinter with hydrocephalus

greater prognostic value than the fragment lodged in the brain *per se*. Suppurative complications are more likely if the paranasal sinuses or orbit has been breached or there is brain swelling and persistent external CSF leak.

Epilepsy

The epileptogenic effects of retained fragments, especially those containing copper have been mentioned.[15] However, the true incidence is difficult to assess, since these patients are routinely put on antiepileptic drugs.

Migration

Migration of retained intracranial fragments has been of considerable interest. Migration possibly occurs due to creation of paths wider than the diameter of the missile itself, the weight of the missile and pulsation of the brain. Migration can occur across the midline[19] and into the cervical canal.[56] Migration can lead to fresh neurological deficits, hydrocephalus and traumatic aneurysm.[26] Migrations of a bullet from the cranium to the lower end of the spinal canal after months of injury have been reported.

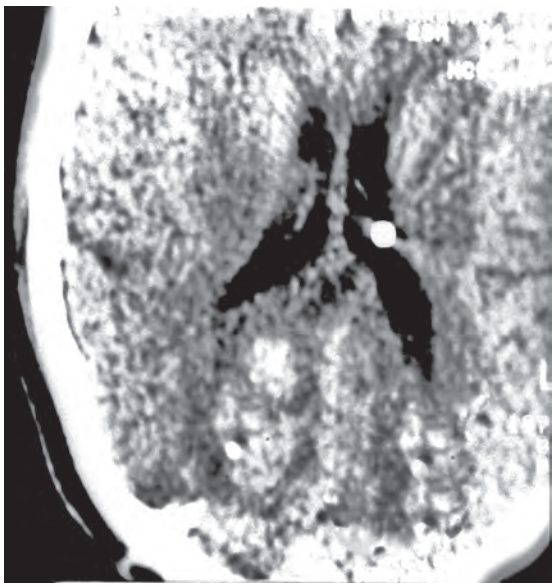

Fig. 8: CT brain showing retained intraventricular splinters

ADJUNCTS TO OPERATIVE MANAGEMENT

Anticonvulsants

The exact role of prophylactic anticonvulsants in CMI is not yet settled, although what is clear is that there is a higher incidence of post-traumatic epilepsy after CMI, as compared to that seen after closed head injury. Although anticonvulsants were used in the Korean and Vietnam conflicts, the incidence of PTE following CMI was the same as in earlier wars, where these were not used[13,15] In the VHIS, one half of the patients with early seizures had late epilepsy.[13,46] During the Iran-Iraq War, 32% patients developed PTE after CMI.[1] Thus, it would be reasonable to assume that approximately one-third of patients with combat CMIs develop seizures.[13] There are few series that document the incidence of PTE after civilian CMIs. Crockard.[17] reported a seizure incidence of 35% and Gordon,[24] an incidence of 40–50%. Thus, it would be reasonable to believe that all penetrating brain injuries must have anticonvulsant prophylaxis, since the true incidence of epilepsy in such injuries may be as high as 35%.[51]

Management of Raised Intracranial Pressure

Management of raised ICP in CMI is a source of trepidation because few of the therapies aimed at ICP reduction and maintenance of CPP are physiologically benign. While head elevation by 30 degrees in euvolaemic patients can significantly reduce ICP without altering CPP,[22] some of the other therapeutic measures used in routine management of head trauma, such as hyperventilation and diuresis risk converting relatively uncomplicated neurologic injuries into complicated multisystem injuries. Hyperventilation can result in alkalosis, which contributes to hypokalaemia and diuresis can provoke hypotension, hypovolaemia and hypokalaemia. Hence, the therapy for lowering raised ICP has to be carefully monitored, so that electrolyte disturbances are avoided or promptly recognised and treated and CPP is maintained. Current concepts in the management of missile injuries to the brain emphasise the frequent occurrence of raised ICP in the post-operative period. To a large extent, judicious debridement of injured cerebral tissue and evacuation of intraparenchymal and extra-axial haematomas can minimise ICP elevations. Medical management of raised ICP consists of proper positioning, ensuring adequate oxygenation and administration of osmotic and loop diuretics. Hyperventilation can be valuable in selected patients. ICP monitoring is a valuable adjunct in the post-operative management.

Antibiotics

Antibiotics that cross into the CSF should be administered in antimeningitic doses for 4–6 weeks. Previously, a combination of chloramphenicol and penicillin was widely used; at present, one of the third generation cephalosporins (cefotaxime, ceftazidime, ceftriaxome) along with an aminoglycoside (netilmicin, amikacin) are favoured. Metronidazole may be added, especially in the presence of extensive soft tissue injury.

CONCLUSIONS

Initial GCS is the single most important prognostic factor in predicting the outcome in missile injuries of the brain. Rapid evacuation of these patients to a neurosurgical centre, aggressive resuscitation in both the field and during transit and prompt correction of physiologic abnormalities are of paramount importance to clinical outcome. CT is the cornerstone in the diagnostic evaluation of these patients. The surgical principles of aggressive treatment of mass lesions, limited brain debridement, watertight dural closure and tension free scalp closure should be applied to all situations. Postoperative management of raised ICP, administration of antibiotics and anticonvulsants are required for optimising the outcome of victims of missile brain injuries.

45 Endocrine Abnormalities following Traumatic Brain Injuries

Deepak Kumar Gupta, Ashok Kumar Mahapatra

INTRODUCTION

Severe head injury still continues to be a great challenge for management as its outcome is still depressing. Concentration on injury to the brain results in neglect of other body systems. The marked improvement in life support measures for patients following traumatic brain injury (TBI) has kept more patients alive after injury than was the case earlier. Despite growing recognition among those who provide care for TBI patients, endocrine dysfunction following brain injury is an often under-recognised phenomenon. On the basis of earlier literature one would conclude that endocrine dysfunctions hardly ever occur following trauma to the head. However, recent studies suggest that a significant proportion of patients suffer some degree of hypopituitarism. To date, there are no clear predicting factors identifying patients at risk for developing hormonal disturbances and thus no parameters exist for screening. Despite a number of case reports of patients with post-traumatic endocrinal disturbances,[11,23,28,37,60] prospective studies or even large retrospective studies dealing with head trauma induced pituitary dysfunction are not available. Severe craniocerebral trauma very often results in persistent deficits and invalidity. The chronic neurobehavioural problems and quality of life complaints plague many patients of severe head injury, which are often strikingly similar to those of patients who have adult onset hormone abnormalities.[44] Cyran first made the association between head injury and development of hypopituitarism. Since then, till the last decade of the last century, sporadic case reports of endocrine abnormality following head injury have appeared. Pituitary function studies are infrequently considered in the acute stage or even in long-term management of patients with TBI, even though it is now a well-known fact that severe head injury results in considerable risk to pituitary function. Earlier autopsy studies had demonstrated anterior pituitary necrosis in as high as one-third of fatally head-injured patients.[16,48] It is thus obvious that TBI poses significant risk to the pituitary gland, leading to elevated risk of diabetes, hypopituitarism and other endocrinopathies. Signs and symptoms associated with hypopituitarism often mimic the sequel of TBI, although the severity of symptoms is not necessarily related to the severity of the injury. Patients with TBI-induced hypopituitarism may benefit both physically and psychologically from appropriate hormone replacement therapy (HRT).

Anterior pituitary insufficiency due to pathologic causes was first reported by Simmonds[73] in 1914, thus it is sometimes referred to as Simmonds' disease. The first report of anterior pituitary insufficiency as a result of head trauma was published in 1918.[21] A complete literature review of Simmonds' disease in 1942 found that of the 595 cases included, only four (0.7%) were related to brain trauma and the others were related to other pathologic causes.[30] Subsequent reviews and case reports identified additional instances of hypopituitarism following head injury.[10,50,75] Benvenga et al.[10] found that 'the anatomical integrity of the pituitary' varies from 14% to 74% in cases of head injury.

TBI poses a significant risk to hypothalamic and pituitary function. Structural abnormalities in the hypothalamus and the pituitary are commonly, anterior lobe necrosis, posterior lobe haemorrhage or stalk laceration.[47] Trauma-mediated vascular injury to the hypothalamus may be the basis of TBI-mediated hypopituitarism, although pituitary lesions are also a prominent factor. Hypothalamic lesions have been reported in greater than 50% of head trauma cases, affecting hypothalamic nuclei and resembling the lesions found in ruptured cerebral aneurysms.[19,24] Pituitary function is at particular risk because of the vulnerable physiologic location of the gland within the sella turcica as well as its delicate infundibular hypothalamic structure and its fragile vascular supply.[43] At present, there are no studies that suggest head injuries of a certain type or in a certain location are more likely to produce hypopituitarism.

Growth hormone deficiency (GHD) is most often seen in patients with TBI because the growth hormone-secreting somatotrope cells are located in the wings of the pituitary gland and the vascular supply and oxygen they receive come from the hypothalamo-pituitary portal vessels. Consequently, damage in this area impairs the blood and oxygen supply resulting in cell death. In contrast, the cells that secrete adrenocorticotrophic hormone (ACTH) and thyroid-stimulating hormone (TSH) are located ventrally in the more protected, medial portion of the pituitary, and they receive blood from the portal vessels and the anterior pituitary artery branch, which provides nutrients and oxygen to this area and to all the cells located in the sub-capsular part.[43] Evidence

from previous and current studies on pituitary deficiencies following TBI demonstrate that total, multiple and particularly single pituitary deficits occur fairly often. These data clearly indicate the need for routine monitoring of pituitary function in all at-risk patients after brain injury.

Several groups of researchers have characterised the prevalence of TBI-induced hypopituitarism. These studies evaluated endocrine function in patients with TBI with no overt symptoms of hypopituitarism or pre-existing history of endocrine disease and whose clinical features at presentation were attributed entirely to TBI.[2,3,43,54] Overall, alterations of the hypothalamic-pituitary axis occurred in 33–50% of the patients studied, with severe GHD reported in 15–20% of adult patients.

Bondanelli et al.[13] studied pituitary dysfunction in 50 patients with TBI over a 5-year period. Basal pituitary hormone assessments conducted between 1 year and 5 years after TBI revealed a total of 27 patients (54%) with pituitary dysfunction: seven (14%) with hypogonadotrophic hypogonadism; five (10%) with central hypothyroidism; four (8%) with low prolactin levels and four (8%) with high prolactin levels. Seven (14%) patients had low insulin-like growth factor-1 (IGF-1) levels for age and sex. Provocative testing with GHRH plus arginine revealed 10 patients with partial GHD and four with severe GHD. In this study, pituitary dysfunction was not correlated with the type, outcome or number of years since TBI.

The neurobehavioural, cognitive and psychosocial profiles of patients with moderate or moderate-to-severe TBI are similar in many ways to the signs and symptoms of hypopituitarism. For instance, in a study of 96 patients with moderate or severe TBI Hellawell et al.[39] reported that, 1 year after injury, 40–60% of patients experienced clinical signs and symptoms that are similar to those of individuals with hypopituitarism from other causes. Léon-Carrión et al.[52] reported that 50% of patients with severe TBI (n = 39) experienced depression—a common manifestation seen in individuals with hypopituitarism from other causes—more than 18 months after injury. However, neither of these studies specifically addressed the issue of TBI-induced hypopituitarism.

SCREENING FOR TRAUMATIC BRAIN INJURY-INDUCED HYPOPITUITARISM

Who Should Screen Patients?

TBI patients are typically first seen and treated by trauma surgeons and neurosurgeons, and by psychiatrists and neurologists if appropriate, with subsequent treatment provided by rehabilitation physicians. These front-line specialists must be able to determine which patients are candidates for screening TBI-induced hypopituitarism and be able to identify the signs and symptoms. It is important to note, however, that because pituitary deficits may not be diagnosed for many years after the TBI itself, rehabilitation physicians must continuously monitor their patients for signs and symptoms indicative of hypothalamic-pituitary impairment.

Although endocrinologists and internists are generally not among the first physicians called to attend patients with TBI, they must be educated about and encouraged to actively share their expertise—eliminating the need for rehabilitation doctors to seek them out about patients with possible endocrinopathies. Appropriate replacement therapy is necessary for patients with hypopituitarism to prevent increased mortality and reduced quality of life. Since evidence shows that pituitary function is impaired in at least 20–30% of patients following TBI, all patients with moderate-to-severe TBI and clinical signs or symptoms associated with hypopituitarism should be screened for their pituitary function.

Screening

The first step in diagnosing hypopituitarism is recording of a detailed patient and family history. In cases of presumed idiopathic hypopituitarism, the family as well as the patient should rigorously be questioned about any history of head injury because the patient's memory of the event may be compromised. A patient history can also reveal possible risk factors for hypopituitarism [age, sex, acute diabetes insipidus (DI)]. Additional risk factors may include abnormal pupillary reactivity, presence of hypotension or hypoxia within 24 hours after injury, presence of major pathological findings and/or diffuse brain swelling on the first two CT scans obtained.[43] However, it should be stressed that results of other studies indicate no relationship between the severity of an injury and the incidence of TBI-induced hypopituitarism.[55] From the perspective of the endocrinologist, patients with proved vital endocrinological deficits (namely DI, secondary adrenal insufficiency and thyroid insufficiency) should immediately be treated for their deficiency. In the context of multiple hypopituitary deficits, other pituitary deficits such as secondary gonadal insufficiency and severe GHD will probably require appropriate replacement, provided these diagnoses are reconfirmed after correction of other deficits. On the other hand, hormonal replacement for patients with proved isolated gonadal deficit or severe GHD could be reconsidered after retesting and in the appropriate clinical context.

Although the incidence of TBI-induced hypopituitarism is likely to be under-diagnosed, not all patients will have deficits and not all of those with deficits will benefit from therapy. For instance, the ramifications of a permanent vegetative state are so profound that it is highly unlikely that such patients would actually benefit from replacement therapy for conditions such as a gonadal deficit or GHD. In general, patients in a permanent vegetative state should be evaluated for DI, inappropriate ADH syndrome, hypoadrenalism and thyroid deficits if indicated, but excluded from further endocrinological testing. Furthermore, because these consensus guidelines are primarily targeted for outpatients,

typically patients who function at a very low level and consequently who are institutionalised as a result of a TBI should also be excluded from replacement therapy beyond hydrocortisone, vasopressin and T4, along with any other patients who, in the opinion of the physician, would not benefit from therapy. With these exceptions, all patients with moderate and severe TBI should routinely undergo baseline hormonal evaluation for pituitary deficiencies, particularly if they were hospitalised for at least 1 day following injury.

Notably, it has been hypothesised that there may be a difference between patients with TBI-induced GHD and those with GHD that is not related to a TBI, and that the group with TBI-induced hypopituitarism might benefit slightly more from therapy with GH. If this is true, the slight advantage offered by GH replacement would likely be of particular interest to the rehabilitation physicians since there are so few therapeutic options currently approved specifically for management of the persistent signs and symptoms after TBI.

WHO SHOULD UNDERGO IMMEDIATE HORMONAL REPLACEMENT?

There is considerable controversy within the medical community over the potential ramifications of HRT. Class I studies have yet to be conducted on hormone replacement in the treatment of patients with TBI-induced hypopituitarism, and such studies are necessary to determine the degree to which these patients will benefit from replacement in terms of either rehabilitation or endocrinological function. This controversy underscores the need for physicians to be able to accurately identify that sub-population of patients with TBI who could benefit from HRT. Even then, the advantages and disadvantages of hormone therapy must carefully be weighed before the decision is taken to initiate therapy.

Physicians who manage patients with TBI should carefully examine the natural history of each individual patient's endocrinological abnormalities and try to determine if the disorder is permanent or transient. To date, there are no study data regarding the transient or late-onset nature of hypopituitarism following TBI, and it is necessary to determine whether it is possible for early-onset hypopituitarism (particularly isolated deficits) following the occurrence of a TBI to be transient or, conversely, for late onset of impaired hypothalamic-pituitary function following a TBI. To conduct such a study, it is essential that baseline values be clearly defined and that the criteria for measuring improvement be clearly delineated. Prospective studies would also increase one's understanding of how and why patients improve and what factors are responsible for triggering improvement. Specifically, because pituitary abnormalities appear to occur very early following TBI, a prospective study is needed comparing the endocrinological status of patients shortly after TBI with that of patients 1 year after brain insult to determine whether abnormalities are transient or chronic.

Nevertheless, it is clear from present knowledge that immediate HRT should be instituted for patients with isolated hypopituitarism in the cases of:

- diabetes insipidus (DI),
- secondary adrenal insufficiency and
- secondary thyroid insufficiency (just after adrenal replacement has been started).

Patients with panhypopituitarism or multiple pituitary deficits should also undergo immediate replacement therapy of all pituitary deficiencies, with the notable exception of GHD. It has been demonstrated that replacement of other hormonal deficits can restore normal GH response to provocative testing; thus, it is mandatory that appropriate replacement therapy be provided for other hormonal deficits to avoid unnecessary replacement therapy in patients with transient GHD that simply reflects other pituitary impairment. Replacement hormone therapy should be reserved for patients who are truly GHD, so GH replacement should only be provided once the diagnosis of GHD is confirmed following optimised replacement of other deficits.

In a somewhat similar fashion, replacement therapy for a gonadal deficit is always recommended in the context of panhypopituitarism or multiple deficits including a gonadal deficit. However, as with GHD, transient impairment in the gonadal axis may occur as a result of concurrent stressful conditions but can recover over time. Thus, when an isolated gonadal deficit is indicated or suspected, the patient should be retested before hormonal replacement is initiated.

After GHD has been demonstrated and replacement therapy is about to be initiated, the endocrinologist and rehabilitation physician must collaborate to tailor the precise dose and modality of therapy for each patient. For instance, recombinant human growth hormone (rhGH) doses must be individualised and titrated based on circulating IGF-1 levels and desired therapeutic outcome. Initial dose should not exceed 0.3 mg kg^{-1} per week, with older patients usually requiring lower doses of human GH. Approximately 4–8 weeks after initiating GH therapy, the dose should be titrated according to age-adjusted IGF-1 levels or symptom tolerance.

For patients with permanent disabilities, therapy for symptoms of hypopituitarism will result in a substantial improvement in the quality of life. Furthermore, HRT for management of TBI-induced hypopituitarism would be a targeted intervention that directly addresses the underlying cause for many of the symptoms of a TBI.

For instance, treatment with GH may increase energy level, degree of socialisation, emotional stability and psychological well-being and it may enhance the physical condition by increasing lean body and muscle mass, decreasing atherogenic lipids and reducing carotid intima-media thickness.[34]

WHO SHOULD UNDERGO FURTHER FOLLOW-UP BEFORE HORMONE REPLACEMENT?

All patients with proved TBI-induced hypopituitarism who are already receiving HRT should undergo periodic

follow-up testing by an endocrinologist to monitor their overall health and endocrinologic status, not simply the status of their GH replacement therapy.

According to the Consensus Guidelines for Diagnosis and Treatment of GHD, for patients with total hypopituitarism or multiple deficits including severe GHD, rhGH therapy must be delayed until the diagnosis of severe GHD is confirmed, which can only occur after appropriate (optimal) replacement of other pituitary deficits, e.g. hypothyroid or hypoadrenal states, has been instituted for at least 3–6 months. For patients with an isolated pituitary deficit of severe GHD, it is proposed that initiation of rhGH replacement therapy also be delayed until retesting 12 months following the TBI to determine persistence.

For patients with isolated, secondary hypogonadism, hormonal replacement should be evaluated on a case-by-case basis. For instance, replacement therapy may be helpful in men to take advantage of the anabolic action of testosterone. In contrast, a better approach for women with secondary amenorrhoea may be to forestall hormone therapy and monitor menses over time, since post-menopausal women do not need oestradiol replacement therapy. As in the case of immediate replacement therapy, the modalities and doses of delayed replacement therapy should be determined by the endocrinologist in collaboration with the rehabilitation physician.

PATHOGENESIS OF ENDOCRINAL ABNORMALITIES

The endocrinal problem following TBI could result either due to damage to the pituitary or hypothalamus. The pituitary is highly vulnerable due to its location in the sella turcica, its vulnerable blood supply and delicate infundibular hypothalamic structures. In contrast to the low incidence of clinical dysfunction, autopsy reports indicate a higher incidence of pituitary lesions (30–33%) in fatal cases of head injury.[16] Daniel et al. reported hypopituitarism in 40% of patients with moderate and severe head injury. Kornblum and Fischer[48] demonstrated pathological lesions secondary to trauma in 62% of pituitary glands. Capsular haemorrhage was the most common finding on histopathology, being detected in up to 50–59% cases.[2,3,10,13,19,21,24,30,34,39,43,47,48,50,52,54,55,65,73,75] Anterior lobe infarcts have been reported to occur in about 13–22% of cases.[2,3,10,13,19,21,24,30,34,39,43,47,48,50,52,54,55,65,73,75] No report of posterior pituitary infarct is available. The confinement of the pituitary gland in the sella turcica by the diaphragma sellae makes the stalk as well as the infundibulum vulnerable to the shearing strain. Subsequent swelling of the gland is limited by the diaphragma sellae, which has only a small circular opening serving as a passage for the pituitary stalk. As it swells, the fragile long hypophyseal vessels get compressed, resulting in anterior pituitary infarction.[48] Hormone abnormalities may exist even in the absence of pituitary lesions, suggesting the active involvement of other areas of the brain in regulating the hormonal milieu of the body. It is generally believed that pituitary dysfunction following head injury is by and large due to diffuse brain swelling, hypotension or hypoxic insult.[1,29] However, primary pituitary damage is well described.[16] Prior to CT scans, most of the evidence was autopsy based. In autopsy studies pituitary abnormality is recorded in almost 75%.[48] The significant primary abnormalities include capsular haemorrhage in over 50%, followed by posterior lobe and stalk haemorrhage in 30% and 20% cases approximately. Necrosis is another important finding. The common site of necrosis is the anterior lobe followed by the pituitary stalk (Table 1). In an autopsy study, Kornblum and Fisher in 1969[48] had reported anterior pituitary necrosis in 35% of patients with a fatal head injury who had survived longer than 12 hours. Necrosis patterns always correspond to the blood supply of the long hypophyseal portal veins. Long portal veins pass through the diaphragma sella, where they are vulnerable to mechanical compression from swollen brain and a swollen pituitary gland.[16,23,48] Long hypophyseal portal veins contribute 70% of the blood supply to the anterior pituitary. The somatotrophs and gonadotrophs are laterally placed, hence more frequently involved.[28] This anatomical arrangement very well explains the long-term hormonal insufficiency. Direct stalk injury in the form of stalk transection and stalk haemorrhage also leads to immediate and long-term hypopituitarism.[1,7,11,41] This can result due to fracture of the sella turcica.[11] With the advent of CT and MRI, it is possible to demonstrate rupture of the pituitary stalk.[7,37,41]

Table 1: Pathology in pituitary gland following head injury

Primary	Haemorrhage	Capsular	50–55%
		Posterior lobe	30
		Stalk	15
	Necrosis	Anterior pituitary	20%
		Posterior pituitary	0%
		Stalk	3%
Secondary	–	– Hypoxia	
		– Oedema	
Direct stalk injury		Rupture of stalk	
		Transection of stalk	
		Stalk haemorrhage	

Hypothalamic injury can also lead to hypopituitarism following severe head injury. By and large these patients do not survive long enough to have long-term hypothalamic problems. Massol et al.[58] described hypothalamic lesions in closed head injury patients. Recently, with improved imaging, such lesions are more frequently diagnosed radiologically.[29,41,44] Traumatic SAH with or without vasospasm also contributes to hypothalamic and pituitary dysfunction.

Trauma causes the T3 to fall, but T4 usually remains normal or is marginally elevated (euthyroid sick syndrome/non-thyroid illness/low T3 and normal

T4 syndrome).[82,86] TSH values are found to be higher amongst survivors as compared to those who succumb to their injuries. According to Chiolero et al.[17] significant lower serum TSH values are present amongst non-survivors. TSH has been shown to reduce biological activity due to impaired receptor binding in cases of severe TBI.[9,84]

Severe catabolic response with marked tissue wasting seen in head injury patients is attributed to higher ACTH levels.[46] Abnormally elevated levels of cortisol have been seen as late as four months after head injury.[46] Stimuli from the injured area traverse the peripheral nerves, ascend through the spinal cord and brainstem to integrating centres in the reticular formation and limbic areas, where these impulses may or may not be modified by stimuli descending from the cerebral cortex. Impulses are then transmitted to the median eminence where corticotrophin releasing factor is liberated. This traverses to the anterior pituitary through hypothalamic hypophyseal portal vessels and in turn releases ACTH that is then transmitted into the systemic circulation to the adrenal gland and stimulates secretion of cortisol.[40] Rinne,[66] in a series of head-injured patients who did not present with clinical evidence of endocrine dysfunction or abnormal basal excretion of urinary 17-hydroxysteroids showed that about one-third of patients in his group demonstrated limited ACTH reserve as measured by response to metyrapone.[66] The author found that those with limited ACTH reserve had been unconscious for a longer time than those who had a normal response to metyrapone. Patients who succumb to injury demonstrate a poor rise in cortisol levels as compared to survivors.

A paradoxical growth hormone response is seen in traumatised patients (GH increases post glucose in severe head injury with normal GH response in less severely injured patients).[45] Studies of CSF of comatose patients following head injury indicate increased turnover of nonadrenaline, serotonin and dopamine.[57] All these transmitters exert a positive effect on GH secretion and could favour a paradoxical response.[56] According to a recent report by Bondanelli et al.[12] GH levels were found to be normal in severe head injury patients evaluated at least one month after leaving the intensive care unit (ICU), when their nutritional status had improved.

Basal prolactin increases following head injury and suggests hypothalamic damage.[5,56,59,86] Edwards and Clark[28] in their review on post-traumatic hypopituitarism reported elevated prolactin (4 out of 12 female patients developed galactorrhoea). As the lactotrophes which secrete prolactin are located in the periphery of the gland, anterior pituitary necrosis could occur with destruction of other pituicytes but leaving the lactotrophes relatively intact.[74] Few authors have reported low basal prolactin levels with an absence of response to TRH, indicating damage to lactotrophes with extensive anterior pituitary necrosis.[17,28]

Hypogonadism associated with transient increase in LH concentration falling to subnormal levels with an exaggerated response to exogenous GnRH stimulation is seen in TBI.[18,86] Hypogonadism after trauma could be due to primary gonadal dysfunction with increased levels of catecholamines, and cortisol having a direct suppressive effect on Leydig cells.[20,85] In a series of 99 patients of severe head injury seen at our institute (of which 59 survived and were evaluated for hormonal abnormalities subsequently), elevation of cortisol followed by prolactin was the most common hormonal derangement followed by elevation of GH, TSH, LH and FSH and suppression of T3. There was a statistically significant temporal trend (over 6 months) in T4, cortisol and GH ($p < 0.05$). Fatal outcome was directly related to LH and gonadotrophin elevation and inversely related to TSH elevation ($p > 0.05$) (Table 2).

CLINICAL SIGNS AND SYMPTOMS OF HYPOPITUITARISM

Hypopituitarism is associated with a number of non-specific signs and symptoms. Fatigue is a major symptom[15,49,51,54,62] and it is also a major symptom of TBI. Examples of other signs, symptoms and laboratory abnormalities indicating hypothalamic-pituitary impairment include decreased lean body mass with increased body fat and dyslipidaemia; reduced exercise tolerance and muscle strength;[15,54] DI; decreased TSH and FT_4 levels and adrenal insufficiency;[10,15,54] amenorrhoea/infertility, erectile dysfunction and hyperprolactinaemia;[10,22] diminished cardiovascular function; impaired cognitive function, memory loss, decreased concentration, mood disturbances, increased anxiety and depression, irritability, insomnia[25,39,52] and a greater sense of social isolation.[15,68] A deficiency of GH produces metabolic effects in essentially all organs and is manifested both physically and emotionally. Ultimately, hypopituitarism can compromise a patient's sense of well-being and overall the quality of life.

These signs and symptoms of hypopituitarism have the same potential for presentation among hypopituitaric patients after TBI. Clinical manifestations of TBI widely vary depending on the type, location and severity of the injury. Pituitary gland dysfunction as a result of a TBI is particularly problematic due to the critical role the pituitary gland plays in regulation of essential hormone production from the thyroid, gonads and adrenals—hormones that regulate many processes with profound physiological and/or psychological consequences. Furthermore, as noted by many authors, the signs and symptoms associated with hypopituitarism often mimic the sequelae of TBI. Consequently, pituitary hormone deficiencies could result in sub-optimal rehabilitation for patients with TBI-induced hypopituitarism.

Table 2: Trends of hormone abnormality seen in severe head injury patients*

Hormone	*Post-trauma days*	*No of patients*	*Minimum level*	*Maximum level*	*Mean*	*Std deviation*	*P value*

*Data of head injury patients seen at AIIMS (New Delhi): 59/99 surviving patients (17–60 year age group) admitted within 24 hours of severe head injury (GCS ≤ 8). Those patients with history of endocrine abnormalities suffering from pulmonary/metabolic disorders have been excluded.[56]

Endocrinological Symptoms of Hypopituitarism in Traumatic Brain Injury

Traditionally, the onset of DI was considered a good indicator of hypopituitarism because it is routinely attributed to pituitary insult. However, reports of the incidence of DI following brain injury vary widely, with Benvenga et al.[10] reporting it in as many as 30% of cases compared with Aimaretti et al.[3] who reported an incidence of 5.5%. Likewise, reports of the incidence of hyperprolactinaemia, another marker of hypothalamus-pituitary derangement, following brain injury vary even more dramatically.[3,10,55] While these findings provide evidence that TBI is associated with derangement of the hypothalamus-pituitary unit, it underscores the fact that a full endocrinologic assessment is necessary to determine the extent of the hormonal effects of TBI and the need for a global endocrine evaluation should be considered.

The clinical problem in head injury varies from the acute stage to chronic problems. In the acute stage, there is likely to be cortisol and ADH deficiency which can manifest with persistent hypotension in the absence of any obvious cause as patients cannot withstand stress in the presence of acute pituitary failure. DI is not uncommon in severe head injury. Failure of the posterior pituitary leads to fall of plasma ADH resulting in DI. This can be diagnosed as patients pass a large volume of urine, which is of low specific gravity, of high serum osmolality and low urinary osmolality.[7,58] The syndrome of inappropriate ADH (SIADH) in severe head injury is not rare and can be diagnosed on the basis of biochemical parameters of serum and

urine. Pituitary dysfuctions are also reported following minor or moderate head injury.[28] Ziaber et al.[87] reported plasma cortisol and beta-endorphin abnormality following minor head injury.

DI is an important clinical problem in severe head injury.[7,58,79] In addition to DI, SIADH is not uncommon.[76] These clinical problems are also to be differentiated from patients with cerebral salt wasting (CSW). In these patients, serum sodium is low and 24-hour urinary sodium excretion is very high. For the above reasons electrolyte balance should be monitored in severe head injury patients up to 2 weeks.[76] Electrolyte and plasma osmolality abnormalities are more frequent in patients with diabetes mellitus and chronic alcoholism.

Clinically, significant hypogonadism is not uncommon in major head injury.[18,36,85] The hypogonadism could be transient[85] or long term. Clark et al.[18] in 1988 reported 33 male patients with major head injury in whom total free testosterone was significantly lower on the 3rd day. However, persistent hypogonadism was only reported in 5 of these 21 patients in whom the tests were performed between 3 months and 6 months after injury. They suggested repeated endocrinal assessment in patients with severe head injury. Woolf et al.[85] in 1986 reported transient hypogonadism following head injury. They included both severe and moderate head injury patients. They studied 31 male patients in whom testosterone and other hormonal assessments were performed shortly after injury and on the 4th day. They observed good correlation between severity of head injury and sex hormone abnormalities. Precocious puberty is another rare problem following severe head injury.[36] The precise mechanism is still not clear. Some authors have hypothesised extrahypothalamic involvement.

The neurobehavioural impact of hypopituitarism is significant. Chronic behavioural problems have been recorded in a significant number of patients with brain injury.[27,53,69,71] Both behavioural and cognitive defects have been seen 1 year following injury.[27,53] Saatman et al.[69] in 1997 demonstrated cognitive abnormality in experimental brain injury. It is generally believed that the deficiency of growth hormone or IGF-1 deficiency results in neurobehavioural and cognitive deficit.[67,69] Saatman et al.[69] reported improvement in cognitive functions by supplementing insulin-like growth factor. Loss of memory, higher anxiety level, impaired motor skill and lower quality of life are also attributed to GHD.[8,14,67,69] Sex hormone deficiency leads to mood disturbances and behavioural problems.

INVESTIGATIONS

Routine Baseline Screening Tests

- Both anterior and posterior pituitary functions are tested, when there is a high degree of suspicion of hypopituitarism.[61]
- Insulin tolerance test (ITT) is a simple test to find out corticotrophin and somatotroph secretion by measuring GH and cortisol level.
- TRH stimulation test is important to assess the level of TSH and prolactin. GnRH stimulation test is necessary to assess gonadotroph function (Table 3).

Derangement of posterior pituitary function is not less important, as it may lead to fluid and electrolyte imbalance, DI and SIADH. Hence, measurement of serum sodium, blood urea nitrogen, creatinine and osmolatity of plasma and urine are important. In addition, a regular check of urinary specific gravity and 24-hour urinary sodium excretion is also carried out to differentiate one from the other. Assessment of serum ADH level is also important.[44]

Basal hormonal evaluations are an essential means of demonstrating hypopituitarism—including deficits of the adrenal, thyroid and gonadal axis—without the need for provocative testing. Regarding the diagnosis of GHD, there is a growing body of evidence indicating that IGF-1 levels are the best markers of GH status as these levels provide an integrated measure of GH secretion.[31,35,63,77]

However, total IGF-1 levels do not distinguish between normal subjects and patients with severe GHD due to considerable overlap between the two populations (GHRS Consensus). Moreover, at present, it is not possible to set reliable, internationally acceptable cut-off points for assessing IGF-1 levels because IGF-1 assays vary from laboratory to laboratory. As a general rule of thumb, patients should be considered to have a substantially abnormal value if their IGF-1 levels are more than 2 SD below the norm for their age group as defined in each laboratory. These patients should be referred to an endocrinologist because such low IGF-1 levels are strongly predictive of GHD. However, it must be noted that because normal IGF-1 levels do not rule out the possibility of severe GHD, when GHD is suspected,

Table 3: Hormonal assessment in pituitary dysfunction diagnosis

Hormone	*Test*	*Method*	*Adult hormone levels*
GH	Insulin tolerance test	RIA	0–5 ng/ml
ACTH	Insulin tolerance test	RIA	9–50 ng/ml
TSH	TRH stimulation	Immnochemoluminescence assay	0.4–4.2 mu/l
Free thyroxin		RIA	5.5–11.5 µ/dl
FSH	GnRH stimulation test	Fluroimmunometric assay	FHS-20–250 pg/dl
Testosterone	GnRH stimulation test	RIA	298–1043 ng/dl

further investigation by means of provocative testing is required.[4,38]

Routine basal hormonal testing should be performed on any patient who has been hospitalised with a TBI and who has symptoms such as hyponatraemia and hypotension. Prospectively, all patients who had a TBI—regardless of its severity—should undergo a baseline hormonal evaluation 3–12 months after the primary brain insult or discharge from the hospital or ICU. Patients with adrenal insufficiency, DI or other clinical symptoms of hypopituitarism should undergo immediate testing of the rest of the pituitary axis without waiting for 3 months. Patients with clinical signs or symptoms suggestive of impaired hypothalamic-pituitary function (e.g. polyuria) should be investigated whenever medically warranted (e.g. a decrease in ability that cannot otherwise be accounted for by changes in CT scan or changes in medication).

Retrospectively, all patients with any signs or symptoms of hypopituitarism who experienced a moderate or severe TBI more than 12 months before their onset should undergo immediate hormonal testing. Given the 12-month passage of time, it is unlikely that any hormonal deficit is transient, so for these patients the screening can be done in a single session.

Provocative Testing

Abnormal or questionable results from basal hormonal testing should always be reviewed by an endocrinologist. Patients should be referred to an endocrinologist for provocative testing if results of their basal evaluations are unclear. For instance, a low IGF-1 level in the absence of malnutrition is highly suggestive of severe GHD and calls for provocative testing. However, since a normal IGF-1 level does not rule out the possibility of GHD, provocative testing is recommended regardless of IGF-1 level when other pituitary deficits are present or if there is a high index of clinical suspicion of GHD.

The ITT is considered the gold standard for the diagnosis of GHD as well as for ACTH deficiency. In fact, hypoglycaemia represents a potent stimulus of both somatotrophic and corticotrophic function. However, the ITT is generally contraindicated in patients who have central nervous system pathologies and hypoglycaemia-induced side effects are known to be potentially hazardous. Among classical provocative tests, glucagon is considered a good alternative to ITT for investigation of either GH or ACTH and cortisol secretion.[70] However, GHRH in combination with arginine[33] as well as in combination with GH secretagogues (synthetic GHS such as GHRP-6 or hexarelin or the natural GHS ghrelin)[33,64] has been shown to represent the best alternative test for the diagnosis of GHD.

Other available provocative tests used to further investigate the existence of deficiencies of other anterior pituitary hormones include GnRH, TRH, CRH, ACTH and metyrapone tests. Specific provocation tests to be performed for each patient should be determined by the endocrinologist in collaboration with the rehabilitation clinicians.

TREATMENT OF HYPOPITUITARISM

Endocrinal abnormality, be it in the acute phase of head injury or chronic state requires careful evaluation and replacement therapy. In the acute stage, patients with DI, or SIADH or CSW, need treatment to correct the deficiency. The treatment may be long-term or short-term depending on the need of an individual patient. DDAVP nasal spray, arginine vasopressin and pitressin injections are widely used.[7,44,58] Several studies dealing with GH deficient patients showed the beneficial role of GH replacement, which included improved memory, attention, comprehension and vocabulary. Improvement also included general well-being of mood and reduction in depression and anxiety state[26,61] GH also helps in increasing muscle mass. Some authors have used IGF-1 and shown improvement in various cognitive functions.[67,69]

Other important replacement therapy includes the deficiency of testosterone. Testosterone replacement in men helps in normalisation of libido and sexual function, helps in bone formation and increases the muscle mass.[80,81] Sex hormone deficiency in women is adequately treated with oestrogen therapy, which improves their neurobehavioural and cognitive functions.

CSW occurs due to unregulated release of natriuretic peptide.[6,32,42,72,78,83] Patients present with persistent hyponatraemia, hypernatriuresis with hyperosmolar urine. In CSW, volume is depleted, hence volume is replaced with Na-containing fluids and deranged haematocrit should be restored. Infusion of saline, plasma and blood is necessary depending on the need. Fludrocortisone acetate is the specific treatment for CSW,[6,32,42,72,78,83] which helps in sodium retention with fluid and corrects hyponatraemia.

CONCLUSIONS

Endocrinal abnormality related problems in head injury are a neglected aspect of comprehensive management of such patients. Overall, 40% of severe head injury patients develop either short-term or long-term endocrinal problems. Basic reasons may be hypothalamic or pituitary damage, which may be primary or even secondary to hypoxia or hypotension. The anterior and posterior pituitary may be involved. Pituitary stalk necrosis or avulsion can also occur. Elevation of cortisol followed by prolactin is the most common hormonal derangement followed by elevation of GH, TSH, LH, FSH, ADH and suppression of T3. GH and gonadotrophin deficiency is also to some extent responsible for long-term behavioural and cognitive problems. Diabetes insipidus, SIADH and CSW are quite frequent. The entire endocrinal problem needs proper evaluation and adequate short-term or long-term hormonal replacement to improve the overall outcome in patients with both severe and minor head injuries. Results of recent and ongoing studies have made it clear that TBI poses substantial risk to pituitary function, perhaps even greater risk than previously believed.

It is essential that patients with TBI be screened both prospectively and retrospectively for pituitary deficits—both isolated and multiple. Patients with demonstrable TBI-induced hypopituitarism should initially receive critical replacement therapy such as with antidiuretic hormone (ADH), glucocorticoid and thyroid hormones. Gonadal and growth HRT should also be introduced if there are persistent demonstrated deficiencies. It has been suggested that patients with signs and symptoms of hypopituitarism following a TBI may benefit in particular if the hormonal replacement alleviated those signs and symptoms masked by sequelae of the TBI itself.

By increasing awareness among physicians of the risks of TBI-induced endocrinopathies and the need for appropriate endocrinological testing, it may be possible to improve the quality of life and enhance the rehabilitation prospects for these patients.

46 Optic Nerve Injury

Ashok Kumar Mahapatra, Deepak Kumar Gupta

INTRODUCTION

Optic nerve injury is a rare condition; nevertheless, it is important as it can cause significant visual loss and even blindness after blunt or penetrating injury. While projectiles or other sharp objects injure the optic nerve directly, the most common form of traumatic optic neuropathy (TON) is indirect, as a result of a concussive force to the head, particularly the forehead. This impact is thought to transmit a shock wave to the optic canal, damaging the optic nerve. In some cases a relatively mild concussive impact can result in indirect TON. Visual abnormalities are uncommon findings following closed head injury. The exact incidence of optic nerve injury is difficult to determine, as many unconscious patients with this pathology may die undiagnosed when autopsy is not carried out. Mahapatra et al.[28,41,55,91] reported a 1.5% incidence of optic nerve injury in head injury cases. Jennette et al. noted a 13% incidence of optic nerve injuries in severe head injuries, while Crompton[17] noted a 4.4% incidence of optic nerve injuries with 24% of them being bilateral.

The pathogenesis of optic nerve injuries till date is unclear and, while the diagnosis of indirect TON can usually be made with the aid of a careful history and examination, its optimal management is far less well defined. There is endorsement in the literature for corticosteroids (dosages ranging from 60 mg to 7 g per day), surgical decompression of the optic canal (via intracranial, transethmoidal, endonasal, sublabial or other approaches) (Table 1) and observation alone. Evidence for the relative benefits of these approaches has mainly been based on small retrospective and anecdotal studies and, therefore, a convincing rationale for treatment is lacking. This chapter highlights a few of these issues.

ANATOMICAL AND PATHOLOGICAL CONSIDERATIONS

The visual pathway is divided into anterior and posterior parts. The anterior visual pathway includes the optic nerves and chiasma. The posterior visual pathway includes the rest of the visual system distal to the chiasma. Barring occipital infarction due to herniation, involvement of the posterior visual pathway in head injury is rather rare. The most important pathology in optic pathway injury is optic nerve involvement.[20,22,23,28,58,70,91,93] The optic nerve extends from the globe to the chiasma and is approximately 5 cm long. The optic nerve is divided into four parts: (1) Intraocular part; (2) Intraorbital part, which is the longest measuring 25–30 mm in length; (3) Intracanalicular part, 4–10 mm long and lies in the optic canal, where the nerve is fixed to the periosteum, and (4) Intracranial part, 10–15 mm long. The intracanalicular part, located in the

optic canal, and the intraorbital portions of the optic nerve are surrounded by dura and arachnoid. The subarachnoid space surrounding the intracranial part of the nerve extends forwards and communicates with the subarachnoid space around the intracanalicular and intraorbital portions of the nerve. The optic nerve passes through the medial part of the annular tendon and below the levator and superior rectus muscles. The dural sheath around the optic nerve blends smoothly into the periorbita at the anterior end of the optic canal. After passing through the optic canal, which forms a prominence in the upper part of the sphenoid sinus immediately in front of the sella turcica and along the medial aspect of the anterior clinoid process, the intracranial portion of the nerve is directed posteriorly, superiorly and medially towards the optic chiasm. The intraocular portion of the optic nerve, which includes the optic disc, lies within the sclera. The intraorbital portion of the optic nerve is surrounded by orbital fat and follows a slightly tortuous course. The ciliary nerves and arteries pierce the sclera in the area around the optic nerve. The ophthalmic artery enters the orbit on the lateral side of the nerve and passes above the nerve to reach the medial side of the orbit. The superior ophthalmic vein arises in the anteromedial part of the orbit and crosses above the nerve to reach the orbital apex. Both the artery and the vein course between the superior rectus muscle and the optic nerve. The branch of the inferior division of the oculomotor nerve to the medial rectus muscle passes below the optic nerve at about the same level that the ophthalmic artery and nasociliary nerve passes above the optic nerve. Near the intracranial opening to the optic canal there is a strong and sharp dural edge. There is a potential risk of damage of the optic nerve against this sharp edge. The blood supply to this part to the optic nerve is important. The intracanalicular part is relatively avascular and derives blood supply from the centripetal branch of the pial vessels. The intracranial optic nerve is supplied by the small pial vessels of the anterior cerebral and anterior communicating arteries. These small vessels play an important role in optic nerve injury and lead to ischaemic neuropathy.

PATHOLOGY

Visual problems following head injury can involve (a) anterior, or (b) posterior visual pathways. According to the site of injury, the lesion can be at various places.

Introduction

The optic nerve is the most frequent site of visual pathway injury in head injury. Hippocrates first described it. Probably the first case of optic nerve injury was described by Dutonchel in 1822. However, in 1879, Berlin[57] described the optic nerve lesion at autopsy. Battle,[7] in 1890, had distinguished direct optic nerve injury from indirect optic nerve injury. Callon,[11] in 1892, had postulated the mechanism of optic canal fracture leading to optic nerve injury and reviewed 80 cases of optic nerve injury reported in the literature.

Optic Nerve Injury

Optic nerve injury is reported to occur in 0.6–3% of all head injuries.[17,28,41,55,91] The most frequent site of the injury is the optic canal. Hughes, in 1962, described the various types of optic nerve injuries, depending on the site: (a) anterior marginal tear; (b) anterior optic nerve injury, and (c) posterior optic nerve injury, which can be intraorbital, intracanalicular and intracranial[41] (Table 2).

Anterior Marginal Tear

It occurs at the optic nerve head in the retina. It was first described by Lowenstein in 1943.[53] Hughes reported an incidence of 13.3% of anterior marginal tear in his patients with optic nerve injury. This type is also associated with retinal and choroidal injury. Ophthalmoscopy reveals haemorrhage and irregular disc margins.

Anterior Optic Nerve Injury

It involves the optic nerve behind the globe till the entry of the central artery of the retina. Hughes[41] observed it in 12.3% of cases in his series. Retinal vessel spasm occurs in 30–35% of cases.

Posterior Optic Nerve Injury

It is more frequently seen. Traumatic orbital apex syndrome is a rare condition, occurring in the muscle cone. In this situation the optic nerve is involved and there is associated proptosis and III, IV and VI cranial nerve palsy. Intracranial optic nerve injury occurs in the optic canal, where the nerve is relatively fixed and the nerve sheath is firmly adherent to the periosteum. This type of injury can occur in anterior cranial fossa fracture. Hughes reported bilateral optic nerve injury in patients with LeFort type III fractures.[41]

PATHOPHYSIOLOGY OF OPTIC NERVE INJURY

The exact mechanism of optic nerve damage is not understood. However, a large number of hypotheses have been put forward. Walsh and Lindenberg,[92] in 1963, classified optic nerve injury into primary and

Table 2: Hughes classification of optic nerve injury based on site of injury[41]

Contusion	Microvascular thrombosis
Haemorrhage: intraneural/ extraneural	Infarction of the nerve

secondary type depending on the nature of the pathology as observed at autopsy (Table 3).

Concussion of the optic nerve was first described by Walsh in 1979.[93] Secondary involvement of the optic nerve is due to oedema and ischaemia, leading to infarction of the nerve, as a result of microvascular thrombosis.[36,41,92] Microvascular thrombosis is probably due to shearing strain on the nerve as a result of acceleration and deceleration injury to the orbit. It is also likely that midline forehead injury can produce bilateral optic nerve injury while a blow over the supraorbital/temporal area produces unilateral optic nerve injury. The shearing and stretching forces can lead to rupture of optic nerve axons.

One of the most favoured mechanisms of optic nerve damage in head injury is vascular insufficiency.[28,41,91] The vascular injury is generally to the pial vessels, which could be immediate. Delayed onset of visual involvement is due to oedema and ischaemia. In patients with irreversible visual loss, the most important cause is probably optic nerve infarction.[8,28,91] In two cases of Hughes, the histology of the intracranial optic nerve revealed infarction.[41] Infarction was also reported by Ramsey,[79] in both the intracanalicular and the intracranial portion of the optic nerve.

Fracture of the anterior cranial fossa, orbital roof, anterior clinoid process and the optic canal can produce optic nerve injury. These fractures can produce tear or compression of the nerve. Contusion of the nerve is a form of primary injury, which results from a shearing force to the nerve. Hooper, in 1951, had reported contusion of the intracranial optic nerve in a patient with anterior clinoid fracture.[40] Rarely, an optic sheath haematoma has also been reported.[29,42,78,87] Intraneural haemorrhage occurs due to the rupture of small veins or capillaries, resulting in a perivascular haematoma. Imachi et al.[42] have reported a few cases of intraneural haematoma. Tandon et al.[87] observed one case of optic nerve haematoma among 100 patients. Mahapatra et al.[65] observed a single case among 27 patients subjected to optic nerve decompression (OND).

In spite of a normal looking nerve at surgery or at autopsy, histopathological abnormalities are consistently reported.[40,41,87,91] Pathological entities, such as degeneration of myelin, loss of axons and chronic inflammation with phagocytosis, are found at microscopic examination. Vascular involvement in the form of thrombosis, ischaemia and infarction are also seen.

PATHOLOGICAL ANATOMY

The optic canal is formed by the two struts of the lesser wing of the sphenoid and carries the optic nerve and the ophthalmic artery. The optic nerve, in contrast to a peripheral nerve, is a direct continuation of the brain and has all three of the meningeal layers—pia, arachnoid and dura—covering it (fasciculus opticus). Different mechanisms of injury are implicated with damage to the various segments of the optic nerve. The intraocular and intraorbital portions are typically damaged by direct ocular injuries; however, occasionally, indirect trauma may result in either an intrasheath or orbital haematoma. These haematomas may compromise the blood supply to the optic nerve via compression and subsequently result in a loss of vision. The intracranial portion of the optic nerve is most frequently injured by blunt trauma, and tears of the optic nerve itself or of the optic chiasm are occasionally seen. If at all indicated, OND in these cases is a neurosurgical approach via craniotomy. The intracanalicular portion of the optic nerve is the site most frequently involved in indirect lesions, such as blunt trauma, and it is with an injury to this segment that OND may be most beneficial (Figs 1A to H). The dural covering of the optic nerve consists of two layers, the outer layer arising at the orbital apex where the central nervous system dura splits to form the periorbita and the optic nerve sheath, and the arachnoid attached to the inner portion of the dural sheath. This anatomical structure has clinical implications, because theoretically it should be possible to incise only the outer layer of the dural sheath and not enter the subarachnoid space, thus, avoiding a potential cerebrospinal fluid leak during OND. Although theoretically possible, it is unlikely that an incision will incise only the superficial layer of the dural sheath because the layers are intimately related. Thus, precautions to avoid a cerebrospinal fluid leak should be taken if the nerve sheath is to be incised.

CLINICAL FEATURES

In conscious patients diagnosis is not difficult. A history of unilateral visual loss or, rarely, bilateral visual loss is the main complaint. The visual loss could be immediate or delayed.[28,55,64,70,91] In 90% of cases, patients do have a history of loss of consciousness. Typically, the retina and optic disc initially appear normal, and the only objective finding is the presence of a relative afferent pupillary defect. Optic atrophy does not become apparent for 3–4 weeks. In severe head injury, when a patient is unconscious, unilateral fixed dilated pupil with retained consensual light reflex should raise the possibility of unilateral optic nerve injury (Marcus Gunn Pupil). In unconscious patients it is difficult to determine the timing of onset of visual deterioration. In 15–20% of patients, visual loss may be partial and patients may also have visual field cuts. In patients with optic nerve concussion, there will be a transient visual loss. Hence,

it may be possible to have some visual recovery by the time patients reach the neurosurgeon[8,20,29,65] [Figs 2 (A to C) and Table 4].

Examination usually reveals a normal cornea, lens and vitreous. In anterior marginal tear, ophthalmoscopy may show retinal haemorrhage.[28,40,91] In the vast majority of cases the fundus reveals no abnormality. Rarely, congestion of the disc may be observed.

Table 4: Results of 800 patients with optic nerve injury at AIIMS (1983-2002)[67]

Visual recovery	*% of recovery*
Complete recovery	10
Partial recovery	48
No recovery	42

Fundus Finding

Fundus findings vary according to the site of the injury and the degree of damage to the nerve. Except anterior marginal tear, immediate or early examination may not show any abnormality. In anterior marginal tear, fundus examination a few hours later usually shows oedema and haemorrhage. In anterior optic

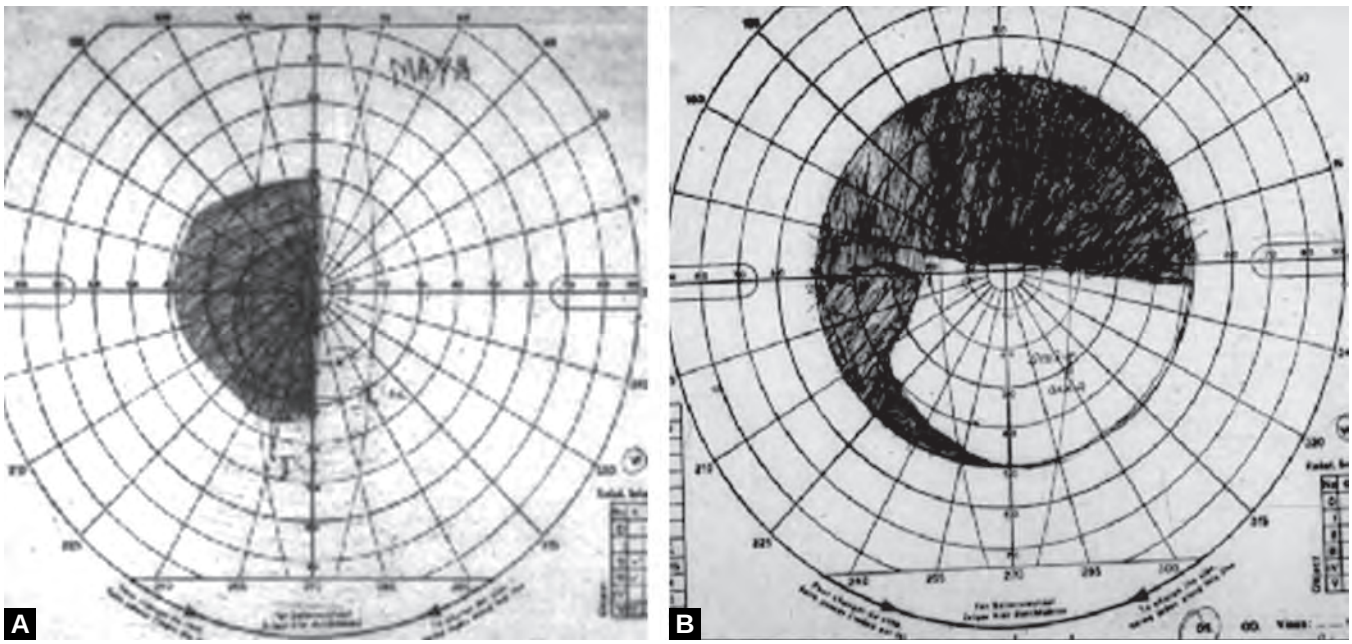
nerve injury, when the site of damage is nearer to the eyeball, fundus changes occur earlier than distal optic nerve injury. Generally, optic atrophy sets in 3–6 weeks time.[1,19,28,41,89]

Field Defects in Optic Nerve Injury

Various types of field defects have been reported in patients with optic nerve injury (Figs 3A and B).[1,19,28,41,60,70,89] Traquir et al.[89] had reported central or paracentral scotoma and altitudinal field cut. Hughes,[41] in 1962, had reported inferior field cuts only in their observation. Mahapatra et al.[56] noted all possible field defects including nasal field. However, the temporal field was most frequently involved possibly resulting from selective involvement of nasal fibres as the bone in the medial side of the orbit is thin and is likely to fracture more frequently.

INVESTIGATIONS

X-rays of skull paranasal sinus view and optic canal view are important radiological investigations. Skull fractures are reported in 50–80% of patients.[19,28,70,91] A wide variation in incidence of optic canal fractures (0–90%) has been reported.[22,23,57,64] This is basically due to differences in surgical, radiological and autopsy findings. With the advent of CT scan, demonstration of optic canal fracture has become easy. CT cuts with bone window helps in establishing the fracture. CT scanning is regularly used in suspected cases of optic nerve injury (Fig. 4).[5,31,44,55,64,68,70] High resolution CT is the procedure of choice. Manfredi et al.[68] reported sphenoid and ethmoid haemorrhages in PNS view and among them five had CT scan evidence of optic canal fracture. Grove[31] had pointed out the role of soft tissue injury. Mahapatra



Figs 3A and B: Perimetry showing visual field deficits in a case of optic nerve injury

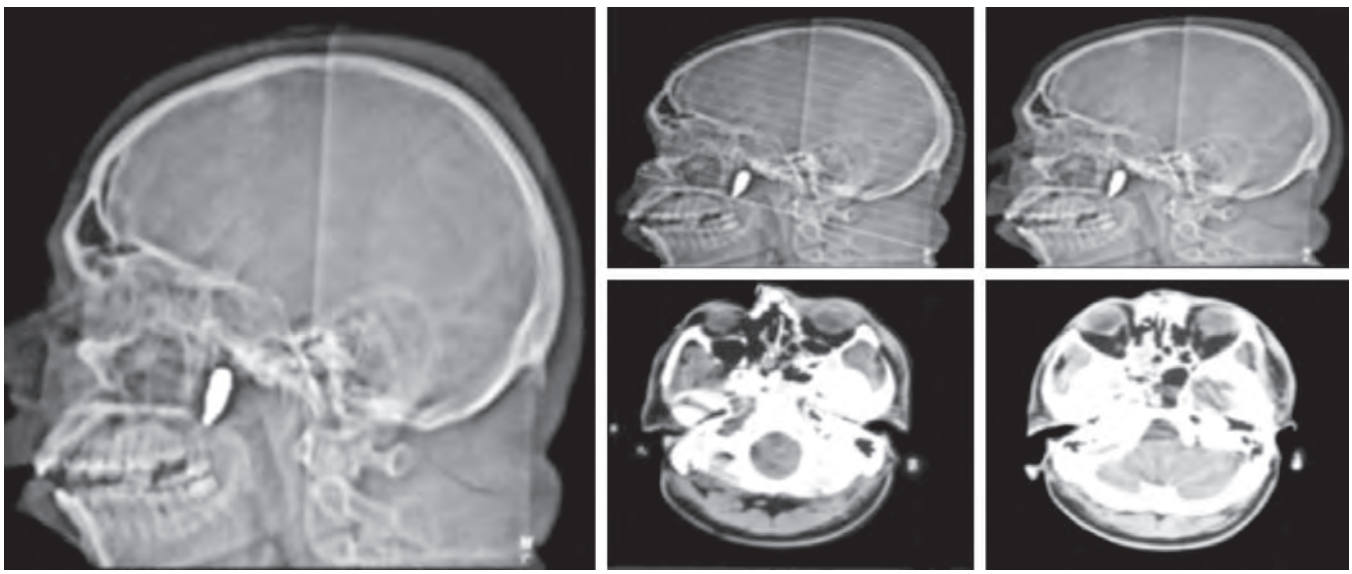


Fig. 4: CT scan of the head in a case of bullet injury in the right eye with optic nerve injury

et al. noted optic canal fracture in 8–10% of their cases in CT scan.[55–57,64] CT frequently shows a fracture in the anterior cranial fossa and opacity in the ethmoid and sphenoid sinuses. Rarely, CT scan may show optic sheath haematoma. Mahapatra et al. reported a single case of optic sheath haematoma among 100 patients.[56] MRI scans show nerve swelling and contusions very well.[56,64,70] Orbital ultrasound is also useful; it can show thickening of the nerve, orbital haematoma or a bony fragment.[15] Mahapatra et al.[56] carried out orbital ultrasound in 20 cases and noticed early optic nerve thickening in their series, which resolved in 3–4 weeks time (Table 5).

Role of Visual Evoked Potentials

Visual evoked potentials (VEPs) provide a good indication of the integrity of the visual pathway.[16,18,43] VEPs must be recorded in every case to assess the integrity of the anterior visual pathways. However, not much literature is available on the role of VEP in the management of optic nerve injury. Till the late 1980s, this test was not frequently used in optic nerve injury. Feinsod and Auerbach,[21] in 1973, and Shaked et al.[81] in 1982, looked at the role of VEP and electroretinography in their series. Nau et al.[74] in 1987, observed poor outcome in patients having no VEP tracings, however, they didn't comment on the value of normal VEP tracings in predicting good outcome. Mahapatra and Tandon showed that there was 85–90% visual improvement in patients who had repeated normal VEPs.[55–57] In their experience, none of the patients with repeatedly absent VEP had shown visual recovery. VEP also helps in diagnosis of visual loss in unconscious patients. Light emitting diodes (LEDs) are used for recording VEP in unconscious patients. In our department, VEPs are routinely performed by using the Nicolet 1170 model or Nicolet Compact four model. VEPs are recorded either by using the pattern reversal method or by LEDs. LED is used in unconscious or uncooperative patients and helps in establishing the diagnosis in those in whom visual loss is suspected. VEPs are routinely performed within 48 hours of initial evaluation and the test is repeated within 7–10 days to assess the electrophysiological improvement. VEPs are categorised as normal, abnormal or absent depending upon their wave formation and latencies. Latencies longer than 2 SD of the control value are considered as abnormal. In a series of 78 cases published by Mahapatra,[66] overall improvement occurred in 29 (56%) patients. All the 10 patients with normal VEP recovered. Among 29 patients with abnormal VEP, 26 (86.6%) showed visual improvement. Thus 36 out of 39 patients (92.2%) with a positive VEP wave had visual improvement ultimately. Among 39 patients with initial absent VEPs 31, who had repeated absent VEP waves, had no subsequent improvement. Mahapatra and Bhatia[55] in a recent study of 45 patients with optic nerve injury established the predictive value of VEPs in patients with traumatic unilateral blindness. They reported improvement in 90% of patients with positive P 100 waves. Mahapatra[39,59,66] in his study established the role of both positive and negative VEPs in the diagnosis and in predicting the outcome and also noted that in unconscious patients VEPs did help in establishing the diagnosis of optic nerve injury.

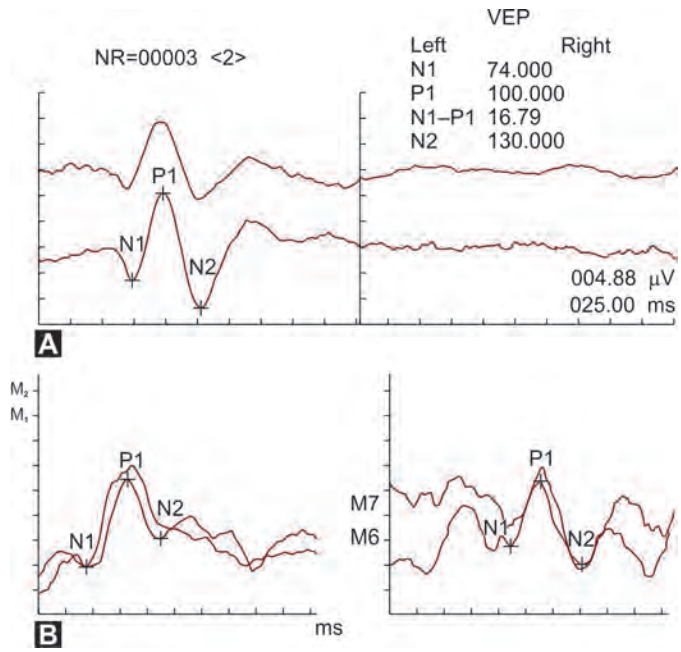
• Orbital ultrasound

Flash Visual Evoked Potential

Flash visual evoked potential [(FVEP) Figs 5A and B] recordings are routinely done as per the technical guidelines developed by the American Clinical Neurophysiology Society.[2,3,39] Visual flashes are delivered by means of light-emitting diode goggles placed over the eyes. These goggles are covered by a clear plastic bandage. Electrodes are placed in the following locations: midoccipital (MO, 5 cm above inion), left occipital (LO, 5 cm left of MO), right occipital (RO, 5 cm right of MO), Cz (midline vertex position, based on standard 10–20 EEG location[2] left or right earlobe (A1/2) and ground (any scalp location). Referential recordings are obtained with monocular stimulation; MO, LO, RO, and Cz are all



Figs 5A and B: (A) Visual evoked potential in a patient with right optic nerve injury showing normal VEP tracing on left side with no waveform seen on the right side. (B) Visual evoked potential in a patient with right optic nerve injury showing normal tracing in the left eye and delay in P1 latency on the right side

referred to A1/2. Filter settings include low frequency at 1 Hz, high frequency at 250 Hz and notch filter (60 Hz) on "off". Sensitivities range up to 100 μV. The protocol calls for 200 flashes for each eye, with stimulus duration of 250 ms and rate of 1.9 Hz. Grand averages are displayed for each of the four channels of each recording. If present, waves labelled I through VI are then identified in each channel within the first 250 ms after stimulation. Latencies and amplitudes of each wave are then calculated. FVEP waveforms are identified in the grand averages of MO-A1/2, RO-A1/2 or LO-A1/2 in the eye with TON and in the normal (control) eye. At approximately 100 ms after the stimulus, the greatest amplitude was exhibited in one of these three channels in the TON eye (corresponding to the "P100" in pattern-reversal VEPs studies). This is typically the second wave, with surface positive polarity, in the MO-A1/2 channel. The corresponding waveform in the same channel on the control side is then identified. The amplitudes of these waves are manually measured peak to peak, with the aid of electronic calipers. An amplitude ratio is then calculated by dividing the FVEP amplitude obtained in the TON eye by the FVEP amplitude obtained in the control eye.

The presence of FVEPs has been considered to reflect at least some functional integrity of visual pathways. However, the information that these studies convey has generally been perceived to be qualitative only, an "all or nothing" phenomenon that provides little if any information on the degree of damage to the optic nerve or visual radiations.[2,3] Until now, in the unconscious head-injured patient, one could only state whether or not optic nerve injury was present. Homes et al.[39] showed that careful assessment of the FVEP ratio in unilateral TON may allow one to grade the severity of optic nerve injury before the patient regains consciousness. This knowledge in turn may help direct therapy and counsel the family regarding prognosis. Whereas VEPs, including FVEPs, have been of value in predicting visual outcome after direct ocular injury, such studies are of more limited value in anticipating neurological outcome after head trauma.[32,37,38,45] However, applying FVEPs to evaluate visual outcome when the optic nerve has been damaged in the setting of head injury may prove to be highly useful.[74] Given that subject co-operation is often problematic in head-injured patients, FVEP is the most practical laboratory method to investigate the visual system in TON. When TON is unilateral, the unaffected eye may serve as the normal eye when FVEP amplitudes are measured (Fig. 6).

Patients with TON fall in two distinct groups: (1) those who eventually have good-to-excellent visual outcome and (2) those who have very poor to no visual recovery.[39] Ultimately, the determining factor for permanent visual loss must be the degree of damage to the optic nerve. The FVEP simply reflects whatever degree of optic nerve injury has taken place, and the FVEP ratio is a method to avoid systemic bias, such as drugs or level of consciousness. The amplitudes alone are not meaningful. When the FVEP ratio, a measure of relative optic nerve functional integrity, is at least 50%, a favourable visual outcome may be anticipated in unilateral TON (Fig. 7).[39]

TREATMENT OF OPTIC NERVE INJURY

Although traumatic optic neuropathy (TON) has been known for long, the best treatment methods remain controversial. No treatments, like megadose corticosteroids, surgical optic canal decompression or a combination, are the present management options. The main controversy,

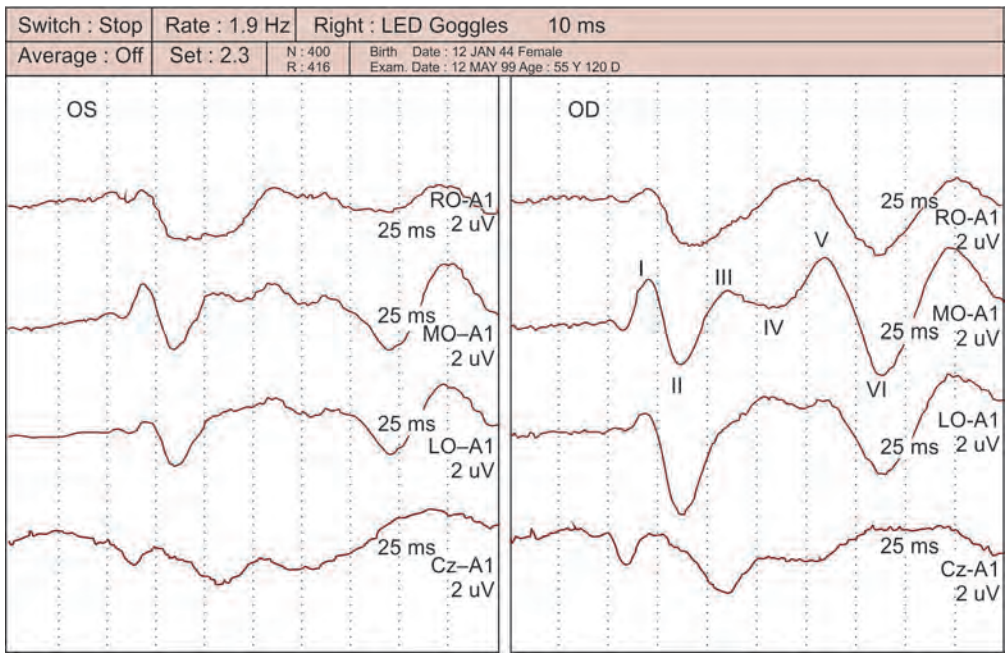


Fig. 6: Amplitude ratio of the eye with traumatic optic neuropathy, (OS)/normal (OD), was greater than 0.5 for this subject. Visual acuity OS was 20/25. Ratios were based on amplitudes of the second wave (wave II) in the mid-occipital–A1/2 channel on either side, occurring 100 ms after stimulation

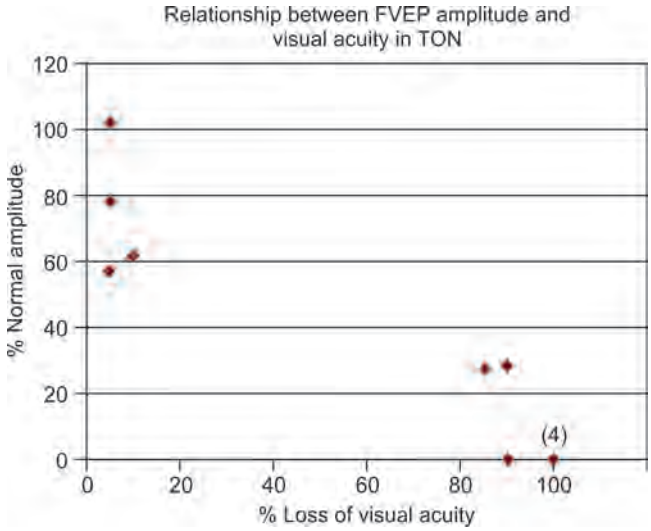

Fig. 7: Comparison of percentage of normal amplitude of flash visual evoked potentials response in traumatic optic neuropathy against percentage loss of visual acuity

however, centres on the indications for surgery. A large number of studies reported in the world literature show similar results in medically managed and surgically treated groups.[23,28,29,55,58,61,70,87,91,93] While many authors from different countries have favoured medical management; the Japanese authors have popularised and favoured surgical treatment[23,26,58,76] (Tables 6A and B).

Various prospective series on optic nerve injury management and evaluating the role of early surgery versus medical management have been published by Mahapatra et al.[57,63,64,67,88] Spontaneous visual improvement has been noted with a frequency of 20–38% in short reports or in small case series.[41,49,66,67,80,94] The treatment of TON with megadose corticosteroids evolved since it was first proposed in 1982, based on the salutary effects of corticosteroids in treating experimental central nervous system injury.[6,80] No effective surgical approaches for decompressing the optic nerve were identified until 1961, when Niho et al. developed a technique based on an extracranial transethmoidal approach.[75,76] Subsequently, other authors published their own surgical techniques and results.[27,44,70,76] However, these subsequent works reported the results of combined medical and surgical treatment, making it difficult to ascertain the therapeutic value of individual treatments. Therefore, the indications for surgical OND alone remain uncertain. Possible prognostic factors include not only the therapeutic intervention implemented but also the patient's age, initial visual acuity (IVA), the presence of optic canal fracture and the timing of treatment.

Medical Management

There is scanty literature on the medical treatment of optic nerve injury.[40,65,67,70] The use of megadose intravenous corticosteroids is based on laboratory studies demonstrating that timely use of corticosteroids can reduce the oedema and tissue damage resulting from ischaemic and traumatic injuries.[34] Notably, the National Acute Spinal Cord Injury Study on the use of megadose methylprednisolone appeared to confirm clinically the laboratory results.[4,10] Moreover, Seiff[80] reported the results of a non-consecutive and non-randomised retrospective series of 36 patients with TON who were either not treated (15 patients) or treated with dexamethasone (21 patients). Seiff found that visual improvement occurred in 62% of treated patients and in 33% of untreated patients, although the difference was not significant. Spoor et al.[84] reported the results of an uncontrolled, non-consecutive, retrospective investigation of 21 patients (22 eyes) with TON studied at two centres. Eight patients at one centre received dexamethasone, whereas 13 patients at the second centre received methylprednisolone. Vision improved in 7 of 9 patients in the dexamethasone group and in 12 of 13 patients in the methylprednisolone group. Although Spoor's study[84] is too small to draw any meaningful conclusions about the efficacy of corticosteroid treatment, it is interesting that patients treated with dexamethasone appeared to do as well as patients treated with methylprednisolone. Methylprednisolone was used in this study, and 44.4% (8/18) of patients treated with it alone gained visual improvement (Table 7).

Many authors, who did not believe in surgical management, offered no treatment. Walsh stated that "cortisone and mannitol may be helpful in patients in whom optic nerve swelling is a feature". However, establishing swelling of the optic nerve is difficult. With the advent of ultrasound and MRI scan optic nerve swelling can be diagnosed. Delayed onset of visual deterioration also suggests swelling or oedema of the optic nerve. Matsuzaki et al.[93] treated 22 patients with a combination of prednisolone, 20% mannitol, urokinase and Vit B_{12} and reported 58.5% recovery in this group. Anderson et al.[19] used high dose steroid in 6 patients and 3 patients showed good recovery. Mahapatra et al.[55–57,61,74,87] observed overall improvements in 53–58% patients and recommended steroid treatment (dexamethasone or methylprednisolone) for 3–4 weeks duration.

Indications for Surgery

Earlier, conservative management was the treatment option followed in the majority with surgery being indicated in only a few subsets of patients. Mahapatra laid down criteria for surgery in optic nerve injuries. Every patient is offered 3 weeks corticosteroid treatment initially. VEPs are monitored and patients are closely followed. Patients progressively improving or not showing any improvement are not subjected to surgery. A group of patients who show minimal improvement and then remain static are subjected to surgery. This situation only suggests that the optic nerve is not completely damaged and given a chance, further improvement may occur. Following this criterion patients are operated. As the group subjected to surgery is highly selective, chances of improvement are also high.[87] Thus, the role of surgery in optic nerve injury is limited.

Optic Nerve Decompression

Although surgical optic nerve decompression (OND) made its debut early in the 1900s, little research was done in this area until Niho et al.[76] developed the extracranial transethmoidal approach. Surgical intervention for TON is empirical due to the lack of a large body of evidence supporting its effectiveness, as well as outlining the potential risks associated with the procedure. Notably, the potential risks associated with surgical OND include further vision loss, cerebrospinal fluid leakage, ascending meningitis and injury to the internal carotid artery.[44] The rationale for OND is that it will reduce bone fragments impinging on the optic nerve and open the canal to reduce compression of a swollen optic nerve and its vascular supply within the optic canal. About 30 series of OND have been published, but they are difficult to compare because they each use different techniques, selection criteria and definition of improvement. The frequency of visual improvement after treatment in these series ranges from 12 to 79%.[44,50,77] Besides treatment modalities, some clinical factors also influence the prognosis of TON, including IVA, optic canal fracture, age and time from injury to treatment. In the literature, the treatment of those patients who have immediate vision loss is especially controversial. Matsuzaki et al. echoing Walsh,[70,90] said that recovery was exceptional in such patients. However, visual improvement was reported in these patients treated with steroid alone, with an improvement rate ranging from 12.5 to 62.5%.[72,80,84] Some authors found improvement with steroids and surgical intervention, with a rate of 16.7–57.1%.[27,72] To compare and identify which is superior to other treatment modalities in these retrospective reports is difficult because of selection bias and small patient numbers. In some large series, the incidence of optic canal fracture in TON varied from 21 to 55%.[27,49,70,72] The finding of optic canal fractures has been considered to be an indication for surgical decompression, which is often the source of selection bias. The effect of optic canal fracture on visual improvement is controversial.[27,34,76] Seiff[80] reported that 63% of patients with canal fractures initially had no light perception (NLP) vision, compared with only 40% of those with no fractures or fractures of other orbital bones. Sometimes, optic canal fractures radiologically not detectable are discovered during surgery. In fact, radiologically diagnosed optic canal fracture is not a dependable indicator of OND.[27,63]

Patients with TON are mostly in the 20–40 years age group and represent the major trauma population. Levin et al. reported the relationship between age and the outcome of TON after surgical decompression and drew the conclusion that younger patients (< 40 years) had a better visual outcome from undergoing surgical decompression than did older ones (≥ 40 years).[50] Although it is reasonable to hypothesise that the younger have more potential for recovery, and there is insufficient data in this study to confirm it. Motor vehicle accidents were the most frequent mechanism of injury in this study. Associated head injury and multiple traumas existed in such patients, precluding precise visual examination and often delaying treatment. Joseph et al. described a series of 14 patients with TON operated by transethmoidal/trans-sphenoidal optic canal decompression.[44] They do not recommend surgery if more than 7 days have elapsed since the injury.[44] Analysis of results of this study demonstrated that regardless of the therapeutic intervention employed, patients receiving treatment within 7 days improved more than those treated more than 7 days later. Although the appropriate treatment of patients with TON remains controversial, the benefits of early detection and treatment are universally recognised, making early detection and treatment mandatory.

Decompression of the optic nerve following injury has been tried for many years[23,28,41,46,49,58,73,75,77,83,87,91] (Table 8). Prior to the introduction of transethmoidal surgery by Niho et al.[76] the transcranial route was used for decompression. There is a great deal of controversy regarding the need for surgery and timing of OND. Gjerris,[28] in 1976, stated "Comparison between two groups of patients treated with and without operation reveals that the prognosis is the same in both groups, that there is no clear cut guidelines for one or the other". Walsh and Hoyt[91] considered immediate visual loss at the time of impact as a contraindication for surgery, as visual recovery is unlikely. Other authors have considered optic canal fracture as one of the indications for surgery.[58,75] Gjerris[28] was against surgery in patients with immediate visual loss and showing no signs of visual recovery in the next few days. He also suggested conservative management when optic nerve injury is diagnosed in unconscious patients. Fuzitani et al.[26] suggested a trial of steroid therapy for 3 weeks; patients not improving on steroid were unlikely to benefit from surgery either. Lessell,[49] in 1989, observed that the eyes with total loss of vision at the end of 3 weeks on steroid are unlikely to respond. However, Mahapatra,[62] in 1992, reported delayed

recovery from optic nerve injury. Thakar et al.[88] in 2003, reported the results of delayed OND for optic nerve injury. Determination of potential benefit from OND depends on the cause of injury. Cases with complete disruption of the optic nerve will not recover regardless of whether OND is performed, because the optic nerve is a direct continuation of the brain (fasciculus opticus). In contrast, insults from oedema, haematoma or moderate bony compression may respond favourably to OND. Traumatic injuries of the optic nerve are not the only indications for OND.

Endoscopic Optic Nerve Decompression

Traditional surgical approaches to OND are a neurosurgical or craniotomy approach, extranasal transethmoidal approach, transorbital approach, transantral approach and intranasal microscopic approach. Recent advances in instrumentation and surgical techniques have made an endoscopic approach to OND possible. The endoscopic method offers many advantages over the traditional approaches. Decreased morbidity, preservation of olfaction, rapid recovery time, more acceptable cosmetic results with no external scars, no risk of injury to developing teeth in children and less operative stress in a patient who may have multi-system trauma are some of the benefits associated with endoscopic OND.

In the endoscopic technique of OND, the optic nerve is approached from its medial aspect and several anatomical features should be considered.[77] One typically expects to encounter the optic nerve just superior to where the internal carotid artery creates a bulge in the lateral wall of the sphenoid sinus. In 12% or more of cases the optic nerve will be travelling through a posterior ethmoid cell (Onodi cell).[47] Posterior ethmoid cells are called Onodi cells (or sphenoethmoidal cells) when they have pneumatised considerably laterally to and/or superiorly to the sphenoid sinus and the optic nerve tubercle or even the canal itself is prominent in its lateral wall (Fig. 1C), thus leaving the nerve vulnerable to injury or possible transection if appropriate attention is not given to identify the nerve before entering the sphenoid sinus. Another potential problem with catastrophic results could be surgical transection of the ophthalmic artery. Either way, packing or coagulation would result in a counterproductive effect regarding optic nerve function in such a case. The ophthalmic artery typically enters the nerve sheath from an inferolateral direction and thus is not in the surgical field of an endoscopic endonasal approach. However, 15.5% of patients may have the ophthalmic artery entering on the medial side of the orbital aperture of the optic canal and be susceptible to injury by the medial approach[47,82] (Figs 1D1 and D2).

The orbital apex is the fibrous annulus of Zinn. This is the area where the pia and arachnoid fuse and is a very likely site for compression of the optic nerve, as it is usually located at the entrance to the most narrow portion of the optic canal. It may be identified as a thickened area of fibrous tissue in the region of the orbital apex.[47] Care must be taken to be certain this annulus is incised during slitting of the optic nerve sheath in order to achieve adequate decompression, as this is the least expandable portion of fibrous tissue around the optic nerve.

Surgical Technique for Optic Nerve Decompression

An endoscopic sphenoethmoidectomy is performed using the Messerklinger and Stammberger technique with preservation of the middle turbinate. Care is taken not to violate the lamina papyracea or periorbita at this point. The sphenoid sinus is entered and a circular cutting sphenoid punch is used to enlarge the opening into the sphenoid sinus (Fig. 1Ea). The bulge of the internal carotid artery and optic nerve is identified as they course through the lateral wall and/or roof of the sphenoid sinus (Fig. 1Eb). As mentioned before, it is possible to encounter the optic nerve in an Onodi cell, so care must be taken to avoid an iatrogenic injury to the optic nerve. At a distance of 7–10 mm anterior to the optic tubercle, the lamina papyracea is then removed with extreme care to avoid injury to the periorbita (Figs 1Fa to Fd). Violating the periorbita at this time could result in herniation of the orbital fat into the operative field, obstructing the surgeon's vision. A specially modified diamond drill ideal for endoscopic usage has been developed for thinning out the bony optic canal. This drill is designed so that the rotating burr can be retracted into a protective sheath until it is in the right position for drilling, thus preventing entanglement of the soft tissues in the drill bit. An irrigation system is built into the drill. The drill is now used to thin the bony covering of the optic canal from the orbital apex proceeding posteriorly as it courses towards the optic chiasm. A dissector/elevator modified from the Fisch ear instruments is used to elevate the thinned bony canal from over the optic nerve. Extreme care must be taken not to exert pressure on the optic nerve with the elevators. This completes the bony decompression, resulting in a 180° liberation of the optic nerve on its medial and inferior aspects.

In addition to the bony optic canal, the optic nerve sheath and the annulus of Zinn potentially contribute to pressure on the optic nerve. The opening of the optic nerve sheath and the annulus of Zinn is accomplished with a sickle knife (Figs 1G and H). However, slitting the optic nerve sheath is a controversial procedure for which there are no studies to indicate proper patient selection. In certain cases we routinely open the nerve sheath: these cases include patients with an intrasheath haematoma, fracture of the intracanalicular portion of the optic nerve canal or lateral displacement of the bony optic canal with impingement on the optic nerve as well as cases with papillary oedema and/or bleeding. Also in cases where, upon removal of the bony optic canal, the impression of a bulging optic nerve is obtained, the sheath is decompressed. Avoidance of a potential cerebrospinal fluid fistula with opening of the optic nerve sheath is obtained by placing fibrin glue over the incision site.[85] OND can easily be combined with an orbital decompression at the same sitting if indicated.

As with any surgical procedure, this technique has potential disadvantages and limitations. The lateral and superior aspect of the optic canal cannot be reached by this approach, so decompression is limited to the medial and inferior portions of the bony optic canal. With the opening of the optic nerve sheath, the subarachnoidal space is opened and a cerebrospinal fluid fistula could possibly be created, although clinical experience has not shown this to be a significant problem. Fibrin glue is routinely applied to the region of the optic nerve if the optic nerve sheath is opened to avoid a cerebrospinal fluid fistula.

An iatrogenic injury to the nerve fascicle itself or the ophthalmic artery could occur, resulting in additional damage. Thus, this procedure should only be undertaken by experienced endoscopists. The surgeon must utilise extreme care when incising the optic nerve sheath to be certain that no medially arising ophthalmic artery prevails. A risk of infection, transmitted from the contaminated nasal cavity and paranasal sinus system exists, although we have not encountered any in our cases.[57,64,87,88]

Contraindications to OND exist and these apply not only to the endoscopic approach but to the other surgical approaches as well. Contraindications include complete disruption of the optic nerve or optic chiasm, complete atrophy of the optic nerve, carotid cavernous sinus fistulae and other life-threatening problems making any surgical procedure hazardous.

One should not completely rule out approaches other than the endoscopic approach to OND and each case should individually be evaluated. In patients with large lacerations of the scalp, a transfrontal approach may be the best. If the patient is to undergo a craniotomy for other indications, then the OND should be performed through the craniotomy at the same sitting. An inexperienced endoscopist or a surgeon who has more experience with an external ethmoidectomy approach to OND should proceed with the technique most familiar to him or her.

In the technique described by Yang[95] for endoscopic assisted transorbital decompression, a 0°, 2.7 mm endoscope is placed through a 1 cm medial transconjunctival incision. The subperiosteal dissection is continued posteriorly (Fig. 8A). The anterior and posterior ethmoidal vessels are coagulated to reduce intra-operative blood loss. The bony defect is created in the posterior one half of the orbital medial wall just anterior to the annulus of Zinn to gain access to the medial optic canal ring (Fig. 8B). As the orbital contents are retracted laterally, the thick optic canal ring is thinned by a 3 mm diamond burr and removed with the endoscopic punch forceps gradually (Fig. 8C). After this, decompression of the medial wall and partial roof of the entire optic canal is achieved with a microcurette alone or combined with a small diamond burr in the posterior and superior direction (Fig. 8D). By this technique, the optic canal can be decompressed up to at least 180° medially.

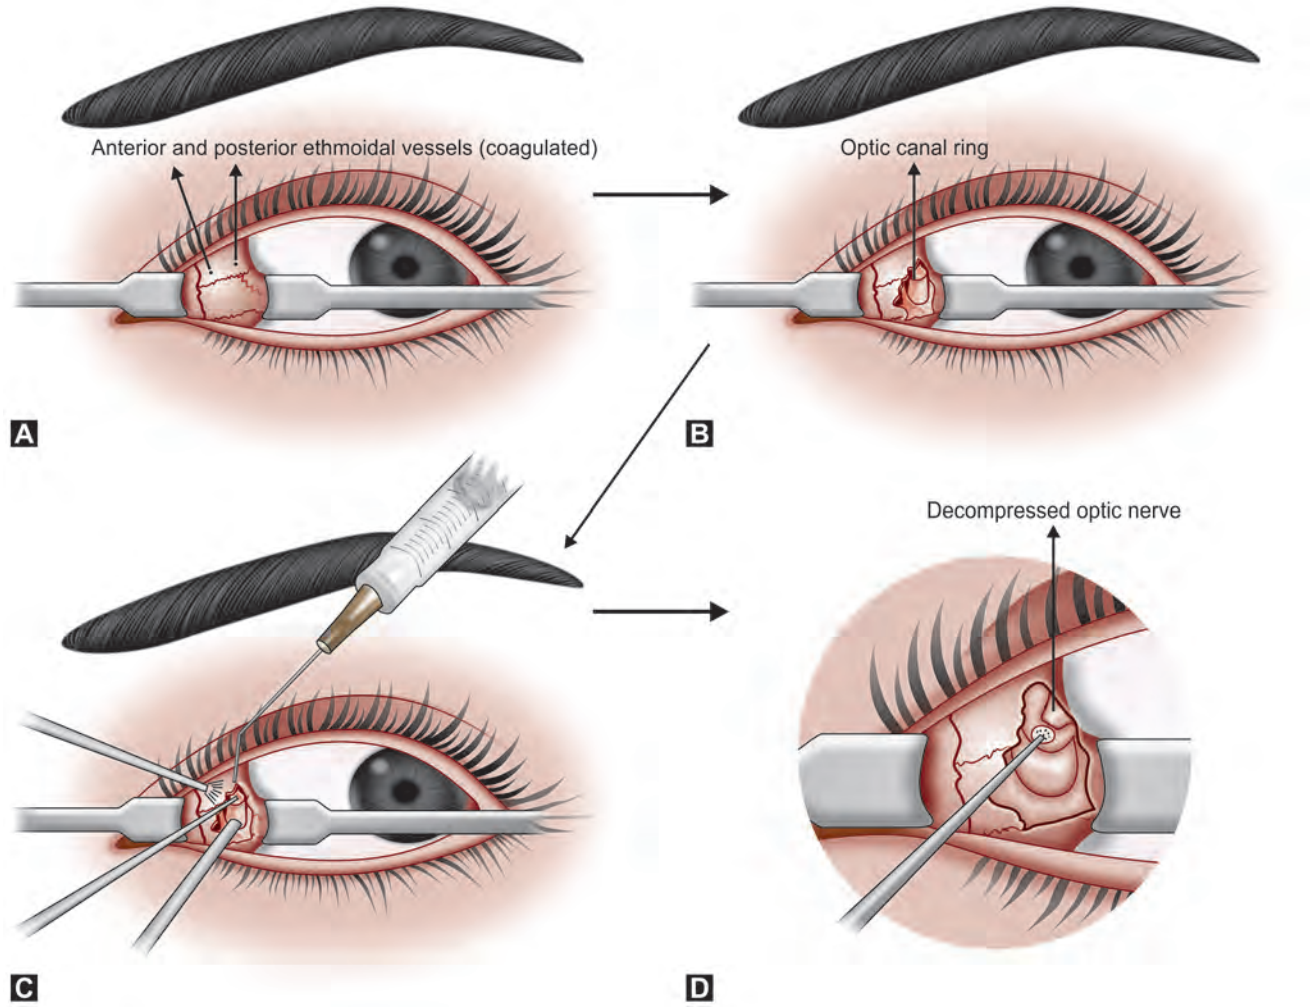
INTERNATIONAL OPTIC NERVE TRAUMA STUDY

The study of International Optic Nerve Trauma Study (IONTS)[9,33] was organised to investigate the optimal treatment of indirect TON (Table 9). It was initially conducted as a randomised controlled pilot study to assess feasibility, one arm being extracranial optic canal decompression combined with very high-dose ("megadose") corticosteroids and the other arm being corticosteroids alone. However, after 2 years of patient recruitment, it became clear that the enrolment of eligible patients would be insufficient to provide statistical validity, even if the study were to continue for several more years. Therefore, the IONTS was transformed into an observational study, with the goal of evaluating which of several treatment paradigms best improved the visual function of patients with indirect TON. Mahapatra contributed the largest number of cases to the IONTS.[67]

A total of 133 patients with TON (127 unilateral and 6 bilateral) who had an initial visual assessment within 3 days of injury were studied. At least 1 month of follow-up was required for inclusion in the primary analysis. On the basis of treatment received within 7 days of injury, patients with unilateral injuries were categorised as being in one of three treatment groups: (1) untreated (n = 9); (2) corticosteroid (n = 85) or (3) optic canal decompression surgery (n = 33). Visual acuity increased by ≥ 3 lines in 32% of the surgery group, 57% of the untreated group and 52% of the steroid group (P = 0.22). The surgery group had more patients whose initial vision was NLP. After adjustment for the baseline visual acuity, there were no significant differences between any of the treatment groups. There was no indication that the dosage or timing of corticosteroid treatment or the timing of surgery was associated with an increased probability of visual improvement. No clear benefit was found for either corticosteroid therapy or optic canal decompression surgery. The number of patients studied was sufficient to rule out major effects in the treatment groups, although clinically relevant effects in specific subgroups could have been missed. These results and the existing literature provided sufficient evidence to conclude that neither corticosteroids nor optic canal surgery should be considered the standard of care for patients with TON. The authors concluded therefore, clinically, it is reasonable to decide to treat or not to treat on an individual patient basis as described in Table 10.[51,72]

OUTCOME AND FACTORS INFLUENCING OUTCOME

Visual outcome in patients with optic nerve injury depends on several factors. In visual recovery, age, mode of injury, unilateral or bilateral involvement, presence or absence of VEP and presence or absence of vision play an important role (Table 11).[28,39,50,55,56,64,70,87,91] In two of our studies in the paediatric age group we reported a recovery which was worse than in the adult. Similarly,



Figs 8A to D: Figure showing steps of endoscopic optic nerve decompression: (A) The medial orbital wall. The anterior and posterior ethmoidal vessels were coagulated. The lamina papyracea will be removed to expose ethmoid sinuses. (B) The lamina papyracea overlying the posterior ethmoid air cells was removed to gain access to the sphenoid sinuses and expose the optic canal ring. (C) A 3-mm diamond burr was used to thin the thick optic canal ring. A straight suction was placed intranasally into the sphenoid sinuses. (D) The decompressed optic nerve. The optic canal ring, medial wall and roof were removed with a microcurette alone or combined with a small diamond burr. The optic canal could be decompressed at least 180° medially

the presence or absence of VEP wave is of great importance.[55,64,70,81,94] Normal VEP indicates a good chance of recovery in all the patients. We find the time interval between injury and surgery and the presence or absence of optic canal fracture is of very little significance. Mahapatra also observed better outcome in patients with bilateral optic nerve injury[17,64] and they also noted only 10% of patients had normal visual recovery and 40–50% had partial visual recovery after optic nerve injury.[56,64,70] Rarely, visual recovery may start 8–12 weeks after injury. Agarwal and Mahapatra reported 23% recovery rate in 100 patients with PL negative vision following optic nerve injury.

Although the degree of visual loss after indirect TON may be quite variable, approximately 50% of patients are left with "light perception" or "no light perception" vision, making TON a significant cause of permanent visual loss.[13,49,86] At present, there is no proven form of treatment for this condition and there is controversy over its optimal management. Cook et al. in a meta-analysis,[14] reported that recovery of vision in patients treated with megadosage steroids or surgical decompression of the optic canal was significantly better than recovery in patients receiving no treatment. As there are no controlled guidelines for correct management, patients affected by TON remain a clinical dilemma. A recent uncontrolled case series reported that visual recovery occurring shortly after trauma may not be permanent at long-term follow-up, with progressive deterioration of visual function.[24,69]

The identification of prognostic signs during the hospital admission of such patients has important implications, as such signs may be used to justify medical or surgical treatment depending on the expected outcome.[14,73] Furthermore, the IONTS group has found that selected cases with initially negative prognostic signs may show clear benefit from treatment versus observation alone. Carta et al.[12] investigated, in their series of 35 cases of TON, for a possible correlation between final

Table 10: Author's criterion for optic nerve injury management[67]

1. All the patients are put on corticosteroids
2. VEP and clinical examination repeated every 2-3 days for the first 3 weeks
3. Patients showing good visual recovery do not need surgery
4. Patients in whom visual acuity remains PL negative in spite of corticosteroid at the end of 3 weeks do not need surgery
5. Surgery is beneficial in those patients in whom visual improvement is marginal and then remains static
6. One emergency indication for surgery is delayed onset optic nerve injury, when vision rapidly deteriorates in spite of corticosteroids

Positive or negative VEP	VEP +ve	VEP –ve
Vision	PL +ve	PL –ve

visual acuity and the presence at baseline of various systemic and local (orbital/ocular) signs. The authors noted that four variables showed a significantly increased risk for no recovery of visual acuity: (1) presence of blood within the posterior ethmoidal cells (RR = 2.25, 95% CI 1.25– 4.04); (2) age over 40 years (RR = 1.79, 1.07–2.99); (3) loss of consciousness associated with TON (RR = 2.21, 1.17–4.16) and (4) absence of recovery after 48 hours of steroid treatment ($p < 0.01$, Fisher's exact test). Recovery documented at the first follow-up visit after treatment was significantly associated with recovery at the last follow-up visit ($p < 0.01$, Fisher's exact test). Carta[12] concluded that the above four prognostic signs in patients affected by TON may be useful in predicting the visual outcome in patients developing visual loss after head trauma and in deciding on the need for surgical treatment.

Previous laser interferometer studies have shown that forces applied to the frontal bone are transferred and concentrated in the optic canal region.[30] Histopathological studies of patients with indirect injury to the optic nerve have been consistent with localisation of the lesion to this area.[17] Bleeding within the posterior ethmoidal cells presumably reflects a greater amount of energy applied to this region and it should therefore make sense that this sign is associated with a worse visual prognosis. Similarly, as ethmoidal bleeding reflects the local severity of trauma, it could also account for the fact that loss of consciousness is associated with a reduced likelihood of visual recovery. Zapala[97] in their study of 100 patients with unilateral post-traumatic optic nerve neuropathy tried to establish new clinical guidelines for patients suffering from post-traumatic optic nerve neuropathy; 76 were blind and 24 with progressive weakening of visual acuity from the time of injury. 56 patients received conservative treatment only, among them 48 underwent steroid therapy. In 23 patients a decompression of the optic nerve in its canal and in 21 in the intraorbital section was performed. Improvement in vision was obtained in 44 patients, 52 did not improve

and in 4 cases their vision deteriorated.[97] Zapala[97] concluded that post-traumatic optic nerve neuropathy is an indication for immediate steroid therapy and progressive visual loss in an optic nerve canal fracture is an indication for its decompression. Cochrane data base review in 2005 was carried out with the aim to examine the effects and safety of surgical interventions in the management of TON analysing only randomised controlled trials of TON in which any form of surgical intervention either on its own or in combination with steroids was compared to steroids alone or no treatment. The conclusions derived were that the current body of evidence consists mostly of small, retrospective case series. Given the wide range of surgical interventions used in TON, it is very difficult to compare these studies, even qualitatively. However, there is a relatively high rate of spontaneous visual recovery and no evidence that surgical decompression of the optic nerve provides any additional benefit. On the other hand surgery carries a definite risk of complications such as post-operative cerebrospinal fluid leak and meningitis. The decision to proceed with surgery in TON therefore remains controversial and each case needs to be assessed on its own merits. Although there is an urgent need for an adequately powered, randomised controlled trial of surgical intervention in TON, this will prove a difficult endeavour.[96]

Yang et al.[95] retrospectively analysed 42 cases of TON to identify factors that can affect the final outcome and to recognise the proper management for patients with TON after maxillofacial trauma (Megadose methylprednisolone was administered to all patients during the first 3 days after diagnosis. Twenty-four patients received treatment with megadose steroids combined with OND and the remaining 18 with megadose methylprednisolone alone). IVA was the statistically significant factor affecting the outcome of TON (P = 0.006 for improvement rate). Patients treated within 7 days after injury had a better improvement degree, P = 0.056. Patients in a surgical group with an IVA of NLP had a better improvement rate and degree (31.3%; 59.34% ± 22.18%) than those in non-surgical group (0%, 0%; P = 0.272). Yang et al.[95] concluded that IVA is the critical factor that affects the outcome of TON and surgical OND is considerable in maxillofacial trauma patients with an IVA of NLP.

CHIASMAL INJURY

Chiasmal injury is a rare condition. Hughes,[41] in 1962, noted 4.4% chiasmal injury and 7.8% opticochiasmal injury in their series. Only over 100 cases have been reported in the literature so far with the largest series being reported by Mahapatra et al.[48]

Pathological Types of Chiasmal Injuries

Primary:
- Sagittal split or tear
- Transverse split
- Contusion
- Laceration.

Secondary:
- Oedema
- Ischaemia
- Necrosis (infarction).

Pathogenesis

The pathogenesis of chiasmal injury is not clear. However, chiasmal injury can be primary or secondary as observed at operation or at autopsy. Primary involvement could be in form of a tear, laceration or contusion.[1,17,28,40,91] In most of these patients, there is evidence of fracture in the anterior cranial fossa. In closed head injury, due to forehead impact, there is anterior-posterior distortion of the skull, which leads to midline chiasmal tear.[40,78] The usual site of the chiasmal necrosis is at the site of decussation. Contusion and chiasmal necrosis of the central part is seen most commonly in primary chiasmal injuries. The chiasm can also get involved secondary to oedema and ischaemia leading to infarction.

Clinical Findings

Patients are usually adult vehicular accident victims.[48] History of unconsciousness is available in over 90% of cases and the head injury is usually severe in such cases.[22,28,40,41] Chiasmal injury is also described as traumatic bitemporal hemianopia, indirect chiasmal injury or post-traumatic chiasmal syndrome. Bleeding from the nose and CSF rhinorrhoea are commonly seen in these patients.[22,41,48]

Bitemporal hemianopia is the most common field defect seen.[48] Temporal field cut in one eye and no PL in the other eye suggest optochiasmal injury. Rarely, patients may present with visual deterioration due to basal meningitis and arachnoiditis. Other unusual symptoms associated with chiasmal injury are anosmia, pituitary insufficiency and diabetes insipidus.[28,41,91] Rarely, there may be cranial nerve deficit, traumatic aneurysm of ICA and carotid-cavernous fistula (CCF).

Diagnosis

Clinical diagnosis is difficult in unconscious patients. However, when a patient is conscious, diagnosis is made by the history of bilateral temporal defect, confirmed by field charting. CT and MRI have made the diagnosis easy.

Treatment

There is no specific treatment for chiasmal injury. As secondary involvement of the chiasma can occur due to oedema, it is probably rational to prescribe corticosteroids.[35] The role of surgery in chiasmal injury remains unproven.[40,41,52]

Visual Outcome in Chiasmal Injury

Almost all patients develop varying grades of optic atrophy over a period of time. As the central field is retained, daily activities of the patient are mostly unaffected. Recovery occurs over several weeks and depth perception is regained.[69]

Injury to Posterior Visual Pathway

Posterior visual pathway is the portion distal to the optic chiasma. Direct injury to these structures could result due to penetrating injury, either due to bullet or by splinters. However, rarely these structures can get involved in closed injury. Injury to the posterior visual pathway occurs in patients with severe head injury.[22,28,91] Injury to the optic tract, optic radiation and calcarine area has been studied well in war injured patients. In closed head injury the optic tract and optic radiation can get involved in contusion or intracerebral haematoma involving the temporal or parietal lobes. Patients with compression of the posterior cerebral artery due transtentorial herniation may not survive.

Damage to the optic tract, optic radiation or geniculate body is difficult to diagnose in unconscious patients. Cortical blindness does occur with head injury and the outcome is unpredictable.

CONCLUSION

The issue of medical, surgical, combination therapy or expectant management for traumatic injuries of the optic nerve remains unresolved. OND has been reported to have a favourable outcome by many surgeons. Various approaches for OND have been advocated, each with its own advantages and disadvantages. The endoscopic approach to OND, owing to its low morbidity and rapid post-operative recovery merits consideration by the surgeon. Endoscopic OND may allow operative intervention and return of visual function in patients whose medical condition would otherwise contraindicate surgical intervention.

Spinal Injuries

Ravi Ramamurthi

47 Assessment and Emergency Management of Acute Spinal Injuries

Anil Pande, Pradeep Kumar Jain N

INTRODUCTION

Spinal injuries are common and their economic and social implications are a problem of great magnitude.[135] The patient is often the only earning member of the family and the consequences of these injuries can be devastating. The annual incidence of spinal cord injuries (SCI) in developed countries varies from 11.5–53.4 per million and the incidence has two peaks, one in the second and third decades of the male population and another in the elderly.[149] Most of the Western studies have shown road traffic accidents as the leading cause of spinal trauma followed by falls, diving into shallow water and sports injuries. Males are more prone to spinal cord injury. Indian epidemiological studies in the rural regions also have shown a high preponderance of spinal trauma involving males, with the ratio of male to female ranging from 9:1–13.5:1.[2,3,9,42,125] In an agricultural country like India, injuries due to fall from trees, unprotected terraces and fall into uncovered wells and specific injuries caused by fall of a coconut on the head are common.

Chacko et al.,[32] Shanmugasundaram[137,138] and Roop Singh et al.[125] found the most common cause for spinal injuries was fall from a height followed by road traffic accidents compared to the West. Gunshot wounds to the spine are comparatively rare in India.[14] About 60% of spinal injuries involve the cervical spine with the maximal incidence at C5-6 level. Bhatoe and Singh reported 22 cases with missile injuries of the spine and the authors emphasised that these can be associated with injuries to other organs. The initial management of these injuries is similar to injuries sustained by other mechanisms. Incomplete injuries and injuries to the cauda equina are definite indications for surgery. Retained fragments rarely lead to infection or delayed neurological deficits and prophylactic removal is not warranted except in cauda equina injury.[16]

In the elderly, the incidence of fractures of C1 and C2 is more frequent due to the relatively high occurrence of odontoid fractures,[94] whereas the incidence of injuries to the subaxial spine is less. The incidence of spinal injuries increased from 1 in 300 to 1 in 14 when seat belts are not used. The use of helmets has not been associated with an increase of spine injuries as was once thought. The absence of national level programmes to educate the public on trauma like "THINK FIRST" is one of the reasons why the actual burden and the large economic cost of spinal injuries continue to escalate in India. The absence of city and town planning leads to a very high incidence of these injuries.

Neurosurgeons must educate the public and policy makers and push for reforms in transportation and civic infrastructure to reduce the incidence of this devastating condition. The setting up of spinal injuries centres in all regions of the country is a priority that has to be met on an emergency basis.

INITIAL TRAUMA EVALUATION

Suspicion of Injury to the Spine

It is mandatory to assume spinal injury in all patients who have significant trauma, with loss of consciousness, altered mental status, evidence of intoxication, spine pain, tenderness or deformity, neurological signs and symptoms of radiculopathy/myelopathy or instability and suspected extremity fractures. Spinal cord injury occurs due to primary and secondary events and surprisingly 3–25% of spinal cord damage occurs after the initial trauma, due to faulty and delayed transportation and inadequate initial management (the golden hour). In addition the primary injury sets off a cascade of cellular molecular events that cause further cell injury and death. Secondary spinal cord injury can also occur due to factors like hypoxia, hypothermia, hyperthermia, hypotension and cardiovascular and respiratory instability.[72,74,78,89] About 20% of spinal injuries involve multiple, non-contiguous vertebral levels and therefore the whole spine must be assessed completely in all such patients.

Clearing the spine[3] is a very important neurosurgical responsibility and must follow stringent criteria. Patients with spinal injuries usually die due to shock and aspiration. The advanced trauma life support (ATLS) protocol specifies; first take care of the airway, followed by assessment of breathing effort, followed by circulation and haemorrhage control ("ABC"s) and thereafter an urgent transfer to a regional spine injury centre.

The patients are seen and evaluated as they are found (as they lie) and the mechanism of injury can be understood from a well taken history and studying the scene of trauma.

PREADMISSION SPINE IMMOBILISATION

All patients suspected to have spinal injury should be managed with spinal column immobilisation till an injury has been definitely ruled out and appropriate treatment has been initiated. Spine immobilisation can reduce the possibility of secondary neurological injury and pain in patients with an unstable spine.[154]

Spine immobilisation consists of a cervical collar, supports on both sides of the head and long and short backboards with associated straps to attach and immobilise the body (Fig. 1). The earlier practice of spine immobilisation using sandbags and tape alone is insufficient. A vacuum splint device, particularly when used with a cervical collar is an effective and comfortable alternative to a rigid board.[31] Kendrick extrication device, extrication plus-one device and Russel extrication device have also been used.[58]

Any limb fracture is also strapped and immobilised. Thoracic elevation or an occipital recess to prevent flexion of the head and neck when restrained supine on an otherwise flat backboard may allow for better neutral alignment and immobilisation of the cervical spine in children younger than 8 years due to the relatively large head in these younger children, and is recommended.[31,61,107]

TRANSPORT OF SPINAL INJURED PATIENT

Definitive assessment, resuscitation and care of patients with an acute spine injury cannot be given at the site of injury and optimal care includes initial resuscitation, immobilisation and early and proper transport to a spinal injuries centre. The transport vehicle should be equipped with respiratory and vascular support measures and the most rapid mode of transport is chosen.[150] Rural areas account for 70% of serious accidents and the mortality rates are 4–5 times higher. The distance to the spinal injury centre and extent of the patients' injuries are the best determinants of the mode of transportation. An ideal situation demands an on-board anaesthetist who can provide respiratory, cardiac and haemodynamic monitoring, resuscitation and intubation if necessary, thereby reducing morbidity and mortality.[150] Survival and outcome for patients with SCI are determined by rapid medically supervised transfer to a specialised centre and initial management in the intensive care unit (ICU).[105,150]

All developed countries possess an effective trauma-care and transport system, which transports the victims, within the first 12–24 hours, to the spine injuries centres in well-equipped ambulances or helicopters. The lack of any such effective transport system in India is a very sad reality. In a study Upendra et al.[152] found that only 59.1% of the victims reached the treating centre within the first 48 hours and only 47.7% of the patients with spinal trauma were transported in an ambulance. Most of the victims were shifted 2–4 times between various health-care centres before reaching the definitive spinal-care centre. Only 7.27% of the patients were transferred directly to the centre, and the average number of transfers was 3.4 per patient. Chacko et al.[32] highlighted that an ambulance is used to transfer only 34% of spine injured patients in rural India. Most of the victims are transferred by relatives of the patient in cars, rickshaws, jeeps, etc., with little knowledge of the importance of spinal immobilisation. Pandey et al.[114] reported that there was an average of 45 days (range 0–188 days) of delay in presentation to a specialised spinal unit and most of the time the cause for the delay was unawareness on the part of patients and doctors regarding specialised spinal units. Early presentation of spinal injured patients to a spinal unit enables early surgery, which is beneficial in terms of reducing complications, length of stay and hospital cost.[150]

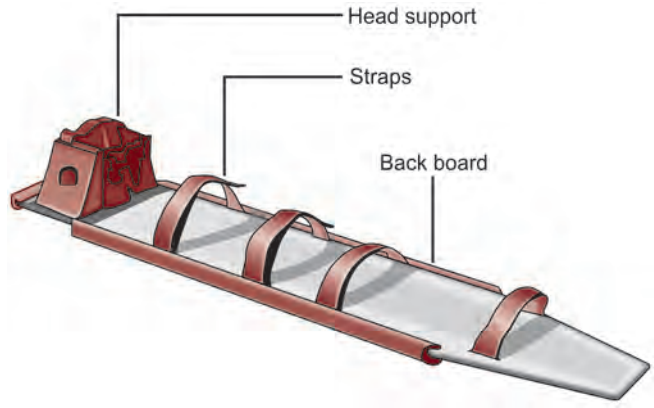

Fig. 1: Spine board

EVALUATION AND TRIAGE

Once the patient reaches the centre, the initial evaluation and triage of the patient is done by the anaesthetist, neurosurgeon, general or trauma surgeon, orthopaedic surgeon and if necessary a vascular surgeon. An urgent initial general evaluation is done to decide on what is to be done first.

CLINICAL EVALUATION

Evaluation of suspected cervical spine injury includes taking a careful and detailed history with attention to mechanism of injury and whether the patient had any neurological symptoms immediately after the event and loss of consciousness, seizures and ENT bleed should alert the neurosurgeon about an associated cranial injury.[4] The clinical examination and radiographic evaluation follows and is used to ascertain the presence of instability, identify neurological deficits, guide management and predict the outcome. During the course of initial assessment, patients are kept in the supine position with rigid collar immobilisation while standard ATLS protocols are followed.

Clinical examination of spinal injury patients is very important and should be very thorough, but has been found to have a sensitivity of only 77% in blunt trauma patients.[50] For a complete assessment the patient must be awake, alert, non-intoxicated and without any serious systemic injuries. Patients with high risk for spine injury include those with facial fractures, polytrauma, closed head injury and those with blunt and penetrating neck injuries. The attending neurosurgeon must get a very careful history about the injury mechanism and its injury severity score (ISS)[4] is calculated (Tables 1A and B). Clinical protocols for determining the need for radiography have been developed, such as the NEXUS low risk criteria [(NLC) Table 2] and the Canadian C-spine (CCS) rule (Fig. 2), which are used to aid in emergency room triage. Stiell et al.[146] found that the CCS is superior to NLC in sensitivity and specificity.

The clinical examination[38] includes inspection and palpation of the spine, and a complete neurological examination, and a general examination is mandatory to rule out polytrauma. Systemic examination to look for bruises, ecchymosis and abrasions will point towards the possible region of spinal injury.

Table 2: The NEXUS low-risk criteria

Cervical-spine radiography is indicated for patients with trauma unless they meet all of the following criteria:
1. No posterior midline cervical-spine tenderness
2. No evidence of intoxication
3. A normal level of alertness
4. No focal neurologic deficit
5. No painful distracting injuries

Beevor's sign: The patient is asked to lift the head with the examiner gently pressing on the forehead and, if the lower abdominal muscles are weaker (below T-9), the umbilicus moves upwards. Priapism indicates a loss of sympathetic tone and is an indicator of poor prognosis in spinal injuries.

Bulbocavernosus reflex is elicited by gently squeezing the glans penis or tugging an indwelling Foley's catheter. A normal response in the form of contraction of the anal sphincter is noted. This reflex is lost if there is injury to the conus medullaris or cauda equina. A negative response in the absence of injury to the conus or cauda equina is suggestive of spinal shock. This is the first reflex to return after spinal shock.

Table 1A: Injury severity score

Region	*Injury description*	*AIS*	*Square only the top three*
Head and neck			
Face			
Chest			
Abdomen			
Extremity			
External			

The injury severity score (ISS) is an anatomical scoring system that provides an overall score for patients with multiple injuries. Each injury is assigned an abbreviated injury score [(AIS) Table 1B] and is allocated to one of six body regions [head, face, chest, abdomen, extremities (including pelvis), external]. Only the highest AIS score in each body region is used. The three most severely injured body regions have their score squared and added together to produce the ISS score. The ISS score takes values from 0–75. If an injury is assigned an AIS of 6 (unsurvivable injury), the ISS score is automatically assigned to 75

Table 1B: Abbreviated injury score (AIS)

AIS score	*Injury*
1	Mild
2	Moderate
3	Serious
4	Severe
5	Critical
6	Unsurvivable

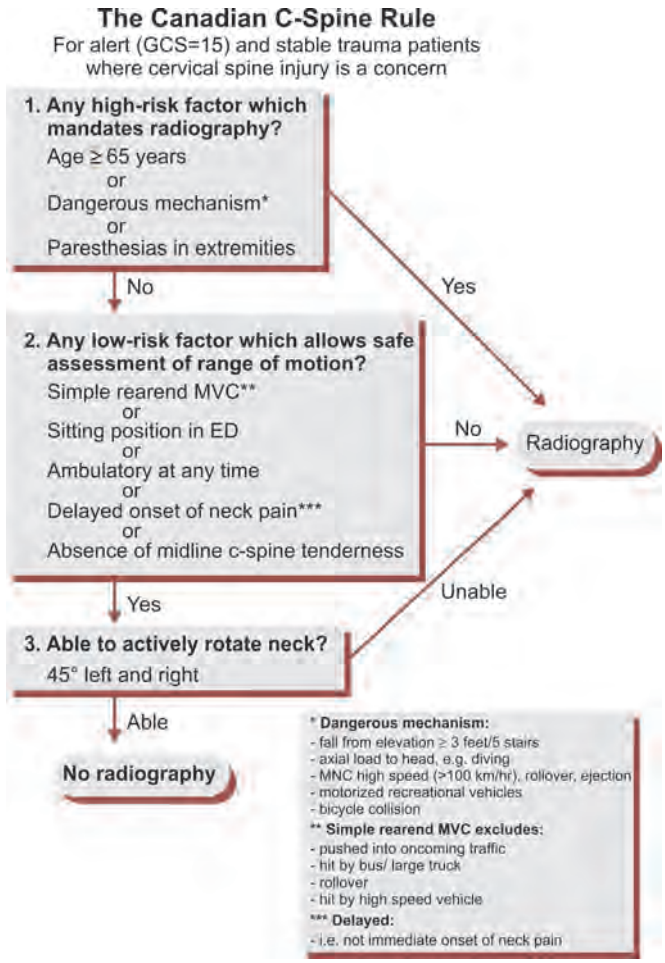

Fig. 2: Canadian C-spine rule

The motor, sensory and autonomic nervous system is rapidly assessed using the American Spinal Injury Association (ASIA) score.[63] Cranial nerve (CN) involvement (VI, VII, IX, X, XI and XII) can occur in association with upper cervical spine injuries or these may be due to associated cranial trauma. Missing other systemic injuries is very common since patients with spinal injury can have concurrent injuries to one or more organ systems.

SPINAL INJURY GRADING SYSTEMS

After the initial general and neurological examination, grading systems, like Frankel's and the currently used ASIA score, are used to standardise the clinical evaluation.

Frankel Grading System

Frankel divided spinal injuries into five gradations with decreasing neurological deficits:

Grade A: Complete loss of motor and sensory function below the level of lesion.

Grade B: Complete motor paralysis with some sensory preservation (e.g. sacral sparing)

Grade C: Retained motor function but useless

Grade D: Useful motor function

Grade E: Free from neurological symptoms

ASIA Score

The ASIA score for neurological and functional classification of spinal cord injury is recommended as the preferred neurological examination tool for clinicians involved in the assessment and care of patients with acute SCI.[63] This is a point score and is used in the initial evaluation and the assessment includes motor and sensory neurological level, completeness of the injury and zone of partial preservation. The motor and sensory levels are the most caudal segment of the spinal cord with normal function on both sides of the body. The most caudal muscle must have grade III power. The assessment of sacral sensations is very important because it may be the only evidence of neurologic function distal to the injury. It is important to distinguish between complete and incomplete injuries as complete injury has a poor prognosis (Figs 3A and B).

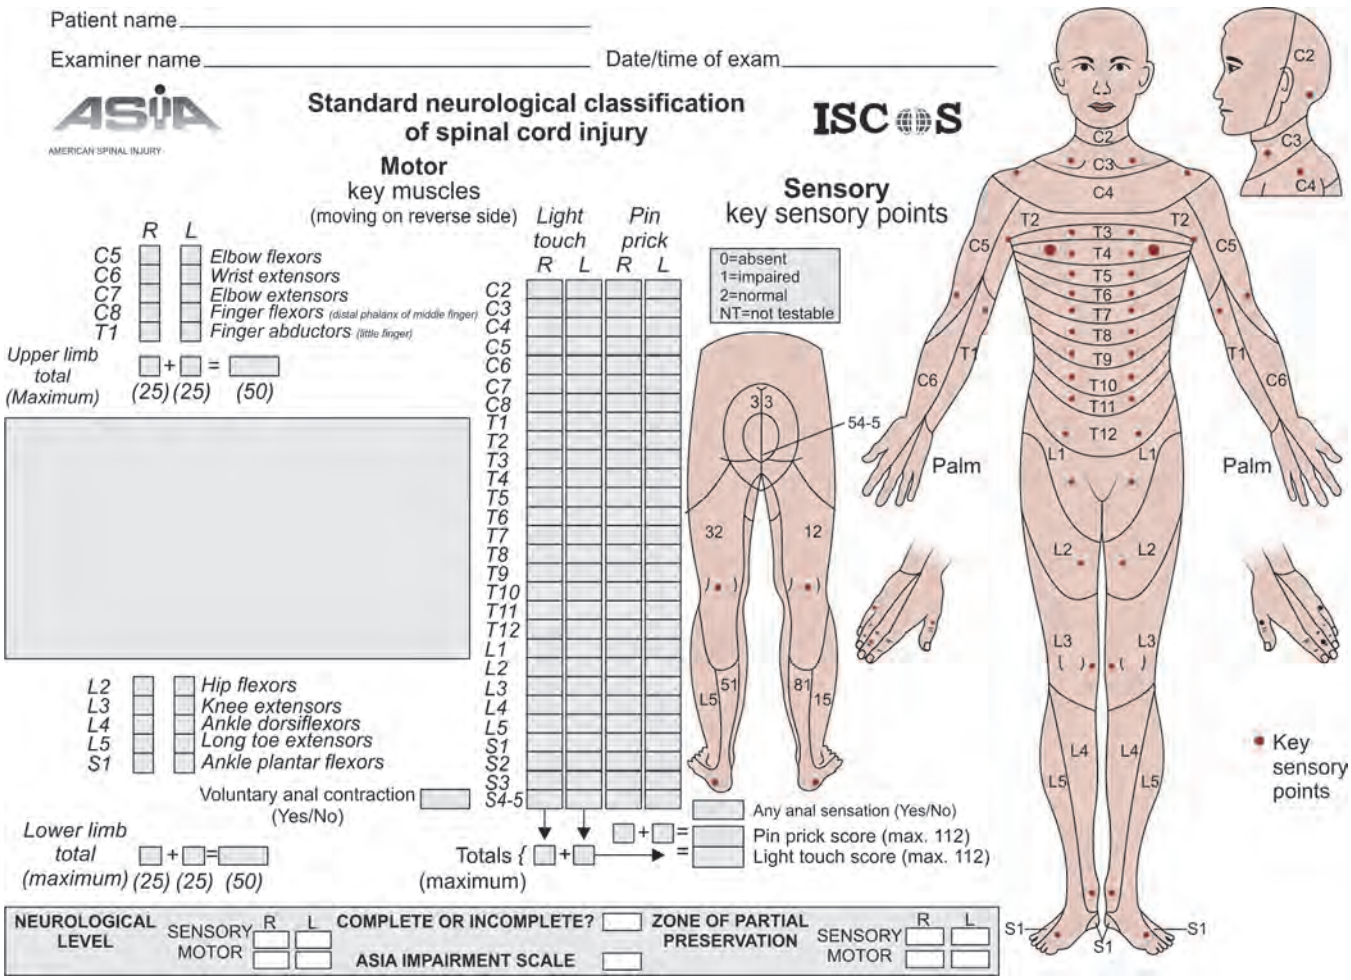

Fig. 3A: ASIA impairment chart

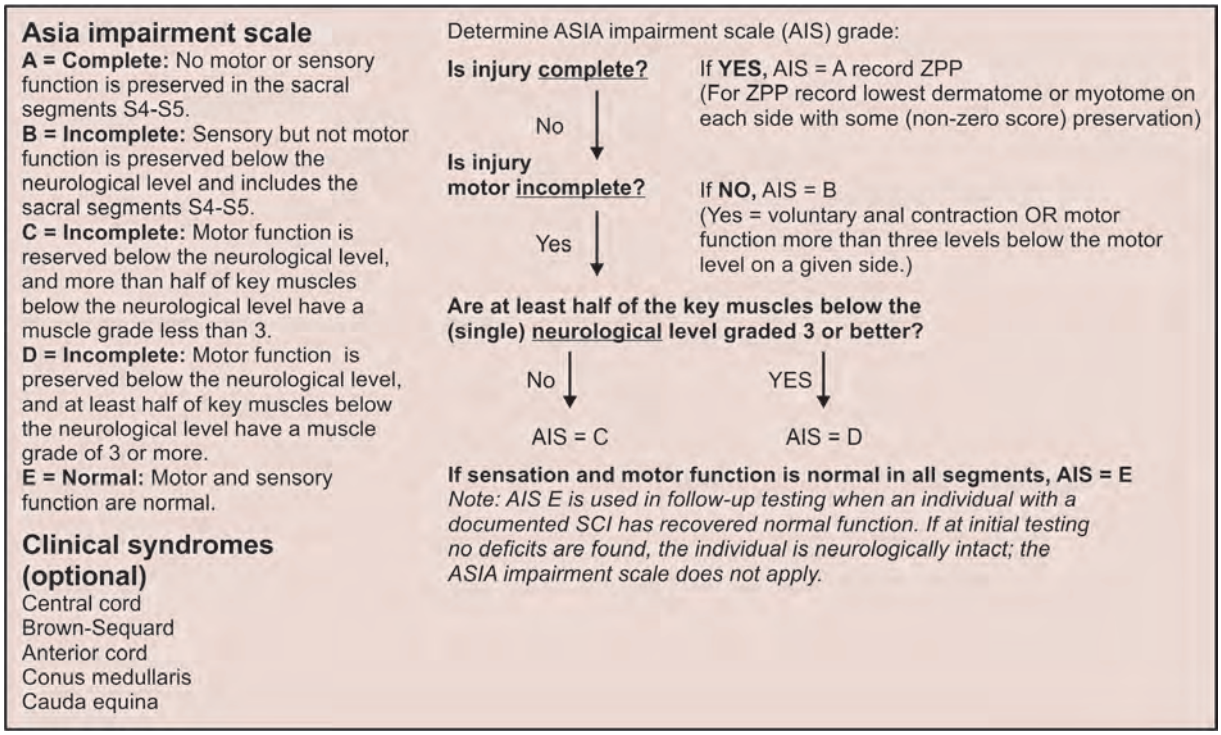

Fig. 3B: ASIA impairment score

SPINAL SHOCK

It is the transient loss of all neurologic functions including segmental and polysynaptic reflex activity and autonomic function which causes flaccid paralysis and areflexia; which can be of variable duration (1–2 weeks) rarely months and sometimes can be permanent below the level of injury.[12] Complete and incomplete injuries can be discriminated only after the spinal shock has elapsed.

SPINAL CORD NEUROPRAXIA

Torg et al.[148] have analysed this transient neurological deterioration that occurs during sport activity and found that the narrowing of the sagittal diameter of the cervical canal in the adult spine was the main causative factor. Cervical cord neuropraxia was not associated with permanent neurological injury and no permanent morbidity occurred in patients who returned to contact activities. But of the patients returning to contact activities, 35 (56%) experienced a recurrent episode.

WHIPLASH INJURIES

An injury caused to the muscles, ligaments, discs and facet joints of the neck by hyperextension, hyperflexion or rotational excessive forces, with no fracture, fracture dislocation or disc herniation is called a whiplash injury. Occipital neuralgia, headaches, cognitive impairment and lumbago are commonly associated symptoms.

Incomplete Injury

It implies the presence of motor and sensory function more than three segments below the injury. The term "sacral sparing" is used to indicate preserved perianal sensation, voluntary rectal sphincter contraction or voluntary toe flexion.

Complete Injury

Complete injury of the spinal cord is the loss of all motor, sensory and autonomic function more than three segments below the level of injury.

SPINAL INJURY SYNDROMES

Spinal trauma can manifest clinically in differing ways. The common presenting syndromes are the Bell's cruciate paralysis, anterior cord syndrome, posterior cord syndrome, Brown-Sequard syndrome, central cord syndrome, conus medullaris syndrome, cauda equina syndrome and cord transection.

BELL'S CRUCIATE PARALYSIS SYNDROME

This syndrome is characterised by weakness and paralysis of the hands and arms and relative sparing of the lower limbs. It is seen usually in patients with cervicomedullary injuries; most common are C2 fractures. The upper limb fibres of the corticospinal tract decussate at a higher and more central level and thereby the lower limb weakness is less.

ANTERIOR CORD SYNDROME

This is characterised as a syndrome involving the anterior and lateral motor corticospinal tracts (motor level) and spinothalamic tracts (pain and temperature) and the sparing of posterior column function (two point discrimination, position sense and deep pressure sense). In trauma, this can result due to injury of the anterior spinal artery or anterior cord pressure by a prolapsed disc, dislocated bone or osteophytes.[133]

POSTERIOR CORD SYNDROME

Injury to the posterior part of the spinal cord by a depressed laminar fracture or contusion has minimal motor signs but is characterised by pain and burning paraesthesias.

BROWN SEQUARD SYNDROME[29]

This syndrome is not frequent[126] and is seen in only 2–4% of traumatic injuries and consists of unilateral involvement of the corticospinal tracts, and posterior column tracts. On the contralateral side of the lesion, the spinothalamic tract is involved causing dissociated sensory loss, i.e. loss of pain and temperature (lateral spinothalamic tract) and preserved light or crude touch (anterior spinothalamic tract).

CONUS MEDULLARIS SYNDROME

The conus medullaris is located between D11-L1,2 and thoracolumbar fractures can cause injury to the conus and this is characterised by symmetrical weakness of the lower limbs, flaccid rectal tone and bladder involvement.

CAUDA EQUINA SYNDROME

Cauda equina syndrome occurs as a result of a traumatic lesion below L2 that occurs at the level of the cauda equina roots presenting as asymmetric pain, sensory loss and bowel and bladder disturbances.

CENTRAL CORD SYNDROME

Central cord syndrome, described by Schneider et al. In the 1950s,[129,132,134] is the most common type of incomplete spinal cord injury.[23,65] This usually occurs in a patient who has a primary or secondary canal stenosis and when an extension injury occurs in the presence of large osteophytes. There is greater motor involvement of the upper limbs with relative sparing of the lower limbs with bladder dysfunction and variable sensory disturbance ("man in a barrel" syndrome, burning hands syndrome). Spinal cord injury here is due to compression between the disc-osteophyte complex and an in-buckling ligamentum flavum.[134] The long tract fibres of the upper limb are located in the central region of the cord, hence, when an injury is more in the centre, the upper limbs are more involved. The treatment protocol for these injuries as proposed by Hardop et al.[81] includes:

- Patients less than 50 years of age with a traumatic injury and instability warrant operative intervention.
- Patients less than 50 years of age with an acute disc herniation may benefit from an anterior decompression.
- The benefit of surgical intervention in "classic" central cord syndrome in elderly spondylotic patients is uncertain.[25,35,51,56,73,103]

SPINAL INSTABILITY

Stability of the spine has been defined by White and Panjabi as "the ability of the spine under physiologic loads to maintain an association between vertebral segments in such a way that there is neither damage nor subsequent irritation of the spinal cord or nerve roots and, in addition, there is no development of incapacitating deformity or pain due to structural changes". White and Panjabi have provided a scoring system that has been widely adopted in predicting the presence of instability on cervical radiographs that have segmental kyphosis greater than 11 degrees and anterolisthesis greater than 3.5 mm of one vertebral body on another. Guidelines for determining instability are published and at times instability must be assumed on clinical and radiological clues. When there is involvement of anterior elements the injury is unstable in extension. A posterior column injury is unstable during flexion. Delayed instability is that which is recognised only 20 days after injury after initial pain and muscle spasm have subsided.[45]

Degrees of Instability

- First degree is mechanical.
- Second degree is neurological.
- Third degree instability is a combination of both.

RADIOLOGICAL ASSESSMENT

For optimal examination of patients with suspected cervical spine injuries, it is recommended that specific diagnostic algorithms including complete sets of proper radiographs with functional flexion/extension views, secondary evaluation of the radiographs by experienced staff, and further imaging like computed tomography (CT), magnetic resonance imaging (MRI) has to be done. Guidelines for symptomatic and asymptomatic patients have been published.[122,123] Bono et al.[24] emphasised that analysing radiographic findings should be only done using a standardised and uniform set of measurement techniques. Only through prospective studies can the clinical significance of these imaging characteristics be fully appreciated.

X-Rays

Plain X-rays are still the initial investigation and are used in the initial evaluation of spine injuries,[36] and doing a

cross table lateral, AP and open mouth odontoid views are standard.[122] The threshold for getting an X-ray of the suspected region should be very low when a possible spine injury is suspected.

Cross Table Lateral View

The radiographic features which are looked for in a lateral view are the presence of soft tissue swelling anterior to the vertebral bodies; a loss of the normal smooth cervical lordosis with special attention to the normal lordotic lines; disc space narrowing; segmental kyphosis; antero or retrolisthesis of one vertebral body relative to another and spreading apart of the spinous processes, chip and tear drop fractures and opening of the anterior disc space.[22] In elderly people and in patients with DISH and ankylosing spondylosis careful evaluation of the fracture of the anterior osteophyte may help to localise the injury.

Anteroposterior view X-ray is studied for alignment, canal encroachment, and pedicle morphology. Foreign bodies, like nails and bullets, are also visualised well on these X-rays. False positive X-rays are not infrequent and may require re-evaluation by CT and MRI.[97]

Oblique view X-rays demonstrate the uncinate process, pedicles, superior and inferior facets and the laminae, and will show the neural foramina which may be blocked by a unilateral locked facet. The articular facets and laminar alignment can also be studied.[15]

The swimmers view is also called the "twining view" and while taking this view the X-ray tube is positioned above the opposite shoulder and the film is placed centred on the axilla with the arm raised above the head, the tube angled 10–25 degrees towards the head and this is used to visualise the cervicothoracic junction.

Oblique pillar view of the dens is used to visualise the articular masses and C2 fractures. The head is rotated to one side and the X-ray tube is off centred 2 cm from the midline in the opposite direction and the beam is angled 25 degrees caudally centred at the superior margin of the thyroid cartilage.

Synchondroses of the atlas can be mistaken for odontoid fracture, but a fracture can pass through the synchondroses and this can be difficult to interpret and may require dynamic imaging on MRI.

Pseudospread of the atlas is due to a normal but disproportionate growth of the atlas on the axis and can be misdiagnosed as a Jefferson's fracture. More than 2 mm of total overlap of the C1 lateral masses on C2 on the AP view is common in children aged 2–5 years.

Pseudosubluxation is seen in children in the presence of spasm and when the X-ray is not taken in a true neutral position. This is usually seen at C2-3, C4-5 and C5-6 in children older than 10 years.

Missed diagnosis of a spinal injury is usually attributed to:

- Not taking an X-ray.
- Radiological misinterpretation.
- Incomplete sets of radiographs.
- Inadequate poorly taken radiographs (which do not show the level of the injury) and, finally, failure of the treating surgeon to see and properly interpret the X-rays.

Computerised Tomography

The CT remains the most valuable modality to assess cranial trauma, visualising bone, blood and contusions very well. It is very often used to screen the whole spine and specially the cervicothoracic junction, which is usually not visualised well on routine X-rays even with the shoulders pulled down. Sharma et al.[140] reported that cervical spine radiographs were false negative in 29% of patients, who were found to have SCI on spine CT. Spine CT had 98% sensitivity and detected 45% additional injuries in cervical spine X-ray positive patients. The advantages of CT are its easy availability, rapidity of the latest generation scans and the "One Stop"[28] ability to rule out polytrauma, thus making it a good screening tool. Brandt et al.[28] have suggested that data collected from CT scans obtained for workup of chest or abdominal injuries can provide data that is sufficient to screen for spinal fractures and this can decrease the cost and time of spine evaluation after trauma. The CT can miss ligamental and soft tissue injuries. Studies have suggested that CT alone is sufficient for spine injury clearance in unreliable patients based on follow-up MRI. But newer generation CT continues to miss injuries in patients. The MR changed the management in 7.9% of patients having had an admission CT with no acute injury.[110,117]

The CT based spine clearance protocols have been published.[128] Thin cuts (1.5–3 mm) CT followed by 2D, 3D sagittal reconstruction is done in regions where an injury is suspected. The body, posterior arch fractures, facet fractures, dislocations of facets, C1-C2 injuries and intracanal fragments are best seen on a CT. Spiral CT is widely available and has largely replaced traditional plain radiography in many institutions.[10] Spiral CT has been found to have a sensitivity of 99% and specificity of 100% and the risk of missed spine injury is 0.04%.[8,109,117,118,142] The CT scan of the chest and abdomen should be done immediately if blunt visceral trauma is suspected and chest X-ray or ultrasound abdomen show signs of injury.

CT Myelogram

CT myelogram is done where MRI is not available or is contraindicated in patients with a pacemaker or metallic implants.

CT Angiogram

The CT angiogram may be required for studying vertebral artery injuries or to rule out an anomalous vertebral artery course, especially when planning transarticular screw fixations.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is currently the investigation of choice for imaging the traumatic spine. The MRI visualises ligamentous injuries, disc injuries and herniations, compression of the neural elements, cord oedema, contusion, haematomas (EDH, SDH, SAH) and haematomyelia, and provides information which helps in neurological prognostication. Signal intensity changes in the cord may be due to repetitive cord trauma as seen in chronic segmental instability of cervical spondylotic myelopathy. In patients on traction and on ventilator support, precautions have to be taken, e.g. MRI compatible traction sets and ventilators with long circuits are used. Central cord injury is well characterised by MRI.[51] Ligamentous injury is seen as increased signal on T2-weighted images due to oedema and disrupted ligaments demonstrate a discontinuity in the normal low signal intensity of the ligament. This is very useful in studying craniovertebral junction injuries where a disrupted ligament may be the only sign of instability. Vertebral artery injuries can be visualised on the MRI and MR angiography will give more details.

Dynamic Imaging

Dynamic X-rays, dynamic fluoroscopy, dynamic CT[55] and MRI flexion and extension are useful to assess instability.[79] These should be done very cautiously and in patients who are conscious and oriented. They are avoided if instability is apparent or is clinically obvious.

SPINAL SCREENING

A new tool total imaging modality (TIM) is very useful in picking up a second noncontiguous injury. If this is not available CT screening or X-ray screening of the whole spine is mandatory in high-risk cases, e.g. fall from significant height or polytrauma. A suspicion of noncontiguous spinal injury must be maintained in all patients with known spinal injuries as they have an incidence of 15–20%.[140] Sharma et al.[140] recommend that assessment of the entire spinal column should be done in patients with spinal column injuries.

CLASSIFICATION AND A BRIEF OVERVEIW OF SPINAL TRAUMA

Spinal trauma is a problem with a wide spectrum from spinal cord neuropraxia and minor ligamentous injury to severe osteoligamentous rupture with spinal cord transection.

Classification systems of spine injuries have been developed to predict instability, standardise injury types and guide standardised management protocols. These systems are specifically designed for each region of the spine. Nicoll, in 1949, identified stable and unstable spinal injuries.[19] Holdsworth recognised the importance of the mechanism of injury and classified injuries into five types. Whitesides proposed a two column crane hypothesis with the anterior body and disc being the weight bearing structures and the posterior elements acting as the guy ropes. Louis pioneered the 3 column concept and differentiated between osseous and temporary instability and chronic instability due to discoligamental injury. Lob, Bohler and Roy-Camille further modified these concepts and Denis[46] added the middle column (the posterior part of the anterior column) which had to be injured to create acute instability. McAfee combined the Denis model with the White and Panjabi classification and, using CT, simplified the classification according to the type of failure of the middle column.

OCCIPITOCERVICAL DISLOCATION

Occipitocervical dislocation is uncommon and has high mortality.[6,45] These injuries are more common in children and may be asymptomatic or with CN involvement and cord injury. Classification of these injuries is based upon the displacement of the occiput:[80]

- Type I injuries are anterior subluxations and are the most common.
- Type II injuries have vertical distraction greater than 2 mm of the atlanto-occipital joint.
- Type III injuries are posterior dislocations and are rarely reported.

Traction is contraindicated. Treatment options are immobilisation, but an occiput to C2 fusion is usually required to provide long-term stability.

OCCIPITAL CONDYLE FRACTURES

Occipital condyle fractures[8,21,112] have been reported to occur in 3–15% of trauma patients. These present with lower CN deficits and cord injury. Anderson and Montesano[8] have classified them into different types. Type I fracture, which is a result of axial loading and lateral bending and there is no instability. Type II is a skull base fracture that extends into the occipital condyle. This is also a stable injury, because the alar ligaments and the tectorial membrane are not injured. Type III is an avulsion injury of the occipital condyle. If there is disruption of the alar ligaments and tectorial membrane, then potential for instability exists. Traction should be avoided as it is associated with a risk of neurological deterioration. Type I and II fractures are typically treated conservatively with immobilisation in a rigid cervical collar for 6–8 weeks. Type III may require occiput to C2 fusion.

ATLAS FRACTURES

Atlas fractures comprise 1–3% of all spinal injuries and 3–13% of cervical spine fractures.[75,86,91,95,99] The common mechanism of injury is axial loading. Type-I fractures involving a single arch. Type-II burst fracture of C1 (Jefferson's fracture),[83] Type-III Lateral mass fractures. Fractures without injury of the transverse ligament or

associated with bony avulsion of the transverse ligament can be treated with halo-brace immobilisation and instability may be excluded with flexion-extension imaging. Surgical fixation is recommended for injury of the transverse ligament with instability. Posterior arch fractures are the most common and are typically bilateral, and these are stable. Lateral mass fractures are usually unilateral and may be unstable if there is associated ligamentous injury.[30,58]

AXIS (C-2) FRACTURES[70,90]

The fractures of C-2 are: (1) Odontoid fracture; (2) Hangman's fracture and (3) Miscellaneous C-2 fractures.

Odontoid Fractures

Odontoid fractures are common cervical spine fractures, representing up to 10–20% of all cervical spine fractures and are often missed.[1,54] They have a bimodal incidence, with the first peak in young patients in association with high-velocity trauma; and the second peak occurring in elderly patients.[94,98] The Anderson and D'Alonzo classification[7] is based upon the location of the fracture line.

Type I fracture is the least common. The fracture line occurs at the tip of the odontoid. These are usually stable injuries and have a high union rate, and are treated conservatively.

Type II fractures are the most common. The fracture line is at the odontoid base and these have a high incidence of nonunion.[1]

Type II(a) are comminuted fractures involving the base of the dens with associated free fracture fragments and these form 5% of type II fracture. These are very unstable and managed by posterior fusion of C1 and C2.

Type III fractures are fractures of the odontoid which extend into the body of C2. These have a much higher union rate, with only 8% going on to nonunion. Factors associated with higher rates of nonunion are age greater than 65 years, smoking[11] and displacement greater than 5 mm or angulation greater than 10 degrees. Anterior odontoid screw fixation or a posterior fusion may be necessary.

Traumatic Spondylolisthesis of the Axis

Traumatic spondylolisthesis[41,53,66,76] of the axis called, "Hangman's fracture" by Schneider,[131] is a bilateral pars interarticularis fracture of C-2 with a C2-3 subluxation. The Effendi classification[57] modified by Levine is in current use. Type I is a bilateral pars fracture with a vertical fracture line, less than 3 mm of displacement and no angulation. Type 1(a) has an "atypical" fracture pattern[101,145] and the fracture runs through the posterior body of C2. Type II injuries have a vertical fracture line with displacement of greater than 3 mm and significant angulation and with associated fracture of the anterior and superior endplate of C3. Type II(a) fractures, representing 10% of "Hangman's" fractures differ from Type II fractures and have an un-displaced oblique fracture of the pars, but with angulation which is greater than 15 degrees. They are associated with severe disc and posterior longitudinal ligament (PLL) injury caused by a flexion-distraction injury force. A Type III fracture is a Type I fracture with bilateral C2-3 facet dislocation.

Miscellaneous C-2 Fractures

These include fractures of C-2 lamina, spinous process facets and lateral mass, and these may require external immobilisation or Halo immobilisation, if unstable.

ATLANTOAXIAL DISLOCATION

It occurs due to ligamental injury involving C-1, C-2 and rarely due to Os Odontoidium.[47,48]

Atlantoaxial Rotatory Instability

It is an uncommon injury in the adult patient population and may be associated with other upper cervical spine fractures. Fielding and Hawkins classification: Type I—Rotatory fixation without anterior displacement of the atlas. Type II—Rotatory fixation with anterior displacement of the atlas of 3–5 mm. Type III—Rotatory fixation with anterior displacement greater than 5 mm. Type IV—Rotatory fixation with posterior displacement.

Atlanto-Dens Instability

Atlanto-dens instability is usually a result of injury of the transverse ligament and occasionally the alar ligaments and tectorial membrane. It is usually due to a flexion injury and is assessed by a measurement of the anterior atlanto-dens interval. In adults up to 3 mm is considered normal.

OS ODONTOIDEUM

It is an ossicle with smooth circumferential cortical margins representing the odontoid process that is separate from the body of C2.[37,113,143] It is of two types: (1) Orthotopic type—an ossicle that moves with the anterior arch of C1 and (2) Dystopic type—an ossicle that is fused functionally with the basion and can sublux anterior to the arch of the atlas. Patients who develop instability and have neurological deficits are surgically fused. Transoral decompression may be considered in patients with os odontoideum who have irreducible ventral cervicomedullary compression.

COMBINATION FRACTURES OF C1-C2

Treatment of atlas-axis combination fractures is based on the specific characteristics of the axis fracture. External immobilisation of most C1-C2 combination fractures is recommended. C1-Type II odontoid combination fractures with an atlanto-dens interval of 5 mm or more and C1—Hangman's combination fractures with C2-C3

angulation of 11 degrees or more should be considered for surgical stabilisation and fusion. In some cases, the surgical technique must be modified as a result of loss of integrity of the ring of the atlas.[106]

SUBAXIAL CERVICAL SPINE TRAUMA (C3-T1)[100,151]

Subaxial spine traumatic lesions are classified according to Allen and Ferguson's[5] classification into six groups based on the initial force of injury and the position of the spine at the time of injury.

Flexion Injuries

These are caused by vehicular accidents, falls and diving into shallow water and constitute 15% of all cervical trauma.

A. Flexion-compression injuries: Posterior element fractures occur in 50% of compression flexion injuries.
B. Flexion-distraction injuries: These types of injuries are the most common injury patterns in Allen and Ferguson's classification and range from mild posterior ligamentous sprains, subluxations and severe bilateral facet dislocations.[15,24,52,77,130]
C. Vertical compression injuries:[13] These types of injuries result in examples of cervical burst fractures and are the most severe injury. The C6 and C7 bodies are exposed to greater axial compression and flexion loads and are prone to develop burst fractures.

Extension Injuries

A stage I lesion is manifested by abnormal widening of the disc space due to disruption of the ALL and disc. In the stage II lesion, the posterior ligaments are also disrupted and the upper vertebrae retropulse into the canal.

Thoracolumbar Injuries

These are common and are usually associated with severe abdominal and vascular injuries. The McAfee classification based on CT scans describes six types and uses the Denis three column model of stability:[26,46,84,102,109]

1. Wedge compression fractures are failures of the anterior column.
2. Burst fracture is a combined anterior and middle column injury. Surgery is indicated when there is neurological deficit, an angular deformity of more than 20 degrees, 50% canal compromise and reduction of anterior body height by 50%.[34]
3. Seat belt fractures are severe injuries and involve flexion compression of the anterior column associated with distraction and failure of the middle and posterior columns.
4. Fracture dislocation is a three column injury.

Sacral Injuries

Sacral fractures[68,127] are caused by fall from a height and seen in association with pelvic fractures. The neurologic deficits in pelvic fracture are due to associated sacral fractures. These have been classified into three zones.

Zone I: Fracture involving the ala and sparing the central canal.

Zone II: Fracture involves the sacral foramina on one side causing L5, S1 and S2 involvement with sciatic pain.

Zone III: These fractures involve the canal and cause sphincter disturbance and saddle anaesthesia. Zone III fractures are divided into vertical and transverse types; vertical associated with pelvic fractures while transverse are associated with severe deficits.

Intensive Care Management of Spinal Injuries

In the emergency department the "Trauma Team" comprises of an anaesthetist, intensivist, general surgeon, orthopaedic surgeon and the neurosurgeon. Simultaneously and quickly they evaluate the patient.

Potentially life threatening cardiac and respiratory events occur within the first 2 weeks after the injury and patients with severe injuries (ASIA grades A, B) benefit the most when initially they are kept in the ICU for 7–14 days after injury.[105]

Management of patients with acute spinal cord injury, particularly patients with severe cervical level injuries, in an ICU or similar monitored setting is recommended.[103,105] Use of cardiac, haemodynamic and respiratory monitoring devices to detect cardiovascular dysfunction and respiratory insufficiency in patients after acute cervical spinal cord injury is routine.

Cardiovascular

This intensive care management[104,105] is critical to prevent life threatening cardiovascular instability and respiratory insufficiency and to maintain mean arterial pressure at 85–90 mm Hg for the first 7 days after injury, which may improve spinal cord perfusion and neurological function.[20] Guha et al.[74] recommend that normotension should be attempted, irrespective of the severity of spinal cord injury. Induced hypertension after severe spinal cord injury was not found to be beneficial in improving spinal cord blood flow at the injury site while potentially increasing the risk of haemorrhage and oedema. Measures are taken to control bleeding. Intravenous (IV) access and fluid resuscitation must be started with 0.9% saline or ringer lactate solution. Fluids are replaced with colloids, crystalloids and, if required, with blood. If a pressor is necessary, dopamine is the drug of choice and phenylephrine is avoided. Concomitant low dose dopamine should be used with phenylephrine as a precaution against renal ischaemia. Atropine and vagolytics, like glycopyrolate, are used for preventing bradycardia associated with hypotension.

RESPIRATION

Respiratory complications are common after traumatic injuries to the spine, especially if the injury is cervical. There is decreased vital and inspiratory capacity due to diaphragm paralysis and intercostal muscle dysfunction. After assessing the respiratory effort, oxygen supplementation via mask/prongs is given. Prophylactic intubation in conscious patients is not done. When there is need for respiratory support "chin lift" instead of "jaw thrust" is used, with great care taken not to extend the neck. Endotracheal intubation should be performed with inline traction of the spine. Awake blind nasal intubation is another option, but the safest option is awake fibreoptic intubation. Cricothyroidectomy and tracheostomy are the other options to secure airway and should be done early when indicated. Neurogenic pulmonary oedema is rare and can lead to adult respiratory distress syndrome if not recognised and treated. It is managed pharmacologically and by ventilation.

AUTONOMIC SYSTEM MANAGEMENT

Spinal shock is the complete loss of motor, sensory and autonomic function of the spinal cord and may last for a few hours to weeks. This can cause haemodynamic instability due to loss of vasomotor tone attributable to injury of the spinal cord.[12] Spinal shock has to be differentiated from vascular shock which may coexist. Ryle's tube insertion is required to prevent vomiting and aspiration as paralytic ileus is common. Decreased sweating can cause hyperthermia in tropical countries like India. Prevention of decubitus ulcers is very important and can be done by frequent turning of the patients, proper skin care and nursing the patient on air or water beds. Bladder and bowel care are of great importance and most patients with spinal injuries may have retention and should be catheterised with proper precautions.

NUTRITION IN SPINAL INJURY PATIENTS

The hypermetabolic, catabolic injury cascade occurs immediately after both traumatic brain and SCI leading to depletion of whole body energy store, loss of lean muscle mass, reduced protein synthesis and finally loss of gastrointestinal mucosal integrity and compromise of immune competence. This prolonged nitrogen loss and severe malnourishment occurs within 2–3 weeks of injury; therefore, nutritional support of patients with SCI is done expeditiously. Energy expenditure is best determined by indirect calorimetry in these patients, because equation estimates of energy expenditure and subsequent caloric need tend to be inaccurate.[111] Due to poor nutrition spinal injury patients have poor wound healing and increased susceptibility to infections.

MEDICAL AND PHARMACOLOGIC

Injury to the spinal cord involves mechanical forces like compression, penetration, laceration, shear and distraction. The secondary mechanisms include reduced blood flow, loss of autoregulation, loss of microcirculation, vasospasm, thrombosis and haemorrhage. Other events are electrolyte shifts, permeability changes, loss of cellular membranous integrity, oedema and loss of energy metabolism. The pathological cascade also includes neurotransmitter accumulation, arachidonic acid release, free radicals and prostaglandin production and lipid peroxidation. All these lead to axonal disruption and cell death.[63,135,141] Pharmacotherapy has been very ineffective in the management of these cascades and research into compounds, like tirilazad mesylate, nalaxone, methylprednisolone, GM-1, is still ongoing and results are awaited.[116]

METHYLPREDNISOLONE

Giving methylprednisolone after spinal injury is an option that can be undertaken with the knowledge that side effects are very common.[85,116,121] The benefits of methylprednisolone[27] are only seen when the drug is given within 8 hours of the injury and when given later the outcomes are worse. The initial bolus is given as 30 mg/kg/IV over 15 minutes and the maintenance infusion is started 45 minutes after the bolus and is at a rate of 5.4 mg/kg/hr for 23 hours if therapy was started within 3 hours of injury and 47 hours if begun 3–8 hours after injury.

Sharma et al.[139] suggested that methylprednisolone sodium succinate was effective in promoting post-traumatic clinical and histological recovery and to a greater extent when given 1 hour after trauma. Methylprednisolone sodium succinate is more effective than dexamethasone in reducing oedema.

TRACTION

Traction, which earlier was the only modality of treatment of spinal injuries has a limited stand alone application in the modern era of spinal surgery.[93] Traction is used for initial closed reduction of cervical fracture dislocation injuries.[88] It is absolutely contraindicated in the management of atlanto-occipital dislocation, Type II(A) and III Hangman's fractures, in children below 3 years, in patients with a distraction injury and in any patient who develops severe local pain, radiculopathy, myelopathy or autonomic dysfunction.[59] It should not be used in patients with impaired sensorium. In patients with a locked facet, it is a safe option to get an MRI and exclude a sequestered disc which can cause neurological deterioration when traction is applied. Today, most neurosurgeons practicing spine surgery would put in a 3 pin fixator and reduce a dislocation with controlled

traction under fluoroscopic control and maintain reduction with different anterior or posterior instrumentation. Most fracture dislocations can be easily reduced by careful positioning of the neck in extension. Over-distraction may occur due to excessive weight, nature of injury and poor muscle tone, and due to the use of muscle relaxants during anaesthesia.

Applying Traction

The Gardner-Wells tongs are the ones in current use and many Indian variations of the same are available. The site of application is usually 1.5–3 cm above the pinna and below the equator of the skull. Placement of pins is avoided beyond 1 cm anterior to the meatal line as risk of pin perforation in the thinner squamous temporal bone increases and temporalis muscle injury can cause pain.

Extension Traction

The pins are placed 3 cm above and 2–3 cm in front of the external auditory meatus. This is rarely used because retroluxations are very rare.

Neutral Traction

The pins are placed 3 cm above and in line with the external acoustic meatus.

Flexion Traction

The pins are placed 3 cm above the pinna and 3 cm behind the external auditory meatus and above the mastoid process. This is the position used for reduction of locked facets.

ORTHOTIC DEVICES IN SPINE TRAUMA

Halo

The 4 pin halo can also be used for immediate immobilisation for acute subaxial spine injuries[33,39] and Indian versions are also available. Traction can be applied using the halo and after the fixation, if necessary, the halo can be continued for immobilisation. The halo provides relative immobilisation of the upper cervical spine, but the lower cervical spine is not immobilised well.[69,82]

Minerva Jacket

This is still used occasionally and new thermoplastic Minerva jackets limit cervical "snaking" better than the Halo.

Soft Cervical Collar

This is used only in the treatment of pain caused by muscle spasm and provides very little immobilisation and should not be used in patients with bony and discoligamental injuries.

Philadelphia Collar

It is used postoperatively to limit flexion and extension.

Yale Brace

It is characterised by extended support to the sternum and upper thoracic spine and is better at immobilisation than the Philadelphia collar.

SURGERY

Surgery is usually indicated in incomplete cord lesions, unstable injuries and in patients with a radiculopathy or myelopathy due to pressure on the spinal cord or roots. Surgery in complete injuries may be necessary to optimise recovery, prevent deformity and allow for early mobilisation.[40]

Early surgery: Timing of surgery in trauma is controversial and many surgeons prefer earlier cord and root compression.[62,147,154]

PAEDIATRIC SPINE INJURIES

These are infrequent and most paediatric spine injuries can be treated by immobilising in Halo and rarely Minerva jackets. Anatomical reduction of deformity, stabilisation of unstable injuries and decompression of the spinal cord, and isolated ligamental injuries associated with deformity are indications for surgical management.[107]

Spinal Cord Injury without Radiographic Abnormality[120]

Pang and Wilberger[115] described spinal cord injury without radiographic abnormality (SCIWORA) in 1982. Patients are usually children and this is seen rarely in adults. Patients present with signs of myelopathy as a result of trauma and no evidence of fracture or ligamental instability on plain X-rays and CT. This can appear as late as 4 days after injury.

The spinal column in children is more flexible and elastic and in the absence of bony or ligamental injury, the MR images can show a spectrum of injuries including cord contusion, vascular injury, traumatic disc prolapse, traction injuries, meningeal rupture and even cord transection. SCIWORA is more common in patients with asymptomatic Chiari 1 malformation.[23] Patients with SCIWORA,[119] have a 20% rate of repeat injury within 10 weeks of the original injury and so patients are recommended immobilisation for 3 weeks to 3 months. Contact and non-contact sports are prohibited for 3 months before allowing these children to go back to their normal routine. Dynamic imaging is done to rule out occult asymptomatic instability.[144]

Geriatric Spine Injuries

The elderly population is at a higher risk of spine injuries after even minor falls due to the loss of the normal spine biomechanics and flexibility, osteoporosis, cervical

spondylotic myelopathy, cord ischaemia and secondary canal stenosis. Abnormal ossification, ossification of posterior longitudinal ligament (OPLL), diffuse idiopathic skeletal hyperostosis (DISH), flurosis and ankylosing spondylitis are other factors that complicate spine injury in the elderly. Patients with ankylosing spondylotis[71,96] are highly susceptible to extensive neurological injury and spinal deformity after sustaining cervical fractures from even minor traumatic forces.

Deep Vein Thrombosis[44]

Thromboembolism leading to complications is very high in spinal injured patients and the incidence of a thromboembolic event ranges 7–100%. This is diagnosed clinically by observing signs of inflammation and confirmed by duplex Doppler, ultrasound, impedance plethysmography and venography. The prophylactic measures advocated are low molecular weight heparin and rotating beds. Heparin is given as a titrating dose to achieve a PTT of 1.5 times the control. Low dose heparin with pneumatic compression stockings or electrical stimulation is another option. Vena cava filters are used for patients who do not respond to anticoagulation and in those in whom anticoagulants are contraindicated. The prophylaxis therapy is given for 6–12 weeks.[44]

Vertebral Artery Injury

About 0.5% of all trauma patients can have a vertebral artery injury, and the pathology can be arterial dissection, occlusion, transection or pseudoaneurysm formation. This can cause cerebral, brainstem and spinal cord strokes.[17,60,87] Cervical spine translation injuries and transverse foramen fractures are the most common injuries associated with vertebral artery injuries. Most patients remain asymptomatic, but sudden unexpected deterioration is possible. The incidence of neurologic deficits ranges 0–24%. Wallenberg's syndrome, which is characterised by V, IX, X and XI CN deficits, Horner's syndrome, ataxia, dysmetria and contralateral pain and temperature loss is a frequent clinical presentation. Digital subtraction angiography is the most sensitive imaging study. CT angiography has sensitivity and specificity close to that of catheter angiography. Anticoagulation is recommended in patients with evidence of posterior circulation stroke, either observation or anticoagulation in patients with evidence of posterior circulation ischaemia, and observation of patients with no evidence of posterior circulation ischaemia.[18,108]

Double Noncontiguous Spinal Injuries

The incidence of noncontiguous injuries approaches 15% in patients with multiple injuries. Vaccaro et al.[153] found that 15 fractures in 12 patients were missed on admission and 25% of these patients had a progressive neurologic deficit as a result of improper initial immobilisation. The locations of missed fractures were found to be primarily at the extremes or junctions of the spine (i.e. cervicothoracic, thoracolumbar). Double noncontiguous cervical injuries have an incidence of 3.2%.[86] The reason for the second lesion in the same trauma event can be due to a pre-existing benign spinal lesion or because of a biomechanical event due to spinal column position at the time of injury. The second lesion in double noncontiguous cervical lesions can appear through a single great impact in pre-existing lesions, double impacts at the same time with injuries at two levels or repeated impacts in very quick succession in the same trauma.[153]

Neglected Spinal Injuries

Sengupta[136] found that spinal injuries are most often missed in unconscious or intoxicated patients and in patients with polytrauma. These were 4.5 times more frequent in the cervical spine compared with the thoracolumbar spine. The most common cause was the failure to obtain radiographs.[43,67,92,136] Use of CT and MRI scans as screening tests may be good ways to diagnose these injuries. The most serious consequence of overlooked spinal injuries is progressive neurological deficits.[124] Deformity and persistent pain require surgical intervention. Untreated or inadequately treated spinal injuries with late presentation are more often seen in the developing countries like India.

The reported frequency of missed injuries in the cervical spine varies from 4–30%.[124] Characteristic injury patterns which are commonly missed include odontoid, teardrop, facet and Hangman's fractures.[64] No radiological imaging modality can be 100% accurate and X-rays, CT and MRI have missed injuries, and even in the absence of fractures, clinically significant instability can exist. Spinal cord injury without radiographic abnormality has been found to occur in 0.08% of adults with blunt cervical spine trauma. When injuries are missed on initial assessment, a delay in diagnosis occurs that puts the patient at risk for progressive instability and neurologic deterioration. In one series by Davis et al.,[43] 29% of patients with missed injuries developed permanent neurologic sequelae.

OUTCOME SCORES

The standardisation of studying outcomes is very important as otherwise analysis of surgical and management protocols will not be possible.[49,152]

The functional independence measure and the modified Barthel index are recommended as the functional outcome assessment tool for clinicians involved in the assessment and care of patients with acute SCI.[38]

FUTURE GOALS

The main target is preventive neurosurgery and the prevention of spinal trauma. Educating the attendants of the patients regarding precautions to be taken while transporting and shifting spinal cord injured patients, creating awareness amongst the Indian population for

identifying spinal trauma and its initial management and providing tertiary level hospitals with specialised spinal trauma units.[114,120,152] Implementation of guidelines as published by the Congress of Neurological Surgeons in 2002 will decrease time for spine clearance and incidence of missed injuries. Rehabilitation is a greater responsibility of the treating neurosurgeon and requires dedicated facilities, physical medicine specialists, physiotherapists and psychologists.[120] The establishment of spine injury centres have been associated with better standard of care all over the world and these centres must be created all over India also.

48 Biomechanics of the Spine

Anil Pande, Goutham Cugati

INTRODUCTION

Biomechanics is the study of the functional anatomy of the spinal column. This includes the study of its normal structure, curves, attachments of ligaments and muscles and intrinsic biological tissue characteristics. The dynamic character of the vertebral column, intervertebral disc and a large number of variables makes this subject difficult and forbidding. Yet not knowing the subject makes the treatment of patients with spinal disorders inappropriate, incomplete and, sometimes, the treatment worse than the disease. Traumatic, neoplastic, infectious and other diseases of the spine and spinal cord are difficult problems, combining issues of biomechanical instability and neural injury. These two problems are often inseparable. Spinal surgery often involves the handling of the spine to a degree that may affect its stability and the neurosurgeon must be capable of managing instability and reconstructing the functional anatomy of spinal column. Modern biomechanics involves the application of engineering and computational principles to biological problems and has been aptly described by Benzel[150] to be the root of spine surgery.

HISTORICAL BACKGROUND

Sannan and Rengachary,[150] in their comprehensive review of the development of biomechanics, detail concepts which have lead to modern spinal surgery. Ancient Indian, Sumerian, Chinese and Egyptian among other sources, point to a long tradition of knowledge of spinal ailments.[62,83,102,103] In the Srimad Bhagawat Mahapuranam (3500–1500 BC) we find the oldest documentation of spinal traction.[80] Giovanni Alfonso Borelli 'Father of spinal biomechanics' proposed the term "Iatromechanics", i.e. application of mechanics to physiology in "De Motu Animalium" in 1680, the first comprehensive text devoted to biomechanics.[141]

Most of the experimental models for biomechanics are based on work done by the neurologist Alfred Reginald Allen[152] who, in 1911, developed a research model using graded weights. 'Allen's Weight drop technique' remains the basis on which experimental spinal lesions are created, even today.[152]

Walter Jones, in the 1930's, classified spinal injuries to be mostly of the flexion type. Junghans, in 1932, proposed the concept of "Motion Segment", which is the functional unit of the spine formed by the intervertebral disc and two adjacent vertebrae. In 1945 Nicoll,[106] on analysing 166 thoracolumbar fractures in coal miners, brought an early classification which bracketed these injuries into, anterior wedge fractures, lateral wedge fractures, fracture dislocations and neural arch fractures. He also tried to define the concept of stability and felt that the interspinous ligament was an important component.

Penning, in 1962, described biomechanical aspects of plain radiography of the cervical spine in chronic myelopathy[136,137] and, in 1971, published the normal movement of the cervical spine and postulated "the Pincer mechanism of Penning", an important biomechanical cause of myelopathy.

Frank W Holdsworth introduced the first modern classification on the basis of the "Two column theory" of spinal injuries.[60,61] This classification helped to better treat thoracolumbar injuries.[150,155] In the 1980s, Denis proposed the "Three column theory" based on a study of more than 400 radiographs of spinal fractures.[33,34] White and Panjabi's classic work on the biomechanics of the spine has been seminal[118–127,129,130] Benzel,[6–10] Yoganandan and his colleagues,[87,90,91,178–184] Pintar et al.[138] and Goel,[47–50] have been among others who have contributed to the understanding of the complexity of the biomechanics of the spine.

Currently, complex computer software programmes are used to study and understand normal and applied biomechanics. The "Finite element method" is a mathematical model using "elements" and "nodes".[46,48,77,82,94]

BIOMECHANICAL TERMINOLOGY

Voltaire once aptly said "Before you converse define your terms" and nowhere it seems more so than in the field of biomechanics, which is an amalgam of the biological and mechanical and also new properties that arise which are characteristic of living systems.

Scalar

This is a quantity defined by only its magnitude and has no direction. An action that changes the state of rest of the body to which it is applied can be defined as a force, because force has no direction, it is a scalar.

Vector

Forces applied to the spine can be broken down into component vectors. A vector is force oriented in a fixed and well-defined direction in 3-dimensional space. It is a quantity that possesses both magnitude and direction.

Force Vector or Load Vector

This is a force applied in a particular direction. In the laboratory, pure vector forces such as flexion, extension, vertical compression (axial loading, vertical distraction, lateral flexion or bending, rotation, shear or a combination of these) produce bony and ligamental injuries of the spine. The injuries are classified according to the vector forces causing them.[22]

Cartesian Co-ordinate System

This consists of X, Y and Z axis. These can have both rotational and translation movements along these axes, which can be positive or negative. The right handed cartesian system is used in biomechanics (Fig. 1).

Deformation

Deformation results when force is applied to a non-rigid body. The forces that can act can be rotational or translational and deformation results in strain.

Strain

This is the change in unit length or angle in a body subject to a force.

- Shear strain is the change in the right angle.
- Normal strain is the change in the length divided by the original length.

Stiffness

It is the ratio of force to the deformation.

Biomechanical Load Deflection Response

This curve has three components (Fig. 2):

- Physiological loading phase
- Traumatic loading phase
- Failure or post-traumatic loading phase.

During the physiological loading phase, the stiffness offered gradually increases and this is a mechanically efficient phase with no structural damage.

During the traumatic loading phase, micro failures start occurring and stiffness starts to decrease. In the post-traumatic loading phase, the structure has an increase in the deformation that results in the decrease in the load.

Coupling

The spine is a three-dimensional structure and coupling is a unique characteristic of the spine, where every primary motion can have associated obligatory movements like translation or rotation. Principal motion is the motion associated with the direction of the external force.

Instantaneous Axis of Rotation

This is the axis perpendicular to the plane of motion of the body and this passes through a point within the confines of the body. It is also the central point about which the vertebra rotates (Fig. 3). This is not a static point but is dynamic and changes with position, posture and direction of movement.[170] Each segment has a unique instantaneous axis of rotation (IAR) for every movement and is influenced by spine alignment, anatomy, muscles and loads exerted. According to White and Punjabi,[173] the IAR is located in the ventral portion of the vertebral body. The human body's centre of gravity is located approximately 4 cm ventral to the sacrum.[71]

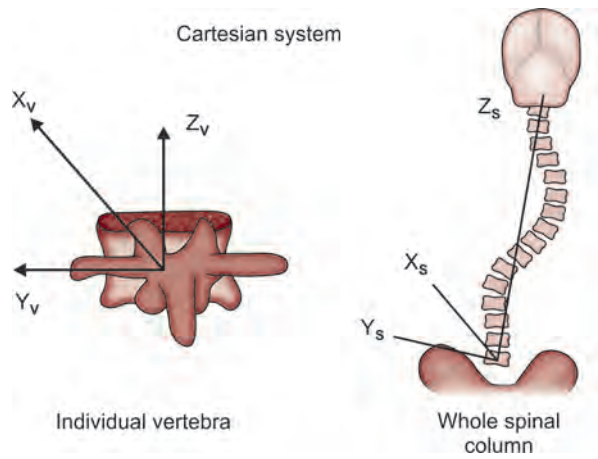

Fig. 1: Diagrammatic representation of cartesian co-ordinates of individual vertebrae and the whole spine

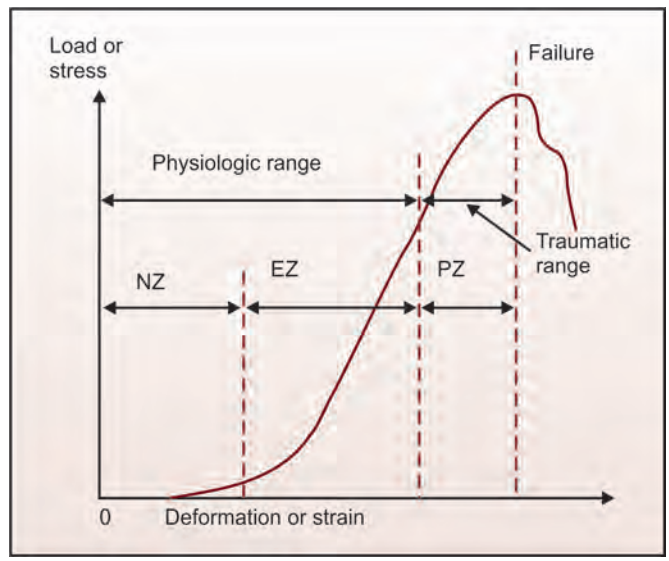

Fig. 2: Load deflection response curve showing physiological range, traumatic range and failure

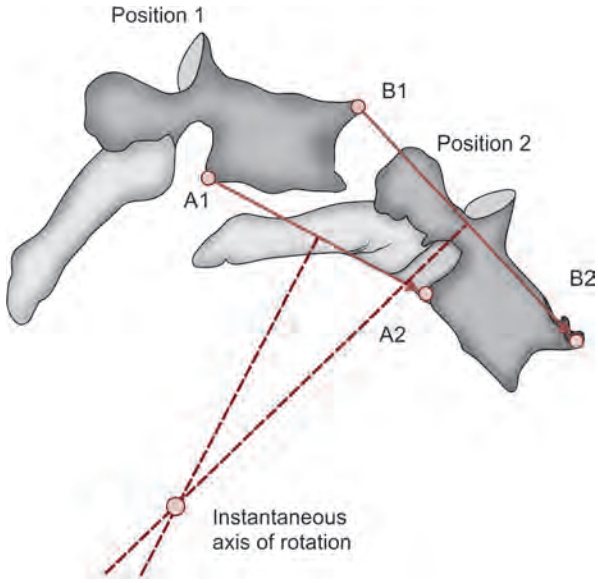

Fig. 3: Instantaneous axis of rotation

Range of Movement

They are the limits of rotational and linear motion. The spinal cord has six degree of freedom with three angles and three displacements of a chosen point along a coordinate axis.

- Extension is a backward bending moment
- Flexion is a forward bending moment
- Subluxation is an anteroposterior or postero-anterior shear
- Rotation is an axial turning or torsion
- Distraction is stretch or tension.

Relaxation

The return or adjustment of a system to equilibrium following displacement or abrupt change is relaxation.

Creep

A rheologic effect of metals and other solid materials (disc) that may become elongated or deformed as a result of a load being applied for a long period.

A constant applied load causes a deformation over time or creep response.

Elastic Modulus of Young The constant or scale factor which defines quantitatively the relationship between the deformation of any elastic medium and the deforming force.

Elastic Deformation

It is the reversible deformation of tissue: The change in shape of an object under an applied load from which the object can recover or return to its original unloaded state when the load is removed.

Plastic Deformation

Any irreversible deformation of tissues is plastic deformation.

Break Point

This is a point of discontinuity, change or cessation beyond which the strength of a structure fails.

Hysteresis

This is a lagging or retardation of one of two associated phenomena or a failure to act in unison of different parts of a body.

Kyphosis

This is an excessive sagittal angular deformity that is beyond the established normal range. Thoracic spine curvature is 25–40 degree with a transitional zone of 40–55 degree. Kyphosis greater than 60 degree in the thoracic spine is abnormal. In the thoracolumbar junction, the normal kyphosis is 0 degree and the lumbar spine is normally lordotic. A post-traumatic deformity of greater than 30 degree at the thoracolumbar junction and a kyphosis of greater than 5 degree in the lumbar spine are considered abnormal.

Junghans Motion Segment

Junghans defined the basic functional unit of the spine. This consists of two vertebral bodies and an intervening disc with the ligaments and joints (Fig. 4). The basic structure of a spine functional segment is an anterior column, mechanically supported by a hydraulic cushion and posterior secondary joints, resulting in a strong load-bearing and flexible structure. Thus, the motion segment is the smallest structure for performing biomechanical tests of the human spinal column. The human spine has 24 motion segments.

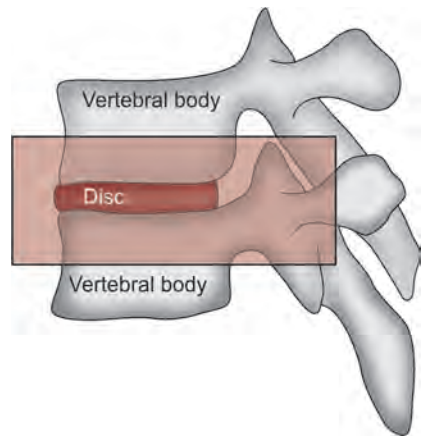

Fig. 4: Diagrammatic representation of Junghans motion segment

Bending Movement

The bending moment (M) is the product of the force (F) applied to the lever arm and length of the lever arm (D).

$$M = F \times D.$$

BIOMECHANICAL TESTING METHODS

The study of spine biomechanics includes the use of mechanics and mathematical principles. The validation and application of theories have been accompanied by *in vitro* tests of both animal and human spines, to determine stiffness, strength, strain and failure loads of spinal segments and surgical implants.[4,36,89,145,172,173] *In vivo* instrumentation has been used to measure strains and pressures in the spine during daily activities.[128]

In vivo Testing

These may be *in vivo*, in animals[164] and rarely in human beings where intradiscal pressure measurements or instrumentation that has sensors has been used to give information about biomechanics.[8]

In vitro Testing

This is usually of complete or part preparations of human cadavers[172] and animal specimens, (e.g. sheep, porcine spine functional unit).

Mathematical Model Testing (Finite Element Analysis)

Computational mechanic techniques, in particular the finite element method, have been widely applied to the analysis of spinal problems. This testing involves the breaking down of the structure to be studied into a finite number of geometric shapes or elements which are interconnected by nodes.[46-48]

The geometric information is obtained from CT study of human spines and the material properties of various components, such as the modulus of elasticity, the shear modulus, density and Poisson's ratio and these are based on predetermined values. These are then studied with complex computer programmes and are easily reproduced.[51] Kumaresan et al.[81] have described the physiological mechanics of the growing spine specific to 1, 3 and 6-year-old and compared them with mature spines. Such data will assist mathematical models of the spine to improve validation and lead to better design of stabilising systems.

Biomechanical Tests can be Dynamic and Static

- *Strength test:* This is a static test where load is applied till failure occurs.
- *Stability test:* The load is applied, avoiding permanent deformation and the specimen is only tested on the elastic segment of the stress versus strain curve. It studies stiffness, creep and viscoelastic properties of the material.
- *Fatigue or cyclic load tests:* These tests involve cyclical loading with subfailure loads till failure occurs and a fatigue curve is plotted out.

ROLE OF IMAGING IN BIOMECHANICS

The precise quantification of spine motion behaviour in the clinical setting remains difficult and imaging the spine is critical to evaluating instability in the clinical sense.

Radiography

Plain dynamic radiography should be used with great caution in evaluating trauma but it is indispensable. It is useful in diagnosing instability, classifying injuries and fractures, evaluating surgical results and follow-up. Digital X-rays have better resolution and clarity. The cost effectiveness, utility and pre-operative uses make these the best resource to study applied biomechanics. 3D radiography is useful in studying axial rotation and lateral bending.[135] Dynamic radiographs have been used to study the characteristics of sagittal vertebral alignment.[84]

Computed Tomography

It has been used to study the bony anatomy, especially in the craniovertebral junction and can give great information about various anomalies and abnormal biomechanics and guide surgical restoration of the column.[21] McAfee et al.[93] have emphasised the value of the CT scan in studying and classifying spinal column injuries, specifically the thoracolumbar spine. Where MRI is unavailable or contraindicated, CT myelography can be a valuable tool to study dynamic canal stenosis, abnormal disc response and CT angiography can give an idea about safety of the instrumentation. CT studies are also used to study structural dimensions and morphology of the spine and this data is then used for the computer models and finite analysis. Computer assisted anatomic study to evaluate canal size was done by Ebraheim et al.[38]

Magnetic Resonance Imaging

It has allowed three-dimensional imaging of the spine for accurate assessment of anatomy, sagittal balance, pathology, deformity and kinematics.[167] Pathology of the ligaments at the craniovertebral junction is very well visualised. In trauma, the role of MRI is invaluable and when combined with whole neuraxis screening is very comprehensive. Soft tissue and ligament injuries, including tears of the ligaments of the craniovertebral junction are well seen.[79,96,97,99] The area of signal intensity change in the cord can help in localising segmental instability.[72] Dynamic MRI and MRI that can image while a patient is standing have been in clinical use.

BRIEF NORMAL ANATOMY OF THE SPINE

It is customary to sub-classify the spinal column as each of the regions has specific anatomic and biomechanical characteristics. The spinal column must be also considered holistically because the normal curves, shape and structure correspond to other biomechanical properties which cannot be understood by studying the subdivisions alone. In fact, the spine cannot be studied in isolation to all the tissues that surround it and that mutually support one another.[74,75] Studying the motion segment in a preparation is informative but the normal *in vivo* spine mechanics and anatomy is absolutely essential for neurosurgical planning and management of complex spinal pathologies.

Curvatures of the Vertebral Column

The spinal column *in utero* has a thoracic and lumbosacral kyphosis and when the child starts raising the head post-natally, the cervical and lumbar curvatures begin to form. The adult vertebral column has a cervical and lumbar lordosis and a thoracic and lumbosacral kyphosis (Fig. 5). The thoracic and lumbosacral kyphosis are called primary curves. The lumbar lordosis develops after the upright position of the trunk is attained during growth. The shape and size of the intervertebral disc, the vertebrae and muscles contribute to the curves. The centre of gravity of the spinal column passes from the dens of C2 through the body of the vertebrae to the promontory of the sacrum. Abnormal curves may be congenital or acquired.[5,98] Iatrogenic flat back syndrome[174] is a well recognised condition where the loss of the normal curve causes severe symptoms. The altered biomechanics of spinal deformity have been elaborated on by Schlenk et al.[151] Kyphosis[92,158] is a frequent result of injury.

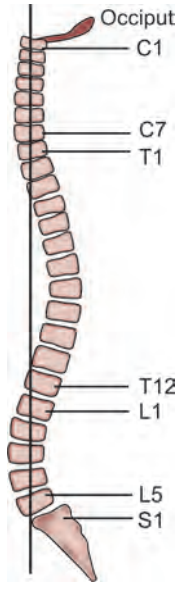

Fig. 5: Diagram showing normal curvatures of the spine

Vertebral Body

The vertebral body is a box-like structure with a central spongy and cancellous core, surrounded by a hard cortical shell and the upper and lower endplates. The endplates support the nucleus pulposus and provide points of attachment for the annulus fibrosus.[24] The cortical bone has vertical lamellae to resist axial loads.[53,126] The trabeculae of the cancellous bone also resist loads. The superior and inferior vertebral body surfaces are concave and interspersed with the fibrocartilaginous discs. Dorsally, there is an arch formed by the facet joint, pedicles, laminae and the spinous processes. The thoracic and lumbar vertebrae have transverse processes. The cervical vertebrae are smaller and cylindrical and their spinous processes are short and bifid. The transverse processes have a foramen for the vertebral artery. The pars interarticularis is also called the lateral mass. The facets from C2 to C7 are oriented at 45 degree and aligned in a coronal orientation.[119,120] Thoracic vertebrae are heart shaped and have special costal facets on the body and transverse processes and these articulate with the ribs. T1 to T4 have cervical features and T9 to T12 have lumbar features. The lumbar vertebrae are large and wider in the transverse diameter and their facets are aligned in a sagittal plane.[12,45,78] The atlas is a bony ring with two lateral masses and anterior and posterior arches. The axis has a body unlike the atlas and odontoid process at its superior anterior surface. It has two superior facets on the lateral aspects. The sacrum is a fused triangular structure. The coccyx is a terminal part of the column. The vertebral bodies and the intervertebral discs support 80% of the spinal loading and 20% is by the facet joints and the posterior elements.

Facet Joints

The cervical facet joints have a coronal orientation, the thoracic ones are of intermediate orientation and the lumbar have a sagittal orientation. The orientation of the facet joints in the lumbar area makes the lumbar spine weak to flexion and translational forces but is able to resist rotational forces.[171] The cervical spine facets do not resist flexion, extension, lateral bending and rotation and thus, the cervical spine is very mobile.[140]

Pedicles

The morphology of the cervical, dorsal and lumbar pedicles has been studied[70,78,188] because it allows for a single trajectory to stabilise all three columns via a posterior approach, using pedicular screws.[66]

Intervertebral Discs

The human vertebral column has 33 vertebrae and 23 intervertebral discs. The discs vary in size and constitute 1/3rd to 1/5th of the total height of the column. The lumbar disc is the largest avascular structure in the body and the disc consists of three zones; the outer annulus

fibrosus, the central nucleus pulposus and the intermediate transition zone. Three types of macromolecules, collagen, proteoglycans and glycoproteins constitute the disc parts.[32,44]

Annulus Fibrosus

This is a concentrically arranged outer layer of collagen fibres, fibrocartilagenous area and a transitional area. The fibres of the annulus pass obliquely from the vertebral body and are arranged in a helicoid manner. The orientation of the fibres in the adjacent layers defers by 40–70 degree and each band is oriented to the opposite direction, leading to a 120 degree difference in orientation. The inner layer of the annulus is attached to the cartilaginous end plates and the outer layer is attached directly to the vertebral bodies by Sharpey's fibres.

Nucleus Pulposus

This consists of a soft pulpy elastic mucoprotein gel. The elastin fibres are loosely and irregularly arranged. It occupies 30–50% of the cross sectional area and in the lumbar region the nucleus is located in the dorsal aspect of the disc.

Because of the complex structure of the disc, there is three-dimensional deformation which allows the disc to resist great loads.[101] The first component to fail in the functional spinal unit is the end plate. The disc also resists compression, tension, shear, bending and torsion forces. These qualities reduce significantly in an ageing and degenerated disc.[104]

The weakest component of the functional spinal unit is at the end plate and not the disc itself. The disc loses its strength as it degenerates and the effects of discectomy on the kinematics of the lumbar spine have been described by Goel et al.[49] The intervertebral disc contributes significantly to the stability of the spine.[165] Repeated micro-trauma cause intervertebral disc pressure changes and these lead to low back ache.[180,183]

Spinal Canal

The spinal canal varies in size from the craniovertebral junction to the sacrum and the dorsal canal has the smallest diameter. Congenital canal stenosis and acquired types have been described. The canal size may be reduced due to osteophytes, disc, ligamental hypertrophy or OPLL.[55] The sagittal diameter of the canal has long been recognised as an important cofactor in varied spinal cord pathologies.[176] Dynamic canal stenosis has been characterised by the Penning effect in cervical spondylotic myelopathy. Lumbar canal stenosis is the most common congenital stenosis followed by congenital cervical canal stenosis.

Ligaments

These are composed of elastin and collagen and connect the vertebrae. They may be short, connecting adjacent segments or long. They are the anterior longitudinal ligament (ALL), posterior longitudinal ligament (PLL), ligamentum flavum, interspinous ligament, intertransverse ligament, capsular ligament and supraspinous ligament (Fig. 6). The upper cervical spine and CV junction ligaments include the atlanto-occipital capsule, cruciate ligament, tectorial membrane, atlanto-axial capsule, ligamentum flavum, apical ligament, alar ligament and posterior atlanto-occipital membrane. These ligaments respond to tensile forces and their effectiveness depends on the morphology and movement arm through which it acts.

A weak ligament which has a long lever arm may provide more stability and ligaments that are away from the IAR demonstrate greater strength. Each ligament resists physiological loads differently, because of the orientation and location in relationship to the IAR of each vertebral segment.[50,100,121,138,177,178,182]

The effectiveness of each ligament is related to the strength of the ligament and also the movement arm through which the ligament acts. A weak ligament with a long lever arm provides more support to the spine than a very strong ligament with a short movement arm.

The incompetence of ligaments, either primary, due to collagen disorders or secondary, due to trauma and rarely degeneration, infection and neoplastic disorders leads to instability and may require surgical management. Spinal instrumentation and fixation changes the biomechanics and histology of the ligaments.[58,75,110,149] Conditions like Forestier's disease,[42] which cause loss of normal elasticity of the ligaments, reduce the capacity of the spine to bear physiologic loads.

Anterior Longitudinal Ligament

This begins as the anterior occipito-atlantal membrane at the occiput and ends at the sacrum. It is multilayered, with the deep layer binding to the adjacent intervertebral discs. The middle layer binds to the discs and vertebral bodies over three levels. The superficial layer extends to 4 to 5 vertebral bodies. ALL maximally resists extension loads. ALL disruption allows hyperextension.[56]

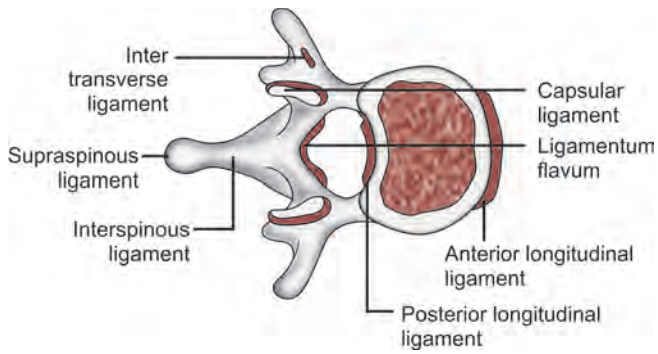

Fig. 6: Diagrammatic representation showing attachment of various ligaments to the spine

Posterior Longitudinal Ligament

This begins as the tectorial membrane and extends down to the sacrum, the fibres being spread out at the disc level and narrowing at the body level. It has several layers with the deep layers attached to adjacent bodies and superficial layer spanning several levels. PLL prevents mainly flexion and lateral bending. PLL disruption allows hyperflexion.[56]

Ligamentum Flavum

Extending from C1-C2 level to L5-S1 level, these have very high elastin content and are the most elastic tissues in the human body and are distinctively yellow. These begin from the ventral surface of the lower lamina and attach to the dorsal surface of the upper border of the superior lamina. They are absent in the mid vertebral region and have a gap at the midline. Laterally, they blend with the ligament of the joint capsule.

Capsular Ligaments

These ligaments surround the facet joints and are attached to the bone outside the synovial joint with the fibres running perpendicular to the plane of the joint. They resist lateral bending, axial rotation and flexion.

Interspinous and Supraspinous Ligaments

These attach from the base to the tip of each spinous process and begin at C2-3 and end at L5-S1 levels. The supraspinous ligaments connect the spinous processes at the tips.[25]

SPECIAL REGIONAL ANATOMY

Craniovertebral Junction

The craniovertebral junction (CVJ) is an exceedingly mobile region, especially in children. It is uniquely adapted for both stability and motion. Menezes'[95] classification of CV junction pathology into reducible and non-reducible is very useful in the management of patients. The CV junction is less stable in children, as the plane of articulation between the cranium and atlas is almost horizontal and the occipital condyles of children are not deeply seated into the fossa of the superior facet of the atlas. Hyperflexion is prevented by the contact of the basion with the anterior arch of atlas. Hyperextension and ventral translation is checked by the tectorial membrane. Lateral flexion is limited by the alar ligaments. The occipito-atlantal joints allow 15–20 degree of flexion and extension and 5–10 degree of lateral bending. The atlanto axial joint allows 47–50 degree of axial rotation, 15–20 degree of flexion and extension and 15–20 degree of lateral bending coupled with axial rotation. Head nodding occurs at the occipito-atlantal joint. Knowledge of the bony configuration, ligamentous attachments, joint articulations, vascular supply, muscle function and lymphatic drainage, as well as the kinetic anatomy of the craniocervical junction is necessary to understand the aetiology of abnormalities in this area and their treatment.[39,68,95,142,148]

Sub-Axial Cervical Spine

The cervical spine is very mobile and there are eight motion segments related to this region and all of these are coupled multi-planar movements described as range of movements (ROMs). The cervical IAR is located ventral to the vertebral bodies. The biomechanical analysis of the extensors of the cervical spine showed that the semispinalis muscle acted as a dynamic stabiliser and removal of its attachment resulted in loss of cervical lordosis.[15] Cervical spine muscles and ligaments[182] maintain the lordotic curve and without muscle support the cervical spine buckles and fails at 1/5th of the weight of the human head.

The cervical lordotic curve is important as the axial loads are dispersed dorsally into the facet joints and large articular pillars, rather than the vertebral body.[30] The greatest motion in the subaxial cervical spine occurs at C4-5 and C5-6 and the least at C2-3. The total range of motion (ROM) from C2-7 is 50 degree to greater than 90 degree with a normal Gaussian distribution and a mean of 67 degree. This decreases with age.[183] White and Panjabi[127] proposed a working classification for acute instability in which greater than 3.5 mm of anterolisthesis or more than 11 degree of angulation constitutes instability in the lower cervical spine. Disc arthroplasty retains the normal range of motion at the treated and adjacent levels.[41] Cervical axial and coronal segment specific non-linear moment angulation corridors have been evaluated by Yoganandan et al.[184] and may be used to evaluate dysfunction and instability.

Cervicodorsal Junction

This area is subject to complex biomechanics because it is between the highly mobile cervical spine and the relatively immobile thoracic spine. The spinal canal is narrow in the thoracic region and this leads to a high incidence of severe neural injuries. Surgical access can be difficult and the morphology of the dorsal pedicles and the narrow canal makes management of pathologies in this region difficult.

Thoracic Spine

The thoracic spine is well protected by the musculature and the rib cage. However, as explained above, the narrow canal in this area predisposes the spinal cord to injuries. The normal curve of the thoracic spine is kyphotic and the normal sagittal curvature of the thoracic spine is between 20 degree and 45 degree. Females have a greater degree of kyphosis. The apex of the thoracic kyphosis is at the 7th thoracic vertebra and there is a mild right sided lateral curvature. Biomechanics of the ribcage and sternum, which have a significant stiffening

effect on the thoracic spine are indispensible in studying this region.[2,88,122,123,126,165] Table 1 shows the ROMs in degrees in the thoracic spine.

Thoracolumbar Junction

The thoracolumbar junction again is a borderland between the rigid thoracic spine and the relatively mobile lumbar region and there is a change of the shape from the dorsal vertebra to the lumbar vertebra, which is large for weight bearing. The thoracolumbar epidural space was measured between T7-L4 by Reynolds et al. and they found the ventral epidural space to be 1 mm and 2 mm laterally.[144] The thoracolumbar region is commonly involved in severe spine trauma, due to its biomechanical characteristics and location.[23] The transition zone is a change from the stiff thoracic spine to a mobile lumbar spine. This zone of transition across T10 to L2 is related to the absence of the stabilising effect of the rib cage and also the change in the orientation of the facet joints.

Lumbar Spine

The lumbar spine has five vertebrae (L1-L5) and five intervertebral discs and the lumbar vertebrae have a large body and a wide canal with sagittally oriented facet joints. Lumbar facet dislocations are very rare due to the orientation of the facets and very strong ligamentous attachments.[1,138] The normal lordotic curve is 20 degree at L4-L5 and 28 degree at L5-S1. The pedicle size and morphology permits a comparatively easy placement of pedicle screws which are biomechanically superior as they are able to stabilise all three columns.[43,54,64,168] Appropriate surgical corridors and short segment fusions can be used to manage biomechanical problems in the thoracic and lumbar region.[9,10] Table 2 shows the ROMs in degrees in the lumbar spine.

Lumbosacral Junction

The integrity of the pelvic ring is dependent upon the sacroiliac, sacrotuberous and sacrospinous ligaments

Table 1: Limits and representative values of ranges of rotation of the thoracic spine

	Limits of range in degrees		
Level	*Combined Flexion and extension*	*One side Lateral bending*	*One side Axial rotation*
T1-2	3–5	5	14
T2-3	3–5	5–7	4–12
T3-4	2–5	3–7	5–11
T4-5	2–5	5–6	5–11
T5-6	3–5	5–6	5–11
T6-7	2–7	6	4–11
T7-8	3–8	3–8	4–11
T8-9	3–8	4–7	6–7

and the sacroiliac joints. Resection through the mid body of S1 retaining one-third of the sacroiliac joint is still compatible with clinical stability. Amputation of the sacrum higher than this and involvement of the sacroiliac joint require lumbopelvic stabilisation. Understanding the anatomy and biomechanics of the spinopelvic apparatus and the lumbosacral junction, as well as having a familiarity with the various techniques available for carrying out sacrectomy and pelvic ring reconstruction, will enable the neurosurgeon to effectively manage sacral tumours.[105]

SPINAL STABILITY AND INSTABILITY

Instability in an engineering sense refers to a loss in the mechanical stiffness of a structure, such that small applied loads may result in unusually large or catastrophic displacements. Another definition of instability of the vertebral column is excessive motion beyond physiological limits of one vertebra upon another in at least one of the three motion planes; X axis (flexion-extension), Y axis (rotation) and Z axis (lateral bending). The most common cause of instability is trauma. The other causes are degenerative, metabolic, neoplastic, congenital and iatrogenic.[116,131,156,163,164]

The central nervous system, an osteoligamentous system and a muscle system combine to maintain spine stability.

NEURAL CONTROL

The fine tuned multiple spinal segmental loops involving the alpha and gamma motor neurons and the proprioception system are responsible for the normal muscle tone which maintains the axial and transverse stability. Axial stability is maintained along a vertical column: this consists of two columns at the C1–C2 level and three columns from C2 to the sacrum. Transverse stability at the motion segment levels is produced by a coupling of joints and ligaments.

ROLE OF THE MUSCULATURE

Spinal column instability and injury is caused by overload. This can be due to macro-trauma or repetitive micro-trauma. Motor control is a key component in injury prevention, and muscles and their role in spinal stability are being recognised. An unexpected sudden load is likely to cause spinal column failure and, in patients with muscle and ligamental incompetence spinal instability is much more frequent.[52,139]

DEFINITION OF CLINICAL INSTABILITY OF WHITE AND PANJABI

"The loss of the ability of the spine under physiologic loads to maintain its pattern of displacement, so that there is no initial or additional neurological deficit, no major deformity, and no incapacitating pain".[127,129]

Benzel has categorised four subcategories of instability of the spine.

Acute

a. Overt acute instability
b. Limited acute instability.

Chronic

a. Glacial instability
   For example, Spondylolisthesis, trauma, tumour and infections
b. Dysfunctional segmental motion associated instability.

Current quantification of instability of the sub-axial cervical, thoracic and lumbar region based on a point system suggested previously by White and Panjabi, was modified by Benzel, so that the point system could be applied uniformly to the complete spine (Table 3). Instability also can vary in magnitude: first degree (mechanical), second degree (neurological) and third degree (mechanical and neurological).

Table 3: Benzel point system for quantification of acute instability in the sub-axial, cervical, thoracic and lumbar spine

Loss of integrity of anterior (and middle) column	2
Loss of integrity of posterior column(s)	2
Acute resting translational deformity	2
Acute resting angulation deformity	2
Acute dynamic translation deformity exaggeration	2
Acute dynamic angulation deformity exaggeration	2
Neural element injury	3
Acute disc narrowing at level of suspected pathology	1
Dangerous loading anticipated	1

A score of 5 points or more implies the presence of instability.
A score of 2 to 4 implies the presence of limited instability.
From clinical or radiographic evaluation; one point if incomplete evidence exists.
Three points for cauda equina injuries, 2 points for cord injuries and 1 for isolated root injuries

THEORY OF LOUIS

The spine bears weight principally by sustaining axial loads along the vertebral body, intervertebral disc and two facet joint complexes at each segmental level.[85]

TWO COLUMN THEORY OF HOLDSWORTH

Holdsworth[60,61] on the basis of clinical experience along with that of Nicoll[106] and the experimental work of Roaf[146] and Louis,[85] began describing stability in terms of columns.[156] In the 'two column theory', he defined the anterior column as consisting of the anterior vertebral bodies, the anterior longitudinal ligament, the disc and the posterior longitudinal ligament (Fig. 7). The posterior column consists of everything posterior to the posterior longitudinal ligament, including the capsular ligaments, the facet joints, ligamentum flavum and the interspinous and supraspinous ligaments. Holdsworth believed that the stability of the spine depended on the integrity of the dorsal ligament complex.

THREE COLUMN THEORY OF DENIS

Denis,[34,35] in 1983, described the three column theory in relation to thoracolumbar fractures and this is currently applied to the complete spine. Posterior column disruption did not lead to instability and Denis then divided the anterior column into the anterior and middle column, the anterior part of the disc, annulus and anterior longitudinal ligament, forming the middle column and the posterior disc, annulus and the posterior longitudinal ligament forming the posterior column (Fig. 8). This theory helps in evaluating bony collapse associated with axial loading and the effects of distraction, flexion and extension injuries. This was based on experimental studies that showed that when the PLL and dorsal part of the disc were transected, instability occurred and, thus, instability requires injury to at least two columns with an emphasis on preservation of the middle column for the maintenance of stability.

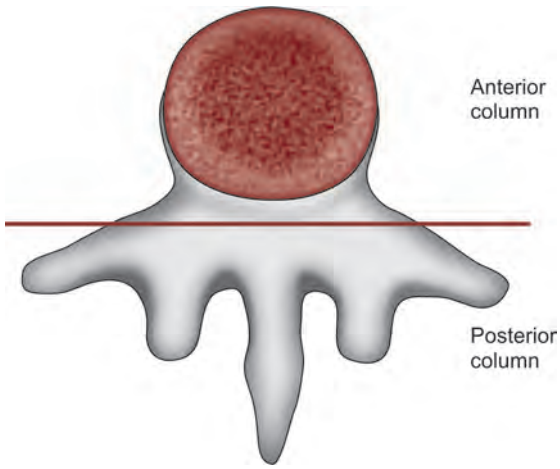

Fig. 7: Two column theory of Holdsworth

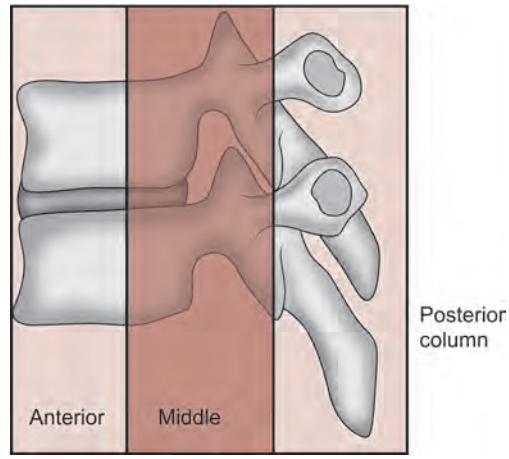

Fig. 8: Three column theory of Denis

Of the three columns, the anterior and posterior columns are the principle support structures. The anterior column resists compression and axial loading and the posterior column maintains the tension. To maintain the correct posture, all forces and movements must be balanced about the IAR. The IAR is located dorsal to the annulus fibrosis in the intact spine.

EVANS FLAGPOLE CONCEPT

The stability of the spine is not dependent solely on the integrity of the spinal column but also on the functional capabilities of the paraspinal muscles and the ligaments of the spine, which participate in the "Flagpole" concept of spinal stability (Fig. 9). Evans uses the Flagpole model to describe the biomechanical advantages of PLIF. The central graft placement represents the flag pole, with the facets, remaining annulus anteriorly and posterior ligamentous restraints representing the surrounding guy wires. This construct, according to Evans, balances both compressional and torsional forces.[40]

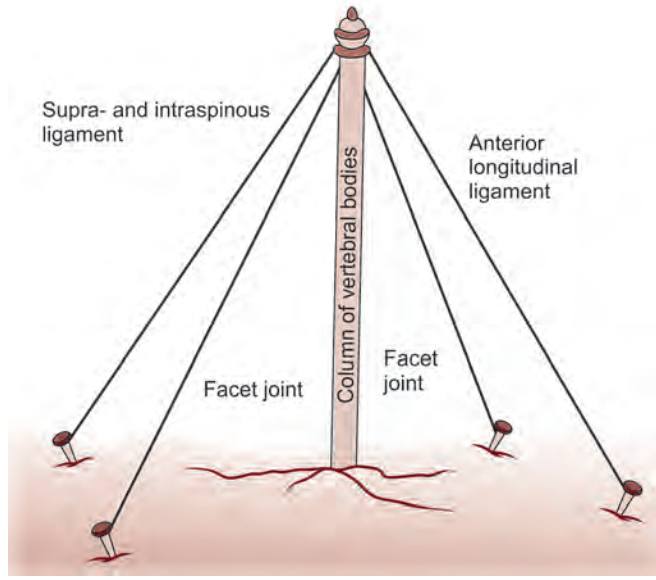

Fig. 9: Evans Fagpole concept

WHITESIDE'S CONSTRUCTION CRANE ANALOG OF THE SPINE

Kelly Whiteside,[174] in 1968, proposed that the anterior column resisted compressive forces and the posterior column resisted distraction. The equilibrium is maintained by anterior compression vectors against the posterior tension vectors. The dorsal ligamentous complex and paraspinal muscles act as a dorsal tension band. The gravitational forces exert an axial load leading to a ventral angular vector. Whiteside used the analogy of the construction crane to illustrate this mechanical principle.

BIOMECHANICS AND AXIAL TRACTION

Currently, MRI should be performed to exclude the presence of a traumatic disc before traction is applied and closed reduction is attempted. Traction is contraindicated in Hangman's type 2A fractures, where traction can worsen the translation and cause stretch injury to the spinal cord. The major liability of axial traction is the inability of being able to directly measure the distraction force in order to make sure that this force does not exceed the compliance of normal body tissue and cause traction injury. The neutral zone (NZ) is a region of intervertebral motion around the neutral posture where little resistance is offered by the passive spinal column.[26,130] The NZ appears to be a clinically important measure of spinal stability function.[187] Its size may increase with injury to the spinal column, which in turn may result in spinal instability or low-back pain.

BIOMECHANICS OF TRAUMA

Modern vehicular transport and high rise buildings have increased the incidence of severe spinal trauma. The adoption of safety features such as seat belts, airbags and helmets have been biomechanically tested and are indispensable in reducing the incidence of grievous injuries.[63,90] In the AO classification, the 'A' type injuries are axial injuries (compression and burst fractures). The 'B' injuries are the distraction injuries (flexion, distraction and chance injuries). The 'C' injuries are rotational injuries (fracture dislocation, shear injuries). The key factor is the integrity of the ligaments. The knowledge about the causative mechanism of injury may hold a key to its treatment, as exemplified by the management of locked facets by ventral reduction and fusion.[11,76,115] Bhatoe,[14] in an analysis of 89 patients, found that degenerative changes and developmental narrowing were important pre-existing factors related to the extent of the injury. Pang and Wilberger[117] reported on spinal cord injury in children without radiographic abnormalities and SCIWORA is much more common in children.

APPLIED BIOMECHANICS

Soft tissue injury, the whiplash trauma was studied by Cusik et al.[29] who found ligamentous and facet joint injuries in whole body post-mortem on human subjects, secondary to single rear impact acceleration and they were able to explain the mechanisms of headache and neck pain. These findings were also indicative that females were more susceptible to soft tissue spinal injuries. Yilmez et al.[177] in a study, found that instability increased with the number of levels of discectomy and that the excision of the PLL did not increase instability.[154]

BIOMECHANICS OF SPINE DEFORMITY

The normal curves of the spine are a major factor in maintaining the normal biomechanics of the spine. Pathological spinal deformation is usually a result of one unstable motion segment. The goals of spinal deformity surgery are reasonable correction of deformity, prevention of further deformity, restoration of sagittal and coronal balance, cosmetic optimisation and improved neurological function.[20] Scoliosis is a complex deformation that is nearly always associated with the phenomenon of coupling.[65,151,157] There is no generally accepted, scientific theory for the aetiology of idiopathic scoliosis, which is a developmental abnormality in the central nervous system creating a rib vertebra angle asymmetry.

The flat back syndrome[175] results from iatrogenic loss of lumbar lordosis with forward inclination of the trunk, inability to stand upright and back pain. The other causes are post-traumatic, neuromuscular, degenerative or infectious. The management options for spinal deformity include bracing and dorsal, ventral and combined surgical procedures.[28,57,107,175]

Biomechanically ventral reconstruction and instrumentation provides superior mechanical stability over an equal number of spinal segments to compressive loads than the dorsal instrumentation techniques.[111,112] The removal of the dorsal tension band after trauma with ventral compression leads to further neurological compromise caused by the tethering of the neural elements (bow string effect) over ventral bony components.

BIOMECHANICS OF CORD INJURY

Tator[166] described spinal cord injury and the various resulting syndromes were described by Schneider.[153]

The presence of cervical spine mobility, instability and kyphosis is strongly predictive of clinical progression in patients with cervical spondylotic myelopathy.[185,186] Deformation of the spinal cord by the presence of spondylotic transverse bars and tethering of the cord by local stenosis appear to be major factors leading to stretching of the deformed and tethered cord.[16–19,31,59,109] This shear and strain theory is supported by the concept of dynamic stenosis which was earlier studied by Penning.[137] There is a decreased cross sectional area of the spinal canal due to the dorsal bulging of the annulus as well as the infolding of the ligamentum flavum and the scaffolding of the lamina, leading to a pincer like action on the cord. Irreversible damage occurs when compression exceeds more than 30% of the initial cord diameter.[113] In 1966,

Penning, on the basis of 20 myelograms in cadavers found that in compressive spondylotic myelopathy, the cord was becoming pinched between the anterior and posterior walls of the canal. Especially in extension, the available canal diameter became smaller and the cord was getting pinched, a finding confirmed in the era of the MRI. In flexion, the cord had 1–2 mm more space but there was functional stenosis between C4-T1.[96,114]

BIOMECHANICS OF BONE GRAFTS

Sir William Macewen[86] introduced bone grafting to replace missing bone and induce new bone formation. Enhancing spinal fusion[6] has biomechanical and other components. The Wolf law postulates that the form and function of bone is a result of changes in the internal architecture, according to self ordered mathematical rules and the remodelling of bone is influenced by level and distribution of functional strain, thereby bone heals optimally under compression.[108] Dynamic implants are implants that prevent stress shielding and allow a limited and controlled type of deformation. As per White and Panjabi, the placement of a fusion mass at the maximum distance from the IAR will be more effective in preventing movement around those axes. Instrumentation without structural bone grafts generally fails and a strong structural graft is required to resist axial loading and flexion. Tricorticate illium, fibular graft and titanium cages packed with autogenous graft provide good anterior column support. Single rib graft may not provide adequate structural support, but multiple rib grafts stacked together and tied, provide excellent support and osteoinduction. The instrumentation causes stress shielding, but generally rigid fixations result in better fusion rates.

BIOMECHANICS OF SPINAL IMPLANTS

It is a rapidly expanding field and the biomechanical properties of screws, plates, wires, cages and newer disc arthroplasty and dynamic implants are tested along with the associated vertebral column. Dynamic systems, semi-rigid countoured plates and implants that are lighter and stronger and more similar to biological tissues (Titanium, carbon fibre, PEEK, ceramic and bioabsorbable implants)[147] are undergoing biomechanical testing.

Instrumentation also adds to the stability of fusion by load sharing and preventing graft extrusion and mal-alignment. Osteoporotic bone[35,53,132,160] presents unique biomechanical problems during instrumentation. Ventral cervical plating loads the graft in extension and may lead to graft pistoning and failure in multilevel constructs. The dynamic plates share loads more effectively than static plates. The lower end of the construct is more likely to fail, due to the longer moment arm and increased forces on caudal end of the construct. Comparison between anterior and posterior implants provides clinical guidelines.[27,68,133] The application of locking screws[161] to plates has greatly reduced the incidence of screw pullout. Ventral approaches to thoracic and lumbar spine have advanced because of better understanding of biomechanics and sagittal balance and permit short segment fixation. Circumferential fixation provides more stability than anterior instrumentation alone after cervical corpectomy. After corpectomy or spondylectomy, long circumferential instrumentation provides better stability than short circumferential fixation, except during axial rotation. Circumferential fixation more effectively prevents axial rotation after corpectomy than after spondylectomy.[37,134,159] In comparison to a tricortical iliac crest bone graft and a non-expandable cage, expandable cages have no biomechanical advantages. Due to the low extension and rotational stiffness, none of the implants can be recommended as a stand-alone device. Additional anterior plating increased biomechanical stability adequately.[69,73,162] Therefore, additional posterior stabilisation should only be considered in cases of severe rotational instability of the cervical spine. Threaded cages are comparable with 360 degree fusion.[143] The screw angle was the most important parameter that affected the final stiffness and the coupling behaviour. The initial stiffness was mainly afforded by the bone grip of the screw. Betz et al.[13] recommend that the anterior instrumentation should be put in place with the axis of the screws aligned as close as possible with the coronal plane and bi-cortical purchase is preferable. Biomechanical comparison of pedicular screws[63] has demonstrated that they are biomechanically more stable. A conservative construct utilising a single screw per vertebral body and a one-holed plate system appears to be strong enough to afford stability in both traumatic and non-traumatic lesions of the sub-axial cervical spine, comparable to others.[169,172]

FUTURE OF BIOMECHANICS

Fernstrom, in the 60s, implanted stainless steel spheres and began the modern era of applied biomechanics. This was followed by the AcroFlex artificial disc, the Charite artificial disc, disc nucleus replacement, posterior dynamic stabilisation systems, interspinous devices and facet joint arthroplasty.[3]

Non-fusion surgery using artificial ligament stabilisation,[67] dynamic stabilisation and the use of image guidance and dynamic imaging has become routine. Finite element method has been used in spine biomechanics research for nearly a quarter of a century and is being used to study spinal loading movements. It is also used to analyse load distributions and study mechanisms of injury.[186] These are then used to develop therapeutic interventions.[187] The micro-electro-mechanical system (MEMS) technology uses nano machines and integrates them on a chip. These are then used to measure, transmit and modify biomechanical properties and functions.[8] The combination of minimally invasive and image guided neurosurgery and restoration of normal biomechanics will lead to better outcomes in spine surgery.

49 Injuries of the Craniovertebral Junction and Upper Cervical Spine

Sarat Chandra P, Vamsi Yerramani

INTRODUCTION

The region of the craniovertebral junction includes the occipital bone and condyles, the atlas and the axis. It is different from the remainder of the cervical spine with regard to its bony anatomy, joint shape and orientation. The craniovertebral junction has a complex bony anatomy designed to protect the vital neurological structures while offering the mobility required for head movements. Given the extent of mobility in different axis, this area is very much susceptible to injuries, especially in high-velocity automobile accidents. As the injuries at this level affect the cervical cord and the brainstem, it is imperative to maintain high index of suspicion and investigate this region thoroughly. Compounding the problems is the fact that most of the injuries in this region cannot be detected on routine cervical X-rays. In general, injuries of this region can be categorised as an isolated ligamentous or bony injury or as mixed ligamentous and bony injury. The bony injuries heal well with immobilisation when the fractured segments are well apposed. In contrast, ligamentous injuries heal poorly with immobilisation alone. In this chapter we deal with the fractures involving the individual bones forming the craniovetebral junction.

SURGICAL ANATOMY

The craniocervical ligamentous structures may be divided into intrinsic and extrinsic ligaments. The extrinsic ligaments include the ligamentum nuchae, which extends from the external occipital protuberance to the posterior aspect of the atlas and all the cervical spinous processes. Fibroelastic membranes replace the anterior longitudinal ligament, intervertebral disks, and ligamentum flavum between the occiput and atlas and between the atlas and axis. The atlanto-occipital and atlantoaxial joint capsules also contribute to the extrinsic stability.

The intrinsic ligaments, located within the spinal canal, provide most of the stability for the spine. These ligaments form three layers anterior to the dura (Fig. 1). From dorsal to ventral, they include the tectorial membrane, the cruciate ligament and the odontoid ligaments. The tectorial membrane connects the posterior body of the axis to the anterior foramen magnum and is the cephalad continuation of the posterior longitudinal ligament. The cruciate ligament lies anterior to the tectorial membrane, behind the odontoid process. The transverse atlantal ligament is the strongest component, connecting the posterior odontoid to the anterior atlas arch, inserting laterally on bony tubercles. Vertical bands extend from the transverse ligament to the foramen magnum and body of the axis. The odontoid ligaments (alar and apical ligaments) are the most ventral ligamentous structures. The paired alar ligaments connect the odontoid to the occipital condyles. They measure 5–6 mm in diameter and are relatively strong, in contrast with the small apical ligament that runs vertically between the odontoid and foramen magnum.

The range of motion between the occiput and atlas is 25 degree in flexion-extension, 5 degree to each side in lateral bending, and 5 degree to each side in rotation. The range of motion between the atlas and axis is 20 degree in flexion-extension, 5 degree in lateral bending, and 40 degree in rotation. The major stabilising structures between the occiput and upper cervical spine are

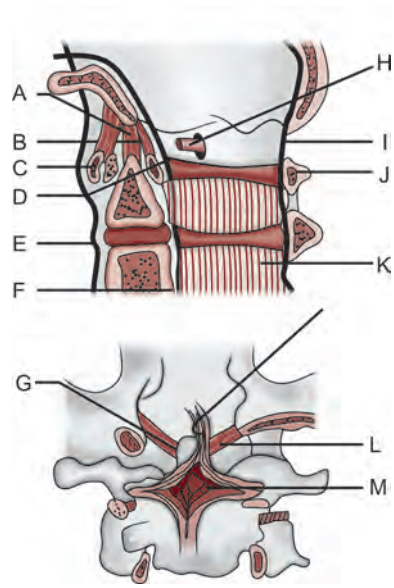

Fig. 1: Schematic diagram of the anatomical structures constituting the craniovertebral junction: (A) Apical ligament of dens. (B) Superior longitudinal band of cruciate ligament. the tectorial membrane and alar ligaments. Flexion is limited by the bony anatomy, while extension is limited by the tectorial membrane. Rotation and lateral bending are restricted by the contralateral alar ligaments. Distraction greater than 2 mm is prevented by the tectorial membrane and alar ligaments. Translation should not exceed 1 mm and is limited by the facet joints, when there are an intact tectorial membrane and alar ligaments.[11,44,46]

CLINICAL FEATURES

Craniovertebral junction and upper cervical spine injuries can result from various traumatic events. Motor vehicle accidents are the most frequent cause; however, falls, diving accidents and gunshot wounds are also common mechanisms. In addition, individuals may be predisposed to severe spine injury due to underlying congenital or developmental abnormalities, arthritic conditions or tumours.

Patients with an upper cervical injury may have an associated head injury, which can alter their level of consciousness and complicate obtaining an accurate history and physical examination. Consequently, all patients who sustain significant polytrauma and/or head trauma should be thoroughly screened for cervical spine injuries.

In history, it is important to find out the mechanism of injury (including potential forces imparted by the injury), whether the patient was restrained, and whether transient motor or sensory deficits occurred at the scene of the accident. Awake patients will often complain of neck pain or headache. Advanced Trauma Life Support procedures to maintain the airway, breathing and resuscitation should be the first priority. A careful, complete physical examination of the entire spine should follow—inspection, palpation and neurologic evaluation while the head and neck are stabilised in neutral alignment. Neurologic examination should include testing of the cranial nerves as well as motor function, sensory perception and reflexes in the extremities. Results of neurologic examination may range from normal sensorimotor functions to variable sensorimotor impairment, including incomplete to complete spinal cord injury. Cranial nerve injury—including of nerves VI, VII, IX, XI and XII—may result from upper cervical injuries and should not be overlooked.

The screening radiography should include anteroposterior (AP), lateral and open-mouth views. If detailed radiography is not possible, then even a good quality lateral view is sufficient in a patient without suspected injury, yet the examination should include an open-mouth view whenever upper cervical spine injury is suspected. The lateral radiograph should visualise the entire cervical spine from the base of the skull to T1.

With a normal atlanto-occipital relationship, the clivus on lateral radiograph should point towards the tip of the odontoid, and the basion (tip of the clivus) should be within 5 mm of the odontoid vertically. Retropharyngeal soft-tissue swelling greater than 5 mm at C3 is abnormal and should raise suspicion for the presence of an anterior arch fracture of the atlas. A diastasis greater than 2 mm between the occiput and atlas is also abnormal. Harris et al.[27] described the rule of 12, which is superior to the Powers ratio for identifying occipitocervical dissociation. The rule of 12 uses three landmarks:

- The basion
- The rostral tip of the odontoid
- The rostral extension of the posterior cortical margin of the axis (posterior axial line)

The basion-axial interval is the distance between the basion and the posterior axial line; the basion-dental interval is the distance between the basion and the tip of the odontoid. The method is applicable to adults and to children older than 13 years. Both intervals should be less than 12 mm in normal individuals (Fig. 2).

An open-mouth radiograph allows visualisation of the atlas, odontoid process and lateral masses of the axis. Although the lateral masses of the atlas normally articulate symmetrically with the axis, asymmetry between the dens and the lateral masses of the atlas is not always indicative of injury.

Careful follow-up is necessary in patients with initial cervical muscle spasm because the spasm may mask instability in the acute setting. Computerised tomography (CT) is a very sensitive method for evaluating craniocervical relationships and is the preferred method of investigation for evaluating most suspected injuries in the upper cervical spine. Properly oriented thin slices are necessary in the CT scan for proper visualisation of fractures. Magnetic resonance tomography (MRI) is

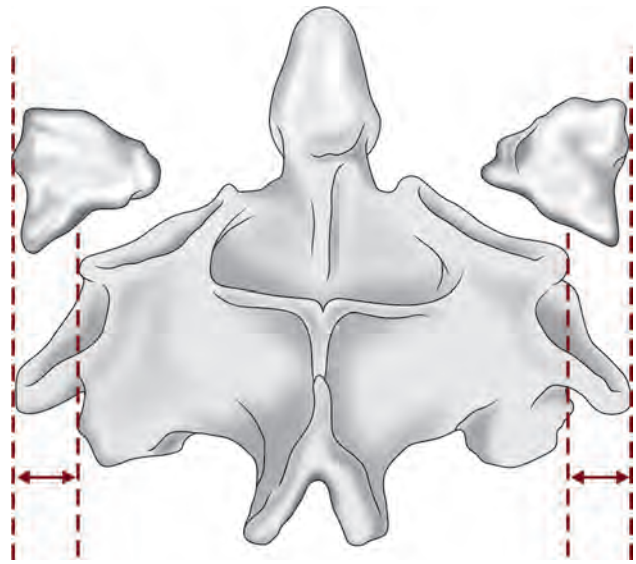

Fig. 2: Occipitocervical dissociation. The upper cross shows the basion and the lower cross the odontoid process. The distance between them is the basion-dental interval. The thick line represents the posterior axial line drawn posterior to the odontoid process and C2 body. The distance between it and the basion (upper cross) is the basion-axial interval. Both distances are >12 mm and clearly abnormal

useful in patients with neural deficit or with suspected ligamentous injury (especially the transverse atlantal ligament).[31]

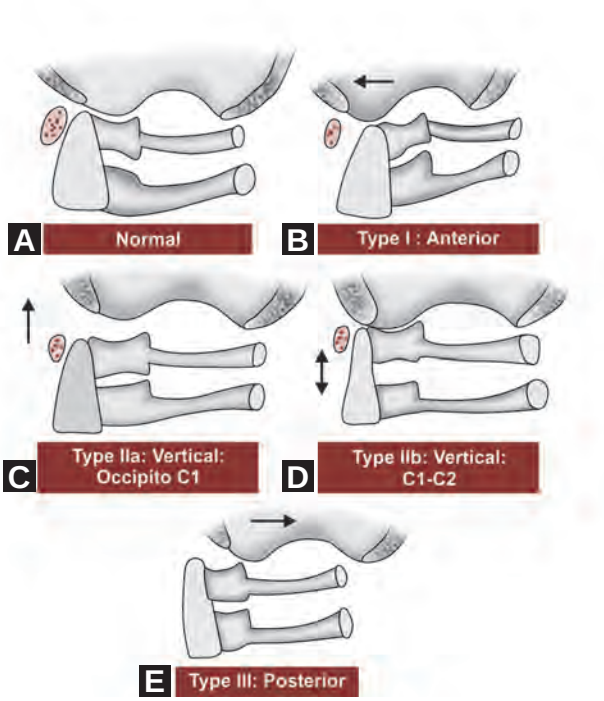
OCCIPITOCERVICAL DISSOCIATION

Occipitocervical ligamentous injuries have a high mortality rate and often do not reach the hospital. In autopsy studies, they represent 5–12% of identified cervical injuries; the most common mechanism is pedestrians struck by motor vehicles.[5,7,10] Prompt recognition, high index of suspicion and immobilisation are essential. Children are predisposed to these injuries because of their inherent ligamentous laxity; immature occipitocervical joints; and larger ratio of head to body size than in adults.

OCCIPITOCERVICAL INSTABILITY

This injury may occur due to several different mechanisms and can be classified according to the direction of occipital displacement[20] (Figs 3A to E):

1. Type I injuries are most common and have anterior occipital displacement
2. Type II injuries have vertical displacement greater than 2 mm between the occiput and C1 (Type IIA). Vertical instability also can occur at C1-2 (Type IIB) because the same ligamentous structures, the tectorial membrane and alar ligaments, resist distractive forces at both levels
3. Type III injuries are rare and have posterior occipital displacement.



Figs 3A to E: Schematic diagram showing various types of occipitocervical instabilities. (A) Normal relationship of occiput, C1 and C2 bodies. (B) Type I: anterior—the occiput has translated anteriorly. (C) Type IIa: vertical—vertical occipito C1 distraction. (D) Type IIb: vertical—vertical C1-C2 distraction. (E) Type III: posterior—posterior dislocation of occiput in relation to the C1

Early diagnosis and treatment are critical because patients are at high risk for neurologic injury or even sudden death. Once occipitocervical instability has been diagnosed, reduction of displacement should be performed carefully under fluoroscopic guidance by carefully positioning the head with a bolster behind the thorax (for anterior displacement) or the occiput (for posterior displacement). "Traction and collar immobilisation can precipitate axial displacement, precipitating neurologic injury and accordingly should be avoided". For vertical displacement, reduction can be performed by providing gentle downward pressure or by elevating the head of the bed. A halo vest can provide temporary immobilisation, but surgical stabilisation is necessary. Occipitocervical fixation and arthrodesis, using plates with C2 fixation obtained with C1-2 transarticular screws or C2 pedicle screws is preferable to wire and graft techniques. Fixation with plates and screws removes the need for a post-operative halo vest and more accurately maintains reduction.

CONDYLAR FRACTURES

Occipital condyle fractures are commonly caused by an axial compression mechanism and are frequently diagnosed as a concurrent finding on head CT scan done for trauma. The classification system described by Anderson and Montesano[1,3,6] was based on CT pattern and evaluates the potential for instability.

A type I injury is a comminuted (impaction) fracture of the condyle and is generally stable. A type II fracture is a condyle fracture with associated basilar skull fracture. This injury is stable except when the entire condyle is separated from the occiput. A type III injury is an avulsion fracture of the attachment of the alar ligaments. This injury can be bilateral and occurs in 30–50% of patients with atlanto-occipital dislocations. Stable type I and II fractures should be treated in a collar for 6–8 weeks. Displaced type II injuries should be treated in a halo vest for 8–12 weeks. Type III injuries are treated based on stability; stable undisplaced injuries are treated using a collar with a chin support, and minimally displaced injuries are treated in a halo vest. Any evidence of AP displacement, joint incongruity, or abnormal diastasis makes the injury unstable, necessitating an occiput-C2 fusion.

ATLAS FRACTURES

The atlas acts as a transitional structure between the occiput and cervical spine. In various adult series, fractures of the C1 vertebra have accounted for 25% of craniocervical injuries, 3–13% of cervical spine injuries, and 1.3–2% of all spinal injuries.[11,27,44,46] The most common causes are motor vehicle accidents and falls. The most common mechanism is axial loading. Atlas fractures are commonly associated with other injuries of the cervical

spine. Axis fractures are associated with 40–44% of atlas fractures.[21,24,25,30,41] Isolated fractures of the anterior or posterior arches are the commonest with isolated burst fractures next in line. Other associated injuries include subluxation, rupture of the transverse ligament, non-contiguous cervical spine fractures and closed head injuries.

Classification of Atlas Fractures

Sir Geoffrey Jefferson, a British neurosurgeon, presented a series of 42 patients with atlas fractures in addition to four of his own patients with the injury[28] (Fig. 4).

Type I fractures involve the posterior arch alone.

Type II fractures involve the anterior arch alone.

Type III fractures are bilateral posterior arch fractures associated with a unilateral or bilateral anterior arch fracture.

Type IV fractures involve the lateral mass.

Type V fractures are transverse fractures of the anterior arch.

The classic Jefferson fracture is the burst type III fracture associated with lateral displacement of the lateral masses. Based on Jefferson's classification, the most common fracture types seen in various clinical series are type I followed by type III.

The transverse ligament plays a crucial role in determining atlantoaxial stability.[15] Atlas fractures have often been defined as stable or unstable based on the inferred integrity of the transverse ligament. According to the Spence[43] rule, if the sum of the displacement of lateral masses exceeds 6.9 mm after an atlas burst fracture, the transverse ligament is probably torn (Fig. 5).

Clinical Presentation

Patients with upper cervical spine fractures frequently present with neck pain, spasms of the cervical muscles and limited neck motion.[44] Neuralgia and paraesthesias related to compression of or injury to the C2 nerve are common. Retropharyngeal swelling may cause difficulty in swallowing. Dissecting injuries of the vertebral artery and neuropathies of the lower cranial nerves are some of the uncommon presentations. Isolated burst fractures of the atlas usually are not associated with neurological deficits as they cause the spinal canal to expand.

Diagnosis

To evaluate atlas fractures using plain X-rays, it is essential to obtain open-mouth odontoid, lateral and

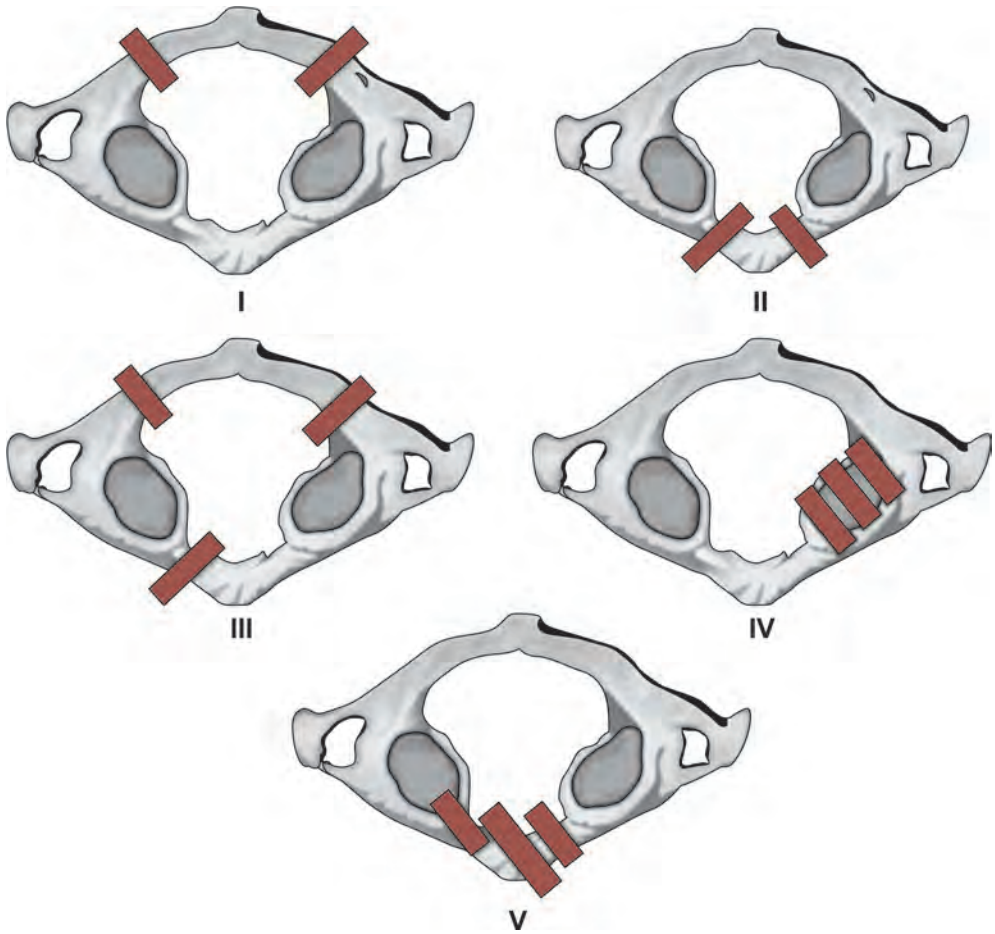


Fig. 4: Jefferson's classification for atlas

Fig. 5: Assessing for transverse atlantal ligament injury on an open-mouth view of C1-2. The sum total of lateral displacement equals a + b. When the total displacement is >6.9 mm, rupture of the transverse ligament is confirmed. (Adapted from Anderson PA. Injuries to the occipital cervical articulation. In: Clark CR, Dvorak J, Ducker TB (Eds). The Cervical Spine, 3rd edition. Philadelphia, PA: Lippincott-Raven; 1998. p. 411.)

Fig. 6: The following roentgenogram shows the criteria for atlanto-axial instability: (1) Atlantodental interval (ADI) >3 mm (5 mm in children). (2) Posterior atlantodental interval (PADI) <13 mm (measured as the distance between posterior border of the dens and the C1 arch. (3) Unilateral axial rotation >45 degrees. (4) Lateral mass overhang >7 mm. Criteria 3 and 4 are better made out on anteroposterior views

flexion-extension views. An open-mouth odontoid view will show overlapping of the C1 and C2 facets. Any displacement of the C1 lateral mass over C2 facets is suggestive of an atlas burst fracture. In a normal variant (pseudo-spread of the atlas) in children younger than 7 years old, the ossified lateral masses of the atlas may project beyond the ossified articular processes of C2, giving a false sign of a Jefferson fracture in children.

In lateral views, an atlantodental interval (ADI) greater than 3 mm in adults and greater than 5 mm in children is highly suggestive of a ruptured transverse ligament. The MRI is the modality of choice for assessing the transverse ligament integrity.[12] Posterior atlanto dental interval (PADI) is measured from the posterior border of the dens to the anterior border of the posterior tubercle. This index may be more important because it more directly assesses the space available to the spinal cord. The degree of neurologic deficits has been demonstrated to correlate with the PADI. A PADI of less than 13 mm is considered significant (Fig. 6). Posterior arch fractures can be assessed on lateral or 60 degrees oblique X-rays. Anterior arch fractures are often difficult to diagnose from plain X-rays. To rule out pseudo-spread of the atlas, thin-slice CT with cuts parallel to the C1 arch is the optimal imaging modality and is recommended for all children suspected of harbouring a Jefferson fracture.

Treatment and Results

Treatment of atlas fractures depends on whether they occur in isolation or in conjunction with other cervical spine fractures. Treatment recommendations are based on several case series (class III evidence), which are summarised below:

- Isolated atlas fractures can be treated by external immobilisation of the craniocervical junction for 8–12 weeks
- Late instability must be ruled out by using dynamic imaging studies such as flexion-extension X-rays
- Instability persisting after external immobilisation should be treated by an occiput–C2 fusion or a C1-C2 fusion, whatever suits the given case
- There are no established standards or guidelines for the treatment of combined C1-C2 fractures. The treatment strategy is based on the nature of the C2 fracture and the integrity of the transverse ligament.
- Presence of an occipitoatlantal dislocation warrants occipitocervical fusion.

RUPTURE OF TRANSVERSE LIGAMENT

Rupture of the transverse atlantal ligament is generally caused by a flexion force and often affects not only the transverse ligament but also the alar and apical ligaments. With an intact ligament, the maximal ADI is 3 mm in an adult and 5 mm in a child. Experimentally produced transverse ligament insufficiency with intact alar and apical ligaments results in a maximal translation of 5 mm, as shown by Fielding et al.[16] Displacement greater than 7 mm was associated with loss of integrity of the alar ligament and tectorial membrane. Complete ligamentous disruption can be accompanied by a significant incidence of neurologic injury. In addition, headache, nausea, visual abnormalities and sensorimotor deficits may result from vertebral artery compression.

Disruption may occur in isolation or in association with other upper cervical injuries. Using thin-section CT or MRI Dickman et al.[12] classified disruptions of the mid substance of the ligament as type I injuries and avulsions of the ligament from the C1 lateral mass as type II injuries.

Treatment depends on the degree of initial displacement and identification of any coexistent fractures. If the ADI is less than or equal to 5 mm in a neurologically

intact patient, collar immobilisation is sufficient initially. For an ADI greater than 5 mm, non-surgical treatment including halo immobilisation has generally yielded poor results except in selected cases when a bony avulsion can be documented on CT. The method used for C1-C2 arthrodesis in patients with this injury needs to be carefully selected; some wire techniques, even with halo immobilisation can result in post-operative displacement. C1-C2 transarticular screw fixation for arthrodesis may be indicated.

ODONTOID FRACTURES

The first description of the surgical management of an odontoid fracture was in 1910 and is credited to Mixter and Osgood.[36] Odontoid fractures constitute 8–18% of all cervical fractures, with neurologic deficits occurring in 10–20% of cases.[13,37,38] They represent 75% of childhood cervical spine fractures as a result of the large ratio of head to body size. High-velocity trauma, such as motor vehicle accidents, accounts for most of these injuries in young adults, while low-velocity injuries, such as falls, account for the majority of injuries in the elderly and children.

The classification system of Anderson and D'Alonzo[2] is based on the anatomic level of the fracture, which has been shown to have a correlation to prognosis for fracture healing (Fig. 7).

Type I fractures occur at the tip of the odontoid process cephalad to the transverse atlantal ligament. They are the least common odontoid injury and generally are stable. They may also represent an avulsion of the alar ligaments, which can occur in atlanto-occipital distraction injuries.

Type II fractures occur at the junction of the base of the odontoid and body of the axis. They are the most common fracture type and are least likely to heal with non-surgical treatment and are unstable. These fractures were subdivided into three types by Hadley et al:[23]

- Type IIA: The fracture line is transverse and with less than 1.0 mm of displacement. Both surgery and external immobilisation have good success rates. The treatment strategy has to be decided based on the individual merits of the case
- Type IIB: The fracture line is from antero-superior to postero-inferior or a transverse fracture with displacement greater than 1.0 mm. Surgical fixation is the treatment of choice
- Type IIC: The fracture line passes from antero-inferior to postero-superior or a fracture with significant comminuted segments of the dens. This subtype is best treated with posterior atlantoaxial fixation. The fractured odontoid process may be displaced anteriorly or posteriorly relative to the body of C2. Odontoid screw placement in these fractures is technically difficult and also the non-union rates are high. Posterior fixation is a good option in this group of patients

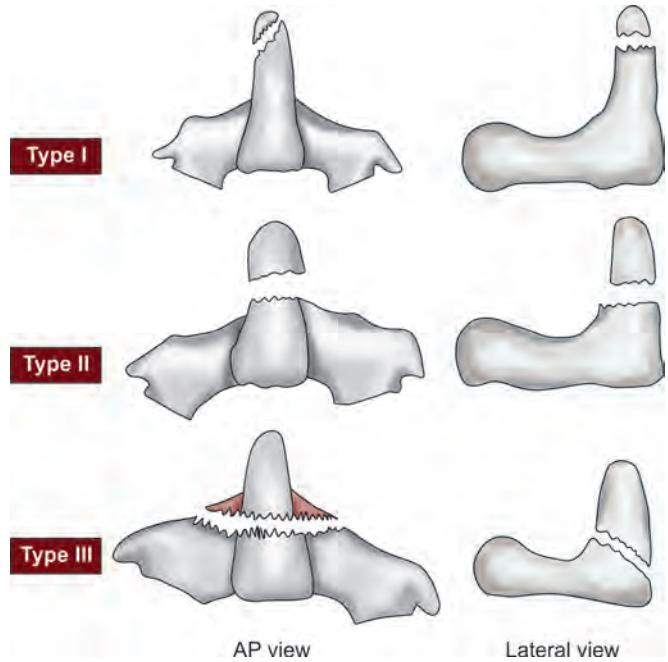

Fig. 7: Classification of dens fractures

Type III fractures extend into the body of the axis. They may be more stable than type II fractures and have a higher union rate with non-surgical treatment.

Treatment

There have been many treatment strategies proposed for odontoid fractures. These strategies are based on fracture type, the degree of initial dens displacement, the angle of the fracture line with respect to the body of the axis, the integrity of the transverse ligament and the age of the patient. Treatment options include both non-operative and surgical strategies. There are several external immobilisation orthoses available for non-operative management of odontoid fractures, each with variable results. Surgical options include both anterior and posterior approaches. Anterior approaches include odontoid screw fixation and a rarely used salvage technique of anterior transarticular screw fixation. Posterior arthrodesis approaches include the use of wiring techniques, Halifax clamps, screw and rod constructs, and posterior transarticular screw fixation.

Julien et al.[29] performed an evidence-based analysis of the literature to evaluate the management of odontoid fractures. Halo/Minerva fixation or cervical traction followed by immobilisation in a rigid cervical collar resulted in fusion of all type I odontoid fractures and 84–88% of type III fractures. Cervical traction followed by immobilisation is not the most effective treatment of type II odontoid fractures. They reported that treatment of type II fractures with cervical traction/cervical collar resulted in a fusion rate of only 57%. Management with a halo-type orthosis has a variable non-union rate from

7% to 100%. Hence, it is clear from this study that while type I fracture may be treated conservatively, type II has to be always treated surgically. Both surgery and medical treatment have been shown to be effective for type III fractures, hence either option is suitable.

TRAUMATIC SPONDYLOLISTHESIS (HANGMAN'S FRACTURE)

Traumatic spondylolisthesis of the axis most often occurs as a result of either motor vehicle accidents or falls and represents approximately 15% of all cervical spine fractures. Although the fracture pattern may resemble that resulting from judicial hanging, the injuries are quite different. A properly accomplished judicial hanging results in a violent hyperextension injury to the spine with distraction, severing the spinal cord. Traumatic spondylolisthesis, however, results from hyperextension with axial load. Neurologic injury is uncommon because the fracture fragments separate, decompressing the spinal canal.[32]

The hyperextension and axial load mechanisms result in fractures of the pars interarticularis. With increasing severity of injury, the rebound flexion or flexion/distraction mechanism results in disruption of the C2-3 disc and posterior longitudinal ligament. Additionally, the anterior longitudinal ligament may be stripped from its bony attachment. The most severe and complex injuries most likely occur as a result of flexion, causing dislocation of the C2-3 facets, followed by hyperextension with axial load, producing the pars fractures secondarily.

The classification system for this injury was first described by Effendi et al.[17,32,33,40] in 1981 and was later expanded by Levine and Edwards,[32] who described four fracture patterns. Others have added a fifth type[17] (Fig. 8). The classification is based on translation and angulation between C2 and C3. Type I injuries are bilateral pars fractures with translation less than 3 mm and no angulation. The C2-3 disc and ligamentous structures remain intact because the major injury is bony.

Type IA is an atypical fracture and the most recently recognised. There is minimal translation and little or no angulation. Elongation of the C2 body is often seen radiographically. The CT will reveal extension of one fracture line into the body and often through the foramen transversarium. As a result, injury of the vertebral artery may occur.

In Type II fractures, the C2-3 disc and posterior longitudinal ligament are disrupted, resulting in translation greater than 3 mm and marked angulation. The anterior longitudinal ligament generally remains intact, but is stripped from its bony attachment.

Type IIA fractures are less common. In contrast with type II, the fracture line is more oblique than vertical. There is little or no translation, but there is significant angulation. Traction will cause further fracture displacement and should be avoided.

Type III injuries are a combination of pars fracture with dislocation of the C2-3 facet joints. This injury is very unstable with free-floating inferior articular processes. This is the most common injury to be associated with neurologic deficit and requires surgery; it is irreducible by closed means.

Type I and IA fractures can be treated by collar immobilisation, both initially and definitively. Type II and IIA fractures require gentle reduction. Type II fractures require light traction and extension by placing a bolster behind the shoulders to achieve reduction. Type IIA fractures require extension and gentle axial load to achieve reduction. Type III fractures are irreducible because the dislocated inferior facets of C2 are not connected to any other bony structure as a result of the bipedicular fracture lying just anterior to them. Closed traction is, therefore, unable to provide reduction and open reduction is required.

Once reduction is verified radiographically, type II fractures are immobilised in a halo vest for 6–8 weeks. Adjustment of the halo may be performed as necessary while monitoring fracture alignment. For type II fractures with displacement greater than 5 mm and/or angulation greater than 10 degree, traction is performed to reduce the displacement, followed by halo immobilisation for an additional 6–8 weeks. Alternatively, surgical stabilisation with transpedicular lags crews may be considered if anatomic alignment can be achieved. Because spontaneous anterior fusion is common, non-surgical

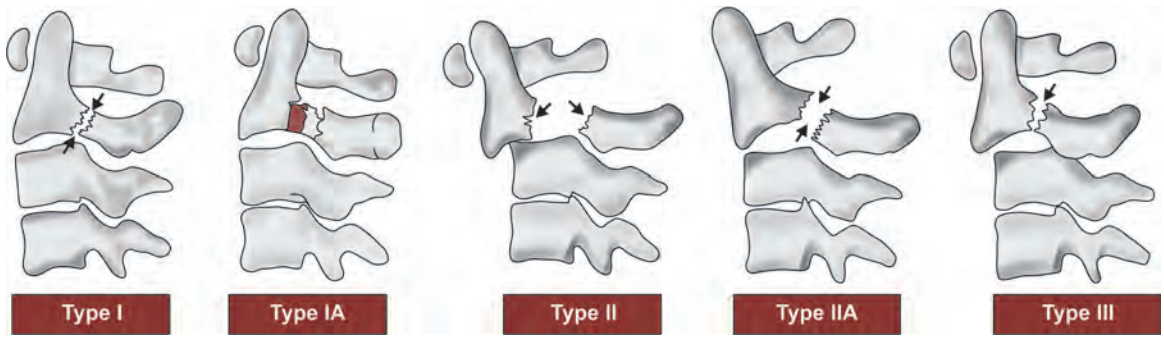

Fig. 8: Classification of traumatic spondylolisthesis (Adapted from Levine AM, Edwards CC. The management of traumatic spondylolisthesis of the axis. J Bone Joint Surg Am. 1985;67:217–26)

management is favoured with type II injuries. Type III fractures require open reduction followed by internal fixation with a wiring or plating technique, based on the integrity of the facets and/or lamina. Anterior C2-C3 plating also has been used.

Although no long-term studies exist, Levine and Edwards[32] reported on 52 patients with a 4.5-year follow-up. Ninety percent of type I fractures healed; 10% had symptomatic degenerative changes; 70% of type II fractures developed spontaneous anterior fusion. Type III fractures generally had a poor prognosis related to the resultant neurologic deficit. Francis et al.[17] reported on 123 patients with traumatic spondylolisthesis of the axis, who had a 94.5% union rate regardless of initial displacement or angulation. Seventy two percent were treated with traction and halo immobilisation, with a 5% non-union rate. Duration of traction did not influence fracture healing because 47% were treated with less than 2 weeks of traction, with only one non-union. Alternatively, more recently, surgical treatment is the preferred option[8,9,14] as it has a low-risk and up to 98% fusion rates with transpedicular screw fixation.

OPTIONS OF SURGICAL PROCEDURES FOR CRANIOVERTEBRAL JUNCTION TRAUMA

Posterior Fusion Techniques

Historically, posterior cervical fusion (Figs 9A to L) was the primary operative alternative when external immobilisation failed or was considered unsuitable.

Wiring Techniques

Over time, wiring techniques have evolved to the use of braided cables instead of monofilament wire. Braided cables have the advantage of being flexible, strong, and resistant to distortion and fatigue. Braided cables also are not susceptible to over twisting because a crimping mechanism is used to securely lock and fix the construct. Braided cables, however, can cut through bone via a Gigli saw-type action. Therefore, it is recommended that crimping not exceed a torque of 8–12 in-lb of force for normal healthy lamina and 6–8 in-lb for osteoporotic bone (Fig. 9A).

Gallie's Technique

Gallie[18] described his method of C1-C2 arthrodesis in 1939. A superior notch in the spinous process of C2 holds the H-shaped on-lay graft more securely in place, and the graft is secured with a wire that is only sublaminar at C1. The drawback of his technique is that it is a solitary, midline fixation and fusion construct susceptible to rotational forces.

Brooks' and Jenkin's Technique

It involves two wedge bone grafts secured between C1 and C2 with sublaminar wiring. They designed it to overcome the rotational deficiencies of the Gallie method.

Dickman and Sonntag

Dickman and Sonntag described an atlantoaxial arthrodesis secured with a sublaminar wire at C1 that incorporated an iliac crest strut-graft between the posterior arches of C1 and C2 secured with wire around the base of the spinous process of the axis.

Interlaminar Clamps

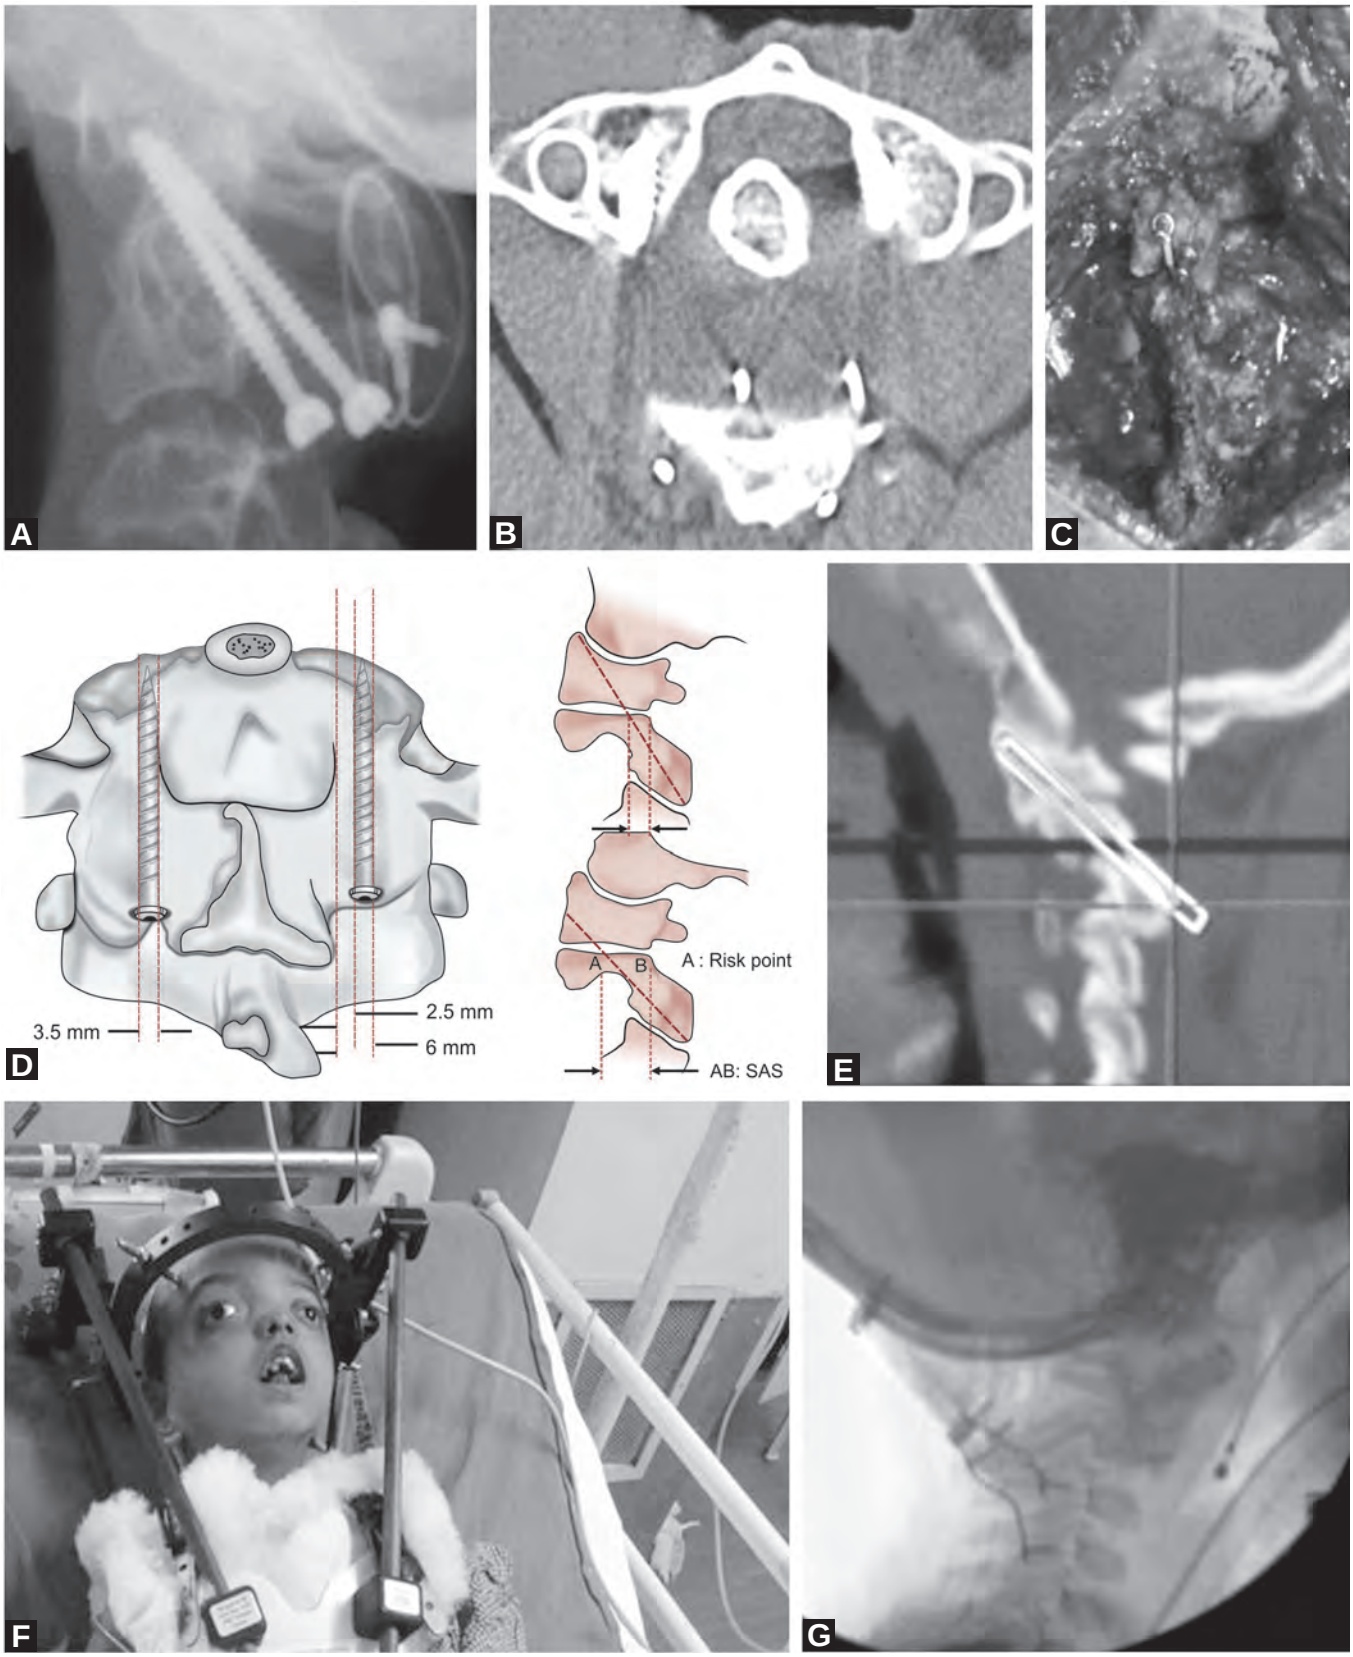
Halifax clamps were initially described by Tucker[45] in 1975. Several problems were observed with these clamps, and they ultimately fell out of favour. One problem was that in tightening the clamps, the odontoid could be angulated dorsally, causing ventral encroachment upon the spinal cord. There were several other problems reported. The superior clamp sometimes did not mate well with the C1 lamina. The screws and, therefore, clamps became loose with time. A large C2 spinous process makes vertical alignment of the clamps difficult, causing suboptimal interface of the clamp with the C1 lamina. Any one of these problems could cause the clamps to disengage.

Jeanneret and Magerl Transarticular Screw Technique

Transarticular screw fixation of C1 and C2 was first described by Magerl and Seeman.[34] The entry point on C2 is 2 mm lateral from the medial edge of the facet and 3 mm superior to the caudal edge. The trajectory is straight up across the C1 and C2 articular surfaces and into the lateral mass of C1. The drill is aimed at the superior portion of the C1 anterior arch. Transarticular screws offer good biomechanical stability in all directions of motion compared to the wiring techniques. Bone fusion rates range between 98% and 100%. When the anatomy is favourable, this is the preferred method of posterior fixation. Transarticular screws combined with C1-C2 wiring techniques have achieved 100% fusion rates. Posterior fusion may be preferred in patients who have a comminuted type II or III fracture or an associated unstable Jefferson fracture. C1-2 joint fusion eliminates 50% of the rotation of the head, a significant loss of motion. Consequently, a technique for treating odontoid fractures, anterior odontoid screw fixation, has been developed to preserve the normal motion of the C1-2 joint.

Goel and Laheri/Harms and Melcher Fixation

The use of lateral mass screws in C1 and pedicle screws in C2 with plate fixation was first described by Goel and Laheri[19] in 1994 and later with polyaxial screws and rods in 2001 by Harms and Melcher.[26] A point of difference between the two methods is that Goel and Laheri described distraction of the C1-C2 joint space with spacers. Resnick and Benzel[39] described a C1-C2 fixation method similar to the Harms and Melcher method using C1 and C2 pedicle screws. This method of atlantoaxial fixation is the procedure of choice for



Figs 9A to G: Posterior procedures for craniovertebral complex. (A) C2-C1 transarticular screws (Magrel's) with braided titanium wiring. (L) Schematic diagram showing the entry point for cervical (C3-C6) lateral mass screws

patients with C1-C2 fixed (irreducible) subluxation or an aberrant vertebral artery that may make transarticular screws difficult and/or dangerous.

Crossed C2 Intralaminar Screws

In 2004 Wright[47] described the most recent technique for screw fixation of the axis. This technique involves the use of polyaxial screws inserted into the lamina of C2 in a bilateral crossing fashion.

Occipitocervical Lateral Mass Polyaxial Rod and Screw Placement

This technique has become very widely accepted due to rigid long segment immobilisation and distraction forces provided, along with the ease, safety and strength of the lateral mass screws. Lateral mass screws are available as 12, 14 and 16 mm polyaxial screws of diameter 3.5 mm. They are placed about 1 mm medial to the centre of the lateral mass (C3-C6) and directed lateral and superiorly at an angle of 25 degree. However, before performing the procedure, it is essential that the adequacy of the lateral mass of the cervical vertebrae is confirmed on CT scan bone windows.[4,35,42]

If all the techniques are compared, Magrel's (C2-C1 transarticular) provides maximum strength against axial rotation, followed by Brook's, Halifax, the least being Gallie's technique.[22] Likewise, if other movements like flexion, extension and lateral bending are assessed, Brooks has the most stability followed by Magrel's, Halifax and again least by Gallie's procedure. Not surprisingly, bone fusion is least for Gallie's (60–80%) and Magrel's has the highest incidence of bone fusion (95–100%).

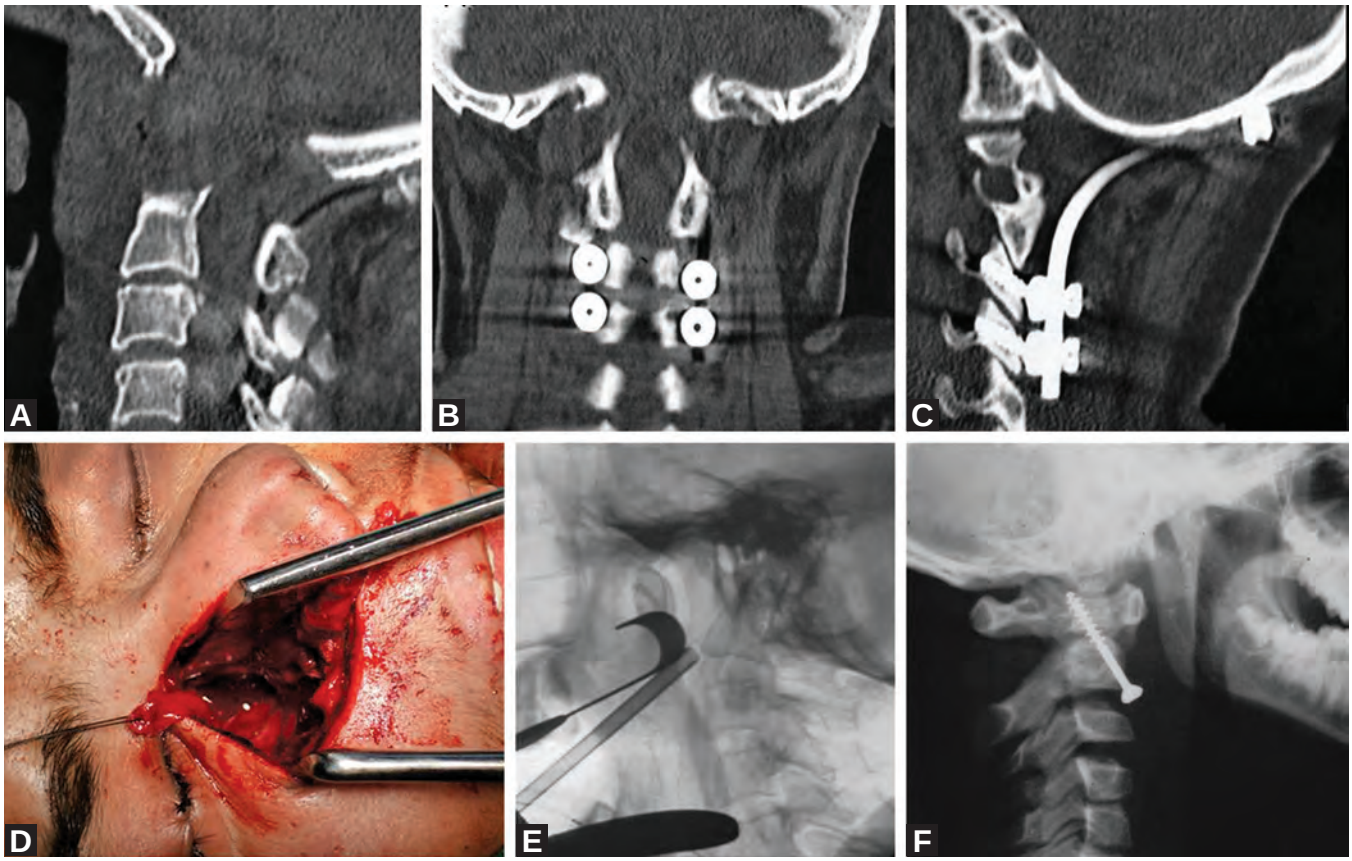
Anterior Fusion Techniques

Anterior fusion can be performed by techniques (Figs 10A to F) as mentioned below.

Odontoid Screw Fixation

There occurs a reduction of 47 degree of axial rotation and a reduction of 10 degree of flexion and extension after posterior atlantoaxial internal fixation and fusion. Odontoid screw fixation allows the surgeon to directly reduce and fixate the fracture itself, while maintaining atlantoaxial rotational mobility. Disruption of the transverse ligament is an absolute contraindication to odontoid screw fixation. Displacement more than 6 mm, age greater than 50 years, fractures more than 6 months old and poor patient habits are associated with high rates of non-union.

The issue of whether to place one or two odontoid screws is controversial. Two-screw constructs have been



Figs 10A to F: Anterior procedures for the craniovertebral junction. (A) Transoral odontoid excision indicated for old odontoid fractures type III fractures with impingement on the cord. (B and C) Transoral odontoid excision should be followed by a long segment posterior fixation, e.g. occipitocervical lateral mass fixation. (D and E) Extended approaches for transoral odontoid excision are rarely required unless the dens is placed quite high up, e.g. in fracture clivus. (F) Odontoid screw fixation is indicated in type II and some type III fractures

advocated to prevent an axis of rotation around a single screw. In some patients, however, the odontoid process is not large enough to accommodate two screws.

Anterior Atlantoaxial Facet Screw Fixation

This is a rarely used technique described by Feiz-Erfan et al.[14] for failed posterior atlantoaxial fusion or for C1-C2 instability with destruction of the posterior elements of C1 and C2. The approach for this procedure is the same as that for odontoid screw fixation. The C1-C2 joint is identified bilaterally, and screws are placed in the anterior cortex of C2 and through the C1-C2 joint space at a 90-degree angle.

SUMMARY

Injuries of the upper cervical spine are a major cause of morbidity and mortality. Although survival is increasing secondary to improved traffic safety measures and advances in spinal stabilisation techniques, the injury patterns are numerous and the neurologic sequelae many. Careful emergency management, a high index of suspicion and complete evaluation minimise delays in diagnosis. The possibility of concomitant injuries should always be suspected because the incidence is high. The goals of treatment are to protect the neural structures, reduce and stabilise the injured segment, and provide long-term stability. Non-surgical treatment often can be instituted with a satisfactory outcome.

50 Injuries of the Subaxial Cervical Spine

Anil Pande, Ravindranath Kapu

INTRODUCTION

The subaxial cervical spine, also called the middle and lower cervical spine, includes the cervical spine from C3 to C7 and the craniovertebral junction is excluded, as the anatomy and biomechanics of these two regions are quite different. The cervical region is the most vulnerable part of the spinal column due to increased mobility, small vertebral bodies, oblique articular facets and the mobility of the heavy skull on the cervical spine. Cervical spine injury occurs in 2–3% of patients with blunt trauma who undergo imaging and is the most frequently injured spinal region following trauma.[3] An incidence of 14,000 injuries/year in North America has been reported with most of these being cervical.[22] Accidents are the most common cause of injury. Subaxial spine injuries include musculoligamentous sprains, whiplash injuries, traumatic disc prolapse, fracture dislocations, burst fractures, locked facets, posterior element fractures, cord contusions and, rarely, extradural haematoma and subdural haematoma. The paediatric and geriatric age groups present differently.[71,105] Spinal cord injury without radiological abnormality (SCIWORA) is seen in children who have a more elastic spine. Patients with congenitally narrow canals (<13 mm) are more predisposed to neural injury. Patients who have connective tissue abnormalities, e.g. Down's syndrome, collagen disorders, diffuse idiopathic skeletal hyperostosis (DISH) and fluorosis, have more serious injuries.[117,118]

HISTORICAL BACKGROUND

The ancient Indian surgical classic "*Sushruta Samhita*" has a chapter on the management of recent traumatic wounds, followed by a chapter on the management of fractures and dislocations. Twelve types of fractures and six types of dislocations are mentioned along with four methods of reduction, i.e. traction, pressure, apposition and bandaging with bark splints. Sushruta describes the reduction of a cervical fracture by manual traction followed by splinting and bandaging.[104] For the next 2,700–2,900 years, the treatment guidelines did not change significantly.[63,64,79]

Most technical advances in cervical spinal surgery have been made in the last 50 years.[79] Before the era of spinal instrumentation and routine use of the operating microscope, most of these injuries were managed with traction, postural reduction and external immobilisation.[63,79] Surgical corridors were then developed to approach the subaxial cervical spine according to the site of pathology.[116] The experimental work of Roaf[90] was based on many earlier contributors to the study of spinal instability and the understanding of the biomechanics was essential for the evolution of surgery of subaxial spine injuries.[5,11,25,79,119] In 1968, Kelly and Whitesides proposed the evaluation of thoracolumbar spinal injuries in terms of anterior and posterior columns[79] which was adopted by Holdsworth for the cervical spine, and he suggested several mechanisms of cervical spinal injury.[45] The work of the American neurosurgeon Schneider[95–99] has been seminal in the understanding and management of spinal cord syndromes.

Posterior Era

The results of spine trauma surgery were poor with no microscope and modern imaging and surgical approaches that were essentially posterior. Although, most spinal injuries involve the anterior and middle column, approaching the spine from the posterior side was detrimental, as the only undamaged column was injured during surgery. Berthold Hadra[42] described his technique of spinous process wiring in 1891 and pioneered the spinal instrumentation era and, in 1942, Rogers suggested his interspinous wiring method for cervical trauma. This was modified by Bohlman as quoted by Omers et al.[79] as "Triple Wiring Technique". Scoville and Whitcomb in 1966 introduced the posterior approach to the cervical disc. Roy-Camille[92] introduced screws into the lateral masses of the cervical spine to stabilise the unstable spine in 1964. Luque rods with sublaminar wires were introduced in the 1970s[79] and this technique has been used of late with less frequency in the subaxial cervical spine. Facet wiring was modified in 1977 by Callahan to stabilise the spine in the absence of laminae. Posterior wiring techniques have been modified by Benzel[10] and others[19] for use in middle and lower cervical spine injuries. Thereafter, interspinous wiring, facet wiring and sublaminar wiring techniques evolved to the current lateral mass screws and pedicle screws with plates and rods.

Anterior Era

The anterior approach to the cervical spine was introduced in 1955 by Robinson and Smith.[91] Verbiest[116] reported on 47 cases of subaxial spine injuries and their surgical management. In the presence of multiple column injury and resultant instability, anterior fusion, when attempted using bone graft alone, was followed by graft extrusion and retropulsion, causing neurological deterioration and deformities. The need to provide immediate stability and allow for bone fusion led to the development of anterior plate systems. Bohler,[13] in 1967, first reported the use of anterior cervical plate and screw fixation in a patient with cervical spinal trauma. Cloward[23] popularised the anterior approach and introduced dedicated instrumentation for this procedure. An early plating system for anterior stabilisation was designed by Orozco.[80] He described the use of a one-third tubular plate in the 1970s, and subsequently designed custom "H" and "HH" plates, which were adopted by the Arbeitsgemeinschaft fur Osteosynthesefragen (AO) for use throughout Europe in anterior cervical spine surgery.[79] Caspar[20] developed a "trapezoidal" rigid plate with bicortical screws in 1980 for use in the cervical spine. Morscher devised unicortical locking screws in the 1980s.[79] In 1994, Abumi et al.[2] were the first to report the successful use of cervical pedicle screws in managing subaxial traumatic instability. Dynamic load-sharing plates with variable angle screws were introduced in 2000.[15,79]

The use of the surgical microscope, high-speed drills, intra-operative fluoroscopy and somatosensory, and motor evoked potential monitoring have become common in surgery of the subaxial cervical spine. The availability of neuronavigation allows for precise cervical screw placement and, recently, there has been resurgence in the use of posterior approaches and instrumentation in subaxial spine surgery.

ANATOMICAL CORRELATES OF THE SUBAXIAL CERVICAL SPINE

Knowledge of the surgical anatomy of the subaxial cervical vertebrae, spinal cord and the arterial and venous relations is essential to effectively manage traumatic lesions of the subaxial cervical spine.[32,66,78,81,82] The subaxial cervical spine includes the vertebral bodies, upper and lower articular processes, pedicles, lamina, a bifid spinous process, transverse process and uncinate process which forms the uncovertebral joint (Fig. 1). The vertebral body height increases from C3 to C7 with a slight reversal of this relationship at C6. Each body has an uncus; laterally is the ventral ramus of the transverse process and dorsolaterally the pedicle. Computer-assisted anatomic images of cadaver cervical spines were obtained for measurements of the disc spaces and vertebral bodies by Lu et al.[66] and this data from cadavers may be helpful during the anterior approach for discectomy, vertebrectomy and anterior screw-plate placement. The anteroposterior (AP) depth gradually increases from 16.56±2.21 mm at C3 to 19.32±2.30 mm at C7. Greater values of AP depth at the inferior endplate were found at C5 (20.75±2.87 mm) and C6 (20.56±2.31 mm) compared with the values at C3 (18.26±1.82 mm), C4 (19.27±2.88 mm) and C7 (19.21±3.22 mm). The AP depth at the superior endplate was greater than that at the inferior endplate. The height of the disc space was found to be lowest at the posterior disc space from C2-3 to C7-T1 (2.95±0.86 mm at C2-3, 2.78±0.93 mm at C3-4, 2.45±0.79 mm at C4-5, 2.92±0.64 mm at C5-6, 2.46±0.59 mm at C6-7, 2.93±1.05 mm at C7-T1), when compared to the height of the disc space at the anterior disc space from C2-3 to C7-T1 (4.07±0.85 mm at C2–3, 4.34±1.18 mm at C3-4, 3.95±1.37 mm at C4-5, 3.55±1.37 mm at C5-6, 3.55±0.76 mm at C6–7, 3.67±1.17 mm at C7-T1). The mid-axis of the disc space was situated at approximately 3 mm above the anterior midpoint of the annulus fibrosus at the level of the lower cervical spine. To reach the posterior portion of the disc space from the anterior midpoint of the annulus fibrosus, a 5 degree cephalad angulation of the drill relative to the mid-axis of the disc space was considered necessary by Lu et al.[66] The uncovertebral joints prevent excess lateral translation and allow for coupled lateral bending and rotation of the cervical spine. The lateral surface of the pedicle, the dorsal surface of the anterior tubercle and the ventral surface of the posterior tubercle form the foramen transversarium, which transmits the vertebral artery. Oh et al.[78] found that the vertebral artery migrates from posterior to anterior, from C3 to C6 and posteriorly again at C7; and these variations were relevant while decompressing the neural foramen. Subaxial spine pedicles connect the vertebral bodies with the lateral masses. The lateral mass consists of the facet joint, which is a coronally oriented (average angle being 45 degree) synovial joint. The Inter-Luschka distance increases from C3 to C7, which should be known in detail for adequate lateral decompression in anterior cervical spinal surgery.[78] The pedicle to the

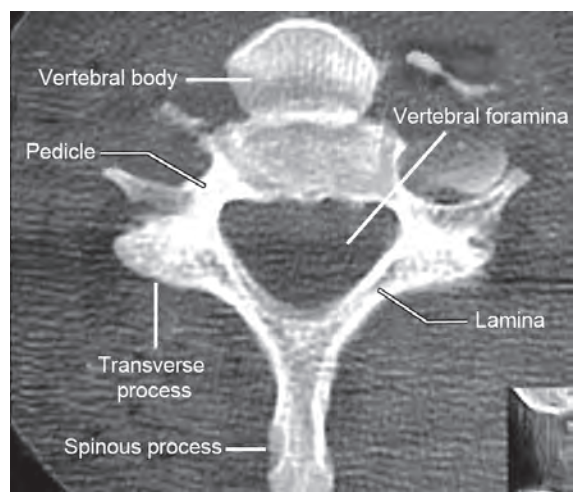

Fig. 1: Subaxial cervical vertebra-parts

Luschka joint distance has been measured by Oh et al.[78] at different levels and they found that the pedicle is lateral to the Luschka joint from C3 to C6 and medial to the joint at C7. This variation explains the lack of root decompression at some cervical levels, even when decompression extends to the Luschka joint bilaterally. The distance between the medial borders of the longus colli muscles increases in a rostral to caudal direction.[81] The lower subaxial spine, especially the C6-7 vertebrae, is exposed to great axial compression and flexion loads due to its location, and the transition between a very mobile cervical and a rigid thoracic spine. Ebraheim et al.[31] found that the sympathetic trunk may be more vulnerable to damage during anterior lower cervical spine procedures because it is situated closer to the medial border of the longus colli muscle at C6 than at C3. The longus colli muscles diverge laterally, whereas the sympathetic trunks converge medially at C6. As the transverse foramen or uncovertebral joint is exposed with dissection or transverse severance of the longus colli muscle at the lower cervical levels, the sympathetic trunk should be identified and protected.

Sherekar et al.[103] have studied the standard values for normal alignment of the upper and lower cervical spine in healthy individuals of the Indian population and the normal ranges of values of the cervical spine was established. It was found that the mean C1-C2 angle was significantly larger in females. The mean C2-C7 angle was significantly larger in males. The mean Oc-C2 angle had a weak negative correlation with the C2-C7 angle and the authors found that the alignment of the occiput and upper cervical spine and occiput and lower cervical spine are inter-related. If lordosis of the occiput and upper cervical spine increases (the Oc-C2 angle increases), the alignment of the lower cervical spine becomes kyphotic and vice versa.

The intervertebral foramen contains the exiting nerve root and is related anteriorly to the lateral portion of the intervertebral disc and the uncovertebral joints, superiorly and inferiorly to the pedicles and posteriorly to the lateral masses. The exiting root corresponds to the lower vertebra (C6 root exits the C5-6) foramen. Pait et al.[82] described the anatomy of the cervical articular pillar (lateral mass) and defined key bony landmarks and their relationship to critical neurovascular structures. They divided the articular pillar into four quadrants and, the superior lateral quadrant, under which there are no neurovascular structures, was considered the "safe quadrant" for placement of posterior screws and plates.

Ebraheim et al.[32] evaluated the anatomic relationship between the vertebral artery foramen and the posterior midpoint of the cervical lateral mass using cervical spine specimens and found that there was no risk of damaging the vertebral artery, if a screw is directed perpendicular to the posterior aspect of the lateral mass at C3-C5 and 10 degrees lateral to the sagittal plane at C6 starting at the midpoint of the lateral mass.

The ligamentum nuchae is attached to the external occipital protuberance and ends at the spinous process of C7; it limits excessive flexion of the cervical spine. The flexion extension movements have a range of 65–75 degree and translation is restricted to 2–3 mm. The cervical disc has an average height of 4 mm anteriorly and this reduces to 2.5–3 mm posteriorly. The anatomy in the Indian population has yet to be studied, but the average morphology is smaller, and this has to be taken into consideration, e.g. the longus colli muscles are very small and may not hold the self-retaining Cloward's retractors safely.

MECHANISMS AND TYPES OF INJURY

Subaxial cervical spine injuries are common and range in severity from minor ligamentous strain to complete fracture dislocation with osseous and ligament injury, and severe spinal cord injury (SCI). Multiple contiguous and non-contiguous cervical injuries can occur due to a single or multiple impact forces.[46,61] Pre-existing lesions, like haemangiomas of the bone, osteoporotic or sclerotic spine due to ageing, spondylotic myelopathy, DISH, ossification of the posterior longitudinal ligament (OPLL) and ankylosing spondylosis (AS), cause a spectrum of injuries. A whiplash injury is commonly seen in motor vehicle accidents and presents with nagging neck pain, radiculopathy and, rarely, myelopathy, and also a non-specific post-traumatic concussional syndrome is often associated.

AS, DISH, OPLL and fluorosis are disorders characterised by abnormal ossification of the spinal column, which predisposes these patients to spinal injuries with potentially devastating consequences.[117,118] Patients with AS are much more prone to serious neurological injury and spinal deformity after sustaining cervical fractures from even minor trauma forces and are more likely to require surgical management.[51]

Maiman et al.[67] tested the hypothesis that initial alignment of the head-neck complex affects cervical spine injury mechanism, trauma rating, injury classification based on stability and fracture pattern, and confirmed that spinal alignment is a strong determinant of the biomechanics of impact-induced cervical spine injury.

Subaxial cervical spine injuries are divided into stable or unstable injures. Instability exists, if there is greater than 3.5 mm of translation or greater than 11 degree of angulation changes as compared to other segments. The degree of ligamentous injury on magnetic resonance imaging (MRI) correlates with instability in patients with lateral mass facet fractures, with rupture of multiple ligaments including the anterior longitudinal ligament, posterior longitudinal ligament, interspinous ligament, or facet capsule. Patients with congenitally narrow canals and those with less than 13 mm length of the sagittal canal are predisposed to neurological injury. Conversely, patients with a wide canal may escape injury of the spinal cord.[74] Vertical compression injuries can also cause canal occlusion and vertebral column shortening.

CLASSIFICATION OF SUBAXIAL CERVICAL SPINE INJURIES

Allen, et al.[5] in 1982, put forward a mechanistic classification of middle and lower cervical spine injuries and subdivided them into eight groups based on a force vector (initial dominant force) and resultant injury based on the three-dimensional position of the spine at the instance of failure. Each of these is further graded according to severity. The failure of the anterior column results in more instability in extension and posterior element failure predisposes to instability in flexion. Patel et al.[83] reviewed the subaxial injury classification (SLIC) and severity score SLIC system, which identify three major injury characteristics to describe subaxial cervical injuries:

1. Injury morphology
2. Discoligamentous complex integrity
3. Neurological status.

Minor injury characteristics include injury level and osseous fractures. Each major characteristic is assigned a numerical score based upon injury severity. The sum of these scores constitutes the injury severity score. This system addressing both discoligamentous integrity and neurological status, overcomes the major limitations of earlier classification systems. Vaccaro et al.[113] reiterate that the SLIC and severity scale provide a comprehensive classification system for subaxial cervical trauma.

The common injuries of the subaxial spine are compression flexion, compression extension and distraction flexion injuries. Vertical compressions are of intermediate frequency and lateral flexions are the least frequent.

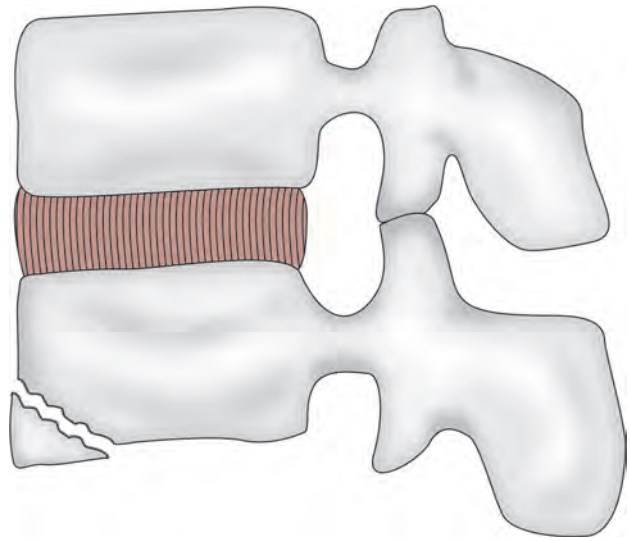

Fig. 2: Tear drop fractures

Compression injuries	I. Anterior compression	II. Comminuted fracture	III. Tear drop fracture
Flexion-extension-distraction injuries	I. Moderate sprain dislocation	II. Severe sprain	III. Bilateral fracture
Rotation injuries	I. Unifacet fracture (UFF)	II. Fracture separation of the articular pillar (FSAP)	III. Unilateral dislocation (UD)

Fig. 3: Allen and Ferguson subaxial cervical spine classification

Flexion Injuries

These form about 15% of injuries of the subaxial cervical spine and usually result due to fall from a height, diving into shallow water or empty pools and road traffic accidents.

Flexion-Compression Injuries

These represent a spectrum of spinal injuries with simple vertebral body compression fractures and injuries that result in the triangular "teardrop" fracture (Fig. 2) of Schneider and Kahn[97] or a "quadrangular" fracture with posterior ligamentous disruption. The most severe injury is posterior subluxation of the posterior vertebral body into the canal, causing acute kyphosis and disruption of the ALL, PLL and posterior ligaments. The SCI in these compressive flexion injuries ranges from 0 to 91% in the most severe cases. Posterior element fractures occur in up to 50% of these cases and pure ligamental injury is usually rare.

Tear drop fractures are serious injuries and patients are seen with complete spinal injury or central cord syndrome.[95–99] There is a fracture of the vertebral body in the sagittal plane and retrolisthesis of the vertebrae and these require to be differentiated from simple avulsion fractures. These have associated facet joint and discoligamental injuries.

Quadrangular fractures are characterised by oblique vertebral body fracture, subluxation, angular kyphosis and discoligamental injury, and are unstable.

Flexion-Distraction Injuries

These injuries represent a spectrum of pathologies from mild posterior ligamentous sprains to bilateral facet dislocations (locked or jumped facets).[106] These are the most common injury patterns in Allen and Ferguson's classification (Fig. 3).[5] They include subluxation injuries and dislocation injuries. The mildest form of injury in this class is facet subluxation which can present as instability, due to the poor healing of posterior ligamentous injuries. Horizontal subluxation of more than 3.5 mm of one body over another or more than 11 degree of angulation of one vertebral body relative to the next indicates instability. Jumped facets or sprung facets may be unilateral or bilateral. The normal facets have a shingled relationship (inferior facet of level above is

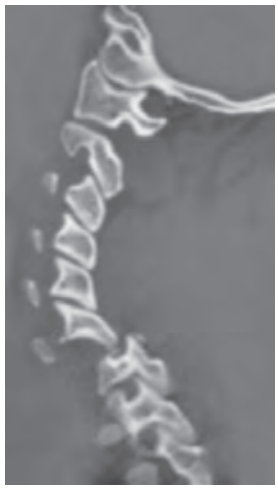

Fig. 4: Unilateral facet dislocation—computed tomography scan

Fig. 5: Bilateral facet dislocation—computed tomography scan

posterior to superior facet of level below). Mild injury of the facet capsule leads to ligament laxity, resulting "perched facets".

Beatson[8] classified facet dislocation injuries into four stages of progression:

1. Posterior ligament strain with facet subluxation and interspinous widening and rounding of the anterior-superior aspect of the caudal vertebral body
2. Unilateral facet dislocation, with varying degrees of posterior ligamentous injury
3. Bilateral facet dislocations
4. Complete anterior subluxation of the rostral vertebral body.

Dislocation injuries: These include unilateral and bilateral facet dislocations.

Unilateral facet dislocations: These are caused when there is flexion and a rotational vector acting together and facet fracture dislocations represent the next pattern seen in the spectrum of injury (Fig. 4). They typically present with translation of 25% of one vertebral body on another and have a pathognomonic "sail" or "bow tie" sign on lateral X-rays. The C6-7 is the level most commonly involved, and patients present with radiculopathy and SCI.

Bilateral facet dislocations: These dislocations have a higher incidence of neurological injury (Fig. 5). These injuries require reduction with traction or internal reduction and may have associated large anterior disc prolapse.

Vertical Compression Injuries

Vertical compression injury to the subaxial cervical spine results in the cervical burst fracture. These burst fractures are subdivided into three categories of severity. They are classified as the most severe pattern in the Allen and Ferguson vertical compression phylogeny and are classified as A3 lesions in the AO classification; they represent about 10% of all subaxial cervical spine fractures. Roaf[90] found that the vertical compression injured the vertebral end plate rather than the intervertebral disc. The cervical spine has a lordotic curve and a small spinal canal. Axial loading of the cervical spine causes compression of the vertebral body and the posterior wall retropulses into the canal causing neural injury. These can be associated with posterior ligamentous injury when there is an associated flexion component of the injury force.

Extension Injuries

These were described by Taylor and Blackwood.[109] These represent approximately 8% of all subaxial cervical spine injuries and two stages have been described:

1. Stage I injury is disruption of the anterior longitudinal ligament without posterior displacement and is seen on imaging as abnormal widening of the disc space due to the ALL and disc injury.
2. Stage II injury is when both the posterior ligaments and the anterior ligaments are injured and the superior vertebra is retropulsed into the spinal canal. Extension injuries without bony injuries lead to the central cord syndrome in adults and SCHIWORA in children. These are more commonly seen in the elderly and in patients with pre-existing cervical spondylotic disease or other conditions like DISH, AS and OPLL.

MANAGEMENT

Intensive Care and Initial Management

Management of spinal injuries is begun by taking an accurate clinical history, and doing a complete general and neurological examination including motor, sensory and autonomic systems using the American Spinal Injury Association (ASIA) score. The clinical evaluation then guides an appropriate radiological evaluation protocol.[22]

All trauma patients with a cervical spinal column injury or with a mechanism of injury having the potential

to cause cervical spine injury should be immobilised at the scene of accident and during transport with a combination of a rigid cervical collar and supportive blocks on a backboard with straps. This is effective in limiting the motion of the cervical spine. The long-standing practice of attempted cervical spine immobilisation using sandbags and tape alone is not recommended.[21] Evaluation of cervical spine injuries should begin in the emergency department.[70] Management of patients with acute SCI, particularly patients with several cervical level injuries, in an intensive care unit or similar monitored setting is recommended.[70] Use of cardiac, haemodynamic and respiratory monitoring devices, to detect cardiovascular dysfunction and respiratory insufficiency in patients after acute cervical SCI, is routine. Hypotension (systolic blood pressure <90 mmHg) should be avoided, if possible or corrected as soon as possible after acute SCI. Maintenance of mean arterial blood pressure at 85–90 mmHg for the first 7 days after acute SCI is required to improve spinal cord perfusion.[12] Use of protocols and management algorithms reduce the possibilities of error and arbitrary treatment.[7]

Steroids

Treatment with methylprednisolone for either 24 hours or 48 hours immediate post-trauma is recommended as an option in the treatment of patients with acute spinal cord injuries that should be undertaken only with the knowledge that the evidence suggesting harmful side effects is more consistent than any suggestion of clinical benefit.[86]

Venous Thromboprophylaxis

Steps to prevent venous thromboembolism are guided by clinical acumen and protocols. Ploumis et al.[88] on the basis of a literature review, concluded that the prevalence of deep-vein thrombosis following a spine injury is higher among patients who have a SCI than among those who do not, and the consensus was that thromboprophylaxis should start as early as possible once it is deemed safe in terms of potential bleeding complications. Within this population, low-molecular-weight heparin was more effective in the prevention of deep-vein thrombosis, with fewer bleeding complications, than un-fractionated heparin. The use of vitamin K antagonists appeared to be effective for the prevention of pulmonary embolism.

EXAMINATION

The instability of the cervical spine is picked up by the clinical signs of radiculopathy, neck pain or myelopathy. In clinical practice, the presence of instability can be inferred from an abnormal position of the neck, injury signs, like bruises and rope marks, and spinal deformity and tenderness are obvious pointers to an occult injury to the subaxial cervical spine. The nature of the accident should be inquired into.[49] The ASIA international standards for neurological and functional classification of SCI are recommended as the preferred neurological examination tool for clinicians involved in the assessment and care of patients with acute spinal cord injuries.[22] All precautions to rule out polytrauma and, especially concurrent carotid and vertebral artery, injuries should be undertaken.[34,47]

INVESTIGATIONS (IMAGING OF THE SUBAXIAL CERVICAL SPINE IN TRAUMA)

In light of clinical signs and symptoms and even in asymptomatic patients who have had significant trauma[74] including inebriated patients, imaging must be very carefully ordered and studied.[16] Usually static X-rays, computed tomography (CT) scans, MRI scans or, very rarely, a myelogram is done. In patients with cervical pain and those who do not have any radiculopathy or myelopathy, instability can be confirmed by dynamic imaging (flexion and extension views).[11,35,89,119] Bono et al.[14] have attempted consensus in techniques of measurement of kyphosis (Cobb angle and posterior vertebral body tangent methods); vertebral body translation; vertebral body height loss; maximal spinal canal compromise and spinal cord compression; facet fracture fragment size and percentage of facet subluxation.

Agarwal,[3] in a recent review of cervical spine injuries and cervical spine clearance protocols, emphasises the importance of early recognition of high-risk patients, and three-view cervical spine X-rays (AP, lateral and odontoid views) are usually done in radiographic evaluation of the cervical spine in patients who are symptomatic after traumatic injury. Digital X-rays are taken with the shoulders pulled down to visualise up to C7. A swimmers view may be necessary, if there is suspicion of injury to the C7-T1 region, clinical signs of progression or development of radiculopathy or myelopathy. This is followed, if necessary, with CT to define areas that are suspicious or not well-visualised on the plain cervical X-rays. Immobilisation in awake/conscious patients can be discontinued after either (a) normal X-ray or adequate dynamic flexion/extension radiographs with no evidence of movement or (b) a normal MRI study which is obtained within 48 hours of injury. Cervical spine immobilisation in obtunded patients may be discontinued if there is:

- Normal cervical spine X-rays (including supple mental CT as necessary)
- Normal dynamic flexion/extension studies performed under fluoroscopic guidance
- After a normal MRI study is obtained within 48 hours of injury
- At the discretion of the treating physicians.[44,89]

Delfini et al.[27] caution that patients with even mild cervical trauma must be scrupulously evaluated during the acute phase and that, in some cases, it may be advisable to perform a more detailed neurological investigation.

In children who have experienced trauma and are alert, conversant, have no neurological deficit, no midline cervical tenderness, and no painful distracting injury, and are not intoxicated, cervical spine X-rays are not necessary to exclude cervical spine injury. In children who have experienced trauma and who are either not alert, non-conversant, have neurological deficit, midline cervical tenderness, or painful distracting injury, or are intoxicated, it is recommended that AP and lateral cervical spine X-rays be obtained. In children younger than age 9 years, who have experienced trauma, and who are non-conversant or have an altered mental status, a neurological deficit, neck pain, a painful distracting injury, are intoxicated, have unexplained hypotension, AP and lateral cervical spine X-rays should be obtained. In children aged 9 years or older who have experienced trauma, and who are non-conversant or have an altered mental status, a neurological deficit, neck pain, or a painful distracting injury, are intoxicated, or have unexplained hypotension, AP, lateral and open-mouth cervical spine X-rays should be done.[71,89]

Static X-Rays

Proper interpretation of lateral cervical spine X-rays is very important and it remains an essential radiological tool.[120] Patients with potential neck injury must be identified rapidly and handled carefully.

Williams et al.[120] stress the urgency in obtaining a good, readable lateral C-spine film and advice a systemic "ABCS" approach to reading this film. This approach includes specific, sequential attention to alignment, bony integrity, cartilaginous structures, and the surrounding soft-tissue spaces. Kim et al.[55] discussing the pitfalls in plain film diagnosis of cervical spine injuries, found that 14% of patients referred as having cervical injury on X-rays were subsequently found to have no fracture or dislocation when re-evaluated.

Dynamic X-Rays: Flexion Extension Views

Flexion/extension cervical X-rays or fluoroscopy may be considered to exclude gross ligamentous instability when there is a suspicion of cervical spine instability after static X-rays are obtained, but flexion extension X-rays must be ordered with caution, and neurosurgeons must supervise personally them being taken in high-risk cases in patients with significant ligamental instability. These may require to be repeated as the immediate post-injury painful muscle spasm can mask the instability. Criteria for demonstrating instability of the cervical spine have been published, but require clinical judgement and experience.[11,25,119]

Computerised Tomography

Cervical CT scan is a very efficient imaging modality in picking up bony injuries, having a sensitivity of 100%. A single cross-table lateral view X-ray appeared to be insufficient, as a sensitivity of only 63% was found, but functional radiography or MRI is also necessary, as plain radiographs and CT scan may fail to detect significant ligamentous injuries in 6% of the patients.

Tan et al.[108] reported that CT of the inadequately visualised C7-T1 level on plain radiography is cost-effective, especially given the relatively young age of the trauma population and, therefore, the high-associated morbidity of the sequelae of these injuries overtime.

CT scans are useful in studying and measuring kyphosis (Cobb angle and posterior vertebral body tangent methods), vertebral body translation, vertebral body height loss, maximal spinal canal compromise and spinal cord compression, facet fracture fragment size and percentage of facet subluxation.

Clearing the cervical spine[87] in polytrauma patients still presents a challenge to the trauma team. The risk of an overlooked cervical spine injury is substantial, since these patients have multiple injuries and clinical examination may not be possible. Poor-quality X-rays, poor technical quality or incomplete visualisation of the cervical spine may not show the extent of the injury as dynamic imaging does usually. Ligamentous injuries are missed despite complete sets of standard radiographs and cervical CT scans.[35] Factors which point towards a discoligamental injury include severe head injury, higher energy of trauma and focal neurological deficits. Stassen et al.[107] feel that in the obtunded patient, expeditious cervical spine evaluation is important as missed injuries and prolonged unnecessary immobilisation can result in adverse outcomes. They confirmed that cervical spine CT, when used in combination with MRI, provides a safe and efficient method for cervical spine clearance in this patient population and CT alone misses a statistically significant number of cervical spine injuries.

Magnetic Resonance Imaging

Benzel et al.[9] have emphasised the importance of MRI in evaluation of patients with occult spinal injury. D' Alise et al.[26] confirmed that sagittal T1-weighted and T2-weighted MRI appears to be a safe, reliable method for evaluating the cervical spine for non-apparent injury in comatose or obtunded trauma patients. In the early post-injury period, nursing and medical care are thereby facilitated for patients in whom occult injury to the spine is ruled out and for whom those attendant precautions are unnecessary.

Menaker et al.[73] found that newer generation CT continues to miss cervical spine injuries in unreliable patients and magnetic resonance (MR) changed the management in 7.9% of patients having had an admission CT with no acute injury. They recommend continued use of MRI for cervical spine clearance in the unreliable patient and ongoing evaluation as the quality of CT imaging continues to evolve.

Neurosurgeons prefer to do the MRI study before attempting closed reduction.[14,38] Grauer et al.[39] found

that timing of MRI and its influence on management of patients with cervical facet dislocation remains highly variable.

MRI of the cervical spine may also be considered to exclude cord or nerve root compression, evaluate ligamentous integrity, or provide information regarding neurological prognosis. The presence of injury to at least three ligaments, like those of the facet capsule, interspinous ligament and either of the longitudinal ligaments may be related to instability in unilateral facet fractures.[43]

Keiper et al.[53] reported posterior soft-tissue injury or ligamentous injury to be the most common finding in 10 paediatric patients with mild-to-moderate trauma, and acute disc bulges and longitudinal ligament disruption were uncommon. The MRI was superior to CT for assessment of the extent of soft-tissue injury and for identification of spinal cord injuries and intracanalicular haemorrhage in six patients with more severe trauma. The MRI specifically influenced the management of all four patients requiring surgery by extending the level of posterior stabilisation. Traumatic cervical facet dislocations are very serious three column injuries. These are associated significantly with disruption to the posterior and anterior longitudinal ligaments and facet capsules. The MRI is an excellent means of assessing ligamentous disruption, disc herniation and compression of the neural elements.

A study by Vaccaro et al.[115] showed that MRI allows visualisation of disruptions and damage of the posterior longitudinal ligament, which was less frequent in unilateral facet dislocations than bilateral facet dislocations.

Disc injury is defined on MRI as the presence of herniation or disruption. Herniation is described as deformation of the thecal sac or nerve roots, and disruption is defined as a disc with high T2-weighted signal characteristics in a widened disc space.

Yagi et al.[125] stated that cervical instability was a risk factor for the post-operative expansion of the high-signal intensity and indicated that this high-signal intensity area occurred not only from necrosis secondary to ischaemia of the anterior spinal artery, but also from the repeated minor trauma inflicted on the spinal cord from an unstable cervical spine. The long-term neurological outcome found in the preliminary study of patients with compressive cervical myelopathy who had cervical instability and intramedullary signal intensity changes on MR images suggested that surgical treatment should include posterior fixation along with cervical laminoplasty or anterior spinal fusion. These findings can be extrapolated to signal intensity changes seen on MRI scans of patients with post-traumatic discs.

The vertebral arteries are seen as regions of signal voids, and MR angiography and CT angiography may aid in picking up vertebral artery injuries and carotid injuries.

TREATMENT

The management of patients with subaxial cervical injuries lacks consensus, particularly with regard to decisions like which surgical approach or combination of what approaches to use and which approach yields the best clinical outcome in the distinct injury and is highly dependent on the nature of injury, its severity, the experience and competence of the surgeon and the availability of resources.[111] Management is also guided by the issue of instability and as per White and Panjabi[119] loss of function of all anterior or posterior bony or ligamental elements cause spinal instability. Generally, an operating microscope and good bipolar and monopolar electrocautery are essential, along with anterior and posterior spinal instrumentation. Fluoroscopy and neuronavigation are also very useful.

CONSERVATIVE

Many injuries of the subaxial cervical spine without significant discoligamental injury, fracture or dislocation can be managed conservatively using orthoses like the soft cervical collar, Philadelphia collar, Guilford brace, sternal occipital mandibular immobiliser (SOMI) brace and the Yale brace. But these patients must be followed up with great caution, and patients with SCIWORA and sports related injuries, like spinal concussion, spinal cord neuropraxia and burning hands syndrome, may be advised avoidance of high-risk activities for up to 6 months after the injury event.

Lemon et al.[60] identified the following risk factors in association with failure of conservative management in subaxial cervical spine injuries: patients with more than 40% of compression of a cervical vertebra, more than 15 degree of kyphotic angulation or more than 20% of subluxation of one vertebra over another. Persisting pain, progressing myelopathy, radiculopathy or deformity are the indications for surgery as per the modified recommendations of Schneider.[96] Acute central cord syndrome[95–99] is usually managed conservatively.

Axial Controlled Traction

Traction has been used for a very long time in subaxial spine trauma.[63] Traction can be used with caution to re-align and maintain the alignment, usually following an MRI prior to this, as nearly 80% of bilateral locked facets will have an associated post-traumatic disc. Early closed reduction of cervical spine fracture dislocation injuries with craniocervical traction is recommended to restore anatomic alignment of the cervical spine in conscious/awake patients. Closed reduction in patients with an additional rostral injury is not recommended. Patients with cervical spine fracture/dislocation injuries, who cannot be examined during attempted closed reduction, or before open posterior reduction, should

undergo MRI before attempted reduction. The presence of a significant disc herniation in this setting is a relative indication for a ventral decompression before reduction. MRI study of patients who fail attempts at closed reduction is also recommended. Pre-reduction MRI performed in patients with cervical fracture dislocation injury will demonstrate disrupted or herniated intervertebral discs in one-third to one-half of patients with facet subluxation. Vaccaro et al.[112] reported that the process of closed traction reduction appears to increase the incidence of intervertebral disc herniations.

Halo

Halos which have been used since 1959 were regarded as a standard for external stabilisation of the injured cervical spine. The use of the halo has been increasingly questioned as an immobilisation technique in cervical trauma due to reports of high complication rates and unacceptable treatment results. Treatment with halo was successful in 85% of patients and 74% of survivors completed their intended treatment period. Their use is associated with several complications like infection, pin loosening, dysphasia, skull and dural penetration, and pressure ulcers.[17] A pin less non-invasive halo has been introduced with the goal of providing cervical spine stabilisation and control approaching that of the conventional halos in a less invasive fashion.[94]

Surgery

There is lack of consensus in the management of subaxial cervical spine trauma,[30,59,77,113] due to the lack of a clinically relevant system for classifying these injuries.[14,83,113] The aim of surgery is to maintain alignment, correct deformity to restore the sagittal balance, and prevent radiculopathy, myelopathy and instability. Vaccaro et al.[113] presented an algorithm to guide the choice of surgical approach in cervical subaxial burst fractures, distraction injuries, and translation or rotation injuries. Burst or compression injuries and distraction injuries are more likely to be treated with a single anterior approach, whereas the more severe translation or rotation injuries may more commonly be approached posteriorly or with combined anterior and posterior surgery. This algorithm, derived from the SLIC scoring system, may assist surgeons in answering the two most common questions they face when managing subaxial cervical spine trauma: "Should I operate?" and "Which surgical approach should I select?"[113]

GUIDELINES

Subaxial Cervical Facet Dislocation Injuries

Closed or open reduction of subaxial cervical facet dislocation injuries is recommended.[48] Treatment of subaxial cervical facet dislocation injuries with rigid external immobilisation, anterior arthrodesis with plate fixation, or posterior arthrodesis with plate or rod or interlaminar clamp fixation is recommended.[41,76,77] Treatment of subaxial cervical facet dislocation injuries with prolonged bed rest in traction is recommended, if more contemporary treatment options are not available.[48,69]

Subaxial Cervical Injuries Excluding Facet Dislocation Injuries

Treatment of subaxial cervical spinal injuries with external immobilisation, anterior arthrodesis with plate fixation, or posterior arthrodesis with plate or rod fixation is recommended for patients with fracture dislocation without facet dislocation.[101]

Closed reduction is successful for most patients with subaxial cervical spine fracture dislocations injuries. Closed reduction is usually not successful with facet dislocation injuries[48] and may be injurious when there is a large disc.[29]

Immediate open anterior reduction of bilateral cervical locked facets and combined AP fixation/fusion is safe and reliable.[84,85,106] This treatment strategy avoids time loss and patient discomfort from attempted closed reduction by traction and results in excellent stability.

Unilateral Locked Facets

Unilateral facet injuries were earlier treated with halo immobilisation. Currently they are surgically decompressed, reduced and fixed.[36] Shapiro et al.[102] suggested that a reduction procedure in which internal fixation and bone fusion are performed will be the most successful treatment for this injury and this reduces the incidence of malalignment, glacial instability and pseudoarthrosis.

LATERAL MASS FRACTURES

Lateral mass fractures are divided into the following four subtypes by Kotani et al:[57]

1. Separation
2. Comminution
3. Split
4. Traumatic spondylolysis.

The subtype analyses of lateral mass fractures demonstrated; high rates of anterior translation in separation, split, and traumatic spondylolisthesis, as well as significant coronal malalignment in comminution and split types. Cervical pedicle screw fixation of these fractures provided superior deformity correction without pseudoarthrosis, as well as excellent neurological recovery.

Spondyloptosis

An unusual case of traumatic C6-7 total spondyloptosis with neurological intactness at the time of injury was reported in a 35-year-old man by Menku et al.[74] The patient was treated with a single-stage combined anterior-posterior and anterior operation to restore the

cervical spondyloptosis, and creation of a three-column stabilisation of the spine without neurological deficits.

Burst Fractures

Burst fractures of the subaxial cervical spine are common as described earlier and usually involve the C6-7 vertebrae depending upon the amount of canal compromise and reduction in vertebral body height. These are usually operated upon by an anterior cervical approach and median vertebrectomy is done to decompress the cord followed by iliac crest graft and anterior plate fusion. These may be associated with injury to the vertebral arteries.

Laminar Fractures

Laminar fractures are rare and, unless causing cord pressure, are managed conservatively. These may also be associated with posterior ligamental injury and, if there is evidence of instability posterior single stage decompression, and lateral mass screw and rod fixation can be done.

Management

There are four general indications for spinal stabilisation as outlined by White and Panjabi:[119]

1. To restore clinical stability to a spine in which the structural integrity has been compromised
2. To maintain alignment after correction of a deformity
3. To prevent progression of a deformity
4. To alleviate pain.

A patient was considered to have an unstable injury, if he had five points or more in the White and Panjabi instability checklist.

Anterior Instrumentation

The choice of surgical approach in the treatment of traumatic cervical dislocations is highly variable and may be influenced by a variety of factors. There are a variety of ventral subaxial fixation techniques.[68] Khosla et al.[54] reviewed the advantages of the anterior approach to the subaxial cervical spine and described a number of technical modifications of the procedure. Neurosurgeons commonly use anterior approaches either alone[72] or as the first stage in a combined approach when a disc herniation is present regardless of the neurological status of the patient. When a patient is neurologically intact, an anterior approach is more commonly used than a posterior approach even when a disc herniation is not present. Combined approaches were preferred for the treatment of bilateral facet dislocations. Woodsworth et al.[123] reported that anterior cervical discectomy and fusion performed using interbody structural allograft and plate fixation is highly effective in the treatment of unstable posterior cervical lateral mass, facet and ligamentous injuries. This treatment option results in low intra-operative blood loss, short operating time, and a brief length of hospital stay. Radiographic outcome with respect to segmental stability are excellent, and fusion rates with the use of structural allograft alone were high. Outcomes with respect to pain, function and patient satisfaction were high, and complications were acceptably low. The anterior approach has a disadvantage as it causes destruction of the anterior elements in the presence of posterior instability. There has been growing evidence ever since, that anterior decompression and instrumented fusion (Fig. 6) alone is an adequate form of treatment for unstable cervical spine injuries. Lambris et al.[58] opined that many such injuries, including the dislocations, can be managed with anterior instrumented fusion alone. Hacker et al.[40] found that interbody cages were safe and effective in the treatment of degenerative cervical disc disorders, but these are avoided in traumatic lesions. Vaccaro et al.[114] stated that anterior reconstruction of the cervical spine with an anterior cervical graft and plate acting as a tension band is the ideal treatment method for stabilisation of acute distraction extension injuries involving primarily the soft tissue structures (anterior longitudinal ligament and intervertebral disc). Type 2 injuries, depending on the degree of displacement and the adequacy of closed reduction, may need to be approached initially posteriorly to obtain adequate alignment, followed by an anterior reconstructive procedure. Great care should be taken during anterior graft placement to avoid over-distraction of the spine.

Posterior Instrumentation

Posterior fusion of the subaxial cervical spine has become common. Liu and Das[62] have reviewed the indications and techniques of posterior fusion of the subaxial cervical spine. Three major modifications of the original description by Roy-Camille[92] are commonly used in managing cervical instability: (1) Magerl; (2) Anderson and (3) An et al.[6] The screw is generally, directed superiorly and laterally to avoid the nerve root and the technique by An et al.[6] demonstrated the lowest risk of nerve root damage due to over-penetration in drilling or insertion of too

Fig. 6: Anterior cervical fixation

long screw. When screws 15 mm or shorter are used, the chances of injury to the vertebral artery or nerve root were low in all three techniques. Yukawa et al.[126] using posterior instrumentation in 144 unstable cervical spines concluded that the placement of cervical pedicle screws using a fluoroscopy-assisted pedicle axis view technique provided good clinical results and few complications for unstable cervical injuries. Solid posterior bony fusion without secondary dislodgement was accomplished in 96% of all cases, but a careful surgical procedure was needed to safely insert the screws and improvement in imaging and navigation systems are expected. Cervical pedicle screws are alternative fixation devices for posterior cervical plating. In biomechanical studies conducted in animal models and human cadavers, investigators have demonstrated that this technique offers superior stability, fixation and resistance to screw pullout forces compared with lateral mass plating. Abumi et al.[2] have demonstrated in clinical studies that cervical pedicle screws can be effectively used in the reconstruction of the cervical spine after decompressive laminectomy, correcting kyphosis from a posterior approach, and reducing trauma-induced disc herniations.

Wu et al.[124] proposed a modified technique with a universal method of screw placement suitable for stabilisation of every level of the subaxial cervical spine, from C3 to C7. The technique of lateral mass screw placement yielded good fusion rates with very few complications. Cervical pedicle screw fixation is also an effective procedure for stabilising an unstable motion segment; however, it is generally, considered unsafe due to the potential for injury to neurovascular structures, such as the spinal cord, nerve roots or vertebral arteries. A careful surgical procedure is needed to safely insert the screws and more improvement in imaging and with the use of navigation systems is expected to reduce the rate of complications. Roy Camille et al.[92] reported on 221 cases of lower cervical spine injuries, in which posterior stabilisation was done in 89%. They reported no secondary displacement in 85% of cases.

Halifax clamps: The interlaminar clamps[4] are used in managing a subluxation where the injury is mainly due to the posterior ligaments with no bony injury, especially to the facets and lamina. Most neurosurgeons would prefer posterior plating options. Posterior stabilisation procedures may be performed with wires and cables, with or without rods. The plates and screws are biomechanically superior to wiring and avoid canal penetration. They are ideal when there is loss of the posterior elements. Pedicle fixation should be considered when operating on the C2 or C7 level. Posterior wiring techniques of various authors[10,19,33] can be very useful when posterior screws cannot be placed.

POST-TRAUMATIC DISC

The incidence of traumatic disc herniation in one series was 32%.[2] They occur frequently in association with injury of the cervical spine and are usually associated with instability and, being a discoligamental injury, they tend to heal poorly. Conventionally they are approached anteriorly using standard microsurgical techniques and, after discectomy, fusion is done using iliac crest bone graft and anterior plating systems.[37] Many local Indian cervical plating options are available that are affordable and of good quality. Posterior approaches are less commonly used for these injuries. The cervical pedicle screw system has been described as an alternative treatment option for the cervical spine injury-related traumatic disc herniation.[1] Abumi et al.[2] in their experience found that the cervical pedicle screw system allowed three-dimensional reduction of the injured cervical segment and reduction or reversal of a disc herniation. After surgery, compression of the thecal sac and/or spinal cord had disappeared. The cervical pedicle screw system provides effective and safe fixation of the cervical spine injury-related traumatic disc herniation, and the surgery can be performed safely in a single posterior-approach procedure without need of additional anterior decompressive interventions.

Combined Anterior and Posterior Approaches

McAfee et al.[72] on the basis of experience with 100 cases of which there were 31 cases of traumatic injury, used a one-stage anterior decompression followed by posterior stabilisation and stated that the development of more biomechanically rigid cervical instrumentation did not obviate the need for a combined approach. Liu P et al.[63] published a retrospective study of nine patients who underwent operations as treatment of old distractive flexion injuries (Stages 2 and 3) of the subaxial cervical spine. They did a posterior procedure first which comprised of soft tissue release, facetectomy and interspinous wiring, followed by an anterior procedure including soft tissue release, discectomy, reduction, intervertebral grafting and anterior plating, with good outcomes.

Circumferential Fusion

These patients can be treated with a single-stage combined anterior-posterior or anterior operation alone[100] to restore the cervical spondyloptosis, and creation of a three-column stabilisation of the spine without neurological deficits.

Instrumentation

Abraham et al.[1] reported on the indications and increasing trends for anterior cervical fusions. However, good the instrumentation system is, it does not replace the need for bone graft and good fusion techniques, as repetitive loading will cause implant failure unless fusion occurs. Anterior cervical plate fixation has gained widespread acceptance for the treatment of various cervical spine pathologies as, theoretically, it enhances the rate

of arthrodesis (fusion). Kaiser et al.[50] reported that the fusion rates for one and two level anterior cervical discectomy and fusion (ACDF) with anterior fixation were 96% and 91% respectively, compared with 90% and 72% for one and two level ACDF without anterior fixation. Similarly, in their series of 59 patients who underwent three level discectomy with and without plate fixation, Wang et al.[118] found that the pseudoarthrosis rate was 18% for patients with plating and 37% for patients with no plating. Lowery et al.[65] emphasised the significance of hardware failure in anterior cervical plate fixation. Strategies that can minimise screw pull out include triangulation, providing additional points of fixation, minimising the length of the construct and normalising the geometry of the cervical spine.

OUTCOME

Functional and clinical outcome data of subaxial cervical spine injuries using validated measures is vague. Using validated outcome scores the relation between radiographic, functional and clinical outcome parameters can be studied with statistically significant correlations. Miyanji et al.[75] on correlating neurological outcome with MRI findings, found that maximum spinal cord compression (MSCC), spinal cord haemorrhage and cord swelling are associated with a poor prognosis for neurologic recovery. Extent of MSCC is more reliable than presence of canal stenosis for predicting the neurologic outcome after SCI.

Radiographic outcomes include fusion scores and sagittal alignment measurements. Outcome scores with respect to neck pain, satisfaction with surgery and function are recorded for each patient (Fig. 7) according to analog pain and satisfaction scales and the neck disability index (Fig. 8). Koller et al.[56] on reviewing mid to long-term outcome of instrumented anterior cervical fusion for subaxial spine injuries, found that patients were more likely to maintain a high satisfaction level, if they succeeded to maintain segmental lordosis (< 0 degree), had a solid fusion, an increased plate-to-disc distance, and if they were judged to have a successful surgical outcome that included the absence of construct failure and reconstruction of lordosis within +/-1 SD of normalcy.

- Excellent: All preoperative symptoms relieved; abnormal finding improved
- Good: Minimal persistence of preoperative symptoms; abnormal findings unchanged or improved
- Fair: Definite relief of some preoperative symptoms; other symptoms unchanged or slightly improved
- Poor: Symptoms and signs unchanged or exacerbated

Fig. 7: Odom's criteria

Functional Outcome Assessment

The functional independence measure and modified Barthel index (Fig. 9) are recommended as the functional outcome assessment tool for clinicians involved in the assessment and care of patients with acute spinal cord injuries.

COMPLICATIONS

Complications in subaxial cervical spine trauma can be classified as both intra-operative and post-operative,[52] and both the patient and surgeon can be the variables involved. Failure to maintain anatomic reduction of subaxial cervical fracture-dislocation injuries even after operative management ranges from 1 to 18%.[110,111] Anterior procedures were better in maintaining normal alignment. Around 9% of patients had recurrent angulation or subluxation despite surgical management.[111] Other complications commonly encountered are implant failure like screw back-out, poor purchase due to the screws being in the disc space rather than the body and, rarely, screw breakage. Post-operative haematoma, misplaced implant and retraction injury can cause dysphagia and, rarely, respiratory distress.[24,52] Graft extrusion in anterior cervical surgery was seen in as many as 10% of patients.[111] Graft displacement was seen in 4% of patients and in none of the patients who had an anterior cervical plate.[52] Posterior instrumentation was also associated with complications and radiculopathy was reported in 25% of cases in one series. Prolonged bed rest and traction alone for 12–16 weeks has been associated with high mortality and morbidity, especially in patients with facet dislocation.[111]

Carotid Artery Injury

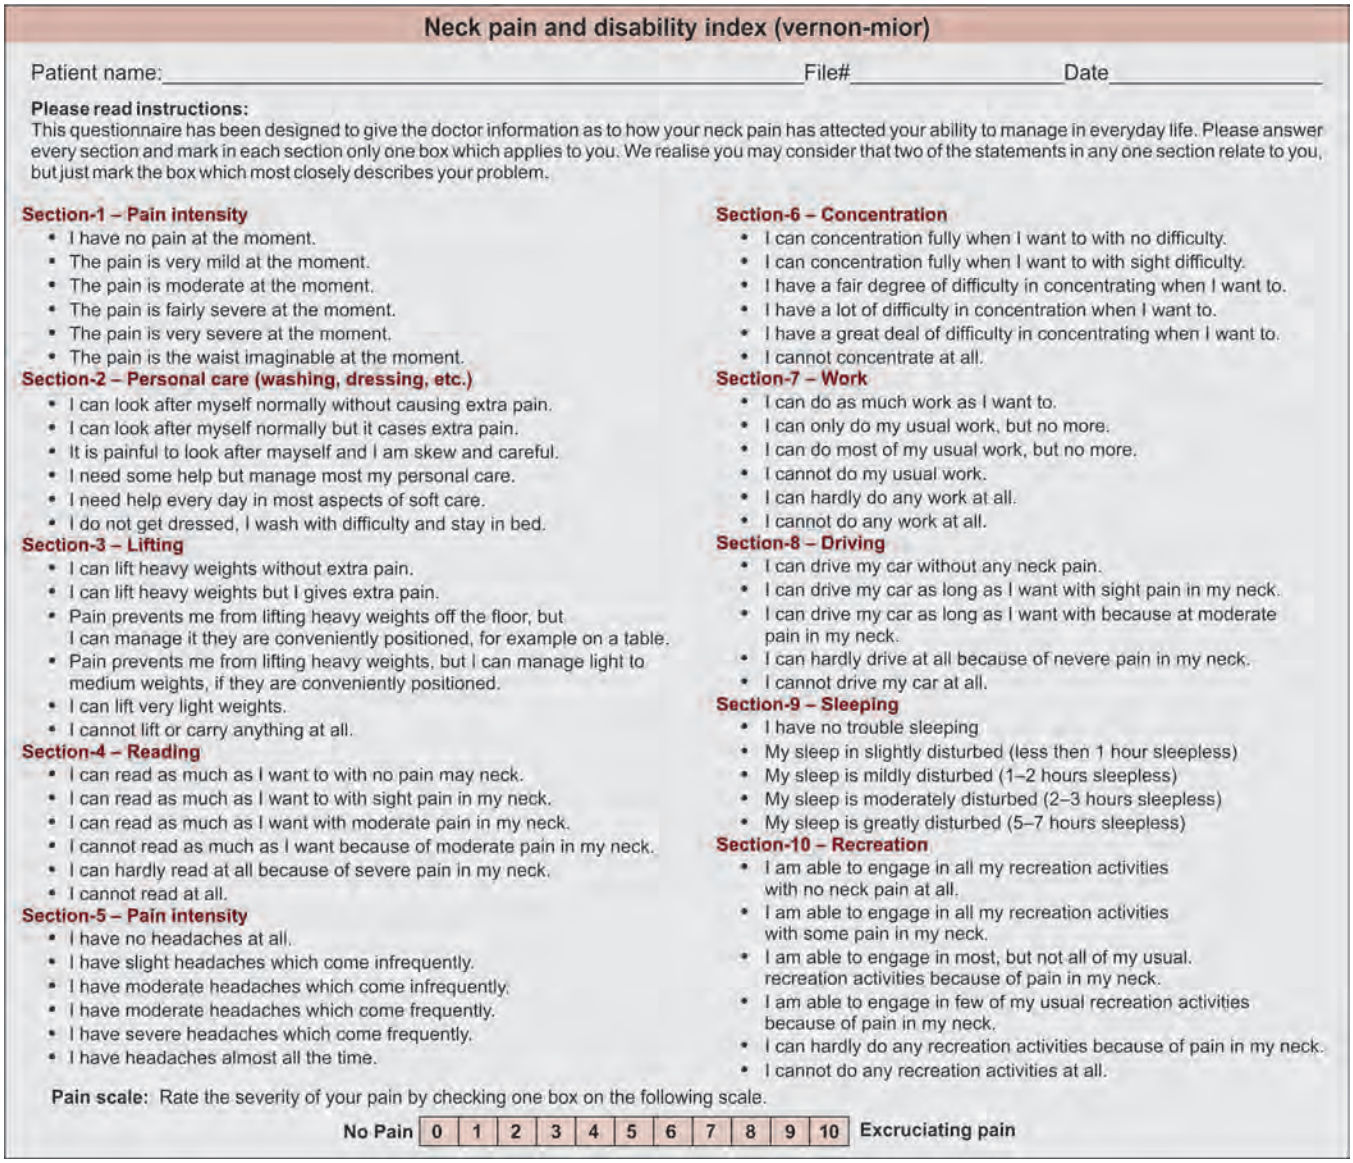
The carotid artery can be injured during anterior cervical exposure and the artery can be occluded due to excessive retraction, which may cause dislodgement of a plaque with subsequent intracranial embolus.

Vertebral Artery Injury

The reported incidence ranges from 0.3 to 0.5%. It is commonly caused by direct injury by instruments and high-speed drills during the lateral decompression.[121] Vertebral artery injuries can be associated primarily with cervical spine injuries.[34,47]

Injury to the Spinal Cord and Roots

The incidence of nerve root injury has been reported to be 0.17%. In anterior procedures the reported rates of C5-C6 radiculopathy range from 2 to 15%. The susceptibility of the C5 rootlet to injury is due to short length and angle of exit from the cord. Saunders[93] identified risk factors associated with the occurrence of post-operative radiculopathy and they include: age greater than 60 years, severity of the pre-operative myelopathy,



Neck pain and disability index (vernon-mior)

Patient name:_____ File#_____ Date_____

Please read instructions:
This questionnaire has been designed to give the doctor information as to how your neck pain has attected your ability to manage in everyday life. Please answer every section and mark in each section only one box which applies to you. We realise you may consider that two of the statements in any one section relate to you, but just mark the box which most closely describes your problem.

Section-1 – Pain intensity
- I have no pain at the moment.
- The pain is very mild at the moment.
- The pain is moderate at the moment.
- The pain is fairly severe at the moment.
- The pain is very severe at the moment.
- The pain is the waist imaginable at the moment.

Section-2 – Personal care (washing, dressing, etc.)
- I can look after myself normally without causing extra pain.
- I can look after myself normally but it cases extra pain.
- It is painful to look after mayself and I am skew and careful.
- I need some help but manage most my personal care.
- I need help every day in most aspects of soft care.
- I do not get dressed, I wash with difficulty and stay in bed.

Section-3 – Lifting
- I can lift heavy weights without extra pain.
- I can lift heavy weights but I gives extra pain.
- Pain prevents me from lifting heavy weights off the floor, but I can manage it they are conveniently positioned, for example on a table.
- Pain prevents me from lifting heavy weights, but I can manage light to medium weights, if they are conveniently positioned.
- I can lift very light weights.
- I cannot lift or carry anything at all.

Section-4 – Reading
- I can read as much as I want to with no pain may neck.
- I can read as much as I want to with sight pain in my neck.
- I can read as much as I want with moderate pain in my neck.
- I cannot read as much as I want because of moderate pain in my neck.
- I can hardly read at all because of severe pain in my neck.
- I cannot read at all.

Section-5 – Pain intensity
- I have no headaches at all.
- I have slight headaches which come infrequently.
- I have moderate headaches which come infrequently.
- I have moderate headaches which come frequently.
- I have severe headaches which come frequently.
- I have headaches almost all the time.

Section-6 – Concentration
- I can concentration fully when I want to with no difficulty.
- I can concentration fully when I want to with sight difficulty.
- I have a fair degree of difficulty in concentrating when I want to.
- I have a lot of difficulty in concentration when I want to.
- I have a great deal of difficulty in concentrating when I want to.
- I cannot concentrate at all.

Section-7 – Work
- I can do as much work as I want to.
- I can only do my usual work, but no more.
- I can do most of my usual work, but no more.
- I cannot do my usual work.
- I can hardly do any work at all.
- I cannot do any work at all.

Section-8 – Driving
- I can drive my car without any neck pain.
- I can drive my car as long as I want with sight pain in my neck.
- I can drive my car as long as I want with because at moderate pain in my neck.
- I can hardly drive at all because of nevere pain in my neck.
- I cannot drive my car at all.

Section-9 – Sleeping
- I have no trouble sleeping
- My sleep in slightly disturbed (less then 1 hour sleepless)
- My sleep is mildly disturbed (1–2 hours sleepless)
- My sleep is moderately disturbed (2–3 hours sleepless)
- My sleep is greatly disturbed (5–7 hours sleepless)

Section-10 – Recreation
- I am able to engage in all my recreation activities with no neck pain at all.
- I am able to engage in all my recreation activities with some pain in my neck.
- I am able to engage in most, but not all of my usual. recreation activities because of pain in my neck.
- I am able to engage in few of my usual recreation activities because of pain in my neck.
- I can hardly do any recreation activities because of pain in my neck.
- I cannot do any recreation activities at all.

Pain scale: Rate the severity of your pain by checking one box on the following scale.

No Pain	0	1	2	3	4	5	6	7	8	9	10	Excruciating pain

Fig. 8: Neck pain disability index

increased number of levels decompressed and the degree of cervical kyphosis. He also found that decreasing the width of the corpectomy defect from 20 to 15 mm led to a decrease in the occurrence of radiculopathy. Injury to the cord may be due to inadvertent slippage of instruments or the high-speed drills and are rare. Graft impingement or implant mis-alignment are other causes.

Injury to the Recurrent Laryngeal Nerve

This is considered the most common neurological complication after anterior cervical spine surgery. The incidence varies between 0.2 and 11%.[18,122] Clinical signs may range from hoarseness and loss of effective cough mechanism, to upper pharyngeal dysphagia with aspiration, to life-threatening airway obstruction from bilateral recurrent laryngeal nerve injury. Bulger et al.[18] suggest considerations for the prevention and treatment. Self-retaining retractors or hand-held retractors, exerting pressure on the trachea and tracheoesophageal groove can result in injury. This is reported to be more common on the right side where the recurrent laryngeal nerve course is more variable. The injury is much more common in redo surgeries. Usually it is better to approach an already operated upon patient from the same side of the earlier surgery to avoid damaging the nerves on both sides. Most commonly the injury to the nerve is transient lasting several weeks, but it may also be permanent. Monitoring of the endotracheal cuff pressure and temporarily deflating the cuff after retractor placement may minimise injury to the nerve. Intermittent relaxation of the retractors may also prevent injury.

Injury to the Sympathetic Trunk

Ebraheim et al.[31] point out the vulnerability of the sympathetic trunk during the anterior approach to the lower cervical spine.

Patient name	*Rater name*	*Date*	
ACTIVITY			**SCORE**
Feeding			
0 = unable			
5 = needs cutting, spreading butter, etc. or requires modified diet			
10 = independent			_____
Bathing			
0 = dependent			
5 = independent (or in shower)			_____
Grooming			
0 = needs help with personal care			
5 = independent face/hair/teeth/shaving (implements provided)			_____
Dressing			
0 = dependent			
5 = needs help but can do about half unaided			
10 = independent (including buttons, zips, laces, etc.)			_____
Bowels			
0 = incontinent (or needs to be given enemas)			
5 = occasional accident			
10 = continent			_____
Bladder			
0 = incontinent, or cathetorised and unable to manage alone			
5 = occasional accident			
10 = continent			_____
Toilet use			
0 = dependent			
5 = needs some help, but can do something alone			
10 = independent (on and off, dressing, wiping)			_____
Transfers (bed to chair and back)			
0 = unable, no sitting balance			
5 = major help (one or two people, physical) can sit			
10 = minor help (verbal or physical)			
15 = independent			_____
Mobility (on level surfaces)			
0 = immobile or <50 yards			
5 = wheelchair independent, including corners, >50 yards			
10 = walks with help of one person (verbal or physical) >50 yards			
15 = independent (but may use any aid, e.g. stick) >50 yards			_____
Stairs			
0 = unable			
5 = needs help (verbal, physical, carring aid)			
10 = independent			_____
		Total (0–100)

Distraction Injury

Axial traction has been used to reduce the dislocation caused by injury to the subaxial cervical spine, but the current practice option involves controlled traction using a three-pin fixation and pre-operative fluoroscopy followed by maintenance of alignment using instrumentation. Various techniques using contoured plates and screws and sequential screw tightening causing controlled reduction and deformity correction are in current

practice. There are instances of surgically related neurological deterioration as a result of over-distraction of the anterior column inter-space at the time of graft placement.

PAEDIATRIC SUBAXIAL SPINE INJURIES

Dogan et al.[28] found subaxial cervical spine injuries were common in children of 9–16 years of age, and occurred mainly between C5 and C7. Multilevel injury was more common in children of 8 years of age and older, than in younger children and infants. Most patients with subaxial cervical spine injuries can be treated conservatively. Keiper et al.[53] found that posterior soft-tissue or ligamentous injury was the most common finding in the 10 paediatric patients with mild-to-moderate trauma, while acute disc bulges and longitudinal ligament disruption were uncommon. Both anterior and posterior approaches are safe and effective.[28,71] Instrumentation in children can be difficult due to the size and the bone quality of the vertebral column. There is also concern about the instrumentation hindering normal growth patterns. Bioabsorbable plates may be an option. In children who have a SCIWORA injury, the parents must be cautioned to avoid any high-risk activity for the next 6 weeks.

GERIATRIC SUBAXIAL SPINE INJURIES

Elderly patients commonly have cervical spine injuries after trivial falls, due to altered biomechanics as the soft tissues, i.e. ligaments and discs degenerate or calcify and there is a high incidence of pre-existing cervical spondylotic myelopathy. Whang et al.[118] found that most of these injuries involved the subaxial cervical spine between C5 and C7. In all, 41.2% of AS patients were considered to be ASIA A, whereas 44.4% of DISH patients were classified as ASIA E. The rate of neurologic injury was high for both groups. The AS patients were more likely to exhibit neurologic deficits and undergo operative management. Although the majority of these spinal injuries were treated surgically, stable fractures without any associated neurologic deficits were often successfully managed with immobilisation. Sokolowski et al.[105] in a large series of elderly patients with cervical spine injuries, found that survival rates were comparable regardless of anatomic level of injury and the operative treatment of subaxial injuries was associated with an improved acute survival rate versus non-operative management.

DELAYED SUBAXIAL SPINE INSTABILITY

Old subaxial cervical spine injuries missed on the primary trauma survey present to the neurosurgeon with progressing signs of radiculopathy and myelopathy, and deformity due to glacial instability. Cervical instability that is not recognised until beyond 20 days after injury is called delayed instability. These injuries may require gradual axial traction, but most can be managed by an anterior approach and a fusion with bone graft and contoured plates using the techniques to correct deformity.

FUTURE TRENDS AND PREVENTIVE NEUROSURGERY

Schneider[95–99] was a pioneer in recognising the mechanisms of spinal trauma and his research paved the way for many modifications of rules in sports to prevent the incidence of subaxial cervical spine injuries. Further research into the biomechanics and classification of subaxial spine injuries will lead to the development of better spinal implant systems which will allow for less invasive surgical corridors and better outcomes. In India there is an urgent need to develop spine injury centres that are located in all parts of the country and deal exclusively with trauma and spine injury.

51 Whiplash Injury

Harjinder S Bhatoe

Acceleration injury or whiplash injury of the neck refers to the cluster of symptoms following application of a propulsive force to the head and neck complex. This has to be distinguished from contact injury in which there is impact to the head and/or neck (as by a hit to the forehead by a beam or bottom of a swimming pool) resulting in a spectrum of fractures and dislocations. Acceleration injury on the other hand is called neck sprain, whiplash or soft tissue neck injury. The clinical presentation presents diagnostic and therapeutic challenges. The mechanism is universally similar—rear-end impact to the body in motion as the neck is unsupported. Although the typical example is the injury suffered by a car occupant with a rear-end collision, there is a variable set of clinical circumstances with an equally variable symptom complex.

MECHANISM AND PATHOLOGY

While it is universally agreed that cervical acceleration injury occurs due to rear-end impact to occupants in a stationary vehicle, the exact biomechanics has been a subject of research. Whiplash injury has been simulated in several experimental studies. McNab suspended anesthetised monkeys with their head and neck unsupported and dropped them from a height; the drop was arrested short of ground impact, simulating neck hyperextension.[7] In a similar study, Clemens and Burrows, studied the mechanics using embalmed cadavers subjected to rear-end impacts producing 13–16 G forces.[3] Both these studies reported minor injuries to the sternocleidomastoid, partial avulsion of the longus colli and retropharyngeal haematomas. The most common finding was intervertebral disc failure and tears of the anterior longitudinal ligament, found in nearly 90% of cases. These findings have been confirmed on autopsy studies. Taylor et al.[9] identified three patterns of injury to the intervertebral disc:

1. Anterior rim lesion—there are linear clefts in the peripheral cartilage plate in the region where this cartilage is continuous with the fibrous annulus. The anterior longitudinal ligament is intact and cervical spine alignment is normal on radiographs.
2. Posterior contusions and herniation of intervertebral discs.
3. Partial or complete avulsion along the disc-vertebral interface—usually seen in children. MRI shows high signal intensity on T2-weighted images. It is important to recognise ligamentous injury since there is potential for segmental instability.

According to a study conducted by Grauer and his coworkers, there is a kinematic biphasic response of the unsupported cervical spine when it is rear impacted.[5] Initially the upper cervical spine as well as the lower cervical spine hyperextends converting the cervical spine to an 'S'. Milliseconds later, this is followed by hyperextension of the entire cervical spine. Injury is sustained in the first phase (Figs 1A to H).

CLINICAL PROFILE

The clinical picture of acceleration injury is dominated by neck pain, which is accentuated on movement. This is accompanied by other symptoms (Table 1), many of which are poorly explained. The symptom complex may be aggravated by various psychosocial factors like anger, anxiety, depression and pending litigation. Clinical examination reveals restriction of neck movements, spasm of paraspinal neck muscles and tenderness over the

• Anxiety

posterior neck muscles. Nearly 70% of the patients are females, often with occupations requiring low physical demands.[6] Neurological examination is normal. Cervical spine radiographs are usually normal, except for loss of physiological lordosis. The symptoms persist for more than 1 year in about 88%, and more than 2 years in 64% of patients.[1] A severe injury in the elderly may rarely be complicated by oesophageal rupture and mediastinitis.[6]

Cognitive dysfunctions are the least understood aspect of cervical spine acceleration injury. Broadly, these dysfunctions fall in two categories: (1) cervicocephalic and (2) lower cervical spine syndrome.[8] In cervicocephalic syndrome, there is demonstrable abnormality of auditory and visual information processing, mood changes, sleep disturbances, psychoneurotic reaction, depression and "litigation neurosis". In lower cervical spine type of presentation, in addition to painful symptoms pertaining to the cervical spine, there is disturbance in visual information processing.

IMAGING

Cervical Spine Radiographs

Dynamic radiographs of the cervical spine show restriction of motion at one level, and loss of the normal lordotic curve (Fig. 2). Prevertebral swelling is variable. Degenerative changes pre-existing at the time of initial presentation are likely to be associated with persistence of symptoms.

Magnetic Resonance Imaging

Many of the changes produced by acceleration injury can only be revealed by MRI. These changes affect the anterior column, and are seen as disruption of the anterior longitudinal ligament, anterior annular tears, occult vertebral end-plate fractures, acute cervical disc herniation, zygoapophyseal joint injury, etc. (Figs 3 and 4).[4]

MANAGEMENT

Management depends upon the severity of the problem, and patients with intense symptoms may require hospitalisation. Usual treatment consists of analgesics, cervical collar, rest, muscle relaxant and anti-inflammatory medication. Narcotic analgesics may be required to interrupt the "pain-spasm" cycle. Trigger point injections

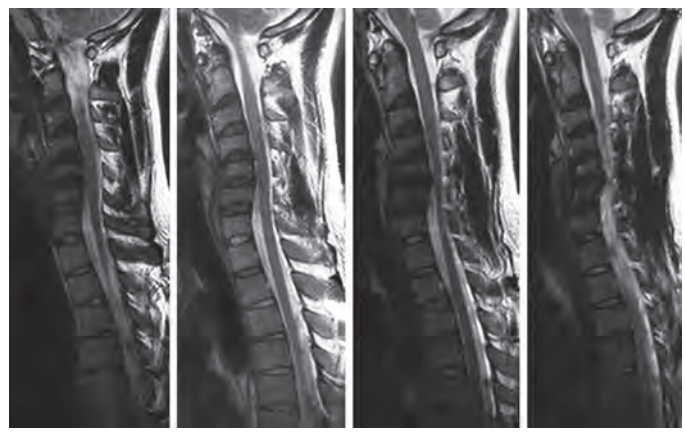

Fig. 4: MRI (T2-weighted images) showing posterior annular bulge at C4/C5 with straightening of cervical spine from C1 to C4

and epidural blocks may be required in refractory cases. Local infiltration with corticosteroids advocated by some is not beneficial.[2] Surgery is reserved for those with disc avulsion, especially with pre-existing degenerative disc disease. These patients require discectomy with fusion. A psychiatric consultation may be required for patients with chronic persistent pain.

52 Thoracic and Thoracolumbar Injuries

Ramakrishna Easwaran

INTRODUCTION

The human spinal cord in most areas measures less than 10 mm in diameter. A permanent traumatic damage to this tiny region leaves a person paralysed for life. Loss of earning is a lesser catastrophe than the loss of self-esteem after traumatic paraplegia. The picture becomes more poignant because of the propensity of polytrauma to pick persons in their prime. The incidence of spinal injury is increasing every decade. A study from Norway shows that the annual population incidence of spinal cord injury (SCI) has risen from 5.9 per million in the 1950s to 21.2 per million in the 1990s.[35] The pathophysiology and management of SCI is dealt with elsewhere in this textbook. About 20% of patients with thoracolumbar spine injury have neurological deficits.[26] This chapter deals with thoracic and lumbar spine injuries. Sacral injuries are dealt with in the next chapter. It is essential to clarify the nomenclature of the various segments of the spine at the outset and this is summarised in Table 1.

EPIDEMIOLOGY AND AETIOLOGY

The population incidence of SCI varies in different countries from 15 to 40 per million per year.[88] Thoracic and lumbar injuries accounted for 75% of all spine injuries in a study from Jammu.[91] The most commonly fractured level in the whole spine is L1, followed by T12. The vulnerability of the T12-L1 region is ascribed to the change from a kyphotic curve of the relatively immobile thoracic spine to a lordotic one in the mobile lumbar spine. Spinal trauma is, world over, commoner in males and the gender bias is more pronounced in India. The male-female ratio of incidence of spinal injury was 3:1 in a report from Haryana,[92] but an earlier rural study showed a ratio of 13:1.[16] The mean age of occurrence is 35 years and the median age group 20–29 years.[92] A second peak is seen in the elderly due to osteoporotic vertebral fracture.[80] A rare case of neonatal SCI has been reported from Vellore.[96]

Table 1: Nomenclature of levels of spinal lesions

Level	*Name*
Occiput to C2	Craniovertebral junction
C1, C2	Upper cervical spine
C2–C7 or T1	Subaxial cervical spine
C7-T2	Cervicothoracic junction
T1–T6	Upper thoracic spine
T6–T12	Lower thoracic spine
T11-L2	Thoracolumbar junction, lumbodorsal junction
L2–L4	Midlumbar spine
L5, S1	Lumbosacral spine
S1–S5	Sacral

Fall from heights are commoner causes than road traffic accidents in most Indian series. Falling from trees, electric poles, staircases, ladder, upper storeys of houses and construction sites account for about 50% of all spine injuries.[91] Falling off camels is common in Rajasthan and the Middle East! When a person falls into a well that is being dug, the caving mud crushes the spine and adds to the injury caused by the fall. Osteoporotic thoracolumbar wedge compression fractures occur after trivial domestic falls and this is the only type of fracture that is commoner in women. Load carriers are prone to spine injury when the load slips from the head or shoulder. Another common mechanism of injury is the 'last seat fracture'—a compression fracture in the dorsolumbar junction sustained by a person travelling in the rear seat of a long bus that hits a big pothole.

Sporting activities associated with spine injury in India include wrestling and bull fighting (known as jallikattu in Tamilnadu). Diving, horse riding, skiing, pole vaulting, gymnastics, motor sports and altitude sports are common causes in other nations. Road traffic accidents cause more than 50% of spinal injuries in Western societies. In a British study, spinal injuries occurred in about 11% of 1,121 motorcyclists and 14% of 2,718 car occupants involved in road accidents.[79] About a third of these patients had isolated spinal injuries. The thoracic spine was injured in over 50% of the motorcyclists in this study. Rollovers and ejection from the vehicle are usually implicated. Seat belt fractures notwithstanding, there is proof that the combination of air bags and seat belts reduce the severity (if not the incidence) of spine injury in motor vehicle accidents.[102]

We live in an increasingly violent society. Missile injuries of the spine, once the sole preserve of Armed Services hospitals,[9] have become commonplace in triage departments of big city hospitals. Non-missile penetrating injuries of the spine accounted for 7% of all spinal injuries in Chandigarh.[95]

CLASSIFICATION

Classification schemes of thoracic and lumbar injuries continue to evolve with our imaging technology and understanding of biomechanics. The major classification systems are presented in Table 2. Holdsworth's scheme of 1953 was based on radiographic findings.[41] In the absence of axial CT, burst fracture could not be well made out in those days and though recognised by Holdsworth, it was not described as a separate entity. He described the slice fracture near the upper part of the lower body with dislocation of the inferior articular process of the upper body in flexion-dislocation injuries. Kelly and Whitesides introduced the two-column model in 1968 (Fig. 1).[47] The concept of stable and unstable fracture was better defined. Wedging fractures are those with an intact posterior vertebral body margin while burst fractures are those with a disruption of the same. They also showed that the surgical approach could be decided from the type of fracture. Those who have anterior column damage need anterior strut grafting. Most importantly, their model showed the danger of performing laminectomy in patients with anterior column injury.

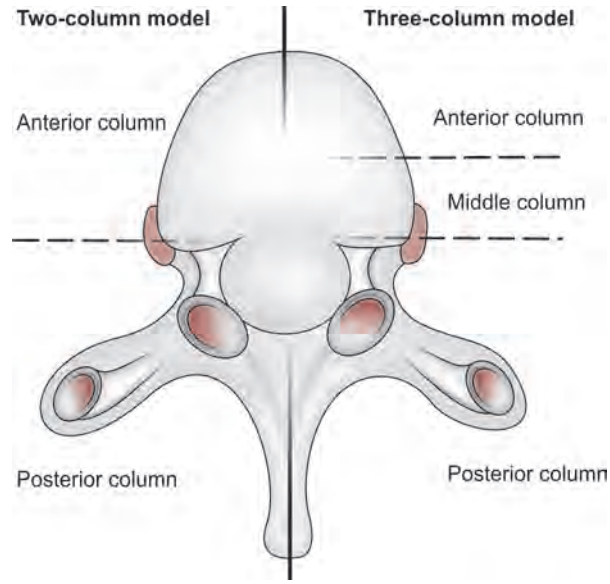

Fig. 1: Diagram showing the Kelly & Whitesides two-column model on the left and the Denis three-column model on the right[26,47]

The introduction of axial CT made it possible to see burst fractures and sagittal body fractures. Denis brought out the importance of the osteoligamentous middle column made up of the posterior wall of the vertebral body, the posterior longitudinal ligament and posterior annulus fibrosus (Fig. 1).[26] He classified wedge compression fractures into anterior and lateral types. The burst fractures are divided into five subtypes in the Denis system, based on the additional force involved, apart from the axial load that is common to all burst fractures. Type A—involves both endplates (pure axial load), type B—only the superior endplate, type C—only the inferior endplate (axial load plus flexion in B and C), type D—additional rotation and type E—additional lateral flexion. Seat belt injury (Chance fracture) is given a separate category. There are three subtypes under the fracture-dislocation category (flexion-rotation, shear and flexion-distraction). It must be remembered that the

force causing the injury is a matter of guesswork. The depiction of the bony injury became more accurate with multiplanar CT reconstruction. The patterns of injury are illustrated with reconstructed CT images in Figures 2A to E, following McAfee's nomenclathure.[59]

The Magerl scheme follows the general principles of Arbeitsgemeinschaft für Osteosynthesefragen (AO) nomenclature.[58] There are three basic types of injuries: (A) vertebral body compression; (B) anterior or posterior element distraction and (C) rotation plus type A injury (C1), rotation plus type B injury (C2) and rotation with shear (C3). These three basic types are further divided into three groups each and some into further subgroups. The severity of the injury and the degree of instability increases between and within each group. They are illustrated in Figure 3. Magerl's system is widely used in Europe. The extensive number of subgroups makes it difficult to be used in daily practice. We must remember that all these schemes apply mostly to the thoracolumbar junction. The Denis scheme had a lower inter-observer and intra-observer reliability than the AO system, but both the systems had only moderate reliability in a comparative study.[105]

A recent development is the thoracolumbar injury classification system (TLICS) designed by the Spine Trauma Study Group.[99] This system makes a departure from the traditional method of using the putative mechanism of injury, which is a matter of conjecture. Instead, this system uses a description of the injury morphology, which is directly observable on imaging. In addition, the TLICS assesses the integrity of the posterior ligament complex (PLC). The PLC is made up by the facet capsules, ligament flavum and interspinous and supraspinous ligaments which contribute to spinal stability, serving as the "posterior tension band" of the spinal column. Due to its poor healing capability, disruption of the PLC alone may necessitate surgical stabilisation. This system also addresses the neurological state. The number of subgroups is not unwieldy as in the AO system. Based on points assigned, a TLICS severity score is calculated (Table 3). If the total score is 3 or less, the patient is managed conservatively. If the score is 5 or more, the patient is offered early surgical stabilisation. The decision has to be individualised for those with a score of 4. The inter-observer reliability and validity of predictions from TLICS has now been well proved.[37,71,78] The McCormack load sharing classification of burst fractures is of great relevance in deciding about surgery and it is described later in this chapter.[60]

ASSOCIATED INJURIES

Thoracic and lumbar spinal injuries may be associated with another spinal injury such as an upper cervical spine injury. Rib fractures, haemothorax and lung contusions are common with severe thoracic spine injuries and they may be missed or picked up only after a delay in a paraplegic patient (Fig. 4).[83] Splenic, hepatic and renal injuries associated with spine fracture are commoner with motor vehicle accidents than with falls. Their incidence is also higher with multiple levels of spine fracture than with single level fracture.[74] Fracture of the lumbar transverse processes may indicate renal or ureteric injury. Seat belt injuries are associated with abdominal hollow or solid viscus injury, especially in children.[86] Chance fracture is associated with mesenteric or bowel injury in 40% of cases.[8] It is equally important to realise that a significant thoracic or lumbar spinal injury may be missed in the unconscious head-injured patient or in patients who have major abdominal or thoracic trauma.[6] A painful calcaneal or femur fracture might overshadow a dorsolumbar junction wedge fracture.

PREDISPOSING FACTORS

Conditions that weaken the bone increase the fracture risk. The most important predisposing factor for thoracic and lumbar fractures is osteoporosis. This is dealt with in detail in another chapter of this textbook. Pathological

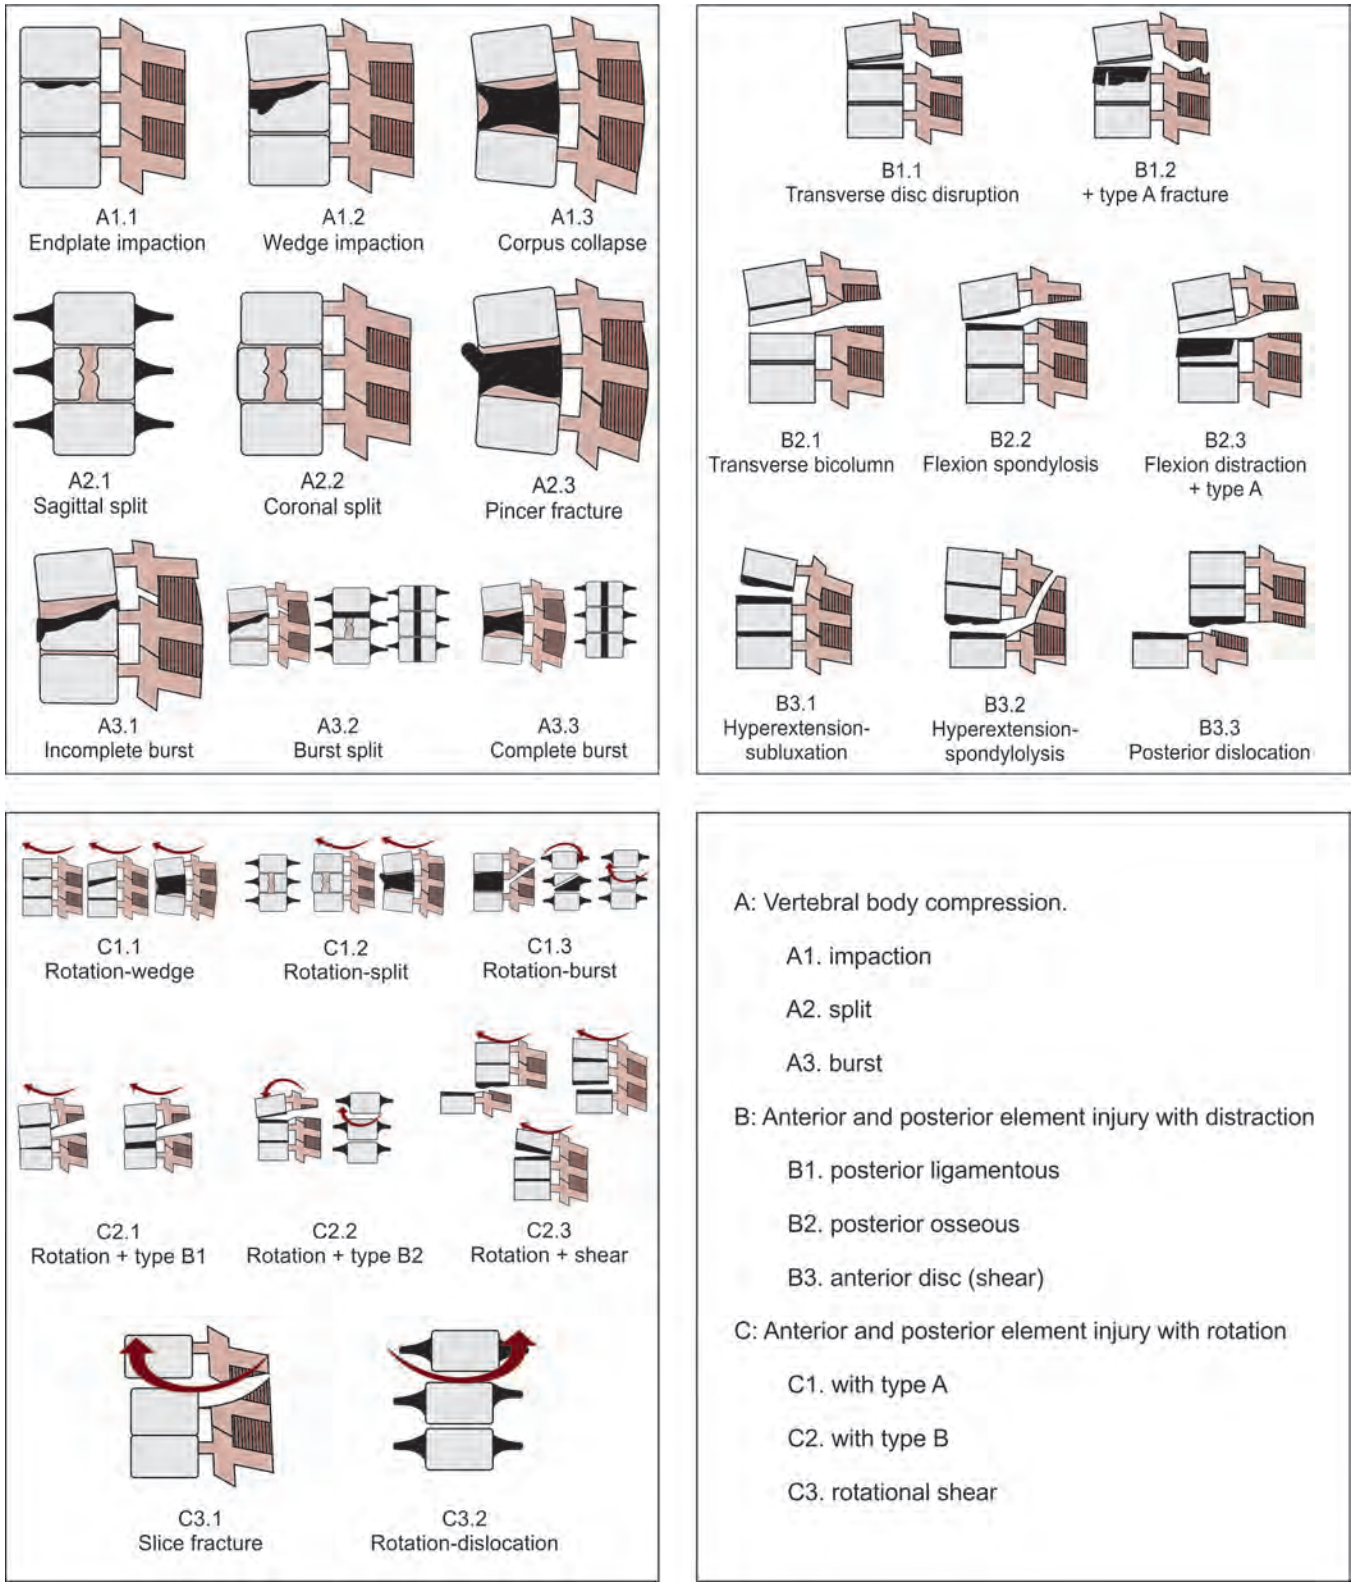

Fig. 3: Magerl's AO classification of thoracolumbar fractures (modified from Cassar-Pullicino & Imhof[14])

fractures are also seen with myeloma,[54] metastasis[72] or tuberculosis.[24] These patients may present with sudden paraplegia after trivial trauma. Conditions that cause narrowing of the spinal canal do not make the spine more prone to fracture, but they render the cord more vulnerable to damage. These conditions include congenital or degenerative thoracic canal stenosis,[46] achondroplasia,[65] ossification of the posterior longitudinal ligament and ossification of the ligamentum flavum.[40] Calcium pyrophosphate dihydrate deposition disease

Table 3: Assignment of point values in the TLICS system[99]

Factors considered	*Assessed by*	*Point value*
Morphology*	Imaging	
Compression fracture	Lateral radiograph, sagittal CT reconstruction	1
Burst component	Axial CT, sagittal CT reconstruction	2
Rotation or	AP radiograph, axial CT	
Anteroposterior translation or	Lateral radiograph, sagittal CT reconstruction	
Side-to-side translation	AP radiograph, coronal CT reconstruction	3
Distraction	Lateral radiograph, multiplanar CT reconstruction	4
PLC integrity	Fat suppressed T2 sagittal MRI	
Intact		0
Indeterminate		2
Disrupted	Splaying of spinous process, facet joint distraction on lateral radiographs and sagittal CT reconstruction are also suggestive	3
Neurological status	Clinical examination	
Intact		0
Nerve root injury		2
Complete		2
Incomplete (cord or cauda equine)**		3

Note:

*For calculating 'morphology score', the most severe component alone is taken. Hence the minimum total score can be 1 and the maximum score 10.

**Incomplete neurological lesions merit a higher score, as they are likely to deteriorate further if not stabilised

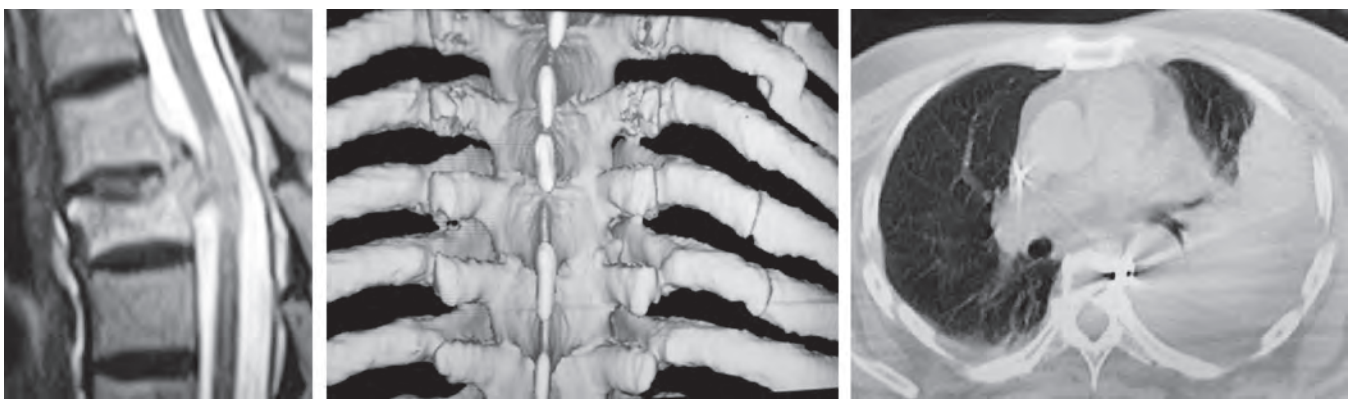

Fig. 4: Thoracic spine fracture (MRI) associated with multiple rib fractures (3D CT) and haemothorax (axial CT)

(pseudogout) may rarely present with paraplegia following minor trauma.[68] There is also a set of conditions that may not show fractures on radiographs but require CT and MRI for demonstrating it, such as ankylosing spondylitis,[98] diffuse idiopathic skeletal hyperostosis[39] and skeletal fluorosis. Extension injuries and shear are commonly seen even with low-energy impacts and the neurological deficit is severe in these ankylosed spines.

CLINICAL FEATURES AND ASSESSMENT

Pain is the commonest presenting symptom of thoracic or lumbar spine injury. Young children, patients with obtundation due to head trauma or ethanol effect and those with minor fractures may not complain of spinal pain in the casualty department. A bruise over the back, a fluctuant haematoma or a tender gibbus may be palpable, but only on turning the patient over—a manoeuvre that is often sadly missed by doctors in the emergency room. Lack of posterior midline tenderness has occasionally been noted with fractures even in sober, alert patients who do not have another painful distracting injury.[25] On the other hand, a minor fracture or ligament injury may present with severe pain and muscle spasm causing total immobility. Priapism is sometimes picked up only when one tries to catheterise the bladder. Conus and cauda injuries might present with isolated inability to void urine in a patient who comes walking

in. A patient who was being treated for a scalp avulsion developing progressive paraparesis 18 hours later due to a total dislocation at T1-T2 level has been reported from Chennai.[93]

Neurogenic shock, manifested by the triad of hypotension, bradycardia and hypothermia may be seen in injuries above T6. It is due to disruption of the thoracolumbar sympathetic outflow and unopposed vagal action.

Neurological syndromes seen are root injury, cauda equina syndrome, incomplete cord lesion and complete cord injury. Note that the American Spinal Injury Association (ASIA) guidelines (International Standards for Neurological Classification of Spinal Cord Injury—ISNCSCI) define complete cord injury as absence of sensory and motor functions in the lowest sacral segments.[5] The completeness of the cord injury can be confirmed only after spinal shock passes off. Spinal shock can be taken to have passed when the anal or bulbocavernosus reflexes reappear. Anterior and central cord syndromes, seen commonly with cervical spinal trauma, are not generally seen in thoracic trauma. Brown-Sequard like syndrome might be seen in non-missile penetrating trauma. It is well to remember that the spinal fracture may be anywhere above the highest neurological level of involvement in incomplete cord injury. With complete injury the rule of minus 2 in the upper thoracic and minus 3 in the lower thoracic spine holds. For example, if the patient has the highest neurological level of impairment at T6, the vertebral lesion is likely to be at T4; neurological impairment at T12 indicates T9 vertebral injury. Though the modified Frankel scale (Table 4) is the most widely used one for assessment because of its simplicity, it has its demerits. The groups are too broad and so one cannot pick up the smaller but useful increments of function. The ASIA Impairment Scale is too detailed for daily clinical use but is useful for research. It can be calculated through a Macromedia Flash based program available for free download at http://www.medicine.usask.ca/pmr/asia.exe.[57] Neurological improvement in paraparesis is best assessed by the WISCI (Walking Index for SCI).[28]

IMAGING

Plain Radiography

Radiographs of the spine are quick and cheap, but the quality of emergency room radiographs is often below par. Patient restlessness, inability to position the patient appropriately and lower output of portable machines may lead to failure in detecting spinal fractures. The cervicothoracic and lumbosacral junction are notoriously difficult areas to depict on radiographs in the triage. Digital radiographs are better than plain film radiographs, but the hard copy should not be in a very small format. Any positive radiographic finding must be backed up by further studies. A normal looking radiograph does not exclude spinal injury and so further studies are warranted, if there is clinical suspicion of spinal injury.

Table 4: Modified Frankel scale

A	No neurological function, complete paralysis
B	Preservation of sensory function below injury level
C	Inadequate motor function below injury level
Da	Allowing ambulation with assistance
Db	Self ambulation with minor difficulty
E	Normal neurological status

Spinal cord injury without radiographic abnormality (SCIWORA) in the thoracic region is mainly seen in the paediatric spine that bends but does not break. Thoracic SCIWORA may be due to high-speed direct impact, distraction from seat belts and run-over when the child is in the prone position.[69] Conversely, one occasionally sees a patient with a gross thoracic fracture dislocation without any neurological impairment.[42] Such a phenomenon has been ascribed to the decompressive laminar fractures, but a congenitally roomy canal and absorption of the impact energy by bone and ligaments might also protect the cord. The situation may be analogous to a vehicle crash, where the front of the car is badly crushed but the occupants escape unhurt.

The finding of one level of spinal injury must lead to a radiographic search for another spinal injury, whether symptomatic or not. Standard antero-posterior and lateral radiographs suffice. Unlike in the cervical spine, there is little role for flexion-extension study in thoracic or lumbar spine injury.

Computerised Tomography Scanning

The wide availability of CT, especially multi-detector CT, has made it possible to image the deformation of the neural canal accurately. Even the 2.5 mm slices of chest and abdomen helical CT done for trauma screening can be reconstructed to obtain good spine images.[81] Table 3 brings out the role of multiplanar CT reconstruction in the TLICS classification.[78] Figure 2 shows some examples of CT in thoracic and lumbar spine trauma. Pneumorachis is associated with skull-base fracture or pneumothorax but may be a primary event in blunt thoracic spine trauma.[17] A "dissolving pedicle" sign has been reported in axial CT of Chance fracture.[8] CT is the best method of identifying canal compromise. The axial transverse canal area might correlate better with neurological state than the mid-sagittal diameter or percentage patency in thoracolumbar burst fractures.[77] The Spine Trauma Study Group suggests measuring the sagittal-to-transverse canal diameter ratio, canal total cross-sectional area and the per cent canal occlusion, to assess canal dimensions.[48] Generally, less than 30% canal narrowing is not associated with neurological deficit but more than 50% is almost invariably accompanied by deficit, at least at the L1 level. Variations between levels and individuals abound.

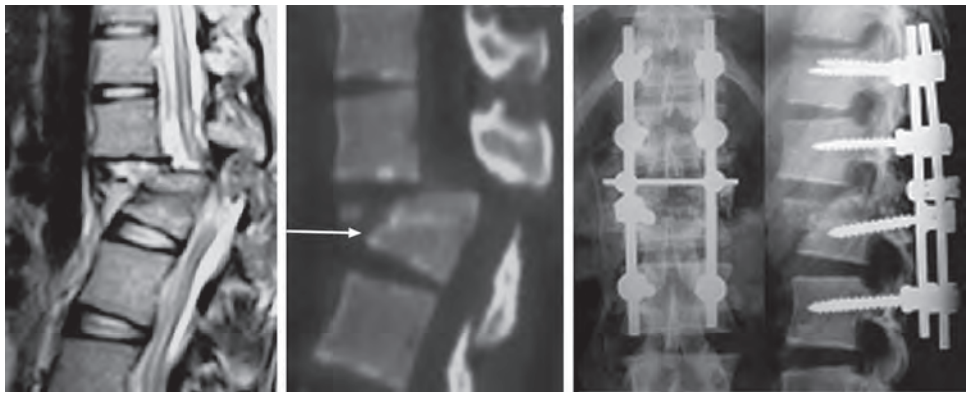

Fig. 5: Sagittal T2 MR imaging of what looks like cord transaction (left). Note the severe canal compromise on CT (middle). This patient has improved from Frankel A immediately after injury to Frankel C in 4 months after extended short segment posterior instrumentation (right- post-operative radiographs), proving that he did not have a true transaction

Magnetic Resonance Imaging

The prevertebral and paravertebral soft tissues, discs, ligaments and spinal cord are best assessed by MRI. Minor fractures missed on radiographs may be suspected from MR by the associated marrow oedema and 'bone bruise'. Acute Schmorl's nodes form due to endplate fracture that allows the disc material to herniate into the vertebral body. These are common in the T8-L1 region and are well imaged by MR.[30] Fat suppressed sagittal T2 imaging best identifies the integrity of the PLC.[56] Rupture of the anterior and posterior longitudinal ligaments, disc disruption and shearing of the subepiphyseal growth zone of the vertebral endplates are demonstrable by MRI in paediatric patients with SCIWORA. These are markers for occult instability and indicate the need for spinal bracing.[70] The 'sandwich sign' of linear haemorrhage in the posterior neural arch framed by marrow oedema has been observed in Chance fractures. These flexion-distraction injuries are also associated with a severe soft tissue injury.[34]

The spinal cord abnormalities seen in MRI are complete transaction (Fig. 5), major or minor haematomyelia and oedema. MRI and somatosensory evoked potentials are also normal in up to 15% of SCIWORA children with persistent myelopathy.[70] The traumatic cord oedema might extend beyond the level of the injury, usually upwards. Figure 6 shows a patient with T12 fracture who had clinical ascent of deficit *pari passu* with the oedema ascending over days to the cervical level. A vascular aetiology has been proposed to explain the delayed ascending myelopathy.[87] Post-traumatic syringomyelia is seen months or years after trauma. T2 hyperintense signal around the cranial border of the post-traumatic syrinx indicates progression.[45] Traumatic extradural haematoma is rarer than the spontaneous variety, unlike in the cranium. Two cases have recently been reported from AIIMS, New Delhi.[49] Gadolinium enhancement is not needed unless there is a suspicion of a tumour or inflammatory disease resulting in pathological fracture.

CONCEPT OF INSTABILITY

At the end of clinical and imaging evaluation, the neurosurgeon should be able to decide if the spine is already rendered unstable by the trauma or if there is a risk of potential instability in the future. While this should be quite straightforward, say, in an isolated spinous process fracture (= stable) or in a fracture dislocation (= unstable), there are grey areas in between. Instability is defined as the inability to limit excessive spinal displacement.[7] Acute instability that results from trauma may be overt or limited. Overt instability is the circumferential loss of spinal integrity resulting in the inability

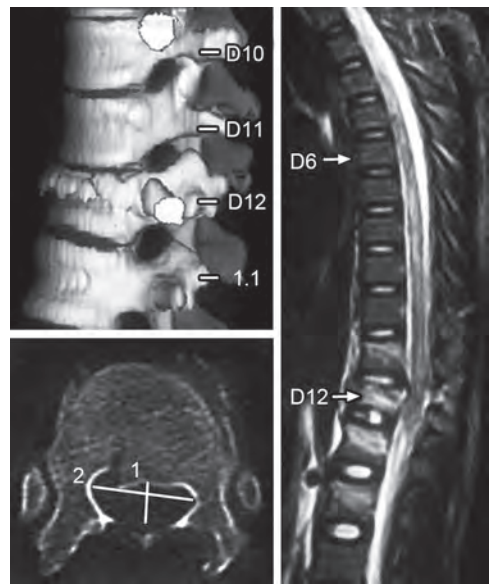

Fig. 6: Ascending cord oedema (right-sagittal T2-weighted MR) up to cervical region 5 days after stable burst fracture of T12 (left-CT). The patient presented with paraplegia that had ascended from L1 level to T6 level at presentation on the 3rd day, following postural reduction at another hospital. Over the next 2 days he had sensorimotor symptoms and signs up to C8 level. He was treated conservatively and the neurological level descended to T3 in a week

Table 5: Quantifying thoracolumbar instability. If the score is > 5, overt instability and if it is 2–4, limited instability exists (modified from White & Panjabi[103])

Factors taken into account	*Points*
Loss of integrity of the anterior (and middle) column	2
Loss of integrity of the posterior column	2
Resting sagittal or coronal plane translation	2
Resting sagittal plane rotation (angulation)	2
Cauda equina (3), spinal cord (2) or root (1) injury	3
Dangerous loading anticipated	1

to support the torso during all normal activities. Limited instability is the loss of either ventral or dorsal integrity with the preservation of the other. Thus the spine with limited instability can support the torso during some activities but not during some others. Denis described three degrees of instability:[26]

1. Mechanical (first degree) instability that results in progressive kyphotic deformity
2. Neurological (second degree) instability that carries the risk of neurological compression
3. Combined (third degree) instability that has both the above components

Table 5 gives a simple method of quantifying the instability, so as to clarify the situation in the grey areas mentioned above.[103] The Spine Trauma Study group advocates the measurement of the Cobb angle (to assess sagittal alignment), vertebral body translation percentage (to assess traumatic anterolisthesis) and anterior vertebral body compression percentage as indicators of instability.[48] Loss of vertebral body height by more than 50% and kyphotic deformity of 20° or more are considered signs of instability.[85] Assigning the Magerl nomenclature, TLICS score or the load sharing score helps decide if an injury is unstable or not. It must be made clear that instability is a clinical concept and not merely a matter of mensuration on images.

MANAGEMENT

Triage Care

The initial goals of resuscitating polytrauma patients must vigorously be pursued in the spine-injured patient. It is necessary to have appropriate oxygenation and perfusion pressures to prevent a secondary damage to the injured cord. Nursing personnel must be instructed to avoid unnecessary movement of patients from beds to trolleys and to take spine precautions when moving. A major chest or abdominal injury takes precedence over spine injury. Methylprednisolone use is recommended by the NASCIS 3 guidelines[11] as a standard of care but niggling doubts remain over the study.[18,43]

A review of pharmacological neuroprotection measures in SCI is available for free download at http://www.ncbi.nlm.nih.gov/pmc/articles/PMC534914/?tool=pubmed.[36]

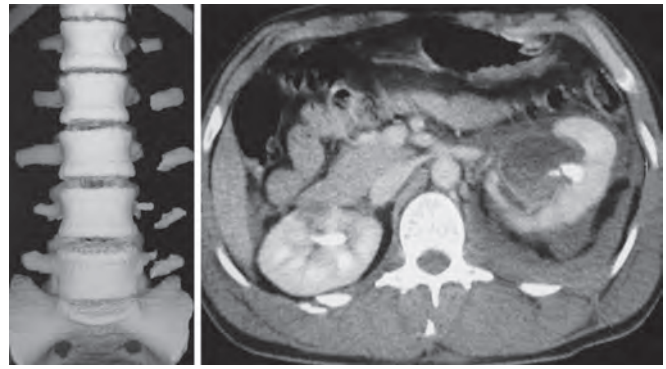

Fig. 7: Multiple lumbar transverse process avulsion fractures on 3D CT reconstruction (left). Since it is a stable injury, this patient was treated with rest and analgesics, followed by lumbar corset use. Renal injuries are common with L1 transverse process fracture as seen in contrast CT of another patient (right)

Non-Surgical Management

Most minor fractures require nothing more than rest and analgesics (Fig. 7). The duration of bed rest has come down over the decades, from months to days. Spinal bracing is popular but its utility remains unproved.[32] Anterior (hyperextension) braces are preferred for thoracolumbar junction fractures. Isolated fractures of the transverse process or spinous process and most stable wedge compression fractures can be treated thus.

Sir Ludwig Guttman established the National Spinal Injuries Centre at Stoke Mandeville near London during the Second World War to treat spinal injuries. He laid down the principles of institutionalised non-surgical management of spinal injuries. Extension of the spine over rolls effected postural reduction in flexion injuries. When the spine is maintained in this position he showed that spontaneous healing by fusion can occur. We must remember that this was at a time when nothing other than laminectomy was available as a surgical option. The rigorous attention to transportation, postural care, pressure sore prevention/treatment and bladder management helped reduce the mortality of paraplegic patients greatly. His work showed the importance of team approach in specialised spine injury centres. These principles are no less relevant today, even in the era of early mobilisation through stabilisation surgery.[29] Guttman's emphasis on rehabilitation extended to wheelchair sports of the Stoke Mandeville Games, the forerunner of the modern paralympics.

Non-operative treatment of burst fractures can be attempted only if the patient is neurologically well preserved, the alignment is acceptable (initial or after postural reduction) and there is no PLC disruption. Conservative treatment is also done for those in whom spine surgery is contraindicated (haemodynamic instability, severe head injury, sepsis or medical comorbidities). The reduction of spinal fractures in frames with head halter and pelvic traction and body slings, followed by application of body casts is out-of-fashion these days

in most centres. One can visit at http://www.maitrise-orthop.com/corpusmaitri/orthopaedic/mo58_spine_fracture/mo58_spine_fractures.shtml to know the details of such techniques. Rotating beds are rarely available in developing nations. Patients find it difficult to accept a body cast or tight-fitting brace in tropical weather. The long-term results of non-operative treatment of selected thoracolumbar burst fractures indicate about 15% incidence of deformity, causing pain and impairment of function and often requiring late surgery.[21]

Surgical Management

Controversy abounds in every area of surgery for spinal injuries. Which patients should be operated, what is the optimal timing of surgery, which route is to be employed and what kind of stabilisation is to be done are all subjects of debate. Spinal surgeons have performed only a handful of prospective trials (and even less randomised ones) to examine these vital issues. It is sobering to note that these studies in general do not show striking differences in clinical or radiological outcome in the different treatment arms. These studies are alluded to in the relevant sections below. Since most of the other studies and reports belong only to level 4 or 5, the recommendations emerging from them can only be given grade C or D status in the language of evidence based medicine (see http://www.cebm.net/index.aspx?o=1025 for the definition of these levels and grades).

Goals of Surgery

The twin goals of surgery in thoracolumbar fractures are neural decompression and restoration/maintenance of spinal alignment. Instrumented fixation and bone fusion are the techniques used to achieve the latter aim. Logically, achieving these twin goals should lead to greater neurological recovery, prevent neural damage, permit earlier ambulation with a painless spine and should prevent delayed deformity. Do the facts justify this logic? Ask any spine surgeon and the answer is a resounding 'yes', but search the literature and the answer is 'may be'.

Controversy over Decompression and Timing of Surgery in Patients with Neurological Deficits

Decompression of the cord can be done directly (removing the bone pieces in the canal) or indirectly through ligamentotaxis (by reducing the fracture, the intact posterior longitudinal ligament pushes the fragments away from the canal). Table 6 presents the routes of decompression of the neural canal. The proponents of decompression argue that continuing compression adds to the cord damage. They hold that faster and greater neural recovery results when the cord is decompressed. They also contend that decompression reduces the incidence of delayed pain. They base their argument on personal anecdotal experience and evidence from experimental situations. In a dog experiment, the longer the compression, the greater was the deficit and lesser its tendency to recover; early decompression resulted in greater return of evoked potentials and lesser motor deficit.[13] Similar findings have been reported in a study on rats.[76] Some studies of the degree of canal compromise (CC) on CT and incidence of neurological deficit indicate a direct and strong correlation (but this relation does not hold for the severity of deficit).[31] More CC is needed lower down the spine to produce deficit. Burst fractures causing ≥ 35% CC at T11–12 had a significant risk of neurological involvement but it required ≥ 45% CC at L1 and ≥ 55% CC at L2 and below.[38]

Non-randomised studies have shown the benefit of decompression. A systematic review of the literature from 1966 to 2000 showed that early decompression (within 24 hours) resulted in better outcome compared with both conservative management ($P < 0.001$) and late surgery ($P < 0.001$).[52] The effect was more pronounced for incomplete SCI than complete SCI. The time limit for decompression has varied from 8 to 72 hours in various reports, making the comparison of results invidious. Early fixation was associated with a lower incidence of pneumonia, a shorter intensive care unit stay, fewer ventilator days and lower charges in a study that retrospectively compared thoracic fracture fixation within or after 3 days of injury.[19] Early fixation was found to result in fewer complications and shorten hospital days in a systematic review.[82] A Turkish study reported in 2008 showed that surgery within 8 hours was associated with not only these benefits but also better neurological outcome.[15] Delayed decompression, months or years after the injury, has also been reported to improve the neurological deficit and reduce the incidence of pain.[97]

The main argument against decompression has been that there is no large prospective randomised trial showing the benefit of decompression in general and early decompression in particular. Those against decompression feel that paralysis occurs at the moment of injury and is not related to the position of the fragments of the fracture on subsequent imaging. A recent Indian study found no correlation between CC and the severity of neurological deficit in thoracolumbar burst fractures, though the authors did mention that this holds for L1 level but not T11 or T12 level.[64] The same group had earlier shown that there was no correlation between the recovery from the neurological deficit and the extent of CC.[63] A review in the year 2000 of 275 publications on burst fractures, of which 60 met minimal inclusion criteria (only 3 prospective studies), failed to establish a significant advantage of surgical over non-surgical treatment as regards neurological improvement. The reviewers concluded that surgical treatment for burst fracture in the belief that neurological improvement can be achieved is not justified, although surgery may still be indicated for structural reasons.[10] There have been more recent retrospective case series that show no benefit of decompression in relation to neurological

Table 6: Methods of decompression and fusion for thoracolumbar injuries

Method	*Rationale and technique*	*Comments*
Indirect	Using ligamentotaxis to force the fragments out of the canal, on reducing the fracture by postural methods or by long or short segment posterior fixation	Fails with large trapezoidal fragment. Requires intact posterior longitudinal ligament. Must be done early, say, within 3 days of the injury. Usually accompanied by posterolateral fusion
Direct	Entails surgical removal of the bone pieces in the canal	Surgeon must ensure that the removal of the bone piece does not add trauma. Must be prepared to tackle CSF leak that often occurs on removing the bone piece
Anterior	This approach is anterior to the cord and exposes the anterolateral part of the vertebral body. Safest for the cord. See routes in Table 9. Best for reconstruction of anterior column	Usually accompanied by anterior fusion with autogenous iliac/fibular bone graft or replacement with titanium spacers/femoral ring allografts. Can be combined with anterior or posterior instrumented fixation
Extended costo-transversectomy or lateral extracavitary approach	Same as 'anterolateral decompression' popular for spinal TB. Done through arched paramedian incision, 7 cm of the rib and entire transverse process removed. Through extrapleural space, the posterolateral part of the body is exposed	Disadvantage of being a unilateral approach. Exposure across the midline makes it possible to do long segment posterior fixation but not contralateral decompression or short segment fixation. Block grafts or cages can be placed but they support only one side of the anterior column
Transpedicular	Aims at creating a cavity in the mid-portion of the vertebral body through bipedicular route, into which the retropulsed fragments in the canal anterior to the cord can be pushed with angled probes from either side and retrieved	Large pieces are risky to manipulate and remove. Only morselised bone grafts can be placed in the interbody interval and not bone blocks resulting in poorer fusion. Must be combined with short segment posterior fixation
Laminectomy	Not to be used as a stand-alone procedure in trauma, especially if there is anterior column injury	Must be combined with long or short segment posterior fixation and posterolateral fusion

outcome.[61] Motor improvements were noted in the non-surgery group, though this was ascribed to there being a greater number of incomplete injuries in this group. This fact must be tempered with the knowledge that greater improvement is seen in incomplete SCI even in the operated group. Injudicious surgery may result in complications. Surgery might reduce hospital stay,[61] but it is innately more expensive. The canal tends to remodel itself over years even if not surgically decompressed or grafted.[3,67]

A prospective single-blinded randomised clinical trial has now been started to assess the efficacy of early and delayed decompression surgery for thoracolumbar injuries. The study plans to recruit about 330 cases, a number that is needed to be able to detect a statistically significant difference in motor recovery.[75] Until the results are available and are found to be reproducible, we have to make decisions based on personal experience and tailor-make the treatment process to each patient. The only consensus now is that patients who are progressively worsening in their deficit must be offered emergency surgery.

Controversy over the Treatment of Burst Fractures without Neurological Deficit

Burst fractures without neurological deficits pose three problems: (1) pain at the fracture site that might continue unabated for months or years; (2) delayed kyphosis and (3) delayed neurological deficits due to stretch of the cord over an internal gibbus. Hence, several surgeons have advocated anterior and/or posterior surgery for such lesions. This matter has been tested in some trials but these trials have been of poor design or of small sample size. A prospective non-randomised study of 80 patients reported in 2001 showed that posterior instrumentation provided early pain relief and immediate correction of kyphosis as compared to non-surgical treatment. However, the advantages of surgery had evaporated by 2 years of follow-up.[89] A study reported in 2003, randomised 47 patients with stable thoracolumbar burst fracture (24 operated) and found no significant difference in pain, kyphosis, canal diameter improvement or work capacity between the operated and the unoperated groups over a minimum follow-up of 2 years.[104]

This was also the conclusion of a Cochrane Database Review in 2006.[106] Another recent study that focussed on functional outcome at 5 years showed no difference between those treated conservatively and those operated upon for type A3 fractures without deficit, but there were more severe fractures (A3.2 and A3.3) in the operated group.[73]

Available Options for Surgery

The types of available procedures for surgical stabilisation of thoracic and lumbar fractures can broadly be categorised into long segment posterior fixations, short segment posterior fixations or anterior fixations. These are summarised in Table 7.

Posterior procedures: It is likely that reducing the kyphosis by posterior instrumentation causes the intact posterior longitudinal ligament to stretch and push the retropulsed fragments into the body, thereby effecting canal decompression without direct surgical handling of the fragments. CT has proved that this phenomenon of ligamentotaxis increases the narrowed canal diameter in the short as well as the long term.[66] However, large trapezoidal fragments resist ligamentotaxis. Such fragments might require direct surgical removal, especially in those with incomplete neurological deficit. The extent of clearance of the canal can be checked during posterior surgery with intra-operative ultrasonography.[55]

Generally, the posterior procedures are most effective in the acute stage (within 72 hours) after trauma (Figs 8A to D). Though multiple segments are incorporated in long segment instrumentation, the fusion is performed only at the level of the fracture. This has been succinctly described as 'rod long but fuse short'.[2] Long segment instrumentation ultimately fails when bony union (by spontaneous or surgical fusion) does not occur. Short segment procedures are based on pedicle screw systems that can theoretically provide three-column support to the spine. Short segment instrumentation immobilises fewer segments and hence causes less interference with whole spinal motion (Fig. 9). Adding a horizontal cross connection increases the strength of the construct (Figs 10A to C).[27] The pedicle screw used must be of the largest diameter that the pedicle can take. This is not a matter of guesswork or slavish application of statistics. The pedicle diameter, the pedicle inclination to the vertical and the screw path length must be measured on the preoperative CT at every required level. Convergent pedicle screws have greater resistance to pullout (Figs 10A to C). Pedicle screw placement is a more demanding surgical technique but involves less blood loss and shorter operating time than long segment or anterior procedures.

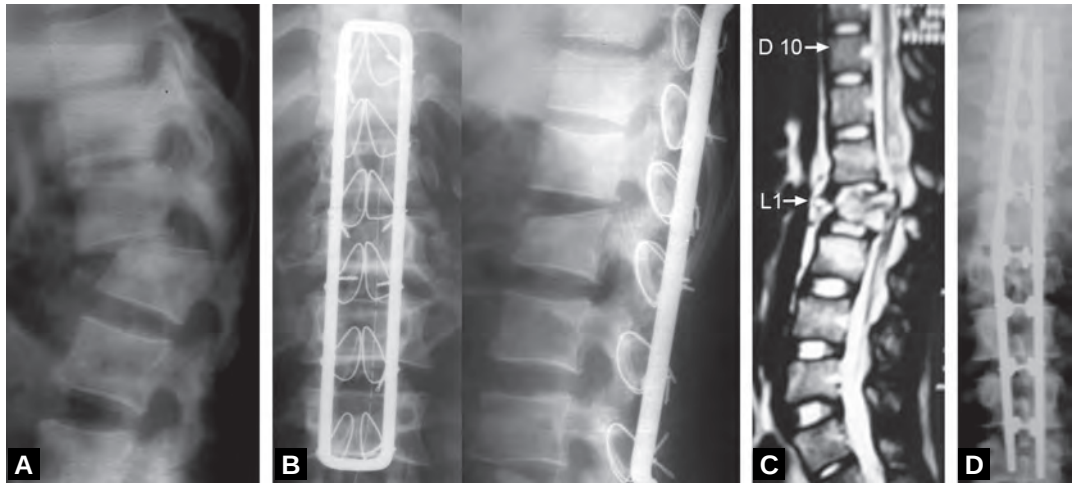
The canal clearance was a shade better with Harrington rods than pedicle devices but both systems produced good enough clearance if surgery was done within 4 days of trauma in a prospective randomised study.[100] Another small prospective randomised study showed better sagittal plane deformity correction with long segment as compared to short segment fixation.[94] Loss of correction in the sagittal plane is seen on follow-up in both conservatively treated and operated patients. Figure 11 shows an example of loss of correction with short segment fixation after 5 years, though the patient was asymptomatic. Passing pedicle screws 2 levels above and 2 levels below the injury site, instead of the customary 1 level above and below is a via media, instead of resorting to long segment (3 levels above and below) instrumentation (Fig. 5).[4] A recent paper suggests that short segment fixation using pedicle screws 2 levels above and 1 below the thoracolumbar junction injury prevents re-kyphosis and hardware failure while retaining the lumbar mobility.[62] The significant complications of pedicle screw placement in the thoracic spine and techniques for minimising these have been pointed out in a review article in Neurology India.[107] In women and persons of small frame the pedicles (especially D11 and D12) may be too narrow to take a screw of adequate diameter. Such persons may need long segment posterior fixation or an anterior approach. A recent trend is to use neuronavigation for placing the difficult pedicle screws.[53]

In order to decide between long or short posterior spinal fixation, a load sharing classification has been developed[60] (Table 8). Those burst fractures that are highly comminuted have wider spread of fragments and that need greater kyphotic correction will experience implant failure after short segment posterior instrumentation.[4] Hardware failure occurred in 40% of 50 cases of unstable thoracolumbar fractures treated by Steffee variable screw-plate device in a recent Indian series, even though there was good kyphosis correction and only a little loss of correction over time.[12] Hardware failure rate was lesser (only 20% of 50) in another Indian series using Moss Miami type of pedicle screw-rod construct and so the type of device also seems to matter.[85] A recent multicentre prospective randomised study (of 34 patients) has shown that Magerl Type A3 fractures without neurological deficits fared significantly better in the kyphotic angle, pain/function scores and ability to work after short segment fixation as compared to non-operative treatment.[90]

The importance of fusion with bone grafts in posterior surgery has recently been questioned. Transpedicular intracorporeal grafting in the treatment of burst fractures did not have a detectable effect on the rate of reconstruction of the canal area or on remodelling in a prospective, randomised, controlled study of 21 patients.[3] However, morselised transpedicular grafts could achieve and maintain kyphosis correction, and provide better anterior vertebral height in a randomised study of 70 thoracolumbar burst fractures from China.[101] On the other hand, a retrospective study of transpedicular grafts found graft incorporation and fusion only in 34% of 29 patients.[50] In a recently reported prospective,

Table 7: Instrumented fixation for thoracic and lumbar fractures

Procedure	*Comments*	*Complications*
Long segment posterior fixation	3 or more levels above and 3 or more levels below the injury. 'Fix long, fuse short' principle	Loss of normal thoracic kyphosis and lumbar lordosis, back stiffness due to greater number of segments being fixed
Hook-rod systems	Hooks on facet-lamina better than transverse process hooks	Hook pull out, rod breakage
Harrington distraction	Anterior longitudinal ligament must be intact. Used for wedge/burst fractures, fracture dislocation, translational injuries, typically in the early phase	Overdistraction. Poor resistance to rotational deformation
Harrington compression	Used for flexion distraction injury/Chance fracture. Uses thoracic transverse process and lumbar laminar hooks. Not to be combined with sublaminar wires	Need to remove long rods after fusion is solid (in 1–2 years)
Wires-rod (Luque 'L'/Hartshill rectangle) systems	Resists rotational deformation better than hook-rod systems	Wire breakage, usually the inferior most. Rods may slip or break but rectangles do not
Sublaminar wires	Flavotomy needed. Wire passes between ligamentum flavum and dura, from below upwards. A titanium rectangle designed by Dr. R. R. Ravi, Neurosurgeon, Kochi, is lighter; wires tightened through holes in the rectangle instead of around the stem; notched external border prevents slippage or cutting	Cord injury and dural tear during wire passage. Generally reserved for complete cord injury
Spinous process wires—Drummond (Wisconsin)	Easy procedure. Less deformity correction in sagittal plane. Less canal restoration. Useful for facet dislocation and coronal plane translational injury	Avulsion of base of spinous process more likely than wire breakage
Combined systems		
Harrington distraction with sublaminar wires	Improves resistance to rotational deformation	
Cotrel-Dubousset (CD) system	Uses multiple hooks, pedicle screws coupled to rods that can be horizontally cross linked. Type 1 provides distraction, Type 2 gives compression and Type 3 maintains lumbar lordosis	Complicated instrumentation
Texas-Scottish Rite Hospital (TSRH) system		Not available in the author's practice
Short segment posterior fixation	1 level above and 1 level below the injury (rarely 2 levels above and below). Only devices to provide all 3-column support. Avoids unnecessary loss of movements at multiple segments. Though compression and distraction can be applied to correct sagittal plane deformation, are less effective in correcting severe deformity or dislocation. Cross linking needed if > 2 levels	Pedicle violation leads to cord or root injury and weakening of construct. Higher rate of pedicle screw breakage and loss of correction over time than in degenerative disease
Pedicle screw-plate systems	E.g. Roy Camille, Steffee, Luque	Difficult to contour plates, screw break at junction
Pedicle screw-rod systems	Mono/polyaxial screws, single/double lock, reduction screws	More versatile
Anterior fixation		Complications due to thoracotomy
Screw-plate systems	E.g. Zdeblick plate	Screw penetration into canal
Screw-rod systems	E.g. Kaneda. Pedicle screws can be used as body screws instead. Above T9, 1 screw per body. T10 and below, 2 per body	Use of staples needed to prevent screw erosion into body
Combined anterior and posterior fixation	Combinations of above	



Figs 8A to D: (A) Lateral radiograph of D12-L1 dislocation with Frankel A complete cord injury. Posterior operative reduction and long segment fixation done in 48 hours using stainless steel sublaminar wires and Hartshill rectangle. (B) Note the correction of deformity and canal restoration in AP and lateral radiographs. (C) MRI of L1 unstable burst fracture operated 14 years ago, before pedicle screw systems were available. (D) AP radiograph after long segment posterior fixation with spinous process Drummond wires. Note the buttons in wires to prevent the wire from cutting through the bone

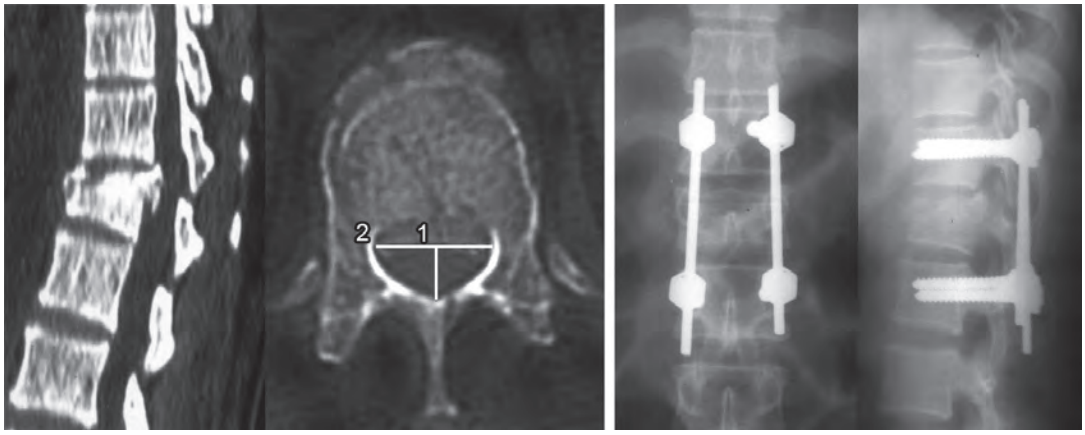


Fig. 9: Sagittal and axial CT of L1 unstable burst fracture with retropulsed fragment (left), treated by short segment pedicle screw (Moss Miami type) system. Note the correction of kyphosis in the post-operative radiographs (right)

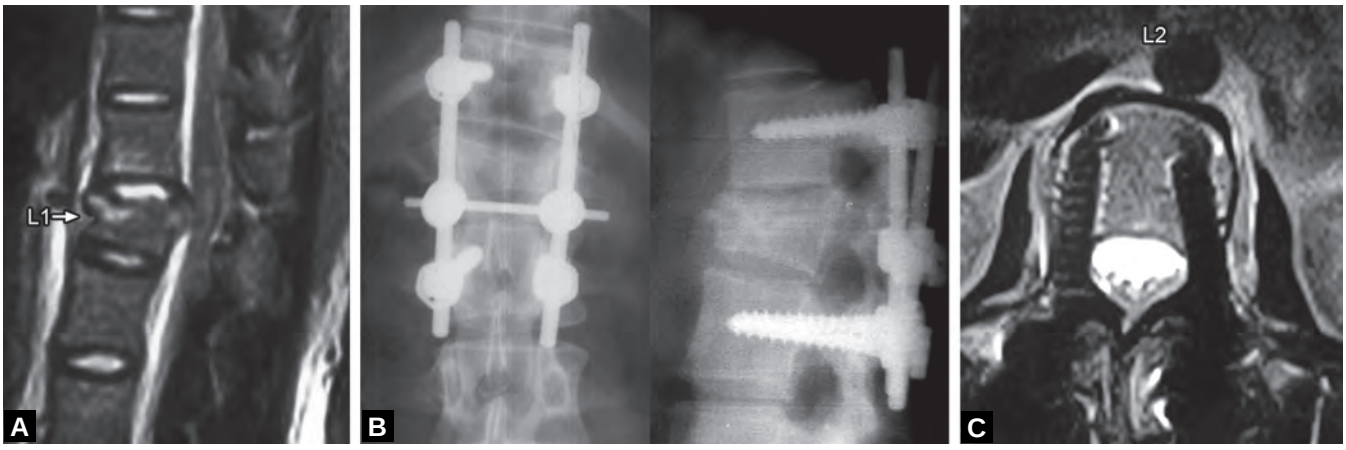

Figs 10A to C: L1 burst fracture in a woman with neurogenic bladder dysfunction alone. Since the canal was preserved and as there is not much comminution of body in pre-operative imaging. (A) Only short segment posterior fixation was done. The use of cross-connector augments short segment posterior fixation. (B) Note artefact-free axial MR imaging with titanium pedicle screws and the correct screw trajectory. (C) The patient made full recovery and had a baby 18 months later

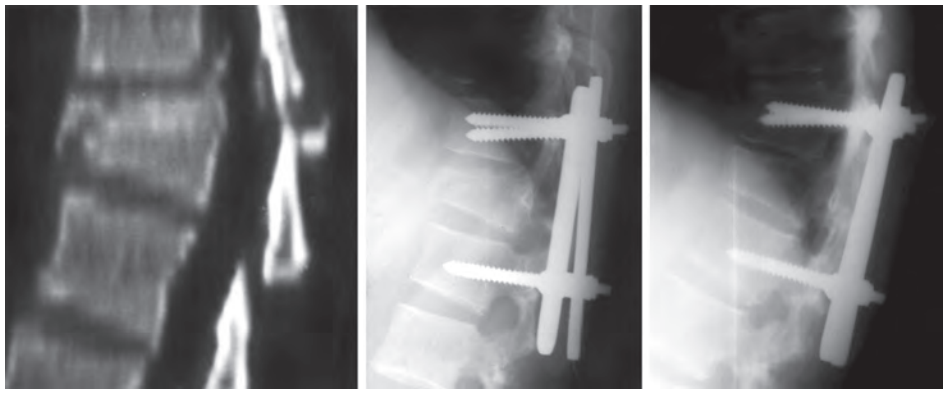

Fig. 11: Sagittal reconstructed CT of unstable burst fracture of T12 body treated by short segment Steffee variable screw plate instrumentation (left). Radiograph immediately after surgery (middle) showed moderate correction of kyphosis, which was partially lost in the follow-up film after 5 years (right), even though the patient was asymptomatic

Table 8: McCormack load sharing classification for surgical decision making in thoracolumbar burst fracture.[60] Patients with score of < 7 can be managed by short segment posterior fixation. Those with score ≥7 will need anterior column support or long segment posterior fixation

Factors considered	*Assessed by*	*Points*
Comminution	Sagittal and axial CT	
Less (< 30%)		1
More (30–60%)		2
Most (> 60%)		3
Apposition of fragments	Axial CT	
Minimal (hardly any displacement of fragments)		1
Spread (2 mm displacement < of 50% of cross section of body)		2
Wide (2 mm displacement > of 50% of cross section of body)		3
Required kyphotic correction	Lateral radiograph	
3°or less		1
4°–9°		2
10° or more		3

randomised, controlled study of 73 patients of burst fracture and a load sharing score of ≤ 6 and followed up for 5 years, no significant difference in radiographic or clinical outcomes was noted between the fusion and the non-fusion groups after short segment posterior fixation.[22] Operative time and blood loss were significantly less in the non-fusion group. Donor site pain was reported by 67% of the fusion group even at the last examination.[22] Posterior bone fusion/long segment fixation/anterior column reconstruction is advisable in fractures with load sharing scores of ≥ 7.

Anterior procedures: Anterior procedures offer the advantage of reconstructing and instrumenting the anterior and middle columns. They also offer the advantage of clearing the retropulsed fragments of bone and disc without stressing the cord (Fig. 12). The flip side is that the procedure is more major, involves more blood loss/operating time and often needs the help of a thoracic or abdominal surgeon. The complications of lung collapse/consolidation, pleural collection, ileus due to retroperitoneal dissection, wound dehiscence and wound pain are significant.[44] The routes of anterior approach preferred by the author are outlined in Table 9.

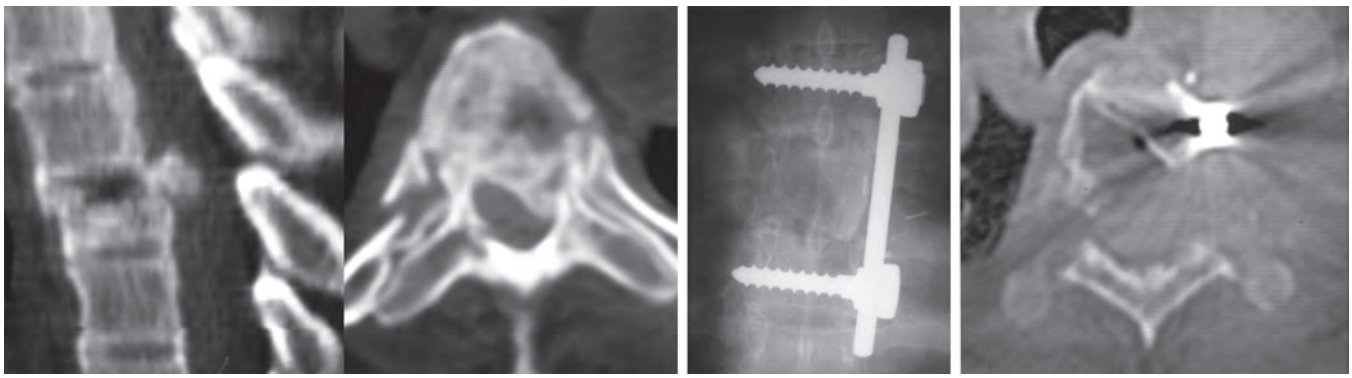

Fig. 12: Sagittal and axial CT of the same patient as in Fig. 4 with T5 burst fracture (left). Transthoracic corpectomy, anterior stabilisation and iliac autograft placement were done (middle). The smaller size of the thoracic body permits only one screw placement in each body but this proves sufficient. The vertical rod also serves to prevent lateral graft extrusion. The graft is impacted with the screws in distraction for restoration of height. Once seated, the graft is placed under compression. Note the canal decompression in the postoperative axial CT (right)

Table 9: Routes of anterior approach to thoracic and lumbar spine injuries

Level of injury	*Approach of choice*	*Comments*
C7 toT2	Low anterior cervical for patients of asthenic build	Left side approach avoids recurrent laryngeal nerve injury,
	Transmanubrioclavicular for corpulent patients	but carries risk of thoracic duct injury
T2 to T3 or T4	Right third intercostal space thoracotomy	Right side approach avoids the arch of aorta and its branches that hinder left side approach
T4 or T5 to T10	Left thoracotomy	Approach through the intercostal space that is in line with the targeted vertebra at the midaxillary line
T11 to L1	Left thoracotomy, transdiaphragmatic retroperitoneal	Retroperitoneal space can be opened by either splitting the costal cartilage or by sweeping off the peritoneum from the under surface of the diaphragm after thoracotomy. Diaphragm is cut and repaired circumferentially
L2 to L4	Left flank incision, retroperitoneal	The lower the level the more anterior the incision extends
L5, S1	Midline transperitoneal	ALIF retractors are very useful to keep the abdominal
	Paramedian retroperitoneal (mini-ALIF approach)	contents away and to increase space between iliac vessels

Anterior reconstruction began with strut bone grafts and went on to incorporate anterior instrumentation. Cages are substituting grafts in some centres (Fig. 13). In a retrospective Indian series of 60 patients, the anterior procedure was chosen for thoracolumbar junction injury with incomplete or complete neurological deficit with a large retropulsed fragment in the spinal canal, when canal compromise was 67%, when the anterior column was comminuted and kyphosis was ≥ 30° and when the patients were operated beyond 4 days from the time of injury.[84] In a Chinese prospective randomised study of 65 patients undergoing anterior plating for a thoracolumbar burst fracture with a load-sharing score ≥ 7 and followed up for a minimum of 4 years, the autograft and titanium spacer groups had similar fusion rates and clinical/radiological results.[20] The details of operative techniques and various instrumentation devices are beyond the scope of this chapter, but the salient points are mentioned in Tables 6, 7 and 9.

Combined procedures: Anterior and posterior procedures are considered for three-column injuries so as to affect 360° fusion/stabilisation. The usual combination is short segment posterior fixation and anterior decompression with strut grafting (Figs 14A to C); which procedure should be done first will depend on the situation. For example, in a vertebral body fracture with severe kyphosis and facet dislocation, the posterior procedure can be done first followed by the anterior. It is vice versa for a comminuted fracture with severe canal compromise and lesser kyphosis (Fig. 15). Anterior surgery can also be combined with posterior long segment fixation (Figs 16A to C). The two procedures can be done in a single session in a fit patient, but it is prudent to stage

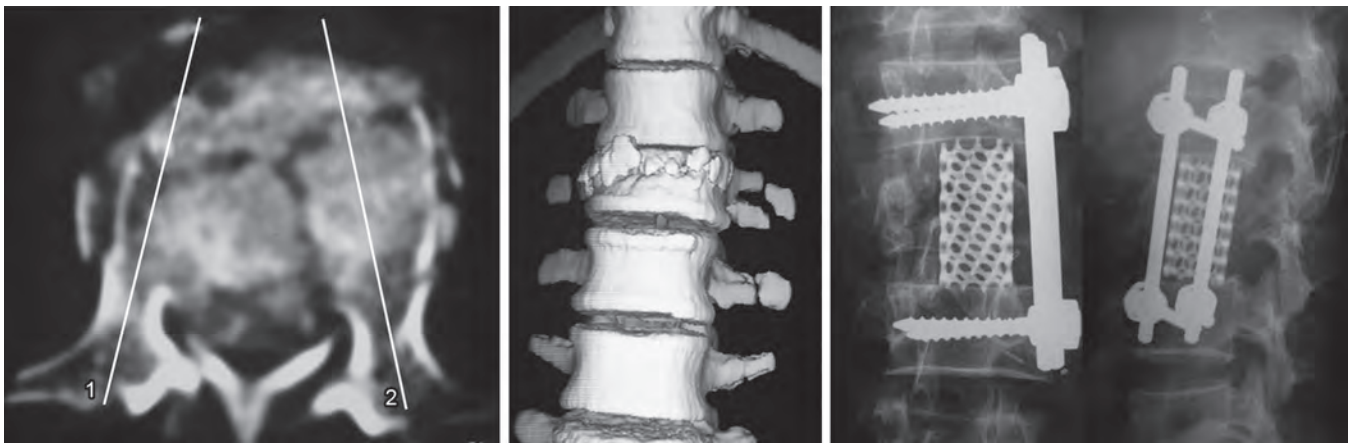

Fig. 13: Axial and 3-D CT of unstable burst fracture of L2 with laminar fracture (left). Anterior corpectomy, placement of titanium spacer and stabilisation with two screws each in L1 and L3 bodies. Note the canal restoration and deformity correction in the post-operative radiographs (right)

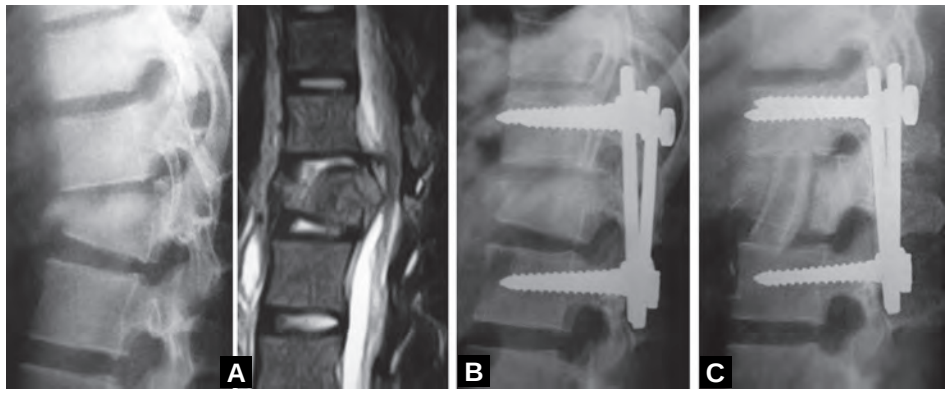

Figs 14A to C: Lateral radiograph and MRI of L1 burst fracture with unilateral motor deficit and sparing of bladder function. (A) The patient underwent short segment pedicle screw instrumentation first. (B) followed by anterior corpectomy and iliac strut grafting after 4 days. (C) Patient made rapid neurological improvement and is asymptomatic

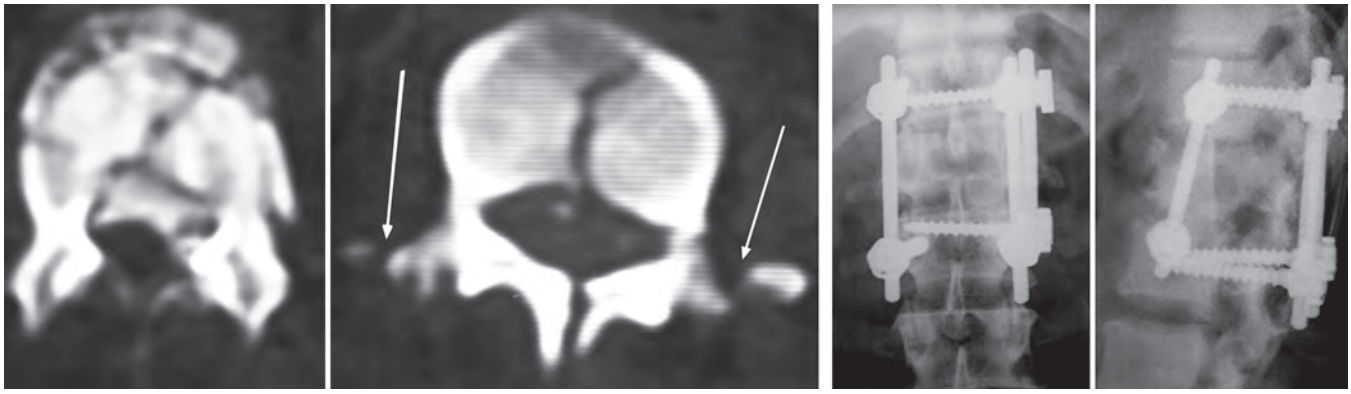

Fig. 15: Axial CT of L1 burst-split fracture with 50% canal compromise and no neurological deficit (left). The patient underwent anterior corpectomy, iliac strut grafting and anterior instrumentation (single body screw per level) followed by short segment pedicle screw instrumentation after 4 days. AP and lateral radiographs after both the procedures (right). Patient remains neurologically normal and is pain-free, back at his job

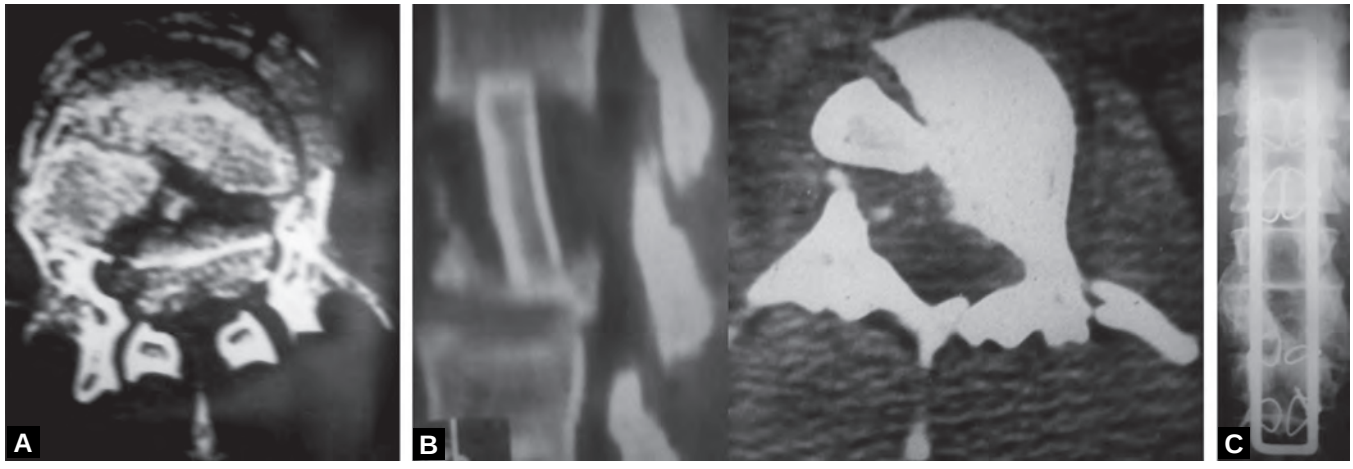

Figs 16A to C: Axial CT of L1 burst fracture in Frankel A with canal compromise: (A) The patient underwent transthoraco-phreno-retroperitoneal corpectomy and strut grafting. Note height restoration and canal clearance in the post-operative sagittal and axial CT. (B) This was followed after 5 days by long segment posterior fixation with sublaminar wires and rectangle seen in AP radiograph. (C) The patient recovered to Frankel D

the procedures 3–7 days apart. Anterior augmentation with polymethylmethacrylate vertebroplasty after short segment posterior fixation has recently been reported to be successful for non-osteoporotic burst fractures.[1] Vertebroplasty and kyphoplasty for osteoporotic fractures has been dealt with in another chapter of this textbook. Laparoscopic or thoracoscopic procedures also reduce the morbidity of anterior procedures, although endoscopic exposures have been used for less complicated cases.[44]

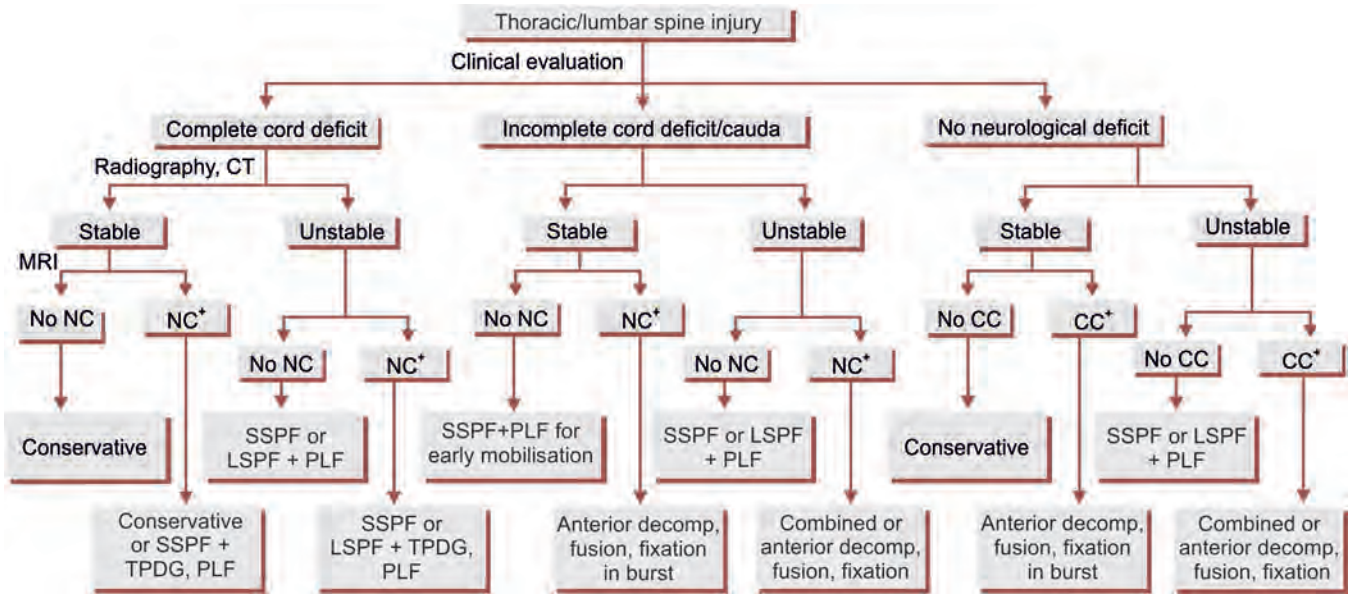

Fig. 17: Algorithm for management of thoracolumbar injuries. NC – neural compression, CC – canal compromise, SSPF – short segment posterior fixation, LSPF – long segment posterior fixation, PLF – posterolateral fusion, TPDG – transpedicular decompression and grafting

The cost and availability of branded titanium spinal implants are limiting factors in developing nations. Stainless steel implants are definitely stronger than comparable sized titanium ones. Stainless steel implants are lower in cost but interfere significantly with CT and MR imaging. The higher torsional resistance of stainless steel implants makes them useful for long segment instrumentation.[51]

Decision Making

The questions to be answered while treating a thoracolumbar fracture are: (1) whether to operate or not; (2) when to operate (emergency/early/delayed) and (3) how to operate (route/level/decompression/fusion/instrumentation).[23] In order to answer these questions, the surgeon must take into account several factors. Age, general medical status, body weight and time since injury must be factored in. Associated injuries might impact the treatment plan. The extent and evolution of neurological deficit matter much. The level of the injury, the classification of injury, the TLICS score and the load sharing score profoundly influence the operative approach. Finally, the experience of the surgeon and the availability/affordability of instrumentation are germane issues. Demonstrable neural compression with progressing deficit is the strongest indication for decompression. Canal compromise with incomplete cord injury, cauda equina syndrome or severe pain is the next best indication. In the face of complete SCI, issues of stability decide the surgery rather than the canal compromise. Since decompression procedures add to the instability, they are almost invariably done along with an instrumentation/fusion procedure. The algorithm currently employed by the author is given in Figure 17, granting that this is oversimplification of a complex issue. It must be emphasised that the decision has to be tailor-made to the individual patient and type of injury.

OPEN SPINE INJURIES

Missile injuries can be either of high-velocity, such as those due to military weapons, or of low-velocity, such as those due to country-made firearms. If a bullet grazes the spine but does not go through it, the cord injury is due to the associated shock wave and this has some potential for recovery; not so with a direct cord laceration, transection or root avulsion.[9] Bullet removal is recommended for cauda equina injuries. Surgical exploration is warranted in most patients with a stable general condition to decompress the cord and to avoid external CSF leak or meningitis, even though the septic complications are less frequent than with non-missile injuries.

Non-missile injuries are common in the thoracic spine when the standing victim is attacked from the back. The sharp object enters the interlaminar space and lacerates the dura. CSF leak from a stab wound in the back is a telltale sign. Brown-Sequard syndrome from stab injury has already been mentioned. The blade of the knife may be retained and one should resist the urge to yank it out in the emergency room. It should be removed after a formal surgical exploration of the tip.[33] CT myelography was needed in one of our cases to locate the site of leak, which might not be necessarily at the site of the entry wound (Fig. 18). Surgical exploration is mandatory for removing retained foreign bodies and for repairing the

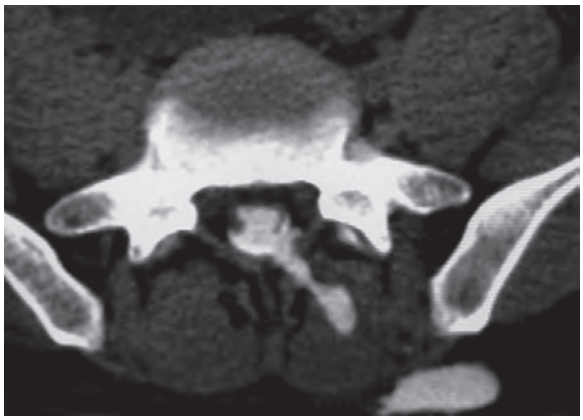

Fig. 18: A young man was knifed in the buttock. There was no neurological impairment. The entry wound in the upper gluteal region was sutured elsewhere. CSF leaked out of the wound 4 days later. CT myelography showed the dural fistula at L5-S1 level with a subcutaneous collection. He made uneventful recovery after dural repair through laminotomy

dura. There is usually no need for stabilisation. Infective complications cause significant mortality and morbidity.

CONCLUSION

Thoracolumbar spine injuries are common in neurosurgical and orthopaedic practice. A thorough clinical and imaging evaluation helps in understanding the mechanism of injury and selecting the correct treatment approach. We are now able to correct the orthopaedic part of the injury well, but recovery of lost cord function remains an unfulfilled goal.

ACKNOWLEDGEMENT

I thank Dr.S.Sundarrajan, Consultant orthopaedic surgeon, Trichy for a) being an invaluable part of our spine surgery team, b) for reading through this manuscript and making valuable suggestions and c) help with the figures.

53 Lumbar and Lumbosacral Injuries

Ramakrishna Easwaran

Sacral fractures are rare, accounting only for 1% of all spinal traumas. In pedestrians struck by motor vehicles, spinal injuries are seen in 8%. These spinal injuries are more or less evenly distributed in the spinal column and 27% of these injuries affect the sacrum.[18] The sacrum completes the pelvic ring and sacral fractures are present in about 45% of pelvic fractures.[8] In such cases, the sacral fracture is the least conspicuous of all the fractures. Only 5–10% of all sacral fractures are isolated fractures.[8]

CLASSIFICATION

The sacral fracture classification scheme of Schmidek, the sacral zones of Denis and a morphological classification of transverse fractures are given in Table 1.[3,14] A direct blow to the coccyx causes the low transverse fracture at S3 or below, whereas the high transverse fracture at S1-2 level is due to indirect trauma, transmitted through the pelvis. Since most sacral fractures are vertically oriented and as the line of the sacral foramina form a weak area, it is logical to divide the sacrum into vertical zones: (1) Zone 1 fractures that are lateral to the foramina are caused by lateral compression of the pelvis; (2) Zone 2 fractures in the foramina by vertical shear and (3) Zone 3 fractures affect the sacral canal and are the least common, and have the highest incidence of neurological damage. The transverse fractures (5–15% of all sacral fractures) may affect all the three zones. Based on sagittal CT and lateral radiographs, the transverse fractures have been classified into four types by Roy-Camille (Table 1).[10] Lumbosacral fracture dislocation follows one of the five types described by Aihara.[2] The type 4 lumbosacral dislocation in the scheme (Table 1) has previously been described as 'acute traumatic spondylolisthesis', but the former name is more apt, considering the amount of anterior and posterior ligament damage in this unstable injury.

CLINICAL FEATURES

Sacral fractures are missed or only detected after a delay in 30% of patients.[8] This is especially true for sacral insufficiency fracture that occurs in the osteoporotic elderly patient after a trivial fall. Sacral stress fractures also occur in athletes[15] and after labour.[16] Suicide jumpers may have an isolated transverse sacral

Table 1: Schemes of classification of sacral fractures

Schmidek (1984)[14] classification	*Denis (1988)[3] classification*	*Root damage*
Direct trauma	Zone 1 (alar zone)	L5 partial in 6%
Penetrating	Zone 2 (foraminal zone)	Sciatica in 28%
Comminuted	Zone 3 (sacral canal zone)	Saddle anaesthesia and sphincter dysfunction in 57%
Low transverse		
Indirect trauma		
High transverse		
Type I		
Type II	*Morphological classification of transverse fractures*	
Type III	H shaped	
Vertical	U shaped	
Lateral mass	T shaped	
Juxta-articular	λ shaped	
Cleaving		
Avulsion		

Roy Camille (1985) classification of sacral transverse fractures[10]
1. kyphotic angulation
2. partial anterior translation
3. complete anterior translation
4. burst fracture

Aihara (1998) classification of lumbosacral dislocation[2]
Type 1: Unilateral L5-S1 facet dislocation with or without facet fracture
Type 2: Bilateral L5-S1 facet dislocation with or without facet fracture
Type 3: Unilateral L5-S1 facet dislocation with contralateral facet fracture
Type 4: Bilateral L5 pars interarticularis fracture with dislocation of L5 body
Type 5: Fracture of L5 body or pedicle with dislocation of L5 body

fracture.[13] Patients without neurological deficit present with pain in the low back, buttock or perianal region, which increases on sitting or defecating. Isolated urinary retention has been reported.[12] Neurological deficits may be unilateral or bilateral. It is important to assess the S2–S5 roots by checking rectal sphincter tone and action, saddle and perianal pinprick sensation and reflexes (anal and bulbocavernosus). Digital rectal examination (and vaginal examination) may reveal an open fracture. The sacral root injury can range from neurapraxia to neurotmesis. The neurological deficit might be obvious only after a delay.[7] Sacral alar fractures cause L5 root injury. Transverse fractures across zone 3 are more prone to produce neurological deficits and even transection of roots.[13] Sexual dysfunction is a common sequel.

DIAGNOSTIC TESTS

Nearly 60% of sacral fractures are missed in the initial plain film radiography.[5] Sacral fractures are difficult to visualise on an anteroposterior (AP) radiograph because of the tilt of the sacrum. The lateral views are obscured by soft tissue of the buttocks. Tracing the arcuate lines in the sacrum may detect an inobvious fracture.[5] The outlet view of the pelvis provides a good AP view of the sacrum and the inlet view displays the sacral spinal canal. Lateral view of the sacrum can be supplemented by sagittal CT reconstruction. The transverse fractures are best made out in coronal or three-dimensional CT reconstruction. H (or U) shaped fracture is often seen in osteoporosis. It is vital to study the entire bony pelvis in a case of sacral fracture. CT can also display anatomical variants due to sacral dysmorphism. MRI is sensitive to the marrow oedema that accompanies a sacral insufficiency fracture. Oblique coronal MRI of the sacrum can show the whole length of sacral nerves and depicts root compression by fracture fragments. A complete urodynamic evaluation with cystometrography and sphincter electromyography is needed for proper bladder management.[12] Sphincter electromyography is useful for monitoring the sacral roots during surgery.

MANAGEMENT

Most sacral fractures can be treated non-surgically. These include stable, undisplaced sacral fractures without pelvic ring disruption, fractures that spare the lumbosacral junction and fractures without neurological injury. Bed rest and analgesics suffice. Transverse fractures with minimal displacement or angulation can also be managed conservatively, if the patient has only minimal deficits.[9] Painful insufficiency fractures can be treated by percutaneous polymethylmethacrylate sacroplasty.[6] Sacral fractures that are a part of an unstable pelvic fracture require external or internal pelvic fixation. The reduction of the pelvic fracture might lead to sacral root entrapment. Delayed entrapment neuropathy can occur due to stretch over a deformity or callus. Surgery is recommended for those with neurological deficits and imaging documented root compression. Delayed pain is a common problem and often calls for surgical exploration. The nerve roots must be exposed by sacral laminectomy/foraminotomy and freed from compression by fracture fragment or entrapment within the fracture.

After operative reduction, internal fixation of sacral fractures is done with iliosacral screws, posterior sacral plating or posterior iliosacroilial bars.[17] Iliolumbar (lumbopelvic) fixation can be done to avoid hardware prominence or skin ulceration associated with iliosacral screws. It can also be done when the sacral screws are precluded by a comminuted fracture. The technique has been described from Amrita Institute of Medical Sciences, Kochi.[1] Triangular osteosynthesis fixation entails placement of L4, L5 pedicle screws, posterior ilial and iliosacral screws. This allows early full weight bearing at 6 weeks while preventing loss of reduction in comminuted vertical shear transforaminal sacral fractures.[11] Lumbosacral dislocation is managed with pedicle screw stabilisation. L4 often needs to be included. Sacral alar or S2 screws may be used to augment the inferior part of the construct. In Aihara type 5 injuries, L5 pedicle screw cannot be placed. Hence, additional anterior fusion is needed. Circumferential fusion is often needed in type 4 and 5 injuries.[2] The improvement in sphincteric and sexual dysfunction is poor compared to the recovery from pain after sacral fracture management. Severe angulation, displacement of fracture and neurotmesis indicate a poor prognosis.[4]

54 Penetrating Injuries of the Spine

Harjinder S Bhatoe

Missile Injuries

INTRODUCTION

Missile injuries of the spine (MIS) are the third most common cause of spinal cord injury after motor vehicle accidents and falls.[1] The poor outcome associated with these has been recognised since the Battle of Trafalgar, when Admiral Nelson was shot through his spine, and died shortly thereafter.[50] Management of MIS has evolved through the various wars; nevertheless, the debate on the aim and scope of surgical management of these injuries is far from settled. Till the early part of the twentieth century, mortality was high due to accompanying injury to visceral structures, and to the inadequate nursing care. Cushing reported a mortality of 71.8% during World War I, with only patients with incomplete injury surviving. The review of War Surgery and Medicine prepared by Harvey Cushing and published in 1918 advised that a transected cord should never be operated upon unless the lesion was below L1.[46] Hanson[14] echoed the contemporary opinion on the management of MIS when he said, "War wounds of the spine are particularly distressing…one scarcely knew where to begin, if to begin at all".

During World War II, advances in resuscitation, antibiotics and prompt evacuation to a hospital saw more of these patients being operated upon early, although pessimism persisted. Some surgeons though started exploration and decompression and, by the time of the Korean conflict, operative exploration was universally advocated.[51] Improvement in resuscitation, helicopter evacuation, early surgery and improved nursing care during the Vietnam conflict, however, failed to show any improvement in neurological outcome in complete injuries. Thus, with multidisciplinary trauma teams and helicopter evacuation, there is improvement in survival of polytrauma victims of missile injuries; however, the prognosis for neurological recovery remains uncertain and the goals of surgery have been redefined.

LOCATION OF WOUND

Spinal injury at more than one site is highly unusual in civilian MIS, while these may be seen more often in military practise. Most of these injuries are located in the thoracic spine (54%), followed by lumbosacral (33%) and cervical (13%) spine.[19] In a report from the Croatian War involving 96 cases, however, the lumbar spine was injured in 55% of cases.[20] Most of the patients are shot from the back.

APPLIED BALLISTICS

The Missiles

Projectiles travelling at less than 2,000 feet/sec fall into the category of low velocity missiles, while those travelling above this speed are high velocity missiles. There is a distinct difference in the pattern of injury and outcome of low velocity missile injuries (LVMIs) and high velocity missile injuries (HVMIs). Most handguns and revolvers use heavy bullets weighing about 0.5 oz and have muzzle velocities ranging from 550 ft/sec to 900 ft/sec. In contrast, most rifles and small arms (rifles, stenguns, machine guns, etc) used in war use light bullets having muzzle velocities averaging 3,000 ft/sec. High velocity missiles, as they reach the limit of their range, become low velocity (spent bullet) and may inflict less severe wounds as compared to that within their effective range. Handgun ammunition can achieve effective muzzle velocity of 1,200 ft/sec over a short distance. Pieces of shrapnel from exploding devices may have a velocity of 600 ft/sec; unlike rifled bullets, however, they rapidly lose energy due to their irregular shape and non-aerodynamic nature. The commonly observed CNS missile injuries are inflicted by one of the following missiles:

- The 7.62 mm bullet can be fired by AK-47 assault rifle (Kalashnikov), self loading rifle (SLR), light machine gun or medium machine gun (LMG/MMG). The bullet weighs 150 gm and has a muzzle velocity of more than 2,000 ft/sec.

- The 5.56 mm bullet fired from Indian Small Arms System (INSAS) and M-16 rifle. The bullet weighs 55 gm and has a muzzle velocity of more than 3,000 ft/sec.
- Low velocity missiles fired from a variety of firearms, viz. revolvers, shotguns, handguns, 12 bore single/double barrel guns and country made weapons (katta, tamancha, etc. as prevalent in parts of Bihar and Uttar Pradesh).
- Fragments of exploding devices: The variety of exploding devices reflects the ingenuity of the minds that assemble them, often in innocuous looking forms. They may be made to look like toys, transistors, cassette players, etc. which are often detonated by handling or by remote access. A domestic LPG cylinder placed on its top often makes an innocuous looking but deadly combination for explosion. Other familiar sources of missiles are the HE 36 mm grenade, rockets and exploding artillery/mortar shells. Fragments of exploding devices initially travel at high speeds of over 3,000 ft/sec, and then rapidly lose speed because of their volume, weight and irregular shape and become low velocity at distances of 10 metres or more.
- Glass fragments, nails, etc. may rarely act as missiles.[38,55]

Energy Transfer

A bullet is stable in its flight through the atmosphere, but becomes less stable on entering the tissues, when it tends to yaw, deform and tumble due to resistance offered by the tissues and thus, releasing kinetic energy (KE). Injury to the tissues by a missile is a function of energy released over time, and of the volume and location of tissue disruption. The amount of KE contained in the missile is defined by the formula $E = -1/2\ mv^2$, where m is the mass of the missile and v its velocity. Since energy contained in the missile directly varies with the square of its velocity, the latter is relatively more important in determining the energy transfer by the missile than the mass. The amount of tissue damage caused by a missile may be correlated with the amount of energy deposited within the tissues by the missile. The energy transferred can be expressed by the equation:

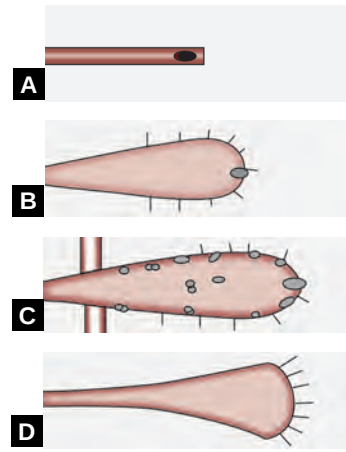
$$E_t = E_{en} - E_{ex}$$

where E_t = Missile energy transferred, E_{en} = Energy of entry at the time of impact and E_{ex} = Energy contained in the missile at the time of its exit from the tissues. If the missile exits, only part of its KE will be deposited within the tissues. The same amount of energy may be deposited by a missile of a smaller mass with a high velocity, or a greater mass missile with low velocity. The amount of energy transfer to the brain is the difference of the energies of the missiles at entry into and exit from the skull. If the missile does not exit from the skull, the energy transferred is the energy contained in the missile at the moment of impact. Thus, lower the residual velocity, greater the energy liberated.[17]

The extent and degree of damage in wounds are proportional to the amount of KE of the missile dissipated in the wound (Figs 1A to D). The injury produced by the missile is increased by factors causing it to give up more of its energy in the tissues. A missile that yaws will give up more of its energy. Similarly, a hollow point bullet that shatters upon impact will tend to give up more KE to the brain and is more destructive than bullets that do not shatter. Likewise, shotgun injuries caused by multiple pellets at close range, each with a relatively small amount of KE are extremely destructive; each of these pellets acts as an independent missile invested with KE according to its mass and velocity. Other factors that determine KE transfer by a missile are the resistance offered by the tissues and the tendency of the bullet to deform and increase the area with which it impacts the spine with a consequent increase in energy transfer to the tissues. Bullets with a flat front and expansion on impact (*dumdum bullets*) present a large surface area to the tissues to transfer energy. A rifled bullet fired at low velocity, spinning with its long axis parallel to the trajectory may pass cleanly through the tissue and exit, retaining much of its KE it had on impact. A high velocity rifle bullet of the same calibre will more likely strike with its long axis at a slight angle to its trajectory[3] and, as a consequence of this and its great velocity, deform and may even disintegrate in the tissues. The much greater tissue resistance to this high velocity deformed and 'tilted' missile and its fragments leads to release of an enormous amount of KE. The tissue damage is proportionately greater. Transfer of energy is greatest in dense tissues with high water content. Thus, wounds of neural tissue (and those of liver, kidney, muscle and bone) are more destructive than wounds of less dense tissue such as lung or fat.

Physical Effects of Missile Wounding

Missile wounding can be understood in terms of physical interactions between the missile and the tissues



Figs 1A to D: Passage of high- and low-velocity missiles through animal tissues: (A) Low velocity, small entrance and exit, no cavitation. (B) High velocity, with cavitation and tissue compression. (C) High velocity with secondary missiles from bone and cavitation. (D) High velocity trough thin tissue and large, ragged exit

through which it passes. The primary destructive effects of a missile interacting with tissues are caused by two mechanisms:

1. *Crushing action of the missile*: There is fracture of the skull, laceration and fragmentation of brain tissue and injury to vascular structures.
2. *Pressure waves and cavitation*: Besides the direct crushing action, a missile moving in water or tissue medium generates distinctive types of pressure waves within the medium it transits:
   a. *Juxta-missile pressure*: Extremely high pressures (thousands of atmospheres) are generated immediately in front of and at right angles to a moving missile, owing to flow of medium (through which the missile is travelling) around the missile.
   b. *Longitudinal shock wave*: When a missile strikes animal tissues, a high pressure compression front or shock wave is formed which spherically moves away from the point of impact. It is doubtful whether these shock waves result in any energy transfer to cause tissue damage.[16]
   c. *Pressure waves from KE transfer (cavitation)*: Cavitation was first recognised as a pathological phenomenon in missile injuries by Woodruff.[13,54] At the same time, Sir Victor Horsley[18] experimentally demonstrated the cavitation in missile injuries of the brain by firing into clay models of the brain. When a high velocity missile passes through tissues, KE is transferred to adjacent tissue elements, which are radially propelled, creating a large subatmospheric temporary cavity directly behind the missile. When the elastic limit of this outwardly displaced tissue is reached, it falls inwards whence it was displaced. This cycle may be repeated several times before the deranged tissue comes to rest around the permanent track created by the missile. The oscillatory, outwards and inwards rush of tissue creates a long lasting (milliseconds) lower amplitude (20–30 atmospheres) pressure wave which propagates throughout the medium. It has been considered that these lower amplitude and longer lasting pressure waves are the causes of damage to the tissues at a distance from the site of actual missile injury. KE deposited by a missile is partitioned between that which directly crushes tissues in its path and that which displaces tissues adjacent to the missile track. The latter is less destructive than the former owing to the elastic properties of the displaced tissue, which may be deformed without being irrevocably destroyed.[6]

Missiles and Mechanism of Injury

In military practise, the missiles are generally bullets or shrapnel, while in civilian practise the injury is sustained due to shotgun pellets and pistol/handguns/improvised explosive devices. The latter are generally LVMIs without significant accompanying visceral or soft tissue injury, especially if fired upon from the back or lateral aspect, since the thick paraspinal musculature and bony spine dissipates much of the KE of the missile. There may, however, be extensive soft tissue damage due to dispersal of pellets. In military combat, the large calibre HVMs usually cause extensive multi-organ damage in addition to spinal injury. The injury is produced by the following mechanisms:

- *Direct crush injury*: The missile crushes the tissue in its path, producing cord and nerve root laceration over more than one segment and an external communicating wound. The cord may be damaged by bone or disc fragments, even though the bullet does not come in contact with the spinal cord.
- *Cavitation*: Cavitation may stretch the neural tissue as the energy is transferred to the wound track producing damage. The temporary cavity collapses, leaving behind a smaller, permanent track.[6]
- *Concussive wave*: Myelopathy may be seen even if there has been no damage to the discoligamentous or disco-corporeal components of the spine in HVMIs. This occurs due to a concussive wave, which traverses the cord as the missile passes close to it, producing cord concussion and oedema. The severity of myelopathy is usually mild.
- *Intramedullary haematoma*: Injury to brachial nerve rootlets may lead to their avulsion at their origin from the cord and an intramedullary haematoma. The patient will have features of brachial plexus injury, with myelopathy; the latter is usually mild and resolves in due course.

Illustrative Cases

a. A 23-year-old soldier sustained a gunshot wound to the left supraclavicular region. The bullet exited through the back of the neck. He was admitted with pain over the left forearm and weakness of the left hand. Clinically, he had weakness of small muscles of the left hand and numbness over C7/T1 distribution. Tendon reflexes were brisk in both lower limbs with extensor plantars and grade 4+/5 power. While cervical spine radiographs and CT did not reveal any bony injury or malalignment, MRI after 7 days demonstrated intramedullary T2 hyperintensity at the periphery of the cord in the region of the ventral root. Nerve conduction studies were normal. He showed complete recovery of myelopathy over the next 3 months.
b. A 20-year-old soldier sustained gunshot wound to his left supraclavicular region and was admitted with weakness of all four limbs. The bullet had exited through the back of the neck. Clinically, he had grade 4/5 power in the triceps, both hands and both lower limbs, with brisk tendon reflexes and hypertonia in all four limbs. There was patchy sensory impairment over the trunk. Cervical spine radiograph was unremarkable. MRI revealed intramedullary

Fig. 2: MRI showing intramedullary T2 hyperintensity in a patient with gunshot wound to the soft tissues of the neck

hyperintensity at C6/C7 (Fig. 2). He was managed conservatively and showed complete neurological recovery over the next 6 months.

APPROACH TO A PATIENT WITH MISSILE INJURIES OF THE SPINE

MIS should never be approached in isolation; the initial principles are resuscitation, securing airway and haemodynamic stabilisation, so as to preserve perfusion to vital organs. Hypotension may be due to neurogenic or hypovolaemic shock, and the distinction may not immediately be apparent; nevertheless, accompanying bradycardia is more often a feature of neurogenic shock. A judicious combination of intravascular volume replacement, vagolytics and vasopressors may be required for resuscitation.

Once haemodynamic stabilisation has been achieved, careful survey of the level of injury together with anatomical structures damaged is carried out. Polytrauma may be sustained due to multiple missiles or by a single missile traversing multiple anatomical levels and structures. Cervical spine injury may be accompanied by vascular, pharyngeal, tracheo-oesophageal or pulmonary injury, while dorsal spine injury may be accompanied by haemopneumothorax or cardiac tamponade. Dorsolumbar injuries may be complicated by retroperitoneal or intraperitoneal injuries, colonic injuries being of immediate concern for their potential for contamination. The attending surgeon should also be able to suspect spinal injury in the presence of these non-neurogenic injuries, especially if the patient's sensorium is altered, or if he is hypotensive. Wounds of entrance and exit are carefully examined for cerebrospinal fluid (CSF) leakage and the extent of tissue damage is assessed.

Table 1: Neurological grading system (Benzel & Larson, 1987)

Grade I: Complete functional neuronal transection. No motor or sensory function below the level of injury.
Grade II: Motor complete. No voluntary motor function below the level of injury, with preservation of some sensation.
Grade III: Motor incomplete—non-functional. Minimal non-functional voluntary motor function below the level of injury.
Grade IV: Motor incomplete functional. Unable to walk; some functional motor control below the level of injury.
Grade V: Motor incomplete—functional. Limited walking, lack of endurance or fear of falling.
Grade VI: Motor incomplete—functional. Unlimited walking, difficulties with micturition and slightly discoordinated gait.
Grade VII: Normal.

Baseline neurological assessment is extremely important. In an unconscious patient, the attitude of the limbs and presence of spontaneous movements is noted as is the response to pain, and the muscle tone. Some idea of sensory level may be possible by noting response to pinprick. In a conscious patient, motor-sensory evaluation is carried out, and an appropriate neurological grade is assigned. Frankel grade is easy to apply and useful to stratify the patients with MIS, and can be used to prognosticate the outcome. Benzel and Larson[2] devised a more comprehensive scale which utilises seven grades instead of five of Frankel grading (Table 1).

Imaging

Missile injuries of the dorsolumbar spine are biomechanically stable injuries, and instability is rare,[36] except in children.[8] The biomechanical vectors that are in force in closed injuries as that seen in flexion, distraction, rotation, axial loading, etc. that result in instability are not operative in MIS; instead, the energy transfer due to missile injury takes place in a sharply focused region of the spinal column, resulting in localised damage without causing major biomechanical disruption of the functional spinal unit. However, in the cervical spine, due to smaller volume of the target organ, these disruptions can cause instability.

Plain Radiography

Multiplanar spinal radiographs should be obtained to detect metallic fragments, and their craniocaudal as well as anteroposterior distribution. Fractures and dislocations are readily detected by plain radiographs. Presence of metallic or bone fragments should be noted within the spinal canal or in the neural foramina (Figs 3 to 5). Plain radiographs will also detect subcutaneous emphysema, haemopneumothorax or pneumoperitoneum in the presence of associated injuries.

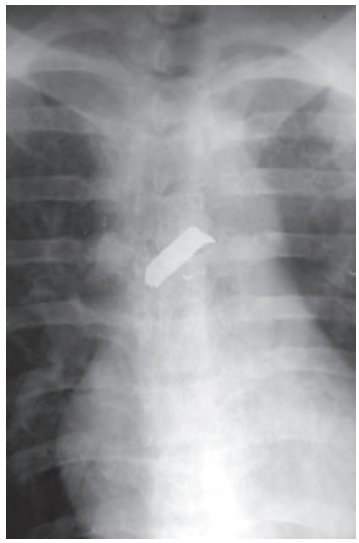


Fig. 3: Dorsal spine radiograph showing bullet embedded in the spine

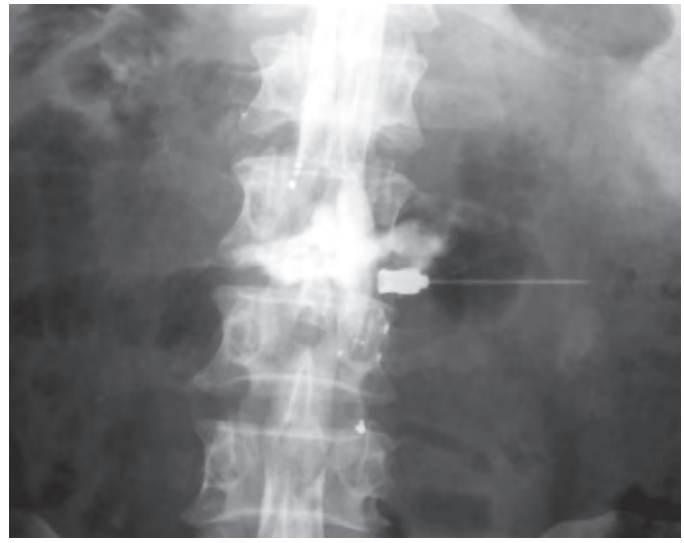

Fig. 6: Iohexol myelogram showing extravasation of the contrast

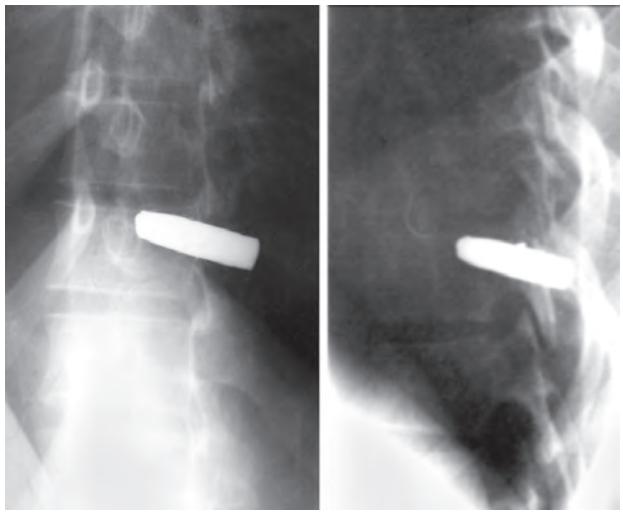

Fig. 4: Dorsolumbar spine radiograph showing bullet embedded in the spine

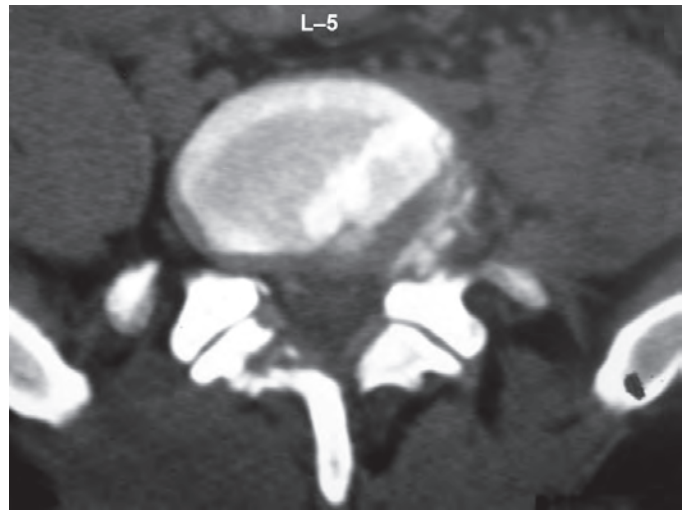

Fig. 7: CT showing missile track in the vertebral body

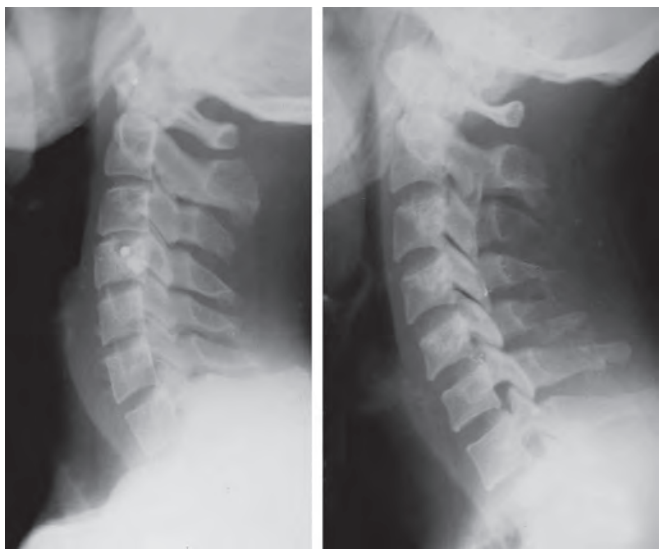

Fig. 5: Cervical spine radiograph (lateral view) showing multiple splinters in the soft tissues

Myelography

In the absence of computed tomogaphy, myelography is a good substitute to detect dural injury as evidenced by extravasation of intrathecal contrast (Fig. 6). A myelographic block may be an indication for surgery, and complications like arachnoiditis are rarely seen with water soluble contrast media like iopamidol or iohexol.

Computed Tomography

Computed Tomography (CT) is the diagnostic modality of choice in the evaluation of MIS. Precise delineation of the fracture can be made, and intraspinal fragments and soft tissue foreign bodies can be visualised. CT myelography (Figs 7 to 13) can be useful to detect the extravasation of contrast and CSF fistula.[8]

Magnetic Resonance Imaging

Magnetic Resonance Imaging (MRI) is the imaging modality of choice for assessing the extent of spinal cord

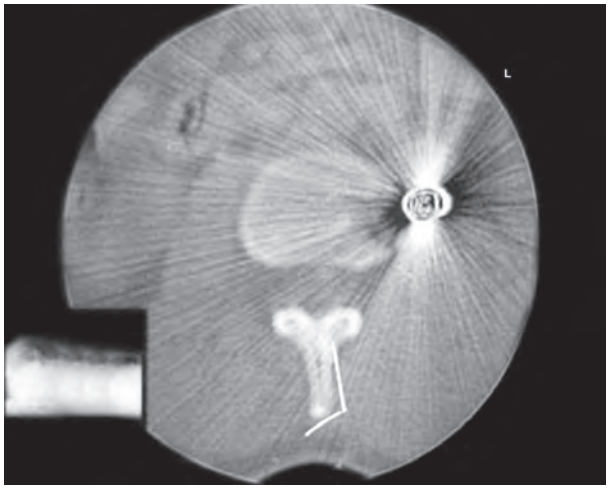

Fig. 8: CT showing missile lodgement near the vertebral body

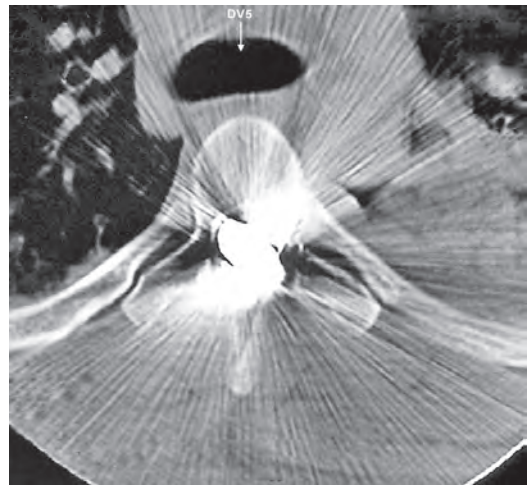

Fig. 11A: CT showing intraspinal lodgement of bullet

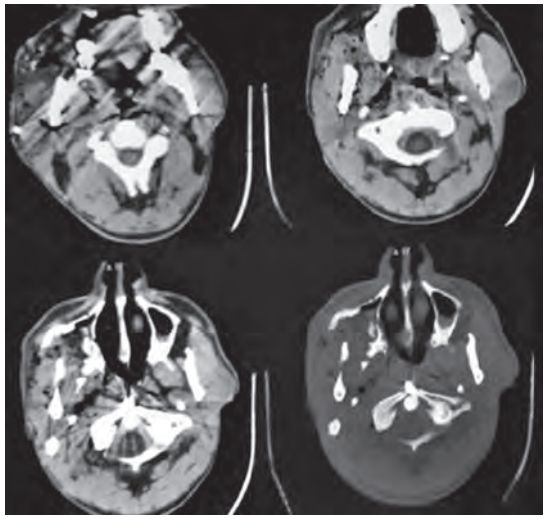

Fig. 9: CT showing splinter lodged at the anterior tubercle of atlas

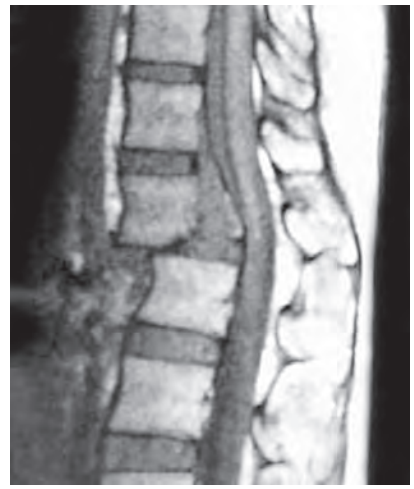

Fig. 14: MRI showing dislocation of D12/LV1 due to missile injury

injury, yet its use in MIS is restricted due to the possibility of movement of the ferromagnetic missile fragments. In addition, movement artefacts can create difficulties in interpretation. MRI is especially useful in the diagnosis of spinal injury if the missile has exited (Fig. 14), provided there has been no associated injury to the disco-corporeal components of the spine (Fig. 2). MRI is also useful in the follow-up of such patients to detect the possible formation of post-traumatic syrinx, in the setting of delayed neurological deterioration (Fig. 15).

Controversies and Evolution of Treatment Philosophy

Surgical versus Conservative Management

Surgery for missile injury of the spine has been a matter for debate, with most of the early military studies uniformly advocating surgical intervention,[35] while the civilian studies have adopted a more selective approach. Proponents of surgical intervention cite prevention of infection, CSF leakage, lead toxicity, pain and late deterioration as the goals, and the possibility of neurological improvement following surgery. Reports of civilian penetrating injuries do not generally advocate surgical intervention unless there is delayed deterioration. The disparity between military and civilian reports of seemingly better neurological outcome following exploration may be due to higher incidence of spinal cord concussion from HVMs in military injuries, which in turn may lead to a higher false incidence of improvement after routine surgical exploration.[57] Moreover, increased incidence of wound infection and CNS infections is reported in patients who have undergone surgical exploration.[21] Differences in the regional anatomy of the spinal cord and the greater potential for recovery in injuries involving the nerve roots account for the differences in the effects of surgery in the thoracic, thoracolumbar and

Fig. 15: Post-operative radiograph showing reduction and stabilisation

lumbar regions. In injuries up to the D12 level, the cell bodies as well as axons in the spinal cord are damaged and the resulting glial scar forms an impenetrable barrier to regenerating axons. A peripheral nerve or root injury leaves the cell bodies intact, and there is relative abundance of myelin surrounding the axon. Disintegration of a motor axon within a peripheral nerve due to local injury progresses proximally to the next node of Ranvier. In the region of axonal degeneration, the Schwann cells proliferate and form neurolemmal tubules. Growth from the central end of the damaged axon can be guided across the sites of trauma, allowing motor reinnervation over-time. These factors contribute to the favourable outcome in cauda equina injury. Based upon a review of various studies in the preceding decades, coupled with their own wartime experience, Bhatoe and Singh[4] formulated indications for surgery in MIS as follows:

- Incomplete neurological deficit
- Cauda equina injuries

- Cervical cord injuries
- Presence of external CSF fistula
- Worsening of existing neurological deficit.

Doubts have been raised about the tenability of the phenomenon of worsening of existing neurological deficit. The role of surgery in the presence of complete deficit is still not settled. However, the presence of a compressive lesion would be an indication for exploration in such cases.

Intraspinal Fragment

The main question to be answered is whether to remove the bullet or not? Removal of a bullet has been advocated for improving the neurological outcome, prevention of infection, prevention of delayed neurological deterioration,[24,56] lead toxicity[12] and prevention or treatment of pain syndromes. Waters and Adkins[52] observed neurological improvement after removal of bullets from the thoracolumbar region, but not after removal of bullets from the thoracic region. However, no increased incidence of infection was seen if broad spectrum antibiotics were administered early.[44] The consensus of opinion at present seems to be to remove intraspinal fragments located in the cauda equina and in the cervical spine. Cauda equina injuries carry the potential for better recovery, and prevention or treatment of radicular pain can be achieved, while the cervical spine fragments are removed to obviate or treat radicular pain as well as with the hope of effecting recovery even of a single root, which can influence the rehabilitation process.

Associated Injuries and Spinal Cord Decompression

A high percentage of MIS are associated with non-neurological injuries, especially to the chest and gastrointestinal tract. Some authors have advocated primary debridement of the spine and paravertebral tissues through the operative incision of the primary procedure, obviating the need for a second procedure.[5,22] However, primary neurosurgical intervention has been implicated in causation of spinal osteomyelitis.[31] After analysing one of the largest series of associated injuries with MIS, Venger et al.[49] came to the conclusion that neurosurgical intervention can safely be deferred till the general condition of the patient improves, and there was no difference in the neurological outcome between operated and non-operated cases. Thus, it can be recommended that neurosurgical intervention in the presence of associated visceral or vascular injury takes second priority, and can safely be deferred till the patient is stable after abdominal/thoracic surgical intervention.

Cauda Equina Injury

Patients with cauda equina injury form a distinct subset of patients with MIS in whom the deficit is usually incomplete, neurological recovery can be expected, and the role of surgery is more definite. During the Korean War, out of 254 servicemen with HVMs of the lumbosacral spine, neurological recovery occurred in 52.22% after surgery.[51] Improvement following surgical exploration has been reported in civilian cauda equina injuries as well.[1] The mechanism of injury may be neuropraxia, traction or concussive wave.[45] Moreover, compression may occur due to fracture fragments, foreign bodies or intraspinal haematoma. Herniated nucleus pulposus has been reported to cause nerve root compression in a case of MIS.[33] Debridement can be accomplished with a low degree of morbidity. Intraspinal fragments deserve special consideration in cauda equina injuries, especially in incomplete injuries and in the presence of radicular pain. The better prognosis in these patients is due to sparing of the nerve roots, first noticed by Matson;[34] recovery may be expected as with peripheral nerve injuries.[30,49] While some patients may achieve recovery without surgery,[44] there are no clinical, radiological or electrodiagnostic predictors for recovery.[7] The nerve roots have a potential both for recovery and to produce pain; doing laminectomy and decompression will provide an optimal environment for recovery of the damaged nerves. Hence, it is recommended that cauda equina injuries should surgically be explored, fragments excised and decompression affected.

Spine Stabilisation

It is generally presumed that most MIS are stable injuries. Meyer et al.[36] reported no instance of instability in 1300 patients with MIS. If, however, the bullet passes transversely fracturing both the pedicles and the facets, the injury is likely to be unstable.[52] The flight path of the bullet must be considered and, if instability is suspected, appropriate imaging is done under supervision, and stabilisation planned. Cervical spine injuries are considered inherently unstable and need to be stabilised after decompression.

CURRENT MANAGEMENT

Broad spectrum antibiotics, preferably ones that cross into the CSF, are administered on admission. There is no reported benefit of administering methylprednisolone in patients with MIS.

Wound Debridement

Debridement of wounds of entry and exit is carried out at the time of initial admission. Devitalised tissue, foreign bodies and debris are excised, and haemostasis is achieved. Extensive soft tissue injuries as those sustained with HVMs or by multiple pellets sprayed over a wide surface area may require assistance from a reconstructive surgeon.

Operative Management for Missile Injuries of the Spine

The injured spinal cord is approached by a standard laminectomy. A longitudinal incision is made centred

over the involved region. Muscles are separated from the laminae by sharp dissection and an assessment is made of the bony injury. Use of electrocautery should be avoided to expose the involved lamina if there is an impacted bullet or shrapnel in the lamina, lest there be further damage to the cord due to electric current (Fig. 11B). The spinous process of the cephalad and caudad vertebrae and that of the injured vertebra are excised and the laminae are nibbled carefully on both sides, so as to avoid compression on the dura, and to avoid dislodgement of the intraspinal fragment at this stage. Once adequate dura has been exposed, the injured site is carefully defined, utilising copious saline irrigation. Comminuted fragments are carefully dislodged and the dural tear is defined. The dura is then opened between stay sutures and normal looking cord is exposed. Devitalised tissue, haematoma and loose fragments are removed. A judicious decision is made whether or not to remove an embedded intramedullary fragment. Obviously compressed roots are decompressed, especially in the cauda equina region. Weak suction is employed so as to prevent nerve roots getting pulled into the suction. One should avoid excising the dura and even free patches can be sutured back. One must make an endeavour to achieve a water-tight yet tension free dural closure. If the dura appears intact, and there is no evidence of intradural haematoma or any other compressive lesion, dural opening is unnecessary. The wound is thereafter closed in layers.

Post-Operative Management

Care of paraplegic and quadriplegic patients demands the highest levels of dedication and care from the nursing staff. Kinetic therapy table provides ease of turning the patient to prevent pressure ulceration. Two hourly change of posture, care of the skin, prevention of contractures, urinary infection, chest infection and deep vein thrombosis form the mainstay of post-operative care of these patients. Antibiotics are administered for a period of 14 days. Rapid mobilisation is essential and a multidisciplinary rehabilitation programme is commenced early. A cheerful, optimistic attitude goes a long way in encouraging early mobilisation and facilitates rehabilitation. Functional recovery (improvement in sensory level, improvement of motor power, return of continence) has to be assessed periodically.

Prevention of Deep Vein Thrombosis

Deep vein thrombosis and thromboembolic disease in adult patients with cervical spinal cord injury are the major cause of morbidity and mortality in the first 2–3 months after injury. The risk decreases with passage of time. Low molecular weight heparin, adjusted dose heparin, pneumatic compression devices and electrical stimulation are effective in prevention. Oral anticoagulation alone does not seem to be as effective as other prophylactic measures.[13]

SEQUELAE

Pain and delayed neurological deterioration constitute two broad groups of sequelae of MIS.

Pain

There are three distinct variants of pain syndrome following initial recovery from MIS. These are:

a. *Central pain of spinal deafferentation:* This type of pain is dysaesthetic in nature. This is poorly localised and quite intractable to medical treatment.[11] Carbamazepine and amitryptyline have been tried with varying success. In thoracic cord injuries, dorsal root entry zone lesioning and spinal cord stimulation have shown promising results.[8]
b. *Radicular pain:* This type of pain is seen more often with cervical cord and cauda injuries, and is characterised by burning sensation over the extremities with a dermatomal localisation. If secondary to a retained intraspinal splinter, this type of pain is most amenable to treatment by removal of the offending foreign body. Relief may be seen even in patients who have been symptomatic for years after the initial injury.[23]
c. *Vertebral pain:* Pain arising from disco-corporeal elements is fairly localised over the region of injury. There may be local tenderness. Imaging may reveal infective sequelae, and treatment would consist of debridement with the possibility of stabilisation.

Delayed Neurological Deterioration

Deterioration may occur due to infective sequelae, especially osteomyelitis.[22,32] Cord compression can also occur due to exaggerated granulomatous response, especially in injury due to steel and glass.[21,56] Other causes of deterioration are formation of post-traumatic spinal cysts (post-traumatic syringomyelia) and intraspinal migration of missile fragments. Post-traumatic cystic myelopathy follows tethering of the contused cord and localised arachnoiditis with alteration in CSF flow; these lead to rostral and caudal cystic degeneration and cord cavitation.[8] Migration of bullets in the subrachnoid space can lead to new deficits.

All patients with delayed neurological deterioration should be investigated by CT myelography or by MRI, subsequent to which further treatment can be planned. Extradural cord compression may require debridement with or without instrumentation. Post-traumatic cystic myelopathy is improved by shunting,[9] and excision of migrating bullets is curative.

Lead Toxicity

Retained bullets and shrapnel tend to get sealed off by fibrosis and lead is not absorbed to cause lead toxicity. However, symptoms of lead poisoning (abdominal pain, anaemia, headaches, memory loss, muscle weakness) may occur if the lead object is in communication with

synovial fluid such as a joint or pseudocyst.[27,39,56] Treatment consists of chelation therapy with ethylenediamine tetra-acetic acid (EDTA), d-penicillamine or dimercaprol (BAL).

It is likely that neurosurgeons will be seeing more patients with missile injury to the spine, and it is important that certain facts are borne in mind when treating such patients. As a general rule, the decision about initial neurosurgical intervention is made after correlating the clinical profile to the imaging findings. Complete neurological deficits generally do not warrant surgical exploration. Incomplete neurological deficits with evidence of cord compression, cauda equina injuries and those injuries with external CSF fistula need neurosurgical intervention. Broad spectrum antibiotics should be administered early and associated visceral injuries should be tackled first. These patients demand the highest standards of post-operative and nursing management in the acute phase, and subsequent watch has to be kept for early diagnosis of neurological deterioration. Rehabilitation should be commenced early in specialised centres so that these patients can once again find their rightful place in society.

Non-Missile Penetrating Spinal Injury (Stab Injury)

Compared to missile injuries, non-MIS are rare. While there have been few reports from India,[43,47] reports from South Africa account for most of the large series reported.[28,29,37]

Mode of Injury

The majority of these injuries are due to assault with knives (stabbing). Penetrating injuries, however, can occur due to fall on sharp objects, and stabbing with screwdriver, bicycle spokes, scissors, garden forks, sickles, etc. have been reported.[37] In general, the penetrating object or weapon is withdrawn after stabbing; rarely, the attacker breaks the blade at the handle. Most of the victims are young males, although such injuries are being often seen in women also.[53] Usually the wound of entry is posterior thoracic (54–63%) or cervical (27–30%).[37,47] In the latter instance, there may be injury to the brachial plexus and carotid vessels.

APPROACH

Careful transportation to a trauma centre is essential for optimum evaluation and assessment of the damage. A complete assessment is made to detect injury to major vascular structures, bronchi, aorta and other visceral organs. Volume replacement is made and chest tube insertion is carried out, if indicated. No attempt should be made to remove an externally visible retained weapon in the emergency room and by the paramedics.

Neurological Presentation

Spinal cord or root injury may occur immediately after the stabbing indicating physical damage by the weapon, and delayed deficit may manifest months later due to the retained weapon and formation of post-traumatic syrinx. Infection causing meningitis or intraspinal suppuration too can result in delayed neurological deterioration.[10,26] Immediate neurological deficit is in the form of Brown-Séquard syndrome in most of the cases, which may be typical or incomplete; nearly 21% of cases have complete spinal cord injury.[37,42,47] On the other hand, nearly a third of the patients may not have any neurological deficit.[47] The injury can remain extradural and may cause deficits months after the injury.[15] Inflammatory reactions in the nervous tissue to retained metallic fragments can also result in delayed neurological deficits. Copper is associated with severe scarring and fibrosis, while nickel and lead excite a less severe response.[41] Oxidation of metallic fragments can result in deposition of rust particles on the nervous tissue.

Imaging

Plain radiography is the initial investigation in all cases. A retained metallic object will be revealed along with other injuries like haemopneumothorax and emphysema. Computerised tomography shows injury to the disco-corporeal components, presence of haematomas and the track of the injuring weapon. Streak artefact can be used to determine the location of the tip of the blade.[25] MR imaging can be employed in those cases with no retained metallic fragment/weapon. Integrity of the spinal cord, presence of haematoma, disc herniation, etc. can be seen with great accuracy.

Surgical Approach

An externally visible stuck weapon has to be removed in the operation theatre after preparing the operation theatre for thoracotomy/laparotomy/neck exploration. The externally visible portion of the weapon or its handle can be grasped and gently pulled in its long axis. The external wound is extended if required, debrided, irrigated with saline, hydrogen peroxide and antibiotic solution, and closed in layers. No definite guidelines exist for the management of stab injuries of the

spine. Only 20 patients out of 450 managed by Peacock et al. underwent laminectomy.[37] While Velmahos et al. reported surgical exploration in 22 out of 143 patients.[48] Thakur et al. explored 9 of their 11 patients.[47] In another review of 16 patients with non-missile penetrating injuries, it was brought out that surgical intervention made no difference to the final outcome.[42] The consensus is that surgical exploration should be carried out for those patients with incomplete neurological deficits, persistent CSF leak, retained intraspinal foreign body or bone fragment and persistent pain.[40] Although CSF leak may stop spontaneously, the patient may develop meningitis and there may be formation of pseudomeningocoeles as these CSF fistulae heal. Hence, presence of CSF leak beyond 96 hours should be an indication for surgical intervention. Surgical intervention is also indicated in cases with delayed neurological deterioration, especially in the presence of a retained intraspinal foreign body.[15] The surgical procedure involves laminectomy, defining the normal dura cranial and caudal to the site of stab, and opening the dura with stay sutures. Conservative debridement is carried out and only the detached, non-viable neural tissue is debrided. The haematoma is evacuated and the dura is closed with a dural substitute if necessary. A lumbar subarachnoid CSF drain is inserted for 5–10 days and antibiotics in antimeningitic dosage are administered. Spinal stabilisation is generally not required, since these injuries are stable.

All patients are closely monitored for delayed neurological deterioration and deafferentation pain. Overall neurological recovery is better than that observed with missile injuries.

Peripheral Nerve

VS Mehta

55 Anatomy and Physiology of the Peripheral Nerve

Sharma M, Gupta A, VS Mehta

The central nervous system is one of the major control centres of the human body. The central nervous system is unique in the vast complexity of thought processes and linked actions it can perform. It receives and processes large amounts of information from the various organs of the body.

It contains about 100 billion neurons and 1,000 to 50,000 billions of glial cells (also called supporting cells). The neurons are the structural and functional units of the nervous system.

The peripheral nerve is a special living conduit that transmits impulses in both directions, with a special structure, so as to maintain its function, vascularity and vitality in the face of adverse mechanical forces, such as those across joints and in different limb positions.

As the peripheral nerve is composed of parts of axons arranged in a special manner, it is appropriate to start with basic details about the neuron.

NEURON

Classification

On the Basis of Processes

- *Unipolar neurons:* Only one process leaves the cell body. They are sensory in function and located in the craniosacral ganglia.
- *Bipolar neurons:* A single dendrite and a single axon leave the body. They are purely sensory in function and located in the cochlear and vestibular ganglia of the VIII nerve, in the olfactory nerve and in the retina.
- *Multipolar neurons:* Most common type of cells. Have numerous branched dendrites projecting from the cell body and on the opposite side there is a single process called the axon. They are the largest population of nerve cells and form motor neurons, interneurons, pyramidal cells, Purkinje cells and neurons of the autonomic nervous system.

On the Basis of Function

- Central cell body
  - Cortical neurons: Impulses from the cerebrum, cerebellum and optic lobes to the affector organs.
  - Interneurons: Connector neurons.
  - Central effector neurons: They include motor neurons, autonomic neurons and hypophyseal neurons.
- Peripheral cell body
  - Peripheral effector neurons: From the autonomic and invertebrate ganglia.
  - Bipolar neurons: Those of the optic, vestibulocochlear, olfactory and cutaneous neurons.

Structure

Cell Body

It is also called the perikaryon. It contains a large, central nucleus with a prominent nucleolus and it gives rise to the axons and the dendrites (Fig. 1). It is located at the dendritic zone end of the axon but it can be within the axon or attached to the side of the axon. It also contains Nissl substance which contains rosettes of polysomes and rough endoplasmic reticulum and hence has a role in protein synthesis. Nissl substance is also present in the dendrites but is not present in the axon hillock or the axon.

Dendrites

The cell body gives rise to 5–6 processes that extend outwards and branch extensively. The small, knobby

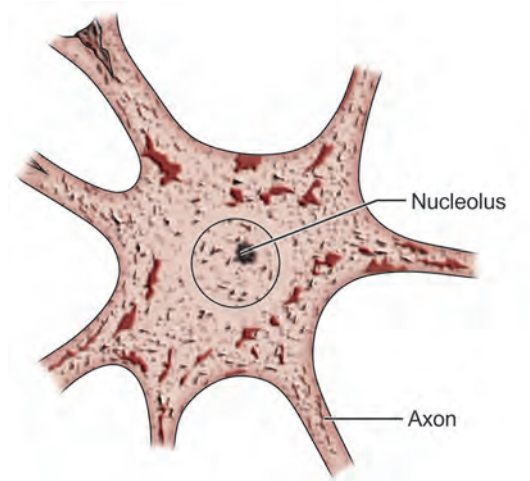

Fig. 1: Diagrammatic representation of a multipolar neuron

projections of the dendrites are called dendritic spines. The dendrites conduct impulses towards the cell body.

Axons

An axon is a neuron process that originates from a thickened area of the cell body called the axon hillock. The first portion of the axon is called the initial segment. The axon divides into terminal branches, each ending in a synaptic knob also called terminal buttons or axon telodendria. The cytoplasm present inside the axon is called axoplasm and the outer membrane is called the neurilemma.

Schwann Cells

They are also called neurolemmocytes. They extend along the axon from its origin to its termination. They form the myelin sheath around the larger axons. Smaller axons are surrounded only by the Schwann cell cytoplasm. Along the length of the myelinated axon are small gaps in the myelin sheath between individual Schwann cells called the node of Ranvier. Such of the axons that do not have a myelin sheath are called unmyelinated.

NERVES

A *nerve* is an enclosed, cable-like bundle of *nerve fibres* or axons, which includes the glia that ensheath the axons in myelin. Neurons are sometimes called nerve cells, although this term is technically imprecise, since many neurons do not form nerves.

Nerves are part of the peripheral nervous system. Afferent nerves convey sensory signals to the central nervous system, for example, from skin or organs, while efferent nerves conduct stimulatory signals from the central nervous system to the muscles and glands. Afferent and efferent fibres are often arranged together, forming mixed nerves.

Most nerves connect to the central nervous system through the spinal cord. The twelve cranial nerves, however, connect directly to parts of the brain. Spinal nerves are given letter-number combinations, according to the vertebra through which they connect to the spinal column. Cranial nerves are assigned numbers, usually expressed as Roman numerals from I to XII. In addition, most nerves and major branches of nerves have descriptive names. Inside the central nervous system, bundles of axons are termed tracts rather than nerves.

Nerves carry action potentials which begin typically in the cell body of a neuron and propagate rapidly down the axon to its tip or "terminus". The signals cross over from the terminus to the adjacent neurotransmitter receptor through the synapse.

Histology of a Nerve Fibre

Endoneurium

It is a connective tissue layer surrounding each nerve fibre.

Perineurium

It is a connective tissue layer which surrounds each fascicle (a bundle of nerve fibres).

Epineurium

It is the connective tissue layer surrounding each nerve (Fig. 2).

Basic Nerve Physiology

Tables 1 and 2 show nerve fibres types, function and the numerical classification.

Excitation and Conduction

Nerve cells have a low threshold for excitation and they respond to mechanical, electrical or chemical stimuli (Figs 3A and B).

Two types of physio-chemical disturbances are produced:

- Electrotonic potentials which are non-tonic propagated potentials.
- Action potentials are the propagated disturbances.

Conduction is an active, self-propagating process and the impulse moves along the nerve at a constant amplitude and velocity. The electrical events in neurons are rapid, being measured in milliseconds and the potential changes are small being measured in millivolts.

Resting Membrane Potential

It is the negative potential inside the cell membrane when the cell is at rest. In neurons it is -70 mV.

Latent Period

If the axon is stimulated and a conducted impulse occurs, a characteristic series of potential changes known as the action potential is observed. When a stimulus is applied there is a brief, irregular deflection of the baseline called the stimulus artefact. The stimulus artefact is followed by an isopotential interval called the latent

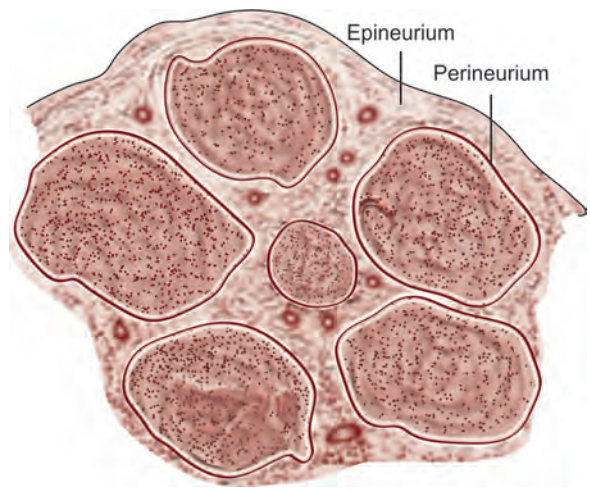

Fig. 2: Cross-sectional anatomy of the human tibial nerve

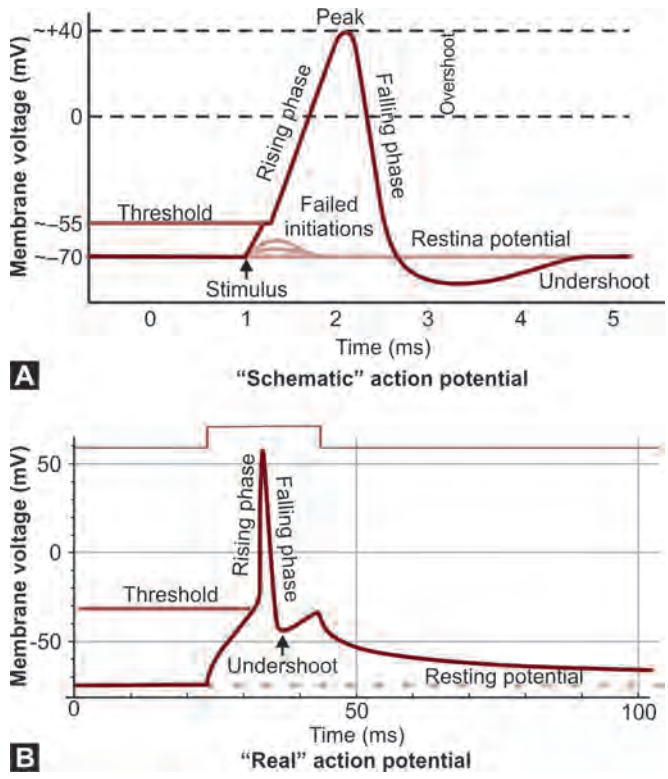
Table 1: Nerve fibre types and functions

Fibre type	*Function*	*Fibre diameter*	*Conduction velocity*	*Spike duration*	*Absolute refractory period*
A alpha	Proprioception and somatic motor	12–20	70–120		
beta	Touch and pressure	5–12	30–70	0.4–0.5	0.4–1
gamma	Motor to muscle spindles	3–6	15–30		
delta	Pain, cold, touch	2–5	12–30		
B	Pre-ganglionic autonomic	<3	3–15	1.2	1.2
C dorsal root	Pain, temperature, mechanoreception, reflex response	0.4–1.2	0.5–2	2	2
sympathetic	Post-ganglionic sympathetic	0.3–1.3	0.7–2.3	2	2

A and B fibres are myelinated, C fibres are unmyelinated.

Table 2: Numerical classification

Number	*Origin*	*Fibre type*
I a	Muscle spindle, annulospiral ending	A alpha
I b	Golgi tendon organs	
II	Muscle spindle, flower-spray endings, touch, pressure	A beta
III	Pain and cold receptors, some touch receptors	A delta
IV	Pain, temperature, and other receptor	Dorsal root C



Figs 3A and B: (A) A schematic view of an idealised action potential illustrates its various phases, as the action potential passes a point on a cell membrane. (B) Actual recordings of action potentials are often distorted compared to the schematic view, because of variations in electrophysiological techniques used to make the recording

period that ends with the start of the action potential and corresponds to the time it takes for the impulse to travel along the axon from the site of stimulation to the recording electrodes.

Action Potential

The first manifestation of the approaching action potential is an initial depolarisation of the membrane. After an initial 15 mV of depolarisation, the rate of depolarisation increases. The point at which this change occurs is called firing level or threshold. Thereafter, depolarisation reaches and overshoots the isopotential line to approximately + 35 mV. It then reverses and falls rapidly to the resting level. When repolarisation is about 70% completed, the rate of repolarisation decreases and the tracing approaches the resting level more slowly. The sharp rise and rapid fall are the spike potential of the axon and the slow fall is called the after depolarisation. After reaching the previous resting level, the tracing overshoots slightly in the hyperpolarising direction to form the small but prolonged after hyperpolarisation.

All or None Law

Threshold intensity: It is the minimal intensity of stimulating current that acting for a given duration will just produce an action potential. The threshold intensity varies with the duration—with weak stimuli it is long and with strong stimuli it is short.

The relation between strength and duration of the stimulus is called the strength-duration curve. Once the threshold intensity is reached, a full-fledged action potential is produced. Further increases in the intensity of the stimulus produce no increment or other change in the action potential as long as the other experimental conditions remain constant.

The action potential fails to occur, if the stimulus is sub-threshold in magnitude and it occurs with a constant amplitude and form, regardless of strength or form, if it is at or above threshold intensity. The action potential is thus all-or-none in character and is said to obey the all-or-none law.

Ionic Basis of Excitation and Conduction

The cell membranes of nerves contain different types of ion channels, some are passive, some are voltage-gated, while others are ligand gated. It is the behaviour of these channels and particularly sodium and potassium channels that explains the electrical events in the nerves.

Ionic Basis of the Resting Membrane Potential

Due to the difference between the permeability of membranes to different ions, there is a greater efflux of K compared to the influx of Na which results in a negative potential inside the cell membrane which is termed as the resting membrane potential.

Ionic Fluxes During Action Potential

This is due to the changes in membrane conductance of sodium and potassium as detailed in Figure 3.

Neuromuscular Junction

The neuromuscular junction is the connection between an efferent nerve and muscle fibres controlled by this nerve. Transmission is universally mediated by acetylcholine released from the presynaptic terminal by the arrival of an action potential. The release of this neurotransmitter is mediated by fusion proteins on the membrane and appears to be dependent on an influx of calcium ions. Once the acetylcholine is released into the synaptic cleft, it rapidly diffuses to the postsynaptic membrane, where it binds to acetylcholine receptors. These, in turn, trigger a rapid influx of calcium into the muscle cells, triggering muscle contraction. The remaining acetylcholine in the synaptic cleft is rapidly degraded by acetylcholinesterase to prevent desensitisation of the synapse.

If, after peripheral nerve injury or transection, the neuromuscular junction does not undergo excitation at all, over a period of time the density of acetylcholine receptors gradually declines. In fact, it has been shown that after 18–24 months of loss of nerve continuity, the neuromuscular junction undergoes irreversible loss of excitability, resulting in no clinical motor improvement, if surgery is delayed up to this time.

Peripheral Nerve Transection

Once a peripheral nerve has been transected, Wallerian degeneration of the distal axons begins and macrophages enter the area to remove the myelin and axonal debris. During this process, the basement membrane which surrounds the axon and Schwann cell remain intact. Schwann cells line up in the basement membrane tube and synthesise growth factors, which attract axonal sprouts, formed at the terminal of the proximal segment of the severed axon. The basement membrane tubes provide pathways for the regenerating axons to follow to the muscles and skin. The Schwann cells then remyelinate the newly formed axons; however, the newly formed myelin is thinner than normal and the newly formed internodes are shorter than normal.

Nerve injury is most commonly classified in one of two ways.

Seddon's Classification of Nerve Injury

This is the earliest and the most well-known classification system. Prior to World War II, no precise classification existed for peripheral nerve injuries. The description by Seddon, in 1943, therefore constituted a major advance in the clinical evaluation and management of these cases. He described three grades of severity:

Neuropraxia: An injury to the nerve covering (called the myelin sheath), but not the nerve, by trauma or compression, which causes blockage of the nerve signals. Larger nerves covered by greater amounts of myelin are most susceptible to this injury. Reflexes, muscle function, vibratory and two-point discrimination are typically lost, while pain, temperature and autonomic function (sweating and circulatory regulation controlled by nerves) is typically preserved. Repair may take days to months and healing is usually perfect as only the sheath needs be repaired. This corresponds to Sunderland's 1st degree injury.

Axonotmesis: Involves disruption of the nerve itself, but the surrounding and supportive nerve myelin sheath is not affected. Causes include long or severe periods of compression, pulling or loss of blood flow to the nerve. All nerve types may be affected. Nerve fibre healing occurs at a rate of 1 mm per day from the point of injury. Recovery is usually good, although the further from the spine the injury occurs, the better the prognosis. This corresponds to a 2nd or 3rd degree injury in Sunderland's system.

Neurotmesis: A disruption of both the nerve fibre and the supportive myelin sheath. This injury may be seen with severe trauma, such as lacerations, gunshot wounds, open bone fractures, punctures, and exposure to toxins. Healing is usually poor without surgical repair. This corresponds to a 4th or 5th degree injury in Sunderland's system.

Sunderland Classification of Nerve Injury

After Seddon's description, Sunderland, in 1978, proposed his own system of grading nerve injuries into five increasing grades. However, clinical distinctions do not accompany various grades as described by him, but the grading itself remains a very useful tool.

First degree: Injury with only local changes to the nerve sheath (myelin).

Second degree: Incomplete injury to the nerve axons (the functional unit of the nerve). Nerve itself is still intact.

Third degree: Severe axonal injury with scar tissue. Nerve itself may be injured, but is still intact.

Fourth degree: Complete disruption of axon. Nerve itself may be severely injured, but is still intact.

Fifth degree: Complete transection of the nerve.

Neurotrophic Factors

Neurotrophins are a family of molecules that encourage survival of nervous tissue. Neurotrophic factors are secreted by cells in a neuron's target field and act by prohibiting the neuron from apoptosis. In this way, target neurons are not removed.

The neurotrophin family includes the nerve growth factors, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT-3) and neurotrophin 4 (NT-4). There are two classes of receptors, p75 and the "Trk" family of tyrosine kinases receptors. p75 is a low affinity neurotrophin receptor, to which all neurotrophins bind. The Trk family includes TrkA, TrkB and TrkC and will only bind with specific neurotrophins, but with a much higher affinity. The Trks mediate the functional signals of the neurotrophins.

Nerve growth factor is the prototype for the neurotrophin family of polypeptides which are essential for the development and survival of certain sympathetic and sensory neurons, in both the central and peripheral nervous systems. NGF was discovered when mouse sarcoma tissue transplants in chicken embryos caused an increase in the size of spinal ganglia. In the course of attempting to characterise the agent responsible for this action, snake venom, employed as a phosphodiesterase, was found to be a rich source of NGF. A homologous tissue, the submaxillary gland of adult male mice, has become the preferred source of NGF; other unusually large concentrations are found in the guinea pig prostate gland and in bovine seminal plasma. The physiological relevance of these sources is not established. NGF is critical for the survival and maintenance of sympathetic and sensory neurons. NGF is released from the target cells, binds to and activates its high affinity receptor (TrkA) and is internalised into the responsive neuron. The NGF/TrkA complex is subsequently trafficked back to the cell body. This movement of NGF from axon tip to soma is thought to be involved in the long-distance signalling of neurons.

There is recent interest in the role of these neurotrophic factors in assisting and guiding the process of nerve and axonal regeneration, which is being tried using synthetic tubes and scaffolds for neuronal and glial cells, in nerve injuries and root avulsions.

56 General Principles of Management of Peripheral Nerve Injuries

David A Omahen, Hazem Eltahawy, Abhit Guha

INTRODUCTION

The goal of peripheral nerve injury management is to maximise functional outcome. This is dependent on a thorough clinical and neurophysiological assessment, proper surgical technique and above all sound decision-making.[16] Given time, many peripheral nerve injuries recover spontaneously, with knowledge of the anatomy, natural history and pathophysiology of peripheral nerve injuries helping to guide if and when neurosurgical intervention may be required. This chapter will endeavour to provide the clinician with a solid background in the basic management principles for peripheral nerve injuries.

ANATOMY

The neuronal axon and its surrounding Schwann cells can be viewed as the functional unit of a peripheral nerve. A collection of connective tissue, known as endoneurium, surrounds each individual nerve fibre. A nerve is composed of several fascicles, or groups of axons, surrounded by a sheath of compact connective tissue called the perineurium. This thin layer is the anatomical substrate of the "blood-nerve barrier" akin to the "blood-brain barrier", to provide a proper external environment for axonal conduction. The tensile strength of a nerve is from the mesodermal derived epineurium, which can be subdivided into the looser internal epineurium separating the individual fascicles and the stronger external epineurium which envelops the entire nerve and provides the main tensile strength. It is this external epineurium that is most often used to insert sutures during nerve grafting (Fig. 1).

Interspersed between these layers of the nerve, there are numerous longitudinally oriented blood vessels to provide a rich vascular plexus to the nerve. However, the microcirculation can be compromised to a significant extent and lead to nerve dysfunction and pain by systemic diseases such as diabetes and local therapies such as radiation. Along the course of the nerve the axonal-fascicular relationships are constantly changing, with axons switching between individual fascicles. However, as the end organs are neared, motor and sensory fascicular differentiation becomes better demarcated. Functional outcome can be maximised when appropriate fascicles are put in the correct spatial juxtaposition.[25]

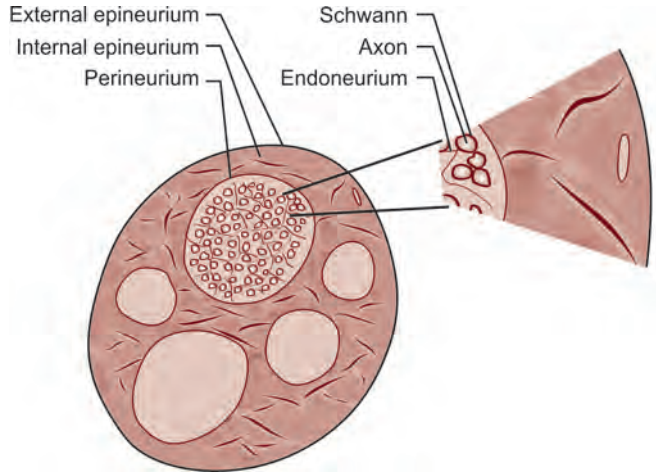

Fig. 1: The internal microarchitecture of a peripheral nerve

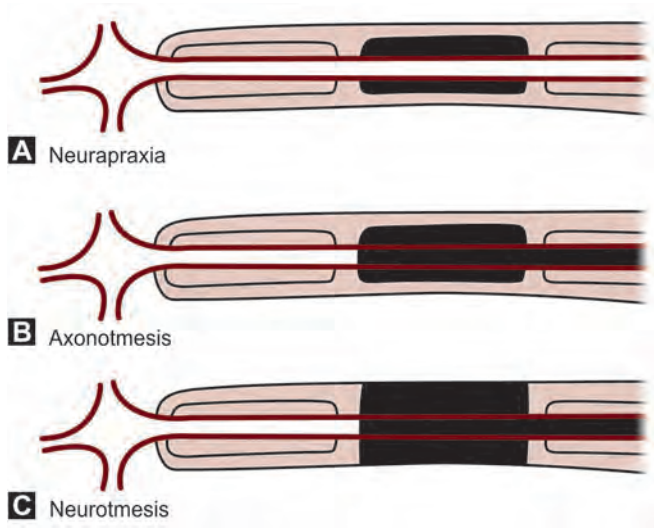
PATHOPHYSIOLOGY OF NERVE INJURY

In cases of nerve entrapment or other forms of compressive nerve injuries, early changes include endoneurial oedema secondary to impaired venous flow and breakdown of the blood-nerve barrier at the level of the perineurium.[18] Morphological studies have revealed relative sparing of smaller and unmyelinated fibres, with greater damage to large myelinated fibres.[6] This process leads to paranodal or segmental demyelination within a few days, resulting in blockage of axonal conduction.[23] This form of injury, if the nerve is caught, leads to a neuropraxic injury, not accompanied by axonal severance and usually full recovery within a few weeks, once the nerve microcirculation is stabilised with restoration of the segmental foci of demyelination.

In cases of more severe nerve injury with interruption of the axon (axonotmesis or neurotmesis), characteristic pathological changes occur.[5,25] Within 24 hours distal Wallerian degeneration begins,[2] with associated fragmentation of cellular components, breakdown of the axon and myelin sheath, and phagocytosis by invading macrophages and Schwann cells. Subsequent failure of conduction at the neuromuscular junction also occurs. Proximal to the site of injury, the process of chromatolysis[2] takes place with swelling of the cell body and clumping of chromatin.

NERVE REGENERATION

Recovery from axonotmesis or neurotmesis involves axonal regeneration.[2] First, there is a reversal in the visible changes of chromatolysis, with an increase in neuronal metabolism leading the cell body to produce axoplasm, which in turn forms the regenerating axon tips called "growth cones". Axonal outgrowth can commence as early as one day after injury and this regenerative response can continue for 12–18 months.[2] The ability of the growth cones to reach their target organs depends upon the distance they need to travel, the presence of residual endoneurial tubes to guide them, and the degree of scarring present at the site of injury. If an axon reaches the correct end target, which is approximated to be at a rate of 1 mm/day or 1 inch/month, effective though often sub-maximal reinnervation can occur up to 12–18 months post-injury.[2] During this time physiotherapy and occupational therapy are of paramount importance to maximise recovery and prevent secondary problems such as contractures. Exercise has the capacity to further improve function resulting from the reinnervation by promoting muscle-fibre hypertrophy and increased size of the motor-units or number of muscle-fibres supplied by a nerve ending by sprouting.



Figs 2A to C: The Seddon classification of peripheral nerve injury. (A) Neurapraxia refers to temporary loss of conduction along a nerve without axonal degeneration. (B) Axonotmesis involves degeneration of the axon with preservation of the surrounding supporting soft tissue sheath. Spontaneous recovery can occur since sprouting growth cones are guided to their appropriate targets along these sheaths. (C) Neurotmesis involves gross interruption of nerve continuity, and requires operative repair to restore continuity

CLASSIFICATION SYSTEMS FOR PERIPHERAL NERVE INJURY

There have been several attempts to classify peripheral nerve injury based on anatomical and clinical criteria. Broadly, nerve injuries may be classified as open or closed. Open injuries can further be subdivided into sharp (knife, glass wound, etc.) or blunt (compound fractures, gunshot wounds, etc.). Closed injuries (brachial plexus stretch injury, etc.) are often injuries in continuity, with mechanical distortion, intraneural and extraneural scarring and ischaemia all playing a role in the pathophysiology.

At a pathological-clinical level, two systems of classification have gained widespread use in clinical practise (Figs 2A to C). The first is the Seddon system,[24] which introduced the terms neurapraxia, axonotmesis and neurotmesis. Neurapraxia is a temporary dysfunction of a nerve with maintenance of anatomic continuity of the axons and connective tissue structures. It has variably been attributed to focal demyelination, haemorrhage or local metabolic or electrolyte imbalances.[25] The prognosis for complete recovery within 6 months is excellent.[29] Physical interruption of the axons with sparing of Schwann cell tubes, endoneurium, perineurium and epineurium is defined as axonotmesis. Since the fascicular structure of the connective tissue elements is still intact, axonal regeneration is possible. Schwann cells form tubules, which guide the regenerating axons to their targets. The time to recovery depends upon the site of the nerve injury. Axonal regeneration occurs at a rate of about 1 mm/day or 1 inch/month.[20,21,29] Both neuropraxic and axonotmetic injuries will eventually result in regeneration, so surgery is generally not needed. Neurotmesis refers to total nerve dysfunction secondary to complete interruption of the entire nerve. Though described later in more detail, neurapraxia may be distinguished from axonal interruption several weeks after injury with the use of electrophysiologic studies. In the setting of a closed injury, the only way to distinguish between neurotmesis and axonotmesis is to surgically explore and inspect the nerve. Figure 2 illustrates the injury patterns described in the Seddon system.

Building on the scheme put forth by Seddon, Sunderland introduced a five grade classification system.[26] Simple neurapraxia was called a Grade 1 injury. Axonotmesis (axonal interruption with an intact endoneurium) was defined as a Grade 2 injury. Neurotmesis was subdivided into three grades. Grade 3 injuries involve loss of endoneurial and axonal continuity with preservation of the perineurium. Grade 4 injuries have in addition interruption of the perineurium with preservation of epineurial integrity. Grade 5 injuries involve division of the entire nerve trunk. Other classification systems based on function, such as LSUMC grading, have merits but of limited wide-spread use.[11,12] Of course, many acute nerve injuries are a mixture of the above subtypes, a situation sometimes referred to as a grade 6 lesion.[19] They often demonstrate a biphasic recovery, with rapid resolution of neurapraxic dysfunction followed by slower or limited recovery of axons undergoing Wallerian degeneration.[24] Table 1 outlines the differences between the Seddon and the Sunderland classification systems.

Table 1: The Seddon and Sunderland classifications of nerve injury

Seddon classification	*Sunderland classification*	*Structures involved in injury*				
		Myelin	*Axon*	*Endoneurium*	*Perineurium*	*Epineurium*
Neurapraxia	1	+/–				
Axonotmesis	2	Yes	Yes	No	No	No
	3	Yes	Yes	Yes	No	No
	4	Yes	Yes	Yes	Yes	No
Neurotmesis	5	Yes	Yes	Yes	Yes	Yes
	6					
	(Mackinnon/Dellon)	Mixed pattern of injury				

PATHOGENESIS OF PERIPHERAL NERVE INJURIES

Open Injuries

Laceration Injuries

Of all the mechanisms of peripheral nerve injury, this is the one most likely to lead to transection.[12] Even with near or complete functional loss, approximately 20% of nerves are left in at least partial continuity.[12,14] Generally these injuries fall into two major categories: sharp and blunt. Sharp laceration, as caused by glass, knives or razors, is usually dealt with via exploration and primary repair if a major nerve injury is accompanied by severe loss of function. Blunt injury, such as that inflicted by chainsaws or commercial machinery, is usually dealt with in a delayed manner, as there is usually a variable and unpredictable amount of non-viable tissue proximal and distal to the site of injury. The injured nerve stumps can be sutured to nearby soft tissue planes to avoid retraction if they are identified during repair of other soft tissue injuries.[12,14] At a later time, non-viable tissue will become more clearly demarcated, allowing trimming of the stumps back to viable tissue prior to repair.[4,16]

Gunshot Wounds

With gunshot wounds, a variety of injuries can occur depending on the nature and velocity of the missile, as well as the trajectory. Even with clinical evidence of nerve injury, the incidence of transection is only 15–20%.[14,18] Progressive loss of function and pain, audible bruits or palpable thrills, or evidence of distal ischaemia may indicate a major vascular injury.[12,14] Entities such as pseudoaneurysm formation, compressive haematoma, major vessel transection or arteriovenous fistulae may necessitate acute exploration. Otherwise, serial clinical and EMG examination to document the course of any spontaneous recovery during the first 2–3 months is usually advised.

Iatrogenic Injuries

Direct injection injuries occur most commonly to the sciatic nerve at the buttock and the radial nerve in the upper arm,[12,14] and may be associated with development of chronic pain. The lesion should be explored if no evidence of improvement occurs during 3 months of serial evaluation. Intra-operative nerve action potentials (NAPs) are invaluable in deciding how to deal with such injuries. Kline et al. report poor results with repair of sciatic injection injuries involving only the peroneal division.[12,14,15,20] Intrafascicular injection seems to be associated with a greater degree of damage.[7,21] Acute repair of sharp injuries (such as scalpel-induced lacerations) is usually indicated. Blunt or traction injury is usually best dealt with in a delayed manner as described below.[12,14]

Closed Injuries

Stretch Injuries

Stretch injuries occur when traction on a nerve exceeds the elastic limit of the nerve.[17] They are often associated with spinal injury or joint dislocation. This often results in formation of a neuroma-in-continuity with a high likelihood of neurotmesis and obliteration of fascicular anatomy.[12,14] Widespread and varying injury occurs along the length of the nerve.[12,14] As with other lesions in continuity, they are best dealt with by careful longitudinal evaluation and delayed surgical intervention when indicated.

Crush Injuries

Crush injuries involve variable combinations of stretch, contusion, ischaemia and blunt transaction.[2,7] They are usually dealt with in a delayed manner, as described for stretch injuries.

Ischaemic/Compressive Injuries

With ischaemia, damage may occur not only to the nerves themselves but also to their supportive environment. Painful paresthesias followed by progressive loss of function, swelling of an extremity, skin discolouration and signs of distal peripheral vascular compromise may signal an evolving compartment syndrome which requires urgent treatment with fasciotomies.[12,14]

Electrical/Thermal Injuries

Severe scar formation and potential extensive necrotic soft tissue loss often accompany these injuries.[3,19] Graft

and/or flap reconstruction is often required. The accompanying nerve injury is usually extensive, non-focal and difficult to treat.[12,14]

CLINICAL AND ELECTROPHYSIOLOGICAL EVALUATION

Symptoms of peripheral nerve injury include pain, dysesthesias and partial or complete loss of motor and sensory function.[2,25] Evaluation involves a thorough history and physical examination, relevant radiological studies and electrodiagnostic evaluation. Answers to the following important questions should be sought out: what was the exact timing and mechanism of injury? Is there concomitant injury to bone, blood vessels or other soft tissue structures? Is the injury open or closed? If an open injury exists, is the nerve lacerated cleanly, or does a blunt injury exist? What is the extent and grade of the injury? Has there been evidence of progression or recovery? Power is tested in individual muscles or muscle groups and graded according to the MRC grading system.[10,22] Examination of sensory function involves assessment of light touch, two-point discrimination, pinprick, vibration and proprioception.[22,23] Tinel's sign refers to paresthesias elicited by regenerating axonal growth cones when tapping along the course of a nerve, and is useful in the localisation of a nerve injury.[9,24] The course of regenerating sensory axons can be mapped by progressive distal advancement of Tinel's sign. Reflex changes should also be evaluated.

Electrophysiological studies involve those undertaken serially pre-operatively to determine if and what degree of spontaneous recovery is occurring to augment the clinical examination. In an effort to identify injuries that will not require surgical intervention, an early study is performed 2 weeks post-injury followed by studies at 2–3 months. These usually include EMG, nerve conduction and specific wave forms such as the "F" wave to determine the status of the proximal spinal nerve roots and dorsal root ganglion. If both clinical and electrophysiological improvement is demonstrated, then further nerve surgery is unlikely. Neurapraxic injuries are characterised by interruption of nerve conduction across the site of injury with preserved distal conduction, without evidence of denervation on EMG evaluation. The situation is different with axonotmesis and neurotmesis. The distal axons will conduct nerve impulses for the first few days, but then cease to do so as Wallerian degeneration ensues.[2,25] After 2–3 weeks the EMG shows clear-cut signs of denervation including denervation potentials, positive waves and spontaneous activity. Differentiation between axonotmesis and neurotmesis requires delayed nerve conduction studies. In the case of axonotmetic injury, regenerating axons will cross the site of injury and grow distally. Regeneration potentials are seen as denervation potentials which decrease and usually precede clinical evidence of motor improvement.[2,25] The absence of advancing conduction on serial testing means spontaneous regeneration is unlikely to occur and a surgical solution is required. Intra-operative electrophysiological examination, comprising direct nerve stimulation, sensory evoked potentials (SEPs) and NAPs are important adjuncts to the microscopic and macroscopic status of the nerve, enabling the neurosurgeon to undertake optimal surgical decisions. Post-operative serial electrophysiological examination, which usually commences after 2–4 months after nerve surgery, are also utilised to augment the clinical follow-up for determining the extent of neural reinnervation.

RADIOLOGICAL EVALUATION

Currently, radiological examination plays little role in the management decisions for nerve injuries. However, emerging improvements in MRI neurography techniques may provide clues about peripheral nerve injuries. Experimental studies in animal models[1,25] have demonstrated the ability to non-invasively distinguish between axonotmetic and neurotmetic injuries based on changes in nerve and muscle. Correlation with histological and clinical evidence of axonal degeneration and regeneration has been good. One day this modality may reduce the need for exploratory surgery.

MANAGEMENT OF PERIPHERAL NERVE INJURIES

Sharp open nerve transections should primarily be repaired with end-to-end nerve suturing of the epineurium at the time of injury. A small amount of the cut surface may be cut to freshen up the cross-sections. Blunt open nerve injuries in which the transected nerve ends are ragged and contused is better repaired after a 3–4 week delay, allowing for a reduction in tissue oedema and more importantly scar formation at the edges of the transected segment. Scarring allows for discrimination between healthy proximal and distal nerve ends and the fibrosed nerve segments. Fibrosed segments can then be resected back to normal fascicular structure at both ends and then a repair with or without nerve grafts can be performed.[8,26]

Closed injuries often require more complex management decisions. The nerve remains in continuity in most such injuries. Stretch or compression injury causes injury of varying severity. Given enough time, spontaneous recovery occurs in 80% of closed nerve injuries.[10] The surgeon's task is early identification of the cases in which there is lack of clinical or electrophysiological recovery. Most surgeons believe that, if no signs of regeneration are seen after 3–4 months, operative intervention is the best course of action. The location of the injury is another important consideration. In proximal lesions, such as in the supraclavicular brachial plexus, waiting too long for recovery to manifest may miss the window of opportunity for useful outcome from nerve repair.[13,27] However, age is an important factor as the regenerative capacity of

infants or young adults is much more than older adults, hence, we tend to be more aggressive in this age group, even after a prolonged delay. However, in general, if recovery of useful motor function is to occur, muscles must be reinnervated within 2 years,[10,24] since after this time period denervated muscles undergo irreversible atrophy and replacement with fatty tissue. In proximal brachial plexus injuries with documented nerve root avulsion, consideration should be given to direct neurotisation. This involves providing viable motor axons from a donor nerve, whose function is redundant or less important, to a denervated distal muscle group.

Early operation is associated with the following advantages:[12,26] (1) less scarring which simplifies dissection of peripheral nerve elements; (2) direct evaluation of anatomic and electrophysiological continuity which dictates the necessity of a surgical repair and (3) earlier repair may result in better outcome with faster reinnervation of denervated muscle. Potential improvements in outcome following early surgical repair must be balanced against the risk of operating on a proportion of patients who would have recovered on their own without surgical intervention.

PRINCIPLES OF SURGICAL NERVE REPAIR

Surgical intervention for peripheral nerve injuries has two goals. The first is diagnostic, whereby one determines the site(s) of nerve injury by macroscopic, microscopic and intra-operative electrophysiological evaluation. Most often this can be predicted by the pre-operative clinical and electrophysiological evaluation, but confirmation with the exposed nerves is required. Multiple sites of injuries along the course of a nerve pathway are common, especially in stretch injuries, hence exposure of the full length of the nerve (i.e. supra-clavicular, retroclavicular and infra-clavicular brachial plexus exposure) is advised. The second surgical goal is therapeutic intervention to optimise nerve regeneration. This depends not only on the extent of the injury, but also the pre-operative goals, knowledge of what reinnervation is realistic given the patient characteristics, etc. Multiple types of interventions may be warranted depending on the specific evaluation of the nerve injury in the same patient. This may include a simple external neurolysis if physical and electrical continuity is present, excision of the neuroma in continuity and direct end-to-end repair if the gap is minimal, interpositional nerve grafts from donor sites such as the sural nerve or direct or indirect neurotisation procedures if endogenous proximal nerve fibres cannot be obtained. Basic principles of surgery include the following:

Exposure of the Healthy Nerve Proximal and Distal to the Site of Injury

A generous skin incision is based on the surface anatomy of the nerve and centred on the site of injury. Careful proximal and distal exposure of the suspected lesioned area is performed. Working towards the injury from both directions, sharp dissection is used to expose the lesion. The deep subperineurial longitudinal blood supply[12,26] to the nerve should be preserved, but most collaterals can be sacrificed to gain a full circumferential exposure of the nerve.[12,14] The lesion in continuity can then be inspected and palpated with certain operative findings helping to predict internal pathology. A hard or firm consistency suggests a greater degree of internal scarring with the degree of internal scarring almost always worse than it appears on external examination. Although, in most cases, a fusiform neuroma is seen, a lateral neuroma suggests partial nerve transection, especially in a setting of partially spared pre-operative function in the distal distribution of the nerve. The size of the neuroma is also important as swelling more than twice the diameter of the nerve is suggestive of a neurotmetic lesion rather than an axonotmesis.[12,26]

Intra-operative Electrophysiological Evaluation

Intra-operative electrophysiological evaluation includes the recording of SEPs, NAPs and electromyography (EMG) (Figs 3A and B). During patient positioning, electrodes are placed in relevant muscles as well as adjacent to relevant peripheral nerves, either superficially on the skin surface or percutaneously. If SEP recordings are used, electrodes are placed over the scalp in the parietal region and percutaneously adjacent the cervical spine. Use of regional or local anaesthetic blocks or a tourniquet is avoided along with long-acting muscle paralytics to prevent compromise of intra-operative electrophysiological testing. Direct electrical stimulation of nerves is performed using bipolar electrodes with a biphasic square wave pulse with a duration of 0.05–0.10 milliseconds. We generally start with a stimulus intensity of 0.5 mA and increase the amplitude up to 5 mA using a frequency of 1 per second. The stimulus is delivered to the nerve segment distal to the site of injury to record SEPs or proximal to the lesion to observe an EMG response, with the functional integrity of motor nerve fibres assessed by either visual observation or electromyographic documentation of muscle contraction. Alternatively, sensory conduction across the lesion in continuity can be measured through recording of SEPs. Both the velocity and amplitude of a nerve conduction response can be measured, with the velocity of the response influenced by the degree of myelination, whereas the amplitude of the response is determined by the number of conducting nerve fibres.[27,28] NAPs are very useful in aiding intra-operative decision-making, especially when evaluating a neuroma in continuity. The presence or absence of a NAP across the lesion helps to determine the need for resection of a damaged nerve segment.[27,28] As early as 6–10 weeks after injury, a recordable response across a traumatic lesion in continuity indicates the presence of at least several thousand functioning nerve fibres.[10,12,24,26,28,29] Such conducting lesions imply an axonotmetic lesion and, therefore, require no

further surgical repair because of the high probability of clinical recovery of function through regeneration. In contrast, lesions in continuity without a NAP should surgically be resected and the nerve ends approximated using grafts as indicated.

Intra-operative Microscopic Examination by Quick (Frozen) Section

Under the magnification of the surgical microscope, the centre of the neuroma is incised using an 11-blade knife and the ends are carefully inspected for fascicular patterning. The neuroma is then serially sliced distally and proximally (Fig. 4). After each slice, the fresh ends are re-examined under the microscope and the cut slice is submitted for quick pathological examination by frozen section to look for a normal fascicular pattern.

Fascicular Microsuture Technique

The nerve ends are carefully inspected under the surgical microscope to determine the fascicular topography. A useful method is to sketch diagrams of the fascicular patterns of the proximal and distal stumps. The sketches are matched and from this an approximate estimate of the corresponding fascicle groups in the proximal and distal stumps is made.[28,29] Another technique is to utilise surface vessels to aid in the correct alignment (Fig. 5) of proximal and distal stumps.[12,14] The nerve stumps are handled with fine tipped 'jeweler's forceps' to minimise trauma to nerve tissue. We use 9-0 nylon epineurial stitches to approximate the fascicles in a tension-free manner.

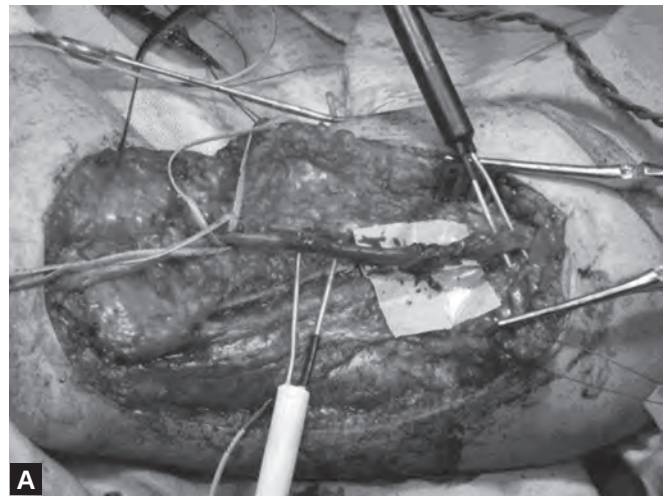
Technical Pearls

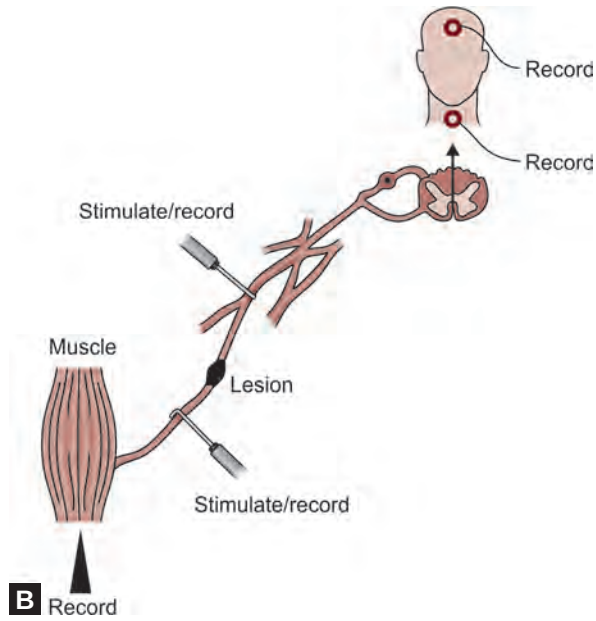
Avoidance of Tension

Tension is highly detrimental and should be avoided in nerve repair surgery.[29] If the gap between the nerve stumps is small and the two ends can be approximated without tension then a primary end-to-end repair is performed. The nerve proximal and distal to the point of injury can be mobilised to reduce the intervening nerve gap. Care should be taken to assess the maximum possible gap created when the appropriate joints are put through their full range of motion. If suturing cannot be achieved without tension, then the two ends should be approximated using interposition nerve grafts. Common donor nerves for grafting are harvested from superficial sensory nerves such as the sural nerve in the lower extremities and the medial brachial and antebrachial cutaneous nerves and superficial branch of the radial nerve in the upper extremities.[12,14] The grafts must be long enough to allow the proximal and distal ends to lie free from tension with the extremity in full extension.

Using a Minimal Number of Sutures

The aim of microsuturing is to effect full coaptation between the cross-sectional area of the nerve fascicle group and the donor graft or distal stump fascicle. If





Figs 3A and B: Intra-operative electrophysiological evaluation of a neuroma-in-continuity: (A) The presence or absence of intra-operative NAPs across a lesion-in-continuity help the surgeon decide whether excision of the lesioned nerve segment is required. In this example, a lesion-in-continuity of the right ulnar nerve has been dissected out, and NAPs are being recorded across the site of injury. (B) To assess sensory conduction, stimuli are delivered to the nerve segment distal to the injury site and SEPs are recorded over the scalp or at the level of the cervical spine. Motor conduction is assessed with stimulation proximal to the lesion to observe an EMG response in the distal musculature

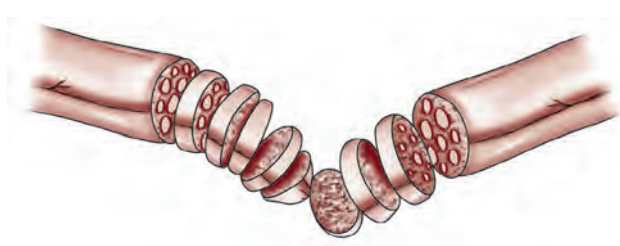


Fig. 4: Intra-operative frozen section evaluation of a neuroma-in-continuity: serial proximal and distal cross-sectional slices at the site of the neuroma-in-continuity are sent for frozen section evaluation until a normal fascicular pattern is identified

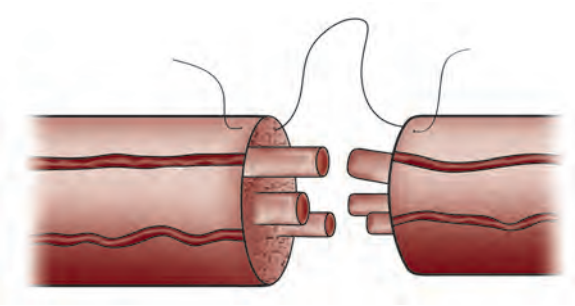

Fig. 5: Matching fascicular anatomy during nerve microsuturing: proper realignment of two segments of the cut nerve can be established by matching both the internal fascicular pattern and the superficial vascular structures

no tension is present, this can be achieved with a single suture for each fascicle group (Figs 6A to C). Fibrin glue and argon beam lasers have been used to approximate fascicles in the hope of reducing scar tissue formation. Improved functional results using these techniques have not yet been definitively demonstrated.[11,28,29]

Maximising the Number of Motor Fibres Available for Repair

Identification of motor fascicles is possible by dissecting the motor branch of the nerve up to the graft site and anastomosing into it. Histochemical methods, such as the use of choline esterase techniques, used during the intra-operative quick section of the cut nerve slices are also sometimes useful to identify the motor fascicles. However, obtaining the results can take several hours, which is usually impractical during surgery.

Matching the Graft to Recipient Nerve Fascicles

The graft should connect corresponding motor fascicles in the proximal and distal nerve stumps. Additionally, the number of grafts should be sufficient to cover the cross-sectional area of the recipient fascicles (Fig. 7).

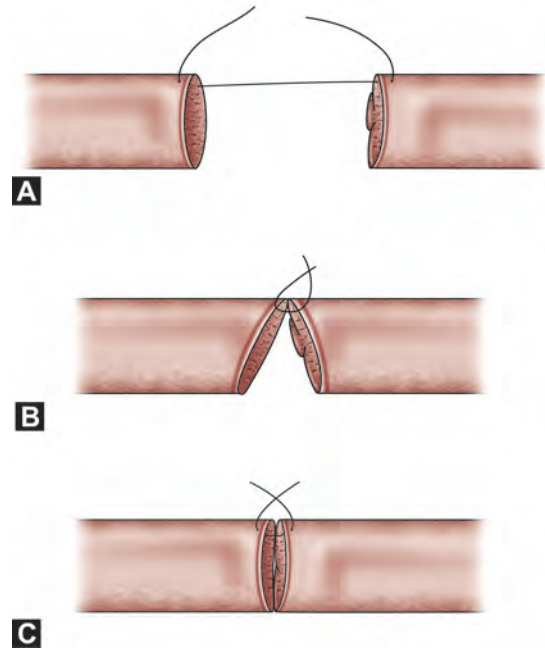
POST-OPERATIVE MANAGEMENT

Immobilisation

The extremity is immobilised in the exact position in which it was placed during the operation. We usually leave a compression bandage on for 24 hours and the limb is put in a splint for 3 weeks. After that gradual mobilisation is encouraged. An active physiotherapy program is crucial to maintain muscle bulk and prevent frozen joints.

Follow-up Electrodiagnostic Studies

Serial electrophysiological studies can be very useful in detecting early signs of muscle reinnervation several months before muscle contraction is clinically evident. The results of these studies, when positive, can provide



Figs 6A to C: Microsuture fascicular re-approximation: when a tension-free repair is performed, a single suture for each fascicular bundle is sufficient

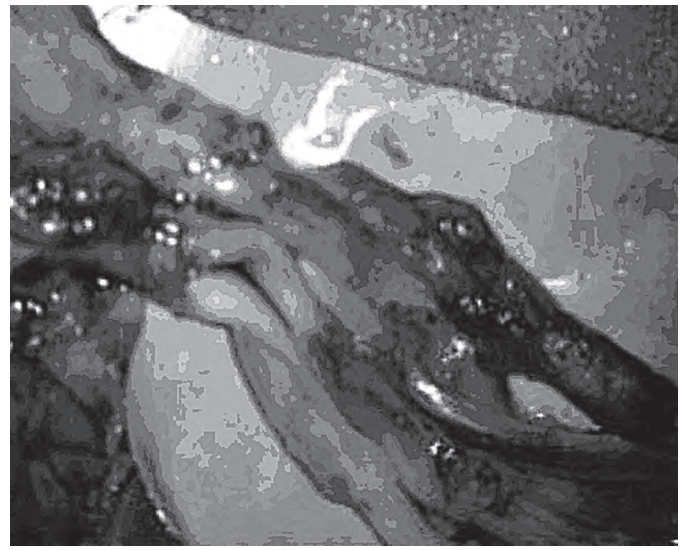


Fig. 7: Matching nerve grafts with motor fascicles: Ideally, nerve grafts should connect corresponding motor fascicles in the proximal and distal stumps. The size and number of grafts should be sufficient to cover the entire cross-sectional area of the fascicles being grafted. In this example, several sural nerve cable grafts were required to repair a common peroneal nerve injury

hope to the patient and can also be helpful in predicting clinical outcome. Nerve conduction studies will hopefully show an advancing conduction response across the graft or repair site. Realistic expectations should be given to the patient regarding the time for regeneration, which can take many months depending on the distance

that needs to be travelled by the regenerating axons at the rate of 1 mm/day.

Prognosis and Reasons for Failure

Many factors influence the quality of nerve regeneration. Advanced age and a long interval between the injury and doing the repair are unfavourable factors.[28,29] Other causes of poor results include delayed wound healing, infection and presence of scar tissue crossing the nerve graft site. Scarring at the repair site may be due to rupture of one of the suture anastomoses or due to scarring at the distal site of the graft. This is characterised by a failure of the advancing Tinel's sign or nerve conduction response to cross the distal anastomosis site after successfully progressing along the graft. If this persists for more than 2–3 months, then reoperation is indicated for the resection of 'distal coaptation scar'.

57 Surgical Anatomy and Management of Brachial Plexus Injuries

Venkataswami R, Purushothaman V

INTRODUCTION

One of the most challenging problems in neurotrauma is the management of brachial plexus injuries. With the advent of microneural surgery and the better understanding of nerve grafting under the microscope, the results have improved, thanks to pioneers like Narakas, Seddon, Millesi, Mackinnon, Julia Terzis, Gu, Chang, Oberlin, Bertelli and Mehta (who pioneered brachial plexus surgery in India). The difficulties in locating the level of the lesion, various pathologies existing in the same individual, the prolonged operative sessions and above all the unpredictable results due to several variables, add to the challenges.

SURGICAL ANATOMY

It is very essential to know the detailed anatomy of the brachial plexus (Fig. 1).[6]

The brachial plexus is constituted by the ventral rami of C5 to T1 nerve roots. They can have a contribution either from C4 wherein it is called prefixed or contribution from T2 when it is called post-fixed. As the roots emerge from the intervertebral foramina, they lie on the scalenus medius muscle behind the scalenus anterior. In a large percentage of brachial plexus injuries, there is tremendous scarring involving these muscles. This is as a result of the injury to the area. It becomes very difficult to locate the roots, unless the scarred muscles are released by multiple cuts along their lateral border. The phrenic nerve travelling on the surface of the scalenus anterior must be identified, dissected and neurolised, if necessary and kept out of harm's way, while dividing the scarred muscles. The phrenic nerve, when traced upwards, leads to the C4 root and, sometimes, this will be an important guide to locate the C5 and proceed downwards.

The roots and trunks lie in the posterior triangle, the divisions lying behind the clavicle, the cords behind the pectoralis major and the nerves below the pectoralis minor. This is the tentative arrangement. In avulsions and severe traction injuries, the whole plexus may migrate downwards and this has to be kept in mind while dissecting to identify the various structures. The C8 and T1 lie on the first rib in close relation with the subclavian vessels. While dissecting them from the scar, one has to be very careful to identify and keep the vessels away.

The suprascapular, axillary and musculocutaneous nerves are important as they control shoulder and elbow function. Most of the nerve crossings involve these branches. The suprascapular nerve is the first branch from the upper trunk. The axillary nerve is the smaller of the two main divisions of the posterior cord. The other one is the large radial nerve. The musculocutaneous nerve is the lateral branch from the lateral cord.

From the clinical examination and functional point of view, the C5 and C6 roots are for shoulder and elbow functions and C8 and T1 for hand and forearm functions. C7 contributes to shoulder, elbow and hand functions. In other words, C7 has considerable cross-innervations with C5, C6 and C8. Because of this cross-innervation, no single muscle is innervated by C7 alone. Therefore, C7 transection will cause minimal muscle dysfunction which is compensated very quickly.

CLASSIFICATIONS

A classification is necessary to evaluate and plan the line of management. The pathological classification of Sunderland [15] into various degrees is well-known. Third and fourth degree injuries have to be differentiated carefully on exploration. When the fascicular pattern is preserved only neurolysis is required, otherwise, resection and grafting will be required.

It can be classified on functional and clinical basis under various headings:

Anatomical

- Upper plexus
- Lower plexus
- Total

All this can be either complete or incomplete.

Depending on the nature of violence, it can be compression, traction, division, rupture or avulsion.

Division is usually seen in direct penetrating injury like stab or gunshot injuries. Based on the level of lesion in relation to the clavicle, they can be supraclavicular or infraclavicular lesions. Infraclavicular lesions can be associated with vessel injury and skeletal injuries, including fractures of the humerus and scapula (Figs 2A and B). In relation to the sensory ganglion in the dorsal rami, it can be pre-ganglionic or post-ganglionic. The pathological classification of Sunderland helps in

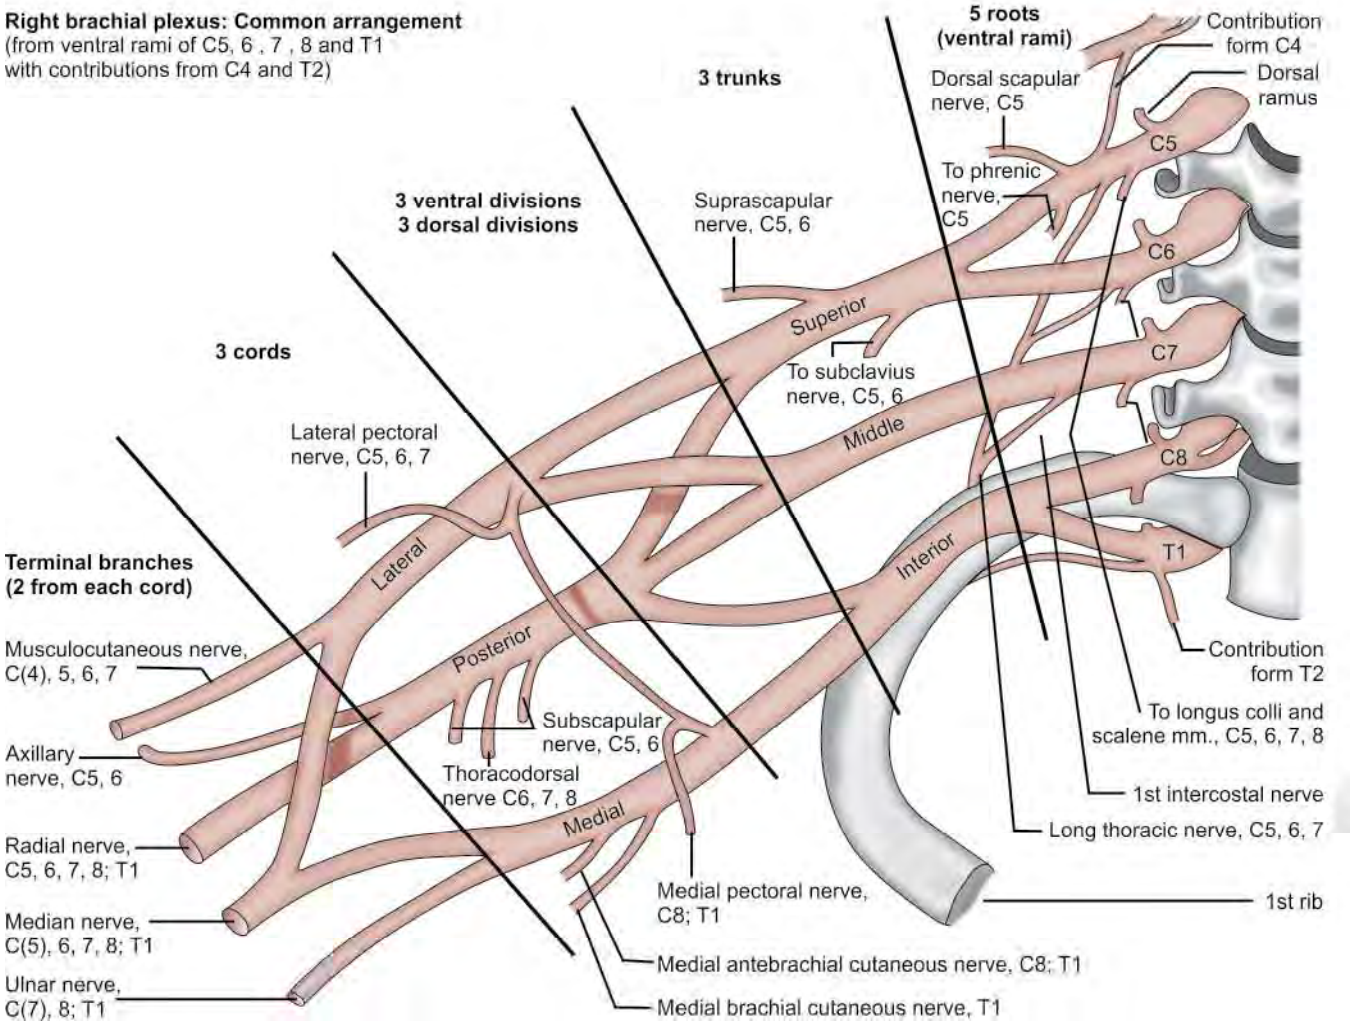

Fig. 1: Normal arrangement of right brachial plexus

Fig. 2A: Left lower plexus palsy

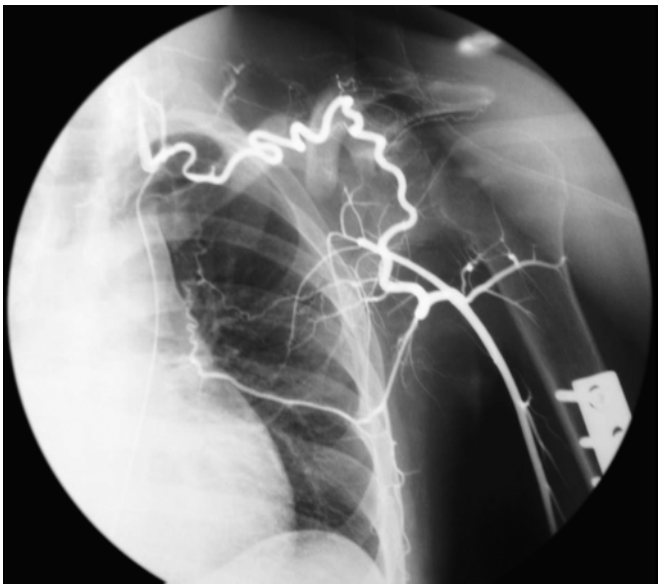

Fig. 2B: Same patient with fracture clavicle with subclavian artery injury with well formed collateral

deciding on the type of repair required in each instance. It is interesting to note that all the types can exist in a single patient. This makes the diagnosis of locating the level of lesion more difficult. It also adds to the problem of choosing the line of management.

CLINICAL EXAMINATION

In spite of the availability of a spate of sophisticated invasive and non-invasive investigations, a systematic clinical examination is the sheet anchor in the diagnosis of brachial plexus injuries. Routine examination of motor and sensory functions in the territory of the brachial plexus is essential. A chart of this nature (Fig. 3A) will help immensely. At a glance, you can find out each muscle and its corresponding roots.

One should be familiar with areas of absolute sensory loss and their corresponding roots. This will help in sharpening the clinical localisation of the lesion. Absence of sensation over the palmar aspect of the index and little fingers indicate lesions of the median and ulnar nerve, respectively. Anaesthesia in the dorsum of the metacarpophalangeal joint of the thumb indicates a radial nerve lesion (Fig. 3B).

It is essential to differentiate a pre-ganglionic from a post-ganglionic lesion. Horner's syndrome (Fig. 4) is characteristic of root avulsion of C8 and T1. Diaphragmatic paralysis is seen in a C4 lesion. Tinel's

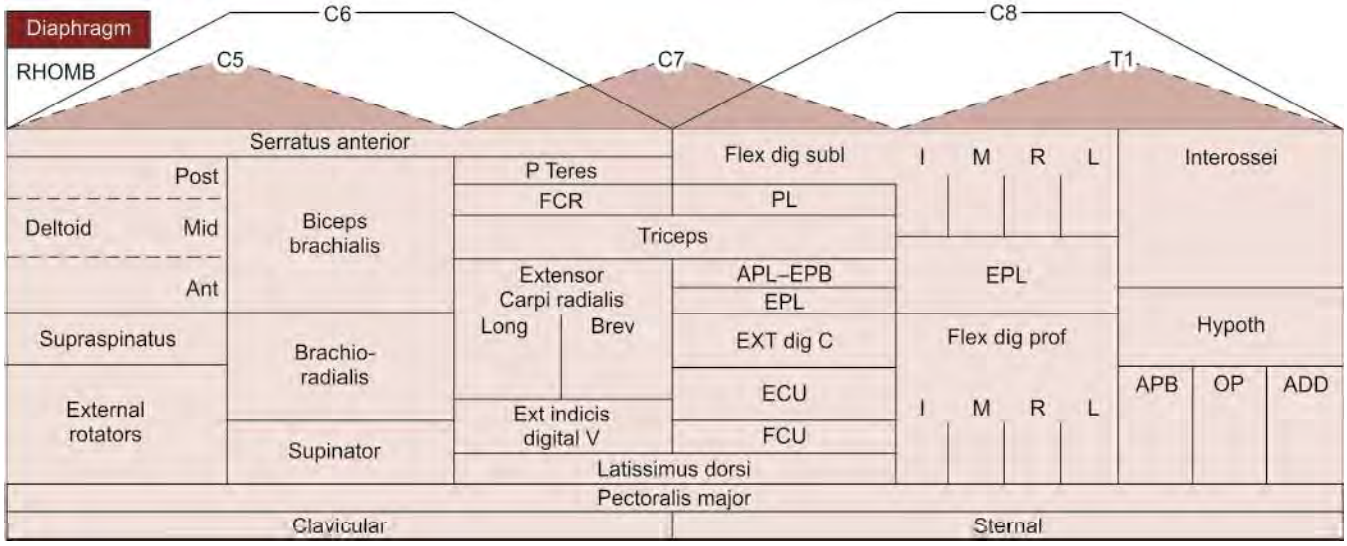

Fig. 3A: Muscle chart

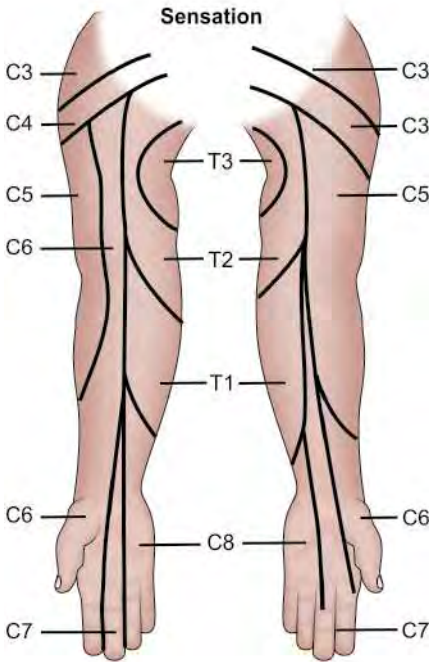

Fig. 3B: Sensory chart

Fig. 4: Left Horner's sign in a case of birth palsy

sign is absent in pre-ganglionic lesions. The presence of Tinel's sign is quite useful, as it indicates that some roots are regenerating and it is a post-ganglionic lesion. The paravertebral muscles are paralysed in pre-ganglionic lesions. A classical example is winging of the scapula (Fig. 5). Paravertebral anaesthesia and sweating in the anaesthetic area are pathognomonic of a pre-ganglionic lesion. Sensory nerve action potential (SNAP) is positive in the anaesthetic areas and there will be a positive axonal reflex. Somato sensory evoked potential (SSEP) will be absent.

The roots can be damaged at five possible sites:

- Immediately proximal to the trunks. In this case the serratus anterior and rhomboids may be intact.
- Proximal to white rami communicans—C8. Horner's syndrome will be present.
- Proximal to grey rami communicans. Sweating in anaesthetic areas will be seen.
- Proximal to dorsal root—Paravertebral muscles are paralysed.
- Proximal to posterior root. Here axonal reflex will be present.

The presence of deep pressure pain is an indication of continuity of that nerve and its roots. This is performed by applying full pinch pressure across the patient's finger tip at the base of the nail. Then, with the pressure maintained, the patient's finger is pulled sharply out from between the examiner's thumb and index finger. This is painful in a normal finger and the pain is carried by the smallest sensory fibres in the nerve. In an apparently anaesthetic finger, if any burning sensation is appreciated in the limb after this manoeuvre, there must be some continuity of the nerve supplying the finger (Thumb tip—C6, tip of middle finger C7, tip of little finger C8). These small fibres seem to be the least affected by compression of a nerve trunk following injury and swelling and they continue to function when all other nerve fibres have stopped functioning. This finding does not help in any way in assessing the value of the intact nerve root. In summary, although clinical examination can easily identify unambiguous physical signs, interpretation may be difficult when multiple lesions are present that involve the various roots or when an extensive lesion leaves a few informative findings.

DIAGNOSTIC STUDIES

They can be broadly classified into imaging studies and neurophysiological investigations. The understanding of the accuracy and reliability is crucial in planning the treatment.

Imaging Studies

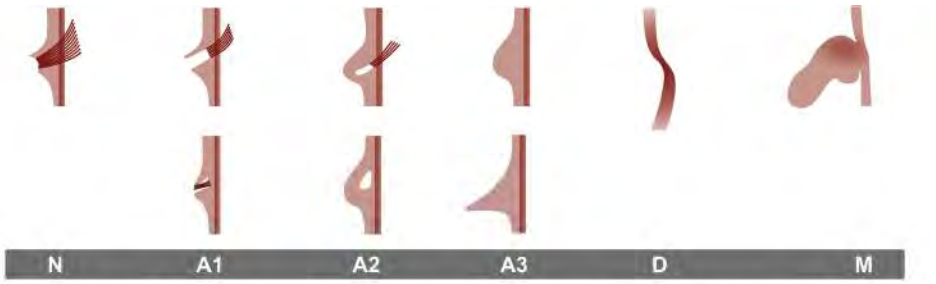
Plain radiographs of the cervical region, upper chest and upper arm are essential. Fracture of the transverse process of the cervical spine strongly indicates avulsion of the roots at C4, C5 and C6 levels from the spinal cord, as these roots are intimately related to the transverse processes. C7, C8 and T1 roots are not attached well to the transverse processes. One should suspect damage to C8 and T1 roots and, the subclavian vessels when there is an associated fracture of the first rib and clavicle. X-ray chest is essential. Elevation of the diaphragm indicates damage to the phrenic nerve (Fig. 6).

CT myelography is sensitive in identifying small meningocoeles at the site of root avulsion. Water soluble contrast material is very useful, according to some authors, in assessing the damage to nerve roots. Nagano et al.[11] have done detailed analysis on the role of myelography. Normal rootlets are shown as thin linear filling defects that arise from the cord and converge as they enter the nerve root sheath. The origin of the roots is seen as fine streaks. They cause the filling defect in a normal myelogram.

They have classified the picture into six types including the normal (N, A1, A2, A3, D and M) (Fig. 7). It varies from a slight irregularity to a full fledged meningocoele. By definition, N is a normal shadow; A1 is a

Fig. 5: Winging of the scapula

Fig. 6: Elevation of the left dome of the diaphragm



N: Normal, A1: slightly abnormal root sleeve shadow, A2: obliteration of the root tip of the root sleeve with shadow of root or rootlets showing, A3: obliteration of the tip of the root sleeve with no root and rootlets shadow visible, D: defect instead of root sleeve shadow, M: traumatic meningocoele

Fig. 7: Classification of myelographic findings

slightly abnormal root sleeve shadow in which shadows of roots and rootlets can be recognised but appear different from those on the unaffected side; A2 is obliteration of the tip of the root sleeve with the shadows of roots or rootlets visible; A3 is obliteration of the tip of the root sleeve with no shadows of roots or rootlets visible; D is a defect instead of a root sleeve shadow; and M is a traumatic meningocoele. They claim 96% correct diagnosis with this method. Four percent false positive and 12% false negative have been reported by others. Yet, it is an important adjuvant in the diagnosis of pre-ganglionic lesions.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has advanced considerably and plays an increasing role in peripheral nerve pathology diagnosis and treatment. MRI is helpful in identifying root avulsion. A good MRI can show an intact root, a pseudomeningocoele, the continuity of the plexus, the scarring in the scalene muscles, etc. Being non-invasive, MRI has literally taken the place of CT myelogram. The recent 3 T MRI is even more valuable in assessing the integrity of the brachial plexus (Figs 8 to 10).

Neurophysiological Examination

In recent years, neurophysiological examination has been used in locating the level of the lesion in brachial plexus injuries, but it has its own limitations and clearly defined areas.

Electromyography

Electromyography (EMG) is not useful in the first 10–14 days, when axonal degeneration changes do not appear, but the presence of voluntary motor unit action potentials excludes complete transaction of a nerve root. Absence of signs of denervation in a paralysed muscle after 2–3 weeks indicates a neuropraxic lesion. Paraspinal EMG can differentiate pre-ganglionic and post-ganglionic lesions.

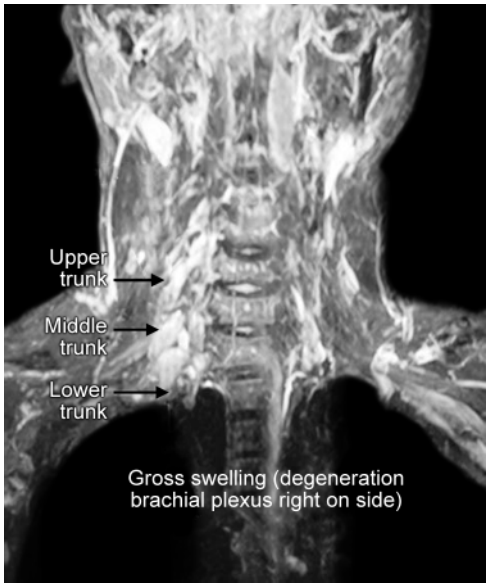


Fig. 8: MRI showing right brachial plexus and its derangement

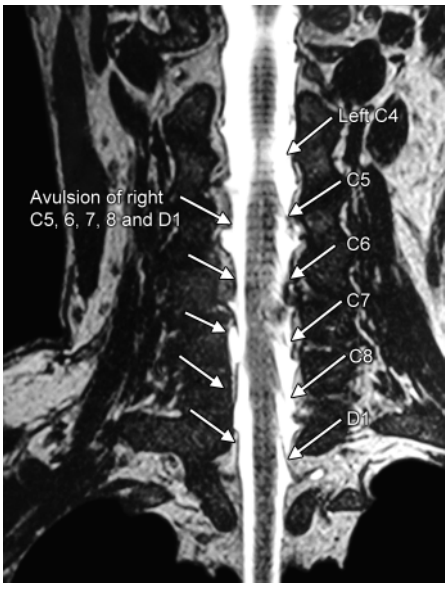

Fig. 9: MRI showing root avulsion on the right side

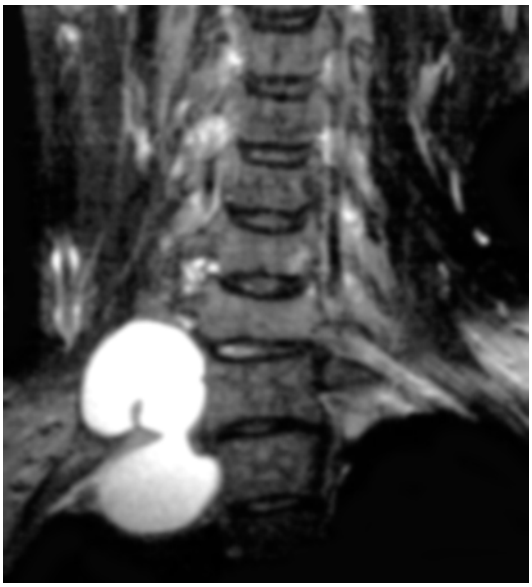

Fig. 10: Pseudomeningocoele C8, T1

Sensory Nerve Action Potentials

The cell bodies of the sensory axons are located in the dorsal root ganglion. When the lesion is proximal to the dorsal root ganglion, the peripheral sensory axons retain continuity with their cell bodies and do not undergo Wallerian degeneration. Therefore, demonstration of SNAP in nerves whose cutaneous territories are anaesthetic is evidence of a pre-ganglionic lesion.

SNAP can be elicited in the superficial radial (C6), median and ulnar nerves (C6, 7, 8). C5 cannot be studied, as it has no significant representation in these peripheral nerves. In this situation, histamine test of the axonal reflex may be useful in examining the C5 root. In a combined pre-ganglionic and post-ganglionic lesion, SNAP is not reliable.

Somatosensory Evoked Potentials

SSEP is essentially an intra-operative test to establish the continuity of the root with the cord and to the brain in cases of post-ganglionic lesions where the root stumps are seen in the region of the intervertebral foramen. In essence, absent SSEP means root avulsion.

In summary, all the investigations narrated above have their specific roles in coming to a conclusion. All of them have to be correlated with the clinical findings. Tinel's sign indicates a post-ganglionic lesion, but it cannot rule out root avulsion in another root. Operative exploration is imperative to establish the diagnosis and to decide on the further course of management.

MANAGEMENT

When to intervene surgically is the most debatable point. Whether we operate or not, from day one the following have to be ensured:

- Mobilise all the joints
- Splint the shoulder in abduction
- Electrical stimulation of the muscles to keep up the nutrition.

Electrical stimulation is advised in all patients even while they are at home. In the pre-operative period, all groups of muscles are targeted, whereas in the post-operative period, only the repaired nerves and their target muscles are stimulated. Stimulation of the repaired nerves and target muscles is done with a frequency of 2 Hz, pulse width of 200 microseconds and output current of 5–10 mA. This is done twice daily for 15 minutes per nerve muscle unit.

There are two schools which have divergent views. Nagano et al.[12] in a series of 50 cases came to the conclusion that all post-ganglionic lesions should be treated conservatively with the expectation of spontaneous recovery leaving behind ultimately some residual defects. In their study of these cases, they had 44% useful recovery in total paralysis, 38% recovery in upper plexus lesions and 18% did not show any recovery. After a period of 15–18 months, further reconstructions are advocated.

The other school, which forms the majority all over the world, is in favour of early exploration and nerve reconstruction. In early exploration, some are in favour of operating on day one or after 3–4 weeks; the period required for neuropraxia lesions to recover. Some wait for 3–4 months.

All agree that surgical intervention is necessary, if the lesions are pre-ganglionic. During the last 15 years, a policy has evolved from a conservative approach to a more aggressive approach. Nowadays, surgeons prefer to operate, if the patient has no signs of any recovery in 4–6 weeks time—the time for the neuropraxic lesion to recover. In direct injury to the plexus as in stab injury or gunshot injury early elective exploration is ideal.

Early exploration has many advantages. It is easy to dissect. Diagnosis of various lesions is made early. Before the muscles start wasting, one must pave the way for their re-innervation. Immediately after the accident, other major associated injuries take precedence. If the general condition is good, early exploration can be done.

If and when the patient shows signs of recovery, the patient is watched carefully over the coming weeks and months. Both in these cases and following nerve reconstruction, the limb is splinted in such a way that the muscles are not overstretched and at the same time permit mobilisation of all joints. When the improvement comes to a halt, the residual deficits have to be made good by suitable muscle and tendon reconstruction.

Surgical Exploration

The aim of exploration is to do a nerve reconstitution which may be by decompression, neurolysis, direct repair, nerve grafting, nerve crossing or direct neurotisation.

Techniques

The classical incision as shown in Figure 11 aims to expose the entire posterior triangle of the neck. If extension is needed, it is extended into the axilla and arm as shown. Tumescence solution is used to have a bloodless field. (Tumescence solution contains 500 ml of Ringer lactate with 1 vial of hylase with 20 ml of sodium bicarbonate and 1 ampoule of adrenaline without xylocaine).

After raising the skin and platysma as a flap, the fibro-fatty layer is reflected based laterally. This layer is incised along the sternomastoid and elevated by sharp dissection.

Once it is raised anteriorly, with dry gauze dissection, this fatty layer can be elevated as a superolateral based flap and this vascular layer can be placed on the scarred bed for the nerve grafting or crossing. Sometimes, one is amazed to see the severe scarring surrounding the plexus. In such instances, it is better to dissect the unaffected plexus distally or more proximally and proceed towards the scar. The scalenes form an important landmark as the plexus emerges in between them, but in some cases they too are badly scarred and the roots cannot be located. In such a situation, it is better to identify the phrenic nerve on the sclaneus anterior and start dissecting upwards. If the nerve is ensheathed in the scar, it has to be carefully neurolysed. On following this proximally, one reaches the C4 roots. The other method to identify C4 is to follow the supraclavicular sensory nerves. Once the C4 is identified, one can come down separating the scalenes, to locate the nerve roots. If the scalenus anterior is badly scarred, it has to be resected carefully avoiding injury to the phrenic nerve and the roots. The roots tend to bulge out after resection of the scarred muscles.

While dissecting C8 and T1, one should positively identify the subclavian artery and keep it out of the field of dissection. If the T1 is badly tethered, it is better not to continue but instead choose the other option of going down to locate its branches. When dissecting on the left side, one has to be careful about the thoracic duct. In case it is divided or damaged, the cut ends are identified and ligated with non-absorbable sutures.

Division of the clavicle is a debatable point. In an occasional case, where the scarring extends down to the cords and their branches, the clavicle may be divided. This increases the exposure and helps in dissection of the major vessels from the plexus. Division of the clavicle does not cause any morbidity or disability. Actually, in a case of a compression neuropathy following a fracture clavicle, the patient (Figs 12A to D) had a large callus pressing on the nerves causing progressive paralysis. Exploration and complete excision of the fracture clavicle and neurolysis resulted in complete recovery of all the nerves and he did not have any disability in movements of the upper limb due to removal of the whole clavicle.

Various possible scenarios might present themselves. There may be division, avulsion, traction or loss of segments of the various constituents of the plexus. As mentioned earlier, combination of a variety of lesions may exist. The aim is nerve reconstruction, which may be by direct repair, neurolysis, nerve grafting or nerve crossing.

Direct Nerve Repair

It is not indicated commonly. Only in sharp penetrating injuries it is possible, especially when the exploration is immediately after injury. It will be a rewarding experience as the recovery is good. Figures 13A to C show an example of direct repair done for a C 5–6 injury after excising the neuroma. But, even here, by the time the axons reach the hand, the muscles are wasted. When the gap is not suitable for direct repair, interfascicular nerve grafting is the procedure of choice.

Neurolysis

It is indicated in the presence of scarring involving the plexus. It is common in compression and traction lesions.

Fig. 11: Classical incision

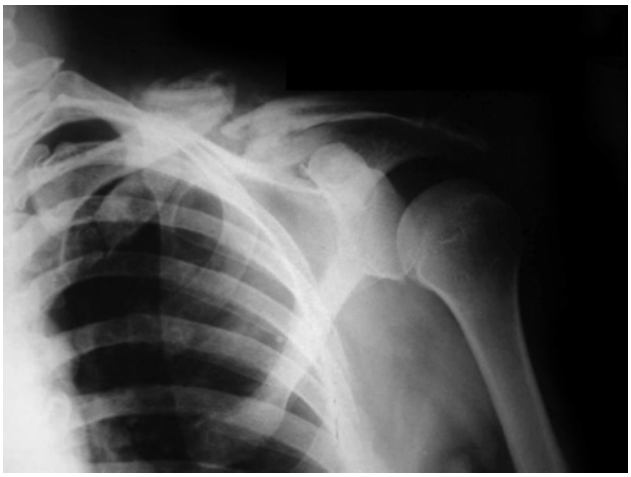

Fig. 12A: Fracture clavicle with a large callus pressing on the plexus

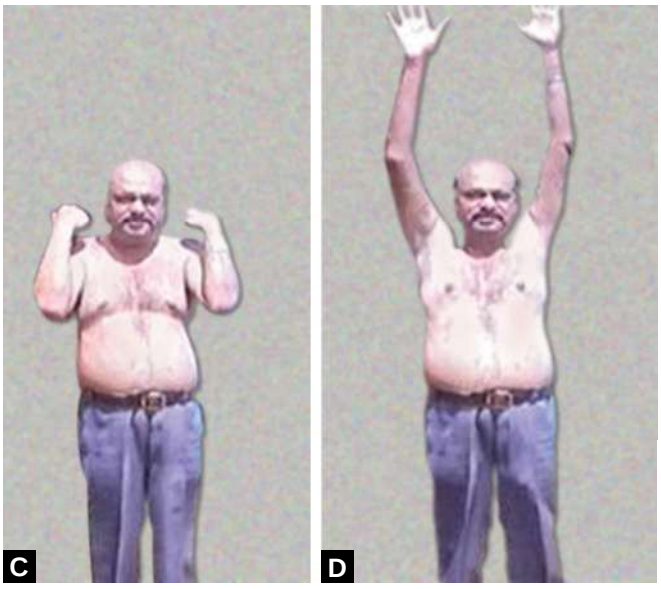
Fig. 12B: Upper plexus paralysis



Figs 12C and D: Complete recovery

This scarring is classified into three types.

Type A: Scarring outside the plexus
Type B: Interfascicular scarring
Type C: Scarring involving the perineurium and endoneurium.

Neurolysis is done under magnification. If the fascicular pattern is preserved, simple neurolysis will suffice (Fig. 14). Otherwise, resection of the affected segment and nerve grafting will be necessary.

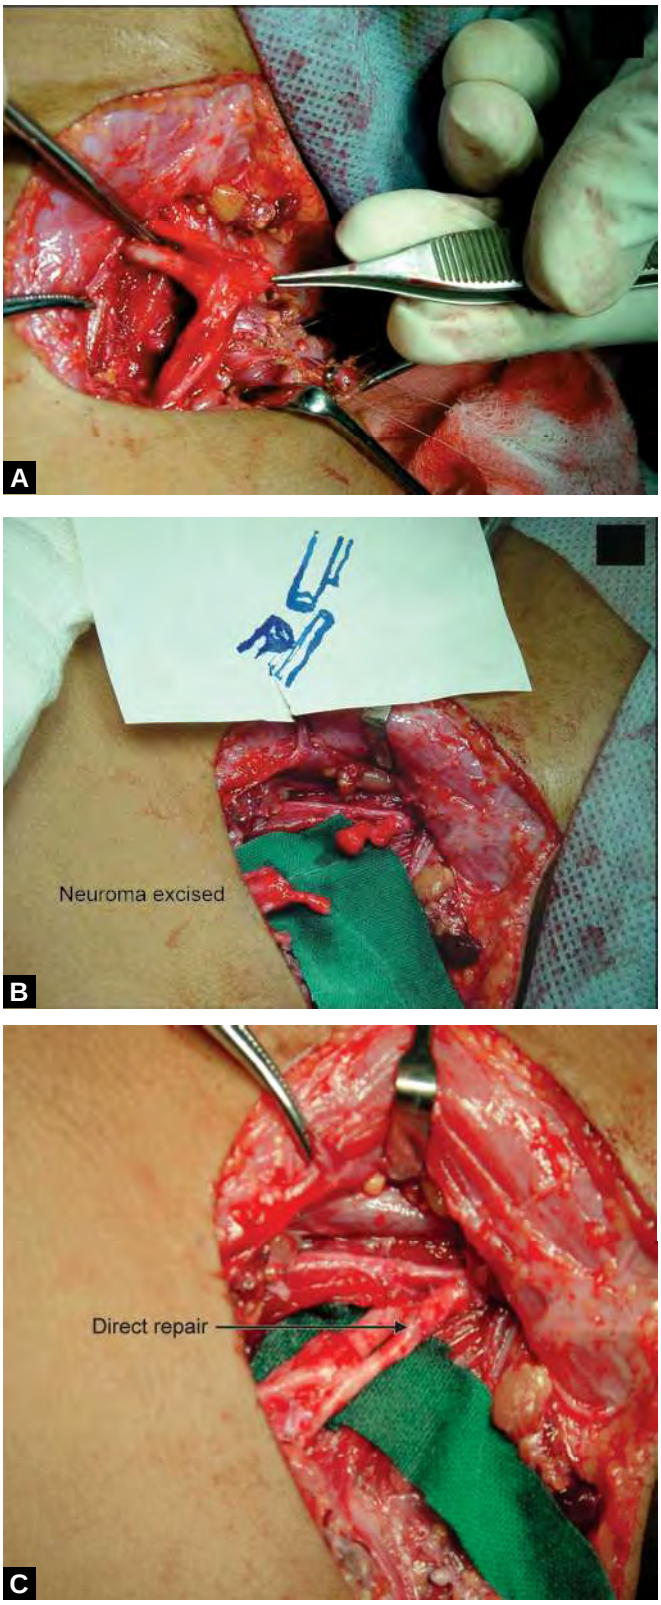
Nerve Grafting

In cases of post-ganglionic rupture and in 4th degree damage, it is essential to resect the scarred areas and connect the cut ends with a nerve graft. If the rupture is just outside the intervertebral foramina, one has to assess the viability of the proximal roots. Root cross-section should show the fascicles, and positive SSEP and muscle contraction on stimulation of proximal motor branches confirm the viability.

It is well known that shorter grafts give better results. When the gap is more than 7–8 cm, it is better to connect the roots to the selected individual nerves rather than to the main roots, trunks, divisions or the cords. This will obviate the wastage of axons to the important branches. This concept of targeting the individual nerves is gaining ground in several centres across the globe in severe traction and avulsion injuries.

As discussed earlier, restoration of shoulder and elbow functions are more important. Hence, the suprascapular nerve, axillary nerve and musculocutaneous nerve are connected to the appropriate roots with grafts. The median nerve can be connected for sensory re-innervation of the hand.

It is always better to spread the grafts, so that there is space between them. This will facilitate vascularisation. It is better to abduct the shoulder before laying the grafts so that there is no tension at the site of coaptation after surgery.



Figs 13A to C: (A and B) C5, 6 neuroma excised. (C) Primary repair

The vascular fatty layer elevated during exposure is useful for giving a scar free bed to the graft. It provides both vascular supply and a good bed for the nerves to glide.

In penetrating injuries, one should anticipate injury to nearby major vessels.

A young man (Figs 15A to D) had a penetrating injury dividing the C5 and C6. He came 10 days after the injury and exploration was undertaken. There was a haematoma under the fat—fascial flap. When this was sucked out, there was a gush of fresh blood from behind the clavicle. There was a rent in the subclavian vein junction with the internal jugular. This had to be repaired. The 10-day interval made it impossible for a direct repair and nerve grafting had to be done.

Nerve Crossing

In pre-ganglionic and in severe post-ganglionic root avulsions where the proximal nerve is not available, the only option is to neurotise the distal nerves. It is not possible to get donor nerves to neurotise the entire brachial plexus if there is total avulsion. The aim should be to restore shoulder, elbow and hand functions by neurotising the suprascapular, axillary, musculocutaneous, nerve to triceps and median nerve, utilising nearby healthy nerves. The motor branches of the deep cervical plexus (C4) have a good number of myelinated fibres. The branches to the levator and rhomboid can also be used.

There are several donor nerves available. It is better to have nerves that have more number of myelinated fibres. The spinal accessory, phrenic, muscular branch of C4, ipsilateral C7 and intercostals are the commonly used donor nerves. If the nerve can be transferred directly without a graft in between, two suture lines can be avoided and the results are better.

Once it is ascertained that the nerve lesion is severe and spontaneous recovery is next to impossible, one must decide quickly to restore nerve continuity, because nerve regeneration is a race against time. Every nerve repair is a nerve crossing, unless otherwise proved. Only the connective tissue can be joined and the growing axons have to find their own way. Predictable good results can be achieved by nerve crossing, wherever possible, in nerve reconstruction. Nerve crossing is like nerve rerouting or nerve bypass. Nerves destined to do certain functions are diverted to do some other function. This is not a new concept, way back in 1913 itself, Tuttle[17] has done multiple nerve crossings both intraplexal and extraplexal.

Shoulder stability and abduction is essential to provide greater range of motion for the arm and forearm. Shoulder abduction is a very complex mechanism, requiring synchronous movements of the scapula and humerus. There are several muscles involved. The scapula thoracic group to move the scapula forward, the depressors to keep the humeral head in the glenoid and finally the abductors to abduct. It is impossible to get them all back. In practice, the supraspinatus and deltoid can achieve 80–150 degrees of abduction. Next is elbow function; the biceps to flex and the triceps to extend. Finally, the hand function will recover.

One has to follow certain rules in nerve crossing. First and foremost is the timing of surgery. When can

Fig. 14: C5, 6 palsy—after neurolysis complete recovery

Fig. 15A: 10 days old stab injury with C5, C6, C7 palsy

you do this? How far you can stretch the time limit? It is well known the earlier it is done the better, but sometimes the patient comes after about 6–8 months resulting in a dilemma, whether to do a nerve reconstruction or not. If the nerve has to grow only 4–6 cm, then nerve reconstruction can be done even after 1 year.

The ideal donor nerve must have synergistic function, it must be from a nearby cortical representation and it must have adequate quantity of neurons. It is better to avoid nerves like the phrenic, intercostals and the hypoglossal. Finally, it must be dispensable either partially or totally. Shoulder elevation is synergistic with shoulder abduction. So, one can use nerves supplying shoulder elevation for shoulder abductors.

One of the most important factors for success in nerve crossing is the neuronal quantum. It must have adequate axons to achieve good functions. The density of the axons of each nerve has been worked out and it is mandatory that at least 30% of axonal density is recruited to achieve good results.

The neuronal density of some of the common donor nerves:

Spinal accessory – 1700,
Phrenic – 800,
Intercostal – 1300,
C4 – motor branches (4) – 3400 – 4000,
C7 – 16,000 – 40,000.

Nerve crossing is always better, if it is done more peripherally, because the recovery can be quick. Sensory motor mismatching can be avoided, co-contractions can

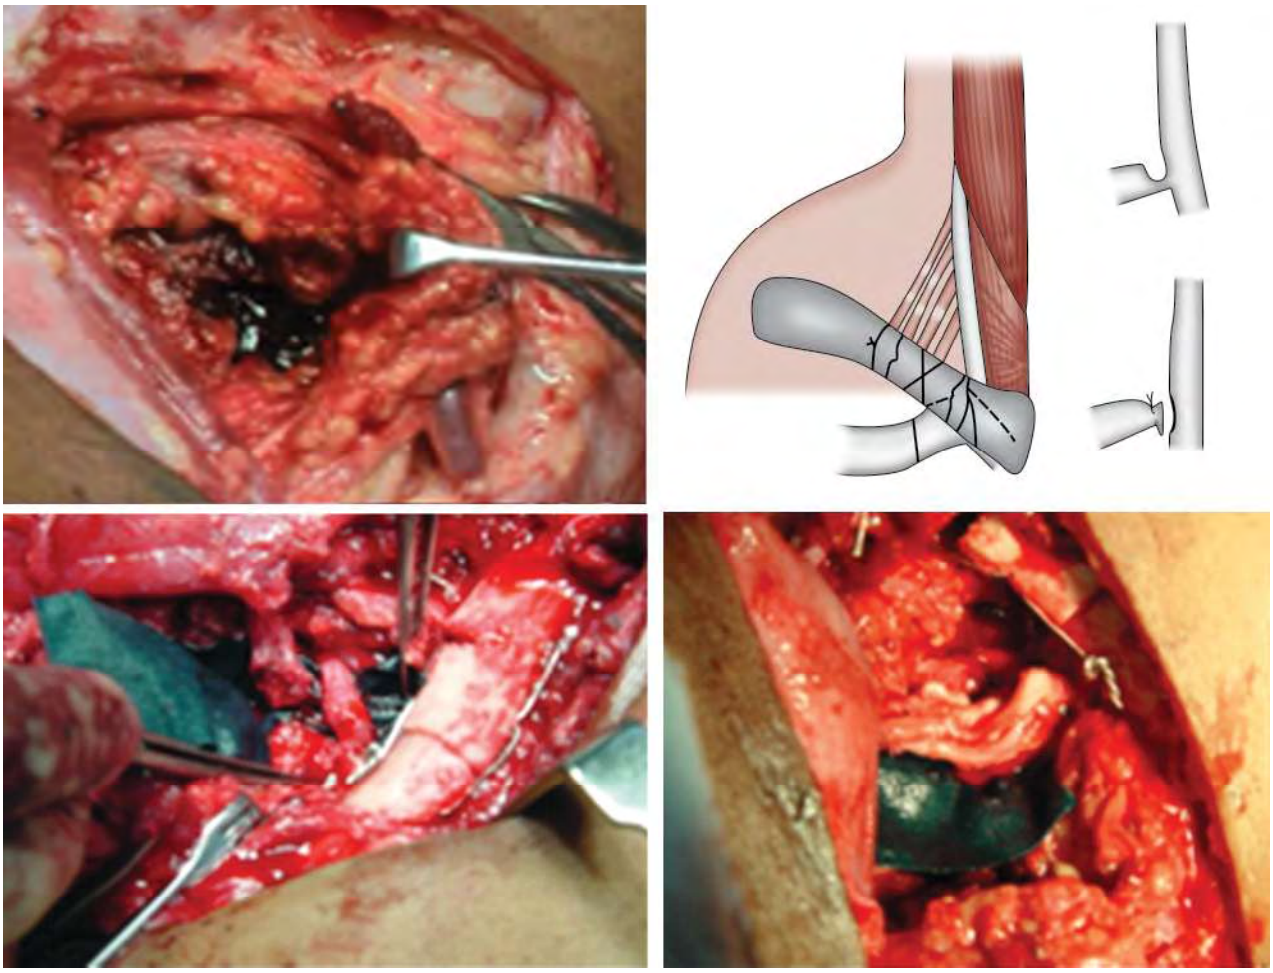


Fig. 15B: On exploration after haematoma evacuation a rent in the subclavian-jugular junction, repaired and nerve grafting done

Figs 15C and D: One year follow-up. (C) Shoulder. (D) Elbow recovering

be avoided and double level lesions can be skipped which are common in the suprascapular and axillary nerves.

Ideal recipient nerves are pure motor nerves like the suprascapular, nerve to biceps, nerve to brachialis, nerves to triceps, anterior and posterior interosseus nerves and the axillary nerve, where the sensory branch can be isolated and left behind. These nerves are dissected close to the hilum. They must supply a single muscle, but if they supply multiple muscles, all of them must have a synergistic function. Nerve crossing can be done for sensory nerves also.

Spinal accessory to suprascapular: The spinal accessory nerve supplies the trapezius and this is synergistic with the shoulder abductors and, being in the same territory, it is easy to dissect and transfer without the need for a nerve graft. Since both are pure motor nerves having a similar density of axons, the results are predictable (Fig. 16).

The spinal accessory can be located one finger breadth above the emergence point of the great auricular nerve. Stimulation of the nerve confirms it. This is dissected and followed to the trapezius. The branches to the sternomastoid and the first branch to the trapezius can be spared and the remaining two terminal branches can be taken and divided. These are taken to the suprascapular nerve. The great advantage of the spinal accessory is that it is a pure motor nerve and all its fibres are useful in re-innervating the motor end plates. Since its function is related to shoulder elevation, rehabilitation after transfer to the suprascapular is easy. The nerve can be identified lower down also. It lies just one finger breadth below the anterior border of the trapezius.

The suprascapular nerve is found regularly along the upper margin of the upper trunk and this is the first branch of the upper trunk. Unless shifted downwards, it is usually located in the supraclavicular fossa.

Intact ulnar nerve as donor: The next commonly done nerve transfers for elbow flexion are Oberlin 1 and 2 procedures. Oberlin 1 procedure was suggested by Christophe Oberlin[14] in 1994. In Oberlin 1 (Fig. 17), one fascicle is dissected from the ulnar nerve and sutured to the motor branch to the biceps. It is a simple, safe procedure which leads to recovery in a high percentage—M3 in 6 months. If the power of elbow flexion has to be increased, the brachialis also has to be neurotised and this can be achieved by taking one fascicle from the intact median nerve to the brachialis and this is called Oberlin 2 procedure[10,13] (Fig. 18).

Triceps nerve branches to axillary nerve: Motor branches supplying either the long head or the lateral head of triceps can be transferred to the entire axillary nerve[1] or only to the anterior branch of the deltoid[9] (Fig. 19) and the results are very promising (Fig. 20 and Figs 21A to C). If the C7 is also paralysed another donor nerve, either the phrenic, intercostals or C4 motor branches have to be used to neurotise the axillary nerve.

Intercostal nerves: Ever since Yeomen and Seddon[19] used these nerves for neurotisation, intercostal nerves were used to neurotise the axillary, musculocutaneous,

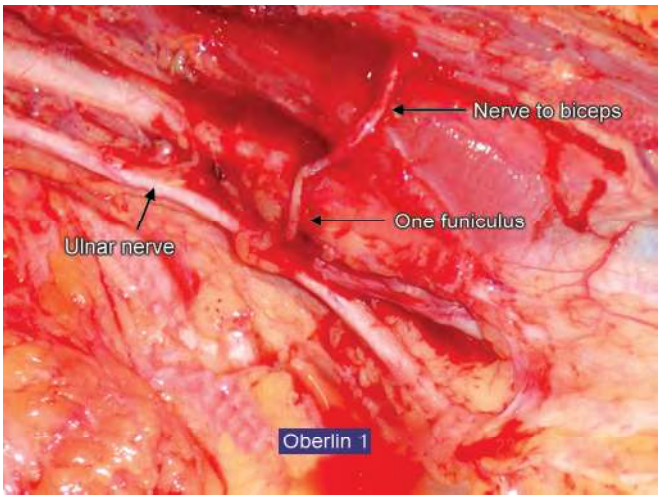

Fig. 17: Oberlin 1 procedure

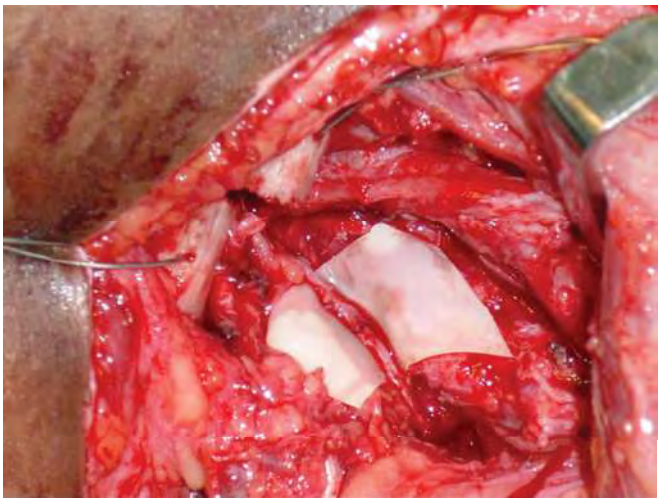

Fig. 16: Spinal accessory to suprascapular transfer

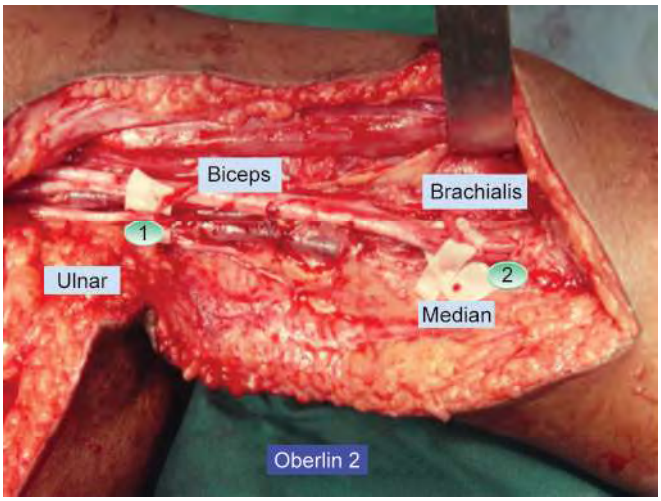

Fig. 18: Oberlin 2 procedure

median and radial nerves (Fig. 22). They are mainly used for restoration of elbow function by the majority of surgeons and for neurotising the free muscle transfer. The 3rd, 4th and 5th intercostals are commonly used. Up to five nerves can be used without problems.

Meticulous technique has to be used to dissect the intercostal nerves. The periosteum is stripped off the rib from the posterior axillary line to the nipple region. The rib is lifted up and the central motor branch is identified by incising the periosteum and hooked with a curved artery forceps or a hook. The nerve is then lifted and dissected both medially and laterally, as far as possible, collecting all the motor branches. On proceeding laterally, one can locate the sensory branch which passes inferiorly and laterally. This is also developed to the same length as the central motor branch. All the three intercostal nerves can be coapted together and anastomosed to the musculocutaneous nerve. One way of preventing axonal wastage is to separate the muscular branch of the musculocutaneous nerve near its entry into the muscle and anastamosing it to the intercostal nerves. This may need a sural graft.

Another technique adapted by Chang et al.[3] is to dissect the musculocutaneous nerve up to its origin from the posterior cord and turning it down to reach the

interocostals without an interpositional graft. They have found the motor fibres mainly concentrated in the middle third of the musculocutaneous nerve. The upper pole has mainly the sensory nerves and the lower has a mixture of motor fibres meant for the brachialis and sensory fibres. The cut surface of the musculocutaneous nerve is monofascicular but it can be separated into three parts. By coapting the central motor branches of the intercostals to the central area, one can achieve maximum use of motor fibres. The sensory branches are anastomosed to the upper and lower poles. Biceps neurotisation with the intercostals leads to consistently good results.

It is generally observed that EMG changes of reinnervation in the biceps, following intercostal neurotisation, appear 4–8 months after surgery. Clinically, muscle contraction appears with deep inspiration. Patients learn to flex the elbow with respiration. It takes 1–1½ years for them to flex the elbow without relating to the respiratory rhythm, but EMG changes persist with respiration for nearly 2–2½ years before they disappear finally. Similarly, sensation returns in the musculocutaneous nerve area, but there is cortical misrepresentation. In some reported series, it takes 6 years to disappear. The intercostals can be used for neurotising the triceps and axillary also.

Phrenic nerve: The phrenic nerve is the other possible donor nerve. It is easily identified over the surface of the scalenus anterior. It is not advisable to use this nerve in children, as the diaphragm is not fixed to the vertebral bodies unlike in adults. If it is sacrificed in infants, the diaphragm will elevate and occupy half the hemithorax causing severe respiratory distress. In adults it rarely causes any problem. Some may develop mild dyspnoea on the 1st day. The phrenic nerve is dissected down to the level of the jugular fossa and shifted to the axillary nerve. Endoscopic harvest[18] of the intrathoracic portion of the phrenic nerve also has been reported in order to avoid a nerve graft.

Direct Neurotisation[8]

Re-innervation of the denervated muscle can be done by implanting into it a new nerve or grafts connected with the proximal stump of the proper nerve and divided into several artificial branches.

When new nerve fibres are inserted into a denervated muscle, they are accepted and form a new motor end plate. These motor end plates are two or three times bigger than normal as has been proved by electron microscopy and EMG study. It has been postulated that a regenerated axon is probably able to adopt muscle fibres belonging to three or four non-regenerated axons.

The proximal nerve should be healthy and if it does not reach the muscle it can be extended by a graft. The distal end of the graft is divided into as many slips as possible. A normal looking area in the denervated muscle is chosen and nerve slips are buried into that as atraumatically as possible. Bleeding is avoided, to limit the scarring. The epineurium is sutured to the muscle fascia with 6 '0' and 8 '0' ethilon. The anastomosis has to be protected by immobilisation for at least 3 weeks (Fig. 23).

Contralateral C7:[7] As discussed earlier, the C7 can be transected without much noticeable deficiency. Several series from China, Taiwan and Thailand have reported using the contralateral C7 (C-C7). The entire C7 can be used or its anterior or posterior division. Since the anterior division has more sensory fibres it is co-opted to the median nerve. The posterior division has more motor fibres and, hence, it is used to neurotise the radial nerve. As mentioned earlier, there is no significant damage to the donor side. Even this can be prevented by selective transection.

The vascularised ulnar graft:[16] The vascularised ulnar nerve graft can be taken as a pedicled nerve graft based on the superior ulnar collateral vessels and the nerve can be flipped to reach the same side neck or the C-C7 (Fig. 24). In case the superior ulnar collateral vessel is damaged, then one has to harvest the vascularised ulnar nerve graft as a free flap based on the ulnar artery and transferred as a free tissue transfer. The distal end of the ulnar nerve is divided at the wrist level and dissected proximally with the ulnar artery and its veins. The dissection is continued up to the origin of the ulnar nerve from the medial cord and divided. The vascularised nerve is tunneled under the skin to the C-C7 and anastomosed to the main trunk. The ulnar vessels are anastomosed to the transverse cervical vessels. In the opinion of the authors, the results are better where the ulnar vessels are revascularised. Here again, the spinal accessory is transferred to the suprascapular and the

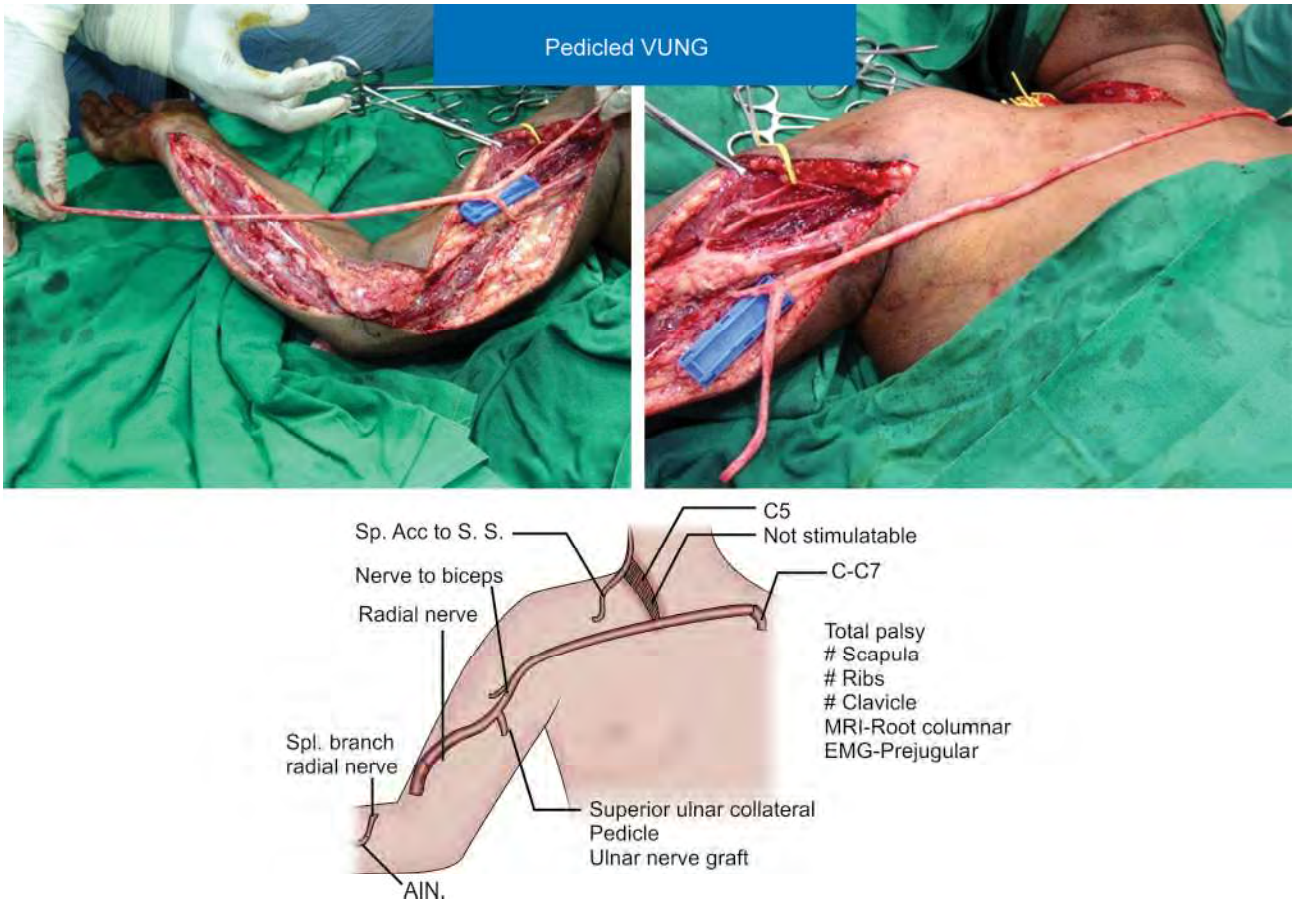

Fig. 24: Vascularised ulnar nerve graft: operative pictures and diagrammatic respresentation

remaining recipient nerves namely, the axillary, nerve to biceps and anterior and posterior interosseus nerves are connected sequentially (Figs 25A to C). The authors have done seven cases of vascularised ulnar nerve graft and seen good shoulder stability, elbow flexion and later on a flicker of flexion in the fingers. Some do it in two stages. In the first stage the distal end of the ulnar nerve is anastomosed to C7. After the appearance of Tinel's sign in the axilla (usually within 10 months), the proximal end of the ulnar nerve is divided for neurotising the nerves or for neurotising the free vascularised muscle that is transferred. Too long a delay between the two stages gives rise to poor results.

FUNCTIONAL FREE MUSCLE TRANSFER

Doi Procedures[4,5]

The original technique of double functional muscle transfer consisted of five established reconstructive procedures done in two stages. This technique yielded the most reliable prehensile function after irreparable injuries according to Doi.

First Stage

1. Surgical exploration of the brachial plexus, intraoperative diagnosis using electrophysiologic testing and repair of the disrupted cervical roots when possible.
2. The first "first functional muscle transfer" (FFMT) supplied by the spinal accessory nerve transfer to restore elbow flexion and finger extension.

Second Stage

3. The second FFMT supplied by the fifth and sixth intercostal nerves to restore finger flexion.
4. Transfer of the third and fourth intercostal nerves to the motor branch of the triceps brachii muscle (done concomitantly with the second FFMT) to restore elbow extension.
5. Transfer of the supraclavicular sensory nerves or the intercostal sensory rami to the median nerve or the ulnar nerve component of the medial cord of the brachial plexus (done concomitantly with the second FFMT), to restore hand sensibility.

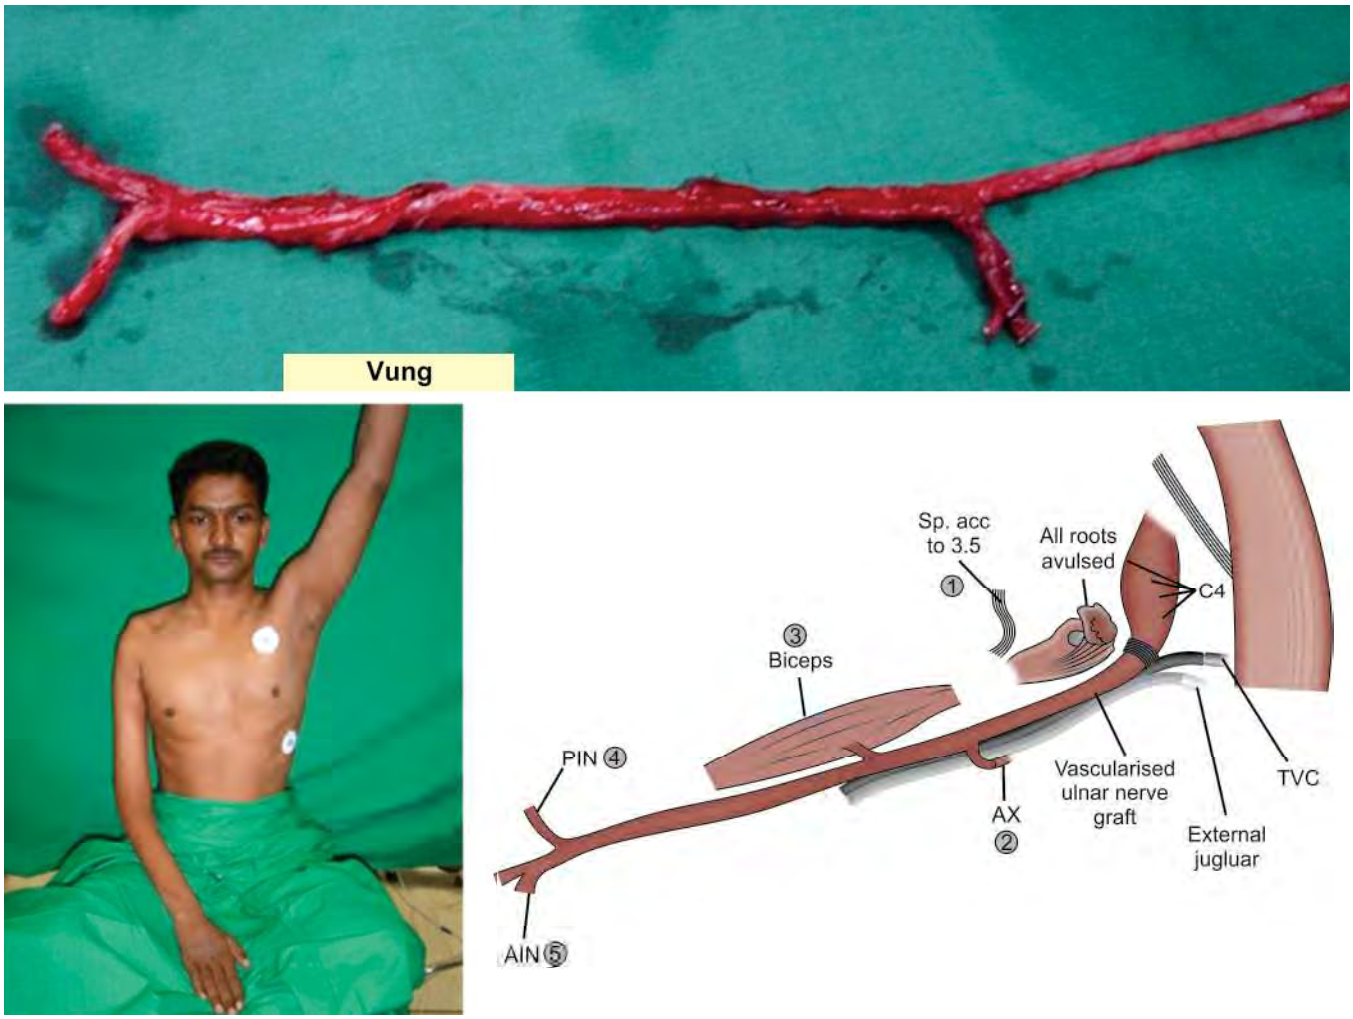

Fig. 25A: Intraoperative picture of Vung, pre-operative of a patient who underwent Vung and diagrammatic representation of the branches in Vung

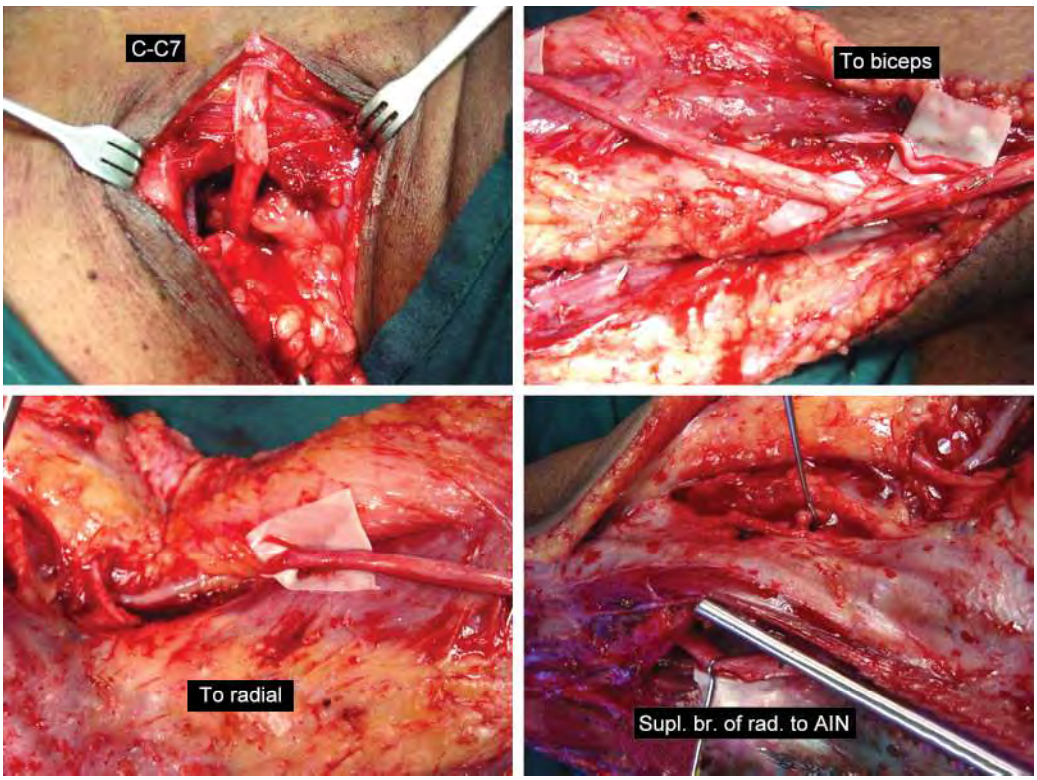

Fig. 25B: Intraoperative pictures of vascularised ulnar nerve graft surgery

Figs 25A and B: Post-operative picture of the patient who underwent Vung showing good shoulder stability and biceps motor power (M3)

The gracilis muscle is the choice for free muscle transfer. Two of them are transferred in two stages. The first transfer is for flexion of the fingers. The gracilis is anchored to the 2nd and 3rd ribs. The donor vessels are the thoracodorsal and the 4th and 5th intercostals for innervation of the muscle. The muscle is routed to the forearm by taking it along the medial side of the arm and forearm to the flexor digitorum sublimis tendons. It is taken underneath the pronator teres which acts as a pulley and sutured to the flexor digitorum profundus tendons. At the same time the 2nd and 3rd intercostals are sutured to the nerve to triceps to get elbow extension. The stability of the elbow in extension is very essential for finger flexion and extension. Hence, the functioning of the triceps should be ensured by intercostals neurotisation.

The second muscle should be transferred after 6 months for finger extension. It is attached to the coracoid process and taken along the anterolateral aspect of the arm and under the brachioradialis at the elbow, which acts as a pulley and attached to the common extensors. The vessels are the pectoral vessels as donors and the spinal accessory to neurotise the muscle.

The literature claims a range of 40–110 degrees finger flexion with power ranging from M2 to M5. The clawing is overcome by splinting or by correction by static procedures like Zancolli's. The wrist can be stabilised by arthrodesis.

In summing up, as it stands today, the prognosis of brachial plexus injuries is good as far as the restoration of shoulder and elbow function. The restoration of hand function in total palsy or lower plexus palsy is not possible following primary reconstruction, as the hand muscles degenerate by the time the growing nerves reach their destination. As an alternative, free functional

muscle transfer is available for restoration of hand function.

OBSTETRICAL BRACHIAL PLEXUS PALSY

For a long time, these were being treated conservatively. This resulted in severe disabilities and deformities. With growing interest, the modalities of treatment have been crystallised. If there are no signs of recovery of deltoid and biceps by the 2nd month, the prognosis is poor and so, surgical intervention is favoured for the following indications:

Biceps power Mo after 3 months

Insufficient recovery of extensors of elbow, wrist and fingers.

Once exploration is undertaken, the nerve and muscle reconstruction are similar to adults (Figs 26A and B). Phrenic nerve crossing is to be avoided in children for the fear of respiratory compromise.

PROGNOSIS

The collective opinion based on the experience of the last few decades is that there are clear prognostic pointers as shown here. Early exploration in younger age group gives better results. So also early recovery signs point to ultimate better results.

FUTURE

The greatest breakthrough in this field is the attempt to re-attach the avulsed root to the spinal cord. Animal and human experiments have yielded encouraging results. Carlstedt[2] is the pioneer in clinical replantation of avulsed nerves. He published two cases in 1995. The unsolved problems and surgical difficulties are many. It is expected that these will be solved one day and this will become a routine procedure.

The major challenge in any peripheral nerve surgery is to make the growing axons in their full quantum to reach their original destination, crossing the suture lines without getting arrested. In the meantime muscle nutrition should be kept going without wasting of muscle fibres and disappearance of motor end plates. Today there are many questions unanswered. Why some cases show recovery even after 1–1½ years of injury? Why a recovering muscle does not gain more power beyond a

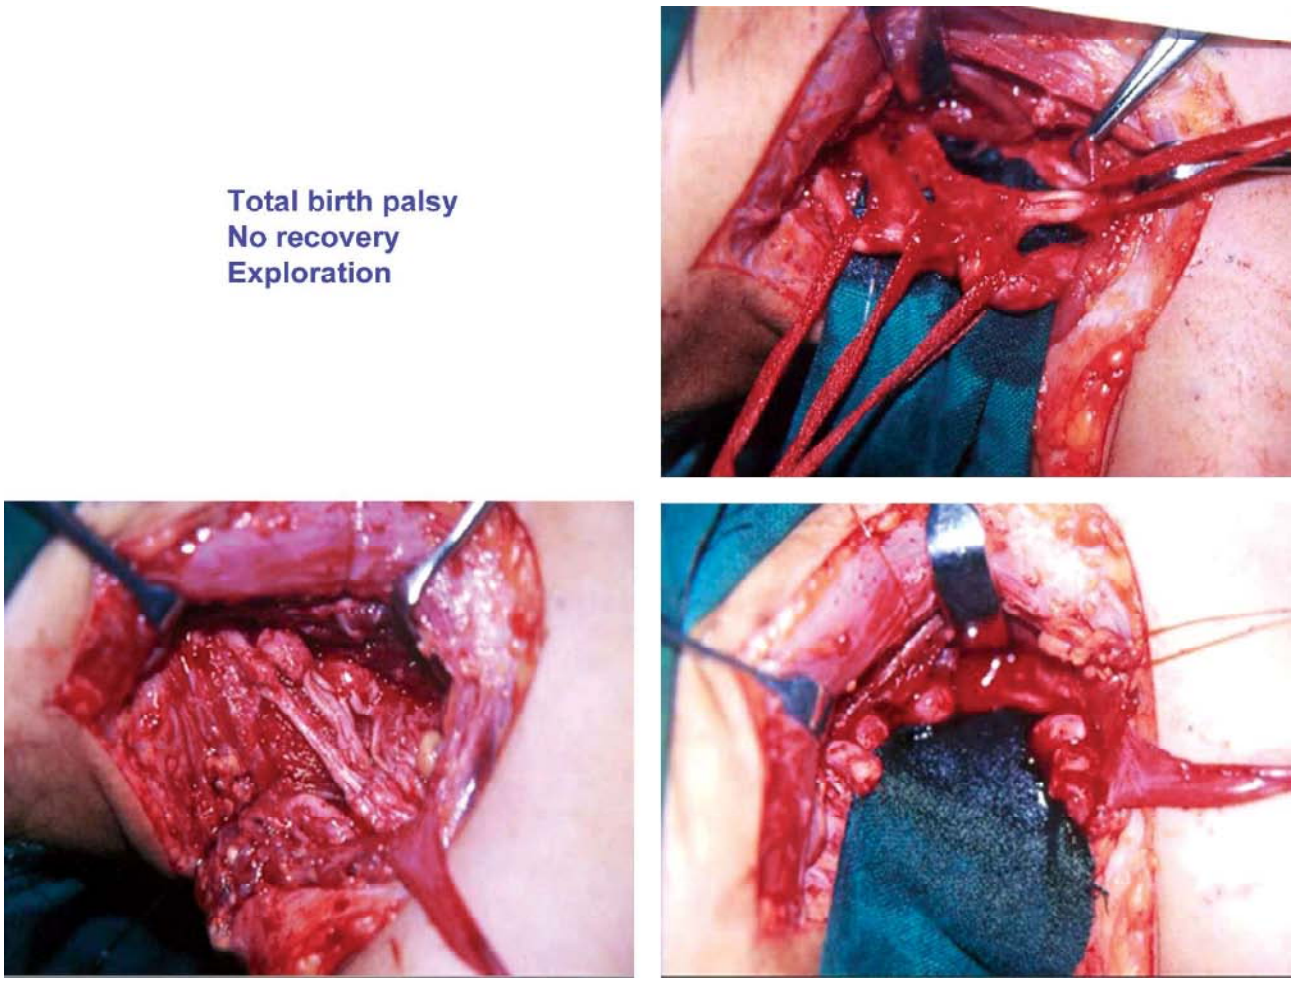

Fig. 26A: A young boy, 2 years of age, with no biceps function had his brachial plexus explored and was found to have a post-ganglionic injury. (A) The scar was resected and nerve grafting done

Fig. 26B: Six years post-operative good recovery of shoulder and elbow, but only partial recovery of the hand

point, in spite of best techniques of microneural repair? How to pin point the diagnosis pre-operatively with all the investigations at our command? Future research should directed towards answering these questions.

In countries like India, this problem should be taken up as a national problem to obviate and ameliorate the disastrous consequences of this palsy, affecting the most productive age group of the country.

58 Management of Injuries to Specific Peripheral Nerve

Gupta A, Ahmad FU, VS Mehta

GENERAL CONSIDERATIONS

Introduction

Neurosurgeons often encounter patients who suffer from peripheral nerve injuries, either in isolation or with other vascular or systemic injuries. A thorough understanding of the anatomy of the nerves, physiology of nerve repair and pathology helps in deciding the need for surgery, timing of surgery and the correct procedure to be adopted. Proper management of these injuries is vital to regain maximum possible function of limbs. The other coexistent injuries also need to be managed appropriately, calling for a team approach, as is required for any patient with polytrauma.

It must be stressed that peripheral nerve injuries may also occur during surgical procedures, undertaken by general surgeons, orthopaedic surgeons or others. It is, therefore, preferable, that all surgical specialists have some degree of familiarity with this topic, so as to take appropriate steps to safeguard against iatrogenic injury, or to manage/refer such injuries in a timely fashion when they are detected.

Anatomy

Peripheral nerves comprise of three components: 1) conducting axons, 2) insulating Schwann cells and 3) a surrounding connective tissue matrix that can support axonal regeneration. The axons are bounded within a semi-permeable membrane called the axolemma, which is surrounded by a myelin sheath of Schwann cells. The entire axons are embedded within a connective tissue compartment called the endoneurium. The endoneurium, in turn, is encircled by a compact layer called the perineurium, which is composed of concentrically arranged elongated perineural cells.[32] The axon bundles inside a perineurial sheath constitute a 'fascicle' and they are the smallest structural element of a nerve which is visible under the operating microscope (Refer to Fig. 2 of chapter 55 on Peripheral Nerve: Basic Anatomy and Physiology).

The perineurium is a thin but important physiological layer forming the structural basis of the blood-nerve barrier. These nerve fascicles are embedded within a connective tissue compartment called the internal epineurium, which is encircled by external epineurium. Both the internal and external epineurium contains fibroblasts, macrophages, mast cells, blood vessels and fat.[34,35,38] The external epineurium provides the main tensile strength to the nerve.

The axons inside each fascicle are repeatedly branching and follow an undulating course. Similarly, fascicles repeatedly branch and reunite to form a complex fascicular structure within the nerve. These features of the nerves ensure protection against traction forces generated by the movement of joints. It is only in the distal parts of the nerves that motor and sensory fascicles form separate groups.

An important feature of the peripheral nervous system, in comparison with the central nervous system, is its remarkable capacity for recovery through both remyelination and regeneration of axons and this physiologic capacity is the key resource utilised for successful nerve repair after trauma.

Mechanisms of Nerve Injuries

Open Injuries

They can be sharply incised wounds like those caused by knives, glass, etc. They can be repaired primarily unless any contraindication exists (see later). Injuries associated with extensive laceration, contusion or tearing of nerve fibres, as caused by a chainsaw or missiles are associated with ragged nerve edges and a great deal of tissue injury and are thus unfit for primary repair.

Closed Injuries

Most of these are caused by stretch or traction. They are usually associated with anatomical continuity of nerves and are more difficult to treat, because of the following reasons:[24]

a. Extensive intrafascicular damage and fibrosis is a significant impediment to regenerating fibres.
b. Injury is often concealed inside the fascicles and the complete extent of the injury cannot be appreciated on inspection or palpation.

c. Associated rupture of blood vessels may lead to extensive haemorrhage and post-traumatic scarring.

Miscellaneous Injuries

They include injection injuries, thermal/electrical injuries, pressure injuries, iatrogenic damage during surgery, fracture reduction, tight casts and splints, etc. Bullet injuries deserve special mention because they cause damage, not only by direct injury but also by cavitation effect. The injury is often more severe than what appears from the wound and such injuries should always be repaired after an interval of 3–4 weeks.

Grading of Nerve Injuries

In 1943, Seddon[31] defined three grades of nerve injury (neuropraxia, axonotmesis and neurotmesis) based on the extent of injury to the three structural components of the peripheral nerve described above. While he admitted that these three grades were only a rough approximation, these terms have been retained in literature. The beauty of the three-grade classification scheme lies in its simplicity and clinical relevance in predicting functional outcome and formulating an appropriate treatment plan.

Neuropraxia, the mildest grade of nerve injury, is characterised by disruption of the myelin sheath with conduction block across a segment of nerve. Axonal continuity is maintained. The key feature is its reversibility within hours to weeks of injury.[40] After complete nerve palsies, neuropraxia can be distinguished from other forms of injury only in retrospect, after recovery has taken place sooner than would be expected from Wallerian degeneration. In incomplete injuries, the motor component is often affected more than sensory and autonomic functions. Tinel's sign is absent due to preservation of axons.

Axonotmesis represents a more severe grade of nerve injury and is characterised by disruption of the axons with preservation of the fascicles. Distal Wallerian degeneration of the axons occurs over several days.[8,11,15] Recovery can occur through axonal regeneration because of the preservation of the connective tissue 'tubes', which consists of Schwann cells and their extracellular matrix.[30] Regeneration can be followed by an advancing Tinel's sign or by electrophysiological evaluation. Since one cannot reliably predict whether the injury is purely axonotmic in nature or the fascicles are also disrupted, the degree of recovery in such lesions cannot be predicted with certainty. Even if the lesion is purely axonotmic, many proximal motor neurons may enter sensory tubules and vice-versa, thus decreasing the effectiveness of regeneration.

Neurotmesis is the most severe grade of peripheral nerve injury. Neurotmesis is characterised by disruption of the axons, myelin and connective tissue components of the nerve, with various grades of internal disruption of the endoneurium, perineurium and epineurium and/or complete disruption of nerve ends. These injuries generally require surgical correction.[15,42]

To better distinguish between different grades of neurotmesis injuries, Sir Sydney Sunderland[33] categorised nerve injuries into five grades. Grades I and II correspond to neuropraxic and axonotmetic grades of injury. In Sunderland Grade III injuries, the continuity of the endoneurium is disrupted, while preserving the continuity of the perineurium. In Grade IV injuries, there is additional disruption of the perineurium also, while in Grade V injuries epineurial continuity is also disrupted, which corresponds to a neurotmesis lesion in discontinuity. An additional level of complexity is introduced, in that peripheral nerve injuries can represent combinations of these different grades of nerve injury, such as Grade VI presented by Mackinnon and Dellon.[21]

However, we should remember that neural injury is a continuum and clear differentiation into these grades is not always possible. Also, different grades of injuries may coexist in a particular patient with nerve injury.

Evaluation of Nerve Injury

Clinical history should include the mode of injury, time since injury, extent of functional impairment, associated injuries (vascular, bony, visceral, etc.) and recovery of functions. Examination should include the degree and distribution of muscle wasting, grade of power in different muscles, range of movements and extent of sensory impairment. Local examination for the presence of neuroma, Tinel's sign, associated bony or vascular injury, external wounds and deformities is important.

The presence of Tinel's sign is useful to localise a nerve injury. Tinel's sign refers to paraesthesias elicited by tapping along the course of a nerve. Progressive distal advancement of Tinel's sign over time can be useful clinically to follow the course of regenerating sensory axons.[10,15] Serial electrodiagnostic studies can also detect a distally advancing nerve conduction response representing the regenerating front of axons.

Electrodiagnostic tests are useful adjuncts to clinical examination. Two to three weeks after an axonotmetic or neurotmesis grade of injury, the results of electromyography (EMG) become abnormal.[4,12,20,36,39] Spontaneous activity, including fibrillations, fasciculations and positive sharp waves, develops in the affected muscles.[20] The results of EMG performed after a neuropraxic injury, usually remain normal and can be used to distinguish a neuropraxic grade of injury from the more severe axonotmetic and neurotmesis grades of injury. Radiology is not of much use in surgical decision making, except for demonstration of associated fractures and callus formation.

Philosophy of Management

Both neuropraxic and axonotmetic grades of traumatic injury do not require surgical intervention. Patients with such injuries should be followed-up with serial clinical and electrodiagnostic examinations, to document recovery and confirm the diagnosis. Complete nerve injuries may represent either an axonotmetic or neurotmesis

grade of injury. It is important to distinguish between these two, as the latter requires surgery for recovery to occur.[32]

As mentioned earlier, traumatic peripheral nerve injuries can be classified into open and closed injuries. Decision making for open injuries is relatively straightforward.[15,21–23,35] Immediate repair of acute sharp lacerating injuries should be undertaken, with the aim of performing a primary end-to-end suture repair. Contraindications to primary repair are extensive bruising, destruction of tissues, contamination of the wound, ragged nerve ends or loss of length of nerve.[24] Under these circumstances, the nerve ends should then be tagged together to prevent further retraction and for identification later. The surgery should then be performed 3–4 weeks later when the associated wound has healed. This delay will allow for demarcation of the healthy proximal and distal nerve ends from the intervening scarred segment. Lesions in continuity cannot be accurately assessed during the acute period, when seen during tendon repairs or open reduction of a fracture.

Closed Injuries

In the majority of closed traumatic injuries, however, the nerves are not actually transected. Instead, a "lesion in continuity" representing the damaged segment of nerve may be produced, which results in either a neurapraxic, axonotmetic or neurotmesis grade of injury.[19,25]

These injuries should be explored:[24]

a. When nerve function is steadily deteriorating.
b. When recovery stops before reaching any useful degree.
c. When spontaneous recovery is overdue: if there is no clinical or electrophysiological evidence of recovery, even after the time it was expected to occur (3–4 months in brachial plexus injury but different in different nerve injuries), the patient should be explored.
d. When there is a painful traumatic neuroma.

It is necessary to time the surgical exploration, so that a successful nerve repair results in muscle re-innervation within 1–2 years of the injury. If there is no clinical or electrodiagnostic evidence of muscle re-innervation after 3–4 months of injury, then a surgical exploration using intra-operative electrophysiological monitoring should be performed.[9]

Another philosophy of management, not practiced by the authors, is to operate as soon as feasible, as there is less scarring in the beginning and earlier repair may result in a better outcome. However, many patients recover on their own without surgical intervention and this approach risks exposing those patients to unnecessary surgery.

Treatment Options

The surgical techniques applicable to peripheral nerve surgery include both external and internal neurolysis. External neurolysis involves freeing the nerve from its bed, by removing constrictive adhesions attaching it to the surrounding tissues. Although controversial, it has been hypothesised that scar tissue around nerves can produce pain, as well as sensory and motor deficits through tethering and/or compression.[33,41] Surgical resection of the scar may promote recovery of nerve function.

Before suture or graft repair can be performed, any epineural scarring must be resected using fine dissecting scissors, micro-scissors or a scalpel and regions of bleeding at the epineural or subepineural level must be coagulated, using an irrigating bipolar forceps. It should always be done with the aid of the operating microscope and healthy fascicles should be isolated both proximal and distal to the scar tissue before intra-operative neural action potentials (NAPs) are recorded. Careful observation and palpation are important at this stage.

Kim et al.[13] suggest that, while performing intra-operative recordings of the NAP on a lesion in continuity, stimulating and recording electrodes should be placed on the nerve proximal to the lesion to assess the NAP. The recording electrodes should then be moved distally from the lesion and changes in the evoked NAP observed. If the NAP is present, external neurolysis, with or without internal neurolysis, is sufficient to achieve a favourable outcome. If NAP is absent across a lesion in continuity, resection and repair of the injured nerve is necessary.[14,17] The velocity and amplitude of the nerve conduction response can be measured.

Tiel[41] and Kline[14] and their colleagues showed that intra-operative NAP recording is a reliable indicator of useful electrophysiological recovery in the assessment of nerve injury. It can assist with more precise localisation of pathological findings and aids the decision concerning whether or not to resect the nerve lesion.

Internal neurolysis is indicated in cases in which an injury is more severe at one portion of the nerve than another, in the presence of an NAP transmitted across the lesion. Split or partial graft repairs may be necessary, when individual fascicles or bundles of fascicles do not transmit NAPs.[9,15,34] Conducting fascicles are spared and non-functioning elements are repaired, either end to end or with an interposition nerve graft. However, there is a risk that if it is done in a clumsy manner, it can lead to further neurological deficit.[21] Intra-operative frozen section of the cut nerve ends can be used to determine if normal fascicular anatomy is present.[6]

Kim et al.[13] suggest that in cases of transected nerves or those in which a nerve segment is unable to transmit an NAP, resection is required, and end-to-end epineural repair can sometimes be achieved with the aid of magnification. Sharp dissection is necessary before suture or graft repair to mobilise the proximal and distal stumps, with adequate resection of the stump to healthy epineurium and fascicular structure. We prefer approximating the two ends of the nerves with 9-0 or 10-0 nylon sutures. Meticulous attention should be paid to the surgical technique to ensure good coaptation of the nerve

ends. It is well known that tension can impair recovery of nerve function.[27] If mobilisation of the nerve is inadequate for a tensionless repair, the two ends should be approximated using interposition nerve grafts to avoid tension.

The nerve ends should carefully be looked at to determine the fascicular topography before approximating them. Another method is to utilise surface vessels for alignment. A minimum number of sutures should be used to decrease scarring.

Two leading causes of regenerative failure across the suture repair site are inadequate preparation of the nerve stumps and persistent tension. Both of these factors can lead to the formation of an intraneural scar, which interferes with regenerating nerve fibers.[2,16,18,19,26,27,28,35,38]

Sutureless Repair

Laser welding, cuff union or fibrin adhesives of axon conduits have been used to approximate fascicles in the hope of reducing scar tissue formation. Improved functional results using these techniques have not yet been demonstrated definitively.[1,3,5,7,29,37]

Nerve Grafts

Several types of nerve autografts have been described which include:[24]

Cable nerve graft: Many parallel grafts of donor peripheral nerves are used to match the thickness of the recipient nerve.

Group interfascicular nerve graft: The fascicles at the proximal and distal ends are appropriately grouped and matched with cable grafts.

Free neurovascular nerve grafts: A nerve is transferred along with its vascular pedicle.

Pedicle nerve graft: A full thickness nerve graft is transferred in a two-stage procedure.

Tubal graft: Using a vein, artery or other mesothelial tubes.

Post-Operative Management

The management of peripheral nerve injury does not end with surgery. It is extremely important that patients undergo regular physical therapy, both supervised and on their own, to maintain range of movement and to optimise the recovery of motor function as re-innervation of muscles occurs.

When suture-repairing a nerve with or without grafts every effort is made to minimise nerve tension, by either mobilising or transposing the nerve or by using nerve grafts of adequate length, so that the repair site is not disrupted. Despite these precautions, overzealous post-operative mobilisation can result in disruption of the suture repair site(s) and therefore should be avoided.

Follow-up electrodiagnostic studies can be very useful in detecting early signs of muscle re-innervation, 3–6 weeks before clinically evident muscle contraction. The results of these studies, when positive, can provide hope to the patient and can also be helpful in predicting clinical outcome.

Along with physiotherapy, occupational therapy, orthosis, limb reconstruction, and wherever required, psychotherapy should be used in the post-operative period.

Injuries to Specific Nerves

Radial Nerve

Most of the serious radial nerve (RN) injuries result from fractures, lacerations, contusions or gunshot wounds. Seventy percent of RN injuries related to fractures occur at the level of the arm. In particular, fractures involving the junction of the middle and distal third of the humerus and the midpoint of the humerus at the level of the spiral groove were associated with RN injuries. The RN supplies branches to the long and medial heads of the triceps (elbow extension) before the radial groove, while braches to the brachioradialis and extensor carpi radialis longus are supplied after the radial groove, before crossing the elbow. All extensor muscles of the hand and forearm are innervated after the RN pierces the supinator muscle. Loss of wrist extension significantly reduces the ability to grasp, due to a reduction in the mechanical advantage of flexion at the distal interphalangeal joints by the flexor digitorum profundus muscle. This adds to the functional disability, which is present already due to loss of elbow and wrist extension. In spite of the generally poor outcome seen in recovery of wrist extension after brachial plexus injuries, outcome after repair of RN is surprisingly fair. Taha and Taha[29] have highlighted several factors contributing to this: 1) the predominance of motor fibres that reduce the possibility of cross motor-sensory re-innervation; 2) muscles innervated by the RN receive their input relatively proximally within the limb and are not involved in delicate movements that require complex coordinated muscle contraction and 3) even though the initial loss of the extensor carpi radialis longus muscle results in significant disability, the muscle recovers well.

A period of observation is recommended for fracture-related RN injuries because spontaneous recovery rates as high as 76% have been reported in the literature.[3,21,23,24,30] In their series of patients, Bostman et al.[2] observed that it was more common for the distal third of the humerus to sustain a longitudinal spiral fracture. The nerve often gets trapped in the fracture line after attempted closed reduction of the humeral fracture.[3,28,30] However, if the fracture is to be reduced openly and internally instrumented or if vascular repair is necessary, the injured nerve should be explored.[13,17,20,21,23] Further management depends upon several factors, including the time elapsed after injury and the status of the nerves. Kim et al.[13] observed motor function recovery to Grade 3 or better in 10 (91%) of 11 patients who underwent primary suture repair, 25 (83%) of 30 who underwent secondary suture repair, 43 (80%) of 54 who received graft repair and 63 (98%) of 64 in whom neurolysis was performed after RN injury.

Median Nerve

The median nerve (MN) does not give any branches in the arm. It supplies all the forearm flexor muscles (except the flexor carpi ulnaris and medial part of the flexor digitorum profundus) in the proximal part of the forearm and three thenar muscles and two lumbricals in the hand, resulting in impairment of important functions of pinch and grasp after its injury. The mechanisms of injury include lacerations, gunshot wounds, stretch injury or contusion, fracture-related contusion, iatrogenic injury, compression and electrical injury.

Surgical intervention for MN injuries with complete or severe deficits achieves a favourable outcome. The most common mechanism of injury seen at all levels by Kim et al.[13] was laceration. They observed that for lesions in continuity, a functional recovery of Grade 3 or better was seen in 72 (95%) of 76 patients who underwent neurolysis, 18 (86%) of 21 who received suture repair and 21 (75%) of 28 who received graft repair. In lesions not in continuity, favourable results (Grade 3) were seen in 10 (91%) of 11 patients who underwent primary suture repair, seven (78%) of nine who had secondary suture repair and 15 (68%) of 22 who underwent graft repair.

However, several factors determine the outcome after these nerve injuries. Surgical timing is vitally important for patients who have severe or poorly recovering MN injuries that show little spontaneous improvement.[3,12,13]

In their study of 132 delayed repairs of sharp and blunt MN injuries, Kallio and Vastamaki[8] observed that injuries farther than 56 cm from the fingertip, delays in surgery longer than 24 months and graft repairs more than 7 cm long were associated with relatively poor outcome.

Ulnar Nerve

This nerve arises from the medial cord of the brachial plexus and lies on the medial side of the axillary artery. Like the MN, it also does not give any branches in the arm. It supplies the flexor carpi ulnaris and medial part of the flexor digitorum profundus in the proximal forearm. The ulnar nerve has its greatest importance at the hand level, where it innervates most of the intrinsic muscles. It has been reported that recovery of small muscles of the hand is poor after repair of the ulnar nerve and the results are much worse when compared to outcome after radial or MN repairs.[1,22,25] This is in spite of the fact that an additional 2.5–3.5 cm of length of the ulnar nerve can be gained by transposing it anterior to the elbow, thereby avoiding the need for a nerve graft in many cases. However, we normally do not recommend anterior transposition of the ulnar nerve at the elbow, as it may cause vascular damage to the nerve and, if not performed adequately, it may cause acute angulation of the nerve.

The most common mechanism of injury observed by Kim et al. was laceration.[11] Stretch, fractures and firearm injuries were other common mechanisms. They observed that functional recoveries of Grade 3 or better were seen in 81 (92%) of 88 patients who underwent neurolysis, 42 (72%) of 58 patients who received suture repair and 24 (67%) of 36 patients who received graft repair. Nevertheless, fewer Grade 4 or 5 recoveries were achieved than those seen in patients with RN or MN injuries. [11–13]

Axillary Nerve

The axillary nerve is the most commonly damaged by stretch/contusion injuries, with or without associated other nerve injuries, like posterior cord/suprascapular nerve or brachial plexus injuries. Kline and Kim[19] observed that these injuries usually began in the posterior cord. In their analysis of 99 patients with axillary nerve repair, they found better recovery after neurolysis of intact nerves (to mean grade 4), as compared to suture repairs or graft repairs (mean grade 3.7). They concluded that operative intervention is worthwhile in carefully selected cases.

Sciatic Nerve

The sciatic nerve is the biggest peripheral nerve of the whole body, far from the target organs and with a complicated structure. The tibial nerve (TN) and the common peroneal nerve (CPN) keep relatively independent from the early part of their course. Injuries of the CPN are the most frequent and lesions of the sciatic and TNs are rather rare.[4,5,7,9,18] Injury at the thigh level can produce complete injury of both divisions of the sciatic nerve, complete injury in one and incomplete in the other, incomplete in both divisions or complete/incomplete in one and none in the other. Lesions of the femoral and obturator nerve are uncommon.[5,7] The mechanism of injury of the lower extremity nerves includes laceration, compression, traction and focal ischaemia. Penetrating trauma, bone fractures, joint dislocations, injection injuries and operative iatrogenic lesions are relatively more common causes of lower limb nerve injuries, as compared to upper limb injuries. Nerve injuries in the lower limbs are also said to have a worse prognosis than those in the upper limbs.[26,27,31]

Kline et al.[18] in their review of 380 cases of sciatic nerve injury managed over 24 years, observed that surgical exploration was not warranted in one fourth of injuries at the thigh level and almost half of hip level injuries. They found good to excellent outcome in only 36% of cases after suture repair/nerve graft of the peroneal nerve. However, they found that outcome after TN repair was more favourable, regardless of the level or mechanism of injury.

Kim et al.[15] analysed 353 surgically treated cases over 32 years and observed that sciatic nerve divisions in which positive intra-operative nerve action potentials were found and who underwent neurolysis, attained at least Grade 3 functional outcomes in 108 (87%) of 124 and in 91 (96%) of 95 buttock and thigh-level tibial divisions, respectively, compared with 84 (71%) of 119 and 75 (79%) of 95, respectively, in the peroneal divisions. For suture repair, recovery to at least Grade 3, occurred in eight (73%) of 11 buttock-level and in 27 (93%) of 29 thigh-level tibial division injuries and in three (30%) of 10 buttock-level and 20 (69%) of 29 thigh-level peroneal division lesions. These observations support the findings of Kline et al.[18] that outcome after TN lesions is more favourable.

In their analysis of 270 cases with lower extremity injuries Gosk et al.[6] found CPN injuries to be most common (125 cases), followed by those of the sciatic nerve (93 cases). This is because of the more susceptible location of the CPN and also its increased sensitivity to trauma. They observed that the efficacy of surgical intervention (very good and good results) in these groups was 68.5% after neurolysis, 48% after reconstruction—sural nerve grafting and 50% after reconstruction—direct suture.

Results of surgery are consistently better for TN lesions, as compared to those of CPN, regardless of the local factors and aetiology of the injury. Of 75 patients with thigh level TN lesions, 69 (92%) improved to grade 3 or better after surgery. Of patients with CPN lesions at the thigh, only 50 patients out of 77 improved after surgery. Similarly, for buttock level injuries, 48 out of 53 patients with TN injuries improved to grade 3 or better, as compared to 29 out of 48 operated for CPN injuries at the same level.[10]

Femoral Nerve

The femoral nerve (FN) originates from the anterior divisions of the L2, L3 and L4 roots. After a long retroperitoneal course over the iliopsoas muscle, it travels under the inguinal ligament, medial to the femoral artery and FN. It divides in the upper thigh (around 4 cm distal to the inguinal ligament) into muscular and sensory branches. FN is a major flexor of the hip joint (iliopsoas) and extensor of the knee (quadriceps). Sensory branches supply the medial part of the thigh and knee.[10,16]

Results of FN surgery are encouraging.[14,16] Of the 54 cases of FN injuries operated upon by Kim and Kline,[14] 42 patients (77%) improved to grade 3 or better power (average follow-up 26.1 months). Iatrogenic injury was the most common mode of injury seen by them (arterial bypass/angiography/hernia repair/gynaecologic surgery) followed by hip/pelvic fracture[19] and laceration.[30] Of the 24 cases managed conservatively, 12 improved to grade 3 or better after an average follow-up of 20 months.

59 Entrapment Syndromes

Sarat Chandra P, VS Mehta

INTRODUCTION

Entrapment neuropathy is defined as a condition in which a nerve is continuously irritated by compression created by encroachment or impingement of a nearby anatomical structure.

There may be a number of conditions and even a larger number of situations, including trauma, where this may occur. The most common ones are listed below. The most common entrapment neuropathy is carpal tunnel syndrome followed by ulnar nerve entrapment at the elbow.

TRAUMATIC AND ENTRAPMENT NEUROPATHIES[18]

- Carpal tunnel syndrome
- Ulnar nerve at elbow or wrist
- Cervical or lumbosacral radiculopathies (includes thoracic outlet syndromes)
- Median nerve at elbow
- Anterior interosseous syndrome
- Radial nerve in upper arm
- Sciatic nerve
- Common peroneal nerve at knee
- Tibial nerve at knee
- Lateral cutaneous femoral nerve (meralgia paraesthetica)
- Spinal accessory nerve in posterior cervical triangle
- Subscapular neuropathy.

The clinical manifestations of neuropathy depend on the type and distribution of the affected nerve modalities, the degree of nerve or myelin damage, and the course of the disease. Demyelinating neuropathies primarily affect the myelin sheaths whereas, axonal neuropathies target the peripheral nerve axons. When motor nerves are damaged, weakness and muscle atrophy occur. Damage to sensory nerves can cause loss of sensation, paraesthesia and dysaesthesia, pain and sensory ataxia. Autonomic dysfunction can result in postural hypotension, impotence, gastrointestinal and genitourinary dysfunction, abnormal sweating and hair loss. Involvement of small myelinated and unmyelinated sensory fibres typically results in impaired pin prick and temperature sensation, numbness, and painful burning, cold, stinging, or tingling paraesthesia. Large diameter sensory fibre involvement manifests as loss of vibration and position sensation, sensory ataxia and numbness or tingling paraesthesia. Deep tendon reflexes are frequently diminished or absent, particularly in the demyelinating neuropathies. Since most nerve trunks have a mixture of fibre types, damage to the peripheral nerves often affects more than one of these functions.

Carpal Tunnel Syndrome

Synonym: Median nerve entrapment at the wrist.

This is the commonest kind of entrapment seen in clinical practice. The first description of a chronic median nerve entrapment at the wrist was by Paget[42] concerning a patient with a previous distal radius fracture.[48] This was a severe entrapment accompanied by ulceration in the fingers 1 to 3. The first surgery for carpal tunnel syndrome was done in 1933 at the Mayo Clinic. Carpal tunnel syndrome received increasing attention in the 1940s and 1950s from both neurologists and surgeons. The clinical importance of carpal tunnel syndrome is illustrated by the more than 2,000 papers published in the last 10 years by neurologists, neurosurgeons, orthopaedic, plastic and hand surgeons, as well as physicians specialised in occupational medicine and physiatry.

Aetiology

The aetiology of carpal tunnel syndrome is compression of the median nerve in the carpal tunnel. The carpal bones form the floor and walls of the carpal tunnel, and the roof is created by the transverse carpal ligament (Fig. 1). Nine flexor tendons with their sheaths accompany the median nerve in the carpal tunnel. Just before entering the carpal tunnel, the median nerve gives off the palmar cutaneous branch that carries sensory fibres from the thenar eminence. After the median nerve exits from the carpal tunnel, it gives off the thenar motor branch innervating the abductor pollicis brevis, the opponens pollicis and the first and second lumbrical muscles. It, sometimes, also supplies the flexor pollicis brevis. The other branches are sensory digital branches that supply the thumb, index finger, middle finger and the lateral half of the ring finger.

Carpal tunnel syndrome occurs in conditions that either reduce the space in the tunnel or cause increased susceptibility of the nerve.

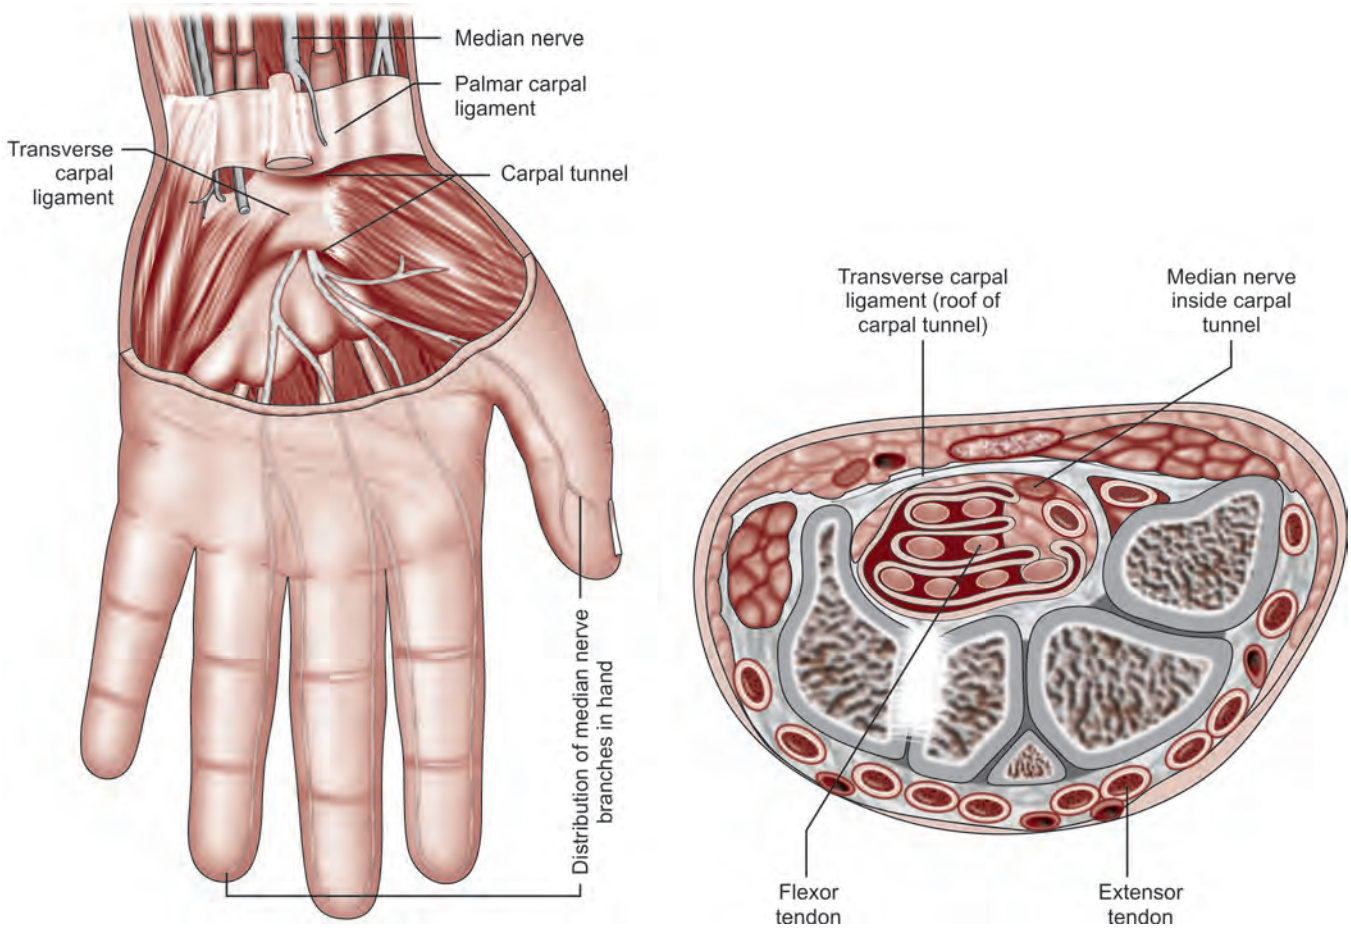

Fig. 1: Anatomy of carpal tunnel in the wrist

Reduced space may be caused by tenosynovitis, rheumatoid arthritis, ganglia, osteophytes, osteosis, anomalous muscles or tumours. Fluid retention is thought to be responsible in pregnancy, during lactation or during the use of oestrogens. Conditions which increase the susceptibility of the nerve are diabetes, hypothyroidism, hereditary neuropathy with pressure palsies, acromegaly, focal amyloid deposition that can be idiopathic or secondary to a genetic defect, systemic amyloidosis or dialysis. Work-related carpal tunnel syndrome occurs with repetitive hand and wrist movement and is seen with a variety of activities and occupations. Increased pressure within the carpal tunnel due to certain positions of the hand and wrist and oedema of the flexor tendons are thought to contribute to occupational carpal tunnel syndrome.

Although the vast majority of carpal tunnel syndrome occurs sporadically, genetic factors may play a role. There is reportedly an autosomal dominant form of carpal tunnel syndrome.[38] Rare, inherited connective tissue diseases, such as mucopolysaccharidosis, can cause severe carpal tunnel syndrome.

Acute carpal tunnel syndrome is mostly seen in the setting of traumatic injury to the hand or wrist and, occasionally, the forearm. It can be caused by the common Colles' fracture of the distal radius. Furthermore, bleeding into the carpal canal due to coagulation disorders seen in cases of leukaemia, haemophilia or anticoagulant therapy can provoke acute carpal tunnel syndrome. Urgent surgical release is indicated for acute severe carpal tunnel syndrome.

Subacute carpal tunnel syndrome, with symptoms usually presenting within 1 week, may occur after rear or front end automobile collisions, presumably through hyperextension of the wrist against the steering wheel.[14] Manifestations of carpal tunnel syndrome can also be seen in a much more delayed fashion after traumatic injury and have been described after a variety of fractures, lacerations and burns.

Pregnancy: During pregnancy there is an increased incidence of carpal tunnel syndrome, presumably due to fluid retention. Treatment is usually conservative as spontaneous recovery occurs after delivery in about 50% of patients.[44] If symptoms persist, steroid injection or surgical carpal tunnel release should be considered.

Associated Disorders

- Amyloid neuropathy
- Amyloidosis
- Colles' fracture
- Diabetes mellitus
- Dialysis
- Hereditary neuropathy with pressure palsies

- Hypothyroidism
- I-cell disease and pseudo-Hurler polydystrophy
- Median neuropathy
- Mucopolysaccharidoses
- Repetitive strain injury
- Rheumatoid arthritis

Epidemiology

Epidemiological studies are not available from India. However, the incidence, as quoted in the literature, is 2–3% of the population.[5] In general, a higher incidence of carpal tunnel syndrome is associated with activities where repetitive hand movements are frequent.

Clinical Manifestations

The incidence of carpal tunnel syndrome is highest among middle-aged women. There is also an association with pregnancy. The clinical manifestations of carpal tunnel syndrome consist of intermittent pain, numbness and tingling in the fingers that is dependent on the position of the hand and wrist and commonly associated with subjective weakness of grip. The symptoms occur initially at night only and may wake the patient from sleep. In more severe cases, the symptoms occur also during the day. They are often provoked by hyperextension or hyperflexion of the wrist during activities such as driving, or during work-related repeated hand movements. The pain can radiate up into the forearm or even up to the shoulder. There frequently is subjective hand swelling and stiffness. The patient will often shake the hand and fingers in an effort to obtain relief from the discomfort (flick sign).

On clinical examination, there can be a discrete sensory disturbance in the lateral three fingers and weakness or atrophy of the thenar muscles with a positive Tinel's sign over the carpal tunnel. Phalen's test, where the patient is asked to hyperflex the wrist for one minute, may provoke the symptoms.[43] Hyperextension of the wrist for one minute may have the same effect. Phalen's test is more specific for carpal tunnel syndrome than Tinel's sign, but both can be present in normal individuals.[24] It is, more often, the clinical history than the physical examination that is highly suggestive of carpal tunnel syndrome.

Prevention

Ergonomic intervention may be helpful in preventing carpal tunnel syndrome by focussing on tool design, improvement of workstations, the avoidance of repetitive pinching, wringing and grasping motions as well as other measures.

Differential Diagnosis

Carpal tunnel syndrome should be differentiated from other neurologic disorders that can cause pain, numbness, tingling and weakness in the hand, such as cervical radiculopathy, polyneuropathy, other entrapment of the median nerve, ulnar neuropathy, and brachial plexopathy. Non-neurologic causes of wrist and hand pain include de Quervain tenosynovitis of the abductor pollicis longus and extensor pollicis brevis tendons, trigger finger, non-specific tenosynovitis, osteoarthritis of the basal joints of the thumb, and Raynaud's disease.

A thorough clinical examination in combination with electrodiagnostic testing usually leads to the correct diagnosis. Occasionally, radiological investigation is necessary, especially when cervical radiculopathy is suspected.

Diagnostic Workup

Electrophysiological testing has an important role in the diagnostic workup for carpal tunnel syndrome. It can document a median nerve entrapment at the wrist and, thereby, support the diagnosis of carpal tunnel syndrome in the presence of appropriate symptoms. Since the first description,[5] increasingly refined nerve conduction techniques have demonstrated slowing of conduction in the median nerve across the carpal tunnel.

Electrodiagnostic testing usually includes motor and sensory nerve conduction studies of both median nerves and at least one ulnar nerve. Needle examination of the abductor pollicis brevis muscles is routinely performed to look for denervation. Needle examination of several other upper extremity muscles and the cervical paraspinal muscles is often necessary to exclude other entrapment neuropathies, plexopathy or radiculopathy.

Sensory nerve conduction studies are the most sensitive in confirming the diagnosis. The most common finding is an increase in distal latency due to focal slowing of conduction across the carpal tunnel. Special adaptations may be necessary to demonstrate milder carpal tunnel syndromes.[26,52]

The next most sensitive feature is a decrease in amplitude of the sensory response. Increased distal motor latency is seen less frequently, and reduced amplitude of the median motor response is even less common. In severe carpal tunnel syndrome there is acute or chronic denervation on needle examination of the abductor pollicis brevis, suggesting axon loss of median motor nerve axons. The severity of clinical weakness and sensory loss, but not of the complaints of tingling and pain, correspond in general with the severity of electrodiagnostic findings.

Median and sensory nerve conduction studies provide accurate and reproducible measurements that can confirm a clinical diagnosis of carpal tunnel syndrome with a high degree of sensitivity (66–82%) and specificity (82–97%).[26]

The MRI of the wrist can document abnormalities in the median nerve that are compatible with carpal tunnel syndrome.[27] The MRI may be helpful if tumours or other structural abnormalities are suspected. A routine wrist X-ray is not useful unless it is to demonstrate a fracture of the wrist.

Management

Carpal tunnel syndrome, unless accompanied by a severe clinical deficit, is usually first treated conservatively with the use of a resting wrist splint and advice to reduce provoking activities. This is successful in about 50% of patients and gives permanent relief only in 50% of these patients. Steroid injections into the carpal tunnel can provide immediate relief, but this is usually not sustained and local complications may occur. If conservative treatment is not effective, surgical carpal tunnel release is performed. This results in an improvement rate of 80–90%.[15] Patients can usually return to work in 2–3 weeks. It should be kept in mind that this rate of success comes down significantly in patients who would be seeking compensation. Endoscopic carpal tunnel release supposedly produces less scarring than open surgery, but precludes visualisation of the median nerve properly. Controversy remains regarding which procedure is the best.[13,17,39,45,50,54,57] However, certain advantages of endoscopic treatment are earlier return to work, less immediate post-operative pain and avoidance of post-operative splinting. More recent innovations like the use of single portal endoscopic technique has made the procedure much less invasive. At the All India Institute of Medical Sciences, New Delhi, both the authors developed an endoscopic carpal tunnel system, which is compatible with most of the endoscopic systems. Since 2000, about 127 patients were operated upon using a patented disposable endoscopic carpal tunnel instrument (patent no. 306/DEL/2009). Using this instrument, the procedure requires just two small sutures (wrist and palm) and the procedure takes about 5–10 minutes. In the majority of patients the symptoms were severe (87%). Post-operative relief was obtained in more than 90% of cases over a follow-up period of 6–56 months.

Prognosis and Complications

The prognosis for recovery is good with either conservative or surgical treatment. The complications include persistent weakness and sensory loss in the distal median nerve distribution. The most dramatic complication is complex regional pain syndrome, a condition which is characterised by severe pain, hyperalgesia, dysaesthesia and trophic disturbances.

Median Nerve Entrapment at Other Sites

Entrapment of the median nerve at other regions of the upper limb is much less common (Fig. 2).

After carpal tunnel syndrome, the most common median nerve entrapment is the pronator teres syndrome.[4] Other less common entrapment sites include the ligament of Struthers, lacertus fibrosus and the tendinous origin of the flexor digitorum superficialis. In 1848, Struthers depicted in fine detail the supracondylar process 5 cm above the medial epicondyle and its ligament. Struthers' ligament can compress the median nerve.[36] Anterior interosseous neuropathy was originally described in two patients who had spontaneous recovery.[30] Median nerve entrapment under the bicipital aponeurosis was described over three decades ago.[33]

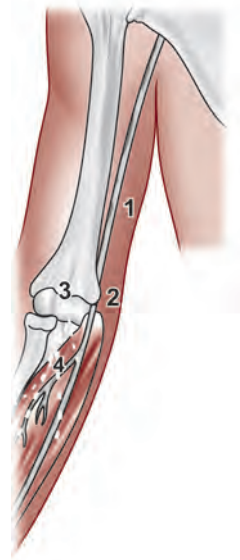

Fig. 2: Median nerve entrapment at other regions of the upper limb (apart from carpal tunnel): (1 and 2) Paralysis des amants; (3) Ligament of Struthers compression 1–2%; (4) Lesion in the pronator teres space (most common cause of median nerve entrapment after carpal tunnel)

Ulnar Entrapment at the Elbow

Ulnar neuropathy is the second most common entrapment neuropathy. In contrast to carpal tunnel syndrome, in which sensory impairment is generally the most significant disability, motor loss is usually the most important problem in ulnar nerve entrapment, most notably in the intrinsic muscles of the hand.[8,11]

Aetiology

There are at least four potential sites of compression of the ulnar nerve in the region of the elbow:

1. At the medial intermuscular septum (arcade of Struthers) just above the elbow.
2. In the retroepicondylar (ulnar) groove.
3. At the humeroulnar aponeurotic arcade ("cubital tunnel").
4. At the nerves' point of exit from the flexor carpi ulnaris.

Lesions in the ulnar groove account for most cases, but humeroulnar aponeurotic arcade compression is also common.[11] The exit compression syndrome is infrequent, but does turn up regularly if one is sensitive to its existence. Compression at the medial intermuscular septum is rare.

In the majority of patients with ulnar neuropathy at the elbow, the initial symptoms are intermittent ulnar distribution numbness and tingling, often associated with elbow flexion. Similar to carpal tunnel syndrome, these symptoms are most noticeable at night. With mild

involvement, such intermittent symptoms may persist for months or years. Patients may not seek medical care until significant intrinsic hand muscle atrophy develops. The ulnar sensory distribution typically includes the palmar surface of the little finger and the ulnar half of the ring finger. The ulnar aspect of the palm is innervated by the palmar cutaneous branch that arises proximal to the wrist. The dorsal cutaneous branch supplies the dorsal ulnar aspect of the hand and fingers. Sensory loss is usually easiest to detect over the tip of the little finger, and diminution of sensibility is usually more pronounced for light touch and two-point discrimination as opposed to pinprick and temperature. The ulnar nerve provides fine motor control, co-ordination, and dexterity to the hand, in contrast to the median nerve that provides more in the way of raw power. The median nerve has been called the "workman's nerve" and the ulnar nerve the "musician's nerve". A frequent early manifestation of ulnar neuropathy is a tendency of the small finger to get "hung up", as when placing the hand in a pocket, and an abducted posture of the small finger on examination (Wartenberg sign). Observing the patient's ability to touch the index to the small finger is a good test of interosseous function. Another useful manoeuvre is to have the patient press their first dorsal interosseous or abductor digiti minimis together to see if one side overpowers the other.

Froment sign results from substituting the flexor pollicis longus to adduct the thumb and provide a pincer function. The ulnar griffe, or claw deformity, is due to weakness of the third and the fourth lumbricals. The lumbricals flex the metacarpophalangeal joints and extend the proximal interphalangeal joints. In ulnar lesions, unopposed extensor tone at the metacarpophalangeal joints and unopposed flexor tone at the proximal interphalangeal joints draw the ring and small fingers into a position with extension at the metacarpophalangeal joints and flexion at the proximal interphalangeal joints. Clawing varies depending on the amount of muscle weakness, the laxity of the metacarpophalangeal joints and the level of the lesion. A "low" (distal) ulnar lesion with preserved function of the flexor digitorum profundus induces more clawing than a "high" (proximal) ulnar lesion, where the accompanying long finger flexor weakness creates less of the unopposed flexor pull deforming the ring and small fingers. Conditions other than ulnar neuropathy can produce a hand deformity mimicking ulnar clawing.[10]

Evaluation of a patient with suspected ulnar neuropathy at the elbow should include examination of the elbow both for range of motion and for deformity. Impaired range of motion, flexion contracture, valgus deformity, or other bony or joint abnormality suggests an elbow level lesion. Reproduction of symptoms with elbow flexion and ulnar groove pressure can be informative. Worsening of the hypaesthesia or pain with sustained elbow flexion, especially if combined with digital pressure over the nerve, suggests ulnar nerve compression near the elbow (the "elbow flexion" test). Eliciting Tinel's sign can be useful, but many normal individuals "Tinel" over all their nerves; only the presence of a disproportionately active Tinel's sign over the clinically suspect ulnar nerve has any localising value. Palpation of the nerve itself may disclose an area of thickening or point tenderness. Each of these tests should be compared with the opposite extremity.

A nerve conduction study is also a useful diagnostic test, with conduction delays of at least 10 m/s in the affected arm relative to the unaffected arm. When significant atrophy is noted, differences of at least 15 m/s are typically found.[4] Pronounced ulnar nerve thickening at the time of the diagnosis is associated with poor outcome at follow-up, especially in conservatively treated cases, whereas electrodiagnostic signs of demyelination on testing indicate a favourable outcome.[8]

Prevention

The symptoms, when they occur due to external pressure and excessive elbow motion, can be prevented by avoiding the precipitating factors.

Differential Diagnosis

Weakness of non-ulnar C8 muscles is the usual clue to disease involving the lower brachial plexus, C8 root or cervical spinal cord. This finding should, in turn, prompt further examination of the cervical spine and a check for Horner's syndrome. Elderly patients, particularly those with dementia, Parkinson's disease and other debilitating illnesses, may have non-specific atrophy of the hand muscles that should not be mistaken for ulnar neuropathy. An ulnar nerve lesion at the wrist can usually be identified by more significant slowing of nerve conduction across the wrist than across the elbow, a normal dorsal ulnar cutaneous sensory potential, and by lack of denervation in the forearm. A lesion of the deep palmar branch produces a characteristic, but complicated electrodiagnostic picture. True neurogenic thoracic outlet syndrome (TOS) classically produces ulnar distribution paraesthesias and sensory loss accompanied by median distribution weakness and atrophy. Possible diagnoses of amyotrophic lateral sclerosis and syringomyelia can be excluded by identification of sensory nerve abnormality and the finding of denervation restricted to ulnar-innervated muscles. A polyneuropathy presenting as an ulnar nerve lesion can be recognised by identifying generalised abnormalities of nerve conduction. Several neurologic and non-neurologic conditions can produce an abnormal hand posture (pseudoulnar claw) that could be confused with an ulnar griffe.[11]

Dupuytren contracture is a painless thickening characterised by fibroblastic proliferation and disorderly collagen deposition of tissue beneath the skin on the palm of the hand and fingers. Subsequently, nodules will form due to contraction of fibroblasts in the superficial palmar fascia.

Management

The treatment of ulnar neuropathy at the elbow is generally considered surgical, but many patients, especially those with mild involvement, may recover spontaneously or with conservative treatment (Table 1).[16] Conversely, the best surgical outcomes occur in patients with the least severe neuropathies and the shortest duration of symptoms; patients with end-stage neuropathies do poorly. Ulnar nerve surgery, however, does not have the excellent success record of carpal tunnel release; studies generally report a good outcome rate of approximately 70%.

Anterior transposition is the most common ulnar nerve operation. It is done by mobilising the nerve, freeing any attachments at the humeroulnar aponeurotic arcade or medial intermuscular septum and then moving the nerve anterior to the medial epicondyle. The two types of transposition methods now commonly employed are: (1) the subcutaneous, or superficial, and (2) the submuscular, or deep. The nerve is placed superficial to the flexor pronator muscle mass for subcutaneous transposition, and deep to it for submuscular transposition. Complications from any of these procedures include persistent or recurrent symptoms due to inadequate surgery or to recurrent scarring of the nerve. Patients are occasionally left with painful paraesthesias and significant disability due to chronic pain. Submuscular transposition is often used as a salvage procedure following failed anterior subcutaneous transposition.[1] Recently, there has been renewed interest in the old surgical concept of reconstruction of the ulnar groove.

The main advantage of decompression and medial epicondylectomy over transposition is preservation of the ulnar nerve blood supply, as extensive dissection with the possibility of devascularisation of the ulnar nerve is unnecessary. More recently, an endoscopic release has also been described but the results are too early to derive any conclusions.[41]

Table 1: Conservative treatment of ulnar neuropathy at the elbow

Minimisation of elbow flexion
Elbow pads
Arms never crossed
Forearm supinated and resting on thigh while sitting
Telephone in asymptomatic hand only
Book stand for reading
Avoidance of external pressure
Elbow pads or night splints
Elbow resting on pillow during desk work
Nonsteroidal anti-inflammatory drugs when repetitive motion is involved

(Source: Modified from Dellon et al. 1993)[21]

Ulnar Entrapment at Other Regions

This is much less common (Fig. 3).

Prognosis

Electrodiagnostic studies can predict which patients may have a progressive or deteriorating course. The likelihood of spontaneous recovery is greatest in those with the mildest electrophysiological abnormalities. In patients with persistent paraesthesias, abnormal two-point discrimination and any degree of muscle wasting, surgery will eventually be necessary. A history of elbow injury significantly worsens the outcome. The best surgical approach remains a matter of dispute and likely differs from patient to patient. A 27-year literature review was unable to formulate a uniform guideline for operative treatment.[7]

Radial Nerve Entrapment

Radial neuropathy most commonly presents with sudden painless wrist and finger drop. There may be associated paraesthesias or numbness over the dorsum of the hand. The clinical picture sets radial neuropathy apart from confounding conditions and generally helps in lesion localisation.

Radial neuropathy is most commonly due to compression at or around the spiral groove. Due to its more proximal innervation, the triceps muscle is spared. Elbow flexion may seem to be intact due to the biceps muscle compensating for the weakened brachioradialis muscle. More commonly, brachioradialis muscle palpation during elbow flexion reveals a flaccid tone. Motor deficit involves wrist and finger extensor muscles. Sensation is impaired over the dorsum of the hand, mainly in the region of the first and the second metacarpals. Radial

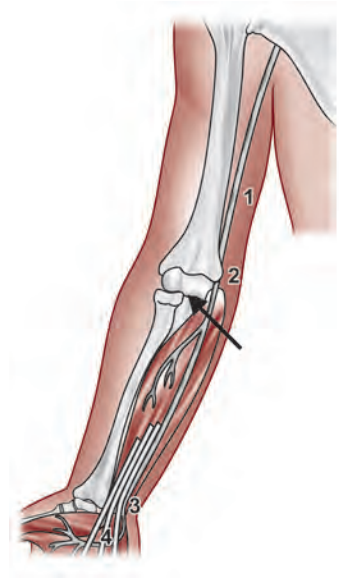

Fig. 3: Ulnar nerve entrapment at various regions of the upper limb: (1) Paralysie des amants; (2) Tardy ulnar nerve palsy; (3) Proximal portion of Guyon's canal; (4) Within palm (Bicyclist's paralysis); (5) Cubital tunnel syndrome (long arrow)

nerve injury proximal to the spiral groove is less common. In addition to spiral groove lesion manifestations, the triceps muscle is weak and the triceps deep tendon reflex is reduced or absent. When present, sensory loss may extend beyond the hand to the posterior forearm.

Lesions a few centimetres distal to the elbow result in posterior interosseous neuropathy. The acute to subacute progressive weakness involves one or more adjacent metacarpophalangeal joint extensors. Interphalangeal joint extension is innervated by the ulnar and median nerves and is, therefore, spared. Elbow pain occurs in 50% of these patients and usually clears in a few days. Tenderness can occur 5 centimetres distal to the elbow. Useful features are pain reproduction or exacerbation by pressure, resisted supination with 90-degree elbow flexion or middle finger extension, and relief by local anaesthetic injection. There is typically no sensory loss. The spared extensor carpi radialis brevis and longus muscles result in radial deviation on wrist extension.

Superficial radial neuropathy induces paraesthesias over the dorsum of the hand. At times, this may be painful. A handcuff or watchband may additionally compress the median and ulnar nerves. Superficial radial neuritis, or Wartenberg syndrome, is associated with pain at the radial styloid radiating to the hand and is exacerbated by ulnar deviation of the wrist. Tinel sign is usually positive over the junction of the middle-to-distal third of the radius.

Aetiology

Compression, trauma and entrapment are the main mechanisms of radial nerve injury. Tumour, systemic disease and birth trauma constitute less common causes.

Radial nerve compression is most frequently at or within close vicinity of the spiral groove.[55] The radial nerve, in "saturday night palsy", may be compressed during sedation, deep sleep, inebriation or by the head of a sleeping partner. Triceps muscle fibrosis induced by chronic analgesic intramuscular injection may cause severe progressive painless radial neuropathy. Radial nerve compression may occur more proximal due to inappropriate crutch pressure at the axilla, prolonged tourniquet application, frequent automated blood pressure cuff inflation or poor arm position during anaesthesia. Radial nerve compression at the axilla or arm may be associated with ulnar or median nerve dysfunction. Windmill pitchers may develop radial neuropathy at variable sites proximal to the spiral groove.[53] Due to its course around the spiral groove the radial nerve is injured in 15% of humeral fractures.[9]

The differential diagnosis of radial neuropathy includes C7 radiculopathy, posterior cord brachial plexopathy and extensor tendon rupture. Radial neuropathy can be confused with stroke due to apparent intrinsic hand muscle weakness. When the wrist and metacarpophalangeal joints are passively extended, patients with radial neuropathy can better activate median and ulnar-innervated lumbricals, thereby extending their interphalangeal joints. Similarly, wrist extension dramatically improves interosseus muscle strength. These manoeuvres eliminate most of the mechanical disadvantage in radial neuropathy. They do not, however, improve stroke-related hand weakness.

Radial neuropathy at the spiral groove is typically associated with motor conduction block. Additionally, 60–90% of cases display active denervation mostly due to secondary axonal loss. Distal muscle denervation may persist in 60% of cases for at least 2–4 years after full clinical recovery. In most instances, denervation involves the brachioradialis muscle as well as the extensor digitorum communis, extensor indicis proprius and the extensor carpi radialis.

Management

With few exceptions, conservative management with clinical and electrodiagnostic follow-up is the rule for radial neuropathies. Most patients with radial palsies induced by compression recover fully within 2–12 months. Faster and more complete recovery is anticipated with neuropraxia. All patients with radial neuropathy should wear a splint with passive dorsiflexion at the wrist and fingers. In the absence of clinical and electromyographic recovery of severe radial neuropathy, surgical exploration after 3–5 months is indicated, and intra-operative radial nerve conduction studies are helpful.

Indications for early exploration of post-traumatic radial neuropathy include complex humeral fractures or weakness developing after closed reduction of a simple fracture. Exploration of a simple humeral fracture may be delayed for 2 months to allow for spontaneous radial nerve recovery. Successful nerve graft induces return of function in 12–18 months. Delayed tendon transfers may restore wrist extension.

Conservative management of spontaneous superficial radial neuropathy includes prevention of external compression at the wrist, avoidance of repetitive wrist movements, nocturnal wrist splints and local anaesthetic or steroid injection. Otherwise, surgical decompression is effective as it is for traumatic radial nerve laceration.

Most patients with tennis elbow respond well to 6–12 months of conservative therapy including rest, activity modification, physical therapy, nonsteroid anti-inflammatory drugs and local steroid injection. Very few cases require decompression of the posterior interosseous nerve to reduce tension at the lateral epicondyle.

Sciatic Neuropathy

Sciatic neuropathy presents, usually acutely, with foot weakness, pain and sensory loss. Foot pain and dysaesthesia are common major symptoms in most patients. Not infrequently, signs of reflex sympathetic dystrophy (allodynia with skin, nail and bone dystrophic changes) become dominant and disabling. The foot weakness is commonly manifested as a foot-drop, which results in a

diagnostic challenge as sciatic neuropathy may imitate a peroneal neuropathy at the fibular head. In severe sciatic neuropathy, weakness of hamstrings (knee flexion) and gastrocnemius muscles (plantar flexion) is also present. The ankle jerk is usually depressed or absent. Sensory loss and dysaesthesia of the sole and dorsum of the foot and lateral leg are common.

Piriformis Syndrome

The sciatic nerve along with the inferior gluteal and pudendal nerves exits the pelvis through the lower part of the great sciatic foramen deep to the piriformis muscle. The piriformis is attached to the inner face of the bony pelvis and the greater trochanter. The nerve passes over the tendon of the obturator internus muscle and the gemelli. The development of the syndrome depends on muscular activity and hypertrophy. The symptoms are pain, paraesthesiae and motor weakness. Due to the involvement of the pudendal nerves the patient, along with sciatica, may have pain radiating to the groin.

Aetiology

Sciatic neuropathy is caused by external compression of the nerve, or by stretching around the hip during surgical procedures. Less common causes include injection injuries, vasculitis and gunshot or knife injuries.

The treatment of patients with sciatic neuropathy is mostly directed towards the management of pain with tricyclic antidepressants, anticonvulsants and topical analgesia. Initially, the foot-drop will require an ankle-foot orthosis. Leg elevation and stockings are useful when swelling is prominent. Surgical exploration and neurolysis or grafting is sometimes necessary in patients who do not show signs of re-innervation. In cases of sciatic nerve lesions due to a number of aetiologies, the presence of positive intra-operative nerve action potentials seems to indicate a better surgical prognosis. In those patients with nerve action potentials who underwent neurolysis, 87% of buttock-level injuries and 91% of thigh-level injuries attained at least Grade 3 functional outcomes post-operatively.[32]

Management

The treatment of the piriformis syndrome is controversial and often difficult. Conservative therapy includes stretching of the piriformis muscle by flexion, adduction and internal rotation of the symptomatic hip. Injection into the piriformis muscle with corticosteroids, preferably done under imaging guidance, may also result in relief of buttock pain. Botulinum toxin injection may reduce the pain in a significant number of patients.[20] Surgical exploration of the sciatic nerve in the region of the piriformis muscle is indicated only in cases resistant to conservative therapy. Abnormal bands or vessels constricting the sciatic nerve in the buttock should also be removed.[25] Section of the piriformis muscle is the most popular advocated procedure, but its value is uncertain. Sciatic nerve varices may respond to foam sclerotherapy, leading to complete obliteration of the offending vein.[46]

Peroneal Neuropathy

The most common causes of peroneal neuropathy include external compression, trauma, tumours or vasculitis.

Peroneal neuropathy usually presents with acute foot-drop. However, in some instances, the foot-drop develops subacutely over days or even weeks. Foot-drop may be complete, with failure to dorsiflex the ankle and toes, or partial. The foot may get trapped or may cause the patient to fall. Numbness while walking usually involves the dorsum of the foot and lower lateral leg; pain, however, is rare and, when present, is deep and ill-defined, usually located around the knee. On examination, the weakness is restricted to ankle eversion and ankle and toe dorsiflexion. Ankle inversion, toe flexion and plantar flexion are normal. An apparent weakness of ankle inversion is common with complete foot-drop, since inversion is best obtained with the foot slightly dorsiflexed. To avoid this misleading sign in a patient with foot-drop, the ankle should be dorsiflexed passively to 90 degree while testing ankle inversion. In a large study of common peroneal neuropathy,[2,29] 43% of cases were clinically misdiagnosed by physicians, including neurologists. Hypaesthesia to touch and pain is limited to the lower two thirds of the lateral side of the leg and dorsum of the foot. Tinel's sign may be elicited by percussion of the peroneal nerve around the fibular neck. Knee and ankle reflexes are normal. The hamstrings, glutei and quadriceps are normal. In selective deep peroneal neuropathies, which are much less frequent than common peroneal neuropathies, the sensory manifestations are lacking (except occasionally in the first web space), and ankle eversion is normal.

Table 2 shows the clinical differences between various causes of foot drop, which could be confused with peroneal neuropathy.

Diagnosis

Conduction block at the level of the neck of the fibula is a useful localising electrodiagnostic sign. Focal slowing is present in a minority of patients and is usually associated with conduction block. Conduction block can be found in 50–70% of patients with common peroneal nerve palsy related to postural positioning and weight loss.[3] Low amplitude or absent motor response (consistent with pure axonal loss) is observed in half of the patients, whereas pure conduction block and mixed lesions share the other half. At least three fourths of patients have a significant degree of axonal loss as revealed by a low distal compound muscle action potential. The MRI of the knee can be useful in the detection of tibiofibular joint cysts as a cause of suspected idiopathic peroneal nerve palsies.[6]

Table 2: Clinical differential diagnosis of common causes of foot drop

	Peroneal neuropathy at the fibular head	*L5 radiculopathy*	*Lumbar plexopathy (lumbosacral trunk)*	*Sciatic neuropathy (mainly peroneal)*
Common causes	Compression (weight loss, peri-operative), trauma	Disc herniation, spinal stenosis	Pelvic surgery, haematoma, prolonged labour	Hip surgery, injection injury, coma
Ankle inversion	Normal	Weak	Weak	Normal or mildly weak
Toe flexion	Normal	Weak	Weak	Normal or mildly weak
Plantar flexion	Normal	Normal	Normal	Normal or mildly weak
Ankle jerk	Normal	Normal (unless with S1)	Normal (unless with S1)	Normal or Depressed
Sensory loss distribution	Peroneal only	Poorly demarcated, predominantly big toe	Well demarcated to L5 dermatome	Peroneal and lateral cutaneous of calf
Pain	Rare, deep	Common, radicular	Common, can be radicular	Can be severe

Management

In managing acute compressive lesions, patients should be observed to allow for improvement by remyelination or reinnervation. Conduction block lesions (due to segmental demyelination) recover spontaneously in 2–3 months time, as long as further compression is prevented. Ankle bracing is important when the foot-drop is profound to prevent ankle contractures and sprains. Surgical intervention is appropriate in certain situations.[21]

- In cases of compound injuries when the nerve is lacerated and visibly discontinuous: This repair could be primary (at the time of suturing of laceration) or secondary (if local infection is feared). In cases with open wounds and when a nerve transection is suspected, surgery can be performed on an emergent basis and may be advisable in some cases, although factors favouring surgery have not been determined. Recovery in this group is uniformly poor.
- When clinical or electromyography (EMG) evidence for re-innervation has not been established in the tibialis anterior despite 4–6 months passing since the time of injury. Here, the nerve lesion is likely to be severe, at least of the third degree. In such cases, neuroma formation occurs in 66%, and surgery consists of neuroma resection and grafted nerve repair.
- In slowly progressive peroneal neuropathies, a nerve tumour, ganglion, cyst or, rarely, when true entrapment is suspected, the nerve is explored after appropriate electrodiagnostic localisation. Imaging studies, particularly MRI, are helpful in these situations.

One procedure for correction of such common peroneal nerve traumatic injuries is a 1-stage procedure of nerve repair and tibialis tendon transfer.[21] At 2-year follow-up, evidence of nerve regeneration is present in 90% of patients undergoing such a procedure.

Depending on the nature of the traumatic common peroneal nerve injury, different surgical procedures will be required. Neurolysis in patients with knee-level common peroneal nerve lesions with recordable intra-operative nerve action potentials led to 88% of the patients recovering useful function. In cases of nerve transection, end-to-end suture repair can lead to good recovery in 84% of patients by 24 months.[31] The length of graft required in traumatic lesions where graft repair is necessary impacts on outcome. When grafts less than 6 cm long are required, 75% achieve good peroneal function, whereas only 38% of patients requiring 6–12 cm grafts and 16% of patients requiring 13–24 cm grafts attained good peroneal function.[31]

Tibial Neuropathy

Tibial nerve injuries are best considered based on the anatomic site of the lesion. The divisions are arbitrary, but include the proximal tibial nerve, the distal tibial nerve or plantar nerves (including the individual plantar nerves at or distal to the tarsal tunnel), the interdigital nerves and the sural nerve.

Proximal Tibial Nerve

Due to its anatomic location, damage solely to this nerve is rare. It has been associated with Baker's cysts, trauma to either the knee or ankle, nerve sheath tumours, soleus muscle tendinous arch entrapment, and a host of rare and unusual causes including posterior tibial nerve impingement from a tibial spine fixation screw. More recently, tibial nerve injuries have been reported following subfascial endoscopic perforating vein surgery.

Due to the proximal nature of these lesions, patients present with weakness of foot plantar flexors and foot invertors, long toe flexors, and intrinsic foot muscles. Sensory loss usually involves the sole of the foot. It is important during the physical examination to palpate the popliteal fossa looking for evidence of a mass such as a Baker's cyst or neoplasm.

Distal Tibial and Plantar Nerves

The tibial nerve and its terminal branches, the medial and lateral plantar, and medial calcaneal can be compressed within the tarsal tunnel (the roof of which is formed by the flexor retinaculum) at the ankle. The most common pathology relates to external compression from shoes that are too tight or to plaster casts. Others include post-traumatic fibrosis, tendon sheath cysts, rheumatoid arthritis and hypothyroidism. The plantar nerves may be damaged within the tarsal tunnel or more distally, as they course through the arch and sole of the foot. The medial plantar nerve is injured more commonly than the lateral.

Clinical manifestations include foot and ankle pain along with paraesthesias on various areas on the sole of the foot depending on the particular terminal nerve involved. If there is sensory loss on the heel, usually the medial calcaneal sensory branch is involved, localising the lesion to within or proximal to the tarsal tunnel.

Digital Neuropathies (Morton Neuromas)

The inter digital nerves can become compressed between the adjacent metatarsal heads or stretched where they cross the deep metatarsal ligament. Although debated, the nerve in the third metatarsal interspace is most frequently involved. Joplin neuroma refers to a digital neuroma on the medial side of the great toe being compressed by ill fitting shoes or scarring after bunion surgery.[28]

Sural Neuropathy

The sural nerve can be injured by a Baker's cyst in the popliteal fossa or more distally by vein stripping or compression. The most common cause of an isolated sural neuropathy, currently, is nerve grafting or biopsy. After biopsy, the nerve may occasionally become hyperpathic, with unpleasant or painful paraesthesias experienced over the lateral side of the ankle and foot. The sural nerve can also be injured at the ankle by tendon sheaths and scar tissue. Sural nerve entrapment, localised to its course as it passes through the superficial sural aponeurosis, is described in athletes. Such entrapment results in chronic calf pain, exacerbated by physical exertion. Electrodiagnostic testing may be helpful in making the diagnosis. The results of surgical decompression are encouraging.[19]

Thoracic Outlet Syndrome

The term thoracic outlet syndrome (TOS) is a misnomer, as there are truly multiple forms of this syndrome, and the term thoracic outlet syndromes should always be used instead. Partially as a result of multiple syndromes being expressed as one, there has been great confusion and controversy about the thoracic outlet syndromes. Many physicians doubt the existence of thoracic outlet syndromes, while other physicians have a great deal of disagreement regarding the diagnosis and optimal treatment of the thoracic outlet syndromes. Problems with the diagnosis of TOS have led to great variance of incidences ranging 3–80 cases per 1,000 populations.

Clinical Manifestations

Before discussing the clinical manifestations, it is important to distinguish the different forms of TOS.

True neurologic or neurogenic TOS: This is the only type with a clear definition that most clinicians will agree with. The disorder itself is rare and is usually due to congenital anomalies, but presents in middle-aged women and almost always unilaterally. Symptoms include weakness and wasting of hand muscles, and numbness in the hand. Although pain can be a feature, it is often disproportionate to the development of sensory and even motor dysfunction within the hand. Here, the neurologic and electrophysiological abnormalities are more marked.

Non-neurogenic TOS: This is the common form of TOS, and also the most non-specific form. This is the highly controversial disorder, which frequently frustrates clinicians and leads to disputes in the literature. The most prominent symptom of this disorder is pain and neurologic/electrophysiological findings are limited.

Arterial TOS: Arterial TOS is rare and is also caused by a congenital anomaly. It affects both males and females, and is often found in young people. Symptoms may include hypersensitivity to cold in the hands and fingers, numbness or pain in the fingers, and finger ulcers (sores) or severe limb ischaemia (inadequate blood circulation) in unusual cases.

Venous TOS: This is also a rare disorder which affects both men and women. The exact cause of this type of TOS is unknown, but it has been reported as presenting suddenly following unusual, prolonged limb exertion.

Traumatic TOS: This syndrome may be due to either trauma, such as a motor vehicle accident, repetitive activities, or with hyperextension injury. The common presentation in this syndrome is pain and paraesthesias, and uncommonly, weakness.

Aetiology

There are three major causes of TOS: (1) anatomic; (2) trauma/repetitive activities and (3) neurovascular entrapment at the costoclavicular space.

1. *Anatomic:* Anatomical variants at the scalene triangle, often due to the anterior scalene muscle frontally, middle scalene muscle posteriorly, and the upper border of the first rib inferiorly, can account for at least some cases of neurologic TOS. Cervical ribs are an uncommon cause of neurologic TOS, but congenital fibromuscular bands may lead to as much as 80% of neurologic TOS.[23]

2. *Trauma or repetitive activities:* This is a more controversial cause of TOS and specifically of neurogenic TOS. Hyperextension injury during motor vehicle accidents, with subsequent fibrosis and scarring may lead to non-neurogenic forms of TOS. Musicians may be susceptible due to positioning of their shoulder in abduction or extension for long periods of time, although this is unlikely to lead to neurogenic TOS.
3. *Neurovascular entrapment:* Entrapment may occur in the costoclavicular space between the first rib and the head of the clavicle. This is a more frequent cause of non-neurogenic TOS.

True neurologic TOS usually presents with unilateral symptoms and signs, and often starts with pain. The typical patient has previously been described as a young, thin female with a long neck and drooping shoulders,[22,34] although the droopy shoulder syndrome may be mistaken for TOS. It is the lower two nerve roots of the brachial plexus, C8 and T1, which are most commonly (90%) involved, producing pain and paraesthesias in the ulnar nerve distribution. Often, pain may be the only feature for years, and the development of other symptoms occurs slowly. Pain is often described as dull and aching, and is felt over the lateral side of the neck, shoulder, axilla and parascapular region. Pain may be accompanied by paraesthesias, which are often intermittent and often can be nocturnal, leading to the patient waking up from sleep. Discomfort may be provoked with repetitive use of the arm, particularly with overhead activities. Both pain and paraesthesias over the arm are frequently localised over the medial forearm and the 4th and 5th digits. Sensory loss may occur over the same anatomical distribution, with a pattern clinically referable to the lower trunk of the brachial plexus. Weakness and muscle atrophy will tend to affect distal muscles of the arm, and classically affect the thenar muscles more than the hypothenar muscles.

Although much less common and even more disputed, the second most common anatomic pattern involves the upper nerve roots of the brachial plexus, C5, C6 and C7, with symptoms referred to the neck, ear, upper chest, upper back and outer arm in a radial nerve distribution. These patients present with pain and few neurologic or electrophysiological abnormalities.

A number of provocative tests have been described for TOS. The Adson, costoclavicular and hyperabduction manoeuvres are unreliable. Approximately 92% of asymptomatic patients have variation in the strength of the radial pulse during positional changes. Tinel's sign over the supraclavicular fossa has been described as a potential sign.

The elevated arm stress test (EAST) is possibly the most reliable screening test, although it is non-specific and evaluates all three types of TOS. This test can be performed by having the patient sit with the arms abducted at 90 degree from the thorax and elbows flexed at 90 degree. The patient then opens and closes the hands for 3 minutes. In patients with TOS, they cannot continue due to reproduction of symptoms.[22] In contrast, patients with carpal tunnel syndrome would be expected to have dysaesthesias in the fingers, but not shoulder or arm pain.

Differential Diagnosis

A number of diseases can mimic the presentation of TOS. In most clinical situations, TOS is a diagnosis of exclusion.

- Ulnar and median nerve entrapment
- Cervical disc herniation
- Cervical vertebral osteophyte formation
- Brachial plexitis
- Pancoast tumour
- Nerve sheath tumour
- Spinal cord tumour or other mass lesion
- Syringomyelia
- Multiple sclerosis
- Complex regional pain syndrome.

Diagnostic Workup

Nerve conduction studies and EMG can be helpful in the diagnostic evaluation of patients with suspected TOS.[34,56] In severe cases of true neurogenic TOS, nerve conduction studies may reveal the following characteristics:

- Decreased amplitude of ulnar sensory nerve action potentials
- Decreased amplitude of median compound motor action potentials
- Normal or slightly decreased ulnar compound motor action potentials
- Normal median nerve sensory nerve action potentials.

The EMG may reveal severe abnormalities in the intrinsic muscles of the hand in some cases. These electrodiagnostic findings are due to abnormalities within the lower trunk of the brachial plexus (C8-T1). All of the C8-T1 sensory fibres course within the ulnar nerve, accounting for the decreased ulnar SNAPs. The C8-T1 motor fibres are carried within both median and ulnar nerves, but the median motor fibres are preferentially injured due to their location within the lower trunk.

Imaging studies can be useful in the diagnosis of true neurogenic TOS. Cervical spine and chest X-rays can identify bony abnormalities, including cervical ribs or prominent, often "peaked" C7 transverse processes. Anomalous cervical ribs are found in approximately 10% of patients with TOS (compared to 0.5% in the normal population).The MRI and CT are most useful in the identification of conditions in the differential diagnosis of neurogenic TOS.

Management

For most patients with true neurogenic TOS, conservative treatment is reasonable to offer first. Conservative management includes the modification of behaviour

by avoiding provocative activities and arm positions. Improvement with purely conservative management of TOS ranges from 50 to 90%.[22,34,40,43,51]

Surgical intervention is usually indicated in the true neurogenic form of TOS, in which conservative management most often is unsuccessful. Surgical management for patients with the non-specific or non-neurogenic type of TOS is more controversial. The two most commonly used surgical approaches for the treatment of neurogenic TOS are the anterior supraclavicular and the transaxillary approach for resection of the first rib. The anterior supraclavicular approach is preferred by most neurosurgeons, as it provides for wide exposure of the supraclavicular plexus and middle two thirds of the first rib, where most of the congenital bands are located. The first rib can be resected using this approach. Relief can be expected in about 80% of cases.[43] The transaxillary approach with resection of the first rib is the technique preferred by most thoracic surgeons and many vascular surgeons.[47] The advantage of this approach is easy access for resection of the entire first rib without significant risk to neurovascular structures.

Since 2005, it has been seen that pectoralis minor syndrome (PMS) was associated with more than 75% of patients diagnosed with neurogenic TOS. Its recognition is important as many patients with suspected neurogenic TOS may be treated successfully with a simple, essentially risk-free pectoralis minor tenotomy. Should this fail, thoracic outlet decompression can always be performed at a later date.[49] The clinical picture is of pain or tenderness in the anterior chest wall and axilla together with physical findings of tenderness over the pectoralis minor tendon. Other symptoms include extremity pain, weakness and paraesthesia, similar to symptoms of neurogenic TOS. Recently, endoscopic transaxillary rib resection has been described for TOS.[12]

Meralgia Paraesthetica

This is a painful condition attributed to entrapment or injury to the lateral femoral cutaneous nerve at the site where the nerve leaves the pelvis. The patient with meralgia paraesthetica may complain of a dull ache, itching, numbness, tingling or burning sensation over the lateral and anterolateral thigh.[18,35,37,58] The pain associated with this condition may vary in intensity from mild to very severe and frequently occurs following activity with relief following rest. The lateral femoral cutaneous nerve originates from the posterior division of the L2 and L3 nerve levels and is a pure sensory nerve. Following emergence from the intervertebral foramina of L2 and L3, the nerve traverses the abdomen, first making an appearance at the lateral border of the psoas muscle, and then passing obliquely across the iliacus muscle towards the anterior superior iliac spine. The nerve then exits the pelvis just medial to the anterior superior iliac spine (ASIS) by traversing the fibres of the inguinal ligament. The nerve is surrounded by the tendinous fibres of the inguinal ligament at this point and makes a right-handed bend to change direction from a horizontal course in the pelvis to a more vertical course in the lateral and anterolateral thigh. Various hypotheses have been formulated for the cause of this condition based on the anatomical relationship between the lateral femoral cutaneous nerve and the structures associated with the inguinal region:

- The nerve may be angulated or compressed against a sharp edge of fascia as it pierces the iliac fascia prior to exiting the pelvis beneath the inguinal ligament.
- The nerve may be subjected to friction where it is wedged between the attachment of the inguinal ligament and the ASIS.
- The nerve may pass through the tendinous fibres of the inguinal ligament and be pinched at this site.

In diagnosing meralgia paraesthetica, care should be taken to rule out intraspinal, retroperitoneal, abdominal, or pelvic pathologies, diabetes mellitus, and L3 disc prolapse.[18,35] Clinically L3 disc prolapse may produce alteration of the patellar reflex. In contrast, the reflex will not be altered in meralgia paraesthetica.

Most cases of meralgia paraesthetica will respond to conservative care. Modalities that may prove helpful in the treatment of this condition may include ultrasound, electrical stimulation, or transverse friction techniques to break up possible adhesions affecting the lateral femoral cutaneous nerve at the inguinal region. Postural alterations and functional spinal problems should also be addressed in the management of this condition. Rarely, surgical release is required.

Preface

Since the publication of the second edition of this Textbook in 1996, phenomenal advances have been made towards improved understanding of the pathophysiology of various neurosurgical disorders, their diagnosis and therapy. Advances in molecular biology and genetics on one hand, the refinements of imaging technologies, introduction of image-guided techniques for neuronavigation, and refinements in endoscopic and minimally invasive procedures on the other hand have markedly reduced the morbidity and mortality of neurosurgery. Simultaneously, better availability of radiosurgery and safer endovascular approaches have led to the development of non-surgical therapy for a variety of lesions.

Recent years have witnessed a rapid increase in the number of well-equipped neurosurgical departments across the country providing both state-of-the-art services to the patients and training to specialists in the diverse subdisciplines of neurosurgery. It has been our endeavour to meet their needs for an updated account of the current knowledge of the subject.

The third edition of the textbook includes a comprehensive account of all the recent advances succinctly provided by a galaxy of outstanding contributors especially selected on the basis of their expertise and experience. Care has been taken to include relevant published literature both from India and abroad.

As in earlier editions, special attention has been given to tropical disorders not often adequately covered in publications of the West. This may be an additional attraction for neurosurgeons in other developing countries as also to those in the developed ones who often encounter such conditions in their practice.

The present editors deeply miss the invaluable, wise and experienced guidance of the Senior Editor Prof B Ramamurthi who was the moving spirit behind the earlier editions. The editors would like to thank all the contributors, their associates and the secretarial staff for their co-operation. The Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India deserve our special thanks for the excellent quality of the publication.

PN Tandon
Ravi Ramamurthi

Caraka Samhita

The early medical writer Caraka tells us that when setting out to learn about Indian medicine, we should have certain criteria in mind for choosing the texts we wish to study (Caraka. 3.8.3):

"A discerning person who wants to become a physician should start by selecting a text based on a consideration of his ability to cope with hard or easy tasks, the results he is after, the likely aftermath, the place and the time. After all, there are numerous physicians' manuals in circulation in the world, so he should apply himself only to a text which is extremely famous, which is used by scholars, which covers a lot of topics and is respected by qualified people. It has to be good for pupils of all three levels of ability, and it should not be flawed by repetitiousness. It should be derived from the tradition of the saints. The connection and the sequence of the text and commentary should be well organised. It should be solidly based, and have no corrupt or missing words. It should be full of significance, its ideas should follow in sequence and it should give importance to the exactness of what ideas really refer to. Its ideas should be coherent and its topics should not be haphazard. It should have both definitions and examples.

This type of text is like a flawless sun; it dispels darkness and throws light on everything."

The Roots of Ayurveda

60 Brain Abscess

Dharkar SR, Sardana VR, Purohit D

INTRODUCTION

Pyogenic brain abscesses are one of the common neurosurgical emergencies. Although the introduction of antibiotics may have reduced the incidence of brain abscess, it is still a condition which causes a formidable problem in this part of the world.[30] Over the past three decades due to improved diagnostic imaging, particularly with the advent of computed tomography (CT) scan and magnetic resonance imaging (MRI), improved neurosurgical techniques, improvement in neuroanaesthesia and critical care, a better understanding of the pathophysiology and management of intracranial hypertension and with the development of newer anti-microbials, the mortality rate due to brain abscess has reduced from 38% during the 1950s to 25% in the 1980s and 5–10% at present.[106] Despite this reduction in mortality, brain abscess remains a serious and potentially life threatening infection.

INCIDENCE

The incidence of brain abscess is comparatively higher in developing countries as compared to developed countries. In India it is approximately 8% of all intracranial space occupying lesions.[8,30] The annual incidence in the United States is 1 in 10,000 hospital admissions.[88] Brain abscesses are encountered about one sixth as frequently as bacterial meningitis and account for approximately 0.7% of all neurosurgical operations.[106] Several authors have reported a male preponderance (as high as 3:1).[72]

HISTORY

The first reference to brain abscess is attributed to Hippocrates, who in 460 BC, while reporting a febrile patient with purulent otorrhoea and delirium, postulated that intracranial infection was the primary focus and the ear involvement secondary with the ear canal draining the intracranial suppuration.[99] Although Morand (1768) described the disease along with a therapeutic proposal, including the first description of successful drainage of non-traumatic brain abscess,[37] Sir William Macewen was the first physician to diagnose, localise and suggest surgical treatment of brain abscess in a patient.[61] The therapy Macewen recommended for these lesions was drainage of the infective process and treatment of the underlying sinusitis.[62]

Macewen, the father of modern day abscess management, was the first to report 80% survival (8 out of 10 patients) following surgical drainage of temporal lobe abscesses,[62] which is still today a benchmark in the management of brain abscess and has been equalled only recently.[19] Dandy, in 1926, recommended aspiration as the primary surgical modality.[26] Vincent first advocated complete surgical extirpation of brain abscesses.[102]

AETIOPATHOGENESIS

Brain abscess develops either:

- In association with a contiguous suppurative focus
- After cranial trauma
- Haematogenous spread from a distant focus
- Cryptogenic origin
- Due to miscellaneous causes

In Association with Contiguous Suppurative Focus

Brain abscesses occurring due to local extension from contiguous infective foci, like traumatic, surgical, congenital, otic or paranasal infections, usually manifest adjacent to the predisposing focus. They occur as a result of either:

- Direct extension through associated osteitis or osteomyelitis
- Retrograde thrombophlebitic spread via diploic or emissary veins into the intracranial cavity
- Via local lymphatics

Bone infection of the walls of the paranasal sinuses or of the middle and inner ears is the usual precursor of brain abscess. The bone is infected through a necrotic area of mucosa, or by spread through lymphatics and veins penetrating the bone leading to osteomyelitis. In long standing cases caries of the bone leads to dehiscence, the common sites being the posterior wall of the frontal sinus, the tegmen tympani and the lateral part of the posterior surface of the petrous bone (Trautmann's triangle).[90] As compared to the Western countries, in India the commonest source of infection is middle ear suppuration, spread from paranasal sinuses being uncommon.[7,8]

The second line of defence is the dura mater which offers considerable protection against infection on account of its close and tough texture and its good blood

supply. The dura mater may completely resist infection so that an extradural abscess is formed. During the process granulation tissue covers the outer surface of the dura mater. Penetration of the dura mater probably takes place along the course of small vessels which traverse its thickness; they may thrombose and provide convenient pathways. In the majority of cases where a brain abscess is secondary to adjacent bone disease, the brain is adherent to the patch of inflamed dura mater. It is at this point that the abscess cavity usually is near the surface of the brain. This point of attachment is often described as the stalk of the abscess. Cases have been described in which the abscess has discharged its contents through the stalk, through a hole in the dura mater and in the bone, to the exterior.[90]

Otogenic Abscess

The commonest cause of brain abscess is spread of infection from the middle ear and mastoid, which in India accounts for 40–63.3%.[7,30] Typically brain abscesses related to otogenic infection are solitary and they most often develop in the inferior portion of the ipsilateral temporal lobe. In contrast to otogenic infections, mastoid infection typically leads to an abscess in the ipsilateral cerebellar hemisphere. Chronic otitis media and/or mastoiditis leads to intracranial extensions 4–8 times more frequently than does the acute disease. Cholesteatomas complicating chronic otitis or mastoiditis are additional risk factors, increasing the incidence of intracranial extension of infection from 23.2–74%.[65]

Paranasal Sinus Infection

Local spread from infection of the paranasal sinuses leading to abscess formation in the brain, accounts for approximately 15% patients.[12] However, because of earlier diagnosis and treatment of purulent sinusitis and development of more effective antibiotics, the incidence of paranasal sinusitis is decreasing. Most abscesses complicating infection in the frontal, ethmoid or maxillary sinuses occur in the frontal lobe. Intracranial abscess resulting from sphenoid sinusitis tends to occur in either the temporal lobe or the pituitary fossa.

Periodontal Infection

Brain abscess either by contiguous extension from dental infection or by haematogenous seeding occurs in 6–13% of patients.[65,91] They are more likely to occur after infection of the molar teeth, since the infection can spread between the muscles of mastication along the fascial planes to the skull. The site of the abscess is most commonly the frontal lobe, but temporal lobe abscess can also occur by direct extension. Unlike otogenic brain abscesses, odontogenic brain abscesses occur as sequelae of acute rather than chronic infection.[49]

Bacterial Meningitis

Rarely, brain abscesses can result as a complication of meningitis. They occur more frequently in neonates, particularly infants with gram negative meningitis. Cerebral abscesses have been associated with more than 70% of *Citrabacter diversus* meningitis in infants.[106]

Post-Traumatic

The incidence of brain abscess in penetrating and open head injuries is 3–17.2%.[30,76,80] These abscesses result from retained contaminated bone fragments, foreign bodies, hair, etc. However, some investigators have recently questioned the belief that retained bone fragments are the source of brain abscess formation.[16] High velocity bullet injuries or missile injuries devitalise brain tissue leaving fragments of metal or bones which may serve as foci for infection. In general, high velocity bullet fragments and even pellets do not present a significant risk for development of brain abscess because of heat sterilisation and, therefore, do not require removal.[89,106] Patients having skull base fractures with cerebrospinal fluid (CSF) fistula or bleeding through the ear and/or nose are always at risk of developing intracranial infection and rarely an abscess.[89] Post-traumatic abscesses may not develop immediately after the primary injury and in fact many years may elapse before such abscesses appear.[42,75]

Metastatic Abscess

Metastatic abscess results from haematogenous spread of micro-organisms from other parts of the body, frequently from chest infection like lung abscess, bronchiectasis, empyema and cystic fibrosis. Other remote foci of infection include wound and skin infections, osteomyelitis, pelvic infection, cholecystitis and other forms of intra-abdominal sepsis. About 5–18% of patients with cyanotic heart disease develop brain abscess. These patients are ten times more prone to develop brain abscess than patients with acynotic heart disease. Among cyanotic heart disease, Fallot's tetralogy is the most common cause for brain abscess.[98] Intracardiac right to left shunt allowing direct entry of blood containing bacteria to the cerebral circulation bypassing the pulmonary filter, hypoxaemia, metabolic acidosis, increased blood viscosity from compensatory polycythaemia resulting in low perfusion areas (microinfarcts) in the brain provide the perfect milieu where micro-organisms settle down and multiply to form an abscess.[9,40,78] Regardless of the source, haematogenous brain abscesses occur in the distribution of the middle cerebral artery, mostly in the parietal and frontal lobes with a predilection for the left side. Metastatic abscess formation usually begins at the corticomedullary junction (grey and white junction) where brain capillary flow is slowest.[89,106] They are more frequently multiple and are more likely to be multi-loculated. They tend to be less well encapsulated than those which occur by spread from a contiguous site.

Cryptogenic

In a number of cases in which no focus of primary infection can be found, they are embolic in nature and originate from minute lesions giving rise to bacteraemia.[5] Such bacteraemia may occur during surgical procedures on the tonsils[50] and teeth.[49]

Miscellaneous Causes of Brain Abscess

Brain abscesses may result as a complication of other non-neurosurgical procedures such as submucous dissection of the nasal septum,[45] cranial traction with Crutchfield skull tongs,[22,64] use of a halo orthosis[41,81] and secondary to bacteraemia following dilatation of oesophageal stricture and sclerosis of oesophageal varices.[3,24,33,87]

Post-Operative Abscess

Brain abscesses as a complication of intracranial procedures are rare as compared to local wound infection, cranial bone flap oestomyelitis, epidural abscess, subdural empyema or meningitis. Deep wound infections, cranial bone flap infections and the presence of CSF leak increase the risk of formation of brain abscess.

In about 10–20% patients of brain abscess no identifiable predisposing factor is found.[20,82,86]

MICROBIOLOGY OF BRAIN ABSCESS

The microbes responsible for the formation of an abscess depend on the pathogenic mechanism involved. In many instances more than a single bacterial species can be isolated from the brain abscess.

In non-traumatic brain abscess, streptococci including aerobic, anaerobic and microaerophilic streptococci are isolated in 60–70% of cases. These bacteria, particularly *Streptococcus milleri*, are part of the normal bacterial flora of the oral cavity, appendix and female genital tract. Bacteriosides and Enteric bacteria are recovered in 20–40% of cases and *Staphylococcus* in 10–15% of cases. *Staphylococcus* infection is usually caused by penetrating head trauma or bacteraemia secondary to endocarditis. *Clostridia* infections are most often post-traumatic. *Listeria monocytogenes*, a gram-positive bacillus with special tropism for the central nervous system (CNS), accounts for 10% of CNS infections. Brain abscess due to *Listeria* has a poor prognosis and is associated with a high mortality.[66] A high index of suspicion is needed to reach an early diagnosis and establish appropriate antibiotic treatment, which will improve the outcome.[84] *Klebsiella pneumoniae* is a very uncommon microbial agent to cause multiple brain abscesses in neonates that respond poorly to antimicrobial agents. *K. pneumoniae* brain abscess may occur in the absence of meningitis and even in the absence of any identifiable risk factors.[95]

PATHOGENESIS OF DEVELOPMENT OF BRAIN ABSCESS AND CAPSULE FORMATION

For adopting a rational approach to the management of brain abscess, it is valuable to have a better understanding of the pathogenesis and histopathology. The formation of brain abscess progresses through several well defined stages. Abscess development and maturation depends on a number of factors including local tissue oxygen tension, the underlying cause of infection, virulence of the offending organism, the type of organism (e.g. bacterial, fungal, etc.), and the host immune response. The development of brain abscess has been clearly delineated by Britt and Enzmann[15] in their classic experimental and clinical studies. Using a canine model of streptococcal abscess based on histopathological changes of development of brain abscess, Britt et al.[14] identified four stages in the encapsulation process namely:

- early cerebritis (1st to 3rd day)
- late cerebritis (4th to 9th day)
- early capsule formation (10th to 13th day)
- late capsule formation (day 14th and beyond).

The onset and duration of each of these stages is not absolute and may be altered by antibiotic therapy, administration of corticosteroids and alterations in the immune status of the host.

Early Cerebritis Stage (1st to 3rd Day)

It is characterised by the presence of a necrotic centre of purulent material accompanied by local inflammatory response surrounding the adventitia of blood vessels. This response is maximal on day 3 and results in marked oedema formation. The lesion is not demarcated from the surrounding brain at this stage. Histopathologically the early cerebritis stage is characterised by a core of purulent material surrounded by a zone of granulation tissue of variable thickness comprised of inflammatory cells, neovascularity and hyperplastic fibroblasts. Thrombosis of the local vasculature, perivascular cuffing and perilesional oedema is seen extending into the surrounding white matter.

Late Cerebritis Stage (4th to 9th Day)

The necrotic centre enlarges due to pus formation during the late cerebritis stage, which is surrounded by a zone of inflammatory cells and macrophages. Fibroblasts begin to lay down a reticular network, which is the precursor of the collagen capsule. Oedema is maximal during this stage and reactive astrocytes become evident.

Early Capsule Formation (10th to 13th Day)

The spread of infection and subsequent destruction of the parenchyma is limited by the important event of capsule formation which begins by the 10th day after the initial response to bacterial invasion. During this process, fibroblast activity infiltrates the brain surrounding

the zone of cerebritis, and collagen and reticulin fibres are deposited. The developing capsule is surrounded by an active zone of vascular hyperplasia and perivascular cuffing. Inflammatory cells may be observed infiltrating the adjacent leptomeninges if the abscess is near the brain surface. On the medial and ventricular side of the abscess capsule formation is slow and incomplete. This is believed to be related, at least in part, to the amount of cerebral blood flow and tissue oxygen tension adjacent to the developing capsule, which in turn may affect the ability of collagen to form triple helix strands. This probably explains the propensity for abscesses to rupture into the ventricular system rather than into the subarachnoid space and also may account for the predilection of daughter abscesses to form on the thinner side adjacent to the white matter.

Late Capsule Formation (14th Day and Beyond)

Late capsule formation is characterised by five distinct histologic zones:

1. Necrotic centre
2. Peripheral zone of inflammatory cells and fibroblasts
3. Dense collagen capsule
4. Layer of neovascularity just external to the capsule with residual cerebritis
5. Zone of oedema and reactive gliosis external to the capsule

This pattern has been confirmed by studies in other animal models as well as clinical observations[82,103] suggesting that it takes approximately 2 weeks from infiltration of the infective organism for a well formed abscess with encapsulation to develop in the majority of patients who have the capacity to mount a host response to the infection.[15,32,83,103]

Recent studies using an experimental mouse brain abscess model have found a complex role for Toll-like receptors (TLRs) in the pathogenesis of brain abscess. Toll-like receptor 2 (TLR2) has limited impact on the innate immune response during the acute stage of brain abscess formation induced by *S. aureus*, but influences adaptive immunity. In contrast, mice deficient in MyD88, a central adapter molecule for the majority of TLRs in addition to IL-1R and IL-18R, demonstrate severe defects in innate immunity coupled with exaggerated tissue destruction. Esen et al. feel that a better understanding of the roles for TLRs in both resident CNS glia as well as infiltrating immune cells will provide insights into how the immune response to bacterial infection can be altered to achieve effective pathogen destruction without causing excessive bystander damage of surrounding non-infected brain parenchyma.[34]

Syed et al. demonstrated that the pro-inflammatory cytokine tumour necrosis factor-alpha (TNF-alpha) enhances TLR2 expression in microglia, whereas interleukin-1beta has no significant effect on mice. The TLR2 expression was significantly attenuated in brain abscesses of TNF-alpha knockout mice. Their results indicate that in response to *S. aureus*, TNF-alpha acts in an autocrine/paracrine manner to enhance TLR2 expression in microglia and that this effect is mediated, in part, by activation of the nuclear factor-kappa β pathway.[96]

To delineate the importance of MyD88-dependent signals in brain abscesses, Kielian T et al. compared disease pathogenesis using MyD88 knockout (KO) and wild-type (WT) mice. Mortality rates were higher in MyD88 KO mice, which correlated with a significant reduction in the expression of several pro-inflammatory mediators, including but not limited to IL-1beta, TNF-alpha and MIP-2/CXCL2. These changes were associated with a significant reduction in neutrophil and macrophage recruitment into brain abscesses of MyD88 KO animals. Also, microglia, macrophages, and neutrophils isolated from the brain abscesses of MyD88 KO mice produced significantly less TNF-alpha, IL-6, MIP-1alpha/CCL3, and IFN-gamma-induced protein 10/CXCL10 as compared to cells from WT. They found the lack of MyD88-dependent signals had a dramatic effect on the extent of tissue injury, with significantly larger brain abscesses typified by exaggerated oedema and necrosis in MyD88 KO animals. They concluded that their findings indicate that MyD88 plays an essential role in establishing a protective CNS host response during the early stages of brain abscess development, whereas MyD88-independent pathway(s) are responsible for pathogen containment.[38,55]

Kielian et al. also addressed the importance of neutrophils in the early containment of *S. aureus* infection in the brain. Mice were transiently depleted of neutrophils before implantation of bacteria-laden beads. Neutrophil-depleted animals consistently demonstrated more severe brain abscesses and higher CNS bacterial burdens compared with control animals. *S. aureus* led to the induction of numerous chemokines in the brain, including macrophage-inflammatory protein (MIP)-1alpha/CCL3, MIP-1beta/CCL4, MIP-2/CXCL1, monocyte chemoattractant protein-1/CCL2 and TCA-3/CCL1, within 6 hours after bacterial exposure. Since neutrophils constitute the majority of the cellular infiltrate in early brain abscess development, their subsequent analysis focused on MIP-2 and KC/CXCL1, two neutrophil-attracting CXC chemokines. Both MIP-2 and KC protein levels were significantly elevated in the brain after *S. aureus* exposure. Neutrophil extravasation into the brain parenchyma was impaired in CXCR2 knockout mice and was associated with increased bacterial burdens. Their studies demonstrate the importance of the CXCR2 ligands MIP-2 and KC, and neutrophils in the acute host response to *S. aureus* in the brain.[53,54]

CLINICAL FEATURES

Brain abscess mostly occurs during the first two decades of life with a prediliction for males.[13,86] In infants they usually occur following septicaemia or meningitis and are mostly multiple (Fig. 1). The presenting features

Fig. 1: Contrast computerised scan of an infant showing multiple abscesses

depend on the size, location, multiplicity of the lesion, the virulence of the organism, the host response, and the severity of cerebral oedema. The symptoms of brain abscess are indistinguishable from those of a tumour or a space occupying lesion. However, the symptoms of brain abscess are more rapidly progressive than those associated with a neoplasm[103] and are like rapidly expanding intracranial mass lesions. They include headache, seizures and focal neurological deficits.[84] The classical clinical triad of headache, fever and neurological deficit is seen in 50% of cases. Headache is usually constant, progressive and refractory to therapy, occurring in 70–97% of cases.[67,68,86,105] It is often generalised but may localise to the side of the abscess and increases in severity as the size of the abscess increases. Nausea and vomiting, which indicate raised intracranial pressure (ICP), occur in 25–50% of cases.[67,86]

Fever, which is usually low grade, is present in about 50% of cases.[67,86,105] However, in children fever occurs in 80% of cases.[85] Fever higher than 38.5°C indicates the presence of a systemic infection or concomitant meningitis.[21] Altered level of consciousness is present in approximately two-third of patients, ranging from mild confusion to coma.[63,67,86,105] Papilloedema develops in about 50% of cases, which is a relatively late event.[85]

Focal neurological deficits occur in more than 60% of cases.[63,67,86,105] The neurological deficit will depend upon the location of the abscess. An abscess in the posterior frontal and parietal lobe causes hemiparesis, whereas varying degrees of dysphasia and visual field defects are seen in a temporal lobe abscess. Cerebellar abscess manifests with ataxia and nystagmus. Pre-operatively, seizures occur in 30–50% of cases. Involvement of the III or VI cranial nerve may occur due to raised ICP.[63,67,86]

Infants usually present with progressively enlarging head, bulging fontanelle, separation of sutures, vomiting and seizures. Infants usually have irritability and poor feeding.

Adults with normal host response frequently show a rapid onset and progression of symptoms. In contrast, immunocompromised patients may have an insidious onset of symptoms, in which case high index of suspicion is necessary to make an early diagnosis.

LABORATORY INVESTIGATIONS

Routine laboratory studies are not very helpful in substantiating a diagnosis of brain abscess. The total leucocyte count is frequently normal and is only mildly elevated (less than 15,000 cells/cubic mm) in 60–70% of patients.[21,63,67] In cases of brain abscess with concomitant meningitis or acute systemic infection the WBC count may be elevated above 20,000 cells/cubic mm.[21] The erythrocyte sedimentation rate is elevated in about 90% of cases, but it is a non-specific indicator of inflammation.

Jamjoom[51] reported elevated serum C-reactive proteins (CRP) in 77% of patients with brain abscess. The CRP has been found to be a useful marker for differentiating brain abscess from other slowly progressive intracranial mass lesions. CRP levels return to normal after successful treatment and persistently elevated CRP indicates incomplete treatment.[51]

The blood cultures are usually negative. However, in patients with brain abscess associated with septic embolisation from an intravascular endothelial infection such as endocarditis or mycotic aneurysm it may grow organisms.

The CSF analysis is non-specific. There may be mild pleocytosis with WBC count lower than 100 cells/cubic mm unless there is co-existing meningitis.[67] The CSF protein contents are mildly elevated (usually < 100 mg/dl) and CSF glucose levels are generally normal except in patients with frank meningitis where CSF glucose is low. Cultures are usually sterile, particularly in patients who have been receiving antibiotics. Since the CSF findings are non-specific and lumbar puncture is potentially dangerous in the presence of an intracranial mass lesion and also easy accessibility to the CT scan, lumbar puncture should not be performed.

Molecular techniques can increase the number of identified microbial agents in cerebral abscesses. The ability of detecting bacterial pathogens directly from the clinical brain abscess specimens can be achieved by polymerase chain reaction (PCR) amplification and sequencing of bacterial 16S ribosomal deoxyribonucleic acid (rDNA). Bacterial 16S rDNA sequences provide reliable clues to the identification of unknown pathogens. The PCR analysis of 16S rDNA and sequencing may identify pathogens to the species level directly from brain abscesses. This approach is rapid and is useful, especially in the identification of slow-growing and fastidious organisms. Mycoplasma species, an emerging pathogen, is common and should be detected in these situations.[2,100]

RADIOLOGICAL INVESTIGATIONS

Advances in neuroimaging, most notably the routine use of CT scanning, have substantially improved the diagnosis and management of CNS infections in general and brain abscesses in particular. Diagnostic studies that have been used in the evaluation of patients with suspected brain abscess include plain radiography of the skull, pneumoencephalography, ventriculography, arteriography, radionuclide scan, CT scan and MRI.

X-Ray Skull

The skull radiographs are often normal in patients with brain abscess, but in some patients signs of raised ICP may be evident. In post-traumatic abscess, air inside the cranial cavity may be visualised. Evidence of paranasal sinusitis and mastoiditis can also be seen in the plain skiagrams of the skull.

Computed Tomography

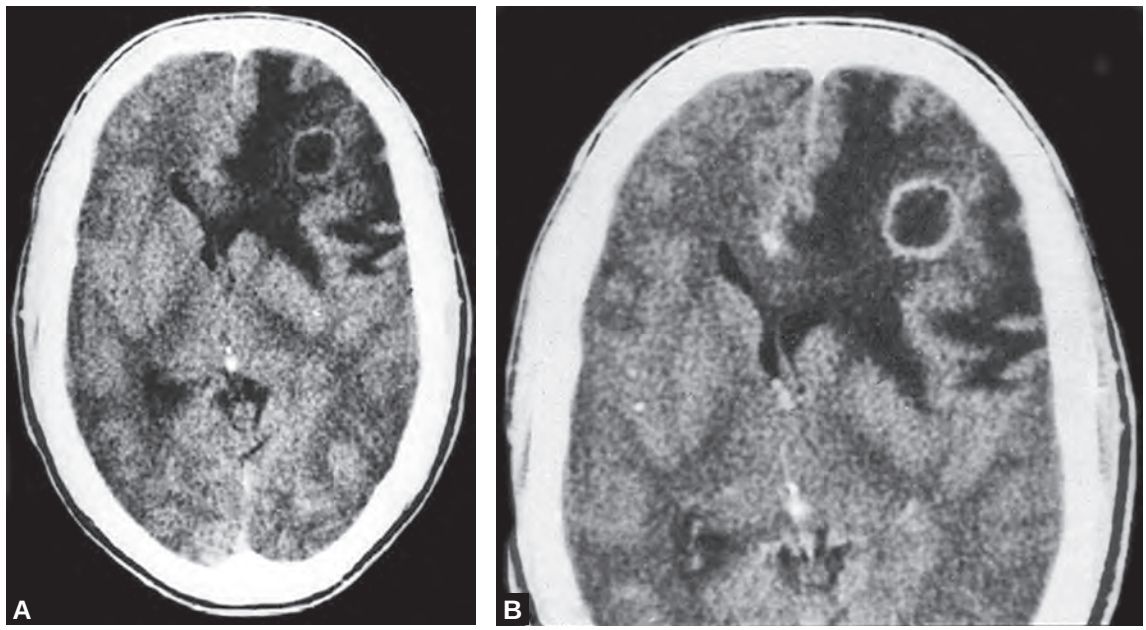
The CT scan has remarkably improved the ability to diagnose and localise pyogenic brain abcesses. Before the advent of CT scan, delay in diagnosis contributed significantly to the high morbidity and mortality. The CT scan has rendered diagnostic tests such as angiography, ventriculography, pneumoencephalography and radionuclide brain scanning virtually obsolete and of historical interest only. In addition to the diagnosis of the abscess *per se*, CT is excellent for detecting sinusitis, mastoiditis and soft tissue infections that may be predisposing factors for a brain abscess. Apart from early detection and accurate localisation, it provides valuable information regarding staging of an abscess, associated hydrocephalus, raised ICP, oedema, associated infection, pathology like subdural empyema, ventriculitis, meningitis, multiplicity of an abscess, loculations and to some extent the nature of the pus. This additional information has proved helpful in better planning and management of a brain abscess.[84,89,106] It is invaluable in assessment of adequacy of treatment and subsequent follow-up also.[89]

The classic appearance on a contrast enhanced CT scan is a lesion having a smooth, thin, regular wall with a decreased density both in the centre of the lesion (representing pyogenic material) and in the surrounding white matter (representing oedema). On non-contrast scan, the wall may be isodense or denser than the brain[84] (Figs 2A and B). Various authors have described CT scan findings as per staging of an abscess and demonstrated that the CT classification correlated well with the histopathologic stage confirmed on surgery or autopsy.[15,32]

Magnetic Resonance Imaging

The MRI is more sensitive than CT scan and is capable of detecting a brain abscess in the earliest stage of development.[1] Even the plain MRI is characteristic of brain abscess and is specific to make an accurate diagnosis. Additional advantages of MRI include better anatomic details, multiple imaging planes, lack of bony artifacts, especially in the posterior fossa and increased sensitivity for follow-up examination.[97]

Characteristic T1-weighted images show a peripheral zone of mild hypointensity relative to adjacent brain, representative of oedema formation, surrounding a central region of more marked signal hypointensity, indicative of the necrotic centre of the abscess. The capsule separates these two regions and appears as a discreet rim that is isointense to mildly hyperintense[46] (Fig. 3).



Figs 2A and B: (A) Non-contrast computerised scan showing isodence capsule wall of frontal abscess. (B) Contrast computerised scan of the same patient showing enhancing capsule wall

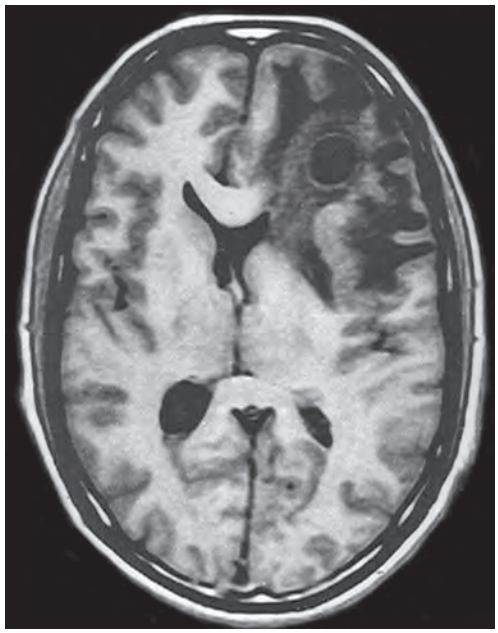


Fig. 3: T1-weighted magnetic resonance showing left frontal abscess

Fig. 4: T2-weighted magnetic resonance of the same patient showing hypointense rim at the margin of the abscess

On T2-weighted sequences the signal intensity of the zone of oedema increases markedly compared with the adjacent brain, while the central core is isointense to hyperintense compared with grey matter. The capsule now appears as a well defined hypointense rim at the margin of the abscess (Fig. 4).

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) has emerged as a powerful tool to non-invasively differentiate a brain abscess from a tumour.[79] The MRI when combined with *in vivo* MRS may help to better characterise cystic intracranial mass lesions.[77] There are lesion specific spectral patterns that may assist in tissue characterisation. Spectral pattern from MRS may permit differentiation of a brain abscess from necrotic or cystic tumours.[56] The presence of amino acids (AAs) on *in vivo*[1] H-MR spectroscopy is a sensitive marker of pyogenic abscess, but its absence does not rule out a pyogenic aetiology. The presence of acetate (Ac) with or without succinate (Suc) favours an anaerobic bacterial origin of the abscess, which may also be seen in some of the abscesses secondary to facultative anaerobes.[74] It might be possible also to differentiate tuberculous abscesses from pyogenic abscesses by using magnetisation transfer MRI and *in vivo* MRS, which could be of value in influencing the management of such cases.[44]

Diffusion Weighted Imaging

Ebisu et al.[31] described high signal intensity in the abscess fluid associated with low apparent diffusion coefficient. In contrast, necrotic or cystic tumours show low signal intensity in diffusion weighted imaging indicating a high apparent diffusion coefficient.

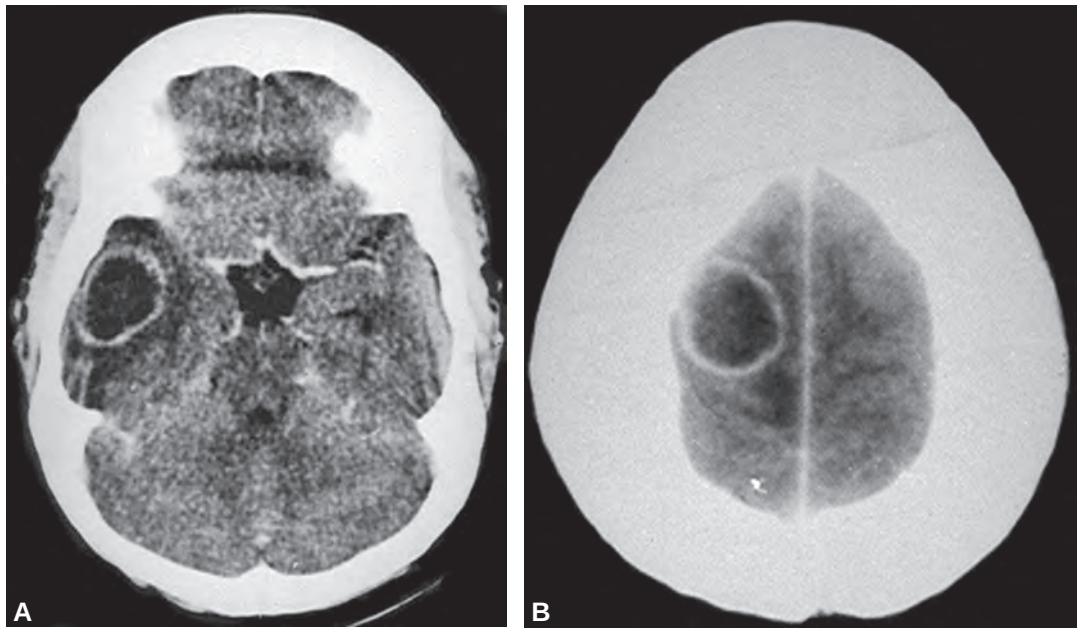
TREATMENT

The advent of CT scan and better understanding of pathogenesis have changed the management of brain abscess. Until the early 1970s surgery (aspiration, drainage, excision, etc.) was considered the method of choice for the management of brain abscess. The controversy over whether all brain abscesses require surgical treatment began in the early 1970s when Heineman and Braude[47] and subsequently other authors[6,10,23,83] published reports about non-surgical treatment of brain abscesses. Age, neurological status, location, number, size, loculations and stage of abscess formation influence the choice between conservative versus operative treatment. Each case must be individualised and treated on its own merit.[89]

Medical Treatment

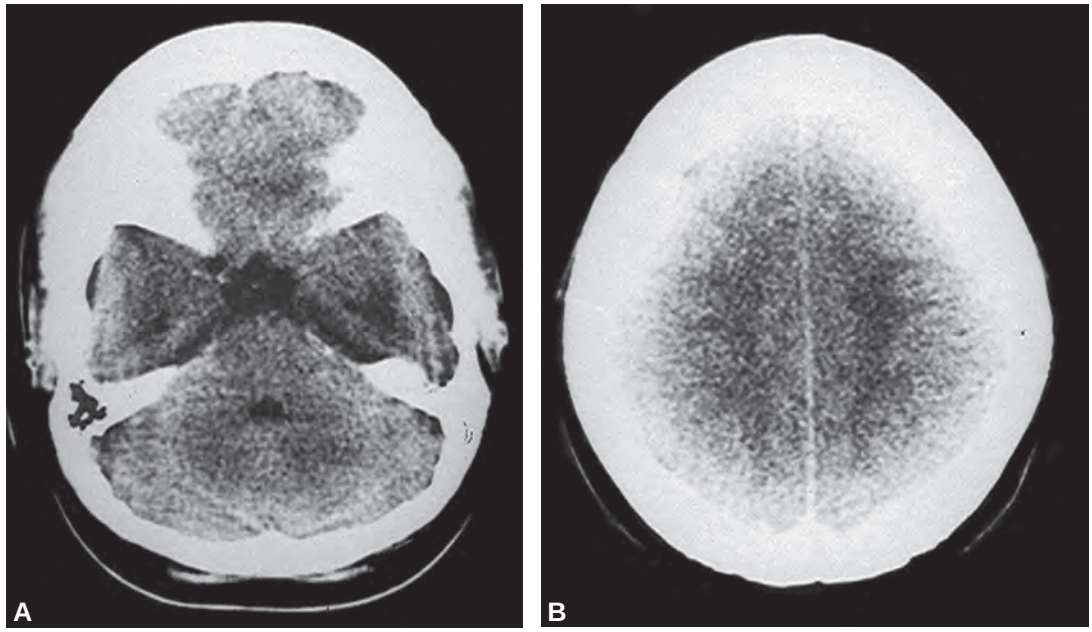
In selected patients, especially those in whom the abscess is still in the cerebritis stage and in those patients where the brain abscess is not associated with signs of raised ICP (clinically as well as on CT scan) and particularly those patients who have an abscess less than 3 cm in size, it can be managed conservatively with antibiotics alone[84] (Figs 5A and B, 6A and B). High-risk patients with bleeding diathesis caused by thrombocytopaenia (platelet count less than 30,000 cells/cubic mm) or coagulopathy where even minor surgery is contraindicated are best treated with medical treatment. Antibiotic therapy started early during the cerebritis stage or in small abscesses may result in complete cure.[89] However, serial CT scans are essential as an abscess may enlarge despite adequate antibiotics.[10,89]

Widespread use of antibiotics has reduced the mortality and morbidity associated with brain abscess. The



Figs 5A and B: Contrast computerised scan showing multiple abscesses in right temporal and frontal lobe

choice and efficacy of antibiotic depends on a number of factors including whether a particular antibiotic is bacteriocidal or bacteriostatic, type of microbials, concentration in CSF, whether it can cross the blood-brain barrier and blood CSF barrier, route and duration of therapy, the host response to infection, the concentration of the drug at the site of abscess and predisposing factors.[27,29,35,39,43,84,89] The concentration of antibiotic achieved in human brain abscess has been studied by Black et al.,[10] DeLouvois et al.[27] and Everett and Strausbaugh.[35] Antibiotics, like chloramphenicol, metronidazole, sulphonamides, isoniazid, rifampin and flucytosine, which penetrate well into normal brain and CSF, have potential utility for the treatment of brain abscesses.[84] When the permeability of the blood-brain barrier is altered by inflammatory conditions such as cerebritis and abscess, antibiotics that usually do not penetrate into CSF or brain tissue such as penicillin and cephalosporins, can penetrate well. Studies in experimental abscesses have demonstrated variable penetration of the aminoglycosides particularly gentamicin. Aminoglycosides are poor penetrators, especially into CSF and cannot be used intravenously to treat gram-negative meningitis. However, adequate correlation regarding chemical efficacy in the treatment of brain abscess and penetration capabilities of these antibiotics has not been done as in the case of meningitis.[84]



Figs 6A and B: Follow-up computerised scan of the same patient after 6 weeks of antibiotics, showing complete resolution of abscess

Evaluation of vancomycin in cases of Staphylococcal brain abscess has shown that the penetration of vancomycin is excellent; concentration of vancomycin in the abscess fluid was found to be 80% of the simultaneously obtained serum concentration.[60] In patients with meningitis the concentration of vancomycin in CSF is only 10–20% of the serum concentration. The correlation between penetration of an antibiotic into the infected area and the success of therapy has also not been well established.[84]

Pre-operative use of antibiotics would prevent the spread of infection during aspiration or surgical removal of the abscess. However, the possibility of obtaining false negative culture, particularly from a small lesion, is high with the pre-operative use of antibiotics.[84] Selection of antibiotics pre-operatively will be based on the aetiology of an abscess and organisms most frequently encountered. The best choice would be of those antibiotics which would cross the blood-CSF and blood-brain barrier. Later on, after obtaining the culture and sensitivity, proper antibiotics should be started. If no organism is identified, the antibiotic should be selected depending on the predisposing cause (primary source) and anatomic location of the abscess.[28,58] Earlier, penicillin and chloramphenicol were mainly used in treatment of brain abscess, particularly before cultures were obtained. They are now replaced with cefotaxime, vancomycin and metronidazole.[63]

Song et al. reported that in their series of 90 consecutive patients with brain abscess the rate of positive bacterial culture was only 12%. The outcome of superficial abscesses was better than those of abscesses in deep-seated locations ($p < 0.01$); multiple brain abscesses led to significantly poorer outcomes than unilocated abscesses ($p < 0.01$). There was no significant difference between the paediatric group and the adult group ($p > 0.05$). The differences in outcomes between intrathecal injection combined with systemic administration of antibiotics versus only venous administration could not be found ($p > 0.05$). They concluded that the effectiveness of tertiary-generation cephalosporin + vancomycin + metronidazole for bacterial brain abscess was 88%, and recommend combined antibiotics in cases with no positive cultures.[92]

The indications for non-surgical treatment are:
Patients who have a small abscess (less than 3 cm in diameter)

- Patients who have no signs of raised ICP
- Patient who is alert
- Clinically stable patient with no neurological signs
- Patient with multiple lesions
- Patients having high risk for surgery and anaesthesia

Patients in whom the diagnosis is firmly supported by identification of a predisposing factor, imaging studies, and patients in whom the organism has been identified presumably from culture elsewhere.[84,89]

Accurate assessment of therapeutic response can now be analysed with treatment-induced changes in diffusion tensor imaging indices [i.e. fractional anisotropy (FA) and mean diffusivity] in follow-up patients with brain abscess after treatment. The reduction in FA value reflects the down-regulation of the neuroinflammatory molecules in response to treatment of patients with brain abscesses.[71]

Surgical Treatment

Surgery is indicated to confirm the diagnosis, to obtain a sample for culture for identification of specific pathogens and sensitivity to particular antibiotics, and to remove as much purulent material as possible. Surgery should also be performed when there is clinical deterioration, significant mass effect, neurological deficit, multiple lesions in surgically accessible locations, doubtful diagnosis, presumably resistant organisms[89] and multiple loculations.

Many surgical procedures (including drainage, aspiration, excision) have been described for the treatment of a brain abscess,[19,84,89,93] but these days aspiration and surgical excision are the most commonly and widely used procedures. There is, however, some controversy whether aspiration or excision should be performed. In choosing between aspiration and excision various factors including surgical morbidity, success rate, and sequelae such as recurrence, seizure disorder, etc. should also be considered. Drainage is seldom used nowadays.[83]

Due to easy availability of CT scan for initial diagnosis and follow-up, these days aspiration of a brain abscess rather than primary excision has been widely used. Aspiration is a rapid and safe procedure, especially when the patient has markedly raised ICP and the abscess is located in an eloquent area. Aspiration is usually performed under local anaesthesia, except in children. It can be done with the use of stereotactic technique, real time ultrasound, particularly in infants with open fontanelle or under CT scan guidance. All these techniques provide precise localisation of an abscess. Stereotactic aspiration of an abscess is useful in a deep-seated abscess; abscess in the brainstem or thalamus, and even in a multi-loculated abscess. Callovini et al. treated three consecutive cases of thalamic abscess by stereotactic puncture as the first step, followed by histological analysis, external drainage and targeted intrathecal and systemic antibiotic therapy. They felt deep-seated abscesses behave differently as they are associated with an increased risk of intraventricular rupture and antibiotic resistance, which justifies a more aggressive and immediate surgical treatment.[18] CT or MR image-guided stereotactic aspiration via the suboccipital transcerebellar approach has been found an effective procedure for the treatment of brainstem abscesses. This procedure is less invasive than open surgery and can be performed even in patients in poor general condition.[11,70] Hellwig et al.[48] and Frisch and Manwaring[36] have reported encouraging results with endoscopic stereotactic aspiration of brain abscess. Kutlay et al. treated brain abscess patients with

stereotactic aspiration combined with antibiotics and hyperbaric oxygen (HBO) therapy. Their results indicate that the duration of antibiotic usage can be shortened with the use of HBO as an adjunctive treatment.[57]

Usually most abscesses respond to and reduce in size after repeated aspirations, particularly cerebellar abscesses, where burr hole aspiration is mostly sufficient.[17,69,105] If the abscess does not reduce in size and the quantity of pus does not subsequently decrease (even after 3–4 aspirations), excision of an abscess can be planned. The advantage of secondary excision over primary is that the surrounding oedema is significantly less after multiple aspirations. Post-traumatic abscesses containing bone fragment or foreign body, however, require primary excision. Proper and thorough wound toilet and removal of hair, foreign body, etc. are essential to prevent recurrence. Multi-loculated abscesses also mostly require secondary excision.

Su et al. reported an incidence of 20% of multiloculated abscesses in a series of 25 patients with pyogenic brain abscess. They conclude that excision seems to be the more appropriate surgical choice in multiloculated abscess, and prognosis can be as good as that for patients with uniloculated abscess. However, clinicians must carefully monitor these patients because the possibility of recurrence after surgery is significantly higher in patients with multiloculated abscess than in those with uniloculated abscess.[94]

Cerebellar and cerebellopontine angle abscesses, by virtue of their size and associated oedema, may obstruct the CSF pathways resulting in hydrocephalus, which may require immediate CSF diversion by adopting external ventricular drainage.[69]

Management of Multiple Abscesses

The detection rate of multiple abscesses has increased with the advent of CT scan and thus improved their management. They are mostly haematogenous and are often found in patients with cyanotic heart disease and in immunocompromised patients. Corticosteroids in particular are significant predisposing factors in patients with two or more brain abscesses.[25] They account for 5–50% of all brain abscess patients. Aspiration should be done in patients with large abscesses particularly those with neurological deficit and those which are accessible. Repeated aspirations reduce associated oedema and raised ICP. In patients who have one or more large abscesses and are not reducing on repeated aspiration, surgical excision may be considered. With regards to multiple brain abscesses due to *L. monocytogenes*, Cone et al. advocated therapy with high-dose ampicillin in combination with gentamicin as the drugs of choice, followed by trimethoprim/sulfamethoxazole and vancomycin. In general, antimicrobial therapy appears to be satisfactory treatment without surgical intervention.[25]

Role of Corticosteroids

The use of corticosteroids in the treatment of brain abscess is controversial. Corticosteroids significantly reduce cerebral oedema and mass effect that accompany brain abscess. Corticosteroids, however, inhibit the migration of leukocytes and diminish the effectiveness of the host response when used in the early cerebritis stage.[84,106] Administration of corticosteroids should, therefore, be avoided in the early stages of brain abscess development.

Whelan and Hilal[103] reported that administration of corticosteroids decreases enhancement of the abscess wall on CT scan and that withdrawal of corticosteroid occasionally results in increased enhancement despite clinical stability and eventual cure. Britt and Enzmann also observed decreased wall enhancement, but only in the cerebritis stage of abscess formation.[15,32] The majority of experimental evidence seems to indicate that steroids have more deleterious than beneficial effects.[106]

COMPLICATIONS

Epilepsy

Epilepsy is a common sequel of brain abscess occurring in 30–50% of patients.[4,20,52,67] The maximum frequency of seizures occurred during the 4th and 5th year after diagnosis.[106] Nielsen et al.[73] reported high incidence of seizures with frontal lobe abscesses. Patients treated with aspiration alone tend to have less seizures than patients in whom the abscess is excised.[20,59,67,86] Due to the high incidence of seizures, all patients with supratentorial brain abscess should be given prophylactic anticonvulsants for 1–2 years. The anticonvulsant should be tapered if the electroencephalography shows no epileptogenic activity. Patients having intractable seizures may sometime respond to temporal lobe resection or resection of the seizure focus.[106]

OUTCOME AND PROGNOSIS

With the introduction of CT, stereotactic techniques and broad-spectrum antibiotics, the outcome for brain abscess has dramatically improved, and depends on prompt awareness of the diagnosis and effective infection control. Tseng et al. found no association between outcome and other factors, including age, focal neurological deficits, seizures, laboratory findings, characteristics of the abscess, associated factors and treatment modalities.[101] The poor prognostic factors of brain abscess are poor glasgow coma scale, immunodeficiency and presence of underlying disease. Aggressive treatment with surgery, when indicated, and careful management of the aetiology might improve the outcome.[104] Once the abscess is cured, secondary operation is indicated to remove the primary cause, e.g. chronic mastoiditis, paranasal sinusitis, congenital heart disease, bronchiectasis, etc.

61 Scalp and Skull Infections

Ravi Ramamurthi, Goutham Cugati

Scalp infections are encountered as a complication of scalp lacerations. They are also seen as a complication of various surgical procedures, like craniotomy, shunt surgery, from scalp electrodes used in deep brain stimulation and pin site infection for halo or skull pin traction.

SCALP LACERATIONS

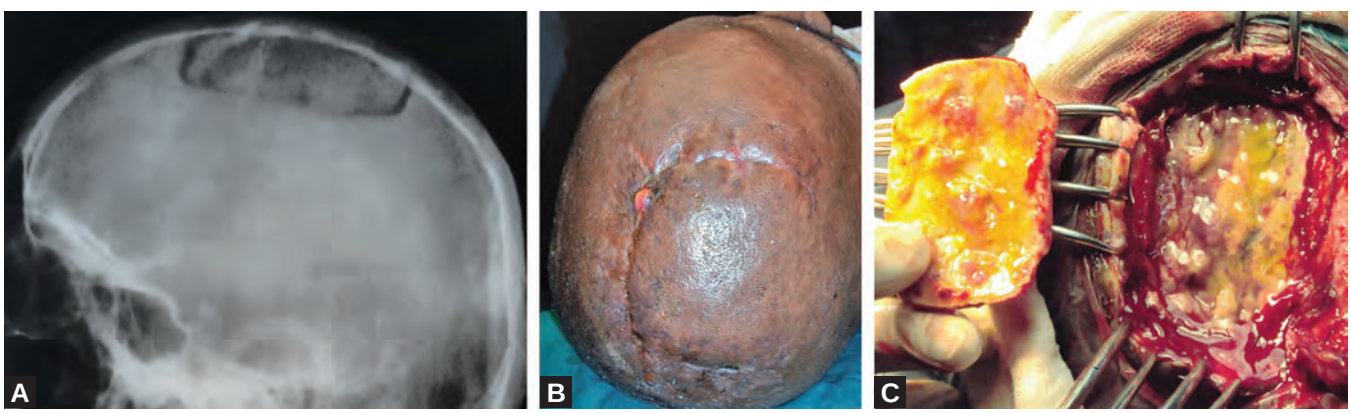
Most scalp lacerations heal without complications, but mismanagement of the same may end up in infections. Preventing scalp infections can be achieved by following the basic principles of wound management like reducing tissue contamination, meticulous wound toilet, debriding devitalised tissue, restoring perfusion in poorly perfused wounds and establishing a well-approximated skin closure without tension. Care has to be taken to remove any contaminants or foreign bodies within the wound. Continuous irrigation of the wound under moderate pressure reduces wound bacterial counts. Routine use of prophylactic antibiotics may be required if there is evidence of bacterial contamination or host risk factor. The patient's tetanus immunisation status should be evaluated, with the need for further immunisation determined as per US Centers for Disease Control and Prevention recommendations.

POST-OPERATIVE SCALP INFECTION

Accurate identification and evaluation of post-operative infection is very essential in neurosurgery as it can have devastating effects if left unattended. Narotam et al.[30] conducted a study of post-operative wound infections where the study group was divided into five categories as: (1) Dirty (brain abscess, ventriculitis, meningitis, etc.); (2) Contaminated (compound skull fractures, open lacerations, CSF fistulae, etc.); (3) Clean contaminated (entry into paranasal sinuses, transphenoid/transoral procedures, prolonged surgery, etc.); (4) Clean with foreign body (shunts, EVD, ICP monitors, DBS electrodes, etc.) and (5) Clean (ideal operating conditions). They have suggested that all abnormally appearing wounds be considered as wound infection as bacterial culture may not be positive in all the instances. With increasing degree of contamination, there was increasing rates of infection. The difference in rates of infection was very marked between the clean cases and the other four groups. The clean with foreign body and the clean contaminated groups had similar infection rates. Widespread use of permanent foreign materials has been an important predisposing factor.

CRANIOTOMY AND SCALP INFECTION

The incidence of scalp infection following a clean craniotomy varies from less than 1 to 5%[34] (Figs 1A to C and 2). Baumeister et al.[4] who conducted a meta-analysis found that 1–8% of craniotomy cases land up having post-operative infection necessitating removal of the bone flap and requiring secondary cranioplasty. The predisposing factors for post-craniotomy infection include:[16,19,30,34]



Figs 1A to C: Forty-year-old gentleman who underwent craniotomy for astrocytoma presented with post-craniotomy osteomyelitis. (A) Skull lateral X-ray showing lytic changes in the bone flap. (B) Clinical photograph showing discharging sinus along the operative scar. (C) Operative photograph showing infected bone with epidural collection of pus

Fig. 2: Clinical photograph showing burr hole site scalp infection in a patient who has undergone craniotomy

Fig. 3: Clinical photograph showing scalp infection and exposure of the acrylic in a patient who underwent cranioplasty

- Emergency level of surgery
- Long duration of surgery (>200 min)
- Duration of stay in ICU (>72 hrs)
- Penetration of paranasal sinuses
- CSF fistulae
- Multiple surgeries via same incisions
- Use of permanent implantable foreign materials (acrylic, metal wires, ventricular catheters, etc.) (Fig. 3)
- Tight haemostatic skin clips resulting in skin necrosis.

DEEP BRAIN STIMULATION AND SCALP INFECTION

Placement of the hardware in cases treated by deep brain stimulation has its potential complications of malfunction, lead migration, fracture, scalp erosion or infection. Spiotta et al.[44] have advocated two different approaches to address the problem of skin erosion or impending skin erosion in DBS patients. To tackle the above problem a temporo-parieto-occipital flap based on the superficial temporal artery with or without scalp expansion, and a scalp fasciocutaneous flap with or without cranioplasty can be used. Further refinement of the hardware is required to minimise hardware related complications.[44]

PIN SITE SCALP INFECTION

Various types of spinal immobilisation devices are in use for patients with spinal injury. Immobilisation using the Halo vest and Gardner Well's skull tongs requires placement of skull pins. In such patients pin site infection may be seen. In patients with Halo vest immobilisation, Van Middendorp et al.[46] have found pin site infection in 12% of 239 patients, and Botte et al.[8] and Garfin et al.[13] have found up to 22%. Pin site infection was mostly seen in those patients where the outer table was penetrated. *Staphylococcus aureus* has been the most common pathogen in these infections. Superficially infected pins can be managed with local pin care and oral antibiotics. Persistent or severe infections require pin replacement to a nearby site, parenteral antibiotic therapy, and incision and drainage as needed.[7]

OTHERS

Patients having presurgical scalp infections, like pediculosis capitis or scabies, are prone to peri-operative scalp infections. This problem is seen more in developing countries and in the paediatric age group. Early recognition of these conditions and prompt treatment is necessary.[41] If the neurosurgical procedure is not an emergency, as not the case always, then it is advisable to operate after complete treatment of local scalp infections.

Diagnosis

The infection may be superficial when the dermis and epidermis is involved or deep when the galea and the underlying bone are involved. *Staphylococcus aureus* is the predominant pathogen followed by hospital acquired pathogens like *Pseudomonas* and *Klebsiella*. Anaerobic pathogens and the gas forming *Clostridium* species infecting the scalp have also been reported.[47]

The patient may have evidence of local signs of infection like erythema, swelling, inflammation, tenderness and warmth. There may be a fluctuant collection or a discharging sinus with a serosanguinous or purulent discharge. The discharge needs to be sent for aerobic, anaerobic and fungal cultures. If tuberculosis is suspected, then tubercular culture also needs to be done.

Management

General risk factors for infection, like diabetes mellitus, obesity, malnutrition, chronic renal failure, advanced age and use of steroids, should be noted and appropriate measures taken to tackle them.

When the infection is superficial, oral antibiotics and anti-inflammatory agents are sufficient. If the infection is deep, it may require wound debridement along with administration of intravenous antibiotics depending

on the sensitivity of the organism. If the infection has spread to the bone, then, often it necessitates removal of the bone flap. A secondary cranioplasty will be required at a later date.[4] In cases of large scalp defects, there may be difficulty in scalp adaptation for cranioplastic surgery, especially in patients having scalp atrophy, poor nutritional condition and tense sutures. In such patients scalp expansion is effective. Instead of a hasty single sitting cranioplasty, two-stage cranioplasty can be done after tissue expansion with a scalp expander.[28]

There has been a controversy regarding shaving of the head for cranial surgery. Tokimura et al.[45] investigated 632 patients who underwent cranial surgery without head shaving and found no increased risk of wound infection. The low risk of infection was attributed to the use of the electrosurgical scalpel for skin and soft tissue dissection, which minimises bleeding and the probability of wound infection. Paolini et al.[33] who observed less than 1% of post-operative scalp infection have advocated shaving a small strip of hair along the planned wound. Closure of the wound was by intradermal sutures instead of traditional sutures or metal staples which requires removal in the post-operative period. Review of earlier studies and a search into the history of aseptic surgery shows that the practice of shaving the head does not have a scientific basis. There is no advantage in shaving patients in terms of reducing wound infection rates.[20] The use of depilatory agents has a lesser rate of infection than using razors.

General guidelines for prevention of surgical site infection were elucidated by Mangram in 1999.[25] Further information regarding the same may be obtained at www.cdc.gov/ncidod/dhqp/pdf/guidelines/SSI.pdf.

SKULL OSTEOMYELITIS

Although osteomyelitis can affect any bone in the body, involvement of the skull bones is a rare entity. One of the earliest reports of osteomyelitis of the skull was the one by Sir Percival Pott, where he described a subperiosteal abscess of the frontal bone occurring as a complication of trauma causing a puffy swelling in the forehead. Since then it derived its name, Pott's Puffy tumour.[35]

Pathogenesis

Haematogenous spread of infection to the skull is a rare entity. Skull osteomyelitis, in most of the instances, is a result of contiguous spread of infection. The probable sources of infection being:[9,21]

- Post-traumatic following compound fracture of the skull
- Post-craniotomy
- Sinusitis
- Intracranial infections
- Scalp infections
- Dental procedures
- Dermatological procedures
- Cryptic osteomyelitis

Osteomyelitis after craniotomy occurs in approximately 1.1–8.1% of cases and often necessitates bone flap removal[14] (Figs 1A to C). In a patient with spread from sinusitis, the frontal sinus is frequently seen as the offender. In patients with malignant otitis externa, especially in the paediatric population, spread of infection may result in osteomyelitis of the cranial base.[3] In a few instances the source of infection is not diagnosed as in cryptic osteomyelitis. Most of such cases have atypical/central type of skull base osteomyelitis. Such patients have been observed to have an immunocompromised state or other predisposing factors like diabetes.[10] In newborns, secondary to birth trauma, cephal haematoma, a subperiosteal collection of blood may be formed. Very rarely, due to bactraemia there may be colonisation of bacteria in the blood resulting in osteomyelitis.[27]

Pathogens

The common pathogens are microaerophilic streptococci, including *alpha-haemolytic Streptococcus, Staphylococcus, Peptostreptococcus*, bacteroides species and other anaerobes such as *Fusobacterium*. These organisms may be more common in this setting due to the relatively lower oxygen concentration in the frontal sinus, caused by compromised ostial patency.[37] Lee et al. have reported that *Pseudomonas* is the causative organism in 74% of 28 patients who were treated for skull base osteomyelitis.[22] In the report by Clark et al. who reported four cases of atypical skull base osteomyelitis, *Pseudomonas* species were isolated in three cases and a literature review by them showed *Pseudomonas* species in 8 out of 15 cases where a pathogen was isolated. Other organisms that have been reported include gram-positive organisms, *Aspergillus, Mycobacterium* and *Candida*.[40] In patients with immunocompromised state and prolonged steroid use organisms, like *Salmonella*,[5] *Cryptococcus* and *Treponema pallidum*, have been isolated.[2,17] There are a few reports of skull osteomyelitis from fungi like mucormycosis, madura mycosis and others.[38] A rare pathogen like *Propionibacterium acnes* has been isolated in a case of post-craniotomy osteomyelitis.[14]

Clinical Features

These patients present with generalised symptoms like fever, headache, vomiting, fatigue/malaise along with scalp tenderness and swelling. Pott's puffy tumour is the term given to a subperiosteal abscess of the frontal bone, usually presenting as a localised swelling of the soft tissues in the overlying region of the forehead, and is associated with localised osteomyelitis. It can be seen in the setting of frontal sinusitis or as a post-traumatic complication.[26,29] The incidence of this entity has come down in the antibiotic era. In some instances, there may be evidence of intracranial infection/abscess spreading to the calvarium and then extracranially to the soft tissues. It may mimic a calvarial bony tumour.[18,42]

Patients with skull base osteomyelitis can present with headache and a variety of cranial neuropathies, often a combination of VI and lower cranial nerve (CN) neuropathies. The source of infection in the form of ear infection needs to be looked for. In a typical case of skull base osteomyelitis the temporal bone is involved, whereas in atypical or central type of skull base osteomyelitis the sphenoid, occiput or the clivus can also be involved.[10]

Tubercular osteomyelitis rarely involves the upper extremities and non-weight-bearing bones. Skull involvement is exceptionally rare and is seen mainly in children. The lesions may be solitary or multiple involving both tables of the skull. They may form a scalp swelling with a sinus. Careful examination to look for other evidence of tuberculosis is required.[1]

If the treatment is inadequate (<4 weeks) or the patient is immunocompromised, then the patient may have recurrent infection. In chronic cases, the infection may persist for more than three decades.[31]

Investigation

Blood investigations often show an increase in the acute phase reactants like ESR, WBC count and CRP counts.[10] On plain radiographs, the skull lesions appear as lytic areas and these changes take several months to be seen. Initial CT scan may not show evidence of the disease, whereas in the later part of the disease evidence of lytic bony lesions is seen. Seabold et al. found no CT evidence of bone erosion in 13 out of 35 patients with biopsy-confirmed cranial osteomyelitis.[10,15,39] Once the treatment is completed, the changes on the CT take a long time to revert to normal. Hence, CT may not be a good choice to follow-up patients. On MRI the lesions appear hypointense in T1 and hyperintense in T2. In skull base osteomyelitis, it is very difficult to differentiate this condition as various conditions like skull base malignancies and other non-neoplastic conditions may mimic this entity. Various nuclear medicine imaging techniques, like gallium-67 scintigraphy, indium-111 white blood cell scans, technetium-99m methylene diphosphonate (MDP) bone scans and single-photon emission computed tomography (SPECT), have been used to investigate for postoperative osteomyelitis and also to follow-up patients on treatment.[23]

Lee et al.[22] classified the patients with skull base osteomyelitis using Technetium-99 SPECT into four grades:

1. Mild uptake
2. Focal mastoid/temporal bone uptake not reaching the midline
3. Petrous temporal bone uptake reaching the midline
4. Uptake crossing the midline, involving the contralateral temporal bone

Histopathological examination of the biopsy/debrided tissue is essential along with pyogenic, fungal and tubercular cultures as HPE may be non-diagnostic at times.[10]

Management

Surgical resection of the diseased bone with adequate clearance is required.[36] Post-operatively the patient has to be on long-term antibiotics for complete clearance of the infection. Pseudomonas being the commonest pathogen, antipseudomonal antibiotics have to be started empirically and once the sensitivity is available it may be changed, if necessary.[43] In various reports the duration of antibiotic treatment varied from 1 month to 6 months.[12] The Bone Infection Unit in Oxford, United Kingdom, recommends up to 6 weeks of intravenous treatment followed by 6–12 months of oral medication, guided by clinical response.[10] The patient needs to be started on ATT if the HPE is in favour of tuberculosis.[24]

In a few patients with troublesome chronic osteomyelitis, in spite of repeated debridement, the infection might persist. In such instances a combination of extensive surgical debridement and a free flap transfer is effective. A latissimus dorsi muscle flap with a split skin graft has been preferred by a few surgeons.[6] A multidisciplinary approach with an infection specialist and a plastic surgeon might be necessary for such cases.[10] In patients with malignant otitis externa, adjuvant hyperbaric oxygen improves the success of treatment by reversing tissue hypoxia, enhancing phagocytic killing of aerobic micro-organisms and stimulating neo-microangiogenesis.[11] Lee et al. have observed that long-term prognosis depends on the initial stage of presentation of skull base osteomyelitis as seen on SPECT.[22]

Complications of skull osteomyelitis include intracranial extension resulting in epidural, subdural or brain abscess, sinus thrombosis, cranial nerve palsies and death. Mortality from complications is 20–40%.[32] With accurate diagnosis and prompt treatment the complications can be avoided to get a better outcome.

62 Subdural Empyema

Mathuriya SN, Pathak A, Khandelwal N

INTRODUCTION

The term subdural empyema (SDE) is used for suppuration in the pre-existing space between the dura and the arachnoid. The first patient with SDE reported to be operated upon was in 1869 by De la Peyronie, which was documented 10 years later.[32] Kubik and Adams[34] introduced the term "Subdural Empyema" which gained wide acceptance. Various other synonyms of this condition are pachymeningitis interna, purulent pachymeningitis, cortical abscess and subdural abscess.[32]

It has been described either intracranially or in the spinal canal, the latter localisation being quite rare. It is a rare, but serious illness with a declining mortality rate and rather frequent neurological sequelae. Morbidity and mortality in intracranial and spinal SDE directly relate to the delay in diagnosis and therapy.[17]

Although considered uncommon, subdural empyemas (SDEs) constitute 13% and 23% of all intracranial bacterial infections,[27,54] usually presenting with a fulminant clinical picture and rapidly progressive neurological deficit.

They occur more frequently in children than in adults. However, we have to consider subdural infection as one of the differential diagnoses in an elderly patient with subdural hygroma when a new abnormal density lesion develops in the subdural space.[66]

Intracranial SDEs, the majority of which are supratentorial in location, are common neurosurgical emergencies in developing countries, especially in the paediatric age group. They result in significant morbidity and mortality despite improvement in neuroimaging, surgical techniques and antibiotic therapy.[1,2]

Infratentorial SDE is a life-threatening rare complication of bacterial meningitis. Infratentorial SDEs constitute only a small portion of all cases with intracranial infectious diseases. Empyema should be considered in patients with suspected or proven bacterial meningitis and associated ear, nose or throat infection with neurological signs that suggest a posterior fossa lesion.[57]

The commonest source as reported in the Western literature is paranasal sinus infection[10,14] and otitis media, whereas trauma constitutes a major aetiological factor in the African continent.[39,50,62] Upper respiratory tract infection,[65] subdural effusion[64] and meningitis[52] can also be some important aetiological factors in the causation of SDE. Rare causes may include SDE secondary to the use of a halo fixator,[46] shunt surgery or after evacuation of subdural haematoma.[50]

The spread of infection into the subdural space can be due to direct extension through the bone and dura, which is the common route in patients with otitis media or mastoiditis. However, in SDEs secondary to sinusitis,[31] the mode of spread is usually by retrograde thrombosis of the dural and intracranial veins from septic thrombophletitis.[48] The location of a SDE varies according to the source of infection: frontal in case of sinusitis, occipital and temporal region in case of otitis media. Intracranial tubercular SDE in the paediatric age group is an extremely rare but curable entity.[2]

The pathological findings consist of an inflammatory process mostly in the subdural space, with a small group having associated meningitis. However, the secondary changes, e.g. venous thrombosis, cerebral oedema, haemorrhagic changes and superficial abscess formation are responsible for the overall clinical presentation and prognosis.[23,48]

The clinical presentation usually is dramatic. The majority of the patients have alteration of sensorium.[22,50] Features of raised intracranial pressure, headaches, nausea and vomiting are also quite common. Focal symptoms in the form of speech disturbances, hemiparesis and seizures may also be seen.[50] However, patients developing SDE after surgery, trauma or secondarily in a subdural haematoma may have an indolent course and are diagnosed only on suspicion. Infection in the wound might be the only clue.

Despite modern diagnostic and therapeutic modalities, delayed diagnosis of SDE is not uncommon and is associated with a significant mortality. The factors to be incriminated for rapid clinical deterioration in SDE are: (i) products of bacterial metabolism including toxins which may have a direct effect on neural and glial tissue[15] or (ii) venous obstruction and stasis leading to infarction secondary to cerebral venous thrombosis.[19,26,63] Diagnosis of SDE is based on a high index of clinical suspicion in the initial stages. The outcome is affected the most by the time interval between presentation of symptoms and operation.[55] If operated upon within 72 hours of onset of symptoms only 10% are disabled, but after 72 hours 70% are either disabled or dead.

IMAGING

In the past, radioisotope scan had been a useful tool for diagnosis of SDE.[37,51] The CT scan[15,37,45] still remains the initial, common modality for diagnosis. Minimal midline shift and swelling of the ipsilateral hemisphere may be the only clue[20,53] as distinction of SDE from the surrounding brain is difficult in the acute phase prompting the need for serial CT scans with contrast enhancement[7,28,33,47,51] (Figs 1 and 2). Magnetic resonance imaging (MRI) has a major role in diagnosing and reducing mortality in subdural empyema as the actual empyema can be demonstrated in the acute phase using coronal and sagittal images, especially for collections near the base of skull, tentorium and over the convexity[12,61] (Fig. 3). However, in infants, the role of ultrasonography as a primary screening modality cannot be ignored.[13]

SDE have high signal intensity on diffusion weighted images (DWIs) and low signal intensity on ADC maps, with an ADC value lower than that of the normal cortical grey matter. Diffusion MRI can be valuable in distinguishing SDE from effusion and in the follow-up of subdural collections.[59] In earlier years angiography has been used for diagnosis.[30]

MICROBIOLOGY

The primary source of infection may have a relationship to the organism isolated from SDE. Aerobic, microaerophilic streptococci and anaerobic organisms are commonly isolated from empyemas secondary to paranasal sinusitis.[22,23] In post-traumatic or post-surgical cases *Staphylococcus aureus* is found. In children with SDE secondary to meningitis the organism commonly encountered is *Haemophilus influenzae* or *Streptococcus pneumoniae*. It is, however, not uncommon to isolate species of *Salmonella, Escherichia coli*[50] or other rare organisms.[16,24]

MANAGEMENT

SDE is a neurosurgical emergency which requires prompt intervention. Although no relationship exists between the mortality and the time taken to develop SDE,[42] a direct relationship exists between mortality and delay in referral[62] or a delay in treatment.[10,26,42] Seriously ill patients are claimed to have greater focal deficit.[42] The

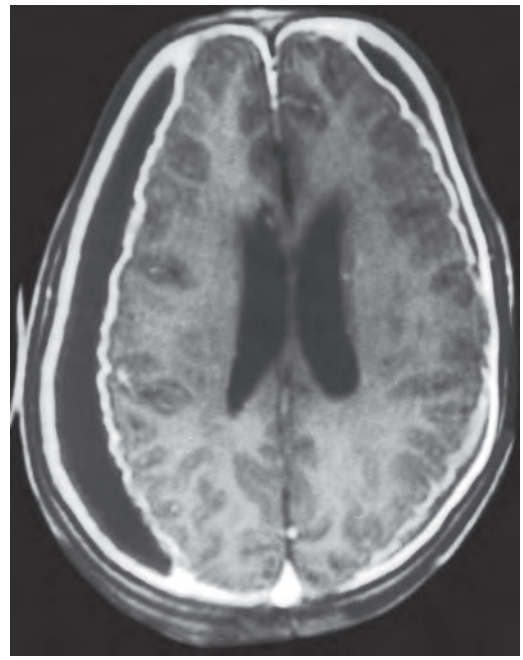

Fig. 3: Contrast enhanced MR (T1-weighted image) axial planar imaging showing convexity subdural empyema

extent of subdural pus accumulation has a statistically significant bearing on the chances of survival without severe disability, as extensive SDE involves the adjacent cortex, especially through widespread thrombophlebitis.

A wide range of options are available for the management of SDE. Surgery was the mainstay of treatment in the pre-antibiotic era. Subsequently surgery along with antibiotics helped to lower the mortality rates.[4,25,58] However, sporadic reports suggest that conservative management with antibiotic therapy for SDE has emerged as an accepted practice.[35,43,56]

Bradley and Shaw[10] considered early diagnosis followed by appropriate antibiotic therapy and early treatment of the primary source more important than rapid drainage of the empyema. Exploration of the paranasal sinuses and mastoids is suggested within 24 hours of the patient becoming stable.[9]

Proponents of surgical treatment of SDE claim an added advantage that it decreases the toxic and inflammatory influence on the brain and its blood supply which diminishes due to mass effect.[37] The advantage of surgery lies in achieving two main objectives, e.g. penetration of antibiotics into loculated areas of suppuration and identification of the offending organism.[6]

The type of surgical procedure is variable. Craniotomy or craniectomy is non-controversial for posterior fossa SDE. Percutaneous aspiration through an open fontanelle in infants or twist drill hole aspiration in children still remains a preferred method of treatment.[3,18,29,40,50]

SDE due to meningitis in infants is unique with respect to the pathophysiology, presentation and treatment. Early detection and removal of SDE lead to a favourable outcome.[36]

Bannister et al, in a review of 66 cases of SDE, reported gross difference in outcome based on burr holes or craniotomy.[4] There was a high mortality of 48% in burr holes in contrast to 8% in craniotomy. Burr holes are sometimes complicated by incomplete evacuation due to occlusion of a small dural opening by oedematous brain, and also in cases of multiloculated collections, parafalcine and posterior fossa empyemas.[4] Multiple burr holes are preferred in other series laying stress on treatment of the primary source,[10] early referral[5,62] and early diagnosis[44] in order to achieve better outcome. However, craniotomy has better outcome as it is possible to remove loculated pus and evacuate the SDE from the interhemispheric fissure.[15,58] A compromise between the two procedures can be brought about by preferring craniotomy for abscesses with thick pus and for abscesses in inaccessible areas like the interhemispheric fissure.[58] The role of a subdural drain is controversial.[8,21,41,49,50,59]

Early surgery can salvage most patients and obviate the need for permanent cerebrospinal fluid diversion procedures. Surgery (evacuation of empyema and mastoidectomy), antibiotics and management of hydrocephalus are the mainstays of treatment.[38]

Paediatric supratentorial SDEs, although rapidly fatal if not identified promptly, can be effectively managed with early surgical drainage; preferably craniotomy should be done.[2]

Statistically no significant relationship exists between different surgical procedures and the outcome in SDE.[42] For unconscious patients properly placed burr holes, located according to aetiology, clinical picture and CT scan, are the preferred procedure since, in the acute stage, the pus usually remains as an extended thin film. However, encapsulated pus in the chronic state with usually mild or no disturbance of consciousness needs a craniotomy.[50]

Mortality rates for SDEs range from 13 to 55%.[58] The level of consciousness has a significant bearing on the chances of survival and severe disability[42,60] reaching up to 80% in some series.[19] Fully alert or drowsy patients have a better prognosis than stuporous and comatose ones.[19,42]

The occurrence of seizures has no relationship with the outcome in SDE. Reports exist of 18% increase in incidence of seizures in frontal SDE in contrast to 100% in those located in the parietal region.[11] The duration of anticonvulsant therapy thus varies from a short period[15] to an indefinite period.[26]

Planning of treatment for an individual patient with SDE is based on several considerations.[50] Neurologically preserved patients without focal neurological deficit, and a localised area of pus on CT scan deserve a trial of conservative management. Patients with altered sensorium, deteriorating neurological status, focal deficit or failed conservative therapy demand surgical evacuation. A localised area of pus in the supratentorial compartment needs percutaneous needle aspiration and evacuation in infants or through burr holes in children and adults. Diffuse area of pus with midline shift, multiloculated or parafalcine SDE should be evacuated through craniotomies. All posterior fossa SDEs should have a craniotomy/craniectomy for evacuation. Follow-up CT scan is mandatory for all patients, whether treated conservatively or surgically. Once the patient improves, the relevant aetiological factor should be treated. Any residual pus with no improvement or deterioration in neurological status should be re-explored.

63 Spinal Epidural and Intramedullary Abscess

Ashish Suri, Shashwat Mishra, Ajay Garg

SPINAL EPIDURAL ABSCESS

Spinal epidural abscess (SEA) is an uncommon pathology. In 1975, Baker et al.[3] had estimated their incidence at 0.2–1.2/10,000 hospital admissions. However, spinal epidural space infections are being noted more frequently in recent times as a result of increasing number of spinal surgeries, percutaneous spinal procedures, emergence of the human immunodeficiency virus epidemic and advances in spinal imaging modalities. Prior to the appearance of neurological deficits, the initial signs and symptoms of spinal epidural abscesses (SEAs) are non-specific and can erroneously be attributed to a plethora of commonly occurring spinal disorders. Due to their low incidence and confusing symptomatology, they continue to pose a diagnostic challenge. The SEAs, which escape recognition, can eventually result in permanent neurological deficits or even death due to systemic sepsis.

Relevant Anatomy and Pathophysiology

The spinal epidural space is a sleeve-like compartment between the dura and the periosteum and is filled with fat, epidural arteries and venous complexes. This compartment is developed well posterior and lateral to the thecal sac, but is only a potential space anteriorly where the dura and the periosteum are closely approximated. The posterior space is attenuated in the cervical region but enlarges in the midthoracic (T4-T8), lower lumbar and sacral (L3-S2) regions. When suppuration of the epidural space occurs, it spreads over several contiguous spinal segments[11,38,44] and is typically located in the posterior space. Epidural space collections anterior to the spinal cord generally result from infectious spondylitis or neoplastic affection of the vertebral bodies. Thus, in the Indian context, anteriorly located epidural abscesses are mostly noted in association with tubercular spondylitis. Tubercular epidural abscess occurring without an apparent spondylitis is rare. Tubercular epidural abscess in the absence of an osseous lesion have occasionally been described prior to the era of modern imaging. This was mostly due to the osseous lesion being missed on conventional X-rays. The SEAs most frequently occur in the thoracic and lumbosacral spine, which are also the most commonly accessed spinal segments in surgery and other procedures.[11–13]

The mechanism of spinal cord injury due to epidural abscesses remains unclear. The pathological mechanisms suggested include mechanical cord compression and septic thrombophlebitis with subsequent cord infarction. Although animal experiments[16] have suggested a primary role for mechanical compression in SEAs, some post-mortem studies[4] have also demonstrated infarction of the cord. Moreover, the appearance of cord damage due to either mechanism is indistinguishable on magnetic resonance imaging (MRI).

Epidemiology

The current annual incidence of SEAs stands at 2.5–3/10,000 hospital admissions.[39,44] All age groups are susceptible. However, SEAs are more frequently diagnosed in the 4th decade onwards. A male predominance has been noted in some studies.[11,35,38,39] The mortality rate for SEAs ranges from 6 to 32%.[17,25,39] Risk factors identified include predisposing medical conditions (diabetes mellitus, alcoholism and immunosuppression), spinal abnormalities, surgical intervention, spine trauma and presence of potential sources of infection (skin and soft-tissue infections, osteomyelitis, urinary sepsis, indwelling vascular access, intravenous drug use). *Staphylococcus aureus* is the commonest micro-organism isolated from these suppurations. Common microbial patterns seen in different clinical scenarios are listed in Table 1. Data from several series[12,25,39] suggest that in one half of cases, a contiguous spread of infection to the epidural space

Table 1: Risk factors and common micro-organisms causing spinal epidural abscesses

Risk factors	*Common micro-organisms*
Injected drug use	*Staphylococcus aureus, Pseudomonas aeruginosa*
Diabetes mellitus	Multiple
Recent invasive spinal procedures	*S. aureus, S. epidermidis*
Morbid obesity	Multiple
Skin infections or abscesses	*S. aureus, S. epidermidis*
Penetrating spinal trauma	*S. aureus, S. epidermidis*
Immunosuppression	Bacterial, mycobacterial, fungal
Transient bacteraemia	Multiple
Multiple medical illnesses	Multiple

occurs while haematogenous dissemination is responsible in a third. In the remaining cases, the source of infection remains unidentified.

Clinical Features

Fever, back pain and neurological deficits constitute the classical clinical triad of SEAs. However, this triad is recognisable only in a minority of patients.[10,14] Back pain is the most common and earliest symptom reported by patients. A staging system has been proposed describing the progression of symptoms in SEAs[21,33] (Table 2). The duration of these symptoms and the time of progression from one stage to another are highly variable between patients and may range from hours to months.[1]

It is apparent that clinical features of SEAs in the initial stages mimic common pathological spinal conditions. Radicular pain in the cervical and lumbar regions radiates to the extremities in classical patterns, but in the thoracic region, pain may vaguely extend to the chest or the abdomen, misguiding even the most discerning clinician.

The SEAs following invasive procedures (secondary SEAs) on the spine differ in clinical presentation from the spontaneously occurring SEAs (primary SEAs). The secondary SEAs occur in otherwise healthy individuals without significant comorbidities. Typically the patient presents with worsening pain at the surgical/puncture site along with tenderness and, occasionally, purulent discharge from the wound. The risk of developing SEAs following spinal epidural catheterisation has been variably estimated[5,7] to be around 1/1,350 procedures with the incidence of serious infections significantly increasing with prolonged placement of the catheter in the epidural space.

Patients developing spontaneous or primary SEAs following haematogenous dissemination of infection to the vertebral bodies or disc spaces develop discitis or osteomyelitis prior to the appearance of SEAs.

Isolated SEAs in tuberculous spondylitis are rare and the SEAs develop generally as a consequence of granulation tissue and purulent material spreading to the epidural space from spondylodiscitis of the vertebral segment(s). Due to the chronic inflammatory nature of the infection, the patients generally have back pain, systemic complaints (e.g. fever, anorexia, night sweats, weight loss, etc.) and neurological symptoms of prolonged duration. Spinal cord compression by epidural granulation tissue and caseous pus may be responsible for sudden neurological worsening in Pott's spine and may warrant urgent surgical decompression.

Table 2: Clinical staging of spinal epidural abscesses

Stages	*Clinical features*
I	Back pain
II	Radiating pain
III	Sensory deficits, motor deficits, and bladder and bowel dysfunction
IV	Paralysis

Diagnosis

Clinical findings, supporting laboratory data and suggestive imaging features are collated to establish the diagnosis of SEAs. However, it can be confirmed only by drainage of the abscess.

Laboratory Investigations

Routine laboratory studies reveal leukocytosis and elevated acute phase reactants (C-reactive protein), which are non-specific markers of any inflammatory process. Bacteraemia can be detected in up to 60% of cases,[10,11] especially where *S. aureus* is the likely causative organism. However, it is almost never seen in mycobacterial aetiology. Cerebrospinal fluid (CSF) examination typically reflects parameningeal inflammation with leukocytic pleocytosis and increased protein levels. The CSF cultures are usually negative and lumbar puncture carries a high risk of dissemination of the infective organism into the CSF. Moreover, the risk of neurological dissemination is compounded if the lumbar puncture is performed below the level of the spinal subarachnoid space block. Thus, a routine diagnostic lumbar puncture (except for myelography) should be avoided when a diagnosis of SEA is being suspected.

Imaging

Both contrast-enhanced MRI and computed tomography (CT)-myelography of the spine are highly sensitive (more than 90%) in diagnosing SEA.[22,38]

A plain radiograph or CT of the spine may reveal narrowing of the disc space and bone lysis to indicate the presence of discitis and osteomyelitis (which coexist with SEA in up to 80% of patients).[23] Similarly, radionuclide scanning (with technetium, gallium or indium) may show increased uptake, helping to identify the affected site. However, these imaging findings are neither sensitive nor specific for SEA.

The MRI is the imaging method of choice because it is non-invasive, multi-planar and without any radiation exposure. It delineates both the longitudinal and the paraspinal extension of the SEA and thereby helps in surgical planning. In addition, it may help to differentiate infection from cancer on the basis of the appearance and the signal intensity of the image.[32] The SEA is isointense to hypointense compared with the spinal cord on unenhanced T1-weighted images, and increased in intensity on proton-density and T2-weighted images[40] (Figs 1A and B). After contrast administration, SEA may show homogeneous enhancement, likely representing thickened, inflamed tissue with microabscesses or peripheral enhancement surrounding a central focus of low signal intensity representing a necrotic abscess, or a combination of both patterns.

Figs 1A and B: Spinal epidural abscess. (A) T2-weighted sagittal image showing posterior epidural abscess extending from D6-D11 spinal levels with spinal cord hyperintensity suggesting cord oedema. The core of the abscess is bright on T2-weighted image. (B) The rim enhances following gadolinium administration

Treatment

Prompt surgical drainage of SEA followed by appropriate systemic antibiotic therapy is almost always indicated to reduce the risk of sepsis and further neural injury.[31,37–39] In addition to blood cultures, other potential sources of infection are sampled prior to the initiation of systemic antibiotics.

Other treatment paradigms (applicable only in select cases with a small abscess and minimal symptoms) include systemic antibiotic therapy only and CT guided drainage of the abscess followed by antimicrobials.[40,42]

Pre-operative neurological status is an important predictor of outcome; hence early surgical intervention is appropriate. If profound neurological deficit persists for greater than 24–36 hours, recovery is unlikely following decompression. Depending upon the location of the abscess and surgical feasibility the epidural space is explored by laminectomy, hemilaminectomy or interlaminar fenestration. The purulent material and granulation tissue are then removed and samples collected for microbial culture.

Purely medical therapy may be considered in a few clinical scenarios. If the patient is a poor surgical risk, declines surgery or has complete paralysis of more than 3 days duration, antibiotic therapy is initiated following collection of samples for microbial culture and the patient is closely monitored for response. Very small abscesses without significant neurological symptoms may also be managed conservatively under close observation and frequent neurological assessment. Surgical drainage is indicated if the symptoms worsen or signs of sepsis appear during systemic antibiotic therapy. The abscess size can be monitored by Gd-MRI at a 2–4 week interval.[41]

While awaiting culture results, empirical antibiotic therapy must be directed against *S. aureus* (the most common pathogen), including coverage for methicillin resistant organisms and gram-negative bacilli, especially in scenarios where infection from gram-negative bacteraemia is likely, e.g. urinary tract infection.[13] However, it is important to remember that vancomycin is less active against methicillin sensitive staphylococci than β-lactams. Hence, documented methicillin-sensitive *S. aureus* is treated with nafcillin or cefazolin. The antibiotic regimen can be modified later on the basis of culture sensitivities.

The ideal duration of therapy is not well established and generally systemic antibiotics are recommended for a period of 6 weeks, as vertebral osteomyelitis frequently coexists with SEAs.

When SEA develops following spinal instrumentation or epidural electrode implantation, removal of the foreign material is necessarily required for elimination of infection. The role of steroids is controversial and may be used for temporary stabilisation while preparing for surgery.

For tubercular epidural abscesses, in neurologically intact patients, standard four-drug (HRZE) or five-drug (HRZES) antitubercular therapy is initiated. The patient is then monitored neurologically for therapeutic response. Although standard treatment guidelines for tubercular epidural abscesses are lacking, we generally intervene surgically when the patient deteriorates neurologically on antitubercular therapy. A costotransversectomy in the thoracic region and laminectomy in other spinal segments is the preferred approach for drainage of pus and removal of granulation tissue. At least 18 months of antitubercular therapy is recommended [1 month HRZES + 3 months of HRZE and 15 months of HRE (H = Isoniazid, R = Rifampicin, Z = Pyrazinamide, E = Ethambutol, S = Streptomycin)].

Outcome

The outcome for SEAs strongly correlates with the severity of neurological dysfunction before surgical decompression, making a case for early and aggressive surgical intervention.[3,12,28] If the duration of paresis is less than 24–36 hours, improvement is generally noted post-operatively. There is no conclusion that extent of elevation of erythrocyte sedimentation rate, C-reactive protein or MRI findings (canal compromise and number of vertebral segments involved) influence the ultimate outcome.

Uncontrolled sepsis, CNS spread of the infection or comorbid illnesses may ultimately result in mortality in up to 5% of patients. While the patient is recovering

neurological function, adequate measures should be taken to avoid the development of secondary complications such as decubitus ulcers, urinary tract infections, deep vein thrombosis and chest infection.

SPINAL INTRAMEDULLARY ABSCESSES

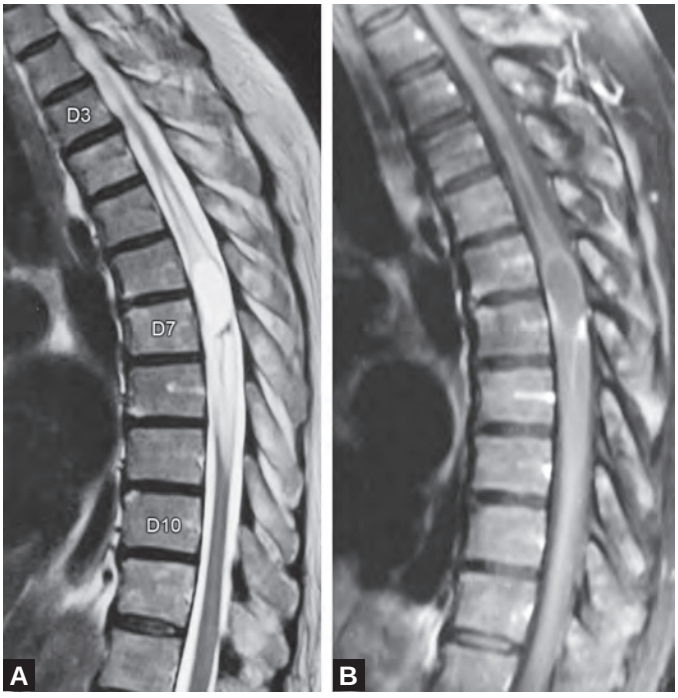
Intramedullary abscesses within the spinal cord are extremely rare, if one excludes cases where the infection spreads to the spinal cord from the contiguous vertebral body, disc space or a dermal sinus (Figs 2A and B). Only about 120 cases have been reported in the literature so far,[26] with the first case being described by Hart in 1830.[20]

The precise incidence of spinal intramedullary abscesses (SIAs) remains unclear. An autopsy series found only a single intramedullary abscess in 40,000 cases.[9]

Pathogenesis

Metastatic dissemination of infection from extraneous foci, contiguous spread from an infected dermoid, dermal sinuses, disc or vertebral bodies are commonly implicated in the causation of these abscesses.[6] Iatrogenic intramedullary abscesses, following surgical procedures on the spinal cord, may also occasionally be encountered. Compared with the pre-antibiotic era, haematogenous spread from septic foci has become infrequent in modern times.[6,30] Cryptogenic abscesses, with an unidentified primary source of infection now constitute the largest proportion.[2,6,26] In a review of 25 cases, the authors found the cervical and upper dorsal cord to be the commonest site of cryptogenic abscesses. Congenital midline neuroectodermal defects (spinal dysraphisms) were identifiable in 44% of the cases. The commonly noted stigmata of these dysraphic defects were pigmented naevi, sinus tract openings, blind dimple and inflamed skin nodule. Abscesses seen in this setting were common in the thoracolumbar region. Intramedullary abscesses are the common in the paediatric age group because of the frequent predisposing developmental spinal cord anomalies.[43]

Normally, the spinal cord substance is highly resistant to microbial colonisation. However, areas of subclinical spinal cord injury/ microinfarcts form a nidus for infection during transient bacteraemia. The stages of evolution of spinal intramedullary abscesses are similar to those seen in a pyogenic brain abscess. Areas of necrosis surrounded by purulent myelitis are seen in the initial stages. Later, a well-vascularised thick capsule surrounds the core of purulent material. Subsequent CSF dissemination and leptomeningeal spread of infection can complicate the clinical picture. Septic phlebitis with cord infarction may also contribute to cord damage.[6] Abscesses resulting from septic emboli have a predilection for the lower cervical and upper thoracic cord as these spinal segments have a relatively richer blood supply.



Figs 2A and B: Spinal intramedullary abscess. (A) T2-weighted sagittal image showing intramedullary abscess extending from D6, D7 spinal levels with spinal cord hyperintensity suggesting cord oedema. The core of the abscess is bright on T2-weighted image. (B) The rim enhances following gadolinium administration

Clinical Features

Pain, fever and rapidly progressive neurological deficits constitute the commonest symptomatology of SIAs.[6,26,30] Evidently, transverse myelitis and SEAs closely mimic the presentation of these abscesses and must be entertained in the differential diagnosis. Deterioration in sensorium and clinical features of sepsis are ominous and indicate leptomeningeal or systemic spread of infection. Fortunately, such complications are rare in the modern era with the availability of potent antimicrobials.

Staphylococcal species are the most common organisms isolated from these suppurations. The observed microbial pattern in relation to the proposed mechanism of infection is presented in Table 3.[6]

Management

Similar to pyogenic brain abscesses, generally a combination of medical and surgical therapy is considered appropriate for intramedullary abscesses. Surgical intervention is absolutely necessary in cases of abscesses associated with dermoids and epidermoids and dermal

---

Gulati et al. described 11 cases of spinal suppuration-epidural, one case of subdural, and later, in 1983, VK Khosla and VK Kak reported 10 cases of spinal intramedullary abscess.[18,24]

Tandon and Pathak provided a detailed review on spinal tuberculosis including extradural, subdural and intramedullary lesions in Tropical Neurology.[45]

Table 3: Microbiology of intramedullary spinal abscesses

Mechanism of infection	*Microbiology*	*Antimicrobial therapy*
Contiguous spread from dermal sinus opening	*Staphylococcus epidermidis, S. aureus* and anaerobes	Vancomycin + cefotaxime + metronidazole
Following spinal surgery	*S. aureus, S. epidermidis,* Enterobacteriacea, Gram negative bacilli	Vancomycin + ceftazidime ± metronidazole
Haematogenous spread	Similar to primary source	Culture based
Cryptogenic	Listeria monocytogenes, Viridians streptococci, Hemophilus species, anaerobes	Ampicillin + cefotaxime + metronidazole

sinus tracts. However, medical management may suffice for small cryptogenic abscesses showing good neurological response to antibiotic therapy. A minimum of 4–6 weeks of parenteral antibiotic therapy is essential.

The standard surgical management entails laminectomy, midline myelotomy and drainage of the pus and excision of an underlying lesion if any.

Outcome

In the pre-antibiotic era, intramedullary abscess of the cord carried mortality as high as 90%.[2,6,43] The mortality rate has substantially declined to less than 10% with effective antimicrobial therapy in modern times. However, following successful treatment of intramedullary abscesses the prognosis for functional neurological recovery still remains grim.[2]

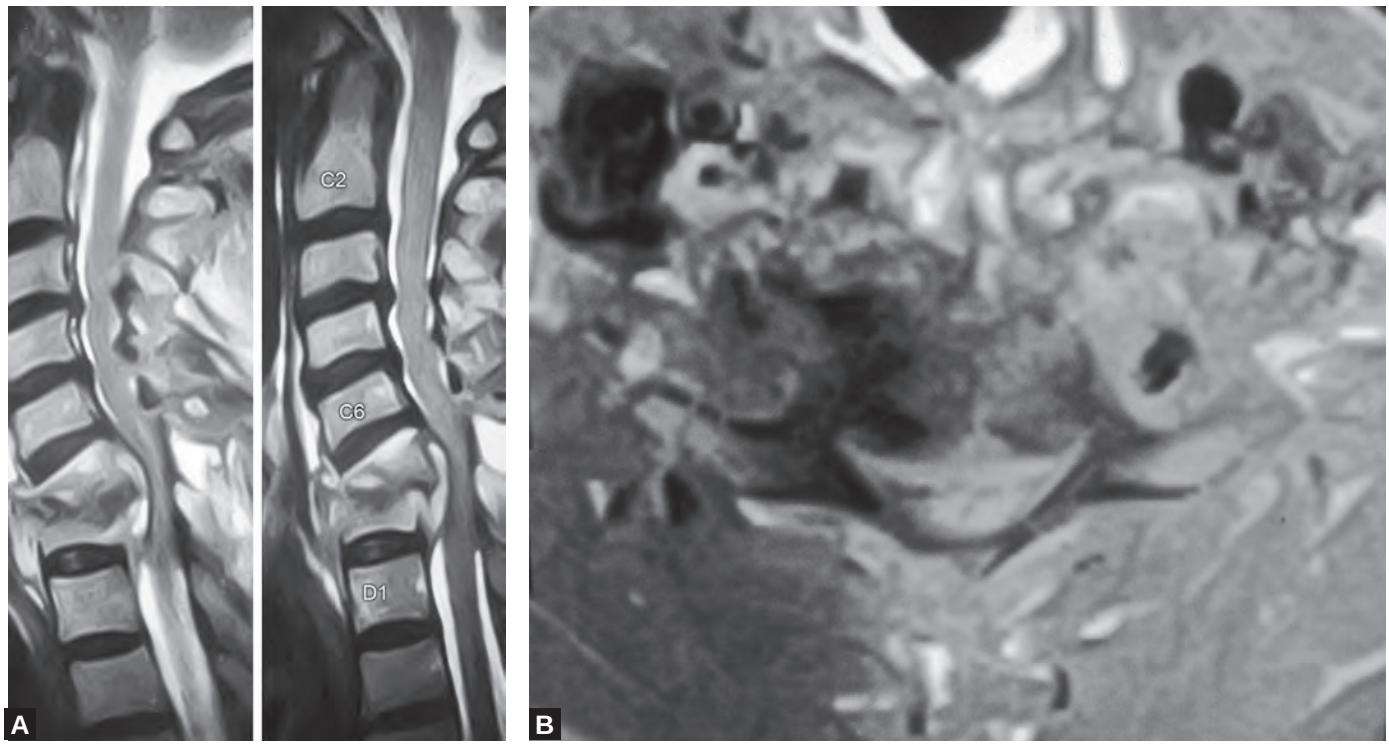
SPINAL INTRAMEDULLARY TUBERCULOMAS

Intramedullary tuberculomas in the spinal cord are extremely rare even in regions where tuberculosis is endemic. Nevertheless, it remains an important differential diagnosis of intramedullary lesions in the Indian population.

Intramedullary tuberculomas are encountered usually in the younger age groups and have been most frequently reported in the thoracic spinal cord.[29] However, they may affect almost all spinal segments.[15,34]

The patient may present with signs of subacute cord compression with classical signs of myelopathy. However, varied presentation, such as Brown-Sequard syndrome,[8] and acute urinary retention have also been reported.[15] The clinical presentation, however, is uncharacteristic and must be considered in context of the epidemiological setting and imaging features of the lesion.

The MRI appearance of intramedullary tuberculomas can vary according to the stage of evolution of the lesion. In the early stages, tuberculomas may be indistinguishable from myelitis with homogeneous enhancement of the cord (Figs 3A and B, Fig. 4). Eventually,



Figs 3A and B: Spinal tubercular spondylitis with epidural abscess. (A) T2-weighted sagittal image. (B) Axial image shows tubercular spondylitis C6, C7 spinal levels with anterior epidural abscess

Fig. 4: Spinal tubercular spondylitis with epidural abscess. T1-weighted Gad DTPA enhanced sagittal image showing tubercular spondylitis of C5, C6 spinal levels with multiple cervical anterior epidural abscess

these lesions progress to the characteristic ring enhancing "target appearance" with a central hypointense core and hyperintense periphery on T2-weighted sequences along with evidence of expanded cord substance.[18,36]

The ideal treatment of intramedullary tuberculoma is controversial. Although, undoubtedly, tuberculomas exert mass effect upon the spinal cord, yet surgery on the cord is fraught with risk. A balanced approach is adopted, with the understanding that antitubercular therapy (12–18 months duration, standard four drug regimen) is the cornerstone of management (Figs 5A and B). In our experience, conservatively managed and surgically explored intramedullary tuberculomas showed comparable results.[34] Surgery is presently recommended for patients who worsen on antitubercular regimen with increasing mass effect or in patients with uncertain diagnosis.[27,29]

Improvement is generally seen with antitubercular therapy, unless the patient harbours a resistant form of the organism or the deficits are long-standing and established.

64 Tuberculosis of the Central Nervous System

PN Tandon, Anil Pande

INTRODUCTION

Tuberculosis, a disease as old as recorded history, continues to exist in India and other developing countries and there is resurgence in the developed world consequent to the emergence of AIDS in epidemic proportions.[23,41,78,90,92,124,172,173,188] Worldwide, tuberculosis remains the leading cause of mortality from an infectious agent.[98] Approximately one-third of the world's population harbours *Mycobacterium tuberculosis* (*M. tuberculosis*). Individuals infected with *M. tuberculosis* have a 10% lifetime risk of developing the disease. Tuberculosis had affected 8.3 million patients worldwide in 2000.[165,166] The most dangerous form of the disease is neurotuberculosis. The manifestations of central nervous system (CNS) disease may involve the meninges and[1,9] parenchyma, or there may be focal involvement of the spinal cord and its adjacent osseous structures.[62,66] Cranial tuberculosis may be parenchymal (tuberculoma, abscess, encephalopathy), meningeal (meningitis, pachymeningitis)[56,122,135,137,202,204–206] or calvarial (osteomyelitis). Spinal tuberculosis can be vertebral[66] (caries or Pott's spine), meningeal (pachymeningitis, arachnoiditis) and parenchymal (spinal tuberculoma).[177] Craniovertebral junction tuberculosis has been reported on by Indians and others extensively.[60,91,99,134,178,184] Ramamurthi, in 2000, clarified that this entity should not be called a tuberculoma of the CV junction. Autopsy series of patients dying of tuberculosis identified CNS involvement in 19.3–42.2% of paediatric cases and in 2.9–5.9% of adult cases.[187] Children are commonly affected between 6 months and 4 years and adults between 20 years and 50 years. In addition to HIV-1 co-infection, other conditions associated with CNS tubercular involvement include recent measles infection and malnourishment in children; and alcoholism, malignancies, immunosuppressive medication and non-HIV immunosuppressive conditions in adults.

HISTORY

Hymns in the Rig Veda testify that the early Indo-Aryans (1500 BC) were familiar with this disease;[90] so were the Chinese, in the second or third millennia BC.[214] Egyptian mummies dating 3000 BC were found to have unequivocal evidence of skeletal tuberculosis.[32] The writings of Homer (900 BC), Hippocrates (400 BC) and Aristotle (350 BC) suggest the prevalence of this disease at that time.[127] Acid fast bacilli could be demonstrated in the spinal lesion of a Nazca culture child cadaver (approximately 700 AD) by Allison et al.[2] *M. tuberculous* DNA was identified in a pre-Columbian Peruvian mummy[170] and from a Bison fossil dating 17000 years ago.[164]

The infective nature of the disease was, however, not suspected till the early 18th century. Benjamin Marten, in 1722,[12] proposed that the cause of tuberculosis was "animaliculae or their seed, inimical to our "Nature" that can be transmitted by a "Breath" (a consumptive) emits from his lungs…. that may be caught by a sound person". Green, in 1835,[71] was the first to characterise tubercular meningitis and published the first description of the disease. The formal demonstration of its contagious nature was made in 1865 by Jean-Antoine Villemin.[212] It was only in 1882 that Robert Koch[97] isolated *M. tuberculosis* from crushed tubercles. It is interesting to note that, in the 18th century, CNS tuberculosis was primarily identified as "Dropsy in the Brain"[179] or "febris hydrocephalica".[113] The credit for recognising involvement of the meninges as the cause of hydrocephalus goes to Odier (1790),[130] even though the term meningitis was used for the first time by Herpin only in 1803.[79]

Charles Morehead (1847–48), working in Bombay, described the autopsy findings in a number of children with meningitis as undoubtedly tuberculous in nature. Ford[63] has been credited with the first description of a brain tuberculoma. Successful excision of such lesions was reported by Wernicke and Hahn,[217] Horsley[81] and MacEwen.[114] It is interesting to note that Blocq and Marinesco[21] described, in 1893, that a tuberculoma within the substantia nigra was responsible for Parkinson's syndrome. Spiller[185] observed, in 1905, two discreet tuberculomas in each anterior quadrant of the spinal cord in a patient with bilateral loss of pain and temperature sensations. This observation led him to advocate spinothalamic tractotomy for the relief of intractable pain. Scott and Graves[175] collected, in 1933, 815 cases of tuberculomas of the brain reported till then. Dott and Levin[58] reviewed the results of 91 patients operated upon by 17 British neurosurgeons. Most authoritative works in this field since 1950 have been by Indian neurosurgeons.[18,45,49,52,53,116,150,155,183,189,192]

PATHOGENESIS

The *M. tuberculosis* is member of the *M tuberculosis* complex that includes *M. africanum*, *M. bovis* and *M. microti*. The description that follows applies to CNS tuberculosis in general and not specifically to meningitis or tuberculoma. Though the TB bacillus was one of the earliest pathogenic organisms to be isolated, it is surprising that we still have a very inadequate knowledge about the pathogenesis of tuberculous infections. *M. tuberculosis* is an anaerobic, non-motile, non-spore forming bacillus that stains weakly gram-positive and the main cellular reservoir is tissue macrophages though the organism exists extracellularly. The bacteria resist decolourisation of carbol fuschin by acid alcohol in the Ziehl-Neelsen process due to the high lipid content of the cell wall. These mycobacteria are not fully understood with regard to their metabolism, host-pathogen interaction, mechanism of infection and damage and resistance by the host. It is still not clear how the pathogens get into the cells and then paralyse the protective machinery of the host cell leading to tolerance, and under appropriate circumstances to multiplication of the organisms. There are numerous macrophage receptors capable of binding *M. tuberculosis* that can participate in its internalisation including CD11b, CD14, the macrophage mannose receptor, scavenger receptor A and CD44.[107,112,115,211] Intracellular parasitism is accomplished by a variety of mechanisms that include altered trafficking of bacteria during endocytosis, interference with host Ca^{2+} signalling pathways and induction of maturational arrest of the phagosome. The mycobacteria then lie enclosed in the intracellular compartment that does not contain mature lysosomal enzymes.[24,139]

Recent molecular biological studies have revealed that *M. tuberculosis* contains diverse chemical substances, lipids, polysaccharides and tuberculoproteins which are responsible for the various immune phenomena, viz. resistance, sensitivity, virulence, granuloma formation and chronicity of infection. These immune responses are primarily cell mediated, involving a complex interplay of T and B lymphocytes and macrophages, and mediated by various lymphokines, and immunoglobulins. However, as of today, the nature of the antigen that stimulates the protective immune response, the type of cells involved in protection and the manner in which the macrophages kill the mycobacteria are not known. Although over a dozen somatic and secreted antigens have been cloned, the immunodominant antigen concerned with either virulence or protection has not been identified. In spite of phenomenal advances in molecular genetics, not a single gene involved in the pathogenesis of tuberculosis has been identified. Kinger and Tyagi[96] claimed to have identified and cloned genes differentially expressed in the virulent strain of *M. tuberculosis*. Many laboratories all over the world, including India, are currently engaged in this field. The entire sequence of the DNA that forms the genome of mycobacterium has been worked out.[64] Genomic libraries of several mycobacteria, including *M. tuberculosis*, have been constructed by several groups in India.

There is growing evidence to suggest that the host's genetic traits also play some role in determining susceptibility to infection. The classical study of Kallman and Reissner (1943) revealed that the risk of a contact consort developing tuberculosis is 7.1%. It was 11.9% in half-siblings, 25.5% in siblings and 87% in monozygotic twins. Increased phenotypic frequency of HLA-DR2 has been reported by Mehra[120] from Delhi and of HLA-A10, B-8 and DR2 by Pitchappan[140] from Madurai, India.

CENTRAL NERVOUS SYSTEM TUBERCULOSIS

Central nervous system tuberculosis is usually secondary to a haematogenous spread from a primary infection elsewhere in the body. Uncommonly, it could be the result of direct spread from a lesion in the neighbourhood, e.g. otitis media or spinal caries. There is enough clinical and experimental evidence to indicate that meningitis is the result of a discharge of tubercle bacilli into the CSF from a caseous focus ("Rich focus") in the brain or the meninges, and not a consequence of primary haematogenous spread.[194] In contrast, a parenchymatous tuberculoma is due to direct haematogenous spread to the brain. The inflammatory cells (lymphocytes, monocytes and plasma cells) accumulate in the subendothelial region of the vessel and with further cellular proliferation there is a displacement of the intact endothelium with or without tuberculoma formation, and this proceeds to complete involvement of the vessel with a contiguous inflammatory process. TNF-alpha is an important proinflammatory cytokine, once the bacteria enter the CSF. Infected monocytes and macrophages show increased expression of surface ICAM-1 and increased migratory activity across the endothelial and epithelial bilayers, activating intracellular signalling pathways and secretion of proinflammatory cytokines.[14,15,61,67,82,222] The precise reasons for a given patient developing either meningitis or a tuberculoma or both are not known. In an experimental study on rhesus monkeys, the nature of the lesion could be modified by manipulating the state of immunity or sensitivity of the animals.[80,193,197] This led to the conclusion that the nature of the lesion would depend upon the number of bacilli, their virulence and their site of deposition on the one hand and the state of immunity and allergy of the host on the other. It is important to realise that such a statement fails to provide a precise answer.

The majority of cases of CNS tuberculosis seen in India have been found to be due to the human type of tubercle bacillus (*M. tuberculosis* var. hominis). The bovine type of Tubercle bacillus, though a common cause of infection in Europe in the early years of this century,[22,72,86] is probably responsible for less than 5%. Isolated cases of meningitis have been attributed to avian[59,103] or atypical mycobacteria, both photochromogens and scotochromogens.[33,83,88,191,209] A scotochromogen was isolated from an

intracranial tuberculoma in one of our patients with disseminated tuberculosis. It is as yet difficult to say, if the coexistence of HIV infection or AIDS will alter the relative incidence of the various types of mycobacteria producing CNS tuberculosis.[31,36] The *Mycobacterium avium* complex was found in 50% of AIDS patients at necropsy. The presence of HIV-1 induced immunodeficiency is a powerful cofactor for the development of disseminated tuberculosis and, therefore, the proportion of extrapulmonary cases has increased. Berenguer et al. identified meningitis in 10% of HIV-1 co-infected patients when compared with 2% of non-HIV-1 co-infected individuals and 26% of HIV infected patients have meningeal involvement.[94,174] Patients with tuberculous meningitis can have associated tuberculomas or may develop them after successful initiation of antitubercular therapy.[6] Unal and Sultas[208] reported on 22 cases of intracranial tuberculomas; 8 of these were coexistent with tuberculous meningitis and 12 tuberculomas developed during therapy with ATT and steroids. They advise a careful follow-up of cases. Yaramis et al.[221] in their analysis of 214 cases of patients with tuberculous meningitis found tuberculoma in only 2%.

INTRACRANIAL TUBERCULOMAS

Incidence

There are distinct geographical differences in the incidence of intracranial tuberculomas, in different countries and even within a given country. In most developed countries, by the middle of the 20th century, there was a dramatic reduction in their incidence, though they had not been eradicated completely. Even before the AIDS epidemic broke out, there were several reports on tuberculomas from the UK,[3,118,138] the USA,[109,119,219] Spain and Canada, where most of the reported cases were among the immigrant population, the native Red Indians and the Eskimos.[4]

A higher incidence of tuberculomas among all intracranial space occupying lesions (ICSOLs) (above 10%) was reported from Bombay, while it was less than 5% in Delhi and Calcutta. No adequate explanation is available for such differences, especially when the overall incidence of tuberculosis or even tuberculous meningitis is not very different in these regions. It is interesting to note that in Nigeria[131] and Taiwan,[199] where tuberculosis is widely prevalent, the incidence of intracranial tuberculomas was around 1% only.

There has been a progressive decline in the incidence of intracranial tuberculomas.[147] Reports from Bombay indicated an incidence of 30.5% of all ICSOLs in 1963, 21.5% in 1968 and 12.3% in 1974.[54,105] Similarly, the reported incidence of 20% in 1960 from Madras came down to 14% in 1973.[153] These figures refer to the incidence of tuberculomas diagnosed in the pre-CT scan era. Since 1979, tuberculomas are being diagnosed much earlier and, in the majority of these, as there is no histopathological diagnosis it is difficult to assess the true incidence. The response to antituberculous therapy cannot always be taken as proof of pathology, as one encounters "disappearing lesions" in the CT which resemble a tuberculoma, but disappear in many instances without using antituberculous drugs.[48] With these limitations, one may state that the incidence of probable tuberculomas proved by CT has been on the increase.[152] Ramamurthi[149] encountered 381 cases of tuberculomas over a 28-year period between the years 1950–1978 (pre-CT era) and 246 cases over 12 years between 1979 and 1991 in the CT scan era. It should be emphasised, however, that the incidence of tuberculomas requiring surgical excision has gone down from 78.6% to 13.4%.

Pathology

Tuberculomas of the brain vary in size from less than a centimetre to 8–10 centimetres in diameter (Fig. 1). In its mature form it presents as a well-circumscribed, nodular, firm to hard, greyish-yellow relatively avascular mass. Some present on the surface of the brain, in which case they may get adherent to the dura. Rarely, it is known to cross the dural barrier and in an exceptional case has been seen to go through the overlying bone (Fig. 2). The lesion is surrounded by varying degrees of oedema and gliosis.[55] The so-called capsule of a tuberculoma is nothing more than compressed gliosed brain tissue. A true fibrocollagenous capsule does not exist, even though at surgery the lesion appears to shell out from the surrounding brain. The cut surface presents a creamish-white gritty caseating centre with crenated margins, surrounded by a firm to hard greyish rim of varying colour, composed of granulomatous tissue and compressed gliosed brain matter.

Microscopically, the lesion is a classical tuberculous granuloma,[46] with central coagulative necrosis surrounded by epithelioid cells, Langhans giant cells and

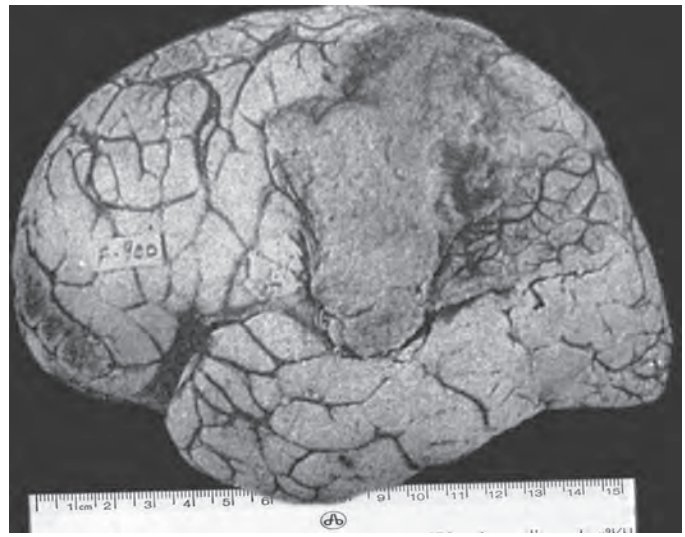

Fig. 1: Gross appearance of an unusually large tuberculoma presenting at the surface of the brain

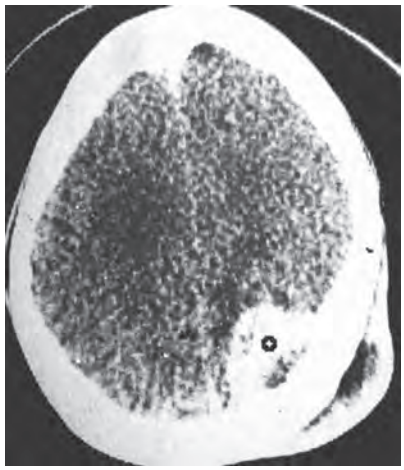

Fig. 2: CT scan showing a right occipital tuberculoma which involved the bone and presented as a subgaleal swelling

an admixture of lymphocytes and plasma cells (Fig. 3). There may be satellite granulomas at the periphery of the lesion and foci of perivascular infiltration may be seen further afield. A fibrocollagenous reaction is seen only where the lesion has reached the surface of the brain.

Careful examination of the central region of the mass may reveal acid fast bacilli in appropriately stained sections. As a rule, there is a paucity of organisms. Radhakrishnan et al.[144] have reported immunohistochemical demonstration of mycobacterial antigen within the cytoplasm of the giant cells and macrophages, while routine examination had failed to reveal any acid fast bacilli. In this connection, it is interesting to consider the possibility raised by Chandramukhi and Shankar,[34] that the evolution of a tuberculoma may not be dependent upon the presence of live tubercle bacilli. The tuberculoprotein or some of the antigenic components released by the destruction of the bacilli may, by complex immune reactions with a number of polyclonal and monoclonal antibodies, lead to the formation of the tuberculoma. They have demonstrated the variability of the immunoarchitecture of tuberculomas and find support for their hypothesis in the experimental work of Ridley.[161]

Besides the classical lesion described above, there are a variety of atypical manifestations of which practitioners in high endemic regions must be aware of.[213] Sinh et al.[183] described several of these atypical lesions.

Tuberculoma En Plaque

According to Pardee and Knox,[161] this type of tuberculoma was first demonstrated by French authors, notably Chantenesse[37] in 1884, under the term 'meningite en plaque tuberculeuse'. Ramamurthi and Varadarajan[150] reported that the angiographic appearance of such lesions may mimic a meningioma due to their increased vascularity. At surgery also, these are found to be adherent to the dura and may grossly resemble a meningioma en plaque. Welchman[216] described for the first time the CT appearance of this lesion.

Tuberculous Abscess

Tuberculous abscess of the brain has been known since the early days.[101,157,217] Dandy[44] referred, in 1932, to the existence of pus in some tuberculomas resembling a pyogenic abscess. It is important to differentiate a tuberculous abscess from a classical tuberculoma with central caseation, softening and liquefaction. A 'tubercular abscess' lacks granulomatous change, and histologically resembles a chronic pyogenic abscess, except that acid fast bacilli are seen in the pus.[141] A number of cases fulfilling these criteria have been described not only from India[35,57,123,151,171] but also from other countries[9,38,106,129,159,207,218] (Fig. 4). Tang et al.[198] reported, in 1991, a case of multiple tuberculous abscesses in the brain in a Chinese child who had tuberculous meningitis. We could produce a characteristic tubercular

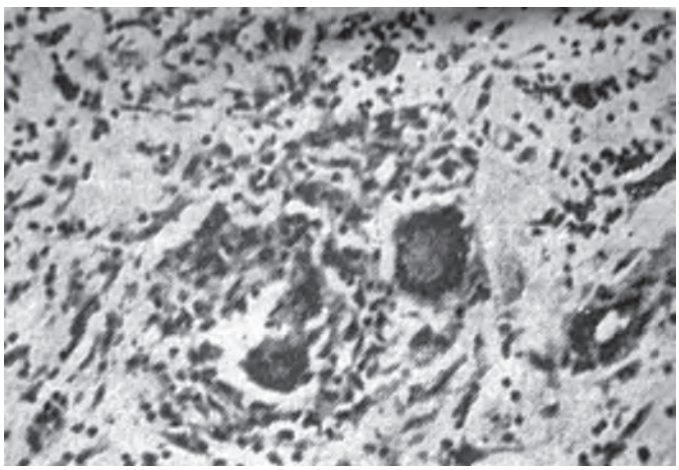

Fig. 3: Typical histological picture seen at the edge of a tuberculoma—giant cell and ill-defined epithelioid cells surrounded by lymphocytes

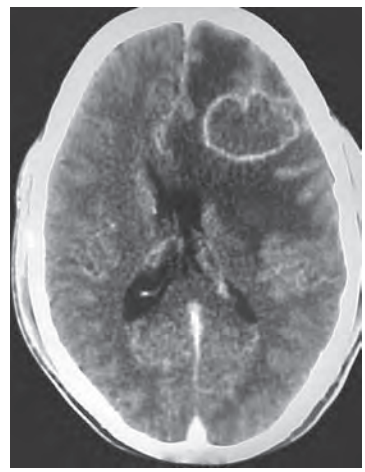

Fig. 4: CT scan of left frontal tubercular abscess—a unilocular hypodense lesion with a thin rim of enhancement

abscess in BCG vaccinated monkeys by injecting tubercle bacilli into the substance of the brain.[194] It is likely that abscess formation may be more frequent in AIDS patients than the classical tuberculoma due to immune suppression. Tuberculous meningitis and abscess, caused by *Mycobacterium avium* in a non-immunosuppressed woman, have been reported by Uldry et al.[207] Kumar et al.[104] reported on 6 cases and emphasised that a long clinical history and a thick walled abscess are indicative of a possible tubercular abscess and these can be aspirated, and rarely may require excision.

Cystic Tuberculoma

These tuberculomas are rare. The first case of cystic tuberculoma was reported by Dastur et al.,[51] in 1962, in a 4-year-old boy with hemiparesis. The cyst contained clear yellow fluid and the cyst wall had typical tuberculous pathology. There have been further reports of such cases from India.[127,158,168,183,186] Liberman et al.[110] reported a cystic tuberculoma containing green cloudy fluid in which acid fast bacilli were demonstrated. It has been suggested that these cases represent the various stages in the resolution of the necrotic core of some tuberculomas (Figs 5A and B). Sridhar et al.[186] have proposed a classification of cystic tuberculomas: Type I—intralesional cyst within tuberculoma; Type II—intralesional cyst at the periphery of the lesion; Type III—extralesional (the cyst is subdural in location) and Type IV—extralesional (the cyst lies between the lesion and the brain). The authors advocate that types I and II require radical excision whereas types III and IV require excision of the solid part alone.

Multiple Grape-like Tuberculomas

Another rare presentation is in the form of a grape-like cluster of multiple immature tuberculomas.[192] These may resemble a cluster of cysticercus cysts. It has been postulated that some of the large mature tuberculomas develop as a result of coalescence and caseation of such multiple lesions (Fig. 6).

Microtuberculomas

With the advent of the CT scan, a large number of cases who presented with a solitary small disc or ring, 5–7 mm in diameter, surrounded by perifocal oedema were reported from all over India. In some cases such small lesions could be multiple or be associated with a large tuberculoma elsewhere in the brain (Fig. 7). It is now, obvious that this CT morphology could be due to a variety of conditions, cysticercosis, "microabscess", non-specific encephalitis, etc., but at least some of these have proven to be tubercular on biopsy.[20] Such a lesion may represent the initial stages of evolution of a tuberculoma. These have been observed at autopsy in cases of tubercular meningitis.[47,142,195]

Calcified Tuberculoma

Calcification is uncommon in a tuberculoma and is reported in 2–6% of cases.[5,8,150] However, occasionally, a tuberculoma may present as a fully calcified mass. It is important to realise that such a lesion is not inactive or healed. A very high incidence (60%) of calcification has been reported in Eskimos and Canadian-Indians.[4]

Tuberculous Encephalopathy with an "Inconsequential" Tuberculoma

Dastur and Udani,[49,50] have drawn attention to the occurrence of diffuse brain damage in children with tuberculosis with a minimal or no inflammatory lesion, meningitis or significant granuloma. The condition is characterised by obvious oedema with varying degrees

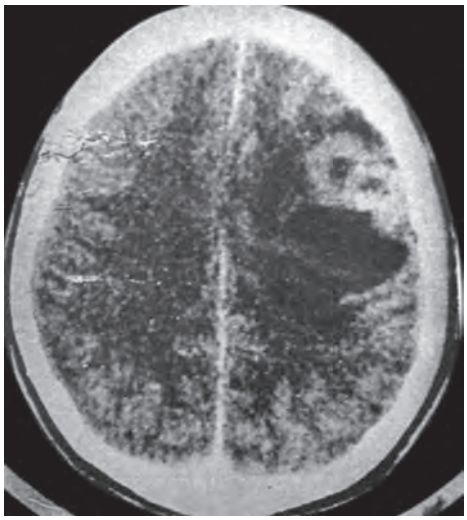

Fig. 5A: Contrast CT scan showing a parietal tuberculoma with a posterior cystic component

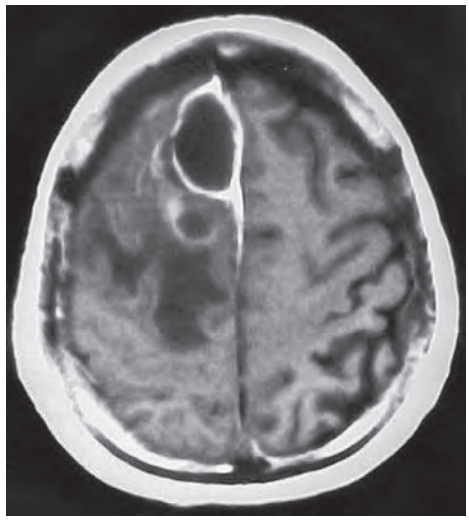

Fig. 5B: MRI axial view showing right parafalcine cystic tuberculoma

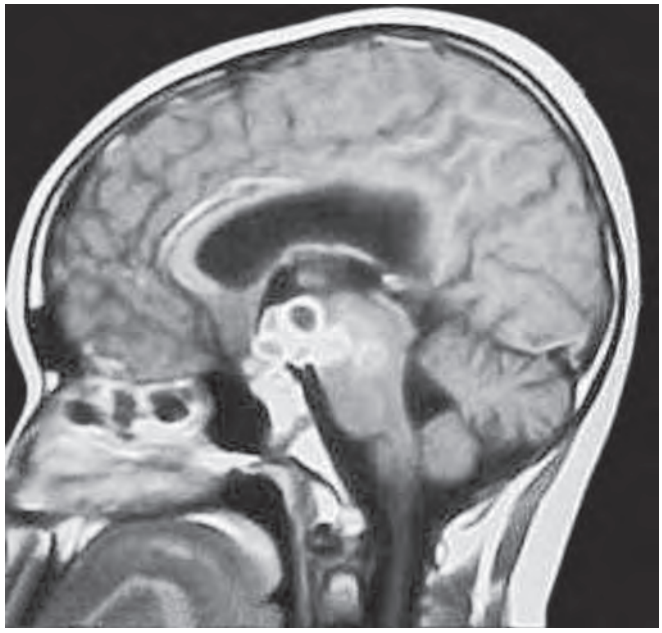

Fig. 6: CT scan of tuberculoma brain—grape-like cluster

of perivascular myelin loss and, in some, even haemorrhagic leucoencephalopathy. They have designated it as 'tuberculous encephalopathy' and attributed it to an allergic reaction to proteins liberated from lysed tubercle bacilli. We had demonstrated a somewhat similar pathology in hypersensitised monkeys challenged with a small number of tubercle bacilli.[194] Wisniewski and Bloom[220] produced evidence in favour of a hypersensitivity mechanism for this type of pathology. Crowle et al.[43] have further elaborated on the chain of complex cellular and molecular events constituting the mechanisms in human tuberculosis.

Fig. 7: Contrast CT showing microtuberculomas in the left frontal and parietal regions

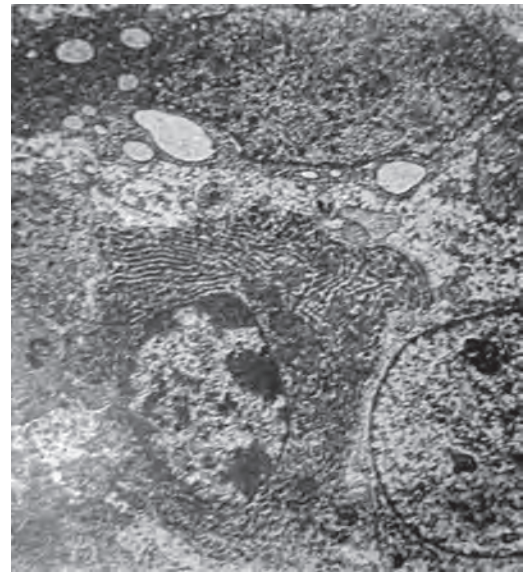

Fig. 8: Electron micrograph of the periphery of a brain tuberculoma—at the top a macrophage is seen with a large nucleus and vacuolated cytoplasm, in the lower half, a plasma cell is seen with the characteristic rough endoplasmic reticulum and peripheral heterochromatin in the nucleus. A part of another large cell with a very pale nucleolated nucleus possibly an epithelioid cell, is seen in the lower right corner

Microscopy

Dastur and his colleagues, in a series of publications, have provided details of electron microscope (EM) studies of brain tuberculomas (Figs 8 and 9). In addition to describing the fine structure of these lesions, including evolution of the epithelioid cells, they elaborated the ultrastructural basis of vasculopathy in and

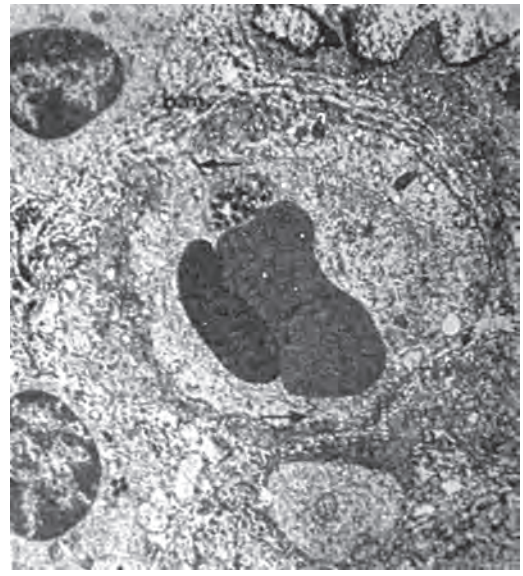

Fig. 9: Electron micrograph of a tuberculoma brain—showing an entire blood vessel, possibly a venule, with two intact endothelial cells and normal tight junction (arrow). Two RBCs and a platelet are seen in the lumen. Note the two lymphocytes on the left and the two epithelioid cells on the right infiltrating the vessel wall

around a tuberculoma. EM examination of the reactive border zone revealed the varied pleomorphic cellular, vascular and necrotic reactions characteristic of these lesions. It was demonstrated that a variety of cells surrounding the central necrotic area participate in phagocytosis. All these cells were large mononuclear cells, the commonest being the epithelioid cell. They demonstrated the evolution of the epithelioid cell from a mononuclear cell and also showed that overt macrophages full of secondary lysosomes and phagosomes contained ingested osmophilic debris. A feature of these cells was their proclivity to fuse with their fellows, forming characteristic Langhans giant cells which also retain the capacity for phagocytosis. These varied responses probably resulted from a delayed type of hypersensitivity to a very small quantity of antigenic tuberculoprotein in the absence of demonstrable tubercle bacilli, which were hard to discover in these lesions. Dastur and Dave[45] had also studied the ultrastructural morphology of blood vessels in tuberculomas. They observed marked proliferation of the basement membrane into concentric layers in the vessels in the reactive border zone. They postulated that the proteinaceous material in the basement membrane may act as an antigen and be responsible for the vasculitis and brain damage associated with tuberculomas.

Clinical Features

The symptoms and signs of an intracranial tuberculoma resemble those of other intracranial tumours. There is no clinical feature which could unequivocally provide the diagnosis. There are, however, certain findings which collectively may suggest a possible diagnosis.

Age and Sex

There is no age immune to CNS tuberculosis, but 60–70% of patients with tuberculomas are below the age of 20 years. The youngest child seen by us was 9 months old and the oldest patient was 69 years old. Ramamurthi[154] reported that 111 out of 280 tuberculomas (40%) were in children. Dastur[53] found 50% to be below the age of 10; 59% below the age of 15 and 83% below the age of 25 years. A higher incidence has been reported in females, but in the author's experience this does not appear to be significant.

Sites

Tuberculomas may occur at any site within the brain; the cerebrum and cerebellum, owing to their bulk, are the most common sites (Figs 10 and 11). The cerebellum was found to be a more frequent location in children and the cerebral hemispheres in adults. This observation no longer appears to be true with much earlier diagnosis being made now with CT scans. The surgical verification of the lesion is also much less frequent, as few cases require surgical excision as compared to four decades earlier.

Tuberculomas have been documented in the intrasellar region, brainstem, thalamus, basal ganglia, mesencephalon, cerebellopontine angle, optic chiasma, the pineal region, in the ventricles and the aqueduct[13,19,20,27,52,53,68,70,85,116,133,182,216] (Figs 12A and B, 13). CT and magnetic resonance (MR) scans reveal a much higher incidence of multiple lesions than was suspected earlier,[17,18] about 15–20% of patients having multiple lesions. Tuberculomas in different stages of evolution and varying in size often coexist. Intracranial extraparenchymal tuberculomas have been reported in the pituitary

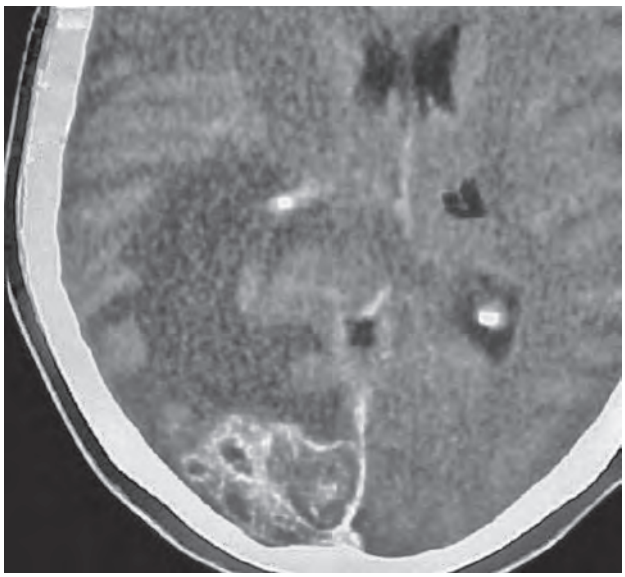

Fig. 10: Contrast CT scan of the brain showing enhancing tuberculoma in the right occipital lobe which is surfacing and minimal shift of the posterior falx to the left due to mass effect

fossa,[28,39,40,100,102,160,181] in the superior orbital fissure and involving the lesser wing of the sphenoid.[21,189]

Symptoms and Signs

Tuberculomas generally, present as slow-growing intracranial space occupying lesions. The constitutional symptoms and signs of an inflammatory lesion are uncommon. Unlike patients with tuberculous meningitis, those with a tuberculoma often look physically well-preserved.[148] A history of fever is recorded in no more than 10–20%. A history of exposure to a person with open pulmonary tuberculosis, especially a close relative, should arouse the suspicion of tuberculous aetiology in a patient suspected to harbour a brain tumour. Concomitant evidence of healed or active tuberculosis acquires great significance. Mayers et al.[119] reported the coexistence of an active extracranial tubercular lesion in 50% of patients and an abnormal chest X-ray in 30%. Mathai[117] identified positive chest X-rays in 51% of 200 cases of intracranial tuberculomas. It is important to remember that in a community in which tuberculosis is as prevalent as in India, patients with neoplastic lesions may have extracranial tubercular lesions as was observed by Mathai[117] in 12.5% of cases. The association of a clinically manifest tuberculoma with tubercular meningitis is uncommon. This was reported in only 3 out of 200 cases by Mathai.[117] However, a much higher incidence of coexistence of the two has been reported in patients investigated by CT or coming to autopsy.[47] A tuberculoma may, uncommonly, appear for the first time after the initiation of antitubercular therapy for tuberculous meningitis or a coexisting tuberculoma may enlarge following treatment.[25,33,77,108,126,195,200]

Fig. 13: Contrast enhancing CT scan showing a thalamic tuberculoma

Focal seizures are frequently the first symptom. Symptoms and signs of raised intracranial pressure are seen in large tuberculomas. Focal neurological deficit, appropriate to the site of the lesion, is observed in approximately 50%. A higher incidence of false localising signs and focal seizures in patients with cerebellar tuberculomas was reported by Dastur and Desai.[52] These were most likely due to multiple lesions, not detected by the investigations available then, viz. ventriculography or angiography. An interesting comparison of the clinical features of 107 cases each of brain tuberculomas and gliomas has been provided by these authors.

Investigations

None of the currently available diagnostic procedures, either singly or in combination, are able to provide an unequivocal diagnosis of an intracranial tuberculoma. Efforts are underway to develop specific and sensitive immunodiagnostic tests, but so far these fall short of the desired accuracy.

The erythrocyte sedimentation rate is often raised, though it may be normal. The Mantoux test is generally positive, though Arseni[5] found it positive in 25%

only. A negative Mantoux test does not rule out tuberculoma, nor does a positive test establish the diagnosis. A plain X-ray of the chest is mandatory as an active tubercular lesion significantly increases the possibility of an intracranial mass being a tuberculoma. PCR is a useful diagnostic aid.[132] Plain X-rays of the skull may show signs of raised intracranial pressure and, uncommonly, calcification.

Computerised Tomography

The computerised tomography (CT) morphology of intracranial tuberculomas has been well-documented in a series of publications since 1976.[111] Welchman[216] has provided a comprehensive account and concludes that the CT appearance of tuberculomata in the majority of cases is sufficiently characteristic to permit a positive or high probability diagnosis.

The CT morphology depends on the stage of evolution and the maturity of the lesion. The important CT characteristics[16,18] are summarised below (Fig. 14):

- In a non-contrast enhanced scan tuberculomas are generally, isodense with the surrounding brain. However, hypodense or slightly hyperdense lesions are well-documented.
- These enhance markedly on administration of contrast.
- Perifocal oedema, usually quite out of proportion to the size of the lesion, is common.
- The lesions manifest in one of the following three forms:
  1. Small discs and rings measuring less than a centimetre. They are sharply outlined and homogeneously enhancing, surrounded by perifocal low attenuation representing oedema (Fig. 15).
  2. A large ring, usually 1–2 cm in diameter, with a uniformly enhancing periphery and central lucency, though not as marked as in a pyogenic abscess (Fig. 1). In a few cases, there may be a central dense nidus producing the so-called "target sign" of Welchman.[216]
  3. Large nodular masses with an irregular outline.
- Multiple lesions representing one or more of the above varieties, occurring in the same patient, are seen in 15–20%.

It must be realised that in spite of the accumulated experience over the years, CT does not provide an unequivocal diagnosis of brain tuberculoma. CT findings considered with the clinical features can, however, provide enough justification for instituting medical therapy.

Magnetic Resonance Imaging

Intracranial tuberculomas usually show complete hypointensity, isointensity or central hyperintensity with a hypointense rim on T1-weighted images and isointensity and/or hypointensity on T2-weighted images.[74–76,215] However, some tuberculomas have been found to be hyperintense on T1 and hypointense on T2 images. Gadolinium MR may show thin rim enhancement in a tuberculoma.[169] Gupta et al.[75] correlated the MR images with histopathology. They concluded that the intensity of a tuberculoma on T1-weighted images depends on the number of macrophages, the degree of fibrosis, gliosis and lipid contents. Lipids are the major contributor to the low-signal intensity on T1 images. Solid caseation appeared hypointense and liquid appeared hyperintense on T1-weighted images. The characteristic hypointensity of intraparenchymal tuberculomas is not found in most other space occupying lesions. It is obvious that the MR image morphology may show

Fig. 14: CT scan showing right parietal tuberculoma with surrounding oedema and mass effect

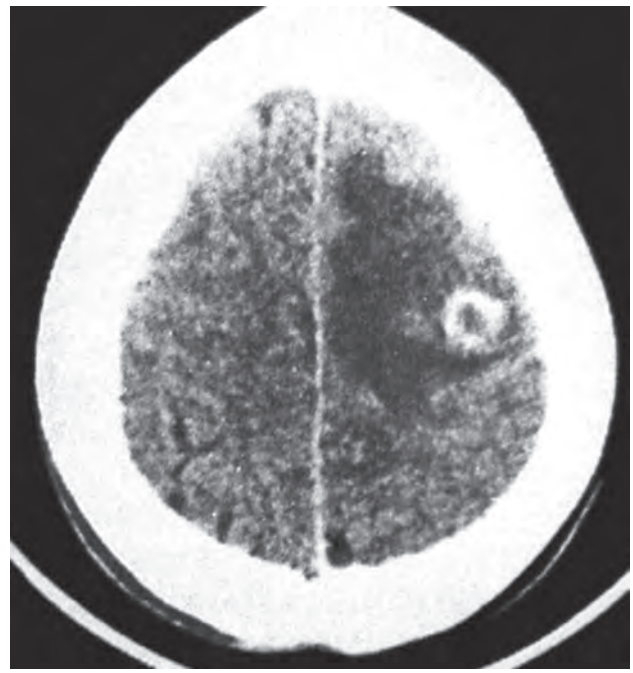

Fig. 15: CT scan showing a small ring lesion in the right parietal region

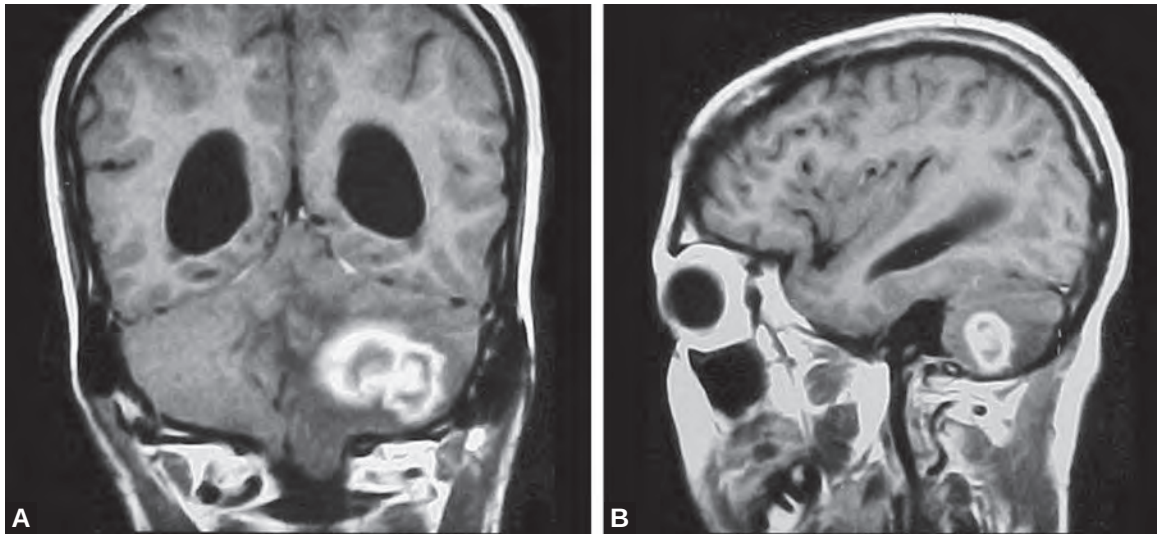

Figs 16A and B: MRI—coronal and sagittal views of gadolinium enhancing tuberculoma in the left cerebellar hemisphere

variations from lesion to lesion and within the same lesion depending upon the stage of evolution and its histopathological characteristics (Figs 16 to 19).

Magnetic Resonance Spectroscopy

In vivo, proton MR spectroscopy[11,88-90,155] of the hypointense lesions shows a characteristic lipid peak on stimulated echo acquisition mode (STEAM) and point resolved spectroscopy sequence (PRESS).

Stereotactic Biopsy

When the diagnosis of a lesion, suspected to be a tuberculoma, is in doubt, one may start a trial of antituberculous treatment or do a stereotactic biopsy. Stereotactic biopsy gives a definite diagnosis to enable the treatment to be based on firm grounds.[26] Vedantham et al.[210] have advocated CT guided stereotaxy to avoid empirical treatment of small brain masses.

Treatment

Till 1970s, emboldened by the availability of antitubercular chemotherapy, neurosurgeons advocated excision of tuberculomas as the treatment of choice.[73,192] This attitude was dictated by the uncertainty of preoperative diagnosis, inability to follow-up reliably the effect of medical treatment and the earlier experience of post-operative meningitis following partial excision. No doubt there were several reports of cures following chemotherapy alone,[4,149,150,163] but in most of these cases there was no objective verification of the diagnosis.

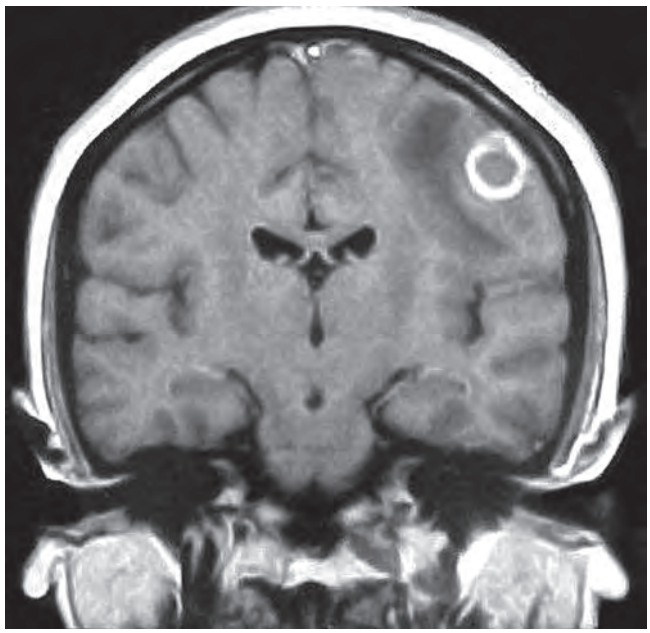

Fig. 17: MRI coronal view showing left parietal solitary ring enhancing tuberculoma with surrounding oedema

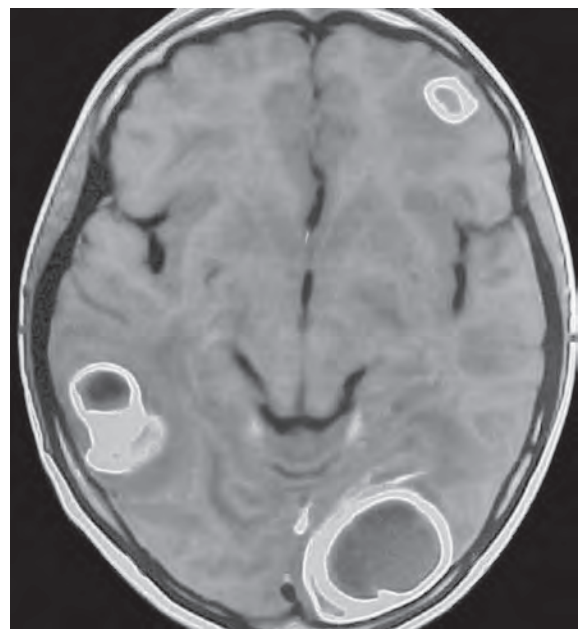

Fig. 18: Post-contrast MRI of the brain showing multiple ring enhancing lesions of various sizes in both hemispheres

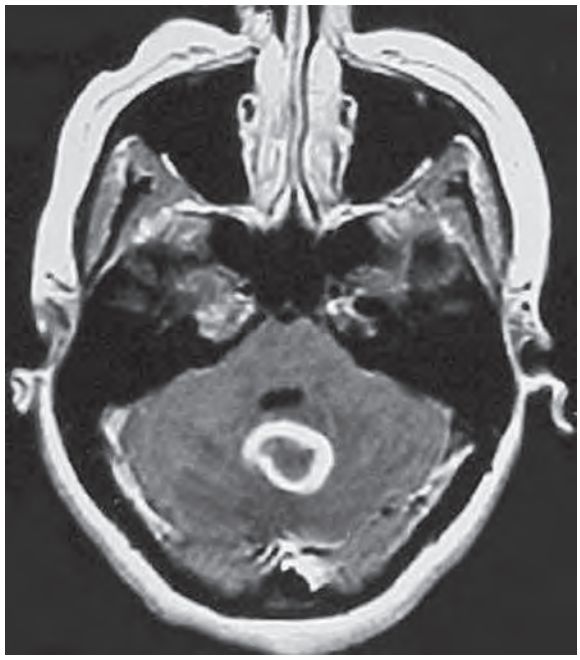

Fig. 19: T1-weighted axial MRI scan of a patient with vermian tuberculoma

With the availability of CT, the diagnosis has become more reliable and the effect of treatment can be evaluated non-invasively.[7,18] This has radically changed the indications for surgery.[190,196] It is now generally, agreed that surgery is indicated: (a) if vision or life is threatened due to a severe increase in intracranial pressure and (b) when the diagnosis is in doubt. In all patients with a reasonable suspicion of a tuberculoma, with no imminent threat to vision or life, a course of multi-drug antitubercular chemotherapy is initiated. Steroids may be added in case CT or MR response to treatment is closely monitored. As a rule, clinical improvement is obvious within 2–3 weeks and significant reduction in the size of the lesion can be documented by CT or MR within 4–6 weeks. Complete resolution of the lesion depends on its size, and is seen as early as 10–12 weeks for small lesions and even large lesions may resolve completely in 6–8 months time.[18-20,108,138,190] Medical treatment may not resolve all tuberculomas. The lesion may develop central liquefaction,[133] may remain unchanged[20] or even paradoxically increase in size.[10,126,146] The reason for the lack of response and the paradoxical response is not clear. There is enough evidence to suggest that this is not only due to drug resistance of the bacilli but also due to factors as yet unknown. A number of these cases ultimately respond to continued therapy and carefully worked out combinations of antitubercular drugs including, if necessary, streptomycin injections. Rajkumar et al.[146] found that the atypical response was seen from 3 weeks to a year of therapy and well-formed lesions more than 3 cm have a greater risk of paradoxical increase.

There are two controversial questions in respect of medical therapy: (1) The ideal combination of drugs and (2) The duration of the treatment. There have been some prospective trials conducted by the Tuberculosis Research Centre of India and Indian Council of Medical Research (ICMR) at Chennai, India. Among the antitubercular drugs, rifampicin, isoniazid, pyrazinamide and streptomycin are bactericidal, and the former three penetrate the blood-brain barrier both in the presence and in the absence of inflammation.[128] Hence, ideally, these constitute the important first line of drugs. After the initial treatment with three drugs, any two of these three or only INH and ethambutol are used for another 12–15 months. Para-aminosalicylic acid (PAS) and streptomycin are seldom used now, though they were in use for many years. Recently, streptomycin had to be reintroduced in some patients in whom there was no adequate response to a three drug regimen. The ICMR research study group[145] recommended a reduction in the duration of therapy to ensure adequate compliance, which reduces the chance of recurrence and to overcome drug resistance induced by irregular therapy. An intermittent regimen gave equally good results with less toxicity. The group concluded that short course chemotherapy gives good results in tuberculosis of the spine and in brain tuberculomas.

In spite of these recommendations, we are reluctant to reduce the treatment to less than 18 months, except in cases of a solitary microlesion described earlier. Pandya and his colleagues[69,133] do not favour short-term chemotherapy for CNS tuberculosis. Poonnoose et al.[40] reported that 75% of patients with biopsied and partly resected tuberculomas exhibited residual lesions even after 18 months of treatment and caution that the duration of ATT should be based on radiological response and some may require prolonged periods of ATT.

It is important to realise that most antitubercular drugs have side/toxic effects. These should be assiduously looked for and patients should be warned to report immediately, if any untoward reactions are observed. Liver toxicity is a real problem with the use of rifampicin. It may be better to evaluate liver function periodically by appropriate tests. There is a risk of optic neuritis when ethambutol is used. It is desirable to use pyridoxine (10 mg) as prophylaxis against peripheral neuritis encountered with the use of isoniazid and ethambutol. The ototoxic complications of streptomycin are well known.

The causes of non-response to antitubercular therapy were identified as inappropriate drug therapy (needing the addition of another drug), bacterial resistance and the lesion not being a tuberculoma. In cases not responding even after a change in therapy and the addition of steroids, the possibility of a glioma is high and stereotactic biopsy or surgical excision is indicated.[167]

Multi-Drug Resistant Tuberculosis

Multi-drug resistant tuberculosis is becoming a common problem and results from inappropriate dosage, use of a single drug or inadequate duration of therapy. The resistance is influenced by bacterial genome changes.[30,136] The coexistence of HIV/AIDS infection increases the chances of developing multi-drug resistance.

Role of BCG

The protective nature of BCG vaccination is well-proven.[121,125,162] Farinha et al,[62] in an analysis of patients with CNS tuberculosis over 20 years, found that no patient who had received BCG vaccination died or had severe neurological sequelae.

Surgical Treatment

The indications for surgery have already been described above. It is desirable to initiate chemotherapy, preferably a few days prior to surgery, if the patient is not already on it. Administration of pre-operative corticosteroids is also desirable. The guiding principles for surgery are:[155]

- Total excision of easily accessible lesions in non-eloquent areas of the brain must be done. No attempt should be made to excise large tuberculomas en-masse. Piecemeal removal or initial debulking does not increase the risk of meningitis if the patient is covered with antitubercular drugs.
- Subtotal or partial excision of lesions situated in or near eloquent areas.
- No attempt should be made to excise aggressively tuberculomas attached to vital structures like the brainstem or the major dural venous sinuses.
- Simple evacuation of the central liquefied caseous material from a tuberculoma or pus from a tubercular abscess may be adequate for treatment of deeply situated lesions, i.e. those in the thalamus, basal ganglia and brainstem.[156] This may preferably be carried out stereotactically.[19]
- Small, circumscribed lesions, the so-called microtuberculomas could be excised stereotactically, if the diagnosis is in doubt.
- Residual lesions, or in cases of multiple tuberculomas, the lesions that have not been excised, respond to chemotherapy.
- A ventriculoperitoneal shunt may be required for patients with gross hydrocephalus.
- The CUSA (ultrasonic aspirator) can be very useful in debulking a large tuberculoma. Chiasmal decompression may be required for a suprasellar tuberculoma developing during treatment for tuberculous meningitis.[29,42,43,65,84,95,118,176,201]
- Endoscopy[87,180] has a role in management of associated hydrocephalus and can be used to do ETV, fenester the septum, break loculations and reduce the need for multiple shunts.

In short, even when surgery is indicated, it is better to be conservative rather than risk an undesirable neurological deficit. With the use of modern techniques, the mortality and morbidity of surgery are negligible.

Reviewing an experience of 40 years, Ramamurthi,[149] in 1993, pointed out the changes that have taken place in the presentation and management of tuberculomas in the CT era. Of the 380 patients with tuberculomas seen between 1950 and 1978 (the pre-CT era), 303 (78.6%) required surgical treatment. Between 1979 and 1999 (the CT era), of the 246 patients seen only 13.4% required surgery. During the CT era smaller lesions are diagnosed early, long before the ICP rises. On a presumptive diagnosis from the CT, antituberculous treatment was started and the majority of cases responded to therapy, as proved by serial CT studies. It is obvious, of course, that in all these patients the pathology has not been proven by histology. Some of them could have been what have been termed 'disappearing lesions' whose aetiology is not clear and may be multi-fold. Puri and Gupta, in 1994,[143] evaluated with MR these focal CT lesions in 67 patients and identified four distinct groups: 38 (56%) were diagnosed as tuberculomas; 12 (17.9%) as cysticercosis; 1 as abscess and the rest (23.8%) were classified as non-specific. The non-specific lesions were hyperintense on T2-weighted and hypointense or isointense on T1-weighted and resolved completely in 5 months without any antitubercular therapy.

65 Tuberculous Meningitis

PN Tandon, Anil Pande

INCIDENCE

In spite of the intensive public health measures adopted by governments and various agencies, tuberculosis continues to be a major problem, and tuberculous meningitis (TBM) a major cause of neurological morbidity and mortality all over India and the developing countries. The incidence of TBM, in patients with tuberculosis, has been reported to vary from 7% to 12%. TBM is a disease of childhood, with the maximum incidence around 3 years. It is uncommon before 6 months of age and rare before the age of 3 months. The incidence in adults is increasing and adults account for 50% of patients. There is a resurgence of TBM in the developed countries due to the prevailing AIDS epidemic. Since 1995, an increase of 15% in the incidence has been reported.[1,23,39,139,150,152,153,164] The BCG vaccine was introduced in 1921 and the protective efficacy of this vaccine against miliary tuberculosis and tubercular meningitis is proven. The children who have been vaccinated with BCG have a better outcome than those who have not been protected.[5,6,17,74,81,112]

AETIOPATHOGENESIS

Much of the characteristic pathology of TBM is recreated with the subarachnoid injection of tubercular protein alone. The spectrum of CNS tuberculosis is varied,[149] and both the host and bacterial genotype influence the development of disseminated disease.[22] A cascade of proinflammatory cytokines (e.g. tumour necrosis factor, TNF alpha, interferon, Gamma-cytokines) influence the cell mediated response.[97] TBM is correctly characterised as a meningo-vasculo-encephalitis as the meninges, parenchyma and vasculature are all involved. There is a thick subarachnoid tubercular exudate caused by basal arachnoiditis. The small and medium sized arteries that traverse the exudates develop an inflammatory tuberculous arteritis and the adventia and intima develop typical tubercular granulomatous lesions.[162] The intima may be damaged by fibrinoid hyaline degeneration and this leads to vascular occlusion by a reactive subendothelial cellular proliferation.

EARLY DIAGNOSIS

The protean manifestations of this disease may mimic almost any neurological disorder affecting the central nervous system.[130,144,147,154,156] Constant awareness of the disease and clinical suspicion are prerequisites for diagnosis. Usually the clinical features include fever, meningismus, nausea and vomiting, and neurological deficits including cranial nerve involvement, motor paresis and a bulging fontanelle in infants. Only less than 20% of patients with TBM present with fever, hence, the absence of fever does not exclude the possibility of TBM. In 1994, the Ahuja criteria[1,4] were proposed to aid in the diagnosis of TB meningitis.

Modified criteria of Ahuja[126] are useful to diagnose the disease and include the following:

A. *Clinical*—Fever with or without change in the temperature over a period of 2 weeks with or without any cause (mandatory), loss of appetite, irritability, headache, vomiting, meningeal signs, convulsions and focal neurological deficits; known contact with sputum positive adult tuberculosis (optional).
B. *Cerebrospinal Fluid (CSF)*—Pleocytosis with more than 20 cells/mm^3, lymphocytes more than 60%, protein more than 100 mg% and sugar less than 60% of corresponding blood sugar.
C. *Radiological*—Computerised tomography (CT) studies of brain showing two or more of the following:
    1. Exudates in the basal cisterns or in the Sylvian fissures
    2. Hydrocephalus
    3. Infarcts
    4. Gyral enhancement
D. *Extraneural tuberculosis*—Active tuberculosis of lungs, gastrointestinal tract, lymph nodes, skeletal system as evidenced by appropriate radiological or microbiological evidence or by the presence of caseation necrosis on histological examination.

Diagnosis of TB meningitis is classified into four groups based on the above clinical and laboratory criteria.

1. Definitive TBM:
    a. Clinical criteria
    b. Bacterial isolation from CSF or diagnosis at autopsy
2. Highly probable TBM:
    a. Clinical criteria
    b. All three of B, C and D
3. Probable TBM:
    a. Clinical criteria

b. Any two of B, C or D
4. Possible TBM:
   a. Clinical criteria
   b. Any one of B, C or D

These criteria have been modified by adding Mantoux reaction and contact history. The modified Ahuja's criterion has a sensitivity of 83% and a specificity of 63%.[126] If diagnosed and treated early, the disease is curable with minimal or no residual neurological disability.

LABORATORY INVESTIGATIONS

CSF examination at the least suspicion is essential.[86,90] Apart from changes in cells and proteins, enzyme-linked immunosorbent assay (ELISA) tests are most useful.[68,72] The polymerase chain reaction (PCR) is useful in the rapid diagnosis of tubercular meningitis and has a sensitivity varying from 31% to 60%.[8,100,101,103,109,128] Microscopic observation drug susceptibility (MODS) assay format detects the presence of 65 kD hsp antigen which is specific to *M. tuberculosis* and is a reliable diagnostic marker of TBM.[7,80,91] of IgG reactivity to lipoarabinomannon (LAM) in the CSF is very useful in the early diagnosis of TB meningitis and is superior to PPD in the diagnosis of TBM. The novel wide range qualitative nested real time PCR assay for mycobacterium tuberculosis DNA is used to rapidly diagnose TBM and is a useful and advanced assay technique for assessing the clinical treatment course of TBM.[140,142] Culture of the bacteria takes 2–6 weeks. Centrifugation and filtration methods are used to increase the yield of positive cultures.[125] The isolation rates for the BACTEC 12B medium and LJ medium were 93% and 39%, respectively.[58,159] Notwithstanding the recent advances, a totally reliable diagnostic test is still not available.

LATE DIAGNOSIS AND COMPLICATIONS

If diagnosed late, the course of the disease is prolonged with numerous complications like hydrocephalus, arachnoiditis, infarcts and tuberculoma. In addition, many chronic and localised forms of the disease appear with atypical manifestations, posing diagnostic and therapeutic problems and often require surgical help. A thorough knowledge of these problems is essential for neurosurgeons practising in the developing countries in the East and the West.

The most common complication of tubercular meningitis where surgery is helpful is post-meningitic hydrocephalus resulting from a blockage of the CSF pathways as a result of inflammation, the incidence of which may range from 38% to 80%. Tubercular meningitis may also present with raised intracranial pressure (ICP), mimicking a brain tumour, cerebral abscess or tuberculoma.[85] A progressive hemiparesis due to vascular involvement in tubercular meningitis may resemble an intracranial space occupying lesion. Occasionally, a tuberculoma may follow or be associated with tubercular meningitis.[137,138] Basal arachnoiditis due to tuberculosis may be localised and cause neurological deficits or hydrocephalus. Compression of the optic chiasma may result in impairment of vision.[34] Spinal arachnoiditis, often associated with meningitis, may result in spinal cord compression.[37] The different aspects of the disease and its presentation are described here as many of these conditions may simulate other surgical problems and may require surgical relief.

Acute Stage of the Disease

Raised Intracranial Pressure Pathogenesis

TBM may present primarily with the problem of raised ICP.[93] Most of the cases of TBM are associated with raised ICP, which is caused by brain oedema, increased proteins in the CSF, poor absorption of CSF and obstruction to CSF flow. In the early stages, there is a mild increase in ICP due to the general inflammatory processes. Later, cerebral oedema with associated tuberculous encephalopathy occurs, possibly on the basis of an allergic reaction. The large arteries at the base of the brain get occluded or compressed with resulting ischaemic oedema and infarction in the affected territory. In some, softening of the brain may occur without major arterial involvement.[30,155] Increased proteins in the CSF retard CSF absorption and lead to raised ICP. Radioisotope studies have shown no significant obstruction to the flow of CSF from the ventricular system to the subarachnoid space in the acute stage.[141] However, in later stages the obstruction to CSF flow may be at a variety of sites—aqueduct, fourth ventricle, tentorial opening or the arachnoidal villi. It may even be at more than one of these sites.[145]

Diagnosis and Treatment

A patient with TBM and associated acute intracranial hypertension may present with an alarming picture of impaired level of consciousness and decerebrate spasms. These patients are usually young and the signs of meningitis minimal. The correct diagnosis can be arrived at only by an examination of the lumbar CSF. Hence, it is wiser for neurosurgeons in countries where TB meningitis is widely prevalent to bear in mind such an uncommon clinical presentation and in suspected cases to resort to a careful LP for the purposes of examination, preferably after CT studies. The risk of lumbar puncture in the presence of raised ICP is minimised by anti-oedema measures like IV mannitol which helps to reduce cerebral oedema. CT studies may show acute oedema with compressed narrow ventricles or hydrocephalus with a dilated ventricular system. The addition of acetazolamide and furosemide, to antituberculosis chemotherapy, is effective in controlling ICP.[123] If acute hydrocephalus still develops, repeated ventricular tapping or external ventricular drainage with a closed system is essential to reduce ICP.[14] This may directly be done through suitably placed burr holes or after inserting an Ommaya reservoir.

Subacute and Chronic Stage of the Disease

Tuberculous Endarteritis

Vascular involvement in TB meningitis is usually a tuberculous endarteritis affecting the smaller blood vessels and resulting in multiple focal neurological signs, due to localised areas of infarction. In late cases, these areas get calcified and are visible in the plain X-rays as irregular small areas of dense calcification. Such calcification is more common than the one seen infrequently in tuberculomas. The resultant clinical picture will vary with the areas involved, e.g. hypopituitarism or hypothalamic obesity in association with basal calcification.

Involvement of Large Arteries

The large arteries may be displaced, kinked or obstructed by the tuberculous exudates at the base of the brain. The siphon of the internal carotid artery, its bifurcation and the proximal segments of the middle cerebral artery are most commonly involved. Occasionally, the anterior cerebral artery may also be narrowed or occluded. The affected artery shows changes of periarteritis and a massive subintimal fibrosis, narrowing or occluding the lumen. These changes have been demonstrated by arteriography[50,51,87,117,162] and in autopsy studies by Dastur et al.[29,31,32] Of the 33 cases of TBM studied by Wadia and Singhal[161] with carotid arteriography, narrowing of the siphon of the internal carotid artery and the proximal segments of the anterior and middle cerebral arteries was seen in 17 cases. Narrowing of the arteries was seen most frequently in those with a neurological deficit and thus suggested infarction as the probable cause of hemiplegia. Cerebral infarction occurs in 14–38% of children with TBM and the most common vessels involved are the medial striate and thalamostriate arteries.

Tuberculomas and Tuberculous Abscess

These may infrequently follow TBM. More often, these occur in patients without any history of previous TBM.[110,157] They can also appear during or after completion of antitubercular therapy.[36,69,113] They manifest as a space occupying lesion, requiring appropriate investigations and treatment. CT or MR helps to localise the lesion, which may be excised with complete relief (see the chapter on Tuberculosis of the Central Nervous System). Kumar et al.[76,77] reported on six cases of tubercular abscess. These are characterised by an encapsulated collection of pus containing viable tubercular bacilli and 50% of the cases developed TB abscess while on ATT for TB meningitis. Only multilocular abscesses or those with thick capsules required excision, the rest were managed with aspiration and ATT. Poonoose and Rajshekhar[107] found that 46% of patients being treated for tuberculomas had residual lesions on imaging 2 years after treatment. Muthukumar et al. described concurrent syringomyelia and intradural extramedullary tuberculoma as a late complication of TBM.[57,94,105,135] Extended treatment may be required in such cases.

Basal Meningitis

Plaque simulating a neoplasm: as the disease becomes more chronic, the meningeal exudates become firm, organised and adherent to the base of the brain. In some areas the exudates becomes plaque-like, a few millimetres thick, almost like a granuloma, whilst the rest of the exudates clear up.[35] At times, when the process has become more chronic and localised, woody hard fibrosis of the leptomeninges may produce a bizarre clinical picture without clinical evidence of meningitis.[54] Such cases may simulate posterior fossa tumours, foramen magnum lesions or intracranial abscesses.[35] MR is helpful in differentiating these conditions. In these cases, the disease, though localised, is still in an active form.[141] The patient may present with headache, vomiting and drowsiness, and mild pyrexia is present. The clinical picture often simulates a posterior fossa neoplasm if a definite history of TBM is not available. The CT shows a dilatation of the ventricular system with no enlargement of the subarachnoid space. The fourth ventricle may be displaced and distorted. At surgery, a thick carpet of granulation tissue is seen obliterating the cisterna magna and the exit foramina of the fourth ventricle. It is better to avoid posterior fossa exploration in such cases. A ventriculoperitoneal shunt is more effective.

Hydrocephalus

More often, the exudates get organised and there is a fibrous obliteration of the subarachnoid space. The disease dies down, but hydrocephalus develops and leads to progressive mental deterioration and impairment of the level of consciousness. The hydrocephalus may be communicating or non-communicating.[16] Lampreche et al.[79] found non-communicating hydrocephalus in 58.5% and communicating in 41.5% of shunted cases.

The raised ICP in subacute and chronic TBM is essentially due to the hydrocephalus produced by the obstruction of the CSF pathways.[95] Blockage of the arachnoid villi contributes to the production of hydrocephalus.[119,120] A common site of obstruction is in the basal cisterns like the cisterna pontis, interpeduncularis and ambiens. In the majority of cases, the hydrocephalus is of the communicating variety as confirmed by isotope cisternography. At times, the exudates block the foramen of Munro or the foramina of Luschka and Magendie preventing the exit of CSF from the fourth ventricle. Blockage of the aqueduct of Sylvius may be caused by the exudates or by ependymitis with local oedema, or an associated small intrinsic tuberculoma.[111] Usually, a combination of these factors is responsible for the hydrocephalus, and this was demonstrated by RIHSA studies of CSF circulation by the author in 1975.[146] The block at the level of the foramen of Monro may lead to the necessity of two shunts or an endoscopic fenestration of the septum.

Clinical Picture

This depends upon the stage of the disease when hydrocephalus sets in. In the acute stage, when the symptoms

and signs of meningitis dominate, the development of hydrocephalus is heralded by increasing ICP, while the systemic and meningitic signs appear to be responding to treatment. Infants develop a bulging fontanelle, enlarging size of the head and increasing drowsiness. Upadhyaya et al.,[158] in a series of 70 cases of TBM and hydrocephalus in children five months to 11 years of age, found fever, altered sensorium, vomiting and convulsions as the common symptoms. Disturbed state of consciousness, decerebrate rigidity, meningeal signs and focal neurological deficits may be observed. These signs may develop any time during the course of the illness, even after a few months of an apparent arrest of the disease. In some cases, the initial acute illness may be mild or be modified by inadequate therapy, the patient thus presenting for the first time with evidence of raised ICP.

On the other hand, hydrocephalus may manifest months after the treatment for meningitis has been completed. At this stage, there are no clinical features of meningitis or systemic toxaemia. The patient presents with symptoms and signs of raised ICP, only the history indicating the aetiology.

Amongst adults, one occasionally sees a patient presenting with raised ICP, with or without any neurological deficit, and with no clinical evidence of meningitic or infective pathology. Investigations reveal a communicating hydrocephalus. CSF examination or a contrast enhanced CT may reveal the inflammatory nature of the lesion. The possibility of tuberculosis being the cause of the condition is often presumptive.

Investigations

In the acute stage, CSF examination reveals evidence of meningitis, predominantly lymphocytic pleocytosis, raised proteins and diminished sugar. In the chronic stage, the CSF may be normal or may show mild pleocytosis and increase in proteins. Coexistent syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and cerebral salt wasting syndrome should be diagnosed and treated. Polyurea, hyponatraemia, volume depletion and increased sodium excretion are pointers.[25,118]

Computerised tomography: It establishes the diagnosis of hydrocephalus and may suggest a possible tuberculous aetiology.[10,13,16,19,62,98,99,115,121,137,158] Ozates et al. reported that abnormal CT scans were seen in 98% of patients and hydrocephalus was seen in 84%.[99] Basal exudates can be detected and their severity ascertained. Such exudates, characteristic of TBM, are not diagnostic and can be seen in other bacterial, fungal[24] and carcinomatous meningitides.[98]

The most specific feature of TBM is hyperdensity in the basal cistern area prior to IV contrast medium administration, and the most sensitive feature is basal enhancement (Fig. 1).

The severity of hydrocephalus can be quantified in the CT by planimetric measurement of the surface area of the brain and the ventricle.[158] The degree and significance of hydrocephalus is calculated by the Ventricular Size Index, which is a ratio of the bifrontal diameter over the frontal horn diameter. A VSI range of 30–38% signifies mild hydrocephalus, 39–45% moderate hydrocephalus and severe hydrocephalus is indicated by VSI of 46% and above. Periventricular lucency indicates transependymal CSF flow and is caused by elevated ICP or spread of the inflammatory process. CT also reveals the presence or absence of infarcts and tuberculomas which have a direct relevance to therapy and prognosis. Abnormal CT scan findings may persist even after 6 months and despite good clinical improvement.

SPECT reveals more frequent abnormalities compared with EEG and CT scan.[63] Cortical hypoperfusion with or without basal ganglia hypoperfusion is associated with

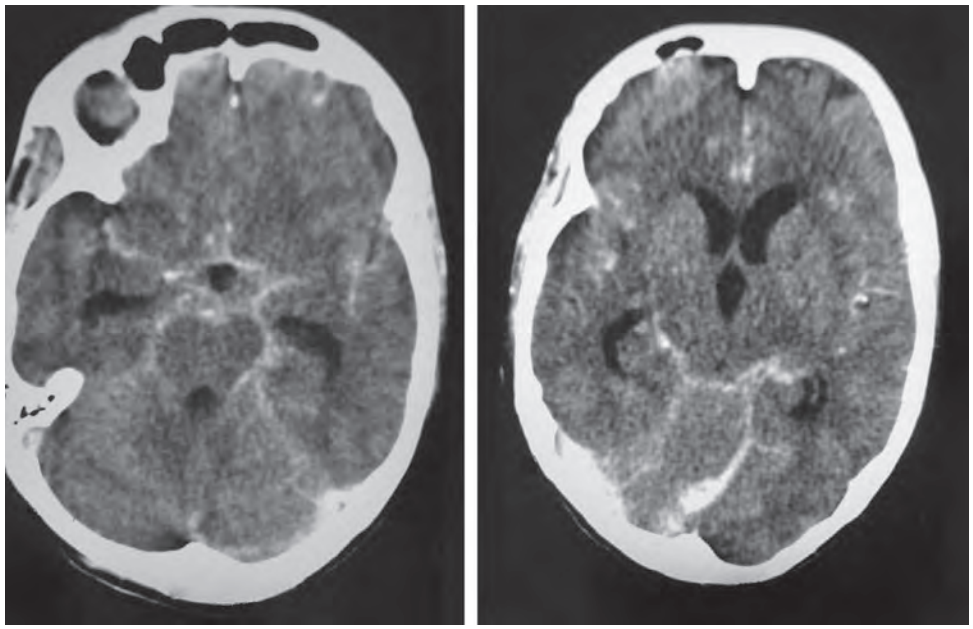

Fig. 1: CT scan of the brain showing post-contrast enhancement of the basal exudates

frontal rhythmic intermittent delta activity (FRIDA) and diffuse slowing on EEG.[62,88] BAER and VEP may have a role in evaluating these patients and show characteristic changes.[9]

Magnetic resonance imaging: Reactive diffuse meningeal enhancement occurs in the early period of tubercular meningitis on contrast medium enhanced T1 weighted MR; this later becomes limited to the basal regions.[100] The most specific feature of TBM is hyperdensity in the basal cisterns prior to administration of contrast medium. Magnetisation transfer MRI[65] is an important modality to detect infectious meningitis of different aetiology and the visibility of the meninges on precontrast T1 weighted MTMRI images is highly suggestive of TBM.

Treatment

Sir Hugh Cairns[21] was a pioneer in suggesting a CSF diverting procedure for post-meningitic hydrocephalus in tuberculosis in 1951. Since then the scope of surgical management has increased due to availability of shunt systems and the endoscope.[3,11,46,114,131,133,148] In those subacute and chronic cases of TBM, which have developed hydrocephalus, a ventriculoperitoneal shunt is indicated.[69] Mild hydrocephalus (VSI 30–35%) is treated with acetazolamide (20 mg/kg/day in three divided doses). It is important to remember that mild to moderate hydrocephalus, in the acute stage of the disease, is reversible following medical treatment of the meningitis and resolution of the basal exudates.[42,121,145] On the other hand, it is imprudent to delay the shunt in the face of impaired sensorium, increasing ICP or progressive neurological deficits.[15,134] In a series reported by Karande et al.,[67] hydrocephalus was seen in 84% of patients and 56% required shunt surgery.[27] It is not necessary to wait for the CSF to become free of evidence of active disease before shunt insertion. In patients with CSF protein higher than 1 gram/litre, an external ventricular drain is inserted initially which is converted into a VP shunt when the protein level becomes near normal.

A large volume of evidence has accumulated to show that dissemination of the disease is rare if the shunt is inserted under adequate cover of chemotherapy, even whilst the disease is active. There are, however, reports of the occurrence of military tuberculosis after a ventriculoatrial shunt and of tuberculous peritonitis after a lumboperitoneal shunt.[50]

After the insertion of the shunt, most of the patients show gradual recovery, even though the CSF may continue to show some abnormality. The level of consciousness improves and the neurological deficit regresses.[158] Long-term follow-up studies by Bhargava et al.,[16] showed that shunt surgery was followed by significant reduction in the size of the ventricles, but only rarely did the ventricles return to normal or near normal size. There was a close relationship between the cerebral mantle thickness and later intellectual attainments. Series dealing with post-tubercular hydrocephalus treated by shunt placement indicate that early shunt placement in cases of mild to moderate hydrocephalus leads to a better outcome. In HIV positive patients with TBM hydrocephalus a poor prognosis is common.[66,95]

Endoscopic surgery: Confirming that the hydrocephalus is non-communicating is very important in the management of hydrocephalus secondary to TB meningitis. Jha et al.[60] elaborated that endoscopic third ventriculostomy[61] can fail in the presence of advanced clinical grade, extra-CNS tuberculosis, dense prepontine cisternal adhesions and unidentifiable third ventricular floor anatomy. An associated tuberculoma in the brain can be associated with a successful outcome of the ETV.[59,60] The endoscope can also be used to fenestre loculations and the septum, thereby reducing the number of shunts.[41,165]

Corticosteroids: The use of steroids under ATT cover is advocated and improves outcome. Girgis et al.,[44] from Cairo, found that the addition of dexamethasone to antituberculous chemotherapy significantly reduced mortality and morbidity in patients with TBM, and this has been well validated.[2,108]

The use of steroids decreases cerebral oedema, and the production of cytokines and other chemicals in the immunopathogenesis of TBM.[151] Corticosteroids are given during the first month of treatment with IV dexamethasone (0.6–1.2 mg/kg/day in three divided doses) for 1 week followed by oral prednisolone (2 mg/kg/day in three divided doses). Corticosteroids affect outcome by reducing hydrocephalus and preventing infarction.[151]

Antituberculous drugs: Streptomycin was introduced in 1946[136] and since then a number of first-line and second-line antitubercular drugs have been introduced. The first-line drugs used are isoniazid, rifampicin and pyrizinamide, all of which are bactericidal. Ethambutol, a bacteriostatic drug or streptomycin in children too young to be monitored for visual acuity, are included in the initial treatment regimen if there is a possibility of drug resistance.[113] *Rifampicin* is given orally (10 mg/kg). It is contraindicated in jaundice and pregnancy and has adverse effects of liver toxicity, GI symptoms and rarely shock and respiratory collapse. *Isoniazid* is given orally or by the intramuscular route (3–10 mg/kg). It is contraindicated in drug induced liver disease and has adverse effects like peripheral neuropathy, psychosis, optic neuritis and, occasionally, lupus syndrome. *Pyrazinamide* is given orally (20–30 mg/kg) and is contraindicated in liver damage and can cause hepatitis. *Ethambutol* is given orally (15 mg/kg) and is contraindicated in optic neuritis and can cause optic neuritis, colour blindness and peripheral neuritis. *Streptomycin* is given as intramuscular injections (1 gm/day) (20–25 mg/kg). It is contraindicated in pregnancy and old age and can cause ototoxicity and renal damage.

The duration of ATT (short term/long term) is controversial and many neurosurgeons prefer to give 18 months of antituberculous drugs. However, Rajeshwari et al.[110] found satisfactory outcome after 9 months of ATT in 108 patients of tuberculomas. Goel et al.[45] reviewed 35

cases of TBM and found that short-term treatment was associated with recrudescence of TBM and a higher incidence of infarcts and neurologic sequelae. The problem of multidrug resistance[20,38,70] is very real and is seen in 2.4% of isolates.[96,104]

Anticonvulsants: Anticonvulsants are necessary because of the high incidence of seizures in patients with TBM. Patwari et al.[106] proposed a protocol that includes the consideration of clinical, EEG and radiological findings. Patients with focal or generalised seizures or tonic spasms that occur more than once, or associated with abnormal scans or EEG findings are started on anticonvulsants.

Results

The improvement depends upon the pre-operative condition of the patient.[82,83] Patients with prolonged pre-operative coma and semicoma show only marginal improvement. However, if a shunt is inserted when the level of consciousness is good, the results are gratifying. Most of these patients become alert, the hemiplegia improves and they may regain normal speech. Even in advanced disease the vision may return. Several series of patients treated with shunt surgery reported from India[26,89,102,158] and elsewhere[19,92] have established the safety and utility of shunt operations. Palur et al.,[102] from Vellore, India, reviewed 114 patients who underwent shunt surgery for hydrocephalus due to TBM. The patients were graded according to their sensorium. Palur grade I (headache, vomiting, fever and neck stiffness with normal sensorium and no neurologic deficit), Palur grade II (normal sensorium with neurologic deficit), Palur grade III (altered sensorium but easily arousable with or without dense neurological deficit) and Palur grade IV (deeply comatose, decerebrate or decorticate posturing). The best results were seen in grades I and II. They advocate early shunt surgery in these grades. For the others, external ventricular drainage is placed and if this results in improvement of the neurological status within 48 hours, shunt surgery was done. Bhargava et al.[15] emphasised the prognostic value of the amount and density of the exudates as seen in a contrast enhanced scan. The presence of thick exudates was associated with poor prognosis for survival and residual brain damage. The usual complications of shunt surgery like shunt obstruction, displacement, etc. may occur and need to be dealt with appropriately.

The pathology, in patients who show neurological recovery, is more likely to be vascular ischaemia rather than infarction. The blood flow is reduced as the dilated ventricles cause a narrowing of the arteries by elongation and stretching. A satisfactory restoration of blood flow, consequent on relief of hydrocephalus, results in neurological improvement.

Prior to the introduction of shunt surgery, direct intervention to relieve the obstruction locally has been performed on many occasions. These procedures are risky and are better avoided.

SEQUELAE OF THE DISEASE

Long-term sequelae[64] are seen in 78.5% of patients with 55% having cognitive impairment, 40% having motor deficit, 37% optic atrophy and 23% having cranial nerve involvement. These sequelae were common in patients who presented with deficits and altered sensorium. These patients need follow-up and there is the possibility of late development of tuberculomas after completing the ATT course successfully. Schoeman,[124] in analysing 76 cases of TB meningitis treated with modern antitubercular drugs and aggressive ICP management, found only 20% of children were functioning at normal level with 80% having cognitive impairment.

Optochiasmal Arachnoiditis

Defective vision following TBM is not an uncommon disability. The optic nerves may primarily be affected in an ischaemic process leading to primary optic atrophy. Loss of vision may also be due to compression of the visual pathways by basal meningitis. Fibrosis occurring near the optic chiasm may cause irregular field defects or blindness due to optochiasmal arachnoiditis. Choroidal tubercles, commonly described in textbooks, are rarely seen.[20] Blindness may also result from prolonged increase of ICP. When a child is brought with a complaint of blindness following TBM, plain X-rays of the skull are valuable in indicating raised ICP. In case the plain X-rays are normal and the visual defect is irregular, CT or MR has to be done to visualise the chiasmatic cisterns. In selected cases surgery around the chiasm may lead to improvement in vision.

Malnourishment

Malnourishment is common in patients with TBM, especially children, with nearly a third being malnourished. Shunt infection and dysfunction is related to the patient's nutritional status. Early pre-operative nutritional status screening and its optimisation may decrease the morbidity and mortality of shunt surgery for hydrocephalus. Jain et al.[47] studied 124 patients with hydrocephalus and in 66 patients the aetiology was TBM. They found that post-operative complications were significantly higher in undernourished patients and serum albumin was the most significant predictor of post-operative mortality.

Endocrine Signs

Involvement of the pituitary and hypothalamus, due to ischaemia, may lead to obesity, diabetes insipidus or hypogonadism.[78] Such a picture, when associated with field defects and primary optic atrophy, may simulate a neoplasm in the chiasmal region. SIADH is often observed in children with TB meningitis. Electrolyte disturbance in the form of hyponatraemia is very common and is seen in 42–85% of patients. Incidence of SIADH in 89% of patients was reported in one series.

Tuberculous Spinal Arachnoiditis

Incidence

Tuberculous spinal arachnoiditis is generally a complication of meningitis. It has been reported in 10–30% of cases, either during the course of treatment of TBM[71] or several months or even years after the arrest of the disease.[56,116,143,160] Isotope cisternography in patients undergoing treatment for TBM revealed a much higher incidence of spinal involvement than clinically suspected.[145,146]

Primary spinal TBM, though described in the early years of this century,[53,55] failed to be recognised as a clinicopathological entity till recently. A paper by Harbitz, in 1922,[53] which provided a detailed pathological account of this condition has generally been overlooked. Isolated cases were reported under a variety of titles. Singh et al.[132] and Bawa and Wahi[12] described such cases under the title of spinal TBM. In a series of publications, Wadia and Dastur[12,164] have elaborated the clinical, radiological and pathological features of this condition. This condition is certainly more common than would appear from the number of publications on the subject.

In some cases, the disease may start primarily as spinal meningitis. This is due to rupture into the subarachnoid space of a tuberculous focus (tuberculoma) on the surface of the cord, as described by Harbitz.[53] In some cases, the spinal lesion may spread to involve the cranial cavity resulting in a full fledged picture of TBM. Wadia and Dastur[163] observed that the secondary cranial lesion was more proliferative, while the spinal lesion was more organised and tenacious. Lumbar spinal arachnoiditis may occur in TBM, secondary to an irritation caused by repeated administration of intrathecal streptomycin,[33] a procedure seldom practised nowadays. Described as early as 1871 by Michaud, quoted by Garceau and Brady,[43] transdural spread of infection to the spinal meninges in cases of caries spine, though uncommon, has been well documented.

Pathology

Tuberculous spinal arachnoiditis usually occurs concomitantly with TBM. The spread of infection from the cranial cavity to the spinal canal is responsible for those cases associated with a known case of TBM. In these cases, besides the cranial basal exudates, there is often a thick exudate in the spinal theca. At times the cranial basal exudates may be slight, whereas the spinal involvement may be quite marked. The maximum involvement is in the dorsal or dorsolumbar region. The leptomeninges are infiltrated with fibrinopurulent exudates in varying stages of organisation depending upon the stage and duration of the illness. The longitudinal extent of the lesion is variable, involving only a few segments or extending throughout the spinal canal. It surrounds the spinal cord, varies in its thickness and is generally more marked on the posterior surface. Macroscopic nodular tubercles may be seen on the surface pointing to the diagnosis. The dura is adherent to the exudates overlying the spinal cord. In chronic cases, the fibrocollagenous tissue may acquire a woody hardness. The cut surface of the cord is atrophic and soft due to oedema. There may be one or more tuberculomas in the substance of the cord.

Microscopically, the characteristic tubercular lesions, fibrinous exudates, caseation necrosis, granulomas[18] with epithelioid cells, Langhans giant cells, lymphocytes and plasma cells are obvious. Interestingly, besides the arteritis, a common feature of tuberculous infection, phlebitis was found to be more pronounced both by Hughes[55] and Dastur and Lalitha.[28]

With the passage of time, the exudates get organised and tuberculous granulation tissue is found to envelop the cord. Occasionally, fibrosis sets in and thick fibrous tissue may either constrict the spinal cord or the spinal nerve roots or both, producing a myeloradiculopathy.[160]

Clinical Features

The possibility of the coexistence of spinal arachnoiditis with TBM is considered when such a patient develops root pains, weakness of the lower limbs and sphincter disturbances. This is confirmed by lumbar puncture, which reveals evidence of a partial or complete block with increase in the protein content of the CSF with a variable lymphocytic cellular response. The glucose tends to be low. RIHSA cisternography, studied by Tandon et al.,[145] showed early evidence of spinal arachnoiditis even before the clinical manifestations appeared.

When spinal arachnoiditis is not associated with the cranial manifestions, it presents essentially as spinal cord compression. In the acute stage, there may be systemic manifestations like malaise and pyrexia. Both in the subacute and chronic stages of the disease, root pains, progressive paraparesis or quadriparesis with sphincter involvement are the presenting features. As the lesion is usually diffuse, one often finds a mixture of a level of sensory loss and extensor plantar responses that suggest a high dorsal lesion, and absent reflexes in the lower limbs. Lumbar puncture reveals a partial or complete block with the CSF showing increased proteins and a mild cellular lymphocytic response.

Lumbar myelogram may show an incomplete block, with the contrast flowing very slowly in small fragmented globules or a complete block with an irregular margin. The block is likely to be at a level lower than the expected clinical level. Cisternal myelogram shows the upper level of the block which often confirms a very extensive lesion. Rarely, one may see in the myelogram a curvilinear outline suggestive of a cyst. Intramedullary cavitation or cysts may also be seen.[40,134] Water soluble contrast myelography, CT myelography or MR helps to reveal the level and the extent of the arachnoiditis or cysts.

Magnetic Resonance Findings

TB leptomeningitis is characterised by loculation of the CSF, subarachnoid nodular lesions, nerve root thickening

and clumping seen in the lumbar region, or complete obliteration of the subarachnoid space. Gadolinium MR may show linear enhancement of the surface of the spinal cord and nerve roots or plaque-like enhancement of the dura-arachnoid complex. Intramedullary lesions, like tuberculomas, cord oedema and cavitations, are well seen.[52,75,84,94,122,129] Increase in CSF intensity on T1 weighted images leads to loss of cord CSF interface or a shaggy outline. Sharma et al.[127] advocated contrast enhanced MRI as the first line of investigation for evaluation of suspected tuberculous arachnoiditis. As there is usually a long segment involvement, extended FOV image should be acquired for the whole spine in all patients.[49,73]

Treatment

Having established a diagnosis of spinal arachnoiditis, the treatment is essentially medical. Antituberculous drugs, with a full course of steroids, may be of help in a fair number of patients. Intrathecal administration of hydrocortisone 25 mg or methyl prednisolone twice a week may help in the further resolution of the exudates. Gourie Devi[48] has found intrathecal administration of hyaluronidase useful in the treatment of TB spinal arachnoiditis. Recurrence is not uncommon and similar medication may have to be repeated. The prognosis in such cases is not encouraging.

Surgery may be offered only if the diagnosis is in doubt, if the lesion is fairly localised and not diffuse or if the imaging is suggestive of a cyst at the expected clinical level.

66 Tuberculosis of the Spine

Sridhar K

HISTORY

The classical paper by Percival Pott entitled, "Remarks on that kind of Palsy of the lower limbs which is frequently found to accompany a curvature of the spine, and is supposed to be caused by it, together with the Method of Cure", has led to paraplegia of tuberculous origin being named Pott's paraplegia.

INCIDENCE

The world has nearly 30 million people suffering from tuberculosis.[170] Of all the patients with tuberculosis, nearly 1–3% has involvement of the skeletal system. Vertebral tuberculosis is the commonest form of skeletal tuberculosis, most series reporting an incidence of up to 50% of osteoarticular tuberculosis.[43,49,67,104,120,126,132,171] Tuli[170] from Banaras reported that out of a total of 1,074 cases of osteoarticular tuberculosis, 440 cases affected the spine.

Spinal tuberculosis can occur at any age and affects both sexes equally. When tuberculous disease was ubiquitous in all countries of the world, spinal tuberculosis was found to be most common in the first three decades of life.[148,165,170] In recent decades, with the near abolition of tuberculosis in the developed countries and preventive measures undertaken in the poorer countries, there seems to be a shift in the incidence to older age groups.[103,164] The pattern of the disease in the developed countries appears different from that in the developing countries.[29,44,70,71,95] In the developed countries and urban populations, tuberculosis of the spine affects more commonly the elderly, while in the developing countries it is still a disease of the young adult. The disease was uncommon in the advanced countries of the world.[27,95] However, the frequent and easy communication facilities and exchange of population and the emergence of HIV infection and intravenous drug abuse[40,85,102] are leading to an increasing incidence.[62,76,77]

PATHOLOGY AND PATHOGENESIS

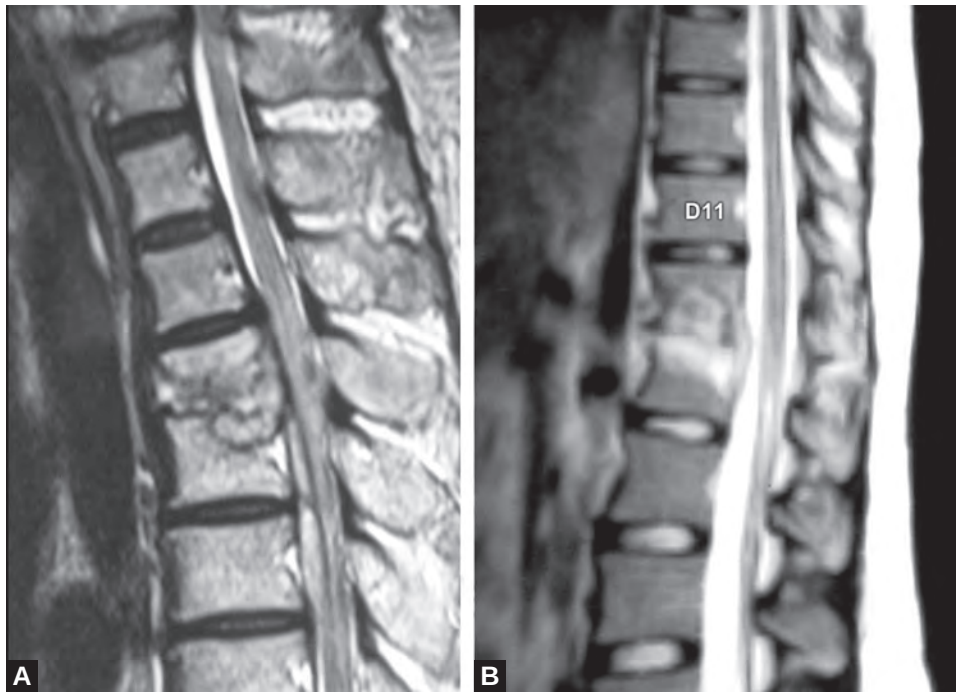
Tuberculosis is the prototype of a granulomatous disease in man. The tubercle comprises of an organised microscopic aggregation of plump rounded histiocytes (macrophages) that vaguely resemble epithelial cells and are therefore called epithelioid cells. At the margin of a cluster of epithelioid cells there may be some Langhan's multinucleate giant cells, formed by the fusion or internal nuclear divisions of macrophages. Around this is a collar of plump fibroblasts interspersed with mature macrophages and lymphocytes. The tubercles thus formed grow by expansion and coalescence. The characteristic caseation occurs in the central region of the epithelioid cells. The caseous material may soften and liquefy. Marked exudative reaction is a common feature of spinal tuberculosis. The incidence of exudative response is much higher amongst patients from developing countries.[75] A "cold abscess" is composed of serum, leucocytes, caseous material, bone debris and bacilli. It can penetrate the ligaments and migrate along fascial planes, often presenting far from the site of infection.[165, 170]

Route of Infection

The spinal disease is always secondary to a primary lesion, usually from a visceral focus, and occurs due to haematogenous spread.[95,165,170] Involvement of different parts of the spine and the presence of associated visceral lesions imply a bacillaemia causing the spread of infection from the primary focus. Infection may reach the spine due to a bacillaemia or through the Batson's plexus of veins. The primary focus may be active or quiescent and may be in the lungs, mediastinal lymph nodes, kidneys or other viscera. Simultaneous involvement of the paradiscal part of two contiguous vertebrae suggests spread of infection via the common blood supply to the region (Figs 1A and B). On an average, an involvement of 3.4 vertebrae was reported in two series[57,103] and 3.8 in another.[120] Kaila et al.[79] found the incidence of non-contiguous multilevel involvement to be as high as 71.4% when screened with whole spine magnetic resonance imaging (MRI).

Types of Lesions

Classically, four types of involvement of the spinal column have been described in spinal tuberculosis: (i) a paradiscal lesion which arises from arterial spread of the infection (Figs 1A and B); (ii) the central type of vertebral body involvement of one or more distant or adjacent vertebrae (this is often associated with tuberculous meningitis as the spread of the infection is via the Batson's plexus of veins); (iii) the anterior type with



Figs 1A and B: Paradiscal location of caries spine as seen on sagittal MRI T2-weighted images. (A) C7-T1 caries. (B) D12-L1 caries

cortical bone destruction (Fig. 2) and (iv) appendiceal type (Fig. 3).[37,165,170]

The paradiscal lesion (Figs 1A and B) begins in the vertebral metaphysis, erodes the cartilage plate and destroys the disc. The cartilaginous end plate acts as a barrier, but once invaded, destruction of the disc progresses rapidly due to its relative avascularity,[147] and the infection goes on to involve the adjacent vertebrae. The early resorption of the disc leads to narrowing of the disc space, although with progressive involvement of the body and accumulation of debris, the space may sometimes be widened.[95]

In the central type of lesion the infection begins in the midsection of the body instead of the metaphysis. It extends centrifugally to involve the whole body. Following the infection, marked hyperaemia and osteoporosis occur. The body, which is thus softened, easily yields under gravity and muscle action, leading to compression, collapse and bony deformation.[95,170]

Anterior lesions lead to cortical bone destruction beneath the anterior longitudinal ligament. Spread of the infection in the subperiosteal and subligamentous planes, allows extension of the infection to adjacent bodies without involvement of the intervening disc space.[95] Stripping of the periosteum results in loss of the periosteal blood supply to the body. This, along with thromboembolic phenomena, periarteritis and endarteritis can lead to ischaemic reactions of the bone contributing to the vertebral collapse[32,46,164,165,170] (Figs 2 and 4A and B).

In the appendiceal type the pedicle, the lamina, the articular process or the spinous process is affected primarily (Fig. 3).

Infection and infarction lead to the formation of bone and cartilage sequestrae. The granulomatous debris and infective material may be compressed between normal bony and ligamentous structures, and get pushed along tissue planes, resulting in lateral extension, retropulsion into the spinal canal or propulsion anteriorly.

Tuberculous spondylitis commonly occurs in the thoracic spine followed by the lumbar and cervical spines (Fig. 5)[14,63,95,96,164] Tuli[170] found a higher incidence in the cervical spine and thought it to be due to a larger number of paediatric patients in his series.

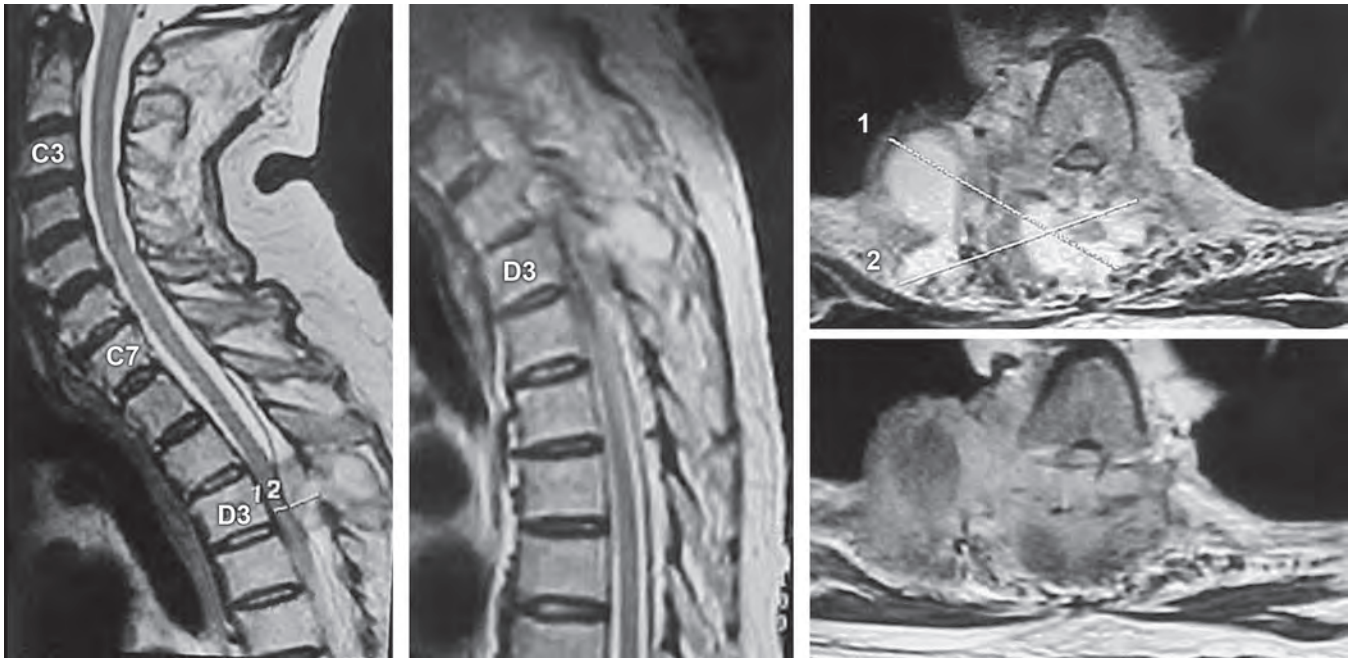

Fig. 3: Sagittal MRI scan showing apendicular dorsal caries at D3 with dorsal epidural collection causing cord compression. Axial MRI T1-weighted and T2-weighted images showing the extent of involvement of the posterior elements

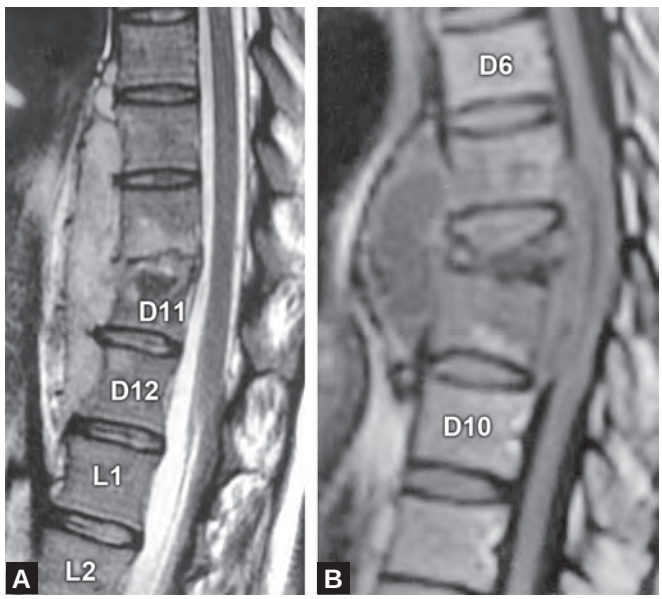
Neurological Involvement

Neurological involvement is the most serious of the complications of spinal tuberculosis. The overall incidence of neurological complications varies between 10% and 40%.[24,70,75,120,126] Janssens and de Haller[71] reported neurological involvement in 46% of their cases, while Friedman[44] reported 8 patients (12%) with paralysis in a series of 64 adults. Reporting on a prospective series of 45 cases of the lower cervical spine, Prabhakar et al. found cord compression in 37.8% of patients.[134] The risk of paraplegia is highest in lesions of the cervico-dorsal region,[164,165] although Tuli[170] reported a higher incidence amongst those with mid thoracic lesions. Out of 200 patients with neural involvement, Tuli found the lesion to be in the mid-dorsal region in 139.[170] Involvement of the cauda equina in the lumbar and lumbosacral regions is seen less frequently.

The spinal cord may be involved during any phase of the disease, in the active phase within the first 2 years or in later years after the disease has become quiescent.[24,150,162] The severity of the neurological deficit can be graded depending on the degree of motor involvement.[47,90]



Figs 4A and B: Sagittal MRI of two different patients showing prevertebral collection in dorsal caries

Fig. 5: MRI cervical spine sagittal view in a patient with tubercular involvement of C6,7 showing gross dislocation and severe cord compression

The cause of paraplegia in most cases is compression of the spinal cord[106,120,145,150,165,170] due to one of the following mechanisms:[58]
(1) In active disease: (a) abscess (fluid or caseous); (b) granulation tissue; (c) sequestrated bone and disc; (d) pathological subluxation or dislocation of vertebrae.
(2) In healed disease: (a) transverse ridge or bone anterior to the spinal cord; (b) stretching or attrition of the cord due to spinal deformity; (c) fibrosis of the dura.
In a given case more than one factor may contribute to the pathogenesis.

Other causes are infective thrombosis of the cord, and the spinal tumour syndrome. Non-compressive pathologies may rarely lead to neurological deficits. There is no proof that the paraplegia can be caused by toxic or vascular reactions in the cord secondary to the presence of active tuberculosis in close relationship to the dura,[164,165] as was proposed by Butler.[24]

Pathology

The extradural mass, caused by an abscess, sequestrae or granulation tissue, fills the epidural space and spreads around the dural sac, thus compressing the spinal cord. It may get adherent to the dura, which becomes thickened by the formation of new fibrous tissue on its outer surface. The granulation tissue causes loss of function by not only direct compression of the cord, but also by impeding venous drainage, thus causing cord oedema. As a rule the dura constitutes a very good barrier against the spread of infection. Rarely, the barrier is broken and the infection spreads intradurally to result in focal or diffuse meningitis, arachnoiditis or a granuloma.[58,143]

The usual pathological lesion in the cord, in the early stages, is a vacuolar type of myelin degeneration seen in the lateral or anterolateral columns.[44,169] This is more diffuse than seen in ischaemic lesions and may be secondary to venous obstruction. Wallerian degeneration above or below the lesion is uncommon in spite of considerable myelin damage at that level. Autopsy findings in chronic cases show vacuolisation and myelin degeneration.[44]

Acute severe lesions of the cord may be produced where there is rapid collapse of a vertebral body with the cord stretched over a relatively intact intervertebral disc or when sequestrae are pushed backwards into the spinal canal by a sudden angulation (Fig. 6).[150] Infarction of the spinal cord may occur due to endarteritis, periarteritis or thrombosis of the arterial supply of the cord.[95,164,170] An important radicular supply to the cord may be compromised occasionally at the intervertebral foramen before it enters the dura.[164,165,169] Angulation of the spine on healing may lead to the formation of a bony ridge or spur called 'an internal gibbus' on the anterior wall of the spinal canal, resulting in a slow and progressive paraparesis.[165,170]

Fig. 6: Sagittal MRI T2-weighted image showing collapse of the body with retropulsion causing cord compression

CLINICAL PRESENTATION

The clinical picture has three components: (1) the systemic illness; (2) the osseous lesion and (3) neurological complications.

As with tuberculosis elsewhere in the body, there may be malaise, pyrexia, loss of appetite and weight, and night sweats. Fever was seen in 32% of patients reported by Alothman et al. from Saudi Arabia.[5] Back pain is a predominant clinical feature.[70] The spine is stiff and painful on movement, with spasm of the paravertebral muscles. The associated localised muscle spasm is so characteristic, that an experienced physician usually suspects the disease immediately. Progressive backache is so often seen, that many authors are of the opinion that tuberculosis must be considered in its differential diagnosis when the patient belongs to an endemic region.[29] A soft tissue swelling or mass is often obvious and in late cases a draining sinus may be seen. Tuli[170] reported a 20% incidence of palpable cold abscesses, while Janssens and de Haller[71] had an incidence of 57%. Angulation of the spine in the form of a kyphosis or gibbus was seen in 95% of the cases seen by Tuli.[170] This he felt was due to the poor socio-economic condition of the patients and their ignorance of the disease process, resulting in late presentation to the hospital. Weakness of the legs (69%), gibbus (46%), pain (21%) and a palpable mass (10%) were the most common clinical features seen in 694 cases reported by Turgut.[175] Heroin addicts have been noted to have a distinct presentation with an acute toxic febrile illness associated with pain, weight loss, anaemia and neurological deficit.[4,42,62] Rare forms of presentation include abdominal symptoms, occasionally leading to unwarranted surgery before the correct diagnosis is made.[64]

Jain and Sinha, on evaluating the ASIA scoring system and Tuli's classification for assessment of the neurological status of patients with tuberculosis of the spine, found both systems wanting. In their study they found the Tuli system insensitive to early detection of improvement or deterioration, while the ASIA system failed to score all types of neurological involvement. They have suggested a new staging system for Pott's spine.[66]

Associated Lesions

The incidence of associated visceral lesions (of the lung, kidney or lymph nodes) varies between 40% and 50% in different series.[44,132] Bahemuka and Murungi[10] found tuberculosis outside the nervous system in 33% of cases and Chan et al.[29] found pulmonary tuberculosis in 25% of their cases. Simultaneous involvement of other bones and joints has been reported to be between 12% and 15% in patients with caries spine.[44,170]

Neurological Deficit

The degree and extent of the neurological deficit depends on the site of the disease, the direction of spread and the pathological changes produced.[165] While usually the onset of symptoms is slow and progressive, in a small percentage of cases the paraplegia may be of sudden onset and nearly complete from the beginning. Tandon and Pathak[164] have divided the clinical picture of Pott's disease into four groups: (1) Paraplegia arising in a known case of spinal tuberculosis; (2) Paraplegia as the presenting symptom of spinal tuberculosis; (3) Spinal tumour syndrome and (4) Paraplegia due to tuberculosis of the posterior neural arch.

Lesions of the posterior neural arch, including the lamina and pedicle, while reported to be rare by orthopaedic surgeons[147] are more frequently seen in neurosurgical practice.[7,53,114,121,141,164,165] This is probably due to the higher incidence of neurological morbidity in these cases[7,114,164,165] and to the increasing use of the CT scan and the magnetic resonance (MR).[61] Kumar[89] studied 27 cases of tuberculous involvement of the posterior elements of the spine and proposed a four-point classification based on the site of the lesion, the stage of the lesion, the presence of associated lesions and of neurological deficits. Baibus and Garbuz have, after studying 2,500 patients with tuberculosis of the spine, also classified the neurological condition into five grades.[134]

IMAGING

Plain X-rays

The paradiscal lesion is the commonest lesion seen. Narrowing of the disc space is the earliest radiological finding on plain X-rays, and when associated with a loss of definition of the paradiscal margins of the vertebra, the diagnosis of tuberculosis is obvious. Lytic areas in the metaphyseal regions of the body may not be seen early, as foci less than 1.5 cm in diameter are not demonstrable on a conventional radiograph.[147] At least 30–40% of calcium should be lost before a radiolucent area is visible on a plain X-ray.[170] Sclerosis may be seen in up to 50% of patients at presentation.[23]

The central type of disease arises from the centre of the vertebral body, which loses the normal bony trabeculae and may show as areas of destruction. Occasionally, and especially in children, the body may be ballooned out as a result of the accumulation of inflammatory debris which expands the weakened cortical bone.[59] Towards the later stages, the diseased vertebral body may show a "concertina" collapse[170] and may resemble a collapse due to secondary deposits.

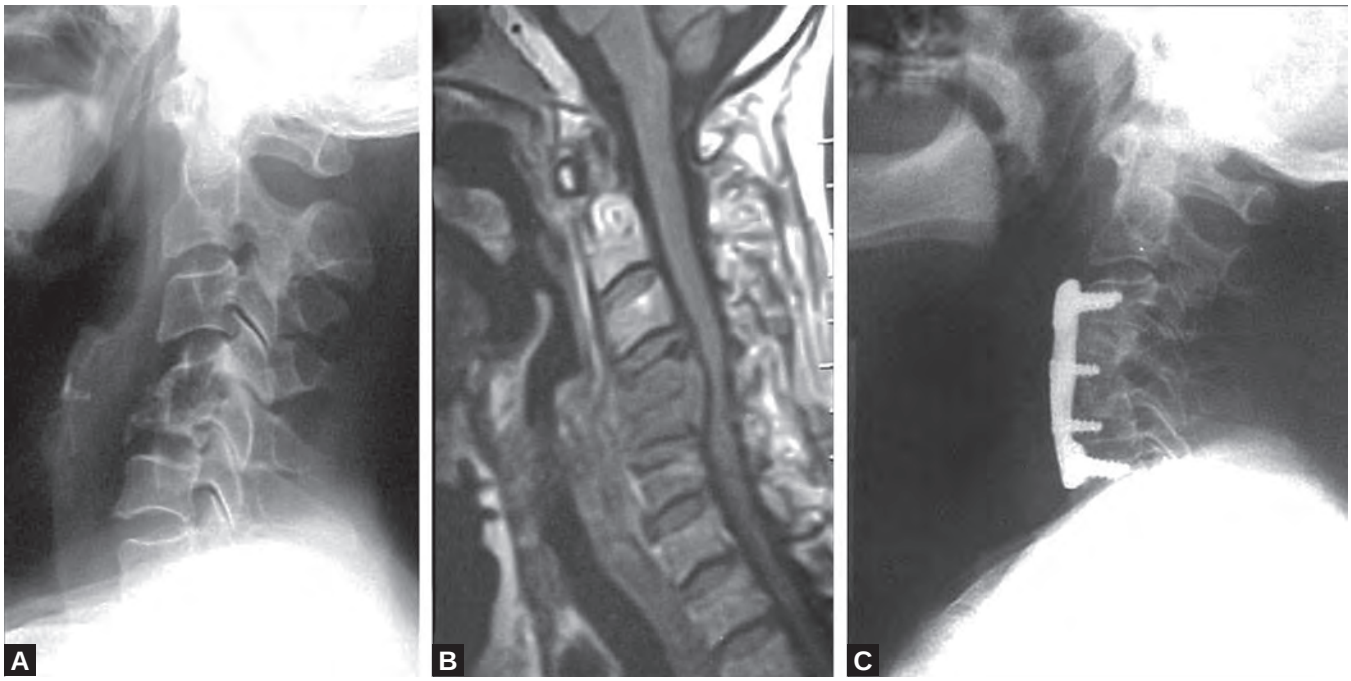
In the anterior type of lesion, the infection begins beneath the anterior longitudinal ligament. This results in erosion of the peripheral parts of the vertebral body (in front and on the sides), which is seen well in the lateral or oblique views as shallow excavations. Destruction of the anterior surface of the vertebral body due to a tense paravertebral abscess may simulate scalloping due to an aneurysm of the abdominal aorta.[149] The tendency for erosion is greater when the aorta is in close proximity to the paravertebral abscess as the transmitted pulsations compound the pressure caused by the abscess. Stripping off of the periosteum deprives the bone of its blood supply, making the bone more liable to the destructive and scalloping effects of the lesion (Figs 7A to C).

Lesions of the pedicle, transverse process and the spinous process appear as erosion of the region involved and may be missed in the plain X-rays unless specifically looked for.

Wedge collapse of adjacent vertebrae with paradiscal bone destruction causes forward angulation of the spine and when this involves a large number of adjacent vertebrae a severe kyphotic deformity results. Rarely, a lateral curvature and deviation may be seen and is caused by the greater destruction of a vertebral body on one side.[60] The final effect is due to a combination of lateral deviation and lateral rotation.[52] Tuli[170] is of the opinion that lateral shift occurs where there is involvement of the posterior spinal articulations along with the usual paradiscal lesions.

A paravertebral shadow is seen on the plain X-rays due to the presence either of an abscess or extension of tuberculous granulation tissue. An abscess produces typical radiological findings depending on its size and location: an abscess in the cervical region causes a widening of the space between the pharynx and the vertebral body and upper thoracic abscess causes a squaring of the superior mediastinal shadow when small, or a V-shaped shadow when large, shifting the apices of the lungs laterally and downwards; abscesses below D4 take up a typical fusiform shape; and those below the diaphragm produce a widening of the psoas shadow.

CT scan is useful in assessing the destructive lesions in the vertebral column. It is considered by most authors to be the investigation of choice for spinal tuberculosis.[9,25,99,129,145,155,157,176] Based on a study of 30 patients



Figs 7A to C: (A) Pre-operative X-ray of the cervical spine showing destruction of C4 and C5 vertebrae. (B) Pre-operative MRI of the cervical spine showing destruction of C4 and C5 vertebrae with epidural soft tissue compression. (C) Post-operative X-ray of the cervical spine showing anterior cervical plating from C3 to C6

with clinical suspicion or diagnosis of spinal tuberculosis, Jain et al. classified the findings on CT scan into fragmentary, osteolytic, subperiosteal, and localised and sclerotic types.[69] The fragmentary type was most common followed by the osteolytic variety. Vertebral body destruction, intraspinal extension, paravertebral soft tissue masses, extension of involvement into the neural arches and calcification can be seen on plain scans.[129] With contrast, rim enhancement may be seen around a multiloculated fluid collection. Coppola et al.[33] found destructive osseous changes associated with adjacent soft tissue masses showing a characteristic rim enhancement. In all their cases CT demonstrated more extensive involvement than could be seen on plain radiographs (Fig. 8). CT helps to diagnose spinal tuberculosis in the initial stages.[25] Inaccessible fixed areas of the spine, difficult to see in conventional radiographs, are seen with ease on axial CT sections.

Calcification, representing retained bone fragments, seen with paraspinal collections and in regions of bone destruction, is said to be pathognomic of tuberculous infection. It represents the lack of the necessary proteolytic enzymes in *Mycobacterium tuberculosis* that are necessary to lyse the bone.[69,76]

Magnetic Resonance Imaging

The advantages of MR include high resolution, direct multiplanar imaging, detection of marrow infiltration

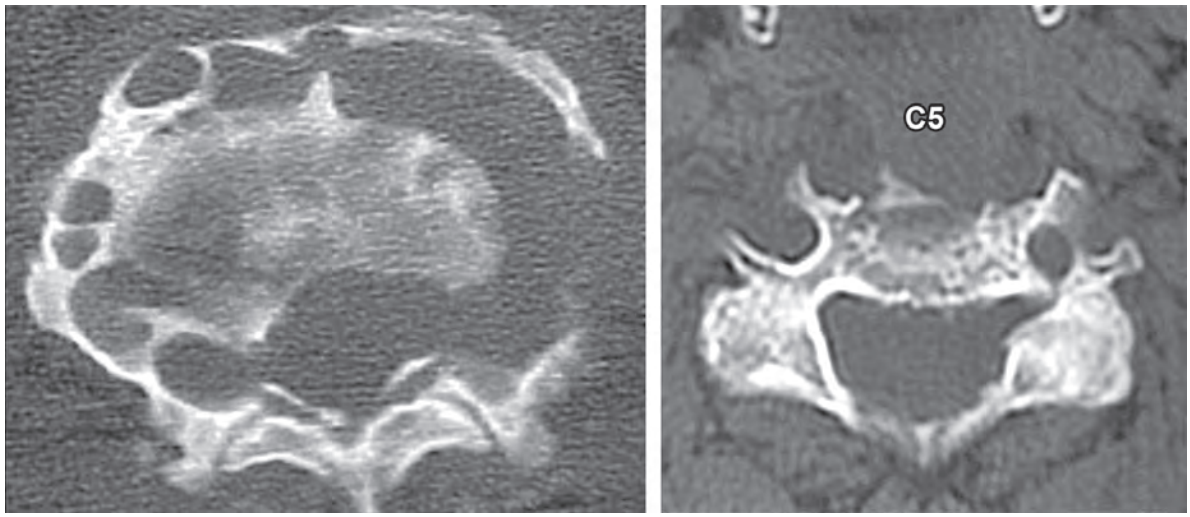


Fig. 8: CT axial views of a patient with cervical caries showing significant bony destruction

and the early detection of intradural infection.[18,89,176] The technique used should be modified, depending on the site and extent of the infection, using spin echo and T1-weighted imaging for localisation. Extradural extension of the disease is better visualised with either a T2-weighted image or a short T1 inversion recovery technique (STIR).[21,113,152,153,159,160,168] The latter technique has a higher sensitivity, but is less specific than the T2-weighted images.[13,39] Both are useful in showing vertebral and intradural disease, but epidural spread may not be detected early, as the abnormal signal obtained may be isointense with CSF,[152] Sagittal T1-weighted images using contrast are necessary to detect early epidural spread of the infection.[133,153] The involvement of the paraspinal soft tissues is best seen in coronal sections.[6,34,153,154]

MR is also helpful in revealing associated lesions like intraosseous abscesses, paraspinal cold abscess, vertebral body and disc collapse, spinal deformity, skip lesions, epidural and intraspinal extension, involvement and compression of the cord or nerve roots and appendicular lesions (Figs 9 to 11).

T1-weighted images may show a decreased signal from the affected vertebral marrow, reduced disc height, involvement of the paraspinal tissues and extradural extension. The T2-weighted images show an indiscriminately increased signal from the marrow, discs and soft tissues. The use of gadolinium enhanced imaging is advantageous. Post et al.[133] have shown that contrast MR imaging provides: (a) excellent anatomical delineation of all epidural abscesses, differentiating them from the compressed thecal sac when this was not possible by plain MR; (b) localisation of those portions of paraspinal masses most likely to yield a positive percutaneous biopsy; (c) identification of foci of active infection from those which had responded adequately to therapy and (d) unequivocal detection of early vertebral and disc space infection. Contrast MRI is useful, especially in the diagnosis of abscesses: rim enhancement being characteristic of tuberculosis.

Response to therapy may be seen as an increase in the signal intensity on T1-weighted images from the affected vertebra. This has been found to correlate well with clinical signs and symptoms. However, radiologically evidenced progression of bone destruction may be seen up to 14 months after the initiation of anti-tubercular therapy. This should not be taken as an indication of treatment failure.[23] Jayasundar et al. have reported excellent specificity in diagnosis with Proton MR spectroscopy.[72] Distinguishing spinal tuberculosis from other spinal diseases, especially pyogenic and fungal spondylitis and also metastatic disease of the spine is important. Features that are indicative of a tuberculous infection are: (1) calcification within a paravertebral abscess, (2) presence of a large paravertebral abscess, (3) involvement of more than two vertebral levels, (4) involvement of the posterior elements, (5) multicentric disease, (Figs 12A to E) (6) subligamentous spread and (7) heterogeneous MR signal.[76] MRI can distinguish tuberculous from pyogenic infection in most instances.[30,54] Shankar et al. have reported that CT perfusion could also help in differentiating spinal inflammatory from neoplastic lesions.[151]

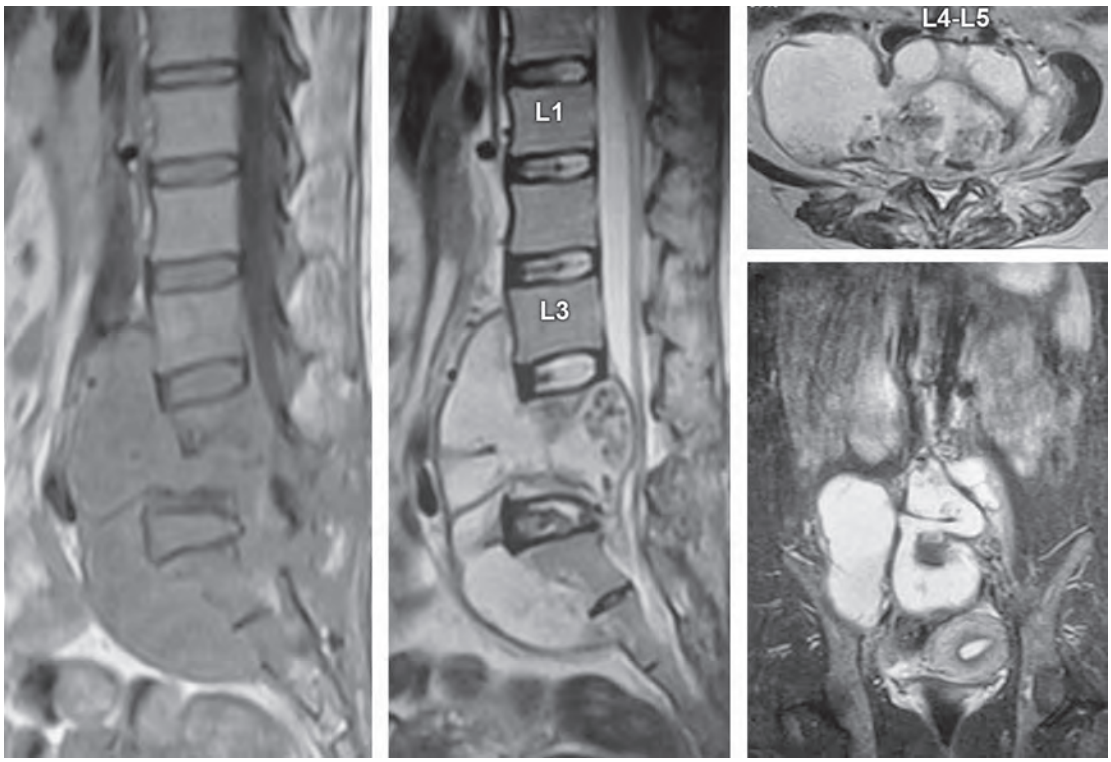

Fig. 9A: MRI of a patient with lumbosacral caries showing significant pre- and paravertebral cold abscess along with compression of the thecal sac and the exiting nerve roots

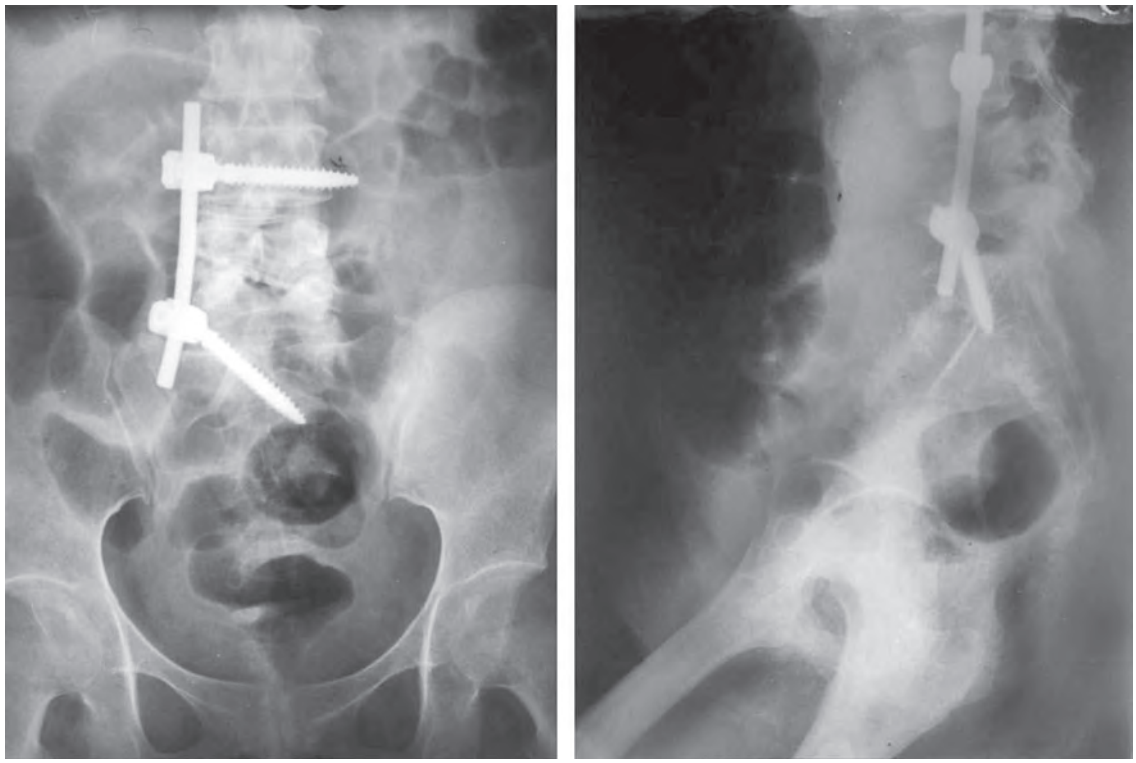

Fig. 9B: Post-operative X-rays showing spinal fixation

Radioisotope Bone Scans

While bone scans are useful in delineating osteomyelitis, in spinal caries, Technetium scans may be negative in one-third of cases and gallium scans negative in two-thirds.[97,135] Their diagnostic value is limited and of historic interest only.

TREATMENT

Evolution of Treatment

In ancient India, the Atharvans (1800–1000 BC) used to treat cases of skeletal tuberculosis with sunshine and "Sipudru", a herbal preparation.[38] Hippocrates and

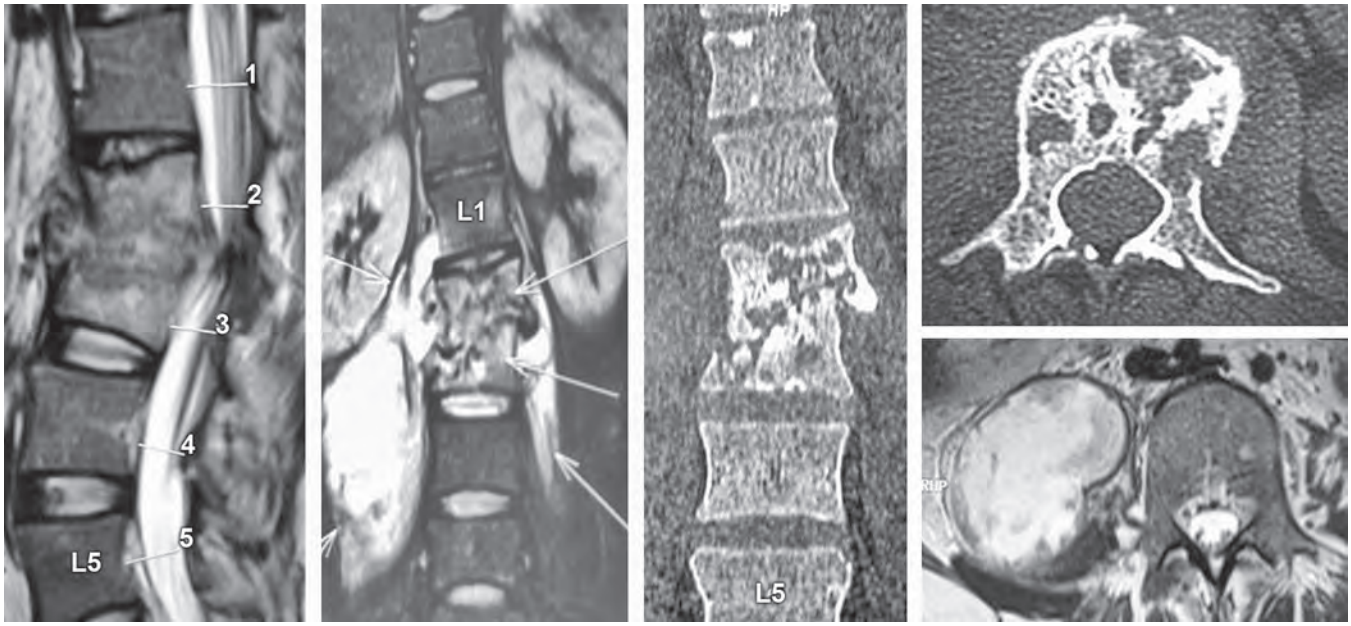

Fig. 10A: Imaging of a patient with L2,3 caries showing large paraspinal and psoas abscess with bony destruction causing dislocation

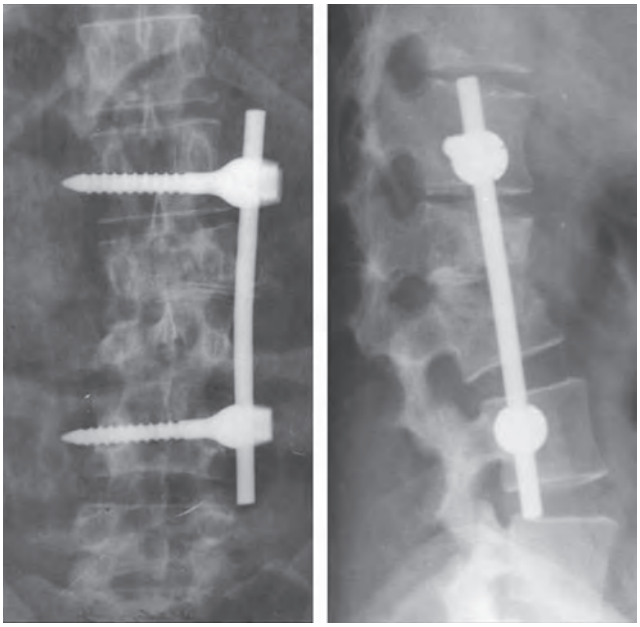

Fig. 10B: Post-operative X-rays showing spinal fixation done by the retroperitoneal approach

Galen tried to correct the kyphotic deformity due to spinal caries by manual pressure, traction and mechanical appliances, but with little success.[170] The orthodox conservative treatment in modern times was entirely constitutional and included recumbency and immobilisation by body casts, plaster beds and braces, but the results were often unsatisfactory[35,91] and the healing took many months or even years. This led surgeons to attempt direct surgical procedures. Unfortunately, these had disastrous results so that Calot in 1930[26] remarked, "the surgeon who, so far as tuberculosis is concerned, swears to remove the evil from the very root, will find only one result awaiting him—the death of his patient". The surgical procedures performed in the pre-antibiotic era included the created abscess (Pott 1779), laminectomy (Chipault 1896), laminotomy (Fraser), costotransversectomy (Menard 1894), posterior mediastinotomy (Obalinski), lateral rachiotomy (Capener 1933) and anterolateral decompression (Ito 1934, Dott and Alexander 1947). Tuli has provided an excellent historical review of spinal tuberculosis.[48,92,174]

Posterior Fusion

Albee, in 1911[3,4] and Hibbs in 1912,[55,56] introduced posterior spinal fusion. This provided internal stability to the diseased spine, and helped to avoid recurrence of the disease and the development of paraplegia. It also shortened the period of immobilisation. Bekalim[17] reviewed the results of posterior spinal fusion before the use of anti-tubercular therapy and found that 40–80% of patients were "healthy and fit for work", 60% were "improved" and 14–19% "not healed". However, kyphosis could develop in spite of the posterior fusion and there was also an appreciable incidence of pseudoarthrosis following the procedure. Long-term follow-up showed that paraplegia could still occur in some patients, in spite of a posterior spinal fusion. Hallock and Jones[53] found that 23 out of 192 operated cases developed paraplegia subsequently. It became apparent that the surgery did nothing for the diseased bone where the organisms may remain quiescent until reactivated.

Antibiotic Therapy

The introduction of anti-tubercular drug therapy dramatically improved the results of non-operative therapy and of posterior spinal fusion.[17,45,158] The most spectacular effect of the drugs was the disappearance of sinuses, ulcers and abscesses and the elimination of post-operative dissemination of the infection.

Such a dramatic improvement in the prognosis encouraged surgeons to adopt total excision of the lesion along with anti-tuberculous chemotherapy. This was the standard treatment between 1950 and 1960.[57,58,108,170]

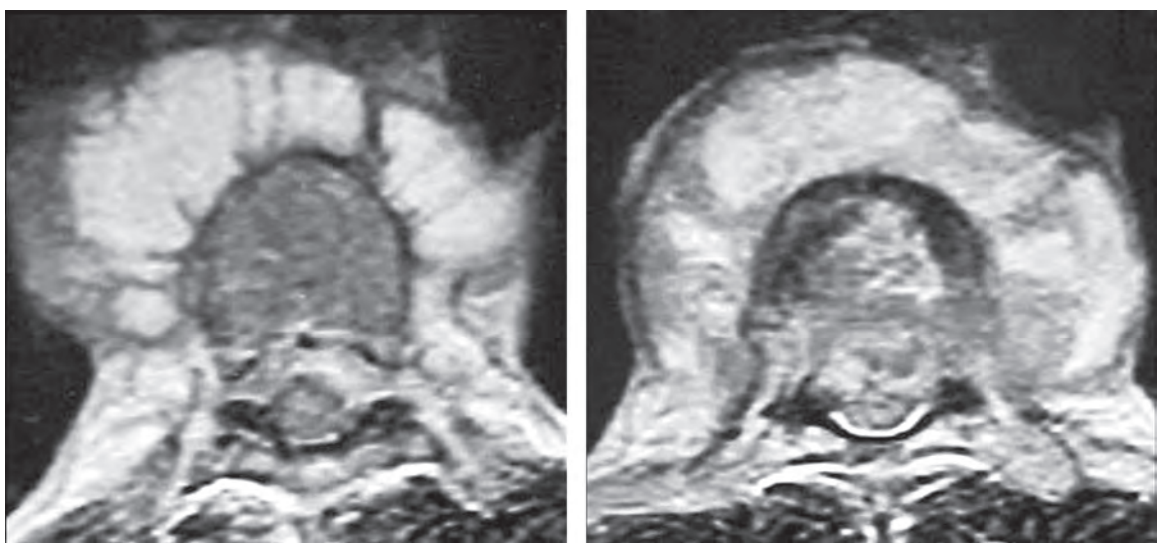

Fig. 11: Axial MRI showing a paraspinal collection in a patient with caries spine

(C) MRI axial of dorsal spine. (D) Post-operative X-ray lateral view of cervical spine. (E) Post-operative X-ray AP view of dorsal spine

Conservative Therapy

Conservative therapy had many advocates and has successfully been used in many countries. Friedman[44] treated 64 patients with Pott's disease by the administration of anti-tubercular drugs, bed rest and braces and 50 patients had good results. Laminectomy had to be done in eight patients who developed paresis.

Bed Rest or Ambulation

Should a patient with tuberculous disease of the spine be immobilised in bed with a plaster cast, or can he be ambulant? Controlled studies[84,107] by the Medical Research Council, UK, compared the results of ambulatory outpatient treatment with bed rest inpatient therapy. At 18 months the response rate was 66% for the inpatients and 58% for the outpatients; while at 36 months the rates were 84% and 88%, respectively. The mean total vertebral loss and angulation of the spine were a little more in the ambulatory group. Neurological outcome was the same in both groups. Later studies by the MRC[110] showed that ambulant chemotherapy achieves good results when treating children with tuberculosis of the thoracic and lumbar spines.

Our policy is to advise our patients on chemotherapy to have bed rest without immobilisation for 4–6 weeks till the pain and spasm disappear and the general health improves. They are then allowed to get up, but wear braces which can be discarded after a period of 6–8 weeks. The chemotherapy is continued for 18 months (Figs 13A to D). The family members and contacts are checked for the presence of tuberculous infection at the beginning of the treatment.

Excisional Therapy and Grafting

Excisional therapy has given good results and is widely followed. Where there is extensive destruction and sequestra, evacuation of tuberculous pus and debris and removal of sequestra of disc and bone result in the opening up of new vascular channels in the ischaemic areas with reduction of general toxaemia and reduction in total healing time.

Paus[132] treated 37 cases with anti-tubercular drugs and ambulation, and achieved complete working capacity in 35. Of the 86 cases treated by him with direct surgery and anti-tubercular drugs, 94% achieved complete working capacity, while 11% required reoperation for either relapse or failure. A similar experience was reported by Somerville and Wilkinson[161] who treated 130 patients by direct operation and achieved sound healing in 92% with a relapse or recurrence rate of 12.5%. However, they achieved similar results in 105 patients treated non-surgically with only anti-tubercular therapy.

Tuli[170] is of the opinion that cases without extensive destruction and sequestration would heal without surgical intervention. Indications for surgery proposed by him include, progressive bone destruction, increase in the size of the abscess, failure to respond to conservative therapy, uncertainty in diagnosis, recrudescence of local disease and development of neural complications or pain in the spine due to mechanical instability.

Bone Grafting

After excisional surgery, should bone grafting be done? Neville and Davis[123] reported 92% bone fusion in those patients who were treated with surgical fusion and 50% bone fusion in patients who had only drainage of the abscess. Hodgson et al. in 1960[58] reported on a series of 412 patients treated by radical removal of the diseased area and anterior spinal arthrodesis. The mortality was

Figs 13A and B: MRI of the lumbosacral region showing tubercular involvement of L1, L2, S1 and S2

Figs 13C and D: MRI of the lumbosacral region showing resolution of the tubercular lesions after 6 months of anti-tubercular therapy

2.9% and no patient developed paraplegia after operation. They advise surgery for all patients with early tuberculosis of the spine and believe that it should supplant conservative treatment in most instances.[57-59,177] Chu[31] reported satisfactory healing in 71 of 74 consecutive patients treated by the method of Hodgson.

The Medical Research Council Working Party on Tuberculosis of the Spine[109] studied 119 patients with tuberculosis of the thoracic and lumbar regions who underwent excisional surgery with or without bone grafting. Bony fusion occurred earlier and in a higher proportion of patients in the group with bone graft, but at 5 and 10 years there was little difference between the two. At 10 years, there was a small reduction in the angle of kyphosis in the bone grafted group and a small increase in the angle in the no grafted series. These changes had occurred early and had persisted subsequently.

Instrumentation

Instrumentation helps to produce rigid fixation of the involved segments of the spine to allow uninterrupted healing, as movement in and around the spinal cord is still possible after anterior strut grafting. The instrumentation procedures also prevent any increase in spinal deformity that may occur in the course of healing. Bailey et al.[11] supplemented their surgery with posterior arthrodesis, whenever the graft spanned more than two disc space levels. Kemp et al.[81] used posterior fusion if the infection involved more than two vertebral bodies, so that immediate stability was achieved.

The problem associated with instrumentation in the presence of infection is the possibility of persistence of a focus of infection.[50,51] Biomaterial-centred infections are related to the preferential adhesive bacterial colonisation on inert surfaces.[105,124,125] Mycobacteria produce less biofilm than other bacteria. Oga et al.[125] Louw[100] and others[10,68,129,144] using instrumentation have followed up their cases and have not encountered problems related to the persistence of infection or reactivation.[74]

The type of instrumentation used is of individual choice and is also dependent on the age of the patient. The fixation devices and techniques are variable. It is essential that all internal implants are MR compatible, to permit future MR examinations of the patient.

Factors Influencing Results

The decision on the type of surgical therapy depends on many factors which include the general health of the patient, the presence of concomitant infection elsewhere, the facilities available for surgery and the avoidance of secondary infection. Prolonged disease, undernutrition and the presence of disease elsewhere influence the overall results and additional measures may have to be adopted. Rajasekaran and Soundarapandian[137] reviewed 81 patients, eight years or more after treatment with debridement and anterior arthrodesis. Arrest of kyphosis with good improvement was seen in 48 patients (59%) who had minimal destruction of the vertebral body, limited excision of bone, short graft, marked intraoperative correction of deformity and involvement of the lower lumbar segments. The unfavourable factors

were extensive vertebral destruction necessitating a graft spanning more than two disc spaces, the involvement of thoracic vertebra or a marked pre-operative kyphotic deformity. As the graft was found to be stable only in 41% of their cases, they concluded that it was unwise to rely solely on the graft to prevent vertebral collapse, especially in patients whose grafts spanned more than two disc spaces. They suggested additional measures like extended period of non-weight bearing, posterior arthrodesis after 6–12 weeks and the prolonged use of a brace until complete consolidation was achieved.

Surgery for Paraplegia

Surgery to decompress the spinal cord is indicated in patients: (i) who fail to respond to conservative treatment; (ii) develop paraplegia while on appropriate chemotherapy; (iii) patients in an advanced stage of disease when delay in decompression is risky; (iv) patients with posterior neural arch disease; (v) those with "spinal tumour syndrome" and (vi) if the diagnosis is in doubt.[108,164,165] Relief of pressure on the spinal cord by the most appropriate technique is the aim of treatment when paraparesis starts to appear. Bed rest and anti-tubercular therapy alone have been found sufficient in mild paraparesis. However, if there is no obvious improvement within two or three weeks, surgical decompression becomes necessary. Simple drainage of the cold abscess would be sufficient in those cases where the tension inside the abscess is the cause of cord compression. In cases where the cord is compressed due to debris, sequestra or granulation tissue, a direct approach becomes necessary. Laminectomy is an unsatisfactory procedure except in a few cases when the compressing element is posterior, as in tuberculous disease of the neural arch, or in spinal tumour syndrome. In most cases, a lateral or an anterior approach to the diseased area, with radical removal of the compressing material is indicated. This opportunity may also be utilised to fuse the spine anteriorly, in those cases where the patient can stand the prolonged surgery. Many reports indicate the usefulness of this approach to surgical therapy.[1,2,36,61,82,95,107]

The route of approach has to be tailored to the level of the lesion, the amount of compression and the general health of the patient. Korkusuz et al. in 1989,[86] reporting on 108 patients, described an extrapleural, extraperitoneal approach for those patients with lower thoracic and upper lumbar spinal involvement. The approach was recommended, especially for those patients with compromised pulmonary reserve.

Delaying surgical decompression for too long in the presence of paraplegia may lead to problems, like extradural fibrosis, which may be difficult to eradicate.

Conservative Approach Justified

Many authors, like Pattison,[131] argue that the case for urgent early surgical intervention in the treatment of Pott's paraplegia may have been overstated. He reviewed a series of 89 consecutive cases of Pott's disease, out of which 85 were treated conservatively. Around 83% of these returned to normal life and full activity. Of 41 patients, who deteriorated neurologically in the first 3 months, 37 recovered completely. Moon et al.[115] treated 75 cases of spinal tuberculosis conservatively, with a favourable outcome in 95% of cases. They recommend that the conservative regime be used confidently, especially in less privileged countries where adequate facilities for hospital treatment may not be available.

RECENT TRENDS IN THE MANAGEMENT OF SPINAL TUBERCULOSIS

The aims of treatment are to confirm diagnosis, achieve bacteriological cure, prevent and/or treat deformity and neural compression. With technological advancements in the field of spinal imaging, early diagnosis of spinal tuberculosis is possible. With better chemotherapeutic drugs available that reach pus, granulation, caseous material and bone, non-operative management has become more effective, especially in cases diagnosed early.[67,78,87,116,173] The fourteenth report of the MRC working party on tuberculosis of the spine has clearly shown that the 5-year report of the 6 and 9 months courses of isoniazid plus rifampicin was excellent and similar to that of the 18 months course of ethambutol plus PAS. They, however, found the 9 months ethambutol plus PAS regime inferior to the others.[119]

Radical resection has been defined as excision of the disease focus to uncover the dura mater as completely as possible until healthy bleeding bone is reached.[65] Debridement, on the other hand, has been defined as removal of pus, granulation tissue, caseous tissue and loose sequestrated bone from lesions and also part of the viable bone needed to decompress the spinal cord leaving a relatively stable spine.[67] It is now recommended that radical excision is not necessary for infective spinal lesions, like tuberculosis, where effective anti-tubercular chemotherapy is available. The indications for surgery are well defined as is the extent of surgical decompression.[22,117,122,130,146] In cases of tuberculous infection of the lumbosacral region, Rajasekharan et al. feel that surgery is indicated in the group who are younger than 10 years old, as they have a tendency to a greater kyphosis.[138]

When one considers spinal instability related to tuberculosis it is essential to remember that the pathophysiology is different compared to trauma. Pathological fractures, involvement of the anterior and posterior spinal elements, translation or dislocation of the destroyed vertebrae, and long segment disease with kyphosis should all be considered as signs of instability. Mehta and Bhojraj proposed a classification system using MRI, dividing patients into four groups based on the treatment received. In their opinion the appropriate surgery for each case could be planned based on MRI findings.[111] Lesions affecting the vertebral body should be decompressed anteriorly. Performing a posterior decompression

like a laminectomy is not recommended as it removes the healthy segment of the spinal column and renders the spine unstable.

In the cervical spine the anterior approach is presently established as the approach of choice. In the case of thoracic tuberculosis, a transthoracic transpleural approach gives an excellent exposure of the diseased segments. However, in the presence of compromised pulmonary function, systemic morbidity factors and extensive disease, the risk of surgery increases and one may opt for an extrapleural anterolateral exposure. Jain et al. reported that the extrapleural anterolateral approach provides the surgeon the exposure to perform anterior decompression as well as a posterior instrumentation at the same sitting with decreased morbidity.[68] The lumbar and lumbosacral spine may be approached retroperitonially.

Video-assisted thoracoscopic surgery (VATS) has been used by a few surgeons for short segment disease where there is no lung disease and especially for biopsy or for decompression of a cold abscess.[73,101] The surgeon should be prepared to convert to an open thoracotomy at all times.

Jain and Dhammi found, in their review of PubMed in 2006, 1,097 patients underwent anterior or posterior instrumentation for tuberculous spondylitis.[12,67] Of the cases reviewed, the kyphosis correction on instrumentation was 30–35 degrees pre-operatively to 15–18 degrees post-operatively. On follow-up, the loss of kyphosis correction was a mean of two degrees for those who underwent posterior instrumentation and 2.3 degrees for those patients who underwent anterior instrumentation. While the majority of authors prefer to stabilise the diseased segments using internal fixation, Moorthy et al.[118] found good clinical and radiological outcome in patients with subaxial cervical spine tuberculosis who were not instrumented. Klockner and Valencia, in a retrospective study, concluded that in single level disease with no major substance loss, anterior debridement and grafting alone was adequate. They recommend the use of instrumentation in the presence of multi-level disease and extensive kyphotic deformity.[83] Rajasekaran is of the opinion that there is an average increase of 15 degrees deformity in all patients who are treated conservatively and 3–5% of patients finally have a deformity that is greater that 60 degrees. Surgery, therefore, must be done early and stabilisation by instrumentation gives a good result.[139] Various types of implants have become available to the surgeon to internally stabilise the spine. Despite the availability of systems that are biomechanically better, Jain and Dhammi argue that in some cases, especially in long segment disease, fixators like the Hartshill rectangle are still a reasonable option as they take purchase against the posterior healthy segment of the vertebra and a single healthy vertebra on either side of the diseased segment could give adequate stabilisation.[67] Many authors presently prefer anterior instrumentation done at the same sitting as the debridement.[19,112] Ramani et al. reporting on a mean 36 months follow-up of 61 patients with subaxial cervical spine tuberculosis found that anterior reconstruction of the column using titanium plates and locking screws provides segmental stability and is a useful adjunct in preventing a kyphotic deformity[142] Benli et al. comparing anterior instrumentation systems, did not find any significant difference between rod-screw and plate instrumentation systems even at 5 years follow-up.[20] However, there are some who still prefer posterior instrumentation following an anterior decompression.[68,93,163,166]

Late Onset Paraplegia

Years after the primary disease of the spine, paraplegia may develop due to recrudescence of active disease at the original site or as a result of chronic compression and ischaemia of the cord due to pronounced kyphosis. Anterior decompression is helpful for these patients.

Hsu et at.[61] treated twenty-two patients with late onset paraplegia by anterior decompression and fusion, and reviewed them seven years later. Twelve patients had active disease at the internal kyphus and, in two, a soft healing bony ridge was the cause of cord dysfunction. In the eight patients with healed disease, hard bony ridges compressed the cord. The response to anterior decompression was faster, better and safer in patients with active disease. Nine patients recovered completely and three significantly. In patients with healed disease, anterior decompression was technically more difficult and the recovery less satisfactory and with significant complications. Rajeswari et al. reported on five patients who developed paraplegia even after successful treatment of the initial disease. MRI was useful in diagnosing the exact cause of the late paraplegia, and surgery could be offered in selective cases.[140]

Correction of Kyphosis

In many cases, proper posturing and wearing of braces when indicated, help to correct a tendency for kyphosis. In patients with kyphosis, correction can be attempted successfully during excisional surgery and bone grafting. Occasionally, special measures may be required.

Louw[100] reported 19 patients with thoracic or thoracolumbar spinal tuberculosis treated by anterior debridement, decompression and vascularised rib grafting. This was followed either during the same procedure or 14 days later by multi-level posterior osteotomies, instrumentation and fusion. The average pre-operative kyphotic angle of 56 degrees was reduced to 27 degrees post-operatively and 30 degrees at follow-up. Around 95% of the patients had normal neurological function at 14 months and the rest could walk with crutches.

Rajasekaran and Shanmugasundaram[136] studied 90 cases with spinal caries and compared the angles of the gibbus deformity. They were able to predict the

final angle of the gibbus with 90% accuracy in patients who were not treated surgically. The ability to predict the final angle of the gibbus allows the surgeon to select the patients who will require radical resection and bone grafting to prevent a severe kyphosis. Other authors[170] have found that multiple vertebral involvement, active growth and thoracic lesions were responsible for excessive increase in kyphosis. Correction of kyphosis is presently done at the time of debridement surgery with elegant instrumentation systems that are available.

Indications of Surgical Therapy

The experience of many surgeons in the treatment of Pott's paraplegia suggests the following useful criteria for deciding on surgical therapy:[170,178]

- Neurological signs not improving or worsening within 4 weeks of adequate conservative and drug therapy
- Development of neurological signs with progression while on adequate therapy
- Recurrence of neurological signs after improvement
- Rapid onset paraplegia
- Paraplegia with flexor or painful spasms
- Posterior spinal disease with spinal tumour syndrome
- Prevertebral cervical abscess with difficulty in deglutition
- When the diagnosis is in doubt
- Late onset paraplegia
- Correction of kyphosis.

CRANIOVERTEBRAL TUBERCULOSIS

Tuberculous disease involving the structures at the craniovertebral junction requires special mention, due to the difficulties in early diagnosis and the possibility of serious complications. Craniovertebral tuberculosis is rare, forming less than 1% of spinal tuberculosis;[172] however, it seems to be more frequent in the developing countries as is spinal tuberculosis itself. Teaching hospitals in India may see two or three cases every year.[80,128]

Amongst Karapurkar's[80] 31 cases, 13 were between 20 and 30 years of age, seven between 10 years and 20 years and five below 10 years. There was a female preponderance of nearly 2:1.

Karapurkar[80] described five types of clinical presentations:

1. The commonest was that of progressive pain in the neck, restriction of movement and torticollis. The pain radiates to the occipital region. Neurological deficit is usually progressive, but may be stuttering or sudden. Some patients in this group had no neurological deficit.
2. Low grade fever, progressive neck pain and stiffness without any neurological deficit.
3. Fever, neck pain, difficulty in swallowing and an oropharyngeal bulge.
4. Neck pain and stiffness associated with dysphagia and involvement of the lower cranial nerves.
5. Fever, neck pain and progressive quadriparesis starting in one leg, successively followed by the other and then the upper limbs.

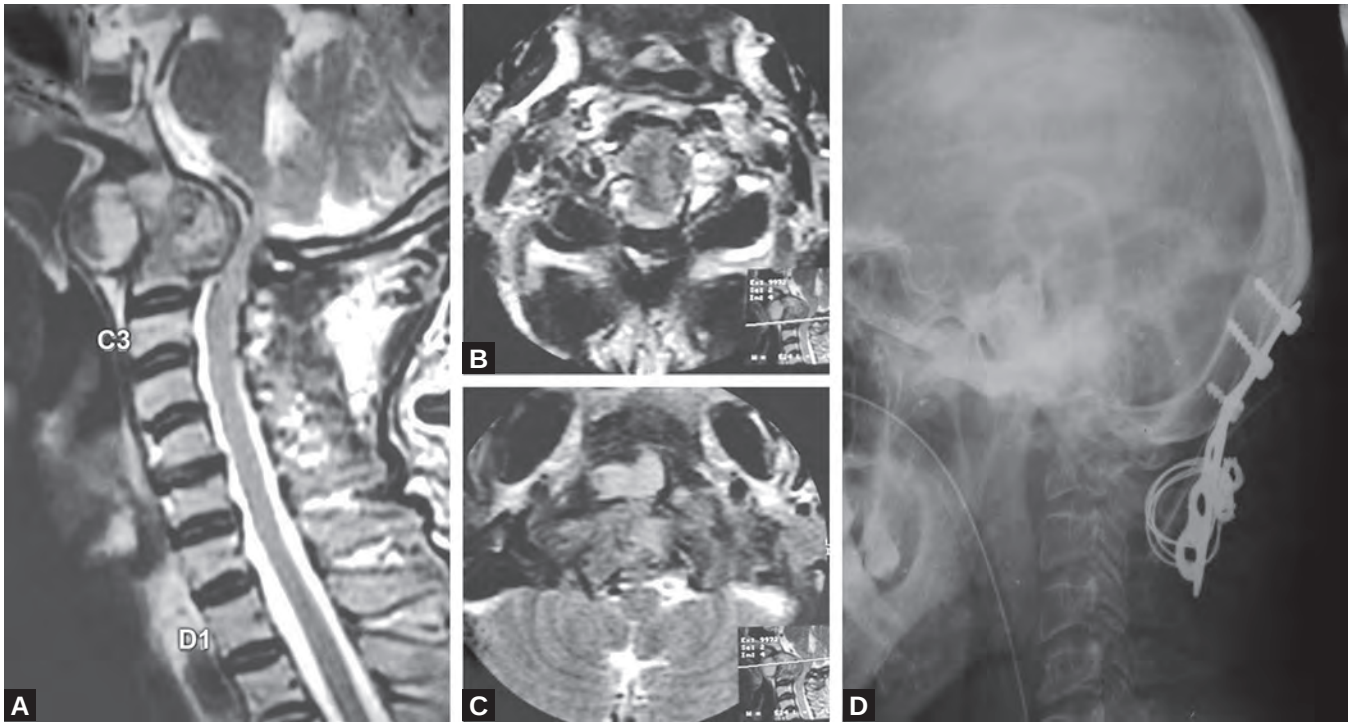
Tuberculosis of the craniovertebral junction may cause atlantoaxial dislocation, upward translocation of the dens, cervicomedullary compression by tubercular abscess or direct invasion by tuberculous disease.[41] According to Pandya[128] this is the cause of the neurological problem and not hyperaemic decalcification and loosening of the ligaments, as suggested by several authors earlier.

Plain skiagram of the CV junction may sometimes fail to reveal the diagnosis. Special oblique views and tomograms are helpful. Osteolytic erosions, subluxation of the atlantoaxial articulations and increase in the retropharyngeal space are to be looked for. CT scan and MR findings are conclusive[88] (Figs 14A to D).

Treatment

John Hilton first described a case of tuberculous atlantoaxial dislocation and stressed the importance of rest.[98,127,128] Both conservative and surgical therapy has been advocated.[94] Skull traction is indicated when there is subluxation.[27] If adhesions have formed, reduction may be achievable only after excision of the diseased tissue.

Traction and anti-tubercular drugs are the principal modes of therapy[170] and stability may be achieved within 3–6 months. The neck may be immobilised by a halo vest or a four post-cervical collar and the patient is allowed normal activities. Chadha et al. are of the opinion that CV junction tuberculosis can be management adequately using conservative methods regardless of the extent of bony erosion.[28] Surgical decompression is indicated in patients who do not stabilise spontaneously or if there are progressive neurological signs. All diseased bone, synovium and granulomatous tissue are removed; and after reducing any subluxation by traction, anterior fusion is performed using homologous iliac or rib grafts inserted into troughs across the lateral facet joints. Following such a transoral decompression, halo traction is used till radiological union (8–17 weeks) becomes apparent, or else a posterior fusion and internal stabilisation may be done as second stage surgery.[41] Sinha et al. have reported their results with a transcervical retropharyngeal approach for their cases, all of whom underwent a posterior fixation also.[156] Teegala et al. have suggested a scoring system and management algorithm, where the patients are divided into one of three grades.[167] Behari et al. have divided their patients into four clinical grades and based management options on the clinicoradiological presentation.[16] Anti-tubercular therapy was continued for 18 months in all patients. While a conservative neck immobilisation was adopted in patients with milder degrees of deficits (Grades I and II), those with severe deficits and



Figs 14A to D: (A to C) Sagittal and axial MRI showing tubercular involvement of the craniovertebral junction with significant pressure over the cervicomedullary junction. (D) Post-operative X-ray after anterior decompression followed by foramen magnum decompression and occipitocervical fixation

significant cervicomedullary compression underwent anterior decompression and posterior fusion. Direct posterior fusion was performed on patients with a reducible dislocation. Arunkumar and Rajshekhar are of the opinion that patients with CV junction tuberculosis are ideally managed with an anterior decompression followed by occipitocervical fusion as this provides immediate neurological improvement, stability and allows early mobilisation.[8]

Bapat et al. have compared traditional occipitocervical fusion techniques with transarticular screw fixation in tuberculous atlantoaxial instability.[15] They have reported early brace free mobilisation, 100% fusion and a patient satisfaction rate of 90.90% in the transarticular group compared to 83.16% fusion and patient satisfaction of 62.5% in the occipitocervical fusion group.

67 Surgery for Leprosy

Sridhar K

INTRODUCTION

Leprosy, in spite of being a bacterial disease, remains to be eradicated completely from the world. "If leprosy is a disease of the skin alone, it can be easily eliminated, but it is also and mainly involves the nerves and this makes the disease more formidable"—Bourrel. Even after the disease process has been controlled or eliminated, the residual sensory and motor deficits produce a crippling deformity. This creates the need for corrective surgery, to restore the patient to his occupation and to society. Surgery for leprosy involves improvement of function and appearance, the former being more important. The deformities and disabilities, which require surgical correction, are due either to the direct involvement of the tissues by the disease process or due to anaesthesia produced by the nerve involvement. The paralysis produced by the nerve involvement can be corrected, but the pathology produced as a result of anaesthesia can only be prevented by due care of the hands, feet and eyes. With the correction of motor paralysis, the patient starts using the hands and feet more and more, increasing the risk of trophic ulceration in such patients.

HISTORICAL REVIEW

One of the earliest recorded descriptions of leprosy is found in the works of Susrutha, who wrote his treatise on surgery "Susrutha Samhitha" in the 6th century BC. He describes many types of "Kushta" and distinguishes leprosy from vitiligo and other conditions. Mention about anaesthesia, paraesthesia and loss of sweating are found in his description, so also the facial disfigurement. The earliest skeletal remains, which showed signs of leprosy, were found in El Bigha in Upper Egypt, which dates back to the 6th century AD. Some references to this disease are found in the Bible.

Surgical procedures for leprosy developed only during the 20th century. As early as 1953, Gudagnini[15] suggested nerve decompression to prevent deformities. Surgical decompression was weighed against medical treatment alone and was debated for long in the past. But the works of Gudagnini, Carayan and Hunt,[4] Vaidhyanathan,[32] Pandya[26] and Palande[24] clearly emphasise the benefits of early decompression of the nerves. Tendon (FDS) transfer for paralysed hands was pioneered by Stiles (1922) and popularised later by Bunnell[3] during the Second World War. Later Brand,[2] Fowler,[11] Zancolli,[34] Srinivasan[30,31] and Palande[25] described various procedures for claw hand correction and opponens palsy.

EPIDEMIOLOGY

During the period between the mid-sixties and the mid-eighties, the global prevalence of leprosy was estimated to be around 10–12 million. After the successful implementation of multidrug therapy (MDT),[21] the incidence came down remarkably and, as per 1991 WHO data quoted by Noorden,[20] the prevalence was estimated to be around 5.5 million in the world, and India contributes nearly 3 million of these. The incidence of deformity, including in those patients already cured of the disease, was estimated to be around 2–3 million. In our series at the V.H.S. Sakthinagar, the incidence of deformities is 11.7%.

As per the WHO weekly epidemiological record[33] dated 14th July 2000, the global prevalence has come down to 2.2 per 10,000 and among the 11 endemic countries in the world, the prevalence is 4.1 per 10,000. India has a prevalence rate of 5.0 per 10,000. In stark contrast to 1991 situation, during January, 2000 only 495,073 registered cases were there in India.

PATHOLOGY OF NERVE INVOLVEMENT

Common Sites

Starting with the classical studies by Khanolkar,[18] a number of Indian pathologists have contributed a great deal towards understanding the pathogenesis and pathology of neural lesions in leprosy. Dastur from Mumbai has made major contributions in this field.[6–9] A detailed review of the subject has been provided by Antia.[1]

The nerve gets involved either during the normal course of the disease or during a reactive phase. The nerves which are usually involved are the ulnar, the median and the radial nerves in that order in the upper limb, and the common peroneal and the posterior tibial nerves in the lower limbs. The facial and the trigeminal nerves are the only cranial nerves commonly involved. The superficial radial, the superficial peroneal, the greater auricular and the sural nerves which are purely sensory, when involved, show thickening which may help in establishing the diagnosis. These are of little surgical importance except for taking a nerve biopsy.

The reason why some nerves are involved at specific sites is not clear. Some common anatomical features have been noted in these nerves at these specific sites:

- The affected nerves lie at a comparatively superficial plane where the temperature is low.
- The site of involvement is near a joint where there is constant motion.
- The involvement is near an area of constriction like an osseofibrous tunnel, intermuscular septum or retinaculum.
- The nerves lie over bony prominences.

The ulnar nerve is the commonest nerve to get involved; the common site of involvement being proximal to its passage under the osseofibrous tunnel behind the epicondyle. Rarely, it is involved near the wrist proximal to its passage through Guyan's canal.

The median nerve, which in its proximal part lies deep behind the muscle bellies, becomes superficial near the wrist and it is here, before its passage through the flexor retinaculum, that it is involved. Commonly, the proximal thickening is noticed where it is crossed by the flexor digitorum superficialis to the fingers. Hence, median nerve palsy is commonly at a lower level; the long flexors of the fingers and thumb escape and only the intrinsic muscles of the hand are paralysed. The common peroneal nerve, like the ulnar nerve, is involved as it curves round the neck of the fibula and produces a foot drop. The posterior tibial, like the median nerve, gets involved before it enters the flexor retinaculum near the ankle.

Branches of the VII cranial nerve, mainly the ones supplying the orbicularis oculi and frontalis, are involved as they cross the zygomatic arch and are near the temporomandibular joint.

Entry of Bacilli into the Nerve and Establishment of Neuritis

Various theories have been postulated regarding the mode of entry of the bacilli into the nerves:

- Phagocytosis by Schwann cells in the outer layers of the dermis and once engulfed the bacilli travel by contiguity from Schwann cell to Schwann cell or within the axons. There are many objections to this theory.
- Penetration of the perineurium. The perineurium is a formidable barrier in leprosy and this explanation is also not satisfactory.
- The most plausible hypothesis is that the bacilli enter via the endoneurial blood vessels.[10,17,27] Bacteraemia is a normal finding in patients with untreated lepromatous leprosy.

Once the bacilli enter the nerves, they multiply and produce an inflammatory response and the antigens, which leak out, produce an immunological response. Both the inflammatory and the immunological responses promote nerve damage. Depending on the immune response of the body, the pathology of destruction varies from the tuberculoid to the lepromatous spectrum. In the tuberculoid variety, the host resistance is high and the immunological reaction is primarily responsible for the destruction. At the opposite end of the spectrum is lepromatous leprosy, where the host resistance is very poor and bacilli enter and multiply unchecked. However, the multiplication is a slow process. Borderline leprosy produces a mixed picture.

Nerve Damage in Reactions

Type I Reaction (Reversal or Upgrading Reaction)

This occurs most commonly in the borderline type of leprosy and tends to develop in the early months of treatment. It may also occur in untreated cases. The existing lesions flare up with erythema and oedema due to an increase in the immune response. In borderline leprosy, there are surviving Schwann cells enclosed in rigid inflammatory tubes. During the reaction, the pressure within the tubes increases rapidly causing demyelination. The damage is sometimes very rapid without even pain or tenderness. Hence, decompression becomes urgent to preserve function.

Type II Reaction (Erythema Nodosum Leprosum)

Erythema nodosum leprosum (ENL) is an immune-mediated complication of leprosy presenting with inflammatory skin nodules and involvement of multiple organ systems including the peripheral nervous system, often running a protracted course. Immune complex production and deposition as well as complement activation have long been regarded as the principal aetiology of ENL.[16]

Here, crops of new lesions appear and the nerve damage is a slow process with the formation of antigen-antibody immune complexes. These are usually found in patients with lepromatous leprosy who are under treatment for months or years. Nerve decompression is not urgent as the disease process is slow and conservative treatment can be tried for an adequate period. The vasa nervorum may get involved in both the reactive phases and in the natural process of the disease and contribute to the nerve damage. This may not be relieved by simple decompression, as there is no pressure build-up inside the nerve.

Nerve Abscess

These are focal areas of necrosis involving one or more fascicles. Early in the disease, the fascicles change from a greyish to a yellow colour and undergo liquefaction. Initially, the epineurium thickens around the area of inflammation and as the pressure builds up, the epineurium may give way and the contents track outside the nerve, forming a paraneural abscess which may reach the skin. Surprisingly, a fair amount of nerve function may remain even in cases with large abscesses and hence, careful evacuation of the abscess is to be done without interfering with the surviving fascicles to prevent further damage.

CLINICAL FEATURES OF NEURITIS

Local pain in the area of involvement of the nerve, sometimes, excruciating and not relieved by analgesics is a common symptom. Absence of pain does not rule out

neuritis; sometimes neuritis may progress rapidly, without any appreciable discomfort. Pain, numbness or tingling in the distribution of the affected nerve is noticed by many patients.

Thickening of the nerves, generally at specific sites (described above) is common. Thickening of the ulnar, lateral popliteal, greater auricular, radial cutaneous and median nerves can be easily made out. This feature is an important sign in suspecting the diagnosis. Occasionally, when only one nerve is thickened, diagnosis may be difficult and a biopsy may be needed. Pain and restriction of movement may be present on stretching the nerves by moving the adjoining joint.

Sensory loss along the distribution of the nerve is an important clinical feature. The loss is usually patchy. The common areas of sensory loss are: (a) the pulp and proximal phalanx of the little finger and the hypothenar area (the ulnar nerve); (b) the pulp and proximal phalanx of the index finger and the tip of the thumb (the median nerve); (c) a small area around the anatomical snuff box (the superficial radial nerve) and (d) the lateral border and the sole of the feet (the posterior tibial nerve). Glove and stocking anaesthesia may be present in advanced cases, but careful examination will reveal some islands of intact sensation.

Motor weakness occurs in the concerned muscles, with evidence of wasting. For rapid assessment, the abductor digiti minimi and the first dorsal interosseous function will give an idea of ulnar nerve involvement. The function of the abductor pollicis brevis will demonstrate the involvement of the median nerve. Opposition of the thumb to a straight little finger will show the integrity of the median and the ulnar together. Making the patient cross the index over the middle finger, keeping it straight, will test the integrity of the intrinsic muscles. It is impossible to do this in the presence of an ulnar palsy. With this background assessment, a diagnosis of nerve involvement can be made. Nerve conduction studies may support the diagnosis.

DIFFERENTIAL DIAGNOSIS

The diseases most commonly confused with leprosy include:

I. Those associated with spinal cord diseases like syringomyelia, amyotrophic lateral sclerosis and motor neuron disease.
II. Those associated with peripheral nerve lesions:
    1. Damage by pressure such as spinal root compression, carpal tunnel syndrome and Bell's palsy.
    2. Polyneuritis:
        i. Hereditary—Hypertrophic interstitial neuropathy, peroneal muscular atrophy.
        ii. Metabolic—Diabetes, poryphyria, amyloidosis.
        iii. Deficiency—Vitamin B_1 and B_{12}, especially associated with malnutrition and alcoholism.
        iv. Toxic—Lead, mercury and alcoholism
        v. Malignant—Carcinoma of bronchus.
III. Those associated with muscle disease—myopathies.
IV. Those associated with trophic changes—diabetes, tabes dorsalis.

The salient features of nerve involvement in leprosy can be summarised as: localised irregular nerve enlargement in an endemic area is almost always due to leprosy. Muscle weakness is always of the lower motor neuron type and never involves the girdle or trunk muscles. Sensory loss is patchy and mixed. Position sense is always preserved. The central nervous system (CNS) is never damaged and the reflexes are normal.[28]

TREATMENT

Medical

In the past, medical treatment for the control of leprosy was mainly with monodrug therapy using Dapsone. Now, with the advent of MDT, the control of the disease is much better. As per the National Leprosy Eradication Programme Operational Guideline 1988[20] depending on the severity of illness, the patients are divided into two categories, viz. "paucibacillary" in less severe cases and "multibacillary" in more severe cases.

For the paucibacillary disease, a 6 month regimen with Dapsone 100 mg daily and Rifampicin 600 mg once a month is given as a supervised dose. For the multibacillary cases, the treatment is for 2 years. Dapsone 100 mg and Clofazamine 50 mg are given daily. Rifampicin 600 mg and Clofazamine 300 mg are given once a month under supervision. The patients are followed up regularly to watch for progress, sensory and motor involvement and reactions.

Treatment of Acute Neuritis

Prednisolone given in high doses is useful as an anti-inflammatory drug and as an immunosuppressant. The initial dose of 50–60 mg/day is gradually stepped up under supervision. Before and during the course of treatment, sensory and voluntary muscle testing is to be done to keep track of any deterioration in nerve function, especially muscle weakness. Other anti-inflammatory drugs are also administered along with steroids. Thalidomide and Cyclosporine A have also been used. During this period, anti-leprosy treatment should be continued. The muscles affected must be rested and splintage of the affected part with the muscles in the resting position is necessary.

Surgical Decompression

If there is progressive nerve involvement under medical treatment, decompression is necessary. In type I reaction, the progress may be rapid and if no response is detected in 8–10 days, it is better to decompress. Earlier the decompression is done, before permanent nerve damage sets in, the better are the results. Vaidhyanathan[32] clearly demonstrated the benefits of early decompression. In the ENL type of reaction, a conservative line of management may be followed.

Indications for Decompression

If any of the following occur in spite of full medical treatment, decompression is indicated:

- Progressive nerve deficit.
- Sudden increase in nerve deficit indicating an active increase in the internal nerve pressure.
- Increase in the intensity of pain and tenderness in the nerve.
- Positive stretch sign.
- For the ulnar nerve, a positive compression sign and pain elicited by flexion and ulnar deviation of the wrist with the fingers closed.
- Pain as the ulnar nerve slides forward on flexion of the elbow.

Ulnar Nerve Procedure

The skin incision is started about 7 cm above the medial epicondyle, carrying it anteriorly around the epicondyle down into the forearm for about 5 cm below the epicondyle and exposing the common flexor origin. The deep fascia is incised, the medial intermuscular septum is divided and the osseofibrous tunnel behind the epicondyle deroofed by cutting the olecranon ligament. The nerve is released in the forearm between the heads of the flexor carpi ulnaris by cutting the fibrous origin. The release of these constricting areas relieves the external compression. Medial epicondylectomy is done to prevent repeated trauma to the nerve during movement. To relieve the internal compression, median epineurotomy is done by incising the thickened epineurium along the whole length of the affected segment. This is the minimum which must be done, but most authors feel that at least the superficial hemi-circumference of the nerve should be freed from the epineurium by cutting away the thickened portion, leaving the vascular supply from the bed undisturbed. Only if multiple abscesses are seen, are these deroofed carefully.

Anterior transposition of the ulnar nerve is generally not recommended, as freeing an inflamed nerve totally from the bed over a long segment would compromise the vascularity.

Carayan, in 1957[4] and 1962,[5] proposed fascicular endoneurolysis. This type of fascicular dissection must be done only under magnification, taking care to preserve the anastomosis between the various fascicular bundles inside the nerve and is possible only by specially trained surgeons.

Median Nerve

The carpal tunnel is deroofed to relieve the external compression.

Radial Nerve

The nerve is rarely compressed by the fibrous arch from which the lateral head of the triceps originates and where the nerve is in the radial groove. The fibrous band is cut to relieve it.

Common Peroneal Nerve

The fibrous origin of the peroneus longus compresses the nerve and it is to be cut where the nerve winds around the neck of the fibula. The results of conservative management are quite encouraging in involvement of the common peroneal nerve and hence, decompression is rarely indicated.

Posterior Tibial Nerve

Decompression of this nerve has been extensively studied by Palande et al.[23] The incision is made behind the medial malleolus for 6 cm above and 6 cm below, extending it up to the lower border of the calcaneum. The flexor retinaculum is incised and the neurovascular bundle is released by incising the thickened sheath. The inferior calcaneal bands are cut and the nerve is released up to its division into plantar branches. Palande claims excellent results both in terms of sensory recovery and healing of plantar ulcers.

PARALYTIC DEFORMITIES

Hand

To understand the mechanism of the deformities and the restoration of function, one must know some basic concepts about the function of the hand. The prehensile functions of the hand are: (i) grasp; (ii) pinch; and (iii) hook. Srinivasan,[31] during the early seventies, has added one more function which he calls as "the syringing function" like pushing the piston of a syringe, holding it between two fingers. Among these if grasp and pinch can be restored useful function of the hand results.

In an ulnar claw hand, as the intrinsic muscles are paralysed, the metacarpophalangeal (MP) joints are kept hyperextended and the arch gets reversed with the convexity on the palmar side. The interphalangeal (IP) joints are kept flexed due to the paralysis of the interossei. The hand is unable to initiate even the first phase of grasp, which requires the diametrically opposite position. The aim is to restore MP joint flexion and IP joint extension to enable grasping.

In median nerve palsy, the abductor pollicis brevis and the opponens pollicis are paralysed and the patient is not in a position to rotate the thumb medially. Usually, as the ulnar nerve is also weak and the intrinsics paralysed, the index finger does not move as required, and the thumb cannot press against the index, and pinch is not possible. The primary aim in restoring pinch is to provide abduction and rotation of the thumb, so that it can oppose the other fingers.

I. The procedures adopted to restore function in the hand are:
   a. Dynamic tendon transfer
   b. Static procedures
II. The procedures to correct secondary deformities include release of skin contracture, capsulotomy and arthrodesis.

DYNAMIC TENDON TRANSFER

Eighty per cent of the patients with deformities in leprosy require minor surgery and the rest require major surgery. Tendon transfer is the only option available in cases of deformities like Simian hand, ulnar claw hand, wrist drop and failure of the metacarpals.[29]

General Principles

- In any paralysed part, when a tendon transfer is done, the available muscle power is redistributed and hence, one cannot expect full return of power and function, but improvement can be effected.
- Tendon transfers are possible only when the joints concerned are supple and mobile. Therefore, any skin or capsular contractures, when present, are to be attended to before the tendon transfer is performed.
- It is preferable to transfer a synergistic muscle, as re-education is easy, e.g. wrist extensor for metacarpophalangeal flexion, wrist flexor for extension.
- The tendon is to be routed as directly as possible to the new location of insertion.
- The power of the muscle transferred must be at least Gr. IV, so that at least Gr. III power may be obtained if the transfer is to be meaningful.
- The functional loss of the transferred tendon should be acceptable.

Claw Hand

The most common paralytic deformity in leprosy is the claw hand.[19] Applying the above principles, appropriate tendon transfers help to improve claw hand. After correcting the extension of the MP joint, the IP joints are extended by the long extensors. The pinch function of the thumb is restored by using the flexor digitorium sublimis going to the ring finger. Techniques have been perfected by surgeons experienced in the field of leprosy rehabilitation.

Foot Drop

When there is lack of improvement after conservative treatment or when the patient comes with an established foot drop, the options are to give the patient a foot drop splint or offer a dynamic transfer. Dynamic transfer gives the patient a permanent solution. The most common method which is used is the tibialis posterior transfer, as suggested by Ober.[22]

Facial Palsy

Commonly, the zygomatic branch of the facial nerve is involved in leprosy and leads to lagophthalmos. Early correction of this deformity is necessary to prevent exposure keratitis. When the cornea is also involved due to direct involvement by the bacillus or due to trigeminal nerve involvement, corneal sensation is also lost. Therefore, it is imperative to correct the disability to prevent blindness.

Initially, the eye is protected with oily drops applied frequently to prevent drying of the cornea. Patients can be administered steroids to see if the palsy improves with conservative treatment. The facial nerve recovers faster, if it responds to conservative treatment. A maximum period of 3 months of this treatment can be tried and that too if the patient is co-operative enough to apply the eye drops properly. Surgery is indicated if medical treatment fails to provide relief within three months.

Tarsorrhaphy

This is a passive procedure, wherein the palpebral fissure is narrowed and the cornea remains covered during sleep. Normally, a lateral tarsorrhaphy is done to avoid injury to the canaliculi which are situated medially, but Fritschi[12] prefers medial tarsorrhaphy and claims excellent results. The superficial nature of the dissection, according to him, prevents any damage to the canalicular system. Whatever be the site, it is preferrable to do a Z-plasty and interchange the triangular flaps of the upper and lower eyelid so as to narrow the palpebral fissure.

Kuhnt-Szymanowsky Procedure

When the lower eyelid is flabby and severe ectropion is present, tarsorrhaphy alone is not enough. In this procedure, an incision is made just outside the ciliary margin in the lower eyelid and the incision is extended on to the cheek laterally. The whole of the eyelid skin is pulled outward, the excess skin removed and sutured. This corrects the ectoprion and supports the eyelid against the globe.

Dynamic Transfer

Temporalis transfer is the commonest dynamic procedure used for lagophthalmos. The patient is able to close the eyelid consciously by biting his teeth and the tone of the temporalis keeps the palpebral fissure narrowed, even when it is relaxed. The patients can be trained easily and a near normal appearance can be achieved by meticulously adjusting the tension.

MISCELLANEOUS SURGICAL CONDITIONS

Contractures

Skin and capsular contractures are noticed in the hands and feet of patients with long standing disease. Most of these contractures respond to serial splinting with POP. When there is no improvement, surgical release is done either by a Z-plasty, excision of scar and skin grafting, or local flap over cover. Capsular contracture needs capsulotomy and mobilisation. Especially in the hand, all contractures are to be attended to before any tendon transfer is contemplated. If the finger joints cannot be released, then it is better to arthrodese them in a functional position.

Trophic Foot Ulcer

Dressing of the wound and rest in a light POP cast will help to heal plantar ulcers. If osteomyelitis is demonstrated, scraping or sequestrectomy is necessary. Palande claims good results with posterior tibial nerve decompression along with conservative management. Once the ulcer

heals, proper foot wear made of microcellular material is to be used with relief on pressure points.

Facial Deformities

A mini facelift will help remove the thick coarse wrinkles in the face, especially in the nasolabial region, and make the facial appearance more acceptable. Loss of eyebrows, which is another prominent feature, can be reconstructed with a free graft from the scalp. A hypertrophic and lax ear lobule can be reduced to normal size. The depressed nose is a result of mucosal involvement and subsequent contracture. The dorsum collapses and the nose appears as if it has been tucked in. Gillies[13,14] described the procedure of release of the scar through the sulcus of the mouth and pulling the nose outward. The raw area created in the inner aspect of the nose is covered by an inlay skin graft. Later a bone graft can be applied to the dorsum as a second stage procedure.

Gynaecomastia

Gynaecomastia is commonly noticed in lepromatous leprosy. Reduction of the breast through a periareolar incision is the procedure of choice.

With modern surgical techniques, many of the disabling and disfiguring deformities caused by leprosy can be corrected, resulting in both physical and emotional improvement of the patient.

68 Cysticercosis

BS Sharma, Sarat Chandra P

INTRODUCTION

Cysticercosis is a zoonotic parasitic disease caused by infection with the larval stage of the pork tapeworm *Taenia solium (T. solium)*.[27,41,47] In humans, the parasite commonly infests the central nervous system (CNS), where it produces a pleomorphic clinical disorder called neurocysticercosis (NCC).[11] Cysticercosis is currently considered the most common parasitic disease of the CNS, affecting thousands of individuals living in developing countries and in industrialised nations with a high index of immigration of people from endemic areas.[24,110]

This disease represents a major health problem in many of the developing countries. Endemic subcontinents include Central and South America, Eastern Europe and Asia. Conservative figures mention 50,000 deaths every year due to NCC, and no less than 20 million people infested by cysticerci.[18,49] The disease is widely prevalent in countries like Mexico.[77] General autopsy incidence has been reported up to 3.5–4%.

According to the International League Against Epilepsy, cysticercosis is probably the single most common cause of acquired epilepsy in the developing world, where prevalence rates of active epilepsy are twice those of developed countries.[18,49] These numbers indicate only the tip of the iceberg, as the actual prevalence of human cysticercosis is not known.

LIFE CYCLE AND PATHOGENESIS

Life Cycle

T. solium has a complex two-host life cycle. Humans are the only definitive hosts and harbour the adult tapeworm, whereas both humans and pigs may act as intermediate hosts (Fig. 1).

The Adult Worm

The adult *T. solium* is a hermaphrodite and inhabits the small intestine of man, where it attaches to the bowel wall by its suckers and hooks. It has a head (scolex) outfitted with four suckers and a double crown of hooks, a narrow neck and a large body (strobila) that measures 2–4 metres and is composed of several hundreds of units (proglottides).

Disposition of Gravids

Gravid proglottides are frequently detached from the distal end of the worm and are excreted in the faeces. Each proglottid contains as many as 50,000–60,000 fertile eggs, which can remain viable for a long time in water, soil and vegetation. In places with deficient disposal of human faeces, pigs may ingest stools contaminated with *T. solium* eggs.

The Larval Stage (Intermediate Host-Pig)

Once ingested by the pig, the invasive oncospheres (embryos) in the eggs are liberated by the action of gastric acid and intestinal fluids and actively cross the bowel wall, enter the bloodstream, and are carried to the muscles and other tissues where they develop into larval vesicles or cysticerci.[42]

Ingestion of Larvae by Humans

When humans ingest undercooked pork meat infected with cysticerci, the larva evaginates in the small intestine, its scolex attaches to the intestinal mucosae and it begins forming proglottides.

Humans are Accidental Intermediate Host

Humans act as intermediate hosts for *T. solium* by accidental ingestion of *T. solium* eggs, leading to development of cysticercosis.[40]

The mechanism by which eggs cross the bowel wall and lodge in human tissues is the same as that described in pigs.

Pathogenesis

The main sources from which humans acquire cysticercosis are ingestion of food contaminated with *T. solium* eggs and fecal-oral contamination in tapeworm carriers.[44] In addition, poor hygienic practises in food handling by *T. solium* carriers represent a threat to their communities. Improperly cooked vegetables or improperly washed salads represent an important source of contamination.

The cysticerci are fluid-filled vesicles consisting of two main parts: (1) the vesicular wall and (2) the scolex (Fig. 2). The vesicular wall is a membranous structure composed of three layers: (1) an outer or cuticular layer;

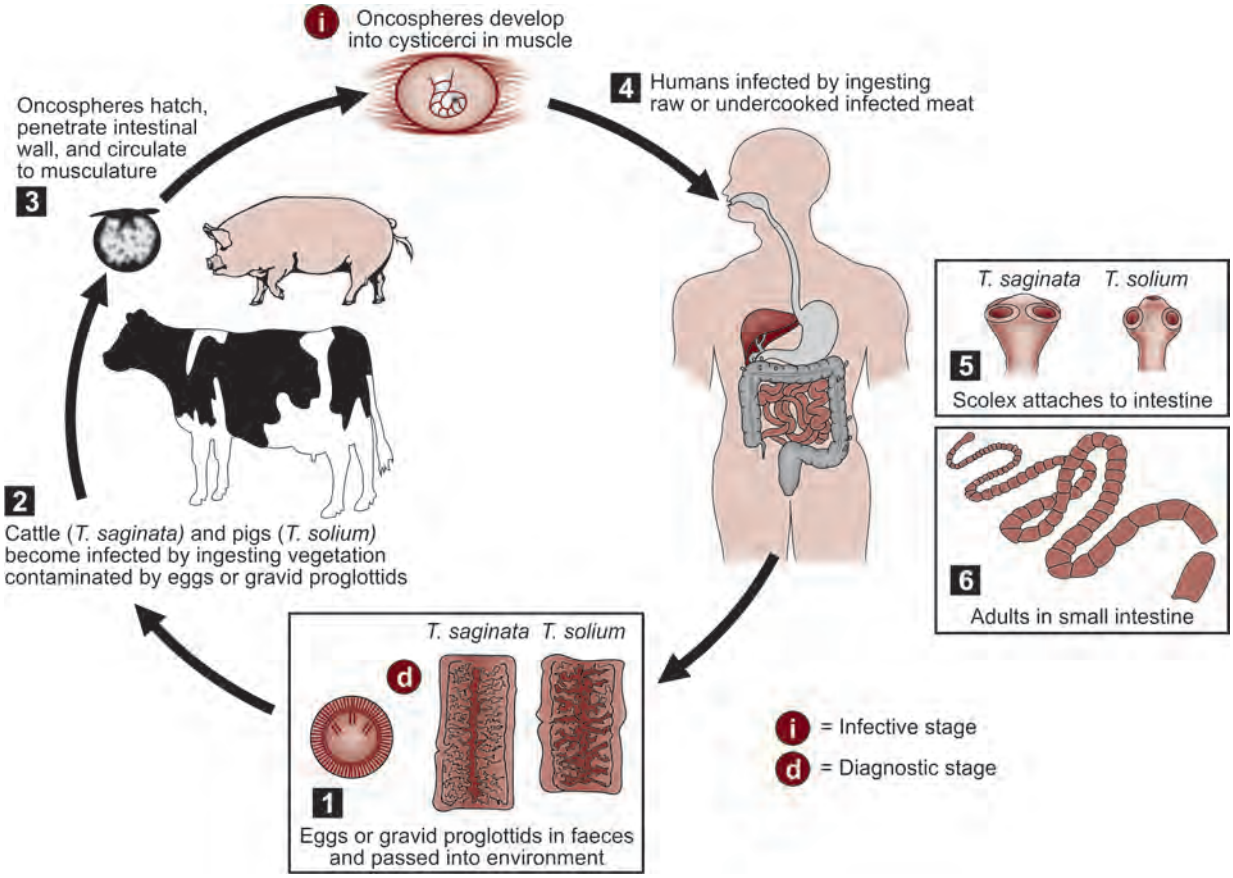

Fig. 1: Life cycle of *T. solium* (pig tapeworm) and *T. saginata* (cattle tapeworm). Note: Humans normally behave as definitive hosts by lodging the adult worms. However, either by regurgitation of eggs, igestion of food contaminated with cysticercal eggs or by orofecal contamination, they become accidental intermediate hosts and develop cysticercosis

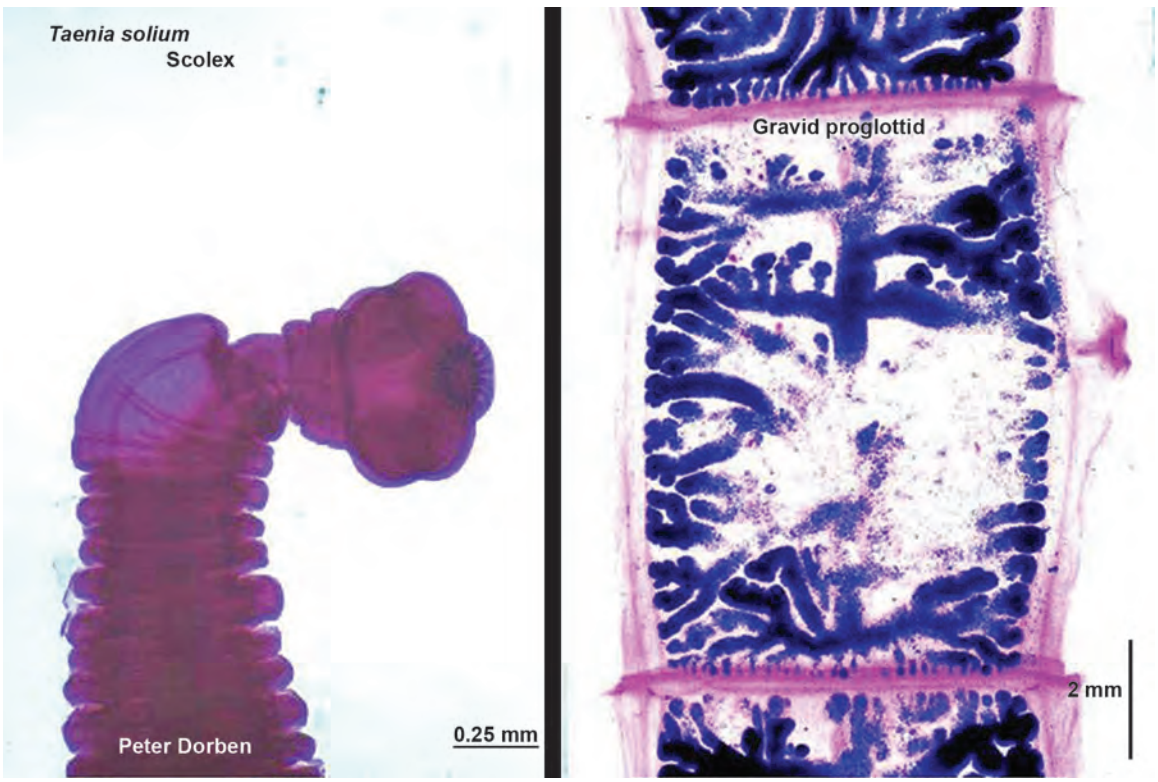

Fig. 2: Microscopic section of the scolex of *T. solium* and gravid proglottides

(2) a middle or cellular layer with pseudoepithelial structure and (3) an inner or reticular layer.[37] The invaginated scolex has a head or rostellum armed with suckers and hooks and a rudimentary body or strobila that includes the spiral canal.

Cysticerci in the brain parenchyma are usually small and tend to lodge in the cerebral cortex or the basal ganglia. These cysts rarely measure more than 10 mm because the pressure of the brain parenchyma usually does not allow further growth of the cyst, but giant cysticerci have been described.[103] The most common location of *subarachnoid cysticerci* are the Sylvian fissure and the basal cisterns.

Ventricular cysticerci may be small or large are usually single, and may or may not have a visible scolex. They may be attached to the choroid plexus or may be freely floating in the ventricular cavities. The most common location of these cysts is the fourth ventricle, although they may also be found in the third and lateral ventricles. Intraventricular cysts tend to acquire large size (Wani et al. 1981) (Fig. 3).

Spinal cysticerci may be intramedullary or located in the subarachnoid space, and their morphology is similar to those cysts located in the brain.[37]

Cysticerci located in the basal CSF cisterns may undergo a disproportionate growth of their membrane, with extension processes attached to each other, which tend to gather in clusters resembling a bunch of grapes (*racemose cysticercosis*)[7] In these cases, the scolex is frequently absent and cannot be identified even after microscopic examination. It is believed that their scolex regresses as the result of a hydropic degenerative process[78] resulting from the availability of space or the continuous entrance of CSF into the vesicles. It is a common practise to refer to cysts that have a scolex as *Cysticercus cellulosae*, and those without a scolex as *Cysticercus racemosus*; however, such terminology may create confusion because they are both forms of the same parasite—*T. solium*—and commonly coexist in the same patient.

Stages of Involution of Cysticerci

After entering the CNS, cysticerci are in a vesicular stage in which the parasites are viable and elicit little inflammatory changes in the surrounding tissues. Cysticerci may remain for a long time in this stage because the host develops a state of immune tolerance to the parasites, caused by active immune evasion mechanisms of the cysticerci. After a variable and undetermined time (estimated to be several years on the basis of the classic epidemiological studies in English soldiers returning from India),[33] cysticerci enter, as the result of immunologic attack from the host, a process of degeneration that ends with the death of the parasite. This continuation of involution has been classified by Escobar into four stages which these cysticerci pass through in this degenerative process, namely: *viable; colloidal; granular nodular* and *nodular calcified cyst*.[37] Each stage of development is characterised by specific changes in the parasite and in the surrounding brain parenchyma as well as with a distinctive appearance on radiological studies (Bhargava 1983).

Pathologic Changes in the Central Nervous System

NCC may lead to multiple of pathologic lesions in the CNS. Apart from the diversity in number, location, size and shape of parasites, the inflammatory reaction around cysticerci usually induces various changes in the brain parenchyma, meninges, cerebral ventricles and spinal cord.

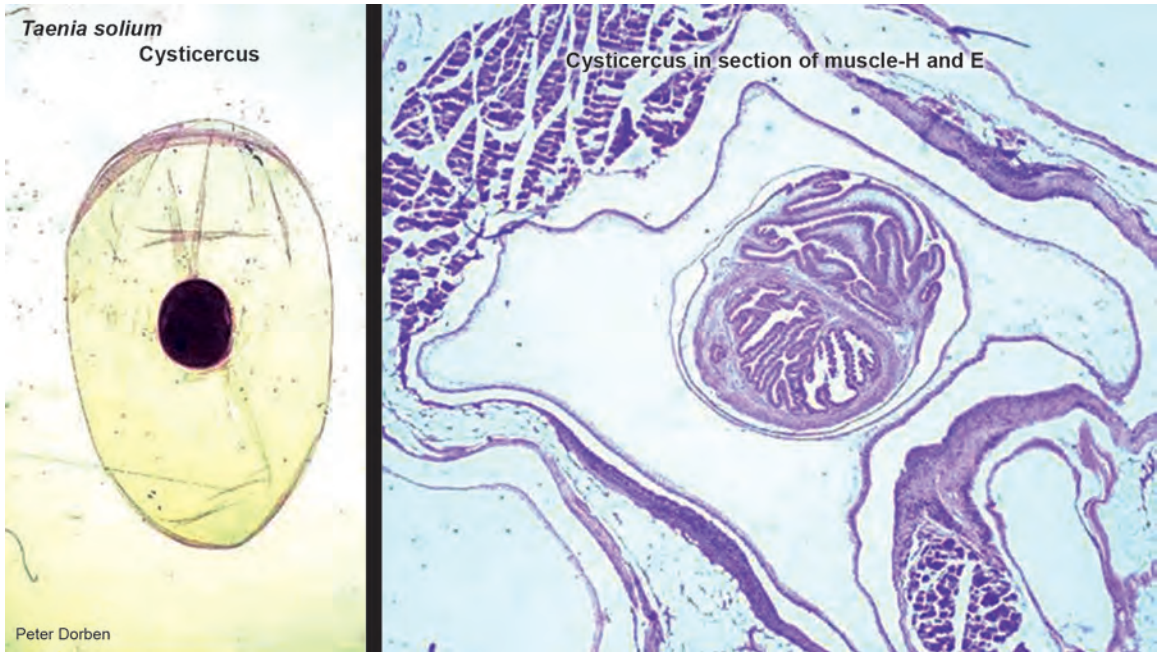

Fig. 3: Section of muscle showing the parasite impregnated within it

Parenchymatous

The inflammatory reaction surrounding parenchymal brain cysticerci is mainly composed of lymphocytes, plasma cells and eosinophils, and is usually associated with some degree of oedema and reactive gliosis, and varies according to the stage of development of the cysticerci.

Massive cerebral infections may cause an encephalitic picture (*cysticercotic encephalitis*) because of overwhelming inflammation around many parasitic cysts, a syndrome that occurs more frequently at younger ages and in women.[85] In contrast, some patients may tolerate hundreds of intraparenchymal cysticerci with only minimal symptoms.[45] In the latter presentation, infestation with the adult tapeworm is frequently found. In some of these cases, intraparenchymal or subarachnoid cysticerci may occasionally grow to exaggerated dimensions, with diameters that may reach 10 cm or more ("giant" cysticercosis).[103] In such cases, symptoms result from the mass effect exerted by the parasite.

Single small enhancing lesion (SSEL) is the commonest form of NCC in India.[94] It commonly presents with simple partial, partial complex, simple partial with secondary generalisation or generalised seizures. Tuberculous granuloma, microabscess, focal meningoencephalitis, postictal enhancement, neoplasm and vascular lesion should be considered in the differential diagnosis.[81–83] Chandy et al.[15] showed that 12 out of 15 patients with SSELs proved to be cysticercosis.

Meningeal

Meningeal cysticerci elicit an intense inflammatory reaction in the subarachnoid space, with formation of a dense exudate composed of collagen fibres, lymphocytes, multinucleated giant cells, eosinophils and hyalinised parasitic membranes. This causes abnormal thickening of the leptomeninges at the base of the skull, from the optochiasmatic region (*optochiasmatic arachnoditis*) to the foramen magnum. The optic chiasm and cranial nerves arising from the ventral aspect of the brainstem are usually entrapped in this dense exudate, leading to visual field defects and other cranial nerve dysfunction. Luschka's and Magendie's foramina may be occluded by the thickened leptomeninges, with the subsequent development of hydrocephalus. Blood vessels, mainly those arising from the circle of Willis, may also be affected by this inflammatory reaction. The walls of small penetrating arteries are invaded by inflammatory cells, leading to a proliferative endarteritis with occlusion of the lumen (*cysticercal vasculitis*). In addition, large vessels may be occluded by atheroma-like deposits resulting from disruption of the endothelium; this vascular involvement may result in the development of a *cerebral infarct*.[10] For some unexplained reasons, this type of pathology is very common in patients from Latin America and Mexico, as well as is also seen very infrequently in India.

Table 1: Causes of hydrocephalus

1.	Direct obstruction by intraventricular cysts
2.	Cysticercal meningitis
3.	Ependymitis (obstructive by granular proliferations and communicative by reducing absorption)

Intraventricular and Subarachnoid

This form of NCC is seen in 15–54% of cases (Table 1).[3,64] The oncosphere reaches the ventricular cavity by way of the choroid plexus. It migrates through the ventricular system, occluding vital communication corridors causing acute episodes of ventriculomegaly with sudden death or mass effect with focal compression. Thirty-eight per cent of patients are present with rapid clinical deterioration. Larval death initiates ependymitis and occlusion of ventricular outlets producing hydrocephalus.[3,63,100] This form has a rapidly progressive clinical course demanding prompt action. It tends to occur in isolation in the majority of cases; however, parenchymatous disease may be associated in 24%.[112] The fourth ventricle is the commonest site (53%) followed by third ventricle (27%), lateral ventricle (11%) and the aqueduct (9%). Isolated cystic lesions within the lateral ventricle are mobile (migratory) and transventricular migration is usually towards the fourth ventricle due to the effects of gravitational forces favouring migration of the cyst from superior cavities to inferior ones (Wani et al. 1982). This results in entrapment of cyst in the fourth ventricle due to the small size of foraminae of Luschka and Magendie. Ventricular entrapment may occur secondary to ependymitis causing a double compartment syndrome.[3]

Spinal

This form occurs in 1.6–13% of cases with NCC. The clinical features depend upon site of lodgement of parasite. Two forms of spinal NCC are recognised.

Leptomeningeal (Extramedullary) form: It is 6–8 times more common than the intramedullary form. This occurs by downward migration of larva from the cerebral to the spinal subarachnoid space.

Intramedullary form: This form is uncommon. It occurs through haematogenous spread. The parasite commonly lodges in the thoracic spinal cord according to the percentage distribution of blood flow to the spinal cord.[20,92]

EPIDEMIOLOGY

NCC is the most common parasitic disease of the CNS and a rather frequent neurological disorder in many countries of Latin America, Africa and Asia. In addition, massive immigration of people from endemic to non-endemic areas has caused a recent increase in the number of cases of NCC in some developed nations where this condition was considered eradicated.[91,110] According to the World Health Organisation (WHO), more than 2 million people harbour the adult tapeworm and many more are infected with cysticerci.

T. solium carriers are infective sources of cysticercosis, endangering everyone coming into contact with them. Indeed, epidemiological studies suggest that almost every newly diagnosed patient with cysticercosis has been infected by someone harbouring *T. solium* in the patient's close environment. In endemic areas, NCC accounts for 10–12% of all hospital admissions to neurology departments. In addition, this disease is a major cause of epilepsy in developing countries, where the prevalence of active epilepsy is almost twice at Western countries (Ahuja and Mohanta 1982). NCC is an important public health problem: it affects people of productive ages and causes an estimated 50,000 deaths every year, and many times that number of patients is left with irreversible brain damage.[105]

Neurocysticercosis in Developing Countries

With the possible exception of Chile, Argentina and Uruguay, all Latin American countries are endemic for cysticercosis. Studies from Mexico, Peru and Ecuador documented that up to half of patients with adult-onset seizures had evidence of NCC by neuroimaging studies and that NCC is a leading cause of hospital admissions and neurosurgical procedures.[26,45] Among these, Mexico and Peru are the countries where the disease has been more extensively studied. Necropsy studies from general hospitals have shown that the prevalence of NCC in Mexico ranges from 2.5 to 3.6%.[26] Major studies have documented a high prevalence of infection throughout Latin America, especially in Brazil,[4] Colombia[74] and Ecuador,[24] where NCC is also a leading cause of seizure disorders. The endemia of cysticercosis in Latin America is related to the poor socioeconomic conditions of the inhabitants and the lack of public awareness about the nature of this disease, its form of transmission and the harm that it produces in human beings.

The endemia of cysticercosis in Asia and Africa is mainly related to the religious practises of their inhabitants. As the Quran prohibits the consumption of pork, taeniasis and cysticercosis are almost unknown conditions in Muslim regions of Asian countries. On the other hand, NCC is endemic in areas where pork is massively consumed under poor hygienic conditions, such as in most sub-Saharan African countries,[36] in India[109] and in several other countries of Southeast Asia. Whereas in some of these countries NCC is a common disease, its prevalence is still underestimated due to the lack of diagnostic facilities in rural areas where the cases reported actually represent the "tip of the iceberg".

This disease was uncommon in developed nations till recently. However, cases of NCC are now being reported more commonly with influx of emigrant population.[56,64,72]

Cysticercosis in India

The disease is widely prevalent in India, but the exact incidence is not known as no major epidemiological study has been carried out. The first reported case is attributed to Krishnaswami in 1912.

Solitary cysticercus granuloma[62,107] accounts for 60% of NCC cases reported from India,[79] and have also been described in other regions of the world where this disease is endemic.[31,71] A relationship between NCC and Japanese encephalitis has been suspected, the former predisposing to the latter (Liu et al. 1957). An autopsy study reported from Bangalore found 33% cases of Japanese encephalitis having coexistent cerebral cysticerci (Shankar et al. 1983).

CLINICAL MANIFESTATIONS

Clinical manifestations of NCC are varied and nonspecific, and recognition of a typical syndrome is not possible.[24,26,27,72] This pleomorphism is related to individual differences in the number, size and topography of lesions and in the severity of the host's immune response to the parasites (Shankar et al. 1994). Epilepsy is the most common form of presentation of NCC and usually represents the primary or sole manifestation of the disease. Seizures occur in 50–80% of patients with parenchymal brain cysts or calcification, but are less common in other forms of the disease.[26,27,45,47] In endemic regions, the presence of recent-onset seizures in otherwise healthy middle-aged individuals is highly suggestive of NCC.[4,24,47]

Most of these patients have normal neurological examinations. In general examination, it is important to look for any subcutaneous, submucosal, subconjuctival or intramuscular swellings (Fig. 3). The routine practise of neuroimaging and serological studies in every patient with adult-onset epilepsy is mandatory to confirm or exclude the diagnosis of NCC.

A variety of focal neurological signs have been described in patients with NCC, particularly in those with strategically located parenchymal brain cysts and in those with large subarachnoid cysts[28] (Ahuja et al. 1978). Pyramidal tract signs, sensory deficits, cerebellar ataxia, signs of brainstem dysfunction and involuntary movements are among the most common focal signs observed in patients with NCC. These manifestations usually follow a subacute or chronic course, making the differential diagnosis with neoplasms or other infections of the CNS difficult on clinical basis alone. Focal signs may also occur abruptly in patients who develop a cerebral infarct as a complication of subarachnoid NCC.[10] Such infarcts are usually small and induce lacunar syndromes (ataxic hemiparesis or pure motor hemiparesis), although large infarcts associated with severe neurological deficits have also been reported in this setting.[29]

A number of patients with NCC present with increased intracranial pressure that may be associated with seizures, focal neurological signs or dementia. Hydrocephalus, related to cysticercotic arachnoiditis, granular ependymitis or ventricular cysts, is the most common cause of this syndrome.[39] In these cases, intracranial hypertension has a subacute onset and a slowly progressive course that may be punctuated by episodes of sudden loss of consciousness related to movements of the head (Bruns' syndrome) when

the cause of hydrocephalus is a fourth ventricle cyst.[89] Increased intracranial pressure also occurs in patients with giant cysts and in patients with cysticercotic encephalitis. The latter is a particularly severe form of NCC that occurs as the result of a massive cysticercus infection of the brain parenchyma inducing an intense immune response from the host resulting in severe brain oedema and raised intracranial pressure. This condition is more frequent among children and young women and is characterised by a clinical picture of subacute encephalitis associated with clouding of consciousness, seizures, diminution of visual acuity, headache, vomiting and papilloedema.[85]

Clinical manifestations of spinal NCC are also nonspecific, and the differential diagnosis with other diseases of the spinal cord is not possible on clinical grounds alone. Arachnoiditis is characterised by root pain and weakness of subacute onset, and cysts in the cord parenchyma usually present with motor and sensory deficits that vary according to the level of the lesion.[9] The various clinical manifestations of NCC are depicted in Table 1.

RADIOLOGICAL INVESTIGATIONS

Plain X-rays of muscles and skull may show cigar-shaped calcification. In the CT scan, single or multiple, variable sized, low density rounded cystic lesions with a small hyperdense eccentric mural nodule (spot) representing the scolex giving a "starry night" effect in the parenchyma, are suggestive of NCC. Ring enhancement occurs either due to inflammatory reaction or granuloma formation. Perilesional oedema is seen around dying cysts. The ventricles look small and throttled. The encephalitic variety shows extensive oedema (Bhargava 1983). Degenerated cysts are seen as single or multiple pin head size calcified dots without preferential localisation. Additional extracranial cysts in the temporalis or nuchal muscles with a honeycomb appearance may be seen.[108]

Plain and intravenous contrast CT may not delineate an intraventricular cyst. It demonstrates hydrocephalus and a round enlargement of the fourth ventricle. Ventricular or periventicular enhancement suggests ependymitis. In cases of hydrocephalus, contrast CT ventriculography is required for localisation of CSF obstruction and to confirm the actual presence of the parasite. This may be performed by intrathecal injection of contrast. A regular rounded filling defect similar to an inverted cup suggests the presence of a cyst. CT scan performed in different positions may define its mobility in addition,[89] whereas a cul-de-sac suggests inflammatory obstruction. A cyst within the third ventricle may mimic a colloid cyst.[21,70]

MR imaging is quite specific (Fig. 4). The number, clumps, multiplicity and additional cysts in other locations are well delineated by this non-invasive diagnostic tool. It differentiates the various stages of evolution, i.e. live, dying and calcified cyst.[58] These are described here in detail. Fluid in live cysts parallels CSF in its intensity. The scolex appears as a mural nodule of high-signal intensity on T1 and low-signal intensity on T2 weighted images like a hole with a dot or pea-in-a-pod. There is no perilesional oedema at this stage.[102] In a degenerated cyst, the fluid becomes turbid (colloid vesicular stage) appearing as high-signal intensity in the T1 image. In the granulonodular stage on gadolinium injection, ring enhancement (isointense on T1 and hypointense on T2 image) occurs and there is a variable degree of perilesional oedema. However, calcified cysts are better delineated by CT scan. The racemose type cysts are seen as large lobulated cysts without a scolex, whereas the cellulose type contains a scolex inside a vesicle. An intraventricular cyst is well delineated with a small metacystode inside the cysts.[50] Abnormal enhancement after gadolinium suggests ependymitis and ventricular entrapment.[76] MRI is useful on follow-up to see the disappearance or reduction in the number and size of cysts in patients on treatment.

The degeneration occurs via a sequence of events, which may be differentiated with MR imaging studies:[73]

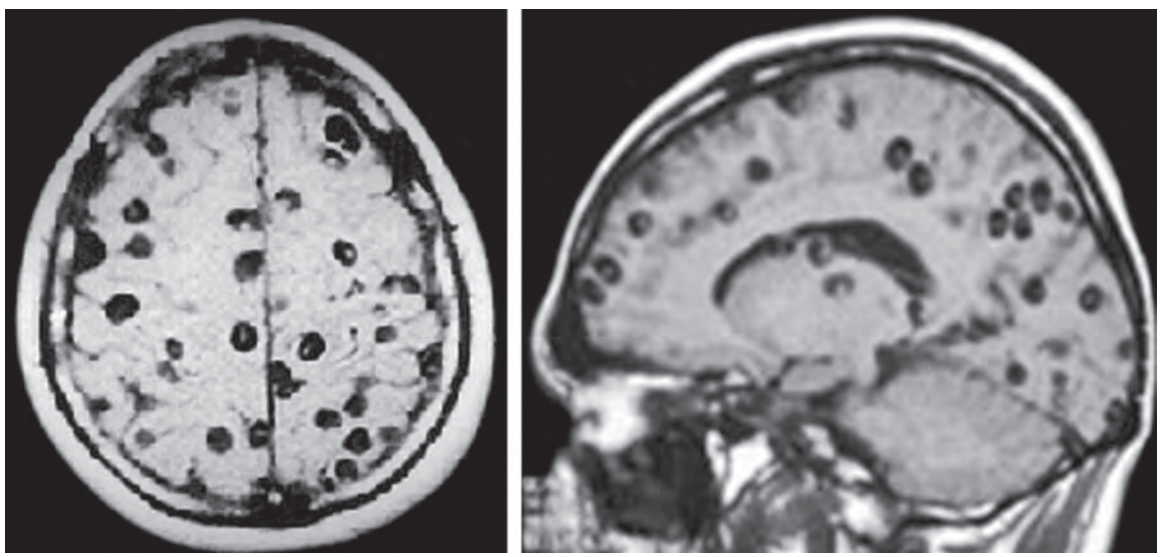

Fig. 4: MR imaging, axial and sagittal sections, T1 sequence showing severe infectation by the parasite

1. *Vesicular stage (active, live or developing cyst form)*: This presents as a fine, brittle, translucent membrane of uniform thickness with a small denser area corresponding to the scolex and containing colourless transparent fluid similar to CSF intensity on MRI. The scolex appears as a mural nodule of high-signal intensity on T1 and low-signal intensity on T2 sequences like a hole or pea-in-a-pod. There is no perilesional oedema. This type of cysticercosis cellulosae is common in the brain parenchyma. Cysticerci developing in the ventricle and subarachnoid spaces reach a larger size without a scolex, with a membrane of irregular thickness and usually clustered in multiple vesicles like raceme called cysticercus racemosus.
2. *Colloid stage (degenerating cyst)*: The membrane becomes thick and opaque and clear fluid is replaced by whitish gel appearing as high-signal intensity on T1 weighted images.
3. *Granular stage*: The gel undergoes calcium deposition. Ring enhancement occurs after gadolinium injection and there is variable degree of perilesional oedema.
4. *Calcified stage*: This appears as hypo-intensities on both T1 and T2 sequences.

DIAGNOSIS

Diagnosis of NCC is made when there is history of exposure in an endemic area, positive stool examination, peripheral blood or CSF eosinophilia, CSF lymphocytosis, positive immunological tests in blood and CSF, viz. Complement fixation test (CFT), Enzyme-linked immunosorbent assay (ELISA) and Enzyme linked immunoelectrotransfer blot assay (EITB).[18,42,45]

NCC is a common disease, but its diagnosis remains problematic. The most common clinical manifestations—seizures, headache and focal deficits—may be caused by a variety of neurological conditions. Neuroimaging studies are usually abnormal but, in most cases, not pathognomonic. Serological tests have been developed to support the diagnosis. However, older tests had low specificity and current assays have decreased sensitivity in patients with single lesions.[80,86] In 1996, Del Brutto, Rajshekhar and a panel of experts from various centres proposed certain diagnostic criteria for cysticercosis, based on the objective evaluation of clinical, radiologic, immunologic and epidemiologic data.[52] Whereas these criteria have proven useful in the diagnosis of this parasitic disease, concern has been raised about the specificity of some of them.[13,52,90] In 2001, a more simplified and comprehensive criteria[25] was proposed as the earlier one was more for patients (apart from nervous system cysticercosis) with exclusively muscular or cutaneous cysticercosis. These criteria are clinically more relevant as cysticercosis outside the nervous system rarely produces manifestations and is usually not relevant clinically. These criteria are shown in Table 2.

Table 2: Revised diagnostic criteria for neurocysticercosis

Categories of Criteria	Criteria
Absolute	1. Histological demonstration of the parasite from biopsy of a brain or spinal cord lesion
	2. Cystic lesions showing the scolex on CT or MRI
	3. Direct visualisation of subretinal parasites by funduscopic examination
Major	1. Lesions highly suggestive of neurocysticercosis on neuroimaging studies*
	2. Positive serum EITB† for the detection of anticysticercal antibodies
	3. Resolution of intracranial cystic lesions after therapy with albendazole or praziquantel
	4. Spontaneous resolution of small single enhancing lesions‡
Minor	1. Lesions compatible with neurocysticercosis on neuroimaging studies§
	2. Clinical manifestations suggestive of neurocysticercosis‖
	3. Positive CSF ELISA for detection of anticysticercal antibodies or cysticercal antigens
	4. Cysticercosis outside the CNS ¶
Epidemiologic	1. Evidence of a household contact with *T. solium* infection
	2. Individuals coming from or living in an area where cysticercosis is endemic
	3. History of frequent travel to disease-endemic areas

ELISA = Enzyme-linked immunosorbent assay

*CT or MRI showing cystic lesions without scolex, enhancing lesions or typical parenchymal brain calcifications.
†Enzyme-linked immunoelectrotransfer blot assay using purified extracts of *T. solium* antigens, as developed by the Centres for Disease Control and Prevention (Atlanta, GA).
‡Solitary ring-enhancing lesions measuring less than 20 mm in diameter in patients presenting with seizures, a normal neurological examination, and no evidence of an active systemic disease.
§CT or MRI showing hydrocephalus or abnormal enhancement of the leptomeninges, and myelograms showing multiple filling defects in the column of contrast medium.
‖Seizures, focal neurologic signs, intracranial hypertension and dementia.
¶Histologically confirmed subcutaneous or muscular cysticercosis, plain X-ray films showing "cigar-shaped" soft-tissue calcifications, or direct visualisation of cysticerci in the anterior chamber of the eye

As in the original publication,[25] the revised criteria include four categories—absolute, major, minor and epidemiologic—so are classified on the basis of their individual diagnostic strength (Table 2). *Absolute criteria* allow unequivocal diagnosis of NCC, *major criteria*

Table 3: Degrees of certainty for the diagnosis of neurocysticercosis

Diagnostic Certainty	Criteria
Definitive	1. Presence of one absolute criterion
	2. Presence of two major plus one minor and one epidemiologic criterion
Probable	1. Presence of one major plus two minor criteria
	2. Presence of one major plus one minor and one epidemiologic criterion
	3. Presence of three minor plus one epidemiologic criterion

The presence of two different lesions highly suggestive of neurocysticercosis on neuroimaging studies should be considered as two major diagnostic criteria. However, positive results in two separate types of antibody detection tests should be interpreted only on the basis of the test falling in the highest category of diagnostic criteria

Adapted from reference [57]

strongly suggest the diagnosis but cannot be used alone to confirm the disease, *minor criteria* are frequent but non-specific manifestations of the disease and *epidemiologic criteria* refer to circumstantial evidence that favour the diagnosis of cysticercosis.

The revised criteria are simpler, containing only definitive and probable diagnosis as the diagnostic guidelines (Table 3).[25] A brief description of each criterion is provided here.

Absolute Criteria

Histological Demonstration of the Parasite from Biopsy of a Brain or Spinal Cord Lesion

Visualisation of the scolex with its suckers and hooks, or the presence of parasitic membranes in the histologic sections confirms the diagnosis.[75] However, biopsy of calcified cysticerci only may not confirm the diagnosis, as the characteristic scolex or the membranes are not seen in this.

Cystic Lesions Showing the Scolex on CT or MRI

A large number of imaging findings have been described for NCC (Fig. 4). From these, only the presence of cystic lesions along with a scolex should be considered pathognomonic.[35] The scolex is visualised as a bright nodule within the cyst. This produces the so-called *"hole-with-dot"* imaging that is seen in some vesicular cysts located in the brain parenchyma, the subarachnoid space or the ventricular system.[60] This finding is more clearly seen on MR images.

Direct Visualisation of Subretinal Parasites by Funduscopic Examination

Because the retina is considered part of the CNS, patients with subretinal cysticerci may be considered to have NCC. This, however, does not apply to patients with cysticerci in the anterior chamber of the eye. Subretinal cysts are usually located over the macula and have a yellowish colour with a central dark spot corresponding to the scolex. Subretinal cysticerci may rupture the retinal layers and enter the vitreous. In such a situation *in vivo* evagination and invagination movements of the parasite may be observed and is considered confirmative of CNS cysticercosis.[65]

Major Criteria

Lesions Highly Suggestive of NSS on Neuroimaging Studies

Among a myriad of imaging features, only a few have been described to be highly suggestive. These include: cystic lesions without a scolex, single or multiple ring or nodular enhancing lesions and parenchymal round calcifications. Such CT and MRI findings may also be observed in other diseases of the CNS and must be interpreted with caution to avoid over diagnosis of NCC, particularly in HIV-infected patients or in those with evidence of a systemic disease.[25,74] A common neuroimaging finding in NCC is the presence of intracranial lesions in different evolutive stages, i.e. calcifications and cystic or ring-enhancing lesions.[27]

Positive Serum Enzyme-Linked Immunoelectrotransfer Blot Assay (EITB) for the Detection of Antibodies to T. Solium Glycoprotein Antigens

Although many serologic assays for human cysticercosis have been reported, most of them are limited in value due to poor sensitivity and specificity. Only tests based on detection of antibodies specific for *T. solium* antigens are reliable for clinical diagnosis and epidemiological studies. To date, these are limited to those based on the use of purified glycoprotein antigens derived from *T. solium* cysticerci. The current assay of choice is EITB using partially purified antigenic extracts.[104] This assay has been documented to have a specificity approaching 100% and a sensitivity of 94–98% for patients with two or more cystic or enhancing lesions. A major weakness of this test is frequent false negative results in patients with single intracranial cysticerci, in which fewer than 50% test positive. The detection of antibodies to antigens of 26 kDa and 8 kDa by immunoblot using a crude antigenic preparation of *T. solium* cysticerci has been shown to approach 100% specificity.[55] This assay has been less extensively assessed than that using purified *T. solium* glycoproteins described previously, but has the potential advantage of the antigen preparation being simpler. The results need to be interpreted with more care, however, due to the presence of a number of non-specific interactions with antigens with molecular weights close to those of the specific antigens. This assay is less sensitive than the glycoprotein based antigen EITB.[87]

Spontaneously Resolving Small Single Enhancing Lesions

Single enhancing lesions may occur in several infectious and neoplastic diseases of the CNS. However, Rajshekhar and Chandy[78] demonstrated that when those lesions fulfil a rigid set of clinical and radiological criteria, the diagnosis of NCC can be established with a sensitivity of 99.5% and a specificity of 98.9%. Solitary cysticercus granulomas measure less than 20 mm in diameter may be associated with oedema not severe enough to displace the midline, and occur in patients with seizures, a normal neurological examination and no evidence of an active systemic disease. When those lesions resolve spontaneously, either disappearing or transforming into a calcified nodule, the diagnosis of NCC is almost certain. Solitary cysticercus granuloma accounts for 60% of NCC cases reported from India[79] and have also been described in other regions of the world where this disease is endemic.[31,71] Care should be taken not to interpret resolution of an intracranial lesion with the use of steroids as definitively indicative of NCC, because other diseases that may present with similar neuroimaging findings are known to respond to steroid therapy.

Resolution of Intracranial Cystic Lesions after Therapy with Albendazole or Praziquantel

Several studies have shown that cysticidal drugs hasten the destruction of cysticerci[8,46,95] and the disappearance of intracranial cystic lesions or their transformation into calcified nodules after therapy with either albendazole or praziquantel should be considered as a strong factor favouring the diagnosis of NCC.

Minor Criteria

Lesions Compatible with NCC on Neuroimaging Studies

Some imaging features are not strong enough to be included in the major criteria.[74] They have thus been classified under minor criteria. These include CT or MRI showing hydrocephalus or abnormal enhancement of the leptomeninges and myelograms showing multiple filling defects in the column of contrast medium. So are multiple filling defects seen on myelogram suggesting presence of spinal subarachnoid cysts.

Clinical Manifestations Suggestive of Neurocysticercosis

Large series have shown that seizures, focal neurological deficits, increased intracranial pressure and intellectual deterioration are the most common clinical manifestations of NCC.[27,47,72,109] These features have thus been included under minor criteria. More than 70% of symptomatic patients develop seizures, which in many of these cases are the primary or sole manifestation of the disease.[4,24,26,45,74] Several studies have shown that NCC is the single most common cause of adult-onset epilepsy in developing countries, and the presence of recent onset seizures in an otherwise healthy middle-aged individual coming from an endemic area is highly suggestive of NCC.[4,24,74] Other clinical manifestations of the disease include focal neurological deficits, signs and symptoms of increased intracranial pressure and intellectual deterioration.[93]

Positive CSF Enzyme-Linked Immunosorbent Assay (ELISA) for Detection of Anticysticercal Antibodies or Cysticercal Antigens

The detection of anticysticercal antibodies by serum ELISA has been used for the diagnosis of cysticercosis in endemic regions.[16,88] However, recent studies have demonstrated a large number of false-positive and false-negative results.[84] In contrast, the detection of anticysticercal antibodies by ELISA using CSF was 87% sensitive and 95% specific, and remains a useful tool for the diagnosis of NCC in areas with limited access to the EITB assay.[75] However, this test may falsely be negative in patients with parenchymal brain cysticercosis or in those with inactive disease, and it may falsely be positive in other helminthic infections.[88] However, the specificity of this assay has not been adequately assessed on samples of patients with other diseases. Pending further experience with the use of this test, it should only be considered as a minor diagnostic criterion. Several other serodiagnostic tests have been proposed for immunodiagnosis of cysticercosis. These assays are not sufficiently well standardised at this time for inclusion as diagnostic criteria (Fig. 5).

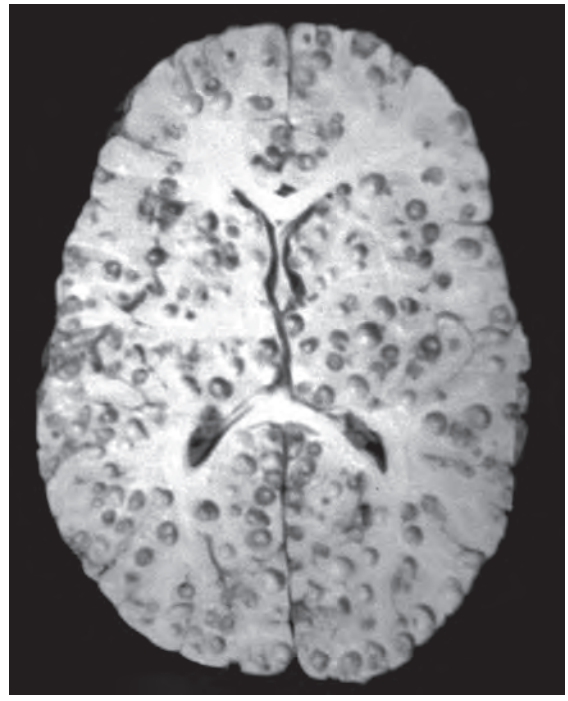

Fig. 5: Cut section of a brain showing heavily impregnated cysticercal cysts

Cysticercosis Outside the Central Nervous System

From the pioneering studies of McArthur[68] and Dixon and Lipscomb,[33] it was considered that the presence of soft-tissue calcifications or palpable subcutaneous cysticerci in a patient with seizures strongly suggests the diagnosis of NCC. This may be true, but in endemic regions a patient may have systemic cysticercosis and neurological manifestations due to an unrelated cause. Therefore, a probable or even a definitive diagnosis of cysticercosis outside the CNS only provides circumstantial evidence favouring the diagnosis of NCC. Definitive diagnosis of extraneural cysticercosis requires one of the following: (1) histological demonstration of the parasite from biopsy of a subcutaneous nodule; (2) plain X-ray films showing multiple "cigar-shaped" calcifications in thigh and calf muscles; (3) direct visualisation of a cysticercus in the anterior chamber of the eye or (4) positive EITB test. Since the latter is already considered a major criterion for the diagnosis of NCC, only the three previously enumerated findings should be included in this category of minor diagnostic criteria for NCC.

Epidemiologic Criteria

Epidemiologic data, including the place of birth, residence and travel history, provide important information when evaluating patients with suspected NCC. Cysticercosis is endemic in Latin America, sub-Saharan Africa and in some regions of Asia, including the Indian subcontinent, China, Korea and Indonesia. The disease is rare in most European countries, in North America, in Oceania and in some muslim countries of Asia and Africa.[2] However, in these areas, it may occur in the immigrant population. Clinicians must be aware that NCC is an infection acquired from a human tapeworm carrier and the disease is sometimes diagnosed in persons born in non-endemic countries who have never travelled to endemic regions.[14,91] In such cases, it is of value to search for a close contact—usually a household contact—with a tapeworm infection. This finding will support the diagnosis of NCC in a patient with suggestive clinical, radiological and immunological criteria and, by treating the tapeworm carrier, will permit the elimination of the source of contagion. A definitive diagnosis of *T. solium* infection can only be established when the scolex or a gravid proglottid is available for microscopic examination.[42] A probable diagnosis can be suspected in those with history of having passed proglottids in faeces as well as in those with positive stool examinations for *Taenia* eggs or with a positive coproantigen test.[1] These latter criteria should only be considered as probable indicators of *T. solium* infection because they may represent an infection with *Taenia saginata*. It may be pointed out that positive stool examination was an exception than a rule in proven cases of NCC.

TREATMENT

The mainstay of NCC is medical management. However, some cases do require some form of surgical intervention either to treat the pathology itself (e.g. cyst excision) or to treat the consequences of the pathology (e.g. hydrocephalus). NCC has been classified depending upon the location of cysts,[96] clinical presentation,[106] prognosis[38] and viability of cysts.[26]

Treatment of NCC principally consists of control of seizures, oedema and intracranial pressure followed by definitive treatment. This can be accomplished with both medical and surgical modalities, which are complementary to each other.

Medical Treatment

A brief review of medical treatment will be provided before dealing with the surgical aspects. Cysticidal drugs, namely albendazole and praziquantel, have been shown to be effective in all forms of NCC.[2,8,32,46,95]

Albendazole in a dose of 15 mg/kg/day for 8 days is reported to be more effective than praziquantel in a dose of 50–100 mg/kg/day for 15 days. The duration of treatment ranges 8–21 days and 1–30 days for albendazole and praziquantel, respectively. Recently, ultrashort single day therapy with praziquantel 75 mg/kg/day divided in three 25 mg/kg/doses each, given at 2 hourly intervals (7–9–11 AM) has been introduced.[8,46,95] Four hours later (3 PM), 10 mg dexamethasone intramuscular or 80 mg oral prednisolone is given followed by the same doses of steroids for the next three mornings. As the half life of praziquantel is 2–3 hours, a four-hour interval between praziquantel and anti-inflammatory treatment is without pharmacological conflicts. Steroids prevent secondary inflammatory reactions triggered by acute destruction of the parasite. Long-term steroid therapy depends on parasitic load and inflammation.[19] Wadia et al.[108,109] have cautioned against the use of cysticides in the disseminated variety. Such patients should be monitored in an intensive care unit and steroids and mannitol must be used to decrease the oedema along with cysticidal treatment.

Cysticides induce destruction of 96% of the parasites located in the brain parenchyma including giant or large clumps of cysts. In the intraventricular form, 80% of cysts completely disappear and another 10% decrease in size.[2,8,46,95] Prompt elimination of the cyst prevents chronic inflammation and granuloma formation (focus of epilepsy) around the cyst in the parenchymatous form and ependymitis and ventricular entrapment in the intraventricular form.[8]

If cystic lesions remain unchanged on repeat MRI, 1–2 months after praziquantel therapy, an additional course of praziquantel is given. However, in partial response to a cysticidal drug, administration of the other cysticide (albendazole 15 mg/kg/day in two divided doses for 8 days) is better than repetition of the same drug.[95,99]

Currently, albendazole 15 mg/kg/day for 2 weeks is the treatment of choice in patients with uncomplicated fourth ventricle NCC without hydrocephalus. Repeat albendazole therapy or an additional course of praziquantel 100 mg/kg/day for 2 weeks may be required in non-responders.[34,56] In patients with hydrocephalus, a ventriculoperitoneal shunt should be inserted and steroids in the form of dexamethasone 10 mg intramuscular or prednisolone 80 mg orally should be started prior to cysticidal treatment to reduce the risk of shunt block. Menezes et al. (1996)[70] reported that cysticidal treatment in the intraventricular form may be disastrous due to development of ventriculitis and recurrent obstruction of ventricular drainage system.

Corral et al. (1996)[20] successfully treated intramedullary spinal cysticercosis with cysticidal therapy. In the meningeal form, cysticidal treatment may only give marginal benefit and the prognosis is poor because of hydrocephalus, meningeal fibrosis and multiple brain infarcts secondary to vasculitis. In these patients, administration of 50 mg prednisolone three times a week is useful in preventing or diminishing chronic inflammation.[60,99]

Symptomatic Medical Therapy

Since most patients with NCC have seizures, antiepileptic drugs are frequently used. In patients with calcifications, the administration of standard doses of a single, first-line antiepileptic drug, e.g. phenytoin or carbamazepine, usually results in adequate control of seizures. Whether the control of seizures (always with antiepileptic drugs) in patients with viable parenchymal brain cysts is aided by antiparasitic therapy is still to be conclusively demonstrated. Prospective evidence is inconclusive,[12,69] whereas retrospective studies demonstrated a strong association between seizure control and the use of praziquantel or albendazole: seizures were adequately controlled in 83% of patients who received antiparasitic therapy but in only 27% of those who did not. The optimal length of antiepileptic drug therapy in patients with NCC has not been determined. Successful antiepileptic withdrawal is difficult to achieve. One prospective study showed that up to 50% of albendazole-treated patients had relapses after withdrawal of antiepileptic drugs, after 2 years free of seizures.[30] Prognostic factors associated with seizure recurrence included the development of parenchymal brain calcifications as the result of albendazole therapy and the presence of recurrent seizures and multiple brain cysts before the institution of antiparasitic therapy. In a large prospective study of patients with focal epilepsy due to antiepileptic drug alone was found to be adequate therapy. Additional of cysticial drug provided no statistically significant advantage.

Corticosteroids are also frequently used in patients with NCC. They are usually administered at the time of antiparasitic therapy to decrease neurological symptoms resulting from the death of the parasite. Also, steroids represent the primary form of therapy for cysticercotic encephalitis, where up to 32 mg/day of dexamethasone may be needed to reduce the brain oedema accompanying this condition.[27,85] Corticosteroids may be used alone or in association with mannitol at a dosage of 2 gm/kg/day. High doses of intravenous dexamethasone are also of value in the acute treatment of patients with cysticercotic angiitis to avoid the risk of recurrent cerebral infarcts[29] followed by chronic oral therapy with dexamethasone (10 mg/day) or prednisolone (50 mg/day) to ameliorate the inflammatory reaction in the subarachnoid space that initially caused the angiitis. The same protocol of chronic corticosteroid therapy may be followed in patients with diffuse cysticercotic arachnoiditis causing hydrocephalus and progressive entrapment of cranial nerves at the base of the brain. In both conditions, corticosteroids should be administered until the inflammatory reaction in the subarachnoid space subsides; serial cytochemical analysis of CSF determines the optimal time for corticosteroid withdrawal. Absolute indications for corticosteroid administration during antiparasitic drug therapy include the management of patients with giant subarachnoid cysticerci, ventricular cysts, spinal cysts and multiple parenchymal brain cysts. In most of these cases, corticosteroids must be administered before, during and even some days after the course of antiparasitic drugs to avoid the risk of cerebral infarcts, acute hydrocephalus, spinal cord swelling and massive brain oedema.

Surgery

In general, surgery is required when:

- The diagnosis is uncertain.
- Cysts exhibit tumour-like effect (oedema and/or mass effect) which are refractory to medical treatment.
- Hydrocephalus.
- Intraventricular cysticerosis is diagnosed.
- Presence of acute or sub-acute rise of ICP.

For parenchymatous type of cysticercosis, the following surgical approaches are recommended.[3,17,99,112]

Stereotactic excisional biopsy/open craniotomy and cyst removal is recommended in cases of a single giant cortical cyst or large clumps exhibiting tumour like behaviour, if the lesion is in a surgically accessible area, is producing progressive deficits or not responding to cysticidal therapy. This approach may also be used when diagnosis is uncertain, e.g. SSEL with atypical features, and worsening or not responding to cysticides or in cases of multiple lesions.

Supratentorial decompressive craniectomy/craniotomy/ lobectomy is undertaken when the pseudotumour type of oedema is refractory to medical treatment, particularly in the disseminated variety of the disease frequently seen in India.

For Intraventricular and subarachnoid forms of NCC, the surgical procedure usually used which includes a shunting procedure for managing hydrocephalus, cyst removal or excision through a posterior fossa craniotomy

for fourth ventricle/subarachnoid cysts and supratentorial open or stereotactic craniotomy for subarachnoid third or lateral ventricle cysts.

Endoscopic Excision

More recently, endoscopic excision has been advocated both for supratentorial and infratentorial intraventricular cysts. Endoscopic third ventricular cyst removal may be carried out very effectively using a rigid rod lens endoscope through a frontal burr hole. The foramen of Monro may be identified on entering the lateral ventricle by noting the presence of the choroid plexus and the thalamostriate vein. It is not uncommon in long standing hydrocephalus to find multiple perforations within the septum; hence it is important to identify the correct portal of entry into the third ventricle. It is usually not possible to remove the cyst *in toto*, and the cyst usually gets ruptured during removal. Some authors have hence advocated intraventricular injection of steroids to prevent an anaphylactic reaction.[5,22] In a recent review, Bergsneider et al.[6] have reported a series of 10 cases of intraventricular cysticercosis cysts presenting with hydrocephalus. Combined endoscopic removal of the cysts with a third ventriculostomy and/or a septal pellucidotomy gave excellent results. They have advocated endoscopic removal of cysts as the primary therapy of intraventricular cysticercosis and were able to avoid shunts. Endoscopic removal of fourth ventricular cysts has also been described.[6] This may be achieved by using a paramedian suboccipital burr hole as a portal of entry. In a small ventricle, a pre-operative ultrasound or image guided neuronavigation may be used to reach the fourth ventricle. Overall, endoscopic removal of cysts is a minimally invasive procedure, reduces blood loss and operative time and provides excellent visualisation of the anatomy.

Spinal Neurocysticercosis

For spinal cysticercosis, excision needs to be undertaken.[9] Intramedullary and clumped leptomeningeal cysts producing symptoms by mass effect and not responding to cysticidal drugs may be removed via laminectomy or laminoplasty. When diagnosis is in doubt, surgery also helps in obtaining a histopathological diagnosis.[20,92]

Surgery has been considered to be therapeutic procedure of choice for intraventricular cysticercosis (Figs 6A and B),[2,5,6,22,66] but successful treatment with cysticidal drugs in this location has raised some controversy. Proano et al.[76] now consider cysticidal drugs as the treatment of choice for uncomplicated intraventricular NCC without hydrocephalus. Surgical removal of the cyst prevents acute complications, like sudden death, and chronic complications like ventriculitis and ventricular entrapment.[2,22]

Excision of simple cysts in the absence of radiographic or surgical evidence of arachnoiditis or ependymitis may be performed with stereotactic localisation, craniotomy and microsurgical techniques. Madrazo et al.[67] proposed the pipette suction technique for atraumatic extraction of intraventricular NCC. Here they have devised a special long pipette, which may be attached to the cyst, and it may be removed without rupturing the cyst. Madrazo et al.[67] considered cyst rupture a dangerous event, whereas other do not share this view.[5,6,22,66] However, in all cases of intra-operative rupture large doses of glucocorticoids and vigorous intraventricular lavage with Ringer's lactate solution (at body temperature) is advocated. While selecting the surgical approach for intraventricular NCC, the surgeon should consider:[2,5,22]

- Presence of associated ependymitis with its implications in accomplishing complete excision of cyst and the need for a shunt.
- Presence of ventricular entrapment (double compartment syndrome).
- Potential of cyst migration with posture and frank transition from one ventricular cavity to the other.
- Potential for increase in size of the cyst with local mass effect.
- Potential for rapid clinical deterioration and/or sudden death.
- Potential for presence of additional cysts at other sites.
- Feasibility of stereotactic/endoscopic excision/aspiration in lateral and third ventricular cysts.
- Selection and institution of surgical approaches that establish alternative routes of CSF flow, e.g. fenestration of the septum pellucidum. Following surgical excision or shunt, cysticidal therapy may be given to take care of cysts present at other locations or for treating small intraventricular NCC not seen during surgery.

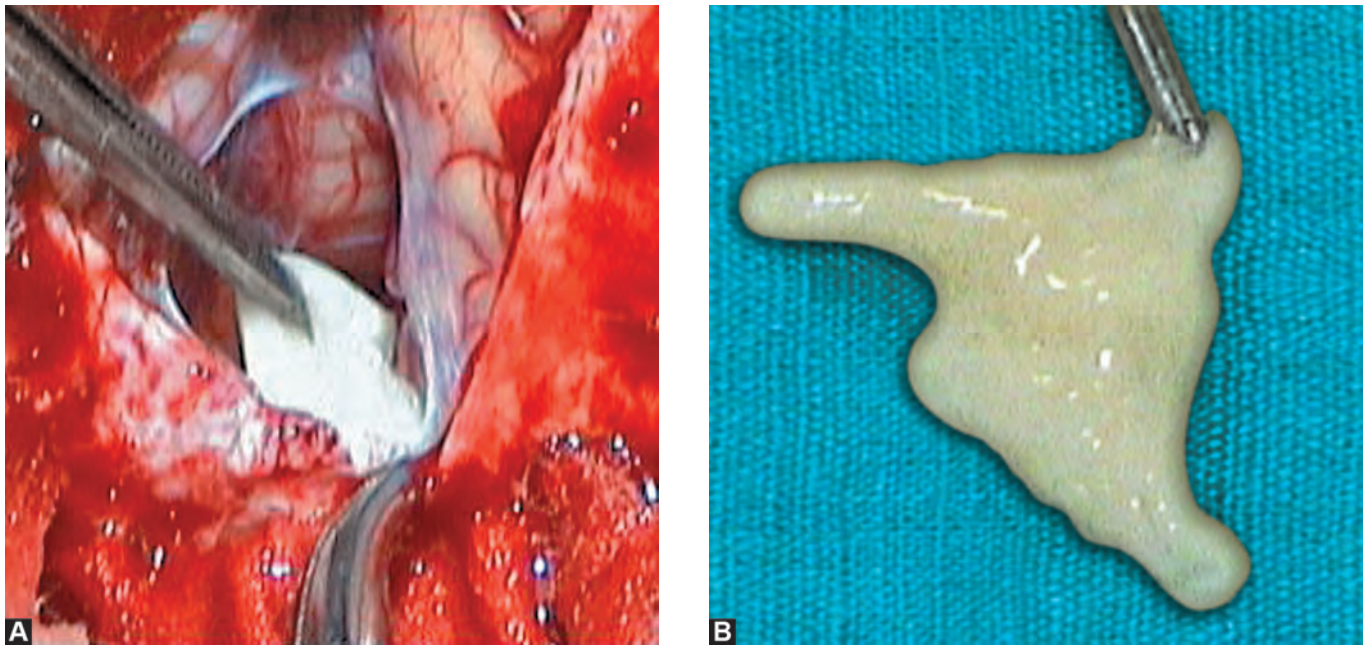
Shunt

Insertion of the ventriculoperitoneal shunt is indicated in the presence of hydrocephalus.[97] Shunt is associated with high percentage of complications like blockage and infection. Shunt obstruction rate is 50% within the first 4 months.[61,101] Intermittent long-term prednisolone therapy after V.P. Shunt reduces shunt malfunction and may improve the functional status of the patient.[102] Prednisolone is started within the first post-operative week in doses of 50 mg three times a week.

Sotelo et al.[94,98] introduced a new shunt system devoid of a valve mechanism with drainage capacity limited to physiological parameters of CSF production to avoid over-drainage and occlusion. This shunt system has shown to have 96% functional results.

PREVENTION AND CONTROL

Transmission of *T. solium* has largely been eliminated in developed countries by improving public sanitation and meat inspection. Due to economic reasons, this approach has consistently been failed in areas where pigs are raised by peasant farmers.[23,54]



Figs 6A and B: Intra-operative photographs showing removal of a fourth ventricular cysticercal cyst

The cycle of *T. solium* may be interrupted by intervening at the human level (tapeworm carriers—the only infective source for human and porcine cysticercosis) and at the pig level (infected pork—reservoir for human taeniasis). Tapeworm carriers play a key role in transmission of infection. Because they rarely have significant symptoms and are usually missed by routine stool examination, detection is often problematic. Stool examination to detect parasite antigen is more sensitive,[27] but is not widely available. A recently described serologic test for tapeworm carriers will enhance the detection of carriers.[111] Human infection with adult tapeworms is prevented by freezing or adequate cooking of measly pork.

Another important source of human cysticercosis is through fecal-oral contamination, and hygienic measures, such as adequate hand washing, proper education, periodical deworming, that reduce the risk are highly recommended.[52] Transmission through consumption of uncooked vegetables and fruits (e.g. use of improperly washed salads) is yet another source of contamination. Hence, eating salads or raw fruits from street side vendors should be avoided.

The introduction of oxfendazole as effective and cheap single-dose therapy for porcine cysticercosis permitted the design and execution of combined pig-human chemotherapy interventions.[51–53]

Apart from the control measure to be tested, monitoring the effect of an intervention requires the use of simple epidemiological indicators. Human seroprevalence is useful, but cannot be used easily to demonstrate changes in infection patterns, because antibodies to cysticercosis persist in man for years, even after successful treatment. Studies in Peru[43] have shown that infection in pigs, monitored by serology, is a useful indicator of both the prevalence of cysticercosis infection in a community and the changes in infection intensity over time.[111] Similarly, the rate of infection that occurs in uninfected (sentinel) pigs over time can be used to estimate the intensity of *T. solium* infection in the community.[51] In most cases, the prevalence of porcine infection correlates well with the prevalence of human cysticercosis. These indicators of porcine infection can be used to evaluate the effect of control programmes in communities, because they are measures of the intensity of *T. solium* egg environmental contamination of the community. In most rural communities, pigs are kept for less than 1 year, so that a new cohort is available yearly. The use of the pig as an indicator permits the results of control programmes to be easily and cheaply evaluated.

Other than improvement of sanitary conditions and changes in porcine-rearing practises, development of an effective vaccine against porcine cysticercosis may prove the best potential tool for eradication of the disease. A recombinant vaccine has been developed for *Taenia ovis* that can provide nearly complete protection.[59,61] This vaccine is currently commercially available in several countries. A *T. solium* homologue of a *T. ovis* vaccine antigen has been cloned.[48] Development of such a vaccine is hampered at the present time by the lack of a simple, reproducible model of animal infection in which vaccine candidates may be tested.

69 Hydatid Disease

Dharkar SR, Vikram M

Hydatid disease is caused by the parasite tapeworm (Taenia) *Echinococcus* (Platyhelminth). *Echinococcus* has been recognised since the times of Hippocrates (410–379 BC) and Galen (131–210 AD) who described hydatid cysts of the liver.[23] In the 17th century (1626–1694). Redi and Hartmannus Tyssen[54] established that hydatid disease was caused by an animal. Guesnard reported the first case of cerebral hydatid cyst, while vertebral hydatidosis was first described by Chaussier in 1807.[15] In 1808, Rudolph coined the term *Echinococcus* to describe the vesicular worms.

PARASITOLOGY

There are two main varieties of *Echinococcus*: (i) *Echinococcus granulosus*, causing the classical hydatid disease, prevalent in various parts of the world and (ii) *Echinococcus multilocularis*, uncommon and reported only from some parts of Europe.

Echinococcus granulosus produces hydatid cysts in man and in other animals and is endemic in sheep rearing areas. Its larval form is called the hydatid cyst. The definitive hosts of the are the various carnivores, the important one being the dog. The mature tapeworms live in the small intestines of the dog. The intermediate host includes all mammals, especially sheep. Man gets infected occasionally by accidental contamination of the hand with the faeces of infected dogs or by ingestion of food infected with the ova. There are variations in the host-parasite relationship between different animal species. In parts of North America, wild animals are involved. In Great Britain, horses have been found harbouring hydatid cysts. In the Madurai district of Tamil Nadu, 20% of the slaughtered cattle were found to have hydatid cysts.[40] Human beings are infested by eating contaminated food, or from the fingers as a result of fondling dogs whose skin may be contaminated by the ova of the worm. The dog, in its turn, is infected by eating the offal of infested sheep. In man, the eggs, after reaching the stomach, lose their enveloping layer, thereby releasing the hexacanth embryos. The hexacanth embryo passes through the wall of the gut into the portal system and then to the liver, where a hydatid cyst may develop. The embryo can successfully pass through the capillary filters of the liver and lungs and get entry into the systemic circulation and thus reach the central nervous system,[30] the cranium and the vertebrae. The liver is affected in about 65% of cases, the lungs in about 15–20% and the brain in about 2–5%.

EPIDEMIOLOGY

Echinococcosis is widely distributed in the whole world, being most common in sheep and cattle rearing countries such as Uruguay, Argentina, Australia,[63] New Zealand and South Africa. The disease is also relatively common in Europe and Central Asia. In India, the disease has been reported from different parts of the country, but is more common in the Kurnool district of Andhra Pradesh, in Punjab and in the Madurai district of Tamil Nadu.[52]

CEREBRAL ECHINOCOCCOSIS

Incidence

Hydatid cysts constitute only a small percentage of space occupying lesions of the brain. There were only two cases of hydatid cysts, among the 2,000 cases in Cushing's classic series.[19] In New Zealand, 1% of all intracranial space occupying lesions[14] are hydatid cysts. At the Institute de Neurologia of Montevideo hydatid cysts constituted 3.64% of intracranial space occupying lesions in adults and 24.3% in children[22] during a period of 13 years from 1958 to 1971.[7] Ramamurthi et al.,[50] in Madras, found an incidence of 0.2%. A similar incidence was found by Raja Reddy et al.[49] in Hyderabad, Dharker et al.[21] in Gwalior and Sardana et al.[60] in Jaipur.

Pathology

The hydatid cyst is unilocular, slow growing and may attain a large size in the liver, lungs and spleen. The cysts are somewhat smaller in the brain, although a cyst measuring up to 12.5 cm in diameter has been reported.[21] The cyst wall is made up of three layers: (1) the outer layer is thin; (2) the intermediate layer is made up of laminated chitinous material and (3) the inner one is the germinal layer. To the inner layer are attached brood capsules, containing scolices, which are the heads of the embryonic worm. The fluid in the cyst is watery and colourless, but, occasionally, may be whitish or yellow. It contains scolices, brood capsules (referred to as hydatid sand) and, occasionally, daughter cysts. The cyst

is well delineated from the surrounding brain. Cerebral cysts are nearly always single, large and confined to the white matter. Multiple hydatid cysts represent a secondary form of the disease, resulting from either rupture of a cyst in the left side of the heart,[5,10] or traumatic, spontaneous or surgical rupture of the primary cerebral hydatid cyst.[7,20,23,25,27,75] Secondary cysts lack a brood capsule and are infertile.[45,61] For unknown reasons, the hydatid cyst has a predilection for the white matter.[17]

Cerebral hydatid cysts are more common in children and young adults. They are mostly supratentorial and tend to occur in the distribution of the middle cerebral artery.[35,69] Infratentorial involvement is unusual.[2,8,48] Rarely, hydatid cysts are found in the supratentorial as well as the infratentorial compartments.[37,60] Hydatid cysts have been reported at unusual sites, e.g. cavernous sinus.[54,55] Multiple primary hydatid cysts in the brain are rare.[10,43] A subdural hydatid cyst can grow to a large size and resemble intracerebral cysts. As the hydatid cyst grows in size, it compresses and distorts the surrounding brain tissue and displaces blood vessels. There is no neural tissue reaction, unless the cyst is disturbed. Daughter cysts are more frequent in the brain than elsewhere.[6] A rare instance of infection in a hydatid cyst has been reported.[24] The cyst may cause raised ICP by its size and/or interference with cerebrospinal fluid (CSF) pathways. The cyst, as it grows, may produce asymmetry of the cranium, and localised thinning, erosion and bulging of the calvarium overlying the cyst. The cyst does not infiltrate the bone. The average growth of a hydatid cyst has been estimated at about 1.5 cm/year[62,70] to 10 cm/year.[45]

Clinical Features

Cerebral hydatid cysts are most commonly seen in children and in young adults.[61] While in adults, focal neurological signs predominate children primarily present with features of raised intracranial pressure.[35] Cracked-pot resonance (McEwen's sign) is common in children. Macrocrania or swelling of the head over the area of the hydatid cyst is seen quite commonly.[12,21,26,38,42] Papilloedema occurs not infrequently and may progress to secondary atrophy.[2,12,21,26,38,44,53,73] The cyst is located most commonly in the posterior part of the cerebral hemisphere and hemianopia is an important sign. Contralateral hemiparesis may be present. Mental changes are more frequent in adults and seizures more frequent in children. Minimal contralateral cerebellar signs may be present and may lead to faulty localisation.

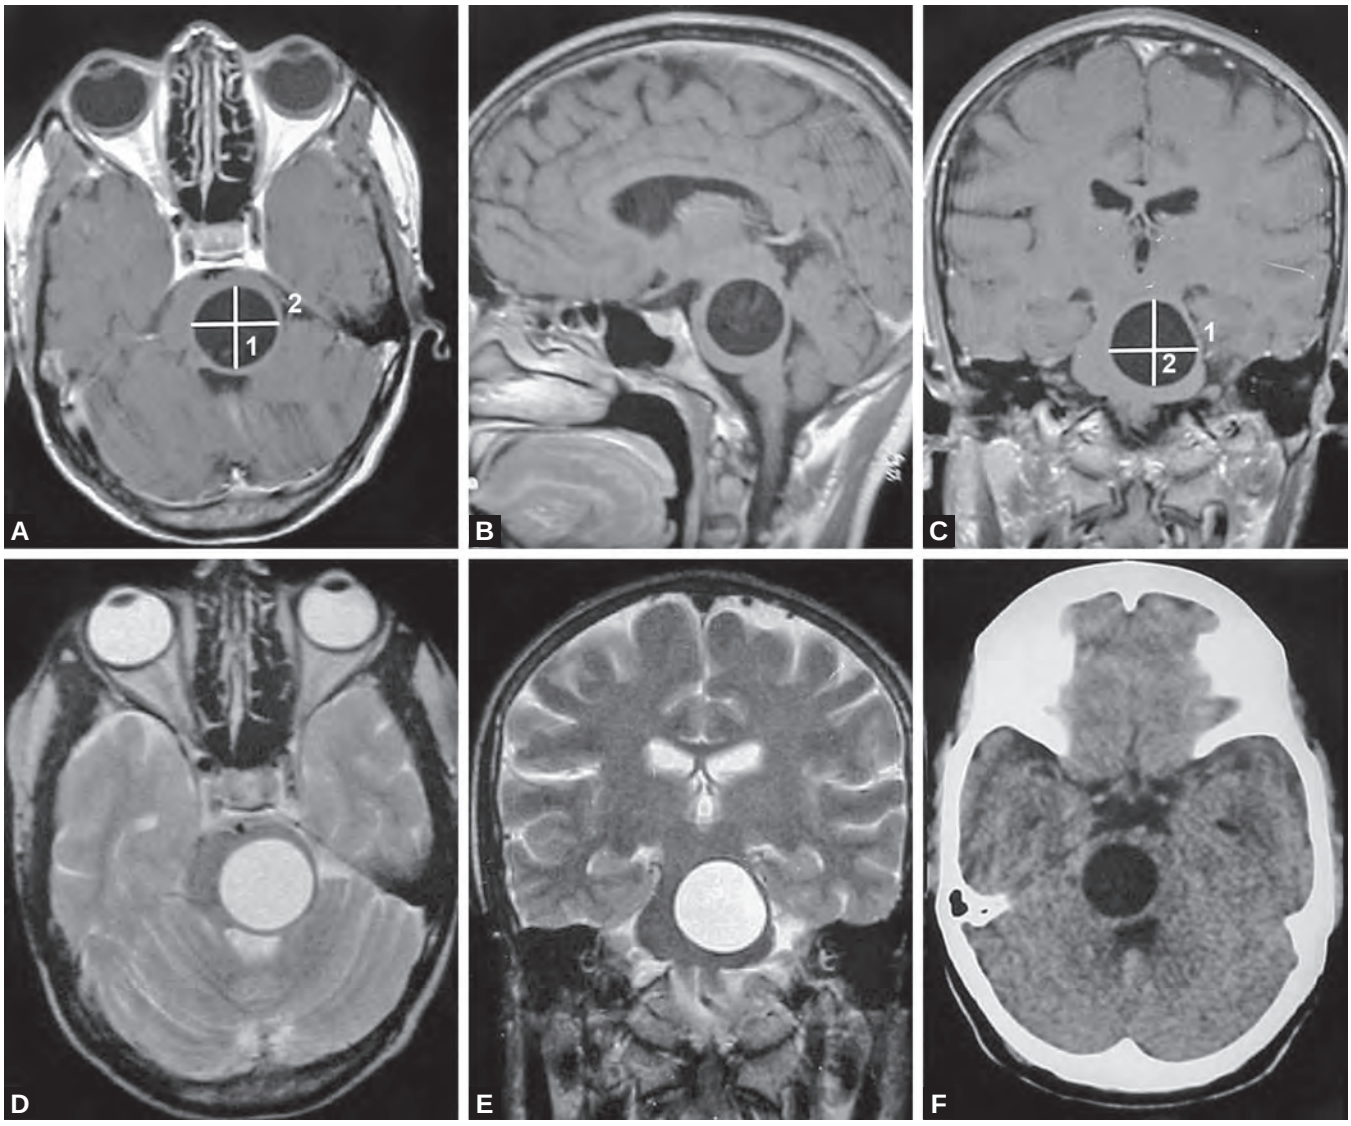
Arana-Iniguez[6] has described what is known in Uruguay as the tetrad of Schroeder: (a) a patient who is a country dweller; (b) in good general condition; (c) with the picture of raised intracranial pressure and (d) without marked focal findings. This tetrad was seen in 86% of his cases. This is, however, not specific for hydatidosis.

Diagnosis

A raised eosinophil count in the blood, a positive Casoni's intradermal skin test and Weinberg's complement fixation test may be of help in diagnosis. Arana-Iniguez[6] has proposed that when there is suspicion of hydatid disease, indirect haemagglutination, immunoelectrophoresis and indirect immunofluorescence should be carried out. As a screening test, radial double diffusion and latex agglutination tests should be performed. Positive results may then be confirmed by immunoelectrophoresis and indirect immunofluorescence and negative ones by electrophoresis and electrosineresis.

Radiological examination of the skull may show evidence of raised intracranial pressure. The skull vault overlying the cyst may show localised thinning, erosion and bulging. Angiograms show marked displacement of the vessels which curve around the periphery of a circular avascular area. There are no abnormal vessels. Rarely a blush may be noted if the surrounding tissue is inflamed but this carries less significance than in tumours.

The CT scan reveals an intraparenchymal hypodense lesion with a clearly defined margin (Fig. 1F). The cyst fluid has the same density as that of the CSF, but hydatid sand, if present, may increase the attenuation values. Rarely, the margin may show enhancement.[3] This occurs when the cyst is infected.[11,36] Peripheral enhancement has also been reported in an extradural cyst.[37,60] There is usually significant ventricular shift and hydrocephalus may be pronounced.[2] Perilesional oedema and mural nodules are significantly absent, thus differentiating the lesion from a brain abscess and other cystic tumours except in a rare case.[9] Calcification may be seen rarely.[2,57] On the MR, the unilocular cysts are large and spherical with thin walls which partially reach the brain surface. The contents of the cyst are generally indistinguishable from the CSF.[16,72] In MRI scan, these lesions have high signal intensity on T2-weighted images and low signal intensity on T1-weighted images, and are slightly hyperintense with respect to CSF on balanced images[33,47,51,76] (Figs 1A to E). After contrast administration, the walls of these lesions may or may not enhance mildly. A secondary process involving the cyst, such as calcification, infection, rupture of entodermic membrane or perifocal oedema, may also be identified. MR imaging is believed to be more sensitive and reliable than computed tomography (CT)[1,74] in depicting the pericyst layer, which appears as a halo, or in showing perilesional oedema. In formulating a differential diagnosis, the most difficult lesions to distinguish from hydatid cyst are arachnoid cyst and epidermoid tumuor. Epidermoids usually have a slightly hyperintense signal intensity on proton density weighted MR images and they usually engulf nerves and vessels, whereas arachnoid and hydatid cysts displace adjacent structures. Racemose cysticercosis in the subarachnoid space should also be considered in the differential diagnosis.



Figs 1A to F: (A to E) Pre-operative MRI of the brain showing distinct rounded lesion in the brainstem which is hypo-intense on T1-weighted images and hyperintense on T2-weighted images. (F) Pre-operative CT scan of the brain study showing hypodense lesion in the brainstem with well-defined margins

CSF examination does not contribute to the diagnosis.[69] The presence of a proved hydatid cyst elsewhere in the body would suggest a similar aetiology for a suspected intracranial lesion.[33,47,51,76]

Treatment

Treatment of a hydatid cyst is surgical. The aim of surgery must be total removal of the cyst without rupturing it so as to prevent contamination of the operative field with living scolices (Fig. 2). To achieve this, the surgeon must be familiar with the external surface of a hydatid cyst, in case one is unexpectedly encountered. The technique which has been found most useful is that described by San Julian and Arana-Iniquez.[4,58,59] They recommend that the craniotomy should be large and that the cyst wall be exposed by a series of radiating cortical incisions, termed Dowling's episiotomies. It is advisable to cover the surrounding exposed brain with lintines soaked in normal saline to prevent contamination of the surrounding brain by accidental rupture of the cyst. The head is then lowered so that the cyst is dependent, facilitating its expulsion which is helped by gently irrigating the cleavage plane between the cyst and the brain with saline. This simple technique is possible, because of the absence of adhesions between the cyst wall and its bed. A thin cyst wall, periventricular location and micro-adhesions to the surrounding brain tissue were the main surgical problems resulting in rupture in about 12% of cases resulting in distal deposit of secondary cysts elsewhere on follow-up.[31] If accidental rupture of the cyst occurs, irrigation with hypertonic saline (3%) is recommended in the hope of destroying the scolices in the operative field through osmotic desiccation. If the cyst is completely removed without spilling its contents, complete cure can be expected.

Intracystic injection of 10% formalin, 0.5% silver nitrate, hydrogen peroxide or 1.0% acqueous iodine hypertonic saline has been used to destroy residual larvae.[2,12,32,42,62] It is, however, not advisable to do this in cerebral lesions.

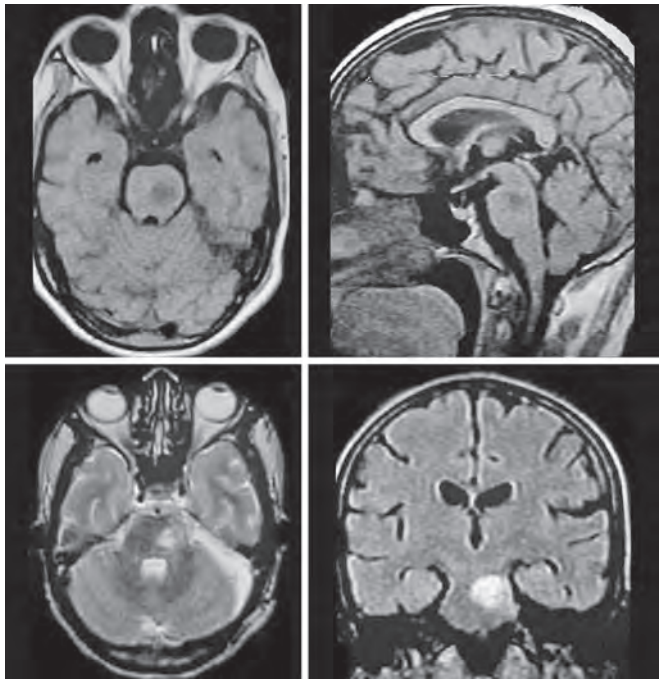


Fig. 2: Post-operative MRI of the brain showing total excision of the brainstem hydatid cyst

Saline injection into the opposite lateral ventricle has also been performed to facilitate the removal of cysts without spillage.[41] Aspiration or opening of the cyst should be avoided, unless removal cannot otherwise be accomplished.[61] In deep-seated cysts located in eloquent and vital areas such as the brainstem, management by internal decompression by aspiration followed by extirpation of the cyst wall, protecting the surrounding cisterns and CSF spaces may be done without anaphylaxis or dissemination.[72] After primary infestation, the host develops an immunologic response that is protective against re-infection but not effective against the lodged parasite. The absence of anaphylaxis has been explained by evasion of the host immune attack against the parasite by the suppression of T-lymphocyte function and inhibition of macrophage-lymphocyte interaction. Rapid decompression caused by evacuation of a large cyst may result in disturbances in autoregulatory mechanisms, which need to be watched for in the postoperative period. Occasionally, when there is previous spillage or added infection, the cyst becomes adherent to the surrounding brain and removal without rupture becomes difficult.[56]

Praziquantel does not pass through the hydatid cyst wall,[46] but high levels are seen in the CSF. As it has a powerful lethal action on free scolices,[28,67,71] it may be used in the event of spillage of the cyst fluid. Although protoscolicidal agents do not penetrate large hydatid cysts in sufficient quantity,[18] highly soluble albendazole can be used over a prolonged period for the treatment of small multiple cysts in inaccessible sites.[28,29,39,40,68] A combination of praziquantel and albendazole is more effective than either drug used alone.[67]

HYDATID DISEASE OF THE CRANIUM

Hydatid disease of the cranium is exceptionally rare.[58] Among all the cases of hydatid disease, less than 2% occur in the bones. Of these almost 50% affect the vertebrae and only 2–3% occur in the skull, the rest being located in the long bones of the body. Arana-Iniguez[7] came across only 11 cases of hydatid disease of the skull, accounting for 6.5% of his cases of echinococcosis affecting the nervous system.

Hydatid disease of the cranium is a primary disease. It initially invades the diploe and, as it grows, it widens the diploic space. Subsequently, it extends in both directions. As it erodes through the inner table, it extends freely in the extradural space causing compression of the brain. Multiple vesicles are formed both in the bone and in the extradural space reaching a considerable size. The dura is rarely invaded. It is extremely rare to have simultaneous cerebral and cranial vault extradural involvement in a single patient.[60] When the outer table of the skull is pierced, large subgaleal collections occur which may form fistulae after bursting through the scalp.[58]

Clinical Features

When the disease invades the outer table of the skull, a small firm lump is usually felt beneath the scalp. Further extension of this could lead to a soft swelling of the scalp which may ultimately result in fistulae formation. With erosion of the inner table and formation of a large extradural mass, signs of raised intracranial pressure appear. Basal lesions produce cranial nerve palsies.

Diagnosis

Plain X-rays of the skull demonstrate destruction of the skull, and CT defines the extent of the disease. Ring-like calcifications in the lesion[32] and extensive calcification in the cyst have also been reported.[13,64] Eosinophilic granuloma, cystic fibrous dysplasia and calvarial epidermoid tumour/ cyst, in particular, must be considered in the differential diagnosis of intraosseous hydatid cyst.[65] Computerised tomography scanning demonstrates a sharply marginated lytic skull defect more frequently involving the outer table than the inner table. Serological tests mentioned previously have great utility in the diagnosis of cranial hydatidosis.

Treatment

Treatment of cranial hydatidosis consists of complete excision of the affected bone. Total resection of the cyst via a craniectomy without rupture is the recommended management. Extradural hydatid cysts of intraosseous origin, however, may be difficult to excise completely because of their adherence to the dura, and osseous trabeculae. This, of course, is not possible when the disease affects the base of the skull. Patients with intraosseous hydatid cysts should be treated with albendazole for at least 3 months and monitored for up to 12

months before they are considered cured.[34,66] Steroids are helpful in relieving cranial nerve palsies, if any. The efficacy of biological treatment by means of inoculation with hydatid antigens remains a matter of dispute.

70 Other Parasitic Infestations of the Brain

Sridhar K, Vikram M

COENEUROSIS CEREBRALIS

Coeneurosis, a rare infection in man, is caused by *Coeneurosis cerebralis*, the larva of the dog tapeworm Multiceps multiceps (Taenia multiceps). The life cycle is similar to that of *Echinococcus granulosus*. Systemic infection, though reported from many countries,[1,2,3] is the most common in tropical Africa.[6] *Cerebral coeneurosis*, however, has been reported only from temperate climates.[9] Infection in humans is via the faeco-oral route. The ingested ova hatch in the intestine. After migration through the intestinal walls, the larvae settle in the viscera where they metamorphose into the cystic form or coeneurosis.[5] The cyst in the brain is usually single and unilocular, with sizes of up to 5 cm having been described.[7] Occasionally, multiple cysts may be present, forming grape-like collections resembling the racemose variety of cysticercosis.[8,9] These are found in the ventricles, usually the fourth, or in the subarachnoid cisterns. Though Kuper et al.[6] thought that the coeneurosis cysts develop only in the CSF pathways they have also been described in the cerebral hemispheres[1,7] and in the spinal cord.[10] The arachnoid around the cyst is thickened. Unlike in hydatid cysts, the wall of the coeneurosis is thin, opaque and milky white.[9] It is not surrounded by a fibrous capsule nor does it show a laminar structure. Multiple scolices project into the cavity of the cyst. Occasionally, however, the cyst may be sterile. The surrounding brain may show astrocytic proliferation and changes of chronic inflammation. Meningeal adhesions and vessel thrombosis have also been reported.[4] Diagnosis is usually retrospective. Treatment is surgical excision of the cyst.

SCHISTOSOMIASIS (BILHARZIASIS)

This is an ancient disease, the parasite having been found in the bodies of the Pharaohs in the Nile valley. Infestation by Schistosoma annually affects approximately 200 million people worldwide.[3]

PARASITOLOGY

The parasite belongs to the group of trematodes or flukes and three varieties have been recognised: *S. japonicum, S. haematobium* and *S. mansoni. S. japonicum* is found in China, Japan, Philippines and Burma,[8] *S. haematobium* in Africa and *S. mansoni* in Africa, West Indies, South America and the Middle East. A few cases of *S. haematobium* have been reported from Maharashtra, India.[8]

Man is the definitive host, while the intermediate host is a freshwater snail. Infection occurs in human beings as a result of bathing or wading in infected water. The adult worms live in the veins and travel to different parts of the body via the nervous plexuses. The eggs and the adult worm may travel through the veins to the brain or the spinal cord. The lungs are the common site of infestation. The most important schistosomal disorders are the vesical or urinary form caused by *S. haematobium* and the intestinal form caused by *S. mansoni*. Involvement of the central nervous system (CNS) in Schistosomiasis is uncommon.

Route of Involvement

S. haematobium prefers to settle in the pelvic venous plexus, especially the vesical, while *S. mansoni* and *S. japonicum* prefer to settle in the haemorrhoidal-portal vein tributaries. The most common route of infection of the CNS is through the venous communications described by Batson. The adult worm lies in the pelvic venous plexus and the ova are carried via the anastomoses between the pelvic veins and the vertebral venous plexus. This explains the more common involvement of the conus medullaris. Adult worms themselves may, occasionally, enter the spinal canal presumably via this route.[32] Another possibility is that a gravid schistosome may find its way into the cerebral venous system (occasionally, it may enter the spinal venous plexus and the spinal canal).[4] A third possibility is that the ova are discharged into the pulmonary blood stream, from which they are disseminated as arterial emboli.[13] The eggs may also embolise to the brain via pulmonary arteriovenous shunts or portal-pulmonary arteriovenous shunts. This physiological situation is more likely to occur in advanced hepatosplenic and cardiopulmonary schistosomiasis and may explain the high incidence of asymptomatic CNS involvement in these patients.[28,29,36] Pre-existing trauma with some disruption of tissue may enable the ova to get a hold once they gain access to the nervous system.[23] Such a history of injury has been recorded by several authors.[4,19,23]

S. japonicum has been noted to infest the brain, but almost never the spinal cord,[20] while *S. mansoni* and *S. haematobium* clinically involve the spinal cord more frequently than the brain.[36] *S. mekongi* and *S. intercalatum* have never been reported to cause ectopic CNS lesions.[13]

The reason for the differential involvement of the CNS by different species is not entirely clear, but it is likely that the physical characteristics of the egg influence venous access to the CNS. The ova of *S. japonicum* are much smaller than those of the other species and are generally produced in much greater numbers daily. This may account for their relatively frequent deposition in the brain. Conceivably, the large size and protruding spines of *S. mansoni* and *S. haematobium* eggs result in a tendency to lodge in the lower vertebral plexus and spinal cord.[13]

Since, the parasite inhabits the portocaval venous system, cerebral schistosomiasis and myelopathy are forms of ectopic schistosomiasis.[12] Depending on the parasite species and localisation of the eggs within the CNS, a variety of neurological syndromes may occur. Infestation of the brain may result in acute encephalopathy, seizure disorders, mass lesions and paresis.[6,19,25]

CEREBRAL SCHISTOSOMIASIS

Though clinically apparent involvement of the CNS in schistosomiasis is rare, cerebral involvement is almost always due to *S. japonicum*.[31,39] Clinically silent ova deposition in the brain occurs frequently in severe hepatosplenic schistosomiasis.[24] Shimitzu (1935) reported the first case of surgically verified cerebral *S. japonium* granuloma.

Schistosoma Japonicum

The ova of *S. japonicum* have a strong tendency to localise in the brain, especially in the cerebral cortex, basal ganglia and internal capsule.[19] The main neurological manifestations include: (i) diffuse meningitis and/or encephalitis; (ii) varying degrees of motor deficit from cortical, subcortical or capsular lesions and (iii) syndromes simulating brain tumours.[19]

On CT scanning, a variety of abnormalities may be seen including focal contrast-enhancing mass lesions and parenchymal lucencies with or without oedema.[40] Multiple focal lesions may also be seen. Magnetic resonance imaging (MRI) demonstrates one or more areas of hypointense and hyperintense signals with contrast enhancement.[21,39] These findings are, however, non-specific as are the other laboratory findings of eosinophilia and CSF pleocytosis.[19]

Histopathologically, the affected areas show inflammatory changes around the ova, with oedema, parenchymal necrosis, cellular infiltration with giant cells and granuloma formation and occasionally, vasculitis.[19] Often, a fibrocaseous mass is formed which closely resembles a tuberculoma.

Schistosoma Mansoni and Schistosoma Haematoma

Though ova are commonly detected in the brain tissue of chronic fatal *S. mansoni* and *S. haematobium* infections, these are usually clinically silent.[27] In post-mortem studies, ova of *S. mansoni* have been found mainly in the cerebral and cerebellar cortex and the leptomeninges.[27] Histopathological changes vary from no inflammation to massive granulomatous reactions. Focal arteritis and vascular lesions have also been noted.[27,29] Levy et al.[24] have reported encephalitis in a series of eight patients. Large tumoural masses[1,15] and cerebral and subarachnoid haemorrhage[30,35] have also been reported.

In most cases, the diagnosis is presumptive and is based on an epidemiological history, ova in the stool, systemic signs of hepatosplenic infestation, neurological signs and radiological findings. In endemic regions, where other parasitic infestations are prevalent and the differential diagnosis includes non-parasitic granulomas, a tissue diagnosis may be necessary. CT or MR guided stereotactic biopsy of the lesion or CT guided stereotactic craniotomy and excision of the lesion may be helpful in such cases. These are invasive procedures and require excellent support from pathology and microbiology services.[13]

Treatment

Antischistosomal drugs, corticosteroids and surgery are the modalities of therapy available for treating NS.[39] Praziquantel is the drug of choice for *S. japonicum* infestation. A single dose is capable of complete clinical cure and resolution of mass lesions and oedema on CT.[39,41] The post-treatment inflammatory exacerbation of lesions is not seen in schistosomiasis, unlike in cysticercosis.[13] Ferrari et al. treated schistosomal myeloradiculopathy (SMR) with PZQ (60 mg/kg/day for three days) given in two daily doses at a 4 hour interval and prednisone (1.5–2.0 mg/kg/day) administered in three daily doses or methylprednisolone 500 mg every 12 hour for 5 days followed by prednisone as described above. This high dose of prednisone is maintained for about 3–4 weeks, followed by progressive reduction over several weeks.[33,38] The duration of therapy has not been defined, though prolonged courses have been recommended.[13,33,34] The immediate prognosis is good but some patients have residual neurological deficits. Epilepsy is a common problem and status epilepticus is the most common cause of death.

SPINAL SCHISTOSOMIASIS

The spinal cord may be involved in schistosomiasis.[18] SMR is less frequent than the cerebral disease.[39] This may be in the form of granulomatous masses involving the conus medullaris or cauda equina, acute or subacute transverse myelitis,[5,9,17,35] radiculitis from granulomatous root involvement[5,14] or rarely an anterior spinal artery

occlusion syndrome.[37] Spinal cord disease is almost always caused by either *S. mansoni* or *S. haematobium*.[39]

Granulomatous intrathecal lesions involving the lower spinal cord, conus medullaris and cauda equina are the most commonly reported lesions.[13,14,35] The lesion appears as a yellowish, amorphous or rubbery granuloma with a tendency to extend along the nerve roots of the cauda equina.[14]

Patients with schistosomal myelopathy are predominantly male with a mean age at presentation of 28 years for *S. mansoni* and 19 years for *S. haematobium*.[34] An acute or subacute onset, with a flaccid are flexic paraplegia including sphincter dysfunction, is the typical mode of presentation. Progression of symptoms could mimic Guillain-Barré syndrome.[26] The systemic features of acute schistosomiasis often precede or accompany the onset of spinal symptoms.[13] The disease more frequently starts with lumbar pain and/or pain in the lower limbs, usually of a radicular nature, which is followed, often within hours to a few days, by muscular weakness and sensory impairment in the lower limbs, almost always associated with autonomic dysfunction, particularly bladder dysfunction.[39]

The presentation of schistosomal transverse myelitis is similar to that of granulomatous myelopathy. The pathogenesis is not clear. It may be an allergic or hypersensitive reaction or may be related to a critical disturbance in blood supply. Like in granulomatous myelopathy, this form of spinal schistosomiasis also primarily involves the lower spinal cord and conus.

In an endemic region, diagnosis of spinal schistosomiasis can be made by the characteristic radiological findings. Routine laboratory investigations provide supportive evidence of hepatosplenic or genito-urinary infestation.[13] The classical myelographic appearance is a partial or complete block extending at least the length of a vertebral body, usually at T12-L1 level, with trifid edges and signs of an intramedullary lesion.[11] On CT with intrathecal contrast, the lower cord or conus may be expanded in an irregular fashion, with irregular beading and matting along the nerve roots of the cauda equina.[17,20] In schistosomal transverse myelitis, CT myelography may be normal or equivocal with later studies showing atrophy of the cord.[9,17] MR imaging will show moderate expansion of the distal spinal cord in all cases. The abnormality is isointense to the cord in T1 and patchily hyperintense in T2-weighted spin-echo images. Three forms of contrast enhancement occur: (1) intramedullary nodular; (2) peripheral and (3) linear radicular.[21,34,36,38]

Treatment

Praziquantel and oxamniquine are used against *S. mansoni* and praziquantel and metrifonate against *S. haematobium*. The drugs not only kill the parasite but also reduce the immunological reactions.[10,35] Ischaemic changes within the spinal cord may occasionally be reversed.[7] The role of corticosteroids is controversial with reports of both benefit and the lack of it.[5,16,17,23,35] With appropriate drug therapy, Scrimgeour and Gajdusek[35] reported a reduction in the mortality rate from 72% to 11.5% from 1965. Recovery is achieved in 54% of cases in 1 week to 4 months' time. It is essential that treatment be instituted early so that there is a greater probability of recovery.[40]

The role of surgery is limited. Laminectomy is an important adjunct, especially for patients who develop acute paraplegia with spinal block or whose condition deteriorates while on medical therapy. In diffuse granulomatosis, a small but adequately selected biopsy should be taken and the dura left open.[13] The surgeon must ensure that further damage does not occur to the already compromised cord.[2,22,35]

PARAGONIMIASIS

Paragonimiasis or "lung fluke infestation" is caused by tissue invasion by the adult trematode of the genus paragonimus. Human infestation is most commonly by *P. westermani*, though other species, e.g. *P. mexicanus*, *P. africanus* and *P. kellicotti*, also cause human disease.[6] Humans acquire paragonimiasis by ingesting immature forms of the parasite (metacercariae) in raw or undercooked food containing freshwater crabs or crayfish. There is no direct human transmission. The ingested metacercariae of paragonimus undergo ex-cystation in the duodenum, penetrate the intestinal wall and enter the peritoneal cavity. Most worms penetrate the diaphragm and enter the pleural space. They ultimately invade the lung parenchyma and encapsulate near the bronchioles. After a 6–8 week maturation period, the adult worm releases eggs which pass into the bronchial tree. The eggs are passed out of the body in the sputum or if swallowed, in the faeces. The eggs hatch into miracida in freshwater and infest snails, the intermediate hosts. Cercariae which are released in turn into the water encyst themselves in the muscles of crayfish and freshwater crabs.

Human paragonimiasis is endemic in East Asia (e.g. Korea, Japan, China, Taiwan, Philippines, Thailand), West Africa (e.g. Gambia, Nigeria, Congo valley) and in Central and South America (e.g. Mexico, Peru, Columbia, Costa Rica).[6] In India, it has been reported in the Eastern parts, viz. Assam and Bengal.

Chronic pulmonary disease is the most common result of paragonimus infestation and clinically presents as rusty sputum, haemoptysis and pleuritic chest pain. CNS involvement in paragonimiasis ranges from 0.8% to 26.6%,[1,11,14] forming the most common focus of extrapulmonary infestation.[2,4,18]

The pathophysiology of cerebral paragonimiasis is uncertain. The worms are thought to migrate from the lungs through the perivascular soft tissue in the jugular foramen to the CNS.[2,8] Brain infestation has also been shown to occur as emboli.[8,9] The temporal and occipital lobes are the most frequent sites though, occasionally, lesions have been found in the parietal lobe.[6]

Patients with cerebral paragonimiasis are usually young[2,8,10] and have symptoms for years before diagnosis.[1] Pulmonary symptoms occur before or simultaneously with cerebral symptoms. The clinical picture of CNS paragonimiasis is variable with considerable overlap of the different clinical syndromes: Meningitis, arachnoiditis (cranial or spinal), mass lesions, visual disturbances and seizure disorder.[5,6] Meningitis, seizures, visual disturbances and motor deficits are the most common presentations.[6,12] A deteriorating mental status with personality changes, disorientation and depressed levels of consciousness may also be seen.

Oh[13] has divided the varied presentations into: (i) a meningitic form; (ii) a subacute encephalitic form; (iii) a mass lesion; (iv) dementia; (v) epilepsy and (vi) a presentation with hemiplegia.

Spinal lesions are mostly lower thoracic and lumbar in location and include extradural granulomas and cysts, which may extend over several vertebral segments.

In the acute phase of infestation meningoencephalitis occurs. Granulomas and cysts result from chronic infection. Histologically, the lesions are seen as having a central necrotic zone surrounded by a layer of collagen. The eggs of the parasite are found in the necrotic tissue close to the collagen and are surrounded by foreign body giant cells. Mature worms are rarely seen in the brain.[16]

Diagnosis

Laboratory studies show peripheral eosinophilia in 20–50% of patients[6] and anaemia and leucocytosis in 10–30% of patients.[10] Supportive evidence of infestation can be got by the demonstration of ova in the sputum, faeces, pleural or peritoneal fluid or from lung biopsy. Serological studies, while sensitive, are not specific for CNS disease, and also cannot distinguish between active disease and prior infection.

Electroencephalography is abnormal in almost all cases of CNS paragonimiasis, with findings of focal epileptogenic activity and focal slowing.[2,6] Chest radiographs are abnormal in 70–100% of cases. Plain X-rays of the skull show calcification in 40–70%.[2,4,11] Higashi et al.[2] have described the calcification as "aggregated oval or round cystic calcifications with an increased peripheral density". Multiple cystic calcifications which look like "soap bubbles" are highly suggestive of paragonimiasis.[10]

In acute or subacute cases, CT scan shows multiloculated crowded abscess like cysts in the temporoparietal or temporo-occipital regions and with surrounding oedema with ring enhancement on contrast.[7,17] In chronic cases, soap bubble calcification with cerebral atrophy and hydrocephalus may be seen.

In pulmonary paragonimiasis, the same lesions resembling clusters of grapes can be seen on chest radiographs. The ring enhancing cerebral lesions are 1–3 cm in diameter and round or oval. The walls of enhancing masses are smooth and 1–4 mm thick. If no normal brain tissue is interspersed among the conglomerate granulomas, the lesion may be mistaken for a single lobulated neoplasm with multi-focal necrotic centres. The presence of conglomerated, multiple ring-enhancing lesions (grape-cluster appearance) with surrounding oedema was the most characteristic finding at the early stage of cerebral paragonimiasis. Non-specific CT or MR features include non-enhancing oedema-like lesions, parenchymal haemorrhage including haemorrhagic infarction, and irregularly enhancing solid lesions.[3,15]

On histopathology, arachnoiditis, granulomas and encapsulated abscesses may be seen.[2,4] In the granuloma, a central area of caseous necrosis is seen, as also the parasite ova and giant cells. Calcification may be seen in chronic lesions.

The treatment of CNS paragonimiasis is primarily medical.[6] Praziquantel is the drug of choice and there is significant response. Bithionol, though effective against pulmonary disease, is not effective in cerebral disease. Corticosteroids may be needed if there is worsening of symptoms due to increased local inflammation. Surgery may be required to control secondary complications, e.g. hydrocephalus or when the disease and symptoms are progressive while on medical therapy.

STRONGYLOIDIASIS

In humans, the intestinal nematode strongyloides stercoralis produces a broad spectrum of clinical illness. The manifestations of the infestation in an individual are dependent on the balance between the host and the parasite.[3]

Infection by *S. stercoralis* occurs by the penetration of the skin by the filariform larvae of the nematode. The larvae then enter the lung through the pulmonary circulation, from where they enter the alimentary canal. Larval development occurs in the duodenum and small intestine. An individual harbouring, the worms may be asymptomatic. Autoinfection and hyperinfection may lead to a state of disseminated strongyloidiasis, in which penetration of all major organs occurs. During this dissemination the major neurologic sequelae of the infestation occur.

There is a worldwide distribution of strongyloides stercoralis. Measurable rates of infection have been reported from Central and South America, Africa, Europe, Southeast Asia, the Caribbean and the South Pacific.[4,7]

Clinically, patients present most commonly with gastrointestinal symptoms (including the "swollen belly syndrome" of Papua New Guinea), cutaneous manifestations (larva currens), chronic urticaria and respiratory symptoms. Human immunodeficiency states pre-dispose towards the development of disseminated strongyloidiasis, especially where the disease is endemic. The nature of the immune defect also appears important. Corticosteroids, especially, have been found to stimulate

egg production and larval development, while depressing the host's cell-mediated immunity at the same time.[8]

The parasite, in the rhabditiform larval stage, gains access to the CNS and the systemic circulation. The neurological symptoms and signs described include headache, changes in mental status, meningismus, focal seizures, motor or sensory deficits and loss of consciousness.[1,11,19] For some unknown reason, bacterial meningitis, due to enteric pathogens, is commonly associated with CNS strongyloidiasis.[2,3] A variety of pathologies have been seen, including: Parenchymal abscesses, intravascular parasites causing parenchymal infarction, intraparenchymal and leptomeningeal larvae without tissue response, and intraparenchymal larvae in granulomata.[11,14,15,20] Degenerating larvae are usually surrounded by a modest inflammatory response, while actively migrating larvae do not excite any host response.[3] It is thought that patients with defects in cellular immunity are most at risk, although the contributions of humoral immunity and eosinophilic response are not yet understood. Hyperinfection with strongyloides stercoralis was thought to be rare in acquired immunodeficiency syndrome (AIDS), despite endemicity in areas where infection with human immunodeficiency virus is highly prevalent.[17] Further surveillance is needed in geographically susceptible populations.

Diagnosis

A definitive diagnosis of strongyloidiasis requires the identification of the larval forms in body fluids or tissue specimens. Isolation of the larvae from CSF is not common and may require repeated sampling and centrifugation to increase the yield.[3] Serological assay to detect the IgG antibody to strongyloides stercoralis antigen has a sensitivity of 85–95%. However, cross reactivity with other parasitic infestations does occur.[6,13] Eosinophilia which is found in chronic infestation may be absent in hyperinfection or disseminated disease.

Treatment

The drug of choice is thiabendazole[10] which is given orally in two 25 mg/kg doses daily for 2 days. A success rate of about 80% is reported, though up to 23% of cases have side effects referable to the CNS. In hyperinfection, the drug is given for 5–7 days. Invermectin (50–400 mg/kg) has also been found to be effective.[12] Steroids must not be given and, if already started, must be withdrawn. Periodic examination of the stool specimen should be carried out in immunosuppressed individuals for surveillance and appropriate therapy instituted with thiabendazole, albendazole or ivermectin to prevent hyperinfection and its complications.[1,5,9,16,18]

Morality with disseminated strongyloidiasis approaches 60%, even with appropriate therapy. Recurrence of symptoms may occur even years after treatment and repeated courses of therapy may have to be given.[3]

TRICHINOSIS

Trichinella spiralis is endemic in all areas of the world except Australia and some islands of the Pacific Ocean. The parasite is a gut and tissue dwelling nematode. While the clinical manifestations of *T. spiralis* infections are varied, most infestations are asymptomatic.[8] Only 5–10% of infected persons may have significant morbidity or may die due to involvement of the cardiopulmonary or CNS.[6] Involvement of the CNS occurs in 10–20% of patients and is usually associated with heavy Trichinella infection. The mortality rates may be as high as 50%.[12]

Human infestation is due to ingestion of meat containing the larvae. The ingested larvae transform into the infective larvae in the stomach. They then pass into the small intestine where they moult four times and are transformed into sexually mature adult worms which attach to the duodenal and jejunal mucosa. New born larvae, released by the female worm, penetrate the gut mucosa and migrate into the draining lymphatics and vessels. Systemic dissemination occurs mainly into tissues with a high blood flow. The larvae encyst in their new surroundings and may remain viable for several years even if they calcify. Kratz, in 1866, recognised neurological involvement due to Trichinella, while Frothingham, in 1906, related to the presence of the parasite in the brain to focal neurological signs.[8]

Systemic manifestations of the infestation coincide with the life cycle of the parasite. Patients suffer diarrhoea and abdominal cramps within 1–2 weeks of infestation. On systemic dissemination, fever and intense myalgias occur, especially in the extraocular muscles and the masseter. Periorbital oedema, conjunctivitis, headache and subconjunctival and subungual petechiae may also occur.[1]

Neurological complications occur in 10–24% of cases.[3,6] Patients most commonly present with symptoms and signs of meningoencephalitis (96%), focal paresis (73%) and delirium (71%).[8] Later signs include persistent drowsiness, disorientation and emotional lability. Cerebral invasion occurs during the 2nd week, the larval migratory stage, producing varying degrees of encephalitis manifested by emotional instability, psychotic behaviour, delirium, insomnia, inattentiveness, disorientation, lethargy, headache or memory loss. They are frequently mild and evanescent, but can be severe and prolonged in certain cases. During the 3rd week (the encystment stage) localised or focal nervous system involvement may occur. When focal involvement occurs, it is often superimposed on previous meningeal or encephalitic symptoms and is rarely the sole manifestation.[3,10,12]

Focal deficits occur with encystment of the larvae.[5] These include sphincter dysfunctions, cranial nerve palsies, seizures, vertigo, anisocoria, decreased auditory acuity and ataxia.[4] When hypotonia is present, it is most likely due to primary muscle involvement.[9] Peripheral nerves may also be involved. Occlusion of cerebral

venous sinuses causing extensive venous infarction and intracerebral haemorrhage may also occur.[12]

The manifestations of CNS and peripheral nerve trichinosis are due to granulomatous inflammatory reactions which surround the larvae or parasite antigens. Pathological findings in CNS trichinosis include infiltration of the pia-arachnoid by lymphocytes, macrophages, fibroblasts and gitter cells. Perivascular inflammatory changes with occasional granuloma formation may be found around the Virchow-Robin spaces.[9] Glial cell nodules and occasional periventricular haemorrhages may also be seen.[8] A diffuse eosinophilic meningoencephalitis is rare.

Treatment

A definitive diagnosis of *T. spiralis* infestation can be made by identification of the larvae in muscle, usually by biopsy of the gastrocnemius or other large muscles in which there is pain. Laboratory tests, such as eosinophil count, though sensitive are not specific for trichinosis. A modest elevation of muscle enzymes, e.g. creatine kinase and lactate dehydrogenase, occurs in about 50% of subjects. CSF studies are neither sensitive nor specific, as in up to 75% of cases the CSF may be normal.[2,4] While serodiagnostic test by ELISA has a high degree of sensitivity, its specificity is only about 60% due to its cross reactivity with other nematodes.[8]

The role of imaging in trichinosis is not yet established. CT scan of the brain may appear normal despite neurological signs of trichinosis.[4,11] In other cases, the CT may show multiple nodular or ring-like lesions, with contrast enhancement or ring calcification.[7] MR imaging in trichinosis has still to be defined though there are stray case reports.[4]

There are no antihelminthics with documented efficacy against CNS trichinosis.[9] Thiabendazole or mebendazole may be used but their usefulness is doubtful. Corticosteroids may be used as an adjunct.

The overall prognosis in cases of CNS trichinosis is related to the severity and intensity of the initial infection, the host defence mechanisms, the structural damage which has occurred and the effectiveness of the antihelmenthic and anti-inflammatory therapy.[8]

CEREBRAL SPARGANOSIS MANSONI

Sparganum mansoni is the larva of *Spirometra mansoni*. The incidence of this infestation is especially high in Japan, though cases have also been reported from Korea, China and South East Asia.[2,5,11]

Human infection may be via: (a) drinking water containing Cylops, the first intermediate host; (b) eating raw freshwater fish, frogs or snakes, the second intermediate hosts or (c) by the application of infected tissue (frog poultice) to a raw wound. Human infection is most often by the larva.[11] Soft tissues, such as the subcutaneous tissue of the abdominal wall, are the most common sites of parasitism. Brain involvement is rare.[4,6] Yamashita et al.[11] found only 19 cases of cerebral sparganosis in their review of the literature.

Cerebral sparganosis presents with focal signs and convulsions.[3,8,11] The offending lesion is a granuloma in the cortical or subcortical tissues of the brain. However, the worms may move causing a shift of focal signs and symptoms. On the CT scan, an extensive hypodense area with nodular enhancement different from that seen in paragonimiasis or cysticercosis is seen. The hypodensity is thought to be due to the movement of the worm and the protease enzyme released by it. The presence of white matter hypo-attenuation with dilatation of the adjacent ventricle, irregular or nodular enhancing lesions, small punctuate calcification and a change in the location of the enhancing nodule on the follow-up CTs are characteristic. Occasionally, subcortical haemorrhages are also noticed. Brain MRI demonstrated multiple cystic areas of hyperintensity on T1-weighted images with rim enhancement and areas of hyperintensity on T2-weighted images. Moon et al.[7] reported that areas of hyperintensity on T1-weighted images and areas of hypointensity areas on T2-weighted images were detected only in MRI. They believed that these changes in signal intensity represented petechial haemorrhage and may be due to capillary or venous injury by the migrating worm,[2,10] but cyst formation is uncommon.[1] ELISA is the only specific investigation available preoperatively.[11] It is quite difficult to differentiate sparganosis from cerebral tumours on CT and laboratory data pre-operatively. The diagnosis is usually confirmed by post-operative histological examination.[11]

As there is no effective chemotherapy, surgical excision of the granuloma is the only treatment.[10] Larvae being the most common infective agent recurrence is uncommon once the granuloma is removed. Prevention is important and care should be taken in respect to the food eaten, especially for those visiting endemic regions.

VISCERAL AND OCULAR LARVA MIGRANS

Visceral and ocular larva migrans (VLM and OLM) are zoonoses, which occur when humans become an accidental host for the larval stage of a parasitic helminth. Beaver coined the term "visceral larva migrans" to differentiate it from creeping eruption or cutaneous larva migrans.[1,2,3] Classic causes of VLM and OLM are: Toxocara sp. and *Baylisascaris procyonis*. The other agents implicated include nematodes, like Gnathostoma sp., Angiostrongylus cantonensis, and cestodes like Spirometra sp. (which cause sparganosis) and Taenia multiceps (which cause coeneurosis). Visceral larva migrans due to *T. canis* has a worldwide distribution, including Canada, England, France, Germany, New Zealand, Australia, Africa, Turkey, Malaysia and India.

Toxocara canis has three, possibly four, types of life cycle. First is the classical pathway, embryonated ova in soil being ingested by the dog (the natural host) with larvae migrating from the intestine through the liver and

lungs to return to the intestine to become adult forms capable of perpetuating the life cycle. A second type of life cycle is characterised by migration of larvae from the lungs to somatic tissues of the female, there to remain dormant until pregnancy when they become active and migrate across the placenta to infect the foetus *in utero*. For this reason, the majority of newly born puppies may be infected and may eliminate advanced stages of larvae in the faeces. A third type of life cycle occurs when these larvae are ingested by the dog or possibly by humans. When swallowed they become adult forms and produce fertile eggs within the gastrointestinal tract so that the liver-lung migratory pathway is not essential for larval maturation. A fourth kind of life cycle may not be important for transmission of parasites from or to man, but may have relevance concerning the clinical expression of human toxocariasis. This life cycle involves the phenomenon of paratenesis, a term introduced by Beaver[2] to define situations in which there is "passage of infective-stage larvae without essential development through a series of transport (paratenic) hosts to the final host with the transport hosts serving at the same time to maintain the infective-stage larvae from one season of transmission to the next." Two features of this phenomenon are noteworthy. The tissue distribution of the larvae is unique for each type of transport host, involving primarily the liver in some, the skeletal muscles in others and the CNS in many. A second feature is the extraordinary capacity of the larvae to maintain viability for long periods. In the monkey, experimentally infected with canis, larvae may remain alive and infective for at least 10 years. Thus, the parasite is capable of passing through several intermediate hosts, for example, rodents and other small mammals, before coming in contact with and infecting its natural host, the dog. Although man has been referred to as an aberrant or unnatural host for canis, it is possible that man is an intermediate host and that visceral larva migrans is a clinical expression of paratenesis. A consideration of the different types of life cycle indicates several ways in which man may become an intermediate host for the parasite. The most common route of infection is ingestion of soil containing larvae or embryonated ova. Another and less frequent way of becoming infected includes close contact with nursing bitches or puppies and in particular hand-to-mouth spread of larvae or eggs in the environs. Since third-stage larvae may be present in this type of setting, it is possible, although extremely unlikely, that infection with adult canis may be acquired.[6]

Zoonotic ascarid larval infection is frequently asymptomatic. The classical picture of VLM can be found in a child one to five years of age, presenting with fever, hepatomegaly and pulmonary infiltrates. The blood picture shows leucocytosis with eosinophilia and hypergammaglobulinaemia.[1] Neurologic manifestations include neuropsychiatric disorders, seizures, encephalopathy, meningoencephalitis and transverse myelitis.

OLM due to *T. canis* presents as unilateral visual loss and strabismus. Four clinical syndromes are described: (1) a peripheral granuloma involving the retina; (2) a raised lesion at the posterior pole; (3) diffuse endophthalmitis and (4) papillitis. These may result in heteropsia or macular detachment.

The diagnosis is by a combination of clinical signs and laboratory testing. The latter includes serodiagnosis and extraction of the larvae from biopsy tissues.

As most of the manifestations of LM are due to host response to dead and dying larvae, the administration of antihelminthics can potentially exacerbate the disease. Diethylcarbamazine or thiabendazole may be given in combination with corticosteroids and antihistaminics.[4,5]

71 Spinal Hydatidosis

Harjinder S Bhatoe

Echinococcosis or hydatid disease is the larval stage of infection caused by cestodes of the genus *Echinococcus*, whose life cycle involves two mammalian hosts. The definitive hosts are carnivores, in whom the adult worm is present in the intestines. Classic cystic echinococcosis is caused by the larva of *Echinococcus granulosus (E. granulosus)*, a species adapted to dogs and a wide variety of domestic and sylvatic animal intermediate hosts (e.g. sheep, buffalo, etc.). The large size, often attained, is responsible for neurological pathogenicity and morbidity.

LIFE CYCLE AND SPINAL IMPLANTATION

After ingestion of protoscolices originating from fertile hydatid cysts, sexual maturity of the adult tapeworm is reached within 4–7 weeks. The fully mature adult *E. granulosus* is a small tapeworm approximately 3–7 mm in length. It firmly attaches to the mucosal wall of the small intestine of the canine host. Development from ovum to oncosphere takes place *in utero* in the adult worm. The oncosphere measures about 0.018 mm and is bilaterally symmetrical, possessing three pairs of hooks, muscle fibres and glands that aid in penetration and locomotion in the intermediate host. The oncosphere and its surrounding membrane are called the cestode eggs. These eggs are shed with faeces into the external environment, and remain viable on the furry coat of the canine. These eggs reach the alimentary canal of the intermediate hosts by ingestion (close contact with dogs, contamination of water, foodstuffs, salads, etc.). Their own lytic secretions facilitate the oncospheres to hatch, and their passage through the gut mucosa. Entry into the circulatory system occurs:

- Through the portal system, when the preferred site of implantation is the liver
- Lymphatics

Once the oncosphere passes through the liver, it enters into the pulmonary circulation where it can evolve into a pulmonary hydatid. Passage into the systemic circulation can lead to any of the organs becoming the site for implantation. Spinal implantation can occur via the systemic circulation, or through the valveless epidural venous plexus that communicates with the pelvic and retroperitoneal venous channels; the circulation in the epidural venous plexus is transiently reversed during straining and Valsalva manoeuvre. Once the oncosphere reaches its preferred site, cystic development begins by degeneration of the oncospheral stage and emergence of the vesicular metacestode stage. The cyst expansively grows by concentric enlargement. In general, hydatid cysts increase in diameter by 1–5 cm each year. Under natural conditions, transmission and perpetuation of echinococcosis is the result of predator-prey relationship between the hosts, and man is an accidental host where the parasite reaches a dead end. However, transmission in synanthropic cycles is considerably modified by human behavioural factors.

INCIDENCE

The human form of echinococcosis is more common in warmer climates, especially in rural and farming communities where sheep rearing is an important occupation. While skeletal hydatid constitutes 2.8–3% of human echinococcosis, spinal involvement occurs in one third to half of these cases.[2,24] Spinal hydatid was first described by Churrier in 1807, which was reported in 1819,[41] and is considerably rare when compared to cranial hydatid. There have been case reports from India,[4,6,7,13,38,39,44,47] and Iyer et al.[22] reported the largest Indian series of five cases collected over a period of 12 years. Worldwide, the largest series of 24 cases has been reported by Sami et al.[42]

PATHOGENESIS AND PATHOLOGY

Spinal hydatid is always primary, i.e. due to the implantation and development of the larva in the affected organ.[1] The primary lesion in the bone is characterised by multiple infestations through the arterial circulation or via the epidural venous plexus through portovertebral channels whenever the flow in the latter is transiently reversed (as during straining or Valsalva manoeuvre). The embryos lodge preferentially in the vascularised region of the centre of the vertebral body. Growth occurs within the intratrabecular space, destroying the bone-like tumour and eliciting no inflammatory response. The organism spreads beneath the periosteum and ligaments.[2] Formation of vesicles replaces the medullary tissue and bony architecture is destroyed by pressure, with widening of bony canals resulting in formation of rounded areas of rarefaction; eventually, the pedicles, adjacent ribs and laminae are eroded. The unyielding

nature of the osseous compartment restricts cyst expansion resulting in fragmentation and conglomeration of daughter cysts.[18] Perforation of the cortex and periosteum results in extraosseous extension, which may be extraspinal, paraspinal or intraspinal. Spinal cord compression occurs once, when the bony centre has been perforated. Spinal cord compression may also result from transforaminal extension of the cyst into the spinal canal,[6] and there may be a dumb-bell extension of the cyst into the spinal canal.[21,37] Adjacent vertebrae may be involved by extension beneath, the anterior longitudinal ligament, and rarely across the intervertebral disc. The intervertebral disc is relatively resistant to invasion;[33] discal involvement has been reported in a 76-year-old male who was earlier operated upon for extraspinal hydatid cyst.[26] Discal involvement probably occurred due to direct implantation or via vascular dissemination. Extraspinal extension leads to encystment of the lesion by a common adventitial membrane.

The fully developed metacestode (hydatid) of *E. granulosus* is typically fluid-filled and unilocular, but multiple communicating chambers also occur. Structurally, the cyst consists of an inner germinative layer of cells supported externally by a characteristic acidophil staining, acellular, membrane of variable thickness. Cytoplasmic extensions of the germinative layer unite to form a syncitium, which is differentiated into numerous microtriches. The microtriches project peripherally into the laminar layer towards the host tissues surrounding the cyst. Surrounding the parasitic cyst is a host-produced granulomatous adventitial reaction of extremely variable intensity. Small secondary cysts, called brood capsules, bud internally from the germinative layers and by polyembryony. They then produce multiple protoscolices. A protoscolex is a scolex with the rostellum and suckers deeply withdrawn into the post-sucker region. In humans, the slowly growing hydatid cysts may attain a volume of many litres and contain thousands of protoscolices.

Primary infection with *Echinococcus* larva elicits an early immune response in the intermediate host as evidenced by specific antibody and cellular responses.[43] The immune response is biphasic: an early response that is directed against the recently hatched preimplantation stage of the larva, and the second against the established metacestode at the site of formation of hydatid cyst. Immune mechanisms in the first phase are more effective in destroying the larva than those against the established metacestode.[43] In *E. granulosus* cysts, the protective mechanism is probably related to sequestration of the parasite by the laminated and germinative membranes and host capsule, which greatly limit the exchange of high molecular weight substances between the host and the parasite.

CLINICAL FEATURES

Spinal hydatidosis is a slow growing lesion usually seen in the third or fourth decades of life. Clinical presentation is determined by the vertebral level of involvement and the degree of spinal cord compression. An expanding cyst in the vertebral body gives rise only to persistent backache, which worsens with passage of time. A diffuse paraspinal swelling may be visible externally, while craniovertebral junction involvement may present with a visible mass in the oropharynx and nasopharynx.[8] There are no specific features diagnostic of the lesion and the diagnosis may be suspected in patents living in endemic areas, or in those people who have stayed in endemic areas. Spinal hydatidosis has been reported in a married couple.[31] Almost all reported cases have myelopathy as their presenting feature. The onset is insidious in the form of easy fatigability, stiffness of the limbs with difficulty in brisk walking or doing fine skilful motor work with the hands. However, if the cyst is intramedullary or intradural extramedullary, myelopathy sets in early and is more severe as compared with predominantly vertebral involvement. A pathological fracture of the vertebra or vascular involvement may cause acute paraplegia. The continued slow growth of viable cysts precludes regression or spontaneous cure.[25] Spinal echinococcosis has been classified into five clinical subgroups:[9]

a. Primary intramedullary hydatid cyst: Rarest form of spinal involvement, myelopathic features are early and progressive.[35]
b. Intradural extramedullary hydatid cyst.[10,24,39]
c. Intraspinal extradural hydatid cyst.[45,48]
d. Hydatid disease of the vertebra: This is the commonest form of spinal involvement seen clinically, where a growing cyst encroaches upon the spinal canal. Thoracic and lumbar spinal involvement occurs in about 75% of all cases with vertebral echinococcosis.[18] Multiple vertebral involvements are rare[27] as it is the involvement of the cervical spine and the sacrum.[29,36] Association of vertebral with costal involvement is considered as a diagnostic of vertebral echinococcosis.[19]
e. Paravertebral hydatid disease: The spinal canal may be invaded secondarily by cysts located in the mediastinal, retroperitoneal and paraspinal regions.[16,20,40]

IMAGING

Plain Radiographs

Plain radiographs may reveal an osteolytic lesion of the vertebral body (with destruction of the areolar pattern of the bone). There may be erosion of transverse processes, adjacent ribs and pedicles. Preservation of discs is a common finding. The enlargement of the cyst results in punched out radiolucent areas initially without sclerosis. Sclerosis around the radiolucent area may be seen later in the course of the disease. Vertebral collapse due to a pathological fracture along with a paravertebral soft tissue shadow may be seen in advanced stages of the disease. A paravertebral mass is often seen, which may be fusiform in appearance. Many of these patients have already had treatment with antituberculous therapy for variable periods.[7] Chest radiograph may show an associated pulmonary hydatid.

Magnetic Resonance Imaging

Since the first description of magnetic resonance imaging (MRI) appearances of vertebral hydatid by Mikhael et al.,[32] MRI is now the imaging modality of choice for diagnostic evaluation of spinal echinococcosis. MRI provides accurate details of the intradural and extradural compartments together with multiplanar imaging, so that the exact relationship of the cyst with the surrounding structures is known and the surgical approach can be planned. Typically, the cyst appears as a multiloculated hypointense mass on T1-weighted images, which is brightly hyperintense on T2-weighted imaging (Fig. 1). Marani et al.[30] and Tekkok and Benli,[45] while reporting MR imaging findings in patients with spinal echinococcosis, found signal intensity alterations on T2-weighted images. The intensity differences may reflect the viability of the cyst. Whereas a viable cyst appears hypointense on T1-weighted images with isointense or mildly hyperintense cyst wall, it is the T2-weighted sequence that indicates whether the cyst is viable.[23] A decrease in hyperintensity and an increase in hypointensity from a collapsed cyst indicate a non-viable cyst.[23,45] Proton density weighted images are also useful in determining cyst viability[45] and gadolinium enhancement correlates well with various stages of cyst degeneration.[11]

Computed Tomography

With increasing utilisation of MRI in the evaluation of myelopathy, the role of CT has become more specific. Detection of calcification in the cyst wall, delineation of bony erosion and size of intraosseous cysts and assessment of adjacent bony architecture prior to instrumentation are the principal uses of CT.

SEROLOGICAL DIAGNOSIS

While imaging is the mainstay of pre-operative diagnosis in spinal hydatid disease, serologic tests may be useful in confirming presumptive imaging diagnosis. The limitations of serodiagnosis must be kept in mind to interpret the findings correctly. False positive reactions with tests using whole hydatid cyst fluid antigens occur frequently in the presence of helminthiasis, malignancies and chronic immune disorders. Regardless of localisation, antibody detection tests are least sensitive in patients with intact hyaline membranes, although cysts in the bone stimulate the formation of antibody regularly in contrast to those cysts that occur in the liver, lung, etc.[43] Rupture of the cyst is followed by an abrupt rise in antibody titre. Enzyme linked immunoabsorbent assay (ELISA) and indirect haemagglutination or indirect immunofluorescence tests are highly sensitive procedures for screening of serum for diagnosis of hydatid infestation.[14] Confirmation can be obtained with an immunoblot assay for specific antigen-antibody bands or gel diffusion for echinococcosis arc[5] protein. However, serological tests may falsely be positive in 5–25%. The patients with neurocysticercosis, a condition that shares the endemicity and imaging appearances with echinococcosis.[49] Eosinophilia is present in less than 25% of infected persons.

In seronegative cases, a presumptive diagnosis may be confirmed by demonstrating protoscolices or hydatid membranes in the liquid obtained by percutaneous aspiration of the cyst contents. Ziehl Neelsen stain is particularly useful for easy identification of the elusive hooklets.[3] Closed aspiration under ultrasound or CT guidance combined with medical treatment appears to be safe and is now a standard practice.

SURGICAL MANAGEMENT

Surgery is the mainstay in the definitive management of spinal echinococcosis, especially in the presence of compressive myelopathy. The aim of surgery is to preserve and improve neurological function and provision of spinal stability with eradication of the parasite. The exact location of the cyst determines the surgical approach to the lesion. Posterior exposure may be made by laminectomy, especially in the presence of an intradural cyst.[1] Extensive involvement of vertebral bodies requires an anterolateral transthoracic approach. Vertebral body resection and stabilisation by instrumentation and fusion can be carried out.[18,46] A combination of anterior and posterior approaches may be required. Spinal fixation can be done as a first step, before excision of the cyst.[8] A reasonable suspicion of hydatid cyst can be made from pre-operative imaging studies, and appropriate precautions should be taken to prevent spillage of cyst contents. Scolicidal-soaked gauze should be packed around the cyst wall. Hypertonic saline and formalin are best avoided in the vicinity of neural tissue; instead of aqueous iodine in glycol (Betadine®) is used. A layer of isotonic saline-soaked gauze is first placed over the neural tissues, and scolicidal-soaked gauze is then placed over the saline-soaked gauze to avoid direct contact of neural tissue with scolicidal solution.

Inspite of attempts at extensive exposure for radical excision, the cyst may be removed incompletely.[15] Spillage from a viable cyst should promptly be recognised and antianaphylactic measures instituted. All patients, irrespective of the extent of resection of the cyst, must receive albendazole or mebendazole in the post-operative period.

MEDICAL MANAGEMENT

Medical management of hydatid disease has evolved over the past several decades, and drug treatment can now be recommended for many patients. While one-third patients can be cured of their disease, nearly 30–50% have favourable response in the form of regression of cyst size. Small isolated cysts respond better than the large multiloculated ones and those with thick calcified walls. Both albendazole 10–15 mg/kg/day and mebendazole 40–50 mg/kg/day have been effective. Drug treatment may have to be administered continuously or punctuated by treatment-free intervals for a period of three to six months. These drugs can also be administered pre-operatively to inactivate the scolices, altering the integrity of the membrane and thus safe surgical manipulation of the cyst(s); clinical evidence of this approach however is lacking.[43] There have been reports of reduction in cyst size with medical treatment after incomplete cyst excision.[5,17] These drugs are teratogenic and are contraindicated during pregnancy. All patients must undergo MRI after 12 months of treatment: static size, reduction in the cyst size or disappearance of the cyst indicates effective therapy.[12]

PERCUTANEOUS ASPIRATION, INJECTION, REASPIRATION (PAIR)

According to the WHO advisory group, PAIR is indicated in inoperable cases and those who refuse surgery.[50] The procedure involves percutanous puncture using sonographic guidance, aspiration of substantial amounts of liquid contents and injection of scolicidal agent (e.g. 95% ethanol and 0.5% cetrimide) for at least 15 minutes, followed by reaspiration.[28] Concurrent treatment with albendazole/mebendazole improves the efficacy and safeguards against spillage and secondary implantation.

PREVENTION OF ECHINOCOCCOSIS

Echinococcosis is a major health care problem in endemic regions like Turkey and Australia, and Kashmir in India. In the Madurai district of Tamil Nadu, 20% of the slaughtered cattle were found to have hydatid cyst.[34] CNS involvement can cause major morbidity and mortality, especially in cases of rupture of these cysts. Prevention of human echinococcosis involves the dual approach of regular deworming of dogs and ensuring meat hygiene. Infected animal carcasses have to be destroyed, so that these are not consumed by dogs. All these measures involve a concerted effort on the part of medical and veterinary personnel, and public health authorities.

72 Fungal Infections

Anil Pande

GENERAL CONSIDERATIONS

Fungi are everywhere and an estimated 70,000–150,000 different species exist around us.[25,75,101] Only a small fraction of these cause human fungal infections. These are members of the phylum thallophyta, but lack chlorophyll. They do not have the usual plant structure, lacking stem, leaves and roots. They may be unicellular or multicellular. Many are dimorphic, that is, they can take two different types of form; a unicellular (yeast form) and a multicellular (mycelial form). The mycelial forms can be septate or non-septate, that is branched or unbranched. They may be capsulated or non-capsulated. The fungal cell wall is of great complexity and this polysaccharide capsule is of great use in characterising these lesions, and in protecting them and the fungal cell wall components. Ergosterol, chitin and beta 1,3 and 1,6 glucans are the targets of antifungal agents excepting flucytosine, which acts due to its antimetabolite effect. The human immune system, normal colonising bacteria and fungus and low pathogenicity are all responsible for the rare occurrence of these infections. Whenever the immune system wavers in its effectiveness in extremes of age, disease and debilitation or, whenever immunosuppression occurs due to AIDS, diabetes, drugs or blood dyscrasias, the fungi find a foothold.

Fungi are thus basically simple plants, lacking chlorophyll; they are parasites or saprophytes thriving on other living or dead organisms. Fungal infections of the central nervous system (CNS) have been recognised since the end of the 19th century. Paltauf, in 1885, reported a case of cerebral mucormycosis.[110] Von Hanseman in 1905 reported from Germany, a yeast isolated from the cerebrospinal fluid (CSF). Since then, numerous reports of cryptococcal and other fungal CNS infections have appeared.[44,51,58,59,158,160,161] In India, after the publication of a case of intramedullary cryptococcal granuloma by Ramamurthi et al.[120] in 1954, and blastomycosis of the spinal cord in 1956, many cases of fungal infections of the brain and spinal cord have been reported.[4,9,18,28,35,38,88,97,118,123,132] Recently, they are being encountered more frequently as opportunistic infections in patients whose host defence mechanisms have been compromised due to disease or due to techniques of immune suppression and immune modulation used for managing malignant and autoimmune diseases[146] and for organ transplantation.[155]

The factors that have contributed to the increasing incidence of fungal infections are:

- Prolonged use of broad-spectrum antibiotics and the use of antimetabolites and steroids.
- Social evils such as drug addiction and substance abuse.[3,87]
- Diseases like diabetes mellitus, renal failure, malnutrition, AIDS and systemic lupus erythematosus.[79,147]
- Increase in international travel with the risk of environmental exposure.[146]
- Longer survival of patients with lymphoproliferative malignancies.[28]
- Larger ageing population.
- Near drowning episodes.

CNS mycoses can also affect healthy individuals without any of the predisposing factors mentioned above.[19,93,96,119,140] Asha et al.[7] from India reported that 17 out of 25 of their patients with fungal infections of the CNS were not immunologically compromised. This is also a common observation in other centres in India.[31] In contrast to the Western literature, poor nutritional status, antibiotics, steroids and parasitic infestations have been cited as causes of reduced host defences and increase of CNS fungal infections in India. Also a hot dry climate with high aspergillus spore content is cited as a cause of increased cases reported from India.

Mycotic infections enter the differential diagnosis of many neurological conditions, even in an apparently fit individual. They produce a wide range of pathology depending on the host response to the fungus: Inflammatory reactions, chronic round cell inflammation, chronic suppuration, granulomatous inflammation, calcification, infarction, hypersensitivity and/or antibody production.[8,111]

CLASSIFICATION

Fungi are classified as follows:

Pseudo Mycetes

Blastomycetes, Candida, Coccidiodes, Cryptococcus, Histoplasma, Paracoccidiodes and Sporotrichum.

Septate Mycetes

Aspergillus, Cephalosporum, Cladosporum, Diplo-rhinotrichum, Hormonodendrum, Paecilomyces, Penicillum.

Non-Septate Mycetes

Absidia, Basidobolus, Cunninghamella, Mortierella, Mucor, Rhizopus.

Fungi Like Bacteria[109]

PATHOGENESIS

The pathogenicity of fungi is attributed to their neurotropism, and to the altered defence mechanisms in the host.[28] Fungi causing systemic and CNS infections possess thermotolerance and resist phagocytosis by capsule formation, intramacrophage germination and toxin production. Fungi can grow either as yeast or moulds at different times of their life cycle. This is known as dimorphism. The morphology and size of the fungus determine the pathology of these lesions. Small yeast forms (Blastomycosis, Coccidiodes, Cryptococcus and Candida) reach the small arterioles and capillaries and produce meningitis and subpial ischaemic lesions. Intermediate size pseudohyphae (Candida) obstruct small blood vessels leading to necrosis and abscess formation. The larger hyphal forms (Aspergillus, Zygomyces, Cladosporium) block larger vessels and give rise to large infarcts. Disorders of phagocytic function predispose patients to develop CNS aspergillosis, mucormycosis and candidiasis.[141] Impairment of cell-mediated immunity predisposes to CNS Cryptococcal, Histoplasma, Coccidioidal and Blastomycotic infections. Impairment of granulocyte function predisposes to Candida, Aspergillus and Zygomycetes.[41]

Recently, in some fungi, cytoplasmic hormone receptors have been demonstrated, which interact with human corticosteroid and sex hormones. The receptors have been reported in *Candida albicans, Coccidioides immitis* and *Paracoccidioides brasiliensis*.[86,116] This discovery has aided our understanding of the growth and virulence of pathogenic fungi.

Basically, fungi affecting the CNS can be divided into two groups:

1. Pathogenic or Endemic fungi: They affect healthy hosts. These are endemic in various parts of the world.
2. Opportunistic fungi: These fungi usually cause infections in immunologically compromised hosts and in the presence of predisposing factors (diabetes, malignancies, renal failure, AIDS, etc.).

Many other miscellaneous fungi, like Penicillum, Curvularia, Alterneria, Cephalosporium, Paecilomyces, Fusarium, Pseudoallescheria, Rhizopus arrhizus, Rhodotorula, Trichosporon and Ustilogo, can cause CNS mycosis on rare occasions.[49]

Pathogenic Fungi

The site of primary infection is usually in the lung and rarely in the skin. In addition, primary lesions may occur in the mucosa of the mouth and pharynx as in paracoccidioidomycosis and in the gastrointestinal tract as in histoplasmosis[131] The organisms spread to the CNS by the bloodstream from the primary site. Rarely, meningitis may ensue due to direct spread from osteomyelitis of the skull or vertebra, e.g. *Coccidioides immitis*. Direct spread can also occur from the paranasal sinuses and middle ear.

Opportunistic Fungi

The primary site of entry in aspergillosis and cryptococcosis is the lung, with subsequent bloodstream spread to involve the CNS.[129] Some fungi (Aspergillus, Zygomyces) spread directly from the nose and paranasal air sinuses and less often from the ears. Occasionally, the brain is directly infected after a head injury or craniotomy.[129] In candidiasis, the normal commensal multiplies and enters the blood at any site where there is a defect in normal surface defence mechanisms.

Meningitis

The prototype fungus that primarily causes meningitis is *Coccidioides immitis*. Involvement of the leptomeninges is typically widespread, the basal meninges being maximally involved.[73] The basic pathologic lesion of coccidioidomycosis is a combination of suppurative and granulomatous inflammation. In the infected tissue, the endospores are surrounded by polymorphs[27] and in granulomas the spherules are surrounded by mononuclear cells and giant cells. The chronic inflammatory response results in thickening of the meninges, hydrocephalus, arteritis, cranial nerve palsy and infarctions. Other fungi (Blastomyces, Paracoccidioides and Histoplasma) may also cause meningitis. As in tuberculosis, there may be spinal meningitis in blastomycosis where there is an extradural infection of the vertebrae and intervertebral discs.

Meningoencephalitis

Fungi, like *Cryptococcus neoformans* and the Candida species, are prone to cause meningoencephalitis. In cryptococcosis, cystic clusters of fungi are spread throughout the brain with little or no surrounding inflammatory response and predominantly involving the basal ganglia and the cortical grey matter.[27] Large focal collections of fungi with inflammatory cells (cryptococcomas) may be observed in rare cases. The cystic lesion contains a gelatinous polysaccharide material. This polysaccharide antigen is detectable in spinal fluid and serum, and forms the basis of a commercially available latex agglutination test, which is 90% sensitive and highly specific for diagnosis of cryptococcosis.

Brain Abscesses/Infarction/Haemorrhages

Aspergillus, Zygomycetes, Blastomyces, Paracoccidioides and Candidiasis cause these lesions, as also Nocardia,[68], Actinomyces,[113] and Coccidioidomycoses.[94] Some dermatiaceous fungi produce brain abscess, especially in

the frontal lobes, even in the absence of a disseminated lesion, e.g. *Cladosporium trichoides* and Phialophore.[45]

Disseminated candidiasis mainly produces microabscesses, though macroabscesses, glial nodule formation, granulomas and fungal balls may also be found. Rarely, Candida may directly invade blood vessels causing haemorrhage, necrosis and infarction. Vasculitis is characteristic of invasive aspergillosis and mucormycosis. Direct spread occurs from the paranasal sinus to the brain with subsequent vasculitis, especially in diabetic patients.

CLINICAL FEATURES

There are no pathognomonic signs or symptoms of fungal infection of the CNS. However, a constellation of specifically affected organs and some characteristic pathological features help the physician towards a presumptive diagnosis. In non-endemic areas, a history of travel to a region of the world where the organisms grow, may point towards the correct diagnosis. A history of near drowning episode is inquired into. Occasionally, there may be no neurological symptoms or signs.

The clinical features may be divided into the following groups:[100]

Meningeal Syndromes

The common symptoms are headache, nausea, vomiting, neck stiffness and fever. In 40% of the cases of cryptococcosis, visual impairment, diplopia and papilloedema occur.[160] Cranial nerve palsies may also be seen. Alteration of the mental status may be caused by encephalitis or hydrocephalus. Seizures may occur. Focal signs due to arteritis, granuloma or abscess may be present. In patients with AIDS, cryptococcal infection may cause retrobulbar neuritis,[53,83] choreoretinitis,[142,144] internuclear ophthalmoplegia[151] and reverse ocular dipping.[125] The clinical picture of meningitis varies in the immunocompromised and non-compromised hosts with a paucity of symptoms and signs in the former.

Space Occupying Lesions

Granulomas, abscesses or hydrocephalus cause symptoms and signs relating to the affected area. There may be features of increased intracranial pressure.[42,142] Aspergillosis typically presents in this way. An intraventricular fungal mass has been reported.[78] In blastomycosis, the patient has progressive paraplegia with sensory manifestations and sphincter disturbances. Blastomycosis may also involve the vertebrae and the intervertebral discs producing a gibbus simulating caries spine.[4] Extradural or intradural cryptococcal granulomas have been reported in the spinal cord, producing features of compressive myelopathy.[10,12,120]

Rhinocerebral Syndrome

This syndrome presents with orbital pain preceded by a watery nasal discharge, which becomes bloody and purulent. There is facial oedema with proptosis and visual loss. Involvement of the carotid artery produces hemiparesis. Subsequently, the trigeminal nerve and the adjacent brain may be involved.[112,145] This is classically found in zygomycosis, where blackish necrotic areas called eschars are seen on the hard palate or the nasal turbinates. Rhinocerebral mycosis has a high morbidity and mortality, despite institution of aggressive management.[69,148] Allergic fungal sinusitis can lead to formation of a "fungocoele", which expands with time causing bony destruction and intraorbital and intracranial extension, but characteristically is non-invasive and can be removed bluntly leaving the mucosa intact. Transsphenoidal, trans-ethmosphenoidal, endoscopic transnasal and, rarely, transbasal bifrontal approaches may be utilised. Prolonged antifungal treatment is not required, but steroids help.[85]

Stroke Syndromes

Aspergillosis or zygomycosis may produce sudden onset of a focal deficit due to invasion of blood vessels. Rarely, subarachnoid haemorrhage may occur due to rupture of a mycotic aneurysm.[60,64,117,157] Unlike bacterial mycotic aneurysms, fungal mycotic aneurysms occur in the larger arteries.[60] Candida infection may result in an embolic stroke.[62]

Skull Base Syndromes

Orbital apex syndrome, cavernous sinus syndrome, proptosis with or without ocular palsy, polyneuritis cranialis and orbitocranial syndrome may occur.

Spinal Syndromes

Myelopathy and radiculopathy due to involvement of the vertebral column, and extradural, intradural and intramedullary lesions may be seen.

DIAGNOSIS

Suspicion of CNS mycosis is the most important initial step in the diagnosis. Laboratory tests should be directed to discover evidence of immunological compromise and of fungal infection elsewhere in the host.[17,33]

Evidence of Fungal Infection in the Central Nervous System

Cerebrospinal Fluid Examination

i. *CSF protein* is elevated and glucose diminished. In aspergillosis with deep-seated granulomas, the CSF is normal. If a high protein level is found (1.0 gm/dl or more), subarachnoid block should be considered.[146] High levels of proteins, often greater than 1.0 gm/dl are not uncommon in cases of cryptococcal meningitis even in the absence of a spinal block.
ii. *Cell count*: A mononuclear pleocytosis is seen ranging between 20 cells/cubic mm and 500 cells/cubic mm,[115]

but, occasionally, in candidiasis and zygomycosis, there may be a polymorphonuclear increase.

iii. *Cytological examination* of the CSF may occasionally reveal the fungus. For cryptococcal meningitis, India ink preparation is a simple and effective test. It is positive in approximately 50% of all cases and the sensitivity increases to 80% in patients with AIDS.[146]

iv. *Positive cultures* confirm the diagnosis of fungal meningitis, but may be difficult to obtain or may take a long time. Cryptococcal meningitis shows a positive culture in 75% of patients and Coccidioidomycosis meningitis in 30–50% of patients. Blastomycosis and histoplasmosis rarely yield positive cultures. It may be necessary to centrifuge and culture the sediment. Candida yields positive culture within a few days and Cryptococci within 7–10 days, while Histoplasma and Coccidioides require longer incubation periods of up to 6 weeks.

v. *Immunological tests*: In cryptococcal meningitis, the latex agglutination test for capsular polysaccharides in CSF is positive in 90%. False positivity may occur in 20%. In CNS coccidioidomycosis, complement-fixing antibody is found in 95% of patients in the range of 1:2–1:25. CSF antibody to Histoplasma has been found by both complement fixation and radioimmunoassay. False positivity occurs in 50%. In sporothrix meningitis, CSF antibody in a titre of 1:8 or more is detected by the latex agglutination or ELISA test.[128,137]

Imaging Techniques

CT or MR scan may reveal features of meningitis, granulomas, hydrocephalus, infarction or spinal cord compression. In rhino-orbital syndromes, CT or MR is especially helpful. CT scan usually underestimates the degree of involvement by the organism, and shows paranasal sinusitis, small areas of bony destruction, and absence of separation of periosteum from the medial orbital wall. The granulomas appear as irregular hypodense lesions with irregular and minimal contrast enhancement and disproportionate perilesional oedema. For example, in cryptococcal meningitis the scan may be normal in up to 40%.[47,67] The MRI is very useful to visualise ocular muscle or nerve involvement and will show involvement of the paranasal sinuses or mastoid involvement. Granulomas have a low T2 intensity compared with surrounding hyperintense cerebral oedema. MR can be used to follow treatment response in fungal meningitis.[163] This characteristic low intensity in T2 is due to high levels of iron, magnesium and manganese in the fungus. Diffusion weighted imaging is useful in detecting early lesions and in differentiating these from progressive multifocal leukoencephalopathy and neoplasm. MR spectroscopy in aspergilloma is non-specific with high choline, low creatinine and lactate with no N-acetyl aspartate.[71] Cryptococcus pseudocysts which are formed due to the dilatation of the Virchow Robin spaces with mucoid gelatinous material produced by the capsule of the organism are seen in clusters in the basal ganglia and thalamus and are pathognomic of cryptococcal infection. Deep cerebral infarcts are seen as areas of hyperintensity on T2W1 images. Ring enhancing T2 heterointense lesions with irregular walls and non-enhancing intracavitary projections having a low ADC are indicative of a fungal abscess. Spinal involvement shows disc involvement or sparing, heterogeneous marrow signal alteration and extensive extraosseous involvement and variable bony deformity and destruction. Rarely, CNS fungal infection can present with subarachnoid haemorrhage due to rupture of a mycotic aneurysm or thrombosis of large vessels[53,62] and these require conventional angiography as CT angiography may miss small aneurysms.

The authors have proposed a classification of Rhinocerebral fungal infections depending on the extent of the lesion (Figs 1 to 5)[138] (*Reproduced with permission from Neurology India*).

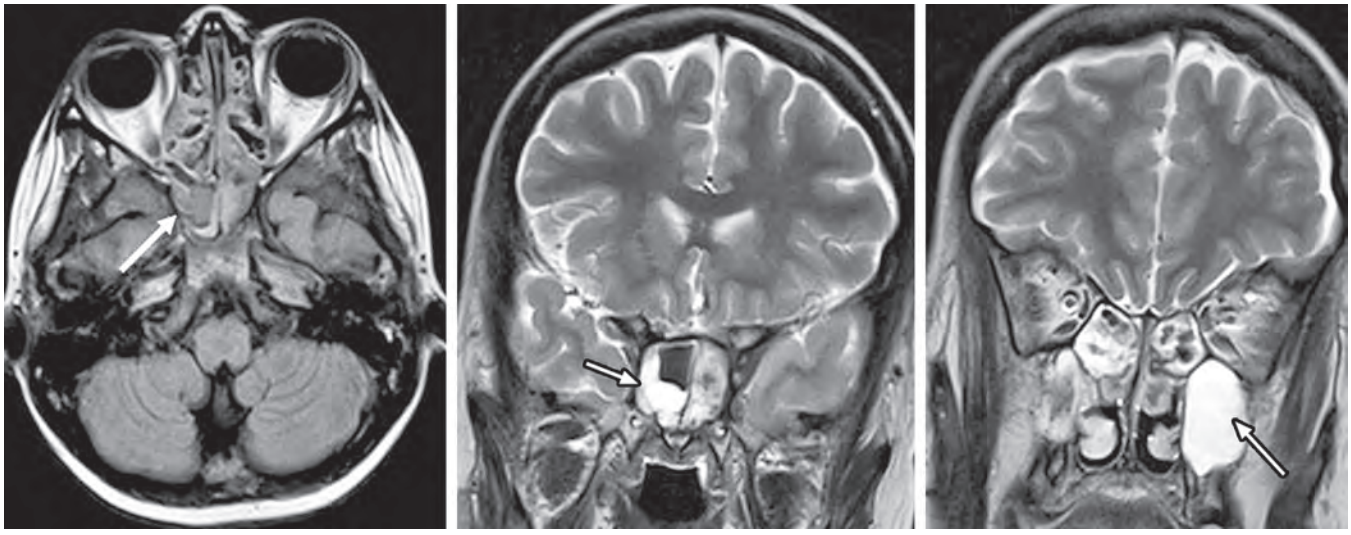

Fig. 1: MRI of the brain showing evidence of fungal infection in the ethmoidal and maxillary sinuses (arrows). Infection is limited to the sinuses and not involving the dura or extending intracranially (Stage I)

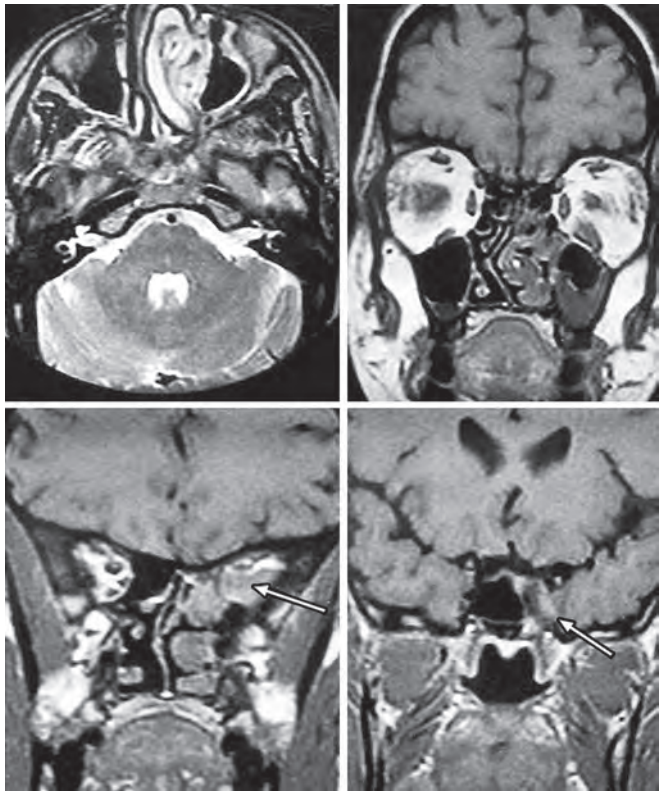

Fig. 2: MRI of the brain showing pansinusitis with erosion of the bone and without dural breach or parenchymal spread (Stage II)

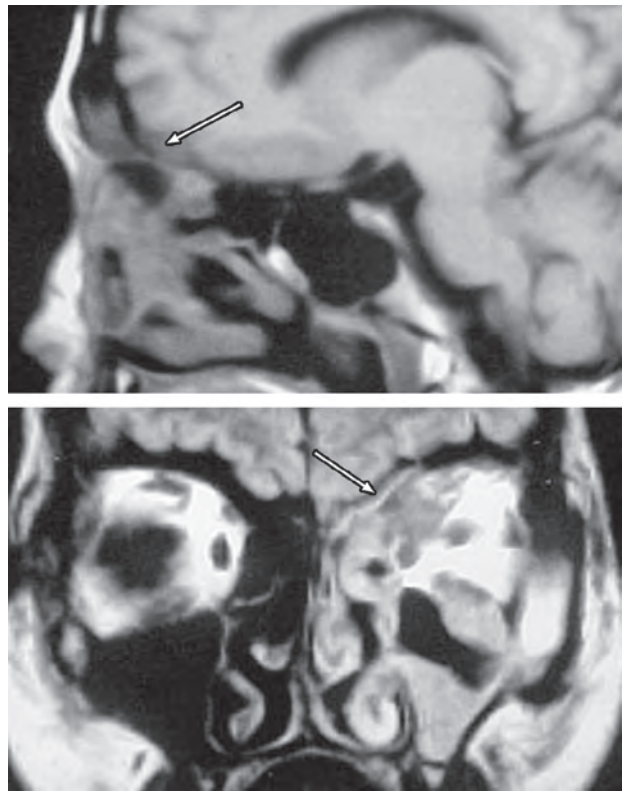

Fig. 3: MRI of the brain showing evidence of infection in the ethmoidal sinuses with skull base erosion and spread to the dura seen as dural thickening (arrow) (Stage IIIA)

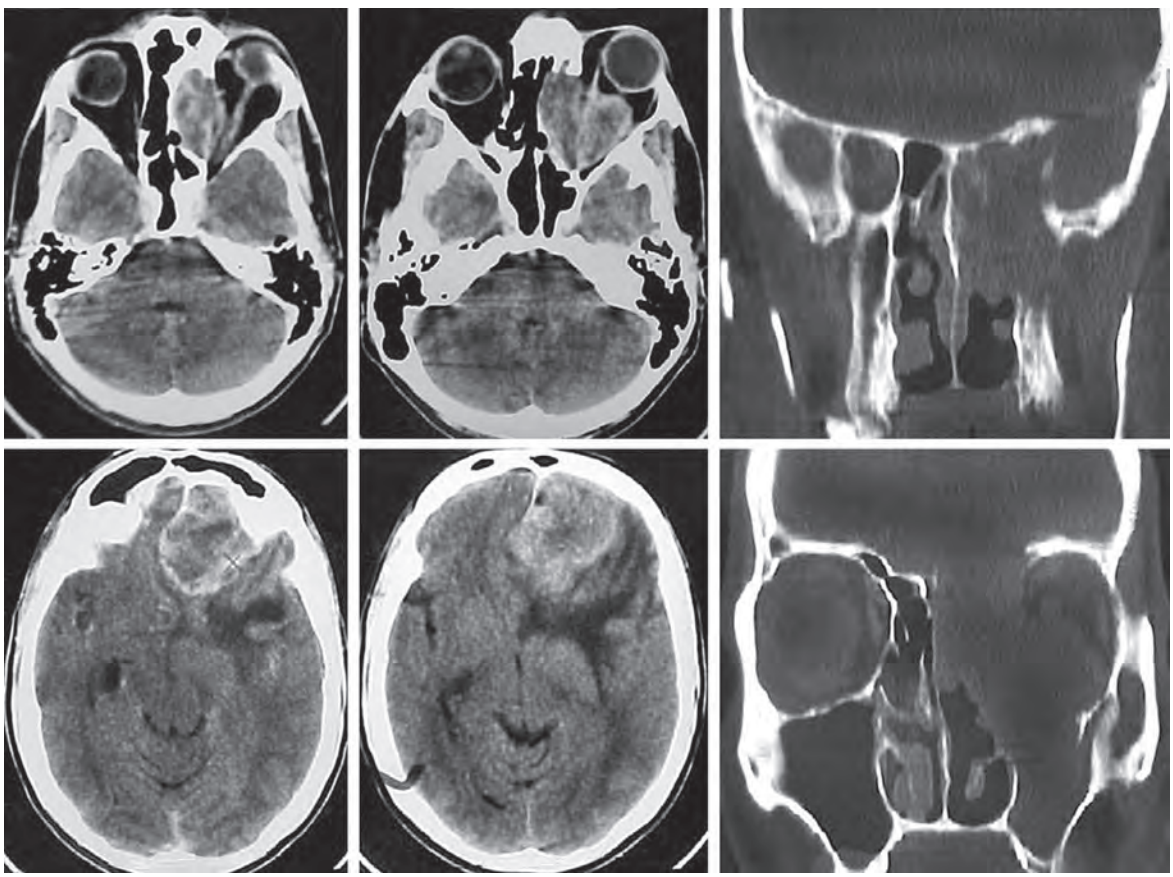

Fig. 4: CT of the brain showing infection in the maxillary and ethmoidal sinuses with extension into the orbit. There is evidence of erosion of the skull base and spread to brain parenchyma with perilesional oedema (Stage IIIB)

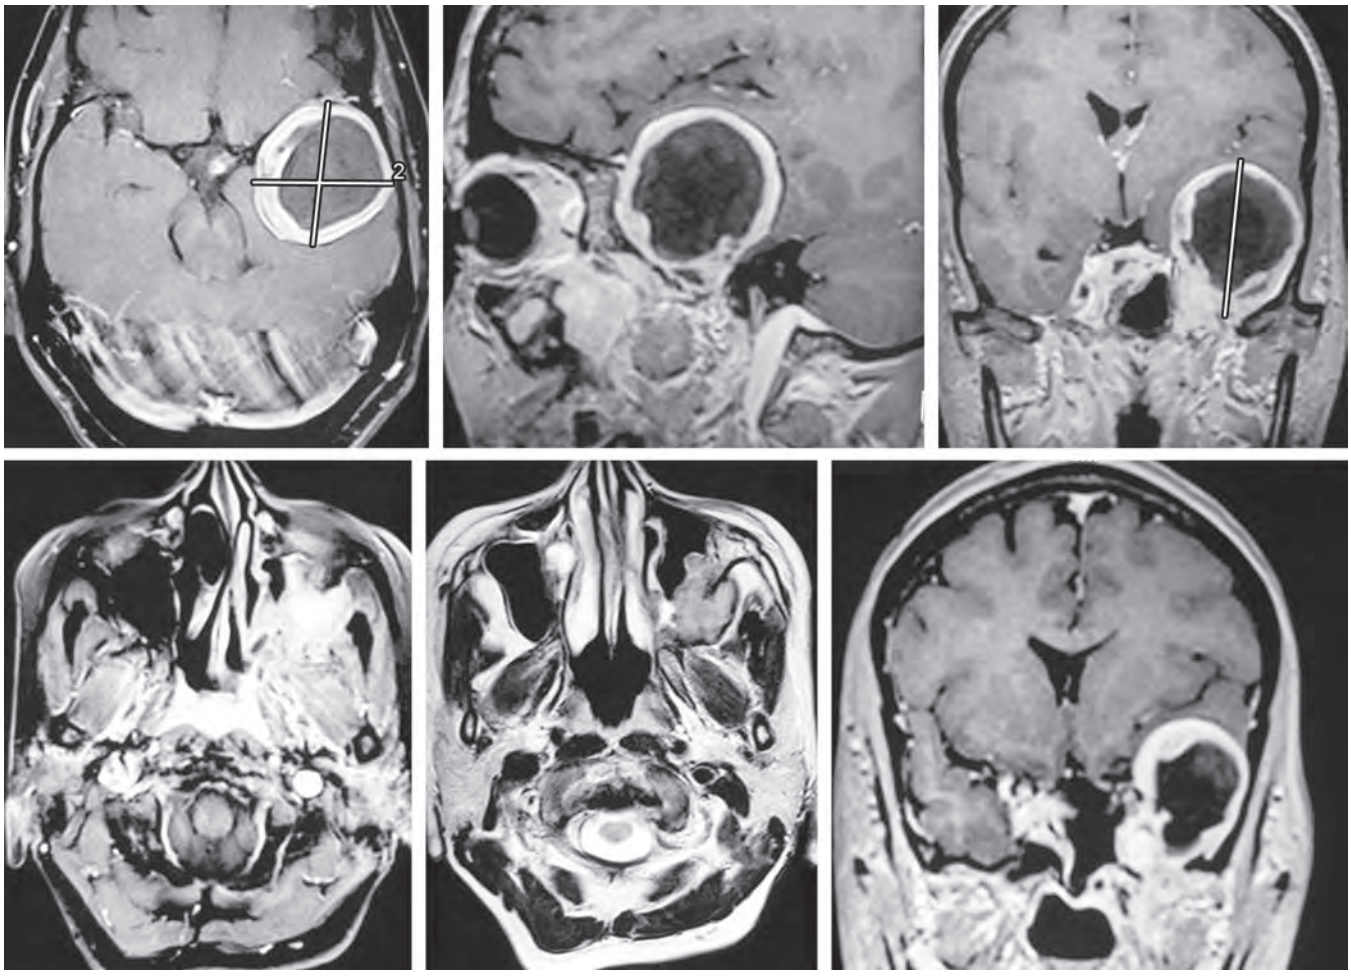

Fig. 5A: MRI scan of the brain. Well circumscribed extra-axial lesion measuring 4.3 x 4.5 cm in the temporal base with erosion of the skull base and involvement of the dura. There is evidence of the disease in the maxillary sinus (Stage IIIA)

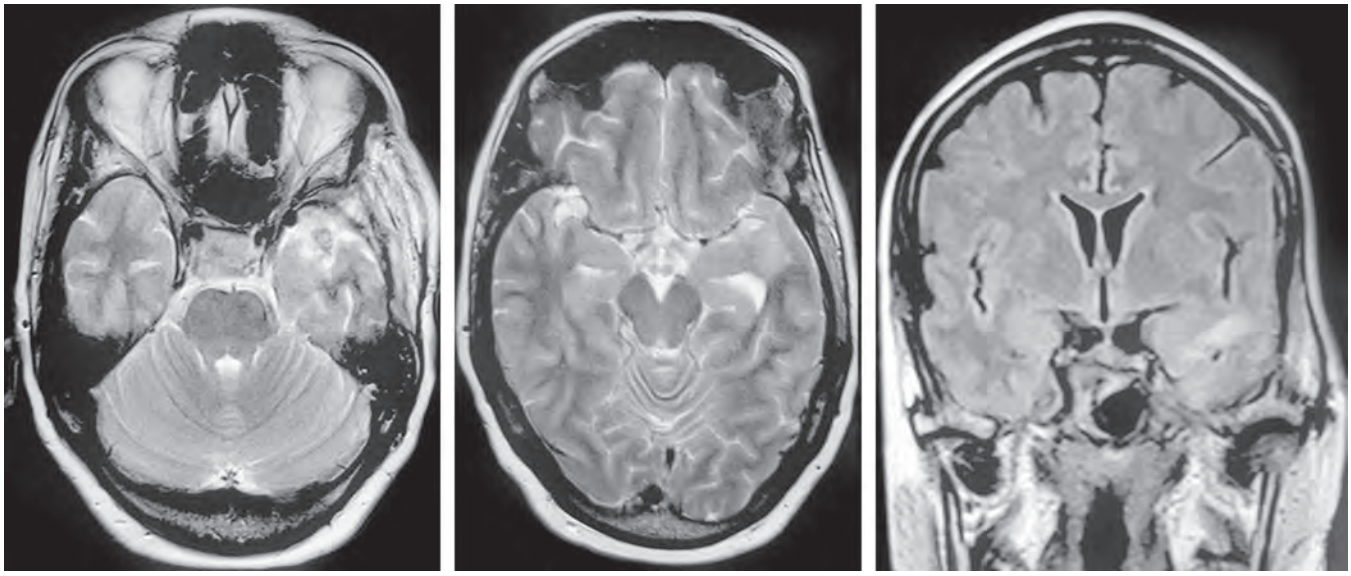

Fig. 5B: Post-operative contrast MRI of the brain showing total excision of the intracranial lesion

Stage I: Purely rhino-sino-orbital.
Stage II: Involvement of the bone without dural breach in addition to sinus involvement.
Stage IIIA: Spread of infection from the sinus to the skull base, involvement of the bone and breach of the dura.

Stage IIIB: Infection involving the brain parenchyma.

Stage IV: Fulminant meningoencephalitis and large infarcts.

Biopsy

When a diagnosis cannot be made otherwise, biopsy of the lesion may become necessary. In every case where a granulomatous lesion is encountered, investigations for fungi should be done in addition to histopathology and culture sent for pyogenic organisms. The specimen should be sent in normal saline and stained with Periodic Acid Schiff stain or Grocott's methanoamine silver stain, especially for aspergillosis and zygomycoses. In the case of Cladosporium and other dermatiaceous fungi, hematoxylin and eosin stain is adequate.

Evidence of Fungal Infections Elsewhere in the Host

Searching for the source of infection elsewhere in the body is essential, e.g. lung, skin, bone and sinuses using X-rays and serological tests; and identification of the organisms by smear, culture, histopathology from pus, sputum, blood and skin. Skin tests for Coccidioides, Histoplasma or Blastomyces may indicate exposure to the particular fungus.

Evidence of Immunological Compromise

Complete blood count and blood chemistry are carried out to identify predisposing conditions, such as leukaemia, lymphoma, diabetes mellitus, renal failure and AIDS.

TREATMENT

Non-Specific Measures

a. Control of predisposing factors which are mentioned earlier.
b. Treatment of intracranial hypertension, e.g. mannitol and furosemide.

Specific Measures

Antifungals can be classified as:

Polyenes: Amphotericin, Nystatin

Azoles: Miconazole, Ketoconazole, osaconazole, Ravucon-azole, Voriconazole, Eberconazole, Itraconazole.

Antimetabolic: Flucytosine

Antiprotozoal: Atovaquone

Echinocandins: Caspofungin, Misafungin, Aniducafungin

The antifungal agents commonly used are amphotericin B, flucytosine and azole derivatives.[124] The duration of the treatment is from 4 to 6 weeks. Immunocompromised patients take longer to experience remission. The treatment should continue till active systemic or CNS infection has disappeared. Long-term maintenance therapy is considered in immunocompromised patients.

Other drugs under trial: Amphotericin B encased in liposomes reduces toxicity to the host, allowing administration of higher doses of the drug. Voriconazole is considered the gold standard of systemic antifungal treatment and is superior to conventional amphotericin and has improved survival rates in patients with cerebral aspergillosis.

Capsofungin and Posaconazole are other agents, and combination therapy is preferable. Amphotericin B deoxycholate given as a continuous infusion, with appropriate saline loading through a dedicated line is a safe and affordable treatment option with similar toxicity profiles compared to expensive lipid based formulations.[124] Rifampicin given with amphotericin B potentiates the activity of the polyene against multiple yeasts, including Candida, Histoplasma and Cryptococcus.[92] Immune based therapies for fungal infections are at an exploratory level and merit further evaluation in clinical trials.[114]

Surgical Management

Surgery may entail stereotactic biopsy and, if possible, aspiration of an abscess. Stereotactic craniotomy can be useful to place an appropriate flap and localise the lesion.[18,61,119,143]

Besides diagnostic biopsy, surgery may be needed for CNS mycoses.[57] Brain abscesses, especially Blastomyces and Histoplasma abscesses, can surgically be removed and treated with amphotericin. Large cryptococcomas (greater than 3 cm) in accessible locations should also be considered for surgery.[50,120,166]

Drainage of the paranasal sinuses with excision of the granuloma is indicated in the rhinocerebral syndrome. Focal infection with Cladosporium requires surgical removal of the lesion.[70] Hydrocephalus may require shunt surgery. Insertion of the Ommaya type reservoir helps in prolonged intraventricular or cisternal chemotherapy. Spinal compression requires surgery to remove granulomas or abscesses.

PROGNOSIS

In most fungal infections, the prognosis depends on the duration of the disease before the diagnosis and on whether any underlying disease can be controlled. Specific prognosis factors have been identified in cryptococcal, candidal and coccidioidal meningitis.

Poor Prognostic Factors

1. Cryptococcal meningitis:[39]
   i. Initial positive India ink test.
   ii. High CSF opening pressure.
   iii. Low lumbar CSF leucocytes (less than 20/cu mm)
   iv. Cryptococci isolated from extraneural tissue.
   v. Absent anticryptococcal antibody.
   vi. Initial CSF or serum cryptococcal antigen titre greater than 1:32.
   vii. Corticosteroid therapy for lymphoreticular malignancy.

2. Candidal meningitis:[14]
   i. An interval from the onset to diagnosis of more than 2 weeks.
   ii. CSF glucose level below 35 mg/dl.
   iii. Development of intracranial hypertension or focal neurological deficit.
3. Coccidioidal meningitis:[20]
   i. Presence of hydrocephalus.
   ii. Presence of an underlying disease.
   iii. Non-Caucasian races.

Without treatment, fungal meningitis is a fatal disease. In CNS coccidioidomycosis, virtually all the patients die within 2 years. By administering amphotericin B directly into the CNS the mortality has decreased to less than 50%.[146]

CRYPTOCOCCOSIS

Cryptococcus neoformans has a worldwide distribution and is associated with soil enriched by pigeon droppings. It is also known as Torula histolytica. The disease may be seen in patients with disorders of the reticuloendothelial system[32,105,144,161] and also in previously normal individuals.[43,56,126,154,159] The route of infection is through the respiratory system, which may result in a subclinical infection or a cavitating lesion in the lung.[48,159] It is disseminated via the bloodstream and, when it reaches the CNS, commonly causes meningitis.[32,82,122] Verse, in l9l4, first reported cryptococcal meningitis.[122] The first case published from India was by Krainer et al. in 1946.[76] Since then there have been more case reports.[9,13,74,118,120] Cryptococcosis appears to be the commonest type of mycosis in AIDS. Involvement of the CNS is in the form of basal meningitis,[130] meningoencephalitis and mass lesions such as granulomas or cysts.

Cerebral Cryptococcosis

Pathology

Meningitis is localised mainly to the cerebral and cerebellar hemispheres, and the meningeal exudate is made up of a minimal inflammatory response.[133] The leptomeninges become thickened and the infection spreads along the distended Virchow-Robin spaces. The formation of perivascular granulomas, similar to tubercles, has been noted.[105,133] Changes in the brain are seen near the surface, but may extend deeper. Recent foci distort rather than destroy the brain tissue and produce gelatinous pseudocysts. There is only a minimal inflammatory reaction and this is usually delayed.[152] When present, it consists of lymphocytes, plasma cells, eosinophils and multinucleate giant cells. The nuclei of the giant cells are more centrally located than in the Langhans' cell and may contain cryptococci.[133]

There is a change in infection trend due to the marked improvement of the quality of life produced by the highly active antiretroviral therapy.[130]

Cryptococcal mass lesions may be seen in the subependymal regions of the thalamus and basal ganglia.[1] Multiple lesions may be found in up to 35% of cases.[11] Patients are mostly male and in the fifth decade.[1,11] Both cystic and granulomatous lesions have been identified.[48,89] The cerebral hemispheres are involved in 56%, the cerebellum in 10% and the spinal cord in 17%. Multiple organ involvement may be seen in up to 25% of cases.[65] The granulomas are greyish pink in colour and appear grossly encapsulated.[65] Some may be attached to the overlying dura. These are firm to hard in consistency. Histologically, the lesion presents the picture of a histiocytic granuloma. Depending on the tissue reaction, the lesion may appear gelatinous or granulomatous. Caseation is not seen. Staining techniques used for fungi, like PAS or mucicarmine, reveal the fungus, which appears as small yeast-like bodies approximately the size of an erythrocyte. These may be single or grouped in a jelly-like mass.

Spinal Cryptococcosis

Involvement of the spinal cord by Cryptococcus is quite rare. In 1951, Carton and Mount[24] reported one case of a cryptococcal granulomatous mass involving the spinal cord. In their review of the literature, they found ten cases with spinal cord involvement. In the same year, Ley et al.[82] described the successful removal of a cervical cord cryptococcal granulomatous mass, with good recovery of the patient. In 1954, Ramamurthi and Anguli[120] from India reported an intramedullary cryptococcal granuloma of the spinal cord which was removed surgically.

Pathology

Involvement of the spinal cord by Cryptococcus is usually in the form of compression by a granulomatous mass. This may be an infiltrating extradural mass,[84,123] an intradural extramedullary granuloma[24,82] or an intramedullary granuloma.[120] The lesion presents the picture of a histiocytic granuloma.[122] Caseation is not seen. Davidson, in 1968,[32] described spinal arachnoiditis due to Cryptococcus, a complication of cryptococcal infection of the CNS not described before.

Diagnosis

The diagnosis of cryptococcal involvement of the spinal cord should be considered in any patient with a subacute or chronic presentation, especially when superimposed on a previously existing debilitating disease. The chest X-ray may show the pulmonary pathology. CT and MRI show meningitis, granulomatous lesions and hydrocephalus. The CSF may be used for culture and serodiagnosis. While encapsulated budding cells may be seen in up to 90% of cases, their absence does not rule out the diagnosis.[32,161] The latex agglutination test for detection and titration of the polysaccharide capsular antigen is of diagnostic and prognostic value.[63,161]

Treatment

Treatment of cryptococcal infection is by a combination of amphotericin B and 5-fluorocytosine (Flucytosine), which provides the best opportunity for a cure.[15,154] Patients treated with amphotericin alone have a higher mortality and the organism becomes resistant to flucytosine when used alone.[161] Miconazole has been used intravenously and intrathecally, but its place in treatment regimes is less certain than the older drugs.[150] Garlic tablets were used as supplementary therapy by Tjia et al.[154] and the mortality was low. While cryptococcal meningitis is generally fatal if untreated,[161] there are reports of good recovery without drugs after removal of a granulomatous mass.[120] Elevated CSF pressure occurs in 75% of patients and is treated by repeated lumbar punctures, and lumbar drain or shunts are resorted to when these measures fail resulting in frank hydrocephalus.

ASPERGILLOSIS

Aspergillus species are among the commonest saprophytes and are found abundantly in the soil and decaying vegetation. *Aspergillus fumigatus* is the most common cause of granulomatous infection in man and in a recent series it was identified in 63% of cases. In the majority of cases infection occurs through haematogenous spread from a pulmonary or gastrointestinal focus.[23,36,102,103,165] Infection may be associated with an immunocompromised state[23,79] and may also occur during intravenous drug abuse,[72] open heart surgery,[34] trauma, etc. Infection may also start in the paranasal sinuses and mastoids and spread to the surrounding tissues[96,97,131] and the basal dura.[98] Cerebellar aspergilloma has been reported.[46] Generalised aspergillosis spreads to the nervous system in about 18–50% of cases,[23] both by direct and by haematogenous spread.[26,36] Rarely, it may be a post-surgical infection.[40] Aspergilloma refers to a large granuloma which sometimes is literally a ball of fungal elements.

The organism shows a high affinity for blood vessels. The vessel walls are invaded, resulting in secondary thrombosis and haemorrhage. Involvement of small vessels may lead to multiple small haemorrhagic infarcts.[104,161] Larger vessels, like the carotid artery or the basilar artery, may also be involved. Subarachnoid haemorrhage may occur from the rupture of mycotic aneurysms.

Abscesses may form and may be single or multiple. They are seen as pale areas with petechiae or as necrotic and haemorrhagic areas with a central cavitation. The most striking histological picture here is the vascular invasion and thrombosis. The degree of inflammation varies according to the stage of the infection and the individual patient. Granulomatous masses occur, either in association with a chronic infection or as a solitary mass. Microscopically, these are made up of aggregates of lymphocytes, plasma cells and epithelioid cells in necrotic tissue, with varying amounts of collagen. Langhans' type of giant cell may occasionally be seen.[31]

Clinically meningeal irritation is not a common feature, unlike in Cryptococcus infection. Focal deficits in the presence of immunocompromise should arouse the suspicion of infection.

Spinal aspergillosis is uncommon.[23] The infection may present with bone involvement, occasionally simulating spinal tuberculosis,[91] as an epidural abscess,[22,29] or there may be direct involvement of the spinal cord.[139] It may also present as infection of the disc space in patients who have undergone previous laminectomy,[90] or as part of the picture of systemic dissemination of the infection.[161]

Diagnosis of aspergillus is made following biopsy and culture of the fungus.[95] Patients with invasive aspergillosis may produce specific antibodies which may be detectable by ELISA, double diffusion or counter immunoelectrophoresis. As the aspergillus is not a member of the normal microflora, the detection of antibodies becomes significant.

As antifungal drugs are not very effective against aspergillus, excision of the mass lesions is the treatment of choice.[6,24,134,161] Operative decompression may be required for patients with granulomatous masses causing cord compression. Complete excision may not be possible and may cause cord damage. Amphotericin B in combination with 5-fluorocytosine are the drugs of choice. Recently, good results have also been achieved with imidazole derivatives, e.g. ketoconazole and miconazole. Itraconazole in high dose (16 mg/kg/day) is given. The prognosis of established CNS disease is poor. Voriconazole alone, or in combination, is currently the drug of choice.[136]

NORTH AMERICAN BLASTOMYCOSIS

Blastomycosis is a fungal infection caused by *Blastomyces dermatitidis*. It is a soil saprophyte and is endemic in the Mississippi and Ohio River valleys and the south-eastern parts of the United States of America, though occasional cases are being reported from Canada, Mexico, India, Africa and Latin America.[14,21,37,53,73,81] The infection is acquired by inhalation of air-borne spores and the formation of a primary pulmonary focus. The infection most commonly affects middle-aged healthy males who have a history of high alcohol consumption.[23] Involvement of the CNS follows haematogenous spread either directly or to adjacent bony structures with associated abscess formation.[121,149,161] CNS involvement by abscess, granuloma and meningitis has been reported.[49,161] The incidence of bone involvement in cases of systemic blastomycosis is about 30%.[127] The bones involved are, in the order of frequency, the vertebrae, ribs, tibia, skull and the tarsal and carpal bones.[30,52,162] Meningitis may be diffuse or localised to the base of the brain close to an abscess. It may occasionally be the result of spread from an extradural lesion. A thick fibrinopurulent exudate may cause obstructive hydrocephalus, the clinical course of which may be subacute or chronic.[55,133] Abscesses, if long standing, are enclosed in a thick capsule infiltrated

by plasma cells. The centre of the abscess contains caseous necrotic material with neutrophils and lymphocytes and is surrounded by epithelioid and Langhans' like giant cells.

Spinal blastomycosis commonly infects the thoracic and lumbar vertebrae, often leading to kyphosis.[23,77,161] Clinically and radiologically the disease may simulate tuberculosis.[23,37,161] Radiological findings include osteolytic lesions with minimal surrounding reactive bone changes and narrowing of the disc spaces with an adjacent paraspinal abscess. Vertebral collapse occurs late and there is a segment-to-segment spread.[52] Granulomatous lesions occurring in and around the spinal cord are difficult to differentiate from other causes of cord compression, except when presenting as a complication in pre-existing meningitis.[16]

The diagnosis is established by biopsy, fungal stains and appropriate cultures. There are no reliable serological tests for blastomycosis.[16,23,161] Treatment is by surgical removal of the lesion wherever possible and a full course of amphotericin B, which may cure the disease.[37,76,153,161]

NOCARDIOSIS

Nocard, in 1888, first described a granulomatous disease in cattle caused by a slow growing soil saprophyte. Nocardiosis is caused by organisms belonging to a group of actinomycetes. They are neither true bacteria nor fungi. *Nocardia asteroides* is common in the soil and in decaying vegetation, and is the only one of its group able to infect the CNS.[23] Though it may infect previously fit individuals, nocardiosis has a propensity for causing disease in debilitated, immunosuppressed individuals or those receiving immunosuppressive agents.[49] It has also been associated with AIDS.[23,161] Primary infection is pulmonary or cutaneous,[1,3] with the CNS involved in up to 44% of patients.[23,122]

In the brain, Nocardia produces abscesses, granulomas and meningitis. Abscesses may be single or multiple and are generally secondary to haematogenous spread. Microscopically, the abscesses have a fibrous wall infiltrated by neutrophils. Small abscesses occasionally coalesce to produce a large lesion.[133] Granulomatous lesions are rare. Microscopically, there are no giant cells. Meningitis occurs usually due to an underlying brain abscess. Clinically, systemic illness is apparent and the clinical signs are dependent on the location of the abscess or granuloma. Rarely cranial osteomyelitis and a cranial epidural abscess may occur.[161]

Treatment is with sulphonamides in combination with trimethoprim (4–8 g/day in divided doses for 6–12 months); erythromycin, amikacin, clindamycin and minocycline are also used. While occasionally good results have been achieved with medical therapy alone, drainage of the abscesses or surgical excision may be required for diagnosis and to relieve intracranial pressure.

Spinal involvement is rare and is usually a vertebral osteomyelitis, the organisms reaching the bone by haematogenous dissemination, or by contiguous spread between the retropleural veins and the Batson's plexus.[23]

Most patients present with signs of cord compression, often masquerading as a neoplasm or other granulomatous diseases, with which it often coexists.[164] Rarely, it may present as an extradural granuloma producing cord compression.[106] Spinal nocardiosis must be treated like any other spinal infection, and material must be obtained for histopathology and culture. Surgery is indicated in the presence of neurological deficits, when a decision must be made about decompressing the cord. Many drugs, e.g. sulphonamides, aminoglycosides, trimethoprim, rifamycin and ampicillin have anti-nocardial activity and have been used with good results.

COCCIDIOIDOMYCOSIS

Coccidioides immitis is a soil saprophyte in certain arid regions of the United States of America, Mexico and Central America. Infection results from inhalation of the spores, resulting in a primary pulmonary infection. The disease primarily affects previously healthy individuals.[20] Most infections are subclinical and, in endemic areas, a majority acquire immunity as the result of an asymptomatic primary pulmonary infection. Dissemination occurs in less than 0.5% of patients and about half of these patients run the risk of CNS involvement.

The organism elicits a granulomatous reaction in the CNS. The basal meninges may be studded with small granulomata containing plasma cells, lymphocytes, epithelioid cells and giant cells. Blood vessels may be involved. Occasionally, large intraparenchymal lesions may be formed either as granulomas or abscesses. Cranial osteomyelitis may also occur.

The clinical picture is mostly one of chronic meningitis similar to that of tuberculous meningitis. Hydrocephalus may supervene. Occasionally, patients may present with signs of a large space occupying lesion in the brain.

Vertebral infection may occur in the course of disseminated infection with coccidioidomycosis.[161] While the thoracic and lumbar spines are commonly involved,[23] occasionally the cervical spine may also be infected.[66] Clinically, the lesions present either acutely with pain and tenderness around the involved vertebra or chronically with sinus formation and paraspinal abscesses. Neurological involvement occurs with bone collapse or compression by epidural abscesses. Radiologically there may be involvement of the body, laminae, transverse processes or contiguous ribs, the intervertebral disc space being relatively spared. Sclerosis occurs as a late response to destructive lesions. Vertebra plana has also been reported.

Diagnosis is by a general examination to look for subcutaneous nodules, erythema nodosum or erythema multiforme. CSF, though being abnormal, is not specific for diagnosis. Serum and CSF antibodies are reliable indicators

of disease activity.[20,161] CT scan may show intense basal enhancement or granulomatous lesions. MRI shows evidence of meningitis, granulomas and hydrocephalus.

Large intracranial lesions require surgical excision. Decompression and stabilisation procedures may be necessary in spinal infection when there is a neurological deficit. Amphotericin B and ketoconazole are recommended drugs for the disease. Amphotericin B lipid complex has been found effective[5] as also itraconazole.[156] Prognosis in disseminated disease is not good. Coccidioidomycosis may be fatal, even without systemic dissemination, due to meningeal involvement.

CANDIDIASIS

Candida albicans is a true yeast and a normal constituent of the human flora. It is the single most common cause of human fungal infection: 27 out of the 57 cases of fungal infections of the CNS studied post-mortem by Carey[23] were due to candidiasis. Most of the Candida infections are due to infection from the oropharynx, skin, intestine and vagina of healthy individuals. In most clinical cases, infection is opportunistic and is found in association with surgical or other trauma, immunosuppression, prolonged antibiotic usage, drug abuse or AIDS. Infection in a previously healthy individual is also known. CNS infection is by haematogenous spread, though occasionally direct spread does occur through the oral cavity, orbit or middle ear following surgery or trauma. CNS involvement occurs in 50% of patients with systemic candidiasis and up to 80% of patients with Candida endocarditis.[59] CNS candidiasis may present as meningitis, a granuloma or as an abscess.[14] In the early stages, the lesions resemble haemorrhagic infarcts. These later develop into abscesses and granulomas without a central focus of necrosis.

Seventy per cent of patients with *Candida meningitis* have an extracranial focus of infection. Chronic meningitis with basal exudates may cause multiple lower cranial nerve palsies and/or hydrocephalus.

Candida granulomas are multiple and are most commonly located at the junction of the grey and white matter.[56] Mycotic aneurysms and abscesses are the other presentations of cerebral candidiasis. Occasionally, a patient with candidial endocarditis may present with a stroke due to embolic phenomena.

Candidiasis of the CNS cannot be identified by skin tests. Meningitis can be diagnosed by lumbar puncture and analysis of the CSF.[135] When mass lesions are suspected, CT or MR scan is the investigation of choice. CT scans in an immunocompromised patient may show areas of low density without enhancement. A high index of suspicion is necessary to diagnose Candida on culture as most often the growths are dismissed as contaminants.

Treatment is by removal of the source of infection at the earliest with control or stabilisation of the underlying debilitating disease. Untreated meningitis has a morbidity of 80%, while cure rates in patients with meningitis are about 90%.[14,59] Candida abscesses have a poor prognosis, death being usually due to multi-system failure. Definitive treatment of active infection is with amphotericin B alone (0.6–1.0 mg/kg daily in four divided doses) or in combination with 5-fluorocytosine (100–150 mg/kg daily in four divided doses). Mass lesions require surgical excision for diagnosis and as definitive treatment. Itraconazole, ketoconazole and nystatin may be used as prophylaxis in susceptible patients.

MUCORMYCOSIS

The clinical spectrum of mucormycosis is produced by several genera of fungi including Rhizopus, Rhizomucor and Absidia. Almost invariably, infection with this group of fungi is associated with some other significant disease like diabetes or with drug addiction.[54] The majority of patients have poorly controlled diabetes mellitus, the predisposing factor in such cases being the acidosis rather than the hyperglycaemia.[31] Renal transplant patients, patients with sepsis or severe dehydration and patients with haematological malignancies are affected.

The organisms spread by direct extension along nerves, blood vessels and cartilage. Entry into the CNS is from adjacent structures such as the paranasal sinuses or the orbit. The rhinocerebral form is the commonest type of penetration and is seen in 80–90% of cases.[1] Brain abscess may develop secondary to the pulmonary focus and is seen in immunocompromised patients. Like aspergillus, these organisms show a strong tendency to involve blood vessels. Mucormycosis should always be thought of while examining inflammatory or necrotic tissue from the orbit or nasal region. Microscopically, polymorphs are seen, clustered mainly around blood vessels. Non-septate hyphae with right angle branching are seen in large numbers around and within the walls of the blood vessels of the brain and meninges. A granuloma with giant cells is seen only rarely.[31]

The classical clinical picture of the rhinocerebral form is a poorly controlled diabetic patient with facial or periorbital pain and nasal discharge. Epistaxis may occur. Examination of the nose may reveal gangrenous changes in the turbinates. Black necrotic lesions may be seen on the hard palate. These are not pathognomonic for mucormycosis, as they may also be seen in Pseudomonas and Aspergillus infections.[56] External ophthalmoplegia and proptosis are common findings, and there may be loss of vision may secondary to central retinal artery occlusion. This finding is important, as vision is usually not lost early in bacterial cavernous sinus thrombosis. Eighty per cent of the patients have meningeal involvement by the time clinical signs become apparent. The fungus advances along the base of the brain and may cause facial nerve palsy. Carotid artery involvement may cause cerebral infarction and focal deficit, which is seen in one-third of the patients. Upwards extension of the infection through the orbital roof may result in a frontal lobe abscess.

A high index of suspicion is needed to diagnose mucormycosis, as isolation rates are very low.[11] Diagnosis is however on histology, as reliable serological tests have not been developed.

Mortality is high in this condition even with early institution of medical therapy with amphotericin B (0.6–1.25 mg/kg daily) as penetration of the drug into infected tissue is likely to be poor because of vascular occlusions and gangrene. With aggressive management, the mortality has been brought down to 15% in some series. The value of hyperbaric oxygen is unproven. Despite advances in surgery and antifungal medication, a mortality of 50–63% has been reported in large series.

PSEUDOALLESCHERIA BOYDII

The fungus *Pseudoallescheria boydii* and its asexual (synanmorphic) form the Scedosporium apiospermum is the causative factor of the Madura foot, a chronic suppurative infection common in the southern parts of India.[107] It is found in the soil, polluted water, sewage and manure. In 1964, a case of brain abscess was described and it is being diagnosed with greater frequency, especially in people who survive near drowning.[2,80,108] Direct entry from trauma, haematogenous spread from the lungs, and from IV cannulas and from infected sinuses and lumbar puncture can affect the CNS. Young adult males are the usual victims. After near drowning, signs and symptoms develop after 15–30 days, and can cause a spectrum of lesions: abscess, ventriculitis and ependymitis. The fungus is resistant to amphotericin and is sensitive to miconazole. It is treated with combination of antifungal drugs (terbinafine, caspofungin and voriconazole).[99]

73 Viral Infections

Ravi Ramamurthi, Ramamurthi B, Ravindranath Kapu

Viral infections of the central nervous system (CNS) are of interest to neurosurgeons, as they may have to treat the acute phase of some infections, help in establishing diagnosis by brain biopsy, or deal with the sequelae of viral infections like persistent pain or intractable epilepsy. The possibility of virus aetiology of CNS tumours is also an area of interest.

Recently, interest in viral infections has been renewed due to many factors: the emergence of HIV/AIDS; the increasing use of immunosuppression; the possibility of an increase in viral diseases due to the prevention of bacterial infections; rapid growth of the basic knowledge of virus biology and of CNS structure and function; improved diagnostic techniques enabling better study of viral infections of the CNS and the development of effective antiviral agents.[41,43]

Viruses are minute particles (virions) measuring 20–300 nm in diameter. They consist of only one type of nucleic acid either DNA or RNA, which is surrounded by a protein unit called capsomere, enveloped in a lipid membrane. Viruses may destroy a cell completely, live in it for many years to get reactivated, stimulate the cell to unrestricted growth or disrupt cell function without causing death of the cell.

The CNS seems especially susceptible to viral infections, due to its lack of capacity for regeneration and its complicated metabolic pattern. The presence of a blood-brain barrier, and a limited immune response, also contribute to this susceptibility. *Neurotrophism* refers to the affinity of a virus for a particular neural cell, and *Neurovirulence* is the ability of the virus to produce neurological disease.

Viruses enter the body through the skin, the gastrointestinal tract or the respiratory system. The spread of viruses in the body occurs through the bloodstream as in enteroviruses and measles and mumps viruses, or through the nerves as in polio, herpes and rabies. Neural spread is via axoplasmic transport through axons to the sensory ganglia. Viral spread along neurons may also occur via the perineural lymphatics or the Schwann cells surrounding the axons. It is the presence of specific viral receptors on the neural cells that makes the specific neurons susceptible. The other factors that determine susceptibility are the state of differentiation and mitotic activity of the neural cells, the density of the neural and supporting cells and the various CNS immune responses to viral infections.[43]

Immune responses induced in the body to viral infections may be humoral and directed against the virus particles, or cell mediated directed against the infected cell during which virus specific cytotoxic lymphocytes are generated. A variety of cytokines and lymphokines, such as interferons that limit viral replication, are also produced. Depressed cell mediated immunity leads to the development of viral diseases like subacute sclerosing panencephalitis (SSPE) due to measles virus, progressive multifocal leucoencephalopathy (PML) due to JC virus and encephalitis due to the herpes simplex virus (HSV) and the varicella zoster virus (VZV).[5,64,73] Depressed cell immunity may also lead to persistent polio or echovirus infections of the CNS.

Viral encephalitis may be produced by both conventional viruses and unconventional viruses.[5] The characteristics of conventional viruses have been described. The unconventional viruses, also called slow viruses or prions, contain protease resistant proteins, but neither DNA nor RNA.

Our understanding of viral diseases has been advanced considerably by recently developed technologies like improved methods of serological diagnosis, molecular diagnostic methods and neuroimaging techniques like MR and SPECT. Polymerase chain reaction (PCR) is considered the first line investigation for viral meningitis and encephalitis as a patient with a positive PCR result is 88 times as likely to have a definite diagnosis of viral infection of the CNS as a patient with a negative result.[40] Nucleic acid amplification methods have improved the detection of common (HSV, Enterovirus and VZV) and uncommon viral pathogens. The advantages are that the results of these tests are available more quickly and are more sensitive than viral cultures. Other viral causes of meningoencephalitis, such as arboviruses (including West Nile), can be identified by detection of IgM and IgG antibodies in CSF.[58,86]

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex encephalitis (HSE) virus is the most common cause of viral encephalitis.[92] These viruses are of two types (HSV-1 and HSV-2) which, although morphologically identical, are composed of two antigenetically different viral agents.[60,65] Type I spreads through the oral route and Type II through genital contamination. HSE occurs in about one person per million per year[85] and

may occur at all ages and in both sexes. HSV-1 induces apoptosis (programmed cell death, or "cellular suicide") in neuronal cells, and it causes virtually all cases of HSE in immunocompetent older children and adults.[2,17] It can also cause sporadic necrotising encephalitis in adults.[74] The definition of intractable cases of HSE was developed as follows:[39]

- Cases of HSE that develop to an apallic state and lead to fatality
- Prolonged cases that require more than 6 months' hospitalisation
- Recurrent cases.

Maximum involvement is seen in the temporal and inferior frontal lobes. Oedema and haemorrhages are the prominent features. Lymphocytic infiltration, perivascular cuffing, necrosis and intranuclear inclusion bodies are also seen. The progression of symptoms simulates a tumour and uncal herniation can occur.

Following oral sores (cold sores), the patient develops headache, fever, disturbed consciousness with personality changes and seizures. Seizures may be the presenting feature in 50% of patients with HSE due to involvement of the highly epileptogenic frontotemporal cortex. The occurrence of seizures denotes a poor prognosis.[62] These viruses are also associated with Alzheimer's disease by interacting with the components and receptors of lipoproteins.[19,59]

CSF shows lymphocytosis and the EEG is pathognomonic with periodic high voltage discharges confined to the temporal region.[70] The diagnostic gold standard is the detection of HSV DNA in the cerebrospinal fluid by PCR. The HSV PCR has been noted to have a high sensitivity, around 96–98%. In cases with negative results but high clinical suspicion, the test should be repeated after 3–7 days, as the detection of virus may be difficult in the first few days of illness.[86] HSV-1 DNA may be recovered from the trigeminal ganglion in as many as 50% of ganglia sampled at autopsy.[69] Computed tomography (CT) and MRI show oedema and haemorrhages in the frontotemporal regions.

Brain biopsy from the temporal region with isolation of the virus was for many years a diagnostic measure. With immunofluorescence and electron microscopy, the diagnosis from the biopsy material can be confirmed within a few hours in the majority of cases.[76]

Adenine arabinoside (ara-A) was used as the specific treatment for a long time. Presently acyclovir is the drug of choice. Acyclovir is administered in a dose of 30 mg/kg body weight divided into three daily doses mixed with 100 ml of IV fluids and given over a 1 hour period.[12] The prompt response to early administration of acyclovir in suspected cases is diagnostic and has mostly eliminated the need for brain biopsy. Newer medication, like valacyclovir which provides a high bioavailability of acyclovir 3-fold to 5-fold higher than that obtained with oral acyclovir, is also in use.[80] When symptoms of raised intracranial pressure are present, hyperventilation and diuretics are indicated. If medical measures fail, temporal lobectomy should be done to relieve raised ICP.

Neonatal HSE is caused by HSV II. The infection is acquired by the infant during delivery. The mortality is high. When the mother has genital herpes, it is recommended that caesarean section is performed before the rupture of the membranes to prevent the child from acquiring the infection.

HERPES ZOSTER (VARICELLA ZOSTER)

Varicella (chickenpox) virus may cause meningoencephalitis, transverse myelitis, Guillain-Barré syndrome (GBS), Reye's syndrome or acute cerebellar ataxia. Recovery from meningoencephalitis and ataxia without residual defect is common.[68] Reye's syndrome and GBS may occur in association with other viral infections also. This virus can also cause vasculopathies which can lead to ischaemic infarction of the brain and spinal cord, as well as aneurysm formation, subarachnoid and cerebral haemorrhage, carotid dissection and, rarely, peripheral arterial disease.[32]

Herpes zoster is a late manifestation of varicella infection, and is often a reactivation of latent viral infection of the posterior root ganglion. Other areas where this virus can become latent are the nerve cell bodies, and also in the non-neuronal satellite cells of the cranial nerves or autonomic ganglia.[42] It is more common in the elderly and may affect the trigeminal, the geniculate or the dorsal root ganglion. Motor complications, like facial palsy or localised wasting of muscles, may occur in about 5% of cases. Facial nerve involvement in cephalic herpes zoster occurs in about 12% of patients, causing the Ramsay Hunt syndrome.[1] HSV can cause herpes zoster associated cerebral angiitis.[33] These can be seen as ovoid, round lesions at the grey-white matter junction on imaging.[86] Acyclovir is effective in treating herpes zoster and is helpful in reducing pain. This is given in a dosage of 10 mg/kg every 8 hours for 10–14 days.[23,86] Post-herpetic neuralgia may be a distressing phenomenon requiring treatment. Newer drugs, like valacyclovir and famciclovir, are considered to have similar or even superior efficacy and good safety and tolerability.[87]

RAMSAY HUNT SYNDROME

Also known as herpes zoster oticus, geniculate neuralgia or herpes zoster auricularis, it involves the facial and auditory nerves which accounts for 12% of all cases of facial nerve palsy.[63] It is the second most common cause of atraumatic peripheral facial nerve paralysis.[57] Vesicular eruptions may manifest on the pinna, tragus, in the auditory canal and on the tympanic membrane, as well as anywhere in the facial nerve distribution (Figs 1 to 3). The presenting complaints are hearing impairment, nystagmus, vertigo, facial nerve palsy (mimicking Bell's palsy) and loss of taste sensation in the anterior two-thirds of the tongue. The site of the lesion causing vestibular symptoms in RHS could be in the labyrinth, and/or in the superior and inferior vestibular nerve.[66]

Fig. 1: Clinical photograph of patient showing vesicular rash on right ear pinna, facial nerve palsy and varicelliform rash on the face and trunk [Source: Meher R, Varshney S, Gupta P, et al. Herpes Zoster Oticus with Ménière's syndrome complex. The Internet Journal of Otorhinolaryngology. 2006;(4):2]

Compared with Bell's palsy, patients with zoster oticus often have more severe paralysis at onset and are less likely to recover completely.[57] Petrositis with multiple cranial nerve palsies is also seen in RHS.[25] At times there can be isolated CN VIII paresis without involvement of the facial nerve.[52] Magliulo et al. have described post-operative reactivation of RHS in a patient operated upon for acoustic neuroma.[54] Bilateral Ramsay Hunt syndrome has also been reported in diabetic patients and these patients should be treated with appropriate metabolic control, NSAIDs and intravenous acyclovir, which should be started at the earliest.[83]

Varicella zoster virus DNA level in saliva helps in understanding the kinetics of the viral reactivation in the facial nerve, as well as in the oropharyngeal epithelium, in patients with Ramsay Hunt syndrome.[29] This virus can be diagnosed using real time PCR in cerebral spinal fluid analysis.[30]

Brainstem auditory evoked response shows a significant increase in latencies of waves II and V and interpeak latencies of I-III, I-V suggesting cochlear or retrocochlear involvement or involvement at more than one site along the auditory pathway in Ramsay Hunt syndrome. Pure cochlear hearing loss is not common.[93]

MRI study of the brain shows enhancement of the facial nerves, along with the extent of intratemporal lesions of the facial nerve, especially in the labyrinthine segment[44] (Figs 4 and 5). 3D-FLAIR could be a useful diagnostic tool in the early stages of Ramsay Hunt syndrome which shows high signals in the cochlear and vestibular apparatus which is due to high protein content which is not detected by T1-weighted and T2-weighted MRI.[81]

Acyclovir and steroid therapy is an advisable treatment modality to improve the recovery rate of facial nerve function in Ramsay Hunt syndrome.[45]

REYE'S SYNDROME

This is of neurosurgical interest due to the cerebral oedema and high intracranial pressure seen in the condition. The syndrome was described in 1963. The administration of aspirin during a viral illness in children has been identified as a probable cause of this syndrome.[35] Some children who are recovering from viral infections may become ill with headache, vomiting, confusion and restlessness due to acute cerebral oedema and hepatic failure due to fatty infiltration of the liver. Serum ammonia levels are elevated and sugar levels are low.[35] Urgent treatment with hyperventilation, diuretics like mannitol or furosemide, and control of hypoglycaemia is indicted. The mortality rate is high.

CREUTZFELDT-JAKOB DISEASE

Creutzfeldt-Jakob disease (CJD) is caused by slow viruses or prions that cause Kuru. The neurosurgical interest is brain biopsy to establish the diagnosis. Extreme care is needed during such a procedure to prevent transmission of the disease to other patients and to the surgeons. The other human disease caused by slow viruses is Gerstmann-Straussler syndrome. CJD presents as a subacute dementia, evolving over weeks to several months and is accompanied by pyramidal, extrapyramidal and cerebellar signs. The iatrogenic route is the only route of transmission (contaminated surgical instruments such as EEG electrodes, organ transplants such as cornea transplants and growth hormone prepared from human pituitaries). Mad cow disease caused by consumption of infected beef is a variant of CJD which acquired epidemic proportion in the UK.

POLYOMA VIRUS

These viruses cause progressive multifocal leucoencephalopathy (PML). Although rare, it causes a fatal brain disease. They are also associated with novel neurological disorders such as granule cell neuronopathy and virus encephalopathy, and also cause meningitis. Other diseases caused by these viruses are the immune reconstitution inflammatory syndrome (IRIS).[84]

RABIES VIRUS

This belongs to the Lyassavirus group of the Rhabdoviridae. It contains a single stranded RNA with a helical symmetry. Six to seven nanometres spike projections are present on the envelope and on electron microscopy it has a characteristic bullet-shaped appearance; the virion measures 130–240 x 80 nm. The commonest mode of transmission in man is by the bite of a rabid animal or the contamination of scratch wounds by virus infected saliva. Other modes of transmission are mucous membranes of the mouth, conjunctiva, anus and genitalia, aerosol transmission and infected corneas.

Following inoculation, the virus replicates in the striated or connective tissue at the site of inoculation and enters the peripheral nerves through the neuromuscular junction spreading to the CNS in the endoneurium of the Schwann cells. Finally, there is widespread CNS involvement with the neurons infected with the virus showing structural abnormalities.

Within 2–3 weeks of the rabid dog bite the patient suffers with flu-like symptoms. Soon after, the symptoms expand to slight or partial paralysis, cerebral dysfunction, anxiety, insomnia, confusion, agitation, abnormal behaviour, paranoia, terror and hallucinations, progressing to delirium.[13] These symptoms progress to hydrophobia, brain damage and finally death.

The method for diagnosing rabies is by performing PCR or viral culture on brain samples taken after death. The diagnosis can also reliably be made from skin samples taken before death.[14] Inclusion bodies called Negri bodies are 100% diagnostic for rabies infection, but are found in only about 80% of cases in the saliva and CSF.[20]

One dose of *human rabies immunoglobulin* (HRIG) and four doses of rabies vaccine over a 14-day period should be administered following a bite by a suspected rabid animal. As much as possible of this dose should be infiltrated around the bites, with the remainder being given by deep intramuscular injection at a site distant from the vaccination site.[71]

ENTEROVIRUS CENTRAL NERVOUS SYSTEM INFECTIONS

Approximately 26% of adult aseptic meningitis cases for which an aetiological agent is identified are caused by enteroviruses.[49] These cause hand, foot and mouth disease in association with brainstem encephalitis.[96]

PCR of CSF has proven to be a sensitive test with great cost-saving capabilities, as the patients with positive PCR tests tend to have shorter hospital stays, fewer tests performed and receive IV antibiotics for less time.[4] MR imaging shows hyperintensities in T2-weighted images in the brainstem and spinal cord. The major CNS lesions are in the medulla oblongata, pons, midbrain and the dentate nuclei of the cerebellum. Other lesions are seen in the spinal cord, thalamus and putamen.[77] Pleconaril is an effective drug along with adjuvant corticosteroids.

H1N1 VIRUS

A new pandemic arose in the United States in April, 2009 which was swine-origin influenza A (H1N1) virus. The H1N1 virus usually causes febrile respiratory symptoms including fever, cough, sore throat, etc.[16] These symptoms are usually self-limiting, but they can cause neurological symptoms like seizures and altered sensorium with abnormal electroencephalograms.

The findings on MRI in brainstem encephalitis include pontine enlargement and increased signal lesions in the pons. MRI is superior to CT for detecting brainstem encephalitis.[15,28] Oseltamivir and rimantadine are useful in therapy.[8]

EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV) causes aseptic meningitis, encephalo-myelo-neuritis and neuritis. The EBV neuropathies present with ophthalmoplegia, lumbosacral plexopathy, and sensory or autonomic neuropathy. The association of the virus with neurological disease was suggested by a positive serum heterophile antibody titer, and later by the presence of EBV DNA, antibody or both in CSF.[3] CSF from patients with EBV infection of the nervous system contains mainly EBV-specific CD8+ T cells, a few CD4+ T cells and no CD19+ B cells.[51]

EBV infects B and T lymphocytes of more than 90% of the general population before adulthood. Primary infection results in transient viraemia, followed by a rapid immune response. EBV replicates in the oropharynx and is transmitted through oral secretions. It is estimated that neurological complications occur in 1–5% of individuals with infectious mononucleosis. Virtually all CNS lymphomas in AIDS patients contain EBV DNA.[53] These also cause infectious mononucleosis, nasopharyngeal carcinoma, Burkitt's lymphoma, Hodgkin's disease and lymphoproliferative disease in immunocompromised individuals.[11]

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) produces neurological disease predominantly in infants with congenital infection. Neurological complications include microcephaly, seizures, hypotonia, acute brachial plexopathy and spasticity. In immunocompetent adults, the most common neurological complication of CMV infection is Guillain-Barré syndrome.[21] CMV polyradiculopathy in patients with AIDS begins insidiously as a cauda equina syndrome with paraesthesias and distal weakness (usually asymmetric), incontinence, and sacral-distribution sensory loss.[24] CSF might show neutrophilic or mononuclear pleocytosis, or an elevated protein and depressed glucose content. Imaging studies (MRI) show enhancement in the ventricular ependymal and focal disease has been attributed to CMV vasculitis or demyelination. Characteristic owl-eyed cytomegalic inclusions and CMV-specific antigens have been found in brain tissue and blood vessels of AIDS patients with subacute encephalopathy.

An international panel that developed guidelines for treatment of CMV diseases in adults with AIDS receiving highly active antiretroviral therapy recommended treatment with intravenous ganciclovir, intravenous foscarnet, or a combination of the two drugs.[91]

HUMAN HERPES VIRUS 6

Human herpes virus 6 (HHV-6) causes Roseola. This virus causes neurological complications primarily after bone marrow or stem cell transplantation,[95] presenting as limbic encephalitis.[89]

Diagnosis is confirmed by detection of HHV-6 DNA in the CSF. RT-PCR (98%) is more specific than PCR (84%) in diagnosing active infections. As HHV-6 becomes latent in cells of the monocyte-macrophage lineage,[46] the detection of HHV-6 DNA and antigen in brain tissue is likely to reflect HHV-6 reactivation from latency in blood mononuclear cells trafficking through the brain in patients with inflammatory CNS disease. CD46 is a HHV-6 receptor that is expressed mostly in macrophages and cells lining blood vessels, and less often in cells of neuronal origin. HHV-6 expresses proinflammatory cytokines that are cytotoxic to oligodendrocytes and induce caspase-independent apoptosis.[46] HHV-6 has also been shown to inhibit G1–S-phase transition in glial precursor cells, which are important in remyelination.[18] Treatment includes ganciclovir, foscarnet or both. Real-time fluorescent probe CSF PCR has been used to follow the effects of antiviral therapy on HHV-6 DNA levels in the CSF.[94]

JAPANESE ENCEPHALITIS

This is caused by Flavi virus. It is the most common vaccine-preventable cause of encephalitis in Asia.[26,36] Among the affected individuals 20–30% of patients die, and 30–50% of survivors have neurological or psychiatric sequelae.[38,67]

After an incubation period of 5–15 days, symptoms develop. These include fever, headache and other non-specific symptoms. The classical description of JE includes a Parkinsonian syndrome with mask-like facies, tremor, cog wheel rigidity and choreoathetoid movements.[61,79] Seizures are common, especially among children.[47,48,61,72,75,78] Status epilepticus, brain hypoxia, increased intracranial pressure, brainstem herniation and aspiration pneumonia are the most common complications associated with poor outcome and death.[37,47,78,79]

Microglial activation following JEV infection has been found to influence the outcome of viral pathogenesis. Activated microglia secrete cytokines, such as interleukin-1 (IL-1) and tumour necrosis factor alpha (TNF-α), which can cause toxic effects in the brain. Other soluble factors, such as neurotoxins, excitatory neurotransmitters, prostaglandin, reactive oxygen and nitrogen species, are secreted by activated microglia. In JE, the tight regulation of microglial activation appears to be disturbed, resulting in an autotoxic loop of microglial activation that possibly leads to bystander neuronal damage.[31]

MRI of the brain is better than CT for detecting JEV associated abnormalities such as changes in the thalamus, basal ganglia, midbrain, pons and medulla.[61,90] Thalamic lesions are the most commonly described abnormality; although these can be highly specific for JE in the appropriate clinical context, they are not a very sensitive marker of JE.[22]

JEV infections are confirmed most frequently by detection of virus-specific antibody in CSF or serum. Acute-phase specimens should be tested for JEV-specific immunoglobulin M (IgM) antibodies using a capture enzyme-linked immunosorbent assay (MAC ELISA).[6,7,10,55,56,88] More recent studies have shown the utility of nucleic acid amplification tests (NAAT) for diagnosing JE in some patients with encephalitis or aseptic meningitis, but this method still lacks the sensitivity needed for routine diagnosis.[50,82] JEV-specific IgM antibodies can be measured in the CSF of most patients by 4 days after onset of symptoms and in serum by 7 days after onset.[7,10]

No specific antiviral agent or other medication to mitigate the effects of JEV infection is available.[34] An inactivated mouse brain-derived JE vaccine (JE-MB) has been available since 1992 for use in travellers aged greater than or equal to 1 year. Three doses are administered subcutaneously on days 0, 7 and 30 through the subcutaneous route.[9] In March 2009, the Food and Drug Administration (FDA) approved a new inactivated Vero cell culture-derived JE vaccine (JE-VC) for use in persons aged greater than or equal to 17 years.[27] This is given in two doses of 0.5 ml each by the intramuscular route administered 28 days apart.

74 AIDS and the Neurosurgeon

Sarat Chandra P, Vivek Tandon

HISTORICAL PERSPECTIVE

It was in the early 1980s that a number of gay men in New York and California suddenly began to develop rare cancers and opportunistic infections. The cause for it soon became obvious that they were suffering from a common syndrome which was later named as the acquired immunodeficiency syndrome (AIDS). In 1981,[4] the discovery of human immunodeficiency virus I (HIV I) was made by Barre'-Sinoussi, Montagnier and colleagues.[2] Subsequently, a second virus has been isolated from Western Africa and has been named HIV II.

THE VIRUS

HIV is a type of RNA virus, known as lentivirus[2] which is sub-grouped under the Retroviruses, and attacks the immune system. Lentivirus means 'slow virus' because it takes long to produce symptoms in a patient. HIV virion is icosahedral in shape. The envelope contains two major proteins (gp 120 and gp 41) which form external spikes and it has nine genes. Three genes (gag, pol and env) are needed to make the structural proteins for the new virus particles. HIV is a zoonotic infection, similar viruses have been found in a number of different animals, including sheep, horses and cattle. It is now generally accepted that the lentiviruses are descendants of Simian immunodeficiency virus, which affects Monkeys.[1,5,14]

HIV virus has been found in the body fluids like semen, cervical secretions, plasma, CSF, tears, saliva, urine and breast milk. The concentration of virus in these fluids varies considerably and the most infectious are semen, cervical secretions and blood. The most common modes of transmission are by intimate sexual contact, (anal, vaginal or oral),[32] transfusion of infected blood products, use of contaminated needles, and from mother to child *in utero* or at birth.

Receptive anal intercourse has a strong association with HIV because only thin rectal mucosa separates the semen from the susceptible cells and trauma may be associated with it, leading to direct inoculation into the blood. Occupational risk of acquiring HIV in health and related field workers is around 0.3% with a needle prick, which was contaminated with blood from a HIV positive person.

PATHOGENESIS

Once the virus has gained entry into the body of the host, it attaches to a special glycoprotein called CD4 present on the helper/inducer T cells. This allows the viral envelope to fuse with the cell membrane, and contents of the HIV particle enter the cell. Inside the cell the viral enzyme, reverse transcriptase, converts viral RNA into DNA, which attaches to the human DNA by the HIV enzyme integrase. This provirus may lie dormant for a long time but, on activation of the cell, the HIV gene is converted into messenger RNA using the human enzymes and it is transported outside the nucleus, where it is used as a blueprint for producing new HIV enzymes and proteins. These together form new viral particles which are released from the cells and infect new cells, starting the cycle again. CD4 helper T cells are important for a strong immunological response against foreign antigens. They secrete interleukin 2, interferon, and B cell growth and differentiating factors. They also help in activating CD8 T cells, B cells and macrophages. The defects in immunity are not only explained by the quantitative abnormalities of the lymphocytes, but also by the qualitative defects of the CD4 responsiveness caused by HIV. The defect in the B cells leads to generalised hypergammaglobulinaemia and can depress B cell responsiveness to new antigens. Therefore, the immunodeficiency of HIV is mixed where both humoral and cellular immunity are affected.

The virus directly causes a variety of neurologic effects, mostly due to release of cytokines and other neurotoxins by the infected macrophages and microglia. HIV mediated effects on neurons and oligodendrocytes are felt to involve indirect pathways where viral proteins, like gp120 and Tat, trigger the release of neurotoxins from the macrophages and also from the astrocytes. Impairment of excitatory neurotransmitters and calcium flux are also implicated for neurological deterioration.

CLINICAL FEATURES[7,19,25,35,37,44]

The complications of HIV related infections and neoplasms affect virtually every organ system. This varied clinical spectrum of illness ranges from an acute seroconversion illness to a chronic asymptomatic carrier to full blown AIDS. The acute HIV syndrome is seen in 50–70% of individuals infected with HIV, approximately

3–6 weeks after the primary infection. The typical symptoms are fever, pharyngitis, lymphadenopathy, headache, retro-orbital pain, arthralgias, myalgias, lethargy, malaise, anorexia and nausea. Neurological features may include meningitis, encephalitis, peripheral neuropathy,[34] myelopathy, dermatological rash and mucocutaneous ulceration. These symptoms occur with an initial burst of plasma viraemia. Symptoms can persist for one to several weeks and gradually subside, with development of the immune response. In most patients, the primary infection with or without this syndrome is followed by a period of prolonged latency. The median time for untreated patients is around 10 years, from the initial infection to the development of clinical disease. HIV disease with active replication continues during this latent asymptomatic period and this progression directly correlates with the HIV RNA levels. The hallmark of progressive disease is declining number of CD4 lymphocytes and a low CD4/CD8 ratio. Patients with positive HIV serology and who have ever had a CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14% are considered to have AIDS, because the resulting state of immunodeficiency with such low levels of CD4+ T cells count is severe enough to predispose the individual to opportunistic infections and neoplasms and hence for clinically apparent disease.

When symptoms of HIV occur they are remarkably non-specific and may be seen with other diseases as well. Physical examination may entirely be normal and abnormal findings range from completely non-specific findings of generalised lymphadenopathy to highly specific findings of hairy leukoplakia of the tongue, Kaposi's sarcoma and cutaneous bacillary angiomatosis. Systemic complaints include fever, weight loss and night sweats. Weight loss involves disproportionate loss of the muscle mass and is attributed to multiple factors like anorexia, nausea, vomiting, malabsorption, recurrent diarrhoea and increased metabolism due to fever.

Pulmonary diseases, like *Pneumocystis pneumoniae*, are one of the most common opportunistic infections associated with AIDS; other infections include bacterial, mycobacterial and viral pneumonias. Apical infiltrates and disseminated disease associated with mycobacteria are more common in AIDS patients when compared with immunocompetent persons. The 'anergy' skin tests like Mantoux are not accurate in classifying these patients. Multidrug resistant tuberculosis in this subset of the population is increasing. Other lung diseases associated with HIV are Kaposi's sarcoma, non-Hodgkin's lymphoma and interstitial pneumonitis.

Gastrointestinal manifestations include oral candidiasis or hairy leukoplakia which is caused by Epstein Barr virus, angular cheilitis, recurrent aphthous ulcers, candidial oesophagitis, hepatic disease due to infections (mycobacteria, CMV, hepatitis B/C) and neoplasms like lymphomas, acalculous cholecystitis, enterocolitis and malabsorption syndrome.

Endocrine dysfunctions are hypogonadism in men and thyroid function abnormalities.

Skin manifestations include viral infections (herpes simplex, herpes zoster, molluscum contagiosum from poxvirus), bacterial infections (Staphylococcal boils, furuncles, impetigo; bacillary angiomatosis due to *Bartonella hensalae* and *Bartonella quintana*) seborrhoeic dermatitis, xerosis, psoriasis and skin malignancies.

HIV related malignancies include Kaposi's sarcoma, Non-Hodgkin's lymphoma, primary CNS lymphoma (PCNSL) and invasive cervical carcinoma.

NEUROLOGICAL MANIFESTATIONS OF ACQUIRED IMMUNODEFICIENCY SYNDROME

With the ever increasing number of cases of AIDS in the developing countries the problem of HIV infected patients seeking neurosurgical consultations is increasing. It is believed that 40–60% of all patients with acquired immunodeficiency syndrome will develop neurological symptoms with one-third of these presenting initially with their neurological complaint.[26,30,31,36,39,42,43] Only 5% of patients dying of AIDS have a normal brain on autopsy. The CNS complications of AIDS as shown by the study of Levy et al.[30] and Shankar et al.[39] are summarised in Table 1.

It can be seen from Table 1 that, in the Indian setting, the incidence of cryptococcal and (especially) tubercular infections is much higher as compared to the Western literature. Likewise the incidence of PCNSLs has also been quoted to be much less.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary CNS lymphoma is a primary intracranial tumour occurring commonly in patients who are immune suppressed and typically in AIDS. However, its incidence has been quoted to be very low.[39,45] More than 90% are associated with Epstein Barr virus infection[13] and 20% of all cases of lymphomas in AIDS are due to PCNSL; these are seen to occur in 10% cases of AIDS.[27] Mean CD4+ count at the time of diagnosis is around 50/μL; thus due to severe immune suppression the prognosis is poor. In the immune competent population PCNSL occurs in the later age group, i.e. 50–60 years, median age being 54 years[33,36] (in immune compromised patients median age at diagnosis is 34 years). There is an increasing trend in incidence of PCNSL in the immune competent population.

Most PCNSLs are diffuse large B cell Non-Hodgkin lymphomas and they occur more commonly in the frontal lobes, deep nuclei and periventricular region in the supratentorial compartment, while in the infratentorial compartment the commonest location is the cere bellum.[21,33,38,41] They present with seizures, headache, cranial nerve deficits, altered sensorium and features of mass effect, associated with systemic features of fever, night sweats or weight loss.[21]

Table 1: CNS complications of AIDS (320 patients)[30] (clinical: 588; autopsy: 134)[39,45]

Complication	*Levy et al. (%); clinical*	*Chandra PS et al. (%); clinical*	*Shankar et al. (%); autopsy*	*Wadia et al. (%); clinical*
Viral syndrome				
Sub-acute encephalitis	17			
Atypical aseptic meningitis	6.5			
Herpes-simplex encephalitis	2.8			
Progressive multifocal leukoencephalopathy	1.9			
Viral myelitis	0.93			
Varicella zoster encephalitis	0.31			
Non-viral infections				
Toxoplasma gondii	> 32	12	20	
Cryptococcus neoformans	13	25	30	67
Candida albicans	1.9			
Coccidioidomycosis	0.31			
Treponema pallidum	0.62			
Atypical mycobacteria	1.9			
Mycobacterium tuberculosis	0.31	30	20	19
Aspergillus fumigatus	0.31			
Bacteria (*E. coli*)	0.31			
Neoplasms				
Primary CNS lymphoma	4.7	uncommon	uncommon	uncommon
Systemic lymphoma with CNS involvement	3.8			
Kaposi's sarcoma	0.93			
CVA				
Infarct	1.6			
Intracerebral haemorrhage	1.2			
Miscellaneous/Unknown	7.8			

Imaging (MRI) shows multiple ring enhancing lesions (one to three), usually in the deep white matter (Figs 1A to H). They usually present with multiple ring enhancing lesions with mild mass effect and oedema on CT. On MRI, unlike non-AIDS cases where homogeneous enhancement of contrast is seen, these patients have target lesions on T2-weighted images (hypointense centre with surrounding hyperintensity). Higher incidence of multicentric lesions is seen in AIDS patients compared to non-AIDS cases of PCNSL.

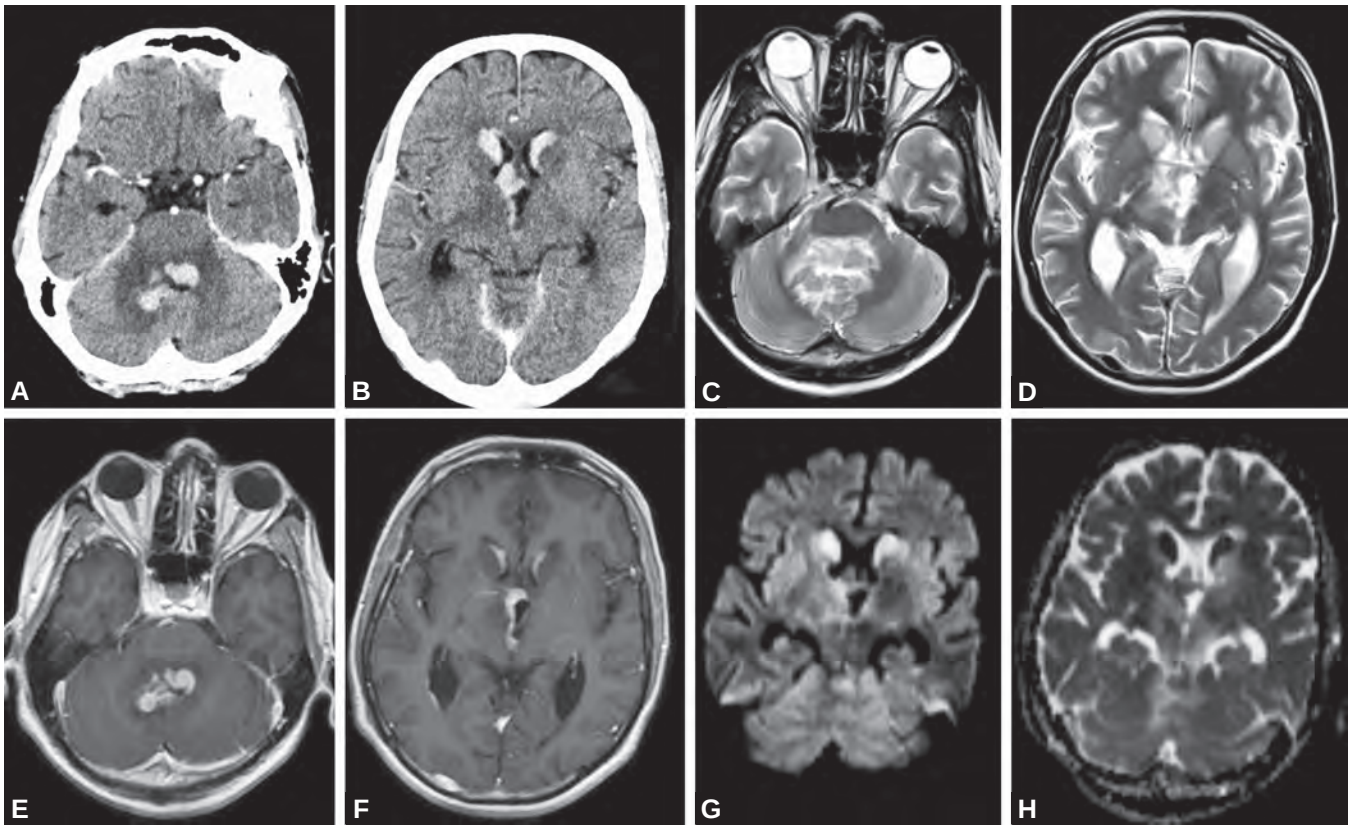
Differentiation with toxoplasmosis may be difficult needing confirmatory brain biopsy in solitary lesions or when trial toxoplasmosis therapy has failed. Surgical decompression does not alter the prognosis and the role of surgery is usually limited to biopsy, for which stereotactic techniques are commonly used as the lesions are often deep seated.

The treatment of choice, once the diagnosis is confirmed by biopsy, is whole brain radiation therapy, a total of 40–50 Gy given in 1.8–3 Gy daily fractions along with corticosteroids. This produces partial response in more than 90% of the patients. Median survival for patients with AIDS is less in comparison to the immune competent patients where it is 10–18 months. Survival advantage is seen with the addition of intraventricular methotrexate and IV folinic acid (leucovorin),[9] but in patients older than 60 years radiation is not recommended in conjunction with methotrexate due to increased risk of leukoencephalopathy and dementia. In patients with AIDS the highly active anti-retroviral therapy which affects the CD4+ count is also important for the final prognosis. In AIDS, the median survival is 3–5 months only.[9,10]

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

It is usually a fatal viral disease caused by a polyomavirus called "JC virus". The antibodies for JCV are present in 60–80% of adults, but usually remain latent[11] and cause PML specifically in patients who are immunocompromised, e.g. AIDS, allograft recipients,[11] patients receiving chemotherapy, drugs (like natalizumab and infliximab[29]), chronic steroid therapy and autoimmune disorders (like SLE). It is believed that PML occurs more commonly in HIV infection in comparison to any other immune suppressive condition because HIV infection of the brain makes JCV more active in the brain.[11] There has been an extremely low incidence of PML in India, and this may be due to some factors such as viral strain differences as well as HIV and JC virus interactions.[40]

PML is characterised by progressive damage or inflammation of the white matter of the brain at multiple locations. Focal myelin loss occurs with sparing of the axon cylinders, causing impairment in transmission of the nerve impulses. These are surrounded by the enlarged astrocytes and abnormal oligodendroglia with eosinophilic inclusion bodies. Symptoms include



Figs 1A to H: Primary CNS lymphoma. (A and B) Contrast enhanced CT scan images show (A) Periventricular homogeneously enhancing lesions in the dorsal pons. (B) Around the third ventricle and frontal horns of lateral ventricles. (C and D) The lesions are isointense on T2-weighted images with surrounding oedema. (E and F) On post-gadolinium T1-weighted images, homogeneous enhancement is seen within the lesions and around the right occipital horn. On diffusion-weighted images, the lesions are (G) Bright on diffusion trace image. (H) Dark on ADC maps suggesting restricted diffusion

cognitive impairment, blindness, cranial nerve or motor weakness, sensory deficit and ultimately coma. PML is like other demyelinating diseases but, since oligodendrocytes, which are myelin producing cells are destroyed, it progresses more rapidly and leads to death within a few months. The median survival with PML in patients with AIDS is 6 months, but longer survival is also seen. Confirmatory diagnosis of PML is made by testing for JC virus in CSF or in brain biopsy.

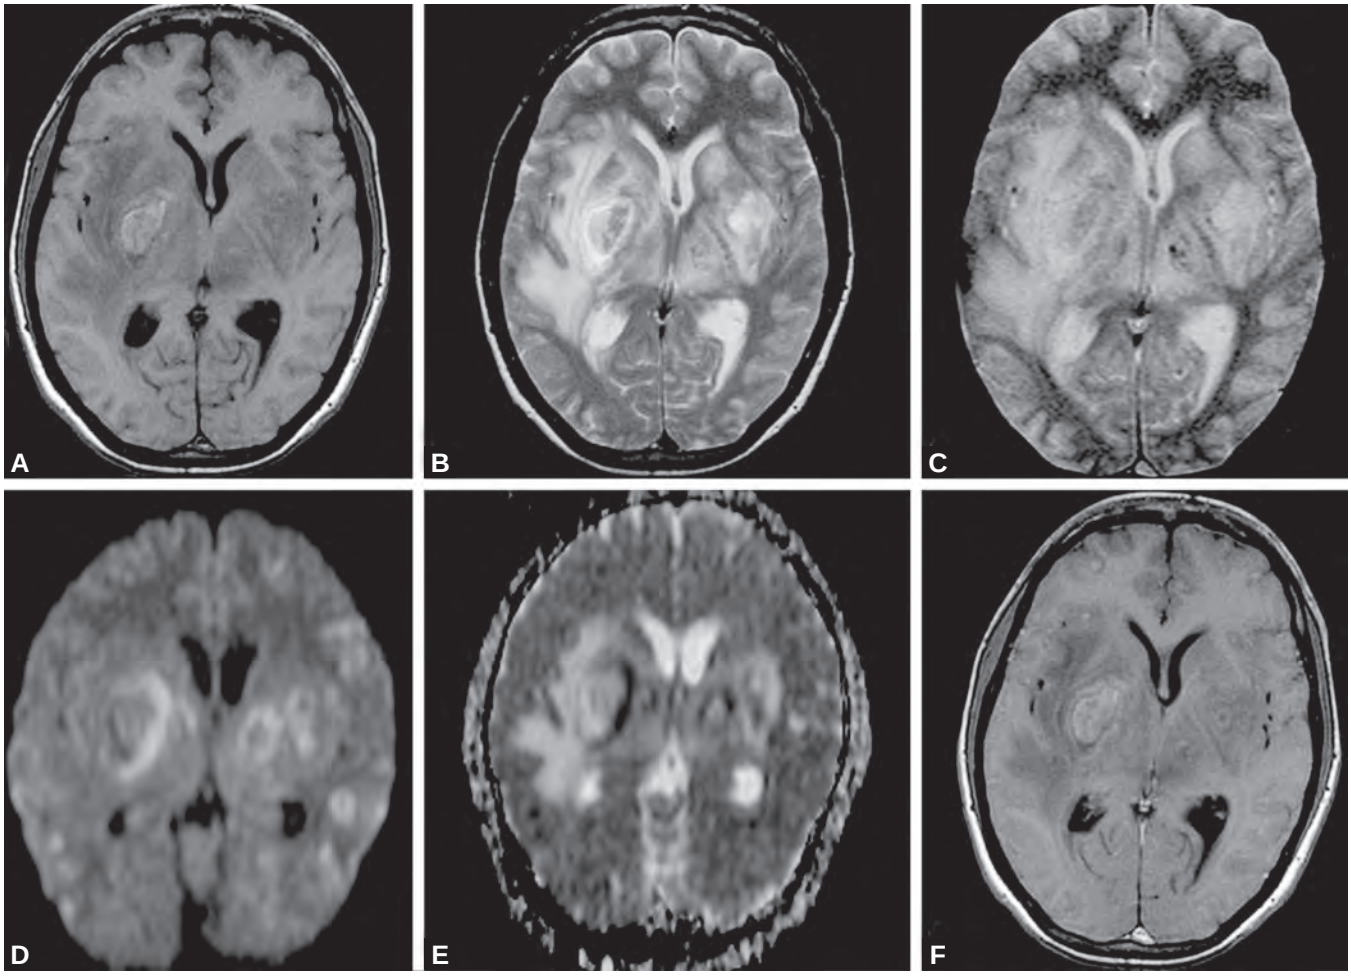
CT scan shows areas of diffuse low density and MRI shows high intensity areas on T2-weighted images. The virus attacks the oligodendrocytes and hence there is progressive involvement of the white matter. Contrast enhancement is absent because there is absence of inflammatory response. Extensive white matter high signal on T2 weighted/FLAIR (fluid attenuated inversion recovery) is therefore the hallmark of this disease with sparing of the cortical grey matter.[11]

No enhancement on contrast, no mass effect, no oedema and more ill defined borders help in distinguishing it from toxoplasmosis. The lesion may be solitary in 36% of CT and 13% of MRI scans.

No treatment is effective, although some promise has been shown with the use of antiretroviral therapy initially, as the immunity improves.[12] However, patients on highly active antiretroviral therapy (HAART) can develop a rare fatal complication of immune reconstitution syndrome which increases the damage caused by the infection.

TOXOPLASMOSIS

It is the most common cause of a space occupying lesion of the CNS in patients with HIV.[39,45] Patients present with headache, focal neurological deficits, seizures and cognitive deficits. Imaging studies show typical peripheral contrast enhancing lesions which have a predilection for the basal ganglia (Figs 2A to F). The major differential diagnosis may be lymphoma and distinction between the two may be impossible in some cases. Features that favour toxoplasmosis are basal ganglia involvement, variable contrast enhancement, ring enhancement and micro haemorrhages. AIDS related lymphoma, in contrast to classical lymphoma, can also be cortical and tends to involve the grey and white matter, is associated with leptomeningeal thickening and is occasionally subependymal or wholly intraventricular. For a single lesion on MRI, an empiric trial of toxoplasmosis therapy may be instituted and MRI is repeated after 2 weeks. If the lesion has not decreased in size, then biopsy of the lesion is indicated to confirm the diagnosis. Toxoplasmal infection can also cause meningoencephalitis and encephalopathy.[39] This usually occurs when CD4 titres fall below 200/mcL.



Figs 2A to F: Cerebral toxoplasmosis. (A) Axial T1-weighted image and (B) Axial T2-weighted image showing multiple ring lesions in bilateral basal gaglion and subcortical white matter. The core of the lesions is (C) Hyperintense on T1-weighted image and (D) Hypointense on T2-gradient image suggesting bleed within the lesions. On diffusion-weighted images, the lesions have (D) Incomplete peripheral hyperintense rim on DWI and dark rim on ADC maps suggesting peripheral diffuse restriction. (E and F) On gadolinium administration, faint enhancement is seen within the lesions, especially subcortical lesions. (*Courtesy*: Dr Ajay Garg, Assistant Professor, Dept of Neuroradiology, AIIMS)

MENINGITIS

Cryptococcal Meningitis

This has been reported to be the commonest opportunistic infection in India[39,45] ranging 25–67%. Diagnosis in patients with AIDS, presenting with features of fever, headache and meningismus is based on positive latex agglutination test (CRAG positive = 70%) or positive spinal fluid examination for *Cryptococcus*. Classical meningial signs may or may not be present. Meningismus is present in less than 20%. Treatment with Amphotericin B and flucytosine for 6–8 weeks is moderately effective in eradicating the infection.

Carcinomatous Meningitis

This can occur in patients with lymphoma, presenting with features of multiple cranial nerve involvement and meningeal signs. CSF may not show any abnormality, but biopsy is diagnostic. Radiotherapy to the skull base and intrathecal methotrexate are the available treatment options, but the prognosis remains poor.

Aseptic Meningitis

It can occur in 1–2% cases of recently infected individuals.[12] A more indolent aseptic meningitis is seen in around 60% cases of HIV carriers.[23] CSF examination is suggestive of meningitis, but serological and culture tests are negative. HIV has been isolated from the CSF, and is believed to be the pathogenic organism.[22]

TUBERCULAR INFECTION

It is one of the most common infections associated in HIV-AIDS in India has been dealt in the chapter on Tuberculosis of the Central Nervous System.

AIDS ENCEPHALOPATHY AND AIDS DEMENTIA COMPLEX

HIV encephalopathy is a part of acute HIV syndrome. HIV associated progressive encephalopathy is a syndrome complex seen in children while, in adults, the AIDS dementia complex (ADC) is also known as HIV

associated dementia complex. These are characterised by cognitive, motor and behavioural features. It is associated with advanced age and lower CD4+ counts. With the use of HAART, a less severe dysfunction, minor cognitive disorder (MCMD) has become commoner than ADC. Clinical features include impaired mentation, decreased work productivity, inattentiveness, memory loss, decreased libido, apathy, depression, sleep disturbances, psychosis and, rarely, seizures. Motor abnormalities include weakness and imbalance of gait. At a later stage global dementia with memory loss and impaired speech may develop leading to a persistent vegetative state. In children regression of milestones is the prominent feature with inability to acquire new skills.[18] The neuropsychological examination corroborates the above findings. Frontal release signs, tremors, hyper-reflexia, increased tone and impaired co-ordination may be seen later.

CSF studies show elevated protein (60%) and immunoglobulin IgG (80%). The CSF is usually acellular but mononuclear infiltrates may be seen in 25%. Presence of oligoclonal bands, HIV antibodies and testing of HIV in CSF using PCR (best) may also yield positive results. Neuroimaging studies may reveal diffuse cortical atrophy with periventricular hyperintense signals in T2-weighted images in MRI. EEG shows generalised slowing in the later stages. Biopsy is not indicated but, if done for another reason, may show cortical and subcortical neuronal loss and infiltrates of microglia, lymphocytes and multinucleated giant cells. Microgliosis is often perivascular and vacuolation may also be seen. HAART is the treatment of choice[3,18] and drugs with good CSF penetration (lamivudine, stavudine, zidovudine, indinavir, nevirapine) should be used. The role of NMDA antagonists, acetylcholine esterase inhibitors, antioxidants and chemokine receptor antagonists is being studied. Tricyclic antidepressants or neuroleptics should be used for the depressed and agitated patients, respectively. The mean time from first symptom to death is 5.6 months. Poorer prognosis is associated with lower CD4 counts, higher HIV RNA levels, anaemia, low body mass index, higher constitutional symptoms and lower educational levels.

HIV MYELOPATHY

Myelopathy is a late presentation of HIV disease and most patients will have concomitant HIV encephalopathy.[17] Vacuolation of the white matter of the cord is seen. The syndrome is similar to Vitamin B_{12} deficiency and, therefore, a nutritional cofactor is believed to be involved. The diagnosis is of exclusion and patients presenting with spastic paraparesis with paraesthesias leading to incontinence should be evaluated by lumbar puncture to also rule out CMV polyradiculopathy. Lymphomatous deposits in the epidural space can cause cord compression in HIV and hence an MRI or CT scan to exclude the above should be done. Transverse myelitis due to herpes zoster or CMV can occur.

PERIPHERAL NERVOUS SYSTEM

HIV may cause inflammatory polyneuropathies, sensory neuropathies and mononeuropathies. Around 30% of patients with AIDS may develop peripheral neuropathy.[30] Presenting features are tingling, numbness and pain in the lower limbs. Symptoms are out of proportion to objective findings on examination. This is believed to be due to the direct effect of HIV on the nerves and is improved with zidovudine. However, drugs like stavudine and didanosine, can also cause peripheral neuropathy. Patients on these drugs, presenting with neuropathy, should be switched to other regimes. Evaluation to rule out other causes, like alcoholism, thyroid disease, vitamin B_{12} deficiency and syphilis, should be done. Gabapentin has been seen to provide symptomatic relief and response to amitryptyline is uncommon. A Guillain-Barré syndrome like demyelinating neuropathy is seen in HIV infected patients and it usually occurs before frank immunodeficiency develops. Improvement with plasmapheresis supports the immune mediated causation.

CEREBROVASCULAR DISEASE

Cerebrovascular complications occur in up to 7% of these patients[30] and autopsy has revealed lesions in one-third of patients. Infarction may be secondary to nonbacterial thrombotic endocardial embolus and cerebral lymphomas can cause intracerebral bleed. Hypercoagulable states in HIV are documented and even thrombocytopaenia due to HIV and CMV is seen leading to ICH.

OTHER UNCOMMON NEUROLOGICAL PRESENTATIONS

1 *Myopathy*: Zidovudine can also cause myopathy. If creatinine kinase levels are greater than 1000 units/L then the dose of zidovudine should either be decreased or stopped.
2 *Retinitis*: CMV retinitis is the most common cause of visual diminution in patients with AIDS and, therefore, visual complaints in HIV patients must be evaluated urgently. Other rare retinal infections can be by herpes virus and *Toxoplasma*.

DIAGNOSIS OF HIV

The tests for HIV include antibody and antigen assays. HIV antibody testing conventionally is done by ELISA, which is a good screening test (sensitivity >99.9%), showing 50% positivity by 22 days and 95% by 6 weeks. To avoid false positive results in repeated tests, confirmation must be done by Western Blot which, when combined with ELISA, yields specificity of greater than 99.99%. Indeterminate results may be seen in HIV II infection, autoimmune diseases, pregnancy and early HIV infection. HIV rapid antibody test produces results in 10–20 minutes and is utilised as a screening procedure and the results need to be confirmed with the standard tests as described above. Complete blood count in HIV cases

may show anaemia, neutropaenia and thrombocytopaenia. Absolute CD4 lymphocyte count (< 200 cell/mcL) is the most widely used predictor for disease progression. The percentage of CD4 lymphocytes may be more accurate (<14%). HIV viral load tests can measure the actively replicating viruses and they are better for diagnosis in acute HIV infection before seroconversion.

MANAGEMENT OF INTRACRANIAL LESIONS

HIV cases are on the rise and due to frequent involvement of the nervous system neurosurgical consultations are being frequently sought for brain biopsy, as the diagnostic dilemma often persists despite rapid progress in the diagnostic and neuroimaging techniques. PML is usually identifiable on neuroimaging, but it might be impossible at times to differentiate toxoplasmosis from lymphoma and, therefore, it is imperative to obtain baseline toxoplasmosis titres of all AIDS patients. The toxoplasmal titres are positive in the general population in 80–90% of cases by adulthood due to the ubiquitous nature of this organism. The chances of toxoplasmosis are higher with serum antibodies greater than 1:16 (usually > 1:256). Thus, patients in whom titres change over a period of time and neuroimaging shows presence of multiple ring enhancing lesions, particularly in the basal ganglia region, they have higher chances of having toxoplasmosis. The treatment of choice for toxoplasmosis is Pyrimethamine 200 mg loading dose, followed by 75–100 mg/d with sulphadiazine 75 mg/kg per orally loading dose then 25 mg/kg every 6 hours. Folic acid tablets (10 mg) should be given along with each dose of pyrimethamine. In cases of sulpha drug allergy, sulphadiazine may be replaced with clindamycin; other alternative treatment options for complete intolerance are spiramycin and atovaquone. When empirically started, check MRI should be done in 2–3 weeks, because both clinical and radiological response is evident by then.[6] In case of good response the dosage can be decreased to 50% of the above doses in 6–12 weeks time, but they are continued throughout the remainder of life. However, in case of no response with the toxoplasmal therapy, biopsy should be done.

PCNSL is suspected in single ring enhancing lesions with neurological deterioration in AIDS. A lumbar puncture should be done in such cases if imaging is not suggestive of mass effect. Around 10 ml of CSF is needed for cytology and is positive for PCNSL in 10–25% of the patients. CSF analysis for PCR amplification of JC virus and Epstein Barr virus can also be done. Biopsy may be needed to confirm the diagnosis prior to starting radiotherapy. Some recommend early biopsy to prevent inadvertent delay in trial of antibiotic therapy, while other centres have even recommended empiric radiation therapy for highly suspicious cases of lymphoma.

BIOPSY IN AIDS

Biopsy is recommended in the following settings in AIDS cases:

- Lesions are atypical for toxoplasmosis
- Negative toxoplasmosis titres in the presence of intracranial space occupying lesion(s)
- Patients who fail to respond to empirical treatment for toxoplasmosis
- Presence of extraneural neoplasm or infectious disease process involving the CNS.

As most of these lesions are usually deep and the risk of open biopsy in AIDS is higher, stereotactic biopsy must be preferred in appropriate cases. The success rate in reported series is as high as 96% with low morbidity and mortality.[28]

Biopsy should be taken from the centre of the lesion which is most accessible and located in the least eloquent area of the brain. All biopsy specimens should be subjected to histopathological examination and microscopic examination for TB and fungus. Immunoperoxidase staining is done for *Toxoplasma* and cultures done for TB, fungi and bacteria.

RISKS IN HEALTH PROFESSIONALS

Professionals working in surgical wards are especially exposed to higher risk of infections.[16,24] This is especially true for hepatotrophic and HIV viruses. Around 2.5% of HIV infections ascertained in 35 million health care professionals worldwide is the consequence of percutaneous injuries with sharp objects.[46] It is seen that damage to the surgeon's skin occurs in 1 per 10–50 surgical procedures depending on the surgical subspecialty. Studies also show that the percentage of patients infected with hepatotrophic viruses and HIV among those admitted to the surgical wards is often greater than that observed in the general population or among blood donors and, therefore, the risk of infection in health care workers from such subset of patients is higher.

There is increasing concern among the operating room staff from the increasing risk of transmission of HIV due to needle stick injuries. The risk of HIV infection from a HIV positive patient after a needle stick injury is around 0.3%. There has also been public debate about the risk of patients who undergo surgeries acquiring these viruses from infected surgeons.

The Centre for Disease Control has recommended universal precautions for the protection of health workers from blood or body fluids that may contain HIV or hepatotrophic viruses. These precautions are based on the fact that a large number of patients with these diseases are frequently asymptomatic carriers who are not easily diagnosed and, therefore, it is imperative to consider body fluids and blood of these patients as infected and to take adequate precautions. Universal precautions should apply to blood, semen, vaginal secretions, CSF, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid and amniotic fluid. These do not apply to urine, sweat, faeces, vomitus, nasal secretions, sputum and saliva unless containing blood. The most effective way of protection is by consistent use of protective gloves, impervious gowns, face mask and goggles.

The precautions recommended for staff during surgery are:

- Have vaccination against hepatitis B
- Cover all cuts and abrasions with waterproof dressings
- Do not pass sharp instruments hand to hand
- Do not use hand needles
- Do not guide needles with fingers
- Do not re-sheath needles
- Dispose of all sharp instruments safely into approved containers
- Put disposables and waste into yellow clinical waste bags for incineration.

ADDITIONAL PRECAUTIONS WHEN CARING FOR KNOWN HIV POSITIVE AND HIGH-RISK PATIENTS

- Consider non-operative management
- Remove unnecessary equipment from theatre
- Observe highest level of theatre discipline
- Have only experienced surgeons and health care workers in the operation theatre
- Use double glove, high efficiency masks, eye protection, boots, impervious gowns, closed wound drainage
- Use disposable anaesthetic circuitry or appropriate method of decontamination
- Disinfect theatre floor with hypochlorite.

TRANSMISSION FROM HEALTH WORKERS TO PATIENTS

It is extremely difficult to quantify the risk of transmission from health care workers to patients, but it must be very low because large volumes of blood from the health care workers would need to enter the patient's bloodstream. The risk is probably much lower than the risk of transmission from patient to health care worker. There is a single report that a Florida dentist with AIDS transmitted HIV to five patients. The mechanism of this transmission is still speculative as the dentist died before his techniques could be verified. By August 1992, there was no report of transmission of HIV from an infected surgeon or other member of the operating theatre staff to a patient. Estimates of the risk of such transfer range from 1:48,000 to 1:10,00,000.[8,20]

PRECAUTIONS FOR INFECTED HEALTH WORKERS

The General Medical Council recommends that all staff who think that they have been at risk of infection should be confidentially tested and that where HIV or hepatitis B virus infection is detected special counselling and expert advice should be sought.[15] If the health care worker is E-antigen or HIV positive, he or she should stop performing invasive procedures.

INVASIVE PROCEDURES TO BE AVOIDED BY E-ANTIGEN OR HIV POSITIVE HEALTH WORKERS

- Surgical entry into tissues, cavities or organs
- Repair of major traumatic injuries
- Cardiac catheterisation and angiography
- Vaginal or Caesarean deliveries or other obstetric procedures during which bleeding may occur
- Manipulation, cutting or removal of any oral or perioral tissue, including tooth structures, during which bleeding may occur.

75 Subarachnoid Haemorrhage

Chandramouli BA, Arivazhagan A

INTRODUCTION

Subarachnoid haemorrhage (SAH) is a neurological emergency characterised by haemorrhage into the subarachnoid space, which is normally filled with cerebrospinal fluid. It is one of the most important causes of acute severe headache and needs to be always considered in its differential diagnosis. In population-based studies, SAH has been estimated to occur at an annual incidence rate of 10.0–10.9 cases per 100,000.[58] Although population-based studies indicate that the condition is not very common in the general population, it is of great importance to diagnose the condition at the earliest because of the associated high morbidity and mortality. Hence, awareness, early diagnosis and management play a paramount role in achieving the goal of reduced morbidity and mortality.

EPIDEMIOLOGY

Few data bases exist regarding the exact incidence of SAH, with variations in data-based on the diagnostic modality used. The incidence of SAH varies between geographical areas. There is also racial, sex and age-related variations. The overall incidence of SAH is approximately 9–10.5/100,000 population/year.[10,49] Finland and Japan have the highest incidence of SAH in the world, with rates between 15.1 and 29.8 per 100,000 population per year,[10,20,37,68] whereas the rates have been documented to be as low as 2.2 per 100,000 population/year in Dijon, France,[22] and about 2 per 100,000 population/year in China.[37] The incidence of SAH in India has not been evaluated by population-based studies in detail, although it had been reported to be lower around 3–4 per 100,000 from hospital-based data.[5]

The incidence is reported to be 1.24–1.6 times more in women compared to men.[10,49] Differences in incidence have also been noted between ethnic groups living in the same geographical areas and exposed to similar risk factors. SAH is reported to be higher in Hispanics and Blacks compared to Whites.[44]

The incidence of SAH has been found to be relatively constant over time. The incidence increases with age.[88] Below 50 years of age, the incidence among men and women are similar, while beyond 50 years, the incidence is higher among women.[10] Autopsy data indicates a high incidence of unruptured aneurysms in the general population. The incidence varies depending on the size of aneurysms taken into consideration. Housepian et al. had reported that 5% of the population harboured aneurysms based on autopsy studies,[33] while prevalence of incidental intracranial aneurysms was found to be 1% in studies of unselected angiograms.[4] Although the prevalence of aneurysms in autopsy studies is high, the incidence of SAH is around 9–10.5/100,000 population/year.[10,49] This indicates that only a small per cent of aneurysms rupture during life. According to the multicentric study conducted under the aegis of ICMR (1970–75) among 404 consecutive autopsies at New Delhi and Chandigarh, there were five aneurysms and one AVM discovered.

AETIOLOGY

The most common cause of SAH is trauma. However, among SAH due to non-traumatic causes, 85% are due to ruptured cerebral aneurysms. In a small proportion of cases, connective tissue disorders have been implicated as the cause of SAH. These include Ehlers-Danlos syndrome, pseudoxanthoma elasticum, polycystic kidney disease and neurofibromatosis type I.[18,69] The other causes of SAH include AVM, dural sinus thrombosis, intracranial arterial dissection, mycotic aneurysms, bleeding diathesis and drug-induced SAH.[18] In about 20% of the cases, no cause can be ascertained. In peri mesencephalic SAH aneurysms are the cause in less than 10% of the cases. It is postulated to be of venous origin and considered to be a benign form of SAH.[18] The various causes of SAH have been discussed in Table 1.

Table 1: Causes of subarachnoid haemorrhage

• Trauma
Vascular
• Ruptured intracranial aneurysms
• Arteriovenous malformations
• Tumours with haemorrhage
• Pituitary apoplexy
Vasculopathy
• Collagen vascular disease
• Amyloid angiopathy
• Arterial dissection
Haematological
• Anticoagulant therapy
• Leukaemia
• Hepatic or renal disease-induced coagulopathy
Drugs:
• Cocaine, amphetamine, ephedrine

CLINICAL FEATURES

Headache is a very common ailment in the general population. A high index of suspicion and careful understanding of presentations of SAH is needed for early and accurate diagnosis. In the general population, migraine is 1,000 times more common than SAH.[78] A careful focussed history and examination helps in identifying patients with SAH.

The most common and classical presentation of SAH is the sudden onset of severe headache, often described as "the worst headache of one's life". The headache is acute, peaks rapidly, wakes the patient if asleep and persists for days in spite of treatment. It is often holocranial, may sometimes be localised to one side or to the occipital region. The sensorium is often altered in patients with SAH due to sudden raise in intracranial pressure. Transient loss of consciousness can occur in 33% of patients and around 20% may be comatose at presentation. Seizures occur in about 20% of patients with SAH.[78] Seizures often occur with MCA aneurysms, Pcom aneurysms, intracerebral haematoma and hypertension. Sometimes neck pain may predominate over cranial symptoms.

Among the patients who present with acute onset severe headache and are neurologically normal, around 12% have SAH.[45,50,56] Nearly 50% of SAH present only with mild symptoms. The following points in history should carefully be evaluated to identify these patients:

- Onset of headache: abrupt onset/during exertion
- Severity
- Quality: distinct/unique
- Associated symptoms: nausea, vomiting, seizure, diplopia
- Alternate causes for headache
- Enquire about: alcohol consumption, smoking, hypertension, cocaine use
- Family history or past history of SAH

Many patients with SAH give history of mild headache with nausea or vomiting suggesting a minor bleed prior to the ictus. This is referred to as "warning leak or sentinel haemorrhage". Sentinel haemorrhage is reported to occur in 40–50% of patients with SAH and is usually noted within 2–8 weeks prior to SAH.[46,57] Verweij et al., in their study, reported that only 50% of patients with warning headache consulted physicians.[92] CT scan of the brain is usually not very reliable in diagnosing or ruling out sentinel haemorrhage.

The patient's level of sensorium, presence of focal motor deficits and cranial nerve palsies, if any, should be recorded on examination. Meningismus or nuchal rigidity is noted in 50% of patients due to meningeal irritation following SAH. It can manifest within 6–24 hours after SAH. The patient also needs to be evaluated for systemic effects of SAH in detail before surgical management. Examination of the fundus may reveal papilloedema, subhyaloid, retinal or preretinal haemorrhage in 20–40% of patients.[59] Ocular haemorrhage in SAH can be subhyaloid, intraretinal or vitreous. Subhyaloid haemorrhage results in bright red blood near the optic disc obscuring the underlying retinal blood vessels.

Certain clinical features in a patient with SAH can suggest the specific location of the aneurysm. Visual symptoms can occur due to aneurysms in the region of the Acom, ophthalmic and superior hypophyseal segments of the internal carotid artery, giant aneurysms of Pcom and anterior choroidal artery. Aneurysms of the posterior communicating artery cause third nerve palsy with pupillary involvement.

Multiple cranial nerve palsies can occur in a cavernous carotid aneurysm. They can present with acute retro-orbital pain, decrease in visual acuity, proptosis and paresis of cranial nerves III, IV and VI. A ruptured cavernous carotid aneurysm does not result in SAH but causes carotid cavernous fistula. An intradural extension of the aneurysm can result in SAH. Hypothalamic dysfunction and diabetes insipidus are more common in patients with anterior communicating artery aneurysms. Basilar bifurcation aneurysms can present with third nerve palsy, chiasmal compression or Weber's syndrome. Intraventricular haemorrhage and hydrocephalus can occur.

Grading of Clinical Status

The clinical condition of the patients with SAH needs to be evaluated and documented in a uniform manner to record periodic changes in the condition, for comparing the data and outcome across the studies and for prognostication based on the clinical condition of the patient. Various clinical grading methods have been proposed for evaluating patients with SAH. Hunt and Hess classification[34] (Table 2) and World Federation of Neurosurgical Societies (WFNS) grading[14] (Table 3) are the most commonly used systems for evaluation.

When there is any associated serious systemic disease, like diabetes mellitus, hypertension, severe arteriosclerosis, chronic pulmonary disease or severe vasospasm seen on angiography, the patient is placed in the next less favourable Hunt and Hess grade (Table 2).

Table 2: Hunt and Hess classification of SAH

Grade	*Clinical features*
0	Unruptured
1	Asymptomatic or mild headache, slight nuchal rigidity
2	Moderate-to-severe headache, nuchal rigidity, no neurological deficit other than cranial nerve palsy
3	Mild focal deficit, lethargy, confusion
4	Stupor, hemiparesis
5	Coma, extensor rigidity

Table 3: World Federation of Neurosurgical Societies grading scale for SAH

Grade	*GCS*	*Focal deficit*
1	15	Nil
2	13–14	Nil
3	13–14	Present
4	7–12	Absent or present
5	3–6	Absent or present

MISDIAGNOSIS OF SUBARACHNOID HAEMORRHAGE

In spite of advances in diagnostic modalities and their better availability, missed diagnosis of SAH is very common. It occurs in 12–51% of patients with SAH on their first consultation with a physician.[15,42,55,60,89] In 75% of cases, the misdiagnosis occurred in the emergency department or the physician's office. The true estimate of the frequency and impact of missed diagnosis cannot be ascertained from hospital records as 12–50% of SAH patients who have rebleeding may die without being hospitalised.[7,70] The missed diagnosis is often attributed to: (1) lack of awareness; (2) failure to do relevant investigations and (3) failure to interpret the investigation results. The most common error was failure to perform CT leading to misdiagnosis in 73%, while misinterpretation of CT or LP results caused misdiagnosis in 16% of cases.[42] The common clinical misdiagnoses made were migraine/tension headache, viral infection, hypertension/encephalopathy, sinusitis, meningitis, etc. Patients with good clinical grade (Hunt and Hess I and II) and small volume bleed had higher chances of missed diagnosis. The significance of the missed diagnosis cannot be overemphasised since rebleed rates are 48% in those misdiagnosed, which reduce to 2% in those correctly diagnosed.[55] Nearly 20% of the patients with good initial clinical grade were misdiagnosed, and these patients had a four-fold increase in the likelihood of death at 12 months and worse functional recovery and quality of life among those who survive.[42]

INVESTIGATIONS

The threshold for investigating a patient with sudden onset of severe headache for the first time in life should be very low. CT scan of the brain is the investigation of first choice, because it has high sensitivity to detect acute haemorrhage, is non-invasive, easily available, relatively low cost and can suggest the possible location of an aneurysm. Other modalities to detect SAH include lumbar CSF analysis and MRI of the brain.

Computed Tomography Brain

CT brain is the most commonly performed investigation in SAH. Subarachnoid blood appears in plain CT scan as a hyperdensity in the subarachnoid space. The hyperdensity of the blood is related to the concentration of globin in the haemoglobin molecule. The identification of subarachnoid blood in CT scan depends on the amount of bleed, density of blood and the time interval between the ictus and imaging. Blood with low haematocrit values does not appear hyperdense in CT scan.[73] If a CT scan is performed within 24 hours after ictus, subarachnoid bleed will be evident in 95–98% of patients who have blood demonstrated on lumbar puncture.[39,86] As time elapses, haemolysis and dispersion of blood in the CSF occurs, reducing the sensitivity of CT in detecting SAH. Only 58% of SAH can be detected by 5 days and at 1 week,[34] only 50% of patients have a positive CT scan.[87] A thin layer of SAH adjacent to a bony structure can be missed in CT and thin slices may need to be performed for its detection.[48] Structures that can mimic SAH include calcification of the basal arteries, falx, partial volume artifacts and streak artifacts. They can be recognised by their focal nature and can be differentiated from SAH. MR imaging, especially the FLAIR sequences may be a better imaging modality to detect subacute SAH.

The amount of bleed has been graded by Fischer et al. and this can predict the outcome of patients with SAH[19] (Table 4). The amount of subarachnoid blood directly correlates with the risk of vasospasm. Patients with Fischer's grade 3 SAH have the highest risk of developing vasospasm.

The location of an aneurysm causing SAH can be predicted in the majority of cases based on the cisterns involved. Intracerebral haematoma in the temporal lobe can occur following rupture of MCA or Pcom aneurysm. Acom aneurysm bleed can cause gyrus rectus bleed. An ICA bifurcation aneurysm can result in intracerebral haemorrhage extending into the putamen and thalamus, although slightly anterior and inferior to the usual location of hypertensive intracerebral haemorrhage. Subdural haematoma can occur due to bleed from MCA or Pcom aneurysm.

Lumbar Puncture

Lumbar puncture is the gold standard against which other investigations have been compared for their sensitivity in diagnosing SAH. Since the sensitivity of CT brain for detecting SAH is very high and it being non-invasive, it is considered the investigation of first choice. SAH may not be detected in CT if the amount of bleed is very little or a longer time has elapsed between the ictus and the time of investigation.[30] A lumbar puncture is

Table 4: Fischer's grading of subarachnoid haemorrhage

Grade 1	No detectable blood on CT scan
Grade 2	Diffuse thin SAH Vertical layers < 1 mm thickness
Grade 3	Localised clot and/or thick SAH vertical layer > 1 mm thickness
Grade 4	Intraventricular or intracerebral clot with diffuse or no subarachnoid haemorrhage

performed when the clinical presentation of the patient is highly suggestive of SAH and the CT scan is negative.

In around 3% of patients with sudden headache, CT scan performed within 12 hours will be normal. A lumbar puncture is usually positive in these patients if it is done after 6 hours, preferably 12 hours after SAH which allows for the formation of metabolites of haemoglobin.[86] Bloody CSF that remains uniformly blood stained when collected in four tubes is highly characteristic of SAH. The collected CSF is centrifuged and analysed. If the lumbar puncture is performed a few days after the ictus, then the supernatant fluid will reveal xanthochromia and crenated RBCs will be detected in the sediment. Xanthochromia is the most characteristic feature of SAH and occurs due to lysis of RBCs in the CSF, which imparts the yellow colour. It appears as early as about 3 hours after the ictus and persists for about 3 weeks. The sensitivity was 100% at 2 weeks and 70% at 3 weeks.[91] Xanthochromia may sometimes not be visible and spectrophotometric analysis needs to be performed for detection.[83] A traumatic lumbar puncture can mimic subarachnoid haemorrhage (SAH). It can be differentiated from spontaneous SAH by the fact that the blood in the CSF clears in serial collecting tubes.

Angiography

Four-vessel catheter angiography is the gold standard investigation for detection of aneurysms, despite the recent surge of alternate techniques, like CT and MR angiography, which are non-invasive. Angiography is mandatory in all patients with a CT diagnosis of SAH and in patients with acute onset third cranial nerve palsy with pupillary involvement. It establishes the cause of SAH in 85% of patients. The risks of angiography needs to be considered while subjecting the patient for the procedure, which include contrast reactions, nephrotoxicity, puncture site haematoma, transient neurological deficits (1%) and permanent complications (0.1–0.5%). The overall complication rate is around 7%, with the majority of them being puncture site haematomas.[27,94]

In 15–20% of patients with SAH, angiogram may be negative and this can be due to interpretive errors, cerebral vasospasm, spontaneous thrombosed aneurysms, vascular lesions of the spine or spinal neoplasms.[39,80,84] These patients require a repeat angiogram after 2–6 weeks. Angiogram is often negative in perimesencephalic SAH, where blood is located in the interpeduncular and perimesencephalic cisterns. This cannot be differentiated from a basilar artery aneurysmal bleed; however, a repeat angiogram is unnecessary in this pattern of SAH if an initial good quality angiogram does not demonstrate any aneurysm.[71] This condition is associated with good outcome and rebleed is unusual.[83] Conditions, like pregnancy-induced hypertension, sympathomimetic drug abuse, bleeding dyscrasias, antiplatelet agents and anticoagulants, can result in SAH and when detected, they have to be corrected.

Computed Tomography Angiography and Magnetic Resonance Angiography

CT angiography and MR angiography have been performed for detection of aneurysms as an alternative to catheter angiography. The main advantage of these procedures is the non-invasiveness. CT angiography can be performed rapidly even in patients not medically fit to undergo angiography, and as an emergent procedure in patients with acute deterioration. It can also be used as a screening tool in the patient group with high risk for aneurysms like those with collagen vascular disease and polycystic kidney disease. The main disadvantages of the procedure include contrast-related reactions and nephrotoxicity. The presence of intracerebral haematoma, calcification or aneurysmal clips can affect the interpretation of the images. Small posterior communicating segment aneurysms may be missed by CT angiography.[93]

Catheter angiography is considered the gold standard, while all other procedures are compared against it for assessing their sensitivity and specificity. The sensitivity of CT angiography varies between 77% and 100%, while the specificity ranges from 79 to 100% as reported in literature.[31,40,41,93,97] This depends on the size and location of the aneurysm, and the experience of the interpreter. For aneurysms of size 5 mm or more, the sensitivity of the procedure is better (95–100%), while it significantly decreases (64–83%) when the size of the aneurysm is less than 5 mm.[93]

MR angiography has a sensitivity of 85–100% for aneurysms larger than 5 mm size, while the sensitivity falls to 56% for aneurysms smaller than 5 mm. The specificity of MRA for aneurysms ranges from 92–100%.[2,23,32,35] The disadvantages of MRA include longer procedure time, difficulty to perform in emergent settings and in critically ill patients. MRA can be performed in pregnant patients, and as compared to CT angiography, can avoid the risk related to iodinated contrast and radiation.

MANAGEMENT OF SUBARACHNOID HAEMORRHAGE

Despite early diagnosis and management, the 30-day mortality of aneurysmal SAH approaches 50%. Most deaths occur in the first week after the ictus. Around 10% die before reaching the hospital and 25% die within 24 hours.[3,7,70] The natural history of SAH is grim even among good grade patients. The 3-month mortality rate among patients who reach major medical centres is approximately 25%.[16] The leading causes of death include large intraparenchymal haematoma, acute hydrocephalus, raised intracranial pressure, myocardial ischaemia, cardiac arrhythmias, pulmonary oedema, respiratory failure, rebleed and ischaemia secondary to vasospasm.[74] The level of consciousness at the time of admission is the most predictive clinical factor of SAH. The 6-month mortality rate among comatose patients was 71%, whereas only 11% of initially alert patients die during the same period.[1]

SAH results in a wide gamut of changes in the patient, affecting multiple systems in varied ways. The goals of medical management include:

- General care, stabilisation of acutely ill patients
- Obliteration of the ruptured aneurysm at the earliest
- Prevention of complications and sequelae of SAH

Acute Management

Patients with SAH need to be managed in medical centres with adequate expertise to treat this disease. Acute life-threatening complications need to be anticipated and treated. These patients have to be managed in an ICU by trained nurses.[54]

Most of these patients experience photophobia due to SAH and hence bright lighting is avoided in the room. A water mattress or pneumatic mattress can be used to prevent deep venous thrombosis. Analgesics are administered to alleviate headache. Patients may be agitated due to brain injury, hydrocephalus, raised intracranial pressure or a full urinary bladder, which need to be taken care of. Sedatives are administered to reduce agitation. Straining at stools should be avoided and hence a good laxative is prescribed.

Intravascular volume depletion is common following SAH.[6,43,75] Disturbances of water and electrolytes occur in about one-third of patients with SAH. They occur more commonly in critically ill patients.[96] Hyponatraemia and volume depletion correlate with poor prognosis.[95] In the past, hyponatraemia in patients with SAH was attributed to SIADH and treated accordingly. It is now recognised that the more common cause for hypovolaemia is cerebral salt wasting (CSW).[95,96] The mechanism of water and sodium depletion in CSW has been correlated with disturbances in levels of atrial natriuretic peptide and C-type natriuretic peptide, as well as direct neural effects on renal function.[26] The clue to diagnosis is excretion of larger amounts of sodium and chloride in urine. There is volume contraction, unlike SIADH where there is fluid retention or euvolaemia. A proper diagnosis of CSW or SIADH should be made as management is very crucial and can be harmful if the condition is not diagnosed and treated properly. Assessment of volume status by careful recording of input and output, Na^+ and Cl^- balance, daily body weight recording, or laboratory tests such as elevated haematocrit or BUN: creatine ratio help in planning therapy.[26] Hypovolaemia predisposes to high incidence of cerebral vasospasm. Hence, patients with SAH should be hydrated well to maintain a central venous pressure of about 12–14 mmHg. Crystalloids are infused at the rate of 125 ml/hour to maintain the central venous pressure.

Arterial hypertension is common in SAH resulting from elevation of catecholamines and rennin production by hypothalamic disturbances.[9,39,81] The other reasons for hypertension include raised intracranial pressure, agitation, seizure, pain or vomiting. Hypertension after SAH has been found to correlate with increased risk of vasospasm and mortality, and recurrent bleed.[81] Rapid and steep reduction in blood pressure might be dangerous, resulting in drop in cerebral perfusion in patients with vasospasm and raised intracranial pressure, leading to neurological complications. The level of hypertension that mandates treatment is not known. Moderate hypertension in a patient with mean blood pressure less than 120 mmHg may be reactive and need not be corrected.[81,90] The initial approach should be to control pain and agitation which can reduce blood pressure. A mean pressure greater than 120 mmHg should be treated with the goal of cautious reduction. Randomised trials have not been performed evaluating the benefit-risk relationship of antihypertensive therapy in the hyperacute phase of SAH prior to surgical or endovascular therapy.

Anti-oedema therapy with 20% mannitol is instituted in the presence of diffuse cerebral oedema following SAH. The treatment with mannitol should be monitored closely to prevent electrolyte imbalance, especially sodium imbalance. An external ventricular drainage may be required in the presence of acute symptomatic hydrocephalus, although there is a risk of rebleed following sudden decompression of the ventricles.

The cornerstone in medical management of SAH includes triple H therapy (hypertension, hypervolaemia and haemodilution) and calcium antagonists. Triple H therapy has been shown to be effective in prevention and treatment of cerebral vasospasm. Nimodipine, a cerebroselective calcium channel blocker, has been found to reduce the risk of poor outcome and secondary ischaemia after aneurysmal SAH. Considering the potential benefits and modest risks of this treatment, oral nimodipine is currently indicated in patients with aneurysmal SAH. Intravenous administration of calcium antagonists is not recommended for routine practise on the basis of the present evidence.[12]

The reported incidence of seizure in patients with SAH is 25%, most of which occur within the first 24 hours.[62,79] Routine practise presently is to prescribe prophylactic anticonvulsants to patients with SAH. Platelet aggregation has also been considered to play a causative role in secondary brain ischaemia following SAH. Hence, some authors have attempted to add antiplatelet therapy in patients with SAH. A Cochrane review of all randomised controlled trials of antiplatelet therapy revealed a trend towards better outcome in patients treated with antiplatelet agents, possibly due to a reduction in secondary ischaemia, although the results were not statistically significant, but antiplatelet agents could also increase the risk of haemorrhagic complications. On the basis of the current evidence, treatment with antiplatelet agents in order to prevent secondary ischaemia or poor outcome cannot be recommended.[13]

Raised intracranial pressure following SAH presents with depression in sensorium, and can occur due to various causes like intracerebral haematoma, intraventricular haematoma, hydrocephalus, cerebral oedema and mass effect secondary to cerebral ischaemia. General

treatment strategies for managing raised ICP include head end elevation, fluid balance, anti-oedema measures, correction of hyponatraemia, prevention of hypoventilation and hypercarbia, treatment of fever and agitation. Specific measures include evacuation of intracerebral haematoma, external ventricular drainage for intraventricular haematoma or hydrocepahlus.

Hydrocephalus is a common acute complication of SAH, reported to occur in 25% of cases in the acute phase.[72] It can occur due to intraventricular haematoma, subarachnoid blood blocking the subarachnoid spaces and/or arachnoid villi. Prolonged presence of extensive subarachnoid clot is associated with hydrocephalus. Hydrocephalus following SAH can be classified according to its time of appearance as: (1) acute: < 12 hrs; (2) subacute: a few days after ictus and (3) delayed: weeks to years after SAH. Acute hydrocephalus is an important cause of raised intracranial pressure and coma. Subacute hydrocephalus is a cause of gradual decline in sensorium 7–10 days following SAH. Delayed hydrocephalus often manifests as subacute dementia. Approximately 16–34% of patients have CT evidence of acute hydrocephalus. Most patients have decreased level of consciousness; some may be asymptomatic. Acute hydrocephalus predisposes to increased morbidity and mortality, and is correlated with subsequent development of vasospasm and ischaemic complications. Management is guided by the clinical situation. The patient can be just observed and medically managed, monitored with serial CT scans and treated with serial lumbar punctures, if required. Although acute hydrocephalus may resolve spontaneously, some patients require temporary CSF diversion procedures.[24,28]

SAH disrupts brain integrity and function and results in multi-system involvement including cardiovascular, respiratory, metabolic, haematological and immunological dysfunction. A patient with SAH needs to be closely monitored for these events and promptly treated to improve the outcome of disease management.

The various changes that can occur following SAH include:[77]

- *Cardiovascular*: Arterial hypertension, intravascular volume depletion, congestive heart failure and decreased cardiac output and left ventricular dysfunction. ECG reveals ST depression, T wave inversion and QT prolongation, and arrhythmias. Creatine kinase-MB and troponin I levels are raised in serum.
- *Respiratory*: Cardiogenic pulmonary oedema, acute lung injury, acute respiratory distress syndrome (ARDS), neurogenic pulmonary oedema (NPE), pneumonia and pulmonary embolism.
- *Metabolic*: Hyponatraemia due to SIADH or cerebral salt wasting, hypernatraemia and stress hyperglycaemia.

Cardiac arrhythmias can be detected in almost all patients during the first few hours of SAH.[11,53,61] In 20%, arrhythmias can be severe and life-threatening. Changes resembling those seen in acute myocardial ischaemia can be seen in 25–80% of patients. It is assumed that release of catecholamines by the posterior hypothalamus is responsible for the development of cardiovascular complications of SAH. Presumably, marked elevation of norepinephrine leads to hypokalaemia, systemic hypertensive effects, left ventricular strain and coronary artery spasm.[21,67,98] Neurogenic pulmonary oedema is rare and occurs in critically ill patients. This complication is frequently attributed to greater sympathetic activity resulting from acute cardiac changes.[47]

Prevention of Rebleed

Prevention of rebleed is the cornerstone of management of SAH. Torner and colleagues found that the period of greatest risk for rebleeding is the first 24 hours after the ictus, which peaked at approximately 4% during this time.[82] In a Swedish series, 9.6% of all patients admitted within 24 hours of SAH had very early rebleed; most of them died.[29] The cumulative rate of rebleed during the first 2 weeks after SAH is approximately 15–20%.[82] Recurrent haemorrhage is a feared complication of SAH, because it is one of the leading causes of death and morbidity.[29,65] Broderick reported rebleed as the cause in 50% of deaths occurring within 2 days following SAH.[7] The mortality rates in patients who have a rebleed are approximately twice as much as in those who have a single bleed. Even in centres performing early surgery, rebleeding remains a major cause of poor outcome.[64] Early treatment to obliterate the ruptured aneurysm either by surgical clipping or endovascular coiling is most important, which will be discussed in the following chapters.

PATIENT OUTCOME FOLLOWING SUBARACHNOID HAEMORRHAGE

SAH results in significant morbidity in spite of optimal treatment. Large studies have reported a 30-day mortality of around 40% following SAH.[17,37,51] A population-based analysis from the United States had documented an overall mortality rate of 2.77 per 100,000 person years following SAH, in the last two decades.[38] Among all those patients who suffer from SAH, roughly one-third of them die acutely, one-third survive with significant residual cognitive and motor deficits restricting functional independence, while only one-third of patients recover well from SAH to get back to normal daily activities.[51,52,58] The cognitive dysfunction following SAH is significant, resulting in deficits in verbal and non-verbal memory, psychomotor speed, executive function, visuospatial function and pattern recognition. It can also result in emotional lability.[25,51,76] Due to these widespread cognitive and motor deficits, only about 50% of the survivors of SAH were able to return to the same level of work prior to the bleed.[8,36] This disease commonly affects people at younger and productive age, resulting in considerable loss of manpower and additional burden to the family and society. An unfavourable outcome was found

to be associated with increasing age, worsening neurological grade, ruptured posterior circulation aneurysm, larger aneurysm size, more SAH on CT scan, presence of intracerebral haematoma and co-morbid factors like hypertension, diabetes mellitus, myocardial infarction, etc. The variables during hospital stay, which influence outcome, include fever, symptomatic vasospasm and cerebral infarction. Among all these, the most important factors which influence outcome are cerebral infarction, WFNS grade, age, occurrence of fever and symptomatic vasospasm.[66]

PERIMESENCEPHALIC SUBARACHNOID HAEMORRHAGE

Perimesencephalic haemorrhage is defined as blood confined to the cisterns around the midbrain, usually in the interpeduncular and prepontine cisterns, sometimes in the quadrigeminal cisterns. Around 2.5–5% of these patients have aneurysms of the basilar or vertebral artery.[83,85] Thus, perimesencephalic SAH needs to be investigated with DSA or high quality CT angiography. Headache in these patients develops gradually in comparison to aneurysmal SAH. Patients are usually conscious, occasionally confused. Rebleeding is very rare, almost unknown in perimesencephalic SAH. The cause is not known with certainty. An arterial cause is ruled out by a normal angiogram. It is assumed to be due to rupture of veins; the basis being that, in these patients, the perimesencephalic veins drain directly to the dural sinuses instead of the vein of Galen. A repeat angiogram is unnecessary in this pattern of SAH if an initial good quality angiogram does not demonstrate any aneurysm.[71] This condition is associated with good outcome, and rebleed is unusual.[83]

CONCLUSION

SAH is one of the most devastating neurosurgical emergencies. A low threshold for investigating a patient with sudden severe headache is mandatory to detect the disease. CT scan is the best imaging modality for detecting SAH. Obliteration of an aneurysm at the earliest by either microsurgery or endovascular techniques is the standard of care at present. SAH has far reaching systemic implications which need to be understood and managed to obtain optimal outcome following the disease. Further research is necessary in this field to manage the modifiable factors, like vasospasm, rebleed and systemic sequelae, which form the major cause for the morbidity secondary to SAH.

76 General Principles of Management of Intracranial Aneurysms

Mathuriya SN

INTRODUCTION

Intracranial aneurysms (IAs) affect 5–10% of the general population[77] and represent a major public health problem. It is estimated that 2.3% of the population have undetected aneurysms,[54] a fraction of which will rupture and lead to devastating consequences. In the absence of trauma, intracranial aneurysm (IA) is the leading cause of subarachnoid haemorrhage (SAH) and accounts for approximately 85% of the cases.[61]

The incidence of aneurysmal SAH in most of the Western countries is approximately 9/100,000 population, but in Finland it is approximately 20/100,000.[133] In the United States, the incidence of SAH is 6–9/100,000; about 28,000 ruptures occur per year.[90] This number may be even higher in other countries, such as Finland, where the incidence has been reported to be much higher. This is likely due to higher rates of rupture of existing aneurysms, rather than a greater number of aneurysms *per se*.[107,113] Progress in understanding the pathogenesis of IA has been hampered by its multifactorial nature. SAH due to rupture of an IA is a serious neurosurgical emergency with a poor prognosis. Approximately 12% of patients die before reaching medical attention[77] and 40% of patients die in the hospital.[45,56,84,115] Only 25% of those who live past the 1st month recover completely, leaving the majority of survivors requiring long-term care[32,41]

Aneurysmal SAH accounts for 3–11% of all strokes, 5% of stroke deaths, and more than one-quarter of potential life years lost through stroke as this is common in comparatively young individuals and, hence, a productive age group.[32] Although the latter half of the 20th century has seen great advances in the diagnosis, treatment and prevention of complications of SAH; the overall outcome has shown only modest improvement.[90] Due to the devastating sequelae of aneurysmal SAH, surgical or endovascular intervention before rupture is considered to be of paramount importance. Guidelines have been established to assist in the decision making between treatment and careful monitoring, with the goal of prophylactically treating those aneurysms that are likely to rupture. Attempts to identify risk factors and the pathophysiology leading to aneurysm formation and rupture have had limited success, although there has been noteworthy progress of late, particularly in the study of aneurysm genetics.[90]

One large multi-centre trial suggested that IAs larger than 10 mm had a risk of rupture of 1% per year, with smaller aneurysms having a much lower risk. However, this initial data conflicted with clinical experience in which a significant number of patients present with SAH owing to aneurysms smaller than 10 mm in size. Furthermore, the data contradicted a previously published series in which aneurysms smaller than 10 mm were at greater risk of rupture.[57,58] Other than aneurysm size, the conditions that lead to aneurysm formation and rupture have not been fully delineated. Contributing to the disease are a number of well established risk factors such as sex, hypertension, smoking, alcohol, low body mass index and drug use.[45,55] These risk factors, however, fall short of a complete explanation. Recent studies suggest that, in addition to these, genetic factors also contribute to the pathogenesis of IA. Given the large number of familial cases and increased incidence with other genetic diseases such as adult polycystic kidney disease (ADPKD),[90] a genetic contribution to aneurysm formation and rupture has long been speculated. Studies have reported that the incidence of familial aneurysms is 10%.[106] The degree to which each risk factor contributes to an individual's aneurysm is likely to be patient-specific. It is considered that both genetic and environmental factors may work independently and/or synergistically to form IA.

GENETICS

Recent advances in genetic disorders and vascular abnormalities have revealed several alterations in genes and gene products involved in the remodelling of the extracellular matrix (ECM). The dynamic nature of the ECM has been theorised to go awry, leading to diminished support of the vasculature, ultimately resulting in an aneurysm. Supporting this notion, the content and structure of collagen and elastin (ELN), the predominant elements in the wall of the aneurysm, are significantly altered. The ECM-related proteins discussed below have been identified in genetic disorders and could be related to IA formation.[90]

These are ELN, elastase 2 (ELA), alpha-1-antitrypsin (AAT), collagen III (COL3A1), endothelial nitric oxidase synthetase, polycystin (PKD1) and fibrillin (FBNI).[21] Neder et al.[131] have identified the 1p35–36 locus in a large family with IAs. Genome-wide sibling pair and kindred

studies have also incriminated 2p13, 7q22.1, 11q25, 14q22 and 19q13.3 as harbouring susceptibility genes. Notable heritable connective tissue disorders which have been associated with IAs include polycystic kidney disease, Ehlers-Danlos syndrome type IV, Marfan's syndrome, neurofibromatosis type I, pseudoxanthoma elasticum (PXE) and AAT deficiency.

Several loci have been identified for the ADPKD gene on chromosome 16 (PKD1) as well as on gene 4 (PKD2). Mutations in gene encoding proα_1 (III) chain of COL3A1 on chromosome 2 are the cause of Ehlers-Danlos syndrome IV.[84] Several vascular disorders have been associated with AAT deficiency, viz. arterial aneurysms, spontaneous arterial dissections and arterial fibromuscular dysplasias. Patients with AAT deficiency are at increased risk of developing IAs as antitrypsin deficiency may cause breakdown of subcutaneous septa resulting in cutis laxa.[115] Antitrypsin gene is located on chromosome 14. It is a highly polymorphic gene which has 75 variants. The locus has been designated as "Pi" for protease inhibitor.[15]

Marfan's syndrome occurs due to mutations in gene encoding fibrillin-1 (FBN-1). FBN-1 is a glycoprotein that is one of the major components of microfibrillin, which in turn is an important constituent of the ECM. FBN-1 plays an important role in maintaining the structural integrity of connective tissue. Neurofibromatosis-1 is caused by mutation in gene (NF-1) encoding neurofibrin, a protein with a centrally located domain homologous to guanosine triphosphatase-activating protein. It is postulated that neurofibromin may have a regulatory role in the development of various connective tissues including vascular connective tissue.

Several cases associated with PXE have been reported. Pathogenesis of PXE appears to involve abnormal elastic fibres. Both autosomal recessive and dominant varieties have been mapped to chromosome 16p13.1.[124]

CLINICAL FEATURES OF RUPTURED ANEURYSMS

The hallmark of SAH is sudden, usually severe headache in about 80% of cases and 45% complain of brief loss of consciousness. About 35% have nuchal rigidity. Aneurysmal rupture can lead to sudden death in about 12–15% of cases. A variety of other symptoms may develop before aneurysm rupture. They depend on the site and size of the aneurysm and include hemiparesis, dysphasia, extraocular muscle impairment, visual loss, visual field defect, localised headache and seizures and, sometimes giant thrombosed aneurysms may present as a mass lesions.[140] Prior to frank bleed, many patients experience warning symptoms, the so-called "sentinel symptoms". These are reported to occur in as high as 60–70%. These consist of headache, retrobulbar pain and nuchal pain.

Ruptured aneurysms at specific sites may produce distinct clinical features. Anterior cerebral artery (ACA) aneurysm rupture may produce brief weakness of the lower extremities bilaterally. Middle cerebral artery (MCA) aneurysms may produce hemiparesis, paraesthesias, hemianopsia and dysphasia. Seizures occur more commonly with anterior circulation aneurysms and more so with MCA aneurysms. Third nerve palsy or unilateral retro-orbital pain suggests an aneurysm arising at the internal carotid artery-posterior communicating artery junction. Third nerve involvement can also occur with aneurysms originating in the superior cerebellar artery (SCA). Carotico-ophthalmic aneurysms and superior hypophyseal aneurysms may produce unilateral visual loss or even bilateral field defects. Focal neurological deficits after SAH may be due to mass effect from giant partially thrombosed aneurysms, vasospasm, seizures or haematomas in an intracerebral or subdural location. In about 25% of patients with SAH there may be vitreous haemorrhage.[112,140]

Editors' comment: Multi-centric study "Epidemiological Study on Subarachnoid Haemorrhage in India" (1972–75) published by the Indians Council of Medical Research, 1984, and a paper by Sambasivan et al. (Neurology India 1984;32:17) provide valuable information on the subject.

CLINICAL PRESENTATION OF UNRUPTURED ANEURYSMS

Unruptured aneurysms may be discovered incidentally or present with neurological symptoms. Raps et al.[105] investigated the presenting symptoms in 111 patients with unruptured aneurysms. They found that, although 51% of these aneurysms were asymptomatic, 17% presented with acute symptomatology, and 32% presented with chronic symptomatology. Acute neurological symptoms included ischaemia (37%), headache (37%), seizures (18%), and cranial neuropathies (12%). Chronic neurological symptoms included headache (51%), visual deficits (29%), weakness (11%) and facial pain (9%). As expected, larger aneurysms tended to present with neurological symptoms because the average aneurysm sizes for these three groups were 1.1 cm, 2.1 cm and 2.2 cm in maximum diameter respectively. In addition, symptomatic aneurysms tended to be located along the proximal internal carotid artery (ICA) with diameters never smaller than 3 mm.

DIAGNOSIS

The diagnosis of SAH due to rupture of IA is made on the basis of clinical suspicion corroborated with non-contrast computed tomography (CT) scan findings, which shows the amount and location of the bleed and, thus, may point towards the vessel from where the bleed has occurred. At times, when the history is suggestive of SAH, but CT is inconclusive, a lumbar puncture may be required. But the main stay of the diagnosis is CT angiography (CTA) which is undertaken after plain CT points to a vessel from which the bleeding has occurred.

Plain CT brain can mostly accurately predict the nature and location of the underlying vascular lesion. Clotted blood is characteristically seen as a high attenuation lesion in the subarachnoid cisterns. The length of time for which the high attenuation persists depends upon the amount of blood in the subarachnoid space, with 90% positivity during the first 5–7 days, 88% positivity within 5 days and 57% positivity up to 6–14 days after the bleed. The location of SAH may give information about the probable aneurysm site, such as anterior interhemispheric fissure (IHF), suggests bleed from the anterior communicating artery (A.Com); distal IHF suggests rupture of a distal ACA aneurysm; unilateral Sylvian fissure suggests rupture of an MCA aneurysm; blood in the suprasellar cisterns is indicative of an ICA aneurysm; interpeduncular cistern bleed points to basilar top aneurysm (basilar top An); prepontine + cerebellopontine angle cisterns suggests a basilar trunk and vertebrobasilar aneurysm and isolated intra IV ventricular bleed is suggestive of distal posterior inferior cerebellar artery (PICA) aneurysm. Frontal intracerebral haemorrhage (ICH) is seen in A_1, A.Com, internal carotid bifurcation and M1 aneurysms. Temporal ICH is seen in MCA aneurysms. Basilar top and postero superiorly directed A.Com aneurysm may produce pure intraventricular haemorrhage (IVH) only.[119]

Computed Tomography Angiography

Spiral and multi-slice CT is used for three-dimensional (3D) pictures to investigate the cause of SAH. The examination includes the area between the first vertebral body and the vertex in order to visualise the intracranial arteries, after intravenous injection of 100 ml contrast medium using a pressure injector. Image reconstruction is done using section thickness of 0.75 mm, overlapping steps of 0.5 mm, and 12 cm field of vision (FOV). Changes in attenuation values are measured with a region of interest placed within the internal carotid arteries and the spiral scan is automatically started as soon as a threshold of 80 Hounsfield units (HU) is reached. Good quality CTA not only depends on the acquisition parameters, but also on post-processing, which should be performed on a fast workstation, capable of real-time 3D volume rendering. There are several methods to analyse the CTA volume.[128] First of all it is mandatory to explore source images in order to identify the aneurysm; partial thrombosis or calcification should be recognised on source images before 3D processing. Multi-planar reformation is the method of choice at the beginning of the evaluation to confirm the aneurysm and to create coronal, axial, sagittal, or oblique sections, followed by maximum intensity projection (MIP) which, however, has a limited utility in CTA due to the higher attenuation of the skull compared with intracranial arteries. With MIP, small aneurysms can be missed, as they are masked by the signal of their parent vessels averaged into the same two-dimensional (2D) plane. Shaded surface display (SSD) and volume rendering technique (VRT) are less straightforward than MIP and require the user to define thresholds for the selection of voxels on the basis of their HU. The VRT uses all voxels within a volume, avoiding the loss of information typical of MIP and SSD techniques. The "ideal" threshold to depict intracranial arteries has to be found interactively and depends on several parameters, including the injection rate of the contrast medium and cardiac output. Once the aneurysm is identified, the volume-rendered 3D images are used for depiction of the position and spatial orientation of the aneurysm neck and sac, characterisation of arterial branching patterns at the neck and depiction of the relationship of the aneurysm to local and regional bone anatomy. An accurate anatomical evaluation is useful for assessment of the suitability of an endovascular approach for aneurysm treatment. The average sensitivity of CTA for the detection of IAs is about 90%. However, for aneurysms less than or equal to 3 mm diameter sensitivity is reduced to 61%, whereas the detection rate increases to 96% for aneurysms with a larger size.[138] More recent studies found overall detection rates of up to 97%,[138] and in some centres CTA has almost completely replaced intra-arterial digital subtraction angiography (IADSA) in patients with SAH[28] (except when dynamic flow study is mandatory). Villablanca et al.[135] reported a CTA sensitivity of 98–100% compared with 95% with IADSA, suggesting a central role for CTA in the evaluation of all patients with symptomatic and potentially asymptomatic IAs.

Four-Dimensional Computed Tomography Angiography

Four-dimensional computed tomography angiography (4D CTA) entails multi-slice CTA with a retrospective electrocardiographic-gated (ECG-gated) reconstruction algorithm by use of technology that was developed initially to examine coronary arteries. It is a novel technology that includes time dimension, which is repeated within the cardiac cycle. This is an important difference between 4D CTA and conventional cerebral angiography. The purpose of 4D CTA is to clarify the value of aneurysm wall pulsations and actual haemodynamic behaviour on the diagnosis and treatment of patients with aneurysm.[49]

Technique

In 4D CTA, angiographic images of the region around the circle of Willis are acquired by using multi-section helical CT systems in ECG-gated mode with a tube current of 260 mA and a tube voltage of 135 kV. The helical pitch/tube rotation speed is usually 0.7–1.2/0.4 seconds per rotation with the 4-row system, and 2.0–2.4/0.4 or 0.5 seconds per rotation with the 8-row system and 2.0–4.0/0.4–0.6 seconds per rotation with the 16-row system may also be used. Images are reconstructed by using the ECG-gated reconstruction method (with the R-R interval divided into 20 phases at 5% intervals). A total of

100 ml of non-ionic contrast medium (iopamidol) with an iodine concentration of 370 mg/ml is injected intravenously at a rate of 3 ml/sec by using an automatic injector. Scanning is started after a delay time of 20–23 seconds following the start of injection or by using the bolus-tracking function of the CT scanner.

Electrocardiographic-gated reconstruction: In the cardiac cycle, systole corresponds to the period from 0 to 50% of the R-R interval, with maximum contraction occurring at approximately 25%. The pulse wave generated during systole propagates towards the periphery at a speed of 4–6 m/s in the aorta and 8–12 m/s in the muscular arteries.[37] Pulsation of IAs can be observed during the period from 45 to 55% propagation of the pulse wave into IAs. About 84% of aneurysms rupture at the dome, 14% in the wall and 2% at the neck.[49] In particular, the presence of a bleb is important as an indication of the rupture site. In 4D CTA studies, the pulsation can be observed only in a bleb on the aneurysm which subsequently can be confirmed at the time of clipping.[37]

Magnetic Resonance Angiography

Although magnetic resonance angiography (MRA) has given very good results in detecting aneurysms in acute SAH,[137] it is often impractical in severely affected patients, due to long examination time, low spatial resolution compared to digital subtraction angiography (DSA), high cost, sensitivity to motion artifacts and difficulty in demonstrating vessels with low flow. These limitations make intracranial MRA a preferred screening modality only for specific groups at higher risk of harbouring an aneurysm than the general population, e.g. diseases of connective tissue such as Ehlers-Danlos type IV, ADPKD, fibro-muscular dysplasia, neurofibromatosis type 1 and AAT deficiency. The MRA is also recommended in families with greater than or equal to 2 first-degree relatives with SAH.[124] Unlike CTA and IADSA, MRA has the advantage of high sensitivity to the flow phenomena and, therefore, cerebral vessels can be displayed without contrast medium administration. Three basic MRA techniques are currently utilised:

1. Time-of-flight (TOF)
2. Phase-contrast (PC)
3. Gadolinium enhanced MRA.

All these techniques are based on 2D or 3D acquisition of flow-sensitive images of intracranial vessels with background suppression and production of angiographic projections for visualisation of the intracranial vasculature. The 3D (volume) acquisitions are preferred for the intracranial arteries, as lower gradient amplifier demands allow reduced echo time as well as higher signal-to-noise ratio, which may be used to achieve greater spatial resolution. For screening examinations 3D TOF MRA has almost replaced PC MRA, which is characterised by longer duration and lower spatial resolution due to a larger imaging matrix. Currently, a standard 3D TOF MRA investigation of the cerebral vessels is performed with multiple overlapping volumes (three to five) from the foramen magnum to the pericallosal artery, fat saturation, magnetisation transfer and high resolution matrix (256 × 512) to increase vessel-to-background contrast, rectangular FOV and 8–10 minutes acquisition time. Selective spatial saturation is often used in arterial TOF studies where a saturating pulse applied distal to the imaging volume is used to suppress venous blood. Spatial resolution is critical for depicting smaller aneurysms and also to minimise the effects of turbulent flow in large aneurysms. Compared with CTA, MRA has the disadvantage of a limited coverage of the intracranial vasculature. The average sensitivity and specificity of MRA for the detection of IAs is, respectively, 87% and 95%. However, sensitivity for aneurysms with a size of 3 mm or below drops to 38%, whereas the sensitivity for aneurysms with a larger diameter is 94%.[138] Aneurysms with a small sac or neck diameter, or which stem laterally to the feeding vessel will tend to receive little flowing blood, and thus are less conspicuous on 3D TOF magnetic resonance (MR) angiograms. Within a large aneurysm, recirculation can lead to saturation of the blood signal and compromise the angiographic contrast between the lumen of the aneurysm and the surrounding static tissue. More recently, gadolinium-enhanced MRA has been done for the evaluation of larger aneurysms with turbulent flow, usually underestimated in size by the traditional technique.[86] Although particularly useful for MR examinations with both a large coverage volume and high spatial resolution, until now contrast enhanced MRA has not reached widespread use, due to the lack of contrast of proximal arteries against enhanced venous structures near the cavernous segment of the ICA.

Intra-Arterial Digital Subtraction Angiography

Angiography is still required for pre-operative planning. The IADSA is the accepted diagnostic procedure of choice for the assessment of IAs and for the pre-operative treatment planning of patients and after a negative CTA or MRA examination in a patient with SAH.

A four-vessel IADSA is still the most sensitive tool to detect an IA and is the gold standard. This is ideally performed with selective injection of the ICAs and vertebral arteries within 24 hours of the bleeding. The IADSA usually succeeds the CT/CTA examination, which often indicates the appropriate vessels where the aneurysm takes origin from. When multiple aneurysms are discovered, in general, the larger and more irregular aneurysm seen on arteriograms is likely to have bled. A nipple irregularity is as highly significant as a focal mass effect or vasospasm.[92] The DSA should include sufficient views, including lateral, anteroposterior or angled anteroposterior, oblique and basal, and an unsubtracted film also is necessary. Adequate demonstration of neck size is important for planning aneurysm clipping, as well as in predicting the success of treatment with the Guglielmi detachable coils, because total occlusion is more likely in aneurysms whose neck is 4 mm or less.[23]

The primary advantage of IADSA over other imaging modalities is the high resolution. The selective

intra-arterial injection of iodinated contrast medium ensures optimal enhancement of the intracranial arteries with superior resolution compared with that of CTA or MRA. Very small diameter vessels and perforators can be imaged only on IADSA. This information is mandatory at certain locations. However, in some cases, IADSA may lead to ambiguity due to its inability to project the aneurysm sufficiently, leading to a less than optimal definition, therefore impairing the choice of the optimal treatment method.

3D rotational angiography reveals aneurysms not seen on conventional DSA and allows a clearer depiction of anatomic details which are important for therapeutic planning.[40] It serves as a useful adjunct to IADSA, providing precise measurements necessary for endovascular coiling.[31,131]

Figures 1–27 show various investigations related to the diagnosis of intracranial aneurysms.

LOCATION OF INTRACRANIAL ANEURYSMS

Aneurysms commonly arise at the bifurcations of major arteries and from branching sites. Most saccular aneurysms arise in the circle of Willis or the MCA bifurcation. Approximately 86.5% of all IAs arise in the anterior (carotid) circulation and about 10% of IAs arise in the vertebrobasilar circulation. About 3.5% of IAs occur at miscellaneous locations like the SCA and the anterior

inferior cerebellar artery. Common locations include the A.Com (30%), the junction of the ICA and the posterior communicating artery (P.Com) (25%) and the MCA bifurcation (20%). The ICA bifurcation (7.5%) and the pericallosal/callosomarginal artery junction account for the remainder (4%). Around 7% arise from the basilar artery bifurcation, and the remaining 3% arise at the origin of the PICA where it comes off the vertebral artery. Saccular aneurysms are uncommon in locations other than the sites mentioned above. Aneurysms that develop at distal sites in the intracranial circulation are often caused by trauma or infection. Non-traumatic distal aneurysms, particularly along the ACA, have a high frequency of multiplicity and spontaneous haemorrhage. The authors' operative experience shows the distribution as under:

AGE AND SEX DISTRIBUTION

Aneurysmal SAH commonly occurs in the age group of 40–60 years with a peak incidence in the fifties. This is two decades older when compared to SAH due to arteriovenous malformations and one decade younger when compared with hypertensive intracerebral haematoma. It thus, occurs in the population at their most productive age.

The following bar diagram (Fig. 28) shows the incidence of aneurysmal SAH in different age groups (NB: In neonates only 19 cases have been reported so far).

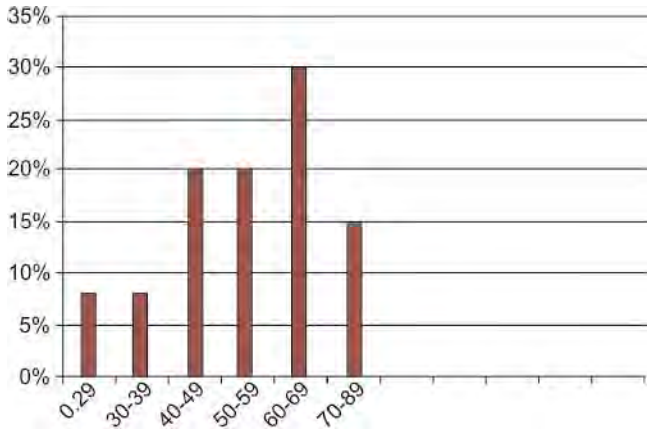

Fig. 28: Incidence of aneurysmal SAH in different age groups

The majority of epidemiological surveys have reported a higher incidence of SAH in women than men.[10-12,48,52,62,98,103,130,131] This observation, however, is not universal. Two large population-based registries found a higher frequency in men[46,113] and a third found no gender related differences at all.[29] Although the source of this variability is not completely understood, differences in age distribution may provide a partial explanation because the relationship between gender and incidence is age dependent.[63,113] Aneurysmal SAH is more common in males than females in childhood and adolescence.[10,24,99] This, however, reverses and, by the sixth decade of life, more women have aneurysmal SAH than men. The reason for gender-related differences is unclear. Longstreth and his colleagues[79] have proposed that hormonal factors may play a role in the pathogenesis of aneurysmal rupture. Gender does not predict the severity of presentation, outcome or survival from SAH.[48,63] Although mortality rates in women are higher than in men,[48,53,130] no significant differences in case fatality rates have been reported.[35,98] This suggests that women are more likely to die from SAH only because they are more likely to experience SAH.

MANAGEMENT OF ANEURYSMS

Patients with ruptured IAs should be treated as soon as possible after the haemorrhage to prevent re-bleeding and to provide adequate medical treatment of vasospasm.

Until recently, the standard method of treatment for IAs has been surgical clipping, however, during the last decade the introduction of Guglielmi detachable coils has completely revolutionised the management of patients with IAs.[31] The endovascular treatment of cerebral aneurysms consists of filling the aneurysm sac with soft platinum coils through a microcatheter which is usually placed at the neck of the aneurysm. The choice of treatment depends upon the anatomical characteristics of the aneurysm, mainly the size, location, neck width and the clinical condition of the patient. The dome:neck ratio should also be measured, since it significantly affects the ability to completely coil the aneurysm.[28] Patients with poor Hunt and Hess grades, namely 4 and 5, are generally poor neurosurgical candidates and can benefit from endovascular treatment. Patients with a basilar top aneurysm are good candidates for endovascular coiling, as surgery is limited by the small working space at a depth and the presence of perforating arteries to the brainstem. MCA aneurysms are less suitable for coiling, as the secondary branches are close to the neck and the neck is usually wide. Although the results of endovascular treatment of small aneurysms (< 10 mm) and aneurysms with small necks are promising, the rate of success is less in aneurysms with larger diameters and wider necks.[135,137] One of the major disadvantages of coiling is the chance of partial re-canalisation of the aneurysm even in the first few months after a successful procedure due to coil compaction. Different options for aneurysm treatment have been recently proposed, among which combined treatment of large-neck aneurysms with intracranial dedicated stents and coils, balloon-assisted coiling (the so-called remodelling technique) and bioactive coils which promote complete neck endothelisation.[86]

The therapeutic management of SAH has considerably changed since the publication of the International Subarachnoid Aneurysm Trial study, the only randomised trial which compared endovascular coiling with surgical clipping in ruptured aneurysms.[92] The study shows that endovascular intervention with detachable platinum coils in patients with ruptured IAs can improve the chances of independent survival compared with neurosurgical clipping of the neck of the aneurysm. The results indicate that embolisation with coils is a reasonably safe procedure with a low complication rate, not only in patients with a ruptured aneurysm, but also in patients with an unruptured aneurysm and in patients with a basilar bifurcation aneurysm. Introduction of flow diverters is a useful addition to existing endovascular therapy. Although the natural history of ruptured aneurysm has been well defined, there is still controversy regarding the natural history of unruptured aneurysms, particularly those aneurysms which are less than 10 mm in size.[23]

ANEURYSMS IN NEONATES AND CHILDREN

Aneurysms are uncommon in children as compared to adults. IAs account for 5–6.8% of cases.[72] The reported incidence is higher in females as compared to males,[59] but Lasjaunias reports that the incidence is higher in males up to 2 years of age and, thereafter, the incidence is higher in females. Posterior circulation aneurysms are more common in children than adults, i.e. 39% in children versus 5% in adults.[72]

Intracranial Aneurysms in Neonates

IAs are extremely rare in neonates and only 19 cases have been reported in the literature. The clinical presentation of SAH in this age group is often non-specific. The mean age at diagnosis is 13 days. There is a slight female predominance (M/F = 7/10), as in adults. This contrasts with the male predominance shown in paediatric aneurysms.[59,78,87] Clinical presentation is extremely variable.[59] Common clinical manifestations are irritability (44%), seizures (44%), alteration of consciousness (31%), bulging fontanelle (31%), vomiting and failure to thrive (25%), and opisthotonus (25%), all of which can be linked to SAH.[125] Other manifestations are apnoea, cyanosis (36%) and fever (13%). No patient presented with focal neurological deficit due to mass effect.

Diagnosis

To confirm a suspected neonatal aneurysm, transfontanelle cranial ultrasonography should be undertaken first and if it fails to show the aneurysm, then an MRA should be performed and, finally, a CTA if the MRA is not sufficient. Conventional cerebral angiography remains a gold standard technique, but bears significant risks in the neonate.[126]

About 56% of neonates had MCA aneurysms and 28% had posterior circulation aneurysms which is in keeping with the general paediatric incidence.[72,122,125] Aneurysms of the PICA are extremely rare in this age group.[18] Over three quarters of neonatal cases involve large (> 10 mm) or giant lesions (> 25 mm), which is also similar to the paediatric population.[24,64,125] Posterior circulation aneurysms and large or giant aneurysms are more frequent in neonates and children than in adults. There was one mycotic and two traumatic aneurysms and the remaining were congenital.

Treatment

Most neonatal aneurysms have been treated conservatively (58%), whilst 37% were managed surgically. Surgery is usually better tolerated in young children than in adults.[42] Indication for surgery depends on the type of aneurysm. For example, dissecting aneurysms with extensive vessel wall damage and no evidence of mural haematoma have a strong tendency to re-bleed and, therefore, need aggressive management.

In contrast, dissecting aneurysms with mural haematomas frequently thrombose spontaneously and can be managed conservatively.[72] Although endovascular interventions are routinely used in the treatment of vein of Galen malformations, often wrongly called aneurysm of the vein of Galen, their application in the treatment of IAs in the very young has been reported in only a few cases,[64,102] with only one case[122] in the neonatal period.

Complications

In children, the overall tolerance to SAH seems better than in adults.[72,74] This is probably due to less sensitivity to post-haemorrhagic spasm, which is a major cause of morbidity and mortality in adults.[27] Vasospasm associated with haemorrhage is usually well tolerated in the paediatric age group with a relatively low incidence of ischaemic deficits,[24,72,125,126] and there also seems to be less incidence of delayed vasospasm.[18] Ferrante[24] et al. even claim that vasospasm is not found to be a significant contributing factor in morbidity or mortality. According to Patel and Richardson,[102] the absence of cerebral infarcts on necropsy studies (even in patients with angiographic evidence of vasospasm) combined with the absence of cerebral atherosclerosis might explain the low incidence of mortality and morbidity of ruptured IAs in the first two decades of life, in contrast to adults in whom up to 60% have infarcts.

Outcome

General outcome in the paediatric aneurysm population is better than in adults. In neonatal aneurysms, favourable outcome was seen in 59% of cases, but mortality was as high as 41%. Considering the progress in diagnosis and surgical treatment made in the 1980s, if we take into account only the cases described after 1980, the mortality rate drops down to 25%. Mortality in the first 48 hours after first bleed is reported to be 11% in early childhood and 14–34% in adults.[78]

The prognosis is poor for ruptured aneurysms in neonates if they are left untreated.[18] Of the 11 aneurysms conservatively treated, seven (64%) died. In the group of aneurysms treated by surgery or embolisation, only one died (14%) despite surgery, but it is important to note that he was initially treated conservatively until he re-bleed a month later.

The prognosis also depends on the aneurysm location. Neonatal MCA aneurysms carry a better prognosis than posterior circulation ones. This has been attributed to the tendency for intracerebral haematomas to be at peripheral sites (due to peripheral location of aneurysm), the rarity of vasospasm and the good functional compensation of the young brain. Tekkok and Ventureyra[126] suggest that the plasticity of the infant brain allows the possibility of recovery even in a seriously sick child, provided aggressive and appropriate treatment is considered early. Early diagnosis and treatment increase rates of favourable outcome,[59,81,122] but long-term prognosis is unknown.[125]

Intracranial Aneurysms in Children

The commonest site in paediatric patients is the ICA bifurcation followed by the MCA bifurcation and the vertebrobasilar system.[72,76] Large and giant aneurysms are commoner in children as compared to adults. The reported incidence is 20–45%. The incidence of multiple aneurysms is less in children as compared to adults.[18,27,38,59,64,72,74,76,78,81,87,102,122,125,126]

The aetiology and pathogenesis of paediatric aneurysms are not clear. While Allison et al.[4] regard it as a congenital disease, Agid et al.[2] do not consider it to be truly of congenital nature. Sekhar and Heros,[116] and Stehbens[123] suggest that it is due to an interplay between the structural changes in the vessel wall and stress. Lasjaunias et al.[72] suggest that aneurysms in children are a result of expression of various vessel dysfunctions which result in transient or permanent failure to repair a partial insult. In addition to congenital conditions (Marfan's syndrome, Ehler-Danlos syndrome, polycystic kidney disease, PXE, sickle-cell anaemia, tuberous sclerosis), infection (bacterial endocarditis) and trauma (closed and penetrating head injury, irradiation) also contribute to the aetiology of aneurysms in paediatric patients.

The presenting features of IAs in the paediatric population are different from those in adults. The incidence of SAH in previous reports has varied from 35 to 100%.[44,104,110] Sharma et al.[120] reported that the incidence of SAH was 82% in their case series, and the majority (86%) of those who presented with SAH had good Hunt and Hess grades. Liang et al.[76] report that the most common presentation was acute severe headache caused by SAH. The incidence of SAH was 46%, which was lower than that reported by others. Besides SAH, the presentation in this group included focal neurological symptoms from mass effect such as proptosis, diplopia, hemiparesis, chronic or intermittent headache, dizziness and so on. The incidence of mass effect was remarkably higher (54%) than in other reports. There can be seizures in about 18% cases.[120]

Treatment

Just as for aneurysms in adults, the treatment for paediatric IAs has undergone significant evolution in recent years. At present, multi-modal treatment strategies are widely used as a standard approach and have, therefore, resulted in significant improvement in patient outcomes.[2,120] The choice of treatment method for a given aneurysm is made by a multi-disciplinary team of neurosurgeons and interventional neuroradiologists. Surgical clipping or endovascular treatment can be decided according to site and size of the aneurysm. Children withstand surgery better than adults due to greater brain functional capacity and better vascular status.[72] The endovascular approach is preferred whenever possible technically, and is less dependent on the patient's

clinical situation because the majority of aneurysms in the paediatric population are either large or giant and/or in the posterior circulation.[76]

ANEURYSMS IN THE EIGHTH AND NINTH DECADE

Elderly patients with aneurysmal SAH account for up to 40% of all patients treated conservatively and surgically.[66] The percentage of elderly patients undergoing surgical treatment varied from 7 to 30% of all aneurysmal SAH patients.[47,70,97]

Advanced age is one of the recognised risk factors for poor outcome in aneurysmal SAH patients.[61,70,97] In the international co-operative study of the timing of aneurysm surgery, Kassell et al.[61] in 1990, clearly demonstrated the linear correlation between age and outcome. Conversely, some studies have shown that increasing patient age was not a risk factor associated with unfavourable outcome in the elderly.[22,34,47]

Horiuchi et al.[43] have shown that the important predictors of outcome of patients in the eighth decade of life were age, clinical pre-operative grade and pre-operative CT findings. By contrast, in the ninth decade, clinical pre-operative grade and pre-operative CT findings, but not age, were significant factors in the prognosis. These results indicate that there are some differences in clinical characteristics between these two decades of life. Favourable outcomes of surgically treated elderly patients have varied from 39.6 to 60%.[34,43,47,141] There is controversy whether poor grade patients be treated conservatively or surgically, but recent studies show that even poor pre-operative grade patients made a good recovery indicating that results of conservative management can be catastrophic. The site and size of aneurysms do not have much bearing on the outcome in the elderly.[141] Other important factors in addition to clinical grade are associated co-morbidities, Fisher grade, associated ICH/IVH, pupillary status and the intracranial pressure.

FUSIFORM ANEURYSM

Fusiform aneurysm (FA) is defined as a circumferential arterial dilatation resulting from pathological involvement of the entire artery.[5,13,25,95,117] All aneurysms exhibit a spindle shape when viewed externally.[16] Conceptually there is still confusion as to the aetiological, clinical and radiological features of FAs. Many investigators have applied the term "atherosclerotic" as the cause of FAs.[19,20,25,88,91] In fact, advanced atherosclerotic arteries have a slightly fusiform appearance. However, the classic dissecting aneurysm also has a fusiform appearance.[88] Several authors have recently reported the presence of FAs caused by dissection.[5,6,13,14,16,25,36,39,42,65,69,82,88,89,91,93,117] Therefore, all cases of FAs based on external view without consideration of aetiology were included in this study except well known typical cases of dissecting aneurysm of the vertebral artery.

The age and sex distribution of patients with FAs differ from those with saccular aneurysms. The mean age of patients is 45.1 years and the male:female ratio is 1.4:1. This contrasts with that of patients with saccular aneurysms.[5,13,16,19,20,25,42,75,88,93,95,96,108,117,136,142]

The clinical features of FAs are categorised morphologically. They can progress from a small focal dilatation or vessel narrowing to a relatively thick-walled, tortuous dilatation and elongation of the artery. FAs can be incidental or asymptomatic, discovered during work up for unrelated symptoms. They can present as a non-specific headache without haemorrhage or other neurological signs or symptoms, as ischaemia, transient ischaemic attack or complete stroke, as mass effect with or without seizure, or as haemorrhage, subarachnoid or intraparenchymal. Patients with small, large and giant aneurysms with focal dilatations of their lumen had SAH rates of 80%, 62% and 23%, respectively, whereas ischaemic symptoms, such as transient ischaemic attack or complete stroke, were the presenting feature in 31%. Haemorrhage is the most common presentation in patients with small lesions with focal dilatation, whereas ischaemic symptoms are the most common presentation of patients with stenosis or occluded vessels.[88] FA of the vertebral artery can present with hemifacial spasm due to mass effect.[114]

About 75% of FAs are seen in the anterior circulation and the rest in the posterior circulation. Dissection has been proposed as the main underlying cause of FAs and most commonly involves the posterior circulation, especially vertebral and basilar arteries.[6,14,16,19,20,25,36,51,65,69,75,80,82,89,91,93,109,113,136] Dissecting aneurysms can originate in any region of the anterior circulation, such as the ICA,[51,96,108,114,136,142] MCA,[6,26,31,50,59,68,79,80,100,118,134,137] the ACA[6,36,65,69,73,89,94,136] and rarely in the anterior choroidal artery.[82] The MCA is the most common site for spontaneous FAs (75%), followed by ICA and ACA.[16] Of the MCA, FAs 69% originate proximal to the MCA genu (M1 segment), 21% at the insular (M2) segment and 10% at distal (M3 or M4) branches.[16] Various aetiological factors for FAs have been proposed, including atherosclerosis, vessel dissection and association with other diseases such as Von Recklinghausen's disease, fibromuscular dysplasia, systemic lupus erythematosus and various collagen-associated vascular diseases.[13,16,100,117] Park et al.[101] found vessel dissection to be the leading cause, followed by atherosclerosis and collagen disease, or unknown factors.

Pathogenesis

The initial event in the formation of atherosclerotic FAs is thought to be lipid deposition in and beneath the intima. This disrupts the internal elastic membrane and infiltrates the muscular wall.[136] Intramural haemorrhage and rupture of the atheroma leads to transmural extension of the thrombus and thickens the intima to create the fusiform shape of the aneurysm.[88,136] Rupture of the vasa vasorum by shear forces or by stress on the luminal

wall then causes intimal tear and fracture of the internal elastic membrane. This permits bleeding into the arterial wall to form a haematoma.[16,51] If the dissection occurs between the internal elastic lamina and the media, the vessel lumen becomes narrow or occluded with an intramural haematoma and the patients present with ischaemic symptoms.[6,16,42,51,88,136] If dissection occurs between the media and adventitia, the aneurysm can rupture and the patient will present with SAH or ICH.[6,16,51,136] An intramural thrombus that ruptures into the lumen will cause distal embolisation and further expansion of the intramural clot will lead to vessel occlusion.[113] After the vessel is occluded by intramural clot, it can re-canalise and enlarge the dissection both laterally and longitudinally. A serpentine channel forms as the disease extends longitudinally, combined with varying degrees of intraluminal thrombosis.

Treatment of Fusiform Aneurysms

It depends on the presence and type of symptoms, the lesion size and location, and the risk of any accompanying intervention. Day et al.[16] have suggested guidelines for the treatment of patients with dissecting aneurysms of the MCA. They recommend that most small and some large focal dilatations, especially those that are asymptomatic, should be treated conservatively unless serial neuroimaging assessment indicates significant enlargement over time. However, the appearance of symptoms requires aggressive intervention. Lanzino et al.[69] and Nikawa et al.[93] also recommend conservative treatment in patients with dissecting aneurysms without neurological deterioration or re-current SAH due to of the possibility of spontaneous evolution of a dissecting aneurysm. In general, the authors agree with the recommendation of conservative treatment for non-symptomatic dissecting aneurysms. However, we recommend clipping using encircling clips for focally dilated dissecting aneurysms if they are found during surgery for another symptomatic aneurysm, and aggressive surgical treatment for FAs which are not caused by dissection, due to the possibility that they will progress. Day et al.[31] and several other authors[6,20,69,109,136] recommend that patients with stenotic or occlusive lesions presenting with acute ischaemic symptoms should be treated conservatively. Kurino et al,[82] learning a lesson from their patient with a dissecting aneurysm in the MCA who presented with ischaemic symptoms and who had a poor outcome after conservative treatment, recommend surgical revascularisation distal to the compromised artery. The authors agree with the policy of conservative treatment for patients with stenotic or occlusive lesions and acute ischaemic symptoms. Park et al.[101] from their experience of a case with a fusiform dilatation dissecting aneurysm in the PICA with cerebellar ischaemic symptoms, which bled later after conservative treatment and was subsequently treated successfully with endovascular methods, recommend consideration of aggressive treatment with endovascular or surgical methods for focal dilating FAs. Direct "aneurysm only" clip application was associated with a high rate of re-growth of the lesion or re-bleeding caused by preserving flow in the normal half of the affected vessel, despite excellent intra-operative aneurysm obliteration.[16,93] Therefore, many authors recommend proximal occlusion or trapping with or without resection combined with end-to-end anastomosis or external carotid-internal carotid (EC-IC) bypass,[6,13,16,25,36,39,42,69,108,117,136] but there is no consensus on this issue. Many authors recommend occlusion of the aneurysm and parent vessel by endovascular methods.[14,75,78,114]

MANAGEMENT OF RUPTURED ANEURYSMS

There is no controversy that ruptured aneurysms need to be tackled either surgically or by endovascular treatment or by combined treatment, but the important consideration is the status of the patient at the time of presentation. Patients who are in good Hunt and Hess grade/World Federation of Neurosurgeons Scale are treated at the earliest while poor grade patients are initially managed conservatively and once they improve then they are taken up for definitive treatment. Once detected or suspected to harbour an aneurysmal bleed the patient is put on bed rest, analgesics are administered and the patient is adequately hydrated. Routine haematological investigations including coagulation profile and biochemical investigations are done to evaluate the patient for CTA and surgery. A CTA is asked for to see the location of the ruptured aneurysm, its relationship with the parent and other vessels, and configuration. In the majority of cases it suffices, but in some cases an IADSA needs to be done in addition. Transcranial Doppler (TCD) sonography is performed to evaluate the flow velocities in the intracranial vessels, which not only serves as a baseline value, but also gives an idea about vasospasm. Medical treatment other than that mentioned above is required in cases in a poor grade where surgical treatment is held in abeyance for some reason.

Surgical Principles

Positioning and Craniotomy

Almost all anterior circulation aneurysms, the majority of basilar top and P1-P2 junction aneurysms can be operated upon by the standard pterional craniotomy. At times some modification to it may be necessary as is required in distal MCA and A2 segment aneurysms. A fronto-orbito-zygomatico temporal craniotomy may be required for some basilar top aneurysms.

For a standard pterional craniotomy the patient is positioned supine and an arterial line is introduced for invasive monitoring of blood pressure. The head is fixed with a three or four pin fixator and is rotated 15–20 degree to the opposite side. The neck is extended and head elevated by 30 degree. A generous scalp flap is raised and a frontal burr hole is made anterior to the coronal suture 3 cm away from the midline and this can be used for external ventricular drainage during surgery.

After raising the bone flap the lateral part of the sphenoid ridge is drilled.

Further Steps

- Good extradural haemostasis should be obtained. The dura is opened at the base and the Sylvian fissure is split. The optic nerve and the ICA are identified and CSF is let out from the optic, carotid and interpeduncular cisterns. If the brain does not relax, the frontal horn may be cannulated and CSF let out. Brain retraction should be as minimal as possible and the face of the spatula should be parallel to the brain surface.
- Arachnoid dissection is the next important step. The arachnoid should be dissected extensively mainly using sharp instruments.
- The intracranial arteries, as far as is possible, should be dissected on their ventral surface as there are hardly any perforators originating from this surface of the vessel. Adequate vascular control is imperative. It helps when the aneurysm ruptures intraoperatively. Proximal and distal control should be achieved after exposing the parent artery and space is made so that a temporary clip can be applied in case of need. The distal artery must be exposed to expose the anatomy of these segments. Sometimes, the distal portion of the parent vessel opposite the side on which the aneurysm arises should be exposed before the neck of the aneurysm is dissected.
  The neck of the aneurysm is dissected before the fundus and all the perforating branches should be separated from the aneurysm neck and the neck should be dissected all around before the clip is passed around the neck of the aneurysm. Blind application of one or both blades of the clip should be avoided and the perforators should be safeguarded. In most cases both the blades of the clip can be visualised by extending the dissection to expose the neck and fundus. After the aneurysm is clipped, the area should be inspected to make sure that the clip is not kinking or obstructing a major vessel or compromising the wall of the main vessel and that the clip has not included any perforators. At no time the entry of the clip in the space created should be forced. In case there is an arterial bleed at the time of clip application, the clip is applied. If the bleeding stops subsequent to clip application a more thorough dissection should be done to see if there is non-inclusion of any vessel in the clip, compromise of the main vessel lumen or incomplete clipping of the neck. In case the bleeding increases or continues after clip application, the clip is removed and a temporary clip is usually applied. If bleeding settles on clip removal adequate dissection is performed beyond the small rupture point. In case prolonged temporary clipping is required it should be intermittent. About 5 minutes of clipping with around 10 minutes of reperfusion in between. It is better if temporary clipping is done under neuroprotection measures.
- If the facility exists then indocyanine green angiography should be used to visualise the adequacy of aneurysm clipping and any vessel compromise by the clip. If available, the surgeon must use intraoperative Doppler sonography to measure the flow velocities in the proximal and distal arteries after clipping of the aneurysm.

Figures 29–32 show operative photographs related to the management of intracranial aneurysms.

MANAGEMENT OF COMPLEX ANEURYSMS

General principles remain the same as that for any other aneurysm. The details are discussed in the specific Chapters.

TRAUMATIC INTRACRANIAL ANEURYSMS

Smith was the first to report about a post-traumatic middle meningeal artery aneurysm after autopsy in 1829,[121] but it was not till 1934 that a traumatic intracranial aneurysm (TICA) was demonstrated angiographically.[129] About 500 cases of TICA have been reported so far. The incidence of TICA is about 1% in adults, but in children TICA contributes to about 30% cases of all IAs.[134] The reason why the incidence is high in children could be due to lower incidence of saccular aneurysms in children.[127] TICAs are commonly seen in young adults in their twenties. This group is more vulnerable to risk of blunt and penetrating trauma. There is

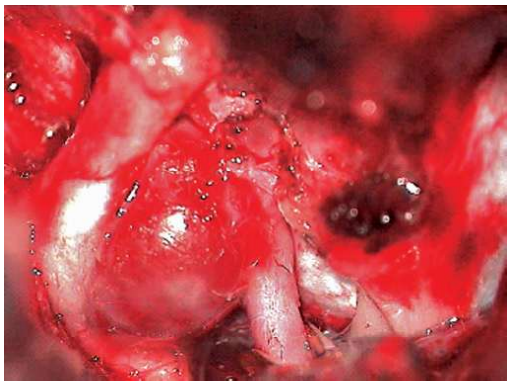

Fig. 29: Operative photograph—giant carotico-ophthalmic artery aneurysm

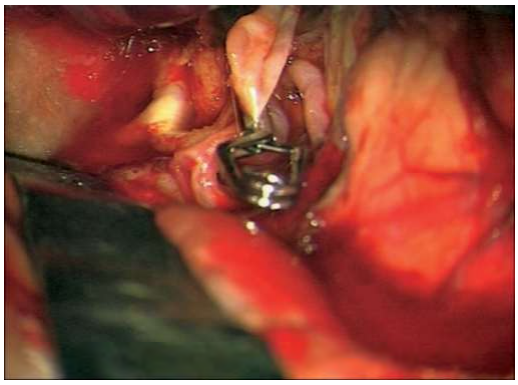

Fig. 30: Operative photograph of clipped large anterior communicating artery aneurysm

Fig. 31: Operative photograph—anterior communicating artery aneurysm

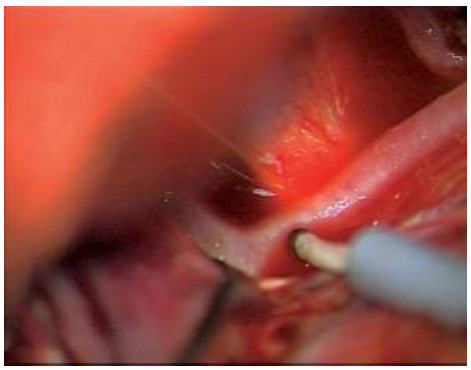

Fig. 32: Operative photograph—microvascular Doppler insonating anterior cerebral artery

a male predominance. The male:female ratio is reported as 12:1[87] and 50:1.[33] In children TICA can occur with less severe trauma and shaken-baby syndrome can lead to TICA.[67] The relative incidence of TICA varies according to aetiology; blunt trauma in 60–70%, penetrating injuries in 16–26% and iatrogenic in about 10%.[7,17,134]

TICAs can be classified in numerous ways either on the basis of aetiology into blunt trauma or penetrating injuries, or iatrogenic injuries.[30] Penetrating injuries are further subclassified into secondary to missile injuries or secondary to stab injuries. Alternatively they can be classified on the basis of anatomy into extracerebral (middle meningeal artery) or intracerebral groups. The latter is again subdivided into two groups as proximal to the circle of Willis which includes ICA supraclinoid and infraclinoid segments and vertebrobasilar artery and distal to the circle of Willis which includes subcortical and cortical branches.

Pathogenesis

The mechanism of TICA formation is different for different aetiologies. While a shearing injury of the vessel or entrapment of a cortical branch within a widened linear skull fracture or tearing process which occurs while a freely mobile vessel is rubbed against a fairly hard edge explains TICA formation in blunt trauma; a low speed bullet injuring the vessel wall explains a TICA following a missile injury. Pathologically TICAs can be classified into three groups:

1. True aneurysms (resulting from partial laceration of the vessel wall, i.e. injury to the intima or adventitia or both)
2. Pseudo or false aneurysms
3. Mixed aneurysms.

In a pseudo-aneurysm there is complete disruption of the arterial wall and subsequent haematoma formation which undergoes fibrous reorganisation enclosing the lumen and forms the wall of the aneurysm. A mixed aneurysm occurs when a true aneurysm ruptures forming a false aneurysm attached to it. TICAs are usually seen on the secondary branches, while saccular aneurysms occur on the large blood vessels at the base of the brain or major branches. TICAs are located along the course of the artery often near the sharp edges, while saccular aneurysms are at the bifurcation of major vessels.[30]

Clinical Presentation

A patient with TICA gives a history of trauma which could be blunt or penetrating. Blunt trauma is usually a major trauma in adults and minor trauma in children. The patient may present either awake or may have any degree of altered sensorium. A person who is awake usually complains of headache. Cranial CT shows haemorrhage which could be either intraparenchymal, intraventricular, subarchnoid or subdural. Initial management focuses on diagnosis and management of the presenting head injury. Delayed depressed levels of consciousness, seizures and new neurologic deficits point towards TICA.[71] Alternatively, a supraclinoid TICA may present with headache, memory changes and visual loss. An infraclinoid TICA can present with diabetes insipidus or compressive cranial nerve palsies caused by an enlarging aneurysm.[83,85] An intracavernous TICA can rupture into the cavernous sinus leading to caroticocavernous fistula formation. A triad of unilateral blindness, cranial base fractures and recurrent epistaxis should lead to suspicion of an ICA injury originating at the base of the brain. Aneurysms of the distal branches like the pericallosal produce deficits that correspond to their location. In about 10–20% of the cases the aneurysm may be asymptomatic. In infants a growing aneurysm can lead to a growing skull fracture.

Editorial comment: In a very large series of growing skull fracture the editor (PN Tandon) did not find a single case of this aetiology.

TICAs can be diagnosed by delayed CTA or MRA. Although TICAs can occur within a few hours after injury, most develop over days and may be missed by angiography. Angiographic features suggestive of TICA include delayed filling and/or excessive delay in emptying of the sac, lack of relationship with arterial branching, irregular appearance and absence of a neck.[1]

A small number of TICAs can thrombose spontaneously with time,[26] but TICAs typically enlarge and rupture and, therefore, it is recommended that once diagnosed, a TICA should be excluded from the circulation regardless of size and location, either surgically or by endovascular means.[30] A large proportion of TICAs, particularly those located close to skull base, result from rupture of an entire arterial wall.[9] The location at the skull base and rupture of the entire vessel wall during surgery are two great problems. In such situations, ICA trapping with or without EC-IC bypass is a better option[17] or endovascular aneurysm obliteration is another option.

Endovascular procedures have their own associated morbidity. A high neck:fundus ratio may make an endovascular procedure difficult. Placement of a balloon or coil directly into a pseudo aneurysm may lead to massive haemorrhage. In such situations endovascular trapping or occlusion of the parent artery with detachable balloon or endovascular stent placement appears to be a safe procedure.[132]

POST-OPERATIVE MANAGEMENT OF INTRACRANIAL ANEURYSMS

In the post-operative period, vasospasm and development of hydrocephalus are the main causes of neurological worsening in addition to other causes such as electrolyte imbalance.

Post-operatively patients are assessed neurologically, and with TCD and CT scan. Patients at risk of developing vasospasm are monitored closely in the intensive care unit. All patients are given nimodipine, starting within 4 days of SAH and continued for 21 days regardless of admission grade. There is controversy regarding this and many surgeons do not give nimodipine. The usual dose for an adult is 60 mg 4th hourly.[3,8] Neurological status is watched carefully and TCD studies are done to detect vasospasm early. Rising values of TCD velocities guides the timing of more aggressive therapy.

The mainstay of medical treatment is triple H therapy where volume expansion is achieved with packed blood cells, and colloids or hypertonic saline solution.[118] As per the literature and the author's experience starch solutions should be avoided due to risk of coagulopathy. A central venous line is inserted for aggressive invasive monitoring. A central venous pressure of greater than 8 mmHg or pulmonary wedge pressure greater than 14 mmHg is usually enough to dilute the haematocrit to less than 35%. An adequate level of haemoglobin should also be maintained. This volume expansion maintains the blood pressure at the desired level. In case the situation demands it, the systolic blood pressure can be raised to 180–200 mmHg with the help of vasopressors.[60] The mean should be 30 mmHg higher than the baseline mean.

Endovascular therapies for vasospasm are used when either aggressive medical therapy fails or when the TCD velocities rise, or when there are several risk factors for vasospasm. Transluminal balloon angioplasty is used to mechanically dilate the segment of the large arteries such as ICA, MCA and ACA A1 segment. The effect of angioplasty lasts for 7 days which corresponds to the duration of vasospasm.[111,139] Smaller vessels, such as the A2 segment, are not amenable to angioplasty and are instead treated with intra-arterial papaverine or verapamil.[111]

Hydrocephalus is a common complication with SAH due to A.Com aneurysms, especially when there is a significant intraventricular bleed. More than half of the patients may require either external ventricular drainage or a permanent ventriculoperitoneal shunt.[116] Fenestration of the lamina terminalis at the time of surgery appears to reduce the need for ventriculoperitoneal shunting.

Patients with A.Com aneurysms are susceptible to electrolyte abnormalities of which hyponatraemia is frequently seen (incidence 18%) lasting 1–5 days after surgery.[68] This is treated with normal saline infusion, supplemental salt intake and if need be with hypertonic saline infusion.[111]
