27 CHAPTER Anesthesia for Thoracic Surgery

◆ *Michael Rieker*

Thoracic surgery is greatly facilitated by the contribution of anesthesia care, which can isolate the lungs and create a quiet surgical field. Although this procedure is an advanced technique of airway management, it has been in existence almost as long as tracheal intubation itself. In 1928, Guedel, Magill, Waters, and other pioneers first achieved closed endotracheal anesthesia. The treatment of tuberculosis and empyema, however, required isolation of the infected lung, and in 1931 Joseph Gale and Ralph Waters first described "closed endobronchial anesthesia." Bronchial blockade for selective ventilation and lung isolation was reported by Magill in 1936. In 1950, Björk and Carlens are credited with the first use of a double lumen endotracheal tube for thoracic surgery, the bronchospirometric double-lumen tube, which Carlens described the year before.[1,2] Double-lumen tubes evolved in design, and the use of the Fogarty embolectomy catheter for bronchial blockade gave way in 1982 to the Univent tube invented by Inoue and colleagues.

Development of airway devices continues, and anesthetists caring for patients undergoing thoracic surgery must be skilled at insertion, maintenance, and monitoring of these devices for proper function. However, the process of lung isolation facilitates the surgical procedure but compounds a central concern in thoracic anesthesia: maintaining effective gas exchange in the face of ventilation and perfusion mismatch. General anesthesia creates atelectasis, which is compounded by muscle relaxants and lateral positioning, but ventilation and perfusion are further mismatched when the thorax is opened, and ceasing ventilation of one lung is the final insult. The cardiac output persists, but only one lung is ventilated. Fortunately, physiologic processes combat the inherent shunt, and anesthetic management is geared toward supporting those processes while fostering oxygenation through various ventilation modalities. The general incidence of hypoxemia is 5% to 10% during one lung ventilation (OLV).[3]

Besides managing a complex tracheal tube, the anesthetist must also be cognizant of the effects of underlying disease as it relates to management of ventilation (bullous disease contraindicating nitrous oxide [N_2O]), interactions with anesthetic drugs (small cell carcinoma being associated with myasthenic syndrome), and even concerns about oxygen toxicity (in patients treated with bleomycin and other chemotherapeutics).

PREOPERATIVE PREPARATION

Bronchogenic carcinoma is the leading cause of cancer deaths in the United States.[4] Because lung cancer is most often discovered only once symptomatic (i.e., advanced), even with aggressive multimodal treatment, prognosis is poor. A review of patients with non–small cell carcinoma found a 5-year survival rate of less than 7%.[5] However, resection of affected lung tissue offers a better prognosis than radiation and chemotherapy, and so cancer is a common indication for lung surgery. There is a strong association between lung cancer and chronic obstructive pulmonary disease (COPD), such that the incidence of lung cancer is four times higher among COPD sufferers than it is in the general population, and underlying COPD almost doubles the 3-year mortality of lung cancer.[6-8] Because many patients presenting for lung surgery will have complex underlying pathology, evaluating respiratory function and predicting postresection function are crucial to anticipating the patient's intraoperative and postoperative care.

The surgical risk assessment for patients in need of pulmonary resection surgery focuses on the risk of potential postoperative complications and whether postoperative pulmonary function will be sufficient to allow reasonable quality of life. Between 20% and 30% of patients with lung cancer are found to be surgical candidates,[9] and almost 40% of them are disqualified based on poor lung function alone.[10] The anesthetic risk assessment specific to pulmonary surgery focuses on how the underlying pathology will challenge the maintenance of adequate gas exchange and general homeostasis under OLV and the potential for postoperative respiratory failure to make weaning and extubation difficult. However, mortality from unresected carcinomas is sufficiently high that the risks of postoperative complications would need to be extraordinarily high before they would preclude surgery. COPD is a disease requiring years of development. Considering the aging nature of our population and the increase in the incidence of obesity, it is not surprising that lung resection surgeries are now being performed on more patients who have end-stage COPD, morbid obesity, or who are of advanced age.[11,12] Evidence shows that these patients can be treated safely. The American College of Chest Physicians does not set a maximal age cutoff for pulmonary surgical candidacy.[13] Changes in surgical techniques, especially the use of video-assisted thoracoscopic surgery, have markedly decreased the incidence of postoperative pulmonary complications and will necessitate a reevaluation of the testing required for preoperative assessment.[14] For smaller lung resections, minimal preoperative evaluations of cardiac disease, gas exchange, and oxygenation may suffice. Given the large physiologic changes that occur after pneumonectomy, complete pulmonary function testing, as well as cardiac testing, may still be reasonable in these patients.

Fear of creating pulmonary insufficiency by lung resection is an important concern, and numerous studies have attempted to determine the lowest limit of pulmonary function that will allow surgery to be safely performed. Research findings are limited in their ability to predict particular complications, though. Studies performed to predict postoperative pulmonary complications after lung resection demonstrate that patients develop both pulmonary and cardiac complications such as dysrhythmias, myocardial infarction, pulmonary embolism, pneumonia, and empyema. These complications influence the duration of mechanical ventilation and outcome; however, none of these complications can be predicted by preoperative studies of pulmonary function. Box 27-1 presents some commonly used preoperative assessment criteria for lung resection.

BOX 27-1

Summary of Preoperative Factors That Predict Postoperative Complications

Factors That Characterize Average Risk

- FEV_1 > 2 L or 80% of predicted
- PPO FEV_1 > 80% of predicted
- PPO FEV_1 + PPO DLCO both > 40%
- $\dot{V}O_2max$ > 15 mL/kg/min
- Ability to climb 3 flights of stairs

Factors That Characterize Elevated Risk

- FEV_1 <2 L or < 40% of predicted
- PPO FEV_1 < 40% of predicted
- PPO DLCO < 40% of predicted
- PPO product, (FEV_1 × DLCO) < 1650
- $\dot{V}O_2max$ < 10 mL/kg/min
- Inability to climb 1 flight of stairs
- Oxygen desaturation > 4% during exercise

DLCO, Carbon monoxide diffusion in the lung; *FEV_1*, forced expiratory volume in 1 second; *PPO*, predicted postoperative; *$\dot{V}O_2max$*, maximum volume of oxygen utilization.

TABLE 27-1 Anesthetic Considerations in Lung Cancer Patients: "The 4 Ms"

Preoperative Parameter	Clinical Assessment
Mass effects	Obstructive pneumonia, lung abscess, superior vena cava syndrome, tracheobronchial distortion, Pancoast syndrome, recurrent laryngeal nerve or phrenic nerve paresis, chest wall or mediastinal extension
Metabolic effects	Lambert-Eaton syndrome, hypercalcemia, hyponatremia, Cushing syndrome, syndrome of inappropriate antidiuretic hormone
Metastases	Particularly to brain, bone, liver, and adrenal glands
Medications	Chemotherapy-induced lung changes bleomycin = pulmonary toxicity, doxorubicin = cardiac toxicity, cisplatin = renal toxicity

Modified from Slinger PP, Johnston MR. Preoperative assessment and management. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.

History and Physical Examination

Cancer patients who undergo lung resection typically have a history of multiple risk factors and signs of respiratory disease. Risk factors include cigarette smoking, air pollution, and industrial chemical exposure. The smoking history that is so common to these patients should also lead to suspicion of ischemic heart disease or hypertension. Therefore, patients must be evaluated for exertional dyspnea, productive cough, hemoptysis, cyanosis, poor exercise tolerance, and chest pain.

The presence of ischemic cardiac disease that is severe, unstable, or associated with dysrhythmias should indicate consultation with a cardiologist to help mitigate risk of cardiac complications. Because severe COPD may significantly limit physical activity, a provocative dobutamine or other type of cardiac stress test may be helpful to identify coronary insufficiency.[15] The use of perioperative beta blockade is controversial, and nonselective agents may be particularly detrimental if they inhibit bronchodilation. However, cardioselective beta-blockers have been found beneficial in COPD patients undergoing vascular surgery.[16] Beta blockade may be considered to reduce cardiac risk,[17] or at the least, patients currently taking beta-blockers should continue their regimen throughout the surgical encounter. The surgical plan must be carefully considered for patients with coronary diffusion defects that show greater than 20% reversibility. In cases of high-risk cardiac disease, lung surgery may be delayed for 6 weeks to allow coronary artery bypass first.[15] With the popularity of off-bypass coronary revascularization, the two procedures can more easily be performed in a single surgical encounter.[18]

Lung cancer patients should be assessed for effects of the primary tumor, as well as effects of secondary pathologies and side-effects of therapy (Table 27-1). Supine dyspnea may result from COPD or compression of the airway by a mediastinal mass. A high index of suspicion should also be maintained for hormonal abnormalities, because many lung tumors cause paraneoplastic syndromes characterized by secretion of endocrine-like substances such as adrenocorticotropic hormone,[19] antidiuretic hormone,[20] serotonin, parathyroid-like hormone,[21] and insulin-like growth factor,[22] causing a variety of metabolic abnormalities.[23] Cushing disease may lead to metabolic alkalosis, hypokalemia, and hyperglycemia.[24,25] Hypercalcemia occurs in 10% to 25% of lung cancer patients and is related to parathyroid-like hormone, increased calcitriol, or overactivity of osteoclasts.[26] The finding of hypercalcemia carries a very poor prognosis. Clinical signs may include polyuria, polydipsia, confusion, vomiting, abdominal cramps, bradycardia, and mental status changes.

Neuroendocrine tumors comprise 20% of lung cancers, and 5% of them produce carcinoid syndrome.[26] In those patients, histamine-stimulating drugs and adrenergics may precipitate the flushing, hypotension, and tachyarrhythmias related to serotonin release. Paraneoplastic neurologic syndromes represent autoimmune dysfunctions associated with cancers; 1% to 2% of patients with small cell cancer develop Lambert-Eaton myasthenic syndrome (LEMS).[27] In this syndrome, antibodies are formed against the voltage-gated calcium channels,[28] causing weakness and sensitivity to nondepolarizing muscle relaxants. The usual presentation is first with autonomic dysfunction (80% of patients with LEMS) such as orthostatic hypotension, and then weakness that progresses upward from the legs.[29] In contrast to myasthenia gravis, because LEMS involves dysfunction of the calcium channels, repetitive stimulation or activity improves function (as more acetylcholine is mobilized), and anticholinesterase drugs are not an effective treatment. Treatment is with immunoglobulin, corticosteroids, or with 4-diaminophridine (DAP), which opens potassium channels and increases calcium in the nerve terminal. Other autoimmune channelopathies can affect voltage-gated potassium channels and prolong acetylcholine release, causing a myotonia, or they can affect autonomic ganglia, causing orthostatic hypotension and arrhythmias.[30]

Physical examination findings in COPD are commonly barrel chest deformity, accessory muscle use or paradoxical breathing movement, pursed-lip breathing, and tympanic percussion notes on the chest. Auscultation reveals rhonchi or wheezing. Signs of cor pulmonale include jugular vein distention or peripheral edema, split S_2 heart sound, pulmonary or tricuspid valve insufficiency murmurs, and rales auscultated over the lungs.[31] Nutritional status, commonly compromised in patients with cancer, is also important to note because hypoalbuminemia and malnutrition are associated with increased postoperative complications such as pneumonia.[32] Box 27-2 lists important elements of the preoperative evaluation.

BOX **27-2**

Preoperative Evaluation of Patients for Pulmonary Surgery

1. Evaluate comorbidities:
   - Smoking-related complications
   - Cor pulmonale
   - Effects of paraneoplasms
   - Cardiovascular disease (unstable angina, MI within 6 weeks, or significant dysrhythmias = high risk of cardiac complications)
   - Treatment side effects (particularly from cytotoxic drugs and radiation)
2. ECG and chest x-ray for signs of cardiovascular dysfunction and effects of lung pathology
3. Laboratory assessment of electrolytes, blood count, albumin, and renal function indicators
4. Lung function testing: 80-40-15 rule:
   - FEV_1 and DLCO > 80% predicted = no additional testing needed; if < 80 or dyspnea present, diffusing capacity and postoperative function should be predicted
   - PPO FEV_1 and DLCO < 40% predicted = increased risk; exercise testing should be evaluated
   - $\dot{V}O_2max$ < 15 mL/kg/min = increased risk
5. For COPD, consider blood gas and response to bronchodilators.

COPD, Chronic obstructive pulmonary disease; *DLCO,* carbon monoxide diffusion in the lung; *ECG,* electrocardiogram; *FEV_1,* forced expiratory volume in 1 second; *MI,* myocardial infarction; *PPO,* predicted postoperative; *$\dot{V}O_2max$,* maximum volume of oxygen utilization.

Diagnostic Data

Chest Radiograph

The chest radiograph should be obtained to assess for associated disease and complications of COPD (tumor infringement on airway or vascular structures, bullous disease, congestive heart failure, or pneumothorax). The radiograph does not provide abundant information regarding the degree of COPD, but findings characteristic of COPD include hyperinflation, increased anteroposterior diameter, and diaphragm flattening. Bullae of emphysema may be present, and infection or pleural effusions may be noted preoperatively and treated to improve the postoperative course. The locations of masses can be identified. In some patients, it can be ascertained whether lesions compress mediastinal structures, cause tracheal shift, or invade the airway. This information is important to predict whether intubation will be difficult, whether induction of anesthesia could cause collapse of the airway, or whether surgical dissection may be difficult and potentially involve excessive bleeding. Evidence of increased pulmonary vascular resistance (PVR) resulting from compression of the vascular bed increases the likelihood of right ventricular failure and worsens the prognosis after lung resection. Relevant signs include prominent pulmonary arteries with rapid tapering of the vasculature, and a widened right heart border.

Electrocardiogram

Assessment of the electrocardiogram (ECG) is useful to assess signs of right ventricular hypertrophy. In such a case, the ECG shows a tall R wave in V_1 (greater than 6 mm), R/S ratio greater than 1 in lead V_1 and a ratio less than 1 in V_6, along with a right-axis deviation and diminished amplitude limb leads.[33-35] Right atrial hypertrophy causes the initial component of a biphasic P wave in lead V_1 to be larger than the second component. Strain characteristics such as S-T segment depression and T-wave inversion, as well as incomplete or complete right bundle branch block, may be observed. The ECG has excellent specificity for identifying left ventricular hypertrophy (LVH), but less sensitivity for detecting it.[36,37] Therefore, if ECG criteria are inconclusive, echocardiography may be helpful to further elucidate the status of the right ventricle. Findings of pathologic Q waves and evidence of left ventricular hypertrophy preoperatively correlates with an increased incidence of postoperative ischemia and infarction.[38]

Echocardiogram

Expected echocardiographic findings are increased thickness of the right ventricular free wall, chamber enlargement, pulmonary artery systolic hypertension, septal shift, tricuspic regurgitation, and decreased right ventricular ejection fraction. Increased PVR and right ventricular strain cause concern in patients undergoing pneumonectomy or extensive partial resection because of the added resistance produced by clamping the vasculature of one lung in the surgical procedure. Echocardiography is the best initial tool for assessing pulmonary hypertension, but additional studies with pulmonary angiography, ventilation-perfusion scintigraphy, computed tomography, and magnetic resonance imaging also may be used for more in-depth evaluation.[39]

Laboratory Assessment

Measurement of preoperative room air arterial blood gases should be considered for patients with COPD, and is useful in guiding the weaning of O_2 and ventilation postoperatively. Carbon dioxide (CO_2) retention with an arterial partial pressure ($PaCO_2$) greater than 45 mmHg is an indicator of poor ventilatory function. However, hypercapnia is not a reliable predictor of increased risk of perioperative pulmonary complications.[40] Preoperative hypoxemia (SpO_2 less than 90%) and particularly desaturation during exercise may be predictive of increased complications after thoracic surgery;[41,42] however, in general, blood gas analysis is not a reliable tool in predicting postoperative pulmonary complications,[43] and the correlation between desaturation during exercise and postoperative complications is not a consistent finding.[44]

Hypoalbuminemia is the most common laboratory finding, which serves as an important predictor of pulmonary complications. Numerous studies have demonstrated increases in postoperative pulmonary complications among patients with low serum albumin levels (generally less than 3.6 g/dL).[45-48] This factor increases risk as much as 2.5 times,[47] and albumin level maintenance is a measured factor in the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP).[49] The blood urea nitrogen is also a factor identified by NSQIP data as a predictive factor for pulmonary complications when the level is greater than 22 mg/dL.[47,48]

Other laboratory analysis of interest includes renal function indicators (particularly for patients treated with nephrotoxic drugs, such as methotrexate, gemcitabine, cisplatin),[50,51] sodium (related to syndrome of inappropriate antidiuretic hormone),[23] and calcium (due to parathyroid hormone-like protein).[21,52]

Pulmonary Function Tests

Patients presenting for lung resection should undergo pulmonary function testing to assess for airflow limitation, diffusion defect, and cardiopulmonary reserve.[53] Assessment should include the response to bronchodilators for patients who demonstrate obstructive disease (see Figure 26-19). In that case, assessment of spirometry should be based upon values obtained postbronchodilator

therapy, because these would represent the patient's potential lung function once optimized on medications. No single measurement provides the overall risk assessment. For example, although the forced expired volume in 1 second (FEV_1) is the most prevalent spirometric measurement, one case series of 100 thoracic surgery patients with very low FEV_1 values (less than 35%) demonstrated a low rate of mortality and ventilator dependence (but patients did show a prolonged duration of hospitalization and air leak).[54] In another series of 109 elderly patients, stair-climbing ability was better correlated (inverse relationship) to postoperative cardiopulmonary complications than was forced vital capacity (FVC) or predicted postoperative (PPO) FEV_1.[55] Therefore, a multimodal approach must be taken, considering airflow (PPO FEV_1), parenchymal function (carbon dioxide diffusion in the lung [DLCO]), and cardiopulmonary reserve ($\dot{V}O_2$max).The general cutoff points indicating increased risk among these parameters is below 40% for predicted postoperative FEV_1 and DLCO, and 15 mL/kg/min for $\dot{V}O_2$max.

It should be noted that guidelines to assess surgical candidacy are not intended to dictate candidacy for anesthesia. If indications are that the patient is a candidate for surgery, it is less likely that there will be anesthetic-specific concerns about pulmonary function that would override the surgical decision, particularly since many of these surgeries are performed to treat cancer. That notwithstanding, it is helpful for the anesthetist to understand the patient's risk stratification to plan for the level of ventilatory support required during and after surgery. Assessment must consider multiple variables of function. Similar to standards set by the American Thoracic Society and the European Respiratory Society, the American College of Chest Physicians (ACCP) proposes the following assessment of risk factors for patients with lung cancer undergoing lung surgery.[40] Preoperative FEV_1 greater than 80% of predicted value (or greater than 2 L for pneumonectomy or greater than 1.5 L for lobectomy) indicates average risk, and no further assessment of lung function is required. The diffusing capacity for carbon monoxide (DLCO) should be assessed if diffuse parenchymal disease or dyspnea on exertion is noted. If the FEV_1 or DLCO is less than 80% of predicted, then the predicted postoperative FEV_1 and DLCO are assessed.[40] This is accomplished either through radionucleotide scanning or mathematically, based on the proportion of total lung that will remain after the planned resection. The PPO FEV_1 can be calculated by multiplying the current FEV_1 by the fraction of functioning lung or the fraction of lung segments that will remain after surgery.[15] For high-risk patients, more detailed assessment via radionuclide scanning, computed tomography (CT) scanning, or magnetic resonance imaging (MRI) is advisable. Predicted postoperative values of PPO FEV_1 greater than 40% of predicted for the patient indicate average risk. Values less than 30% of predicted indicate increased risk, and values in between warrant exercise testing to assess oxygen consumption ($\dot{V}O_2$max). A $\dot{V}O_2$max less than 15 mL/kg/min indicates high risk, whereas a value greater than 15 indicates average risk.[40] The European Respiratory Society places cardiopulmonary reserve ($\dot{V}O_2$max) more prominently in the assessment and considers high-risk cutoffs as being less than 30% for PPO FEV_1 and DLCO, and less than 10 mL/kg/min for $\dot{V}O_2$max.[53] As related to anesthetic planning, average-risk patients (e.g., PPO FEV_1 greater than 40%) are likely to be extubated immediately after surgery. High-risk patients (e.g., PPO FEV_1 less than 30%) have a higher likelihood of requiring some degree of postoperative ventilation. Planning for intermediate-risk patients (e.g., PPO FEV_1, 30%-40%) is further individualized, based upon other assessment parameters.

Ventilation-Perfusion Assessment

When the preoperative lung function tests indicate that the patient is at increased risk for perioperative complications, split lung function tests of ventilation and perfusion are valuable in the prediction of postresection lung function.[53,56] Removal of a diseased portion of lung may not decrease overall lung function; in fact, it may improve it. The extent of pulmonary surgery has been found to correlate inversely with the intraoperative Pa_{O_2}, where patients undergoing pneumonectomy had higher Pa_{O_2} than those undergoing lobectomy, which in turn were higher than those undergoing segmentectomy.[3] This paradox is related to the corresponding amount of perfusion of the diseased lung. With larger, central tumors (such as would require a pneumonectomy), perfusion, and thus shunting under OLV, is diminished in comparison to a more peripheral lesion requiring a limited resection. Likewise, the results of perfusion scanning can provide a prediction of the degree of hypoxemia under OLV, because the degree of perfusion to the operative lung is proportional to the degree of potential shunt produced when ventilation to that lung ceases.[3]

Ventilation can be measured by having the patient inhale one vital capacity breath of a radioisotope and measuring isotope counts with multiple scanners placed over the chest wall. Radioisotope injected intravenously and imaged shows the distribution of perfusion to all areas of the lung. After determining function in various areas of the lung, calculations can then estimate postresection function by multiplying current function by the fraction of functioning lung that will remain postoperatively. Calculations based on segmental lung regions may help predict outcomes for patients undergoing lung volume reduction surgery. This procedure of removing emphysematous portions of lung to improve overall lung function has proved efficacious and particularly beneficial in allowing resection of cancerous lung tissue from patients in whom overall lung function studies would have contraindicated surgery.[40] Lung volume reduction surgery is most useful in patients with heterogeneous emphysema (particularly when the emphysematous lobe is also the one containing the tumor), where removal of a lung segment or lobe will result in better pulmonary function overall. Incidentally, this effect is appreciated more often with upper rather than lower lobectomy, in which patients with a low preoperative FEV_1 tend to demonstrate improvement in the FEV_1 after upper lobectomy.[57]

Dynamic MRI and quantitative CT are newer modalities used to determine postresection pulmonary function.[58,59] Dynamic MRI traces movement of oxygen or sulfur hexafluoride to reflect diffusing capacity.[60] Quantitative CT is intended to provide more specific data than global measurements such as FEV_1. CT can be used to quantify low attenuation (emphysematous) areas of lung to determine both overall proportion and regional distribution of disease. Results are comparable to FEV_1 in predicting obstruction.[61]

Diffusion Capacity

Diffusion capacity of the lung tests the lung's ability to allow transport of gas across the alveolar-capillary membrane. Because it is difficult to measure the diffusing capacity of oxygen, carbon monoxide is used, in which the patient inhales a small amount of carbon monoxide, holds the breath for 10 seconds, exhales, and the amount of carbon monoxide in the exhaled breath is measured. After subtracting the amount of carbon monoxide that should be expired with dead space air, the amount exhaled provides an indicator of the diffusion of gases in the lung. A carbon monoxide diffusing capacity of the lungs (DLCO) less than 40% of predicted has been associated with increased complications after pulmonary surgery. However, DLCO has been found to have good specificity

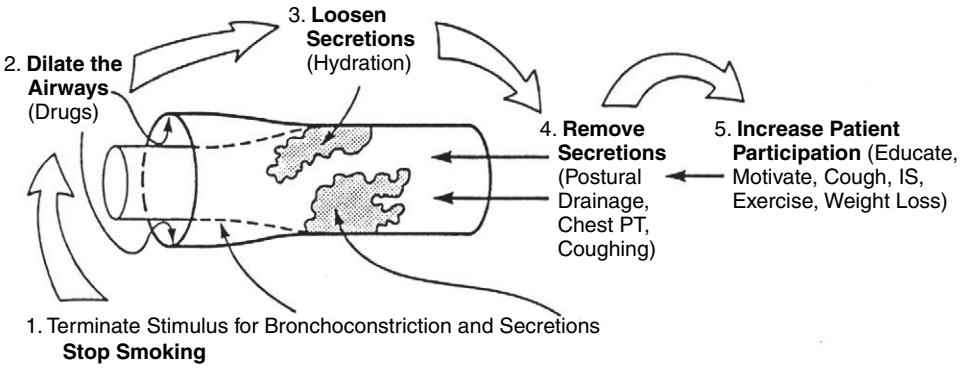

FIGURE **27-1** A full, aggressive preoperative respiratory preparation regimen entails a five-pronged attack. *(1)* Require the patient to stop smoking. *(2)* Dilate the airways. *(3)* Loosen secretions. *(4)* Remove secretions. *(5)* Increase patient participation. *IS*, Incentive spirometry; *PT*, chest physiotherapy. (From Wilson WC, Benumof JL. Anesthesia for thoracic surgery. In: Miller RD, et al, eds. *Miller's Anesthesia*. 6th ed. Philadelphia: Churchill Livingstone; 2005.)

but low sensitivity as an independent measurement. The product of the predicted values for DLCO and FEV_1 may provide better reliability than single measures. This measurement, called the *predicted postoperative product*, was found by Pierce to be less than 1650 in 75% of those who died.[62]

Cardiopulmonary Reserve

Maximal oxygen consumption ($\dot{V}O_2$max) during exercise testing is also assessed as a strong predictor of outcomes.[31,40,63] A $\dot{V}O_2$max less than 10 mL/kg/min (or 40% of predicted) is associated with increased mortality, whereas a $\dot{V}O_2$max greater than 20 mL/kg/min is a favorable finding.[64] These values may be roughly estimated by evaluating the patient's physical ability, in which the ability to climb five flights of stairs suggests $\dot{V}O_2$max greater than 20 mL/kg/min, and the inability to climb one flight of stairs suggests $\dot{V}O_2$max less than 10 mL/kg/min.[65]

Patient Optimization

Aggressive treatment of acute or reversible components of respiratory disease greatly decreases the risk of postoperative complications. Treatable preoperative conditions include infections, excess bronchial secretions, bronchospasm, dehydration, electrolyte imbalance, cigarette smoking, alcohol abuse, and malnutrition (Figure 27-1).

Smoking is not only a major risk factor for chronic lung disease, but it is a strong predictor of perioperative complications, as well. Among patients undergoing noncardiac surgery, pulmonary complications occurred in 22% of smokers, 13% of past smokers, and only 5% of nonsmokers.[66] In a study of lung cancer patients, 87% were smokers, and the smokers had 1.5% mortality, whereas nonsmokers had only 0.4% mortality. Smokers in that study demonstrated twice the rate of complications as did nonsmokers.[67] The correlation of complications with the duration of smoking history can be performed through the pack-year index (the product of the packs per day smoked times the years of smoking at that rate). Patients with greater than a 20 pack-year history have demonstrated increased incidence of complications compared with those who have a more modest smoking history.[68,69]

Smoking cessation may reduce postoperative complications; however, the timing of this intervention is important. Most recent research indicates that smoking cessation for less than 4 weeks prior to surgery does not alter risk of complications at all.[66,70,71] Some data suggests that short-term smoking cessation (less than 1 month) may cause increases in mucus production, which may *increase* complications;[66,72] however, research findings are equivocal on the concept of increasing complications.[71,72] Carboxyhemoglobin levels have shown a significant decrease that occurs rapidly after smoking cessation, and improvement of nasal mucociliary clearance occurs within 1 to 2 weeks; however, the implications of these findings on postoperative complications are unclear.[73,74] Reduction in complication rates occur in proportion to the amount of time after quitting, with a threshold of at least 4 weeks to observe improvement, with even more improvement noted after 8 weeks.[70,71] Only in one very large study was a trend toward *slight* reduction in complications noticed with less than 1 month of smoking cessation, and complications further decreased in proportion to the total duration of cessation.[67] Smoking cessation counseling and intervention is a widely recommended strategy for medical management of COPD patients; however, owing to the urgent nature of treating pulmonary carcinoma, delaying surgery to allow for an adequate period of smoking cessation is an impractical goal.

Monitoring Plan

The purpose of monitoring during thoracic surgery is the quick recognition of sudden and severe changes in ventilation and hemodynamics that can accompany positioning, one-lung ventilation (OLV), and surgical manipulation of the airway and thoracic structures. Standard monitors, according to American Association of Nurse Anesthetists (AANA) guidelines, should be used.[75] An airway pressure monitor helps detect changes in airway compliance and assists in identifying the proper placement of double-lumen tubes (DLTs). Capnography is useful for determining the adequacy of ventilation when one lung is deflated, and also useful for detecting abrupt changes in cardiac output, which may accompany positioning or surgical manipulation. Considering preexisting ventilation derangements and changes with lateral position, the gradient of end-tidal to arterial CO_2 may be wider than the typical 5 mmHg. There is evidence that even if the gradient is determined early, it may not remain the same throughout the case. One-lung ventilation is a good application for transcutaneous CO_2 monitoring where that modality is available.

Electrocardiogram

All patients require continuous monitoring of the ECG. Typically, anesthetists monitor a limb lead (II) for easy rhythm recognition, and a precordial lead to add sensitivity for detection of ischemia. A landmark article by London identified V_5 as the precordial lead

that would add the most sensitivity to ischemia detection.[76] That article noted that monitoring a combination of leads II and V_5 would help detect more than 85% of ischemia. A more recent study, which accounted for both the changing pattern of ischemia over time (onset vs. peak), as well as comparison to preoperative values, found lead V_4 to be the most sensitive for detecting ischemia, followed by V_5.[38] In practice, concerns for positioning, surgical site preparation, and access to the skin electrode may result in the precordial lead not being placed in the precise location needed. Various studies have found ischemic evidence to be frequent in leads V_3 through V_6.[38,77,78] A consistent finding is that monitoring a combination of leads is significantly more effective than monitoring a single lead.[38,76,79] A second intraoperative lead monitored in the V_4 to V_5 position or in whatever anterolateral position provides the most isoelectric S-T segment is desirable.[38]

Arterial Pressure Monitoring

Arterial blood pressure monitoring instantly identifies acute hypotension with surgical manipulation. It also facilitates sampling of arterial blood for gas analysis. For thoracotomies, the arterial cannula is generally placed in the dependent arm, where it is more easily stabilized. For mediastinoscopy, the arterial monitoring site is selected to provide indication of innominate artery occlusion (see Mediastinoscopy later in chapter).

Central Venous Pressure Monitoring

Central venous pressure (CVP) monitoring is not required for routine thoracotomies but may be indicated if the patient's volume status is unclear or if large fluid shifts are anticipated. In complex cases, a CVP line may help manage fluid status. Increased filling pressures (CVP or pulmonary capillary wedge) have been associated with greater lung injury and prolonged mechanical ventilation after complex pulmonary surgery.[80] In addition, a large-bored CVP line can provide access for rapid infusion and an access site if transvenous pacing or pulmonary artery pressure monitoring become necessary.

The CVP line can be inserted via the external or internal jugular veins or the subclavian veins. An external jugular line is more easily kinked in the lateral position. One should remain alert to the possibility of pneumothorax with the insertion of central lines. A pneumothorax on the ventilated (nonoperative) side can lead to severe hypoxemia during OLV. If a subclavian puncture is planned, the insertion site should be on the same side as the planned thoracotomy.

Cardiac Performance Monitoring

Pulmonary artery pressure monitoring is intended to provide estimation of left ventricular pressures and guide the support of cardiac performance with fluids and cardiovascular drugs. In spite of its past popularity, pulmonary artery catheterization has not been demonstrated to improve patient outcomes in either cardiac or noncardiac surgery,[81] nor is it helpful in predicting postoperative complications.[53,82] There have even been suggestions that right heart catheterization may *promote* cardiac complications.[83] If pulmonary artery monitoring is deemed useful, the anesthetist must be cautious in interpreting values in pulmonary disease because the normal correlation of right and left ventricular pressures may be disturbed. The use of pulmonary artery catheters has specific limitations during OLV. Lung pathology or hypoxic pulmonary vasoconstriction may alter the resistance in pulmonary vessels and reduce the correlation between pulmonary artery occlusion pressure and left ventricular pressure.[84] More than 90% of pulmonary artery catheters float into the right lung.[85] During right thoracotomy, then, the catheter will likely be in the nondependent, collapsed lung and give a false low reading for cardiac output. Finally, care must be taken to ensure that a pulmonary artery catheter is not situated in a vessel that will be clamped during the course of lung resection. A better evaluation of cardiac filling, contractility, and valvular performance would come by way of echocardiography. Preoperative echocardiography is indicated when suspicion exists of valvular disease, outflow tract obstruction, ventricular dysfunction, or pulmonary hypertension.[17,53]

LATERAL DECUBITUS POSITION

The position most commonly chosen for surgical exposure during thoracotomy is the lateral decubitus position. A roll is placed beneath the torso just caudal to the axilla to prevent compression of the neurovascular bundle and forward rotation of the humeral head. It is important to note that this commonly called "axillary roll" is better considered an "axillary *support* roll," because positioning it *in* the axilla may cause neurovascular compression. Hyperabduction of the arms is prevented to keep the brachial plexus from stretching against the humeral head. Arms can be separately padded and extended forward with armboards. Strategies for supporting the nondependent arm may include a pillow between the arms, a padded Mayo stand (which provides good access to intravenous or arterial lines in the dependent arm), or specially made double armboards. Pulse oximetry or frequent palpation of the radial pulse ensures the integrity of circulation to the hand.

The head is supported on pillows to maintain alignment of the head and neck with the spine. Lateral flexion of the neck can cause compression of the jugular veins or vertebral arteries, compromising cerebral circulation. The dependent ear can be compressed by the weight of the head. Careful padding or use of a foam doughnut relieves this pressure, but care must be taken to prevent corneal abrasion and retinal ischemia by avoiding pressure on the eyes.

Other pressure points of concern in the lateral position include the peroneal nerve in the area of the fibular head of the dependent leg and the femoral head of the nondependent leg if a stabilizing strap is placed over the patient.

Physiology of the Lateral Decubitus Position

Positional changes and changes in chest-wall integrity produce significant alterations in ventilation and perfusion of the lungs during thoracic surgery.

Upright Position

The distribution of perfusion in the lungs depends on gravity in relation to the level of the heart and on pressures transmitted through alveoli. In a spontaneously breathing, upright patient, perfusion increases from the apex to the base of the lung (Figure 27-2). Ventilation also increases from apex to base, based on the relative compliance of alveoli. Owing to downward traction from gravity, pleural pressure is most negative at the apex of the lung, and this keeps alveoli distended (Figure 27-3). Dependent alveoli are less distended and therefore more compliant (i.e., can expand by a greater volume for a given pressure change because they are starting at a lower resting volume). Therefore, most of a tidal breath is distributed to the dependent alveoli (Figure 27-4). The increase in both ventilation and perfusion from apex to base is not parallel, and is certainly more complexly arranged than in neatly divided zones. However, the general increase in both from top to bottom results in efficient gas exchange.

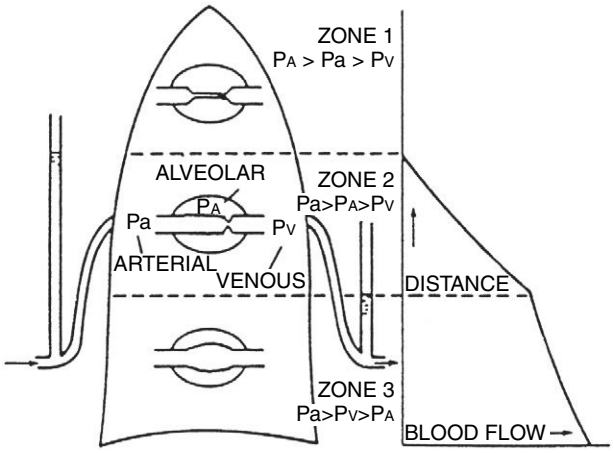

FIGURE **27-2** The lung is divided into three zones according to the relative magnitudes of the pulmonary arterial, venous, and alveolar pressures (*Pa*, *Pv*, and *PA*, respectively). In *zone 1*, alveolar exceeds arterial pressure, so the collapsible vessels are held closed and there is no flow. In *zone 2*, arterial exceeds alveolar pressure, but alveolar exceeds venous pressure. Under these conditions, a constriction occurs at the downstream end of each collapsible vessel, and the pressure inside the vessel at this point is equal to alveolar pressure, so the pressure gradient causing flow is arterial-alveolar. This gradient increases linearly with distance down the lung, and therefore so does blood flow. In *zone 3*, venous exceeds alveolar pressure, and the collapsible vessels are held open. Here, the pressure gradient causing flow is arteriovenous, and there is constant perfusion of alveoli. (From West JB. Explanation of the uneven distribution of blood flow in the lung, based on the pressures affecting capillaries. In: West JB. *Respiratory Physiology: The Essentials*. 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2008.)

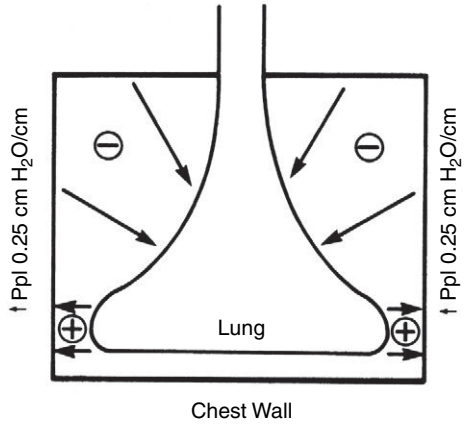

FIGURE **27-3** Schematic diagram of the lung within the chest wall, showing the tendency of the lung to assume a globular shape because of its viscoelastic nature. The tendency of the top of the lung to collapse inward creates a relatively negative pressure at the apex, and the tendency of the bottom of the lung to spread outward creates a relatively positive pressure at the base. Therefore pleural pressure *(Ppl)* increases by 0.25 cm H_2O per centimeter of lung dependency. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

Awake Lateral Position

Less vertical distance is present to cause differences in the intrapleural pressure and blood pressure gradients in the lateral position (Figure 27-5). Abdominal contents displace the diaphragm in a cephalad direction on the dependent side. Starting from a higher position in the thorax, the dependent hemidiaphragm can contract further. During inspiration, therefore, contraction of the diaphragm causes more of the tidal volume (V_T) to fill the dependent lung. Because perfusion is dependent upon gravity, perfusion in the lateral position is also greatest in the dependent lung (Figure 27-6). Overall, the relationship of greater ventilation and perfusion in the dependent lung is unchanged, and gas exchange remains efficient.

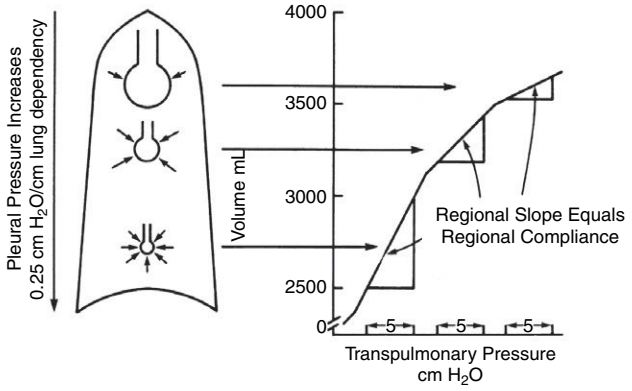

FIGURE **27-4** Due to gravity, alveoli in the most dependent portions of lung are compressed by the tissue above, while those in the most nondependent portions are suspended open. At end-inspiration and end-expiration, pressure inside all alveoli is equalized with atmospheric; however, an increasing gradient of pleural pressure toward dependent areas creates a gradient in transpulmonary pressure at rest. Although the *change* in transpulmonary pressure during inspiration is equal for all, alveoli in dependent regions are on the steep portion of the compliance curve and therefore receive the largest share of the tidal volume. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

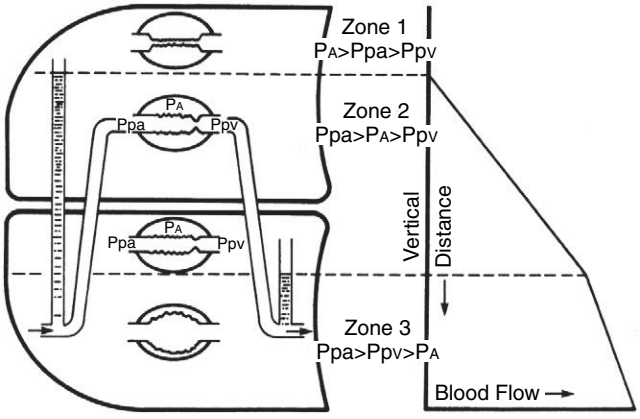

FIGURE **27-5** Schematic representation of the effects of gravity on the distribution of pulmonary ventilation and blood flow in the lateral decubitus position. The vertical gradient in the lateral decubitus position is less than in the upright position; consequently, blood flow in zones 2 and 3 is less. Nevertheless, pulmonary blood flow increases with lung dependency and is greater in the dependent lung than in the nondependent lung. *PA*, Alveolar pressure; *Ppa*, pulmonary arterial pressure; *Ppv*, pulmonary venous pressure. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

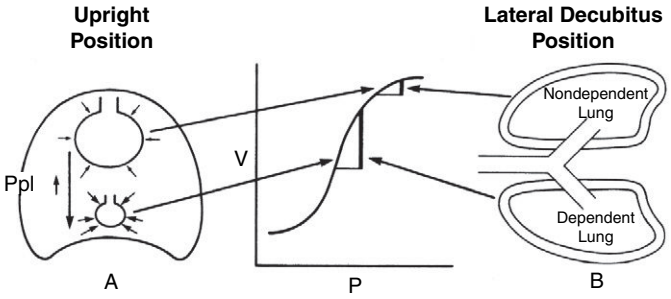

FIGURE **27-6** **A,** An increasing gradient of intrapleural pressure from top to bottom of lungs creates different resting volumes of alveoli and creates variation in regional compliance as described in Figure 27-4. **B,** In the lateral decubitus position, gravity-related effects translate to greater compliance of the dependent lung and less of the nondependent lung. Therefore, in the spontaneously breathing person, more ventilation is delivered to the dependent lung. *Ppl*, Intrapleural pressure; *P,* Transpulmonary pressure; *V*, alveolar volume. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

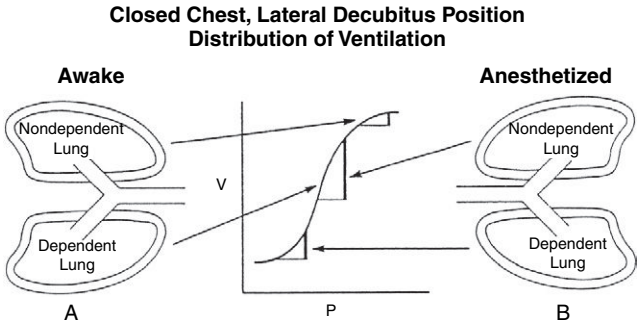

FIGURE **27-7** Diagram showing **A,** regional compliance of lungs in the awake patient in lateral decubitus position and **B,** regional compliance of lungs in the anesthetized patient in lateral decubitus position. Induction of anesthesia causes a loss of lung volume in both lungs, with the nondependent lung moving from a flat, noncompliant portion of the pressure-volume curve to a steep, compliant portion. The dependent lung moves from the highly compliant portion toward the lower flattening of the curve. In some areas of the dependent lung, resting alveolar volume is so low that atelectasis and airway closure impede inflation. Therefore, in the anesthetized patient in lateral decubitus position, more tidal ventilation shifts toward the nondependent lung (where there is the least perfusion), creating ventilation-perfusion mismatch. *P*, Transpulmonary pressure; *V*, alveolar volume. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

Anesthetized Lateral Position, Chest Closed, with Spontaneous Ventilation

A change in the distribution of ventilation is seen with the induction of anesthesia, even when spontaneous respiration is maintained. Functional residual capacity (FRC) decreases almost immediately with the induction of anesthesia. The weight of the mediastinum and the cephalad displacement of the diaphragm by abdominal contents further decrease FRC in the dependent lung and reduce the proportion of the favorable zone 3 area. Lower volumes in each lung shift their place on the compliance curve. The lungs are less compliant when they are either at a very high volume (distended alveoli) or a very low volume (atelectasis). In the anesthetized patient, the nondependent lung moves from a flat, noncompliant portion of the compliance curve to a more compliant position. Although anesthesia results in a net loss of FRC, the relative proportion of FRC in the nondependent lung increases in contrast to the dependent lung.[86] As the dependent lung loses FRC, its volume becomes so low as to decrease its compliance. It shifts to a less compliant, flatter portion of the curve (Figure 27-7). Ventilation is therefore preferentially distributed to the nondependent lung, whereas gravity-dependent blood flow preferentially goes to the dependent lung, resulting in a mismatch of ventilation and perfusion.

Anesthetized, Paralyzed, Mechanically Ventilated

Under mechanical ventilation, the diaphragm no longer contributes to ventilation of the lower lung, and FRC further declines because the compression from abdominal viscera is no longer counteracted by the force of the contracting diaphragm (Figure 27-8). With the initiation of mechanical ventilation and the deletion of effect of the contracting diaphragm, ventilation further shifts to follow the path of least resistance, favoring the nondependent lung. The ventilation-perfusion relationship further deteriorates. The addition of positive end-expiratory pressure (PEEP) to mechanical ventilation may help restore FRC and improve the ventilation-perfusion ratio.

Anesthetized, Open-Chest

The open chest greatly reduces resistance to gas flow in the nondependent lung by detaching the lung from its pleural connection with the chest wall. This causes further loss of ventilation to the dependent lung, in preference for the nondependent lung. The

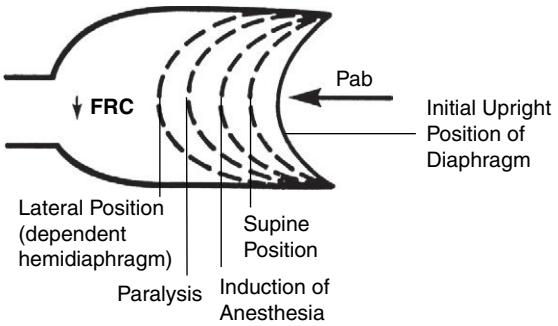

FIGURE **27-8** Anesthesia and surgery may cause a progressive cephalad displacement of the diaphragm. The sequence of events involves assumption of the supine position, induction of anesthesia, causation of paralysis, and lateral decubitus positioning (wherein abdominal contents mostly press upon the dependent hemidiaphragm). This movement of the diaphragm and downward displacement of the mediastinum result in decreased functional residual capacity (FRC) and contribute to pushing the dependent lung to the lower flattening of the compliance curve. *Pab*, Pressure of the abdominal contents. (Adapted from Benumof JL. *Anesthesia for Thoracic Surgery*. 2nd ed. Philadelphia: Saunders; 1995.)

mediastinum also further shifts downward because of loss of negative intrapleural pressure in the nondependent lung, which helped to distend it. Ventilation to the dependent lung is decreased in proportion to the displacement of the lung by the mediastinal structures. Compression of the great vessels may cause a decrease in cardiac output and circulatory compromise. Any spontaneous respiration becomes very inefficient because paradoxical movement of air occurs on inspiration from the open-chest lung into the dependent lung, which has the greater negative intrapleural pressure. On expiration, gas exits the dependent lung and enters both

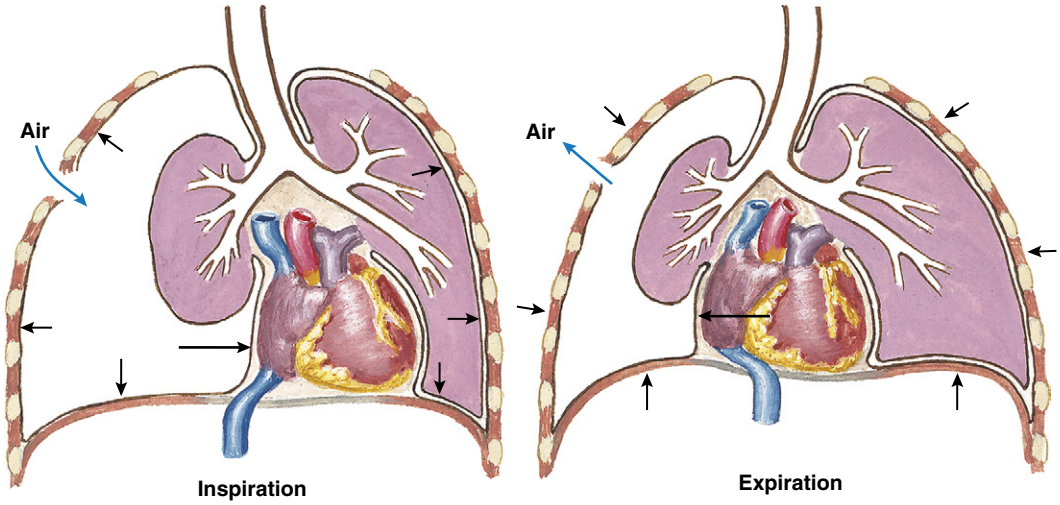

FIGURE **27-9** Paradoxical respiration in the spontaneously breathing patient with open chest. (Netter illustration from www.netterimages.com. ©Elsevier Inc. All rights reserved.)

the trachea and the open-chest lung, causing the lung to expand (Figure 27-9). Paradoxical respiration compromises fresh gas exchange in the dependent lung because part of the V_T moves to and fro between the lungs. Positive-pressure ventilation diminishes the effects of mediastinal shift and paradoxical respiration. However, during mechanical ventilation, the open chest provides no resistance, and the greatly increased compliance of that lung allows a higher proportion of ventilation to go to the nondependent lung, the least perfused area of the thorax. The less ventilated, better-perfused, dependent lung contributes to physiologic shunt, because blood flows through atelectatic areas without acquiring oxygen. Although the prevalence of different zones is not as evenly distributed as diagrams would suggest, the lateral, anesthetized, paralyzed, open-chest patient does exhibit the epitome of significant regional areas of disparity between ventilation and perfusion.

Anesthetized Open-Chest, with One-Lung Ventilation

The succeeding cascade of changes leading up to the anesthetized open-chest patient results in significant ventilation-perfusion mismatch. There is little resistance to ventilation of the nondependent lung, whereas the effects of gravity promote perfusion to the dependent lung. When ventilation to the nondependent lung is ceased, the whole ventilation is directed to the dependent lung. Remaining perfusion to the nondependent lung creates a shunt, but hypoxic pulmonary vasoconstriction reduces the shunt by 50% by diverting much of that blood toward the dependent lung. The Pa_{O_2} is higher during one-lung ventilation in the lateral position than it is in the supine position, because clamping the airway to the nondependent lung reverts some of the changes that caused $\dot{V}/\dot{Q}$ disparity in the anesthetized patient.

ONE-LUNG VENTILATION

Indications for Lung Separation

The ability to provide distinct ventilation to the separate lungs facilitates pulmonary surgery by providing a quiet surgical field. This is particularly helpful in the case of thoracoscopic surgery, in which visualization and the ability to manipulate the operative lung are limited. Thoracic surgeons will commonly consider lung separation an absolute requirement for pulmonary surgery. However, surgery can be performed on a lung that is being ventilated, and thoracic surgery alone is not an absolute indication for OLV. In fact, in the case of pediatric patients, gentle dual-lung ventilation is indicated and appropriate in either the presence of airway concerns that preclude use of a lung-separating device or the inability to maintain oxygenation with OLV. Certain situations, such as infectious contamination of one lung, are absolute indications for OLV, but most common thoracic surgeries create *relative* indications for lung separation in that they can safely be accomplished without it. Indications for lung separation are noted in Box 27-3.

BOX 27-3

Indications for Lung Separation

I. Absolute
- A. Isolation of one lung from the other to avoid spillage or contamination
  1. Infection
  2. Massive hemorrhage
- B. Control of the distribution of ventilation
  1. Bronchopleural fistula
  2. Bronchopleural cutaneous fistula
  3. Surgical opening of a major conducting airway
  4. Giant unilateral lung cyst or bulla
  5. Tracheobronchial tree disruption
  6. Life-threatening hypoxemia related to unilateral lung disease
- C. Unilateral bronchopulmonary lavage
  1. Pulmonary alveolar proteinosis

II. Relative
- A. Surgical exposure—high priority
  1. Thoracic aortic aneurysm
  2. Pneumonectomy
  3. Thoracoscopy
  4. Upper lobectomy
  5. Mediastinal exposure
- B. Surgical exposure—medium (lower) priority
  1. Middle and lower lobectomies and subsegmental resections
  2. Esophageal resection
  3. Procedures on the thoracic spine
- C. Postcardiopulmonary bypass pulmonary edema/hemorrhage after removal of totally occluding unilateral chronic pulmonary emboli
- D. Severe hypoxemia related to unilateral lung disease

Adapted from Hagberg CA, ed. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Saunders; 2013.

Methods of Lung Separation

Several devices have been developed to enable isolation of one lung and ventilation of the other. The single-lumen endobronchial tube was developed in 1931 to isolate an infected lung.[87] Mimicking this simple approach by advancing a 7.5-mm, 32-cm endotracheal tube (ETT) over a fiberoptic scope into one bronchus may still be used in some circumstances. A disadvantage to use of a single-lumen tube for OLV is that the ability to ventilate or suction the operative lung is lost. Another disadvantage is that use of a single-lumen tube in the right lung would probably occlude the right upper lobe orifice. However, in an emergent situation, use of a single-lumen tube advanced blindly down the right bronchus or placed into the left bronchus aided by a bronchoscope can be life saving. A summary of lung separation devices is presented in Table 27-2. Given that each approach (DLT vs. bronchial blocker) has relative merits, neither can be recommended as a clearly superior method of lung separation for thoracic surgery.

Double-Lumen Endobronchial Tubes

Double-lumen tubes (DLTs) consist of a single tube with two lumens. The bronchial lumen is designed to be inserted into either the left or right lung, and the corresponding port will ventilate that lung. The other lumen opens into the trachea, and the corresponding port will ventilate the opposite lung. The bronchial lumen does not necessarily have to be in the operative lung (Figure 27-10).

Features

Several types of DLTs are used in thoracic surgery. DLTs are designed for insertion either in the right or the left bronchus. Right-sided tubes include features to accommodate the proximity of the upper lobe bronchus. Disposable polyvinyl chloride tubes are available in French (Fr) sizes 26, 28, 35, 37, 39, and 41. The internal lumen diameters range from 3.4 mm to 6.6 mm,[88] although there is wide size variation between manufacturers.[89,90] It would be most important for the anesthetist to ascertain the appropriate size fiberscope

TABLE 27-2 Types of Lung Separation Devices

Type	Examples	Notes
Endobronchial tube	Bronchocath, Carlens, Robertshaw, White	Left bronchus intubation preferable; large size increases difficulty of transoral insertion, but facilitates emptying of surgical lung; right side more challenging to position, but may be preferable for descending aortic aneurism; Carlens and White: carinal hook aids placement when visualization is poor (hemorrhage/hemoptysis)
Bronchial blocker	Ardnt, Cohen, Coopdech, Univent	Easier basic tube insertion, but blocker requires fiberscope—longer time to situate; lung deflation may require suction; more often dislodged; preferable if postoperative intubation planned; Cohen: flexible tip can be manipulated; Arndt, Coopdech: blocker is adapted to a regular endotracheal tube

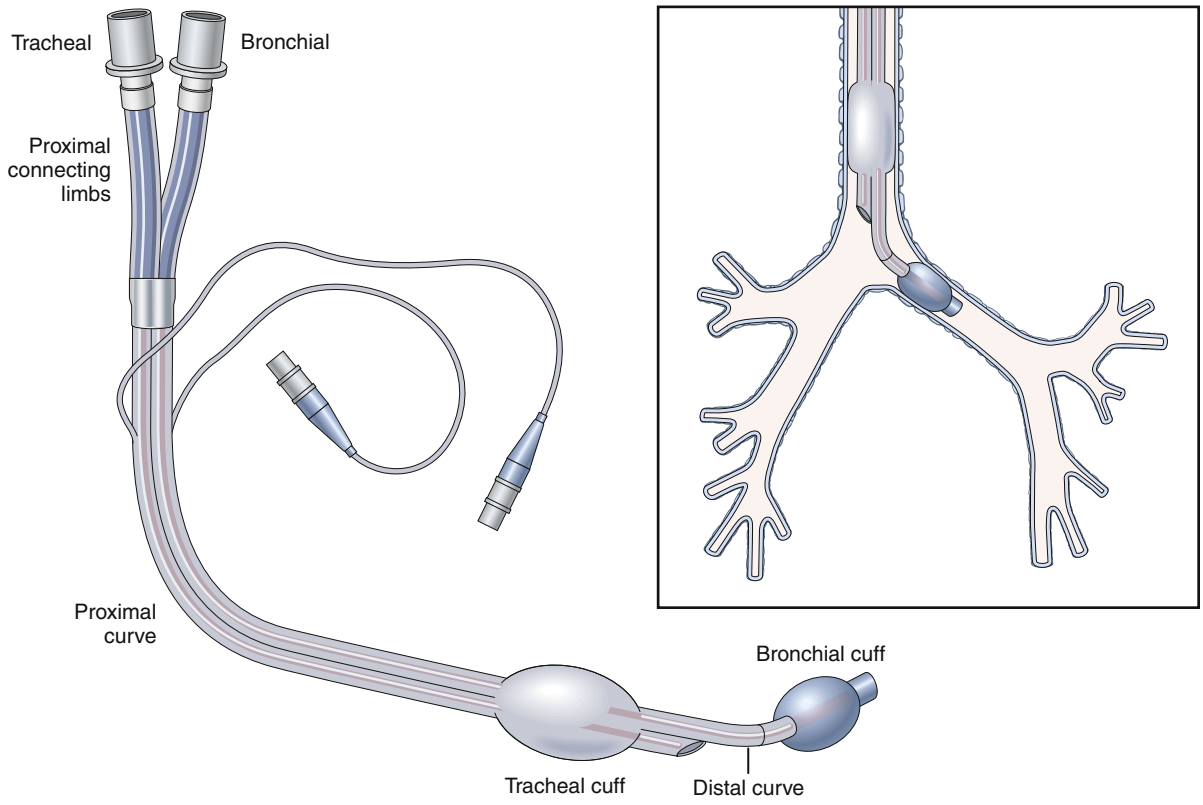

FIGURE 27-10 The double-lumen endobronchial tube. Inset shows a left-sided tube correctly positioned in the bronchus. (From Miller RD, Pardo MC, eds. *Basics of Anesthesia*. 6th ed. Philadelphia: Churchill Livingstone; 2011.)

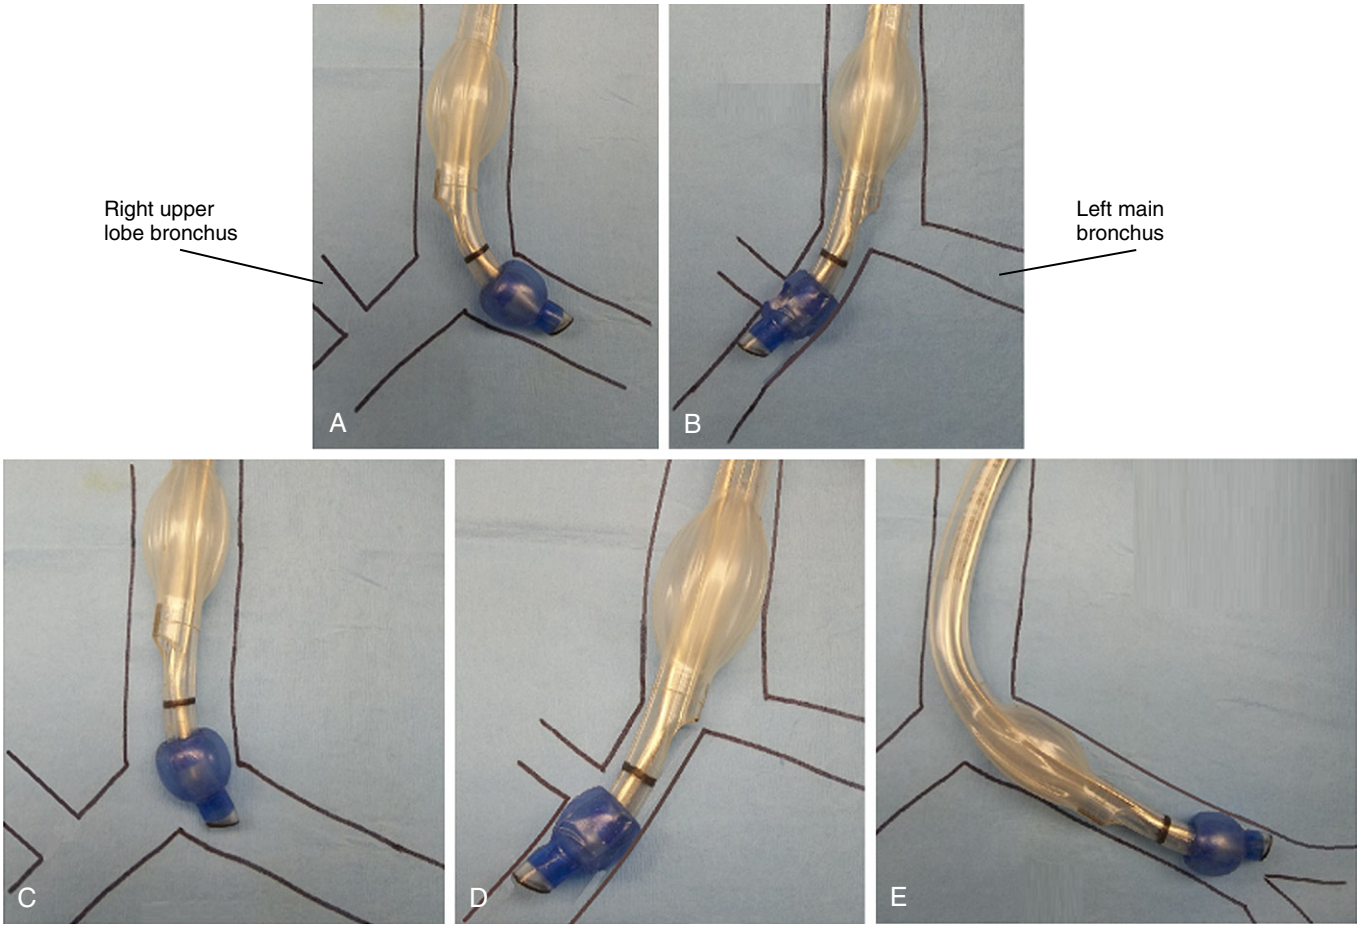

Figure	Description	Ventilating through the bronchial lumen produces breath sounds:	Ventilating through the tracheal lumen produces breath sounds:
A	Correct position of left DLT	Left lung	Right lung
B	Correct position of right DLT	Right lung	Left lung
C	DLT insertion too shallow	Both lungs	Diminished or absent if bronchial cuff obstructs trachea; otherwise, both lungs
D	DLT too deep in right bronchus	Right middle and lower lobes	Left lung or right upper lobe (depending on depth of tracheal cuff)
E	DLT too deep in left bronchus	Left lung	Left lung
Additional variations are possible, such as if a left-sided DLT is inadvertently positioned in the right bronchus, or vice versa. Auscultation provides a quick check, but fiberoptic confirmation is preferable for definitive confirmation.			

FIGURE **27-11** Positioning variations of the double-lumen endobronchial tube.

that will fit through the intended tube. In spite of the perceived smaller size of the lumens, DLTs do not increase breathing resistance significantly in comparison to single-lumen tubes.[88,91]

Advantages and Disadvantages

Although the presence of dual lumens limits the internal diameter of each, the external diameter of a DLT is very large. The 37-F DLT has an outer diameter equivalent to that of a standard 11-mm internal diameter (ID) ETT. For this reason, DLTs are not used for small children; the external diameter of the 26-F DLT is 7.5 mm.[92] Sizing of DLTs is determined by patient height, usually leading to use of 35-F to 37-F tubes in females, and 39-F to 41-F tubes in males.

The short distance from the carinal bifurcation to the right upper lobe is 2.5 cm or less, as compared with a 4- to 5-cm left mainstem bronchus. Modifications have been made in right-sided tubes to allow ventilation through a slot in the endobronchial cuff or to use two bronchial cuffs, but even slight movement of the right DLT can lead to malposition. Many practitioners have resolved to use left-sided DLTs for all right and left thoracotomies unless a left-sided tube is contraindicated by internal lesions of the airway, compression of the trachea or main bronchi by an external mass, or the presence of a descending thoracic aortic aneurysm, which can compress or erode the left main bronchus. Intubation with the large DLT can pose a challenge, even in patients with a normal airway; insertion in those with poor airway anatomy may be particularly challenging.

Complications of Double-Lumen Tubes

The most common complication of DLT use is malpositioning of the tube. Figure 27-11 demonstrates some variations of DLT positioning. Rupture of a thoracic aneurysm is possible with a left DLT

BOX **27-4**

Auscultation of Breath Sounds After Placement of a Double-Lumen Tube

1. Inflate the tracheal cuff.
2. Verify bilaterally equal breath sounds. If breath sounds are present on only one side, both lumens are in the same bronchus. Deflate the cuff and withdraw the tube 1 to 2 cm at a time until breath sounds are equal bilaterally.
3. Inflate the endobronchial cuff.
4. Clamp Y-piece to the endobronchial lumen and open the lumen to atmosphere.
5. Verify breath sounds in the correct lung (tracheal side) and the absence of breath sounds in the opposite lung (bronchial side).
6. Verify the absence of air leakage through the bronchial lumen.*
7. Unclamp and reconnect the endobronchial lumen and verify bilateral breath sounds.
8. Clamp Y-piece to the tracheal lumen and open the lumen to atmosphere.
9. Verify breath sounds in the correct lung (bronchial side) and the absence of breath sounds in the opposite lung (tracheal side).
10. Verify that breath sounds are equal at the apex of the lung and at the base. If the apex is diminished, withdraw the tube until upper lung sounds return.
11. Verify the absence of air leakage through the tracheal lumen.*

*When absolute lung separation is needed, as in bronchopulmonary lavage, connecting tubing from the open, nonventilated lumen to an underwater drainage system will show air bubbles if a leak is present (see Figure 27-13).

if the aneurysm compresses the left mainstem bronchus. Damage to the vocal cords or arytenoid cartilages is possible from a carinal hook. A carinal hook also can break off, requiring retrieval with a bronchoscope. Bronchial rupture, which was thought to be caused by overinflation of the bronchial cuff, has been reported.[93,94] Owing to the possibility of its being inserted too deeply, a DLT also can cause the entire tidal volume to be delivered to a single-lung lobe, creating the potential for barotrauma. The larger size of the DLT is probably also responsible for the slightly increased incidence of hoarseness and vocal cord lesions observed in patients after DLT, versus using a bronchial blocker for lung separation.[95]

Insertion of Double-Lumen Tubes

The DLT has two curves along its length to aid in its placement. A stylet aids placement through the larynx. Some practitioners prefer the Macintosh blade for intubation because it offers greater clearance for the tube and may decrease the chance of balloon rupture from the teeth.[96] For laryngoscopy, the lubricated DLT is advanced with the distal curve concave anteriorly until the vocal cords are passed. The stylet is usually removed at this point to reduce concern about the rigid tube causing mucosal damage. The tube is then rotated 90 degrees toward the bronchus to be intubated. The tube is advanced to around a 27-cm depth in females or 29 cm in males, or until resistance is met.[97]

The tracheal cuff requires 5 to 10 mL of air, and the bronchial cuff requires 1 to 2 mL of air. Overinflation of the bronchial cuff can cause its lumen to be narrowed or occluded and increases the risk of tearing the bronchus. Unlike most tracheal high-volume, low-pressure cuffs, the bronchial cuff holds a small volume and can produce high pressures on the endobronchial mucosa. For that reason, unless unilateral lung contamination exists, the bronchial cuff should be deflated during the procedure once OLV is no longer needed. After the tube is situated in the bronchus, adapters are attached to the two lumens for interface with the anesthesia circuit. Auscultation of breath sounds is a simple though not highly reliable method of determining the position of a double-lumen tube (Box 27-4). When properly positioned, breath sounds should be auscultated in all fields of the lung corresponding to the bronchial lumen (depending on left- or right-sided tube) when that lumen alone is ventilated. Breath sounds should be heard only in the opposite lung, then, when the tracheal lumen is ventilated. Figure 27-11 outlines some auscultation findings expected with various tube positions.

Flexible fiberoptic bronchoscopy is essential to verify placement of the DLT (Figure 27-12 and Box 27-5). Fiberoptic bronchoscopy has revealed a 38% to 83% incidence of malpositioning of DLTs that were judged by auscultation to be properly placed.[88,98] Some particular advantages of fiberoptic inspection of the DLT over auscultation are guidance during initial placement, ability to visualize correct depth of the bronchial cuff, and visualization of proper positioning of the right upper lobe port (if present). Placement of the tube should again be verified by bronchoscopy after the patient is positioned laterally because the DLT will commonly withdraw from the bronchus by 1 cm.[99] When absolute separation of the lungs is required to prevent cross-contamination, the integrity of the bronchial seal can be tested by connecting a tube from the bronchial port to a water seal and then providing ventilation through the tracheal lumen. Incompetence of the bronchial cuff will be evidenced by egress of bubbles in the water seal (Figure 27-13).

Bronchial Blockers

Bronchial blockers consist of catheters with an inflatable balloon that blocks the bronchus of the operative lung. Blockers can be incorporated into a side-channel of an endotracheal tube (e.g., Univent tube) or they can be separate devices and inserted either through the regular endotracheal tube lumen or outside of it (more common in pediatrics) (Figure 27-14). Common options for stand-alone bronchial blockers include the 8F-Fogarty embolectomy catheter, the Cohen Flextip blocker, the Coopdech blocker, the EZ blocker, and the Arndt Bronchial blocker (formerly called the Wire-Guided Endobronchial blocker).

Features

Bronchial blockers are guided into the appropriate bronchus with the aid of a bronchoscope (Figure 27-15). Wire-guided blockers have a loop on the end through which the fiberscope is passed, facilitating guidance of the blocker into the bronchus after the fiberscope. The Cohen blocker has a steerable tip to facilitate advancement into the appropriate bronchus. The Univent tube consists of an integrated ETT with a second lumen for a deployable bronchial blocker. The EZ blocker has a forked distal end that functions like the Carlens hook to rest on the carina. One arm of the fork has the inflatable balloon to occlude the bronchus it occupies.

Advantages and Disadvantages

Because insertion of the DLT is more complicated, bronchial blockers are more useful in patients with a difficult airway or a tracheostomy. These devices are beneficial for patients already intubated, when changing to another tube would be dangerous. They can also be used for pediatric lung separation, even in children less than 2 years of age, with a special small-sized blocker.[100,101]

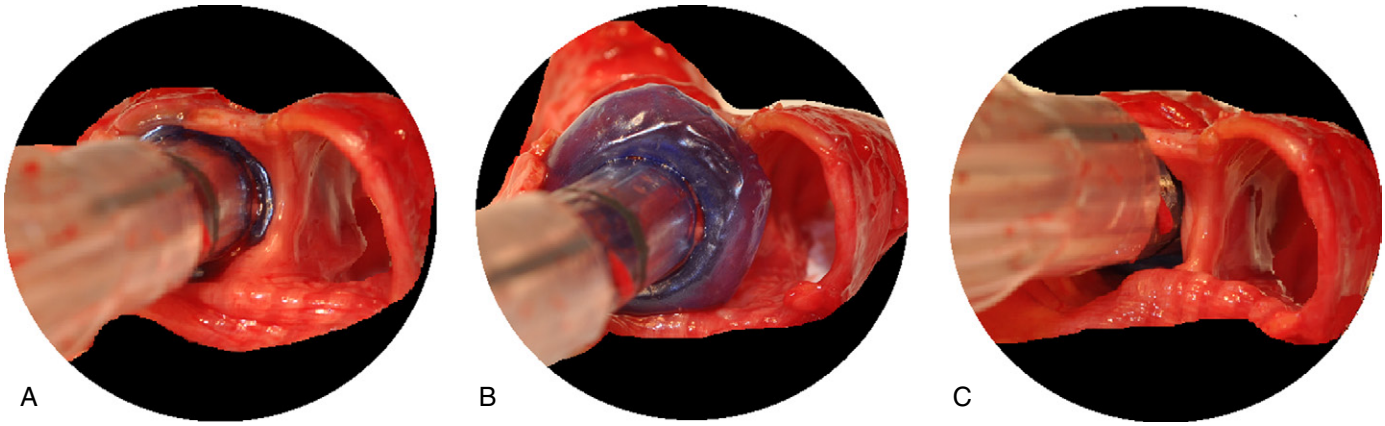

FIGURE **27-12** Verification of double-lumen tube position with fiberscope. **A,** Correct position; bronchial cuff visualized just beyond the carina. **B,** Tube too shallow; bronchial cuff herniating across the carina. **C,** Tube too deep. See additional description in Box 27-5.

BOX **27-5**

Fiberoptic Bronchoscopy to Verify Placement of a Double-Lumen Tube

1. Insert the scope through the tracheal lumen. Visualize the carina distally. (Confirm that the tracheal orifice is within the trachea and not a bronchus, or that the tube is not displaced proximally such that the bronchial cuff fills the trachea.)
2. Visualize the bronchial (blue) cuff 1 to 2 mm beyond the carina. Ensure that the cuff is not too proximal or overinflated such as to herniate across the carina and obstruct the contralateral bronchus.
3. Insert the scope through the bronchial lumen. Visualize that the tip of the bronchial lumen is unobstructed. For left-sided tubes, visualize the bronchial carina distal to the tube tip. For right-sided tubes with a right upper lobe (RUL) ventilation port, visualize that the RUL bronchus is aligned with the ventilation port.

FIGURE **27-13** Water seal set-up to test for leaks around the bronchial cuff.

Although the regular tube is easy to insert, positioning the bronchial blocker requires more time than the DLT, and placement is dependent on use of a fiberscope. In comparison to DLT, blockers have a greater incidence of becoming malpositioned. Because a bronchial blocker affords little conduit for egress of gas, lung deflation is often less effective than with a double-lumen tube. This can be particularly troublesome in thoracoscopic surgery. Suction of the blocker port can be helpful, but excessive negative pressure or duration can cause damage. Blockers also do not allow suctioning for pulmonary toilet, particularly when separation is indicated by unilateral infection or bleeding. In that case, removal must follow special procedures to avoid contaminating the opposite lung.[102] The bronchial blocker is plagued with the same challenge as the DLT in blocking the right bronchus, but the DLT has the advantage of being able to exclude either lung with a left-sided device. Therefore, bronchial blockers are reserved by some exclusively for left-sided surgery.

Insertion of Bronchial Blockers

Insertion of the bronchial blocker depends on the device. Typically, it involves basic tracheal intubation followed by insertion of the blocker through the tube, followed by the fiberscope, which is used for final positioning. Variations include that wire-guided catheters are already mounted on the fiberscope when it is inserted, and pediatric extraluminal blockers are inserted in the trachea, followed by intubation, followed by fiberoptic inspection and positioning of the blocker.

Physiology of One-Lung Ventilation

During two-lung ventilation, blood flow to the dependent lung averages approximately 60% (Figure 27-16). When one lung is allowed to deflate and OLV is started, any blood flow to the deflated lung becomes shunt flow, causing the Pa_{O_2} to decrease. Without autoregulation of pulmonary blood flow, a 40% shunt would be anticipated. The lungs have a compensatory mechanism of increasing vascular resistance in hypoxic areas of the lungs, and this diverts some blood flow to areas of better ventilation and oxygenation. This mechanism, present in most mammals, is termed *hypoxic pulmonary vasoconstriction* (HPV). HPV is a reflex intrapulmonary feedback mechanism in inhomogeneous lungs to improve gas exchange and arterial oxygenation. Whereas hypoxemia causes vasodilation in the general circulation, alveolar hypoxia has the opposite effect on pulmonary arteries. HPV is a unique mechanism, suited specifically to match pulmonary blood flow with well-oxygenated areas of lung.

The cellular mechanism for HPV involves a redox-based oxygen sensor in smooth muscle cells of the pulmonary arteries (probably focused on the electron transport chain of the mitochondria

FIGURE **27-16** When the left lung is the nondependent lung, the distribution of blood flow between the nondependent and dependent lungs is 35%:65%. When the right lung is the nondependent lung, blood flow distribution between the nondependent and dependent lungs is 45%:55%. Average one-lung ventilation blood flow distribution is a nondependent-to-dependent ratio of 40%:60%. (From Benumof JL. *Anesthesia for Thoracic Surgery*. 2nd ed. Philadelphia: Saunders; 1995.)

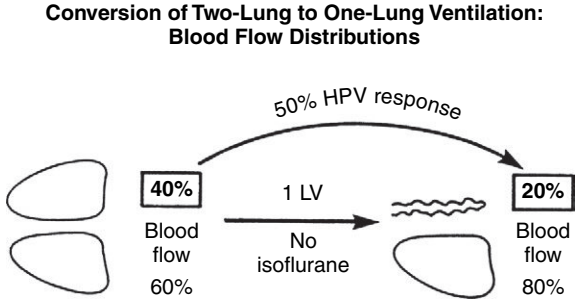

FIGURE **27-17** Two-lung ventilation nondependent/dependent lung blood flow ratio is 40%:60%. When two-lung ventilation is converted to one-lung ventilation *(1 LV)*, the hypoxic pulmonary vasoconstriction *(HPV)* response decreases the blood flow to the nondependent lung by 50%, and the nondependent/dependent lung blood flow ratio becomes 20%:80%. (From Benumof JL. *Anesthesia for Thoracic Surgery*. 2nd ed. Philadelphia: Saunders; 1995.)

BOX 27-6

Characteristics of Hypoxic Pulmonary Vasoconstriction

- A local reaction occurring in hypoxic areas of lung; may be very localized due to regional atelectasis (as in one-lung ventilation), or affect both lungs entirely in hypoxic situations (such as what leads to high-altitude pulmonary edema)
- Opposite to systemic reaction to hypoxia, causes vasoconstriction in all but very proximal pulmonary arteries
- Triggered by alveolar hypoxia, not arterial hypoxemia
- Onset and resolution are within seconds following changes in P_{O_2}
- Peak effect occurs within 15 minutes
- May be inhibited by vasodilators and augmented by chemoreceptor agonists (almitrine)

Data from Moudgil R, et al. Hypoxic pulmonary vasoconstriction. *J Appl Physiol*. 2005;98(1):390-403; Michelakis ED, et al. BOX 27-7

Factors That Reduce Effectiveness of Hypoxic Pulmonary Vasoconstriction

- Alkalosis
- Excessive tidal volume or PEEP
- Hemodilution
- Hypervolemia (LAP > 25 mmHg), atrial natriuretic peptide
- Hypocapnia
- Hypothermia
- Prostacyclin
- Shunt fraction < 20% or > 80%
- Vasodilators, phosphodiesterase inhibitors, and calcium channel blockers
- Volatile anesthetics > 1.5 MAC

LAP, Left atrial pressure; *MAC*, minimum alveolar concentration; *PEEP*, positive end-expiratory pressure.

of these cells). Hypoxia reduces production of activated oxygen species (AOS) such as H_2O_2. These AOS act as second messengers from the oxygen sensors, and reduction in their outflow leads to inhibition of voltage-dependent potassium channels. The result is influx of extracellular calcium, which causes vasoconstriction.[103,104] Box 27-6 lists the characteristics of HPV.

HPV during OLV is effective in decreasing the cardiac output to the nonventilated lung by approximately 50%[105] (Figure 27-17). HPV can increase the PVR by 50% to 300%, and the response can persist for long periods of time in the face of chronic hypoxia.[103] In fact, the chronic increase in PVR from COPD can be responsible for pulmonary vascular remodeling that leads to cor pulmonale.[106] HPV occurs whether the lung is rendered hypoxic by atelectasis or by ventilation with a hypoxic mixture. It is initiated within seconds of hypoxia and reaches its maximum effect in approximately 15 minutes. HPV improves arterial oxygenation when the amount of hypoxic lung is between 20% and 80%, which is the condition during OLV.[107] When less than 20% of the lung is hypoxic, the total amount of shunt is not significant. When more than 80% of the lung is hypoxic, HPV increases PVR, but the amount of well-perfused lung is not sufficient to accept enough diverted flow to maintain arterial oxygenation.

Because HPV is effective in decreasing shunt flow, avoidance of drugs or events that inhibit the mechanism is important (Box 27-7). Alveolar and intravascular volume derangements can inhibit the effect of HPV. Hypervolemia or high cardiac output may override HPV by recruiting constricted vessels.[108] Conversely, hypovolemia may trigger adrenergic vasoconstriction, reducing flow to well-ventilated portions of lung.[109] Overdistention of alveoli may also reduce perfusion to well-ventilated lung areas by creating the "zone 1" ventilation-perfusion scenario. For these reasons, normal fluid volume should be maintained during OLV; moderate tidal volumes (6 mL/kg) should be used, and excessive PEEP should be avoided.[86] Hypocapnia and alkalosis decrease HPV.

Many vasodilating drugs inhibit HPV, including nitroglycerin, nitroprusside, dobutamine, some calcium channel blockers (e.g., nifedipine nicardipine, and verapamil), and some β_2-agonists, such as isoproterenol.[86] Vasoconstrictive drugs, including dopamine, epinephrine, and phenylephrine, may preferentially constrict normally oxygenated pulmonary vessels and reestablish the shunt flow, in opposition to the effect of HPV.[107]

ANESTHETIC MANAGEMENT DURING ONE-LUNG VENTILATION

Choice of Anesthetic

Side effects of general anesthesia from a variety of mechanisms create concern for intraoperative and postoperative pulmonary function. They include impairment of hypoxic pulmonary vasoconstriction, disruption of ventilation-perfusion matching, neural and pain-induced hypoventilation, postoperative residual muscle relaxation, and atelectasis. Few studies have been able to demonstrate clear differences in patient outcomes based on anesthetic technique alone; however, some factors have emerged as being important in the pulmonary surgical patient.

On the basis of the discussion of HPV, clinical doses of potent inhalation agents do not significantly alter the mechanism of HPV. Volatile agents offer several benefits in thoracic surgery. They allow the use of a high F_{IO_2} to help prevent hypoxemia during OLV. They produce bronchodilatory effects and decrease airway irritability in patients to be subjected to direct manipulation of lung tissue. In some studies, volatile agents resulted in less inflammatory response than did IV agents.[110,111] In contrast, the dose of narcotics required to obtund airway reflexes could depress ventilation and necessitate postoperative ventilation. Volatile agents are rapidly eliminated at the end of surgery and allow for early extubation. For these reasons, volatile agents are usually chosen as the primary anesthetics during thoracic surgery.

No intravenous anesthetics inhibit HPV, and although all volatile agents theoretically do, the volatiles act as vasodilators in a dose-dependent manner.[112] HPV can be expected to remain intact if volatile agents are administered at less than 1.5 minimum alveolar concentration (MAC).[113-115] Most analyses fail to demonstrate a difference in gas exchange between intravenous and inhaled techniques.[116]

To prevent hypoxia and any significant increase in PVR, nitrous oxide is generally avoided in favor of an air-O_2 mixture. Nitrous oxide increases PVR in healthy patients as well as in those with preexisting pulmonary hypertension.[84] This is cause for even greater clinical concern with concurrent right ventricular dysfunction. Nitrous oxide should also be avoided in patients with bullous or emphysematous lungs, because it may increase the volume of trapped airspace. An air-oxygen mixture does prolong emptying of the operative lung, in contrast to pure oxygen or a nitrous oxide mixture.[117]

The choice of specific opioids or hypnotics will not influence pulmonary outcomes, but there is concern related to the choice of muscle relaxants used. Postoperative residual paralysis is a common occurrence with both intermediate and long-acting relaxants and is present regardless of the use of neuromuscular monitoring or reversal.[118] However, the incidence of residual relaxation associated with the use of long-acting relaxants (e.g., pancuronium) is significantly higher, and complications from it are more frequent compared with the use of intermediate-acting relaxants.[119] Muscle weakness may follow surgeries of long duration, even with adequate tests of neuromuscular recovery.[120] Therefore, the use of shorter-acting, fast-offset relaxants and conservative monitoring, dosing, and reversal practices are indicated in the pulmonary surgical patient.

The Role of Regional Anesthesia

When compared with general anesthesia, regional anesthesia may be beneficial in reducing atelectasis, pneumonia, respiratory failure, and other pulmonary complications.[121] Unfortunately, regional anesthesia without general is impractical for the open-lung case; however, regional anesthesia can offer postoperative analgesia without the respiratory depressant effects of systemic opioids, which confers great benefits. Epidural anesthesia was found to reduce complications both for patients with normal FEV_1, and those with airflow obstruction.[122] Because epidural sympathectomy causes vasodilation, some have questioned whether epidural anesthesia would inhibit HPV, but because HPV is a locally mediated event, epidural anesthesia is found to be similar to IV or balanced techniques with regard to gas exchange.[123]

Analgesia for Thoracic Surgery

Thoracotomy is known as one of the most painful operations, and postoperative pain can be very protracted (as in post-thoracotomy pain syndrome) and lead to complications such as pneumonia and atelectasis.[87] Pain immediately after thoracic surgery causes splinting, decreased respiratory effort, hypoxemia, and respiratory acidosis. Aggressive management of pain is aimed at seeking a balance between comfort and respiratory depression in patients with decreased lung function. Residual pain exists in half of thoracotomy patients after 1 year and in one third of patients after 4 years.[88]

Several options can be considered in the management of postoperative pain. Patients can titrate intravenous patient-controlled analgesia to obtain a more constant level of analgesia than that provided by intermittent intramuscular injections, but the benefits of avoiding systemic opioids have made regional anesthesia emerge as a superior method of pain control.

Thoracic epidural analgesia is considered one of the most effective methods for treating postoperative pain.[124] An epidural catheter is placed around T6 to T8 and infused with epidural opioids or dilute solutions of local anesthetics to provide analgesia. The efficacy of epidural analgesia may be improved with adjunctive interventions, such as IV administration of ketamine and nonsteroidal analgesics.[125]

As an alternative regional anesthesia technique, paravertebral nerve blocks can be placed at the level of the incision plus one or two intercostal interspaces above and below. This technique provides good short-term pain relief and reduces opioid requirements. Paravertebral block provides quality pain control to rival epidural analgesia.[126,127]

Management of One-Lung Ventilation

Ventilation Modes

The primary goal during OLV is maintaining adequate arterial oxygenation and protecting the lung, while providing a surgical field favorable for visualization and manipulation of the operative lung (Box 27-8). In the past, large tidal volumes (V_T) of 10 to 15 mL/kg were recommended to prevent atelectasis in the dependent lung and maintain an adequate FRC. Contemporary understanding is that high volumes predispose to volutrauma, which is associated with increases in cytokine inflammatory mediators and in alveolar fibrin deposition and other markers of procoagulant effect, which characterize acute lung injury.[128,129]

Many patients develop "auto-PEEP" during OLV and have an increased FRC, such that large tidal volumes are unnecessary in any case. Understanding the detrimental effects of high tidal volumes has led to the more contemporary approach of using more physiologic volumes (e.g., 6 mL/kg on the left and 8 mL/kg on the right), adding PEEP to those patients without auto-PEEP, and limiting plateau inspiratory pressures to less than 25 cm H_2O.[122,128-130] With this approach, patients will maintain adequate or even improved oxygenation (as compared with using higher) and minimal elevations in Pa_{CO_2}.[86,131] It is preferable to allow permissive hypercapnia, rather than too-aggressively attempting to maintain a normal

Pa_{CO_2} because hypercapnia supports HPV and also directly reduces cytokine response.[132,133] The Pa_{CO_2} should be maintained below 60 to 70 mmHg, to reduce the incidence of dysrhythmias, hypotension, and pulmonary hypertension. Although a high Fi_{O_2} should induce vasodilation in the dependent lung and improve blood flow, hypocapnia would cause vasoconstriction and should be avoided. PEEP must be employed when using low V_T; otherwise, alveolar derecruitment will occur and reduce the Pa_{O_2}.[134] Implementation of an alveolar recruitment maneuver prior to initiating OLV can help to support better Pa_{O_2} throughout the OLV period.[135] Recruitment maneuvers are not universally accepted. Besides opening airways, they may also translocate cytokines into the circulation,[136] impede hemodynamics, and provide only a transient effect.[137]

An appropriate air-O_2 mixture, at times as high as Fi_{O_2} of 1, is necessary to maximize the Pa_{O_2}. However, considering the potential for oxygen toxicity (particularly absorptive atelectasis or history of chemotherapeutic administration[138]), Fi_{O_2} should be maintained at the lowest level that will support adequate Sp_{O_2}.[112] This approach also leaves a "reserve" intervention in the case of hypoxemia. Increasing the Fi_{O_2} in the face of declining oxygenation allows time to plan other interventions (such as checking tube placement). On 100% oxygen, by the time the Sp_{O_2} falls, the insult will be more advanced and the saturation will continue to decline during diagnosis and management of the issue.

Recent research validates the "protective ventilation" strategy, including end-expiratory pressures above the lower inflection point on the pressure-volume curve, a tidal volume of less than 6 mL per kilogram, inspiratory pressures of less than 20 cm H_2O above the PEEP value, permissive hypercapnia, and preferential use of pressure-limited ventilatory modes.[139-141] The choice of pressure or volume modes of ventilation is not clear-cut. It is compelling to consider that pressure-controlled ventilation limits maximal airway pressure and that the square pressure waveform provides more widespread alveolar recruitment, but research has been equivocal about demonstrating consistently better outcomes based on the ventilation mode.[142-145]

Hypoxemia During One-Lung Ventilation

Hypoxemia occurs in 5% to 10% of patients under OLV.[3] Although hypoxic pulmonary vasoconstriction attempts to normalize the relationship of ventilation and perfusion, it is not 100% effective at doing so. Certain characteristics predict the degree of hypoxemia that will be exhibited by a patient under OLV. The simple fact that the anatomy of the right lung is larger than the left accurately predicts that hypoxemia is worse in right-sided surgery, because there is a greater baseline amount of perfusion to the right lung[146] (see Figure 27-16).The usual detrimental effect of lateral positioning on oxygenation paradoxically benefits the patient during OLV. Lateral positioning with mechanical ventilation normally imbalances $\dot{V}/\dot{Q}$ matching by distributing more ventilation to the nondependent lung, whereas gravity encourages more perfusion to the dependent lung. During lateral-positioned OLV, direction of all ventilation to the dependent lung creates a more beneficial match of ventilation and perfusion. In fact, Pa_{O_2} is found to be significantly worse in procedures (such as lung transplant) where OLV is performed in supine patients.[112] Some patient data also provide prediction of the degree of hypoxemia that will be encountered during OLV. The reduction in FEV_1, paradoxically, is sometimes inverse to the degree of hypoxemia experienced. As a measure of disease progress, a lower FEV_1 indicates worse disease; but as a measure of air-trapping, patients with a lower FEV_1 sometimes create intrinsic PEEP, which helps keep their airways patent and beneficially reduces hypoxemia during OLV.[146] Ventilation-perfusion scanning, if complete preoperatively, also can provide a suggestion of the potential for intraoperative shunt under OLV, because perfusion to the operative lung is inverse to the potential shunt.[147] A last-minute predictor is the end-tidal CO_2. Being dependent on blood flow to the lung, end-tidal carbon dioxide concentration (ET_{CO_2}) is a surrogate measure of perfusion.[148] The degree of decline in $ET_{CO_2}$when switching from two-lung to OLV indicates the degree of blood perfusing the nondependent lung, and therefore a greater initial decline predicts worse oxygenation during OLV.

If hypoxemia occurs during OLV, the anesthetist should assess for physiologic causes or tube malpositioning. Physiologic causes may include bronchospasm, decreased cardiac output, hypoventilation, low Fi_{O_2}, or pneumothorax of the dependent lung. Tube malpositioning implies that movement of the DLT may have excluded a portion of dependent lung, usually the upper lobe. Positioning should be checked first, because a large proportion of hypoxemic episodes are remedied by tube repositioning.[3] If physiologic causes have been ruled out and adequate lung separation and ventilation have been determined, one or more of the following interventions will help improve Pa_{O_2}. First, continuous positive airway pressure (CPAP) to the nondependent, nonventilated lung is almost 100% efficacious in increasing Pa_{O_2}. This can be accomplished with a compact breathing system, such as a Mapleson C with a manometer for pressure determination, attached to the lumen of the deflated lung (Figure 27-18) or with a calibrated, adjustable device made specifically for this purpose. Application of CPAP should help to oxygenate the persistent blood flow through the nondependent lung, but too much pressure will cause the lung to inflate, reducing surgical exposure. The lowest level of effective CPAP (start at 2 cm H_2O) should be sought. The reservoir bag on the CPAP device also can be used to provide intermittent ventilation to the operative lung, if that intervention becomes necessary. Providing gentle ventilation with a separate system will minimize the diminution of surgical exposure, as opposed to ventilating the lung with the same vigor as that required for the dependent lung. As an alternative to CPAP, a small catheter can be used to deliver low-flow oxygen insufflation to the nondependent lung without generating pressure. This approach may be adequate to reduce the shunt and reverse hypoxemia in mild cases.[149]

Besides shunt flow through the operative lung, atelectasis and reduced FRC in the dependent lung also may degrade the Pa_{O_2}. If CPAP to the nondependent lung does not improve oxygenation, PEEP applied (or titrated upward) in the dependent, ventilated lung acts to recruit collapsed airways, increasing compliance of the lung, and increasing FRC. Excessive PEEP

BOX 27-8

Overarching Goals of Ventilation

- Keep the dependent lung open (nonatelectatic) to avoid hypoxemia
- Prevent repetitive closure and opening of airways to avoid damaging shearing forces
- Prevent overdistention and overventilation to avoid inflammatory injury and auto-PEEP
- Promote perfusion to the dependent lung (permit mild hypercapnia; avoid hypoxia, "Zone 1" alveolar pressure, and vasodilators)

PEEP, Positive end-expiratory pressure.

may detrimentally reduce cardiac output. Combined with a fast respiratory rate and/or high inspiratory/expiratory (I:E) ratio, PEEP may impair adequate exhalation, leading to a net volume increase through auto-PEEP and the potential for volutrauma to the dependent lung. The actual end-expiratory pressure should be monitored during OLV to ensure that it does not significantly exceed the intended level of PEEP. Other methods of improving oxygenation during OLV include combining PEEP and CPAP to the respective lungs, and intermittent reinflation of the nondependent lung. Innovative ventilatory approaches such as high-frequency jet ventilation to the operative lung and selective oxygenation to nonoperative *lobes* of the operative lung via a bronchial blocker or bronchoscope also are used.[149-152] Jet ventilation is effective at reducing the shunt, but lung movement can be deleterious, and monitoring and effecting CO_2 removal becomes challenging.[153]

In the failure of CPAP and PEEP, early ligation of the pulmonary artery in pneumonectomy patients may be used to improve oxygenation. If the pulmonary artery is planned to be ligated during the procedure, clamping it will immediately stop all significant flow through the lung contributing to the shunt. For the same reason, manual compression of the lung also will improve the Pa_{O_2}, but the expense of cardiac output and tissue trauma advises against this as a regular strategy.[154] If it becomes impossible to maintain adequate oxygenation with OLV in spite of CPAP and PEEP, manual two-lung ventilation can be used, with pauses in ventilation coordinated with the surgeon's activities to facilitate exposure, suturing of the lung, or other needs. Communication with the surgical team is vital throughout the procedure, especially during the evaluation and correction of hypoxia.

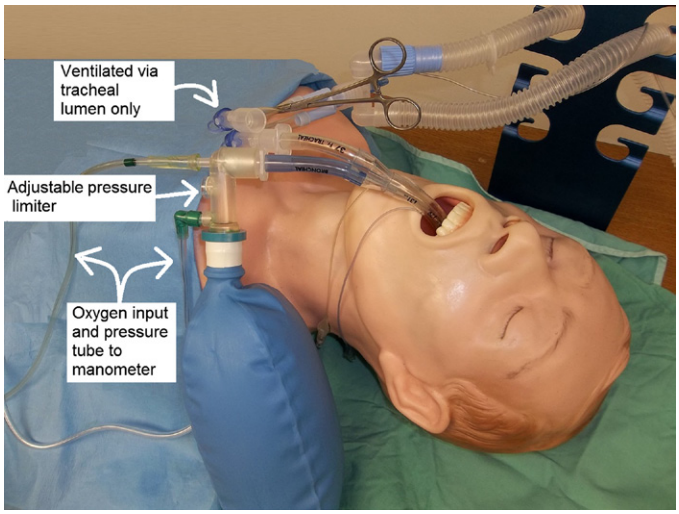

FIGURE **27-18** Continuous positive airway pressure apparatus for improving oxygenation of the nonventilated lung.

At the conclusion of the resection, the surgeon commonly will ask that the operative lung be reinflated using large tidal volumes so that air leaks may be detected. At this time, the lung separator (e.g., DLT clamp, bronchial blocker) should be discontinued and the lung inflated with slow breaths, achieving a peak inspiratory pressure of 30 to 40 cm H_2O.[86] Reexpansion of the lung can be observed while performing this maneuver, which also helps to reverse atelectasis in the lungs. After lung reexpansion, the bronchial cuff should be deflated on the DLT to both reduce pressure on the bronchial mucosa and obviate any detrimental effects of slight tube malpositioning. Deflated, the cuff does not pose the threat of herniating over the carina or obstructing the lobar bronchi. Box 27-9 outlines management of one-lung anesthesia.

Emerging techniques in management of OVL focus attention away from manipulating ventilation of the operative lung to manipulation of perfusion of the nonoperative lung. Ventilation-perfusion matching can be supported by encouraging more perfusion to the ventilated lung or selectively diminishing perfusion to the nonventilated one. Inhaled epoprostenol (prostacyclin) and nitric oxide are beneficial for increasing the perfusion of the dependent lung. The combination of inhaled epoprostenol and IV phenylephrine (for vasoconstriction of the operative lung) is found to be an effective strategy.[155] Another experimental approach is the use of almitrine, which enhances HPV of the nonventilated lung. Studies have shown more than 100% increase in Pa_{O_2} when almitrine and nitric oxide are used on their respective lungs;[156,157] however, toxicity, cost, and challenges to set-up and administer

BOX **27-9**

Management of One-Lung Anesthesia

- Ventilate:
  - Tidal volume: 6-8 mL/kg
  - Rate: 12-15 (permissive hypercapnia okay)
  - Fio_2: 0.4-0.8; maintain Spo_2 > 90%
  - PEEP: 5-10 cm H_2O (2.5-5 if COPD)
  - I:E ratio: 1:2 (1:3 if COPD or PEEPi)
- Consider alveolar recruitment maneuver prior to OLV
- Assess ABG 15 minutes after OLV initiated
- Volatile anesthetics < 1-1.5 MAC or IV agents
- Respond to hypoxemia:
  - Confirm tube position with fiberscope
  - Remedy detrimental effects of anemia or vasodilators
- Perform alveolar recruitment maneuver to DL
- Titrate PEEP in NDL
- Perform gentle recruitment, then CPAP 5-10 cm H_2O to NDL
- Increase Fio_2
- Intermittent or continuous two-lung ventilation
- Low-or no-pressure oxygen insufflation to NDL or selected lobe of NDL
- Reposition to lateral decubitus position if supine
- Alter perfusion with almitrine to NDL; nitric oxide to DL

THORACIC SURGICAL CONCERNS

Mediastinal Masses

Masses in the mediastinum can compress vital structures and cause changes in cardiac output, obstruction to airflow, atelectasis, or central nervous system changes. Masses can include benign or cancerous tumors, thymomas, substernal thyroid masses, vascular aneurysms, lymphomas, teratomas, and neuromas (Box 27-10). Surgical procedures for diagnosis or treatment of these masses may include thoracotomy, thoracoscopy, and mediastinoscopy.

Tumors within the anterior mediastinum can cause compression of the trachea or bronchi, increasing resistance to airflow. Changes in airway dynamics with supine positioning, induction of anesthesia, and positive-pressure ventilation can cause collapse of the airway with total obstruction to flow. General anesthesia can therefore be very dangerous in these patients. Total airway obstruction can occur at any phase of anesthesia and through the recovery phase. Positive-pressure ventilation may be impossible, even with a properly placed ETT, if the mass encroaches on the airway distal to the ETT. The airway can collapse, even when spontaneous respiration is maintained.[158] To anticipate this potential, anesthetic preparation should include availability of a rigid bronchoscope, and readiness to turn the patient lateral or prone in case of airway collapse. Cannulation for potential emergency femoral-femoral bypass should be considered if the tumor is large or symptomatic.[159,160] Localization of the mass by computed tomography or bronchoscopy may facilitate placement of the ETT distal to the mass. A major anesthetic goal is to maintain spontaneous ventilation, which retains normal airway-distending pressure gradients and can maintain airway patency when positive pressure ventilation will not.[161]

Signs and symptoms of respiratory tract compression should be sought preoperatively. Many mediastinal masses are asymptomatic, or characterized by vague signs such as dyspnea, cough, hoarseness, or chest pain. Wheezing may represent airflow past a mechanical obstruction rather than bronchospasm. Symptoms may be positional, worsening in the supine or other position. A chest radiograph may show airway compression or deviation. Computed tomography, transesophageal echocardiography, and magnetic resonance imaging may further delineate the size and effects of masses. Subclinical airway obstruction may be revealed by flow-volume loops, which demonstrate changes in flow rates at different lung volumes. Decreased maximal inspiratory or expiratory flow rate alerts the anesthetist to increased risk of obstruction perioperatively. Comparison of flow rates obtained with the patient in the upright and supine positions can reveal whether the supine position will exacerbate the obstruction intraoperatively (Figure 27-19 and Box 27-11).[162]

Biopsy of masses should be performed with the patient under local anesthesia whenever possible. Biphasic positive airway pressure (BiPAP) has been used in this situation to support the airway and maintain spontaneous ventilation while still providing sedation.[163,164] Radiation therapy may be helpful to decrease the mass of the tumor before major surgery is attempted. For airway management, awake fiberoptic bronchoscopy and intubation enables the anesthetist to evaluate the large airways for obstruction and place the ETT beyond the obstruction while maintaining spontaneous ventilation. The effect of positional changes can be assessed with the bronchoscope. Spontaneous ventilation should be maintained as long as possible or throughout the procedure if feasible. The ability to effectively provide positive-pressure ventilation should be guaranteed prior to administering muscle relaxants. The use of a helium-O_2 mixture can improve airflow during partial obstruction by decreasing turbulence past the stenotic area.[165]

Mediastinal masses can cause compression of great vessels or cardiac chambers. Patients with any cardiac or great vessel involvement should receive only local anesthesia whenever possible, remain in the sitting position, and maintain spontaneous respirations. Cardiopulmonary bypass must be able to be implemented within minutes in case of sudden cardiopulmonary collapse.

Patients with mediastinal masses may develop superior vena cava syndrome, venous engorgement of the upper body caused by compression of the superior vena cava. The following signs and symptoms

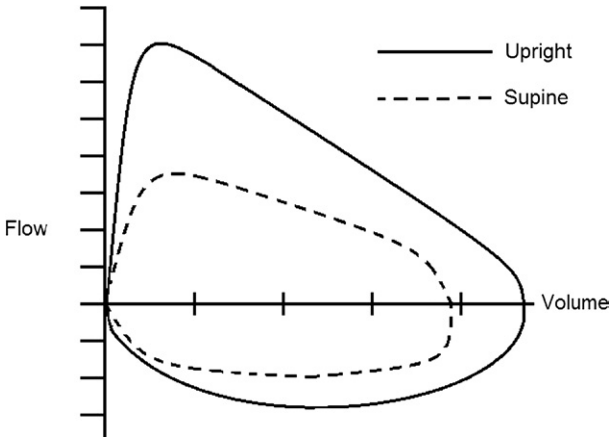

FIGURE **27-19** Upright and supine flow-volume curves representative of anterior mediastinal mass. Note abnormality appears in the supine position, when gravity causes the mass to impinge on the lower airway. The greatest decrement affects the expiratory limb of the loop, which is generally indicative of variable *intra*thoracic obstructions. Thoracic excursion during spontaneous inspiration relieves the pressure. This effect is lost when ventilation is changed to exclusively positive pressure input from above.

may be noted: dilation of collateral veins of the upper part of the thorax and neck; edema and rubor of the face, neck, and upper torso and airway; edema of the conjunctiva with or without proptosis; shortness of breath, headache, visual distortion, or altered mentation.[166] Placement of intravenous lines in the lower extremities is preferred; insertion in sites above the superior vena cava could delay the drug effect as a result of slow distribution. Fluids should be administered with caution because large volumes can worsen symptoms.

Mediastinoscopy

Mediastinoscopy involves passing a scope into the mediastinum via an incision above the sternal notch. The scope is passed anterior to the trachea in close proximity to the left common carotid artery, the left subclavian artery, the innominate artery, the innominate veins, the vagus nerve, the left recurrent laryngeal nerve, the thoracic duct, the superior vena cava, and the aortic arch.

Complications of mediastinoscopy include hemorrhage resulting from disruption of major vessels, pneumothorax, dysrhythmias, bronchospasm, recurrent nerve palsy, laceration of the trachea or esophagus, and chylothorax secondary to laceration of the thoracic duct.[167] Large-bore intravenous access should be in place, and banked blood should be immediately available in the event of a tear in a major blood vessel. Air embolism is also a risk if a venous tear occurs. Dysrhythmias such as bradycardia are possible with manipulation of the aorta or trachea during blunt dissection.

The mediastinoscope can place pressure on the innominate artery as it passes through the upper thorax, causing a decrease in blood flow to the right common carotid artery and the right vertebral artery and a decrease in subclavian flow to the right arm (Figure 27-20).[116] The decrease in cerebral flow could be deleterious, especially if the patient has a history of cerebrovascular disease. Monitoring perfusion to the right arm with a pulse oximeter or radial artery catheter can detect decreased flow to the right arm and signal concurrent loss of flow to the brain via the innominate artery. Repositioning of the mediastinoscope is required to reestablish flow to the brain. A noninvasive blood pressure cuff placed on the left arm enables continued monitoring of systemic blood pressure during periods of innominate artery compression.

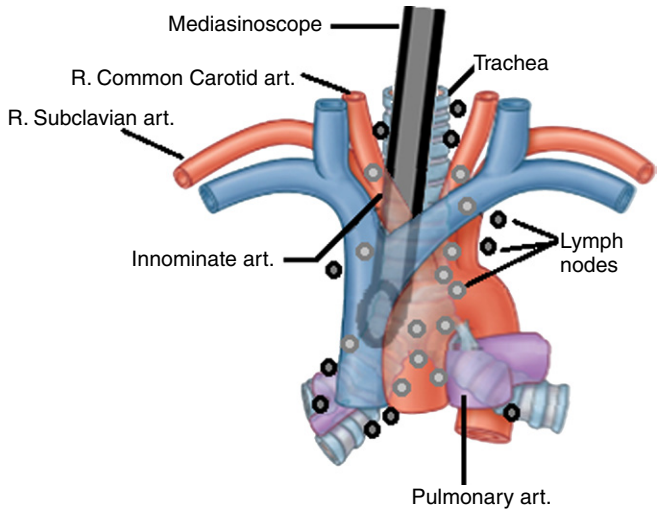

FIGURE **27-20** Placement of a mediastinoscope into the superior mediastinum. The mediastinoscope passes in front of the trachea but behind the thoracic aorta. The mediastinoscope can potentially compress or damage the aorta, innominate artery, trachea, and superior vena cava. (Adapted from Drake RL, Vogl AW, Mitchell WM. *Gray's Anatomy for Students*. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

Thoracoscopy

Advances in videoscopic technology have led to the increased use of thoracoscopy to replace open thoracotomy for a variety of intrathoracic procedures. *Video-assisted thoracoscopic surgery* (VATS) usually involves general anesthesia with a double-lumen endobronchial tube. Because of limited visualization and limited ability for the surgeon to manually compress the lung, a double-lumen tube may be preferable to a bronchial blocker to facilitate lung emptying. An arterial line is generally placed for thoracoscopy, except in selected healthy patients. However, the anesthetic plan should account for the potential need for rapidly obtaining arterial blood gas samples or for possible hemorrhage, which may be difficult to control in the endoscopic procedure. In cases of severe pulmonary compromise, VATS can be performed using epidural anesthesia in the spontaneously breathing patient who is sedated with a variety of techniques.[168]

Thoracoscopic sympathectomy for hyperhydrosis is an outpatient procedure. A DLT is preferred over a bronchial blocker, because the procedure is bilateral, and the DLT can more easily switch from ventilation of one lung to the other. The procedure is performed in the supine position, and no chest tubes are inserted.

Bullectomy

Patients with bullous COPD are often treated with VATS to prevent pneumothorax or tension pneumothorax, which may result from ruptured bullae. To reduce the risk of rupture of bullae, spontaneous ventilation is desirable under anesthesia until the chest is opened. Patients with severe cardiopulmonary disease may not be able to ventilate adequately under general anesthesia, however, and positive-pressure ventilation may be required. Small V_T s, high respiratory rates, and high Fio_2 can be delivered by gentle manual ventilation to keep airway pressures below 10 to 20 cm H_2O.[169] An alternative to positive-pressure ventilation is high-frequency jet ventilation, used to decrease the chance of barotrauma.[170]

Nitrous oxide should be avoided in bullous disease because it rapidly enlarges the air-filled spaces. The anesthetic plan can involve general or epidural anesthesia, and is based on the patient's cardiopulmonary status and the anesthetist's desire to maintain spontaneous ventilation. The risk of bulla rupture persists even after surgery, so the same concerns for avoiding high airway pressure must be observed.

COMPLICATIONS AFTER THORACOTOMY

A number of complications may occur after thoracic surgery. Various factors have been correlated to an increased risk of complications that suggest consideration of intensive care unit admission or heightened surveillance for postoperative patients: pulmonary fibrosis, age greater than 80 years, PPO FEV_1 or DLCO less than 40%, American Society of Anesthesiologists (ASA) status greater than 3, surgical time longer than 80 minutes, intraoperative hemorrhage, among others.[171-174] The following frequent predictors of pulmonary complications are quantified in the *FLAM score*, which shows good predictive capacity for impending respiratory complications: dyspnea, chest x-ray changes, required oxygen administration, auscultated changes, cough, and bronchial secretions.[175] Among the most common postoperative complications are respiratory failure, cardiac dysrhythmia or failure, and acute lung injury.

Significant factors associated with acute lung injury (ALI) after pulmonary resections include right pneumonectomy, intraoperative overhydration with high vascular volume, high intraoperative airway pressure during OLV, and preoperative alcohol abuse. Other factors that have been suggested are female gender, poor postoperative predicted lung function, trauma, infection, chemotherapy,

mediastinal lymphatic damage, transfusion and administration of fresh frozen plasma, O_2 toxicity, prolonged OLV greater than 100 minutes, and an increased postoperative urine output.[123,161,138]

OLV also leads to inflammatory changes in the ventilated and nonventilated lung, and some of the damage appears to occur upon reexpansion of the deflated lung.[176-180] Protective ventilation strategies should always be employed to reduce the generation of inflammatory processes.[131,181] There appears to be a lasting effect of OLV that is not reversed when reverting to two-lung ventilation. A small animal study demonstrated that after OLV has been discontinued, very low $\dot{V}/\dot{Q}$ ratios in the range of 0.3 to 0.5 persist in the dependent lung.[182] This, coupled with diffuse alveolar damage in comparison to controls, suggests that anesthetists should expect hypoxemia from the resultant $\dot{V}/\dot{Q}$ mismatch that may persist for some unknown period of time after OLV. Even in the absence of inflammatory response, there is evidence of vascular injury to lung tissue that is collapsed during OLV, which suggests that CPAP may have both short- and longer-term benefits.[183]

Minimizing pulmonary intravascular pressures by intraoperative fluid restriction is advocated to decrease postoperative complications.[184] Surgical requirements for proper hydration and tissue perfusion must be balanced with the desire to prevent high postoperative intravascular pressures and possible pulmonary edema.

Low cardiac output in the early postoperative period can be caused by several factors, including blood loss, herniation of the heart through a pericardial defect, right-sided heart failure, and dysrhythmias. Generally, blood entering the pleural space drains into chest tubes at a rate of less than 500 mL per day. Chest tube drainage greater than 200 mL per hour necessitates surgical exploration. An obstructed chest tube can conceal bleeding in a hemothorax. Hypotension, unexplained tachycardia, and decreasing hematocrit are other signs of bleeding.

Loss of pulmonary vasculature with lung resection can result in increased PVR and right-sided heart failure. Reduction in cardiac ejection fraction is greater after pneumonectomy than after lobectomy. Conditions that increase the likelihood of right-sided heart failure include postoperative pneumonia, hypercarbia, and acidosis. Vasodilators are useful to decrease the PVR. Amrinone or dobutamine can be administered if an inotrope is also needed.

Supraventricular dysrhythmias are relatively common after thoracotomy and may herald other serious complications.[185] Morbidity and mortality rates in patients with supraventricular tachydysrhythmias are high, with 25% associated with death within 30 days postoperatively, despite institution of aggressive treatment. Administration of a β-blocking agent can help prevent atrial dysrhythmias. Metoprolol or esmolol provide rate control whereas their cardioselectivity limits adverse effects on bronchial tone. Digitalis, adenosine, calcium channel blockers, and β-blockers are useful to treat supraventricular tachydysrhythmias.

Respiratory complications in the early postoperative period include atelectasis, pneumonia, respiratory failure, bronchopleural or bronchocutaneous fistula, pneumothorax, and pulmonary edema. Aggressive respiratory care to prevent deterioration and allow weaning from ventilation is vital.

Nerve injuries that may be evident after thoracic surgery include damage to the phrenic nerve as it passes through the mediastinum and damage to the left recurrent laryngeal nerve, which is vulnerable during dissection of aortopulmonary lymph nodes and mediastinal procedures.[186] Spinal cord injury is a possibility if an intercostal artery supplying a major radicular artery is injured or if an epidural hematoma is created by surgical dissection between the pleura and the epidural space. Nerve injuries related to surgical positioning are also possible complications.

SUMMARY

Anesthetizing a patient for thoracic surgery requires intricate consideration of multiple factors. The patient may have cardiac or respiratory diseases, masses, bullae, and other problems that complicate anesthetic management. Knowledge of respiratory physiology, pathophysiology, and the physiology of OLV is vital to safe and effective practice. Special equipment such as double-lumen endobronchial tubes, bronchial blockers, and fiberoptic bronchoscopes must be understood. A thorough understanding of the properties of anesthetic drugs is necessary so that the most beneficial combination of agents can be selected to manage the patient's anesthesia. Traditional ventilation concepts favoring high Fi_{O_2} and large tidal volumes have given way to protective ventilation strategies, considering the metabolic implications of oxygen toxicity and acute lung injury. Protective lung strategies use lower tidal volumes, PEEP, and modest Fi_{O_2} levels. For pulmonary surgery, lung separation may be achieved by double-lumen tubes or bronchial blockers. Each has its own advantages, but neither is clearly preferable over the other in every case. Fiberoptic bronchoscopy should be used to ensure proper placement of airway devices for lung separation. For hypoxemia caused by shunting during OLV, intermittent expansion of one or both lungs, CPAP applied to the operative lung, or PEEP applied to the nondependent lung should be used. Judicious fluid management is an important component of reducing postoperative lung injury. Regional anesthesia is a useful adjunct for postoperative pain control. Future research and directions will include more practical methods of reducing the shunt during OLV, and a better understanding of the implications of hypoxemia. More critical monitoring (such as effect-site monitoring) of oxygenation will improve the management of thoracic anesthesia.

CHAPTER 28

Neuroanatomy, Neurophysiology, and Neuroanesthesia

◆ *Lee J. Ranalli and Greg A. Taylor*

This chapter reviews the organization of the central nervous system (CNS). Specific neurophysiologic concepts that are essential for the anesthesia provider also are presented. These concepts include electrophysiology, cerebral blood supply, role of neurotransmitters, and the effects of selected anesthetic agents on cerebral physiology. This chapter also provides recommendations for the management of specific neurosurgical procedures.

ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

Cells of the Central and Peripheral Nervous Systems

The central nervous system (CNS) includes the brain and spinal cord. The peripheral nervous system includes the cranial and spinal nerves and their receptors and is divided into the somatic and autonomic nervous systems. The somatic nervous system contains sensory neurons for the control of skin, muscles, and joints. The autonomic nervous system, which consists of the sympathetic, parasympathetic, and enteric subdivisions, is responsible for involuntary innervation of various organ systems.

The CNS is derived from two primary cell types: neurons and neuroglial (or glial) cells. The neuron is the basic functional cell of the CNS and consists of a cell body (perikaryon) and specialized cytoplasmic processes, dendrites, and a single axon (Figure 28-1). A single axon emerges from the cell body at the axon hillock. The axon may branch to form collateral nerves at a point distal to the neuron cell body. Axon diameters range from 0.2 to 20 μm. Most of the axons in the brain are only a few millimeters long, although the axons that run from the spinal cord may be as long as 1 meter. Stimulation of the dendrites produces antegrade impulse conduction (toward the neuron cell body) with subsequent conduction away from the neuron cell body by way of the axon.

Neuron cell bodies vary in size and shape and are classified as unipolar, bipolar, pseudounipolar, or multipolar. Unipolar neurons are found only in lower invertebrates. Bipolar neurons are found in the retina, ear, and olfactory mucosa. Pseudounipolar neurons have one cytoplasmic process that exits the cell and divides into two branches, one serving as the dendrite, the other as the axon. Pseudounipolar neurons are present in the dorsal root ganglia and cranial ganglion cells, enabling sensory impulses to travel from the dendrite directly to the axon without passing through the cell body. Multipolar neurons have multiple dendritic processes but only one axon and constitute the majority of the CNS neurons.

The gray matter of the CNS is composed of neuron cell bodies in the CNS, and the white matter is composed of myelinated axons. Regions of concentrated cell bodies within the peripheral nervous system form the cranial, spinal, and autonomic ganglia.

Neurons may be classified according to their specific function: motor neurons, sensory neurons, or interneurons. Motor neurons are multipolar and innervate and control effector tissues such as muscles and glands. Sensory neurons are pseudounipolar and receive exteroceptive, interoceptive, or proprioceptive input. Interneurons are pseudounipolar and connect adjacent neurons.

The neuron is bound by a bilaminar lipoprotein membrane derived from phospholipid molecules arranged with their fatty acid chains facing one another, producing an inner hydrophobic membrane. The membrane surface in contact with the extracellular fluid contains polar hydrophilic groups of phospholipid molecules. The neuronal membrane contains integral membrane proteins, which form ionic pumps, ion channels, enzymes (e.g., adenylate cyclase), receptor proteins, and structural proteins.

The neuron contains a number of common cellular organelles including a well-developed nucleus, mitochondria (distributed throughout the cell body), and cytoplasmic processes. Ribosomes, endoplasmic reticulum, lysosomes, and Golgi complexes are also found. Neurotubules and neurofilaments extend through the cytoplasm from the dendrites to the axon terminal; they provide structural support and a pathway for intracellular transport of neurotransmitters.

The second major cell type found within the CNS is the neuroglial, or glial cell (Table 28-1). Four types of glial cells are found within the CNS: astrocytes, oligodendrocytes, microglial cells, and ependymal cells. Most neoplasms of the CNS arise from glial cells (astrocytes). Glial cells are smaller, outnumber neuronal cells, and lack dendritic and axonal processes. Although they do not participate in neuronal signaling, glial cells are essential for neuronal function. The role of neuroglia includes the maintenance of a proper ionic environment, the modulation of nerve cell electrical conduction, control of reuptake of neurotransmitters, and repair after neuronal injury.

The astrocyte is the predominant glial cell. Astrocytes provide structural neuronal support, group and pair neurons and nerve terminals, regulate the metabolic environment, and are active in repair after neuronal injury.

Two distinct types of astrocytes exist: fibrous astrocytes, found in the white matter, and protoplasmic astrocytes, concentrated in the gray matter. Astrocytes have multiple processes that radiate from the cell, producing a star-shaped appearance. Some of these processes (astrocytic feet) terminate on the surfaces of blood vessels within the CNS (perivascular feet). The contact of the cerebral endothelium by astrocytes has been proposed to be essential in the development of the blood-brain barrier.[1]

Oligodendrocytes have fewer branches than astrocytes (*oligo*, "few"; *dendro*, "branches"). Oligodendrocytes form the myelin sheath of axons in the brain and spinal cord and are capable of myelinating more than one axon. However, oligodendrocytes are incapable of division and fail to regenerate after injury.

The velocity of nerve impulse conduction in an unmyelinated axon increases with the square root of the diameter of the axon. Accordingly, a doubling of impulse conduction requires that the axon be doubled in size. One could only imagine the size of the peripheral nervous system without the presence of myelin. Myelin is essential to increase the velocity of impulse conduction and minimize the size of the axon.

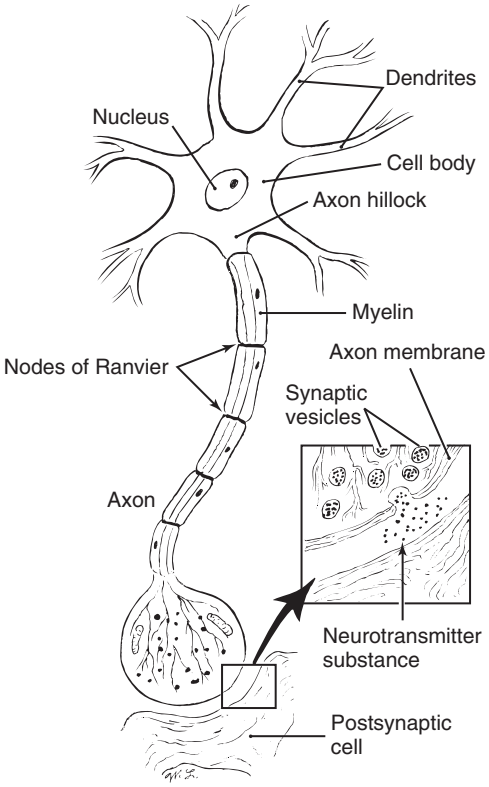

FIGURE **28-1** Neuron and chemical synapse.

TABLE **28-1** Glial Cells

Type	Major Functions
Astrocytes	Support (for neurons) Metabolic and nutritive functions
Ependymal cells	Probable role in cerebrospinal fluid production
Microglia	Phagocytosis
Oligodendrocytes	Insulation (form myelin sheath in the brain and spinal cord)
Schwann cells	Insulation (form myelin sheath in the peripheral nerves)

Myelin is formed in the vertebral peripheral nervous system by modified glial cells termed *Schwann cells*.[2] Unlike the oligodendrocyte, the Schwann cell myelinates only one axon, surrounding the axon and forming successive layers of plasma membrane. The resultant thickness is variable in different axons. The junction between adjacent Schwann cells is devoid of myelin at 1-mm intervals along the length of the axon. This nonmyelinated portion of the axon, the node of Ranvier, is the site of electrical impulse propagation. Impulses in myelinated axons travel from one node of Ranvier to another (saltatory conduction), bypassing the area between the nodes and increasing the velocity of conduction (see Figure 28-1). Wallerian degeneration results in the distal degeneration of the axon after peripheral nerve injury. Proximal axon degeneration also may occur. Within 1 week of the initial injury, Schwann cells proliferate to form a tube into the area of degeneration, forming a scaffold to direct axon regeneration. Myelin regeneration precedes axon regeneration, with the myelin eventually reaching its previous thickness.

Microglial cells are the smallest neuroglial cells and are scattered throughout the CNS. They are transported throughout the CNS to sites of neuronal injury or degeneration, where they proliferate and develop into large macrophages that phagocytize neuronal debris.

Ependymal cells line the roof of the third and fourth ventricles of the brain and the central spinal canal. Ependymal cells form the cuboidal epithelium (choroid plexus), which secretes cerebrospinal fluid (CSF).

Blood-Brain Barrier

The injection of an intravenous dye causes most of the body tissues and internal organs to be stained; yet the brain and spinal cord remain unblemished. This finding led to the discovery of the blood-brain barrier, which effectively isolates the brain and spinal cord extracellular compartment from the intravascular compartment.[3]

The endothelial cells of the CNS form tight junctions between adjacent cells, preventing the transport of polar substances from the intravascular to the cerebral extracellular fluid compartment. CNS endothelial cells lack transport mechanisms, so little intracellular transport takes place. A number of midline brain structures receive neurosecretory products from the blood and therefore lack a blood-brain barrier. These structures, the circumventricular organs, include the area postrema, pituitary gland, pineal gland, choroid plexus, and portions of the hypothalamus.[4]

The blood-brain barrier is incompletely developed in the newborn. The high vascular content of bile pigments in jaundiced newborns may enter the basal ganglia, producing kernicterus. Blood-brain barrier disruption can be caused by traumatic head injury, subarachnoid or intracerebral hemorrhage, or cerebral ischemia. The development of mass lesions also may produce blood-brain barrier disruption. Osmotically active substances may penetrate the brain or spinal cord after blood-brain barrier disruption. Intentional intracarotid injection of a hyperosmolar solution shrinks the endothelial cells, opens tight junctions, and disrupts the blood-brain barrier. This technique allows the delivery of chemotherapeutic drugs through the blood-brain barrier for the treatment of neural malignancy.[5,6]

ANATOMY OF THE CENTRAL NERVOUS SYSTEM

Cerebral Structures

The cerebral hemispheres are the most intricately developed and largest regions of the brain (Figure 28-2). They contain the cerebral cortex, hippocampal formation, amygdala, and basal ganglia. The cerebral cortex consists of the outer 3-mm layer of the cerebral hemispheres. The surface of the cerebral cortex is convoluted, increasing the surface area of the cerebral hemispheres. Elevated convolutions called *gyri* are separated by shallow grooves called *sulci* and by deeper grooves called *fissures*.

The medial longitudinal fissure divides the cerebral hemispheres into right and left halves. The lateral fissure of Sylvius and the central sulcus of Rolando divide each hemisphere into four lobes, which are named for the cranial bones that overlie each area. The frontal lobe, essential for motor control, and the parietal lobe, essential for the senses of pain and touch, are separated by the central sulcus. The cerebral cortex is divided into nearly 50 structurally distinct areas called Brodmann's areas (Figure 28-3). Voluntary muscle activity is controlled by the motor cortex located in the precentral gyrus, or Brodmann area 4. Brodmann's areas 1, 2, and 3 make up primary somtosensory area 1, also referred to as the somatosensory cortex. This area contains a high

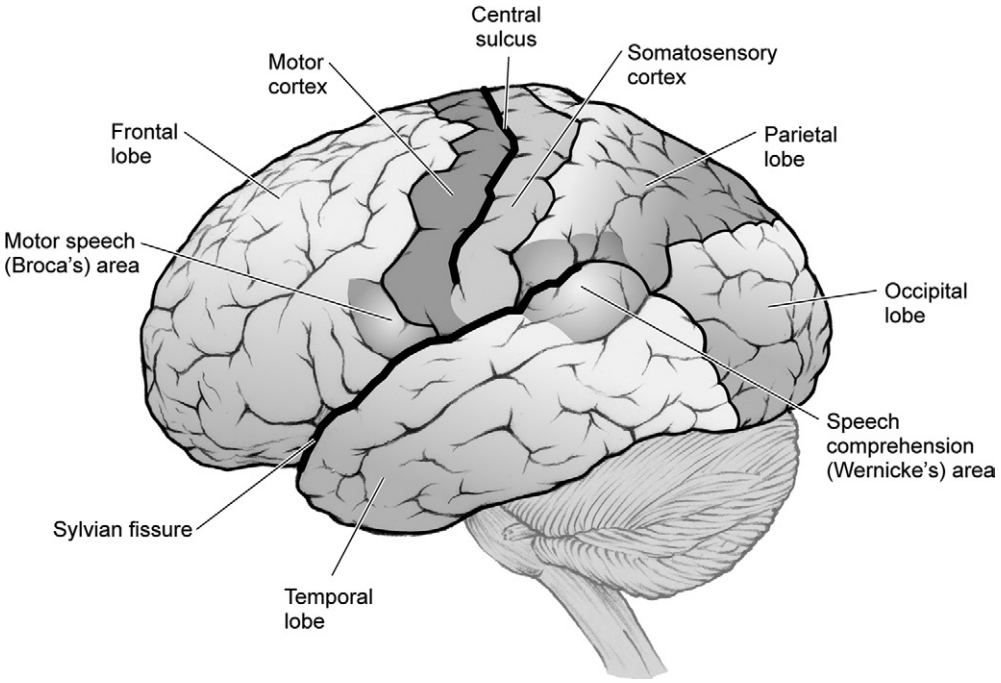

FIGURE **28-2** The cortex is highly convoluted with infoldings called *sulci* and bumps or ridges called *gyri*. Each hemisphere is divided into four major lobes: frontal, parietal, temporal, and occipital. Motor (Broca's) and receptive (Wernicke's) language areas are shown in the frontal and temporal-parietal lobes, respectively. (From Gupta AK, Gelb AW, eds. *Essentials of Neuroanesthesia and Neurointensive Care*. Philadelphia: Saunders; 2008:7.)

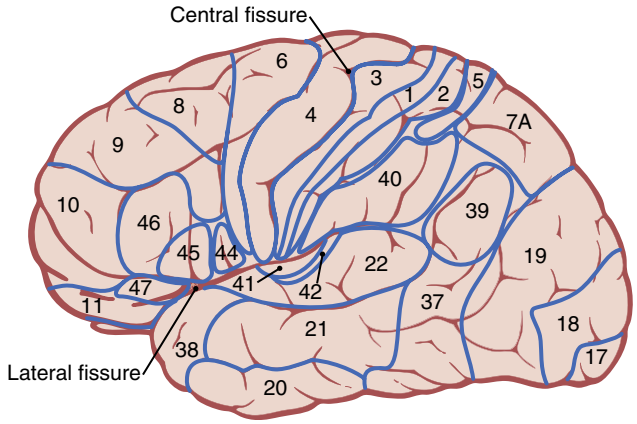

FIGURE **28-3** Structurally distinct areas, called Brodmann's areas, of the human cerebral cortex. Note specifically areas 1, 2, and 3, which constitute primary somatosensory area 1, and areas 5 and 7, which constitute the somatosensory association area. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:575.)

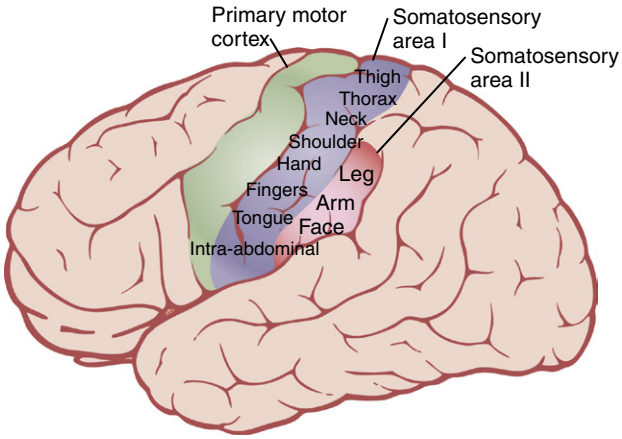

FIGURE **28-4** Two somatosensory cortical areas, somatosensory areas I and II. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:575.)

degree of localization for various body parts, whereas areas 5 and 7 function as the somatosensory association area (Figure 28-4). The sensations of touch, pain, and limb position, as well as the sensory perception of grasped objects, are controlled by the somatic sensory cortex located in the postcentral gyrus of the parietal lobe. The temporal lobe, which contains the auditory cortex, is separated from the frontal and parietal lobes by the sylvian fissure. The occipital lobe lies posterior to the parietooccipital sulcus. Here the visual cortex lies within the walls of the calcarine fissure on the medial brain surface.

The corpus callosum lies deep in the longitudinal fissure and contains commissural fibers that interconnect the cerebral hemispheres. These fibers arise from neurons in one hemisphere and synapse with neurons in the corresponding area of the adjacent hemisphere. The remaining major structures of the cerebral hemispheres include the basal ganglia, the amygdala, and the hippocampal formation. The basal ganglia are involved in the control of movement. The amygdala functions in the regulation of emotional behavior, response to pain, and appetite and is essential in forming the response to stressors. The hippocampal formation is essential for memory formation and learning.

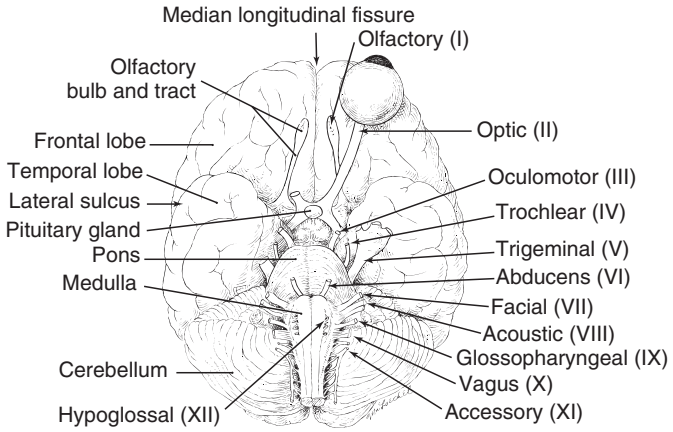

FIGURE **28-5** The pons and medulla and the origin of the cranial nerves.

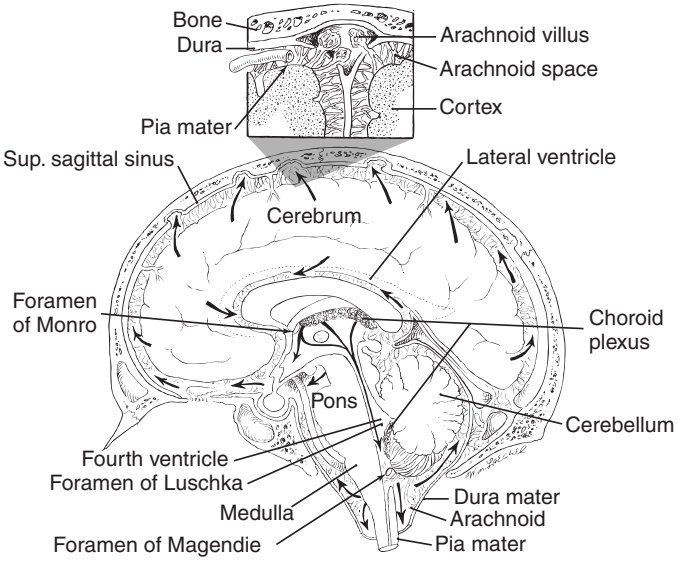

FIGURE **28-6** Meninges and the flow of cerebrospinal fluid through the ventricular system.

The diencephalon is located in the midline between the two cerebral hemispheres and contains two important structures—the thalamus and the hypothalamus. The oval-shaped thalamus integrates and transmits sensory information to various cortical areas of the cerebral hemispheres via separate thalamic nuclei. The hypothalamus is composed of several nuclei, including the mammillary bodies. The hypothalamus is the master neurohumoral organ.

The midbrain, pons, and medulla form the brainstem. The brainstem contains the reticular activating system, which functions to maintain consciousness, arousal, and alertness. The pons is anterior to the cerebellum, separated by the fourth ventricle, connecting the medulla oblongata and the midbrain (Figure 28-5). The pons contains ascending and descending fiber tracts and the nuclei of the trigeminal nerve (cranial nerve V) and the facial nerve (cranial nerve VII). The medulla extends from the pons to the foramen magnum, where it becomes continuous with the spinal cord (see Figure 28-5). In addition to ascending and descending fiber tracts, the medulla contains respiratory and cardiovascular control centers and the vestibulocochlear nerve (cranial nerve VIII), the glossopharyngeal nerve (cranial nerve IX), the vagus nerve (cranial nerve X), the spinal accessory nerve (cranial nerve XI), and the hypoglossal nerve (cranial nerve XII) nuclei.[7]

The cerebellum is convoluted in appearance and lies below the occipital lobe of the cerebral cortex and posterior to the pons and medulla. Structurally it resembles the cerebral cortex, containing an outer layer of gray matter and an inner core of white matter with several nuclei embedded within. The cerebellum can be divided into three functional areas. The flocculonodular lobe (archeocerebellum) is active in the maintenance of equilibrium, and the paleocerebellum (anterior lobe and part of vermis) regulates muscle tone. The neocerebellum (posterior lobe plus most of the vermis) is the largest subdivision of the cerebellum and is essential in coordinating voluntary muscle activity. The cerebellum integrates information received from other areas of the CNS and the peripheral nervous system. Information from the cerebellum is transmitted to the cerebral cortex and to lower motor neurons involved in the maintenance of muscle tone, equilibrium, and voluntary muscle activity.[7]

Meninges

The brain and spinal cord are enveloped by three meningeal layers: the dura mater, the arachnoid mater, and the pia mater (Figure 28-6). The dura mater, the thickest of the meningeal layers, overlies the cerebral hemispheres and brainstem and is functionally separated into an outer periosteal layer (adherent to the inner cranium) and an inner meningeal layer. The dura mater forms a fold, the falx cerebri, that functionally separates the cerebral hemispheres. A similar fold, the tentorium cerebelli, separates the occipital lobe and the cerebellum. The dura mater of the spinal cord is continuous with the meningeal layer of the cranial dura mater and the perineurium of the peripheral nerves. Innervation of the dura mater is provided by the first three cervical roots and the trigeminal nerve. During awake craniotomy, the patient may complain of pain "behind the eye" when traction is applied to the dura.

The arachnoid mater is a thin, avascular membrane joining the dura mater. The subdural space, a potential space between the dura mater and the arachnoid mater, is of clinical importance. The unintentional injection of local anesthetic during spinal anesthesia into the subdural space produces patchy, asymmetric block. In addition, injury to a blood vessel in the subdural space can create bleeding (subdural hematoma), requiring surgical intervention.

The pia mater is a thin avascular membrane adherent to the brain and spinal cord. The subarachnoid space lies between the arachnoid mater and the pia mater. In the spinal cord, the subarachnoid space extends to the S2 to S3 level and is filled with CSF. In addition, the vasculature that overlies the CNS is located within the subarachnoid space. Injury to the vascular structures may produce subarachnoid hemorrhage and hematoma.

The epidural space is located outside the dura but inside the spinal canal. The epidural space contains a venous plexus and epidural fat that provides protection of the neural structures. The distance from the skin to the epidural space may be as little as 3 cm or as large as 8 cm.

Cerebrospinal Fluid

CSF is contained within the ventricles of the brain, the cisterns surrounding the brain, and the subarachnoid space of the brain and spinal cord (see Figure 28-6). The total volume of cranial and spinal CSF in the adult is approximately 150 mL. The specific gravity is 1.002 to 1.009, and the pH is 7.32. CSF bathes the brain and spinal cord, cushioning these delicate structures, and controls and maintains the extracellular milieu for neurons and glial cells.

CSF is secreted by the ependymal cells of the choroid plexus within the ventricular system at a rate of approximately 30 mL/hr. Although CSF is isotonic with plasma, it is not a plasma filtrate. CSF concentrations of potassium, calcium, bicarbonate, and glucose are lower than their respective plasma concentrations, and concentrations of sodium, chloride, and magnesium are higher. The entire CSF volume is replaced every 3 to 4 hours. Normal CSF pressure is between 5 and 15 mmHg. CSF flows from the lateral ventricles of the cerebral hemispheres through the foramen of Monro into the third ventricle, through the aqueduct of Sylvius in the midbrain, into the fourth ventricle. CSF enters the subarachnoid space through the medial foramen of Magendie and the paired lateral foramina of Luschka, openings in the roof of the fourth ventricle.

The cisterna magna, located between the medulla and the cerebellum, is formed from the separation of the arachnoid mater from the pia mater and is filled with CSF. Two additional cisterns exist, the cisterna pontis and the cisterna basalis. CSF drains into the venous blood via the superior sagittal sinus and is absorbed by arachnoid granulations.

Spinal Cord

The spinal cord extends from the medulla at the foramen magnum to the filum terminale, a threadlike connective tissue structure that attaches to the first segment of the coccyx. Thirty-one pairs of spinal nerves carry motor and sensory information: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The first pair of cervical nerves exits the spinal cord between the base of the skull and the first cervical vertebra (atlas), and the remaining 30 pairs exit between adjacent vertebrae. All of the exiting spinal nerves are covered with pia mater. Because the spinal cord is approximately 25 cm shorter than the vertebral canal in adults, the lumbar and sacral nerves have relatively long roots (the cauda equina). The spinal cord fills the canal in utero, but the canal elongates at a greater rate than does the neural tissue as the child ages, forming the cauda equina.

The spinal cord is divided into dorsal, lateral, and ventral regions by the entering dorsal sensory root fibers and the outgoing ventral motor root fibers. Neuron cell bodies and unmyelinated fibers lie in the H-shaped central gray region of the cord, surrounded by fiber tracts that form the white matter. Although it does not have a uniform appearance, this general arrangement continues throughout the entire spinal cord.

The spinal gray matter is divided into the ventral and dorsal gray commissures. The ventral projections of gray matter are called the *gray horns* or *columns;* the posterior projections are called the *posterior gray horns* or *columns*. Intermediolateral gray horns or columns are found between T1 and L2. The gray matter has been subdivided into 10 (I through X) laminae of Rexed. Rexed laminae I through VI are located in the dorsal (posterior) horn and contain cell bodies that receive sensory information from the periphery. Projections from the laminae form afferent tracts. A large number of interneurons are found in laminae V, VI, and X. Laminae VII, VIII, and IX make up the ventral (anterior) horn and contain motor neurons and interneurons involved in motor functions. The gray matter is enlarged in two areas of the spinal cord, C5 to C7 and L3 to S2. The cervical enlargement contains neuron cell bodies that innervate the upper extremities; the lumbosacral enlargement contains neuron cell bodies that innervate the lower extremities.

The tracts or fascicles that make up the white matter are highly organized, similar to the organization of the cerebral cortex and other areas of the brain. The dorsal white matter is composed almost exclusively of ascending sensory fiber tracts. The lateral and ventral white matter contain descending motor tracts. Commonly, fiber tracts at some level in the spinal cord or brain decussate, or cross over to the other side. As in the brain, spinal cord fiber tracts can be projection tracts connecting the spinal cord and brain, or they can be association (intersegmental, fasciculi proprii) tracts that originate and terminate entirely within the spinal cord. The association tracts play an important role in spinal reflexes.[7-10]

Shortly after leaving the spinal cord, the meningeal coverings of the peripheral nerves merge with the connective tissue layers that cover the peripheral nerve. The outermost covering of the peripheral nerve is called the *epineurium*. The bundles or fascicles of axons in each nerve are covered by the perineurium, and each axon in a fascicle is surrounded by the endoneurium.

Peripheral nerves may be classified according to their diameter. Generally, the larger the diameter, the faster the conduction velocity; therefore A alpha fibers, the fibers with the largest diameters, have the fastest conduction velocity, and C fibers, which have the smallest diameter, have the slowest conduction velocity. Between the two extremes lie A beta, A gamma, A delta, and B fibers, in decreasing order of size and conduction velocity. The degree of myelination affects the conduction velocity of the nerves.

PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system is divided into the somatic and autonomic nervous systems (Figure 28-7). The somatic system contains sensory neurons for the control of skin, muscles, and joints. Somatic motor fibers arise from motor neurons in the ventral horn, their axons exiting the spinal cord via the ventral root. A few centimeters after leaving the spinal cord, the somatic motor fibers join with incoming sensory fibers carrying information from afferent receptors (muscles, skin, tendons, and joints) to form a mixed nerve. As a mixed nerve approaches its site of innervation, the motor and sensory fibers separate.

Cranial nerves emerge from the cranium. Cranial nerves provide sensory and motor innervation for the head and neck. The sensory cranial nerves include the olfactory nerve (cranial nerve I), optic nerve (cranial nerve II), and vestibulocochlear nerve (cranial nerve VIII); the motor cranial nerves include the oculomotor, trochlear, abducens, spinal accessory, and hypoglossal nerves; and the four mixed cranial nerves with both sensory and motor function are the trigeminal nerve (cranial nerve V), facial nerve (cranial nerve VII), glossopharyngeal nerve (cranial nerve IX), and vagus nerve (cranial nerve X). Table 28-2 lists cranial and peripheral nerve fiber types, locations, and functions.

The autonomic nervous system controls involuntary visceral functions and is composed of three subdivisions: the sympathetic, parasympathetic, and enteric nervous systems. The sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS) are functionally antagonistic.[8,11] The SNS and PNS originate within the CNS and require two efferent neurons—a preganglionic neuron originating within the CNS and a postganglionic neuron terminating within the effector organ (smooth muscle, cardiac muscle, or sweat gland). Autonomic fibers originating in the brain arise from cell bodies located in the brainstem. PNS fibers supplying the lower gastrointestinal tract and genitourinary systems arise from the sacral portion of the spinal cord.

Sympathetic Nervous System

Preganglionic neurons of the SNS originate in the intermediolateral gray horn of the spinal cord between the first thoracic (T1) and second or third lumbar vertebra (L2 or L3). The myelinated preganglionic axons (i.e., preganglionic fibers of the preganglionic

FIGURE **28-8** Sympathetic ganglia.

neurons) exit the spinal cord via the anterior (ventral) nerve root. These processes leave the spinal cord by way of a small trunk, the white rami communicans. A series of paired paravertebral ganglia is ranged bilaterally along the spinal cord (Figure 28-8). All of the paired segmental paravertebral ganglia are connected, forming the sympathetic trunks. These ganglia may contain the cell body of the second efferent neuron (postganglionic neuron). The preganglionic fibers of the preganglionic neuron enter the white rami communicans and may synapse with the second efferent neuron located within the ganglion. The postganglionic fiber of the postganglionic neuron may either exit the gray ramus to enter a spinal nerve or may extend through a connection between the paravertebral ganglion and one of the three (celiac, superior, or inferior) mesenteric ganglia. The postganglionic fibers then synapse with the smooth muscle of the digestive tract and other abdominal organs. SNS preganglionic axons secrete acetylcholine at their ganglionic synapses, and postganglionic fibers secrete norepinephrine.

Usually one paravertebral ganglion is present for each spinal nerve, except in the cervical area, where they fuse to form two or three ganglia. On entering the sympathetic chain, the preganglionic fiber may synapse at the entry level or travel up or down the ganglionic chain before forming a synapse. Some preganglionic axons pass through the sympathetic chain without synapsing and after leaving the chain form a distinct nerve (e.g., splanchnic nerve) before synapsing in prevertebral ganglia, such as the superior or inferior mesenteric ganglia. Some preganglionic axons in the sympathetic trunk synapse with several postganglionic neurons located in several chain ganglia. This arrangement explains the manner in which a central SNS discharge spreads over several segments. After synapsing in the sympathetic chain, the postganglionic axons, which are unmyelinated, enter the spinal nerve through the gray ramus communicans and travel to the periphery.

The cervical ganglia are divided into superior, medial, and inferior cervical ganglia. The inferior cervical ganglion fuses with the first thoracic ganglion to form the stellate ganglion. Stimulation of SNS fibers from the superior cervical ganglion produces contraction of the radial muscle of the iris (mydriasis), relaxation of the ciliary muscle of the eye, and constriction of the blood vessels of the head. Destruction of the superior cervical ganglion, central SNS damage, or injury to other cervical paravertebral ganglia produces Horner syndrome, clinically distinguished by miosis, anhydrosis (absence of sweating), and ptosis on the affected side. Ptosis is incomplete because the primary innervation to the levator palpebrae superioris muscle of the eyelid is through the oculomotor nerve, and only a few SNS fibers innervate this muscle.

Postganglionic fibers from the upper thoracic chain ganglia (stellate to T4 to T5) innervate the heart and lungs. β-Receptor stimulation produces an increased heart rate (positive chronotropic effect), an increase in conduction (positive dromotropic effect), and an increase in myocardial contractility (positive inotropic effect). Myocardial α-receptor stimulation produces coronary vasoconstriction. The resultant pulmonary effects also depend on the receptor type that is stimulated; bronchial dilation follows β_2-receptor stimulation, and mild bronchoconstriction follows α-receptor stimulation.

The SNS fibers supplying abdominal and pelvic viscera (T5 through L3) pass through the chain ganglia forming the greater and lesser splanchnic nerves, which subsequently terminate in preterminal ganglia. Postganglionic fibers from the prevertebral ganglia, such as the superior and inferior mesenteric ganglia, travel to the abdominal and pelvic viscera. Stimulation of these SNS fibers activates liver glycogenolysis and gluconeogenesis, decreases secretions from pancreatic acinar cells and β-cells, initiates lipolysis, decreases the tone and motility of the gastrointestinal tract, contracts gastrointestinal sphincters, relaxes urinary smooth muscle, and increases renin secretion from the kidney.

Parasympathetic Nervous System

The efferent neurons of the parasympathetic subdivision are located in the gray matter of the midbrain and medulla. The preganglionic fibers exit the brain via cranial nerves II, VII, IX, and X. The remainder of the cell bodies of the first efferent neurons arise from the lateral horn of the sacral portion of the spinal cord (S2 through S5). Acetylcholine is secreted by both parasympathetic preganglionic and postganglionic fibers (see Figure 28-8).

The second efferent neuron (postganglionic neuron) of the parasympathetic subdivision may be located in a small ganglion adjacent to the innervated organ or within the organ itself. Preganglionic axons travel with the vagus to ganglia located near the organ they innervate. The postganglionic axons innervate the bronchioles, heart, coronary arteries, stomach, and large intestine up to the left colic flexure. PNS postganglionic fibers to the descending colon and the genitourinary systems are supplied by parasympathetic fibers from sacral segments of the spinal cord. Most of the parasympathetic preganglionic fibers originate at the S3 and S4 segments. Shortly after exiting the spinal cord with the spinal nerves, the preganglionic fibers form the pelvic nerves (nervi erigentes), which synapse in ganglia in close proximity to the innervated organ.

VASCULATURE OF THE CENTRAL NERVOUS SYSTEM

The brain and spinal cord are dependent on an uninterrupted blood supply to deliver the essential fuels, oxygen, and glucose (Figure 28-9). The brain receives 15% of the cardiac output, or approximately 50 mL/100 g/min. The brain's blood supply originates from two arterial circulations that receive blood from two distinct systemic arteries: the anterior circulation receives blood from the carotid arteries, and the posterior circulation receives blood from the vertebral arteries. These arterial systems communicate through arterial anastomoses that form the circle of Willis. The paired anterior, middle, and posterior cerebral arteries originate from the circle of Willis. Although these arterial communications exist, under normal conditions, little mixing of blood flow occurs. Intraarterial contrast studies demonstrate that the carotid

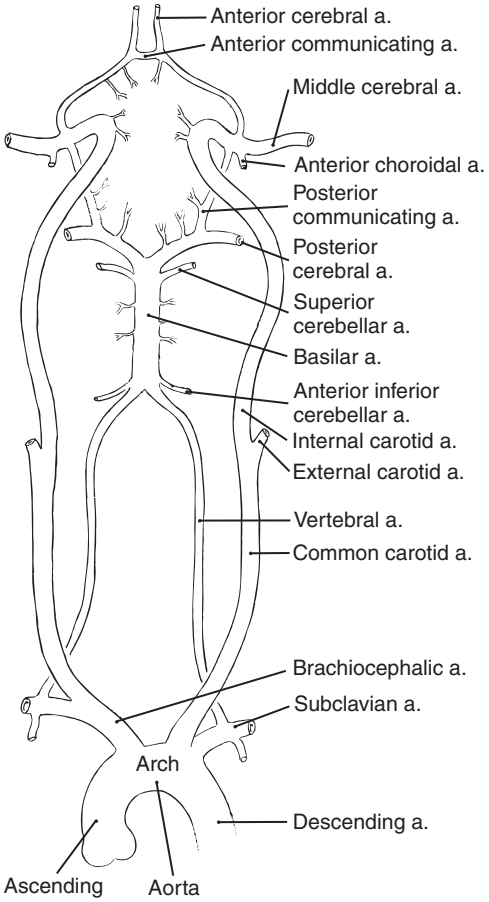

FIGURE **28-9** Cerebral vasculature. *a.*, Artery.

artery supplies the ipsilateral cerebral hemisphere, and the vertebrobasilar system supplies the structures of the posterior fossa.

The internal carotid arteries enter the skull through the foramen lacerum and bifurcate near the lateral border of the optic chiasm, forming the anterior and middle cerebral arteries. The anterior cerebral arteries supply the medial surface of the cerebral hemispheres, and the middle cerebral arteries supply the lateral surface of the hemispheres. The striate arteries, which are branches of the middle cerebral arteries, supply the internal capsule and its motor tracts. Cerebrovascular accidents commonly involve the striate arteries. Communicating arteries provide connections between the two anterior cerebral arteries of each hemisphere (anterior communicating arteries) and between the middle and posterior cerebral arteries (posterior communicating arteries).

The vertebral arteries, branches of the subclavian artery, enter the cranium through the foramen magnum and join to form the basilar artery in the vicinity of the pons. Branches of the vertebral and basilar arteries supply a wide area, including the cervical region of the spinal cord, the brainstem, the cerebellum, the vestibular apparatus and cochlea of the inner ear, parts of the diencephalon, and the occipital and temporal lobes of the cerebral hemispheres.

Venous blood exits the brain via two separate systems. The blood from the cerebral and cerebellar cortex flows through veins on the surface and empties into overlying dural venous sinuses. Venous blood from the basal portions of the brain empties into the great vein of Galen and the straight sinus. These sinuses empty into the internal jugular veins. The superficial veins of the scalp are linked to the dural sinuses by the emissary veins.[7,8]

Like the brain, the spinal cord receives blood from two arterial sources: the anterior and posterior spinal arteries, which are branches of the vertebral artery, and the radicular arteries, which are branches of segmental vessels (cervical, intercostal, and lumbar). The spinal cord blood supply is not continuous along its length, and although each spinal cord segment is perfused, blood is delivered preferentially by one of the supply sources. The cervical cord is supplied by the vertebral and radicular arteries, and the thoracic and lumbar cord is supplied by the radicular arteries arising from this respective region (intercostal and lumbar). Of particular importance is the radicular artery, the artery of Adamkiewicz, which enters the cord at approximately T7 and supplies the lumbosacral segment. Spinal cord segments that receive blood from one source are particularly prone to ischemic injury if this blood supply is interrupted. Interruption of the blood flow from the artery of Adamkiewicz results in paraplegia.

ELECTROPHYSIOLOGY

The physiologic basis for the propagation of a nerve impulse lies in the structural nature of the axolemma, the differential concentration of electrolytes within the axolemma and extracellular space, and the semipermeability of the axolemma to these specific ions. The resting nerve cell has a potential difference, or voltage, created by the asymmetric distribution of sodium and potassium ions. Sodium ions are 10-fold richer in the extracellular medium, and potassium ions are 10-fold richer in the intracellular medium. The resting membrane potential is created through the excess positive charges on the extracellular surface and excess negative charges on the interior of the cell membrane. The nerve cell is said to be *polarized* in the resting state.

In the resting state, the cell membrane permeability to sodium ions is low, so little movement of extracellular sodium ions to the cell interior occurs. Although larger than sodium ions, potassium ions are freely permeable through the axolemma, and their movement creates a net deficit of positive ions within the interior of the axolemma. This ionic asymmetry is maintained by the sodium-potassium adenosine triphosphate (ATP) pump. The distribution of ions outside the cell produces a negative resting membrane potential of approximately −60 to −90 mV.

Nerve impulses are transmitted through action potentials that are generated with membrane alterations in permeability of the axolemma to sodium and potassium ions. Depolarization occurs when a stimulus of sufficient intensity (threshold potential) increases membrane permeability to sodium ions, facilitating the passage of a greater number of sodium ions into the cell interior than potassium ions to the cell exterior. The lowering of the voltage difference of the axolemma occurs as a result of "gating," or the opening or closing of integral membrane proteins. Gating occurs in response to voltage differences across the axolemma (voltage-gated channel) or after the binding of a specific molecule to a receptor or channel protein (chemically gated channel, e.g., the binding of acetylcholine to the neuromuscular junction).

Sodium channels open when the threshold potential is reached, facilitating a rapid influx of sodium into the axolemma interior and producing depolarization (Figure 28-10). The initial flow of sodium ions results in the opening of additional sodium channels. The action potential develops as the cell interior undergoes a transition from negative to positive. At the peak of depolarization, the electrical potential is 30 to 40 mV higher than the cell exterior, and sodium channels close. The action potential develops as a result of the change from the resting potential of −60 to −90 mV to a peak of 30 to 50 mV at the completion of depolarization. The

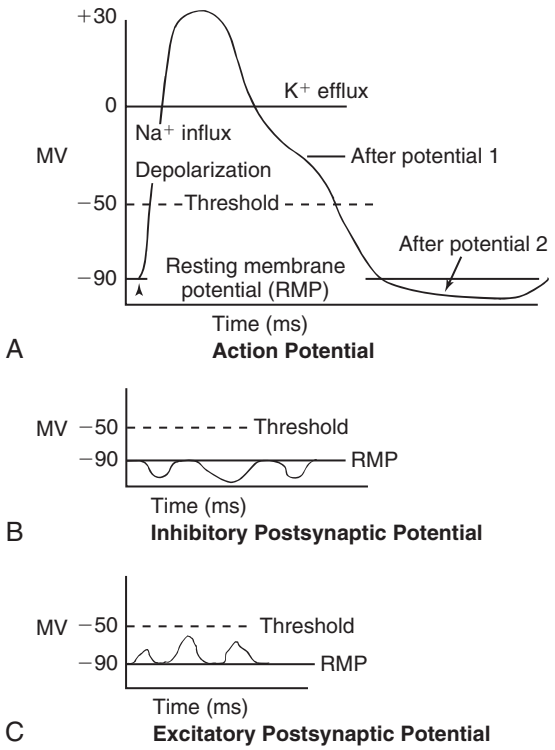

FIGURE **28-10** **A,** Phases of the action potential (AP) and major ionic movements during the AP. **B** and **C,** Subthreshold changes in the resting membrane potential.

action potential cannot occur without the delivery of a stimulus, or critical threshold potential.

For myelinated mammalian nerves, the threshold potential is 20 to 30 mV less than the resting potential. This threshold potential can be modified by a variety of factors, including pH, partial pressure of oxygen (P_{O_2}), and partial pressure of carbon dioxide (P_{CO_2}). Alkalosis increases neuronal excitability, and hypoxemia and acidosis depress neuronal excitability.

After depolarization, cell repolarization is initiated with the closing of sodium channels and the opening of potassium channels, allowing the flow of potassium ions to the exterior of the axolemma to return the axon to the resting potential of −60 to −90 mV. The sodium pump is active in reestablishing this ionic asymmetry. During repolarization, the axon is refractory, or unable to respond to an additional stimulus, no matter how strong (it will not respond to an action potential). In the later phases of repolarization, the axolemma is in a state of ready refractoriness, that is, depolarization can be initiated only by a stimulus with an intensity greater than that which produced the original depolarization.

Chemical, mechanical, and electrical stimulation may elicit an action potential. Mechanical stimulation via pinching or crushing increases the membrane's permeability to sodium ions. The resulting change in ion permeability determines whether the postsynaptic neuron is either excited or inhibited.

Tissues whose sodium channels are not completely closed at rest (cardiac and smooth muscle) have a constant leak of sodium inside the cell, and excitation occurs by electrical stimulation to produce an action potential. Because these tissues repetitively discharge, they are described as having *rhythmicity*. The usual resting membrane potential of cells displaying rhythmicity is −60 to −70 mV. After stimulation, a wave of depolarization is transmitted to the axon terminal. At electrical synapses, the wave of depolarization crosses the 2-nm synaptic space and spreads to the postsynaptic cell (neuron or muscle cell).

Synaptic Transmission

After depolarization, the flow of information is transmitted to adjacent neurons at specialized membrane sites called *synapses* (see Figure 28-1). Synapses are present on dendrites and axons. Synapses may be present on axon terminals of specific neurons in contact with endocrine glands (e.g., salivary glands) or skeletal muscle. The neuron sending the information is the presynaptic neuron, and the receiving neuron is the postsynaptic neuron. Separating the presynaptic and postsynaptic neurons is a small intracellular space (the synaptic cleft). The majority of synaptic transmission occurs in the direction from the presynaptic to the postsynaptic neuron, but retrograde nerve impulse conduction is known to occur and modulates the strength of synaptic connections.

Synaptic transmission may be electrically or chemically mediated. Electrically mediated synapses are large compared with chemically mediated synapses. Electrical synapses have direct cytoplasmic continuity and no synaptic delay. Electrical synapses are excitatory in nature and are located in the CNS, peripherally in smooth muscle, and in cardiac muscle. Synaptic delays (delayed synaptic transmission) occur in chemically mediated transmission because of the transit time of the chemical mediator (specific neurotransmitter) from the presynaptic terminal to the postsynaptic membrane.

The majority of CNS neurons have chemically mediated synapses. The presynaptic neuron releases a neurotransmitter, a low-molecular-weight compound that diffuses across the synaptic cleft and binds to specific receptors on the postsynaptic membrane. Depolarization stimulates the uptake of calcium by the nerve terminal, fusing intracellular vesicles that contain the neurotransmitter to the presynaptic membrane. The neurotransmitters are subsequently released into the synaptic cleft. The neurotransmitter diffuses across the synaptic cleft, interacting with a specific postsynaptic receptor. Neurotransmitters that increase the permeability of the axolemma to sodium ions are excitatory (e.g., acetylcholine, glutamate); neuroinhibitory neurotransmitters (e.g., γ-aminobutyric acid [GABA], glycine) hyperpolarize the membrane by increasing the permeability to chloride ions. The neurotransmitter serotonin excites some neurons and inhibits others. The attachment of the neurotransmitter to the postsynaptic receptor can produce either an immediate (fraction of millisecond) or a delayed (from a few milliseconds up to seconds) effect on the postsynaptic membrane. The delayed transmission involves second messengers, such as cyclic adenosine monophosphate and cyclic guanosine monophosphate, which are activated when the neurotransmitter attaches to the postsynaptic membrane.

NEUROTRANSMITTERS

Neurotransmitters are molecules contained within the presynaptic neuron that are discharged in a calcium-dependent manner after presynaptic depolarization and interact with specific receptors on the postsynaptic membrane. More than 100 molecules meet these criteria. Acetylcholine is an excitatory neurotransmitter that interacts with both nicotinic and muscarinic receptors. Additional neurotransmitters include biogenic amines (e.g., epinephrine, norepinephrine, dopamine, serotonin, histamine), amino acids (e.g., aspartate, glycine, GABA, glutamate), neuropeptides (e.g., substance P, the opioids, several hormones), and the second messenger nitric oxide (Table 28-3).

The synthesis of neurotransmitters occurs within the presynaptic neuron terminal. The neuron regulates the synthesis,

Neuropeptides	Calcitonin family Calcitonin Calcitonin gene-related peptide Hypothalamic hormones Oxytocin Vasopressin Hypothalamic releasing and inhibitory hormones Corcicotropin-releasing factor (CRF or CRH) Gonadotropin-releasing hormone (GnRH) Growth hormone-releasing hormone (GHRH) Somatostatin Thyrotropin-releasing hormone (TRH) Neuropeptide Y family Neuropeptide Y (NPY) Neuropeptide YY (PYY) Pancreatic polupeptide (PP) Opioid peptides β-Endorphin (also a pituitary hormone) Dynorphin peptides Leu-enkephalin Met-enkephalin Pituitary hormones Adrenocorticotropic hormone (ACTH) α-Melanocyte-stimulating hormone (α-MSH) Growth hormone (GH) Follicle-stimulating hormone (FSH) Luteinizing hormone (LH) Tachykinins Neurokinin A (substance K) Neurokin B Neuropeptide K Substance P VIP-Glucagon family Glucagon Glucagon-like peptide (ARP) Bradyknin Cholecystokinin (CKK; multiple forms) Cocaine- and amphetamine-regulated transcript (CART) Galanin Chrelin Melanin-concentrating hormone (MCH) Neurotensin Orexins (or Hypocretins) Orphanin FQ (or Nociceptin) (also grouped with opioids)
Other	Acetylcholine Nitric oxide

packaging, release, and degradation of the synthesized neurotransmitter. The enzymes essential for neuron transmitter synthesis are obtained by axonal transport and taken into the nerve terminal by transport proteins. The synthesized neurotransmitter is then packaged into synaptic vesicles by membrane transport proteins.

Acetylcholine

Acetylcholine is an excitatory neurotransmitter with a widespread distribution. It is the predominant neurotransmitter within the CNS, at the neuromuscular junction, within all autonomic nervous system preganglionic fibers and postganglionic parasympathetic fibers, and within postganglionic sympathetic fibers innervating sweat glands. Acetylcholine is synthesized in the presynaptic nerve terminal from acetic acid, coenzyme A, and choline in the presence of the enzymes acetyl kinase and choline acetylase. This enzyme is also referred to as *choline acetyl transferase*. Acetylcholine is packaged in vesicles and stored in the presynaptic terminal. Calcium uptake into the presynaptic terminal is required for acetylcholine release, and magnesium (Mg^{2+}) and manganese (Mn^{2+}) block the uptake of Ca^{2+} and the subsequent release of acetylcholine. Acetylcholine interacts with the postsynaptic receptor for a few milliseconds before being hydrolyzed by acetylcholinesterase to acetic acid and choline. Both the acetic acid and the choline are taken up by the presynaptic nerve terminal and recycled.

Cholinergic receptors are classified as either nicotinic or muscarinic. Nicotinic receptors are found in autonomic ganglia and at the neuromuscular junction. Muscarinic receptors are found on smooth muscle, cardiac muscle, and sweat glands. Acetylcholine is the neurotransmitter at cranial nerve nuclei and ventral horn motor neurons of the spinal cord, including various collateral nerves to Renshaw cells (interneurons). Acetylcholine may be interactive in neuronal circuits involved with pain reception. Acetylcholine also may act as a sensory transmitter in thermal receptors and taste bud endings.

Biogenic Amines

The biogenic amines include epinephrine, norepinephrine, dopamine, serotonin, and histamine. The catecholamines epinephrine, norepinephrine, and dopamine are synthesized in a series of hydroxylation, decarboxylation, and methylation reactions from the amino acids phenylalanine and tyrosine. The adrenal medulla secretes both epinephrine (75%) and norepinephrine (25%). Postganglionic adrenergic neurons secrete norepinephrine; norepinephrine and dopamine are probably neurotransmitters within the CNS. Amacrine cells of the retina and some neurons of the intrinsic nervous system of the intestine secrete dopamine. As with acetylcholine, the release of norepinephrine, epinephrine, and dopamine is calcium dependent. One notable difference from acetylcholine is that norepinephrine and dopamine act by means of second messengers (slow synaptic transmission), whereas most of the actions of acetylcholine are directly on ion channels (fast synaptic transmission). The duration of effect of catecholamines is regulated by presynaptic reuptake. Enzymatic breakdown of catecholamines by monoamine oxidase and catechol-*O*-methyltransferase within the liver is primarily responsible for terminating their effects.

Dopamine is an inhibitory neurotransmitter and the predominant biogenic amine within the CNS. Dopamine is concentrated within the basal ganglia. Dopamine's inhibitory effects occur through action on adenylate cyclase, which is dopamine sensitive.

Norepinephrine is concentrated in the reticular activating system and the hypothalamus. Norepinephrine acts as an inhibitory neurotransmitter, inhibiting impulses to the cerebral cortex.

Serotonin is an inhibitory neurotransmitter that influences behavior and mood. Histamine is also an inhibitory neurotransmitter concentrated within the hypothalamus and the reticular activating system. Histamine requires the second messenger cyclic adenosine monophosphate to mediate its inhibitory effects.

Amino Acids

Glutamate is the primary excitatory transmitter found within the cerebral cortex, the hippocampus, and the substantia gelatinosa of the spinal cord.[12] Glutamate plays a formidable role in learning and memory (perhaps interactive in memory formation during awareness during anesthesia) and the appreciation of pain. Glutamate also has been implicated in excitotoxic neuronal injury after ischemic or traumatic brain injury.

Glutamate is formed from the deamination of glutamine supplied by the Krebs cycle. Glutamate may activate either an inotropic or a metabotropic amino acid receptor. *N*-methyl-D-aspartate (NMDA) receptors are ligand-gated inotropic receptors that produce a conformational change in the receptor, opening a sodium channel, which results in the depolarization of the postsynaptic membrane. The metabotropic receptor is an integral transmembrane receptor that regulates intracellular second messenger systems.[13]

GABA is the major inhibitory neurotransmitter found in the CNS. It is concentrated in the basal ganglia, cerebral cortex, cerebellum, and spinal cord. Activation of the GABA receptor opens neuronal membrane chloride channels, producing hyperpolarization (the hyperpolarized neuron is resistant to excitation). GABA is important in antagonizing the excitatory effects of amino acid neurotransmitters.[14]

Glycine is the primary inhibitory neurotransmitter in the spinal cord. In the past, glycine irrigation was employed during transurethral resection of the prostate. Postoperative visual impairment after the intravascular absorption of glycine suggests that glycine may act as an inhibitory neurotransmitter within the retina.

Neuropeptides

Neuropeptides are either excitatory or inhibitory. Common neuropeptides include the opioids, substance P, and many pituitary and pancreatic islet hormones.

Substance P is an excitatory neurotransmitter found in the striatum and substantia nigra of the basal ganglia, hypothalamus, brainstem (raphe nuclei), and dorsal root ganglia of the spinal cord. Substance P is released by pain-fiber terminals that synapse with the substantia gelatinosa of the spinal cord.

The opioid neuropeptides include β-endorphin, enkephalins, dynorphins, and endomorphins. They act at opiate receptors distributed throughout the brain and spinal cord. Three classes of opiate receptors have been identified—delta, kappa, and mu. Dynorphin is a potent agonist at kappa receptors, and the enkephalins are agonists at delta and mu receptors. Opiate alkaloids like morphine interact with mu receptors. Morphine-like agents block slow pain pathways, raise the pain threshold, and modify the response to pain. Other effects, such as miosis and respiratory depression, result from the actions of these agents on opiate receptors located in the parts of the brain that control these functions.[2,10,15]

SENSORY PATHWAYS

Sensory or afferent pathways transmit pain, temperature, pressure, touch, vibratory sense, and proprioceptive information to the CNS. Sensory pathways also include the special senses of vision, taste, hearing, smell, and equilibrium.

Receptors for pain and temperature are located in the epidermis and the dermis; those for pressure, touch, vibratory sense, and proprioception are located in the dermis. Receptors can be classified as (1) exteroceptors, which are located near the surface of skin and oral mucosa, and (2) proprioceptors, which are located in deeper skin layers, joint capsules, ligaments, tendons, muscles, and periosteum. Several types of receptors exist. Pacinian corpuscles are

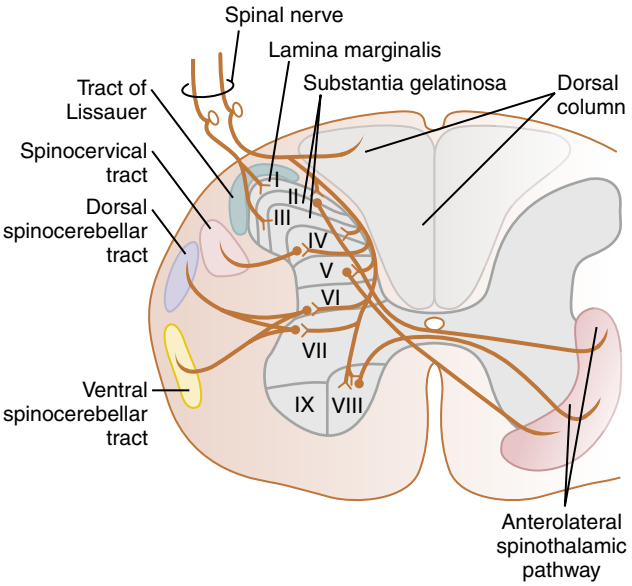

FIGURE **28-11** Cross section of spinal cord, showing the anatomy of the cord gray matter and of ascending sensory tracts in the white columns of the spinal cord. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:573.)

receptors for vibration and pressure. Free nerve endings, Ruffini corpuscles, muscle spindles, and Golgi tendon organs are involved in movement sense. The receptors for light (or crude) touch sensations include Merkel disks, Meissner corpuscles, and the nerve plexuses surrounding some hair roots. Fibers travel from these receptors to a ganglion, where they synapse with first-order neurons, the fibers of which continue to the CNS. Fibers from receptors in the trunk and extremities travel to the dorsal root ganglion, where they synapse with first-order neurons. Most of the sensory fibers from the head, excluding those from the special sense organs (hearing, equilibrium, vision, taste, and smell), synapse in first-order neurons located in the semilunar or trigeminal ganglion.[10,11]

Pain and Temperature Pathways

Pain and temperature fibers from the head synapse in the trigeminal ganglion and enter the pons, forming the trigeminal nerve (cranial nerve V). These fibers subsequently synapse with second-order neurons in the nucleus of the descending tract of cranial nerve V. The second-order axons cross to the ventrolateral side and ascend as the ventral trigeminal tract to the ventral posteromedial nucleus of the thalamus, where they synapse with third-order neurons. From the ventral posteromedial thalamic nucleus, third-order axons ascend in the internal capsule and end in the postcentral gyrus of the cerebral cortex, which is the primary somatic sensory area of the brain.

Pain and temperature receptors in the skin of the trunk and extremities send signals to the spinal cord via the dorsal roots of the spinal nerves. The majority of these dorsal root sensory nerve fibers terminate in the dorsal horn on laminae I, IV, V, and VI (Figure 28-11). This is the origination site of the anterolateral pathway for signal transmission up the spinal cord to the brain.[16] From this point in the dorsal horn, the anterolateral fibers decussate (cross) in the ventral commisure to the opposite anterior and lateral white columns (Figure 28-12). The fibers then ascend cephalad via the anterior spinothalamic and lateral spinothalamic tracts to the ventral posterolateral thalamic nucleus, where they synapse with third-order neurons. Axons from the third-order neurons

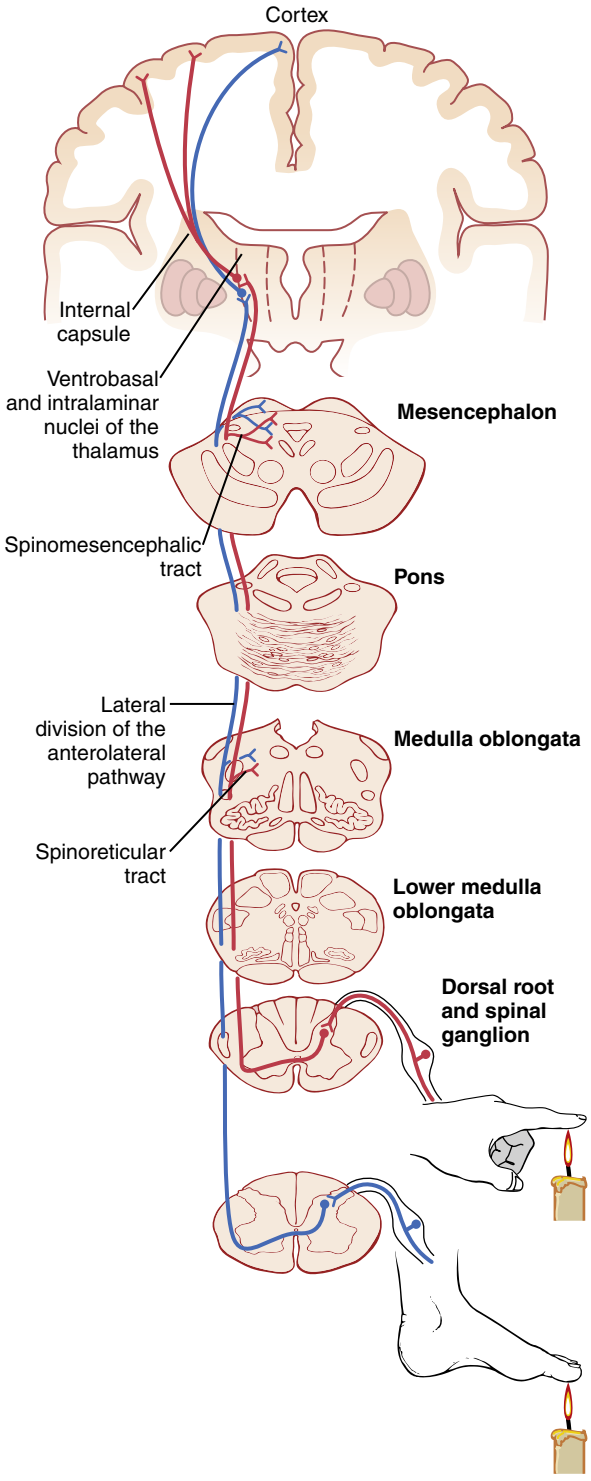

FIGURE **28-12** Pain, temperature, and crude sensations travel via the anterior spinothalamic and lateral spinothalamic tracts. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011:581.)

travel in the posterior limb of the internal capsule and ultimately synapse in the postcentral gyrus, where sensations of pain, temperature, touch, and pressure are interpreted, and responses to the sensations are initiated.

Some pain and temperature fibers in the dorsal horn give off branches that synapse with internuncial (messenger) neurons. The internuncial neurons have axons that synapse with motor neurons in the ventral horn, which are not necessarily at the same level of the spinal cord. The axons can cross over and travel up or down the spinal cord before synapsing. These circuits are part of the reflex response to pain, which results in a rapid, automatic response to nociceptive stimuli.

The afferent fibers from each dorsal root ganglion come from a relatively limited area of the skin termed a *cutaneous dermatome*. Some overlap exists, so if a spinal nerve that supplies a certain dermatome is severed, pain and temperature sensations from that dermatome are supplied by adjacent dermatome fibers. For example, if T6 is severed, T5 and T7 sensory neurons carry pain and temperature sensations from the skin area supplied by T6. Axons entering the dorsal horn from the dorsal root ganglion send branches to one spinal segment above and one segment below in the dorsolateral column of Lissauer.[2,9,11,17]

Pressure and Crude Touch

Pressure and crude (light) touch fibers from the head synapse with first-order neurons in the trigeminal ganglion. From the trigeminal ganglion, first-order axons travel to the pons, where they synapse with second-order neurons in the sensory nucleus of cranial nerve V. From the sensory nucleus of cranial nerve V, second-order axons form the dorsal trigeminal tract, which has both crossed and uncrossed fibers. The second-order fibers terminate in the ventral posteromedial nucleus of the thalamus. Third-order axons from the ventral posteromedial nucleus subsequently terminate in the postcentral gyrus of the cerebral cortex.

After leaving the dorsal root ganglion, crude touch and pressure fibers from the extremities and trunk enter the dorsal white column on the ipsilateral side and bifurcate (see Figure 28-12). One branch immediately enters the dorsal gray horn and synapses with second-order neurons. The other branch ascends for up to 10 spinal segments before synapsing with the second-order neurons in the dorsal horn. Second-order axons from both branches cross over and enter the ventral white column, forming the ventral spinothalamic tract, which ascends to the thalamus and synapses with third-order neurons in the ventral posterolateral nucleus. Tertiary axons travel through the internal capsule to the postcentral gyrus.

Owing to the branching arrangement of the first-order fibers from the trunk and extremities, injuries to the spinal cord rarely result in the total loss of these two sensations. Each cerebral cortex receives both crossed and uncrossed pressure and light-touch fibers from the face; as a result, damage to the postcentral gyrus on one side does not result in loss of pressure and crude touch sensations to the face, even though these sensations are lost on the trunk and extremities of the contralateral side.[2,10,11,17]

Vibratory Sense, Proprioception, and Discriminatory Touch

Proprioceptive fibers from muscles of the face involved in facial expression and mastication synapse in cell bodies located in the mesencephalic nucleus of the midbrain. Little is known about the rest of the pathway.

Fibers from the trunk and extremities carrying proprioceptive, vibratory, and discriminatory (fine) touch sensations synapse with neuron cell bodies in the dorsal root ganglion. From the dorsal root ganglion, first-order axons enter the dorsal white column and immediately ascend to the medulla (Figure 28-13). The fibers are somatotopically organized in the white columns. Axons from the lumbar and sacral parts of the spinal cord travel medially in the fasciculus gracilis, and fibers from the cervical and thoracic areas of the cord are located laterally in the fasciculus cuneatus of the dorsal white column of the spinal cord. Each fasciculus terminates in

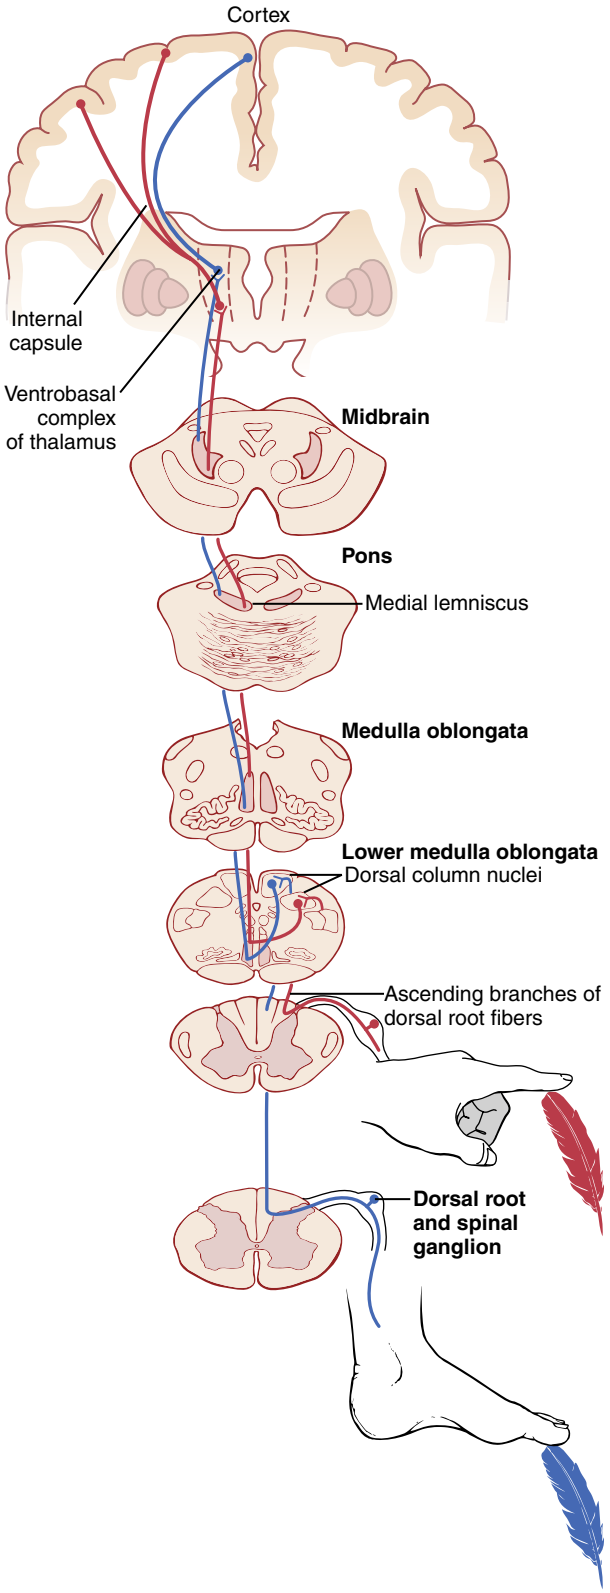

FIGURE **28-13** Vibration, proprioception, and fine tactile sensations travel via the dorsal column–medial lemniscal system. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:474.)

its respective medullary nucleus; for example, the fasciculus gracilis terminates in the nucleus gracilis. Second-order axons decussate after leaving their medullary nucleus and form a bundle termed the *medial lemniscus*, which terminates in the ventral posterolateral thalamic nucleus. Third-order fibers from the ventral posterolateral nucleus terminate in the postcentral gyrus.[2,10,11,17]

There are important distinctions to be made between the *dorsal column medial lemniscal system* and the *anterolateral system*. The differences actually determine the types of sensory information that can be transmitted by the two systems. The dorsal column medial lemniscal system is composed of large myelinated fibers with a high degree of spatial orientation that is maintained from their origin in the dorsal root to their termination in the thalamus. Therefore, sensations that must be transmitted rapidly with a high degree of localization to the stimulus travel via the dorsal column. The anterolateral system on the other hand is composed of smaller myelinated nerve fibers with less spatial orientation. Hence the anterolateral system transmits a wider variety of sensations, at a slower velocity, and with less specificity than the dorsal column system.[16] A summary of the different sensations transmitted between the two systems is shown in Box 28-1.

Pupillary light and accommodation reflexes are mediated through the Edinger-Westphal nucleus and cranial nerve III. Pupillary dilation is produced by postganglionic sympathetic fibers from the superior cervical ganglion that travel with branches of the internal carotid artery to the radial muscle of the iris.[2,10,11,17]

BOX **28-1**

Sensations Transmitted Through the Dorsal Column–Medial Lemniscal System and Anterolateral System

Dorsal Column–Medial Lemniscal System

- Touch sensations requiring high degree of localization of the stimulus
- Touch sensations requiring transmission of fine gradations of intensity
- Phasic sensations, such as vibratory sensations
- Sensations that signal movement against the skin
- Position sensations from the joints
- Pressure sensations related to fine degrees of judgment of pressure intensity

Anterolateral System

- Pain
- Thermal sensations, including both warmth and cold sensations
- Crude touch and pressure sensations capable only of crude localizing ability on the surface of the body
- Tickle and itch sensations
- Sexual sensations

From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:573.

MOTOR PATHWAYS

Motor, or efferent, pathways transmit information from the brain to the voluntary muscles of the body, to smooth and cardiac muscles, and to some glands. The corticospinal tracts supply the voluntary muscles of the trunk and extremities; nine cranial nerves supply the voluntary muscles of the head and neck. Autonomic preganglionic fibers arise in the brain and spinal cord and transmit efferent signals to smooth muscle, cardiac muscle, and some glands (lacrimal, bronchial).

Corticospinal Tract

The corticospinal tract originates in large, upper motor neurons located in the precentral gyrus of the frontal lobe (Figure 28-14).

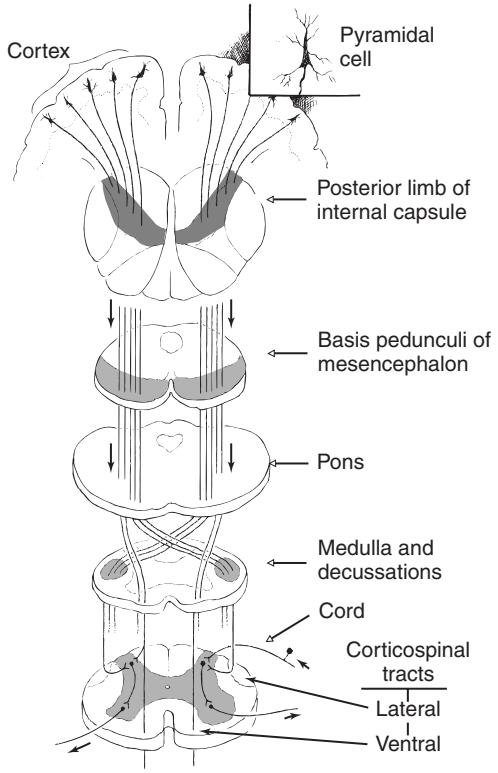

FIGURE **28-14** Corticospinal tracts. (Modified from Guyton AC. *Basic Neuroscience: Anatomy and Physiology*. 2nd ed. Philadelphia: Saunders; 1991:212.)

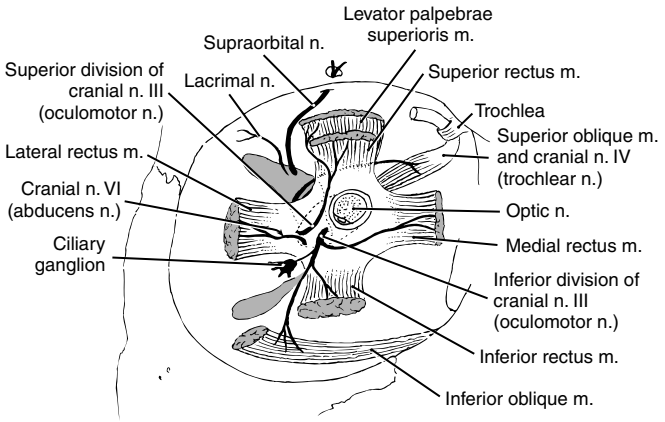

FIGURE **28-15** Frontal view of the posterior orbit with its motor nerves and the extraocular muscles. *n.*, Nerve; *m.*, muscle.

These neurons are arranged in a specific manner. Neurons supplying voluntary muscles of the head are found in the precentral gyrus near the lateral fissure of Sylvius, and those innervating the legs and feet are found in an area of the gyrus near the median longitudinal fissure. All parts of the body are represented in the gyrus. However, areas that perform complex movements (such as the hands when writing, typing, or playing the piano) have a larger area in the gyrus than other parts of the body not involved in intricate movements. Many of the upper motor neurons are pyramid shaped.

Axons travel from the pyramidal cells through the internal capsule, the major pathway for ascending and descending fibers between the cortex and other sites in the CNS. The internal capsule has three parts: the anterior limb, the posterior limb, and the genu, which lies between the anterior and posterior limbs. Fibers in the internal capsule are highly organized. Motor fibers to all parts of the body except the face are located in the anterior limb and part of the posterior limb. Fibers supplying the face are located in the genu. From the internal capsule, the axons travel through the midbrain (basis pedunculi) to the medulla, where approximately 90% of the fibers decussate, forming the pyramids of the medulla. The corticospinal tract is frequently called the *pyramidal tract*, either because of the shape of the upper motor neurons or because of the site at which the fibers decussate in the medulla. The fibers that cross over form the lateral corticospinal tract. Axons from the lateral corticospinal tract continue their descent to the spinal cord. At each level of the cord, some fibers leave the lateral corticospinal tract and enter the ventral horn gray matter, where they synapse with lower motor neurons. The fibers that do not decussate (approximately 10%) in the medulla continue to the spinal cord as the ventral corticospinal tract. The ventral corticospinal tracts cross over before synapsing with lower motor neurons in the gray matter. Axons from the lower motor neurons travel in the spinal nerves to innervate voluntary muscle.

A few corticospinal tract neurons are located anterior to the precentral gyrus. Axons from these neurons have an inhibitory effect on the lower motor neurons because they prevent them from discharging excessively. Damage to these suppressor fibers can stimulate the lower motor neurons either to overfire, resulting in hyperreflexia, or to discharge simultaneously, causing spasticity. Damage to the corticospinal tract anywhere along its route to the spinal cord can cause upper motor neuron paralysis. If the injury occurs above the decussation in the medulla, the paralysis is on the opposite side of the body. Paralysis occurs on the same side of the body if the damage occurs below the medulla. With upper motor neuron paralysis, reflexes are intact, but suppressor-fiber activity is impeded. As a result, hyperreflexia is present, and the upper motor neuron paralysis is spastic. Damage to lower motor neuron cell bodies in the ventral horn or ventral root fibers produces lower motor neuron paralysis, a flaccid type of paralysis. Cerebral palsy and amyotrophic lateral sclerosis are diseases that affect the corticospinal tracts.

Motor Innervation to the Head

Upper motor neurons whose axons supply the voluntary muscles of the head are found in the precentral gyrus next to the lateral fissure of Sylvius. The cell bodies, whose axons supply the extrinsic muscles of the eye, are located in the middle frontal gyrus. Axons from both areas form the corticobulbar tracts, which travel through the genu of the internal capsule to the brainstem, where they synapse with neurons located in nuclei spread throughout the brainstem. Axons from these neurons form many of the cranial nerves.

Axons originating from neurons located in the midbrain form the oculomotor and trochlear nerves (Figure 28-15). The oculomotor nerve innervates most of the external muscles of the eye (inferior oblique and the inferior, medial, and superior rectus muscles), along with the levator palpebrae superioris muscle, which raises the upper eyelid. The trochlear nerve innervates the external oblique muscle of the eye. Three other groups of nuclei have neurons whose axons form the trigeminal, abducens, and facial nerves. The trigeminal nerve innervates part of the soft palate and all of the muscles of mastication. The abducens innervates the lateral rectus muscle of the eye, and the facial nerves supply all the muscles involved in facial expression.

Axons from neurons located in medullary nuclei form the glossopharyngeal, vagal, accessory, and hypoglossal nerves. Both the glossopharyngeal and vagal nerves arise from the ambiguous

nucleus. The glossopharyngeal nerve supplies the stylopharyngeal muscle of the pharynx, and the vagal nerve innervates the muscles of the throat involved in swallowing and phonation. All of the tongue muscles are supplied by the hypoglossal nerve. The accessory nerve innervates the trapezius and sternocleidomastoid muscles of the neck. With the exception of the facial and hypoglossal nerves, the remaining nerves receive information from both the right and the left corticobulbar tracts. The nuclei of facial nerve fibers to the upper part of the face receive axons from the left and right corticobulbar tracts; the facial nerve nuclei whose fibers supply the lower part of the face receive fibers only from the contralateral corticobulbar tract. The nuclei from the origin of the hypoglossal nerves receive innervation from only the contralateral corticobulbar tract.[2,10,11,17]

Subcortical Motor Areas

Several motor areas in the brain are outside the cerebral cortex. For the most part, these are relatively primitive motor areas that have a modulating influence on motor function. Included in the subcortical motor areas are the basal ganglia, the nucleus of Luys, the red nucleus (nucleus ruber), the substantia nigra, and the reticular formation.

The basal ganglia lie deep within the cerebral hemispheres at the level of the internal capsule. They are composed of three nuclei: the globus pallidus, the putamen, and the caudate, which are collectively termed the *corpus striata*. The globus pallidus and the putamen are sometimes termed the *lentiform nucleus*. The globus pallidus makes up the paleostriatum, and the other two nuclei are part of the neostriatum.

The globus pallidus receives input from the motor cortex and from the other basal ganglia; it sends fibers to the subcortical motor areas. The globus pallidus is connected to the thalamus by two tracts, the ansa lenticularis and the lenticular fasciculus, which merge as they enter the thalamus to form the thalamic fasciculus. The thalamus forms a feedback process by sending fibers to the caudate nucleus and motor cortex. In this way, the motor activity of the basal ganglia can be influenced by the motor cortex without the presence of direct connections between the two structures. Dopamine, an important neurotransmitter in the basal ganglia, is produced in the substantia nigra of the midbrain and then travels by axonal transport to the caudate nucleus and the putamen.

The subthalamic nucleus of Luys is located in the diencephalon and is connected to other subcortical motor areas. Lesions in this nucleus result in a suppression of motor activity.

Three motor areas are located in the midbrain: the red nucleus, the substantia nigra, and the reticular formation. The red nucleus is located at the level of the corpora quadrigemina and gives rise to the crossed rubrospinal tract. When stimulated, this tract excites alpha and gamma flexor motor neurons and inhibits extensor motor neurons. The reticular formation consists of a diffuse collection of neurons found throughout the brainstem and into the diencephalon. Two major tracts arise from the reticular formation. One tract is the uncrossed medial reticulospinal tract, which excites alpha and gamma extensor motor neurons and inhibits flexor motor neurons when stimulated. The second tract is the lateral reticulospinal tract, which contains crossed and uncrossed fibers and activates alpha and gamma flexor motor neurons and inhibits extensor motor neurons when stimulated.

Lesions in the subcortical motor areas produce diseases characterized by disturbed muscle tone and dyskinesia (abnormal involuntary movements). In Parkinson disease, the globus pallidus and substantia nigra are affected. Huntington chorea involves atrophy of the caudate nucleus and putamen, as well as degeneration of cortical neurons. Other diseases that involve subcortical motor nuclei include athetosis, dystonia, ballismus, and Sydenham chorea.

NEUROANESTHESIA

Neuroanesthesia must take into account the unique set of circumstances each individual case represents. Comorbidities, pathology to be addressed, positioning, side of surgery, surgical approach, and procedure to be applied are all factors that must be clearly understood and fully addressed to administer a successful neuroanesthetic. Compounding the complexity is the constantly changing landscape of neurosurgical procedures, both cranial and spine. Providing competent neuroanesthesia in this environment demands thorough preparation and a degree of communication between surgeon and anesthesia not seen in other anesthesia environments.

A comprehensive anesthetic plan for each individual patient can only be instituted by thoughtful placement of each patient within the matrix of considerations discussed above. What follows will give a broad overview of the effects of anesthetic agents on cerebral blood flow (CBF), cerebral metabolic rate of oxygen consumption ($CMRO_2$), and intracranial pressure (ICP). The remainder of this chapter provides a general discussion of the preoperative, intraoperative, and immediate postoperative care associated with common intracranial surgical procedures.

Effects of Anesthetic Agents on Cerebral Physiology

CBF, cerebral blood volume (CBV), ICP, $CMRO_2$, and cerebral compliance all must be considered in concert with pharmacologic principles in the design of a neurosurgical anesthetic regimen (Table 28-4).

Inhalation Agents

All anesthetic agents influence ICP by decreasing cerebrovascular resistance through cerebrovascular dilation and by dose-dependent impairment of autoregulation, producing increases in ICP and CBV and a decrease in $CMRO_2$. The changes in ICP are generally greater in patients who have an underlying increase in ICP.[18,19] The potent inhalational agents decrease mean arterial pressure (MAP) and increase ICP, reducing cerebral perfusion pressure (CPP).[20-22] Isoflurane produces the greatest increases in CBF and ICP, followed by sevoflurane and desflurane.[18,23-25]

CBF in humans is unaltered with isoflurane-inspired concentrations of 0.6 to 1.1 minimum alveolar concentration (MAC); however, 1.6 MAC isoflurane doubles CBF. Animal studies have shown that isoflurane may enhance the carbon dioxide (CO_2) reactivity of the cerebral vessels. Cerebral autoregulation is impaired with concentrations exceeding 1 MAC.[26,27] $CMRO_2$ is depressed with isoflurane, as with all potent inhalation anesthetics, and progressive metabolic depression occurs with concentrations of isoflurane greater than 1 MAC until the electroencephalograph (EEG) becomes isoelectric at approximately 2.5 MAC.[28,29] These properties suggest that clinically relevant doses may provide a neuroprotective effect against ischemic insults, as demonstrated in human studies of critical regional CBF during carotid clamping.[30] Although strong experimental data support a neuroprotective potential of several anesthetic agents, consistent long-term protection by either agent has not been demonstrated. Unfortunately, there is a lack of clinical studies to support the use of any one anesthetic agent over the others. Proposed mechanisms related to the neuroprotective effect of inhalation anesthetic agents include activation of ATP-dependent potassium channels, up-regulation of nitric oxide synthase, reduction of excitotoxic stressors and cerebral metabolic rate, augmentation of peri-ischemic cerebral blood

$CMRO_2$, Cerebral metabolic rate of oxygen.

flow and up-regulation of antiapoptotic factors including mitogen-activated protein kinases.[31] Activation of intracellular signaling cascades that lead to altered expression of protective genes also may be involved.[32] The high concentrations of isoflurane necessary for abolishing cortical activity have no toxic effect on cerebral metabolic pathways.[29,33] The majority of human studies show that inspired concentrations of isoflurane of less than 1% have minimal effect on ICP and that any increase in ICP is attenuated by mild hyperventilation. An exception to this generalization is that some patients with malignant brain tumors may show increases in ICP despite prior hyperventilation, particularly if computed tomography shows a midline shift.[34-36]

Desflurane is unique among the potent inhalation agents in that its low blood/gas solubility facilitates a rapid emergence, which may be useful for immediate postoperative neurologic evaluation. Desflurane has effects on EEG, CBF, and $CMRO_2$ similar to those of isoflurane. Young[37] and Ornstein et al.[38] compared the effects of desflurane and isoflurane on CBF at two concentrations, 1 MAC and 1.5 MAC, in an air-oxygen mixture during hypocapnia and reported no difference between isoflurane and desflurane at the two different MAC levels. Holmström and Akeson[39] reported that desflurane was associated with more CBF than isoflurane at the same depth of anesthesia. However, the results of ICP studies are not as definitive. Muzzi et al.[40] reported that desflurane 1 MAC in an air-oxygen mixture with an arterial CO_2 tension ($PaCO_2$) of 26 mmHg resulted in sustained increases in ICP until the dura was incised. The physiologic effects of sevoflurane are similar to those of other inhalation anesthetics, but some consider sevoflurane less vasoactive than isoflurane or desflurane.[41] In summary, all potent inhalational agents are known to increase CBF, CBV, and ICP. Mild hyperventilation attenuates these dose-dependent increases in ICP.

The use of nitrous oxide (N_2O) in intracranial procedures continues to be a controversial area of clinical practice. N_2O can produce increases in CBF, $CMRO_2$, and ICP. The effect of N_2O on cerebral dynamics varies widely and is influenced by what drugs are coadministered, the doses of each, and body temperature. Concomitant hyperventilation or the administration of one of several intravenous anesthetics (barbiturates, propofol, benzodiazepines, opioids) can reduce the increases in CBF and $CMRO_2$ during N_2O administration. However, the combination of N_2O and volatile anesthetics behaves much differently. Administering a volatile anesthetic in low doses (below 1 MAC) may decrease CBF and $CMRO_2$. The addition of 50% N_2O with less than 1 MAC of the volatile anesthetic produces increases in both CBF and $CMRO_2$. The cerebral vasodilation produced by N_2O is greater when increasing doses (greater than 1 MAC) of the volatile anesthetic are administered. N_2O may increase CBF by 100% or more at approximately 0.5 MAC. N_2O appears to produce nonuniform changes in CBF, increasing flow in anterior regions and decreasing flow in posterior brain regions. N_2O is not thought to affect CBV or CSF dynamics.[42-46]

Many clinicians have advocated that N_2O should no longer be administered in neurosurgical patients. But vast clinical experience of N_2O in thousands of neurosurgical patients, with little documentation of adverse neurologic events, argues against N_2O as having major neurotoxic effects during limited exposure. Typically, only very small amounts of N_2O are broken down in the body, but when used on long cases (over 12 hours), substantial accumulation of metabolic breakdown products may occur. These metabolites have been associated with megaloblastic anemia, leukopenia, impaired fetal development, and a depressed immune system. Circumstances in which the practitioner should consider eliminating N_2O are listed in Box 28-2.

Nitrous oxide (N_2O) is more soluble than nitrogen and expands closed-gas spaces. Its use should be restricted in patients with an intracranial or intravascular air compartment such as pneumocephalus.[47] Some practitioners abandon N_2O before closure of the dura to attenuate the development of iatrogenic pneumocephalus.

Intravenous Agents

Propofol is a popular induction and maintenance agent for neurosurgical patients. It is very useful in patients with intracranial

BOX 28-2

Considerations for Eliminating Nitrous Oxide

Nitrous oxide should be eliminated:
- In the presence of intracranial air (recent craniotomy, craniofacial trauma)
- When signal quality during intraoperative evoked potential monitoring is inadequate
- When the patient has clinical evidence of moderate to severe increases in ICP
- When a "tight-brain" is clinically appreciated during the intraoperative period
- When a case longer than 8 hours is anticipated

ICP, Intracranial pressure.

pathologic conditions, provided that hypotension is prevented. The cerebral effects are a dose-dependent reduction in CBF and $CMRO_2$. The reductions are usually in the 40% to 50% range. CPP may decrease because of reductions in blood pressure after bolus induction doses; however, the reduction in CBF appears to be independent of systemic hemodynamic changes.[48,49] They are most likely due to the metabolic depressant effect and cerebral vasoconstriction.[50,51] Reductions in systemic blood pressure produce corresponding reductions in CPP.

Etomidate reduces $CMRO_2$ and CBF in normal brains and in situations of reduced intracranial compliance. It produces a reduction in ICP without reducing CPP. Etomidate, like other CNS depressants, appears to reduce metabolic rate and produce cerebral vasoconstriction, which accounts for the reduction in ICP.[52-54] Major disadvantages include a high incidence of myoclonia, thrombophlebitis, nausea, vomiting, and suppression of the adrenocortical response to stress.[54,55] Many clinicians feel that etomidate should be avoided in brain-injured patients. Although it is considered as an induction drug of choice in situations of hemodynamic compromise, prolonged adrenal insufficiency is a major concern. Adrenal insufficiency is of special concern in critically ill patients, with sepsis and traumatic brain injury. Etomidate should be replaced by an amnestic dose of a benzodiazepine in combination with an opioid or ketamine to facilitate endotracheal intubation. If etomidate is used, empirical adrenal replacement therapy for at least 24 hours should be considered.[52]

Dexmedetomidine is gaining popularity in neuroanesthesia and neurocritical care practice. This presynaptic α_2-adrenergic receptor agonist offers a unique "cooperative sedation," anxiolysis, and analgesia with no respiratory depression.[56] Dexmedetomidine produces a dose-dependent sedation that resembles natural sleep. Sleep patterns differ from the classic gamma-aminobutyric acid (GABA) receptor agonists such as propofol. Patients do not experience respiratory depression and are readily arousable.[57] An advantage of this type of sedation is that procedures requiring "wake-up" tests can be more readily accomplished compared with usual anesthetic regimens.[58] Dexmedetomidine does not interfere with electrophysiologic monitoring, thereby allowing brain mapping during awake craniotomy and microelectrode recording during implantation of deep-brain stimulators. Motor and somatosensory evoked potentials are maintained when added to a desflurane and remifentanil technique. Decreases in the amplitude of motor evoked potentials may occur at high doses.[59,60] Bispectral index (BIS) values are decreased in a dose-dependent manner to a greater extent than with propofol.[61]

Dexmedetomidine does not change cerebral metabolism ($CMRO_2$). Cerebral blood flow (CBF) is decreased due to cerebral vasoconstriction. This suggests uncoupling between cerebral metabolism and flow because of decreases in central catecholamine turnover. Effects on intracranial pressure are not clinically significant.[62,63]

The central sympatholytic effects also result in an antishivering action, hypothermia, and a reduction in the neuroendocrine stress response to surgery. A reduction in postoperative agitation and emergence delirium in children and adults is an increasingly used clinical action. A neuroprotective effect has been proposed, but benefits in head-injured patients remain to be clarified.[62] Analgesic- and anesthetic-sparing effects are well documented and are produced at both the brain and spinal cord level. The greatest utilization of dexmedetomidine outside the neurosurgical intensive care environment is for the awake craniotomy.

Opioid-based anesthetic techniques are popular for neurosurgical procedures because they provide a steady hemodynamic course and predictable emergence. The synthetic opioids produce dose-related reductions in CBF (decrease to 25 mL/100 g/min) and $CMRO_2$ (40% to 50%).[64-67] Later investigations in patients after acute head injury or in those undergoing supratentorial craniotomy noted increases in ICP and decreases in CPP after administration of induction doses of fentanyl, sufentanil, and alfentanil.[68] These opioid-induced changes in ICP have been suggested to occur secondarily to an autoregulatory response to decreases in MAP.[69]

Fentanyl decreases the resistance to CSF absorption and results in a 10% reduction in CBV.[55,64] Sufentanil is 5 to 10 times more potent than fentanyl and has the highest therapeutic index of the clinically used opiates. Of the synthetic opiates, alfentanil produces the greatest decreases in MAP and CPP.[55,64] Remifentanil is the latest available compound of the 4-anilidopiperidine derivatives. It is characterized by an ultrashort duration of action and a metabolism independent of both hepatic and renal functions. Its main drawback is a lack of residual analgesia and the risk of postoperative hyperalgesia.[70] Meperidine should probably be avoided in the neurosurgical patient, because its metabolite, normeperidine, is a well-known convulsant.

Judiciously titrated doses of naloxone reverse opioid-induced respiratory depression and normalize both CBF and $CMRO_2$. The abrupt reversal of opioid-induced respiratory depression should be avoided in neurosurgical patients. Naloxone administered in this fashion is associated with hypertension, cardiac dysrhythmias, pulmonary edema, and intracranial hemorrhage.[71,72]

The benzodiazepines are useful anesthetic adjuncts used for their anxiolytic, anticonvulsant, and amnestic effects. Benzodiazepines produce a dose-dependent decrease in $CMRO_2$ and reductions in CBF; however, their effects on ICP are minimal.

Flumazenil, the benzodiazepine-specific antagonist, has no effect on cerebral dynamics when administered alone. High-dose midazolam anesthetic in the canine was associated with rebound increases in CBF and ICP to values greater than baseline when abrupt reversal was accomplished with flumazenil.[73] Flumazenil may produce seizures when large doses are administered.

Ketamine has had limited popularity in neuroanesthesia. The dissociative mechanism of action and resultant stormy emergence from anesthesia are undesirable after neurosurgical procedures. The primary advantage of ketamine is the stable hemodynamic course in the face of hypovolemia that may occur in the head-injured patient with multisystem trauma. Ketamine is known to produce untoward alterations in cerebral physiology, increasing CBF by 60% to 80% and elevating ICP. Ketamine also increases the resistance to CSF reabsorption, which over time may increase

ICP beyond that produced by increases in CBF alone. Cerebral metabolic rate is unchanged, but regional differences may exist.

A renewed interest in ketamine has been prompted because of its noncompetitive antagonism of the glutamine NMDA receptor. Similar compounds have been demonstrated to afford some degree of neuroprotection. Ketamine is a profound analgesic that has a preference for skin, bones, and joint pain. Analgesia occurs with subanesthetic doses, and it is widely used for sedation in combination with low doses of benzodiazepines, propofol, and other analgesics.[74] The effect on glucose utilization varies by brain region. The response of cerebral vessels to carbon dioxide is left intact. For these reasons ketamine has traditionally been thought to be contraindicated in patients with a head injury or an increased ICP.

Recently, however, it has been noted that ketamine can be used safely in neurologically impaired patients under conditions of controlled ventilation, coadministration of a GABA receptor agonist such as midazolam or propofol, and avoidance of nitrous oxide.[75] Trauma patients with multiple injuries may still benefit from the favorable cardiovascular effects while avoiding untoward neurologic adverse actions. Ketamine produces atypical anesthesia; thus EEG patterns also differ fron standard anesthetics. On loss of consciousness and onset of analgesia, ketamine induces a transition from alpha to theta waves (slow waves with moderate to high amplitude) on the EEG. Alpha waves do not reappear until after consciousness returns and analgesia is lost. Ketamine alone does not decrease the bispectral index (BIS) even when patients are unconscious.[76] Several researchers have in fact noted an increase in BIS levels when ketamine is added to a propofol, fentanyl, or sevoflurane anesthetic. Ketamine does not alter auditory evoked potentials (AEPs), mid-latency auditory evoked potential (MLAEP), or A-line autoregressive index monitors based on MLAEPs.

Nondepolarizing neuromuscular relaxants do not appear to have clinically significant direct effects on CBF or $CMRO_2$, provided MAP is not altered after administration.[77] The depolarizing agent succinylcholine in select circumstances may produce transient elevations in ICP, CBF, and $CMRO_2$.

Upper motor neuron disease may alter the peripheral nerve–stimulating response of nondepolarizing neuromuscular relaxants. Generally, the twitch response shows relative resistance to muscle relaxants on the hemiparetic or hemiplegic side, compared with the unaffected side or respiratory muscles.[78,79] Decreased sensitivity to nondepolarizing muscle relaxants is most exaggerated in the first 3 weeks of upper motor neuron disease. Therefore, monitoring neuromuscular blockade is preferentially performed on the unaffected side. Patients on chronic anticonvulsant therapy may be more resistant to long-acting nondepolarizing muscle relaxants.[80] Patients receiving chronic phenytoin therapy have an increased dosage requirement and reduced duration of action for the nondepolarizing neuromuscular relaxants, with the exception of atracurium and cisatracurium.

Succinylcholine indirectly increases intracranial pressure (ICP), and therefore concern has always existed as to the appropriateness of its use in certain neurosurgical procedures and in patients with brain pathology and ICP. Research conducted in animals shows a small and transient rise of 10 to 15 mmHg for 5 to 8 minutes after administration.[81] The rise is associated with an increased cerebral blood flow, muscle spindle afferent activity, and electroencephalogram arousal. Fasciculation of the neck muscles causing jugular vein stasis appears to be a factor. The ICP effects are blocked by pretreatment with a small dose of nondepolarizing relaxant. In clinical practice, the administration of succinylcholine is preceded by an anesthetic induction agent that lowers ICP, so that may help counteract this effect as well. Nevertheless, the routine use of succinylcholine in neurosurgery has declined. It remains widely used, with nondepolarizing relaxant and lidocaine pretreatment, for emergency procedures requiring rapid airway control via rapid sequence induction As mentioned previously, succinylcholine is contraindicated in patients with neurologic or denervated muscle because of the potential for life-threatening hyperkalemia. Succinylcholine should be avoided in patients with cerebrovascular accident, upper and lower motor neuron lesions, coma, encephalitis, and closed head injury and after severe burns and prolonged bedrest.[82]

The availability of suitable nondepolarizing alternatives such as rocuronium (1 mg/kg intubating dose) facilitates endotracheal intubation within 60 to 90 seconds and avoids the known complications attendant on the administration of succinylcholine.

Antihypertensives

β-Adrenergic antagonists have great utility for the control of the inotropic and chronotropic effects of sympathetic stimulation that attend laryngoscopy, endotracheal intubation, and endotracheal extubation. Esmolol is a rapid-onset, short-acting selective β_1-adrenergic receptor antagonist. Administration of 0.5 to 1 mg/kg 2 minutes before laryngoscopy and endotracheal intubation attenuates the predictable increases in heart rate and blood pressure. Its effects on ICP are thought to be negligible. Labetalol is a selective α_1-adrenergic antagonist and nonselective β_1- and β_2-adrenergic antagonist (ratio of β-blockade to α-blockade is 7:1 for intravenous preparation). Labetalol spares presynaptic α_2-receptors; consequently, released norepinephrine produces further inhibition of catecholamine release via a negative feedback from the stimulation of β_2-receptors. Labetalol and esmolol may be preferred for the control of emergence hypertension after intracranial procedures. In one study, patients treated with labetalol as compared with esmolol experienced a higher incidence of bradycardia in the immediate postoperative period.[83,84]

The smooth muscle relaxants sodium nitroprusside and nitroglycerin produce increases in CBV and ICP. Sodium nitroprusside is a direct-acting cerebrovasodilator, increasing CBV after dilation of cerebral capacitance vessels.[77,85] Deliberate hyperventilation and the administration of a barbiturate may attenuate the cerebrovasodilation. Most contemporary neuroanesthesiologists consider nitroglycerin and sodium nitroprusside to be potent dilators of capacitance vessels and unsafe in patients with abnormal elastance. If a patient is on a tenuous portion of the pressure-volume curve, the dramatic rise in CBV caused by nitroglycerin or nitroprusside use would be catastrophic, resulting in spatial exhaustion and intracranial hypertension.[86]

INTRACRANIAL PRESSURE

In its simplest definition, *intracranial pressure* refers to the supratentorial CSF pressure. The supratentorial pressure may be measured within the lateral ventricle or within the subarachnoid space over the convexity of the cerebral cortex. CSF pressure may vary markedly in different areas within the cranium, and similarly, CSF pressure in the cranial subarachnoid space may differ from that in the spinal subarachnoid space. In individuals free of neurologic pathology in the recumbent position, the CSF pressure measured at the lumbar cistern accurately reflects ICP. However, many factors, including the assumption of the upright position, can alter the relationship between cranial and spinal CSF pressures. In addition, in the presence of intracranial mass lesions, infratentorial CSF pressure (as measured in the cisterna magna or lumbar cistern) often decreases, whereas supratentorial pressure increases.

Therefore, the measurement of supratentorial CSF pressure is a useful clinical concept.[21,87]

Determinants of Intracranial Pressure

The brain is enclosed within a rigid container, and because the brain is not compressible, any increase in total intracranial volume produces an accompanying increase in ICP (Monro-Kelly doctrine). Increased ICP may have a detrimental effect on the well being of the brain. The intracranial contents consist of the brain (12%), intracellular water (78%), CSF (approximately 75 mL), and blood (approximately 50 mL), for a combined volume of approximately 1200 to 1500 mL.[88] The brain is surrounded by the dura mater and rigidly encased in the bone of the calvaria and skull base. In the strictest sense, the intracranial space, volume, and pressure are defined by the limits of the encasing bone. However, should the skull become disrupted, the remaining intracranial contents may be subject to the potential for abnormal pressure accumulation because of the restrictions imposed by an intact dura mater. The same dural restrictions also may contribute to regional ICP gradients in patients with intracranial mass lesions and an intact cranial vault.[89] Intracranial hypertension may lead to global reductions in CPP (CPP = MAP − ICP) from compression-induced ischemia or may produce shifting of intracranial contents, resulting in compression of the brain against the falx, the tentorium, or the foramen magnum.

The ICP is approximately 5 to 15 mmHg in adults; lower values are recorded in children and infants. This pressure is determined by the relationship between the volume allowed by the structures that limit intracranial volume and the actual volume of the intracranial space. Because of the normal elastance of the intracranial contents, individuals without intracranial pathology maintain normal ICP despite transient increases that develop with coughing or during a Valsalva maneuver. Small increases in the intracranial volume do not produce abrupt increases in ICP. This normal elastance exists because the limits of the intracranial contents have not been reached.

Once a growing mass, blood or tumor, has increased intracranial volume to its limit, dramatic increases in ICP may occur.[90] This relationship is depicted in Figure 28-16. Although this ICP-volume curve is commonly used to explain these relationships, Todd et al.[91] suggest that the x-axis be relabeled as the "volume of the growing mass," because this axis does not really represent total intracranial volume. The initial portion of the ICP curve is relatively flat because the total intracranial volume does not change with early periods of bleeding or tumor growth. This portion of the curve reflects the phenomenon of spatial compensation. As the mass (blood or tumor) increases, the volume of the intracranial compartments must decrease to maintain normal ICP. In most cases, the CSF compartment decreases; that is, CSF is absorbed by the arachnoid granulations or shunted to the spinal subarachnoid space to compensate for the increasing intracranial volume. Compensation is exhausted when the CSF compartment cannot decrease further in size and total intracranial volume increases, accounting for the increase in ICP. Once volume compensation has reached exhaustion, the subsequent increasing ICP has a direct relationship with a reduction in cerebral perfusion and an increased herniation risk (see Figure 28-16).[92]

Measurement of Intracranial Pressure

The current gold standard for ICP monitoring is the intraventricular catheter. Although it is highly invasive, it allows for drainage of CSF to lower ICP. As with any indwelling catheter, there can be insertion problems and safeguards against infection are necessary. It is usually zeroed daily, with the jugular foramen projected at the tragus as the reference level. Intraparenchymal probes are a popular method of measuring ICP as well. They are easy to use and transport and are zeroed when inserted. Infection problems are minimal. The microsensor transducer and the fiber optic transducer are the most widely available.[93] Older methods such as epidural and subarachnoid probes are largely obsolete. The primary reasons for monitoring ICP are trauma and subarachnoid hemorrhage, although other indications exist. A Glasgow Coma Scale score of 7 or less in a comatose patient is the classic indication. A ventriculostomy catheter and other brain monitors are depicted in Figure 28-17.[94-96]

Intracranial Hypertension

Intracranial hypertension occurs with a sustained increase in ICP above 20 to 25 mmHg.[97] Intracranial hypertension develops with expanding tissue or fluid mass, interference with normal CSF absorption, excessive CBF, or systemic disturbances promoting brain edema. Often, multiple factors are responsible for the development of intracranial hypertension. For example, tumors in the posterior fossa usually produce some degree of brain edema and readily obstruct CSF flow by compressing the fourth ventricle.[98]

Although many patients with intracranial hypertension are initially asymptomatic, all eventually develop characteristic signs and symptoms, including headache, nausea, vomiting, papilledema, focal neurologic deficits, altered ventilatory function, decreasing consciousness, seizures, and coma. When ICP exceeds 30 mmHg, CBF progressively decreases, and a vicious cycle is established: ischemia produces brain edema, which in turn increases ICP, and further precipitates ischemia. If this cycle remains unchecked, progressive neurologic damage or catastrophic herniation may result.[21,98,99] A consistent increase in intracranial pressure above 20 mmHg must be treated.

When intracranial hypertension is caused by hematoma, contusion, tumor, hygroma, hydrocephalus, or pneumatocephalus, surgical treatment is indicated. In the absence of a surgically treatable condition, ICP may be controlled by correcting the patient's position, temperature, ventilation, hemodynamics, and drainage of CSF. Other first-tier options include controlled hypocapnea (hyperventilation; $Paco_2$ 30-35 mmHg). On average, CBF decreases by 4% for every 1 mmHg decrease in $Paco_2$. Hyperosmolar therapy (mannitol, hypertonic saline) and induced arterial hypertension (CPP concept) are also used.

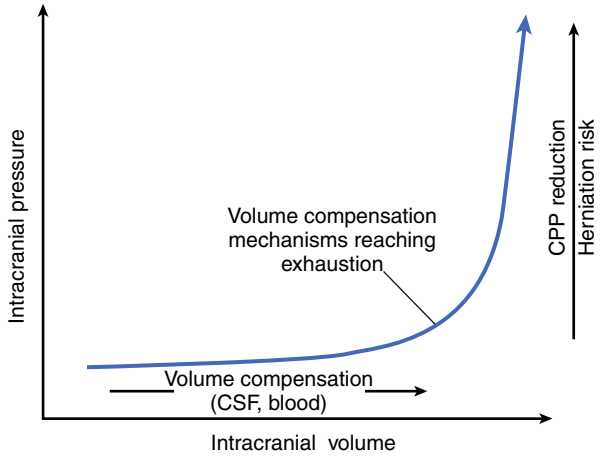

FIGURE **28-16** The intracranial pressure-volume relationship. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2046.)

When autoregulation of cerebral blood flow is compromised, hyperoncotic treatment aimed at reducing vasogenic edema and intracranial blood volume may be applied. When intracranial hypertension persists, second-tier treatments may be indicated. These include forced hyperventilation ($Paco_2$ less than 25 mmHg), barbiturate coma, or experimental protocols such as tris buffer, indomethacin, or induced hypothermia. The last resort is emergent bilateral decompressive craniectomy. These interventions are discussed later.[93]

Intracranial Pressure Reduction

The major methods of treating elevated ICP are listed in Box 28-3. Selective application of these methods often results in ICP reduction accompanied by clinical improvement. A patent airway, adequate oxygenation, and controlled ventilation provide the foundation for neuroresuscitative care in acute intracranial hypertensive states. Frequently, overlap occurs among causes of increased ICP, and this may necessitate simultaneous application of a number of different therapeutic modalities.[68]

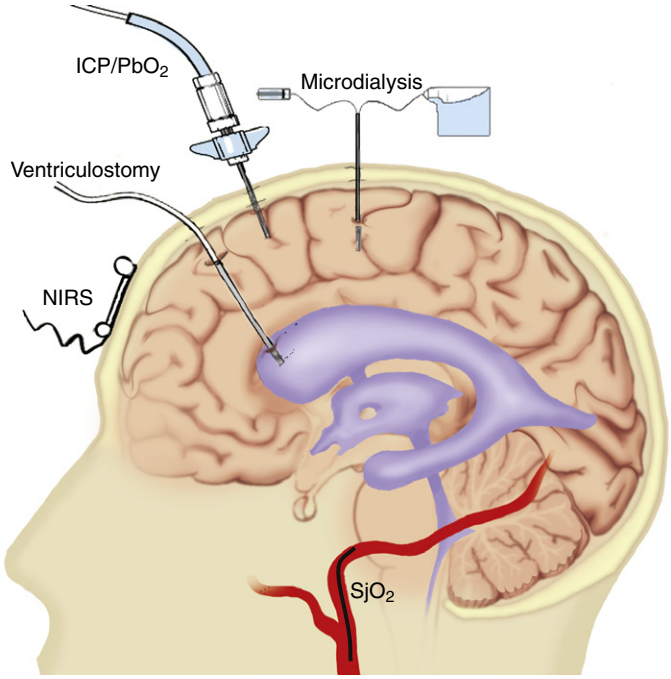

FIGURE **28-17** Schematic of available intracranial monitoring, with near-infrared oximetry (NIRS), intracranial pressure (ICP, either via ventriculostomy or parenchymal probe), brain tissue oximetry (PbO_2), microdialysis, and jugular venous oximetry (SjO_2). (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2904.)

Hyperventilation

Lowering $Paco_2$ increases cerebrovascular resistance, reducing CBV and ICP. It must be kept in mind that controlled hyperventilation is more a rescue maneuver than a standard treatment. The reactivity of cerebral vessels to changes in $Paco_2$ is an important physiologic control system. When the physiologic control is intact, hyperventilation lowers $Paco_2$, resulting in respiratory alkalosis and subsequent vasoconstriction. When vasoconstriction is pronounced, intracranial blood volume will decrease and lower ICP. This is particularly important in known low-CBF conditions, such as severe traumatic brain injury (TBI) or vasospasm. To avoid cerebral ischemia, $Paco_2$ should be lowered to approximately 30-35 mmHg. The vasoconstrictive effect on cerebral arterioles lasts only 11 to 20 hours because the pH of the CSF rapidly equilibrates to the new $Paco_2$ level. When hypocapnea is to be monitored by end-tidal capnometry, as is usually the situation in the operating room, the $Paco_2$ is approximately 2-5 mmHg higher than end-tidal carbon dioxide ($ETco_2$) readings although many conditions can affect this gradient. Compared with autoregulation of CBF, CO_2 reactivity is usually maintained even in the traumatized brain. When CO_2 reactivity is lost, a poor prognosis is probable.[100]

Cerebrospinal Fluid Drainage

Intracranial hypertension may be reduced by a surgical CSF diversion. The long-term effectiveness of this therapeutic alternative depends on the cause of the increased ICP. When brain edema produces elevation of ICP, CSF drainage may provide only transient abatement of intracranial hypertension. If external drainage is continued in this circumstance, ventricular collapse can occur and prevent further venting of CSF. Successful chronic control of high ICP caused by hydrocephalus can be achieved with implanted CSF shunts.[68,93,100]

Surgical Decompression

Surgical decompression may be used for uncontrollable increases in ICP. Internal decompression involves the excision of brain tissue, reduction in ICP, and reduction of the potential for brainstem

BOX 28-3

Methods for the Treatment of Elevated Intracranial Pressure

- Apply mild hyperventilation on demand ($Paco_2$ 30 to 35 mmHg)
- Optimize sedation and analgesia to allow for ventilatory control
- Administer diuretics (osmotic mannitol 0.25-1 g/kg IV) (may repeat once if serum osmolarity less than 320 mOsm/kg and patient is euvolemic) or furosemide
- Perform cerebrospinal fluid drainage (if available)
- Avoid overhydration; target normovolemia
- Elevate patient's head 15 degrees; position to improve cerebral venous return; avoid neck-vein compression
- Insert intracranial pressure monitor such as a ventricular catheter or parenchymal probe; tissue oxygen partial pressure, $AVDo_2$, and CBF monitoring recommended
- Optimize hemodynamics: mean arterial pressure, central venous pressure, pulmonary capillary wedge pressure, heart rate, and cerebral perfusion pressure; consider antihypertensive therapy as needed
- Administer corticosteroids (avoid with traumatic brain injuries)
- Surgical decompression; consider decompressive craniectomy if hematoma is present
- Cerebral vasoconstriction such as propofol
- Consider mild hypothermia

$AVDo_2$, Arteriovenous difference in oxygen content; *CBF*, cerebral blood flow; *IV*, intravenous; *$Paco_2$*, partial pressure of arterial carbon dioxide.

displacement or herniation. External decompression involves excision of the skull overlying the site of either an epidural or a subdural hematoma. Decompressive surgery is generally considered to be a last resort in patients with persistent, intractable increases in ICP.[54]

Hypothermia

Hypothermia may assist in uncontrollable increases in ICP by decreasing $CMRO_2$ 7% for each degree centigrade decrease in core body temperature. Temperature is lowered by convective cooling to a bladder temperature of 35° to 36° C for 48 hours after trauma or hemorrhage.[101]

Pharmacologic Manipulation of Intracranial Pressure

Diuretics

Loop diuretics (furosemide, bumetanide, ethacrynic acid) produce a general diuresis, decrease the rate of CSF production, and decrease cerebral edema. Osmotic diuretics are effective in decreasing the water content of the brain. Mannitol is the most widely used osmotic diuretic for acute control of intracranial hypertension. Rapid administration of mannitol may produce vasodilation, increases in CBF, a transient rise in ICP, and a transient increase in circulating blood volume. Increases in circulating blood volume may prove to be detrimental to patients with underlying cardiac dysfunction. Prior administration of intravenous furosemide may minimize these potential complications. Decreases in ICP begin shortly after mannitol administration and may continue for up to 6 hours. The typically prescribed dose of mannitol is 0.25 to 1 g/kg. Continued use of mannitol may produce hyperosmolality and electrolyte imbalance, which may be attenuated with concurrent administration of a loop diuretic.[102]

Hypertonic saline has an osmotic effect on the brain because of its high tonicity and ability to effectively remain outside the blood-brain barrier. Like mannitol, hypertonic saline produces an osmolar gradient causing shrinkage of brain tissue and reduction in ICP. It also increases circulating blood volume, MAP, and CPP. The ICP reduction is seen for approximately 2 hours and may be maintained for longer periods by using a continuous infusion of hypertonic saline. The ICP reduction is thought to be caused by a reduction in water content in areas of the brain with intact blood-brain barrier, such as the nonlesioned hemisphere and cerebellum. Most comparisons with mannitol suggest almost equal efficacy in reducing ICP, but there is a suggestion that mannitol may have a longer duration of action. Results from studies directly comparing hypertonic saline with standard treatment in regard to safety and efficacy are inconclusive. However, the low frequency of side effects and a definite reduction of ICP observed with use of hypertonic saline in these studies are very promising. Systemic effects include transient volume expansion, natriuresis, hemodilution, immunomodulation, and improved pulmonary gas exchange. Adverse effects include electrolyte abnormalities, cardiac failure, bleeding diathesis, and phlebitis.[103]

Corticosteroids

Glucocorticoids penetrate the blood-brain barrier and decrease edema associated with mass lesions. Steroids have been in use for neurosurgical patients for decades. They are commonly used for primary and metastatic brain tumors to decrease vasogenic cerebral edema.

Increased ICP decreases over 2 to 5 days with treatment. The most commonly used regimen is intravenous dexamethasone, 4 mg every 6 hours. Despite many years of use the CRASH (Corticosteroid Randomization After Significant Head injury trial) results showed that steroids were harmful in TBI. They may be given in spinal cord trauma. There is no indication for steroids with intracranial hypertension after TBI. Classical indications, such as perifocal edema surrounding intracranial tumors or edema associated with cerebral abscess, remain valid.[104]

Barbiturates

Barbiturate coma, hypothermia, or decompressive craniectomy should be considered for intracranial hypertension refractory to initial medical management. Barbiturate coma is used to reduce refractory ICP by decreasing $CMRO_2$ scavenging free radicals, preventing convulsions, and reducing the hyperthermic response to ischemia. Barbiturates induce hypotension, which at times may be very difficult to treat.[105] Volume expansion should be the first-line treatment to maintain systemic blood pressure, although intravenous pressors may be used. The cerebral metabolic rate cannot be lowered further after burst suppression is achieved by barbiturates; theoretically, ICP will be at its lowest barbiturate-induced level when burst suppression is achieved.[106] Patients may be kept in burst suppression–induced barbiturate coma for hours to days. Although routine use of barbiturates has not been effective in reducing morbidity or mortality after severe head injury, beneficial reductions in ICP are produced. A disadvantage is the inability to perform neurologic assessments during the coma.[107]

NEUROPHYSIOLOGIC MONITORING

Great use is made of neurophysiologic brain monitoring. It is important to confer with the surgeon prior to surgery to determine which neurophysiologic monitoring is to be used and to plan the anesthetic in a manner that optimizes the results of the required monitoring.

Intraoperative monitoring (IOM) is used routinely to asses the nervous system during procedures that present significant risk of brain, spinal cord, or nerve injury. Intraoperative testing is used to identify nerves and to define brain regions and structures for resection. There is significant improvement in patient outcomes with monitoring. The Therapeutics and Technology Subcommittee of the American Academy of Neurology concluded that the following are useful and noninvestigational: (1) EEG, compressed spectral array, and somatosensory evoked potentials (SSEPs) in carotid endarterectomies and brain surgeries that potentially compromise cerebral blood flow; (2) brainstem auditory evoked response and cranial-nerve monitoring in surgeries performed in the region of the brainstem or inner ear; and (3) somatosensory evoked monitoring performed for surgical procedures potentially involving ischemia or mechanical trauma of the spinal cord.[108] Motor evoked potentials monitoring is common during spine surgery and has a good correlation to postoperative motor outcome. The novel technique of motor evoked potential monitoring using transcranial electrical stimulation allows reliable assessment of the functional integrity of the corticospinal and corticobulbar tracts while the patient is under general anesthesia.[109]

Surgical procedures that commonly use intraoperative monitoring are shown in Box 28-4. Intracranial posterior fossa cases commonly use brain auditory evoked potentials (BAEPs), somatosensory evoked potentials (SSEPs), and cranial nerve electromyography (EMG) monitoring. Typical applications are cerebellopontine angle and skull base tumor resection, brainstem vascular malformation and tumor resection, and microvascular

BOX **28-4**

Surgical Procedures Commonly Using Intraoperative Monitoring

- Epilepsy surgery
- Cerebral tumor and vascular malformation resection
- Intracranial aneurysm clipping
- Movement disorders electrode placement
- Mapping nerves, tracts, and nuclei during brainstem and cranial base surgery
- Ear and parotid surgery near facial nerve
- Thyroid and aortic arch surgery near laryngeal nerve
- Carotid endarterectomy
- Carotid balloon occlusion
- Endovascular spinal and cerebral procedures
- Spinal deformity correction
- Spinal fracture stabilization
- Spinal tumor resection
- Cervical myelopathy decompression
- Lumbar stenosis decompression and fusion
- Tethered cord and cauda equina procedures
- Dorsal root entry zone surgery
- Brachial and lumbosacral plexus surgery
- Peripheral nerve surgery
- Cardiac and aorta procedures

Adapted from Nuwer MR. Clinical neurophysiology: intraoperative monitoring. In: Daroff et al, eds. *Bradley's Neurology in Clinical Practice*. 6th ed. Philadelphia: Saunders; 2012:440.

decompressions. Intracranial supratentorial procedures include resections for epilepsy, tumors, and vascular malformations as well as for aneurysm clipping. These use multimodality monitoring with a combination of EEG and SSEP monitoring together with functional cortical localization with direct cortical stimulation and electrocorticography (ECoG). Surgery of the carotid, aorta, or heart may use EEG to monitor hemispheric function or assess the need for shunting or adequacy of protective hypothermia. SSEPs for also used these vascular cases.

Spinal surgery is the most common setting for IOM. Procedures include cervical diskectomy and fusion for myelopathy, stabilization for deformities such as scoliosis, resection of spinal column or cord tumors, and stabilization of fractures. Both SEP and MEP often are used to assess the posterior columns and corticospinal tract functions. The use of MEP depends on the case, since it usually requires total intravenous anesthetic and incurs some movements during surgery. As a result, some spinal cases still are done with SEP alone. In cases involving pedicle screw placement, EMG is monitored to detect screw misplacement. Spinal cord monitoring also is used for cardiothoracic procedures of the aorta that jeopardize spinal perfusion. Peripheral nerve monitoring is carried out for cases risking injury to the nerves, plexus, or roots. Testing also can determine which segments of a nerve are damaged when performing a nerve graft.

When SSEP monitoring is used for spinal cord surgery the risk of paraplegia was 60% less among the monitored cases when compared with historical and contemporaneous controls. That amounted to 1 case out of every 200 that did not have paraplegia when monitoring was used. To improve even further, multimodality monitoring combining SSEPs with MEPs and others is now standard for many spinal procedures. The expectation is that the rate of postoperative neurologic deficits will be reduced even further.[110]

Electroencephalography

The EEG recorded from the scalp is a summation of the excitatory and inhibitory postsynaptic potentials produced in the pyramidal layer of the cerebral cortex. EEG activity requires about 50% of the total oxygen consumed by the brain; the remaining 50% is needed to maintain cellular integrity. When oxygen delivery is compromised, slowing of EEG activity ensues.

Changes in EEG frequency and amplitude may be caused by administration of anesthetic drugs and changes in anesthetic depth. Low doses of potent inhalation agents with N_2O produce an active EEG. Steady-state anesthesia, regardless of the agent used, usually produces a stable EEG pattern. It is worth noting that deep levels of anesthesia and cerebral ischemia produce similar EEG changes. In both cases, fast activity is replaced by slower, larger EEG waveforms. Boluses of anesthetic drugs may produce large EEG changes indistinguishable from those seen during ischemia. The EEG provides information about the overall electrical functioning of the cerebral cortex but not much about the subcortical brain, spinal cord, or cranial and peripheral nerves.[110]

Somatosensory Evoked Potentials

An evoked potential differs from the EEG mainly in two ways: (1) the EEG is a random, continuous signal that arises from the ongoing activity of the outer layers of the cortex, and an evoked potential is the brain's response to a repetitive stimulus along a specific nerve pathway, and (2) EEG signals range from 10 to 200 millivolts (mV). Evoked potentials are smaller in amplitude (1, 5, 20 microvolts), requiring precise electrode positioning and special techniques (signal averaging) to extract the specific response from the underlying EEG "noise." The technique of signal averaging has been further developed in computer processing. The technique now used applies a stimulus repeatedly—preferably at randomized intervals—and records the evoked response over the corresponding area of the brain, averaging out mathematically the change over the number of stimuli.[111]

SSEP can be used for detecting localized injury to specific areas of the neural axis by assessing cortically generated waves, or it can serve as a nonspecific indicator of the adequacy of cerebral oxygen delivery.[110]

Although anesthetics alter the generation and transmission of SSEP, suppression of muscle artifact by neuromuscular blocking drugs and the ability to use much higher stimulus intensity in the anesthetized patient allow rapid production of waves that are reproducible, although they differ from those found in the awake patient. Early components of SSEP are generally resistant to anesthetic depression. Etomidate and ketamine both increase the amplitude of scalp-recorded waves by 200% to 600%. Volatile anesthetics and N_2O depress the SSEP waveform in a dose-dependent manner. Avoiding changes in inhaled gas concentration and bolus injection of hypnotic drugs during periods of risk minimizes difficulties in determining whether waveform changes are due to surgical manipulation.[112] The effects of anesthetics on somatosensory evoked potentials are shown in Table 28-5.

Hypothermia increases SSEP latency. Latency increases about 3 milliseconds with every decrease in temperature of 2° C to 3° C. This amount of change is suggestive of neural injury. Hyperthermia suppresses SSEP amplitude, with the amplitude being only 15% of that at normothermia.[112-115]

Reproducible, very-short-latency waves of the trigeminal system are produced by stimulation of the lip at 2 to 4 Hz (512 stimuli). This modality of evoked potential is abnormal in patients with posterior fossa masses in the region of cranial nerve V or in symptomatic hydrocephalus.[116] This modality of evoked

TABLE 28-5 Effects of Anesthetics on Somatosensory Evoked Potentials

potential monitoring may be useful in patients with large posterior fossa tumors that cause severe cranial nerve VIII dysfunction and make brainstem auditory evoked response (BAER) monitoring impossible.[112]

BAER assesses only brainstem function, although long-latency cortical waves can be assessed to evaluate cortical function. BAER has been used extensively in patients at risk of brain injury during intracranial surgery, despite the extremely small amount of neural tissue assessed and the resistance of BAER to oxygen deprivation when compared with other neural monitors such as the EEG or SSEP waves.[112,117]

Compared with SSEPs, intraoperative factors other than surgical brain damage are relatively unlikely to seriously alter the BAER. BAER waveforms are resistant to both intravenous and inhalational drugs.[112] Fentanyl in large doses does not alter BAER.[112,118] Propofol (2 mg/kg, followed by an infusion) increases the latency of waves I, III, and V without a change in the amplitudes, but it completely suppresses middle-latency auditory waves.[112,119] N_2O produces a linear decrease in BAER amplitude from 10% to 40%[112,120]; N_2O at doses of 33% reduces the wave amplitude without altering latency.[112,121,122]

BAER waves are easily identifiable at more frequently used levels of hypothermia (29° C), although latencies are delayed by about 33%.[123] BAER latency is inversely related to temperature over the range of 36° C to 42° C, with a decrease in amplitude as temperature increases.[112,124]

BAER appears to be a sensitive monitor to the auditory apparatus in response to direct injury.[112] The auditory apparatus includes the cochlear hair cells, spiral ganglion, eighth cranial nerve, cochlear nuclei, superior olivary complex, lateral lemnisci, inferior colliculus, and medial geniculate thalamic nuclei.[110] Some have recommended BAER monitoring be undertaken in all patients at risk of brainstem injury, even if the primary disease causes hearing on the affected side to decrease below the functional level.[112] Some also consider BAER clinically useful and probably approaching standard of care for microvascular decompression procedures and acoustic tumor surgery.[110]

Aggressive intraoperative monitoring does not guarantee prevention of neurologic injury, because all parts of the brain are not assessed using currently available monitoring.[112] Except when the entire brainstem is at risk, there will likely be a high incidence of cases in which BAERs are unaffected intraoperatively, yet significant impairment in motor function or consciousness occurs postoperatively.[110]

Electromyography (EMG) monitoring is frequently used for facial nerve monitoring. Generally, two types of EMG activity are monitored. The first involves active stimulation of the nerve for localization and the second, spontaneous EMG activity initiated by irritation or manipulation of the nerve. It has been noted that in the presence of light anesthesia, spontaneous EMG activity caused by slight movements may become apparent and mimic neuronal irritation.[110]

The effects of muscle relaxants on EMG monitoring have not been adequately studied.[110,112] The degree of neuromuscular blockade should be maintained at a light level until response of the respective muscles (orbicularis oris and orbicularis oculi) is verified.[110] Chronically injured facial nerves may show greater sensitivity to the effects of neuromuscular blockade, suggesting lower levels of neuromuscular blockade should be used.[125] Some do not paralyze patients during the time EMG monitoring is used. Facial nerve monitoring is considered the standard of care for acoustic tumor surgery and during other surgery that risks facial nerve function.[110]

The motor component of cranial nerves III, IV, X, XI, and XII also can be monitored using EMG.[110,126,127] Whereas some consider the use of EMG monitoring of cranial nerves other than VII not widespread or universally accepted,[110] recent interest in skull-base surgery has spurred EMG monitoring for lower cranial nerve preservation. Some recent evidence suggests EMG monitoring proved to be a safe tool for the intraoperative identification and localization of the lower cranial nerves, contributing to their anatomic and functional preservation. The predictive value of standard neurophysiologic parameters for functional outcome, however, is limited.[128]

There is great interest in intraoperative use of motor evoked potentials (MEPs) because of the theoretic limitations of SSEPs in monitoring motor function.[110] MEPs assess function of the motor cortex and descending tracts. The peripheral response of the MEP is recorded by measuring the compound muscle action potential.[112] The motor cortex is stimulated by electrical or magnetic stimulation. Both volatile anesthetics and neuromuscular blocking drugs suppress these responses.[112,129,130]

Evoked potentials may be affected by various anesthetics. Neuromuscular blockade resulting in a 70% or less reduction in the height of the response to ulnar nerve stimulation is compatible with MEP monitoring.[110,131] A combination of N_2O-narcotic anesthetic and a stable level of neuromuscular blockade, such as that provided by an infusion of neuromuscular blocking agent, has been advocated to provide a stable response.[112] Some authors recommend that N_2O be kept to less than 50% or not used if monitoring of MEPs is vital to safe spinal surgery.[132,133] Total intravenous anesthesia using infusions of propofol in combination with a narcotic allow stable MEP recordings. Total intravenous anesthesia with ketamine also has been recognized as being compatible with stable MEP readings.[110,134]

MEP responses produced by electrical stimulation of the spinal cord are resistant to the effects of anesthesia and require no special anesthetic considerations other than the need for muscle relaxants to prevent gross movements.[110] Recommended monitoring modalities and anesthestic techniques for various surgical produres are shown in Table 28-6.

ANESTHETIC CONSIDERATIONS FOR SPECIFIC PROCEDURES

Supratentorial Surgery

Intracranial masses may be congenital, neoplastic (benign, malignant, or metastatic), infectious (abscess or cyst), or vascular (hematoma or malformation). Most but not all anesthetics

can be used safely in patients with cerebral lesions. Important considerations are the effects of the agent on ICP, CPP, CBF, $CMRO_2$, promptness of return of consciousness, drug-related protection from cerebral ischemia or edema, blood pressure control, and compatibility with neurophysiologic monitoring techniques.[135]

Most craniotomy surgery in the United States today is performed after a propofol induction of anesthesia with intubation of the trachea after administration of a nondepolarizing relaxant. Maintaining anesthesia is commonly accomplished with a volatile agent (often isoflurane) and a narcotic, such as fentanyl, sufentanil, alfentanil or remifentanil, in various combinations.[135]

Preoperative Evaluation

The clinical signs of a supratentorial mass include seizures, hemiplegia, and aphasia. The clinical signs of infratentorial masses include cerebellar dysfunction (ataxia, nystagmus, dysarthria) and brainstem compression (cranial nerve palsies, altered consciousness, abnormal respiration). When ICP increases, frank signs of intracranial hypertension also can develop.[98]

Preanesthetic evaluation should attempt to establish the presence or absence of intracranial hypertension. Computed tomography or magnetic resonance imaging (MRI) data should be reviewed for evidence of brain edema, midline shift greater than 0.5 cm, and ventricular size. A neurologic assessment should evaluate the current mental status and any existing deficits. Anticonvulsant therapy and medications prescribed for control of ICP (corticosteroids, diuretics) should be reviewed. Laboratory evaluation should rule out corticosteroid-induced hyperglycemia and electrolyte disturbances that may develop secondary to diuretic therapy. For anticonvulsants, amount, time of last dose, and blood levels should be noted.

The decision regarding the amount and timing of the premedication administration should be made only after a thorough patient evaluation. Benzodiazepines produce respiratory depression and hypercapnia. Premedication should be omitted in patients with a large mass lesion, a midline shift, and abnormal ventricular size. Opioids are universally avoided in the preoperative period. If premedication is desired in those patients deemed appropriate, careful titration of intravenous midazolam may begin once the patient has been delivered to the preoperative holding area. In an attempt to help control ICP in patients with mass lesions, the head of the bed should be elevated 15 to 30 degrees during transport to the preoperative holding area and the operating room. Due diligence to all existing hospital recommendations for prophylactic antibiotics given at the appropriate time and in the appropriate amount should be performed.

TABLE 28-7 Cerebral Oxygenation Monitoring

Monitor	Abbreviations	Comments
Jugular bulb oximetry	$Sjvo_2$	Invasive; monitors global not focal ischemia and hypoxia; < 50% desaturation suggests inadequate delivery or excessive consumption; > 75% suggests hyperemia or stroke
Transcranial Doppler monitoring	rso_2	Noninvasive; monitors flow within the Circle of Willis; temporal bone thickness may prevent monitoring; ratio > 3 may be indicative of vasospasm; ratio < 3 suggests hyperemia
Brain tissue oxygen tension	Pbo_2	Invasive; reserved for global head injuries; simultaneously estimates tissue oxygen tension and ICP; normal values 20-45 mmHg; pathologic reading < 15 mmHg
Near-infrared spectroscopy	NIRS	Noninvasive; estimates brain tissue saturation; concerns with reliability and specificity; may be best used as a trend monitor for flow

ICP, Intracranial pressure.

Intraoperative Monitoring

Routine monitors for supratentorial procedures include continuous electrocardiography, cuff measurement of blood pressure, precordial stethoscope, monitoring of the fraction of inspired oxygen, pulse oximetry, temperature, peripheral nerve stimulation, end-tidal CO_2 ($ETco_2$) monitoring, and indwelling urinary catheterization. For patients with ischemic heart disease, use of a modified V_5 ECG lead is recommended. An arterial line placed either before or immediately after anesthetic induction provides for uninterrupted blood pressure monitoring and easy access for blood sampling for laboratory analysis. SSEPs may be assessed. Methods for cerebral oxygenation monitoring are listed in Table 28-7.[136-138]

Fluid Management

Tissues within the CNS are subject to water movement governed by the blood-brain barrier. The pore size in the blood-brain barrier is only one tenth that of the periphery, at 0.7 to 0.9 nm.[139] There is a fundamental difference between capillaries within the CNS and the peripheral capillaries. The blood-brain barrier remains impermeable to both ions and proteins. The number of ions represents a greater magnitude in determining the net movement of water than the number of plasma proteins. There can be little doubt that osmolarity is the primary determinant of water movement across the intact blood-brain barrier.[140,141]

Normovolemia is the goal during intracranial surgery. Preoperative fluid deficits and intraoperative blood and fluid losses must be adequately replaced during neurosurgical procedures. Judicious fluid administration minimizes the occurrence of cerebral edema and increased ICP, reduced CPP, and worsened cerebral ischemia. In most neurosurgical patients, fluids that contain sodium in a concentration similar to that of serum (e.g., lactated Ringer's solution or 0.9% saline) are administered in a volume sufficient for maintaining peripheral perfusion but avoiding hypervolemia (0.5 to 1 mL/kg/hr). Traditionally, less fluid was given than would be administered for nonneurologic surgery, although current recommendations indicate that patients should be kept isovolemic, isotonic, and isooncotic.[142-145] Glucose-containing or hypoosmolar solutions such as lactated Ringer's solution should be avoided. The use of isoosmolar crystalloids is widely accepted and can be justified on a scientific basis.[141,146,147]

Hyperglycemia induces marked detrimental cerebrovascular changes during both ischemia and reperfusion.[148] Multiple studies have demonstrated that hyperglycemia before and during an episode of global cerebral ischemia will exacerbate the neurologic injury.[149]

Hyperglycemia-enhanced ischemic injury is due to several factors including a rise in lactate production and concomitant tissue acidosis.[150-152] Another theory suggests that hyperglycemia enhances ischemic injury by attenuating an increase in adenosine.[150,153,154] Yet another theory suggests that hyperglycemia significantly worsens the degree of acute blood-brain barrier disruption that occurs during ischemia.[150,155] It is also thought that hyperglycemia is associated with a significantly reduced CBF and increased heterogeneity of regional CBF during the postischemic period.[150,156-159]

Fluid therapy is most challenging during prolonged surgical procedures or in the surgical management of multiple traumas. If tissue trauma is severe or if hemorrhage has been prolonged, patients develop a marked reduction in functional extracellular volume as a result of the internal redistribution of fluids (third-space losses). Although the extent of tissue manipulation in most routine neurosurgical procedures is small, third-space fluid losses during prolonged surgery and in patients with severe associated systemic trauma can be sufficient to decrease intravascular volume, reduce peripheral perfusion, and impair renal function. The sequestered extracellular fluid can be cautiously replaced with 0.9% saline. In the absence of diuretic therapy, a urinary output of 0.5 to 1 mL/kg/hr suggests adequate replacement, as do hemodynamic stability and cardiac filling pressures within the normal range. Hematocrit should be kept above 28%.[135]

Anesthetic Induction and Maintenance

Although induction of anesthesia for patients undergoing craniotomy can be performed with various agents, a smooth and gentle induction of general anesthesia is more important than the drug combination used. No evidence indicates that one technique or set of drugs is better than another. A reasonable induction sequence would combine preoxygenation, propofol (1 to 2 mg/kg), and a nondepolarizing muscle relaxant. No evidence suggests that any of the induction agents is superior. The hemodynamic response to intubation may be blunted with the administration of fentanyl (10 to 15 mcg/kg total dose) or lidocaine (1.5 mg/kg) administered 3 minutes before laryngoscopy. The dose of these induction agents may need to be adjusted according to the patient's age and physical status. Whatever agents are selected, the induction should be accomplished without the development of sudden hypertension or hypotension.

The head typically is elevated from 15 to 30 degrees to facilitate venous and CSF drainage. The head also may be turned to the side to facilitate exposure. Excessive neck flexion may impede jugular venous drainage and increase ICP. Because of the flexion-extension-rotation of the head in combination with head fixation in a pinion headrest, the use of an armored or reinforced endotracheal tube (ETT) is recommended to avoid kinking of the tube once positioning is accomplished. The ETT follows the position of the chin. With extension of the neck, the chin and ETT move

cephalad; with neck flexion, the chin and ETT move caudad. The anesthesia circuit connections must be firmly secured by simultaneously pushing and twisting to seat the plastic connectors. The risk of unrecognized disconnections may be increased because the operating table is usually turned 90 to 180 degrees away from the anesthetist, and both the patient and the breathing circuit are almost completely covered by surgical drapes.[98]

Maintenance of anesthesia may be accomplished with an oxygen-air-opioid technique, a selected potent inhalation agent, or oxygen-air and a continuous infusion of propofol. After endotracheal intubation, mechanical hyperventilation is begun, decreasing $ETCO_2$ to 30 to 35 mmHg, confirmed through arterial blood gas analysis. The patient should be covered with blankets or a forced-air warming blanket to maintain core body temperature.

An opioid-based anesthetic technique with air in oxygen with low-dose (less than 1%) isoflurane is a popular choice. Incremental administration of fentanyl, sufentanil, alfentanil, or an infusion of remifentanil is acceptable. Sufentanil as a 0.5 to 1 mcg/kg loading dose, followed by either incremental boluses (not to exceed 0.5 mcg/kg/hr) or an intravenous infusion of 0.25 to 0.5 mcg/kg/hr in combination with less than 1% isoflurane in oxygen may be used. Sufentanil administration should be discontinued approximately 45 minutes before the end of surgery to ensure that the patient awakens promptly. The primary advantage of remifentanil is rapid awakening. If the patient experiences hypertension or tachycardia near the end of surgery, the practitioner should consider giving either labetalol or esmolol, not additional opioids.[160]

A volatile agent (isoflurane, desflurane, or sevoflurane) with little or no opioid supplementation also can be used for maintenance of anesthesia. If isoflurane is used, the concentration should remain less than 1%. Hyperventilation in combination with less than 1% isoflurane generally results in stable intracranial dynamics.[160]

N_2O may be used in an anesthetic regimen if it is deemed desirable. However, if the patient is suspected to have a pneumocephalus or the potential for air embolism exists, N_2O use is contraindicated. N_2O expands both the pneumocephalus and the air embolus. A tension pneumocephalus acts like an expanding mass lesion. A large air embolus can cause cardiovascular collapse.[160]

Hyperventilation is an important adjunct to any neuroanesthetic technique. Hypocapnia decreases ICP before opening of the dura and attenuates the vasodilation produced by the volatile anesthetic agents. Optimal hyperventilation during surgery would yield a $PaCO_2$ of 30 to 35 mmHg. Diuretics, when indicated, may be timed just before or after the cranial vault is opened to facilitate surgical exposure.

Skeletal muscle relaxation prevents patient movement at inappropriate times. It may decrease ICP by relaxing the chest wall, decreasing intrathoracic pressure, and facilitating venous drainage. In choosing an agent for muscle relaxation, the length of the procedure and the effect of the drug on ICP should be considered.[160]

Emergence

Arguably, in no other anesthetic situation is careful attention to appropriate planning for the emergence from anesthesia as important as in neurosurgical brain tumor surgery. Sudden emergence from anesthesia can result in uncontrolled hypertension. Delirium with coughing and straining on the endotracheal tube should be avoided. In a patient with a compromised blood-brain barrier, this stormy emergence can produce devastating consequences. Late emergence from anesthesia can result in a confusing diagnostic picture with possible intracranial hematoma, acute hydrocephalus, or other diagnoses masked by the residual anesthesia.[92]

The goal for emergence is control. A controlled emergence focuses on regulation of blood pressure, ICP, and CBF. Controlled emergence also accounts for the preexisting pathophysiology, the surgical trauma, the length of the procedure, and appropriate management of the airway.[92]

Emergence from anesthesia begins when the surgical pathology has been addressed. Collaboration with the surgeon is essential. Prior to closing the dura, the appropriate levels of postoperative blood pressure can be determined. The $PaCO_2$ should be allowed to return to a normal level. Blood pressure can then be raised to 120% of the normal baseline level prior to closing of the dura. Hypertension is considered a frequent occurrence of the postoperative period.[134,161,162] Tachycardia associated with hypertension "invariably" results from emergence excitement.[163] By raising the blood pressure and the $PaCO_2$ prior to dural closure, the ability of the brain to withstand such challenges can be directly assessed by the surgeon.[92]

Once the dura has been closed, the blood pressure is maintained at baseline levels throughout the remainder of the closure.

There is strong support for the notion that sympatholytic drugs should be used to decrease blood pressure during emergence.[164] Studies have shown that during the first hour after craniotomy for supratentorial lesions, the arteriovenous oxygen content difference is low, suggesting a state of cerebral luxury perfusion.[165,166] This event coincides with a high level of mean arterial blood pressure. Accordingly, it is supposed that this correlation is caused by changes in the mean blood pressure and impaired autoregulation. This may be deleterious, because it enhances blood-brain barrier leakage, provoking edema and hemorrhage.

A relationship between hypertension and postoperative hematoma formation exists.[167] The parameters for these events for each individual patient are unknown. Normal autoregulation of CBF maintains adequate perfusion at mean blood pressures ranging from 50 to 150 torr,[168] but the effects on autoregulation of combinations of anesthetic agents over a prolonged case and under varying temperatures are unknown.[149] Labile hypertension and unstable blood pressure during the perisurgical period may contribute to intracerebral hemorrhage remote from the site of the initial neurosurgical procedure.[169] Given the evidence, and without the need to volume expand and maintain the patient in a hyperdynamic manner, it would seem prudent to institute some form of blood pressure control to provide the most controlled emergence possible.

Judicious titration of short-acting antihypertensives (esmolol, labetalol) has great clinical utility in controlling blood pressure during emergence. When access to the patient is regained, the use of anesthetic gases is discontinued, and the muscle relaxant is reversed. Intravenous lidocaine (1.5 mg/kg) can be given just before suctioning for cough suppression before extubation. Rapid awakening facilitates immediate neurologic assessment and can generally be expected after a pure opioid-N_2O technique. Delayed awakening may result from residual opioid or remaining end-tidal concentrations of potent inhalation agent. After extubation, the patient is transported to the intensive care unit postoperatively for continued monitoring of neurologic function.[164]

Awake Craniotomy

In a small percentage of patients—those in whom a seizure focus may be suppressed during general anesthesia or may be adjacent to an area of eloquent cortical function—awake craniotomy may be necessary.[170] Sources feel awake craniotomy is the most reliable method to ensure neurologic integrity in the presence of

cerebral gliomas that infiltrate or come close to the especially sensitive areas of the brain. Awake craniotomy allows for localization of eloquent cortical areas by electrical stimulation and of epileptic foci through cortical recordings. Continuous monitoring of the functional integrity of the brain in awake patients is inherently protective while surgical removal of the gliomatous tissue is performed.[171] Anesthetic techniques may vary, depending on whether the procedure is for tumor removal or seizure treatment.

Patient Selection

To minimize the risk of intraoperative complications, contraindications for awake craniotomy include developmental delay, lack of maturity, an exaggerated or unacceptable response to pain, a significant communication barrier, and a failure to obtain patient consent. Only those patients with the ability to clearly understand risks and benefits and who, in the opinion of the neurosurgeon and the anesthesia team, will cooperate during surgery should be considered as candidates for an awake craniotomy.[170] Seizure management should be optimized with acceptable levels of antiepileptic medications verified.

Patient Teaching

The single most important element in the successful awake craniotomy is a highly motivated, well-informed patient. Each step of the procedure is discussed with the patient and family. Special emphasis is paid to prolonged surgical procedure, positioning, head immobility, pain anxiety, monitoring, noise, seizure management, and any individual considerations.

Anesthesia Induction and Maintenance

Upon arrival to the holding area, an intravenous line is established. Preanesthesia medications are administered; they may include antibiotics, steroids, antiemetic prophylaxis, and anticonvulsants as indicated.

In the operating room suite, application of noninvasive monitoring is completed. Last-minute questions are addressed, and the patient is induced with propofol. Some sources use either dexmedetomidine singly or in combination with propofol.[172] After satisfactory general anesthesia is established, a laryngeal mask airway (LMA) is placed, with patient ventilation controlled using a continuous propofol infusion. Invasive monitoring is established (arterial line, central line, urinary catheter). The scalp is anesthetized with 0.5% bupivacaine and the head placed in a pinion head holder. The patient is carefully positioned with all bony surfaces padded and the patient carefully secured to the table to minimize a sense of falling when the table is moved during the awake phase of the surgery. Frameless stereotaxis registration is accomplished. Depending on the preoperative radiographic edema findings, hypertonic saline or mannitol is given. During the draping, an area is constructed around the patient's face such that the face may be clearly seen and accessed. A light is introduced under the drapes to keep the patient from darkness. During the scalp opening, spontaneous ventilation is established. Prior to the bone flap removal, the LMA is removed and verbal contact established.

Awake Phase

All sedation is stopped. All issues regarding patient comfort and concerns are addressed prior to the incision of the dura. Conversation with the patient is confined to the surgeon and one member of the anesthesia team. Stimulation of eloquent areas is carried out with results noted. Any seizures are controlled with propofol, or cold saline is available if needed.[173] Following the stimulation and mapping, volumetric surgical removal of the tumor or seizure focus is accomplished with interval monitoring. Upon completion of the surgical removal and requisite monitoring, propofol sedation may be restarted and titrated to patient preference. Sedation is discontinued upon conclusion of surgery. The most common complications associated with awake craniotomy are pain, seizures, nausea, and confusion.[174,175]

BOX 28-5

Clinical Situations Contributing to the Occurrence of Venous Air Embolism

- Patient positioning (seated, prone, steep Trendelenburg)
- Transfusion therapy
- Intravenous therapy
- Central venous catheterization
- Hepatic surgical procedures
- Urologic surgical procedures
- Posterior spinal procedures
- Epidural or caudal catheter insertion
- Bone marrow harvesting
- Laparoscopy
- Radical pelvic surgery
- Obstetric gynecologic procedures
- Thoracic procedures
- Orthopedic procedures
- Cardiac surgery
- Head and neck surgery

Posterior Fossa Surgery

Neuropathology within the posterior fossa may impair control of the airway, respiratory function, cardiovascular function, autonomic function, and consciousness. The major motor and sensory pathways, the primary cardiovascular and respiratory centers, the reticular activating system, and the nuclei of the lower cranial nerves are all concentrated in the brainstem. All of these structures are contained in a tight space with little room for edema, tumor, or blood.

Venous Air Embolus

In addition to the previously mentioned monitoring modalities, monitoring during posterior fossa surgery requires consideration of patient position and the potential for venous air embolus (VAE). Clinical situations that contribute to the occurrence of VAE are listed in Box 28-5. Air also may be entrained from the cranial pin sites of the Mayfield head holder and from improperly connected vascular lines (arterial, central, and intravenous).

The occurrence of VAE depends on the development of a negative pressure gradient between the operative site and the right side of the heart. As the gradient between the cerebral veins and the right atrium increases, the potential for air entry increases. The estimated incidence of VAE during neurosurgical procedures ranges from 5% to 50%, with an increased incidence in the sitting position.[176,177] A recent systematic review of 4806 patients undergoing sitting position neurosurgery noted a 39% rate of VAE for posterior fossa surgery and 12% for cervical procedures.[178]

As the venous pressure at wound level is usually negative, air can be entrained. This air may follow any of four pathways. Most commonly it passes through the right heart into the pulmonary circulation, diffuses through the alveolar-capillary membrane, and appears in expelled gas. It also may pass through a

pulmonary-systemic shunt such as in a patient with a patent foramen ovale (paradoxical air embolism). It may collect at the superior vena cava–right atrial junction. Lastly, rarely it may traverse through lung capillaries into the systemic circulation.[179,180]

The physiologic consequences of VAE depend on both the volume and the rate of air entrainment. In the canine model, large cumulative doses of air produce sudden cardiac arrest and death; smaller cumulative doses produce less profound physiologic consequences, including increased pulmonary artery and central venous pressure, decreased cardiac output with accompanying hypotension, progressive hypotension, and dysrhythmias.[181] Despite the potentially devastating effects of VAE, a retrospective review of neurosurgery patients who had appropriate monitoring for the detection of VAE found that VAE contributed to patient morbidity or mortality in only six instances (0.4%).[182-184]

Paradoxical Air Embolism

Paradoxical air embolism (PAE) develops with the entry of air into the systemic circulation. Individuals with an existing anatomic connection between the right and left sides of the heart (atrial or ventricular septal defect, probe-patent foramen ovale) are at risk. A patent foramen ovale may exist in 30% to 35% of the population.[185] If right-sided heart pressures exceed left-sided pressures (a situation that may occur in fluid-restricted neurosurgical patients), systemic air may embolize and enter the arterial circulation through a probe-patent foramen ovale.

Patients who require the sitting position should be carefully evaluated with echocardiograms if the history suggests the presence of an intracardiac defect (presence of heart murmur) or probe-patent foramen ovale. The presence of a probe-patent foramen ovale may be elicited with the injection of contrast material before, during, and after the patient produces a Valsalva maneuver. If the condition is identified, the surgical procedure should be accomplished in an alternative position.[186]

Detection of Venous Air Embolus

The entrainment of air into the vascular system is usually of little consequence, because the lungs serve as effective blood filters.[187] Small bubbles of air are absorbed into the blood or enter the alveoli, where they are eliminated. However, the efficient filtering capacity of the lung may be breached by a large bolus of air. Air enters the venous circulation as small bubbles that pass through the right side of the heart, entering the pulmonary arterioles. A reflexive sympathetic pulmonary vasoconstriction is produced after the release of endothelial mediators, which are ultimately responsible for the clinical manifestations (pulmonary hypertension, hypoxemia, CO_2 retention, increased dead-space ventilation, and decreased ET_{CO_2}). The continued entry of air produces an airlock within the right ventricle, producing right ventricular failure and decreased cardiac output. Altered ventilation-perfusion relationships parallel the hemodynamic changes. Obstructed pulmonary blood flow increases dead-space ventilation, resulting in decreased ET_{CO_2}. The entry of a large volume of air in the alveoli may be detected by the sudden appearance of end-tidal nitrogen. Studies indicate that entrapement of small amouts of air less than 0.5 mL/kg will manifest as a decreased ET_{CO_2} , increased end-tidal nitrogen (ETN_2), oxygen desaturation, altered mental status, and wheezing. Moderate amounts of entrapped air, approximately 0.5 to 2.0 mL/kg, will produce difficulty breathing, wheezing, hypotension, ST changes, peaked P waves, jugular venous distention, myocardial and cerebral ischemia, bronchoconstriction, and pulmonary vasoconstriction. Large quantities of air entrapement greater than 2.0 mL/kg result in chest pain, right-sided heart failure, and cardiovascular collapse.[188]

The selection of appropriate monitoring for the detection of VAE is based on the various sensitivities of the available monitoring modalities (Table 28-8).[187] Precordial Doppler monitoring can detect air entrainment at rates as small as 0.0021 mL/kg/min.[189] The Doppler probe is affixed over the right side of the heart along the right sternal border between the third and sixth intercostal spaces. Proper positioning over the right atrium is confirmed if a change in Doppler signal is elicited when a 10-mL bolus of saline is injected rapidly into a previously placed right central venous catheter.[189-191] Placement of a right atrial catheter affords the means for diagnosis and recovery of intravenous air and also reflects cardiac preload. When a right atrial catheter is placed, it is recommended that either radiographic confirmation or ECG confirmation of proper placement of the catheter tip be obtained.[191] Advantages and disadvantages of selected monitors for detection of VAE are noted in Table 28-8.

Capnography complements the capabilities of the Doppler device, because small, hemodynamically insignificant air emboli detected with the Doppler device can be differentiated from emboli that may produce arterial hypotension.

Transesophageal echocardiography (TEE) is the most sensitive method of air embolism detection, but it is also the most expensive. With TEE, it is possible to observe both cardiac contractility and air bubbles as they pass through the heart.[192] TEE is also capable of detecting PAE in the heart. The detection of a "millwheel" murmur via precordial or esophageal stethoscope is a late sign of air entrainment.

Treatment of Venous Air Embolus

Detection of VAE should prompt certain crucial steps (Box 28-6). The surgeon should be notified, and N_2O should be immediately discontinued, 100% oxygen delivered, and the right atrial catheter aspirated.[193] The surgeon should flood the surgical field with irrigation or pack the area with saline-soaked sponges. A Valsalva maneuver or bilateral compression of the jugular veins for 5 to 10 seconds increases the cerebral venous pressure and induced bleeding. The addition of positive end-expiratory pressure also slows air entry. However, 10 to 15 cm H_2O may be required to effectively elevate venous pressure when the head is elevated. The head should be lowered to decrease air entrainment. This may be accomplished by placing the operating table in Trendelenburg position. If air entrainment continues, the anesthetist should ask for an assistant. A second pair of hands allows simultaneous jugular vein compression and central catheter aspiration.[194,195]

Supportive therapy is required for hemodynamic compromise. Administration of ephedrine, 10 to 20 mg intravenously, and an intravenous fluid bolus improves the blood pressure. If these measures do not restore blood pressure, additional vasopressors (epinephrine) may be required.

Anesthetic agent and technique may influence the rate of air entrainment and the resulting physiologic consequences. The anesthetist should recall the role N_2O may play in the patient at risk for VAE, because N_2O is known to increase the volume of embolized air. Munson and Merrick[193] demonstrated that the expansion of an intravascular air bubble is proportional to the delivered concentration of N_2O. A 50% concentration doubles the initial air-bubble volume, and a 70% concentration quadruples the air-bubble volume. General endotracheal anesthesia with controlled ventilation is thought to be protective in patients experiencing VAE.

TABLE 28-8 Monitors for Detection of Venous Air Embolism

Monitor	Advantages	Disadvantages
Precordial Doppler ultrasonography	Most sensitive noninvasive monitor Earliest detector (before air enters pulmonary circulation)	Not quantitative May be difficult to place in obese patients, patients with chest wall deformity, or patients in the prone/lateral positions False-negative result if air does not pass beneath ultrasonic beam (about 10% of cases) Useless during electrocautery IV mannitol may mimic intravascular air
Pulmonary artery (PA) catheter	Quantitative, slightly more sensitive than $ETCO_2$ Widely available Placed with minimum difficulty in experienced hands Can detect right-atrial pressure greater than pulmonary capillary wedge pressure	Small lumen, less air aspirated than with right-atrial catheter Placement for optimal air aspiration may not allow pulmonary capillary wedge pressure measurement Nonspecific for air
Capnography ($ETCO_2$)	Noninvasive Sensitive Quantitative Widely available	Nonspecific for air Less sensitive than Doppler ultrasound, PA catheter Accuracy affected by tachypnea, low cardiac output, chronic obstructive pulmonary disease
End-tidal nitrogen (ETN_2)	Specific for air Detects air earlier than $ETCO_2$	May not detect subclinical air embolism May indicate air clearance from pulmonary circulation prematurely Accuracy affected by hypotension
Transesophageal echocardiography (TEE)	Most sensitive detector of air Can detect air in left side of heart, aorta	Invasive, cumbersome Expensive Must be observed continuously Not quantitative May interfere with Doppler ultrasonography

BOX 28-6

Therapy for Venous Air Embolism

- Notify surgeon on detection (flood surgical field with saline and wax bone edges)
- Discontinue nitrous oxide administration; administer 100% oxygen
- Perform a Valsalva maneuver or compression of jugular veins
- Aspirate air from atrial catheter
- Support blood pressure with volume and vasopressors
- Reposition patient in left lateral decubitus position with a 15-degree head-down tilt if blood pressure continues to decrease
- Modify the anesthetic as needed to optimize hemodynamics
- Postoperative follow-up should include ECG, chest x-ray, and arterial blood gases with oxygen as needed

ECG, Electrocardiogram.

FIGURE **28-18** Representation of a patient properly positioned for seated posterior fossa operation with the knees at heart level and the neck not hyperflexed. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1163.)

Surgical Positioning

Although most posterior fossa explorations may be performed with the patient in either the lateral or prone position, the sitting position (Figure 28-18) is occasionally preferred because the enhanced CSF and venous drainage facilitates surgical exposure. The use of this position, however, has declined dramatically because of the potential for serious complications.[196,197] The patient is semirecumbent in the standard sitting position with the back elevated to 60 degrees and the legs elevated (with the knees flexed) to the level of the heart. The latter is important for preventing venous pooling and reducing the risk of venous thrombosis. The head is fixed in a three-point head holder with the neck in flexion, and the arms remain at the sides with the hands resting on the lap.[98]

Careful positioning is essential to prevent iatrogenic injury. Pressure points such as the elbows, ischial spines, and forehead must be protected with foam padding. Excessive neck flexion has

Postoperative Considerations with Posterior Fossa Surgery

- Cranial nerve dysfunction
- Central apnea
- Loss of upper airway control and patency
- Altered level of consciousness
- Altered cardiomotor function
- Cardiac dysrhythmias

Adapted from Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2009:2073.

been associated with swelling of the upper airway (venous obstruction) and, rarely, quadriplegia resulting from compression of the cervical spinal cord and decreased cervical cord perfusion when the neck is elevated above the heart. Preexisting cervical spinal stenosis probably predisposes to the latter injury.[98]

Anesthetic Induction, Maintenance, and Emergence

Increased ICP, although common in patients with supratentorial lesions, is less common in patients with posterior fossa lesions. Obstructive hydrocephalus is more typical because CSF outflow is occluded at the level of the aqueduct of Sylvius or fourth ventricle. This can be readily identified preoperatively by magnetic resonance imaging or computed tomography and may be corrected before definitive surgical intervention with the placement of a ventricular catheter. Premedication is contraindicated in patients with obstructive hydrocephalus.

Induction should be slow and deliberate to avoid changes in cerebral perfusion and increased ICP. Because the head is generally flexed and fixed in this position, a wire-reinforced ETT may prevent intraoperative kinking. These tubes may become permanently kinked if the patient is lightly anesthetized and bites the tube. Intravenous fluid administration during posterior fossa surgery should be limited to the infusion of deficit and maintenance quantities of a balanced salt solution. Major volume resuscitation can be accomplished with the infusion of blood, colloid, or crystalloid solutions.

Emergence from anesthesia should be as smooth and gentle as possible. The intraoperative use of opioids facilitates a smooth emergence without significant coughing and bucking. The administration of lidocaine 1.5 mg/kg intravenously decreases the airway irritation of the ETT.[194]

The decision to remove the ETT should be made after the anesthetic course and surgical procedure are reviewed. Intraoperative air embolism may be followed by the development of pulmonary edema. Although this condition is self-limiting, continued mechanical ventilation is the treatment of choice. Consideration also must be given to the possibility of cranial nerve damage during the operative procedure. Provided the patient is safely extubated, continued vigilant observation is essential because airway compromise may develop after injury to cranial nerves IX, X, and XI (Box 28-7).

Pituitary Surgery

Approximately 10% of intracranial neoplasms are found in the pituitary gland and come to clinical attention because of their mass effects or the hypersecretion of pituitary hormones. These tumors are rarely metastatic and produce local symptoms via bone invasion, hydrocephalus, and compression of a cranial nerve (most often the optic nerve). Frontotemporal headache and bitemporal hemianopsia are the most common nonendocrine symptoms of enlarging pituitary lesions. Nonsecreting pituitary tumors account for approximately 20% to 50% of lesions in this area and are classified as *chromophobe adenomas*.[197,198]

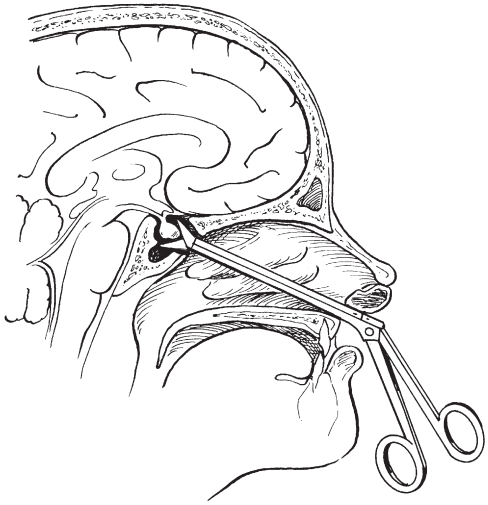

FIGURE **28-19** Transsphenoidal approach to the pituitary gland. (From Black JM, Hokanson Hawks JH. *Medical-Surgical Nursing: Clinical Management for Positive Outcomes*. 8th ed. St. Louis: Saunders. 2009:1829.)

Tumors that secrete excess growth hormone produce acromegaly. Increased growth hormone increases the size of the skeleton, particularly the bones and soft tissues of the hands, feet, and face. The enlarged facial structures may increase the likelihood of difficult intubation. Excess growth hormone also may contribute to the development of coronary artery disease, hypertension, and cardiomyopathy. Hyperglycemia is also a common finding, reflecting a growth hormone–induced glucose intolerance.[199]

Surgical Approach

Medical and surgical therapies exist for both functional and nonfunctional pituitary tumors. Transsphenoidal surgery (Figure 28-19) offers several advantages over the intracranial approach. Statistically, morbidity and mortality rates are reduced because of a decrease in blood loss and less manipulation of brain tissue. In addition, the risk of inducing panhypopituitarism and the incidence of permanent diabetes insipidus are both reduced. For patients with large tumors (greater than 10 mm), tumors of uncertain type, and tumors that have substantial extrasellar (beyond the sella turcica) extension, the transsphenoidal approach is inadequate, and a bifrontal intracranial approach is required for successful removal.[199] Current trends are moving toward endoscopic approaches to the pituitary tumor. Less invasive approaches, such as the transnasal approach combined with endoscopic resection of tumor, have been performed. The endoscopic technique entails less morbidity and a shorter hospital stay than the traditional approach.[200]

Preoperative Evaluation

Patients undergo transsphenoidal operations for the treatment of hypersecreting pituitary tumors. Clinical symptoms of pituitary tumors include amenorrhea, galactorrhea, Cushing disease, and acromegaly.

Each preoperative condition has its own constellation of systemic disorders and accompanying effects on intracranial dynamics that must be considered when an anesthetic technique is

selected. Pituitary tumors can damage decussating optic fibers, producing blindness in the temporal half of the visual field of both eyes (bitemporal heteronymous hemianopsia). Occasionally, an aneurysm of one of the internal carotid arteries may produce nasal hemianopsia on the affected side. Patients who have Cushing disease also may be affected by hypertension, diabetes, osteoporosis, obesity, and friability of skin and connective tissue. Patients who have acromegaly may have hypertension, cardiomyopathy, diabetes, and osteoporosis, as well as cartilaginous and soft-tissue hypertrophy of the larynx and enlargement of the tongue, complicating intubation of the trachea. Patients who have panhypopituitarism may exhibit hypothyroidism, requiring preoperative thyroid supplementation.

The transsphenoidal approach usually necessitates the head and back be elevated 10 to 20 degrees. The patient's head is supported by a three-point pin head holder and centered within a C-arm fluoroscopy unit for radiographic control during surgery. The patient's arms are placed at the sides and padded so that injury to the ulnar nerves is avoided. The patient's airway is shared with the surgeon; therefore, great attention must be directed to the proper securing of the ETT and anesthesia circuit to prevent unintended extubation and anesthesia-circuit disconnect. Hyperventilation is avoided after anesthetic induction, because reductions in ICP result in retraction of the pituitary into the sella, making surgical access difficult. The anesthetist should also consider the potential for massive hemorrhage, because the carotid arteries lie adjacent to the suprasellar area and may be inadvertently injured.

When the resection involves the suprasellar area, postoperative endocrine dysfunction may occur, namely, diabetes insipidus. Diabetes insipidus that occurs after most transsphenoidal procedures is usually self-limited and resolves within a week to 10 days.[196] Although the onset is usually on the first or second postoperative day, diabetes insipidus may develop during the perioperative period or in the immediate recovery period. Intraoperative diagnosis is made with the sudden onset of diuresis. The diagnosis may be confirmed with concurrent urine and serum osmolalities. If diabetes insipidus persists or if it becomes difficult to match urinary losses, the patient may receive aqueous vasopressin (Pitressin) or desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]). Intravenous DDAVP is longer acting and is not associated with the coronary vasoconstriction that follows administration of aqueous vasopressin.

Anesthetic Induction, Maintenance, and Emergence

After anesthetic induction and intubation, the ETT is typically moved to the left corner of the patient's mouth and secured to the chin with adhesive and tape. A right-angled ETT may be effective because such tubes are pre-bent and curve along the mandible when exiting the mouth. The esophageal stethoscope and temperature probe are inserted and secured on the lower left as well, leaving the upper lip totally exposed. An orogastric tube is placed, aspirated, and then put to gravity drainage during the procedure. The oropharynx is then packed with moist cotton gauze. The eyes are first taped closed and then covered with cotton-padded adhesive patches to prevent corneal abrasion and seepage of cleansing solution and blood into the eyes.

Propofol, an opioid (fentanyl, sufentanil, alfentanil, or remifentanil), and a neuromuscular relaxant (either succinylcholine or a nondepolarizing neuromuscular relaxant for intubation, followed by a selected nondepolarizing agent), with a combination of air and oxygen is a commonly used anesthetic combination for this procedure. Isoflurane may be added in low concentrations for blood pressure control; alternatively, it may be used as the primary anesthetic drug.

The topical use of cocaine and the oral and nasal submucosal injection of local anesthetic solutions containing epinephrine help constrict gingival and mucosal vessels and dissect the nasal mucosa away from the cartilaginous septum. Epinephrine use may produce hypertension or dysrhythmias or both. Cocaine interferes with the intraneuronal uptake of catecholamine and can augment both the hypertensive and dysrhythmogenic properties of epinephrine. The use of epinephrine is relatively safe if (1) ventilation is adequate, (2) epinephrine is given in combination with lidocaine instead of saline, (3) epinephrine concentrations of 1:100,000 to 1:200,000 are used, and (4) total dose does not exceed 10 mL of 1:100,000 solution in 10 minutes for a 70-kg adult. A total dose of 200 mg of cocaine should not be exceeded. Persistent dysrhythmias may require treatment with lidocaine or possibly a β-blocker. Hypertension may be controlled with an increased concentration of the selected inhalation agent or with small intravenous doses of labetalol, or esmolol.[201,202]

In some cases, it may be necessary to insert a catheter into the lumbar subarachnoid space to facilitate the injection of preservative-free saline to delineate the suprasellar margins or for prevention of CSF leak postoperatively. If air is injected, N_2O must be discontinued from the anesthetic mixture because of rapid diffusion into the air present in the closed cranial vault.[202]

Emergence from anesthesia should be conducted as described for the previously discussed procedures. Intravenous lidocaine, 1.5 mg/kg given approximately 3 minutes before suctioning and extubation, decreases coughing, straining, and hypertension. Postoperatively, patients should be responsive to commands in the recovery room. Steroid therapy is continued throughout this period and tapered over time, if appropriate.

Cerebrovascular Surgery

Cerebral Aneurysms

Interventional neuroradiology is often the approach of first choice for the management of intracranial aneurysms. Aneurysm coiling or occlusion of the proximal arteries and obliteration of the aneurysm sac is the preferred therapy for many lesions.[203] The International Subarachnoid Aneurysm Trial and subsequent studies have shown this approach to have several advantages over craniotomy with clipping although recurrence may be higher.[204]

Cerebral aneurysms are abnormal, localized dilations of the intracranial arteries. They are classified as berry or saccular, mycotic, traumatic, fusiform, neoplastic, or atherosclerotic. Rupture of a saccular aneurysm is a leading cause of subarachnoid hemorrhage (SAH).[205]

Approximately 6 million people in North America have cerebral aneurysms, with approximately 25,000 to 30,000 new cases of SAH occurring annually. The peak age for rupture of a cerebral aneurysm is 55 to 60 years. A slight female predilection also exists, with aneurysmal rupture occurring in three women for every two men.[206]

More than 40% of patients with SAH die or develop significant and lasting neurologic disabilities before they receive any treatment. A small bleed occurs in approximately 50% of patients and is often tragically ignored or misdiagnosed. Even in patients who receive prompt care, only half remain functional survivors; the remainder die or develop serious neurologic deficits.[207]

Aneurysms may arise at any point in the circle of Willis. Most aneurysms are broad based and located in the middle cerebral

TABLE 28-9 Modified Hunt and Hess Classification for Subarachnoid Hemorrhage

Score	Neurologic Finding	Mortality (%)
0	Unruptured aneurysm	0-2
1	Asymptomatic or minimal headache and slight nuchal rigidity	2-5
2	Moderate to severe headache, nuchal rigidity, but not neurologic deficit other than cranial nerve palsy	5-10
3	Drowsiness, confusion, or mild focal deficit	5-10
4	Stupor, mild or severe hemiparesis, possibly early decerebrate rigidity, vegetative disturbance	20-30
5	Deep coma, decerebrate rigidity, moribound appearance	30-40

Adapted from Cottrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia*. 5th ed. St Louis: Mosby; 2010:219.

system. Traumatic aneurysms develop as a result of direct trauma to an artery, with injury to the wall.

Mirror aneurysms of the internal carotid system are common, and other combinations of locations occur. The site of the bleeding aneurysm is best located by computed tomography studies, evidence of vasospasm in the immediate vicinity, and lobulation of the aneurysm wall on angiographic studies.[205]

Diagnosis of Subarachnoid Hemorrhage

SAH produces an abrupt, intense headache in 85% of patients, and transient loss of consciousness may be seen in up to 45% of patients. Nausea and vomiting, photophobia, fever, meningismus, and focal neurologic deficits are not uncommon. The severity of a SAH can be graded clinically with the use of classifications such as Hunt and Hess (Table 28-9). Although surgical mortality rates vary somewhat among institutions, patients with a neurologic grade I SAH generally undergo surgical clipping with a low mortality rate (less than 5%), whereas grade V patients generally do not survive.[207] Unruptured cerebral aneurysms are commonly detected on brain imaging performed for reasons unrelated to the aneurysms.[208]

General Considerations

Hypertension often accompanies acute SAH and is postulated to develop secondary to autonomic hyperactivity, which may increase transmural pressure in the aneurysmal sac. *Transmural pressure* is defined as the differential pressure between MAP and ICP and represents the stress applied to the aneurysm's wall (Figures 28-20 and 28-21).[207]

Increases in blood pressure directly increase the transmural pressure and the likelihood of bleeding; conversely, reductions in blood pressure reduce transmural pressure and may compromise perfusion. Caution should be exercised when purposefully reducing transmural pressure because cerebral autoregulation may be impaired after SAH, and a reduction in blood pressure may induce or aggravate cerebral ischemia, particularly if vasospasm is present. To balance these opposing concerns, many neurosurgeons attempt to maintain systolic blood pressure between 120 and 150 mmHg before clipping the aneurysm.[203,207]

ECG changes are common after SAH and have been reported to occur in 50% to 80% of patients. The most common changes involve the T wave or the ST segment, but other changes such as

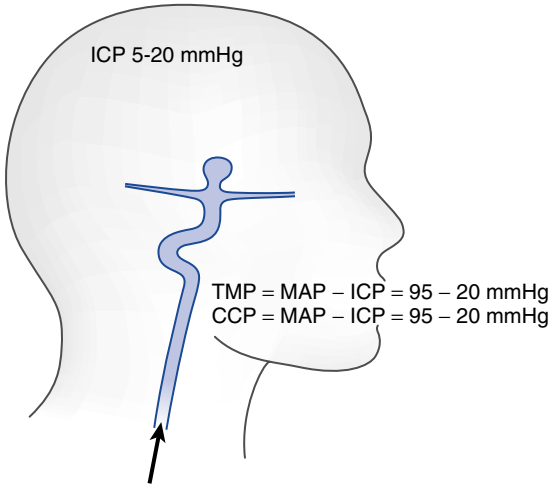

FIGURE 28-20 Determinants of transmural pressure (TMP) and cerebral perfusion pressure (CPP). Both are determined by the difference between mean arterial pressure (MAP) and intracranial pressure (ICP) and are therefore numerically identical. (From Cottrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia: Expert Consult*. 5th ed. Philadelphia: Mosby; 2010:226.)

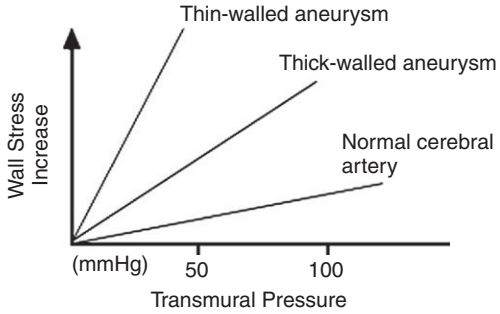

FIGURE 28-21 Aneurysm wall stress.

the presence of a U wave, QTc interval (interval corrected for heart rate) prolongation, and dysrhythmias may be present. Whether such changes in the ECG represent myocardial injury has long been debated. In the majority of patients, these changes do not appear to be associated with adverse neurologic or cardiac outcomes.[207,209]

Rebleeding from a previously ruptured aneurysm is a life-threatening complication. The incidence of rebleeding is approximately 50% in the first days after SAH, and rebleeding is associated with an 80% mortality rate.[210] The chance of rebleeding from an unsecured aneurysm declines over time; by 6 months, the risk stabilizes at approximately 3% per year. Approaches used to decrease the risk of rebleeding include early surgical clipping, the use of antifibrinolytic agents, and blood pressure control.[207,211]

Vasospasm

Cerebral vasospasm, a delayed and sustained contraction of cerebral arteries, continues to be a leading cause of morbidity and mortality in patients with SAH after aneurysm rupture.[205] Vasospasm is reactive narrowing of cerebral arteries after SAH. Approximately one in four patients who have a SAH will develop vasospasm. Although arterial narrowing may be detected with angiography in 60% of patients, only half of these patients develop clinical symptoms. The accompanying neurologic deterioration, arising from impaired cerebral perfusion, ischemia, and secondary infarction of the brain, peaks between the fourth and ninth day after SAH and resolves

over the next 2 to 3 weeks.[211] Angioplasty, either mechanical (balloon) or pharmacologic (intraarterial vasodilators), may be used as a treatment. Angioplasty ideally is done in patients who already have had the symptomatic aneurysm surgically clipped and for patients in the early course of symptomatic ischemia to prevent hemorrhagic transformation of an ischemia region. A balloon catheter is guided under fluoroscopy into the vasospastic segment and inflated to distend the constricted area mechanically. It also is possible to perform a "pharmacologic" angioplasty by direct intraarterial infusion. There is the greatest experience with intraarterial papaverine, or calcium channel blockers. Vasospasm and the ensuing delayed ischemic deficit are thought to result from several factors. Vasospasm is initiated by the release of oxyhemoglobin, one of the blood breakdown products. However, the exact mechanism of cerebral vasospasm after SAH is not completely understood. The mechanism involves multifactorial processes and chemicals such as free radicals, lipid peroxidation, and the release of endothelin-1. Past studies on vasospasm have demonstrated prolonged smooth-muscle contraction in affected arteries. Hypertrophy, fibrosis, wall degeneration, and inflammatory changes were also observed.[205,212,213]

Successful treatment of vasospasm depends on maintaining adequate CPP. This is accomplished by expanding intravascular volume (which augments blood pressure and cardiac output), avoiding hyponatremia, and preserving relative hemodilution (hematocrit approximately 32%).[213] Because of the risk of rebleeding, both hypertension and hypervolemia are used with caution in the period preceding surgical correction.

Pharmacologic vasodilation of spastic vessels has been ineffective because vasospasm involves a structural alteration in the vessel wall rather than just a spastic contracture or failure of relaxation of the smooth muscle cells in the media of the vessels. Nimodipine is commonly used to prevent vasospasm after neurologic trauma or hemorrhage. Nimodipine is the only calcium channel blocker shown to reduce morbidity and mortality from vasospasm. Various agents are being tested as means to prevent or ameliorate vasospasm, including magnesium sulfate, statins, and an endothelin antagonist.[214] Cerebral vasospasm is frequently the cause of poor outcomes after successful surgical or endovascular treatment.

Currently, the most consistently effective regimen to prevent and treat ischemic neurologic deficits due to cerebral vasospasm uses hypervolemia, hypertension, and hemodilution. It is referred to as triple-H therapy. The rationale behind induced hypervolemia and hypertension is that in subarachnoid hemorrhage, the ischemic areas of the brain have impaired autoregulation and thus CBF depends on perfusion pressure. The CBF depends on the intravascular volume and mean arterial blood pressure. Sufficient intravenous fluids are given to raise the CVP to 10 mmHg. Hypervolemia is generally achieved with infusions of colloids (e.g., 5% albumin) as well as crystalloids. Hemodilution, the last component of the triple-H therapy, has the goal of keeping the hematocrit between 27% and 30%. Hypertension often results from the fluid loading; however, vasopressors are sometimes needed. The most widely used vasopressors are dopamine, dobutamine, and phenylephrine. Hypertensive, hypervolemic therapy may induce a vagal response and profound diuresis, requiring administration of large amounts of intravenous fluids. Atropine (1 mg intramuscularly every 3 to 4 hours) may be given to maintain the heart rate between 80 and 120 beats/min, and aqueous vasopressin (Pitressin) 5 units intramuscularly may be administered to maintain the urine output at less than 200 mL/hr.

With this regimen, often only small amounts of vasopressor drugs are required. The blood pressure is titrated to a level necessary to reverse the signs and symptoms of vasospasm or to a maximum of 160 to 200 mmHg systolic in the patient whose aneurysm has been clipped. If the aneurysm has not been clipped, the systolic blood pressure is increased to only 120 to 150 mmHg. The elevated blood pressure must be maintained until the vasospasm resolves, usually in 3 to 7 days. Response to therapy can now be monitored noninvasively with transcranial Doppler (TCD). Improvement in vasospasm may be associated with a decrease in flow velocity, so angiography may be necessary.[215]

Timing of Surgery

There was debate in the past about the timing of surgical intervention. Early surgery has been shown to carry higher procedural morbidity and mortality. The presence or absence of vasospasm on angiographic studies has often been a major determinant. Nevertheless, early surgery prevents devastating rebleeding and enables aggressive hypervolemia/hypertension/hemodilution (triple-H) therapy for cerebral vasospasm. Current evidence supports that either conventional open surgery or endovascular treatment should be performed as soon as possible after the onset of subarachnoid hemorrhage (SAH) unless contraindicated. A good outcome achieved with early operation (within 24 to 48 hours) in patients who are neurologically intact (grades I or II), regardless of whether vasospasm has been demonstrated. Such emergency intervention decreases the likelihood of rebleeding. Only 53% of grade III patients achieve a good outcome after early surgery; this indicates that the gross neurologic condition preoperatively is the best prognostic indicator of intact survival.[205] In the first few days after hemorrhage, the brain is swollen, soft, hyperemic, and prone to contusion and laceration. Practice was guided for many years by The International Cooperative Study on the Timing of Aneurysm Surgery. This multicenter study demonstrated that SAH patients who underwent surgery on posthemorrhage days 4 to 10 had worse outcomes than patients treated on days 0 to 3 and days 11 to 14. It was concluded that patients who present with SAH on days 4 to 10 should have aneurysm surgery delayed until after day 10. Since the introduction of interventional neuroradiology techniques, practitioners have come to believe that coiling of ruptured aneurysms can be performed safely on patients who arrive on posthemorrhage days 4 to 10, and treatment need not be delayed until after day 10, as the results of the Timing of Aneurysm Surgery Study initially suggested.[210,216]

Impaired autoregulation may decrease cerebral tolerance to brain retraction. Although removal of a subarachnoid clot probably decreases the incidence and severity of delayed arterial narrowing, clearly, operative management may be hazardous. In more severely injured patients (grades III through V), surgery is often delayed in anticipation of resolution of vasospasm and improvement in neurologic status.[205,210,216] Currently, most neurovascular surgeons elect to operate within 3 or 4 days of the bleed in good-grade patients to minimize the chances of a devastating rebleed.[217,218]

As mentioned above, endovascular coiling has been used increasingly for treating SAH secondary to aneurysm rupture.[204,219-221]

Preoperative Evaluation

The baseline neurologic status must be ascertained. The level of consciousness may vary from perfect alertness to deep coma and is an important prognostic factor for the postoperative state. Evidence of increased ICP should be elicited preoperatively so it can be managed appropriately. Focal motor and sensory signs may indicate intracerebral extension of SAH, vasospasm, or cerebral edema.[207]

Pulmonary complications, such as pneumonia, neurogenic pulmonary edema, and atelectasis, are not uncommon. Patients often have an increased risk of aspiration because of their depressed level of consciousness, and measures should be taken to reduce gastric

acidity and volume preoperatively. The use of prophylactic hypervolemia also increases the likelihood of pulmonary edema.[207]

The hemodynamic status of the patient should be assessed, with particular attention paid to the relationship between neurologic deterioration and blood pressure changes. Continuous arterial blood pressure monitoring is essential. Serious dysrhythmias or evidence of ventricular dysfunction should be diagnosed preoperatively so appropriate monitoring and management can be instituted.[222]

The syndrome of inappropriate antidiuretic hormone and diabetes insipidus can occur in patients with subarachnoid hemorrhage.

The presence of blood in the subarachnoid space may produce a 1° C to 2° C elevation of body temperature. Temperature elevation increases cerebral oxygen requirements and therefore should be treated to prevent an increase of cerebral ischemia.[207,211,223]

Preoperative sedation is rarely necessary in these patients. Depression of ventilation associated with opioids and benzodiazepines may result in hypercapnia, with resultant increases in CBF and ICP. Additionally, the reduced level of consciousness preoperatively and postoperatively may make clinical assessment difficult. Preoperative anxiety is not a problem in patients with a depressed level of consciousness (grades III through V), so sedation is not required. In awake patients, a reassuring preoperative visit usually allays anxiety. If preoperative sedation is considered necessary, the best choice is probably a small dose of a benzodiazepine (midazolam), with continued observation after its administration.[224-226]

Anesthetic Induction, Maintenance, and Emergence

Maintaining adequate intravascular volume requires two large-bore intravenous cannulas. Intraoperative monitoring includes continuous ECG (V_5), arterial pressure monitoring, peripheral nerve stimulator, central venous pressure monitoring, EEG, ET_{CO_2} monitoring, pulse oximetry, and monitoring of temperature and fluid balance.[227]

Intraoperative neurophysiologic monitoring during intracranial aneurysm surgery is standard practice. It is an important adjunct to surgical inspection and intraoperative angiography to detect cerebral ischemia. Somatosensory evoked potentials (SSEPs), particularly median and posterior tibial nerve SSEPs, are commonly monitored during anterior circulation procedures. Dural monitoring with SSEPs and brainstem auditory evoked responses (BAERs) are preferred for posterior circulation and aneurysm surgeries. There is a significant correlation between alterations in electrical signals and regional cerebral blood flow (rCBF), with transient electrophysiologic changes generally corresponding to good outcomes and permanent changes corresponding to postoperative deficits. Electroencephalography (EEG) is also commonly used. Prior to temporary clip application, the neuroanesthesia team titrates brain protective anesthetics to achieve burse suppression on EEG. Burst suppression helps decrease metabolic demand so that the cerebral tissue can better tolerate induced ischemia such as during temporary clipping.[25]

The anesthetic induction should be slow and deliberate. The anesthetic depth should be sufficient to avoid the hypertensive responses that accompany laryngoscopy and endotracheal intubation. Anesthesia is induced with titrated doses of propofol. The addition of an opioid (5 to 10 mcg/kg of fentanyl or 1 to 2 mcg/kg of sufentanil) and intravenous lidocaine (1.5 mg/kg) further blunts the patient's response to the sympathetic stimulation of laryngoscopy and intubation. An additional dose of opioid or propofol is required for the placement of the three-point pin head holder. Prior injection of local anesthetic minimizes the associated sympathetic stimulation. Epinephrine should not be included with the local anesthetic because delayed absorption (up to 30 minutes after injection) may produce significant increases in blood pressure. Isoflurane may be introduced after hyperventilation before laryngoscopy to increase the depth of anesthesia. Ventilation is controlled with administration of 100% oxygen to achieve a Pa_{CO_2} of 35 to 40 mmHg with normal intracranial compliance. Mild hyperventilation (Pa_{CO_2} of 30 to 35 mmHg) is instituted when intracranial compliance is impaired.[207]

Succinylcholine produces moderate increases in ICP.[228-230] Elevation of serum potassium sufficient to produce lethal dysrhythmias has been reported in comatose, nonparetic, head-injured patients and in patients after SAH who received succinylcholine. Alternatively, intubation can be accomplished with 1 mg/kg of rocuronium.

The patient is placed in one of several positions, depending on the site of the aneurysm. Aneurysms that arise from the anterior part of the circle of Willis require that the patient be supine for a frontotemporal approach. The lateral position for a temporal approach is required for aneurysms that arise from the posterior aspect of the basilar artery. Aneurysms that arise from the vertebral artery or from the lower basilar artery require a sitting or prone position for a suboccipital approach. Aneurysms that arise from the anterior communicating artery are usually approached from the right and those from the middle cerebral and posterior communicating arteries are approached from the side on which the aneurysm is located.[231]

Anesthesia is maintained with air and oxygen or N_2O in oxygen, with incremental titrated dosages of an opioid (fentanyl, alfentanil, or sufentanil), or an infusion of remifentanil and a muscle relaxant. Isoflurane also may be added in inspired concentrations not to exceed 1%. Patients who have intracranial aneurysms may require induced hypertension or hypotesion to rebleeding and counteract vasospasm.[232] In addition, controlled hypotension is commonly used intraoperatively to make aneurysms softer and more pliable at the time of clipping, as well as to minimize blood loss if aneurysmal rupture occurs at this time.[209] Sodium nitroprusside and an inhalation anesthetic agent are the drugs most widely used for induction or hypotension.[232]

The safe limit of controlled hypotension has not been definitively established. Because autoregulation is maintained to a MAP of 50 to 60 mmHg, some argue that this limit should not be exceeded. In addition, because patients with poor-grade aneurysms may not have intact autoregulation, some argue that a lower limit of 60 mmHg should be adopted. Limits of autoregulation are shifted to higher pressures in patients with preexisting hypertension, so decreases in MAP should probably be limited to no more than 40% of preoperative values.[207]

Rather than induce hypotension to facilitate clip ligation of the neck of the aneurysm, many neurosurgeons now routinely use temporary proximal occlusion of the parent vessel.[233]

The use of mild intraoperative hypothermia has been advocated for cerebral protection during periods of temporary occlusion.[234] Deliberate mild hypothermia was first used in 1955 as an intraoperative technique to ameliorate new neurologic deficits after cerebral aneurysm clipping. Subsequently, it was also used after neonatal asphyxia, head trauma, and cardiac arrest. The Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST II) was a randomized, control trial designed to evaluate the effectiveness of mild hypothermia in decreasing neurologic deficits after aneurysm surgery. Intraoperative hypothermia did not improve the neurologic outcome after craniotomy among good-grade patients with aneurysmal subarachnoid hemorrhage.[235]

At the conclusion of the anesthetic procedure, patients with good-grade aneurysms may be extubated in the operating room, although care must be exercised so that coughing, straining,

hypercarbia, and hypertension are avoided. Propofol, lidocaine, or small doses of fentanyl may be used for short-term anesthesia as the procedure is being finished and for reducing the hemodynamic responses to extubation. Although the residual depressant effects of opioids may be reversed with judicious titrated dosages of naloxone, larger doses of naloxone can be hazardous in that they may cause sudden, violent awakening of the patient and marked increases in systemic blood pressure. Endotracheal tubes should be retained in patients with poor-grade aneurysms and in those who have had intraoperative complications; these patients will probably require postoperative ventilation.[211]

Postoperative Care

Postoperative care is directed at the prevention of vasospasm via the maintenance of intravascular volume expansion and moderate hypertension (MAP of 80 to 120 mmHg). Changes in the level of consciousness and development of focal neurologic deficits are usually early signs of vasospasm. These clinical signs should be aggressively managed with hypertension, hypervolemia, and hemodilution. Dopamine may be used for blood pressure support. Computed tomography should be used for ruling out other causes of neurologic deterioration, including rebleeding, infarction, and hydrocephalus.[211]

Aneurysmal Rupture

Intraoperative aneurysmal rupture can be catastrophic. An abrupt increase in blood pressure during or after induction of anesthesia may indicate that an aneurysm has bled. The use of 1 to 2 mg/kg of propofol or 0.5 to 1 mcg/kg of sodium nitroprusside decreases the transmural pressure of the aneurysm, although hypotension can be detrimental at this juncture. Intraoperative aneurysmal rupture necessitates maintaining the MAP between 40 and 50 mmHg or lower to facilitate surgical control of the neck of the aneurysm or the parent vessel. Alternatively, one or both carotid arteries may be compressed for up to 3 minutes to produce a bloodless field. Blood that is lost should be continuously replaced with blood, blood products, or colloid solution so that intravascular volume is maintained.[211]

Although barbiturates have been used for protection against focal cerebral ischemia, their efficacy has not been demonstrated in this clinical situation.[236]

Interventional Neuroradiology

Treatment of aneurysms by an interventional neuroradiology procedure presents some special anesthestic considerations. These include maintaining immobility during procedures to facilitate imaging, rapid recovery from anesthesia at the end of procedures to facilitate neurologic examination and monitoring, or to provide for intermittent evaluation of neurologic function during procedures, managing anticoagulation, treating and managing sudden hemorrhage or vascular occlusion, manipulating systemic or regional blood pressures, and guiding the management of the patients during transport to and from the radiology suites. Both general and intravenous sedation are used; however, general anesthesia is preferred because the procedures can be long and manipulation of blood pressure and respiration may be necessary. The patient is prepared in a manner similar to that for open intracranial aneurysm clipping. Anesthesia considerations and management are also the same; however, if an intracranial emergency occurs during the procedure, several steps should be taken. Box 28-8 outlines the management of intracranial emergencies.[203] Anesthetic considerations for select interventional neuroradiology procedures are noted in Table 28-10.

BOX 28-8

Management of Intracranial Catastrophes*

Initial resuscitation

- Communicate with endovascular therapy team
- Assess need for assistance; call for assistance
- Secure the airway; ventilate with 100% O_2
- Determine whether problem is hemorrhagic or occlusive (see text)
  - *Hemorrhagic:* Immediate heparin reversal (1-mg protamine for each 100 units of heparin given) and low normal mean arterial pressure
  - *Occlusive:* Deliberate hypertension, titrated to neurologic examination, angiography, or physiologic imaging studies; or to clinical context

Further resuscitation

- Head up 15° degrees in neutral position, if possible
- $Paco_2$ manipulation consistent with clinical setting, otherwise normocapnia
- Mannitol 0.5 g/kg, rapid IV infusion
- Titrate IV agent to electroencephalogram burst suppression
- Passive cooling to 33°-34° C
- Consider ventriculostomy for treatment or monitoring of increased ICP
- Consider anticonvulsants (e.g., phenytoin or phenobarbital)

From Lee CZ, Young WL. Anesthesia for endovascular neurosurgery and interventional neuroradiology. Anesthesiol Clin. 2012 Jun; 30(2):127-47.

*These are only general recommendations and drug doses that must be adapted to specific clinical situations and in accordance with a patient's preexisting medical condition. In some cases of asymptomatic or minor vessel puncture or occlusion, less aggressive management may be appropriate.

ICP, Intracranial pressure.

Arteriovenous Malformation

Arteriovenous malformations are congenital intracerebral networks in which arteries flow directly into veins. Patients with these malformations generally are younger than those with aneurysms. They may have bleeding or seizures or, less commonly, ischemia resulting from "steal" from normal areas or occurring with high-output congestive heart failure. The anesthetic problems parallel those associated with patients undergoing aneurysm surgery. Notably, arteriovenous malformations do not autoregulate their blood flow. The operation is likely to be longer and bloodier than that of aneurysm clipping. Surgery may be preceded by an attempt at embolization by the neuroradiologist to diminish the risk of surgery. The neurologic examination should be repeated after embolization to document new deficits that otherwise might be attributed to anesthesia and surgery.

Head Trauma

Head injuries are a contributory factor in up to 50% of deaths resulting from trauma. Most patients with head trauma are young, and many (10% to 40%) have associated intraabdominal injuries, long-bone fractures, or both. The significance of a head injury is dependent not only on the extent of the irreversible neuronal damage at the time of injury but also on the occurrence of any secondary insults. Additional insults include systemic factors such as hypoxemia, hypercapnia, and hypotension; the formation and expansion of an epidural, subdural, or intracerebral hematoma; and sustained intracranial hypertension (Box 28-9). Studies suggest that sustained increases in ICP of approximately 60 mmHg result in irreversible brain edema. Surgical and anesthetic

TABLE 28-10 Interventional Neuroradiologic Procedures and Primary Anesthetic Considerations

Procedure	Possible Anesthetic Considerations
Therapeutic embolization of vascular malformation	
Intracranial AVMs	Deliberate hypotension, postprocedure NPPB
Dural AVM	Existence of venous hypertension; deliberate hypercapnia
Extracranial AVMs	Deliberate hypercapnia
Carotid cavernous fistula	Deliberate hypercapnia, postprocedure NPPB
Cerebral aneurysms	Aneurysmal rupture, blood pressure control*
Ethanol sclerotherapy of AVMs or venous malformations	Brain swelling, airway swelling, hypoxemia, hypoglycemia, intoxication from ethanol, cardiorespiratory arrest
Balloon A&S of occlusive cerebrovascular disease	Cerebral ischemia, deliberate hypertension, concomitant coronary artery disease, bradycadia, hypotension
Balloon angioplasty of cerebral vasospasm secondary to aneurysmal SAH	Cerebral ischemia, blood pressure control*
Therapeutic carotid occlusion for giant aneurysms and skull base tumors	Cerebral ischemia, blood pressure control*
Thrombolysis of acute thromboembolic stroke	Postprocedure ICH (NPPB), concomitant coronary artery disease, blood pressure control*
Intraarterial chemotherapy of head and neck tumors	Airway swelling, intracranial hypertension
Embolization for epistaxis	Airway control

St. Louis: Saunders; 2009:1934-1936.)

management of these patients is directed at preventing secondary insults.[98] Types of cerebral hematomas and mechanisms of head injuries are illustrated in Figure 28-22.

Preoperative Management

Emergency therapy for head injury should begin before hospital admission, because a large proportion of deaths occur in the prehospital phase. Therapy is based on prevention of secondary brain injury resulting from hypoxia, hypercapnia, hypotension, and expanding intracranial masses.

Airway Management

Measures to ensure airway patency, adequacy of ventilation and oxygenation, and the correction of systemic hypotension should be instituted simultaneously with neurologic evaluation. Airway obstruction and hypoventilation are common. Up to 70% of head-injured patients have concurrent hypoxemia, which may be complicated by pulmonary contusion, fat emboli, or neurogenic pulmonary edema. All patients must be assumed to have a cervical spine injury (10% incidence) until disproved by radiography. Axial traction to maintain the head in a neutral position should be used during airway instrumentation. Fiberoptic intubation may be preferred for airway management in some cases. Patients with obvious hypoventilation, absence of the gag reflex, or a persistent total score below 7 on the Glasgow Coma Scale (see Table 19-5) require tracheal intubation and hyperventilation. A modified coma scale for infants is given in Table 28-11 and outlines response patterns seen after neurologic injuries. All other patients

TABLE 28-11 Modified Coma Scale for Infants

Response	Score

Withdraws to pain	4
Abnormal flexion	3
Abnormal extension	2
None	1

should be carefully observed for deterioration. Table 28-12 summarizes respiratory patterns seen with various neurologic injuries. The Glasgow Coma Scale score generally correlates well with the severity of injury and outcome.[98]

When intubation is indicated, the oral route provides the most efficient means of safely securing the airway. Whenever possible, a modified, rapid-sequence endotracheal intubation should be performed; that is, it should be preceded by a period of 100% oxygen administration and hyperventilation supplemented by continuous cricoid pressure.[237-239] Nasal intubation should be avoided in the presence of suspected basilar skull fracture, bleeding diathesis, suspected upper-airway foreign body, or severe facial fractures.[237] If a difficult intubation is anticipated, awake intubation, fiberoptic techniques, or tracheostomy may be necessary.

Cardiovascular Assessment

Multisystem trauma often accompanies head injury. Hypotension results from intravascular loss from associated injuries. These injuries must be identified and treated early in the resuscitative period. Fluid resuscitation is facilitated by the administration of isotonic fluid, either normal saline or lactated Ringer's solution, or colloids if blood is not readily available. Glucose in water should not be used because it decreases serum osmolarity and can aggravate cerebral swelling. The ideal replacement fluid, of course, is blood. Because the cerebral vessels are already dilated from hypotension, rapid restoration of the normal arterial pressure precipitates brain swelling. It is extremely valuable to insert an ICP monitor during resuscitation for the monitoring of both systemic arterial pressure and ICP.[235] Dysrhythmias and ECG abnormalities in the T wave, U wave, ST segment, and QT interval are common after head injuries but are not necessarily associated with cardiac injury.[98] Some guidelines for blood pressure management in select neurosurgical emergencies are noted in Table 28-13.

Coagulopathies

Chronic Subdural Hematoma. Bridging veins run between the dura and the surface of the brain. A subdural hematoma develops when these veins tear and leak blood, usually as the result of a head injury. A collection of blood then forms over the surface of the brain. In a chronic subdural collection, the problem is not discovered immediately, and blood leaks from the veins slowly over time. A subdural hematoma is more common in the elderly because normal brain shrinkage occurs with aging that stretches and weakens the bridging veins. Thus these veins are more likely to break in the

TABLE 28-12 Respiratory Patterns with Head Trauma

Pattern	Description	Location of Injury and Other Causes
Cheyne-Stokes respiration	Regular increase in the rate and depth of breathing that peaks and is followed by a decreasing rate and depth of breathing, which progresses to apnea; then the cycle repeats itself	Bilateral dysfunction of cerebral hemispheres Midbrain and upper pons
Central neurogenic hyperventilation	Deep, rapid, and regular pattern of breathing	Low midbrain and upper pons Increased intracranial pressure with head trauma
Apneusis breathing	A pause at full inspiration occurs; may see prolonged inspiratory pause alternating with prolonged expiratory pause	Mid and low pons Hypoglycemia, anoxia, and meningitis
Cluster breathing	Periodic breathing with frequent apneic episodes	Low pons and high medulla
Ataxic breathing	Irregular breathing with shallow, deep respirations and irregular apneic episodes; usually slow	Medulla

TABLE 28-13 Guidelines for Blood Pressure Management in Common Neurologic Conditions

Diagnosis	Recommendation
Acute ischemic stroke	Keep <180/110 mmHg if thrombolysis Treat only BP >220/120 if no thrombolysis
Intracerebral hemorrhage	Keep SBP <180 and MAP <130 mmHg (ideal SBP <160 and MAP <110 mmHg)
Subarachnoid hemorrhage	Keep SBP <160 mmHg before aneurysm treated Do not lower BP after aneurysm treated
Traumatic brain injury	Keep adequate MAP to maintain CPP >60 mmHg

elderly, even after a minor head injury. Rarely, a subdural hematoma can occur spontaneously. Risks include head injury, old age, chronic use of aspirin or antiinflammatory drugs such as ibuprofen, anticoagulant medication, chronic heavy alcohol use, or many diseases associated with blood-clotting problems.[240]

A recent study of 713 emergency referrals documented over 90 days evaluated the effect of antithrombotic therapy on neurosurgical emergency referral. Of the 713 patients, 174 (24.4%) were discovered to have intracranial or spinal hemorrhage, and 75 (43.1%) of these were on antithrombotic therapy. Seventeen of the 75 (22.6%) had no documented indication for antithrombotic therapy (all of these were on aspirin therapy), and 9 of the 29 on warfarin (31%) had an INR (international normalized ratio [prothrombin time]) in excess of 3.5 on presentation.[241]

The key elements in dealing with coagulation abnormalities in patients presenting for emergent/urgent neurosurgery are (1) identify the coagulopathy, (2) implement a plan that allows for optimum coagulation status given the comorbidities of the patient, and (3) time the period of optimum coagulation to coincide with the conclusion of surgery and the immediate postoperative period.

The coincidence of coagulopathy and chronic subdural hematoma requires correction of coagulation to facilitate surgery.[242] Forty-two percent of 114 patients presenting for drainage of chronic subdural hematoma were found to have coagulation disorders before surgery. Addressing coagulopathies in the geriatric population is a situation best addressed by a multidisciplinary approach. The primary problem in this population has to do with limited vascular space that may not be able to accommodate the volume of blood products necessary for reversal in an urgent/emergent fashion. For example, studies suggest that 10 to 17 mL/kg of fresh frozen plasma is necessary to reverse coumadin toxicity.[243]

This may not be a reasonable option in the face of imminent surgery. The Mayo Clinic asked seven experts on clinical stroke, neurologic intensive care, and hematology to address three scenarios for dealing with reversal of warfarin in patients with intracranial hemorrhage. All experts agreed that anticoagulation should be urgently reversed, but how to achieve it varied from the use of prothrombin complex concentrates only (three experts), to recombinant factor VIIa only (two experts), to recombinant factor VIIa along with fresh frozen plasma (one expert), to prothrombin complex concentrates and fresh frozen plasma (one expert).[244] Although a universally accepted treatment remains to be identified, the options available provide anesthesia providers with a number of options for treating warfarin toxicity that limit the fluid loads associated with fresh frozen plasma.

The broadening use of recombinant factor VIIa in treating active or impending bleeding in brain injury has led some to conclude that the compartmentalized mode of action of recombinant factor VIIa, along with its good safety profile and Intracerebral Hemorrhage Trial results, provide encouraging data to justify its off-label use in selected patients in the presence of any coagulopathy.[245]

Reversal of clopidogrel, aspirin, or aspirin plus clopidogrel may be addressed by platelet administration. Alternatively, recombinant factor VIIa has been shown to reverse the inhibitory effects of aspirin or aspirin plus clopidogrel and could be useful for bleeding complications or when acute surgery is needed during treatment with these antiplatelet drugs.[246]

Severe brain injury initiates the outpouring of tissue thromboplastin and activation of the complement system, causing disseminated intravascular coagulopathy and fibrinolysis and precipitating the development of adult respiratory distress syndrome. Early recognition of abnormal prothrombin and partial thromboplastin times is crucial. Prompt therapy with fresh frozen plasma, cryoprecipitate, whole blood, and if necessary, platelets may abort the development of disseminated intravascular coagulopathy.[239,240]

Increased Intracranial Pressure

The clinical appreciation of elevated ICP is difficult in unconscious patients. Therefore, initial therapy is directed toward lowering ICP or at least toward preventing further increases in ICP. Simple maneuvers such as using a head-up tilt of 15 to 20 degrees to keep the head in the midline position and not rotated to either side (to ensure jugular vein patency), avoiding overhydration, maintaining normovolemia, and maintaining normal (rather than increased) arterial pressure all help control ICP.[238]

In patients in whom intracranial hypertension is suspected, whether from an epidural or subdural hematoma or from diffuse brain swelling, emergency treatment directed at reducing ICP is the rational course. Ideally, a definitive study for identifying the cause of clinical deterioration is performed before therapy. The first and most rapidly effective therapy is hyperventilation. In a patient with multiple trauma and reduced blood volume, care must be taken during controlled ventilation to avoid increasing the intrathoracic pressure, decreasing venous return, and producing secondary hypotension. Corticosteroids (dexamethasone or methylprednisolone) are of little benefit and likely are detrimental in trauma, and these drugs must not be relied on to lower the ICP rapidly.[247]

Although mannitol effectively lowers the ICP minutes after administration, its use remains controversial. The drug is indicated, however, when either elevated ICP or a mass and herniation are responsible for the patient's deteriorating state. The risk of increasing the size of a hematoma is negligible compared with the disastrous effects of untreated progressive uncal herniation. If decompression of transtentorial herniation is delayed, secondary hemorrhage into the brainstem can occur and cause irreversible neurologic deficit. Once mannitol is given and the ICP is reduced, the specific intracranial disorder must be identified as soon as possible if a recurrence of the patient's deterioration is to be prevented.[247]

Animal and human studies have demonstrated that hypertonic saline has clinically desirable physiologic effects on CBF, ICP, and inflammatory responses in models of neurotrauma.[248] Some studies suggest that 23.4% hypertonic saline is a safe and effective treatment for elevated ICP in patients after traumatic brain injury.[249,250]

Mannitol therapy for raised ICP may have a beneficial effect on mortality when compared with pentobarbital treatment, but a detrimental effect on mortality when compared with hypertonic saline in treating increased ICP in head-injury patients.[251]

Neurodiagnostic Evaluation

The choice between operative and medical management of head trauma is based on radiographic and clinical findings. Patients should be stabilized before any computed tomography or angiographic studies are performed. Critically ill patients should be closely monitored during such studies. Restless or uncooperative patients may require general anesthesia if these diagnostic examinations are to be accomplished. Sedation without control of the airway should be avoided because of the risk of further increases in ICP from hypercapnia or hypoxemia. In the event of neurologic deterioration before completion of these studies, intravenous administration of mannitol should be considered.[98] Reductions of $Paco_2$ levels may, by decreasing CBF, allow better angiographic studies. The introduction of computed tomography and MRI has greatly facilitated neuroradiologic diagnosis. Serial computed tomography is an aid in predicting the outcome of patients with severe head injury. New findings after the initial study are associated with poorer outcomes.[252]

Intraoperative Management

Operative treatment is reserved for depressed skull fracture, depressed fractures associated with underlying brain injury, and evacuation of epidural, subdural, and some intracerebral hematomas.[253]

Monitoring during anesthesia is generally similar to that for other mass lesions associated with intracranial hypertension. Intra-arterial and central venous (or pulmonary artery) pressure monitoring should be established if it is not already present, but it should not delay surgical decompression in a rapidly deteriorating patient.[98,240]

Anesthetic Induction, Maintenance, and Emergence

Intubation must be accomplished as expeditiously as possible with the use of small, incremental doses of propofol, rocuronium (assuming the airway can be instrumented), lidocaine, and labetalol (as needed for the treatment of systemic hypertension), with concurrent cricoid pressure. Hyperkalemia may be induced with succinylcholine in a patient with closed-head injury without paresis; therefore, use of this drug should be avoided.[254] Intracranial damage is usually associated with hypertension. The true state of hydration may be realized for the first time after induction, when catastrophic hypotension may occur if fluid replacement is inadequate or barbiturate dosage is excessive.

Ventilation should be controlled. A $Paco_2$ of 25 to 30 mmHg promotes brain relaxation for surgical exposure without producing ischemia from hypocapnic vasoconstriction. A higher $Paco_2$ (30 to 35 mmHg) is recommended for patients who require burr holes for evacuation of chronic subdural hematomas, particularly after decompression, because a slack brain may encourage recurrence.[253]

If the patient is unconscious in the absence of a drug overdose, the ICP is probably elevated. In this case, a barbiturate and an opioid in combination with oxygen (or air in oxygen) and a muscle relaxant are appropriate. A similar technique is indicated in the patient who has a computed tomography scan that demonstrates obliteration of basal cisterns, dilation of the fourth or lateral ventricles, or a midline shift of 10 mm.[253]

Although hyperventilation attenuates the increase in ICP when inhalation anesthetics are used, in patients with head injury, cerebral vasoconstriction in response to hypocapnia is not a dependable indicator. The introduction of inhalation agents in such patients may increase ICP and exacerbate the formation of edema. The administration of inhalation anesthetics in low inspired concentrations may have a role in the treatment of intraoperative hypertension.[253]

Patients who have chronic subdural hematoma and are alert and responsive may have burr holes placed for evacuation of accumulated blood under local anesthesia with sedation. Depressed skull fractures also may be elevated while the patient is awake and under local anesthesia with sedation. This technique must be used cautiously when the patient placed in the three-point pin head holder has a full stomach.[253]

Fluid replacement should be accomplished with glucose-free solutions. Hypovolemia results in systemic hypotension, an unstable anesthetic course, and (by decreasing cerebral oxygen delivery) increased cerebral vasodilation. Rheologic conditions are optimal at hematocrit levels of 30% to 32%.[239]

The decision of whether to extubate the trachea at the conclusion of the surgical procedure depends on the severity of the injury, the presence of concomitant abdominal or thoracic injuries, preexisting illnesses, and the preoperative level of consciousness. A recent study noted that up to 54.5% of patients had an adverse event after surgery.[254] Occurrence of nausea, vomiting, and respiratory and cardiac problems was significantly more likely than in patients undergoing routine surgical procedures. Young patients who are conscious preoperatively may be extubated after the removal of a localized lesion, whereas patients with diffuse brain injury should remain intubated. Moreover, persistent intracranial hypertension requires continued paralysis, sedation, hyperventilation, and possibly a pentobarbital infusion postoperatively.[98]

SUMMARY

Anesthesia management of the neurosurgical patient continues to be one of the most challenging clinical issues encountered by the nurse anesthetist. Advances in surgical approaches to tumors, vascular lesions, and trauma necessitate constant reappraisal of the important role of anesthesia care in improving a patient's long-term outcome. Intraoperative monitoring modalities new to neurosurgical procedures remain to be definitively evaluated. Interventional radiologic approaches are now a primary therapy for several neurologic disorders, and anesthesia management presents many new challenges in caring for these patients. As clinical practice evolves, it is both exciting and satisfying to meet the demands of this area of anesthesia practice.

Renal Anatomy, Physiology, Pathophysiology, and Anesthesia Management

CHAPTER 29

◆ *Joanne Donnelly and Sandra Maree Ouellette*

The kidneys are paired organs that lie retroperitoneally on both sides of the vertebral column. They function to excrete the end products of bodily metabolism and thereby control the concentration of constituents of body fluids. A rich blood supply to these vital organs, coupled with the physiologic processes of filtration, reabsorption, secretion, and excretion, maintains homeostasis of the fluid that bathes each cell. For management of anesthetized patients to be optimal, clinicians must be familiar with physiologic mechanisms that allow the kidneys to control the body's intracellular and extracellular environments.

This chapter addresses the effect of anesthesia and surgery on both the normal and the diseased kidney. After a discussion of the anatomic structure and physiologic mechanisms of the kidney, the effects of anesthesia on normal renal function are addressed. Pathophysiologic mechanisms associated with acute and chronic renal failure follow. Preoperative renal assessment and anesthetic considerations for patients with impaired renal function are emphasized, and pertinent anesthetic considerations for common urologic procedures are identified.

STRUCTURE OF THE KIDNEY

The kidneys are bean-shaped, reddish-brown organs located in the posterior part of the abdomen on both sides of the vertebral column (Figure 29-1). These organs extend from the 12th thoracic vertebra to the 3rd lumbar vertebra; each weighs approximately 125 to 170 g in men and 115 to 155 g in women. Each kidney is about 11.25 cm long, 5 to 7.5 cm wide, and 2.5 cm thick. The right kidney's position is slightly lower than the left because of hepatic displacement. The kidneys and their vessels are embedded in fatty tissue (perirenal fat) and enclosed in renal fascia. Renal fascia and large vessels hold the kidneys in position (see Figure 29-1).

The anterior and posterior surfaces, upper and lower poles, and lateral margin of the kidney have convex contours. The medial margin is concave because of the presence of the hilus (recessed fissure). Structures that enter or leave the kidney through the hilus include the renal artery and vein, nerves, lymphatics, and ureters.

A longitudinal section of the kidney reveals two distinct regions—the outer cortex and the inner medulla (Figure 29-2). The medulla is divided into 8 to 18 triangular wedges called *pyramids*. The base of each pyramid is directed toward the renal cortex, and the apexes converge toward the renal pelvis. Pyramids have a striated appearance because they contain the loop of Henle and collecting ducts of the nephron. The apex of each pyramid, called the *papilla*, is composed of many collecting ducts, and those papillary ducts empty into a cup-shaped structure known as the *minor calyx*. Several minor calyces join to form major calyces, which come together as the renal pelvis. The renal pelvis is the major reservoir for urine. Ureters connect the renal pelvis to the bladder. [1]

Nephron

The functional unit of the kidney is the nephron. Approximately 1,250,000 of these units are present in each kidney. The shape of the nephron is unique, unmistakable, and admirably suited for its function. Each area of the nephron is selective with regard to its performance. Nephrons hold the filtrate that has been filtered from the blood. End products of metabolism are excreted, and metabolically important substances such as water are reabsorbed as needed.

The nephron (Figure 29-3) begins in the cortex at the glomerulus and ends where the tubule joins the collecting duct at the papilla. The glomerulus is a tuft of capillaries derived from the afferent arteriole. Blood is brought to the glomerulus by the afferent arteriole; blood that is not filtered returns to the circulation by way of the efferent arteriole (see Figure 29-3). The filtrate from the glomeruli enters the Bowman capsule, or capsula glomeruli, flows through a tortuous tube, or proximal convoluted tubule, and then goes to the loop of Henle, distal convoluted tubule, and collecting duct.

The nephron, which changes in shape and direction as it follows its course, is contained partly in the renal cortex and partly in the medulla (Figure 29-4). The cortex contains the Bowman capsule, glomerulus, and proximal and distal tubules. The thin, descending loop of Henle comes from the proximal tubule and extends toward the pyramid. The descending loop of Henle eventually bends on itself and forms an enlarged, ascending loop of Henle. The ascending limb joins the distal convoluted tubule.[1]

The kidneys have two kinds of nephrons: cortical nephrons, which extend only partially into the medulla, and juxtamedullary nephrons, which lie deep in the cortex and extend deep into the medulla. One fifth to one third of the nephrons are juxtamedullary and play an important role in concentration of urine.

Renal Blood Supply

To understand how the kidneys function, it is essential to understand their blood supply. The kidneys are highly vascular. Although they represent only 0.5% of body weight, they receive 1100 to 1200 mL of blood per minute, or 20% to 25% of the cardiac output. Blood reaches these organs through the renal arteries. At the hilus of the kidney, the renal artery divides into several lobar arteries and then subdivides again into interlobar arteries, which run between the pyramids. When these vessels reach the corticomedullary zone, they make well-defined arches over the bases of the pyramids. These vessels, known as arcuate arteries, divide into a series of arteries known as interlobular arteries (see Figure 29-2). An interlobular artery may terminate as an afferent arteriole or as a nutrient artery to the tubule.

The afferent arterioles form the high-pressure capillary bed within the Bowman capsule called the *glomerulus*. Because little or no oxygen is removed in the glomerulus, the blood that is not filtered begins its passage to the venous system via the efferent

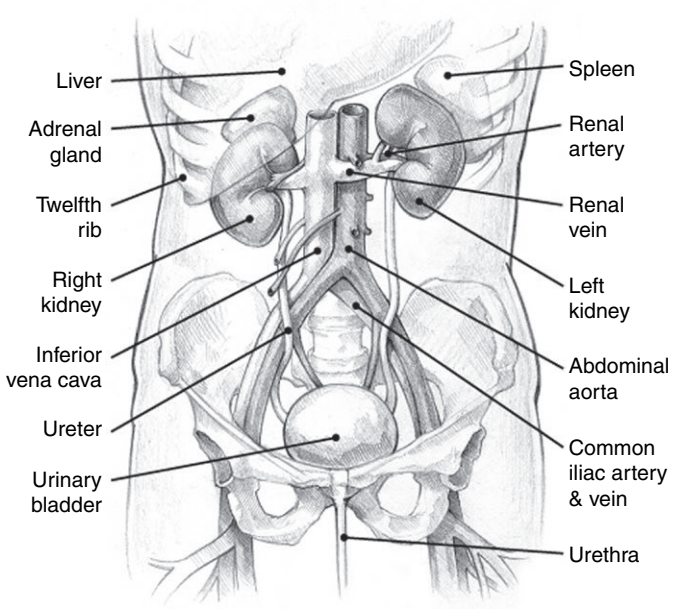

FIGURE **29-1** Kidney position.

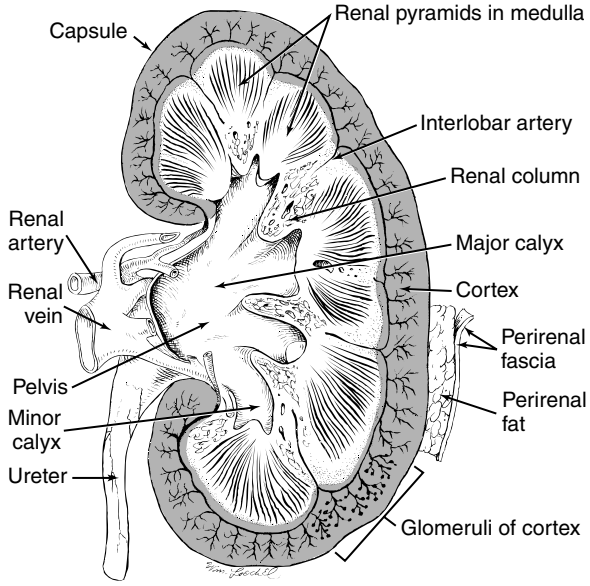

FIGURE **29-2** Longitudinal section of the kidney.

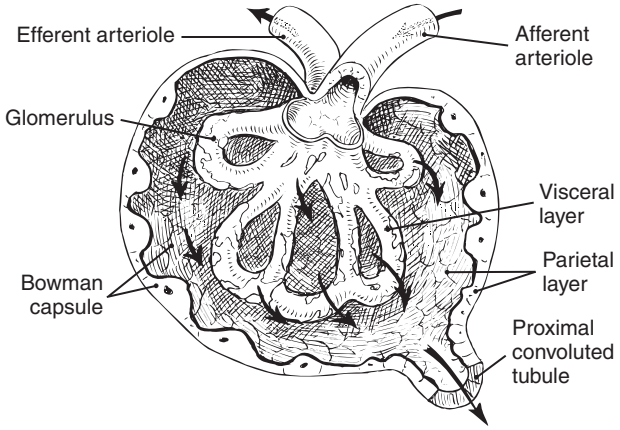

FIGURE **29-3** The nephron.

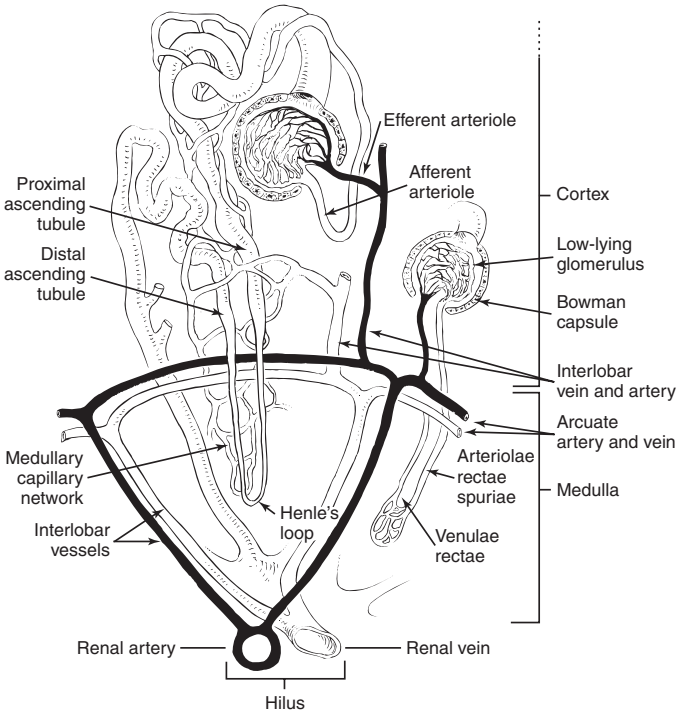

FIGURE **29-4** Renal filtration.

arteriole. The efferent arteriole is smaller than the afferent arteriole, thereby affording some resistance to blood flow. The efferent vessel soon becomes a plexus of capillaries again, and this low-pressure bed is known as the *peritubular capillary*. The peritubular capillary bed winds and twists around the proximal and distal tubule. A few hairpin loops, called vasa recta, dip down among the loops of Henle. Anatomic arrangements of these capillary beds and the renal tubules set the stage for filtration, reabsorption, and concentration of urine.

After leaving the peritubular capillary, blood returns to the central circulation via the veins. Renal veins are named in reverse order of the arteries, and therefore are the interlobular, arcuate, interlobar, lobar, and renal veins. The renal vein leaves the kidney at the hilus and empties into the inferior vena cava.

The portion of the cardiac output that passes through the kidney is called the *renal fraction*. Because cardiac output in a 70-kg man is approximately 5600 mL/min, and blood flow through both kidneys is 1200 mL/min, the normal renal fraction is 21%. This flow may vary from 12% to 30%. Distribution of renal blood flow is to the renal cortex and the medulla, with the cortex receiving the larger amount. Values obtained from dogs indicate that 3 to 5 mL/g/min are distributed to the cortex, 1 to 2 mL/g/min to the outer medulla, and 0.3 to 0.6 mL/g/min to the inner medulla. Only a small portion of blood (1% to 2%) flows through the vasa recta in the medulla. [1]

Regulation of Renal Blood Flow

Blood flow to any organ is determined by the arteriovenous pressure difference across the vascular bed and is given by the following relationship:

$$\text{Renal blood flow} = (\text{MAP} - \text{VP}) \times \text{VR}$$

where MAP is the mean arterial pressure, VP is the venous pressure, and VR is the vascular resistance. Renal blood flow is regulated by intrinsic autoregulation and neural regulation.

Autoregulation of renal blood flow implies that blood flow remains normal despite a considerable change in pressure. With

a MAP between 50 and 180 mmHg, renal blood flow to both kidneys remains 1200 mL/min. If mean systemic blood pressure falls below 50 mmHg, filtration ceases. Afferent arteriole vasodilation and myogenic mechanisms are responsible for autoregulation.[1]

When renal blood flow decreases, glomerular filtration is reduced. A reduction in glomerular filtration leads to dilation of the afferent arteriole. An increase in blood flow to the glomerulus returns glomerular filtration to normal.

Myogenic mechanisms also play a role in renal autoregulation. When arterial pressure rises, the arterial wall is stretched, the vessel constricts, and blood flow remains normal. When arterial pressure decreases, the opposite effect occurs. Therefore renal blood flow remains constant over a wide range of pressure changes.

Neural regulation also has a role in renal blood flow. The sympathetic nervous system innervates both the afferent and efferent arterioles. Although autoregulation overrides the adrenergic system with mild stimulation, acute sympathetic stimulation with its associated vasoconstriction can decrease renal blood flow substantially. The parasympathetic nervous system is not physiologically significant.[1]

RENAL PHYSIOLOGY

The kidneys maintain a steady state essential to life. This is accomplished through three major mechanisms: filtration, reabsorption, and tubular secretion. What is filtered or secreted but not reabsorbed is excreted as urine.

Filtration

Filtration, which results from pressures that force fluids and solutes through the glomerulus, is the first step in the formation of urine. The quantity of glomerular filtrate formed each minute in all nephrons is called the *glomerular filtration rate (GFR)*. The filtration fraction is the quantity of renal plasma flow that becomes filtrate and is defined as GFR divided by the flow to one kidney. Because the GFR is approximately 125 mL/min, and the flow to one kidney is 650 mL/min, the filtration fraction is 125/650, or 19% (approximately one fifth) of plasma flow. Of the 125 mL/min (or 180 L/day) of this protein-free filtrate made, 99% is reabsorbed from the renal tubules, and the remaining small portion is excreted as urine.[1]

Regulation of Glomerular Filtration Rate

Glomerular filtration is also dependent on several physiologic factors:

- The pressure inside the glomerular capillaries
- The pressure in the Bowman capsule
- The colloid osmotic pressure of the plasma proteins

The pressure inside the high-pressure glomerulus (60 mmHg) is an outward force, whereas the colloid osmotic pressure created by proteins in the glomerulus (28 mmHg) is an inward force that tends to hold fluid within the glomerulus. Pressure in the Bowman capsule (18 mmHg) opposes filtration. As illustrated in Figure 29-4, filtration pressure is the pressure that forces fluid through the glomerular membrane. It is equal to the glomerular pressure minus the sum of the glomerular colloid osmotic pressure and the capsular pressure. With the values given, the normal filtration pressure is 10 mmHg. Several factors can alter GFR. Increased renal blood flow, dilation of the afferent arteriole, and increased resistance in the efferent arteriole increase GFR. Afferent arteriole constriction and efferent arteriole dilation tend to decrease GFR.

A special structure called the *juxtaglomerular complex* regulates GFR. At the juxtaglomerular complex, the distal convoluted tubule lies between the afferent and efferent arterioles. Cells of the distal tubule coming into contact with the arterioles are dense and therefore are referred to as the macula densa. Smooth muscle cells of both the afferent and efferent arterioles consist of juxtaglomerular cells, which contain renin. Anatomically this structure is arranged to allow fluid in the distal tubule to alter afferent or efferent arteriolar tone and thus regulate GFR.

Decreased glomerular filtration causes overabsorption of sodium ions (Na^+) and chloride ions (Cl^-) in the ascending limb of the loop of Henle and therefore a reduction in the delivery of these ions to the macula densa. Decreases in the concentrations of sodium and chloride cause afferent arterioles to dilate and thus increase renal blood flow and GFR. Sympathetic stimulation and decreased delivery of both sodium and chloride to the macula densa also cause the juxtaglomerular cells to release renin. Renin clears angiotensinogen from the liver to form angiotensin I. In the lung, angiotensin I is changed into angiotensin II under the influence of a converting enzyme. In addition to having a generalized vasoconstricting effect, angiotensin II causes constriction of the efferent arteriole. This causes the pressure in the glomerulus to increase and the GFR to return to normal.[1]

Filtrate Composition

Although permeability at the glomerulus is 100- to 500-fold greater than that of most capillaries, filtration at the glomerulus is a selective process. The process by which some substances are filtered and others are not is only partially understood. It is thought that the glomerular capillary contains pores that are negatively charged. These pores, which are 70 to 100 nm in size, are freely permeable to water and small molecules, as well as to some ions. Molecules with diameters up to 80 nm that do not have a negative charge are easily filtered. The glomerulus is almost impermeable to all plasma proteins but highly permeable to most other dissolved substances. Glomerular filtrate is therefore similar to plasma, except that it lacks significant amounts of proteins.

Tubular Reabsorption and Secretion

Conversion of glomerular filtrate to urine is the result of filtration at the glomerulus, tubular reabsorption or transport from the tubular lumen to the renal cell, and secretion or transport from the renal cell to the filtrate. Of all that is filtered or secreted, 99% is reabsorbed as the filtrate moves along the nephron.

Tubular reabsorption permits conservation of essential substances such as water, glucose, amino acids, and electrolytes. Some substances, such as water and sodium, are reabsorbed throughout the nephron, whereas others, such as glucose, are completely reabsorbed when plasma concentrations are low. Certain substances have a reabsorption maximum value, and after that value is reached, excess filtered material is excreted, regardless of plasma concentration. This maximum value is termed *maximum transport*. Maximum transport occurs because of saturation of a carrier for a particular substance.

By the time the blood has reached the peritubular capillary, one fifth of the plasma has been filtered into the Bowman capsule. The hydrostatic pressure in this low-pressure capillary bed has dropped to 13 mmHg, whereas the osmotic pressure has increased to 30 to 32 mmHg. The peritubular capillaries are extremely porous compared with those in other body tissues, and their proximity to the proximal and distal tubule sets the stage for movement of water and solutes from the tubule to the peritubular capillary bed. Anatomic location and the colloid osmotic pressure of plasma proteins account for the rapid absorption required in this area.[1]

Transport Mechanisms

Basic mechanisms of transport through the tubular membrane can be divided into active transport and passive transport. Active transport is the net movement of particles across a membrane against an electrochemical gradient, generally at the cost of metabolic energy. Passive transport involves the movement of substances across membranes and relies on either concentration gradients or chemical gradients. Active transport can be further divided into primary active transport, which requires energy, and secondary active transport, which does not require energy. Most primary active transport is for sodium. Secondary active transport is a result of the movement of sodium from the tubular lumen to the interior of the cell. For example, the active transport of sodium pulls glucose and amino acids with it. Because a carrier protein in the membrane combines with sodium and glucose, the process is termed *cotransport*. In addition to glucose and amino acids, chloride, phosphate, calcium, magnesium, and hydrogen ions are co-transported.

Some substances are actively secreted into the renal tubule in exchange for other molecules. Hydrogen, potassium, and urate ions are secreted in this manner. Hydrogen and potassium are generally secreted in exchange for sodium in a process termed *countertransport*.

When substances are actively transported from the tubule to the peritubular capillary bed, a concentration gradient that causes passive absorption of water by osmosis is established. When positive ions are actively transported, negative ions follow to maintain electrical neutrality. Chloride ions and urea are examples of substances that are passively absorbed.[1]

Proximal Tubule

Each portion of the renal nephron is selective with regard to what is reabsorbed or secreted. Active transport of sodium is the primary function of the proximal tubule. Water, most electrolytes, and organic substances are cotransported with sodium. The osmotic force generated by active sodium transport promotes passive diffusion of water out of the tubules into the peritubular capillaries. Passive transport of water is further enhanced by the elevated osmotic pressure of the blood in the peritubular capillaries. Reabsorption of water leaves an increased concentration of urea within the tubular lumen, thereby creating a gradient for its passive diffusion into the peritubular plasma. As positively charged sodium ions leave the tubular lumen, negatively charged chloride ions passively follow to maintain electroneutrality. Hydrogen ions are actively secreted in exchange for sodium. Secretory transport of sodium also occurs in the proximal tubule.

As the filtrate passes along the proximal tubule, 60% to 70% of filtered sodium and water, 50% of urea, and potassium, calcium, phosphate, uric acid, and the bicarbonate (HCO_3) form of carbon dioxide (CO_2) have been reabsorbed. Glucose, proteins, amino acids, acetoacetate ions, and vitamins are completely or almost completely reabsorbed by active processes. Because protein molecules are too large to be reabsorbed by normal mechanisms, a special mechanism called *pinocytosis* is used to save proteins. In this process, the tubular membrane engulfs the protein and internalizes it. Once inside the cell, the protein is digested into amino acids that can then be absorbed into the interstitial fluid.

Loop of Henle

The primary function of the loop of Henle is to establish a hyperosmotic state within the medullary area of the kidney, a function vital to conservation of salt and water. Water conservation and the production of a concentrated urine involve a countercurrent exchange system in which a concentration gradient causes fluid to be exchanged across parallel pathways. The fluid moves up and down the parallel sides of the hairpin loop of Henle in the medulla. The longer the loop, the greater the concentration gradient, because the gradient increases from the cortex to the medulla. Sluggish blood flow in the vasa recta helps maintain the gradient.

Countercurrent exchange begins in the thick, ascending limb of the loop of Henle with the active transport of sodium and chloride out of the tubular lumen and into the medullary interstitium. Because the lumen in this area is impermeable to water, water cannot follow. The tubular fluid becomes hypoosmotic, and the medullary interstitium hyperosmotic. The descending limb of the loop is highly permeable to water but does not actively transport sodium and chloride. Sodium and chloride diffuse into the interstitium, the hypertonic interstitium causes water to move out, and the remaining fluid in the descending loop becomes concentrated at the tip of the medulla. As the tubular fluid rounds the loop and enters the ascending limb, water is retained, and sodium and chloride are removed. The filtrate therefore is very dilute as it reaches the distal tubule. The thick segment of the loop of Henle has a powerful role in renal mechanisms for diluting or concentrating the urine.[1]

Late Distal Tubule

In the late distal tubule, sodium, under the influence of aldosterone, is reabsorbed. In this area, potassium is secreted into the lumen in exchange for sodium. It is mainly by this means that the potassium concentration is controlled in the extracellular fluids of the body.

The late distal tubule also secretes hydrogen against a concentration gradient. This function has a role in acid-base balance and the final degree of urine acidification. The late distal tubule reabsorbs 10% of filtered water. This area is permeable to water only in the presence of antidiuretic hormone (ADH).

Collecting Duct

The permeability of the collecting duct to water also is controlled by ADH. When this neurohypophyseal hormone is present, water is reabsorbed into the medullary interstitium, and the urine volume is reduced and concentrated. The collecting duct also can secrete hydrogen and therefore has a role in acid-base balance. Figure 29-5 illustrates renal blood flow, filtration, reabsorption, and secretion.[1]

Renal Secretion

In addition to renin, hydrogen, and potassium, the kidneys release erythropoietin, a glycoprotein that stimulates red-blood-cell production in the bone marrow. Any condition that causes the quantity of oxygen transported to the tissues to decrease stimulates the release of erythropoietin, production of red blood cells, and correction of hypoxia. A clinical diagnosis of anemia emerges when both kidneys are destroyed by renal disease.

Renal Hormones

Aldosterone

A number of hormones affect renal function. Aldosterone, the chief mineralocorticoid produced by the adrenal cortex, affects the distal segment of the nephron, causing the reabsorption of sodium and water. Several physiologic control systems regulate aldosterone release: potassium concentration in extracellular fluid; the renin-angiotensin system; and sodium concentration in extracellular fluid. Of these, potassium is the strongest trigger, followed by renin and then sodium.

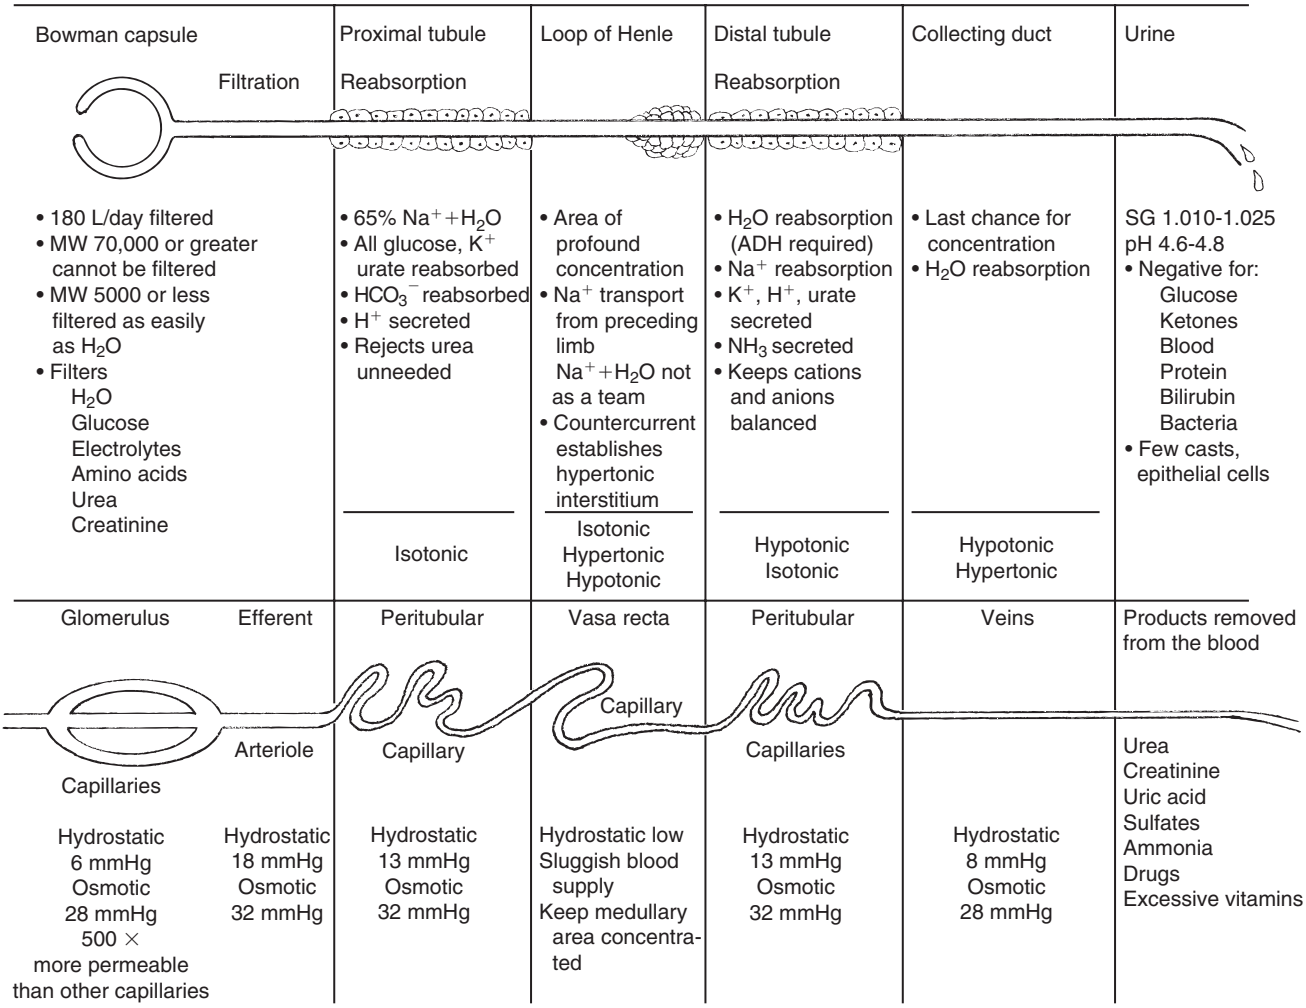

FIGURE **29-5** Renal blood flow, filtration, reabsorption, and secretion. *ADH,* Antidiuretic hormone; *SG,* specific gravity.

Antidiuretic Hormone

ADH, a hormone synthesized in the hypothalamus but released from the neurohypophysis, also has the distal nephron as its target tissue. Because the distal tubule and collecting ducts are almost totally impermeable to water in the absence of ADH, water is not reabsorbed and is lost in the urine. In the presence of ADH, tubular permeability is increased, and water is reabsorbed. The release of ADH is controlled by the osmotic concentration of the extracellular fluids (Figure 29-6). Osmoreceptors located near the hypothalamus sense extracellular fluid concentration and release ADH accordingly. ADH is inhibited by stretch of atrial baroreceptors.

Angiotensin

Angiotensin is a hormone that has a direct renal effect, as well as a general systemic effect. As previously discussed, renin is a small protein enzyme released by the kidneys. Stimuli for the release of renin include β-adrenergic stimulation, decreased perfusion to the afferent arterioles, and reduction in sodium delivery to the distal convoluted tubule. Once released, renin acts on hepatic angiotensinogen to form angiotensin I. Angiotensin I is then converted by the angiotensin-converting enzyme (ACE) in the lung to form angiotensin II. In addition to causing powerful vasoconstriction, angiotensin II stimulates the release of aldosterone from the adrenal cortex. Aldosterone increases salt and water retention by the kidneys. Both of these actions increase arterial pressure.[2]

Atrial Natriuretic Factor

Atrial natriuretic factor (ANF) is a peptide hormone synthesized, stored, and secreted by the cardiac atria.[3] It acts on the kidney to increase urine flow and sodium excretion, and it may enhance renal blood flow and GFR. In addition, ANF antagonizes both the release and end-organ effects of renin, aldosterone, and ADH. The stimulus for ANF release is atrial distention, stretch, or pressure.[4] ANF is one of the most potent diuretics known. Inhibition of plasma renin, angiotensin, and aldosterone can produce a dose-dependent decrease in blood pressure.

Vitamin D

Vitamin D, along with parathyroid hormone and calcitonin, has a vital role in calcium metabolism. Vitamin D or cholecalciferol is obtained in the diet or synthesized by the action of ultraviolet radiation on cholesterol in the skin. To become active, cholecalciferol is first hydroxylated in the kidney to 25-hydroxycholecalciferol, then in the liver to 1,25-dihydroxycholecalciferol. Patients with advanced renal disease often have abnormal serum calcium levels.

Prostaglandins

Prostaglandins (PGs) such as PGE_2 and thromboxane A_2 modulate the renal effects of other hormones. PGE_2 is a vasodilator, and thromboxane A_2 produces contraction of vascular smooth muscle. Renal PGs influence renal excretion.

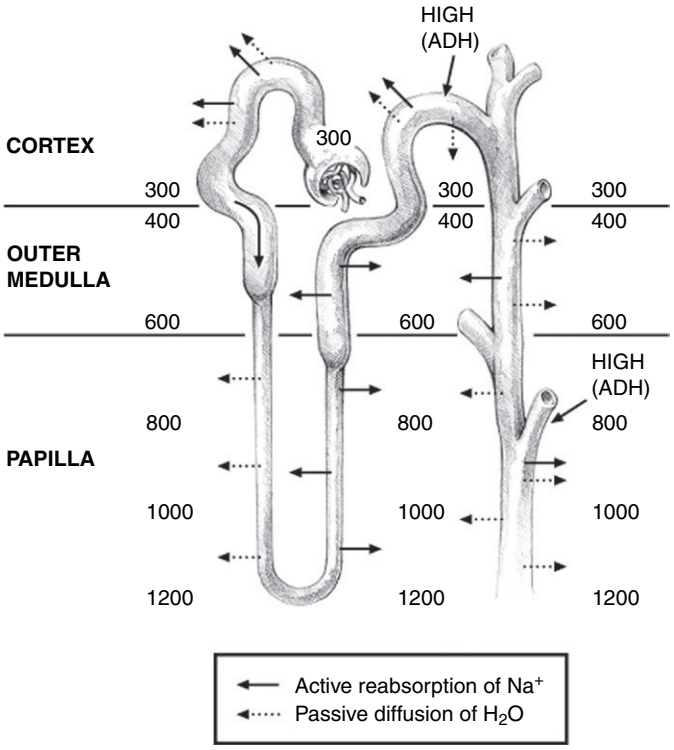

FIGURE **29-6** The countercurrent mechanism. *ADH,* Antidiuretic hormone.

Renal Regulation of Acid-Base Balance

The kidneys, along with the body's fluid buffers and respiratory system, play a major role in regulating acid-base balance. Epithelial cells of the proximal tubules, the thick portion of the loop of Henle, distal tubules, and collecting ducts secrete hydrogen into the tubular fluid. This secretory process actually begins with CO_2 in the epithelial cells, where under the influence of carbonic anhydrase, CO_2 combines with water to form carbonic acid (H_2CO_3). H_2CO_3 dissociates into HCO_3 and hydrogen ions, and hydrogen ions are actively secreted into tubular fluid in exchange for sodium ions. This exchange maintains appropriate electrical balance between anions and cations in the tubular fluid.

An increase in HCO_3 in alkalosis means that the filtered amount of HCO_3 exceeds the amount of hydrogen secreted. Because excess HCO_3 must react with hydrogen ($HCO_3^- + H^+ \rightarrow H_2CO_3 \rightarrow CO_2^- + H_2O$) and be absorbed as CO_2, excess HCO_3 ions are lost in the urine along with sodium. In this way, sodium and excess HCO_3 are removed from the extracellular fluid.

In acidosis the concentration of hydrogen ions increases to a level far greater than that of HCO_3 in the tubules. Excess hydrogen ions are lost in the urine through the phosphate or ammonia (NH_3) buffer system.

The phosphate buffer is composed of hydrogen phosphate (HPO_2^-) and dihydrogen phosphate (H_2PO_4). Both of these ions become concentrated in the tubular fluid because of poor reabsorption. The quantity of HPO_2^- is normally fourfold that of H_2PO_4. Excess hydrogen ions entering the tubules combine with monohydrogen phosphate to form H_2PO_4, which is lost in the urine. A sodium ion is absorbed into the extracellular fluid in exchange for hydrogen. It combines with HCO_3, which was formed in the process of secretion of the hydrogen, and sodium bicarbonate is added to the extracellular fluid.

NH_3, which is synthesized by all epithelial cells except those in the thin segment of the loop of Henle, is also secreted into the tubules. NH_3 reacts with hydrogen to form the ammonium ion (NH_4). Ammonium ions are lost in the urine with chloride and other tubular anions.

The kidneys control extracellular fluid hydrogen concentration by excreting an acidic or basic urine. Excretion of acidic urine removes excess acid from the extracellular fluid, whereas loss of basic urine removes base from the extracellular fluid.

Concentration and Dilution of Urine

The kidneys have the ability to respond to the changing tonicity of body fluids by excreting dilute or concentrated urine. This function involves a countercurrent exchange system in which a concentration gradient causes fluid to be exchanged across parallel pathways (see Figure 29-6). In a countercurrent exchanger, reversal of flow in one stream results in the formation of a gradient that allows water and solutes to be exchanged along the length of the tube. The countercurrent exchanger in the kidney is the descending and ascending loop of Henle. The concentration gradient increases from the cortex to the tip of the medulla. The anatomic arrangement of this part of the nephron and sluggish blood flow in the vasa recta help maintain the gradient.

Plasma water filtered at the glomerulus is isotonic with plasma. The daily urinary output is approximately 1.5 L/day, and its osmolarity may vary from 40 to 1400 mOsm/L, depending on water intake or loss. This is possible because of the countercurrent mechanism.

Approximately two thirds of the tubular fluid is reabsorbed between the glomerulus and the end of the proximal tubule. The tonicity of the filtrate in this area is the same as that of the surrounding tissue, or 300 mOsm. As the filtrate leaves the proximal tubule, it passes through an increasingly more concentrated medulla. Changes in the thick ascending limb of the loop of Henle are responsible for the hypertonicity.

The thick ascending limb of the loop of Henle is responsible for the active transport of sodium and chloride into the medullary interstitium. In contrast to the descending limb of the loop of Henle, the tonicity of which is in equilibrium with that of the interstitium, the ascending loop has a low permeability to water. The active transport of sodium and chloride produces a gradient between the ascending loop of Henle on one side and the descending loop and interstitium of the renal medulla on the other. The descending limb is highly permeable to water but does not actively transport sodium and chloride. The hyperosmotic interstitium causes water to move out of the descending limb, and the filtrate in the descending tubule is concentrated to 1200 mOsm at the tip of the medulla. As the tubular fluid rounds the loop and enters the ascending limb, active transport of sodium and chloride and retention of water create a hypoosmotic fluid of 100 mOsm at the distal tubule.

The hypoosmotic fluid of the distal tubule is delivered to the collecting duct, where the final adjustments of urine volume and concentration take place. In the absence of ADH, water permeability is low, and water is not reabsorbed. Because sodium and chloride can be reabsorbed, the osmolality decreases to below that of the distal tubule, and the urine is dilute. When the need for water conservation arises, ADH is secreted, permeability of the collecting duct increases, and water diffuses out of the duct into the hyperosmolar environment of the medullary extracellular fluid. In this way urine is concentrated and its volume is reduced.

The sluggish blood supply of the vasa recta in the medulla allows blood to flow through the medullary tissue without disturbing the osmotic gradient. If blood flow were rapid, the medullary concentration gradient and the ability to concentrate the urine would be lost.[1,5]

EFFECTS OF ANESTHESIA ON NORMAL RENAL FUNCTION

Before considering anesthetic implications for patients with renal disease, it is important to review the effects of anesthesia and surgery on normal renal function. Numerous studies have attempted to identify the effects of anesthesia on renal function, and although some have contributed to a better understanding of this area, differences among the studies in premedication, depth of anesthesia, fluid regimens, and other aspects of the experimental protocol allow only the broadest comparisons.

Anesthetic Effects

General anesthesia is associated with a temporary depression of renal blood flow, GFR, urinary flow, and electrolyte excretion. Although similar changes occur after spinal and epidural anesthesia, the magnitude of change tends to parallel the degree of sympathetic block and blood pressure depression. This consistent and generalized depression of renal function has been attributed to a number of factors, including type and duration of surgical procedure, physical status of the patient, volume and electrolyte status, depth of anesthesia, and choice of agent.[5]

Anesthesia may alter renal function by direct or indirect effects. Indirect effects are mediated through changes in the circulatory, endocrine, or sympathetic nervous system. Anesthetic drugs alter the circulatory system by decreasing renal perfusion, increasing renal vascular resistance, or a combination of both. Drugs associated with catecholamine lead to vasoconstriction, an increase in renal vascular resistance, a decrease in renal blood flow, and a decrease in renal function. Volatile agents such as isoflurane cause a mild to moderate increase in renal vascular resistance as a compensatory response to decreased perfusion pressure secondary to alterations in cardiac output or systemic vascular resistance.[6-10] Desflurane has been shown to produce hemodynamic effects comparable to those produced by isoflurane.[11] It increases heart rate and decreases both mean arterial pressure and systemic vascular resistance while maintaining cardiac output. In some studies, but not all, desflurane maintains arterial pressure and systemic vascular resistance to a greater degree than equianesthetic concentrations of isoflurane. Otherwise, desflurane and isoflurane have similar effects on most vascular beds, including the renal circulation.

Although earlier studies suggested that renal blood flow was reduced with sevoflurane, no renal functional or morphologic defects were noted after administration of this agent. Issues regarding the renal effects of the release of free fluoride ion associated with sevoflurane metabolism have been debated. Historically, high fluoride ion concentrations in the range of 60 to 90 μmol/L after methoxyflurane metabolism have led to nephrotoxicity characterized by polyuria. This methoxyflurane polyuria was commonly referred to as high-output renal failure. Sevoflurane has not produced the expected toxicity in the same way as methoxyflurane even though significant levels of fluoride ion may result from prolonged administration. A few reasons have been theorized for the lack of nephrotoxicity of sevoflurane, even though levels of metabolically released fluoride ion can approach those of methoxyflurane. They include the fact that sevoflurane metabolism is largely hepatic rather than renal. Intrarenal production of inorganic fluoride may be a more important factor than hepatic metabolism for the nephrotoxicity produced by increased serum fluoride concentration. Sevoflurane also has a much lower blood solubility so that it undergoes rapid elimination Sevoflurane has not been associated with nephrotoxicity.[12-15]

Changes in renal function during barbiturate, opiate, and nitrous oxide anesthesia are similar to those observed during the administration of low-dose volatile anesthesia.[16] Preoperative hydration, lower concentrations of volatile anesthetics, and maintenance of normal blood pressure attenuate reductions in renal blood flow and GFR.[17]

High levels of spinal or epidural anesthesia can impair venous return, diminish cardiac output, and reduce renal perfusion.[18] Epidural blocks at thoracic levels with epinephrine-containing local anesthetics cause moderate reductions in renal blood flow and GFR that parallel the decrease in mean blood pressure.[19] Epidural blocks performed with epinephrine-free solutions generate little change in systemic hemodynamics; however, absorption of local anesthetics is enhanced in uremic patients.[20]

In summary, virtually all anesthetics have the potential to alter the cardiovascular system and affect renal blood flow, GFR, and urinary output. Although systolic arterial blood pressure may not fall below 80 to 90 mmHg, renal blood flow may be decreased by 30% to 40% after the administration of various anesthetics. This suggests impairment of autoregulation. In most cases, changes in renal function are transient and reversible. If they persist into the postoperative period, the cause is often a combination of factors such as preexisting renal or cardiovascular disease, severe fluid imbalance, or mismatched blood, and the importance of the anesthetic effects is decreased.

Physiologic Responses

The renal vasculature is richly innervated by the sympathetic nervous system. Drugs or perioperative events that stimulate this system cause an increase in renal vascular resistance and a decrease in renal blood flow and glomerular filtration. Surgical stress also may alter autonomic and neuroendocrine responses. Norepinephrine from sympathetic postganglionic nerve fibers and epinephrine and norepinephrine from the adrenal medulla shift blood away from the cortical nephrons; this results in decreases in renal blood flow, GFR, electrolyte excretion, and urinary output. Catecholamines also stimulate the release of renin, which ultimately leads to the production of angiotensin II, a potent vasoconstrictor.

Endocrine changes associated with anesthesia and surgical stress involve ADH, aldosterone, and the renin-angiotensin-aldosterone system. Although the perioperative period is associated with high circulating levels of ADH and aldosterone, it is not clear whether anesthetics stimulate the release or the release is secondary to the surgical stress response. General anesthetics and narcotics are thought to be minor stimuli of the release of ADH, but laparoscopic surgical procedures have been shown to increase ADH levels.[21] Clinical studies have specifically identified that pneumoperitoneum during laparoscopic surgery increases the level of ADH.[22] Other studies indicate that patients undergoing anesthetics lasting long durations had significant increases in ADH, with the greatest increase occurring at emergence.[23] Additional investigations have shown that ADH levels increase after the induction of anesthesia and is higher in subjects receiving lower concentrations of remifentanil-propofol anesthesia.[24]

It is clear that ADH release is modulated by blood volume changes that are sensed by stretch receptors in the atrial wall. Hemorrhage, positive pressure ventilation, and the upright position increase ADH release.[25,26] A decrease in arterial pressure stimulates ADH release. Distention of a balloon in the atrium, negative pressure ventilation, and immersion in water up to the neck decrease ADH release.

Renin-angiotensin levels may be elevated during the perioperative period, but the role of anesthetics and stress is not clear. Some studies have reported large increases in plasma renin levels associated with the use of anesthetics, whereas others report

variances dependent on type of anesthesia delivered as well as surgical procedure. Balanced anesthesia has been found to result in higher levels of epinephrine, norepinephrine, and adrenocorticotropic hormones than total intravenous anesthesia.[27] The influence of renin-angiotensin on the renal effects of anesthetic agents needs further clarification. Renin levels have been shown to increase during laparoscopic surgery, as well as vasopressin, epinephrine, norepinephrine, and cortisol.[28] Preoperative hydration is thought to be important in the intraoperative release of renin.

Aldosterone, a hormone released from the adrenal gland, is responsible for the precise control of sodium excretion. It is not known whether anesthetic agents act directly on the adrenal gland to cause aldosterone release. They probably act indirectly through the neuroendocrine system and the renin-angiotensin-aldosterone system. Stimulation of the sympathetic nervous system causes renal vasoconstriction, which is a trigger for the renin-angiotensin-aldosterone system. Aldosterone leads to sodium and water reabsorption and can be associated with decreased urinary output.

Nephrotoxicity of Anesthetic Agents

The kidneys are extremely vulnerable to toxicity because of their rich blood supply and the increase in the concentration of excreted compounds that occurs in the renal tubules during the process of reabsorption. Medullary hyperosmolality encourages concentration of all substances, including toxins. The amount of renal damage associated with nephrotoxic agents depends on the concentration of the toxins, the degree of toxin binding to plasma proteins and nonrenal versus renal tissue, and the length of exposure of the kidneys to the toxin. The nephrotoxicity of anesthetic agents became fully appreciated in 1966, when vasopressin resistant–polyuria renal insufficiency was reported in patients receiving prolonged methoxyflurane anesthesia for abdominal surgery.[29] Evidence gathered indicated that the release of the inorganic fluoride ions (F^-) in the metabolism of this fluorinated anesthetic was the causative agent in nephrotoxicity. Fortunately none of the modern inhalation anesthetics are nephrotoxic.

Fluoride Ion Toxicity

Fluoride alters renal concentration mechanisms by interfering with active transport of sodium and chloride in the medullary portions of the loop of Henle. It also acts as a potent vasodilator, resulting in increased blood flow in the vasa recta and washout of medullary solute. Fluoride is a potent inhibitor of many enzyme systems, including those involving ADH, which is necessary for distal nephron reabsorption of water. Proximal tubular swelling and necrosis associated with fluoride ions also contribute to nephrotoxicity. Signs and symptoms of fluoride nephrotoxicity include polyuria, hypernatremia, serum hyperosmolality, elevations in blood urea nitrogen (BUN) and serum creatinine levels, and decreased creatinine clearance. The extent of nephrotoxicity in general surgical patients has been correlated with dosage or maximum allowable concentration hours (MAC-hours), duration, and peak fluoride concentrations.[29]

Methoxyflurane

Methoxyflurane, an anesthetic no longer used, was the first anesthetic associated with serious nephrotoxicity. The serum fluoride concentration after methoxyflurane anesthesia showed positive correlation with the degree of renal dysfunction.[30] Vasopressin-resistant polyuria similar to that seen after methoxyflurane anesthesia was later produced in Fischer 344 rats injected with sodium fluoride.[31] After 2.5 to 3 MAC-hours of methoxyflurane anesthesia, fluoride concentration was 50 to 80 µmol, and subclinical toxicity evidenced by a delayed return to maximum preoperative urine osmolarity and decreased urate clearance were noted.

Isoflurane

Isoflurane is metabolized only slightly and defluorinated much less than other halogenated agents. In one report of nine surgical patients, mean peak serum fluoride concentration measured 6 hours after anesthesia was only 4.4 µmol.[32] Clinical experience has indicated that renal toxicity does not occur after the administration of isoflurane.[33]

Desflurane

The metabolism of desflurane has been assessed in both animals and humans with the appearance of fluoride metabolites (fluoride ion, nonvolatile organic fluoride, trifluoroacetic acid) in blood and urine. Administration of desflurane to rats that were either pretreated or not pretreated with phenobarbital or ethanol for 3.2 MAC-hours, as well as to swine for 5.5 MAC-hours, produced fluoride levels in blood that were almost indistinguishable from values measured in control animals.[34] In human studies, desflurane administered to patients for 3.1 MAC-hours and volunteers for 7.3 MAC-hours resulted in postanesthesia serum fluoride concentrations that did not differ from background fluoride concentrations. Similarly, postanesthesia urinary excretion rates of fluoride and organic fluoride in volunteers were comparable with preanesthetic excretion rates.[35-37] Small but statistically significant increases in the levels of trifluoroacetic acid were found in both the serum and urine of volunteers after exposure to desflurane. Although these increases in trifluoroacetic acid were statistically significant, they were approximately one tenth the levels seen after exposure to isoflurane. Desflurane strongly resists biodegradation, and only a small amount is metabolized in animals and humans.[38] Desflurane does not produce nephrotoxicity.

Sevoflurane

Sevoflurane undergoes approximately 5% to 8% metabolism, and the primary metabolites are fluoride and hexofluro-2-propranolol (HFIP). The oxidative defluorination of sevoflurane in the liver with the liberation of free fluoride ions raised concerns that sevoflurane, like methoxyflurane, might impair the ability of the kidneys to concentrate urine. Earlier research indicated that with methoxyflurane, renal dysfunction was likely to occur when plasma fluoride levels exceeded 50 µmol. The same does not appear to be true with sevoflurane.

Preliminary investigations with sevoflurane found that some adult patients receiving the drug had plasma fluoride levels that exceeded 50 µmol. However, renal function, assessed by BUN, creatinine, and decrease in urine osmolality, was not different from that in patients receiving similar amounts of other fluorinated anesthetics. In one study, serum fluoride levels averaged 29 µmol after 1 to 7 MAC-hours of anesthesia. The fluoride levels peaked 2 hours after the end of anesthesia and decreased by 50% within 8 hours.[39] The fast decline in plasma fluoride levels was attributed to insolubility of the agent and rapid pulmonary elimination of sevoflurane.

Numerous published reports indicate the absence of renal toxicity after sevoflurane anesthesia.[40-43] As mentioned previously, an explanation for the absence of fluoride-induced nephrotoxicity may be that intrarenal production of fluoride ion is important in the pathogenesis of this complication. The intrarenal metabolism of methoxyflurane is four times greater than that of sevoflurane.[42]

Studies of surgical patients receiving intermediate-duration sevoflurane with high and low fresh gas flow and long-duration

sevoflurane with high fresh gas flow included sensitive measures of renal function or injury. These studies also indicate the absence of renal toxicity after sevoflurane anesthesia.[43-48]

In addition to release of inorganic fluoride ion resulting from biotransformation, CO_2 absorbents degrade sevoflurane, causing the production of a vinyl ether called *compound A*. This reaction occurs in the anesthesia machine, and the resulting toxin, compound A, is then delivered to the patient via the machine breathing system. Factors associated with the generation of higher levels of compound A during administration of sevoflurane to patients include: (1) a high concentration of the agent, (2) increased temperature in the CO_2 absorbent, (3) low fresh gas flow rates, and (4) increased states of CO_2 production. The potential for compound A nephrotoxicity theoretically exists although no reports of problems in clinical practice have been reported.

Because the potential for renal injury exists with sevoflurane, studies in volunteers have raised the question of whether it is important to apply more sensitive measures of renal function in evaluation of this drug. Such tests have included urine concentrations or excretion of enzymes, albumin, protein, and glucose and creatinine clearance.[49] Two studies of volunteers receiving prolonged sevoflurane anesthesia with fresh gas flow no greater than 2 L/min concluded that the potential for adverse renal effects of sevoflurane may exist.[50,51] However, other studies of volunteers did not find the same results.[52-55]

A number of reports describe instances in which sevoflurane has been given to patients with renal dysfunction and other conditions that might enhance renal injury. Such conditions include patients who are hypotensive, hypertensive, elderly, or obese or who have renal insufficiency or hepatic failure.[56-65] The only proven direct toxic effect of any anesthetic agent is the fluoride-related toxicity of methoxyflurane.[65]

Because the amount of compound A produced increases with lower gas flows, the package insert at one time recommended flows of 2 L/min or more. Several studies indicate no effect of low-flow sevoflurane on renal function, even those with moderate renal insufficiency.[66,67] Today, the U.S. Food and Drug Administration recommends the use of sevoflurane for a minimum of 1 L/min of fresh gas flow and advises that 2 MAC-hours at this flow rate should not be exceeded.[68] The use of newer carbon dioxide absorbents such as Litholyme® and others, which do not react with sevoflurane, to replace soda lime–type absorbents in modern anesthesia practice are eliminating any concern regarding compound A toxicity.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) describes the clinical syndrome formerly called acute renal failure (ARF). AKI is defined as a functional or structural abnormality of the kidney that manifests within 48 hours as determined by blood, urine, or tissue tests or by imaging studies. Diagnostically, the reduction in kidney function is associated with either an absolute increase in serum creatinine of 0.3 mg/dL or a percentage increase in serum creatinine of 50%. In addition, a reduction in urine output with oliguria (<0.5 mL/kg/hour) for more than 6 hours also fulfills the diagnostic criteria. Patients are frequently classified based on urine flow rates as nonoliguric (urine output >400 mL/day), oliguric (urine output <400 mL/day), or anuric (urine output <100 mL/day)

Most episodes of AKI occur in the hospital, with an incidence ranging from 5% to 7% among all hospitalized patients and 15% to 40% among patients in intensive care units (ICUs). By contrast, the incidence of community-acquired AKI is less than 1%.

BOX 29-1

Causes of Prerenal Acute Kidney Injury

Intravascular Volume Depletion
- Hemorrhage—trauma, surgery, postpartum, gastrointestinal
- Gastrointestinal losses—diarrhea, vomiting, nasogastric tube loss
- Renal losses—diuretic use, osmotic diuresis, diabetes insipidus
- Skin and mucous membrane losses—burns, hyperthermia
- Nephrotic syndrome
- Cirrhosis
- Capillary leak

Reduced Cardiac Output
- Cardiogenic shock
- Pericardial diseases—restrictive, constrictive, tamponade
- Congestive heart failure
- Valvular diseases
- Pulmonary diseases—pulmonary hypertension, pulmonary embolism
- Sepsis

Systemic Vasodilation
- Sepsis
- Cirrhosis
- Anaphylaxis
- Drugs

Renal Vasoconstriction
- Early sepsis
- Hepatorenal syndrome
- Acute hypercalcemia
- Drugs—norepinephrine, vasopressin, nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, calcineurin inhibitors
- Iodinated contrast agents

Increased Intraabdominal Pressure
- Abdominal compartment syndrome

From Sharfuddin AA, et al. Acute kidney injury. In Taal MW, et al, eds. *Brenner & Rector's The Kidney*. 9th ed. Philadelphia: Saunders; 2012:1045.

AKI is usually divided into three broad pathophysiologic categories based on cause:

1. *Prerenal AKI*—diseases characterized by effective hypoperfusion of the kidneys in which there is no parenchymal damage to the kidney
2. *Intrinsic AKI*—diseases involving the renal parenchyma
3. *Postrenal (obstructive) AKI*—diseases associated with acute obstruction of the urinary tract

Each of the categories represents a unique pathophysiologic process with distinctive diagnostic parameters and prognosis. Causes of prerenal (Box 29-1), intrinsic (Table 29-1), and postrenal (Box 29-2) AKI are summarized in the boxes noted.[69-70]

Classification

Historically, acute kidney injury was classified according to urine output: oliguric, nonoliguric, or polyuric, or by its predominant cause: prerenal, renal, or postrenal. Oliguria is defined as a urinary flow rate less than 0.5 mL/kg/hr. Polyuric failure is associated with elevations of BUN and serum creatinine levels and is characterized by urine flow rates that exceed 2.5 L/day.[71] Prerenal AKI results from hemodynamic or endocrine factors impairing renal perfusion, intrinsic AKI results from tissue damage, and postrenal AKI results from urinary tract obstruction.

TABLE 29-1 Major Causes of Intrinsic Acute Kidney Injury

Tubular Injury	
Ischemia due to hypoperfusion	Hypovolemia, sepsis, hemorrhage, cirrhosis, congestive heart failure
Endogenous toxins	Myoglobin, hemoglobin, paraproteinemia, uric acid
Exogenous toxins	Antibiotics, chemotherapy agents, radiocontrast agents, phosphate preparations
Tubulointerstitial Injury	
Acute allergic interstitial nephritis	Nonsteroidal antiinflammatory drugs, antibiotics
Infections	Viral, bacterial, and fungal infections
Infiltration Allograft rejection	Lymphoma, leukemia, sarcoid
Glomerular Injury	
Inflammation	Anti–glomerular basement membrane disease, antineutrophil cytoplasmic autoantibody disease, infection, cryoglobulinemia, membranoproliferative glomerulonephritis, Immunoglobulin A nephropathy, systemic lupus erythematosus, Henoch-Schönlein purpura, polyarteritis nodosa
Hematologic disorders	Hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, drugs
Renal Microvasculature	
	Malignant hypertension, toxemia of pregnancy, hypercalcemia, radiocontrast agents, scleroderma, drugs
Large Vessels	
Arteries	Thrombosis, vasculitis, dissection, thromboembolism, atheroembolism, trauma
Veins	Thrombosis, compression, trauma

BOX 29-2

Causes of Postrenal Acute Kidney Injury

Upper Urinary Tract Extrinsic Causes
- Retroperitoneal space—lymph nodes, tumors
- Pelvic or intraabdominal tumors—cervix, uterus, ovary, prostate
- Fibrosis—radiation, drugs, inflammatory conditions
- Ureteral ligation or surgical trauma
- Granulomatosis diseases
- Hematoma

Lower Urinary Tract Causes
- Prostate—benign prostatic hypertrophy, carcinoma, infection
- Bladder—neck obstruction, calculi, carcinoma, infection (schistosomiasis)
- Functional—neurogenic bladder secondary to spinal cord injury, diabetes, multiple sclerosis, stroke, pharmacologic side effects of drugs (anticholinergics, antidepressants)
- Urethral—posterior urethral valves, strictures, trauma, infections, tuberculosis, tumors

Upper Urinary Tract Intrinsic Causes
- Nephrolithiasis
- Strictures
- Edema
- Debris, blood clots, sloughed papillae, fungal ball
- Malignancy

From Sharfuddin AA, et al. Acute kidney injury. In Taal MW, et al, eds. *Brenner & Rector's The Kidney*. 9th ed. Philadelphia: Saunders; 2012:1046.

Current classification focuses on serum creatinine clearance and urinary output as markers for severity of injury: the Acute Dialysis Quality Initiative's RIFLE (*R*isk of renal dysfunction, *I*njury to the kidney, *F*ailure of kidney function, *L*oss of kidney function, and *E*SKD [end-stage kidney disease]) or the Acute Kidney Injury Network's (AKIN) stages 1 through 3. Both classifications tout serum creatinine clearance as a more sensitive marker for AKI, versus urine output. The classifications delineate the progression of kidney injury from an at-risk standpoint to complete end-stage kidney disease (ESKD).[72,73] Table 29-2 shows the RIFLE and AKIN classification systems.

Conditions that lead to reductions in urine output include acute reductions in GFR, excessive reabsorption of salt or water, or both. Increases in circulating levels of catecholamines, ADH, or aldosterone are physiologic factors that can decrease urinary output.[72] If not reversed, initial stages of AKI may progress to injury, tissue loss, or end-stage kidney disease with progressively increasing mortality rates.[67]

Acute tubular necrosis (ATN) may be produced by a variety of factors that interfere with glomerular filtration or tubular reabsorption. Reabsorption of urea, sodium, and water are all impaired, in contrast to AKI, in which these functions are maintained.[73]

Renal hypoperfusion or a nephrotoxic insult may initiate renal failure. Surgical patients with external and internal fluid losses or sepsis may have renal hypoperfusion. The renal medulla, with its sluggish blood supply and active transport mechanisms, is especially susceptible to even moderate renal ischemia.

The initiating insult culminates in the development of one or more maintenance factors, such as decreased tubular function, tubular obstruction, sustained reductions in renal blood flow, and glomerular filtration. Urine flow and solute excretion are reduced. Once the maintenance period has begun, pharmacologic interventions to improve renal blood flow do not reverse the failure.

Hemodynamic optimization is crucial in preventing postoperative AKI. Decreasing the need for renal replacement therapy (RRT) decreases AKIN classification as well as the incidence of progression. Administering fluids and inotropes, to maintain adequate perfusion, in the pre-, intra-, and postoperative periods, is associated with significantly decreased mortality and less risk of AKI.[74]

Patients with parenchymal disease have trouble concentrating the urine. Urine sodium levels are high, and osmolality is low. Renal damage is also associated with a progressive rise in serum urea, creatinine, uric acid, and polypeptide levels. Serum potassium levels increase, and a decrease, or dilution, occurs in the serum levels of sodium, calcium, and proteins such as albumin. Exogenous factors may alter BUN level, and subtle changes in serum creatinine concentration are easily ignored.[73,75]

Risk Factors

A number of conditions may place patients at high risk for acute renal injury. Renal reserve decreases progressively with age. Older

TABLE 29-2 RIFLE and Acute Kidney Injury Network (AKIN) Definition and Staging of Acute Kidney Injury

DEFINITION	
RIFLE	**AKIN**
An increase in serum creatinine of ≥50% developing over <7 days *or* A urine output of <0.5 mL/kg/hr for >6 hr	An increase in serum creatinine of ≥0.3 mg/dL or ≥50% developing over <48 hr *or* A urine output of <0.5 mL/kg/hr for >6 hr

STAGING CRITERIA				
RIFLE Stage	**Increase in Serum Creatinine**	**Urine Output Criteria**	**Increase in Serum Creatinine**	**AKIN Stage**
*R*isk	≥50%	<0.5 mL/kg/hr for >6 hr	≥0.3 mg/dL or ≥50%	Stage 1
*I*njury	≥100%	<0.5 mL/kg/hr for >12 hr	≥100%	Stage 2
*F*ailure	≥200%	<0.5 mL/kg/hr for >24 hr or anuria for >12 hr	≥200%	Stage 3
*L*oss	Need for renal replacement therapy for >4 wk			
*E*nd stage	Need for renal replacement therapy for >3 mo			

RIFLE (*R*isk of renal dysfunction, *I*njury to the kidney, *F*ailure of kidney function, *L*oss of kidney function, and *E*SKD [end-stage kidney disease])
From Sharfuddin AA, et al. Acute kidney injury. In Taal MW, et al, eds. *Brenner & Rector's The Kidney*. 9th ed. Philadelphia: Saunders; 2012:1046.

patients are less able to cope with fluid and electrolyte imbalance and are more prone to renal damage. Overall mortality rates associated with AKI increase.[76]

Patients with preexisting renal dysfunction are also at high risk. Cardiac and hepatic failure is associated with abnormal renal hemodynamics. Reduced GFR is associated with cortical redistribution of blood flow and salt and water retention. All of these aberrations are increased by anesthetics, stress, and hypovolemia. Further, these alterations correlate with greater incidences of postoperative AKI and an increase in mortality up to four-fold.[77] Elevated bilirubin is related to acute hepatitis and is an independent risk factor of AKI.[78]

Certain surgical procedures are associated with a higher risk of AKI. The risk increases in patients with preoperative ventricular dysfunction or bacterial endocarditis, those undergoing emergency or high-risk procedures, those who are anemic or receive perioperative blood products, and those who have procedures requiring cardiopulmonary bypass longer than 2 hours. Postoperative bleeding with reexploration and low cardiac output requiring use of the intraaortic balloon pump also carry a higher incidence of injury.[79-81]

A ruptured abdominal aortic aneurysm commonly results in hypovolemia, shock, and the need for high aortic cross-clamping. Of these patients, 40% have renal damage, and 11% develop AKI with an associated mortality rate of 80%. Renal dysfunction after elective surgery is less profound if attention is given to adequate hydration and if a brisk diuresis is established before, and maintained during, aortic cross-clamping. The proximity of the aortic clamp to the renal arteries is critical. Aortic arteriography performed just before surgery also increases risk. Predisposing factors include preexisting renal disease with serum creatinine levels greater than 3 mg/dL; proteinuria; diabetes; and hypovolemia. Risk is reduced by minimizing the amount of dye given, maintaining hydration, and using diuretics such as mannitol to promote diuresis. Postoperative AKI is a common complication of thoracic aorta, thoracoabdominal aorta, and aortic arch surgeries. It is observed in 6% to 18% of such surgical procedures. Predisposing factors for this complication include age older than 50, preoperative renal dysfunction, duration of renal ischemia, and amount of blood transfused.[82]

Mechanical obstruction by calculi or prostatic disease is the most common cause of obstructive uropathy.[73] Risk is increased by the frequent presence of hypovolemia and electrolyte imbalance and by preoperative diagnostic studies that involve the use of dye.

Hypovolemia, decreased pulmonary function, and acidosis are key factors in the development of AKI in septic patients. The use of vasoconstrictive adrenergic agonists and antibiotics with nephrotoxic potential compounds the problem.[83,84]

Complications of pregnancy such as hemorrhage, amniotic fluid embolus, and toxemia carry a high risk of renal failure, but because patients are usually young and healthy, mortality in this group is reduced. Proteinuria, related to or independent of pregnancy, also serves as a major risk factor for the development of AKI.[85]

In the first trimester of pregnancy, hyperemesis gravidum or septic abortion pose a risk for renal injury. Risks in the third trimester include preeclampsia, HELLP (*h*emolysis, *e*levated *l*iver *e*nzymes, and *l*ow *p*latelet count) syndrome, acute fatty liver of pregnancy, or thrombosis. Diagnosis is by serum creatinine because GFR calculations are complicated due to the altered volume status of pregnant women.[85]

Prevention and Management

Prevention of acute kidney injury is far more successful than management. Prevention can be based on the following generalizations:

- The most common cause of AKI is prolonged renal hypoperfusion.
- Prophylaxis reduces mortality more effectively than dialytic therapy.
- The duration and magnitude of the initiating renal insult are critical in determining the severity of AKI.

A key strategy in reducing the incidence of AKI is limiting the magnitude and duration of renal ischemia. Prevention begins in the preoperative period.[74,84]

Preoperative Strategies

High-risk patients and procedures should be identified. Reversible renal dysfunction should be addressed, and fluid losses and hypovolemia should be corrected by intravenous fluids and inotropes.

Perioperative ADH and renin-angiotensin-aldosterone secretion can be minimized with adequate hydration before anesthetic induction. Administration of saline, rather than solutions low in sodium, is helpful in prevention of aldosterone secretion, hyponatremia, and oliguria.[74]

Oliguria often signals inadequate systemic perfusion, and prevention of AKI requires its rapid recognition through adequate monitoring. In addition to standard monitors and a urinary catheter, monitors for patients with questionable cardiac and pulmonary function should include: (1) a direct arterial line for blood pressure monitoring and (2) a central venous pressure (CVP), pulmonary artery catheter, or transesophageal echocardiography as appropriate, for assessment of cardiac function and volume status. The hemodynamic end-point should be adequate cardiac output and renal perfusion.[74]

Perioperative Strategies

Use of a urinary catheter is the standard means of monitoring renal function in the operating room. A fluid challenge may be necessary if hourly urinary output decreases to below acceptable levels.

The use of diuretics in the face of inadequate urinary output is common; however, controversial. Data suggest that diuretic use to prevent AKI is not useful. Diuretic use in established AKI offers little benefit in changing outcome of mortality or need for renal replacement therapy, particularly in the presence of oliguria. Given the current literature, use of diuretics for volume management when necessary in patients with AKI can be considered. However, diuretic use to prevent oliguria in the AKI setting is not indicated.[86,87]

High-dose diuretics have been effective in decreasing 60-day mortality rates associated with AKI. Diuretic therapy must be balanced with fluid administration to prevent hypotension and hypoperfusion. The best outcomes have been with furosemide and fluid balance to avoid a fluid excess or deficit. Mechanisms for protection include the inhibition of sodium reabsorption and the prevention of tubular obstruction through the maintenance of high flow and pressure within the tubules and the reversal of intrinsic renal vasoconstriction. Prophylactic use of diuretics may be of benefit in the case of jaundice in surgical patients, excessive exposure to contrast media, hyperuricemia, or the presence of pigment in the urine.[86,87]

Fenoldopam (Corlopam) is a selective dopamine-1 (DA_1) receptor agonist. It causes both systemic and renal arteriolar vasodilation and has no effect on dopamine-2 (DA_2), α-adrenergic, or β-adrenergic receptors. Unlike dopamine, which causes renal vasoconstriction and systemic cardiovascular changes at higher doses, fenoldopam at high doses produces renal vasodilation with little systemic effects. Despite theoretically promising pharmacology, clinical benefit with fenoldopam has been limited. It is not currently recommended for use in AKI. No benefit in survival or the need for RRT has been noted as compared with placebo. A recent study found that fenoldopam had no greater renal protection in patients undergoing infrarenal aortic cross-clamping for abdominal reconstruction than sodium nitroprusside and dopamine.[88,89] Newer therapies under evaluation include atrial natriuretic peptide, urodilatin, and nesiritide.

Treatment of Acute Kidney Injury

Therapy for AKI involves rapid recognition and correction of reversible causes, avoidance of any further renal injury, and correction and maintenance of a normal electrolyte and fluid volumes. Preventive therapy or medical interventions performed early provide the greatest chance for minimizing injury.

Key approaches include administering volume (e.g., normal saline) to achieve euvolemia, improving cardiac output by afterload reduction, and normalizing systemic vascular resistance. Postrenal AKI secondary to prostatic hypertrophy can frequently be corrected by placement of a bladder catheter or nephrostomy tube. Intrarenal AKI can be the most complex and difficult to treat. AKI caused by glomerulonephritis or vasculitis frequently requires immunosuppressive therapy. For suspected acute interstitial nephritis, the offending medication must be determined and discontinued; a 2-week tapering course of glucocorticoids, beginning with 1 mg/kg of prednisone for 3 days, is commonly recommended despite the absence of definitive data. Serum electrolytes, creatinine, and BUN should be monitored at least daily, more frequently if the patient's renal function appears to be tenuous. Patients with AKI should also receive a low sodium, potassium, and protein diet. Early nephrology consultation will ensure that the patient receives optimal care. Some patients will require urgent hemodialysis because of marked metabolic acidosis unresponsive to sodium bicarbonate infusions; electrolyte abnormalities, such as hyperkalemia that is unresponsive to medical management; pulmonary edema not responding to diuretic therapy; and uremic symptoms of encephalopathy, seizures, and pericarditis. Intermittent hemodialysis and continuous renal replacement therapy may be necessary.[71,74]

Prognosis. Typically, AKI secondary to prerenal causes, if diagnosed and treated early, has the best prognosis for renal recovery. Patients with prerenal AKI commonly return to their baseline level of renal function and have a mortality rate of less than 10%. Similarly, patients with postrenal AKI also have a good prognosis for renal recovery if the outlet obstruction is promptly diagnosed and definitively treated.

In contrast, patients with intrarenal AKI have a less predictable renal outcome, and mortality in this group varies between 30% and 80%, depending on the severity of injury. Patients who have a severe episode of AKI requiring hemodialysis may not recover their renal function and may need hemodialysis indefinitely. AKI hastens progression of chronic kidney disease to end-stage kidney disease and is often the major factor that causes such progression.[71,74] Clinical management of oliguria is found in Box 29-3.

CHRONIC KIDNEY DISEASE

Chronic kidney disease, or chronic renal failure, is a slow, progressive, irreversible condition characterized by diminished functioning of nephrons and a decrease in renal blood flow, GFR, tubular function, and reabsorptive capacity. By definition, chronic kidney disease exists when GFR is less than 60 mL/min/1.73 m^2 for 3 months or more.[90,91] Although many conditions may lead to renal failure, primary causes include glomerulonephritis, pyelonephritis, diabetes mellitus, hyperlipidemia, autoimmune disease, obesity, vascular or hypertensive insults, and congenital defects. Table 29-3 outlines the systemic effects of chronic renal failure.

The general course of progressive chronic kidney disease may be divided into five stages[92,93]:

- Stage 1: Kidney damage with normal or increased GFR
- Stage 2: GFR 60 to 89 mL/min/1.73m^2 with evidence of kidney damage
- Stage 3: GFR 30 to 59 mL/min/1.73m^2
- Stage 4: GFR 15 to 29 mL/min/1.73m^2
- Stage 5: End-stage renal failure with GFR less than 15 mL/min/1.73 m^2

Initial nephron injury causes adaptation in remaining nephrons, including increased glomerular size and pressure, which

BOX 29-3

Clinical Management of Perioperative Oliguria

- Oliguria is a urine output less than 0.5 mL/kg but may be 1 to 2 mL/kg in a patient who has received mannitol.
- Assume oliguria is prerenal until proven otherwise. Signs of prerenal include the following:
  - Oliguria
  - High urine osmolality
  - Low urine sodium
- Begin treatment with serial fluid boluses if assessment does not indicate overload.
- Do *not* give a diuretic to "make urine" in the face of intravascular hypovolemia or hypotension because this may result in exacerbation of renal injury.
- Do give diuretics if there are signs of fluid overload or if oliguria persists despite fluid challenges and stabilized hemodynamics.
- If improvement is not noted with fluid challenge or diuretics, institute invasive hemodynamic monitoring (central venous pressure and arterial pressure monitoring when large fluid shifts are expected).
- Maximize renal blood flow by enhancing cardiac function: normalize preload, heart rate, and rhythm; institute afterload reduction with vasodilators or inodilator agents.
- Maintain renal perfusion pressure.
- Prophylactic pharmacologic agents may be used when renal risk is high, but there is little evidence to suggest they are better at maintaining glomerular filtration rate than volume.
- Diuretic resistance may be related to the following:
  - Acute tolerance induced by hypovolemia
  - Chronic tolerance
  - Refractory states

TABLE 29-3 Systemic Effects of Chronic Renal Disease

System	Effects
Cardiovascular	Hypertension Congestive heart failure Peripheral and pulmonary edema Pericarditis Coronary artery disease
Hematologic	Normochromic, normocystic anemia Platelet dysfunction Leukocyte, immunologic dysfunction
Neurologic	Encephalopathy Peripheral and autonomic neuropathy
Endocrine	Hyperparathyroidism Adrenal insufficiency
Respiratory	Pneumonitis Pulmonary edema
Gastrointestinal	Bleeding Nausea, vomiting Delayed gastric emptying
Metabolic	Acidosis Electrolyte imbalance

BOX 29-4

Indications for Renal Replacement Therapy

Absolute indications
- Volume overload unresponsive to diuretic therapy
- Hyperkalemia despite medical treatment
- Persistent metabolic acidosis
- Overt uremic symptoms
  - Encephalopathy
  - Pericarditis
  - Uremic bleeding diathesis

Relative indications
- Progressive azotemia without uremic manifestations
- Persistent oliguria

From Sharfuddin AA, et al. Acute kidney injury. In Taal MW, et al, eds. *Brenner & Rector's The Kidney*. 9th ed. Philadelphia: Saunders; 2012:1083.

results in progression of renal disease. As the number of functioning nephrons declines, the signs, symptoms, and biochemical abnormalities become more severe.

Clinical signs or laboratory evidence of renal disease are absent until less than 40% of normal-functioning nephrons remain. Loss of nephron function without symptoms is known as a decrease in renal reserve. Renal insufficiency occurs when only 10% to 40% of nephrons are functioning adequately. Nocturia occurs secondary to a decrease in concentrating ability. Elimination of a large protein load or excretion of certain drugs is impaired. Preservation of remaining nephron function is a major goal in renal insufficiency.

Toxic substances such as aminoglycosides, nonsteroidal antiinflammatory drugs, and piperacillin have been implicated in causing interstitial nephritis and renal insufficiency.[92,93] The administration of radiographic contrast media in at-risk patients results in renal insufficiency at the same rate as in 1979. Patients at greatest risk for developing contrast-induced renal insufficiency include those with preexisting renal insufficiency (creatinine greater than 1.2 mg/dL) and diabetes. Strategies including the administration of *N*-acetylcysteine (NAC), sodium bicarbonate, and ascorbic acid have been studied.[94]

As renal function deteriorates further, end-stage renal disease develops. In this stage, concentrating and diluting properties of the kidney are severely compromised, and electrolyte, hematologic, and acid-base disturbances are common. The loss of 95% of functioning nephrons culminates in uremia, which is associated with volume overload and congestive heart failure. Uremia, which can be viewed as urine in the blood, adversely affects almost every organ system. Mortality is inevitable unless dialysis is performed for end-stage renal disease.[95]

Renal Failure and Dialysis

Approximately 350,000 people in the United States today require chronic dialysis, and the end-stage renal failure population is projected to grow about 8% per year. Three hundred thirty-nine patients per 1 million receive renal replacement therapy for end-stage renal disease per year, and almost half of these patients require treatment early in the postoperative period.[96,97] Indications for renal replacement therapy are shown in Box 29-4.

Dialysis Techniques

Dialysis is a general term used to describe therapy in which solute moves from blood through a semipermeable membrane into a chemically prescribed solution. The movement of solute, which

is called *diffusive transport*, depends on differences in molecular concentration between the blood compartment and the dialysate. Ultrafiltration is a technique in which a hydraulic pressure difference across a semipermeable membrane causes the bulk removal of fluid and solute by convective transport.

Major types of dialysis include hemodialysis and peritoneal dialysis. In hemodialysis, blood moves through a device that exposes it to an individually prescribed dialysate solution across a semipermeable membrane. Hemodialysis requires systemic or regional anticoagulation. Concerns about hemodynamic stability during hemodialysis, nephron injury, and the inability to adequately remove excess water and solutes have led to the development of a slower, less aggressive renal replacement therapy: continuous renal replacement therapy (CRRT).

CRRT is an extracorporeal process in which blood is removed from the arterial lumen of a catheter by a peristaltic blood pump and pushed through a semipermeable membrane before being pumped back into patients via the venous lumen of the catheter. CRRT includes a number of treatment modalities. Pump-driven, venovenous CRRT is currently the most common technique. The modalities of venovenous CRRT vary primarily in their mechanism of solute removal: in continuous venovenous hemofiltration (CVVH), solute transport occurs by convection; in continuous venovenous hemodialysis (CVVHD), it occurs by diffusion; and continuous venovenous hemodiafiltration (CVVHDF) is a combination of the two. The hybrid modalities of RRT with conventional hemodialysis equipment that is modified to provide extended-duration dialysis provides enhanced hemodynamic tolerability.[96]

Peritoneal Dialysis. The use of peritoneal dialysis in the management of AKI has diminished as the use of continuous and hybrid therapies have increased. Peritoneal dialysis has the advantage of requiring minimal technology. Access for short-term peritoneal dialysis can be obtained either by percutaneous placement of an uncuffed temporary peritoneal catheter or through surgical placement of a tunneled cuffed catheter. Peritoneal dialysis has the advantage of avoiding the need for vascular access or anticoagulation. Solute clearance and control of metabolic parameters may be inferior to that achieved with other modalities of RRT. Although systemic hypotension is less of an issue than with other modalities of RRT, ultrafiltration cannot be as tightly controlled. Other limitations include the relative contraindication in patients with acute abdominal processes or recent abdominal surgery, the risk of visceral organ injury during catheter placement, the risk of peritoneal dialysis–associated peritonitis, and an increased tendency toward hyperglycemia, which is associated with adverse outcomes in acute illness, due to the high glucose concentrations in peritoneal dialysate.[97]

Physiologic Effects

Dialysis and ultrafiltration are associated with a number of physiologic effects and complications. Major systems involved include the nervous system, cardiovascular system, and respiratory system. The disequilibrium syndrome is the most severe central nervous system (CNS) effect of dialysis. This syndrome is associated with a rapid increase in brain intracellular volume because serum sodium and BUN levels are reduced. Predisposing factors include a BUN concentration greater than 150 mg/dL, hypernatremia, severe acidemia, and preexisting brain disease. The syndrome may be mild or may progress to seizures, stupor, and coma. The incidence is reduced by the avoidance of high rates of hemodialysis therapy in high-risk patients.

Hemodialysis is associated with a 30% incidence of hypotension. Contributing factors include reduced plasma volume and blunted sympathetic nervous system response associated with uremia. Acetate from the dialysate moves into the blood and contributes to the hypotension by causing vasodilation and cardiac depression.

The incidence of hypotension with dialysis is less in patients who have fasted than in those who have not. Fasting prevents the contribution to hypovolemia of increased gastrointestinal blood flow and the secretion of isotonic intestinal juices. Anemia should be corrected if the hematocrit is less than 20% to increase vascular resistance. Leg elevation, a decrease in dialyzer transmembrane pressure, or the use of volume expanders or vasoconstrictors usually corrects hypotension. Substitution of HCO_3 for acetate in the dialysate also decreases the incidence of hypotension.[96-99]

Hypoxemia is a common side effect of hemodialysis and may be seen during peritoneal dialysis.[97] During hemodialysis, arterial oxygen tension often decreases by 5 to 20 mmHg. Pulmonary leukostasis and extracorporeal loss of CO_2 with a reduction in minute ventilation have been implicated. Hypoxemia is managed by increasing the inspired oxygen concentration during dialysis. The use of HCO_3 in place of acetate limits extracorporeal losses of CO_2 and reduces the incidence of hypoxemia.

Muscle cramping is the most common neuromuscular complication of dialysis. It is seen almost exclusively with hemodialysis and results from the rapid reduction of intravascular volume and serum sodium level. Intravenous administration of hypertonic saline relieves muscle cramping.

The nutritional depletion common in dialysis-dependent patients may be caused by the primary disease, dietary restrictions, or the loss of protein associated with peritoneal dialysis. Protein depletion may produce hypoalbuminemia and immunocompromise. The large quantities of hypertonic glucose solutions absorbed with peritoneal dialysis contribute to obesity, hyperglycemia, and hyperlipidemia. Administration of insulin controls hyperglycemia, and diet and exercise limit hyperlipidemia.

PREOPERATIVE RENAL ASSESSMENT

Preoperative assessment of the patient with suspected or known renal dysfunction must include a thorough history and physical examination, as well as appropriate laboratory evaluation (Box 29-5). The medical history is the single most important source of information in establishing the presence or absence of renal disease. Poorly controlled hypertension, trauma to the urinary system, prior renal surgery, or systemic disease (e.g., diabetes) may be associated with renal impairment. A history that arouses suspicion should lead to a more thorough evaluation of renal function.

Although abnormalities are commonly identified by urinalysis, the quality of urinalysis results obtained by dipstick technique varies.[100] Because abnormal results on urinalysis usually fail to lead to a change in management, the test is generally omitted. If the test is available, attention should be directed to the following:

1. *Specific gravity.* Specific gravity, a measurement of solutes in the urine, indicates the ability of the kidney to excrete concentrated or dilute urine. It is a reflection of tubular function and normally varies from 1.003 to 1.030, depending on fluid intake and the presence or absence of high-molecular-weight substances such as glucose or mannitol. In the absence of such substances, a specific gravity of 1.018 or greater after overnight dehydration indicates reasonable function. A low specific gravity is meaningless if the condition under which the sample was collected is not known.
2. *Urine osmolality.* Osmolality, or the number of moles of solute (measured in osmoles) per kilogram of solvent, is more specific than specific gravity. Excretion of concentrated

BOX **29-5**

Preoperative Assessment and Preparation of the Patient with End-Stage Renal Disease

I. Clinical History
   A. Evaluate renal function.
   B. Document central nervous system deficits.
   C. Review cardiovascular history; look for significant hypertension, accelerated atherosclerosis, pericarditis, tamponade; assess extent, stability, and management of coronary artery disease.
   D. Look for history of excessive bleeding; if present consider use of desmopressin.
   E. Assess intravascular volume; correlate body weight changes with changes in blood pressure and heart rate before and after dialysis.
   F. Review pulmonary history.
   G. Dialyze 24 hours or less before surgery; ideal weight preoperatively is 1 to 2 kg above "dry" weight.
II. Physical Examination
   A. Locate and check patency of arteriovenous fistula or shunt.
   B. Evaluate vessels for venous or arterial access.
   C. Look for signs of congestive heart failure, pericarditis, or cardiac tamponade.
   D. Look for evidence of noncardiogenic pulmonary edema or aspiration.
III. Laboratory Tests
   A. Electrocardiography, chest radiography
   B. Glomerular filtration rate or creatinine clearance
   C. Blood urea nitrogen, creatinine
   D. Complete blood count with platelet count
   E. Bleeding time; prothrombin time; partial thromboplastin time
   F. Hematocrit; red-blood-cell index
   G. Electrolytes (especially potassium)
   H. Acid-base status
   I. Hepatitis antigen status

urine (specific gravity 1.030; 1400 mOsm/kg) indicates excellent tubular function, whereas urinary osmolality fixed to that of plasma (serum gravity 1.010; 290 mOsm/kg) suggests tubular concentrating defects. Urinary diluting mechanisms are present after concentrating ability is lost.

3. *Proteinuria.* Proteinuria exists when more than 150 mg of protein is excreted per day. Massive proteinuria or the renal loss of more than 750 mg/day is always abnormal and usually indicative of severe glomerular damage. In addition to its association with glomerular damage, proteinuria also may be present with abnormal plasma proteins or increased concentrations of normal proteins or when the renal tubules fail to reabsorb the small amount of protein that may be filtered. Patients can have proteinuria without renal disease under conditions of stress, fever, dehydration, exercise, or congestive heart failure. Patients who have significant proteinuria are more likely to develop AKI postoperatively than those who do not. The incidence of hypoalbuminemia and its consequences is increased in patients with severe proteinuria. In a concentrated urine sample, trace or 1+ proteinuria is a nonspecific finding, whereas 3+ or 4+ proteinuria suggests glomerular disease.

The kidneys share regulation of acid-base balance with the lungs. Because they provide the sole pathway for the excretion of the 60 mEq of hydrogen ions produced per day, urinary pH is a reflection of the ability of the kidneys to acidify urine. The inability to excrete acid urine in the presence of systemic acidosis is indicative of renal insufficiency.

Laboratory Tests for Renal Function

Patients with suspected or known renal disease should be tested preoperatively to evaluate GFR and renal tubular function. Although urine specific gravity (1.003 to 1.030), urine osmolality (65 to 1400 mOsm/L), and urine sodium concentration (130 to 260 mEq/day) reflect renal tubular function, BUN concentration (10 to 20 mg/dL), plasma creatinine level (0.7 to 1.5 mg/dL), and creatinine clearance (110 to 150 mL/min) are necessary for the evaluation of GFR.

Blood Urea Nitrogen

Urea, the chief end product of protein metabolism, is formed in the liver. It is excreted by glomerular filtration, but significant amounts of urea are reabsorbed along the renal tubule. Although the normal range for BUN level is 10 to 20 mg/dL, it is altered by a variety of factors, including ingestion of protein, anabolic and catabolic states, GFR, state of hydration, and reabsorption of urea by the nephrons. Because of the numerous extrarenal factors that can influence BUN, it is a better indicator of uremic symptoms than of GFR. Levels below 8 mg/dL suggest overhydration or underproduction of urea, whereas those between 20 and 40 mg/dL suggest dehydration, high nitrogen levels, or decreased GFR. Levels higher than 50 mg/dL almost always indicate decreased glomerular filtration. Elevations of BUN level in the presence of normal serum creatinine concentration suggest a nonrenal cause of the elevation. In general, BUN level is a late indicator of renal disease because it does not increase in most patients until the GFR is reduced by more than 50%.[101]

Serum Creatinine

Creatinine is a metabolite of creatine, a major muscle constituent. The daily rate of production of creatinine is constant and determined by skeletal muscle mass. Because body creatinine is eliminated almost entirely by glomerular filtration, its steady-state concentration in the serum has been used as a marker of glomerular function. Normal values range from 0.7 to 1.5 mg/dL, but the serum concentration can be lower in the elderly or in women who have reduced muscle mass. Patients with muscle wasting have lower levels, whereas those who are heavily muscled or those in acute catabolic states have higher values because of more rapid muscle breakdown. Because the production and release of creatinine are relatively stable throughout the day and from day to day, serum levels are inversely related to GFR if a steady state exists. In other words, for every 50% reduction in GFR, creatinine level doubles. Excretion of drugs dependent on glomerular filtration may be significantly decreased despite only a slight elevation in serum creatinine level.

An elevation of both BUN and serum creatinine levels provides more information than an elevation of either level alone. The usual ratio of urea nitrogen to creatinine in the serum is 10:1. Increased ratios are seen with increased urea input, decreased circulatory blood volume, and obstructive uropathy. Decreased ratios are seen with decreased urea input, increased creatinine production, and volume expansion.

Creatinine Clearance

Creatinine clearance is a specific test of GFR and the most reliable assessment tool for renal function. This test measures the ability

of the glomeruli to excrete creatinine into the urine for a given plasma creatinine concentration. Although not dependent on corrections for age or the presence of a steady state, a disadvantage of this test is the need for accurate 24-hour urine specimens. Creatinine clearance is calculated according to the following formula:

$$\text{GFR} = (\text{Urine creatinine} \times \text{Urine volume}) \times \text{Serum creatinine}$$

A 2-hour urine sample collected through a urinary catheter permits acceptable accuracy. In the absence of urine volume, creatinine clearance can be approximated with use of the following Cockcroft-Gault formula:

$$\text{GFR} = \frac{([140 - \text{Age}] \times \text{Lean body weight [kg]})}{(72 \times \text{Serum creatinine [mg/dL]})}$$

where weight is expressed in kilograms. To compensate for their smaller muscle mass, when values for women are calculated, the weight should be multiplied by 0.85.[102,103]

The normal range for creatinine clearance is 95 to 150 mL/min. Mild renal dysfunction is present when creatinine clearance is 50 to 80 mL/min, and moderate dysfunction is present at values below 25 mL/min. In patients with dysfunction, the administration of drugs that depend on renal excretion should be reduced, and fluid and electrolyte balance should be carefully monitored. Patients with creatinine clearance less than 10 mL/min are anephric and require dialysis for fluid and water hemostasis.

Other Tests

Advanced renal disease affects most organ systems. Additional tests that may be useful in patients with advanced renal disease include chest radiography, electrocardiography, complete blood count, serum electrolytes, and acid-base studies.

Systemic Abnormalities and Advanced Renal Disease

Renal failure is characterized by a wide variety of biochemical disturbances. Although most organ systems are involved (see Table 29-3), only those most relevant to anesthetic management are discussed in this section.

Cardiovascular Alterations

Cardiovascular disease accounts for approximately 50% of all deaths in patients on hemodialysis.[96,97] Hypertension and congestive heart failure often accompany end-stage renal disease. Ninety percent of the hypertension is volume dependent and related to sodium and water retention. The remainder can be attributed to high circulatory levels of renin. The combination of hypertension, anemia, hypoalbuminemia, and circulatory overload secondary to salt and water retention contributes to peripheral and pulmonary edema and to an increased risk of congestive heart failure.

In nonsurgical settings, ischemic heart disease is the most common cause of death in patients with chronic renal failure. Multiple risk factors such as hypertension, hyperlipidemia, and abnormal carbohydrate metabolism contribute to this high incidence of ischemic heart disease.[102,103] The anesthetist should assume that clinically significant coronary artery disease exists and should evaluate the extent and stability of the disease. Several uncontrolled studies suggest that correction of coronary lesions with coronary artery bypass grafting is associated with better outcomes than coronary angioplasty in patients on hemodialysis.[104,105] Improvement of symptoms is common after coronary artery bypass grafting. The advent of drug-eluding stents has led to numerous studies to determine the incidence of restenosis in hemodialysis patients. The results of these studies remain inconclusive.[104,105]

A fibrous pericarditis is clinically evident in approximately 50% of patients with severe uremia. Signs and symptoms may include pain on deep inspiration or when lying down, and a friction rub over the pericardium noted during auscultation. An enlarged cardiac silhouette on chest radiography indicates pericardial effusion. Patients with uremic pericarditis occasionally develop a massive hemorrhagic effusion and cardiac tamponade, especially when anticoagulants are used for hemodialysis.

Uremic patients exhibit a wide range of hemodynamic abnormalities when studied during hemodialysis.[96] The striking feature of these studies is that the peripheral vasculature responds abnormally to hypovolemia induced by dialysis. Hypovolemia decreases arterial pressure without increasing heart rate. Peripheral vascular resistance is unchanged or decreased, and cardiac output is increased.

Because the potential for significant cardiovascular complications exists, patients with advanced renal disease should undergo chest radiography and electrocardiography preoperatively. Administration of antihypertensive drugs should be continued, blood pressure should be monitored, and signs and symptoms of cerebrovascular disease should be recorded. The blood pressure should be normal or slightly elevated before induction. Because adequate intravascular volume is necessary for hemodynamic stability, the patient's weight should ideally be 1 to 2 kg more than dry weight at the end of the last dialysis before anesthetic induction.

Hematologic Changes

Normochromic, normocytic anemia is an inevitable finding in advanced renal disease. Hematocrit levels often decrease to the 20% to 30% range and generally parallel the degree of azotemia. The primary reason for anemia is a decrease in erythrocyte formation secondary to a decrease in production by the failing kidney.[106] Also, some evidence suggests that uremic toxins may inactivate erythropoietin or suppress the response of the bone marrow to its action. A second factor that contributes to the anemia in uremic patients is reduction of the life span of the erythrocyte because of an increase in hemolysis secondary to the presence of an abnormal chemical environment. Additionally, blood loss from frequent sampling for laboratory tests, loss in hemodialysis tubing, and a tendency for gastrointestinal bleeding further aggravate anemia.

Hematocrit and red-blood-cell indexes should be measured preoperatively, and their values should be checked against dialysis records to ensure that no acute changes have occurred. Preoperative hematocrit levels that are similar to those of a patient maintained on dialysis suggest that the patient can withstand the chronic anemia. Routine transfusion of blood preoperatively is not recommended for these patients. If transfusion is necessary because of acutely decreased or poorly tolerated hematocrit values, no need exists to withhold red-blood-cell transfusions for fear of sensitization to histocompatibility antigens.[107]

Exogenous administration of human recombinant erythropoietin corrects the anemia associated with chronic renal failure. The risks of treatment with erythropoietin include hypertension, vascular access clotting, and death. Adequate iron stores and good dialysis are essential if the response to recombinant erythropoietin or epoetin is to be maximized.[108,109] Endogenous erythropoietin levels and hematocrit values increase to normal within 8 to 10 weeks after successful renal transplantation.[110] There are three erythropoiesis-stimulating agents (ESAs) currently available to treat anemia in patients with chronic renal disease who are on dialysis. They are peginesatide (Omontys), epoiten (Procrit, Epogen), and darbepoetin (Aranesp). [111]

Patients with chronic uremia have a tendency to bleed excessively. Although platelet counts are only mildly reduced, a defect

in platelet function appears to be responsible for prolonged bleeding time and a tendency for excessive bleeding. Dialysis partially corrects platelet dysfunction, and dialysis 24 hours or less before surgical intervention is recommended.[112-113]

Desmopressin is known to shorten bleeding time and increase circulating levels of factor VIII, the von Willebrand antigen, in uremic patients. Desmopressin is the agent of choice because of its rapid onset and minimal side effects.[114] Repeated doses over time may increase bleeding time between treatments. Cryoprecipitate and conjugated estrogens also shorten bleeding time and may reduce blood loss.[115]

Gastrointestinal Effects

Patients on dialysis have a high incidence of gastrointestinal mucosal inflammatory changes and are at high risk of gastrointestinal bleeding perioperatively. The use of histamine-2 (H_2) blocking drugs or antacids is recommended throughout the perioperative period for decreasing the incidence of stress ulcers.[116]

Infections

Infectious complications are common in patients with renal failure and represent a leading cause of death in dialysis-dependent patients. Protein malnutrition and abnormalities in neutrophil, monocyte, and macrophage function contribute to this problem.[117] Mechanisms that lead to leukocyte dysfunction and increased susceptibility to infection are not known but may be related to uremia, immunosuppressive therapy, and increased exposure to invasive therapy. Frequent exposure to blood and blood products increases the risk of infection with hepatitis B and C and the human immunodeficiency viruses. Universal precautions are mandatory for the protection of both patients and health care providers.[96,97,118]

Neurologic Effects

Neurologic symptoms associated with end-stage renal disease roughly parallel the degree of azotemia. Early symptoms include apathy, decreased mental acuity, and lethargy. Fatigue and weakness are early complaints, and untreated patients eventually become confused and comatose. Seizures may be associated with hypertensive encephalopathy. Peripheral and autonomic nervous system neuropathy is common. Autonomic neuropathy is associated with delayed gastric emptying and places the patient at risk for aspiration pneumonitis.

Endocrine Abnormalities

Endocrine abnormalities in patients with end-stage renal disease include hyperparathyroidism and adrenal insufficiency. Hypocalcemia is common in patients with advanced renal disease, and hyperparathyroidism represents an appropriate compensatory increase in parathormone in response to a reduction in serum calcium levels. Adrenal insufficiency often is secondary to exogenous steroid administration.

Respiratory Effects

Respiratory complications associated with renal failure include pneumonitis and the "uremic lung." Chest radiographs of the uremic lung reveal bilateral butterfly-shaped infiltrates indicative of pulmonary edema. Pulmonary congestion and edema usually are related to volume overload.[119]

Electrolyte Abnormalities

Abnormalities of water, electrolyte, and acid-base balance become more common as the degree of renal failure increases. With a normal diet, the kidneys typically excrete 40 to 60 mEq of hydrogen ions per day to prevent acidosis. Impaired ability of the kidney to excrete hydrogen ions with renal failure results in metabolic acidosis characterized by decreases in plasma pH and HCO_3 concentration. Acidosis is usually moderate, but symptoms of anorexia, nausea, vomiting, and lethargy, which are common in uremic patients, may be partly related to acidosis.

Sodium ion excretion by the kidney normally varies according to intake. Patients with chronic renal failure lose this flexibility and have sodium wasting or retention. In early renal insufficiency with polyuria, an increased solute load for each intact nephron results in sodium wasting. In renal failure, the patient is more likely to retain sodium. Salt and water retention leads to circulatory overload, hypertension, edema, and congestive heart failure.

Although the ability to excrete magnesium is reduced in uremic patients, hypermagnesemia is generally not a serious problem. Magnesium intake is usually reduced because of anorexia, reduced protein intake, and decreased absorption from the gastrointestinal tract.

Calcium balance is controlled by parathyroid hormone, calcitonin, and vitamin D. Vitamin D, or cholecalciferol, is inactive until it has been hydroxylated in the liver and kidney. Inability of the diseased kidney to hydroxylate 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (active vitamin D) results in hypocalcemia. Patients with chronic renal failure have skeletal disorders or osteodystrophy, and defective mineralization of bone predisposes patients to fractures. Special precautions should be taken when these patients are moved and positioned.

Potassium imbalance is one of the most serious disturbances that occurs in patients with renal failure. Although hypokalemia may be associated with the polyuria of renal insufficiency, end-stage renal disease invariably leads to hyperkalemia. Although the major mechanism for hyperkalemia is the inability of distal nephrons to secrete potassium in exchange for calcium, systemic acidosis also contributes to potassium imbalance. Acidosis causes potassium ions to shift from intracellular to extracellular fluid.

Fatal dysrhythmias or cardiac standstill can occur when serum potassium levels reach 7 to 8 mEq/L. Dialysis is the most effective means of managing perioperative hyperkalemia, and hemodialysis is indicated when serum potassium exceeds 6 mEq/L. Other techniques for treating hyperkalemia include insulin in glucose infusions (25 to 50 g of glucose with 10 to 20 units of regular insulin) and administration of bicarbonate (50 to 100 mEq intravenously slowly). These measures promote rapid translocation of extracellular potassium to the intracellular space during hyperkalemic emergencies. Hyperventilation of the lungs with respiratory alkalosis lowers serum potassium concentration by approximately 0.5 mEq/L for every 10-mmHg change in arterial CO_2 tension. Life-threatening cardiac dysrhythmias are treated with intravenous administration of calcium chloride. A typical dose may be 1 g in adults. Although calcium does not change the serum concentration of potassium, it antagonizes the cardiotoxic effects of hyperkalemia.

Unexpected hyperkalemia can develop rapidly, so it is important to measure potassium even when dialysis has been performed within 6 to 8 hours of surgery. Hyperkalemia occurs early postoperatively and is the primary reason patients with renal failure require dialysis within the first 24 hours after surgery.[120]

Surgical procedures are becoming increasingly more common in anephric patients. The perioperative course of these patients may be complicated by a high incidence of untoward events that increase morbidity and mortality. These complications are related to the abnormal physiology of the anephric state. They are predictable and can be minimized by preoperative evaluation and preparation.[121] Pertinent points in the preoperative assessment

and preparation of patients with end-stage renal disease are listed in Box 29-5.

ANESTHETIC MANAGEMENT OF PATIENTS WITH ADVANCED RENAL DISEASE

Preoperative preparation of patients with advanced renal disease should include an evaluation of recent laboratory measurements, coexisting diseases, and current medications. Patients with end-stage renal disease should undergo preoperative determination of BUN and serum creatinine levels, complete blood count, bleeding-time measurement, and electrolyte studies. Special attention should be given to serum potassium, the type of and schedule for dialysis, and volume status.

Premedications

Discussions regarding premedication should take into consideration unexpected sensitivity to CNS depressants and delayed gastric emptying. Benzodiazepines are useful as premedicants. Midazolam is preferred because it has virtually no active metabolites, and its half-life is only slightly prolonged in renal failure. Although this drug is useful when it is carefully titrated, patients with renal disease may be more susceptible to the sedative-hypnotic effects of benzodiazepines than those without renal dysfunction.[122]

Reduced protein binding may be responsible for increased sensitivity to these drugs in patients with advanced renal disease. Protein binding of morphine decreases by 10% in the presence of chronic renal failure.[123] This alters the free fraction only slightly because morphine generally is protein bound to such a small extent. Morphine is almost completely metabolized in the liver, resulting in two metabolites (morphine-3-glucuronide and morphine-6-glucuronide). Both metabolites are excreted by the kidney. Patients with kidney disease can develop high levels of morphine-6-glucuronide and resultant respiratory failure.[124] Morphine is not removed by dialysis.

Meperidine is more lipophilic than morphine. It is 60% protein bound and is metabolized to a normeperidine, which has analgesic properties and stimulates the CNS system. Meperidine metabolites can cause convulsions when used in high concentrations, and cannot be removed by dialysis.[125] Meperidine should be avoided in patients with renal failure.

Hydromorphone does not directly cause adverse effects in renal failure; however, its metabolite, hydromorphone-3-gluconuride does accumulate. For this reason, hydromorphone should be used with caution, although it can readily be removed by dialysis.[126]

A review of recent publications on opioid use in patients with renal failure reveals that transdermal buprenorphine, methadone, fentanyl, and sufentanil appear to be safe in these patients.[127] Anticholinergic drugs, such as atropine and glycopyrrolate, are partially dependent on renal elimination, although no reports of toxicity exist.

Gastric hyperacidity and gastrointestinal bleeding are common in patients with renal failure. H_2 blockers and magnesium-free antacids should be considered. Cimetidine has been used, but renal elimination accounts for 80% of total elimination, and elimination is impaired with reduced renal function. Although newer H_2 antagonists are now available, all H_2-receptor blockers are very dependent on renal excretion. Metoclopramide is partly excreted unchanged in the urine and will accumulate in patients with renal failure.

Intraoperative Monitoring

The selection of monitors for a patient with diminished or absent renal function is based on the physiologic status of the patient and the proposed surgical procedure. Frequent measurements of blood pressure and continuous recording of temperature and heart rate and rhythm are essential. Electrocardiography may allow early detection of hyperkalemia, including observation of peaked T waves, prolongation of the PR interval, and absent P waves with widened QRS complex.[128]

Because these patients are often chronically anemic, a further reduction in oxygen delivery secondary to hypoxia can be extremely hazardous. Pulse oximetry is essential for the early detection of arterial desaturations. Pulse oximetry and capnography are required in all patients. Minor surgical procedures in stable patients can be monitored noninvasively.

The decision to use invasive monitors depends on the patient's functional cardiac reserve and the severity and control of hypertension. Significant hypotension on induction of anesthesia is common in recently dialyzed patients. Continuous monitoring of arterial blood pressure is helpful when major surgical procedures are performed. A femoral or dorsalis pedis artery is sometimes used for cannulation, because vessels in the upper extremities may be needed later for vascular shunts. Vascular volume and fluid replacement can be guided by central venous pressure monitoring. A pulmonary artery catheter is rarely indicated, because sophisticated evaluation of fluid status and ventricular function can be accomplished with echocardiography.[129]

Vascular shunts and fistulas must be protected. Patency is easily monitored with Doppler imaging. Because of the immunocompromised state of these patients, strict aseptic technique is required during the placement of vascular catheters.

Regional Anesthesia

Regional anesthesia is tolerated by patients with advanced renal disease, provided no significant coagulation disorder is present and mean arterial pressure is maintained. Regional techniques avoid most of the pharmacokinetic and pharmacodynamic problems associated with general anesthetics and sedative drugs. Major concerns regarding this type of anesthesia include psychologic intolerance, coagulation abnormalities, the presence of peripheral neuropathies, difficulty in making intravascular volume adjustments, and risk of infection.

Arteriovenous shunts or fistulas may be surgically created with the use of local infiltration or brachial plexus block. In addition to providing analgesia, brachial plexus blocks improve surgical conditions by providing maximum vascular vasodilation and abolishing vasospasm. Studies have shown that brachial plexus block is associated with greater brachial artery blood flow than local anesthesia, greater fistula blood flow, and decreased maturation time.[130] Both brachial plexus block and local infiltration are good alternatives to general anesthesia for creation of arteriovenous fistula. Age, American Society of Anesthesiologists (ASA) class, and cardiac status are the determining factors for choice of anesthetic technique.[131]

Data suggest a similar duration of anesthesia with brachial plexus blocks in patients with renal failure and normal renal function.[132] High-dose mepivacaine has been used for brachial plexus block in patients with end-stage chronic renal failure. Brachial plexus anesthesia with 650 mg of plain mepivacaine did not result in serious systematic toxicity in these patients despite high mepivacaine plasma concentrations.[133] Ropivacaine has been shown have a longer duration of action with higher plasma concentrations in renal dysfunction.[134,135] The use of clonidine (150 mcg) as an adjuvant for lidocaine in axillary blocks for arteriovenous fistula construction prolongs blockade, decreases heart rate and blood pressure, and provides sedative effects.[136]

With regard to spinal or epidural anesthesia, patients with long-standing renal disease often have undergone multiple procedures and prefer general anesthetic techniques. In addition to the history, the uremic patient's bleeding time, platelet count, prothrombin time, partial thromboplastin time, and fibrinogen level should be evaluated before subarachnoid or epidural catheters are placed. Paraplegia secondary to hematoma formation with spinal anesthesia has been reported in patients with chronic renal failure and clotting abnormalities.[137]A case of epidural hematoma in a surgical patient with chronic renal failure and epidural postoperative analgesia has been reported. The only risk factor for development of epidural hematoma was a history of chronic renal failure. High-risk patients should be monitored closely for early signs of cord compression such as severe back pain and motor or sensory deficits. An opioid or opioid and local epidural solution rather than local solution alone allows continuous monitoring of neurologic function. If spinal hematoma is suspected, the patient should undergo immediate magnetic resonance imaging (MRI) or computed tomography (CT) scan, and decompressive laminectomy should be performed without delay.[138]

Peripheral neuropathies should be discussed with the patient and documented before regional anesthesia is undertaken. The incidence of hypotension with subarachnoid or epidural blockade may be increased because of effects of chronic hypertension or hypovolemia related to recent dialysis. Correction of hypovolemia postoperatively is hazardous. Recession of the sympathetic block in patients who cannot undergo diuresis may lead to pulmonary edema. One must weigh the advantages of fluid infusion against the effects of pressor drugs with these factors in mind.

Patients with end-stage renal disease are often acidotic, and local anesthetic toxicity may be increased with acidosis. The onset and duration of blocks have also been shown to vary in these patients. Subarachnoid blockade induced with 3 mL of 0.75% bupivacaine developed more rapidly, attained a greater level, and was of shorter duration in patients with renal failure than in control patients.[139,140] The slower onset of epidural anesthesia is an advantage in these patients.

General Anesthesia

Intravenous Drugs

Intravenous anesthetics can be used in patients with advanced renal disease, but the response of these patients may be more variable than normal. Variability arises from a complex interplay among changes in volume of distribution (which is often increased), protein binding (which may be low), low pH, and dependence on renal excretion for the parent drug or metabolites.

The action of many drugs is potentiated by metabolic abnormalities associated with renal failure. Highly protein-bound drugs may have more target-organ effect in the presence of hypoalbuminemia. The acidemic state associated with renal failure increases the proportion of the agent that is unionized and unbound and therefore more available to target tissue. Anemia associated with renal failure increases cardiac output and enhances delivery to the brain. Uremia alters the blood-brain barrier; this also increases the sensitivity to intravenous drugs.

Ketamine and benzodiazepines are less heavily protein bound. The sympathomimetic effects of ketamine are frequently associated with an increase in blood pressure and cardiac output, which may be deleterious in hypertensive patients who are at risk for coronary artery disease or decreased left ventricular function. In addition, metabolites of ketamine depend on renal excretion and can accumulate in patients with renal failure.[141]

The pharmacokinetic profile of narcotics can be altered in the presence of renal disease. Fentanyl is metabolized in the liver, and 85% of it appears in the urine and feces as inactive metabolites. Its slow elimination half-life is the result of a large volume of distribution. The effect is exaggerated in renal failure. Chronic renal failure is associated with a decrease in alfentanil plasma protein binding, but it does not change plasma clearance of the drug. The volume of distribution at steady state is greater in patients with renal failure. Altered protein binding of alfentanil must be considered in patients with renal failure.[142] Although the pharmacokinetics of sufentanil do not appear to be altered in patients with advanced renal disease, clearance and half-life are more variable in this group. Sufentanil should be carefully administered to these patients.[143] Although remifentanil is metabolized by nonspecific plasma esterases, it has been shown to have a significant reduction in clearance in patients with end-stage renal disease.[144]

Propofol has gained wide acceptance for both induction and maintenance of anesthesia and appears to be safe. Studies suggest, however, that patients with end-stage renal disease require a higher dose to achieve hypnosis. A hyperdynamic circulation in these anemic patients may be responsible.[145] Propofol pharmacokinetics are unaltered by established renal failure. The time interval between cessation of a propofol infusion and eye opening is significantly shorter in renal failure patients compared with controls, although blood propofol concentrations are not significantly different on emergence.[146]

Dexmedetomidine, an α_2-adrenergic agonist with sedative and analgesic properties, is predominantly cleared by the liver. Studies reveal minimal pharmacokinetic differences between healthy volunteers and patients with renal failure. There were no reported differences in hemodynamics during administration of dexmedetomidine, but patients with renal failure exhibited prolonged duration of sedation.[147]

Volatile Anesthetic Agents

Inhalation agents offer some advantage in patients with renal failure. Although biotransformation of some agents may produce metabolites excreted by the kidneys, elimination of volatile agents does not rely on renal function. Volatile agents potentiate neuromuscular blocking drugs, allowing administration of reduced doses. Although the potency of these agents allows them to be administered without nitrous oxide, excessive depth of anesthesia may lead to a depression of cardiac output. Reductions in cardiac output and tissue blood flow must be avoided in these anemic patients if tissue oxygen delivery is to be maintained.

A theoretic disadvantage of inhalation agents relates to their biotransformation and nephrotoxic potential. None of the modern inhalation anesthetics has this problem. Fluoride levels after isoflurane anesthesia increased by only 1 to 2 μmol, and desflurane is metabolized approximately one tenth as much as isoflurane. It is the least metabolized of the currently available volatile agents. In studies of patients and volunteers administered desflurane for prolonged periods, no evidence of renal, hepatic, or hematologic toxicity was observed.[148]

Some practitioners may avoid use of sevoflurane in patients with severe renal dysfunction because of the potential for nephrotoxicity. Studies do not support this concern. One study compared renal function after long-duration, low-flow (less than 1 L/min) sevoflurane and isoflurane anesthesia in surgical patients with normal renal function. Postoperative renal function was no different as assessed by serum creatinine and BUN levels and urinary excretion of protein and glucose, suggesting that low-flow sevoflurane is as safe as low-flow isoflurane.[149] Another study concluded that

TABLE 29-4 Regional Versus General Anesthesia

Technique	Advantages	Disadvantages
Regional	Patient responsiveness Minimal changes in renal hemodynamics	Presence of peripheral neuropathy Tendency for bleeding Patient anxiety Prolonged procedures Hypotension with sympathetic block; may cause reluctance to expand volume
Volatile anesthetics	Good airway control Blood pressure control Duration not dependent on urinary excretion Less neuromuscular blocking with drugs required Fio_2 can be increased because N_2O not necessary	Alterations in renal hemodynamics Decreased cardiac output Hypotension Biodegradation and potential nephrotoxicity; halothane 15%-20%; sevoflurane 5%; isoflurane 0.2%; desflurane 0.02%
Intravenous anesthetics	Hemodynamic stability	Unpredictable response Hypertension Greater need for N_2O and neuromuscular blockers

Fio_2, Fraction of inspired oxygen; N_2O, nitrous oxide.

prolonged low-flow sevoflurane anesthesia had the same effect on renal and hepatic function as high-flow sevoflurane and low-flow isoflurane anesthesia.[150]

In summary, both regional and general anesthesia has been used successfully in patients with advanced renal disease. Advantages and disadvantages of both techniques are listed in Table 29-4.

Neuromuscular Blocking Drugs

The appropriate use of neuromuscular blocking drugs in patients with advanced renal disease has received much attention over the years. At one time, caution was advised in all cases of the use of a muscle relaxant in patients with renal disease. Because these drugs are ionized, water-soluble compounds freely filtered at the glomerulus, it was believed that their action would be prolonged. It was further theorized that as the anticholinesterase or relaxant antagonist level decreased, the patient would be at risk of postoperative residual neuromuscular blockade. It is now known that renal excretion is of major importance for cholinesterase inhibitors as well. Approximately 50% of neostigmine and 70% of edrophonium are excreted in the urine. Excretion of all cholinesterase inhibitors is delayed to the same or to a greater extent than muscle relaxants in patients with renal impairment.[151]

Succinylcholine. Several problems have been associated with the use of succinylcholine in patients with renal failure. Succinylcholine is metabolized by hepatic-derived pseudocholinesterase to succinic acid and choline. A metabolic precursor of these two compounds is succinylmonocholine, which has some nondepolarizing blocking activity and is eliminated by the kidneys. Prolongation of succinylcholine also has been associated with depressed levels of pseudocholinesterase in uremic patients who require hemodialysis.

Serum potassium increases by approximately 0.5 mEq/L in both normal patients and those with renal failure. This elevation in extracellular potassium is not reliably prevented by pretreatment with a nondepolarizing muscle relaxant. The rise in serum potassium level is particularly dangerous in uremic patients who are hyperkalemic. The use of succinylcholine is inadvisable unless a patient has undergone dialysis within 24 hours before surgery and the potassium concentration is less than 5.5 mEq/L. Succinylcholine is safe in normokalemic patients who have recently undergone dialysis.[152,153]

Pancuronium. Up to 80% of pancuronium is excreted in the urine. Biliary excretion accounts for much of the nonrenal elimination.[154] A significant portion of the renal excretion of pancuronium occurs after its biotransformation to a less active metabolite.[155] Pancuronium has a prolonged terminal elimination half-life in patients with reduced renal function. Because of its high dependence on renal excretion and long-acting classification, it should be avoided in patients with renal dysfunction.

Atracurium and Cisatracurium. Initial reports indicated that the action of neither atracurium nor vecuronium was prolonged in patients with decreased renal function; however, it now appears that this is true only for atracurium.[156] Atracurium and cisatracurium are broken down by Hoffman elimination and non–esterase-dependent hydrolysis to inactive products. Neither process is dependent on renal excretion for termination of action. Atracurium is less potent and has a shorter duration of action than cisatracurium. It produces histamine release, which limits its desirability.[146,156] Chronic kidney disease does not alter the pharmacokinetics or pharmacodynamics of atracurium. Cisatracurium pharmacodynamics are not changed; however, there is a slight slowing of onset. Many clinicians consider these the drugs of choice in patients with renal failure.

Vecuronium. Approximately 30% of administered vecuronium is excreted renally, and the duration of neuromuscular blockade is longer in patients with renal failure than in those without renal failure.[157] This accumulation is the result of reduced clearance and a prolonged half-life.[146] If vecuronium is used, a low dose is recommended, and repeated administration should be avoided. Vecuronium neuromuscular blockade is rapidly reversible with dialytic treatment.[158]

Rocuronium. Rocuronium is the most commonly used nondepolarizing neuromuscular blocking drug. It has a rapid onset of action, and in humans it produces good to excellent conditions for tracheal intubation in 60 to 90 seconds.[159] It has no clinically significant cardiovascular effects and an intermediate duration of action.[160] Studies indicate that the onset of action of twice the effective dose (ED_{95}) of rocuronium is not altered in patients with renal failure who are undergoing renal transplantation. A rapid onset is particularly attractive in these patients because they are subject to autonomic neuropathy and delayed gastric emptying. Rocuronium is excreted primarily in the bile, although up to 33% may be excreted renally. Renal failure reduces the clearance of rocuronium by 39%. The duration of action and recovery time are significantly prolonged in patients with renal failure (49 vs. 32 min). Interpatient variability is also increased.[146,161]

INTRAVENOUS FLUID MANAGEMENT

Perioperative management of fluids and electrolytes in patients with renal disease is critical. The state of hydration affects renin, aldosterone, and antidiuretic levels. Dehydration and hypovolemia lead to elevations in these hormones and to a decline in urinary output.

Perioperative Renal Function

Surgical patients at high risk for AKI , or those with advanced disease who do not require hemodialysis, present unique challenges. Preservation of renal function intraoperatively is dependent on the maintenance of intravascular volume and cardiovascular stability and on the avoidance of events that cause renal vasoconstriction. Intraoperatively, urinary output is the most immediate monitor for renal function. A urinary output of 0.5 to 1 mL/kg/hr perioperatively is recommended, because urinary output less than 0.5 mL/kg/hr is a risk factor for renal injury (see RIFLE and AKIN classifications in Table 29-2. Serum creatinine is a more specific assessment of renal function than urinary output.[162]

Patients with normal or mildly compromised renal function should receive balanced salt solutions at 3 to 5 mL/kg/hr. A bolus of 500 mL ought to improve output related to hypovolemia. Use of mannitol or furosemide to increase output may further exacerbate volume depletion. No potassium-containing solutions (lactated Ringer's) should be administered to anuric patients.

Dialysis patients present a unique challenge to the anesthetist. This population requires a narrow window of control between hypovolemic and fluid overloaded states. Insensible losses are replaced with 5 to 10 mL/kg of 5% glucose in water (D_5W). If any urine is produced, it may be replaced with 0.45% saline.

The greater expected fluid losses of thoracic and abdominal surgery cases may require significant volume replacement. Either a balanced salt solution, 5% albumin, or a combination thereof is recommended for replacing these larger volumes in patients with, or at risk for, kidney disease or injury. The administration of blood products should be reserved for patients who need increased oxygen-carrying capacity.[163] The safety of synthetic colloids in patients with preexisting renal dysfunction still remains unclear.[164]

Renal Insufficiency

In patients with renal insufficiency, volume deficits should be replaced preoperatively, as in normal patients. Basal fluids must be carefully regulated because these patients cannot tolerate much deviation. Overall basal fluid requirements must be related to metabolic rate and designed to provide an overall fluid balance that allows an isotonic urine to carry excreted electrolytes and waste products. Intraoperative losses greater than 10% to 15% of the blood volume should be replaced with colloid solution on a 1:1 basis after red-blood-cell losses are corrected. Smaller losses can be replaced with the usual 3:1 ratio of crystalloid infusion to blood loss. Third-space losses are ideally replaced initially with crystalloid solution without potassium or excess chloride. Initial third-space losses should be replaced with crystalloid solution at a rate of 2 to 3 mL/kg/hr. The critical goal in patients with renal insufficiency is sustaining blood volume. Monitoring of colloid osmotic pressure and hemoglobin can guide the choice between crystalloid and colloid infusions. If hemoglobin and colloid osmotic pressure are increasing, crystalloid solution is clearly indicated. If they are decreasing, crystalloid solution should be withheld in favor of colloid solution. Close monitoring of blood pressure, heart rate, CVP, pulmonary artery occlusion pressure, and cardiac output also guides fluid titration. This is especially true in patients with cardiac or respiratory compromise.

End-Stage Renal Disease

With regard to perioperative fluid management, patients with end-stage renal disease who are hemodialysis dependent require special attention. Although these patients are similar to normal patients in terms of fluid deficit, basal, and third-space requirements, they have a narrow margin of safety. The patient's ability to compensate for either fluid excess or fluid deficiency progressively declines as renal function is lost.

Fluid deficits must be replaced preoperatively in patients with end-stage renal disease. If deficits exceed 10% to 15% of the blood volume, invasive monitoring is justified. Dialysis is recommended on the day before anesthesia to allow time for equilibration of fluid and electrolyte shifts that are common with dialysis. Electrolyte levels must be checked before anesthesia.

Basal fluids in patients with end-stage renal disease should be replaced in a manner similar to that for patients with renal insufficiency. Volume restriction is recommended for intraoperative losses. Third-space losses should be replaced with a balanced salt solution that contains no potassium and small amounts of chloride. Close monitoring of hemoglobin and cardiac filling pressures is indicated for all major procedures. Patients with end-stage renal disease generally require dialysis within 24 to 36 hours after major surgery.

Uremia

Deficit replacement in patients with uremia must be guided by hemodynamic monitoring. Basal fluids should be replaced with red blood cells, fresh frozen plasma, or colloid solutions. Third-space losses are best replaced with crystalloid solutions in association with frequent monitoring of hemoglobin. Cardiac filling pressures should be monitored when warranted by the surgical procedure. A moderate degree of volume overload is not a grave problem. Many uremic patients require dialysis within 24 to 36 hours for the removal of mobilized fluid and the control of hypertension.

Although volume overload is most often emphasized in patients with end-stage renal disease, complications of hypovolemia are also serious. Hypotension associated with hypovolemia increases the risk of thrombosis of the arteriovenous fistula and predisposes to cardiac and cerebral ischemia. Hemodynamic goals include the avoidance of hypotension and gross fluid overload. This can be accomplished only through careful titration with the patient well monitored.

ANESTHESIA FOR RENAL TRANSPLANTATION

Patients with end-stage renal failure have a complex medical history with many comorbid diseases. Diabetes and hypertension are the most common causes of end-stage renal disease (ESRD). Multiple cardiovascular disorders also may be present, including ischemic heart disease and congestive cardiac failure. Other frequent problems include anemia, hyperparathyroidism with elevated calcium and phosphate, dyslipidemia, infections, and hepatitis B and C.[165,166]

These patients also are typically on multiple medications. Optimization of the patient's condition results in a smoother operative course.

Transplantation Procedure

Renal transplantation has been performed for nearly a century and is an accepted means of replacing kidney function in patients with end-stage renal disease who are on maintenance dialysis. Kidney transplants are the most commonly performed transplantations in the United States.[165] In this procedure, the donor kidney is placed extraperitoneally in the recipient's iliac fossa. The renal artery is anastomosed to the internal iliac artery, the renal vein to either the external or the common iliac vein, and the ureter to the bladder. The anesthesia provider plays a vital role in management of the viability

of the transplanted kidney. Three interrelated variables affect surgical outcomes: management of the donor, preservation of the harvested organ, and perioperative care of the transplant recipient. Additionally, improved surgical and immunosuppressive techniques have contributed to better outcomes in terms of graft survival.[166]

Harvested Organ Preservation

Ischemic time, beginning with the clamping of the donor's renal vessels and ending with the vascular anastomosis in the recipient, is a crucial factor in graft preservation. Warm ischemia is more deleterious. When renal ischemic time is less than 30 minutes, diuresis begins quickly, but if it is 2 hours or longer, a variable period of oliguria or anuria may occur according to the following ischemic times:

Warm	Cold
Begins: Clamping of donor vessels; initial placement in recipient	Perfusion of harvested organ with cold preservation solution; storage at 4° C
Ends: Vascular anastomosis in recipient; interrupted with perfusion of cold preservation solution	Perfusion by recipient

Donor Preparation

Choice of anesthesia for the living, related donor is not critical. Adequate amounts of balanced salt solution and colloid bolus just before pneumoperitoneum has been demonstrated to ensure a brisk diuresis from the donor kidney and to offset reduced venous return resulting from use of laparoscopy.[166,167] The greatest risk to the donor is hemorrhage. Adequate intravenous access and blood must be available in the event that transfusion becomes necessary.

If the donor kidney is obtained from a brain-dead patient, preservation of graft function is the highest priority. The loss of sympathetic tone after brain death may produce mild hypotension, despite adequate volume replacement. Many patients with irreversible cerebral dysfunction are hypovolemic and require vigorous fluid resuscitation. Anesthetic goals in the donor include maintenance of a Pa_{O_2} over 100 mmHg; normocapnia; hematocrit 30% or greater; and systolic blood pressure 100 mmHg or greater. If pharmacologic support of the cardiovascular system is necessary, a dopamine infusion at a rate of 1 to 3 mcg/kg/min is recommended. Other acceptable pharmacologic support includes dobutamine and low-dose epinephrine. Renal vasoconstrictive properties of high-dose vasopressors reduce immediate allograft function and increase the risk of kidney damage.[168] Maintenance of urinary output is paramount and may warrant the use of adjuncts such as furosemide, mannitol, and a low-dose dopamine infusion.[169]

Recipient Preparation

Because cadaveric kidneys can be preserved for 36 to 48 hours with cold perfusion, time is sufficient for optimal preparation of the transplant recipient (Box 29-6). The recipient should be free of acute illness and infections because of the likelihood of their spread during immunosuppressive therapy. Acute alterations in fluid and electrolyte balance should be corrected with dialysis carried out 24 hours before transplantation. Postdialysis laboratory values should be checked, and serum potassium (K^+) level should be

BOX 29-6

Anesthesia for Renal Transplantation

I. Preoperative Assessment and Preparation
  A. Clinical evaluation
    1. Evaluate status of coexisting diseases
      a. Diabetes mellitus
      b. Hypertension
      c. Cardiac disease
      d. Hyperparathyroidism
      e. Pericardial tamponade
    2. Perform dialysis within 24 hr of transplantation; check weight
    3. Evaluate tolerance to chronic anemia
  B. Laboratory evaluation
    1. Complete blood count with platelet count
    2. Prothrombin time, partial thromboplastin time, bleeding time
    3. Blood urea nitrogen, creatinine, calcium, fluid balance
    4. Electrocardiography; chest radiography
  C. Type and cross-match 2 units of washed, packed red blood cells
  D. Determine current drug regimen
  E. Premedication
    1. Benzodiazepines, narcotics
    2. Antacids, histamine-2 antagonist, metoclopramide

II. Monitors
  A. Electrocardiography
  B. Indirect or direct blood pressure measurement
  C. Precordial, esophageal stethoscope
  D. Neuromuscular blockade evaluation
  E. Foley catheter
  F. Central venous, transesophageal echocardiography, pulmonary capillary wedge pressure measurement, if required

III. Anesthetic Management
  A. Regional techniques
    1. Continuous spinal or epidural
    2. Advantages
      a. No need for muscle relaxants
      b. Potential respiratory tract infection from intubation is avoided
      c. Amount of local anesthetic required is small
      d. Patients awake and comfortable postoperatively
    3. Disadvantages
      a. Patient anxiety
      b. Uncomfortable surgical positions, especially for donor
      c. Coagulation abnormalities present
      d. Fluid management with sympathetic blockade a challenge
      e. Unprotected airway in patients with delayed gastric emptying
  B. General anesthesia
    1. Induction with propofol or etomidate
    2. Maintenance with volatile anesthetic (isoflurane, or desflurane) or narcotic-based technique
    3. Neuromuscular blockers
      a. Succinylcholine
      b. Cisatracurium
      c. Rocuronium

IV. Miscellaneous Drugs
  A. Mannitol or furosemide
  B. Dopamine
  C. Calcium channel blockers
  D. Prednisone or methylprednisolone
  E. Patient-specific immunosuppressants

below 5.5 mEq/L. Coagulation studies and acid-base status should be normal. Serum creatinine concentration should be below 10 mg/dL, and BUN level should be below 60 mg/dL after dialysis.

Chronic anemia is common, and transfusion is not required if oxygen delivery is adequate. Because of the danger of volume overload, anemia should be corrected during dialysis with transfusion of packed red blood cells. It was formerly thought that multiple blood transfusions increased the risk of kidney rejection secondary to sensitization of the human leukocyte antigen system, but this belief has been disproved. Studies have shown a lower survival rate for transplanted kidneys in nontransfused patients and in those receiving leukocyte-poor blood.[170]

Abnormal platelet function, as well as ineffective production of factor VIII and von Willebrand factor, accounts for the syndrome of uremic coagulopathy seen in patients with renal failure. Correction of coagulation abnormalities can be accomplished through dialysis and administration of conjugated estrogen and desmopressin as seen in the following chart[171-173]:

Treatment	Effect
Dialysis	Improves platelet formation
Conjugated estrogen	Decreases transfusion need
Desmopressin	Increases factor VIII and von Willebrand factor

Acceptance of kidney transplantation in patients with type 1 diabetes mellitus is widespread. Patients with type 2 diabetes may have relative contraindications due to significant comorbidities, particularly a recent history of myocardial infarction, stroke, or peripheral gangrene. However, recent evidence suggests some patients with type 2 diabetes may benefit from transplantation.[174]

Patients should fast for 6 to 8 hours if possible. Premedication may include narcotics or benzodiazepines in usual to reduced doses, depending on the status of the patient. The use of antacids, H_2 antagonists, and metoclopramide should be considered if gastric emptying is delayed; however, reduced doses should be considered because these drugs depend on the kidney for excretion, and metoclopramide is partially excreted unchanged in the urine.[175]

In addition to routine monitors, a Foley catheter is inserted for the assessment of graft function. A central venous line is essential for the assessment of volume status. Intraarterial blood pressure monitoring is useful for patients with significant cardiovascular disease. Central venous pressure monitoring may improve graft function by aiding in the assessment of hydration status with the goal of maintaining a CVP of 10- to 5 mmHg.[176] Evaluation of pulmonary artery catheter pressures has been shown to correlate with graft function, although it is usually reversed for select patients with symptomatic coronary artery disease (CAD) or congestive heart failure (CHF). If monitoring pulmonary artery pressures, maintenance of a mean pulmonary artery pressure of greater than 20 has been shown to reduce the risk of acute tubular necrosis.[177] Transesophageal echocardiography may be used for evaluation of fluid status and myocardial function. Protection of vascular access and fistula patency is of prime importance with the use of blood pressure cuffs or if arterial cannulation is necessary. Sterile precautions during insertion of invasive lines are extremely important because transplant patients are immunocompromised. Strict adherence to aseptic technique is mandatory in the management of these lines, catheters, and endotracheal tubes. Commitment to aseptic technique on the part of the entire team may make the difference between safe transplantation and death for the patient.

Fluid management may be generous or conservative, dependent on patient condition. Fluid replacement should be accomplished with a balanced salt solution and albumin as required to maintain a plasma volume of at least 45 to 70 mL/kg. Immediate function of the transplanted kidney cannot be guaranteed, and excessive intraoperative fluid replacement can lead to pulmonary edema and swelling of the grafted kidney.

The early onset of urine output is essential and correlates with improved outcomes and can be improved with aggressive volume expansion with crystalloids and albumin, mannitol, loop diuretics, calcium channel blockers, and dopamine.[178]

Anesthesia

Regional Anesthesia

Both regional and general anesthesia have been used successfully for open surgical renal transplantation. A randomized prospective study compared the incidence of hypotension, bradycardia, and acidemia between regional and general anesthesia for renal transplant. No differences were noted, although combined spinal epidural was preferred to epidural alone for the improved muscle relaxation effects.[179] Advantages of regional anesthesia include avoidance of the use of muscle relaxants and other drugs excreted by the kidney, and the fact that endotracheal intubation is not required. Intubation may increase the risk of nosocomial pneumonia. Pulmonary infection may occur in renal transplant patients after endotracheal intubation, which results in a 40% to 50% mortality rate.[180] An additional advantage of regional anesthesia is postoperative analgesia.

Disadvantages of regional anesthesia techniques in these patients include hypotension associated with sympathetic blockade, the length of the procedure, and heparinization of the kidney. Sympathetic blockade can make control of blood pressure difficult in patients who may be hypovolemic. Given that transplantation procedures may last several hours, large amounts of sedation may be needed to supplement regional techniques. General anesthesia is now the preferred approach for these reasons. Additionally, general anesthesia is indicated for donor nephrectomies, because many of these procedures are now performed laparoscopically.[181]

General Anesthesia

Volatile Agents. When general anesthesia is used, nitrous oxide combined with volatile agents and short-acting opiates is well tolerated. The skeletal muscle relaxant properties, minimal metabolism, and preservation of renal blood flow make isoflurane an attractive choice. Desflurane also has been successfully used and may have beneficial preservation effects. Postconditioning involves the administration of anesthetics during early reperfusion and has been found to have a protective effect on several organs.[166]

Reductions in cardiac output secondary to the negative inotropic effects of volatile drugs must be minimized if suboptimal tissue oxygenation is to be avoided in these anemic patients.

Although the use of sevoflurane during kidney transplantation has not been widely studied, researchers have reported on its effects on the kidney with impaired function. Evidence of increased plasma fluoride concentrations has been the predominant finding, noting peak fluoride concentrations of greater than 30 uM after sevoflurane administration.[182,183] A decrease in fresh gas flow has demonstrated increased Compound A production, which has been shown to be nephrotoxic.[184] Despite these findings, studies of sevoflurane administration in patients with uremia have not yielded a positive correlation between renal toxicity and sevoflurane. Sevoflurane anesthesia appears safe and does not alter kidney function in patients with preexisting renal disease. Sevoflurane anesthesia can be safely used in renal transplant recipients.[166,185]

Muscle Relaxants. The choice of muscle relaxant must take into consideration the unpredictable nature of renal function after transplantation. Relaxants that are independent of renal function for plasma clearance, such as cisatracurium, are excellent for this patient population.[186] The process of Hoffman elimination

and nonesterase hydrolysis are the primary modes of breakdown for cisatracurium. Clearance of cisatracurium has been found to be slightly reduced by approximately 13% in patients with renal failure.[187] Succinylcholine can be used to facilitate intubation if serum K^+ level is normal. Long-acting drugs such as pancuronium are highly dependent on renal elimination and should be avoided.

Opioids. The effect of morphine is prolonged in end-stage renal failure and accumulates the active metabolite morphine-6-glucuronide. Meperidine also should be avoided due to the accumulation of the toxic metabolite normeperidine and potential for seizures.[188] Fentanyl and sufentanil pharmacokinetics are not altered in end-stage renal failure. Remifentanil undergoes rapid metabolism by plasma esterases and results in low concentrations of an active metabolite, which does not appear to be clinically significant. Clearance of remifentanil is delayed and causes accumulation of its metabolite, which can be removed by dialysis. Alfentanil metabolism is not altered by renal failure.[189]

Other Drugs. Mannitol is included in many transplant protocols. It does not depend on renal tubular–concentrating mechanisms to promote urinary formation, and it facilitates urinary output and a reduction in tissue and intravascular volume. The effect of low-dose dopamine administration on cadaver and living graft function also has been evaluated. Dopamine has been shown to have nephroprotective effects.[190,191] Generally inotropic drugs with alpha receptor–stimulation properties are avoided. Early graft function is dependent on ischemic changes, and late graft function is dependent on the management of rejection.

Loop diuretics exert their effect at the Na^+/K^+ pump in the ascending loop of Henle, preventing reabsorption of electrolytes in this segment. The increased osmolarity of fluid in the tubule prevents reabsorption of water and increases urine output.

Cardiac arrest has been reported after completion of the renal artery anastomosis to the transplanted kidney.[192] Arrest occurred at the time the occlusion clamp was released and was attributed to hyperkalemia from washout of the K^+-containing solutions used to preserve the kidney. If clamping of the external iliac artery is necessary during the procedure, K^+ can be released from the ischemic limb. Unclamping also may result in hypotension from the release of vasodilating substances from ischemic limbs and the subsequent increase in vascular capacity.

Immunosuppressants

Patients undergoing renal transplantation require immunosuppression. The goal of immunosuppression therapy is to prevent graft rejection but still allow the immune system to fight infection and malignancy. A multiple-agent strategy allows for a synergistic effect, and reduction of specific drug toxicity T cells is the main target of immunosuppression strategies because of their central role in the alloimmune response. Immunosuppressive medications can be classified in three broad categories relating to their mechanism of action: (1) depleting agents, (2) calcineurin inhibitors (CNIs), and (3) antiproliferating agents, for example, antimetabolites. Immunosuppressive strategies can also be divided into two main categories referred to as induction and maintenance of immunosuppression. Induction of immunosuppression is defined as the rapid achievement of profound immunosuppression, usually at the time of transplant, with the use of depleting agents. Maintenance immunosuppression is achieved by the combination of oral agents that takes advantage of additive or synergistic immunosuppressive effects of different drug categories to minimize their nonimmunosuppressive side effects. Doses are usually greater during the first 3 months after transplantation and decrease afterwards. The combination of a CNI, antiproliferating agent, and steroids is usually used, although steroid sparing or withdrawal strategies are now popular to minimize side effects. Monoclonal and polyclonal antibody induction therapy is frequently given as well.[193,194] Some commonly used immunosuppression drugs are listed in Table 29-5.[194]

Kidney transplant recipients may require surgery for nontransplant-related procedures. Management involves maintenance of adequate volume status, avoiding nephrotoxic medicines such as nonsteroidal antiinflammatory drugs (NSAIDs) or contrast dyes, and proper dosing of immunosuppressive drugs. Whenever possible, immunosuppressive drugs should be given by the enteral route. If this is not possible, a regimen of IV steroids and IV CNIs usually suffices. A simple way to dose IV steroids is to prescribe the same milligram-for-milligram dose of IV methylprednisolone as the maintenance prednisone dose; supplemental stress-dose hydrocortisone is then prescribed separately. IV cyclosporine should be prescribed in slow-infusion form at one third of the total daily oral dose, and intravenous tacrolimus should be at one fifth of the total daily dose. Some specific suggestions for managing kidney transplant patients are noted in Box 29-7.[194]

EXTRACORPOREAL SHOCK-WAVE AND LASER LITHOTRIPSY

Nephrolithiasis is a common condition, with a lifetime prevalence of approximately 13% in men and 7% in women in the United States. Although many kidney stones are asymptomatic, patients with symptomatic stones often require treatment. Between 1.0% and 1.7% of emergency department visits (1 to 2 million visits annually) are for a primary diagnosis of renal colic or renal calculus. The economic burden of urolithiasis is immense. Total health care expenditures reach nearly $4.5 billion annually, and this figure increases to $5.3 billion when the indirect costs of lost workdays are included. Approximately 80% of upper urinary tract stones are calcium-based (composed of calcium oxalate, calcium phosphate, or brushite), with the remaining 20% composed of uric acid, struvite, cystine, or, rarely, other components.[195] Extracorporeal shock-wave lithotripsy (ESWL) is the only noninvasive urinary stone treatment. The technique uses hundreds to thousands of high-energy ultrasonic or pneumatic shock waves or lasers to fragment renal calculi into small particles. ESWL is used for stones less than 10 to 20 mm in the proximal or midureter. Stones in the distal ureters, of all sizes, are removed using ureterorenoscopy (URS). Success rates are highly variable, ranging from 30% to 100%. When lithotripsy fails to resolve the stone, more invasive techniques are employed such as percutaneous nephrolithotomy and ureteroscopy.[196] ESWL uses an external source to deliver pulses of energy into a fluid chamber, generating a shock wave. The shock wave is transmitted unimpeded through the fluid and then through the patient's soft tissues (which have approximately the same density as fluid) until it encounters an abrupt change in acoustic density from body tissue to stone. By focusing the shock waves on a single focal point, the lithotripter concentrates energy at the site in which the stone is located. Fragmentation of the stone by shock waves occurs as a consequence of both direct mechanical stress from the incident shock wave and indirect forces as a result of collapse of cavitation bubbles generated by the trailing negative-pressure wave.[195]

Techniques

Shock-wave lithotripsy is an outpatient procedure that can be performed in a hospital, ambulatory surgery center, or a mobile lithotripter. Initially, all ESWL was accomplished in water baths. Modern lithotriptors create a connection with high-acoustic gel or oil or ionized water bags instead of submersion, providing for a more portable and convenient treatment regimen. Connections between the patient and the shock waves may be diminished by air

TABLE 29-5 Summary of Immunosuppressive Drugs

Drug	Description	Mechanism of Action	Nonimmune Toxicity and Comments
Prednisone	Corticosteroid	Binds nuclear receptor and enhances transcription of IκB, which inhibits NF-κB and T-cell activation	Diabetes, weight gain, psychological disturbances, osteoporosis, ulcers, wound healing, adrenal suppression
Cyclosporine	11-amino-acid cyclic peptide from *Tolypocladium inflatum*	Binds to cyclophilin; complex inhibits calcineurin phosphatase and T-cell activation	Nephrotoxicity, hemolytic-uremic syndrome, hypertension, neurotoxicity, gingival hyperplasia, skin changes, hirsutism, posttransplantation diabetes, hyperlipidemia
Tacrolimus (Prograf)	Macrolide antibiotic from *Streptomyces tsukubaensis*	Binds to FKBP12; complex inhibits calcineurin phosphatase and T-cell activation	Effects similar to cyclosporine but with lower incidence of hypertension, hyperlipidemia, skin changes, hirsutism, and gingival hyperplasia but higher incidence of posttransplantation diabetes and neurotoxicity
Sirolimus (rapamycin; Rapamune)	Triene macrolide antibiotic from *Streptomyces hygroscopicus* from Easter Island (Rapa Nui)	Binds to FKBP12; complex inhibits target of rapamycin and IL-2–dependent T-cell proliferation	Hyperlipidemia, increased toxicity of calcineurin inhibitors, thrombocytopenia, delayed wound healing, delayed graft function, mouth ulcers, pneumonitis, interstitial lung disease
Everolimus	Derivative of sirolimus, similar mechanism and toxicities		
Mycophenolate (CellCept)	Mycophenolic acid from *Penicillium stoloniferum*	Inhibits synthesis of guanosine monophosphate nucleotides; blocks purine synthesis, preventing proliferation of T and B cells	Gastrointestinal symptoms (mainly diarrhea), neutropenia, mild anemia
Azathioprine (Imuran)	Prodrug that undergoes hepatic metabolism to form 6-mercaptopurine	Converts 6-mercaptopurine to 6-thioinosine-5′-monophosphate, which is converted to thioguanine nucleotides that interfere with DNA and purine synthesis	Leukopenia, bone marrow depression, liver toxicity (uncommon)
Antithymocyte globulin	Polyclonal IgG from rabbits or horses immunized with human thymocytes	Blocks T-cell membrane proteins (e.g., CD2, CD3, CD45), causing altered function, lysis, and prolonged T-cell depletion	Cytokine release syndrome, thrombocytopenia, leukopenia, serum sickness
Muromonab-CD3 (OKT3)	Anti-CD3 murine monoclonal antibody	Binds CD3 associated with the T-cell receptor, leading to initial activation and cytokine release, followed by blockade of function, lysis, T-cell depletion	Severe cytokine release syndrome, pulmonary edema, acute renal failure, CNS changes
Basiliximab (Simulect)	Anti-CD25 chimeric monoclonal antibody	Binds to high-affinity chain of IL-2R (CD25) on activated T cells, causing depletion and preventing IL-2–mediated activation	Hypersensitivity reaction, uncommon
Daclizumab (Zenapax)	Anti-CD25 humanized monoclonal antibody	Similar to that of basiliximab	Hypersensitivity reaction, uncommon
Rituximab (Rituxan)	Anti-CD20 chimeric monoclonal antibody	Binds to CD20 on B cells and causes depletion	Infusion or hypersensitivity reactions, uncommon
Alemtuzumab (Campath)	Anti-CD52 humanized monoclonal antibody	Binds to CD52 expressed on most T and B cells, monocytes, macrophages, NK cells, causing lysis and prolonged depletion	Mild cytokine release syndrome, neutropenia, anemia, autoimmune thrombocytopenia, thyroid disease
FTY720	Sphingosine-like derivative of myriocin from the fungus *Isaria sinclairii*	Functions as antagonist for sphingosine-1-phosphate receptors on lymphocytes, enhancing homing to lymphoid tissues and preventing egress, causing lymphopenia	Reversible first-dose bradycardia, potentiated by general anesthetics and beta blockers, nausea, vomiting, diarrhea, increased liver enzyme levels
Belatacept (Nulojix; LEA29Y)	High-affinity homologue of CTLA-4 Ig	Binds to CD80-CD86 and prevents costimulation via CD28	Clinical trials—preliminary results suggest equal efficacy to cyclosporin A but improved glomerular filtration rate

Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 7th ed. Philadelphia: Saunders; 2012.

pockets in the gel or oil requiring an increased number of shocks and therefore greater risk of tissue damage.[196]

Several types of lithotripters are in clinical use, and they differ in the way they generate the shock waves. Electrohydraulic (spark-gap) lithotripters rely on an underwater discharge of a high-voltage spark that rapidly vaporizes the surrounding water, generating spherically expanding shock waves. Electromagnetic lithotripters are composed of an electromagnetic coil and a closely approximated metallic plate (or membrane) inside a water-filled shock tube. Piezoelectric lithotripters produce shock waves with

BOX 29-7

Precautions for Procedures and Surgery in Kidney Transplant Recipients

- Caution with radiocontrast exposure.
- Maintain hydration.
- Avoid nephrotoxic antibiotics and analgesic.
- "Stress-dose" steroids: not always necessary.
- If enteral route of medication is contraindicated, give CNI via IV route (⅓ total oral dose).
- Monitor allograft function, plasma potassium, and acid-base balance daily.
- Consider wound-healing impairment.

From Taal MW, et al. *Brenner & Rector's The Kidney*. 9th ed. Philadelphia: Saunders; 2012:2551.
CNI, Calcineurin inhibitor; *IV*, intravenous.

BOX 29-8

Side Effects Associated with Extracorporeal Shock Wave Lithotripsy

- Hypothermia, hyperthermia
- Cardiac arrhythmias
- Skin bruising hematomas
- Petechiae, soft tissue swelling at site
- Renal edema
- Renal hematoma
- Lung injury
- Flank pain
- Hypertension, hypotension
- Nausea, vomiting

the use of a spherical dish containing an array of small ceramic elements.[195] Ultrasonic waves fragment stones and allow them to pass in urine. Lasers may not be as effective with larger stones (greater than 1.5-2.0 cm).[197,198]

Water Immersion

The original ESWL procedure required patients to be strapped in a chair in a semireclining position, followed by submersion in water up to the clavicle. This technique is not used today, but the principles underlying the surgical procedure are similar. The focused, reflected shock wave passes through the water and enters the body through the flank. Significant effects on several systems may occur (Box 29-8).[199,200] The electrocardiograph must be of good quality because the R wave is used to trigger the shocks. Synchronization of the shock wave to the electrocardiograph has reduced the incidence of cardiac dysrhythmias, most commonly supraventricular or premature ventricular complexes, but has not totally eliminated them. Atropine or glycopyrrolate may be given to increase the heart rate and thus the shock-wave rate.[201,202]

Contraindications and Complications

Contraindications to shock-wave lithotripsy include active urinary tract infection, uncorrected bleeding disorder or coagulopathy, distal obstruction, and pregnancy. Obesity and orthopedic or spinal deformities may make positioning difficult.[195] Dose-dependent hemorrhagic lesions can develop on the kidneys, secondary to vascular damage.[201-203] The colon, hepatic structure, lungs, spleen, pancreas, abdominal aorta, ileac veins, or any structure in the abdominal region may be perforated, ruptured, or otherwise damaged. Moderate to severe hemorrhage may occur, but usually resolves spontaneously; patients with clotting disorders are at an increased risk. Hematuria develops in the majority of patients, secondary to blood vessel rupture. Diabetes, new-onset hypertension, or permanently decreased renal function may result.[201]

Anesthesia

Patients will not tolerate ESWL without some type of anesthesia. Various anesthetic techniques have been used. General anesthesia is advantageous because of its rapid onset and control of patient movement. Other techniques include spinal or epidural anesthesia, patient-controlled analgesia (PCA), monitored anesthesia care, and topical anesthesia with eutectic local anesthetics. Continuous infusions of propofol, ketamine, and alfentanil have been used alone or with midazolam. Regional anesthesia provides effective analgesia with a T4 to T6 level. A short-acting spinal anesthetic using 50 mcg of sufentanil alone is popular. Epidural catheters and dressings may cause absorption of some of the shock wave, decreasing the efficacy of treatment. Akinesis is critical in reducing number and duration of treatments, determining efficacy of ESWL, and preventing potential tissue damage. General anesthesia or deep sedation techniques decrease the risk of patient movement.[201-204] Preoperative preparation includes the discontinuation of aspirin-containing medications, anticoagulants, platelet inhibitors, and nonsteroidal antiinflammatory agents for 7 to 10 days before the procedure and documentation of a negative urine culture to prevent postoperative urinary tract infection or sepsis. In women of childbearing age, a pregnancy test is administered if ionizing radiation is to be used during the procedure. Depending on the size, radiopacity, and location of the stone, patients may be advised to drink clear liquids, take a laxative, or both the day before the procedure to enhance visualization of the stone. Fasting protocols are within standard guidelines for anesthesia.[195]

For lithotripsy to be most effective, the stone must remain at the focal point. Because patient movement and patterns of respiration can change kidney and stone position, movement must be minimized and ventilation carefully controlled. The number and intensity of shock waves can be reduced when stone movement is minimized.[204] An obstructed kidney or a patient exhibiting signs and symptoms of infection qualifies as an emergency case. Adequate hydration is encouraged postoperatively to promote diuresis of fragments and to flush out hematuria. Close proximity to lasers may cause corneal damage; everyone in the room, including the patient, should wear eye protection.[197]

PERCUTANEOUS NEPHROLITHOTOMY

Removal of kidney stones 25 mm or smaller also can be accomplished through percutaneous nephrolithotomy. This procedure requires general anesthesia and postoperative hospitalization. Stones are removed via a rigid operating scope inserted in the lower calyx of the kidney under fluoroscopy. Once located, calculi are pulverized by using laser, electrohydraulic, or ultrasound probes placed directly on the stones.[204] The procedure is performed with the patient in the prone or supine position; therefore associated anesthetic considerations apply. The following is a list of complications of percutaneous nephrolithotomy).

Minor	Major
Pain	Septicemia
Fever	Bleeding
Urinary tract infection	Pelvic or ureteral tears
Renal colic	Pneumothorax
	Hemothorax
	Anaphylaxis secondary to contrast dye

TABLE 29-6 Pathophysiology and Clinical Features of TURP Syndrome

Pathophysiology	Clinical Features
Fluid overload	Hypertension, bradycardia, arrhythmia, angina, pulmonary edema and hypoxemia, ventricular failure and hypotension
Water intoxication or Hypo-osmolality	Confusion and restlessness; twitching or seizures, lethargy or coma, dilated, sluggish pupils, papilledema, low-voltage EEG, hemolysis
Hyponatremia	CNS changes as above, reduced inotropy, widened QRS complex, low-voltage ECG, T-wave inversion on ECG
Glycine toxicity	Nausea and vomiting, headache, transient blindness, loss of light and accommodation reflexes (blink reflex preserved), myocardial depression, ECG changes
Ammonia toxicity	Nausea and vomiting, CNS depression
Hemolysis	Anemia, acute renal failure, chills, clammy skin; chest tightness and bronchospasm; hyperkalemia resulting in malignant arrhythmias or bradyasystole
Coagulopathy	Severe bleeding, primary fibrinolysis, disseminated intravascular coagulation

TRANSURETHRAL RESECTION OF THE PROSTATE

Surgical Technique

Benign prostatic hyperplasia (BPH) is the most common benign adenoma in men. Up to 40% of men will require intervention for urinary difficulty, and the frequency of those seeking medical treatment is increasing, due in part to the increase in life expectancy. Medical management consists of pharmacotherapy, which may be combined with a minimally invasive technique. Drugs such as the α-blocking agents, alfuzosin (Uroxatral) and tamsulosin (Flomax), or the 5-alpha-reductase (5AR) inhibitors, finasteride (Proscar) and dutasteride (Avodart), are used alone or more often in combination. Minimally invasive therapies include Holmium laser resection, plasma kinetic vaporization, GreenLight laser vaporization, and transurethral microwave thermotherapy. Transurethral resection of the prostate (TURP) is one of the most commonly performed surgical procedures in men older than 60 years of age. It is being performed less frequently as medical management improves; however, it remains the gold standard in surgical treatment approaches.[205]

The procedure consists of opening the outlet channel from the bladder using a resectoscope in the urethra to electrically cut away the obstructing median and lateral lobes of prostate tissue. Bleeding is controlled with a coagulation current. For visualization of the area, the bladder is distended and continuous irrigation is used to wash away blood and dissected prostatic tissue. These patients are often at greater anesthetic risk because they are elderly and more likely to have cardiovascular or pulmonary problems. Transurethral resection of the prostate (TURP) syndrome is a rare but potentially fatal surgical complication. The incidence is reported to range from 0.78% to 1.4% of procedures. Severe TURP syndrome is rare, but the mortality rate may be as high as 25%. It may occur as early as 15 minutes after the start of resection up to 24 hours postoperatively.[206] It is a procedure-induced combination of water intoxication, fluid overload, and hyponatremia. The pathophysiology and clinical features of TURP syndrome are summarized in Table 29-6. Other complications of the procedure include excessive bleeding, bladder perforation, and infection. Average surgical parameters associated with a transurethral resection of the prostate are given in Table 29-7. Improved surgical techniques and knowledge of the pathophysiology, prevention, and management of TURP syndrome has minimized the risks of this procedure.[205,206]

TABLE 29-7 Average Parameters with a Transurethral Resection of the Prostate

Parameter	Average
30-day mortality	0.2%-0.8%
Resection time	Less than 80 min
Resected mass	20-50 g
Absorbed volume	10-30 mL of fluid per min of resection time
Blood loss	2-5 mL per min of resection time
Serum sodium nadir	132-135 mmol/L

Complications

Fluid Absorption

A number of complications are associated with resection of the prostate. Large amounts of irrigating solution can be absorbed through venous sinuses. The amount absorbed and the rate of absorption depend on the size of the gland to be resected, the congestion of the gland, the duration of resection, the pressure of the irrigating solution, the number of sinuses open at any one time, and the experience of the resectionist.[207] An average of 10 to 30 mL of fluid can be absorbed per minute of resection time, and 6 to 8 L can be absorbed in cases that last up to 2 hours.[208,209] The uptake of 1 L of irrigant into the circulation within 1 hour can decrease the serum sodium 5-8 mEq/L. In general, limiting resection time to 1 hour is desirable.[206]

Complications may occur with irrigation solutions, as determined by their osmolality and solute composition. Various types of irrigating fluid have been used. Although distilled water is associated with the least optical impairment, its hypotonic composition results in hemolysis of red blood cells. Normal saline or lactated Ringer's solution is highly ionized and promotes dispersion of high current from the resectoscope. Although many different irrigating solutions have been tried, current irrigating solutions typically consist of Cytal (sorbitol 2.7% and mannitol 0.54%), glycine 1.2% or 1.5%, or physiologic saline.[206]

Complications specifically related to absorption of irrigating fluid include volume overload with pulmonary edema, dilutional hyponatremia, hypo-osmolality, cardiac effects, retinal toxic effects (with glycine), and hyperglycemia. As fluid enters the vascular compartment, intravascular pressure and myocardial work increase. The fluid dilutes plasma proteins and electrolytes, and the change in intravascular pressure favors movement of fluid from the vascular to the interstitial compartment. This is poorly tolerated by patients with a cardiovascular disease. Cardiac dysrhythmias may also develop. Progressive increases in blood pressure, CVP, or pulmonary artery wedge pressure (when monitored) suggest hypervolemia. Mannitol irrigating solutions have been reported to contribute to the development of pulmonary edema and hypotnatremia.[210]

Absorption of irrigating fluid also leads to dilutional hyponatremia and hypo-osmolality. Sodium is a major cation of extracellular fluid, and it is responsible for the depolarization of excitable cells and the production of action potentials. The severity and speed of the drop in sodium are related to the resulting symptoms.

The decrease in sodium produces an osmotic shift of fluid into the brain resulting in brain edema, increases in intracranial pressure, and neurologic symptoms. Hyponatremia usually results from water excess rather than from sodium loss. CNS symptoms associated with hyponatremia range from restlessness, headache, irritability, and confusion to blindness, coma, and seizures.

Serum sodium (Na^+) concentrations of 120 mEq/L appear to be borderline for the development of severe reactions, which are mainly ECG and central nervous system (CNS) changes. Electrocardiographic changes characterized by widening of the QRS complex and ST-segment elevation are seen when the serum level decreases to 115 mEq/L. At levels less than 100 mEq/L, ventricular tachycardia and fibrillation can occur.[211] CNS symptoms associated with hypovonatremia include restlessness, confusion, nausea, vomiting, coma, and convulsions. These symptoms can be detected more easily in patients receiving regional anesthesia. CNS symptoms are hidden under general anesthesia. Transient hyperglycemia and hypokalemia have been reported when glucose irrigation solutions have been used.[207,208,211]

Bladder Perforation

Perforation of the bladder is another potential complication of prostatic surgery; however, recent advances in technology have reduced its incidence. Symptoms vary, depending on whether the rupture is intraperitoneal or extraperitoneal. Pathophysiology and clinical features of bladder perforation and TURP syndrome are noted in Box 29-10.[212-214] These symptoms are better recognized when the patient has regional anesthesia if the regional technique does not produce a high block. With general anesthesia, only the surgeon can appreciate the inability to recover bladder fluid as a sign of perforation. Small amounts of intraperitoneal fluid will be excreted by the kidney. However, if hemodynamic compromise occurs, suprapubic drainage is effective for removal of excess intraperitoneal fluid.

Glycine Absorption

Absorption of glycine has been associated with toxicity. Glycine, an amino acid normally found in the body, is a major inhibitory transmitter. Toxic effects may occur from absorption during the procedure. Signs and symptoms include nausea, vomiting, fixation and dilation of the pupils, weakness, muscle incoordination, and hypotension due to a decrease in the release of catecholamines. Glycine is also an inhibitory neurotransmitter in the retina. Absorption of 1.5% glycine can cause a deterioration of vision. TURP blindness is caused by retinal dysfunction from glycine toxicity.[206,214]

Glycine may also result in encephalopathy and seizure activity due to NMDA receptor stimulation. Other signs and symptoms of glycine toxicity include nausea, vomiting, headache, malaise, and weakness. Glycine may also result in CNS toxicity as a consequence of its biotransformation in the liver to ammonia. Ammonia toxicity may result in encephalopathy, delayed awakening, and even coma in the postoperative period.[206]

Skin Burns

The use of high voltage for cutting and coagulation during TURP may result in skin burns. Newer technology for TURP, including bipolar enucleation of the prostate and laser therapy, have reduced the risk of skin burns when compared with monopolar techniques.[215] Electrocardiography pads may be placed at other sites so that potential burns are avoided. Many patients who undergo TURP have pacemakers. These devices must be converted to a fixed rate unless they are designed to operate in the presence of applied currents.[216]

Blood Loss

Significant bleeding occurs in less than 1% of TURP cases. Blood loss during TURP generally is related to the weight of the resected tissue, operating time, and skill of the surgeon.[217] Increased blood loss occurs with greater than 45 g of resected tissue and procedures lasting longer than 90 minutes Assessment of blood loss may be difficult because of the dilution of blood in irrigating fluid. Hematocrit may be increased, decreased, or unchanged, depending on the amount of fluid in the intravascular space at the time. Blood transfusion should be based on preoperative hematocrit, the

BOX **29-9**

Management of TURP Syndrome and Bladder Perforation

- Asymptomatic or mildly symptomatic patients should be observed and monitored.
- Severe TURP syndrome requires immediate aggressive therapy if the patient is to survive. The following measures are suggested:
  - Terminate the surgery as soon as possible.
  - Administer 20 mg of intravenous (IV) furosemide.
  - Immediately obtain the following laboratory tests; hematocrit; serum electrolyte, creatinine, and glucose concentrations; serum osmolality (if available); arterial blood gas analyses; and 12-lead ECG.
  - Continue or start the administration of normal saline. Hypertonic saline (3% or 5%) may be administered (at a rate<100 mL/hour) if the serum sodium concentration is less than 100 mEq/L, severe central nervous system side effects of hyponatremia and hypo-osmolality are evident, or reduced inotropy results in cardiovascular collapse.
  - Administer IV midazolam in 1-mg incremental doses to treat twitching or seizures; a barbiturate may be added if seizures persist.
  - Auscultate chest and obtain chest radiographs to detect pulmonary edema. Intubate and mechanically ventilate the patient at the earliest evidence of pulmonary edema.
  - Transfuse packed red blood cells as necessary.
  - If bleeding continues, investigate for disseminated intravascular coagulation (DIC) or primary fibrinolysis. DIC is treated with crystalloids and blood products to achieve hemodynamic stability and normal coagulation. Primary fibrinolysis responds well to amino-caproic acid (Amicar) administered as an IV infusion of 3 to 5 g in the first hour, followed by continuous IV infusion at 1 g/hour until the bleeding is controlled.
  - Institute invasive monitoring and provide supportive therapy to maintain circulation and pulmonary function and to prevent renal failure.

Bladder Perforation

As soon as bladder perforation is detected, undertake the following measures:

- Stop surgery and achieve hemostasis.
- Treat hypotension with IV crystalloids, vasopressors, and inotropes.
- Obtain a hematocrit. Start blood transfusion if brisk bleeding continues. Occult blood loss into the intraperitoneal or retroperitoneal space may occur.
- Perform a cystourethrogram to locate the perforation.
- For most perforations, suprapubic cystotomy, an indwelling Foley catheter, and (occasionally) ureteral stents are sufficient. In some instances, immediate exploratory laparotomy may be necessary to control bleeding and repair the perforation.

Adapted from Hawary A, et al. Transurethral resection of the prostate syndrome: almost gone but not forgotten. *J Endourol.* 2009;23(12):2013-2020; Malhotra V, Sudheendra V. Complications of transurethral surgery. In: Atlee JL, ed. *Complications in Anesthesia.* 2nd ed. Philadelphia: Saunders; 2007:843-845; Gravenstein D, Hahn RG. TURP syndrome. In: Lobato EB, et al, eds. *Complications in Anesthesiology.* Philadelphia: Lippincott Williams & Wilkins; 2008:474-491.

duration and difficulty of resection, and a general assessment of the patient. A recent study of 951 robotic-assisted laparoscopic prostatectomies noted that men with larger prostates and median lobes requiring longer operative times experienced higher blood loss. Resected tissue less than 30 g generally required no transfusion. Thirty to eighty grams resected possibly required up to 2 units of red blood cells, and greater than 80 g up to 4 units.[218]

Prevention of TURP Syndrome. Prevention of TURP syndrome is, of course, the most important approach. Early identification of evolving symptoms is vital to avoid serious morbidity. Suggested preventative measures include: avoid the Trendelenburg position as it promotes fluid absorption; limit resection time to less than 1 hour; keep the prostate capsule intact until the end of the resection; place irrigating fluids less than 60 cm above the prostate gland; measure electrolytes during and after the procedure as indicated; and use a regional technique with light sedation so mental changes can be identified.[206,219,220]

Treatment of TURP Syndrome. An asymptomatic patient with mild hyponatremia only requires monitoring and observation. Mild symptoms can be managed with supportive treatment such as antiemetics, atropine, vasopressors, or diuretics and careful observation as indicated.

If TURP syndrome is detected intraoperatively, bleeding points should be coagulated and surgery completed as soon as reasonable. Severe hyponatremia less than 120 mEq/L must be treated. The challenge is to promptly institute treatment while avoiding overtreatment. The most feared complication of rapid correction of acute hyponatremia is central pontine mylenolysis, also referred to as osmotic demyelination syndrome (ODS). The etiology is unclear; however, osmotic stress appears to cause changes in neuronal cells and the release of myelin toxins. Symptoms usually occur approximately one week after the osmotic stress and may include seizures, palsy, dysarthria, paralysis, mental changes, and coma. Hypertonic saline (3% to 5% sodium chloride) should be given at a rate no greater than 100 mL/hr. Sodium correction should not exceed 0.5 mEq/L per hour or 8 mEq/day. Severe symptoms may require initial doses of 1-2 mEq/L per hour. Target levels for correction are 120 mEq/L.[206,219,220] Suggestions for the management of TURP syndrome and bladder perforations are given in Box 29-9.

Anesthesia for TURP Procedures. Spinal and general anesthesia are both used for TURP procedures. Spinal anesthesia is believed to be the anesthetic of choice because the early signs and symptoms of TURP syndrome, hypervolemia, and bladder perforation are more easily detected in a responsive patient. Under general anesthesia, cardiovascular changes must be relied on to diagnose complications. Pain impulses from the bladder neck and prostate are propagated by afferent parasympathetic fibers originating primarily from the second and third sacral roots in concert with the pelvic splanchnic nerves. The sympathetic nerves via the hypogastric plexus, which is derived from T11 to L2 nerve roots, transmit sensation from the bladder.[221] As a result, a T10 sensory level is necessary for adequate anesthesia. Intrathecal opioids are commonly included with the local anesthetic. Cautious fluid loading may be used to minimize spinal anesthesia-induced hypotension. Although general anesthesia may mask early complications, it may be desirable in the patient who requires pulmonary support or who cannot tolerate a fluid load for compensation of a loss of sympathetic tone. All inhalation agents have been used successfully.[206,219,222] Some key points for anesthesia management of TURP are given in Box 29-10.

BOX 29-10

Key Points for Anesthesia Management of Transurethral Resection of Prostate

- TURP syndrome is caused by disturbance of intravascular volume and/or serum osmolality.
- Five questions to ask prior to a TURP:
  1. What is the irrigation fluid? (Glycine, Cytal, or Physiologic saline?)
  2. What is the bag height over the prostate?
  3. What is the size of the prostate?
  4. What is the expected duration of procedure?
  5. What is the surgical operating position (avoid Trendelenburg)?
- Techniques for detection of pending TURP syndrome include measurement of serum sodium, monitoring for fluid overload, assessment of mental status, and ethanol breath analysis.
- Treat symptomatic (mental status changes, seizures, hypotension) patients aggressively; treat asymptomatic aberrant lab values (hyponatremia, hyperglycemia) very slowly, if at all.
- CNS symptoms of headache, irritability, confusion, nausea, and vomiting are early warning signs of TURP syndrome.

LAPAROSCOPIC UROLOGIC SURGERY

Laparoscopy is the process of inspecting the abdominal cavity through an endoscope. Laparoscopy started in the mid-1950s when gynecologists began to use this technique to diagnose pelvic pain while reducing postoperative pain and length of hospital stay. Over the years, laparoscopy for general and urologic surgery has become a common procedure. Advantages and disadvantages of laparoscopic surgery are found in Box 29-11. Some examples of surgical procedures that can be done laparoscopically include varicocelectomy, percutaneous stone retrieval, nephrectomy, transplants, and radical prostatectomy.[223-225]

Carbon dioxide is the most universally used agent for insufflating the abdominal cavity to facilitate view during this procedure. Several pathophysiologic changes can occur after carbon dioxide pneumoperitoneum and the extremes of patient positioning required for the procedure. Preparation for hemorrhage and conversion to an open procedure are critical.[226] Most of the considerations for laparoscopic surgery are beyond the scope of this chapter, but two unique problems specific to urologic surgery are worth discussing.

The urogenital system is a retroperitoneal system. As such, carbon dioxide insufflated in this space communicates freely with the thorax and subcutaneous tissue. Subcutaneous emphysema can occur and may extend to the head and neck. In severe cases, it may lead to submucous swelling and airway compromise in the unprotected airway.[227-229]

Carbon dioxide is absorbed from the peritoneal cavity and acidosis may develop. Because the carbon dioxide insufflation, together with steep Trendelenburg position and long procedures, may increase intraabdominal and intrathoracic pressure, controlled ventilation is mandatory. Intraperitoneal pressure greater than 10 mmHg results in hemodynamic alterations, including decreased cardiac output and increased systemic vascular resistance. The pneumoperitoneum can cause renal cortical vasoconstriction due to activation of the sympathetic nervous system. Decreased renal perfusion activates the renin-angiotensin-aldosterone system, which causes vasoconstriction. These effects are additive to those seen with surgical stress. Renal and hepatic perfusion may

BOX **29-11**

Advantages and Disadvantages of Laparoscopic Renal Surgery

Advantages

- More precise operative procedure due to magnification of operative site
- Reduced postoperative pain
- Improved cosmetic results
- Quicker return to normal activities
- Reduction in hospital length of stay
- Reduction of cost of care
- Less intraoperative bleeding
- Fewer postoperative pulmonary infections
- Fewer postoperative wound infections
- Reduced metabolic derangements
- Better postoperative respiratory function

Disadvantages

- Potential for extravasation of insufflated carbon dioxide to retroperitoneal space and thorax
- Potential for postoperative airway compromise secondary to subcutaneous emphysema and pharyngeal obstruction
- Increased incidence of acidosis due to absorption of carbon dioxide
- Higher incidence of intraoperative oliguria potentially due to perirenal pressure from pneumoperitoneum
- Potentially longer duration than open procedure

be altered. Some suggested techniques to minimize the effect of positive pressure pneumoperitoneum include: (1) employ lower insufflation pressures, (2) operate in a gasless environment, (3) substitute inert gas for carbon dioxide, (4) use drugs to antagonize the neuroendocrine response, (5) expand volume, and (6) use mechanical devices. It has been reported that the use of intermittent sequential pneumatic compression (ISPC), activated over the lower limbs 15 minutes after the pneumoperitoneum, improves splanchnic and renal perfusion. This technique augments cardiac output and lowers systemic vascular resistance.[230] A complete discussion of laparoscopic surgery can be found in Chapter 31.

ROBOTIC UROLOGIC SURGERY

Robotic-assisted surgery is an emerging technique for managing various urologic procedures such as prostatectomy. It is performed using the da Vinci surgical system (Intuitive Surgical Mountain View, Calif, USA). It consists of a surgeon's console for surgical work, a surgical cart that houses the video and lighting equipment, and a robotic tower that supports three or four robotic arms. Figure 29-7 shows the da Vinci Si surgical system.

The surgeon's console provides the surgeon with a three-dimensional, 10-times magnified view through a binocular viewpoint. Interaction is achieved through "masters" into which the surgeon's hands are inserted. Robotic technology provides the surgeon an enhanced and magnified 3D view, a reduction in scattered ambient light, reduced surgeon fatigue, reduced hand tremor, and improved manual dexterity. This technology also provides a predominantly bloodless field.[231-233]

Robotic surgery necessitates a coordinated approach by anesthetist and surgeon because the surgery is performed using a modified laparoscopic technique and can be long in duration. The patient is placed in Trendelenburg position, with the addition of lithotomy positioning in prostatectomy surgery. Major complications of surgery in the Trendelenburg position include:

FIGURE **29-7** Da Vinci Si surgical system. (Courtesy Intuitive Surgical Inc., Sunnyvale, California.)

BOX **29-12**

Anesthesia for Robotic-Assisted Surgery

- There is risk of thromboembolism due to lengthy procedures in Trendelenburg position; use thromboembolic stockings to reduce risk.
- Maximize protection over pressure areas to avoid nerve injury and protect face from direct pressure.
- General anesthesia or general and regional combined may be used.
- Difficulties inherent in patients having prolonged surgery in Trendelenburg position are present: increased mean arterial pressure in brain, increased cerebral blood volume, decreased cardiac output and perfusion to lower extremities, and decreased perfusion to vital organs.
- Challenges inherent with lower limbs in lithotomy are present: potential for damage to the common peroneal nerve.
- Difficulties with peritoneal insufflation are present: decreased compliance, increased airway pressure, increased ventilation-perfusion mismatch, and hypercapnia.
- Blood pressure reduction may be necessary secondary to resultant increase in systemic vascular resistance because of the pneumoperitoneum.
- Urine output may be decreased and generally responds to a fluid challenge.

(1) neuropathies, (2) CVP elevation, (3) intraocular/intracranial pressure elevation, (4) increased pulmonary venous pressure, (5) decreased pulmonary compliance, (6) reduced functional residual capacity (FRC), and (7) swelling of the face, eyelids, conjunctivae, and tongue. Facial swelling requires careful airway assessment prior to extubation. Major anesthetic considerations for robotic procedures are summarized in Box 29-12.

SUMMARY

Anesthetic management of the patient during the perioperative period for renal procedures depends upon an understanding of both normal renal function and pathophysiologic changes in the organ system. In addition to normal anatomy and physiology, this chapter highlighted ways to assess renal function and changes in renal function secondary to anesthetics. Various stages of renal pathology were identified and management of patients with acute and chronic renal failure emphasized. Rare and common urologic procedures were identified, and pertinent anesthetic considerations discussed for each procedure.

Hepatobiliary and Gastrointestinal Disturbances and Anesthesia

CHAPTER 30

◆ *Shawn B. Collins and Mason McDowell*

The hepatobiliary system plays an integral role in anesthetic management. An intimate familiarity with diseases of the hepatobiliary and gastrointestinal systems can help avoid negative anesthetic outcomes. The liver is the largest internal organ and is critical in maintaining the homeostasis of many other physiologic systems, the least of which is drug metabolism. As such, acute or chronic liver dysfunction can impair the intended response to anesthesia.[1]

The purpose of this chapter is to give an overview of pathophysiologic processes specific to the hepatobiliary and gastrointestinal system commonly encountered by the anesthetist. Fundamental relevant anesthetic considerations are described. More specifically, this chapter reviews the anatomy, physiology, and pathophysiology of the liver, to include evaluation of liver function, anesthesia effects on liver function, and perioperative management of patients with liver disease. The chapter continues with diseases of the biliary tract, esophagus, stomach, peritoneum, intestinal tract, and spleen and anesthetic management of patients with conditions affecting these systems. Special consideration is given to carcinoid tumors and transplantation.

LIVER DISEASE

Anatomic, Physiologic, and Pathophysiologic Considerations

Located in the thoracic portion of the abdominal cavity, the liver is the largest organ in the body and generally extends from rib 7 to rib 11 along the right midaxillary line. The liver spans from the right hypochondrium to a portion of the left hypochondrium and is classically divided into four lobes, which may be subdivided into multiple segments as described, for example, by the Couinaud system.[2] These subdivisions are based on the anatomic proximity of hepatic and portal veins, though multiple classifications are used that contain different terminology and no system is recognized as superior.

The functional unit of the liver is the hepatic lobule or acinus. The acinus forms around a portal canal consisting of a portal venule, hepatic arteriole, bile ductule, lymphatic vessel, and nerves. The acinus architecture radiates around a central vein that empties into the hepatic veins and then into the vena cava (Figure 30-1). Hepatic lobules number between 50,000 and 100,000 in the normal liver.

The filtering function of the liver has a prominent physiologic role. Blood from the gut contains large quantities of colonic bacilli; it is cleansed of more than 99% of the bacterial load by Kupffer cells (macrophages) that line the hepatic sinuses.[3] Endothelial cells that line the hepatic sinuses permit diffusion of large plasma proteins and other substances into the extravascular spaces in the liver. This phenomenon results in a large quantity of lymph that is nearly equal in protein concentration to plasma.

The metabolic functions of the liver require a significant quantity of blood, which comes from arterial and venous sources. The portal vein and the hepatic artery provide the primary blood supply to the liver, delivering approximately 1.5 liters per minute of blood flow. The hepatic artery branches off of the abdominal aorta and delivers 400 to 500 mL/minute of oxygenated blood. According to the anatomic peculiarity of the double afferent blood supply of the liver, 75% to 80% of the blood entering the liver is partially deoxygenated venous blood supplied by the portal vein, which collects all the blood that leaves the spleen, stomach, small and large intestine, gallbladder, and pancreas. The blood entering the liver via the hepatic portal vein contains some oxygen and is high in nutrients that have been absorbed from the digestive tract into the mesenteric and portal veins. Hepatic venous blood supply is shown in Figure 30-2. It is responsible for 70% of blood flow to the normal liver (≈1 L/minute), but only 50% of the liver oxygen supply. The dual supply of blood allows the liver to be relatively resistant to hypoxemia. The combined blood from both sources joins in the hepatic sinusoidal channels lying between the layers of cells in the lobule. These channels serve as capillaries. Endothelial cells and Kupffer cells line the sinusoids. Bile canaliculi are located between hepatocytes; these canaliculi empty into terminal bile ducts. A coalescence of central veins from hepatic lobules forms the hepatic veins, which empty into the inferior vena cava. An extensive arcade of lymphatic vessels is also present within the layer of cells.[4]

The mean pressure in the hepatic artery is similar to that in the aorta, whereas portal vein pressure has been reported to range between 6 and 10 mmHg in humans. This relatively low pressure allows the liver to function as a circulatory reservoir. Hepatic blood volume may expand considerably in cardiac failure and, in turn, serves as an important blood reservoir in case of bleeding episodes, and compensates up to 25% of the hemorrhage by immediate expulsion of blood from the capacitance vessels.[5] Both α- and β-receptors are present in the hepatic arterial circulation, but only α-receptors are noted in the portal circulation. There is disagreement as to whether the hepatic arterial vasculature exhibits autoregulation of blood flow. Portal blood flow is dependent on the combined venous outflow from the spleen and gastrointestinal tract. A decrease in either portal or arterial blood flow affects a compensatory increase in blood flow delivered by the other system.[6]

Potent inhaled anesthetics can affect hepatic blood flow, particularly portal blood flow, but present evidence suggests that flow is well maintained relative to oxygen demand. None of the present anesthetics adversely influence hepatic integrity by its effects on blood flow.[7] Effects of *volatile anesthetics* on hepatic blood flow are described in Table 30-1.

Changes in hepatic artery or portal vein blood flow may not result in an overall change in total hepatic flow due to the hepatic artery buffer response (HABR). This response is a semi-reciprocal autoregulatory mechanism whereby changes in portal flow inversely affect hepatic arterial flow.[8] The similarity in total hepatic flow between agents implies an intact HABR.

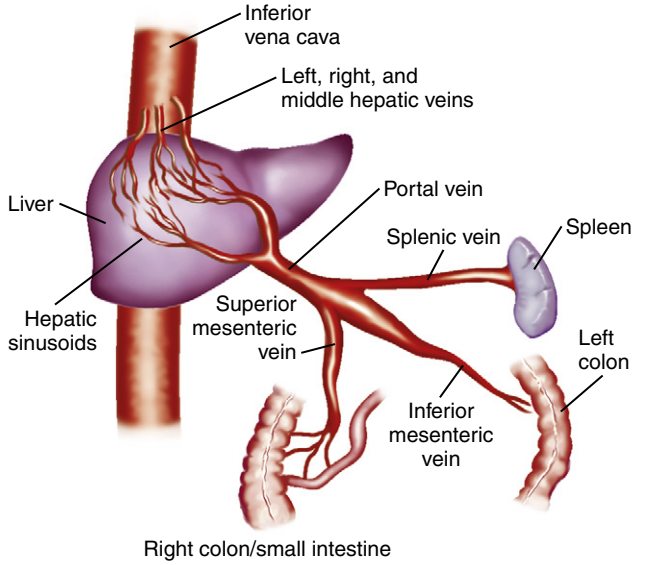

FIGURE **30-1** Anatomy of the portal circulation. Blood vessels that constitute the portal circulation and hepatic outflow tracts are depicted. (From Feldman M, et al, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 9th ed. Philadelphia: Saunders, 2010:1490.)

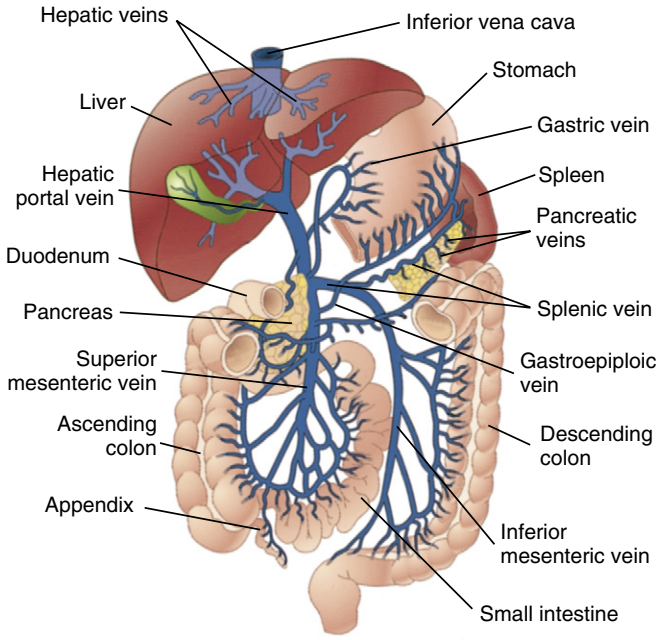

FIGURE **30-2** Hepatic portal circulation. In this unusual circulatory route, a vein is located between two capillary beds. The hepatic portal vein collects blood from capillaries in visceral structures located in the abdomen and empties into the liver for distribution to the hepatic capillaries. Hepatic veins return blood to the inferior vena cava. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 8th ed. St Louis: Mosby; 2013:664.)

The liver has many physiologic functions, including synthesis and metabolism of various essential proteins, lipids, and hormones (Box 30-1). There are no artificial devices that can duplicate all of the functions of the liver.

Carbohydrate Metabolism

Because nutritional ingestion and energy demand may not be synchronous, the body relies upon a dynamic system of energy storage and utilization. Glucose is the primary fuel source for many cells of the body (e.g., kidney, red blood cells) and is the preferred energy source for other tissues (e.g., brain). To maintain a steady blood glucose level, the liver moderates gluconeogenesis and glycogenolysis.

Gluconeogenesis is the formation of glucose from noncarbohydrate molecules lactate and pyruvate and amino acids, all of which are products of anaerobic and catabolic metabolism. It is stimulated by reduction of glycogen stores. During periods of fasting, the liver maintains glucose levels at relatively normal levels through glycogenolysis. Initiated by epinephrine and glucagon, glycogenolysis is the process of liberating glucose from glycogen stores found in the liver (and skeletal muscle). Hypoglycemia may therefore be encountered in patients with severe liver disease caused by derangements in insulin clearance, a decrease in glycogen capacities, and impairment in gluconeogenesis. Because these processes deplete stored nutrients, the body's energy needs can only be maintained for a limited time.

Protein Synthesis

Protein synthesis occurs primarily in the liver; this excludes immunoglobulins, which are produced by the humoral immune system. With significant liver disease, a reduction in circulating plasma protein will result in a decrease in plasma oncotic pressure. Additionally, drugs bound to proteins produced by the liver would have a greater unbound fraction if circulating proteins were reduced due to liver disease. In addition, overexpansion of the interstitial space and third-spacing secondary to derangements in plasma oncotic pressure result in a large increase in the volume of distribution of clinically used medications. Clinical concerns should therefore focus on the potential for an exaggerated effect with a given dose of drug, particularly a drug that is highly protein bound. The amount of nondepolarizing muscle relaxant *may* also need to be increased to achieve a given level of blockade. This is secondary to an increased volume of distribution of the drug (secondary to alterations in plasma protein binding and body fluid shifts). Plasma cholinesterase, which is produced in the liver, also

TABLE 30-1 Effect of Selected Volatile Anesthetics on Hepatic Blood Flow

Volatile Anesthetic	Hepatic Artery Blood Flow	Portal Vein Blood Flow
Desflurane	No change	Decrease or no change
Isoflurane	Increase	No change
Sevoflurane	No change or increase	Decrease

BOX 30-1

Selected Essential Physiologic Functions of the Liver

- Carbohydrate metabolism
  - Gluconeogenesis
  - Glycogenolysis
  - Glycogenesis
- Protein synthesis
  - Albumin (osmolarity)
  - Thrombopoietin (platelet production)
- Amino acid synthesis
- Protein metabolism
- Bile production
- Lipid metabolism
  - Lipogenesis
  - Cholesterol synthesis
- Coagulation factor synthesis
  - Factors I, II, V, VII, IX, X, XI
- Insulin clearance
- Drug metabolism/ transformation
- Bilirubin metabolism

may be deficient. This condition may prolong the effects of succinylcholine as well as enhance the potential toxicity of ester local anesthetics.

Protein Metabolism

Other roles in protein metabolism performed by the liver include synthesis of lipoproteins (important for lipid transport in the blood), deamination of amino acids into carbohydrates and fats for production of adenosine triphosphate (ATP) through citric acid cycle oxidation, and production of urea for the removal of ammonia, which is formed by hepatic deamination processes and bacteria in the gut.

Bilirubin Metabolism

Bilirubin is a breakdown product of heme metabolism and is often classified as unconjugated or conjugated. Heme is turned into unconjugated bilirubin in the reticuloendothelial cells of the spleen. This unconjugated bilirubin is not soluble in water and is neurotoxic at sufficiently high levels. It is then bound to albumin and transported to the liver. Once in the liver, the unconjugated bilirubin is conjugated with glucuronic acid. Bilirubin is then incorporated into the bile and is secreted into the intestine, where it is metabolized by bacterial enzymes and predominantly excreted in feces.

Bile Production

The liver aids intestinal digestion by forming bile and secreting it into the common bile duct (CBD). Hepatocytes in each lobule continuously secrete fluid that contains phospholipids, cholesterol, conjugated bilirubin (the end product of hemoglobin metabolism), bile salts, and other substances. Bile is stored and concentrated in the gallbladder. In response to the intestinal hormone cholecystokinin (CCK), bile is released by the gallbladder. The presence of fat and protein in the duodenum initiates contraction of the gallbladder and movement of bile via the common bile duct. This duct merges with the pancreatic duct at the ampulla of Vater, which empties into the duodenum via the sphincter of Oddi (major duodenal ampulla). Obstruction of either of these ducts may result in pathologic illness that may necessitate surgical correction.

Ductal patency may be confirmed by radiologic evaluation. Endoscopic retrograde cholangiopancreatography (ERCP) is performed by passing an endoscope into the lower gastrointestinal (GI) tract and locating the major duodenal ampulla. The ampulla is cannulated and examined using radiographic dye to determine whether the blockage is due to a common bile duct stone. If a stone is present, typically it can be retrieved endoscopically. Sphincterotomy also may be performed to facilitate removal of CBD stones. Correction of ductal stenosis also may require sphincterotomy or insertion of a stent.

Bile secretion assists in the absorption of fat and fat-soluble vitamins (vitamins A, D, E, K). The metabolic end products of many drugs are also removed via the bile. Liver disease may result in impaired bile production or flow, leading to steatorrhea, vitamin K deficiency, and delayed removal of active drug metabolites.

A deficiency in vitamin K results in coagulopathy due to impaired production of clotting factors II (prothrombin), VII, IX, and X.[9] Except for factor VIII, which is produced in endothelial cells, the liver is responsible for producing all clotting factors. Hepatocellular disease therefore results in decreased clotting factor levels and abnormal bile production. Impaired bile production ultimately manifests as altered production of vitamin K–dependent clotting factors.

Intrahepatic obstruction of blood flow (due to disease pathology) ultimately causes portal hypertension. A consequence of the resultant transmission of backward pressure is congestive splenomegaly, leading to platelet sequestration and thrombocytopenia. Therefore, severe liver disease with portal hypertension induces coagulopathy not only as a result of impairment in hepatic coagulation factor production but also as a result of diminution in circulating functional platelets. In the presence of biliary deficiency, parenteral vitamin K administration helps correct coagulopathy. However, significant hepatocellular disease may dictate the need for fresh frozen plasma (FFP) for immediate correction of coagulation-factor deficits.

The use of subarachnoid and epidural blockade should be avoided in the presence of coagulopathy. Derangements in parameters such as prothrombin time (PT), activated partial thromboplastin time (PTT), and platelet count are a relative contraindication to these techniques; most procedures in which bleeding is a possibility are often postponed when international normalized ratio (INR [prothrombin time]) is greater than 1.5. Nasopharyngeal instrumentation and invasive procedures must be performed cautiously and carefully in the presence of increases in PT and activated PTT, a low platelet count, or other laboratory signs that arouse suspicion of coagulopathy.

Insulin Clearance

The liver is the main site for insulin clearance, removing 50% during the first portal passage, but this percentage varies widely under different conditions.[10] During obesity, hyperinsulinemia, insulin-resistant state, dyslipidemia, and type II diabetes mellitus insulin clearance in the liver decreases. A reduction in hepatic insulin extraction would lead, in insulin-resistant states, to a substantial peripheral hyperinsulinemia (due to insulin hypersecretion and reduced hepatic extraction of insulin).[11]

Drug Metabolism/Transformation

The enzyme systems involved in the biotransformation of drugs are located primarily in the liver. Proper hepatic function is necessary to maintain the pharmacokinetic machinery detailed earlier in this textbook. Orally administered drugs may be metabolically inactivated in the liver before reaching the systemic circulation. This first-pass metabolism may limit the oral availability of highly metabolized drugs. Within the liver, phase I and phase II reactions are responsible for metabolism of many exogenous substances and most drugs. The subsequent products are then excreted via excretory transporters on either the canalicular or sinusoidal membranes[12] (Box 30-2). The end products of these processes (except in the case of prodrugs or an active metabolite) are the result of deactivation and transformation of substances into benign by-products capable of being excreted in the bile or urine.

The cytochrome P450 (CYP) class of enzymes are primarily responsible for phase I reactions. More than 50 CYPs have been identified in humans, yet nearly 50% of drugs currently manufactured are metabolized by CYP 3A4/5.[13] Differences in the rate of metabolism of a drug can be due to drug interactions. When two drugs are coadministered and subjected to metabolism by the same enzyme system, the rate of metabolism can be either decreased or increased. Enzyme *induction* hastens metabolism of certain coadministered medications (e.g., ethanol, barbiturates, ketamine, some benzodiazepines) and promotes tolerance to other medications metabolized by the same enzyme class. This relative tolerance can increase the clinical requirement for other drugs (e.g., sedatives, opioids, steroid muscle relaxants). Conversely, coadministration of drugs metabolized by a single CYP (e.g., cimetidine,

BOX **30-2**

Drug Metabolism in the Liver

Phase I Reactions
- Functionalization reactions
- Add or expose a functional group (e.g., oxidation, reduction, hydrolysis)
- Typically result in loss of pharmacologic activity (excluding prodrugs)
- Important for metabolizing many of the anesthetic drugs (e.g., midazolam, diazepam, codeine, phenobarbital)

Phase II Reactions
- Conjugation reactions
- Phase I product (substrate) conjugates with a second molecule
- Lead to formation of a covalent linkage between a functional group and glucuronic acid, sulfate, glutathione, amino acid, or acetate (e.g., morphine, acetaminophen)

chloramphenicol) will compete for binding to the enzyme's active site. This can result in enzyme inhibition of metabolism of one or both of the drugs and lead to elevated plasma levels culminating in increased sensitivity or toxicity.

Tolerance to certain drugs results from overproduction of enzymes within hepatic enzyme systems, including the cytochrome P-450 system. Drugs capable of inducing this process include ethanol, benzodiazepines, ketamine, barbiturates, and phenytoin. The result is an increased clinical requirement for certain drugs like sedatives, opioids, and muscle relaxants, such as vecuronium and rocuronium.

Certain drugs, such as lidocaine, morphine, meperidine, and propranolol, are highly dependent on hepatic extraction from the circulation for sufficient metabolism. Decreased blood flow to the splanchnic circulation, which occurs during hypotensive states and even during uneventful laparotomy, may decrease metabolic clearance of these drugs.

Laboratory Evaluation of Liver Function

No single laboratory test reliably assesses liver function. As stated previously, the huge capacity and functional reserve of the liver allow for the presence of significant disease processes before evidence of liver failure is reflected in abnormal laboratory findings; abnormalities do, however, aid in differentiating parenchymal from obstructive disorders. Parenchymal disorders reflect dysfunction at the hepatocellular level, whereas obstructive disorders reflect disease processes caused by dysfunctional bile excretion.

Ammonia is cleared by the liver and may be used to evaluate hepatic encephalopathy, but ammonia levels do not correlate well with severity of the clinical presentation. As such, its usefulness is limited. Bilirubin levels also reflect hepatic clearance effectiveness, but it is elevated in most significant liver diseases and is not specific in diagnostic value. Albumin synthesis occurs in the liver, and hypoalbuminemia can indicate chronic liver disease once nonhepatic etiologies have been ruled out. Because albumin has a half-life of 14 to 21 days, quantitative laboratory analysis will be slow to decrease in relation to worsening liver function, making it an unreliable indicator of hepatic synthetic function in acute liver injury. The most common reason for a low albumin is chronic liver failure caused by cirrhosis. The serum albumin concentration is usually normal in chronic liver disease until cirrhosis and significant liver damage has occurred. In advanced liver disease, the serum albumin level may be less than 3.5 g/dL. Biochemical markers of liver function are identified in Table 30-2.

Serum transferases (transaminases) are most sensitive in identifying acute hepatic injury. Elevations in transferase levels are common in all forms of liver injury, but the degree of elevation combined with physical examination and patient symptoms can aid in the differential diagnosis of probable types of hepatic disease.

Patients who present soon after passing common bile duct stones can be misdiagnosed with acute hepatitis because aminotransferase levels often rise immediately, but alkaline phosphatase and γ-glutamyl transferase levels do not become elevated for several days. Asymptomatic patients with isolated, mild elevation of either the unconjugated bilirubin or the γ-glutamyl transferase value usually do not have liver disease and generally do not require extensive evaluation.[14]

Overall hepatic function can be assessed by applying the values for albumin, bilirubin, and prothrombin time in the Child-Pugh classification system, which is modified from the earlier Child-Turcotte grading system[15] (Table 30-3).

Effects of Anesthesia on Liver Function

Patients with liver disease who require surgery are at greater risk for surgical- and anesthesia-related complications than those with a healthy liver.[16] The degree of the risk is dependent on the anesthetic technique and associated sequelae, the surgery being performed, and specific type of liver disease and its severity.

Volatile Anesthetic Selection

Given the global nature of general and regional anesthesia, hepatic blood flow may be reduced in a dose-dependent manner. The reduction in mean arterial pressure and cardiac output frequently seen with the use of volatile anesthetics proportionately reduces hepatic blood flow. Another factor that impairs hepatic blood flow is the vasoconstrictive response of the splanchnic circulation; this response occurs as a sympathetic reflex to reduced mean arterial pressure. Isoflurane increases hepatic blood flow through direct vasodilatory properties. This effect is likely offset, however, by a reduction in portal blood flow. Hypotension secondary to regional anesthetic–induced sympathectomy (e.g., epidural or subarachnoid blockade) principally accounts for the reduced splanchnic blood flow associated with the use of these techniques.

All of the volatile anesthetics also have been shown to reduce hepatic blood flow. Halothane causes the greatest reduction, and the use of desflurane has been shown to have hepatic effects similar to those of isoflurane. A rise in serum glutathione-*S*-transferase (GST) level indicates a decrease in splanchnic circulation, which causes a transient reduction in the oxygenation of hepatocytes. Anesthesia with desflurane has demonstrated that liver function is well preserved.[17] Sevoflurane undergoes hepatic biotransformation, producing organic and inorganic fluoride ion. In human subjects, levels of serum inorganic fluoride ion secondary to sevoflurane metabolism are generally below nephrotoxic levels. Prolonged use of higher concentrations, however, may lead to problematic levels. Anesthetic agents may reduce hepatic blood flow by 30% to 50% after induction. Animal data suggest, however, that isoflurane (along with desflurane and sevoflurane, which are believed to be similar) causes less perturbation in hepatic arterial blood flow than other inhaled anesthetic agents and therefore is preferred for patients with liver disease. Studies continue with sevoflurane to determine the influence of biotransformation on renal and hepatic function, but no significant clinical toxicity has yet been reported and they appear to be safe in clinical use.[18,19]

In developed countries, clinical use of halothane as a volatile anesthetic agent is being superseded by the newer low-solubility agents desflurane and sevoflurane. Halothane, however, is still

TABLE 30-2 Clinical Significance of Liver Biochemical Tests

Test (Normal Range*)	Basis of Abnormality	Associated Liver Diseases	Extrahepatic Origin
Aminotransferases			
ALT (10-55 units/L) AST (10-40 units/L)	Leakage from damaged tissue	*Mild to moderate elevations:* Many types of liver disease *Marked elevations:* Hepatitis (viral, toxic, autoimmune, and ischemic) AST/ALT greater than 2 suggests alcoholic liver disease or cirrhosis of any etiology	ALT more specific than AST for hepatic injury AST nonspecific: can originate from skeletal muscle, red blood cell, kidney, pancreas, brain, and myocardium
AP (45-115 units/L)	Overproduction and leakage into serum	*Moderate elevations:* Many types of liver disease *Marked elevations:* Extrahepatic and intrahepatic cholestasis, diffuse infiltrating disease (e.g. tumor, MAC), rarely alcoholic hepatitis	Bone growth or disease (e.g., tumor, fracture, Paget disease) placenta, intestine, and tumors
GGTP (0-30 units/L)	Overproduction and leakage into serum	Same as for AP; induced by ethanol and drugs GGTP/AP greater than 2.5 suggests alcoholic liver disease	Kidney, spleen, pancreas, heart, lung, and brain
5′ Nucleotidase (0-11 units/L)	Overproduction and leakage into serum	Same as for AP	Found in many tissues, but serum elevation is relatively specific for liver disease
Bilirubin (0.0-1.0 mg/dL)	Decreased hepatic clearance	*Moderate elevations:* Many types of liver disease *Marked elevations:* Extrahepatic and intrahepatic bile duct obstruction; viral, alcoholic, or drug-induced hepatitis; inherited hyperbilirubinemia	Increased breakdown of hemoglobin (resulting from hemolysis, disordered erythropoiesis, resorption of hematoma) or myoglobin (resulting from muscle injury)
Prothrombin time (PT) (10.9-12.5 seconds) (international normalized ratio [INR]: 0.9-1.2)	Decreased synthetic capacity	Acute or chronic liver failure (prolonged PT unresponsive to vitamin K) Biliary obstruction (prolonged PT usually responsive to vitamin K administration)	Vitamin K deficiency (secondary to malabsorption, malnutrition, antibiotics, consumptive coagulopathy
Albumin (3.5-5.0 g/dL)	Decreased synthesis; increased catabolism	Chronic liver failure	Decreased in nephritic syndrome, protein-losing enteropathy, vascular leak, malnutrition, malignancy, infections, and inflammatory states

*The normal values tabulated are for adult men and will vary with the methodology used in testing.
ALT, Alanine aminotransferase; *AP*, alkaline phosphatase; *AST*, aspartate aminotransferase; *GGTP*, gamma glutamyl transpeptidase; *MAC*, *mycobacterium avium* complex.

TABLE 30-3 Grading Liver Function Using the Child-Pugh Classification System

	POINTS		
Feature	**1**	**2**	**3**
Albumin	> 3.5 g/dL	2.8-3.5 g/dL	< 2.8 g/dL
Bilirubin	< 2 mg/dL	2-3 mg/dL	> 3 mg/dL
Prolongation Prothrombin time (INR)	< 4 sec (< 1.7)	4-6 sec (1.7-2.3)	> 6 sec (> 2.3)
Ascites Encephalopathy	None None	Controlled Minimal (1 and 2)	Refractory Advanced (3 and 4)

The Child-Pugh class is calculated by adding the points based on the five features: class A = 5 or 6; class B = 7-9; class C = 10 and higher. The classes indicate severity of liver dysfunction: class A is associated with a good prognosis, and class C is associated with limited life expectancy.
INR, International normalized ratio.

in use in some countries and remains on the 2011 World Health Organization Model List of Essential Medicines, which is a list of minimum medical needs for a basic health care system. Continued awareness of the potentially deleterious effect of halothane on hepatic function is therefore justified.

Halothane administration is associated with two types of postoperative liver injury. Minor injury in 10% to 30% of patients may result in elevations in alanine aminotransferase (ALT) levels during postoperative days 1 through 10. Risk of hepatotoxicity is higher after repeat exposure to halothane. Major injury involves halothane-induced hepatotoxicity, which is a severe hepatic reaction with elements of autoimmune allergy. The phenomenon of halothane-induced liver damage has been termed *halothane hepatitis* due to a similar clinical presentation. Clinical features of halothane hepatitis are listed in Box 30-3. Hepatic necrosis may be seen histologically, and the case fatality rate ranged from 14% to 71% (before liver transplant was an option). Evidence for the role of hypersensitivity is found in the increased susceptibility and shortened latency after repeat exposure, the hallmark symptoms and signs of drug allergy. Risk factors for halothane hepatitis are listed in Box 30-4. An estimated 1 in 10,000 patients develops postoperative jaundice after halothane exposure. In this population, a viral source of infection is more likely to be the cause—for instance, as a complication of intraoperative blood transfusion.

Opioid Effects

Spasm of the Oddi sphincter may cause biliary colic, or it may cause a false-positive result on intraoperative cholangiography. All opioids have been implicated in causing spasm of the Oddi sphincter, with a resultant increase in biliary pressure in relation

BOX 30-3

Clinicopathologic Features of Halothane Hepatitis

- Estimated incidence
  - *After first exposure:* 0.3 to 1.5 per 10,000
  - *After multiple exposures:* 10 to 15 per 10,000
- Female-to-male ratio 2:1
- Latent period to first symptom
  - *After first exposure:* 6 days (11 days to jaundice)
  - *After multiple exposures:* 3 days (6 days to jaundice)
- Jaundice as presenting symptom in 25% (range of serum bilirubin: 3-50 mg/L)
- Fever in 75% (precedes jaundice in 75%); chills in 30%
- Rash in 10%
- Myalgias in 20%
- Ascites, renal failure, and/or gastrointestinal hemorrhage in 20%-30%
- Eosinophilia in 20%-60%
- Serum ALT and AST levels: 25-250 x ULN
- Serum alkaline phosphatase level: 1-3 x ULN
- Histologic features:
  - Zone 3 massive hepatic necrosis in 30%; submassive necrosis in 70% (autopsy series)
  - Inflammation usually less marked than in viral hepatitis
  - Eosinophilic infiltrate in 20%
  - Granulomatous hepatitis occasionally
- Course and outcome:
  - Mortality rate (pretransplantation era): 10%-80%
  - Symptoms can resolve within 5-14 days
  - Full recovery can take 12 weeks or longer
  - Chronic hepatitis not well documented
- Adverse prognostic findings:
  - Age >40 years
  - Obesity
  - Short duration to the onset of jaundice
  - Serum bilirubin level >20 mg/dL
  - Coagulopathy

From Lewis JH. Liver disease caused by anesthetics, toxins, and herbal preparations. In: Feldman M, et al, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 9th ed. Philadelphia: Saunders; 2010:1448.
ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *ULN,* upper limit of normal.

BOX 30-4

Risk Factors for Halothane Hepatitis

- Older age (>40 years)
- Female gender
- Two or more exposures (documented in 80%-90% of cases)
- Obesity
- Familial predisposition
- Induction of CYP2E1 by phenobarbital, alcohol, or isoniazid

From Lewis JH. Liver disease caused by anesthetics, toxins, and herbal preparations. In: Feldman M, et al, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 9th ed. Philadelphia: Saunders; 2010:1448.
CYP2E1, Cytochrome P450 2E1.

to potency. The cause of the spasm is unclear, but occurrence may be reduced with judicious titration. Spasm is low even when a fentanyl-based anesthetic is used. The treatment of suspected spasm of the Oddi sphincter involves administration of naloxone or nalbuphine. Atropine or glycopyrrolate, glucagon, and nitroglycerin also have been shown to be effective.

TABLE 30-4 Reported Surgery Risk in Patients with Liver Disease

Liver Disease	Type of Surgery	Mortality	Prognostic Factors
Cirrhosis	Nonlaparoscopic biliary surgery	20%	Ascites, prothrombin time, albumin
	Peptic ulcer surgery	54%	Prothrombin time, systolic blood pressure, hemoglobin
	Umbilical herniorrhaphy	13%	Urgent surgery
	Colectomy	24%	Hepatic encephalopathy, ascites, albumin, hemoglobin
	Abdominal surgery for trauma	47%	
	Emergency abdominal surgery	57%	Child-Pugh class, urgent surgery
	Laparoscopic cholecystectomy	0.9%-6%	
	Emergency cardiac surgery	80%	Child-Pugh class
	Elective cardiac surgery	3%-46%	Child-Pugh class
	Knee replacement	0%	
	TURP	6.7%	
Chronic hepatitis	Various types	0%	
Hepatitis C	Laparoscopic cholecystectomy	0%	
Acute hepatitis	Exploratory laparotomy	100%	
Obstructive jaundice	Abdominal surgery	5%-60%	Hemoglobin, bilirubin, malignancy

TURP, Transurethral resection of the prostate.

Anesthesia-Related Activity: Mechanical Ventilation

The sequelae of mechanical ventilation have been implicated as a contributing factor in a reduction of hepatic blood flow. Positive pressure ventilation can result in airway pressures that adversely affect venous delivery to the right atrium. Increased airway pressures also result in reduced cardiac output,[20] with a consequent reduction in hepatic blood flow. Positive end-expiratory pressure further exacerbates this condition. Impairment in hepatic blood flow under these conditions may result from increased hepatic venous pressure from increased intrathoracic pressure and from increased reflex sympathetic tone caused by reduced cardiac output. Hypercapnia and acidosis have vasodilatory effects on the hepatic circulation that result in increased blood flow, whereas hypocapnia and alkalosis exert vasoconstricting effects that result in decreased flow. The interplay of various intraoperative variables (e.g., surgical site, ventilatory mode, direct and indirect effects of anesthetics used, physiologic responses to intraoperative events) influences the degree of variation in hepatic blood flow.

Site of Surgery

Surgical site, particularly intraabdominal, also has been implicated as a cause of decreased hepatic blood flow (see Table 30-4 for reported surgery risk in patients with liver disease). Traction

TABLE 30-5 Five Types of Acute Viral Hepatitis

Hepatitis Virus	Size (nm)	Genome	Route of Transmission	Incubation Period (Days)	Fatality Rate	Chronic Rate	Antibody
A	27	RNA	Fecal-oral	15-45 (mean = 25)	1%	None	Anti-HAV
B	45	DNA	Parenteral Sexual	30-180 (mean = 75)	1%	2%-7%	Anti-HBs Anti-HBc Anti-HBe
C	60	RNA	Parenteral	15-150 (mean = 50)	<0.1%	70%-85%	Anti-HCV
D (delta)	40	RNA	Parenteral Sexual	30-150	2%-10%	2%-7% 50%	Anti-HDV
E	32	RNA	Fecal-oral	30-60	1%	None	Anti-HEV

on the abdominal viscera may cause reflex dilation of splanchnic capacitance vessels and thereby lower hepatic blood flow.

Additional factors that may contribute to decreased hepatic blood flow intraoperatively include hypotension, hemorrhage, vasoactive drugs, and pneumoperitoneum during laparoscopic surgery.[21]

Diseases of the Liver

Signs and symptoms indicating liver disease vary widely depending on the etiology of the underlying pathologic process. Decline in liver function may be acute, related to drug toxicity or infection, or it may follow a chronic subclinical course. The following discussion focuses on the more commonly encountered diseases of the liver and offers guided clinical anesthetic implications.

Acute Hepatitis

Acute hepatitis presents a variable clinical picture. Manifestations may extend from mild inflammatory increases in serum transaminase levels to fulminant hepatic failure. The cause of this syndrome is usually exposure to an infectious virus. Other causes include exposure to hepatotoxic substances and adverse drug reactions.

Viral Hepatitis

Hepatitis is a generic term that means liver inflammation. Hepatitis may be caused by several factors (e.g., toxins, alcohol, medications, viral or bacterial infections, autoimmune diseases), and viral hepatitis is the leading cause of liver cancer and the most common reason for transplantation.[22]

Although several types of hepatitis viruses are known to cause illness, typically only hepatitis A, B, and C (infections caused by the hepatitis A virus [HAV], hepatitis B virus [HBV], and hepatitis C virus [HCV], respectively) affect persons living in the United States.[22] Hepatitis D requires co-infection with HBV; hepatitis E virus (HEV) diagnosis is made by exclusion after travel to an endemic area (e.g., South/Central America or Southeast Asia). Hepatitis A and E are transmitted by the oral-fecal route, and hepatitis B, C, and D are transmitted by contact with body fluids and physical contact with disrupted cutaneous barriers.

The common clinical course of viral hepatitis begins with a 1- to 2-week prodromal period, the signs and symptoms of which include fever, malaise, and nausea and vomiting. Progression to jaundice typically occurs, with resolution within 2 to 12 weeks. However, serum transaminase levels often remain increased for up to 4 months. If hepatitis B or C is the cause, the clinical course is often more prolonged and complicated. Cholestasis may manifest in certain cases. Fulminant hepatic necrosis in certain individuals is also possible. Table 30-5 lists the major characteristics of hepatitis types A, B, C, D, and E.

Drug-Induced Hepatitis

Drug-related injury to the liver results from an idiosyncratic reaction to a substance or an overdose resulting in toxicity. For idiosyncratic reactions, genetic predisposition is presumed to be the most critical determinant. Important risk factors include age, gender, exposure to other substances, a history or family history of previous drug reaction, other risk factors for liver disease, and concomitant medical conditions.[23] Factors related to the risk of liver injury are summarized in Table 30-6.

Alcoholic hepatitis is probably the most common form of drug-induced hepatitis and results in fatty infiltration of the liver (causing hepatomegaly), with impairment in hepatic oxidation of fatty acids, lipoprotein synthesis and secretion, and fatty acid esterification.[6]

Chronic Hepatitis

Chronic hepatitis occurs in 1% to 10% of acute hepatitis B infections and in 10% to 40% of hepatitis C infections,[6] but does not occur in hepatitis A infections.

Because chronic persistent hepatitis is limited to portal areas and is relatively benign, hepatic cellular integrity is preserved, and progression to cirrhosis is rare. Chronic lobular hepatitis involves recurrent exacerbations of acute inflammation; as in persistent hepatitis, progression to cirrhosis is rare.

Chronic active hepatitis is progressive and results in hepatocyte destruction, cirrhosis, and progressive deterioration of hepatic function. Hepatic failure and death from chronic hepatitis is marked by clinical manifestations such as multiorgan system failure (e.g., hepatorenal syndrome), encephalopathy, and hemorrhage from esophageal varices. Exposure to certain drugs (e.g., methyldopa, isoniazid, and nitrofurantoin) and autoimmune disorders (e.g., systemic lupus erythematosus) are potential causative factors implicated in hepatic failure, though hepatitis B or C are more typical.

Other symptoms present in chronic hepatitis include marked fatigue and jaundice; thrombocytopenia, glomerulonephritis, myocarditis, arthritis, and neuropathy also may be present. Plasma albumin levels are usually decreased related to synthetic dysfunction and PT is prolonged.

Anesthetic Management for Patients with Hepatitis

Evidence from studies indicates that *mild* chronic hepatitis confers no additional risk of surgical morbidity or mortality during laparoscopic cholecystectomy.[24] Surgical outcomes in patients with acute hepatitis are less well studied, and recommendations suggest that elective surgery should be postponed until normalization of biochemical profiles. Existing studies are many

TABLE 30-6 Factors Influencing the Risk of Liver Diseases Caused by Drugs

Factor	Examples of Drugs Affected	Influence
Age	Isoniazid, nitrofurantoin, halothane	Age greater than 60 years: increased frequency, increased severity
	Valproic acid, salicylates	More common in children
Gender	Halothane, minocycline, nitrofurantoin	More common in women, especially with chronic hepatitis
	Amoxicillin/clavulanate acid, azathioprine	More common in men
Dose	Acetaminophen, aspirin; some herbal medicines	Blood levels are directly related to the risk of hepatotoxicity
	Tetracycline, tacrine, oxypenicillins	Idiosyncratic reactions, but partial relationship to dose
	Methotrexate, vitamin A	Total dose, dosing frequency, and duration of exposure are related to the risk of hepatic fibrosis
Genetic factors	Halothane, phenytoin, sulfonamides	Multiple cases in families
	Amoxicillin/clavulanate acid	Strong HLA association
	Valproic acid	Familial cases, association with mitochondrial enzyme deficiencies
History of other drug reactions	Isoflurane, halothane, enflurane	Instances of cross-sensitivity have been reported among members of each drug class but are rare
	Erythromycins	
	Diclofenac, ibuprofen, tiaprofenic acid	
	Sulfonamides, COX-2 inhibitors	
Other drugs	Acetaminophen	Isoniazid, zidovudine, and phenytoin lower dose threshold and increase severity of hepatotoxicity
	Valproic acid	Other antiepileptics increase risk of hepatotoxicity
	Anticancer drugs	Interactive vascular toxicity
Excessive alcohol use	Acetaminophen hepatotoxicity	Lowered dose threshold, poorer outcome
	Isoniazid, methotrexate	Increased risk of liver injury, hepatic fibrosis
Nutritional status:		
Obesity	Halothane, tamoxifen, methotrexate	Increased risk of liver injury, hepatic fibrosis
Fasting	Acetaminophen	Increased risk of hepatotoxicity
Preexisting liver disease	Hycanthone, pemoline	Increased risk of liver injury
	Antituberculosis drugs, ibuprofen	Increased risk of liver injury with chronic hepatitis B and C
Other diseases/conditions:		
Diabetes mellitus	Methotrexate	Increased risk of hepatic fibrosis
HIV infection/AIDS	Sulfonamides	Increased risk of hypersensitivity
Renal failure	Tetracycline, methotrexate	Increased risk of liver injury, hepatic fibrosis
Organ transplantation	Azathioprine, thioguanine, busulfan	Increased risk of vascular toxicity

decades old and the statistical risks associated may not reflect improvements in either surgical technique or anesthetic management. Anesthetic management recommendations are found in Box 30-5.

Operative procedures performed in patients with alcohol intoxication are likely to be associated with increased perioperative complications, and anesthetic management must be well planned (Box 30-6). Surgery performed in those undergoing alcohol withdrawal is associated with an increased mortality rate. If surgery is of urgent or emergent nature, attention must be paid to managing comorbidities with a focus on risk reduction and symptom management.

Cirrhosis

The term *cirrhosis* derives from the Greek word that means yellowish or tawny and describes the coloration of the diseased liver. Cirrhosis is defined as the histologic development of regenerative nodules surrounded by fibrous bands in response to chronic liver injury, which leads to portal hypertension and end-stage liver disease.[25] Cirrhosis may be caused by a variety of diseases (Box 30-7), but the resultant anatomic alterations secondary to hepatocyte necrosis are the primary cause of deterioration that occurs in liver function. Over time, the liver parenchyma is replaced by fibrous and nodular tissue, which distorts, compresses, and obstructs normal portal venous blood flow. Portal hypertension develops and impairs the ability of the liver to perform various metabolic and synthetic processes.

Cirrhosis characteristics are presented in Table 30-7. Obstructive engorgement of vessels within the portal system ultimately results in transmission of increasing retrograde pressure within the splanchnic circulation. The progressive reversal of portal venous blood flow results in esophageal varices and splenomegaly. As portal hypertension persists, physical changes can be seen systemically (Figure 30-3).

The development of esophageal varices places the patient at risk for spontaneous, severe, upper-gastrointestinal hemorrhage. Development of ascites (related to altered intravascular osmolarity) results in fluid retention and impairment of the renin-angiotensin system. Subsequent reduction in renal perfusion progresses to eventual renal failure concomitant with hepatic failure (hepatorenal syndrome). Hepatorenal syndrome is a severe complication of advanced liver cirrhosis, in patients with ascites and marked

BOX 30-5

Anesthetic Management of the Patient with Acute Hepatitis

Preserve hepatic blood flow:
- Use isoflurane or desflurane and avoid halothane
- Maintain normocapnia
- Avoid PEEP if possible
- Provide adequate/liberal intravenous hydration
- Consider regional anesthesia if coagulation and procedure are acceptable

Avoid medications with potential for hepatotoxicity or inhibition of CYP450:
- Halothane
- Acetaminophen
- Sulfonamides
- Tetracycline
- Penicillin
- Amiodarone

Thoughtful titration of neuromuscular blocking agents may be prolonged in patients with liver disease because of:
- Reduced pseudocholinesterase activity
- Decreased biliary excretion
- Larger volume of distribution

PEEP, Positive end-expiratory pressure.

BOX 30-6

Management Recommendations for the Acutely Intoxicated Patient

- Anesthetic requirement is reduced
  - Acute intoxication reduces MAC
- Aspiration precautions are needed
  - Full stomach, alcohol-related impaired pharyngeal reflexes
- Alcohol increases GABA receptor activity
  - Enhanced effects of benzodiazepines, barbiturates, propofol, other CNS depressants
- Alcohol inhibits NMDA receptors
  - Reduces CNS excitability

CNS, Central nervous system; *GABA*, gamma-aminobutyric acid; *MAC*, maximum allowable concentration; *NMDA*, *N*-methyl-D-aspartate.

BOX 30-7

Causes of Cirrhosis

- Alcohol abuse
- α_1-antitrypsin deficiency
- Biliary obstruction
- Chronic hepatitis
- Hemochromatosis
- Right-sided heart failure
- Wilson disease

TABLE 30-7 Laboratory Tests and Findings in Cirrhosis

Laboratory Finding	Description	Cause
AST/ALT	Normal or modest increase	Leakage from damaged hepatocytes
Bilirubin	Increased (important predictor of mortality)	Cholestasis, systemic inflammation
Albumin	Decreased in advanced cirrhosis	Decreased production; sequestered in ascites
Prothrombin time	Decreased in advanced cirrhosis	Decreased hepatic production of factor V/VII
Sodium imbalance	Hyponatremia	Inability to excrete free water (increased ADH)
Anemia	Low hemoglobin Low red blood cell count	Folate deficiency, hypersplenism, varices
Thrombocytes	Thrombocytopenia	Hypersplenism, decreased hepatic thrombopoietin production

AST/ALT, aspartate aminotransferase/alanine aminotransferase ratio; *ADH*, antidiuretic hormone.

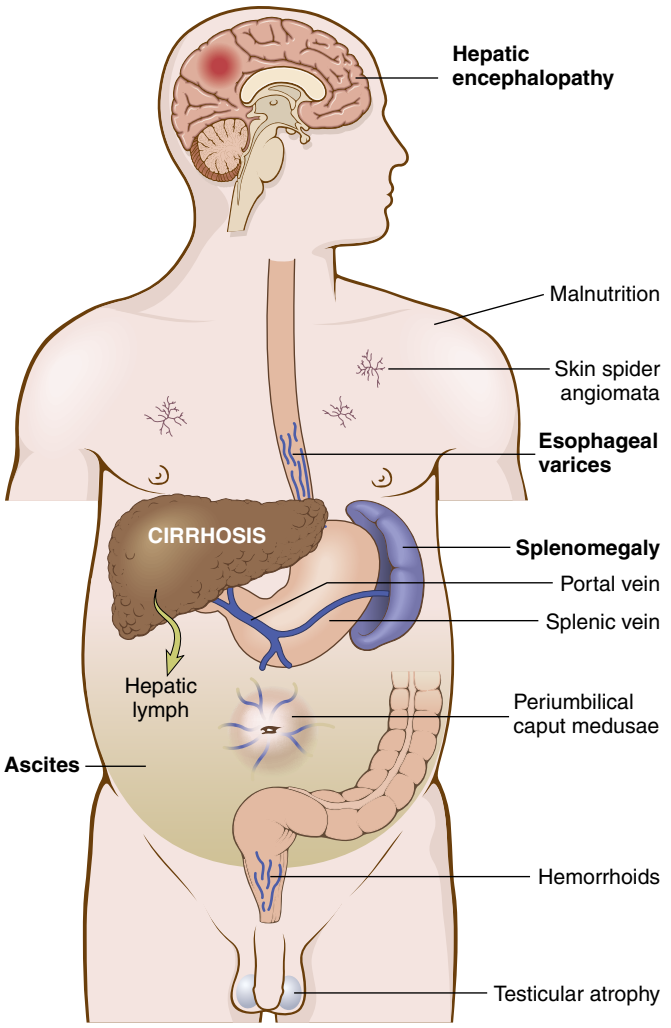

FIGURE 30-3 The major clinical consequences of portal hypertension in the setting of cirrhosis, shown for the male. In women, oligomenorrhea, amenorrhea, and sterility are frequent, as a result of hypogonadism. (From Kumar V, Abbas AK, Aster J. *Robbins Basic Pathology*. 9th ed. Philadelphia: Saunders; 2013:609.)

BOX 30-8

Anesthetic Preparation and Management in Cirrhosis

Preserve hepatic blood flow.
Avoid halothane (isoflurane is the best studied alternative; better preserves flow).
Consider regional anesthesia if procedure and coagulation allow.
- Maintain normocapnia.
- Avoid PEEP if possible.
- Provide generous volume maintenance.

Avoid medications with situational potential hepatotoxicity when possible. Examples:
- Acetaminophen, particularly in the alcoholic patient
- Sulfonamides, tetracycline, and penicillins
- Amiodarone

Anticipate presence, development, or abnormalities of:

Coagulation
- Attempt to correct prothrombin time to within 2 seconds of normal.
- Consider cryoprecipitate if fresh frozen plasma is ineffective or fibrinogen abnormality exists.
- Correct thrombocytopenia approximately for procedure.
- Anticipate higher than normal blood loss for procedure.

Hemodynamics
- Anticipate relative hypovolemia, worsened by treatment of ascites.
- Assess for presence of high cardiac output, low peripheral resistance.
- Suspect portal hypertension and/or variceal bleeding, even without history.
- Anticipate depressed response to inotropes and vasopressors.
- Consider invasive monitoring.

Pharmacokinetics and Pharmacodynamics
- Altered volume of distribution may occur.
  - Decreased serum albumin, increased gamma globulins
  - Intravascular volume unpredictable, especially with ascites treatment
- Portosystemic shunted blood bypasses liver
  - Drugs highly extracted by liver especially affected
  - Increased sensitivity to sedative medications may be present.

From Dhillon A, Steadman RH. Liver disease. In: Fleisher LA. *Anesthesia and Uncommon Diseases*. 6th ed. Philadelphia: Saunders; 2012:198-199.

circulatory dysfunction. It is clearly established that it has a functional nature, and that it is related to intense renal vasoconstriction.[26] Prognosis is very poor once disease has progressed to this stage. Further failure of the liver to clear nitrogenous compounds (ammonia) from the blood contributes to the development of progressive mental-status changes (encephalopathy), ultimately leading to coma and death if untreated. Anesthetic preparation and management in cirrhosis is given in Box 30-8.

Perioperative Considerations in Liver Disease

Preoperative Assessment

Preoperative assessment of patients with hepatic dysfunction necessitates the collection of diagnostic laboratory markers and physical characteristics indicative of the type and severity of liver disease present. Acute derangements in hepatic function should be identified and the risks of surgery must be weighed against the risk of postponing the planned procedure until the physical status of the patient is improved. Urgent or emergent surgery may preclude a rigorous diagnostic workup, so it is incumbent on the anesthetist to focus on the implications of the disease process and prioritize care to minimize further physiologic insult.

TABLE 30-8 MELD Score Prediction of 90-Day Mortality

MELD Score	Mortality
Greater than 40	71.3%
30-39	52.6%
20-29	19.6%
10-19	6%
Less than 9	1.9%

MELD, Model for end-stage liver disease.

The Model for End-stage Liver Disease (MELD) score and the Child-Pugh score have been reported to be correlated with postoperative morbidity and mortality in patients with end-stage liver disease.[27] The Child-Pugh score was described earlier (refer to Table 30-3). MELD is a scoring system that assesses the severity of chronic liver disease and is useful in prioritizing recipients for liver transplant by predicting outcome based on the calculated score. MELD uses the patient's values for serum bilirubin, serum creatinine, and the INR for prothrombin time to predict survival (interpretation of MELD score is given in Table 30-8).

$$\text{MELD} = 3.78\,[\text{Ln serum bilirubin (mg/dL)}] + 11.2\,[\text{Ln INR}] + 9.57\,[\text{Ln serum creatinine (mg/dL)}] + 6.43$$

The MELD calculation is more cumbersome than Child-Pugh, and online calculators are available (e.g., http://www.mayoclinic.org/meld/).

MELD scores have largely replaced the older Child-Pugh scoring system, although systemic reviews comparing MELD and Child-Pugh are inconclusive, particularly in nontransplant settings.[28] Multivariate analysis of a 2007 study of 772 patients with cirrhosis undergoing major digestive, orthopedic, or cardiovascular surgery (586 patients underwent gastrointestinal surgery) revealed that the MELD score, American Society of Anesthesiologists' physical status, and age were predictors of mortality.[27]

The existence of jaundice, prolonged prothrombin time, ascites, encephalopathy, hypoalbuminemia, portal hypertension, renal insufficiency, hyponatremia, infection, and anemia have been proposed as risk factors.[29] In patients with cirrhosis undergoing surgery, preoperative assessment is crucial. The high risk of mortality and morbidity can be reduced by addressing coagulopathy, ascites, renal dysfunction, hyponatremia, hepatic encephalopathy, malnutrition, pulmonary conditions, cardiac conditions, anemia, and administering antibiotic prophylaxis.[29]

Past or current jaundice, ascites, hepatitis, blood transfusion, or substance abuse can be relevant information obtained in the patient history and physical examination. Reviewing previous anesthetic records also may provide guidance for developing an anesthetic plan. Physical signs, such as petechiae, jaundice, ascites, dependent edema, altered mental status, and asterixis (tremor of the wrist indicative of hepatic encephalopathy), suggest the presence of significant liver disease. Laboratory assessment may include the following:
- Albumin (normal, 3.5 to 5 g/dL)
- Bilirubin
- PT/INR
- Creatinine

- Serum liver enzyme levels: alanine transaminase (ALT) and aspartate aminotransferase (AST), alkaline phosphatase, lactic dehydrogenase, γ-glutamyl transpeptidase
- Complete blood count
- Serum electrolyte and glucose levels
- Blood type and screen or crossmatch based on planned surgery and patient condition

Effects of Hepatic Dysfunction on Other Organ Systems

Cardiovascular Considerations

Cardiovascular complications of cirrhosis include cardiac dysfunction and abnormalities in the central, splanchnic, and peripheral circulation and (hemodynamic) changes caused by humoral and nervous dysregulation.[30] Increased levels of endogenous vasodilators such as vasoactive intestinal peptide, ferritin glucagon, and others result in a hyperdynamic circulatory state. Cardiovascular changes associated with liver disease include the following:

- Increased cardiac output
- Decreased systemic vascular resistance
- Decreased arterial blood pressure
- Systemic collateral circulation
- Arteriovenous shunting
- Portal hypertension
- Esophageal varices
- Cardiomyopathy
- Congestive heart failure

Fluid Balance and Renal Considerations

Severe hepatic disease confers a derangement in fluid balance, manifesting as ascites and edema. Ascites is the most common complication of cirrhosis and is associated with increased risk of infections, renal failure, and poor long-term outcome.[31] Absolute intravascular volume typically may be described as increased, but therapeutic paracentesis, diuretic therapy, and arteriovenous shunting create a relative hypovolemia. Severe hepatic disease (e.g., advanced cirrhosis) may result in impairment of compensatory mechanisms that initiate displacement of blood from the hepatic vascular reservoir into systemic circulation in response to sympathetic stimulation or hemorrhage.

Perioperative concerns focus on intravascular volume and electrolyte imbalances. Diuretic therapy should be instituted in the presence of volume overload with attention to maintaining normotension and electrolyte balance. Perioperative preservation of adequate renal perfusion is of the utmost importance. Water restriction, controlled isotonic intravenous fluid administration, and potassium replacement may be necessary components of the preoperative plan of fluid therapy.

Fluid and electrolyte disturbances associated with liver disease include the following:

- Hypoalbuminemia
- Sodium retention
- Progressive decline in renal function
- Decreased free water clearance
- Dilutional hyponatremia
- Hypokalemia

Intraabdominal ascites exerts a profound influence on several organ systems, including the renal system. As cirrhosis progressively worsens, excessive hydrostatic pressure develops within lymphatic and hepatic venous systems. This phenomenon, coupled with impaired albumin synthesis, produces decreased plasma oncotic pressure within the liver vasculature and an exudative process results. Protein-rich fluid accumulates within the peritoneum, resulting in electrolyte abnormalities. The misplacement of fluids within peritoneum establishes an osmotic gradient leading to a relative intravascular hypovolemia and sodium retention.

TABLE 30-9 Summary of Current Pharmacologic Treatment Options for HRS

Treatment Mechanism	Pharmacologic Option
Vasoconstriction of splanchnic circulation	Octreotide Midodrine Albumin 20%
	Ornipressin Albumin 20%
	Terlipressin Albumin 20%
Renal vasodilation	Misoprostol Adenosin-1 receptor antagonist
Selective angiotensin II type I receptor antagonist	Losartan

Adapted from Kashani A, et al. Fluid retention in cirrhosis: pathophysiology and management. *QJ Med.* 2008;101:71-85.
HRS, Hepatorenal syndrome.

Hepatorenal syndrome (HRS) is a clinical condition of renal failure that occurs in patients with chronic liver disease, advanced hepatic failure, and portal hypertension; it is characterized by impaired renal function and marked abnormalities in arterial circulation and in the activity of vasoactive systems.[32] Hepatorenal syndrome may occur as a consequence of gastrointestinal hemorrhage, sepsis, or surgery or as a result of aggressive diuretic therapy, all of which place patients at risk for derangements in renal perfusion. Signs include progressive ascites, azotemia, oliguria, and eventually multisystem organ failure. Hepatic transplantation remains the only definitive treatment for hepatorenal syndrome, and supportive therapy must be instituted until an organ match is made. The aim of most HRS therapy is to increase renal blood flow through renal vasodilation and vasoconstriction of splanchnic circulation.[32] Current treatment options for hepatorenal syndrome are listed in Table 30-9.

Hematologic Considerations

Anemia is commonly encountered in advanced hepatic disease. The reduction in red blood cells is due to hemolysis, folate deficiency, hemorrhage, and bone marrow suppression. Multiple factors can contribute to the development of thrombocytopenia, including splenic platelet sequestration, bone marrow suppression by chronic hepatitis C infection, and antiviral treatment with interferon-based therapy.[33] Reductions in the level or activity of the hematopoietic growth factor thrombopoietin (TPO) also may play a role. Failure of hepatic synthetic processes results in clotting-factor deficiencies, decreased blood viscosity, and enhanced fibrinolysis resulting from decreased clearance of fibrinolytic factors.

In the setting of hepatic dysfunction, excessive blood transfusion may exacerbate encephalopathy, owing to the breakdown of red blood cells and the subsequent increase of protein-rich by-products in the plasma—by-products ordinarily metabolized by hepatocytes. When indicated, FFP, platelet, and cryoprecipitate transfusion should be undertaken to correct coagulation deficiencies before surgery.[34]

Respiratory Considerations

Decline in pulmonary function can be predicted in patients with severe hepatic disease. Arterial hypoxemia is common in the

context of hepatic disease; it is often multifactorial (e.g., ascites, hepatic hydrothorax, and chronic obstructive pulmonary disease in patients with alcoholism).[35] The hepatopulmonary syndrome (HPS) is defined as the triad of liver disease, arterial deoxygenation, and widespread pulmonary vasodilation.[36] HPS can, however, appear in patients with acute[37] and chronic noncirrhotic hepatitis.[38] The exact pathogenesis of HPS is being explored, but it is reported in 15% to 20% of patients with cirrhosis being evaluated for orthotopic (living related donor) liver transplantation. One of the characteristics of HPS is intrapulmonary vascular dilation. The intrapulmonary vascular dilation significantly affects pulmonary gas exchange, and consequently leads to hypoxia and raised mortality of cirrhotic patients.[39] Preoperative focus is on baseline measurement of oxygen tension or saturation and improvement of reversible pulmonary dysfunction (e.g., elective thoracentesis/paracentesis). Preoperative sedatives and opioids should be carefully considered or omitted based on underlying pathology and the patient's current physical status.

Central Nervous System Considerations

Hepatic encephalopathy is a chronically debilitating complication of hepatic cirrhosis and encompasses a wide spectrum of potentially reversible neuropsychiatric abnormalities seen in patients with liver dysfunction. Neurologic impairment stems from various metabolic abnormalities that are a direct result of the failing liver. Inability to clear neurotoxins (e.g., ammonia, short-chain fatty acids, mercaptans, manganese) derived in the gut results in a cascade of systemic maladies, including alterations in mental status that range from subtle personality change to coma. Ammonia is produced in the gastrointestinal tract by bacterial degradation of amines, amino acids, purines, and urea. Once formed, ammonia is detoxified by hepatocytes in the liver. In hepatic failure, there is a decrease in functioning hepatocytes. The alterations in hepatic portal flow (shunting) that accompanies cirrhosis permit entry of ammonia into the systemic circulation. Ammonia, for example, causes neurotransmitter abnormalities and induces injury to astrocytes that is partially mediated by oxidative stress. These disturbances lead to astrocyte swelling and brain edema, which appear to be involved in the pathogenesis of neurologic manifestations.[40] It is noteworthy that the mechanism of encephalopathy cannot fully be attributed to ammonia; some patients with encephalopathy have normal ammonia levels, yet others with elevated ammonia levels have no encephalopathic symptoms. Research into the pathogenesis of hepatic encephalopathy is ongoing, but therapy continues to focus on pharmacologic reduction of ammonia levels with nonabsorbable disaccharides (e.g., lactulose) and antimicrobial agents (e.g., neomycin, rifaximin) that reduce bacterial production of ammonia and other bacteria-derived toxins through suppression of intestinal flora.[41] Given the presence, or potential worsening, of altered mental status, benzodiazepine and other sedatives should be avoided when possible.

Intraoperative Anesthetic Considerations

Monitoring

After thorough preoperative evaluation, anesthetic management of patients with liver disease requires consideration of the underlying pathophysiology and the attendant alterations in pharmacokinetics/pharmacodynamics for each medication administered.

Use of routine intraoperative monitoring may be sufficient for patients with mild hepatic dysfunction undergoing minor surgery. As previously discussed, morbidity and mortality is higher in patients with advanced liver disease. Regarding electrocardiography (ECG) monitoring, a five-cable ECG lead system is preferred over a three-cable ECG system in such patients in that it allows monitoring of a true chest lead. With the former, only a modified chest lead can be used. The ECG lead recognized as being most sensitive in detecting early evidence of ischemia is V_3.[42-45] In patients who have sustained an intraoperative myocardial infarction (MI), V_4 is the most sensitive.[45] Limb lead III is preferred over other limb leads for discerning significant ST segment changes.[42-44,46] Each of these recommendations presumes the anesthesia provider has properly configured the respective computerized ST segment analysis software (e.g., verified the ST point has been positioned over the J point, electrodes have been properly placed on the body). Given the potential for hemodynamic lability related to alterations in intravascular status, ascites, electrolyte irregularities, cardiac comorbidity (e.g., cardiomyopathy), attention should be paid to ST segment analysis for signs of cardiac ischemia. In the absence of an ST segment fingerprint, leads III and V_3 are advocated for the detection of ST segment elevation or depression.[47]

Invasive hemodynamic monitoring may be indicated for patients with cirrhosis and other conditions of severe hepatic dysfunction. Arterial cannulation permits beat-to-beat measurement of blood pressure and provides immediate access for blood withdrawal if laboratory analysis is indicated intraoperatively. Patients with liver cirrhosis frequently require hemodynamic monitoring including cardiac output (CO) assessment, particularly when admitted to the intensive care unit or when undergoing surgery.[48] Arterial cannulation also permits usage of minimally invasive cardiac output monitors (e.g., FloTrac). The reliability of noninvasive cardiac monitors is not universally demonstrated and may be considered unreliable in cirrhotic patients with hyperdynamic circulation.[49] Cirrhosis is associated with a pattern of alterations in the cardiovascular system, known as *cirrhotic cardiomyopathy*, which is characterized by a hyperdynamic circulation, elevated baseline CO, reduced peripheral vascular resistance, and decreased ventricular response to physiologic, pharmacologic, and surgical stressors.[50,51] Furthermore, cirrhotic patients commonly have peripheral autonomic neuropathy, which may result in pronounced hemodynamic instability.[51,52]

Surgery such as liver transplant (discussed later) or hepatic resection require additional preparation in anticipation of extensive blood loss. As such, large-bore peripheral and central venous access is necessary for rapid fluid administration, administration of pressor medications, and invasive monitoring (e.g., central venous pressure [CVP], pulmonary artery catheter), especially if cardiac disease is present. Transesophageal echocardiography (TEE) monitoring also may be used in the absence of esophageal varices or significant coagulopathy.

Additional considerations for hepatic comorbidity may necessitate blood glucose monitoring (e.g., hypoglycemia during hepatic vascular occlusion), forced air and fluid warming to prevent hypothermia (related to prolonged surgery with an open abdomen coupled with large blood loss and fluid replacement), and coagulation profile monitored and corrected with fresh frozen plasma (FFP) as necessary.

Anesthetic Technique and Medication Choices

In patients with severe hepatic disease, hepatic arterial blood flow does not increase when portal blood flow and/or oxygen content in portal venous blood are decreased. This could lead to a decrease in hepatic blood and oxygen supply, with subsequent hepatic oxygen deprivation.[53] Any anesthetic plan must be focused on the maintenance of arterial blood pressure and cardiac output. Often it is not the specific anesthetic agents chosen that matter most, rather the care in which they are administered. General anesthesia can

FIGURE **30-4** Ascites in a patient with alcoholic cirrhosis showing distended abdomen; dilated superficial collateral veins; hemorrhagic scratch marks due to pruritus and coagulopathy; umbilical varices; plaster in left iliac fossa indicating diagnostic paracentesis. (From Forbes A, et al, eds. *Atlas of Clinical Gastroenterology*. 3rd ed. Oxford: Mosby Ltd; 2005.)

be performed safely for patients with liver disease; regional anesthesia also can be used, but coagulopathy should be considered as a contraindication to many types of nerve blockade.

Volatile anesthetic considerations were discussed earlier, with an emphasis on selecting agents with little or no metabolism (e.g., desflurane, sevoflurane, isoflurane).

Nitrous oxide may be avoided in open abdominal cases because of the potential for expansion of the bowel and theoretic risk of exacerbating a venous embolism resulting from positional entrainment of air. Propofol has been used safely in patients with liver disease and may be a consideration for an induction agent. A midazolam induction may confer hemodynamic stability, but this benzodiazepine is NOT a prudent choice in the face of hepatic dysfunction because of impaired metabolism. Other benzodiazepines (e.g., lorazepam, oxazepam) do not require hepatic oxidation—only hepatic glucuronidation. Therefore, impaired liver function is less likely to result in lorazepam accumulation to an extent that would cause adverse reactions[54] and therefore would be a reasonable choice for sedation, although it is not ideally suited for induction of anesthesia.

Neuromuscular blockade selection should be based on patient physical status and the nature of the surgery (e.g., elective or urgent/emergent). Rapid sequence induction may be prudent in the cirrhotic patient with impaired gastric function and increased abdominal pressure related to ascites (Figure 30-4). In chronic liver failure, succinylcholine may exhibit a prolonged duration of action because of decreased synthesis of plasma cholinesterase by the liver. Due to the longer half-life of plasma cholinesterase (14 days), decreases are less likely in acute liver failure. Induction or maintenance with nondepolarizing neuromuscular blocking drugs (e.g., rocuronium) should be titrated cautiously with the expectation that duration of action will be extended if hepatic metabolism and clearance is impaired. Vecuronium is eliminated by the liver, and in cirrhotic patients, its onset is delayed,[55] its clearance is decreased,[56] and the duration of large doses is prolonged compared with controls.[56-58] Similar effects are seen with rocuronium. Liver disease increases the volume of distribution and elimination half-life of rocuronium, but not its clearance. The increased elimination half-life in patients with liver disease prolong rocuronium's duration of action, particularly with larger initial doses or prolonged administration. However, onset time is not altered by the presence of liver disease, preserving a desirable property of rocuronium.[59] A better option after intubation may be cisatracurium, which is metabolized independently of hepatic function and relies on Hoffman elimination (sensitive to temperature and pH).

Opioids are dependent on hepatic metabolism and should be administered cautiously. Coexisting pulmonary derangement may be worsened postoperatively by prolonged sedative and respiratory depressant effects of opioids used perioperatively. The CYP3A4 system is the primary metabolizer of fentanyl. Administration of CYP3A4 substrates or inhibitors can increase opioid concentrations, thereby prolonging and intensifying analgesic effects and adverse opioid effects, such as respiratory depression.[60] Hepatic dysfunction has a direct impact on the CYP metabolic system.

Morphine is metabolized in a phase II reaction, undergoing glucuronidation in the liver, and should be titrated cautiously or avoided in patients with significant liver disease. Elimination of alfentanil is reduced in patients with liver disease; its volume of distribution is increased, and protein binding is reduced by the lack of alpha-1-acid glycoprotein.[15] Remifentanil has a very short half-life due to its metabolism by nonspecific esterases in the blood and is not reliant on hepatic or renal function. Perhaps the most compelling evidence of no effect of hepatic dysfunction on the pharmacokinetics of remifentanil is that its kinetics do not change during the anhepatic phase of orthotopic liver transplantation.[61]

DISEASES OF THE BILIARY TRACT

Biliary tract disease is often characterized by a suppression or stoppage in bile flow. The most common cause of cholestasis is obstruction of the biliary tract outside the liver. Symptomatic presentation of obstruction and/or an inflammatory process can be attributed to gallstones, stricture, tumor, infection, or ischemia. Gallstone formation is most likely caused by physicochemical derangements in the formation of bile. Approximately 90% of gallstones appear as radiolucent structures composed of hydrophobic cholesterol crystals. Calcium bilirubinate generally accounts for the composition of the remaining percentage. Stones composed of calcium bilirubinate are usually seen in patients with cirrhosis and hemolytic anemia. An estimated 15 to 20 million adults in the United States have biliary tract disease, as evidenced by the presence of gallstones.[62]

Anatomic and Physiologic Overview

The biliary tract is the excretory conduit for the liver. It is composed of (1) the intrahepatic ducts, which collect bile from the liver segments; (2) the coalescence of the intrahepatic ducts and the right and left hepatic ducts; (3) the common hepatic duct, which is formed by the junction of the right and left hepatic ducts in the liver hilum; (4) the gallbladder, which serves as a reservoir of bile; (5) the cystic duct, which joins the gallbladder to the common bile duct; and (6) the common bile duct, which begins at the junction of the cystic duct and the common hepatic duct and terminates in the lumen of the duodenum.[62]

The gallbladder is a pear-shaped organ capable of holding 30 to 60 mL of fluid and is attached to the liver in a shallow depression at the inferior junction of the right and left hepatic lobes. The gallbladder drains into the cystic duct, which is usually 1 to 5 cm long and arises from the narrow end, or infundibulum, of the gallbladder. The cystic duct drains into the common hepatic duct. The common bile duct arises from the junction of the cystic duct and common hepatic duct and is approximately 6 mm

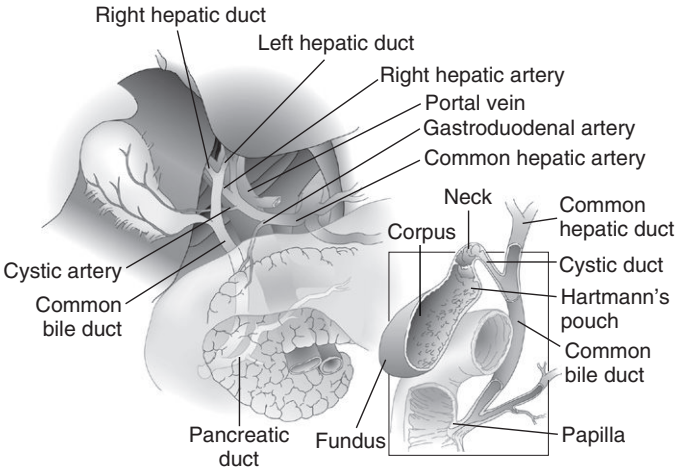

FIGURE **30-5** Anatomy of the biliary tract. (From Townsend CM, et al, eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2008:1548.)

in diameter. It passes behind the duodenum to the right of the gastroduodenal artery, traversing the head of the pancreas before entering the second part of the duodenum. The distal common bile duct may join with the pancreatic duct before entering the duodenum via the ampulla of Vater (Figure 30-5). At the termination, these ducts are enveloped in smooth muscle, the sphincter of Oddi, which provides a barrier to intestinal bacteria to maintain the sterile environment of the biliary tract. At this point, biliary tract obstruction can occur from a pancreatic tumor.

Arterial blood supply to the gallbladder is furnished by the cystic artery, which is a branch of the right hepatic artery. The biliary ducts receive their blood supply distally from the gastroduodenal, retroduodenal, and posterosuperior pancreatoduodenal arteries and proximally from the right hepatic and cystic arteries. Venous drainage flows into the portal vein. Lymphatic drainage flows into a cystic duct node located between the cystic duct and the common hepatic duct.

The area known as the *cystohepatic triangle (Calot's triangle)* is bound by the common hepatic duct, the liver, and the cystic duct and is a critical region that contains the cystic artery, the right hepatic artery, the cystic duct lymph node, and sometimes an aberrant right segmental bile duct. This area must be carefully dissected during cholecystectomy, so damage to these vital and friable structures can be avoided.

The gallbladder mucosa secretes a protective mucus that prevents caustic damage by bile salts. After food is ingested, the gallbladder contracts, emptying its contents (bile) into the duodenum to assist in the digestive processes. Regulation of gallbladder contraction is primarily hormonal through the action of cholecystokinin. The release of cholecystokinin from duodenal cells is mediated by the presence of intraluminal amino acids and fat. Vagal stimulation also serves a role (secondary to the role of cholecystokinin). Indeed, vagotomy is associated with impaired gallbladder contraction and increased prevalence of gallstones.[34]

Bile is the combined secretory product of the hepatocyte and biliary tract epithelial cell and has three main functions: (1) to emulsify and enhance absorption of ingested fats and fat-soluble vitamins; (2) to provide an excretory pathway for bilirubin, drugs and toxins, and immunoglobulin A (IgA); and (3) to maintain duodenal alkalization. The combined output of the ductal cells and hepatocytes is 500 to 1000 mL/day. The bile ducts, gallbladder, and sphincter of Oddi modify, store, and regulate the flow of bile. The liver produces 500 to 1000 mL of bile per day and excretes it into the bile canaliculi. The gallbladder concentrates and stores hepatic bile during the fasting state and delivers bile into the duodenum in response to a meal. Because the usual capacity of the gallbladder is only about 30 to 60 mL, the remarkable absorptive capacity of the gallbladder accounts for its ability to store much of the bile produced each day.[62] Absorbed bile is returned via the portal venous system to the liver.

The hepatocytes secrete bilirubin (the metabolic waste product of heme metabolism), cholesterol, bile salts, lecithin, water, and electrolytes. The epithelial cells contribute water and electrolytes. Vagal stimulation, secretin, cholecystokinin, and gastrin stimulate ductular cell secretion and increase bile flow. In addition, bile acids furnish a positive-feedback mechanism in the elaboration of hepatocyte and ductular secretion. Gallbladder filling during fasting occurs with relaxation and contraction of the sphincter of Oddi. The sphincter of Oddi is a complex structure that is functionally independent from the duodenal musculature. It creates a high-pressure zone between the bile duct and the duodenum. The sphincter regulates the flow of bile and pancreatic juice into the duodenum, prevents the regurgitation of duodenal contents into the biliary tract, and diverts bile into the gallbladder. Vasoactive intestinal peptide produces relaxation of the sphincter of Oddi, whereas somatostatin, an inhibitory peptide, produces contraction. In states of prolonged fasting, the risk of gallstone formation increases because of the lack of cholecystokinin stimulation and consequent biliary stasis.[62]

Cholecystitis

Cholecystitis symptoms are usually the result of obstruction, infection, or both. Obstruction can be extramural (e.g., pancreatic cancer), intramural (e.g., cholangiocarcinoma), or intraluminal (e.g., choledocholithiasis). Acute cholecystitis is related to gallstones in 90% to 95% of cases. Obstruction of the cystic duct leading to biliary colic is the initial event in acute cholecystitis. If the cystic duct remains obstructed, the gallbladder distends, and the gallbladder wall then becomes inflamed and edematous. Obstruction of the cystic duct by gallstones results in a triad of sudden right upper quadrant tenderness, fever, and leukocytosis.

Inspiratory effort usually accentuates the pain (Murphy sign). Increases in plasma bilirubin, alkaline phosphatase, and amylase levels frequently occur. Ileus and localized tenderness may indicate perforation with peritonitis. Leukocytosis and fever are often present. Jaundice indicates complete obstruction of the cystic duct. Symptoms are frequently confused with those of myocardial infarction. Differential diagnosis is accomplished through serial ECG evaluations and laboratory analysis of serum enzymes specific to cardiac muscle. Cholescintigraphy (a contrast study that evaluates gallbladder excretion of a radiographically labeled substance) and ultrasonography are often used for clinical confirmation of the diagnosis.[34]

For most patients, the treatment of acute cholecystitis is cholecystectomy, but for those who are critically ill, the risk of general anesthesia may be greater than the benefit of a surgical procedure. An alternative, temporary treatment for these high-risk patients is decompression and drainage of the gallbladder through the insertion of a cholecystostomy tube. This minimally invasive procedure can be performed with local anesthetic infiltration and intravenous sedation.[63]

Patients with symptoms indicative of acute cholecystitis are often volume depleted because of intolerance of oral intake, vomiting, and possible preoperative nasogastric evacuation of gastric contents. Dehydration calls for preoperative intravenous fluid replacement. Gastric suction may be warranted in the presence of

ileus. The presence of free abdominal air, as determined by abdominal radiography or symptoms of an acute abdomen (e.g., fever, ileus, rigid and painful abdomen, vomiting, dehydration), suggests a ruptured viscus, possibly including perforation of the gallbladder. Under these circumstances, emergency exploratory laparotomy is undertaken.

Cholelithiasis and Choledocholithiasis

Acute obstruction of the common bile duct often produces symptoms similar to those seen in patients with cholecystitis. Recurrent bouts of acute cholecystitis induce the development of fibrotic changes in gallbladder structure, thereby impeding the ability of the gallbladder to adequately expel bile. Presence of Charcot's triad (i.e., fever and chills, jaundice, right upper quadrant pain) aids in establishing the diagnosis of acute ductal obstruction. Weight loss, anorexia, and fatigue complete the symptomatology. Diagnostic modalities include radiography, transhepatic cholangiography, ultrasonography, cholescintigraphy, and computed tomography (CT) scan. A dilated common bile duct and biliary tree are typically observed in these studies.

The use of endoscopic retrograde cholangiopancreatography (ERCP) in patients with suspected common bile duct stones not only confirms the diagnosis but also provides ductal clearance of the stones and sphincterotomy before subsequent laparoscopic cholecystectomy. It is relatively more complex than routine endoscopies and requires adequate patient sedation, analgesia, and patient cooperation. Patients undergoing ERCP have been found to be more anxious as compared with those undergoing a routine esophagogastroduodenoscopy (EGD). Restlessness and lack of cooperation have been reported to be one of the causative factors for post-ERCP complications such as duodenal perforation and pancreatitis. The choice of sedative is chiefly governed by the user and the patient history. Similarly, the level of sedation is also dependent on the clinical condition of the patient and the degree of patient cooperation.[64] Patients presenting for ERCP often have comorbidities. Endoscopic clearance of stones from the common bile duct can avoid the need for an open operation if expertise in laparoscopic common bile duct exploration is not available. Patients with worsening cholangitis caused by ascending bacterial infection of the biliary system, ampullary stone impaction, biliary pancreatitis, multiple comorbidities, and cirrhosis are considered good candidates for preoperative endoscopic therapy.[62]

Anesthetic Considerations in Gallbladder and Biliary Tract Disease

Removal of gallstones is undertaken not only for relief of symptoms but also for prevention of further sequelae, including cholecystitis, cholangitis, jaundice, pancreatitis, and peritonitis, all of which may result from stasis or impediment to bile flow. Contraindications to laparoscopic cholecystectomy include coagulopathy, severe chronic obstructive pulmonary disease, end-stage liver disease, and congestive heart failure.

Since the introduction of laparoscopic cholecystectomy, the number of cholecystectomies performed in the United States has increased from about 500,000 per year to 700,000 per year. More than 90% of cholecystectomies are performed laparoscopically. Laparoscopic cholecystectomy is now often performed in the relatively healthy patient on an outpatient basis with either discharge later in the day of surgery or after an overnight stay in the hospital. Postoperative pain management is typically less challenging with laparoscopic surgery.

Induction is standard or rapid-sequence induction with oral endotracheal intubation. The use of abdominal carbon dioxide insufflation to effect adequate exposure of anatomic structures mandates general endotracheal intubation anesthesia to effectively seal the airway and prevent passive aspiration of gastric contents. Maintenance requires muscle relaxation with appropriate reversal. An orogastric (OG) tube should be inserted to decompress the stomach. Prophylactic antiemetics are needed due to the peritoneal irritation of insufflation, opioid use, and intravascular volume depletion. The peritoneal cavity must be insufflated for surgical exposure.

Insufflation of the abdomen with carbon dioxide impedes diaphragmatic excursion, causing a decrease in functional residual capacity, closing capacity, and increased peak inspiratory pressure. Retroperitoneal insufflation may lead to hypotension and necessitates repositioning of the trocar. Insufflation with carbon dioxide causes a rise in the carbon dioxide partial pressure unless ventilation is controlled. Abdominal insufflation may lead to hypercarbia in the presence of inadequate ventilation. Special attention should be paid to the possibility of needed adjustments in ventilator settings with insufflation. In the setting of intraabdominal insufflation, applying an alternative ventilatory strategy using pressure control ventilation (PCV) rather than a volume control mode may best serve to prevent alveolar derecruitment (measured at the bedside by a pressure-volume curve method) by providing a physiologic minute ventilation while minimizing the risk of barotrauma. The use of a reverse Trendelenburg position during laparoscopic cholecystectomy may induce a variable degree of hemodynamic compromise by impeding venous return. Occult hemorrhage is also possible and may go undetected.

Insufflation also leads to increased intraabdominal pressure. An intraabdominal pressure of 20 to 25 cm H_2O produces increases in cardiac output and CVP secondary to changes in the volume of the venous return of blood. An intraabdominal pressure greater than 30 to 40 cm H_2O may lead to decreased CVP and reduced cardiac output secondary to reduced right ventricular preload. Insufflation to a pressure of approximately 15 mmHg is routine. Abdominal insufflation also displaces the abdominal viscera and diaphragm in a cephalad direction, placing extra pressure on the lower esophageal sphincter (LES) and thereby increasing the risk of gastric reflux.

All maintenance anesthetic drugs may be used. Some surgeons request that nitrous oxide not be used to reduce the risk of bowel expansion, which could hinder surgical exposure. In the presence of hepatic dysfunction, isoflurane, desflurane, and sevoflurane are safe. The choice of muscle relaxant depends on the patient's ability to tolerate possible side effects of the drug, the drug's dependence on hepatic clearance, and the length of the procedure to be performed. Awake extubation is performed after the patient's airway reflexes are adequate. The laparoscopic approach offers the benefit of reduced postoperative pain secondary to smaller abdominal incisions. Patients may experience shoulder pain from pneumoperitoneum, which is usually self-limiting. Evacuation of the pneumoperitoneum with a Valsalva maneuver prior to closing will assist in alleviating postoperative pain. Severe postoperative pain may be reduced by patient-controlled analgesia, intercostal nerve blocks, or neuraxial opioid administration. Abdominal pain or other symptoms originally attributed to the gallbladder may persist or recur months or years after cholecystectomy.

Open cholecystectomy may be indicated for patients who are emergently ill, in the presence of infection, or patients in whom laparoscopy poses a particularly formidable technical challenge (e.g., in cases of morbid obesity or intraabdominal adhesions secondary to previous abdominal surgery or peritonitis). Patients who undergo open cholecystectomy often experience

more complications, including a greater likelihood of severe postoperative pain and respiratory splinting (caused by the use of a right subcostal or upper abdominal midline incision), with the risk of postoperative respiratory embarrassment in the susceptible patient. Patients who have experienced severe traumatic injury or who require aggressive intensive care for multiorgan disease are at particular risk for developing acute cholecystitis secondary to the stress of severe illness. Patients with significant comorbidities, including advanced age, who undergo prolonged or complex surgical procedures (e.g., trauma, cardiac surgery with cardiopulmonary bypass, abdominal aneurysm repair) that are complicated by perioperative hemodynamic lability have also been identified to be at added risk for ischemia of the abdominal viscera. The result may be the development of an acute, postoperative abdominal crisis. Under this circumstance, exploratory laparotomy for an acute abdomen may reveal necrosis and perforation of the gallbladder. This places the patient at extreme risk for developing peritonitis. The acute critical nature of the presenting illness, superimposed upon preexisting patient comorbidities, is another factor potentially complicating perianesthetic management of the patient.[34]

Full-stomach precautions should be used during the induction of and emergence from anesthesia, particularly in the presence of abdominal distention or ileus. Patients with jaundice require a more thorough preparation, owing to the likelihood of a variable degree of hepatic dysfunction. This may make for greater susceptibility to hemorrhage, exaggerated drug effects, and fluctuation in hemodynamics. Invasive hemodynamic monitoring and preparation for blood product transfusion are influenced by the patient's clinical status.

Common bile duct exploration may be carried out in conjunction with cholecystectomy if necessary. Glucagon may be requested by the surgeon for its spasmolytic effect in the GI system and its ability to relax the sphincter of Oddi. Note that Glucagon may cause nausea at doses greater than 2 mg.

DISEASES OF THE ESOPHAGUS

Anatomic and Physiologic Overview

Esophagus is derived from the Greek words *oiso*, which is the future tense of *phero* (to carry), and *phagein* (food).[65] Approximately 18 to 25 cm long, the esophagus is a hollow, muscular tube that serves to carry food or liquid to the stomach. The esophagus extends through three segments: cervical, thoracic, and abdominal. The cervical esophagus is bordered anteriorly by the trachea, bilaterally by the common carotid arteries, internal jugular veins, and vagal nerves, and posteriorly by cervical muscles. Proximally, the esophagus begins where the inferior pharyngeal constrictor merges with the cricopharyngeus, an area of skeletal muscle known functionally as the upper esophageal sphincter.[66] At rest, the upper esophageal sphincter prevents entrainment of air by creating a zone of high pressure through muscle contraction.

Although collapsed when unused, the esophagus is capable of expanding to permit passage of substances, yet it remains the narrowest of the digestive tubes. Peristaltic action continues to push solid matter distally toward the stomach. The lower esophageal sphincter (LES), contracted at rest to prevent passage of gastric contents proximally into the esophagus, relaxes to permit passage of food into the stomach.

Sympathetic and parasympathetic innervation regulates esophageal muscle tone. Peristaltic activity is regulated by parasympathetic innervation via the vagus nerves. Esophageal muscular contraction and relaxation of the LES is regulated by stimulation of cranial nerves IX, X, and XI. Sympathetic fibers act on Auerbach's (myenteric) plexus to modulate motor activity.

Esophageal Disorders

Disorders affecting esophageal motility or sphincter tone may create generalized symptoms of dysphagia, heartburn, or chest pain. Primary esophageal motility disorders include achalasia and gastroesophageal reflux disease (GERD). Achalasia is characterized by impaired relaxation of the lower esophageal sphincter and may develop secondary to systemic disease states, including diabetes, stroke, amyotrophic lateral sclerosis, and certain connective tissue diseases, such as amyloidosis and scleroderma. Chronic achalasia results in dilation of the distal esophagus, and regurgitation becomes more frequent when larger amounts of food and fluid are retained. GERD is a consequence of the failure of the normal antireflux barriers to protect against frequent and abnormal amounts of gastroesophageal reflux. Symptoms range from heartburn to extraesophageal manifestations (e.g., pulmonary, ear, nose, or throat symptoms).

Chronic GERD can result in abnormal epithelial changes in the esophagus that are predisposed to malignancy. Termed *Barrett's esophagus*, damage to the esophageal epithelium results in columnar epithelium replacing the normal stratified squamous cells in the distal esophagus. These changes create no symptoms but are a cautionary risk factor associated with adenocarcinoma of the esophagus.

In many patients, GERD may be managed conservatively with pharmacologic therapy, and surgery is withheld until medical management proves unsuccessful. Medication therapy may include antacids, mucosal protective medications, histamine (H_2) receptor blockers, proton pump inhibitors, and prokinetics designed to facilitate emptying of the stomach. Aside from failed medical therapy, other surgical indications include mechanically defective cardiac sphincter, recurrence of symptoms after discontinuing treatment, and unacceptable side effects related to medications.

Hiatal Hernia

Hiatal hernia refers to conditions in which elements of the abdominal cavity, most commonly the stomach, herniate through the esophageal hiatus into the mediastinum.[67] Hiatal hernias are classified as type I to type IV. Type I, the sliding type, is formed by the movement of the upper stomach through an enlarged hiatus. In type II, the paraesophageal type, the esophagogastric junction remains in normal position, but all or part of the stomach moves into the thorax and assumes a paraesophageal position. A type III has been identified that combines the features of sliding and paraesophageal hernias (Figure 30-6). Type IV hiatal hernias are present when other organs, such as the colon or small bowel, are contained in the hernial sac formed by a large paraesophageal hernia.[68]

The contribution of hiatal hernia to GERD is controversial,[69] but data confirm the importance of hiatal hernia in patients with more severe esophagitis, peptic stricture, or Barrett's esophagus. Several surgical approaches may be used to reduce and correct hiatal hernia although the laparoscopic Nissen fundoplication remains common. The Collis-Nissen (elongation gastroplasty) may be superior to the Nissen fundoplication for select patients with Barrett's esophagus because of the reflux-induced shortening of the esophagus.[70] Anesthetic management may include aspiration prophylaxis, discussed previously. Application of cricoid pressure has been shown to decrease LES; however, normal gastric pressures remain; consequently, the value of cricoid cartilage pressure in rapid sequence induction has been questioned, although it remains a frequent technique in clinical practice.[71]

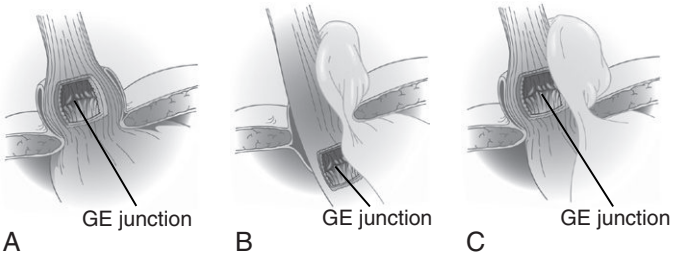

FIGURE **30-6** Three types of hiatal hernia. **A,** Type I, or sliding hernia. **B,** Type 2, or rolling hernia. **C,** Type 3, or mixed hernia. *GE*, Gastroesophageal. (From Townsend CM, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 19th ed. Philadelphia: Saunders; 2012:1068.)

Anesthetic Considerations in Esophageal Disease

Special considerations may be necessary for patients with active esophageal disease. Occult disease (asymptomatic) is generally less concerning compared with patients with uncontrolled disease states that manifest with reflux symptoms. A preoperative history of symptoms that indicate the presence of gastric reflux warrants aspiration prophylaxis during induction and emergence surrounding general anesthesia. Although best practice data does not support a specific regimen, modifying acidity and/or volume of gastric contents remains a common preoperative practice. To gain maximum benefit, it is imperative to have an understanding of the pharmacokinetic/pharmacodynamic profile of selected preoperative medications.

Rapid sequence induction with cricoid pressure may serve to hasten protection of the airway with a cuffed endotracheal tube and limit opportunity for aspiration of gastric contents. Usage of a laryngeal mask airway (LMA) remains controversial in patients with active reflux disease. The absence of definitive airway protection with LMA must be carefully considered, and a reasonable indication against endotracheal intubation should be present prior to implementation.

DISEASES OF THE STOMACH

Anatomic and Physiologic Overview

The principal function of the stomach is to prepare ingested food for digestion and absorption before it is moved into and through the small intestine. The initial period of digestion requires that solid components of a meal be stored for several hours while they undergo a reduction in size and break down into their basic metabolic constituents.

Receptive relaxation is a process whereby the proximal portion of the stomach relaxes in anticipation of food intake. This relaxation enables liquids to pass easily from the stomach along the lesser curvature, whereas the solid food settles along the greater curvature of the fundus. In contrast to liquids, emptying of solid food is facilitated by the antrum, which pumps solid food components into and through the pylorus. The antrum and pylorus function in a coordinated fashion, allowing entry of food components into the duodenum and also returning material to the proximal stomach until it has been processed appropriately for delivery into the duodenum.

In addition to storing food, the stomach participates in digestion of a meal. An example of this is the enzymatic breakdown of starch through the activity of salivary amylase. For this to work, the pH within the center of the gastric bolus needs to be greater than pH 5. Peptic digestion metabolizes a meal into fats, proteins, and carbohydrates by breaking down cell walls. Although the duodenum and proximal small intestine are primarily responsible for digestion of a meal, the stomach clearly facilitates this process.[72]

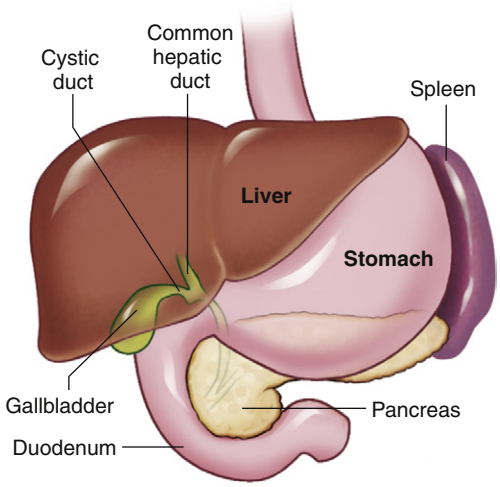

FIGURE **30-7** Position of the stomach relative to the other principal organs of the upper abdomen. (From Patton KT, Thibodaux GA. *Anatomy & Physiology*. 8th ed. St Louis: Mosby; 2013:862.)

The stomach is essentially composed of three sections. The thin-walled and distensible proximal portion (fundus) is located in the upper abdomen and has primarily a storage function. The body of the stomach represents the largest portion and is also referred to as the *corpus*. The body also contains most of the parietal cells and is bound on the right by the relatively straight lesser curvature and on the left by the longer greater curvature. The thick-walled distal portion (antrum) of the stomach is responsible for the mixing of food and its slow release through the pyloric sphincter into the duodenum. The liver is positioned right and ventral to the stomach and left and lateral to the spleen. The biliary tract courses posterior to the stomach (Figure 30-7).

Most of the blood supply to the stomach is from the celiac artery. There are four main arteries: the left and right gastric arteries along the lesser curvature and the left and right gastroepiploic arteries along the greater curvature. In addition, a substantial quantity of blood may be supplied to the proximal stomach by the inferior phrenic arteries and by the short gastric arteries from the spleen (Figure 30-8). Major autonomic innervation is furnished by two branches of the vagus nerve, the right posterior (celiac) branch and the left anterior (hepatic) branch.

The gastric wall consists of an external serosal layer that covers an inner oblique, a middle circular, and an outer longitudinal layer of smooth muscle. The middle layer of smooth muscle is circular and is the only complete muscle layer of the stomach wall. At the pylorus, this middle circular muscle layer becomes progressively thicker and functions as a true anatomic sphincter between the stomach and duodenum.

The submucosa lies between the muscularis externa and mucosae and is a collagen-rich layer of connective tissue that is the strongest layer of the gastric wall. The submucosa contains the rich anastomotic network of blood vessels, lymphatics, and Meissner's plexus of autonomic nerves. The mucosa consists of surface epithelium, lamina propria, and muscularis mucosae. The latter is on the luminal side of the submucosa and is probably responsible for the rugae that greatly increase epithelial surface area. It also marks the microscopic boundary for invasive and noninvasive gastric carcinoma.[72]

Within the gastric mucosa reside the glands responsible for the significant physiologic role played by the stomach during the digestive processes. The functions of the glands and the cells lining the glands vary according to the region of the stomach in which they

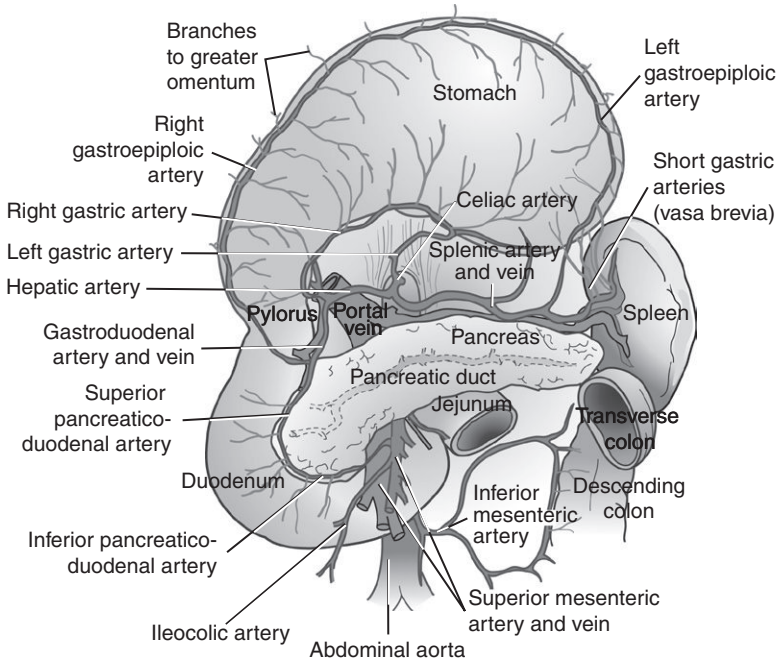

FIGURE **30-8** Blood supply to the stomach and duodenum with anatomic relationships to the spleen and pancreas. (From Yeo CJ, et al. *Shackelford's Surgery of the Alimentary Tract*. 7th ed. Philadelphia: Saunders; 2013:641.)

are found. Within the fundic mucosa lie mucus-secreting glands that provide a protective barrier to the acid outflow of the parietal cells, which are located in the same region of the stomach. The endocrine function of the stomach is apparent through the secretions (pepsinogen) of the chief cells and the secretions (serotonin) of other cells. Within the antrum are cells that secrete mucus (surface epithelial cells and mucous cells) and gastrin (G cells). The two important sphincters are the LES at the gastroesophageal junction and the pyloric sphincter at the gastroduodenal junction.

The stomach is very distensible, can store up to 1.5 liters of fluid without any increase in gastric pressure, and normally stores food for up to 4 hours. The sight and smell of food stimulate acid and pepsinogen production. Gastrin is the major hormonal regulator of the gastric phase of acid secretion after a meal. Gastrin is released by the G cells in response to gastric distention, which stimulates parietal-cell acid (hydrochloric acid) secretion. The duodenum and upper jejunum also secrete a small amount of gastrin. Luminal acid suppresses gastrin feedback (negative feedback).

Pepsinogen and gastrin release are vagally mediated. Acid in duodenal contents induces the release of secretin, an effect that inhibits gastrin release even more and inhibits further acid production. Acid in the antrum also stimulates the release of somatostatin. Somatostatin is able to directly inhibit parietal cell acid secretion but can also indirectly inhibit acid secretion through inhibition of gastrin release and down-regulation of histamine release. Pancreatic bicarbonate release is also stimulated by duodenal acidity.

Gastric acid secretion by the parietal cell is regulated by three local stimuli: acetylcholine, gastrin, and histamine. These three stimuli account for basal and stimulated gastric acid secretion. Acetylcholine is the principal neurotransmitter modulating acid secretion and is released from the vagus and parasympathetic ganglion cells. Gastrin has hormonal effects on the parietal cell and stimulates histamine release. Histamine has paracrine-like effects on the parietal cell and plays a central role in the regulation of acid secretion by the parietal cell after its release from enterochromaffin-like (ECL) cells. Somatostatin exerts inhibitory actions on gastric acid secretion. Release of somatostatin from antral D cells is stimulated in the presence of intraluminal acid at a pH of 3 or less. After its release, somatostatin inhibits gastrin release and also modifies histamine release from ECL cells. In some patients with peptic ulcer disease (PUD), this negative feedback response is defective. Consequently, the precise state of acid secretion by the parietal cell is dependent on the overall influence of the positive and negative stimuli.[72]

Other gastric functions include providing a barrier against ingested pathogens. This goal is accomplished through the maintenance of a highly acidic environment and through a functional role in immunosurveillance. The stomach heats or cools ingested substances as needed for the maintenance of normothermia. Parietal cells also secrete intrinsic factor (in addition to hydrochloric acid), which facilitates ileal vitamin B_{12} absorption.

Peptic Ulcer Disease

A gastric ulcer is defined by the loss of mucosa (including muscularis mucosae) due to inflammation. Ulcers may extend into the submucosa and even muscularis propria. Of course, all ulcers begin as erosions, but not all erosions progress to ulcers. Ulcers may be acute or chronic. Peptic ulcers are considered chronic and are most often solitary. They may occur in any portion of the GI tract that is exposed to acid-peptic juices. Approximately 98% of peptic ulcers occur in the stomach and duodenum.

It is now believed that 90% of duodenal ulcers and roughly 75% of gastric ulcers are associated with *H. pylori* infection. *H. pylori* is detected in the stomach of almost all patients with duodenal peptic ulcer and in more than 90% of gastric ulcer patients who are not nonsteroidal antiinflammatory drug (NSAID) users (after *H. pylori* infection, ingestion of NSAIDs is the most common cause of PUD). Eradication of *H. pylori* facilitates healing of peptic ulcers, and essentially, prevents their recurrence.[73]

The most common complications of peptic ulcer disease, in order of prevalence, are hemorrhage, perforation, and obstruction.

Approximately one third of patients experience at least one of these complications during the course of their peptic ulcer disease; pyloric channel ulcers are the ones most commonly associated with complications, particularly obstruction. Bleeding occurs when the ulcer erodes underlying blood vessels. Ulcers may perforate into adjacent organs, such as the pancreas (more common) or liver.

Gastric outlet obstruction may develop as a result of distortion and narrowing of the pyloric area caused by fibrosis, edema, or smooth muscle spasm resulting from chronic ulcer disease. It occurs almost exclusively in patients with long-standing peptic ulcers of the pyloric channel or duodenum. Surgical repair or endoscopic pyloric dilation are often necessary to alleviate the symptoms of gastric outlet obstruction.[73,74]

A chronic overabundance of hydrochloric acid and pepsin (from various causes) results in erosion of the protective mucous layer of the stomach and duodenum, eventually leading to ulcerative lesions extending beyond the mucosal barrier into the submucosa and muscularis epithelial layers and sometimes into the serosal layer. In the case of LES incompetence, ulcerative involvement of the esophagus may develop.

A chronic ulcerative lesion in the duodenum constitutes duodenal ulcer disease. Because of similarity of symptoms and responses to therapy, this classification is also placed on lesions that occur before the pylorus in the lower antrum of the stomach. Men 45 to 65 years of age and women older than 55 years of age have the highest incidence of duodenal ulcer disease. Affected patients possess twice the number of acid-secreting parietal cells.[75]

Gastritis

Stress gastritis, an inflammatory disorder of the gastric mucosa, has been referred to as stress ulcerations, stress erosive gastritis, and hemorrhagic gastritis. These lesions may lead to life-threatening gastric bleeding and by definition occur after physical trauma, shock, sepsis, hemorrhage, or respiratory failure. They are characterized by multiple, superficial (nonulcerating) erosions that begin in the proximal or acid-secreting portion of the stomach and progress distally. They also may occur in the setting of central nervous system disease such as that seen with Cushing's ulcer or as a result of thermal burn injury involving more than 30% of the body surface area (Curling's ulcer).

Although the precise mechanisms responsible for the development of stress gastritis remain to be fully elucidated, current evidence suggests a multifactorial etiology including drugs, chemicals, or *H. pylori* infection. These stress-induced gastric lesions appear to require the presence of acid. Stress is considered present when hypoxia, sepsis, or organ failure occurs. Other factors that may predispose to the development of these lesions include impaired mucosal defense mechanisms against luminal acid such as a reduction in blood flow, a reduction in mucus, a reduction in bicarbonate secretion by mucosal cells, or a reduction in endogenous prostaglandins.[72] *H. pylori* has been identified as a major etiologic factor of gastritis-associated disease, as well as gastric and duodenal ulcers and gastric carcinoma. Epidemiologic findings indicate a higher prevalence of this organism in older adults, individuals of lower socioeconomic status, and those born outside the United States. Infected patients undergoing stress are at greatest risk for exacerbation of the infection, with potential development of gastric and duodenal ulceration. At present, despite the numerous exposures of anesthesia providers to potential oral and ambient routes of transmission, *H. pylori* has not been recognized as a serious occupational hazard.[75] All these factors render the stomach more susceptible to damage from luminal acid with the resultant hemorrhagic gastritis.

Any patient with upper GI bleeding requires prompt and definitive fluid resuscitation with correction of any coagulation or platelet abnormalities. If blood is required, it should be administered without delay, and if there are specific clotting abnormalities or platelet deficiencies, fresh frozen plasma and platelets should likewise be administered. In patients being treated for sepsis, broad-spectrum antibiotics, in conjunction with source control of the infection, need to be undertaken. Treatment of the underlying sepsis plays a major role in treating the underlying gastric erosions. Saline lavage of the stomach through a nasogastric tube will help remove any pooled blood and prevent gastric distention, which stimulates gastrin release. Nasogastric decompression also removes noxious substances such as bile and pancreatic juice that could potentially further compromise the stomach. More than 80% of patients who present with upper GI hemorrhage stop bleeding using this approach. When the nasogastric tube aspirate is clear, indicating that bleeding has ceased, intraluminal gastric pH should be maintained at greater than 5.0 with antisecretory agents. If the pH can be maintained above 5.0, more than 99.9% of acid will be neutralized, and pepsin will be inactive. Usually this involves the use of proton pump inhibitors or, alternatively, H_2-receptor antagonists with or without combination antacid therapy. There is little evidence to suggest that endoscopy with electrocautery or heater probe coagulation has any benefit in the therapy of bleeding from acute stress gastritis.[72]

Gastric mucosal acidosis has been commonly reported in critically ill patients with respiratory failure and underlying coagulopathy, hepatic cirrhosis, hyperparathyroidism, obstructive airway disease, rheumatoid arthritis; patients undergoing prolonged, complex surgical procedures; and patients undergoing cardiopulmonary bypass. Gastritis associated with gastric mucosal acidosis is associated with increased perioperative morbidity and mortality. The splanchnic viscera is particularly vulnerable to decreased circulatory blood flow in the presence of inflammation, with the potential for breakdown of intestinal barrier function. This occurrence results in translocation of bacteria and endotoxin into the bloodstream, with consequent systemic sepsis. Ischemia and acidosis of the gut is the primary causative factor for erosion of gut barrier function.[34]

Therapeutic Options in Peptic Ulcer Disease

The clinician has three major goals when faced with a patient with ulcer disease: symptoms need to be relieved, the ulcer needs to heal, and recurrence needs to be prevented. The major medical therapies and treatments of choice used for the control of peptic ulcer disease focus on *H. pylori*. Adjuncts include oral antacids, H_2-receptor antagonists, proton pump inhibitors, sucralfate, and antibiotics. A proton pump inhibitor such as omeprazole is used in duodenal ulcer management. EGD and surgical treatment are reserved for patients who continue to experience intractable symptoms despite aggressive medical therapy or for treatment of complications. These complications are often of an urgent nature and consist of GI hemorrhage, ulcerative perforation into adjacent structures such as the pancreas or jejunum, and obstruction.[76,77]

Antacid use in the medical treatment of peptic ulcer disease has potential complications of interest to the anesthetist. Antacids may produce an acid rebound in which gastric acid secretion may increase after acid is neutralized by calcium-containing antacids. Another condition that may result from antacid therapy is the milk-alkali syndrome. In this condition, hypercalcemia, alkalosis, and an elevated blood urea nitrogen level may develop from the daily ingestion of large quantities of calcium-containing antacids

TABLE 30-10 Proton Pump Inhibitors

Generic Name	Trade Name	Adult Dosage Range	Available Dosage Forms*	Dose Adjustment in Renal Dysfunction	Drug Interactions and Comments
Esomeprazole	Nexium	20 mg daily	Capsule: 20, 40 mg	No	Cefuroxime, cefpodoxime, digoxin, dihydropyridine calcium channel blockers, iron salts, itraconazole, ketoconazole, sucralfate
Lansoprazole	Prevacid	15-30 mg daily or bid	Capsule: 15, 30 mg	No	Same as esomeprazole plus theophylline
Omeprazole	Prilosec	20-40 mg daily or bid	Capsule: 10, 20, 40 mg	No	Same as esomeprazole plus benzodiazepines, cilostazol, citalopram, clarithromycin, cyclosporine, disulfiram, methotrexate, phenytoin, sulfonylureas, theophylline, warfarin
Pantoprazole	Protonix, Protonix IV	40-80 mg daily	Tablet: 40 mg Injection: 40 mg/vial	No	Same as esomeprazole
Rabeprazole	Aciphex	20 mg daily	Tablet: 20 mg	No	Same as esomeprazole plus cyclosporine

*All oral forms are delayed release.

and milk. Manifestations of this syndrome include skeletal muscle weakness and polyuria. Ingestion of large quantities of aluminum-containing antacids may result in acute hypophosphatemia because of increased binding of intestinal phosphorus. Skeletal muscle weakness and fatigue follow chronic overuse, resulting in pathologic fractures and osteoporosis.[34]

Hydrochloric acid secretion is blocked by H_2 antagonists, thereby promoting the healing of duodenal ulcers. All four available H_2 antagonists (cimetidine, ranitidine, famotidine, and nizatidine) suppress basal acid output as well as acid output stimulated by meals. After intravenous administration, all four agents are eliminated principally through renal excretion. For cimetidine and famotidine, it is recommended that the doses be cut in half in patients whose creatinine clearance is 15 to 30 mL/min. For nizatidine and ranitidine, the dose should be halved if the creatinine clearance is less than 50 mL/min.[76] A noteworthy side effect is the alteration of cytochrome P-450 enzyme activity in the liver; this alteration may result in prolongation of the effects of concurrently administered drugs that rely on hepatic metabolism and elimination by means of this mechanism. Famotidine is the H_2 antagonist least likely to cause this effect. Other side effects of H_2 antagonists include decreased hepatic blood flow, leukopenia and thrombocytopenia, mental confusion, interstitial nephritis, hepatitis, bradycardia, and hypotension.

The proton pump inhibitors are the most effective antisecretory agents and are listed in Table 30-10. Sucralfate, the aluminum salt of sulfated sucrose, not only binds to ulcers but also increases the gastric mucous layer, thereby promoting healing processes. It has been shown to be equally efficacious when used with H_2 antagonists and antacids and is relatively devoid of side effects.

Misoprostol is a synthetic prostaglandin and may be used as a prophylactic therapy to prevent ulcers in patients taking NSAIDs. *H. pylori* is a species of gram-negative spiral bacteria sensitive to combination therapy with a variety of antibiotics. About 80% of upper GI bleeds are self-limited. Laparoscopic repair is indicated when medical therapy is unsuccessful.

Gastric Ulcer Disease

Gastric ulcers develop as a result of degeneration of the stomach's mucosal barrier to gastric acid. Gastric ulcers can occur anywhere in the stomach, and may or may not be associated with increased gastric acid secretion. Pain and anorexia predispose the patient to metabolic derangements and weight loss. The most frequent complication of gastric ulceration is perforation. Most perforations occur along the anterior aspect of the lesser curvature. In general, older patients have increased rates of perforations, and larger ulcers are associated with more morbidity and higher mortality rates. Similar to duodenal ulcer, gastric outlet obstruction can also occur in patients with type II or III gastric ulcer.[72] Surgery, consisting of antrectomy with pyloroplasty and vagotomy, is undertaken if the patient's condition does not respond to medical therapy.

Gastric Neoplastic Disease

Gastric cancer is the second most common type of cancer worldwide. In the United States, gastric cancer is the seventh most frequent cause of cancer-related death. Most gastric neoplasms are malignant. The incidence of these neoplasms according to type is adenocarcinoma, 95%; lymphoma, 4%; and leiomyosarcoma, 1%. The epigastric pain is similar to pain caused by benign ulcers and similarly may mimic angina. Typically, however, the pain is constant, nonradiating, and unrelieved by food ingestion. More advanced disease may present with weight loss, anorexia, fatigue, or vomiting. Symptoms often reflect the site of origin of the tumor. Endoscopic mucosal resection has become the treatment of choice for early gastric cancer (EGC), and usually is performed in association with endoscopic ultrasonography for staging. Advanced adenocarcinoma is defined as a tumor that invades the gastric wall beyond the submucosa. Most patients are men (male-to-female ratio of 2:1) in their fifth to seventh decades of life. Clinically, symptoms include epigastric pain, dyspepsia, anemia, and weight loss. Hematemesis and symptoms of gastric outlet obstruction are not uncommon. Female patients may develop metastatic ovarian lesions (Krukenberg tumors) composed of diffuse-type cancer cells. Unfortunately, the majority of patients with gastric cancer in the United States are diagnosed at an advanced stage.[78]

Surgical resection remains the primary curative treatment for gastric cancer and represents the best chance for long-term survival. In addition, surgical resection often provides the most effective palliation of symptoms, particularly those of obstruction. In general, total gastrectomy is performed for proximal gastric tumors and diffuse gastric cancer, and partial gastrectomy is reserved for tumors in the distal stomach. Despite increased morbidity and mortality, arguments in favor of an extended lymphadenectomy include the fact that removal of a larger number of lymph nodes

results in more accurate pathologic staging, and that failure to remove these lymph nodes leaves tumor behind in as much as one third of patients.[78]

Anesthetic Considerations in Gastric Disease

Despite advances in medical therapy designed to inhibit acid secretion and to eradicate *H. pylori*, surgery remains important in managing these patients. Patients undergoing surgery for gastric disease are generally either acutely ill and require emergency surgery, as in the case of a bleeding gastric ulcer, or stable and require elective surgical treatment of gastric carcinoma or intractable ulcer disease. Many procedures are performed laparoscopically. Limitations to the laparoscopic approach include the risk of peritonitis and dense adhesions. Acutely ill patients are more likely to be hemodynamically unstable and dehydrated. Elective surgical patients may have a variable degree of debilitation and anemia. Aspiration precautions in both groups are warranted during anesthesia.

Hypovolemia should be corrected with the administration of appropriate colloid, crystalloid, or blood products before the induction of anesthesia. Suggested laboratory tests include complete blood count, electrolytes, blood urea nitrogen, glucose, magnesium, calcium, phosphate, prothrombin time, and partial thromboplastin time. Other tests are performed based on history and physical examination. Preparations for the perioperative transfusion of blood products must be undertaken before anesthesia and surgery. Expect a moderate fluid shift with moderate to large fluid losses. Two large-bore intravenous catheters (14- to 16-gauge) are indicated.

Clinical anemia and coagulopathy should be corrected with packed red blood cells and appropriate blood products (e.g., FFP, cryoprecipitate, platelets). The use of invasive monitoring (i.e., that using a pulmonary artery catheter, central venous pressure line, or arterial line) is determined by the presence of preexisting, age-related, or acquired compromise in the function of other organ systems. Potential postoperative complications include hemorrhage, hypovolemia, hypothermia, atelectasis, and ileus. A postoperative stay in the intensive care unit may be necessary, especially in the case of peritonitis-caused fluid shifts and the need for large-volume fluid resuscitation.

The anesthetic technique used in gastrectomy may include preoperative epidural catheter placement as an intraoperative adjunct and for use in postoperative analgesia. Procedures other than total and partial gastrectomy performed for gastric disease include the following:

- Billroth I (gastroduodenostomy): resection of the distal stomach with reconstruction via end-to-end gastroduodenostomy
- Billroth II (gastrojejunostomy): resection of the distal stomach with reconstruction via end-to-side gastrojejunostomy
- Laparotomy with oversewing of the ulcer and application of an omental patch

Vagotomy is usually performed for gastric ulcer surgery to decrease gastric acid secretion and allow ulcer healing. The vagus nerve can be transected at the main vagal trunks (truncal), which interrupts transmission to the top of the stomach and other abdominal viscera, or selectively, in that only gastric vagal nerves are interrupted. Anesthetic technique is general or laparoscopic; esophageal dilators are used to facilitate traction on the stomach. A nasogastric (NG) tube is placed after induction.

Gastrostomy

Gastrostomy establishes a permanent or temporary artificial opening into the stomach that exits the skin of the abdominal wall and is surgically placed for the purpose of gastric decompression and nutritional support. Patients who require placement of a gastrostomy tube (permanent or temporary) are often neurologically incapacitated or otherwise markedly debilitated and are likely to have compromised command of their airway reflexes. This general finding, along with the need to insufflate the stomach, places the patient at greater risk for aspiration.

Gastrostomy placement is performed percutaneously at the bedside, in the endoscopy suite, or in the operating room. Endoscopic guidance is used with percutaneous placement of the gastrostomy tube. Any tube feedings should be stopped at least 8 hours prior to the procedure. A bite block should be used. As a primary procedure, gastrostomy placement is commonly undertaken with sedation and local anesthesia at the incisional site and in the back of the throat. General endotracheal anesthesia is indicated in patients who require laparotomy in conjunction with endoscopic placement and in those for whom percutaneous placement under local anesthesia with sedation may be contraindicated (e.g., the comatose patient). If general anesthesia is used, the endotracheal tube (ETT) may need to be held as the surgeon inserts and withdraws the gastroscope.

PANCREATIC DISEASE

Physiologic Overview

The pancreas is about 20 cm long, with its head tucked into the curve of the duodenum and its tail touching the spleen. The body lies behind the stomach. The pancreas functions in both an exocrine digestive enzyme and endocrine hormonal capacity.

The exocrine functions of the pancreas include protein secretion and electrolyte secretion. The exocrine function of the pancreas is primarily the continuous transductal secretion of 2.5 liters of clear, colorless, bicarbonate-rich (pH 8.3) pancreatic juice per day. The ionic composition consists largely of sodium, potassium, bicarbonate, and chloride, with smaller concentrations of phosphate, sulfate, zinc, and calcium. The principal function of pancreatic juice is duodenal alkalinization to promote optimal activity of pancreatic enzymes.

Arrival of acidic chyme (partially digested gastric contents) into the duodenum and jejunum stimulates the release of the hormones cholecystokinin-pancreozymin (CCK-PZ) and secretin. Both hormones are produced in the duodenum, jejunum, and ileum. Secretin causes the pancreas to release bicarbonate and water, and CCK-PZ, released in response to the presence of fats and partially digested proteins in the duodenum, stimulates elaboration of the pancreatic enzymes necessary for further intestinal digestive processes. Trypsinogen, produced by pancreatic cells, is converted to the active enzyme trypsin in response to the release of enterokinase by the gastric mucosa. Trypsin is responsible for the conversion of large ingested proteins into smaller peptides and amino acids in preparation for intestinal absorption.[34] The major pancreatic enzyme groups are listed in Table 30-11.

Secretion of the aqueous and enzymatic components of pancreatic juice is controlled by hormonal and parasympathetic stimuli. Administration of vagolytic agents (e.g., atropine, glycopyrrolate) or ganglionic blocking agents, along with physical interruption of the vagus nerve, may induce a decreased response to secretin. Vagotomy also has been shown to result in a decrease in the release of pancreatic bicarbonate in response to duodenal acidity.

The endocrine function of the pancreas consists primarily of regulation of the plasma glucose level through the release of glucagon and insulin. Endocrine cells of the pancreas reside in the islets of Langerhans, and the adult human pancreatic islet contains multiple types: the A (alpha) cell secretes glucagon, the B (beta) cell secretes insulin, the D (delta) cell secretes somatostatin (growth

TABLE 30-11 Major Pancreatic Enzyme Groups*

Enzyme Group	Enzyme, Proenzyme, or Precursor
Proteolytic	Trypsinogen (trypsin), chymotrypsinogen (chymotrypsin), procarboxypeptidase A (carboxypeptidase A), procarboxypeptidase B (carboxypeptidase B), proaminopeptidase (aminopeptidase), proelastase (elastase)
Amylolytic	α-Amylase
Lipolytic	Lipase, prophospholipase A_2 (phospholipase A_2), carboxylesterase lipase, procolipase (colipase)
Nucleolytic	Deoxyribonuclease, ribonuclease
Other	Trypsin inhibitor

*Precursor molecules are listed, with products in parentheses.

hormone–releasing inhibitory factor), which is responsible for controlling the plasma levels of both insulin and glucagon, and gastrin, whereas the D_2 (delta-2) cell secretes vasoactive intestinal peptide (VIP), and the PP (or F) cell secretes pancreatic polypeptide (PP).[79] The chief physiologic function of the endocrine pancreas might be starkly summarized as regulation of body energy (a role largely achieved by hormonal control of carbohydrate metabolism). Simply stated, insulin is the hormone of energy storage and glucagon the hormone of energy release. Insulin stores energy by decreasing blood glucose levels, increasing protein synthesis, decreasing glycogenolysis, decreasing lipolysis, and increasing glucose transport into cells (except beta cells, hepatocytes, and central nervous system cells). Glucagon releases energy by increasing blood glucose levels through stimulation of glycogenolysis, gluconeogenesis, and lipolysis.

α-Adrenergic sympathetic stimulation has been shown to be inhibitory to insulin secretion. β-Adrenergic sympathetic and cholinergic blockade are inhibitory to insulin secretion as well. Arterial hypoxemia, hypothermia, traumatic stress, and surgical stress all suppress insulin secretion through α-adrenergic stimulation. Insulin secretion is enhanced by parasympathetic vagal stimulation, β_2-adrenergic sympathetic activation, and cholinergic drug administration.

Anesthetic considerations in patients with derangements in pancreatic endocrine function, such as diabetes mellitus, are outside the scope of this chapter. The present discussion is directed toward anesthetic considerations germane to patients with inflammatory or neoplastic disease of the pancreas.

Acute Pancreatitis

The cause of pancreatitis is multifactorial. Common causes include alcohol abuse, direct or indirect trauma to the pancreas, ulcerative penetration from adjacent structures (e.g., the duodenum), infectious processes, biliary tract disease, metabolic disorders (e.g., hyperlipidemia and hypercalcemia), vascular and autoimmune causes, toxic causes, and certain drugs (e.g., corticosteroids, furosemide, estrogens, and thiazide diuretics). In industrialized nations, 80% of acute pancreatitis cases are caused by alcohol abuse or gallstones. Although 35% to 40% of attacks are induced by gallstones, only 3% to 7% of patients with gallstones develop pancreatitis. The incidence of gallstone pancreatitis is increased in white females older than 60 years and is highest among patients with small gallstones (less than 5 mm diameter). Severe acute pancreatitis (SAP) is associated with organ failure, local complications, prolonged intensive care stay, and mortality rates greater than 25%. In patients with SAP, the multiple organ dysfunction syndrome (MODS) is the main cause of death.[80]

Patients who have undergone extensive surgery involving mobilization of the abdominal viscera are at risk for development of postoperative pancreatitis, as are patients who have undergone procedures involving cardiopulmonary bypass. Patients who have received large doses of calcium intraoperatively, particularly after cardiopulmonary bypass, also have been shown to be at risk for development of postoperative pancreatitis.[81] Hypothetically, the pathophysiologic mechanism may involve a syndrome of induced autodigestion. In fact, acute pancreatitis is characterized as a severe chemical burn of the peritoneal cavity.

It is generally believed that acute pancreatitis is triggered by obstruction of the pancreatic duct and that the injury begins within pancreatic acinar cells. That injury is believed to include, and possibly be the result of, intraacinar cell activation of digestive enzyme zymogens, including trypsinogen. The pathophysiology of acute pancreatitis can be grouped into three phases. The first phase is characterized by the premature activation of trypsin in acinar cells. The second phase is the inflammatory response of the pancreas, which is disproportionate to the response of other organs to a similar insult. In the third phase, systemic activation of the immune system and remote organ dysfunctions occur.[80] Aberrant activation or release of pancreatic enzymes or injury to the acinar cells caused by one or more of the aforementioned etiologic factors produces a syndrome that results in hemorrhage, edema, and necrosis of the pancreas.

Enzymes implicated as major culprits in the syndrome of pancreatitis are those activated by trypsin, enterokinase, and bile acids. These enzymes are necessary for proteolysis, elastolysis, and lipolysis. The inappropriate elaboration of these enzymes results in pancreatic inflammation, which is caused by vascular breakdown, coagulation necrosis, fat necrosis, and parenchymal necrosis. Cardiovascular complications of acute pancreatitis can lead to pericardial effusions, alterations in cardiac rhythmicity, signs and symptoms mimicking acute myocardial infarction, thrombophlebitis, and cardiac depression. Acute pancreatitis also predisposes patients to the development of acute respiratory distress syndrome and disseminated intravascular coagulopathy.[6]

The pain of pancreatitis may be severe and difficult to control. Most patients require narcotic medications. Meperidine and its analogs are probably preferable to morphine in this setting because morphine can induce spasm of the sphincter of Oddi, which could, at least theoretically, worsen biliary pancreatitis. Pancreatic pain may radiate from the midepigastric to the periumbilical region and may be more intense when the patient is in the supine position. Abdominal distention is often seen and is largely attributable to the accumulation of intraperitoneal fluid and paralytic ileus. Nausea, vomiting, and fever are common symptoms. Hypotension is seen in 40% to 50% of patients and is attributable to hypovolemia secondary to the loss of plasma proteins into the retroperitoneal space. Acute renal failure secondary to dehydration and hypotension may occur.

Immediate circulatory and electrolyte resuscitation restores the microcirculation and represents one of the most powerful and effective interventions, especially in patients with severe acute pancreatitis. Fluid losses can be enormous and can lead to marked hemoconcentration as well as hypovolemia. Inadequate fluid resuscitation during the early stages of pancreatitis can worsen the severity of an attack and lead to subsequent complications. The fluid depletion that occurs in pancreatitis results from the additive effects of losing fluid both externally and internally. The external fluid losses are caused by repeated episodes of vomiting and worsen by nausea that limits fluid intake. Repeated vomiting can result in a hypochloremic alkalosis. Internal fluid losses, which are usually

even greater than the external losses, are caused by fluid sequestration into areas of inflammation (i.e., the peripancreatic retroperitoneum) and into the pulmonary parenchyma and soft tissues elsewhere in the body. These latter losses result from the diffuse capillary leak phenomenon that is triggered by proinflammatory factors released during pancreatitis. Total fluid losses may be so great that they lead to hypovolemia and hypoperfusion, and as a result, a metabolic acidosis can develop.[82]

In patients with severe acute pancreatitis, the magnitude of the proinflammatory response correlates with the severity and concomitant course of disease. A simple predictive tool is C-reactive protein (CRP). A CRP level exceeding 150 mg/L, a cutoff level that has been arbitrarily chosen, within the first 72 hours correlates with the occurrence of necrotizing pancreatitis and the degree of severity.[83]

During the first several days of a severe attack, circulating levels of many proinflammatory factors, including cytokines and chemokines, are elevated. This so-called cytokine storm, in many cases, triggers the systemic immune response syndrome, and as a result, the hemodynamic parameters of these patients may resemble those of sepsis associated with other disease states. Heart rate, cardiac output, and cardiac index usually rise, and total peripheral resistance falls. Hypoxemia also can occur as a result of the combined effects of increased intrapulmonary shunting and a pancreatitis-associated lung injury that closely resembles that seen in other forms of acute respiratory distress syndrome (ARDS). Fluid management, although critical, may be particularly difficult when hypovolemia is combined with the respiratory failure of ARDS.[82]

Severely ill, malnourished patients are often given parenteral nutritional support. Pain is controlled with synthetic opioids, such as fentanyl, which are preferable to morphine. Morphine-induced spasms of the Oddi sphincter may exacerbate bile obstruction and stasis. Normeperidine, the metabolite of meperidine, causes analeptic activity and makes meperidine unattractive for pain management in these patients. Epidural analgesia may be selectively appropriate.[82]

Patients with gallstone pancreatitis can be divided into two groups: those who have or have had gallbladder-derived problems (cholecystitis or biliary colic) and those whose only problems are purely related to stones in the biliary ductal system (i.e., cholangitis and pancreatitis). Patients in the first group undergo cholecystectomy because that operation will prevent additional gallbladder attacks as well as eliminate the source of stones that might trigger another attack of pancreatitis. Patients in the second group, however, do not necessarily require cholecystectomy because their problem relates only to ductal stones. Theoretically, they could be treated simply by endoscopic stone clearance combined with endoscopic sphincterotomy, so that future stones are passed without becoming impacted in the ampulla and triggering either pancreatitis or cholangitis. Indeed, for poor surgical risk patients, the endoscopic approach is generally recommended. Good surgical risk patients are better managed by cholecystectomy.

The choice of anesthetic technique and the extent to which monitoring modalities are used are based on an assessment of the patient's history, the severity of disease, and the degree of preexisting physical compensation. Special attention should be paid to correcting significant intravascular volume deficits. The presence of labile hemodynamics and altered hepatic function also must be discerned and appropriate modifications made to the anesthetic plan—for example, ensuring stable arterial pressure, using anesthetic agents and adjuvants that require minimal hepatic biotransformation, ensuring adequate oxygenation, and replacing electrolytes and blood volume.

Chronic Pancreatitis

Chronic pancreatitis is traditionally defined as having permanent and irreversible damage to the pancreas, with histologic evidence of chronic inflammation, fibrosis, and destruction of exocrine (acinar cells) and endocrine (islets of Langerhans) tissue. Chronic pancreatitis is believed to reflect repeated episodes of subclinical acute pancreatitis with unrecognized pancreatic necrosis evolving into pancreatic fibrosis.

The most common etiology of chronic pancreatitis is alcohol use (70% of cases), with the risk increasing logarithmically with increasing alcohol use. Other causes include tobacco use (increased risk of pancreatic calcifications), genetic mutation, autoimmune disease, and obstruction of the main pancreatic duct by tumors, scars, stones, or duodenal wall cysts.[84]

Chronic pancreatitis is strongly suggested by the classic diagnostic triad of steatorrhea, pancreatic calcification (evidenced radiographically), and diabetes mellitus. Steatorrhea does not occur until pancreatic lipase secretion is less than 10% of the maximum output. The most common clinical problem in chronic pancreatitis is abdominal pain causing loss of appetite that results in weight loss and malnutrition. The clinical picture may also include hepatic disease, as evidenced by jaundice, ascites, esophageal varices, derangements in coagulation factors, serum albumin, and transferase enzymes. A disturbance in pancreatic exocrine function, with consequent enzymatic insufficiency, results in malabsorption of fats and proteins in the intestine. Patients with chronic pancreatitis also have a predisposition for pericardial and pleural effusions.[82]

Many of the patients with chronic pancreatitis are alcoholics who, even before the onset of pancreatitis, had hypoalbuminemia and hypomagnesemia. Those problems are exacerbated by the losses of pancreatitis. The measured values for serum albumin may be even further depressed as fluid losses are treated with albumin-free crystalloid solutions. Although hypocalcemia is common, particularly during a severe attack, the low total serum calcium is usually attributable to the low levels of circulating albumin, and no treatment is needed when ionized calcium is normal. Occasionally, however, ionized calcium levels also may be depressed, and tetany as well as carpopedal spasm can occur. This necessitates monitoring the electrocardiogram (ECG) for cardiac rhythm disorders (e.g., lengthened QT interval with possible reentry dysrhythmias). Under those circumstances, aggressive calcium repletion is indicated.[82]

Endocrine insufficiency is another consequence of chronic pancreatitis and is especially common after pancreatic resection. About half of all patients with chronic pancreatitis develop insulin-dependent diabetes. Unlike type I diabetes, insulin-producing beta cells and glucagon-producing alpha cells are injured, leading to an increased risk of prolonged and severe hypoglycemia with overzealous insulin treatment.[84]

Pancreatic abscesses develop from infected peripancreatic collections of fluid. Abscesses are usually secondary manifestations of chronic pancreatitis and warrant surgical drainage to prevent spread of the infectious contents to the subphrenic and pericolic spaces. Fistula formation is possible, particularly into the transverse colon. Severe intraabdominal hemorrhage is also possible as a result of erosion into major proximal arteries.

Pancreatic Pseudocysts

Most pseudocysts communicate with the pancreatic ductal system and contain a watery fluid that is rich in pancreatic digestive enzymes. Typically, patients with pseudocysts have persistent elevations of circulating pancreatic enzymes. Recent reports have

shown that many pseudocysts eventually resolve without complications and that intervention is not mandatory in all cases unless the pseudocysts are symptomatic, enlarging, or associated with complications. The likelihood that a pseudocyst will resolve spontaneously, however, is dependent on its size. Large pseudocysts (i.e., greater than 6 cm in diameter) are more likely to become symptomatic either because they are tender or because of their mass effect on adjacent organs. Those that compress the stomach or duodenum may cause gastric outlet obstruction with nausea and vomiting. Those that reduce the capacity of the stomach frequently cause early satiety, whereas those impinging on the bile duct can cause obstructive jaundice. Pancreatic pseudocysts that erode into a neighboring vessel can result in formation of a pseudoaneurysm with *hemosuccus pancreaticus* and upper gastrointestinal bleeding.

Most patients who develop symptomatic pseudocysts are best managed by pseudocyst drainage. Internal drainage can be accomplished either endoscopically (by transpapillary drainage, cystogastrostomy, or cystoduodenostomy) or surgically (by cystogastrostomy, cystoduodenostomy, or Roux-en-Y cystojejunostomy). The approach chosen depends primarily on the locally available expertise as well as the location of the pseudocyst, but endoscopic drainage may be preferable in poor surgical risk patients.

Surgical Therapy for Pancreatitis

Depending on the cause of pancreatitis, several surgical approaches can be made. Endoscopic therapy is used to improve drainage of the pancreatic duct. This can be done through pancreatic duct sphincterotomy, stent placement, or pancreatic duct stone removal (including extracorporeal shock wave lithotripsy [ESWL]). Open surgical therapy in chronic pancreatitis is most often considered for intractable abdominal pain for which medical therapy has failed, complications involving adjacent organs, failure of endoscopic management of pseudocysts, and internal pancreatic fistulas.

Surgical drainage of a pancreatic pseudocyst is usually undertaken after a period of maturation of the cyst (usually 6 weeks with acute pancreatitis). Pseudocysts with chronic pancreatitis are generally mature at the time of diagnosis, and delay is not necessary to allow for maturation. The procedure consists of formation of a cystogastrostomy, cystojejunostomy, cystoduodenostomy, or possibly distal pancreatectomy. The location of the pseudocyst dictates the extent and type of procedure used for providing drainage of cystic contents into the gastrointestinal tract. Percutaneous external drainage, guided by CT, is reserved for cases in which the pseudocyst is particularly friable.[85]

Pancreatic Tumors

Pancreatic cancer affects 25,000 to 30,000 people in the United States each year, occurs more often in men than in women, and is more common among blacks than whites. The generation most commonly associated with pancreatic cancer is between 60 and 80 years of age (80%), whereas less than 2% occur in people younger than 40 years. Other risk factors include a family history of pancreatic cancer or a history of either hereditary or chronic pancreatitis, cigarette smoking, and occupational exposure to carcinogens. The incidence of diabetes mellitus is increased in patients with pancreatic cancer, but some studies have indicated that diabetes is a risk factor for the development of pancreatic cancer, whereas others have argued that diabetes may be a manifestation of the cancer. Coffee drinking, which was once considered a risk factor, is no longer thought to play a role in the development of pancreatic cancer.[82]

Eighty to ninety percent of all pancreatic tumors can be accounted for by ductal adenocarcinoma, and an even greater percentage of the malignant tumors are ductal adenocarcinoma. Most ductal cancers (70%) arise in the pancreatic head or uncinate process. They are generally resected by pancreaticoduodenectomy, with or without preservation of the pylorus and proximal duodenum. Ductal cancers originating in the body or tail of the pancreas are often larger and more likely to have spread before their presence is known.[82]

Pancreatic cancers are insidious tumors that can be present for long periods and grow extensively before they produce symptoms. Once symptoms appear, they are determined by the location of the tumor in the pancreas. Those in the head or uncinate process of the pancreas cause bile duct, duodenal, or pancreatic duct obstruction. Because the head of the pancreas is most often the locus of the tumor, biliary obstruction is likely, resulting in progressive painless jaundice. The patient may have symptoms that are vague and nonspecific and include dull, aching, midepigastric or back pain. Anorexia and fatigue are often present and are associated with weight loss. Other symptoms include unexplained episodes of pancreatitis, nausea, vomiting, and steatorrhea. If the tumor spreads beyond the pancreas, peripancreatic nerve plexuses may cause abdominal or back pain. In the presence of peritoneal carcinomatosis or portal vein occlusion, ascites may occur. New-onset diabetes mellitus is occasionally the first symptom of an otherwise occult pancreatic cancer. Recent studies have suggested that this form of diabetes may be mediated by a factor released from the tumor that either inhibits insulin release from islets or induces peripheral insulin resistance. Unexplained migratory thrombophlebitis (Trousseau's syndrome) may be associated with pancreatic and other types of malignancy. It is probably a paraneoplastic phenomenon that results from a tumor-induced hypercoagulable state.[82]

Laboratory studies usually show elevated bilirubin and alkaline phosphatase levels. Radiographic evidence is generally nonspecific; needle biopsy during CT is most helpful in achieving diagnosis. Percutaneous transhepatic cholangiography and endoscopic retrograde cholangiopancreatography are useful diagnostic modalities. Endoscopic retrograde cholangiopancreatography is the most useful modality for defining lesions of the body and tail of the pancreas or of the duodenum and ampulla.[85]

Insulinoma is the most common functioning tumor of the pancreas, and affected patients have a multitude of symptoms referable to hypoglycemia including seizures and coma (symptoms of catecholamine release), mental confusion and obtundation, or both. Hypersecretion of insulin is a major manifestation of this disease and results in profound hypoglycemia. The diagnostic hallmark of the syndrome is the so-called Whipple triad, namely, symptoms of hypoglycemia (catecholamine release) and low blood glucose (40-50 mg/dL) and relief of symptoms after the IV administration of glucose.

Treatment of insulinoma is surgical and performed by either open or laparoscopic approaches except in patients with advanced metastatic disease, and involves distal pancreatectomy, subtotal pancreatectomy, or removal of all but a small portion of pancreatic tissue around the rim of the duodenum (Child procedure).[85]

If neoplastic disease is determined to be respectable, that is, without involvement of mesenteric vessels or infiltration into the mesenteric arterial root or hepatobiliary structures, a pancreaticoduodenectomy (Whipple procedure) may be performed. This

procedure involves excision of the head of the pancreas, the entire duodenum, the proximal portion of the jejunum, the distal third of the stomach, the gallbladder, and the distal half of the common bile duct. A Whipple procedure also can be performed for malignancies of the common bile duct, traumatic injury to the pancreas, or benign obstructive chronic pancreatitis.[86]

Zollinger-Ellison syndrome (ZES; gastrinoma), a neoplasm primarily arising from the duodenum, releases overabundant quantities of gastrin, resulting in the secretion of massive quantities of hydrochloric acid from the parietal cells. This condition is associated with severe, intractable ulcer pain. If other endocrine neoplasias are present (i.e., thyroid or parathyroid adenoma, pituitary adenoma, insulinoma), the condition is referred to as *multiple endocrine neoplasia type I*.

Omeprazole therapy is so effective that surgery is performed only for tumor removal, and every patient with ZES is a candidate for a tumor removal operation until proved otherwise because of systemic illness or widespread metastases. Although gastrinomas have a high rate of malignancy, they are more apt to be cured than cancer of any other abdominal viscera. During anesthetic induction for excision of gastrinoma, a rapid-sequence technique is recommended because of the likelihood of a large volume of stagnant, acidic intragastric fluid. Electrolyte and intravascular volume derangements (e.g., from severe diarrhea) should be anticipated and corrected before surgery. Attention also should be given to intraoperative monitoring of electrolyte and fluid balance. Hypokalemia and metabolic alkalosis are likely to be present if the patient has been vomiting and is dehydrated. Furthermore, preparations for the treatment of patients with known or suspected derangements in endocrine function must be included in the anesthetic plan, to include blood glucose monitoring, vigilance for and timely correction of swings in vital signs and physiologic parameters, maintenance of normothermia and normocarbia, maintenance of an appropriately anesthetized state, and maintenance of renal function.[34]

Gastrinoma is the second most common islet cell tumor and is the most common symptomatic, malignant endocrine tumor of the pancreas. Having said that, current information is that gastrinomas in the duodenum are 3 to 10 times more common than in the pancreas, and although up to 70% of duodenal gastrinomas have lymph node metastases, only 5% have liver metastases. Although gastrinomas have a high rate of malignancy, they are more apt to be cured than cancer of any other abdominal viscera.

Anesthetic Considerations in Pancreatic Disease

The patient undergoing surgical treatment of pancreatic disease exhibits a variable clinical picture, from jaundiced and stable with a painless pancreatic mass to severely ill with multiorgan system involvement. Patients may have severe, acute abdominal pain with possible intestinal obstruction or ileus. Aspiration precautions should be in effect during induction of anesthesia and emergence from anesthesia, and an NG tube should be placed after induction. Because these patients are likely to be diabetic (secondary to beta-cell dysfunction) or hypoglycemic (as in the case of insulinoma), perioperative assessment of serum glucose and institution of appropriate control measures are warranted. Patients with pancreatitis are usually hypotensive and hypovolemic. As such, aggressive blood product and crystalloid resuscitation may be necessary throughout the perioperative period and likely will necessitate placing invasive hemodynamic lines to guide therapy and monitor central pressures.

Severe electrolyte disorders may be present and include hypocalcemia, hypomagnesemia, hypokalemia, and possibly hypochloremic metabolic alkalosis. The serum hematocrit value may be falsely increased secondary to hemoconcentration, or it may be decreased secondary to the presence of a bleeding diathesis. Coagulation parameters, including platelet count, prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen level, should be assessed at regular intervals perioperatively. Preserving renal function mandates the preoperative assessment of blood urea nitrogen, serum creatinine, and 24-hour creatinine clearance (if possible); urinalysis also should be performed. Intraoperatively, a urine output of at least 0.5 to 1 mL/kg/hr should be maintained.

Thorough assessment of preexisting pulmonary status is vital. Pleural effusions, $\dot{V}/\dot{Q}$ mismatching, and atelectasis may be seen and can progress to respiratory failure. A significant incidence of postoperative respiratory morbidity is associated with upper abdominal surgery, especially in association with a preoperative debilitated state and splinting secondary to pain. Pulmonary assessment includes arterial blood gas analysis, chest radiography, and pulmonary function tests when appropriate.

Cardiovascular assessment should assimilate related findings from the assessment of other organ systems so that the degree to which functional hemodynamic impairment may need to be corrected is fully appreciated. Correction of preexisting hemodynamic disturbances entails restitution of plasma volume and the oxygen-carrying capacity of the blood. Ischemic changes noted on the ECG must be treated promptly. ECG changes mimicking myocardial ischemia are often seen in those with pancreatitis.[34]

The celiac plexus transmits visceral afferent impulses from the upper abdominal organs, including the pancreas. Celiac plexus block may be performed in patients with chronic pancreatitis, but its effects are short-lived. A combination of glucocorticoid and long-acting local anesthetic such as bupivacaine are commonly used. Celiac plexus neurolysis also may be performed using an injection of absolute alcohol and administered under CT or ultrasound guidance.[84]

Pancreatectomy

Pancreatectomy is performed for a variety of reasons including ductal obstruction, pancreatic stones or cysts, trauma, benign or malignant tumors, chronic pancreatitis, and endocrine tumors. Complete surgical excision is the only definitive treatment of ductal pancreatic cancer.

In a partial pancreatectomy, part of the pancreas, the duodenum, the gallbladder, and part of the bile duct are removed. The tail of the pancreas is joined to a portion of the small bowel. In a total pancreatectomy, the distal portion of the stomach, the gallbladder, part of the bile duct, the spleen, and the surrounding lymph nodes are removed. The remaining distal portion of the stomach is reanastomosed to a portion of the small intestine.[86]

General endotracheal anesthesia is preferred for pancreatectomy, and muscle relaxants are used. The presence of increased intraabdominal pressure requires a rapid sequence induction. The use of nitrous oxide should be avoided because of expansion of air-filled spaces in the bowel. An epidural is advised with a level of T9 to T10 for postoperative pain control because it seems to improve the surgical outcome.[87] An even better choice may be the use of intrathecal morphine. One study also showed that intrathecal morphine for major hepato-pancreato-biliary surgery is associated with a lower incidence of postoperative hypotension, reduced perioperative intravenous fluid requirement, and shorter hospital stay compared with thoracic epidural anesthesia.[88]

Patients undergoing extensive pancreatic surgery often require postoperative ventilatory support and intensive care unit

monitoring because of the magnitude and length of the procedure, as well as the patient's preexisting cardiopulmonary status.[34] Pancreatic transplants are discussed later in this chapter.

DISEASES OF THE INTESTINAL TRACT

Anatomic and Physiologic Overview of the Small Intestine

The overall length of the small intestine is between 5 and 7 meters and extends from the pylorus to the ileocecal valve. The small intestine is divided into three functional anatomic and physiologic segments. The first segment, the duodenum, begins at the pylorus and has a length of approximately 20 cm. The duodenum joins the second segment, the jejunum, which has a length of approximately 100 to 110 cm, at a suspensory ligament called the treitz ligament. The third and longest segment of the small intestine is the ileum, which has a length of approximately 150 to 160 cm and ends at the ileocecal valve. The jejunum has a larger lumen and is thicker than the ileum with a less extensive blood supply (one or two vascular networks versus four or five in the ileum).[89]

The mesentery, which is rich in lymphatics and blood vessels, is a peritoneal membrane that tethers the ileum and jejunum to the posterior abdominal wall and facilitates intestinal motility. Branches of the superior mesenteric artery provide the primary arterial supply to the jejunum and ileum and to the proximal transverse colon. Venous drainage is primarily furnished by the superior mesenteric vein. This vessel joins the splenic vein posterior to the pancreas, and empties into the portal circulation to the liver. Lymphatic drainage from the bowel wall originates from the central bowel wall lacteal and continues through the superior mesenteric nodes into the cisterna chyli and ultimately drains into the thoracic duct.

The wall of the small intestine is composed of the mucosa, submucosa, muscular layer (muscularis), and serosa. The serosal outermost layer is composed of visceral peritoneum. This layer is formed in the jejunum, ileum, and anterior duodenum and is analogous to the pericardium and pleura that surround the heart and lungs, respectively. There is fluid containing space between the visceral peritoneum and the parietal peritoneum, which aids in lubricating for organ movement. The muscular layer is made up of an outer longitudinal layer and a thin circular layer of smooth muscle, both continuously present along the length of the small intestine. The Auerbach (myenteric) plexus, which primarily controls gross gastrointestinal motility, lies between the two muscular layers. The strongest component of the bowel wall is the submucosa, which consists of fibroelastic connective tissue. Within it lies the Meissner plexus, which controls local blood flow and gastrointestinal secretions. The innermost layer, the mucosa, is composed of transverse folds with millions of villi. These intraluminal projections are the functional units of the intestines and greatly increase the absorptive surface.

The mucosa is further subdivided into three distinct layers:

1. *Muscularis mucosae*. The deepest layer, composed of a thin muscular sheet.
2. *Lamina propria*. A continuous connective tissue layer between the muscularis mucosae and the epithelium. This layer serves as a support epithelium and immunogenic barrier. Constituents of this layer include plasma cells (which produce immunoglobulins), macrophages, and lymphocytes.
3. *Epithelial layer*. Covers the villi and lines the Lieberkühn crypts. The functional units of the intestines, villi, contain goblet (mucus-secreting), absorptive, and endocrine cells. The villi also secrete enzymes necessary for digestion and are useful in nutrient absorption. Cell turnover takes 3 to 7 days.

The intestinal mucosa provides a barrier to the entry of pathogens. The lamina propria provides a rich reservoir of IgA (the secretory immunoglobulin) and plasma cells (responsible for synthesis of IgA). IgA antigen binding initiates mucus secretion, which prevents intestinal bacterial and viral uptake. Furthermore, IgA binds with, disables, and facilitates enzymatic destruction of bacteria. Binding with and preventing entry of toxins is another role of IgA. Lymphocytes, which are instrumental in the elaboration of a specific antibody to a given antigen, are found in Peyer patches, which are located in the intestinal wall.[90]

An additional function of small intestinal mucosa is the production of a rich supply of hormones that regulate gastrointestinal function (Table 30-12).

Both divisions of the autonomic nervous system innervate the small intestine, but innervation is primarily parasympathetic through the vagus nerve and celiac ganglia. Parasympathetic stimulation is responsible for pain sensation, increased motility, secretion, and intestinal reflexes (e.g., relation of the lower esophageal sphincter). Splanchnic nerves from the celiac plexus provide sympathetic innervation, the activation of which inhibits motility and produces vasoconstriction. Sympathetic nerve tracts are also responsible for carrying afferent pain impulses. Intrinsic motor innervation is mediated by the myenteric plexus (Auerbach plexus) and the submucosal plexus (Meissner plexus). The enteric nervous system also plays an important role in the gastrointestinal tract. The enteric nervous system is the network of neurons found within the walls of the gastrointestinal tract, including neurons in the pancreas and gallbladder. The enteric nervous system contains as many nerve cells as the spinal cord, and is unique in its extraordinary degree of local autonomy. The high degree of local autonomy allows digestion and peristalsis to continue in the event of spinal cord transection or spinal anesthesia. Spinal anesthetic inhibition of sympathetic preganglionic fibers from T8 through L3 yields a contracted small intestine that may afford superior surgical conditions.

The intestinal inhibitory reflex responds to abnormal distention by decreasing motility proximal to the locus of distention. This reflex may have significant indirect clinical implications (e.g., aspiration risk).[90] Physiologic functions of the small intestine are summarized in Box 30-9.

Chyme from the stomach stimulates intestinal movements that mix in secretions from the liver, pancreas, and intestinal glands. A basic electrical rhythm in the longitudinal smooth muscle layer initiates action potentials in the circular muscular layers of the small intestine. This activity sets forth the muscular contractions that constitute small-bowel motility. Both segmental contractions, which mix chyme with digestive enzymes and expose it to the villi's absorptive surfaces, and peristaltic (propulsive) contractions to move chyme toward the large intestine are present.

Malabsorption Syndromes

The two most important goals of the small intestine are the efficient absorption of nutrients and maintaining the movement of chyme and indigestible substances along the small intestine. Approximately 85% to 90% of the water entering the gastrointestinal tract is absorbed in the small intestines. Malabsorption syndromes interfere with nutrient absorption in the small intestine through mucosal disruption. Numerous disorders of the small intestine manifest as derangements in absorption. Primary clinical signs include unexplained weight loss, steatorrhea, and diarrhea. These disorders affect the absorption of the major constituents of ingested nutrients, including amino acids, carbohydrates, and fats.[6]

TABLE 30-12 Gastrointestinal Hormones

Hormone	Location	Major Stimulants of Peptide Secretion	Primary Effects	Diagnostic and Therapeutic Uses
Gastrin	Antrum, duodenum (G cells)	Peptides, amino acids, antral distention, vagal and adrenergic stimulation, gastrin-releasing peptide (bombesin)	Stimulates gastric acid and pepsinogen secretion; stimulates gastric mucosal growth	Gastrin analog (pentagastrin) used to measure maximal gastric acid secretion
Cholecystokinin (CCK)	Duodenum, jejunum (I cells)	Fats, peptides, amino acids	Stimulates pancreatic enzyme secretion; stimulates gallbladder contraction; relaxes sphincter of Oddi; inhibits gastric emptying	Biliary imaging of gallbladder concentration
Secretin	Duodenum, jejunum (S cells)	Fatty acids, luminal acidity, bile salts	Stimulates release of water and bicarbonate from pancreatic ductal cells; stimulates flow and alkalinity of bile; inhibits gastric acid secretion and motility and inhibits gastrin release	Provocative test for gastrinoma; measurement of maximal pancreatic secretion
Somatostatin	Pancreatic islet (D cells), antrum, duodenum	Gut: Fat, protein, acid, other hormones (e.g., gastrin, CCK) Pancreas: Glucose, amino acids, CCK	Universal "off" switch; stimulates release of all GI secretion and motility; stimulates gastric acid secretion and release of antral gastrin; stimulates growth of intestinal mucosa and pancreas	Treatment of carcinoid; diarrhea and flushing; decreases secretion from intestinal fistulas (particularly pancreatic fistulas); ameliorates symptoms associated with hormone-overproducing endocrine tumors; treatment of esophageal variceal bleeding
Gastrin-releasing peptide (mammalian equivalent of bombesin)	Small bowel	Vagal stimulation	Universal "on" switch; stimulates release of all GI hormones (except secretin); stimulates GI secretin; stimulates growth of intestinal mucosa and pancreas	
Gastric inhibitory polypeptide	Duodenum, jejunum (K cells)	Glucose, fat, protein adrenergic stimulation	Inhibits gastric acid and pepsin secretion; stimulates pancreatic insulin release in response to hyperglycemia	
Motilin	Duodenum, jejunum	Gastric distention, fat	Stimulates upper GI tract motility; may initiate the migrating motor complex	
Vasoactive intestinal peptide	Neurons throughout GI tract	Vagal stimulation	Primarily functions as a neuropeptide; potent vasodilator	
Neurotensin	Small bowel (N cells)	Fat	Stimulates pancreatic and intestinal secretion; inhibits gastric acid secretion; stimulates growth of small and large bowel mucosa	
Enteroglucagon	Small bowel (L cells)	Glucose, fat	Glucagon-like peptide-1: stimulates insulin release; inhibits pancreatic glucagon release; Glucagon-like peptide-2: potent enterotropic factor	
Peptide YY	Distal small bowel, colon	Fatty acids, CCK	Inhibits gastric and pancreatic secretions; inhibits gallbladder contraction

CCK, Cholecystokinin; *GI*, gastrointestinal.

Fat malabsorption results in deficiency in the uptake of fat-soluble vitamins (vitamins A, D, E, and K). Deficiency in vitamin K manifests through hypoprothrombinemia. This condition is often evidenced through bleeding dyscrasias. Vitamin B_{12} deficiency results in anemia (which also may be encountered in patients with impaired iron absorption), neuropathy, and glossitis. Protein malabsorption may result in the development of peripheral edema and ascites. Tetany, osteomalacia, and pathologic fractures result from calcium deficiency caused by vitamin D malabsorption and calcium malabsorption because fatty acids bind calcium. In the setting of steatorrhea, pancreatic replacement enzymes are often effective in decreasing fat loss.[72]

The cause of malabsorption syndromes is multifactorial. The basic underlying defect is either disruption of intestinal mucosal

BOX **30-9**

Synopsis of Physiologic Functions (Digestion and Absorption) of the Small Intestine

Protein
- Initiated in the stomach
- Completed in the duodenum and jejunum; further hydrolysis (via intracellular peptidases) of peptides to free amino acids occurs before entry into the portal vein (approximately 90% of intact peptides)

Carbohydrates
- Initiated by salivary amylase
- Digested by pancreatic amylase in the duodenum; absorption completed by brush border of the intestinal microvilli (through conversion of monosaccharides into absorbable hexoses)

Fats
- Digestion and absorption of lipid (primarily triglycerides) occurs almost entirely in the small intestine by two processes:
  - Lipolysis
  - Formation of micelles
- Facilitated by pancreatic bicarbonate and bile salts

Water and Electrolytes
- 10 L of water enters small bowel daily; most of this volume is absorbed
- Net absorption of water facilitated primarily via osmosis; another mechanism involves passive diffusion through luminal pores under the influence of hydrostatic pressure
- Sodium absorption occurs essentially in conjunction with bulk flow of water (primarily in the jejunum); this process occurs with concomitant hydrogen ion extrusion
- Bicarbonate secretion and chloride ion absorption occur in conjunction with sodium absorption
- Electrical neutrality is maintained
- Calcium ion absorption (facilitated by an acidic environment) occurs primarily in the duodenum and jejunum via active transport; enhanced by vitamin D and parathyroid hormone
- Passive potassium absorption occurs primarily in the jejunum
- Absorption of iron occurs primarily in the duodenum

Other Vitamins and Minerals
- Ascorbic acid—absorbed in the ileum and coupled to sodium
- Cobalamin (vitamin B_{12})—absorbed in the distal ileum and linked to glycoprotein carrier molecules (especially intrinsic factor)
- Folate—absorbed in the proximal jejunum in conjunction with sodium
- Biotin—absorbed in the proximal small bowel as a result of sodium-linked active transport
- Thiamine (vitamin B_1)—absorbed predominantly in the duodenum
- Vitamin B_6—absorbed in the proximal small bowel
- Niacin, pantothenate, and riboflavin—absorbed passively (mechanism incompletely understood)

Modified from McKenzie S, Evers BM. Small intestine. In: Townsend CM, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 19th ed. Philadelphia: Saunders; 2012.

integrity, such as from disease processes, or loss of absorptive surface area caused by extensive surgical resection of the small intestine (i.e., short gut syndrome). With regard to alterations in small-intestine absorption secondary to surgical resection, the particular part of the small bowel resected and the amount removed have a significant bearing on the degree to which deficiencies in minerals, vitamins, and electrolytes are clinically manifested and of concern to the anesthetist.

Maldigestion Syndromes

Maldigestion syndromes are generally caused by failure of the chemical processes of digestion that take place in the intestinal lumen or at the brush border of the intestinal mucosa. The most common causes include pancreatic, lactase, or bile salt deficiency. Diseases more likely to result in malabsorption syndromes (failure to absorb and transport digested nutrients) may be differentiated from those responsible for maldigestion (failure of the chemical digestive process). The hallmark of maldigestion is steatorrhea. Significant pancreatic disease is usually present when a maldigestion syndrome exists, because the pancreas has a large functional reserve in both normal and disease states. Chronic pancreatitis is the major and most common cause of pancreatic insufficiency. Cystic fibrosis, fistulas, gallstones, ischemic enteritis, and neoplastic disease processes, however, are also etiologic factors.[90]

Anatomic and Physiologic Considerations of the Large Intestine

The large intestine is approximately 3 to 5 feet long, consists of the cecum, appendix, colon, rectum, and anal canal, and may be recognized not only by its size and position but also by the presence of three strips of longitudinal muscle called *teniae coli* and the numerous outpouchings (haustrations) formed by the circular muscles of the colon. The arterial supply comprises the superior mesenteric artery (which perfuses the right side of the midtransverse colon), the inferior mesenteric artery (which perfuses the midtransverse colon to the superior rectum), and the internal iliac artery (which perfuses the middle and lower rectum). Venous drainage parallels arterial drainage, with the middle and superior veins contributing to the portal venous system. The myenteric plexus regulates motor and secretory activity independently of the extrinsic system. Sympathetic innervation is derived from T10 to T12 (right colon), L1 to L3 (left colon), and the presacral nerves arising within the preaortic plexuses (rectum). Parasympathetic innervation is primarily from the vagus nerve (right and transverse colon) and from nerve fibers arising from S2 to S4 (descending colon, sigmoid colon, and rectum). A rich endowment of lymphatics is present throughout the length of the colon and rectum.[34]

The primary function of the large colon is to store and expel waste products. Approximately 500 to 700 mL of chyme are delivered from the ileum to the cecum each day. Another function performed largely in the right colon is the absorption of sodium and water. All but 100 to 200 mL of the 1 to 2 L of ileal effluent presented to the large colon per day is reabsorbed through diffusion and active transport.

Sodium absorption occurs through active transport against a gradient and is enhanced by minerals, corticoids, glucocorticoids, and fatty acids that are produced by indigenous bacteria. Conservation of sodium is so efficient in the large colon that a normal individual may require only 5 mEq/day in order to remain in sodium balance. However, a patient presenting with an ileostomy necessitates a greater intake of sodium (80 to 100 mEq/day) to approximate the high sodium content lost as ileal effluent. The

loss of the normal colonic reabsorption of sodium chloride and water (e.g., after colectomy) may eventually exceed the small intestine's compensatory capacity to increase absorption, and clinical derangements in electrolyte balance follow.

Potassium is passively absorbed and secreted across the electrochemical gradient, whereas chloride is absorbed as the complementary ion to sodium and in exchange for bicarbonate. Potassium is lost through passive diffusion in the colonic mucoid secretions. Significant potassium loss is likely to occur, therefore, in the presence of colitis and villous adenoma, two disease processes notable for mucoid stools.

Inflammatory Bowel Disease

In the United States, about 1 million individuals have inflammatory bowel disease, and approximately 30,000 new cases are diagnosed each year.[91] The two major types of inflammatory bowel disease are Crohn's disease and ulcerative colitis, which have different clinical features and manifestations (Table 30-13).

Crohn's disease can involve any part of the gastrointestinal tract from the mouth to the anus but most commonly it affects the distal ileum and proximal large colon. Th1-mediated inflammation with activation of leukocytes and cytokines causes injury. Involved leukocytes subsequently release proinflammatory substances including prostaglandins, leukotrienes, proteases, and nitric oxide with resulting injury. Progression of the disease leads to neutrophil infiltration of the crypts with resulting abscess formation and crypt destruction. Symptoms of Crohn's disease may initially be described as irritable bowel. Abdominal pain and diarrhea are the most common signs (more than five stools per day), with passage of blood and mucus. If the ileum is involved, patients may have right lower quadrant tenderness, and the individual may be anemic due to decreased vitamin B_{12} absorption.

The deeper layers of the intestinal mucosa are typically involved, a situation that leads to derangements in colonic absorption. Owing to the loss of functional absorptive surfaces in the large colon, patients with Crohn's disease are often deficient in magnesium, phosphorus, zinc, and potassium. They also have deficiencies secondary to the loss of absorptive capability in portions of the small intestine. Protein-losing enteropathy is often encountered, as is anemia resulting from occult blood loss and deficiencies in vitamin B_{12} and folic acid. Disturbance in the enterohepatic circulation of bile in the terminal ileum is reflected in complex nutrient deficiencies, including proteins, zinc, magnesium, phosphorus, fat-soluble vitamins, vitamin D, calcium (leading to bone disease), and vitamin B_{12}. This state is typical of patients with chronic Crohn's disease. Folate deficiency also may be present in patients who receive sulfasalazine preparations.

Fistulas often develop between inflamed portions of the intestine and adjacent abdominal structures. Abdominal and pelvic abscesses, rectocutaneous fistulas, and perirectal abscesses have a high incidence in these patients. Increased calcium oxalate absorption in the terminal ileum frequently occurs, resulting in a high rate of renal calculi and cholelithiasis.[92,93] Medical therapy for Crohn's disease includes a variety of drugs and is given in Box 30-10.

Surgery is performed when medical treatment fails or when complications supervene. Although effective in the relief of complications, surgical resection of the diseased colon and ileum does not alter the progression of the disease. The primary goal of surgical management is to limit the operation to the correction of the presenting complication, which could include bowel obstruction, fistulas, abscesses, perforation, and symptoms that indicate widespread symptomatic disease (for which total colectomy and ileal resection may be warranted). Surgical resection of small intestinal segments can lead to short bowel syndrome, with accentuated complications of malabsorption, diarrhea, and nutritional deficiencies.

Most patients with Crohn's disease eventually undergo surgery, and a large number require repeat or continued procedures. The recurrence rate at 10 years after surgery is 50%. A high likelihood of repeat surgery involves areas of the remaining bowel proximal

TABLE 30-13 Diagnosis of Crohn's Colitis Versus Ulcerative Colitis

Observation	Crohn's Colitis	Ulcerative Colitis
Symptoms and Signs		
Diarrhea	Common	Common
Rectal bleeding	Less common	Almost always
Abdominal pain (cramps)	Moderate to severe	Mild to moderate
Palpable mass	At times	No (unless large cancer)
Anal complaints	Frequent (>50%)	Infrequent (<20%)
Radiologic Findings		
Ileal disease	Common	Rare (backwash ileitis)
Nodularity, fuzziness	No	Yes
Distribution	Skip areas	Rectum extending upward and continuously
Ulcers	Linear, cobblestone, fissures	Collar-button
Toxic dilation	Rare	Uncommon
Proctoscopic Findings		
Anal fissure, fistula, abscess	Common	Rare
Rectal sparing	Common (50%)	Rare (5%)
Granular mucosa	No	Yes
Ulceration	Linear, deep, scattered	Superficial, universal

BOX 30-10

Agents Used to Treat Crohn's Disease

5-Aminosalicylate Acids (5-ASAs)
- Sulfasalazine
- Sulfa-free (mesalamine, olsalazine, balsalazide)

Antibiotics
- Metronidazole
- Ciprofloxacin

Glucocorticoids
- Classic
- Novel (controlled ileal-release budesonide)

Immune Modulators
- 6-Mercaptopurine, azathioprine
- Methotrexate
- Cyclosporine

Biologic Response Modifiers
- Infliximab

From Sands BE. Crohn's disease. In: Feldman M, et al, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 9th ed. Philadelphia: Saunders; 2010:1960-1970.

to the area of a previous anastomosis. Patients with a long history of Crohn's disease are also shown to have a higher risk of intestinal carcinoma.[94]

Ulcerative colitis (UC) is a chronic inflammatory disease that causes ulceration of the colonic mucosa and extends proximally from the rectum into the colon. It is a disease characterized by remissions and exacerbations. UC is more prevalent in females and white populations and has a peak incidence between ages 20 and 40 years. The disorder is speculated to have a strong familial genetic predisposition, but psychological factors have also been implicated in its cause. UC lesions are limited to the mucosa and are not transmural. Inflammation begins at the crypt of Lieberkühn with infiltration and release of inflammatory cytokines from neutrophils, lymphocytes, plasma cells, macrophages, eosinophils, and mast cells.[95]

Symptoms usually include abdominal pain, fever, and bloody diarrhea. Loss of absorptive mucosal surface and decreased colonic transit time can lead to large volumes of watery diarrhea. Ulcerative colitis is typically chronic with periods of remission and exacerbation. Ulcerative colitis has relatively low-grade symptoms, such as bloody stools with purulent mucus, malaise, diarrhea, and pain. In approximately 15% of patients, however, ulcerative colitis with acute, fulminating characteristics may occur. Under this circumstance, continuous severe abdominal pain, profuse rectal hemorrhage, and high fever are seen. Associated symptoms include nausea and vomiting, anorexia, and profound weakness. Physical signs usually include dehydration, pallor, and weight loss. Severe blood loss may result in hypotension and shock.

Associated with an acute onset of fulminating ulcerative colitis is toxic megacolon, which is characterized by severe colonic distention that causes shock. In patients with this condition, the distended bowel lumen (greater than 5.5 to 6 cm on a supine abdominal film) provides an environment conducive to bacterial overgrowth. This condition, coupled with erosive intestinal inflammation and perforation, allows for the systemic release of bacteria-produced toxins. Clinical signs and symptoms of toxic megacolon include fever, tachycardia, abdominal distention, pain, ileus, and dehydration. Electrolyte derangements, anemia, and hypoalbuminemia are also commonly present. If there is no significant improvement within a short period of medical treatment, patients arrive in the operating room for subtotal colectomy with an end ileostomy. Patients with toxic megacolon due to Crohn's disease undergo surgical treatment similar to those with toxic megacolon due to ulcerative colitis.[96]

Patients with chronic ulcerative colitis are at increased risk for the development of left-sided carcinoma of the colon. An increased incidence of large-joint arthritis is seen in patients when the disease is clinically active. Concomitant liver disease, as evidenced by fatty infiltrates and pericholangitis, also may complicate the clinical picture. Other extracolonic manifestations of ulcerative colitis include iritis, erythema nodosum, and ankylosing spondylitis.

Therapy for ulcerative colitis is initially medical. As with Crohn's disease, sulfasalazine preparations, antidiarrheal agents, immunosuppressive agents, and corticosteroids are the cornerstones of medical therapy. Nicotine may have a protective effect in UC but not in Crohn's. Both Crohn's disease and ulcerative colitis result in systemic disorders such as anemia and nutritional deficiencies, which are handled in the same supportive manner. In both diseases, surgical resection is reserved for patients with intractable complications. Whereas surgery for Crohn's disease is nondefinitive and complication oriented, proctocolectomy with ileostomy is generally curative for ulcerative colitis and eliminates the risk of malignancy and long-term steroid use.[97]

Anesthetic Considerations in Inflammatory Bowel Disease

Anesthetic management of patients with inflammatory bowel disease begins with optimization of the patient's medical status. Correction of anemia, fluid depletion, electrolyte and acid-base disorders, and nutritional assessment are mandatory. Possible extracolonic complications (e.g., sepsis, liver disease, coagulopathy, anemia, arthritis, hypoalbuminemia, and other metabolic derangements) also must be considered during planning and perioperative management.

Patients on long-term steroid therapy may require prophylactic steroid coverage. Nitrous oxide should be avoided due to the possibility of bowel distention associated with its prolonged intraoperative use. Many patients require total parenteral nutrition (TPN) and bowel rest because eating may worsen symptoms. As such, the anesthetist should be aware of complications from parenteral nutritional therapy (e.g., hyperglycemia or hypoglycemia, increased carbon dioxide production, renal or hepatic dysfunction, nonketotic hyperosmolar hyperglycemic coma, and hyperchloremic metabolic acidosis). Any preexisting TPN infusion should be maintained throughout the perioperative period at the ordered infusion rate. Correction of fluid, electrolyte, and hematologic derangements may be necessary before surgery. Periodic laboratory assessment of metabolic status (i.e., serum glucose and electrolytes) should be performed and guide corrective interventions for derangements. The severity of extracolonic influence on the function of other organ systems dictates appropriate technique and drug selection, as well as the extent to which invasive monitoring is used. Increased intraluminal pressure caused by the administration of anticholinesterases for reversal of neuromuscular blockade has been shown to have no effect on colonic suture lines. No particular anesthetic technique is mandated; however, the use of a combined technique (epidural and general anesthesia) is attractive for both intraoperative use and postoperative analgesia needs.[98]

Diverticulitis and Diverticulosis

Diverticulosis of the colon is characterized by the presence of numerous asymptomatic mucosal herniations or outpouchings in the large colon, with the highest prevalence noted in the left (sigmoid) colon (65%). The colonic mucosa herniates through the smooth muscle layers. Structural weakness of the colonic wall, usually where arteries penetrate the tunica muscularis to nourish the mucosal layer, and intraluminar hypertension are two mechanisms theorized to be responsible for the development of diverticulosis.

Diverticulitis is inflammation of diverticula; this syndrome manifests as abdominal pain with ileus and other symptoms that indicate an acute abdomen, such as nausea, vomiting, diarrhea, rigid abdominal distention, and dehydration. Diverticulitis occurs in only 1% of patients with diverticulosis. Inflamed diverticula may be localized or more widespread and may involve the mesentery and other abdominal organs. Progression of symptoms may lead to hypovolemia, hypokalemia, and shock. The presence of free intraperitoneal air, as evidenced on radiographic abdominal films, suggests perforation. Air in the retroperitoneum may be indicative of paracolic abscess. Both conditions require urgent surgical exploration. Abscess formation and visceral perforation indicate the need for urgent surgical intervention.[89]

Surgical treatment of diverticulitis is reserved for severe symptoms that are refractory to aggressive medical therapy. Intravenous corticosteroids, antibiotics, and fluid replacement are attempted

initially. Exploratory laparotomy with colectomy may be necessary under emergent conditions of acute bleeding, recurrent bleeding that fails to cease spontaneously, or sepsis. The goals of surgical exploration include fecal diversion and abscess drainage, as well as resection of the diseased colon.[34]

Complications of diverticulitis, which occur in up to 25% of patients, frequently necessitate surgical intervention. Such complications include bowel obstruction; fistulas between the sigmoid colon and the skin, bladder, vagina, or small intestine; abscesses; and peritonitis. Abscess formation after colonic obstruction and perforation is generally confined to the pelvis and may involve such structures as the abdominal wall and the subdiaphragmatic spaces. Abscess formation may be extensive; it may include the deep pelvic organs and the hip and thigh. Patients with pelvic abscesses caused by diverticulitis have significant pain, fever, and leukocytosis.

Bleeding is uncommon in patients with diverticular disease, but when present, it often defies localization through endoscopy and even laparotomy. A bleeding diathesis in diverticular disease may be either occult or massive and is caused by erosion of the vessels adjacent to the diverticulum. Elective colon resection is usually considered in patients with recurrent episodes of acute diverticulitis. After a second attack of acute diverticulitis, the prevalence of complications associated with the disease approaches 50%, and the associated mortality rate is twice that of an initial attack. Diverticulitis, when present in the right colon or cecum, often mimics acute appendicitis. Surgery for appendectomy, therefore, may uncover the presence of an inflamed diverticulum or diverticulitis, necessitating extension of the procedure so that colonic resection can be performed.[34]

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) develops when there is abnormally high intraabdominal pressure (greater than 20 mmHg) with associated organ dysfunction. Also known as intraabdominal hypertension, ACS can be diagnosed by measuring intraabdominal pressures (IAP) with a bladder manometer. Normal IAP is less than 10 mmHg. At pressures greater than 10 mmHg, hepatic arterial blood flow significantly decreases. Cardiovascular perturbations occur at 15 mmHg. Oliguria occurs at 15 to 20 mmHg and anuria at 40 mmHg. Organ dysfunction develops with these increased pressures lasting greater than 6 hours. IAP greater than 20 to 30 mmHg can result in organ failure and death.[99]

ACS is associated with abdominal trauma, hemoperitoneum, mesenteric arterial thrombosis, acute pancreatitis, intestinal obstruction, visceral edema (as occurs in sepsis and shock), and massive fluid volume replacement. Causes of chronic ACS include ascites, pregnancy, and intraabdominal tumors. Resuscitative efforts and exposure of the open abdomen induces mesenteric edema formation and bowel dilation. Under these conditions, attenuation and prevention of worsening ischemic injury to the abdominal viscera are avoided through delayed closure until gross abdominal distention is resolved.

Cardiac output is decreased secondary to decreased cardiac preload (venous return), elevated systemic vascular resistance, and elevated intrathoracic pressure. Reflex tachycardia is a baroceptor-mediated response to decreased preload, with resultant diminished diastolic filling and coronary perfusion. Intracranial filling pressures are increased. Decreased thoracic compliance and decreased lung volumes result from impaired diaphragmatic descent. The outcome is increased pulmonary shunt fraction, atelectasis, and pulmonary edema. Impairment in renal function results from compression of the kidney and diminished glomerular perfusion. The end consequence is multiple organ failure.

Treatment of ACS is urgent decompressive laparotomy, and may be performed at the bedside if the patient is too unstable to move. However, surgical decompression is ideally performed in the operating room. One study showed that overall mortality after surgical decompression was 46%, with preoperative renal failure, lower preoperative IAP, and late decompression being predictive of death. This underscores the point that once the diagnosis of ACS is made, prompt intervention is needed, and if medical interventions are futile or judged to be inadequate, prompt decompression is mandatory.[100]

Affected patients often have myriad medical problems that may significantly influence outcome. The possibility of ACS subsequent to resuscitative "damage-control" laparotomy used in the traumatically injured patient is always a consideration. Under this circumstance, immediate life-threatening injuries are primarily addressed, and then the patient is returned to the operating room from the intensive care unit at a later date. This occurs after a period in which hemodynamic stabilization is accomplished.[34] Definitive repairs of associated, less life-threatening injuries are then undertaken, often in stages. During this time, the abdomen may be left open but packed and sealed with sterile dressings, along with a drainage appliance to resolve postresuscitation intraabdominal edema.[34] The patient may undergo repeated returns to the operating room for dressing changes until conditions are conducive for abdominal wound closure. Providing anesthesia care for these patients can be extremely challenging. Intraoperative monitoring is directed toward maintenance of hemodynamic stability and includes knowledge of the patient's preoperative hemodynamic profile. If the patient is still receiving mechanical ventilatory support, it is of utmost importance to provide intraoperative ventilation as closely as possible to the mode being administered in the intensive care unit. This is particularly vital in the patient with ARDS. This may require a modification of the anesthesia delivery ventilator to approximate as closely as possible the minute ventilation, Fio_2, inspiratory/expiratory (I:E) ratio, ventilatory rate, and level of positive end-expiratory pressure the patient has been receiving. In this way, the potential for perioperative deterioration of previously accomplished improvement in the patient's ventilatory status is minimized. Invasive monitors brought with the patient, such as an arterial line, central venous catheter, and pulmonary artery catheter, should be used for perioperative management. Opioids and inhalation agents are used with discretion in accordance with patient tolerance. Adequate muscle relaxation and amnesia with a benzodiazepine or scopolamine assume priority in the pharmacologic anesthetic management of the physiologically labile patient. Other vasoactive agents are included as indicated for hemodynamic support. Best practice caveats for the anesthetic management of these patients are provision of intraoperative stability and preservation of preoperative homeostatic compensation.

One serious but rare complication of surgical decompression is the so-called "reperfusion syndrome" in which the patient develops severe hypotension and acidosis immediately after the abdomen is decompressed as a result of the release of acidotic blood from the mesenteric beds.[100] Reperfusion washout of by-products of anaerobic metabolism releases an array of cardiac depressant and vasodilatory mediators into the general circulation. Proper preparation is required and includes optimization of intravascular volume, acid-base status, and arterial oxygenation.[101]

Mortality rate in ACS approaches 42%, with most patients succumbing to secondary systemic inflammatory response syndrome,

sepsis, and MODS. Other causes of death include respiratory failure (i.e., ARDS) and the consequences of added stress imposed on cardiac function in susceptible patients.[101]

Anesthetic Considerations in Elective Surgery of the Colon

Using either a laparoscopic or anterior open approach, the surgeon mobilizes the colon and ligates the associated blood vessels. The diseased bowel is removed, and the remaining ends of the distal and proximal colon can be anastomosed together, or alternatively a colostomy or ileostomy may be created. Preoperative elimination of fecal mass and bacterial flora are critical to avoid postoperative infection. The night before admission, the patient can lavage with isotonic and isosmotic solutions orally or by way of a nasogastric tube. Cleansing enemas also may be ordered. These techniques often are used for elective procedures in conjunction with dietary changes that emphasize the intake of fluids and low-residue foodstuffs and that culminate in the intake of only clear liquids for 24 to 48 hours before surgery. Intravenous and oral antibiotics used for bowel cleansing commonly include drugs of the aminoglycoside family (e.g., neomycin, erythromycin) and/or a combination of the cephalosporins and metronidazole.

Awareness of this preoperative preparation in patients who undergo elective bowel surgery is critical because aggressive preoperative bowel preparation predisposes a patient to water and electrolyte imbalances that may have a deleterious influence on perioperative cardiovascular function, hemodynamics, and systemic organ perfusion, particularly if the patient is elderly or debilitated. Depending on how chronic the disease process is, anemia resulting from frank or occult bleeding may be present. Malnutrition with hypoalbuminemia also may be present before surgery.

Preoperative nasogastric drainage may be required if an adynamic colon or obstruction is present. This preoperative intervention may be superimposed on a dehydrated patient or one who is electrolyte depleted, resulting in hypochloremic hypokalemic alkalosis. The resulting fluid and electrolyte derangements may be of sufficient magnitude to require postponement of the procedure until volume and electrolyte resuscitation has been accomplished.

Carcinoma of the Colon

Cancer of the colon is a highly treatable and often curable disease when localized to the bowel. It is the second most frequently diagnosed malignancy in the United States, as well as the third most common cause of cancer death in both men and women. Most colorectal cancers develop from adenomatous polyps. Surgery is the primary treatment and results in cure in approximately 50% of patients. The location and amount of resection depends on the site of the cancer. If the rectum is involved, a permanent colostomy will be created. Recurrence after surgery is a major problem and often is the ultimate cause of death. The prognosis of patients with colon cancer is clearly related to the degree of penetration of the tumor through the bowel wall and the presence or absence of nodal involvement. Carcinoma of the colon accounts for approximately 50,000 deaths annually, and more than 145,000 new cases are diagnosed annually.[96] The etiology is multifactorial and includes a strong environmental correlation with diet (high red meat intake, low dietary fiber intake) and genetic predisposition. Inflammatory bowel disease is usually associated with a greater predisposition to colonic carcinoma. Occult stool testing for blood is a standard screening method. Rectal examination and colonoscopic examination with biopsy are important diagnostic modalities. Genetic markers in stool and blood are being developed.

Right-sided colonic lesions grow along one wall of the cecum and ascending colon and often cause symptoms including pain, a palpable mass in the lower right quadrant, anemia, and dark-colored blood mixed with stool. Persistent blood loss and anemia with fatigue are common, and obstruction is unlikely because the feces are more liquid. Bleeding is usually less profuse than in patients with diverticular disease. Left-sided colonic lesions grow circumferentially and symptoms include progressive abdominal distention, pain, vomiting, constipation, cramps, and bright red blood on the stool. Obstruction is common but occurs slowly.[89]

Volvulus of the Colon

Volvulus is a twisting of the bowel on its mesenteric pedicle, resulting in an occlusion of the blood supply. This condition usually affects a freely mobile colonic segment and a fixed point or set of points about which the colon twists. Approximately 75% of colonic volvulus affects the sigmoid colon, and is often associated with fibrous adhesions in the small intestines.[89]

Although colonic volvulus is relatively rare in the United States, it is responsible for 5% of large bowel obstruction cases. Symptoms usually suggest the presence of acute or subacute bowel obstruction (e.g., sudden onset of acute, severe, colicky abdominal pain, vomiting, and distention). Acute strangulation of the bowel is suggested by generalized severe abdominal pain, hypovolemia, and fever. Initial therapy starts with appropriate resuscitation followed by decompression through placement of a rectal tube through a proctoscope or the use of a colonoscope. This treatment has a high success rate (70% to 80%) and allows resection as an elective procedure, which can be accomplished with reduced morbidity and mortality. If detorsion of the volvulus cannot be accomplished with either a rectal tube or colonoscope, laparotomy with resection of the sigmoid colon with the formation of an end colostomy and a mucous fistula (Hartmann's operation) is required.[96]

Many patients with this condition are elderly (seventh to eighth decade) or are debilitated individuals and are referred from long-term care facilities. Associated disease processes include Alzheimer disease, Parkinson disease, multiple sclerosis, paralysis, pseudobulbar palsy, chronic schizophrenia, and dementia. Medications taken on a long-term basis by these institutionalized patients may include psychotropic drugs, which are known to affect intestinal motility.

Ischemic Bowel Disease

Ischemic injury to the GI tract occurs whenever the oxygen or vascular supply cannot meet the metabolic demands of the tissue. GI ischemia has many causes, including inadequate perfusion, narrowing of blood vessels from any cause, bowel obstruction and distention, drug effects, and infections that can mimic ischemic damage. Most ischemic episodes result from nonocclusive ischemic bowel disease (low-flow states), and in these cases, no vascular lesion or specific cause for ischemia can be demonstrated on pathologic examination.[102] Surgical iatrogenic causes, such as interruption of the inferior mesenteric artery as a result of aortic cross-clamping during abdominal aortic surgery, are also responsible. Prolonged hemodynamic lability in patients with significant comorbidities such as advanced age, chronic diabetes, hypertension, and atherosclerotic disease places them at even greater risk for the consequences of ischemic bowel disease. Any part or length of bowel can be affected depending on the cause and duration of hypoxia and the state of the collateral circulation. The extent, severity, and prognosis of the syndrome of ischemic bowel disease are variable. Localized or segmental ischemia is often present. Differentiation of ischemic colitis from infectious processes, diverticulitis, or inflammatory bowel disease may be difficult.

Definitive diagnosis depends on endoscopic examination with biopsy. Exclusion of bowel perforation in the differential diagnosis is made through radiographic or ultrasonographic examination of the abdomen for the presence of free air.

Patients with ischemic bowel disease are usually elderly. Symptoms of ischemic bowel disease typically include fever, vomiting, rectal bleeding, and abdominal cramping pain and may be present for weeks or months. The development of sudden rectal bleeding associated with left-sided abdominal pain and peritoneal signs strongly suggests the presence of this disease process. Concomitant ischemic heart disease and peripheral vascular disease are often present in these patients.[103] Supportive measures are initially undertaken if bowel necrosis is not suspected. This includes antibiotic therapy and fluid resuscitation. In patients in whom perforation or necrosis is suspected, emergency laparotomy is indicated, with possible bowel resection and temporary or permanent colostomy. Stable patients may be candidates for vascular reconstructive procedures.[6]

Diseases of the Rectum and Anus

Diseases of the anorectal region may include neoplastic lesions. Rectal carcinomas are defined as tumors occurring up to 15 cm from the anal opening. If biopsy findings are consistent with localized adenocarcinoma, abdominal-perineal resection of the rectum and sigmoid colon with permanent colostomy may be curative. Squamous cell carcinomas of the rectum are effectively treated with chemotherapy and radiation, as well as local excision. Rectal carcinoma can spread through the rectal wall to nearby structures (the prostate and vagina), especially in the lower third of the rectum due to the lack of a serial covering. Surgical proctectomy is another treatment option.

Other rectal diseases include rectal prolapse, which is characterized by full-thickness eversion of the rectal wall through the anus and is repaired with rectosigmoidectomy or proctopexy. Rectal prolapse is seen most often in the elderly and females. Another rectal disease is perirectal abscess, which requires drainage; this may be performed on either an inpatient or an outpatient basis.

Perirectal fistulas typically develop secondary to infectious disease processes that cause abscess formation. Four types are generally recognized: extrasphincteric, suprasphincteric, transsphincteric, and intersphincteric. Initial therapy is incision and drainage with delayed fistulectomy to facilitate healing of the abscess.[34]

Hemorrhoids are a common affliction and have been described and treated for more than 4000 years. The refined, low-fiber diet of Western nations makes hemorrhoids extremely common in the United States, where 1 in 25 to 30 individuals is afflicted. Hemorrhoidal tissue is composed of vascular, mucosal, and muscular tissues. Although frequently attributed to varicosities, all three elements compose the hemorrhoid. There are two types of hemorrhoids: internal and external. Internal hemorrhoids originate above the dentate line, are covered with mucosa, and lack sensory innervation. Internal hemorrhoidal prolapse may be painless. Gangrenous, strangulated, extruded, or thrombosed internal hemorrhoids, however, may be extremely painful. Treatment is usually by rubber band ligation or surgical excision. External hemorrhoids originate below the dentate line and are covered with squamous epithelium that makes them easily recognizable because their covering matches the surrounding skin. The inferior rectal nerve innervates external hemorrhoids. A thrombosed external hemorrhoid appears as a bluish mass covered by epidermis. Acute thrombosis occurs suddenly and is usually very painful. Significant bleeding is uncommon but may occur if spontaneous rupture occurs. Increased pressures from straining or trauma from constipation or diarrhea may exacerbate external hemorrhoids. Distention and trauma predispose the hemorrhoidal venous plexus to stasis with ensuing clot formation and edema.[104] Surgical excision is the treatment of choice.

Anesthesia for most perirectal and perianal procedures may be effectively provided by regional techniques such as spinal subarachnoid block or epidural blockade, as well as by local anesthesia infiltration with sedation. A particularly useful technique is a saddle block with hypobaric bupivacaine. In some cases, general endotracheal anesthesia may be necessary. Anesthetic considerations must include the influence of patient position (e.g., prone, jackknife, or lithotomy position) on intraoperative cardiovascular and respiratory dynamics.

Radiation Enteritis

Radiation therapy is commonly used as adjuvant therapy for various abdominal and pelvic cancers. In addition to tumor cells, however, other rapidly dividing cells in the intestinal epithelial lining may be affected by radiation. Surrounding normal tissue such as the small intestinal epithelium may sustain severe, acute, and chronic deleterious effects. The amount of radiation appears to correlate with the probability of developing radiation enteritis. Radiation damage tends to be acute and self-limiting, with symptoms consisting mainly of diarrhea, abdominal pain, and malabsorption. The late effects of radiation injury are the result of damage to the small submucosal blood vessels with a progressive obliterative arteritis and submucosal fibrosis, resulting eventually in thrombosis and vascular insufficiency. Operative intervention may be required in a subgroup of patients with the chronic effects of radiation enteritis. Indications for operation include obstruction, fistula formation, perforation, and bleeding, with obstruction being the most common presentation. Operative procedures include a bypass or resection with reanastomosis, sometimes under emergent conditions. The presence of adhesions and the induced increased friability of the intestinal tissues predispose affected patients to increased intraoperative bleeding and tissue third spacing. Radiation enteritis can be a relentless disease process. Almost half of patients who survive their first laparotomy for radiation bowel injury require further surgery for ongoing bowel damage. Up to 25% of these patients die of radiation enteritis and complications from its management.[90]

Appendicitis

The appendix arises from the apex of the cecum. The length of the appendix varies from 2 to 20 cm, and the average length is 9 cm in adults. The appendiceal artery, a branch of the ileocolic artery, supplies the appendix.[105] The appendix may assume any of a number of positions that influence the quality of symptoms and the site of pain when inflammation occurs.

Appendicitis occurs most often in individuals between 10 and 30 years of age and is the most common general surgical emergency. A slight prevalence for male patients over female patients exists. Obstruction of the appendiceal lumen is believed to be the major cause of appendicitis.

In the classic presentation of appendicitis, patients first note vague, poorly localized epigastric or periumbilical discomfort progressing to localized right lower quadrant tenderness in 80% of patients. Within 4 to 12 hours of the onset of pain, most patients also note nausea, vomiting, anorexia, or some combination of these three symptoms. If vomiting is the main symptom, the diagnosis should be questioned.[106] Patients point to localized pain at McBurney's point, which is midway between the iliac crest and umbilicus; rebound tenderness, muscle rigidity, and abdominal guarding are

noted. In the pregnant patient, Alder's sign is used to differentiate between uterine and appendiceal pain. The pain is localized with the patient supine. The patient then lies on her left side. If the area of pain shifts to the left, it is presumed to be uterine.

The major complication of untreated appendicitis is perforation, with resultant peritonitis, abscess, and portal pylephlebitis. The risk of perforation increases as the duration of the illness progresses, especially beyond 24 hours. Patients with perforation are more likely to have a higher fever, leukocytosis, and physical findings of peritonitis. The most severe complication of appendiceal perforation is septic thrombophlebitis of the portal vein, or portal pylephlebitis.

If the appendix perforates, abdominal pain becomes intense and more diffuse, and abdominal muscular spasm increases, producing rigidity. The heart rate rises, with an elevation of temperature above 39° C. Occasionally, pain may improve somewhat after rupture of the appendix, although a true pain-free interval is uncommon.[105]

Definitive treatment of appendicitis is appendectomy, which may be performed with general or regional anesthesia. The patient is frequently dehydrated and may require a brief period of fluid resuscitation and antibiotics for enteric anaerobic gram-negative bacilli before the induction of anesthesia. Laparoscopic propcedures are the most common technique for simple presentations. If an open appendectomy is performed and regional anesthesia is chosen, the analgesia level should be maintained at the T6 to T8 level. If general anesthesia is selected, muscle relaxation is necessary, and aspiration precautions that include a rapid-sequence induction should be considered. Local anesthesia with intravenous sedation may also be a useful technique.

SPLENIC DISEASE

Anatomic and Physiologic Overview

The spleen is located in the posterior left upper quadrant of the abdomen and is surrounded by the fundus of the stomach (medially), the splenic flexure of the colon (inferiorly), the left kidney and adrenal gland (posteriorly), and the diaphragm (superiorly). Attachment to these organs via suspensory ligaments, which are vascular except for the gastrosplenic ligament, provides protection and support of this organ.[34]

The normal spleen is weighs less than 250 g, decreases in size with age, normally lies entirely within the rib cage, has a maximum cephalocaudal diameter of 13 cm by ultrasonography or maximum length of 12 cm and/or width of 7 cm by radionuclide scan, and is usually not palpable. In fact, a palpable spleen is the major physical sign produced by diseases affecting the spleen and suggests enlargement of the organ.

The encapsulated spleen is divided into three zones by strands of connective tissue (trabeculae) that originate from the capsule. Each compartment contains masses of lymphoid tissue called *splenic pulp*. Each of the three splenic compartments is surrounded by a 1- to 2-mm capsule. These compartments are (1) the white pulp, which consists of lymphatic sheaths and contains lymphocytes, plasma cells, and macrophages; (2) the red pulp, which consists of large, thin-walled, highly distensible venous sinuses, also known as the *splenic sinusoids*, which ultimately form the splenic vein; and (3) the marginal zone, an ill-defined vascular space that interfaces between the white pulp and the red pulp.[34]

Total splenic blood flow is approximately 300 mL/min and comes from the splenic artery. The splenic artery is a tortuous vessel that arises from the descending aorta. The splenic artery divides into several branches within the splenorenal ligament before entering the splenic hilum, where they branch again into these trabeculae as they enter the splenic pulp. Splenic blood flow drains into the splenic vein and then contributes to portal venous blood flow.

The spleen functions in several physiologic capacities, including blood filtering, maintenance of normal erythrocyte morphology, and immune processing of blood-borne foreign antigens. The spleen is also involved in hematopoiesis until the fifth month of gestation in the fetus. In filtering blood, the splenic sinusoids remove nuclear remnants and excess cell membrane found in immature erythrocytes. Abnormal blood cells, such as those found in sickle cell disease, thalassemia, and spherocytosis, are filtered and removed by macrophages and other cells of the reticuloendothelial system. This process can occasionally lead to worsening anemia, symptomatic splenomegaly, and occasionally splenic infarction. Aged red blood cells (older than 120 days) that have lost enzymatic activity and membrane elasticity are removed by the same processes.[34]

The spleen has an important role in specific and nonspecific immune responses. Macrophages and specialized histiocytes engulf and remove foreign cells, particularly those with a layer of affixed antibody. The production of specific antibody (immunoglobulin M [IgM]) is facilitated in the white pulp through the processing of foreign antigens.[34] It is well established that people lacking a spleen are at a significantly higher risk for overwhelming postsplenectomy infection (OPSI) with fulminant bacteremia, pneumonia, or meningitis, as compared with those with normal splenic function. Asplenic subjects have defective activation of complement by the alternative pathway, leaving them more susceptible to infection.[107] Pimpl et al.[108] reviewed 37,000 autopsies over 20 years of adults who died after splenectomy and compared them with a deceased population of 403 who did not have splenectomy. These investigators found higher incidence rates of lethal pneumonia, sepsis with multiple organ failure, purulent pyelonephritis, and pulmonary embolism in the splenectomy group. They concluded that splenectomy carries a considerable lifelong risk for severe infection and thromboembolism.

The spleen has a minor role as a reservoir of platelets. This function, however, is important in only a few pathologic conditions. No significant reservoir function of red blood cells is performed by the spleen, but in the presence of sudden reductions in blood pressure, sympathetic nervous system activation can constrict the red pulp sinuses, contributing as much as 200 mL of blood to the venous circulation and increasing the hematocrit by as much as 4%.[109]

Despite its important and myriad functions, the spleen is not essential for life. Splenectomy may be performed for benign hematologic conditions including idiopathic thrombocytopenic purpura (ITP), thrombotic thrombocytic purpura, hereditary spherocytosis, hereditary hemolytic anemia, and hemoglobinopathies (e.g., thalassemia, sickle cell disease). Splenectomy also may be performed for malignancy such as Hodgkin or non-Hodgkin disease, lymphoma, certain leukemias, or for other benign conditions such as splenic abscess, splenic cysts, presence of an accessory spleen, wandering spleen, and splenomegaly (spleen greater than 20 cm longitudinally). The development of primary (having no identifiable underlying cause) or secondary (having a known cause) hypersplenism may warrant splenectomy. Hypersplenism and acute splenic sequestration are life-threatening disorders in children with sickle cell anemia and thalassemia. Symptoms of hypersplenism include fatigue, malaise, recurrent infection, and easy or prolonged bleeding. These symptoms occur from a hyperfunctional spleen that removes and destroys normal blood cells.[107]

In portal hypertension, transmitted back pressure results in hypersplenism, which leads to congestive failure of splenic

function. Treatment of the primary disease process usually provides relief of symptoms. Splenectomy, however, is often a necessary part of therapy; particularly with long-standing disorders. Splenectomy also offers a curative solution for patients with isolated splenic vein thrombosis and bleeding gastric varices.[110]

Splenic Trauma

Angiographic embolization of hemorrhaging vessels in the spleen has reduced the need for open procedures. However, the spleen is the most frequently injured abdominal organ, being involved in 25% to 60% of adults with intraabdominal trauma. Damage to the spleen is important because it is the most vascular body organ, receives 5% of the cardiac output, and because the bleeding is mostly arterial, it can produce a lethal hemoperitoneum. Unlike the liver, hemorrhage from splenic trauma is always within the peritoneal cavity.[111] Rapid deceleration or puncture from an adjacent broken rib are common causes of spleen injuries. Any patient who has sustained blunt abdominal trauma and who has left upper quadrant pain should be suspected of having sustained splenic injury. Conservative, nonoperative treatment (with avoidance of splenectomy) may be elected in minor splenic injury. The clearest indication for urgent operation is hemodynamic instability. Because there can be no standard criteria for hemodynamic instability, a general guideline is to operate for a systolic blood pressure below 90 mmHg or a pulse of more than 120 beats/minute if there is no immediate response to 1 to 2 L of crystalloid resuscitation and when physical examination, ultrasound, or diagnostic peritoneal lavage (DPL) indicates intraabdominal blood loss.[107] Splenectomy is generally avoided in children because of the greater importance of splenic function (i.e., immunologic function) in growth and development in patients of this age group.[112]

In hemodynamically stable patients with severe splenic damage and hemoperitoneum, the surgery can be performed laparascopically with no related morbidity or mortality. Anesthesia concern with the laparoscopic approach is related to respiratory distress, possibly impaired by the lateral decubitus position and by the pneumoperitoneum in patients, usually associated with multiple trauma and rib fractures. At least one study showed no negative outcomes in this respect and in fact the patients fared better postoperative respiratory compliance.[113]

In the presence of impending shock, emergency exploratory laparotomy is carried out to diagnose and treat all injuries to the abdominal viscera, including the spleen. Anesthetic management in these cases is directed by considerations given all unstable patients undergoing emergency laparotomy, particularly hemodynamic stability and renal function. A paramount consideration is maintaining physiologic hemoglobin and hematocrit levels and arterial blood pressure. Hemoglobin and hematocrit are decreased in the emergent setting, not only by hemorrhagic diathesis but also from dilution secondary to aggressive volume resuscitation with crystalloid solutions. These considerations assume an integral part in the decision to implement perioperative blood product transfusion.

Anesthetic Considerations in Elective Splenectomy

Anesthetic management for splenectomy is individualized based on the patient's medical condition. Patients who have received chemotherapy must be assessed for potential organ system complications.

Minimally invasive procedures have become standard for most splenectomies, and laparoscopy is now the procedure of choice. The spleen may be removed laparoscopically if the spleen is normal or close to normal in size. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, the risk of damage to the pancreas, the likelihood of development of subphrenic abscess and peritoneal adhesions postoperatively, and the nutritional and metabolic challenges to the patient are considerably reduced.[114]

Patients with systemic disease may be chronically ill and have decreased cardiovascular reserve. Patients who have received doxorubicin (Adriamycin) may have a dose-dependent cardiotoxicity that can be worsened by radiation therapy. Manifestations include decreased QRS amplitude, congestive heart failure, pleural effusions, and dysrhythmia. Patients may have a degree of left lower lobe atelectasis and altered ventilation. In patients treated with bleomycin, pulmonary fibrosis may occur. Methotrexate, busulfan, mitomycin, cytarabine, and other chemotherapeutic agents may cause pulmonary toxicity. Neurologically, patients may have deficits after administration of chemotherapeutic agents. Vinblastine and cisplatin can cause peripheral neuropathies. Any evidence of neurologic dysfunction should be documented. Hematologically, patients are likely to have splenomegaly secondary to hematologic disease (e.g., Hodgkin disease, leukemia). Cytopenias are common. Some chemotherapeutic agents (e.g., methotrexate, 6-mercaptopurine) may be hepatotoxic. Evaluation of liver function tests should be considered in patients considered at risk. Renally, some chemotherapeutic drugs (e.g., methotrexate, cisplatin) are nephrotoxic. Patients exposed to such agents may have renal insufficiency.

Laboratory tests that should be performed as indicated by the history and physical examination include a complete blood count, prothrombin time, partial thromboplastin time, bleeding time, platelet count, electrolytes, blood urea nitrogen, creatinine, and urinalysis. Consider aspiration prophylaxis, and administer steroids (25 to 100 mg hydrocortisone) if the patient has received them as part of a chemotherapeutic or medical treatment.

Because of the potential for large blood loss, the patient should be typed and cross-matched, and the use of cell saver is appropriate. The ability to transfuse blood products when indicated should be accommodated with the insertion of at least two large-bore intravenous lines if a central line is not placed. The extent of monitoring modalities is dictated by the patient's preexisting condition and anticipated perioperative course.

General endotracheal anesthesia (GETA) with or without an epidural for postoperative analgesia is used. GETA induction should include consideration of rapid sequence intubation as indicated. Intravascular volume should be restored before anesthetic induction. If the patient is hemodynamically unstable, etomidate or ketamine should be considered. Nitrous oxide should be avoided to prevent bowel distention. Appropriate measures also must be implemented intraoperatively to prevent any further deterioration in preexisting function. These measures include careful patient positioning, administering appropriate intravenous fluids, maintaining adequate urine output, monitoring hemoglobin and hematocrit levels, and avoiding anesthetics and adjuvants that place an extra metabolic burden on the renal or hepatic system. An epidural catheter may be beneficial in postoperative pain control in the absence of ITP.

CARCINOID TUMORS AND CARCINOID SYNDROME

Carcinoid tumors consist of slow-growing malignancies composed of enterochromaffin cells (Kulchitsky cells) and are most commonly found in the GI tract. They also may occur in the lung, pancreas, thymus, and liver.

The GI tract accounts for about two thirds of carcinoids. Within the GI tract, most tumors occur in the appendix (45%), jejunoileum (28%), rectum (16%), and duodenum (4%). Carcinoid

BOX 30-11

Signs and Symptoms of Carcinoid Syndrome

- Episodic cutaneous flushing (kinins, histamine)
- Diarrhea (serotonin, prostaglandins E and F)
- Heart disease
- Tricuspid regurgitation, pulmonic stenosis
- Supraventricular tachydysrhythmias (serotonin)
- Bronchoconstriction (serotonin, bradykinin, substance P)
- Hypotension (kinins, histamine)
- Hypertension (serotonin)
- Abdominal pain (small bowel obstruction)
- Hepatomegaly (metastases)
- Hyperglycemia
- Hypoalbuminemia (pellagra-like skin lesions resulting from niacin deficiency)

Modified from Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-Existing Disease*. 6th ed. Philadelphia: Saunders; 2012.

tumors are capable of metastasis and are composed of multipotential cells with the ability to secrete numerous bioactive humoral agents, the most important of which are serotonin, histamine, and kinin peptides. In addition to these substances, carcinoid tumors have been found to secrete corticotropin, histamine, dopamine, neurotensin, prostaglandins, substance P, gastrin, somatostatin, pancreatic polypeptide, calcitonin, and neuron-specific enolase[105] (Table 30-14).

Adrenergic stimulation causes the release of serotonin into the circulation. It is metabolized by aldehyde dehydrogenase and monoamine oxidase to 5-HIAA (5-hydroxyindoleacetic acid), which is excreted in the urine. Elevated levels of 5-HIAA are monitored in the urine as a marker of excess serotonin production and, therefore, the presence of a carcinoid tumor. Serotonin may cause vasoconstriction or vasodilation; thus both hypertension and hypotension are possible. At normal concentrations, serotonin does not affect cardiac function; however, the elevated levels seen in carcinoid syndrome may cause both inotropic and chronotropic responses. This action is due in part to an indirect effect from the release of norepinephrine. Elevated serotonin levels also result in increased gut motility and the secretion of water, sodium, chloride, and potassium by the small intestine. Other effects attributed to elevated levels of serotonin are vomiting, bronchospasm, hyperglycemia, and prolonged drowsiness after emergence from anesthesia.[115]

Histamine release is seen predominantly in patients with gastric or foregut carcinoids and may be due to the presence of histidine decarboxylase in normal gastric mucosa. Histamine is probably responsible for the bronchospasm seen in some carcinoid patients, and it also may be the cause of flushing.[115]

Other substances thought to be released by carcinoid tumors are the kinins, especially bradykinin. Kinins are produced by the action of proteolytic enzymes, called *kallikreins*, on the inactive precursors of the kinins.[115] Lysosomal kallikrein release is triggered mainly by sympathetic stimulation. When this action occurs, the newly produced bradykinin usually is rapidly broken down and removed from the circulation by plasma aminopeptidases and kinases. When abnormally high amounts of bradykinin are released, the pathways become saturated, causing an exaggerated and prolonged effect from bradykinin. The bradykinins produce profound vasomotor relaxation, causing severe hypotension and flushing, probably via increased nitric oxide synthesis.[116] Bradykinin also causes bronchospasm, especially in known asthmatics, and frequently in the presence of cardiac disease.[117]

Normally the release of vasoactive substances causes little if any symptoms because the liver is able to rapidly inactivate these substances. If these substances reach the systemic circulation without first being metabolized by the liver, they are capable of producing carcinoid syndrome (Box 30-11).

Carcinoid syndrome may produce life-threatening perioperative hemodynamic instability. The syndrome most often occurs with primary tumors that do not drain into the portal system or with hepatic metastases (the most common site of metastasis) because they bypass metabolism in the liver. Although 25% of tumors actively secrete substances capable of causing symptoms, less than 10% of people with a carcinoid tumor develop the classic carcinoid syndrome.[118] Symptoms related to carcinoid syndrome include episodic cutaneous flushing (kinins, histamine), diarrhea (serotonin, prostaglandins E and F), heart disease, tricuspid regurgitation, pulmonic stenosis, supraventricular tachydysrhythmias (serotonin), bronchoconstriction (serotonin, bradykinin, substance P), hypotension (kinins, histamine), hypertension (serotonin), abdominal pain (small bowel obstruction), hepatomegaly (metastases), hyperglycemia, and hypoalbuminemia (pellagra-like skin lesions resulting from niacin deficiency).

Since the introduction of octreotide as a therapeutic option, the prognosis for patients with carcinoids has significantly improved. Nevertheless, carcinoid tumors may prove fatal for some patients. Death in these patients often results from pulmonary, cardiovascular, or hepatic involvement and dysfunction, rather than from carcinoid crisis. Overall survival is significantly worse for patients with cardiac involvement.

Carcinoid crisis, a life-threatening form of carcinoid syndrome, may be precipitated by physical manipulation of the tumor (including bedside palpation), chemical stimulation or tumor necrosis resulting from chemotherapy, and hepatic artery ligation or embolization.[119] It may occur spontaneously or during the induction of anesthesia. Clinical manifestations of carcinoid crisis include severe flushing with associated dramatic changes in blood pressure (BP), cardiac arrhythmias, bronchoconstriction, and mental status changes. The most effective treatment for carcinoid tumors is generally regarded as complete surgical excision of the tumor, often with partial bowel resection and mesenteric lymphadenectomy.[119] Other procedures associated with carcinoid

BOX **30-12**

Anesthetic Considerations in Carcinoid Syndrome

- The most common clinical signs are cutaneous flushing of the head, neck, and upper thorax, wheezing, blood pressure and heart rate changes, and diarrhea.
- Preoperative assessment should include complete blood count, measurement of electrolytes, liver function tests, measurement of blood glucose, electrocardiogram, and determination of urine 5-HIAA levels. Echocardiography should be performed to determine the extent of carcinoid heart disease.
- Confirmation: > 30 mg of 5-HIAA per 24-hour urine sample (normal = 3 - 15 mg/24 hr)
- Optimize fluid and electrolyte status and pretreat with octreotide as noted. Continue octreotide throughout the postoperative period. Aprotinin (kallikrein inhibitor) may be used to treat hypotension refractory to octreotide. Interferon-α has shown success in controlling some symptoms.
- Both histamine-1 and histamine-2 receptor blockers must be used to fully counteract histamine effects.
- Perioperative blockade of serotonin receptors
- Avoid histamine-releasing agents such as morphine and atracurium. Avoid sympathomimetic agents such as ketamine and ephedrine.
- Treat hypotension with an α-receptor agonist such as phenylephrine.
- General anesthesia is preferred over regional anesthesia. Patients with high serotonin levels may exhibit prolonged recovery; therefore, desflurane and sevoflurane, which have rapid recovery profiles, may be beneficial.
- Aggressively maintain normothermia to avoid catecholamine-induced vasoactive mediator release.
- Monitor intraoperative plasma glucose, because these patients are prone to hyperglycemia. Treat with insulin as is customary.
- Pay attention to procedures, treatments, and drugs that may stimulate release of vasoactive substances from tumor cells. These include tumor-debulking surgery or hepatic artery embolization to reduce tumor size and biotherapy (interferon for tumor shrinkage) or chemotherapy for systemic spread.

syndrome include cardiac valve replacement and hepatic resection for metastatic disease.

Anesthetic Management

The primary goal during the perioperative period is to prevent the release of bioactive mediators, thereby avoiding carcinoid crisis. Most patients with carcinoid tumors undergo general anesthesia because of the need to avoid the sympathectomy associated with neuraxial anesthesia; however, both epidural and spinal anesthesia have been used successfully in these patients.[120]

Caution should be exerted in the anesthetic management of patients with carcinoid tumors because anesthesia may precipitate a carcinoid crisis characterized by hypotension, bronchospasm, flushing, and tachycardia predisposing to arrhythmias. The treatment of carcinoid crisis is IV octreotide given as a bolus of 50 to 100 mg, which may be continued as an infusion at 50 mg/hr. In addition, IV antihistamine and hydrocortisone may be of some benefit. Octreotide, a somatostatin analog, is used to blunt the vasoactive and bronchoconstrictive effects of carcinoid tumor products. Octreotide mimics somatostatin's inhibitory action on the release of several gastrointestinal hormones, as well as those derived from carcinoid tumors. Treatment for 2 weeks preoperatively with a dose of 100 mcg subcutaneously three times a day is standard. If prophylactic therapy was not used, a dose of 50 to 150 mcg subcutaneously is given preoperatively. Intraoperative infusion may be continued at 100 mcg/hr. Bolus doses of 100 to 200 mcg given intravenously may be used for intraoperative carcinoid crises. Octreotide is also beneficial if it is given for only 24 hours before surgery. If it is discontinued postoperatively, it should be weaned over the first week.[117]

Many anesthetic techniques have been used successfully in the treatment of patients with carcinoid syndrome (Box 30-12). Most patients with carcinoid tumors undergo general anesthesia because of the need to avoid the sympathectomy associated with neuraxial anesthesia; however, both epidural and spinal anesthesia have been used successfully in these patients. Successful spinal anesthesia has been reported with the use of preoperative octreotide, fluids, and low-dose spinal anesthetic supplemented with low-dose intrathecal opioids.[120] Laboratory tests should include the standard chemistry, blood count, liver function panel, blood glucose concentration, and electrocardiogram (ECG), as well as urinary 5-HIAA measurements.[115] A low threshold for further cardiac workup should be used because the reported incidence of cardiac involvement is as high as 50% to 60%.

Rapid changes in BP are often seen in carcinoid patients; therefore, in addition to standard monitors, invasive monitoring typically is required. Invasive monitors should be inserted before induction of anesthesia and continued postoperatively. Hypotension commonly associated with induction agents may trigger a carcinoid crisis, so an arterial catheter is mandatory prior to the induction of anesthesia. Increased bleeding also may be encountered, because abdominal carcinoids often have a rich vascular supply and metastases may involve vessel-rich organs such as the liver. Central venous pressure (CVP) monitoring may be very useful in these patients, especially during abdominal surgery for tumor resection. CVP monitoring may help exclude hypovolemia as a cause of hypotension and allow better attention and adjustment of fluid balance.

The release of catecholamines should be avoided. Propofol and etomidate have been used to induce anesthesia; however, propofol has a more profound effect in suppressing the sympathetic response to intubation and, as long as hypotension is avoided, may be the best induction agent in patients with carcinoid syndrome. Etomidate may have less effect on heart rate (HR) and BP, but may not suppress laryngeal reflexes. Use of histamine-releasing agents, such as morphine, thiopental, pancuronium, and atracurium, should be avoided.

Succinylcholine-induced increases in intraabdominal pressure from fasciculations may trigger mediator release; however, some researchers have not found any adverse effects with its use. Opioids that are associated with histamine release should not be

used. Furthermore, only nondepolarizing neuromuscular blocking agents that do not cause histamine release should be used. Because of its cardiovascular stability, vecuronium is a good choice, and rocuronium is an effective alternative.

A balanced technique that incorporates positive pressure ventilation, an inhalation agent, a nondepolarizing neuromuscular blocking agent, and an opioid, most commonly fentanyl, may be the best choice in patients with carcinoid. Propofol infusions also have been reported. Inhalation agents with low blood-gas solubility such as desflurane are preferred, although all available inhalation agents have been used. Nitrous oxide also is safe. A technique using high-dose opioids may be indicated because volatile anesthetics may cause myocardial depression and hypotension, resulting in release of tumor peptides. Because these patients often have chronic right ventricular (RV) valvular lesions and heart failure, one should avoid anesthetic factors that increase RV work with potential precipitation of acute RV failure. This includes hypoxemia, hypercarbia, and a light anesthetic plane.[117] Hypotension should be treated with an alpha-receptor agonist such as Neo-Synephrine to avoid beta-adrenergic activation.

TRANSPLANTATION

Transplantation is typically the definitive treatment for end-stage organ disease. Because transplant surgery and patient management is continually evolving, specific details of best practice are perishable and should be reevaluated before clinical implementation. A brief overview is provided here of selected organ transplantation procedures.

Liver Transplantation

In 2010, 6291 liver transplants were performed in the United States (Organ Procurement Transplant network, http://optn.transplant.hrsa.gov/). Ten-year (adjusted) patient survival rate of the 3487 deceased donor liver transplants (DDLT) performed in the United States in 1999 is 59.8%. Living donor liver transplant (LDLT) patient's 10-year survival (of 237 transplants) rate is 67.2%. Compared with DDLT, survival rates at 1, 3, and 5 years for LDLT are markedly higher, ranging from 94% to 85%, respectively. Despite living donor liver transplant patients having significantly higher survival rates in all time measurements, they are performed much less frequently (212 vs. 5170 in 2008) because of a limited number of willing and compatible donors.

Patients with end-stage liver disease who have exhausted medical and surgical therapy may be eligible for liver transplantation. Eligibility requirements are multifactorial but common indications/contraindications[121,122] for liver transplantation exist (Table 30-15 and Box 30-13).

Preoperative preparation and intraoperative anesthetic management for liver transplant surgery requires, at least, an understanding of the various stages of the surgery and the physiologic derangements occurring as a result of baseline hepatic dysfunction and surgically induced hematologic and metabolic insult.

Anesthetic Preparation

The comorbidities accompanying severe liver disease were discussed earlier in the chapter. Coagulopathy and anemia are baseline maladies that become more problematic in the context of significant blood loss expected during liver transplantation. Blood products need to be immediately available during surgery, and a clear line of communication needs to exist with the transfusion service (e.g., blood bank) to handle ongoing replacement requirements.

Arterial cannulation is needed for invasive BP monitoring and serial blood analysis throughout surgery. Changes in commonly monitored parameters are shown in Table 30-16. Large-bore venous access is indicated for liver transplant surgery. Often two 9-Fr introducers may be inserted for central access and a large (e.g., 8.5 Fr) antecubital catheter may be used for volume administration via a rapid infuser device (RID). If venovenous bypass will be used intraoperatively (potentially using the internal jugular if not the axillary vein), those sites should be avoided. Communication with the surgical team can clarify this decision. Pulmonary artery catheter and/or TEE may be used in many patients for managing fluid replacement and monitoring cardiac function. Normothermia should be maintained with appropriate warming devices (e.g., forced air, conductive blankets, fluid warmers, and heated venovenous bypass).

TABLE 30-15 Indications for Liver Transplantation

Indications	Examples
Acute hepatic necrosis	Viral hepatitis, drug toxicity, toxin, Wilson's disease
Chronic hepatitis	Hepatitis B, hepatitis C, hepatitis D, autoimmune hepatitis, chronic drug toxicity or toxin exposure, cryptogenic cirrhosis
Cholestatic diseases	Primary biliary cirrhosis, sclerosing cholangitis, secondary biliary cirrhosis, biliary atresia, cystic fibrosis
Alcoholic cirrhosis	May be considered for transplant if abstinence of alcohol for 6 months and ongoing therapy and evaluation
Metabolic diseases	Wilson's disease, cystic fibrosis hemochromatosis, alpha-1-antitrypsin deficiency, familial homozygous hypercholesterolemia, glycogen storage disease, tyrosinemia
Malignant diseases of the liver	Hepatocellular carcinoma, carcinoid tumor, islet cell tumor, epithelioid hemangioendothelioma

BOX 30-13

Contraindications for Liver Transplant

- Severe cardiopulmonary disease
- Active alcohol or substance abuse
- Extrahepatic malignancy
- Active/uncontrolled infection or sepsis
- Life-limiting neurologic conditions
- Uncontrolled psychiatric disorder
- Acquired immune deficiency syndrome

Surgical Transplantation and Anesthetic Management

Liver transplantation requires vascular reconstruction of the hepatic artery, the portal vein, and the hepatic venous drainage to the inferior vena cava. Biliary reconstruction usually is accomplished using an end-to-end anastomosis of the proximal donor bile duct to the distal recipient duct; however, in recipients with diseased ducts, the donor duct is usually anastomosed to the jejunum using a Roux-en-Y loop.[122] Often the surgery may be divided into three phases: preanhepatic, anhepatic, and postanhepatic (or neohepatic) phase. Anesthesia management guidelines vary between institutions (Box 30-14).

TABLE 30-16 Relative Changes in Parameters During Liver Transplantation*

Preanhepatic Phase. In conventional liver transplantation (CLTx), the preanhepatic stage starts at surgical incision and ends once cross clamps are placed on the hepatic artery, suprahepatic inferior vena cava, the infrahepatic inferior vena cava, and the portal vein. Not all surgical techniques require full venous arrest, because some centers will do a piggyback liver transplant (PLTx) in which caval clamping is avoided. In fact, recent studies have shown that with the advancement of surgical skills, refinement of surgical techniques, and improvements in anesthesiology, there are only limited indications for doing CLTx with venovenous bypass (VVB) routinely. PLTx with preservation of inferior vena cava (IVC) can be performed in almost all primary transplants and in the majority of retransplantations without the need for VVB.[123]

As ascites are drained after abdominal incision, hypovolemia may ensue, requiring volume replacement. Both crystalloid and colloid may be necessary to minimize alterations in preload. Further reduction in preload should be anticipated if flow from the inferior vena cava is halted, and appropriate fluid replacement should be instituted venous shunting or until venovenous bypass is initiated. VVB, which diverts inferior vena cava and portal venous flow to the axillary vein, attenuates the decrease in preload, improves renal perfusion pressure, lessens splanchnic congestion, and delays the development of metabolic acidosis.[124] Disadvantages of VVB, including a high complication rate (10%-30%)[125] and lack of evidence for improving clinical outcome[126], appear to limit its usage now to selected cases.

Some coagulopathy associated with liver transplantations are noted in Table 30-17. Some clinicians may choose to address correctible baseline coagulopathy during this stage and begin infusion of fresh frozen plasma (FFP). Surgically induced vascular injury

BOX 30-14

Anesthesia Guidelines for Liver Transplant at the University of Wisconsin, 2011

Preanhepatic Phase
- Anesthesia induction
- Invasive monitors (arterial catheter, pulmonary catheter vs. FloTrac/Vigilio)
- Forced air and fluid warmers on
- IV antibiotics, baseline laboratory values (including TEG), incision
- Lower CVP to 5 cm H_2O, restrict IV fluid, phlebotomy if Hgb greater than 10g/dL
- Norepinephrine (or vasopressin) to keep mean BP greater than 60 mmHg
- Dopamine (or epinephrine) to keep CO at greater than 5L/min
- Maintain Hgb at greater than 7g/dL, platelets greater than 40,000, MA (TEG) greater than 45, fibrinogen greater than 100 mg/dL
- Mannitol 0.5g/kg IV over 1 hour, prior to anticipating clamping
- Just before clamping:
  - IV heparin 3000-5000 units, if TEG is normal or hypercoagulable
  - Increase CVP to 10 cm H_2O with IVF
  - 25% albumin in severe hypoalbuminemia

Anhepatic Phase
- IV fluids to keep CVP around 5 cm H_2O
- Maintain Hgb at greater than 7g/dL
- Norepinephrine and/or vasopressin to keep mean BP greater than 60 mmHg and CO greater than 5L/min
- Bicarbonate infusion to correct base deficit
- IV calcium chloride to sustain normocalcemia

Neohepatic Phase
- Reperfusion
- When SVR is declining, IV vasopressin 1-5 unit bolus to keep mean BP at greater than 60 mmHg
- Epinephrine 20-100 mcg boluses if heart rate is less than 60/min
- Euvolemia: CVP of 5-10 cm H_2O
- Dopamine (or epinephrine) to keep CO at greater than 5L/min
- Norepinephrine and/or vasopressin to keep mean BP at greater than 60 mmHg
- TEE if needed for detailed hemodynamic assessment
- Maintain Hgb at greater than 7g/dL, platelets at greater than 40,000, fibrinogen at greater than 100 mg/dL
- TEG:
  - Protamine 30 mg IV, if R is more than twofold compared with heparinase-R
  - Maintain MA at greater than 45 mm with platelet transfusion
- If Ly30 is greater than 8%, give IV EACA 5 g over 15 min:
  - Consider indication for postoperative mechanical ventilation per usual criteria
  - Recovery in PACU (if extubated in OR) vs. ICU (if mechanically ventilated)

TABLE 30-17 Coagulopathy During Orthotopic Liver Transplantation

Stage	Coagulopathy
Dissection	Preexisting coagulopathy Dilution Fibrinolysis (mild) Ionized hypocalcemia Dilution
Anhepatic	Heparin effect (with venovenous bypass) Fibrinolysis (moderate) Hypothermia Ionized hypocalcemia Fibrinolysis (severe)
Early neohepatic	Heparin effect Intravascular coagulation Dilution Hypothermia Ionized hypocalcemia
Late neohepatic	Gradual recovery

From Kang Y, Audu P. Coagulation and liver transplantation. *Int Anesthesiol Clin*. 2006;44(4):19.

and impaired clearance of activated coagulation factors caused by decreased hepatic blood flow may result in excessive activation of coagulation and consumptive coagulopathy, whereas surgical bleeding may deplete coagulation proteins and platelets, inducing dilutional coagulopathy.[127]

Prothrombin time, fibrinogen, and platelet count may be evaluated to guide correction of coagulopathy. Thromboelastography (TEG) also has been employed to define the viscoelastic properties of blood. TEG is able to provide information about platelet activation, fibrin formation, and clot retraction. It has been used extensively to guide therapy of coagulation disorders.[128] Wang et al.[129] reported that liver transplantation patients monitored via TEG used significantly less FFP, and there was a trend toward less blood loss in the TEG-monitored patients. Blood loss is typically minor in the preanhepatic stage, although patients with significant portal hypertension have a higher bleeding tendency.

Anhepatic Phase. If performed, transection of the IVC above and below the liver results in predicable hemodynamic changes: decreased cardiac output related to the decrease in venous return, and decreased arterial blood pressure. Historically, venovenous bypass was used routinely (in some centers) to facilitate venous return from the portal system and lower body to the heart via a centrifugal pump to the axillary or subclavian vein. If IVC occlusion is used and VVB is not instituted, the decreased preload may be treated with norepinephrine infusion with addition of phenylephrine for refractory low systemic vascular resistance.

Acidosis encountered during the anhepatic phase because of the accumulation of acid metabolites and reduction of perfusion can be treated with sodium bicarbonate to correct base deficit. Blood loss during this period will necessitate transfusion blood products; calcium chloride also may be infused to correct transfusion-induced hypocalcemia and to maintain blood pressure at the anhepatic phase.

The now more common piggyback liver transplant may be successfully done with an end-to-side cavocavostomy[130] with limited hemodynamic alterations typically associated with complete caval obstruction. Liver transplant surgery was historically associated with massive blood loss and hemodynamic instability. Mangus et al.[131] reported in 2007, in a retrospective review of 526 transplant patients, that piggyback hepatectomy (PGB) can be safely accomplished in nearly all liver transplant patients without venovenous bypass or vena cava clamping and with less warm ischemia. In their analysis, estimated blood loss (EBL) was 1000 mL and median transfusion requirement was 3 units packed red blood cells, 7 units fresh frozen plasma, and 6 units platelets.

Postanhepatic Phase. Reperfusion of the graft begins the neohepatic stage. Once the donor liver is implanted and blood flow is resumed, the release of portal blood flow from the graft can result in significant hemodynamic instability and post reperfusion syndrome (PRS).[132] PRS, defined as a decrease in the mean arterial pressure of more than 30% of the value observed in the anhepatic stage, is marked by hypotension, decreased systemic vascular resistance (SVR), and increased pulmonary artery pressures. The absence of portocaval shunt and the duration of cold ischemia were independent predictors of intraoperative PRS. The etiology may be an influx of a cold, acidic, hyperkalemic fluid and other mediators into systemic circulation. Electrolyte abnormalities should be addressed before reperfusion because acidosis, hyperkalemia, and hypocalcemia are commonly encountered after the transplanted liver is perfused.

Reduction in SVR may be treated with venous hydration to maintain euvolemia (e.g., CVP 5-10), norepinephrine, and/or vasopressin to maintain mean arterial blood pressure at greater than 60 mmHg. Dopamine may be needed to maintain cardiac output (e.g., greater than 4 or 5).

Coagulation status should be monitored and corrected during this phase.

Fibrinolysis (detected by elevated TEG) is most severe after reperfusion. TEG results of patients with fibrinolysis will show a decrease in maximum amplitude (MA) on the tracing. MA measures the strength of the clot, which is an overall reflection of the structural interactions and fibrinogen, interlaced with fibrin polymers. Platelet function and aggregation have the greatest effect on MA.[133] Antifibrinolytics (e.g., aminocaproic acid) and cryoprecipitate may be required. Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) may be administered to help improve platelet function.

Excessive hydration with crystalloid and blood components should be avoided to prevent peripheral and pulmonary edema, decreased oxygenation, and the risks associated with prolonged intubation and ventilation. Some common intraoperative complications and their management are noted in Table 30-18.

Other Intraabdominal Organ Transplants

Intestine

Intestinal transplantation occurs at a much lower rate compared with liver or kidney. In 2008, 158 intestine transplants were performed in the United States. Bowel transplantation was first attempted in the 1960s and had a low success rate until the mid-1980s, which coincided with improved immune suppressive drugs and better methods to prevent infections. The intestine has been more difficult to transplant than other solid organs; some of the possible reasons include a large number of white cells in the bowel (providing a strong stimulus for rejection) and omnipresent bacterial presence in the gut increasing the risk of infection after transplantation.

One-year patient and intestine graft survival is 89% and 79% for intestine-only recipients and 72% and 69% for liver-intestine

TABLE 30-18 Intraoperative Complications and Management

Complication	Management
Hypothermia	Use heat exchanger, fluid warmer, warming blanket, forced-air units, postoperative ventilation, warm blood flush
Hyperkalemia	Elevated by massive transfusion; administer binding resins; perform diuresis, dialysis, hyperventilation; administer sodium bicarbonate, calcium chloride, insulin, or glucose
Hypocalcemia	Administer calcium chloride or gluconate by central line, citrate in blood may bind thus lower calcium
Oliguria	Maintain adequate volume; increase renal perfusion pressure; administer mannitol, furosemide, and ethacrynic acid; renal replacement therapy
Hypotension	Maintain adequate volume, check calcium and magnesium, rule out cardiac dysfunction, administer vasopressors; transfuse blood products if anemia or coagulopathy is present monitor for emboli, vena caval compression
Hypertension	Maintain adequate anesthetic depth, reduce filling pressures, avoid long-acting agents that are used to treat hypertension
Postreperfusion syndrome	Anticipate; ensure that volume loading is not excessive; administer calcium, vasopressors
Coagulation	Monitor coagulation status throughout massive transfusion; administer platelets, fresh frozen plasma, and other antidotes as indicated

recipients, respectively. By 10 years, patient and intestine survival falls to 46% and 29% for intestine-only recipients, and 42% and 39% for liver-intestine recipients, respectively.[134] Given the relative infrequency of this transplant, specialty texts or current research should be reviewed for surgical and anesthetic implications of these procedures.

Pancreas

Pancreas transplantations in diabetic patients are divided into three categories: (1) simultaneously with a kidney (SPK) (75%), (2) after a previous kidney transplantation (PAK) (18%), and (3) pancreas transplantation alone (PTA) (7%). Transplantation may be performed on patients with poorly controlled diabetes mellitus with impending complications, but more often it is done concurrently for patients with end-stage renal disease undergoing simultaneous renal transplantation (Figure 30-9).

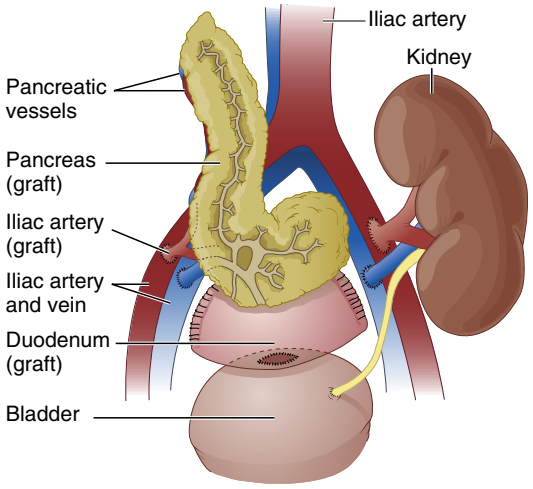

FIGURE **30-9** Simultaneous kidney-pancreas transplant. (From Carlson KK, ed. *AACN Advanced Critical Care Nursing*. St. Louis: Saunders; 2009:834.)

In 2011, Gruessener[135] reported that changes in surgical technique and immunosuppressive protocols have led to improved patient and graft survival. One year post-transplant patient survival is now over 95%, and over 83% after 5 years. The best graft survival was found in SPK with 86% pancreas and 93% kidney graft function at 1 year. PAK pancreas graft function reached 80%, and PTA pancreas graft function reached 78% at 1 year. In all three categories, early technical graft loss rates decreased significantly to 8% to 9%. Likewise, the 1-year immunologic graft loss rate also decreased: in SPK, the immunologic 1-year graft loss rate was 1.8%, in PAK, 3.7%, and in PTA, 6.0%.

As identified, pancreas-only transplantation represents a very small percentage of the overall pancreatic transplant surgeries. Anesthetic management will therefore vary depending on the organ being transplanted with the pancreas (e.g., kidney 75% of the time).

SUMMARY

Managing the anesthetic needs of patients with hepatobiliary and gastrointestinal disorders requires a thorough understanding of normal physiologic functions of the encountered organ system, as well as an appreciation for the systemic implications of pathophysiologic derangements discussed in this chapter. Advances in anesthetic and surgical management of patients are resulting in improved outcomes, but also requires ongoing inquiry by clinicians and researchers. The discussions in this chapter represent some of the most current evidence available in regard to providing quality anesthesia care and patient management.

31 CHAPTER Anesthesia for Laparoscopic Surgery

◆ *Nancy A. Moriber*

The advent and expansion of laparoscopic surgical techniques over the past 30 years has transformed the way in which practitioners approach the care of patients during the perioperative period. Surgeons in gynecology, urology, and general surgery are using laparoscopy to perform increasingly more complex diagnostic and therapeutic procedures (Box 31-1). In fact, in some cases laparoscopic approaches have almost entirely replaced the traditional open laparotomy. These "minimally invasive" surgical procedures offer many advantages over "open" procedures, but have also created unique challenges for the anesthesia community.

Although considered to be a relatively new phenomenon in health care, the origins of laparoscopic surgery date back over 100 years. In 1901 the first endoscopic examination of the peritoneal cavity, known at the time as "celioscopy," was attempted by the German surgeon George Kelling to evaluate the effects of pneumoperitoneum on intraabdominal hemorrhage associated with such conditions as ectopic pregnancy and bleeding ulcers.[1-3] Over the next 70 years several surgeons used laparoscopic techniques, but because of technologic limitations and a high complication rate from bowel and cautery injuries and vascular perforation, few mainstream surgeons embraced the techniques.[2] With the development of the open entry Hasson trocar in 1971 and videoscopic imagining in the mid-1980s, the safety of laparoscopy improved. Finally, in 1988 the first videolaparoscopic cholecystectomy was performed by the French surgeon Philip Mouret and the technique soon spread worldwide as the healthcare community began to realize the true benefits of laparoscopy—a safer, less painful, minimally invasive alternative to open laparotomy with a faster recovery and return to normal function.[2,4,5]

After the success of laparoscopic cholecystectomy, surgeons began to explore minimally invasive approaches to a vast array of complex intraabdominal procedures including herniorrhaphy, prostatectomy, hysterectomy, nephrectomy, and many others. These techniques are now employed by many surgical specialties in patients across the life span and with significant coexisting disease. As a result, the challenges associated with laparoscopy, such as pneumoperitoneum and unique positioning, are coupled with increasingly critical patients adding unique complexity to the anesthetic management for these procedures. Figure 31-1 depicts a classic approach to a laparoscopic appendectomy.

CREATION OF THE PNEUMOPERITONEUM

To perform laparoscopic procedures, it is necessary to create an environment in which the surgeon can clearly view all intraabdominal structures and successfully manipulate the instruments required for surgical dissection. This is accomplished through the creation of an artificial *pneumoperitoneum*—the installation of air or gas into the peritoneal cavity under controlled pressure. Although complications associated with laparoscopic surgery are rare, initial entry into the abdominal cavity and establishment of the pneumoperitoneum are responsible for a significant proportion of those that do occur.[6-9] Large multicenter studies have demonstrated the pooled risk of severe vascular or bowel injury at the time of abdominal entry to be 0.2 and 0.4 per 1000, respectively.[6,8] In addition to the risks caused by the placement of the surgical trocars, insufflation of gas into the peritoneal cavity produces significant physical stress on multiple organ systems. These physiologic effects are seen intraoperatively and can carry over into the immediate postoperative period, increasing the morbidity and mortality associated with these procedures.

Two entry methods are used most commonly for the establishment of the pneumoperitoneum during laparoscopic surgery—the closed technique or the open (Hasson) procedure.[6,8] Other techniques are available but are used less often because little evidence exists to support their superiority in respect to preventing the complications associated with needle and trocar placement. These techniques include direct entry without prior establishment of the pneumoperitoneum and the use of optical entry trocars.[10-12] The choice of technique is determined by the surgeon; however, the evidence indicates that patients who are extremely thin, obese, or known to have abdominal adhesions are at increased risk for laparoscopic entry-related injuries at the umbilical entry point, and they may benefit from an alternative entry procedure such as the open (Hasson) or left upper-quadrant (Palmer's point) entry technique.[6,13,14]

The closed technique involves the use of a spring-loaded needle known as a Veress needle to pierce the abdominal wall at its thinnest point, either in the infraumbilical or intraumbilical region. Various different techniques have been used to test for proper placement of the Veress needle including attempted saline aspiration and hanging-drop techniques. However, a review of recent case control and cohort studies of women undergoing laparoscopic procedures has shown that an intraabdominal pressure (IAP) of 10 mmHg or less reliably indicates correct placement of an umbilically placed Veress needle.[6,15-17] An appropriate nonflammable gas, usually carbon dioxide (CO_2), is then insufflated through the needle to increase the intraabdominal pressure, lift the abdominal wall, and create a space between it and the underlying organs. After insufflation of the abdomen, a trocar is inserted blindly or under direct vision to allow the surgeon to pass instruments into the abdominal cavity.[6,7]

The open technique was developed by H. M. Hasson in 1970 in an attempt to combine the benefits of laparoscopy with the safety of open laparotomy.[18] The technique involves the development of a 1- to 2.5-mm midline vertical incision that begins at the lower border of the umbilicus and extends through the subcutaneous tissue and underlying fascia.[19] The surgeon is then able to directly separate the abdominal wall from the underlying tissues,

minimizing the risk of damage to the bowel and vasculature. Once the surgeon has entered the abdominal cavity, a trocar can be placed under direct vision and sutured in place. Gas can then be insufflated directly through a side port in the Hasson trocar establishing the pneumoperitoneum.

BOX 31-1

Applications of Laparoscopy

General Surgery
- Diagnosis
- Evaluation of abdominal trauma
- Lysis of adhesions
- Cholecystectomy
- Appendectomy
- Inguinal hernia repair
- Bowel resection
- Esophageal reflux surgery
- Splenectomy
- Adrenalectomy
- Bariatric surgeries of all types

Gynecologic Surgery
- Diagnosis
- Lysis of adhesions
- Fallopian-tube surgery (sterilization, ectopic pregnancy surgery)
- Fulguration of endometriosis
- Ovarian cyst surgery
- Laparoscopic-assisted hysterectomy

Urologic Surgery
- Nephrectomy
- Varicocele

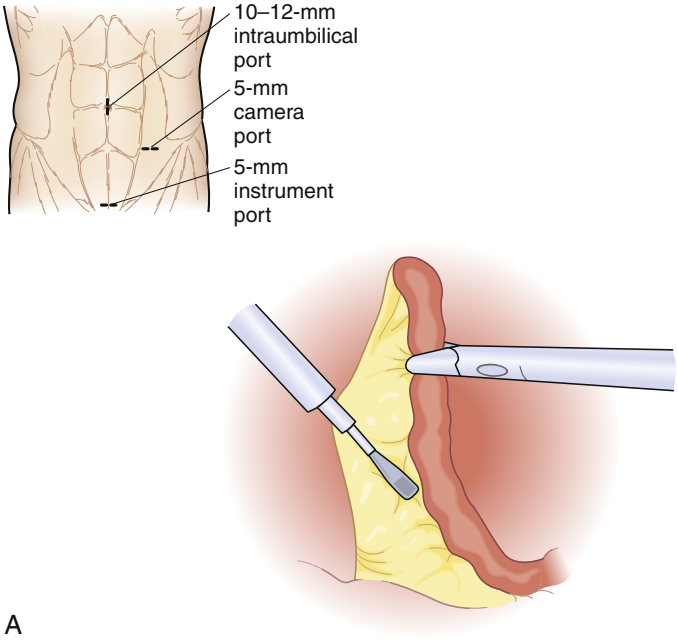

FIGURE 31-1 *Upper left*, Location of port sites for laparoscopic appendectomy. *Right*, **A,** Division of the mesoappendix using the harmonic scalpel. **B,** Placement of the appendix into a specimen bag before removal of the appendix with the umbilical port. PHYSIOLOGIC EFFECTS OF THE PNEUMPERITONEUM

As the complexity of laparoscopic surgery and the severity of illnesses in patients undergoing these procedures increase, the need to have a comprehensive understanding of the physiologic effects of pneumoperitoneum becomes paramount. The magnitude of patient response to pneumoperitoneum depends upon multiple factors, including the degree of intraabdominal pressure generated during creation of the pneumoperitoneum, the length of surgery, patient position, patient age, perioperative volume status, and the presence of preexisting pulmonary and/or cardiovascular disease.[9,20,21] Although no clinical complications have been demonstrated as being a result of transitory elevations in intraabdominal pressure, prolonged periods of high intraabdominal pressure and tension, such as those required for successful laparoscopy, have been associated with significant physiologic effects.[9,22-24] These changes occur as a result of direct mechanical pressure and the stimulation of intrinsic neurocirculatory responses. When combined with surgery-specific conditions, unique patient positioning needs (i.e., steep Trendelenburg), and variations in anesthetic technique, the net effect of intraabdominal pressure on physiologic hemostasis may be unpredictable. Fortunately, long-term clinical complications are rare.

Cardiovascular Effects

Current research has shown that creation of a pneumoperitoneum is associated with significant changes in hemodynamic parameters (Box 31-2). Consistently, increases in mean arterial pressure (MAP), systemic vascular resistance (SVR), and heart rate (HR) that are sustained over the duration of insufflation have been demonstrated.[9,20,25,26] Compression of the intraabdominal vessels and release of neuroendocrine hormones (i.e., vasopressin and renin) are implicated as causative factors in this hemodynamic response. The increases in MAP and SVR are observed regardless of whether the pneumoperitoneum is created under low pressure (12 mmHg) or high pressure (20 mmHg).[9]

Reports on the impact of abdominal insufflation on cardiac filling pressures are mixed. Several studies demonstrate increases in central pressures, whereas others show significant reductions.[20,26-28] Confounding variables, such as the use of vasodilating anesthetics and perioperative fluid restrictions, can significantly alter preload. It is known that insufflation compresses abdominal vasculature, but the extent to which this impacts venous return is not fully understood. Changes in position appear to have a greater effect on central pressures than does the pneumoperitoneum itself.[20,26] Steep Trendelenburg produces significant increases in central venous pressure because it increases hydrostatic pressure at the level of the external auditory meatus.[20]

BOX 31-2

Hemodynamic Changes Associated with Pneumoperitoneum

- Central venous pressure/LVEDP ↑ or ↓
- Mean arterial pressure ↑
- Stroke volume ↓
- Cardiac output ↑, ↓, or without change
- Systemic vascular resistance ↑
- Heart rate ↑
- QT dispersion prolonged

↑, Increased; ↓, decreased; *LVEDP*, left ventricular end-diastolic pressure.

Uniformly, studies demonstrate that creation of the pneumoperitoneum produces significant decreases in stroke volume.[26,27] These changes appear to be secondary to decreases in venous return and not changes in myocardial function. Russo et al.[26] demonstrated that in patients with healthy myocardium, left ventricular systolic function and ejection fraction as measured by transesophageal echocardiogram (TEE) were preserved regardless of surgical position. Changes in stroke volume were associated with early diastolic impairment as a result of prolonged deceleration time and augmented isovolumetric relaxation time. The decreases in stroke volume caused by increased intraabdominal pressures can be offset through adequate perioperative hydration, changes in patient position, and the application of compression stockings because these interventions augment venous return.[27]

Although it is clear that stroke volume decreases as a result of abdominal insufflation, the impact of pneumoperitoneum on cardiac output (CO) and cardiac index (CI) is variable because these parameters are influenced by a multitude of factors. In several studies, CO was maintained because reductions in stroke volume were offset by increases in heart rate and venous return, especially when patients were placed in the Trendelenburg position.[26,28] Other researchers have observed significant reductions in CI after operative insufflation pressures are achieved.[29,30] Healthy patients undergoing laparoscopic cholecystectomy have demonstrated 30% to 40% reductions in CO using a thermodilution technique.[29] In addition, significant reductions in left ventricular end-diastolic pressures have been demonstrated, which in turn negatively impact cardiac function if not accompanied by sufficient increases in heart rate.[30] Despite the variability in findings, patients who have been adequately fluid loaded and who have received therapies to augment venous return (e.g., compression stockings) experience significantly smaller reductions in CO as compared with control patients (20% versus 50%).[27]

Finally, the pneumoperitoneum appears to have an effect on the cardiac conduction system, even in healthy patients. A study by Ekici et al.[31] showed that high-pressure insufflation significantly prolonged QT dispersion (QTd) in patients undergoing laparoscopic cholecystectomy as compared with a low-pressure control group. The QTd reflects ventricular instability, and prolongation of this parameter is associated with an increased risk of arrhythmias and cardiac effects. Although these changes would not be expected to have clinical significance in healthy patients undergoing elective laparoscopic procedure, they may produce significant hemodynamic effects in elderly patients with significant cardiac disease.

Hemodynamic Changes in the Elderly

Most research on the hemodynamic effects of abdominal insufflation has been conducted in young healthy patients. Therefore, little is known about the impact of the pneumoperitoneum in the elderly population, who often present with significant comorbidity. When compared with healthy patients, patients with significant comorbidity have been shown to exhibit exaggerated hemodynamic responses to pneumoperitoneum.[32,33] The cumulative effects of carbon dioxide gas (CO_2) in the pneumoperitoneum and the reverse Trendelenburg position can result in moderate decreases in CO, as well as significant increases in filling pressures and afterload in sick patients. In one study of patients undergoing laparoscopic colorectal surgery, elderly patients exhibited greater increases in central venous pressure (CVP) and decreases in MAP, as compared with younger, healthier patients.[33] In addition, the magnitude of these changes at different time intervals was also greater in the elderly population. These findings may reflect baseline physiologic differences in organ function and compensatory mechanisms in the elderly population.[33]

Respiratory Effects

Although laparoscopic surgery is associated with a significant decrease in postoperative respiratory complications, intraoperative pulmonary function is greatly impacted by both the mechanical effects of the pneumoperitoneum and introduction of CO_2 into the intraperitoneal cavity itself. Increases in intraabdominal pressure shift the end-expiratory position of the diaphragm cephalad, decrease functional residual capacity (FRC), and create areas of atelectasis, making ventilation difficult.[34] In addition, CO_2 insufflation causes acid-base alterations that can have deleterious effects on multiple organ systems.[35]

In the presence of fixed minute ventilation, CO_2 pneumoperitoneum is associated with increases in the partial pressure of arterial CO_2 ($PaCO_2$) and end-tidal CO_2 ($ETCO_2$) with or without acidosis.[35] The increases in $PaCO_2$ are primarily caused by CO_2 absorption through the peritoneal serosa secondary to the increased intraabdominal pressure caused by the pneumoperitoneum. The resultant acidosis is considered to be respiratory rather than metabolic in nature. Studies show that during laparoscopy, decreases in arterial pH are accompanied by a rise in partial pressure of carbon dioxide (PCO_2), but not by increases in lactate or decreases in the apparent strong ion difference (SIDa).[35] These parameters return to baseline after discontinuation of CO_2 insufflation. Maximum absorption of CO_2 is noted with an intraabdominal pressure of 10 torr (mmHg pressure). $PaCO_2$ levels are noted to reach a plateau approximately 40 minutes after the induction of the peritoneum.[35-37]

A major concern during the creation of the pneumoperitoneum involves the risk of subcutaneous tracking of CO_2 through misplaced trocars or rents in the peritoneum that develop during trocar placement. Compared with intraperitoneal insufflation of CO_2, extraperitoneal insufflation (subcutaneous absorption) has been associated with an unusually rapid increase in $PaCO_2$ and exceptionally high, sustained levels of CO_2.[38-40] Cases of pneumopericardium and severe emphysema of the orbit have been documented after subcutaneous absorption of CO_2.[38,39] Factors that increase the incidence and degree include body mass index (BMI) less than 25, prolonged operative time, higher end-tidal carbon dioxide tensions, and operative approach.[40,41] Although mild hypercapnia (45 to 50 torr) is not believed to be clinically significant, profound hypercapnia with $PaCO_2$ levels in the range of 50 to 70 torr is associated with physiologic effects such as increased cerebral blood flow, peripheral vasodilation, pulmonary vasoconstriction, and increased risk of cardiac dysrhythmia.[20,42]

The mechanical effects of peritoneal insufflation impair ventilation. Insufflation of the peritoneum displaces the diaphragm in a cephalad direction, decreases functional residual capacity, decreases vital capacity, and in turn induces collapse of the dependent regions of the lungs.[34,43] Perfusion of these nonventilated alveoli causes the development of pulmonary shunt with impaired oxygenation and CO_2 elimination.[34,43] The development of atelectasis is also associated with an increase in the arterial to end-tidal PCO_2 difference.[34] Therefore, techniques such as transcutaneous carbon dioxide (P_TCO_2) monitoring may serve as a better predictor of arterial carbon dioxide ($PaCO_2$) levels than end-tidal $PaCO_2$ monitoring.[44] Increases in intraabdominal pressure also affect pulmonary compliance; in supine patients, pulmonary compliance has been observed to be reduced by 43%.[20,32]

The impact of atelectasis on gas exchange has been shown to be offset by a redistribution of perfusion away from collapsed lung

BOX **31-3**

Pulmonary Function Changes Associated with Pneumoperitoneum

- Positive inspiratory pressure (PIP) ↑
- Pulmonary compliance dV/dP ↓
- Vital capacity ↓
- Functional residual capacity ↓
- Intrathoracic pressure ↑

↑, Increased; ↓, decreased; *dV/dP*, change in volume/change in pressure.

units when the pneumoperitoneum is established.[43,44] Although the exact mechanism is not known, it appears to be the result of activation of the hypoxic pulmonary vasoconstriction (HPV) reflex.[43] Because many anesthetics inhibit the HPV reflex, increases in ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching and changes in oxygenation during laparoscopic surgery may reflect the physiologic effects of the anesthetics used, rather than the impact of the pneumoperitoneum itself. This may have implications for the choice of anesthetics used during these procedures. Physiologic pulmonary changes associated with pneumoperitoneum are listed in Box 31-3.

An additive effect is observed when general anesthesia, which in and of itself reduces FRC and pulmonary compliance, is combined with pneumoperitoneum.[34,43] The surgical position employed to facilitate exposure can either aggravate or attenuate pneumoperitoneum-induced pulmonary changes. The Trendelenburg position has been shown to increase the effects of pneumoperitoneum on pulmonary mechanics. During robotic laparoscopic prostatectomy in the steep Trendelenburg position, pulmonary compliance decreased approximately 50% and peak plateau pressures increased by 50%, and remained stable over the duration of the CO_2 insufflation.[20] In contrast, the reverse Trendelenburg position partially counteracts the effects of pneumoperitoneum on the diaphragm and improves diaphragmatic function.[45]

Another impact of pneumoperitoneum is the potential for the development of endobronchial intubation as a result of a shortening of the distance from the tip of the endotracheal tube to the carina.[46-48] Since the carina is attached to the lungs, cephalad displacement of the diaphragm compresses the lungs and shifts the position of the carina upward. Studies indicate that displacement of the tube occurs within 10 minutes of creation of the pneumoperitoneum; therefore the authors recommend reconfirmation of tracheal tube position after establishment of the pneumoperitoneum.[47,48]

Controlled mechanical ventilation is necessary to maintain normocarbia in anesthetized patients undergoing laparoscopic surgery with CO_2 pneumoperitoneum. Studies of patients in the Trendelenburg position during pneumoperitoneum reveal that a 20% to 30% increase in minute ventilation is necessary to maintain pre-pneumoperitoneum levels and prevent respiratory acidosis.[35,49] Increasing the minute ventilation by preferentially increasing tidal volume rather than increasing respiratory rate was the preferred method. In addition, the use of the pressure control (PC) modes appears to be more effective in maintaining arterial pH when compared with the volume control (VC) modes of ventilation.[50] Patients ventilated using PC were also easier to ventilate, generating significantly lower maximum peak airway pressures and increased mean airway pressures.

Patients with marginal cardiopulmonary function undergoing laparoscopic surgical procedures are at increased risk of decompensation when faced with the stress introduced by increases in intraabdominal pressure and CO_2 insufflation. Patients particularly vulnerable to the effects of exposure to prolonged CO_2 insufflation are those with increased metabolic rates (as in sepsis), large ventilatory dead space, and decreased cardiac output.[21] Patients with chronic obstructive pulmonary disease (COPD) are at increased risk of developing postoperative complications after laparoscopic procedures.[51,52] One study demonstrated the odds ratio for postoperative complication to be 1:63 in patients with significant COPD.[51] Studies also indicate that although healthy patients experience minor changes in $Paco_2$ and $ETco_2$ during CO_2 insufflation, patients with COPD show significantly higher levels of CO_2 retention and subsequent respiratory acidosis.[53] Although $ETco_2$ is standard of care for all patients, careful intraoperative monitoring of CO_2 levels during laparoscopic surgery in these patients is essential. Because of the significant arterial to end-tidal Pco_2 gradient that develops during sustained pneumoperitoneum, and which is compounded in patients with chronic CO_2 retention, $ETco_2$ may underestimate arterial CO_2. Therefore, direct measurement of $Paco_2$ via arterial blood gases or P_Tco_2 may be warrented.[34,42] Recent studies show that P_Tco_2 is an accurate, noninvasive predictor of arterial carbon dioxide levels and can be used as a proxy.[42]

Mild pulmonary dysfunction after laparoscopic procedures has been shown to persist into the immediate postoperative period in patients recovering from laparoscopic surgery. A slight restrictive breathing pattern in the postoperative period has been observed secondary to the residual effects of anesthesia, pain, and diaphragmatic dysfunction induced by stretching or reflex inhibition. In addition, after laparoscopic surgery, patients may still be subjected to an elevated CO_2 load secondary to systemic absorption and subcutaneous tracking of gas during the procedure. Moreover, if surgery is prolonged and exposure to pneumoperitoneum is sustained for the majority of the procedure, CO_2 may be stored in skeletal muscle and bone. It may take hours for this excess CO_2 to be excreted from the patient.[54]

Renal Effects

The effects of pneumoperitoneum on renal physiology primarily manifest as transient increases in creatinine clearance and decreases in urinary output.[23,55,56] Oliguria has been reported but most commonly occurs only during periods of sustained high intraabdominal pressures.[23,55,56] It is proposed that the high intraabdominal pressures created during the pneumoperitoneum cause transient renal injury by reducing renal blood flow and subsequently causing hypoperfusion of the renal cortex. High intraabdominal pressures (15 mmHg or greater) create renal oxidative stress and the generation of tissue oxidases that promote tubular injury.[23] In addition, the neuroendocrine response to pneumoperitoneum, the release of antidiuretic hormone (ADH), and the presence of respiratory acidosis induces a sympathetic response and renal vasoconstriction, which further diminishes renal blood flow.[23,57,58]

Hepatic and Splanchnic Effects

There is conflicting evidence regarding the effects of increased intraabdominal pressure on hepatic and splanchnic blood flow. Several animal studies have demonstrated that abdominal insufflation can cause marked decreases in splanchnic and liver perfusion, as well as intestinal ischemia secondary to the production of oxygen free radicals and bacterial translocation.[59,60] This is further supported by the fact that approximately 50% of patients undergoing laparoscopic cholecystectomy demonstrate elevated liver enzymes.[61,62] Other studies indicate that low-pressure insufflation

of the abdomen either did not disrupt or improved hepatic and splanchnic perfusion, possibly secondary to the local vasodilatory effect of CO_2 on splanchnic vasculature.[63,64]

Immunologic Effects

CO_2 pneumoperitoneum also may have a negative effect on the local immune response by altering the concentrations of certain cytokine levels with the peritoneum. Several studies have demonstrated that CO_2 pneumoperitoneum influences the growth of cultured human cancer cells, and that this effect is pressure dependent.[65,66] Other studies have shown no significant differences in levels of cytokines and other proinflammatory factors between low- and high-pressure insufflation.[67] Proinflammatory cytokines and angiogenic factors have been shown to influence neoangiogenesis, adhesion formation, and normal wound healing processes.

COMPLICATIONS OF LAPAROSCOPIC SURGERY

Although laparoscopy has revolutionized the way surgery is conducted today, it is not devoid of complications. Even though major complications are rare, when they do occur, they are usually associated with significant morbidity. More than 50% of all complications occur during entry into the abdomen and insertion of trocars.[8,68] Entry-related complications involve intestinal, urinary tract, and vascular injuries, as well as carbon dioxide gas embolism.[68] The reported incidence of these injuries is between 0.3% and 1.0% of all laparoscopic procedures.[68,69]

Unfortunately, approximately 30% to 50% of these injuries go undiagnosed intraoperatively, resulting in significant surgical mortality (3.5%-5%).[8] Rates as high as 30% have been reported when major bowel and vascular injuries occur.[70] Delayed diagnosis may occur because initial signs and symptoms may be confused with other conditions such as anaphylaxis, gas embolism, or perioperative cardiac events. Frequently, bleeding may be occult and confined to the retroperitoneal space, which can tamponade significant hemorrhage.

The potential for injury to intraabdominal structures during the creation of the pneumoperitoneum is easily understood when one considers the proximity of anatomic structures to the site of incision and infraumbilical puncture. The major abdominal vessels including inferior vena cava, aorta, and iliac arteries and veins, as well as the bladder, bowel, and uterus, lie in close proximity to the entry points. Factors that increase risk of injury include body habitus, anatomic anomalies, prior surgery, surgical skill, degree of abdominal elevation during trocar placement, patient position, and the volume of gas insufflation.[6,68]

A prompt and coordinated response is required to prevent morbidity associated with vascular injury. Blood on aspiration of the Veress needle, free intraperitoneal blood, or unexplained hypotension and tachycardia should alert the operative team to a potential vascular injury.[69] Retroperitoneal hematomas are often difficult to visualize during laparoscopy and may become apparent only when blood loss is significant. Temporary measures to control bleeding may be possible through the abdominal trocar while resuscitative measures are instituted, but definitive treatment is usually achieved via conversion to an open laparotomy.

Visceral injuries can occur at any time during laparoscopy and are associated with significant morbidity and mortality. Intestinal injuries occur in 0.3% to 0.5% of operative laparoscopies, and less than 50% of these are recognized at the time of surgery. Diagnosis is difficult because presenting symptoms vary significantly depending upon the location of injury and degree of peritoneal contamination. Early recognition and surgical repair is essential to prevent mortality from bowel injuries. Untreated patients may develop peritonitis, sepsis, respiratory distress, and multisystem organ failure.[69] Because of the seriousness of these complications, many practitioners advocate the use of the open (Hasson) entry laparoscopic technique, because it is believed to be associated with a lower incidence of unrecognized vascular and visceral injury.[6]

Injury to the urinary tract occurs in 0.5% to 8.3% of cases secondary to trauma from instrument manipulation, electrocautery, or laser.[71] These injuries are easily recognized by direct visualization of urine leakage from damaged structures. Therefore, urinary bladder catheterization and instillation of methylene blue dye is often employed during these procedures when significant risk of damage to urinary structures is suspected.[68]

To help decrease the incidence of major vascular and visceral injury during laparoscopic surgery, the Royal College of Obstetricians and Gynaecologists (RCOG) has established evidence-based practice guidelines for abdominal entry.[6] Quality randomized controlled trials and systematic reviews consistently demonstrate that placement of the primary trocar under high pressure (25 mmHg) creates the safest distance between the anterior abdominal wall and underlying abdominal contents in order to minimize injury from trocar insertion. In addition, in healthy patients these transitory, high intraperitoneal pressures appear to be well tolerated without significant adverse clinical effects.[9]

Another potentially life-threatening complication of laparoscopic surgery is gas embolism. Gas embolism is defined as the direct entrainment of air and/or other medical gases such as carbon dioxide into the arterial or venous system.[68,71] Significant gas embolism is rare, having a reported incidence of 0.001% to 0.59% and an associated mortality rate of up to 28.5%.[68] Massive and/or fatal gas embolisms have been reported during all types of laparoscopic procedures including laparoscopic cholecystectomy, liver resection, and hysterectomy.[72-74] It can occur any time there are open vessels that have an intravascular pressure that is below intraabdominal pressure or with the erroneous placement of a Veress needle or trocar into the lumen of an intraabdominal vessel.

Recent animal and human studies using transesophageal echocardiography and monitoring of pulmonary artery pressure have shown that the actual incidence of gas embolism during laparoscopic procedures is between 65% and 100%.[71,75,76] The majority of these embolisms, while minor, were still associated with respiratory and hemodynamic changes that usually resolved spontaneously. These studies raise concerns regarding best practices for appropriate monitoring during the perioperative period in patients undergoing laparoscopic procedures. Intravascular insufflation of large volumes of gas can travel to the right side of the heart where they enter the pulmonary circulation and lodge in the pulmonary outflow tract, causing increased pulmonary artery pressure, right ventricular failure, decreased pulmonary venous return with subsequent decreased left ventricular preload, decreased cardiac output, asystole, and cardiovascular collapse.[68]

Signs and symptoms of a significant gas embolism in the anesthetized patient include an acute decrease in end-tidal pressure of carbon dioxide ($P_{ET}CO_2$), and an increase in end-tidal nitrogen, hypotension, or hypoxia that cannot be explained by deep anesthesia or hypovolemia.[71] Dysrhythmias, severe hemodynamic instability, and cardiovascular collapse can occur with large volumes of gas, especially in patients with impaired cardiovascular function and minimal cardiac reserve.[71]

Diagnosis of gas embolism depends upon recognition of the physiologic manifestations of gas emboli and/or visual detection of gas emboli in the right side of the heart and pulmonary outflow tract. Transesophageal echocardiography is the most sensitive diagnostic technique for the detection of gas emboli and can

identify emboli as small as 0.02 mL/kg.[77] However, this technology is rarely used because these volumes of air are well tolerated and usually not associated with hemodynamic changes. Changes in Doppler sounds and increases in pulmonary artery pressures will occur with volumes of 0.5 mL/kg of gas. Unfortunately, when the "classic mill wheel murmur" is audible, gas volumes of 2 mL/kg or more have been entrained, and significant hemodynamic instability is present manifesting in tachycardia, hypotension, cardiac dysrhythmias, cyanosis, and electrocardiogram (ECG) changes indicative of right-sided heart strain.[78]

Management of gas embolism includes halting the insufflation of gas, eliminating nitrous oxide (N_2O) from the anesthetic gases if it is being administered to prevent expansion of the embolism, releasing the pneumoperitoneum, flooding the field with normal saline to halt gas entrainment, placing the patient in left lateral decubitus position (Durant maneuver), aspirating the gas through a central venous catheter if in place, and supporting the hemodynamics with volume and pressors as required.[71] Low central venous pressure (CVP) increases the risk of venous gas embolism; therefore adequate hydration should be provided for the patient undergoing laparoscopy.[79] Box 31-4 lists the signs, symptoms, and treatment of gas embolism.

Another set of serious but rare complications related to the creation of pneumoperitoneum occur as a result of migration of gas into adjacent body cavities and include unilateral or bilateral pneumothorax, pneumomediastinum, and pneumopericardium. Gas may enter the thoracic cavity via congenital defects in the diaphragm, embryonic connections between the thoracic and abdominal cavities that may open under high pressure, or through perforations in the diaphragm or pleura during upper abdominal laparoscopic procedures, most commonly during laparoscopic esophageal surgery.[80,81] A retrospective review of 968 cases revealed an incidence of pneumothorax or pneumomediastinum in 1.9% of patients.[82] Another possible cause of pneumothorax is barotrauma secondary to increased airway pressures and decreased pulmonary compliance as a result of abdominal insufflation.[83] Pneumothorax caused by CO_2 insufflation may rapidly resolve spontaneously without intervention.[84] However, pneumothorax that results from barotrauma, such as a ruptured bleb, requires surgical decompression and chest tube placement.[83]

Mild to severe localized or generalized subcutaneous emphysema is a frequent manifestation of pneumoperitoneum that occurs as a result of gas entry into the subcutaneous tissues. As previously discussed, it can be the result of trocar or Veress needle misplacement in subcutaneous tissue or the result of high intraabdominal pressure and movement of gas through defects in the peritoneum.[38-40] Most cases of subcutaneous emphysema are clinically insignificant; however, it has been associated with the development of severe hypercarbia, decreased chest compliance, and hemodynamic instability.[20,42] Most cases resolve spontaneously.

The ideal gas for the creation and maintenance of pneumoperitoneum would demonstrate several properties, including colorlessness, lack of flammability in the presence of electrocautery, physiologic inertness, and excretion via a pulmonary route.[85] Several gases have been investigated in an attempt to find an alternative to CO_2 that is devoid of hemodynamic and respiratory effects. Both nitrous oxide and air support combustion and could not be used in the presence of electrocautery, which is essential for successful laparoscopy.[54] Inert gases such as helium have been evaluated for use in abdominal insufflation, but helium is not highly insoluble and raises issues about safety in the presence of a significant gas embolism.[86]

To date, carbon dioxide has proven to be closest to an "ideal" gas for abdominal insufflation. CO_2 is readily available and inexpensive, does not support combustion, and is rapidly absorbed from the vascular space and is readily excreted by the respiratory system. However, when used in a pneumoperitoneum, prolonged CO_2 absorption can cause hypercarbia and respiratory acidosis.[80] It is also a known peritoneal and diaphragmatic irritant, which has been implicated as a causative factor in the development of postoperative shoulder pain.[87]

BOX 31-4

Gas Embolism

Signs and Symptoms
- ↓ $P_{ET}CO_2$, ↑ end-tidal nitrogen
- Increased pulmonary artery pressures
- Hypotension
- Dysrhythmias
- Cyanosis
- Hypoxia
- Pulmonary edema
- "Mill wheel" murmur

Treatment
- Discontinue gas insufflation
- Discontinue nitrous oxide
- Administer 100% oxygen
- Release pneumoperitoneum
- Flood surgical field with normal saline
- Position patient in left lateral decubitus position
- Attempt to aspirate gas via central venous catheter
- Supportive measures to maintain hemodynamics

↑, Increased; ↓, decreased; $P_{ET}CO_2$, end-tidal pressure of carbon dioxide.

ANESTHETIC MANAGEMENT

Laparoscopic surgeries have been performed using local, regional, and general anesthetic techniques. The choice of anesthetic technique is dependent upon the specifics of the surgical procedure and patient preference.

Local anesthesia with sedation has been used successfully in the United States for patients undergoing minor gynecologic laparoscopic surgical procedures such as diagnostic laparoscopy or sterilization since 1971.[88] The use of local anesthesia is facilitated by surgical techniques such as the use of single-port techniques, low-pressure pneumoperitoneum, and port and small-diameter laparoscopes.[89] Research indicates that compared with patients who received general anesthetics, patients who received local anesthesia had shorter hospital stays and a reduction in overall hospital and anesthesia costs.[88,89] In addition, they demonstrated a faster recovery, decreased incidence of postoperative nausea and vomiting, and fewer hemodynamic changes. However, use of this anesthetic technique requires a cooperative patient and gentle surgical manipulation. When heavy sedation is required, the combination with pneumoperitoneum can result in hypoventilation and arterial oxygen desaturation.[90]

Regional anesthesia techniques, including spinal and epidural anesthesia, also have been used successfully for laparoscopic procedures including cholecystectomy without significant ventilatory compromise.[91] However, significantly high sensory levels are required for these procedures, which may lead to patient discomfort. In addition, shoulder pain secondary to diaphragmatic irritation from insufflated carbon dioxide is not well managed by means of regional techniques.[92]

General anesthesia is the most common anesthetic technique for the diagnostic and surgical laparoscopy. General anesthesia allows for control of ventilation and facilitates management of patient discomfort associated with the creation of the pneumoperitoneum and changes in intraoperative position such as steep Trendelenburg.

Most often the airway is secured with a cuffed endotracheal tube to facilitate ventilation and prevent aspiration of gastric contents. Minute ventilation is increased by approximately 15% to 35% to offset CO_2 absorption and maintain $P_{ET}CO_2$ between 35 and 45 mmHg. This is most effectively performed using pressure-controlled versus volume-controlled ventilation.[50] Intraoperative recruitment maneuvers, the application of positive end-expiratory pressure (PEEP), and the use of innovative ventilator modes have all been successful in improving lung compliance, oxygenation, and ventilation.[93-95] Studies show that the combination of PEEP 10 cm H_2O and intermittent positive airway pressure (40 cm H_2O) for 40 seconds was most effective in improving end-expiratory lung volumes, lung compliance, and arterial oxygenation in both healthy weight and obese patients than either intervention alone.[93,94]

The use of laryngeal mask airway (LMA) and other supraglottic airway devices in patients receiving general anesthesia for laparoscopic surgery remains controversial. Several authors have expressed concerns that the increased intraabdominal and intrathoracic pressures characteristic of pneumoperitoneum place the patient at increased risk of gastroesophageal reflux and pulmonary aspiration. In addition, the classic LMA does not secure the airway and the low seal pressures preclude the use of high airway inflation pressures without causing gastric distention.[96]

The barrier pressure (BrP) quantifies resistance to gastroesophageal reflux and is defined as the difference between the lower esophageal sphincter pressure and the gastric pressure.[97] To prevent aspiration, the gradient needs to remain positive because this will help prevent the lower esophageal sphincter from opening. A study examining the effect of induction, intubation, anesthesia, and pneumoperitoneum on barrier pressure in nonobese patients undergoing laparoscopy and obese patients undergoing laparoscopic gastric bypass showed that BrP decreased in both groups but at all times remained positive.[97] The obese patients, however, had lower BrP at all points when compared with the nonobese patients, suggesting that they may be at increased risk for aspiration. In addition, Rabey et al.,[98] in a study of general and orthopedic surgery patients, demonstrated reductions in lower esophageal sphincter pressures when an LMA was used as an airway in general anesthesia.

Researchers have conducted studies to evaluate the safety and efficacy of LMAs in a variety of laparoscopic procedures. A meta-analysis by Brimacombe and Berry[99] of 547 LMA publications, which used multiple anesthetic techniques, found the incidence of pulmonary aspiration to be two in 10,000 or 0.02%. Most of these patients demonstrated preexisting risk factors for pulmonary aspiration. A study comparing the ProSeal LMA and Laryngeal Tube Suction demonstrated that both devices were able to provide a secure airway under conditions of elevated intragastric pressure and positive pressure ventilation, without evidence of pulmonary aspiration.[100] In addition, both devices allow for decompression of the stomach so that continuous gastric decompression can be accomplished. The efficacy of the LMA supreme versus the i-gel was also evaluated in approximately 100 patients undergoing laparoscopic surgery in the Trendelenburg position.[101] Again, both devices provided an adequate seal during controlled ventilation and allowed for decompression of the stomach throughout the procedures. Similar findings were demonstrated in a randomized prospective study evaluating the Cobra Perilaryngeal Airway and the LMA classic.[102] There have been reports of aspiration after improper placement and foldover of ProSeal LMA.[103] The authors recommend that placement be guided using a gum elastic bougie and that positioning be confirmed by determining patency of the gastric lumen.

Research suggests that under certain circumstances, the use of the LMA and other supraglottic devices may be appropriate during laparoscopy, but no general consensus exists to date.[104] Many clinicians feel that the risk of airway difficulties is too high to warrant their use. With the development of newer supraglottic devices that allow for decompression of the stomach and adequate high-pressure ventilation, the issue may become clearer. Guidelines for use of the LMA in laparoscopy were developed by Brimacombe and Brain in 1996.[105] They recommend that clinicians who use the LMA during laparoscopy should, among other considerations, be experienced and adhere to the "15" rule, which requires that the surgery not exceed 15 minutes' duration, the tilt of the bed be less than 15 degrees, and the intraabdominal pressure be less than 15 cm H_2O. Box 31-5 lists some LMA guidelines for laryngoscopy.

There is no one specific anesthetic technique that is best for laparoscopic surgery. The choice is dictated by a combination of factors including the surgical procedure, postoperative disposition of the patient (ambulatory or in-patient) and the presence of coexisting disease processes. However, the use of nitrous oxide (N_2O) in laparoscopic surgery has been a source of controversy because of beliefs that N_2O contributes to bowel distention and increases the incidence of postoperative nausea and vomiting (PONV). Based upon the evidence, the jury is still out.

The effect of nitrous on the incidence of PONV has been evaluated in several recent studies. A randomized controlled trial in three groups of patients undergoing gynecologic laparoscopy showed that N_2O increases the incidence and severity of PONV in a dose-dependent manner.[106] Patients who received 70% nitrous oxide had a statistically significant greater incidence of nausea than patients who received no nitrous oxide or 50% nitrous oxide. However, a similar study showed that the elimination of nitrous oxide from a propofol-based anesthetic for ambulatory gynecologic

BOX 31-5

Some Guidelines for Use of the Laryngeal Mask Airway During Laparoscopy

- Ensure that clinician is an experienced LMA user.
- Select patients carefully (e.g., fasted, not obese).
- Use correct size of LMA.
- Use LMA that allows for gastric drainage.
- Make surgeon aware of the use of LMA.
- Use total IV anesthetic technique or volatile agent.
- Adhere to "15" rule: <15 degree tilt; <15 cm H_2O intraabdominal pressure; <15 min duration.
- Avoid inadequate anesthesia during surgery.
- Avoid disturbance of the patient during emergence.

Data from Roth H, et al. The ProSeal laryngeal mask airway and the Laryngeal Tube Suction for ventilation in gynaecological patients undergoing laparoscopic surgery. *Eur J Anaesthesiol.* 2005;22(2):117-122; Maltby JR, et al. surgery had no effect on readiness to discharge and did not increase the incidence of adverse postoperative events including PONV.[107]

The effect of N_2O on bowel distention has been examined in two studies. In a randomized controlled trial involving 28 patients undergoing laparoscopic donor nephrectomy, the use of N_2O caused bowel distention in 50% of patients.[108] In 25%, the distention was severe enough to interfere with the progress of the surgery and as a result needed to be discontinued. In contrast, a randomized controlled trial examined the use of N_2O in 50 morbidly obese patients undergoing laparoscopic bariatric surgery.[109] Half of the patients received N_2O as part of the anesthetic and the other half did not. The surgeons, unaware of anesthetic technique, were unable to detect any differences in bowel distention between the groups over a 90-minute time period.

POSTOPERATIVE CONCERNS

Postoperative nausea and vomiting is a major concern for patients undergoing laparoscopic surgical procedures. In fact, patients report that they are more worried that they will experience nausea and vomiting after surgery than they are about experiencing postoperative pain.[110] The incidence of PONV in the laparoscopic population has been reported to be as high as 72% and is known to be associated with significant postoperative complications such as surgical wound dehiscence, aspiration, and unanticipated hospital admission.[111-113] Because the etiology of PONV is multifactorial, multimodal therapy using antiemetics that target different receptors has become standard of care.[113,114] The use of total intravenous anesthesia (TIVA) and a combination of antiemetics has been reported to decrease the incidence of PONV to less than 10%. A randomized controlled trial compared TIVA and multimodal therapy with inhalation anesthesia plus multimodal therapy or propofol anesthesia alone.[114] The study showed that patients who received TIVA and multimodal therapy had a 90% response rate versus 63% and 66% in the other two groups. In addition, multimodal therapy was associated with a greater degree of patient satisfaction.

Although the development of laparoscopic surgical procedures has reduced the overall need for analgesia both intraoperatively and postoperatively, pain still continues to be a concern in the postoperative period. Pain after laparoscopy is comprised of three components; incisional pain (parietal pain), deep intraabdominal pain (visceral pain), and shoulder pain, which is believed to be referred visceral pain.[115] However, the majority of postoperative pain after laparoscopic surgery is typically of a visceral quality on the day of surgery, with shoulder pain predominating on the first postoperative day.[116] The creation of the pneumoperitoneum is associated with distention of the peritoneum and abdominal wall, and in conjunction with visceral dissection and resection activates nociceptors via the enteric nervous system.[86] The enteric nervous system is a complex system that functions to some extent independent of the central nervous system.[86] The peritoneum and viscera convey unpleasant sensations and autonomic reactions to injury via the vagus nerve giving rise to both painful and nonpainful sensations.[117,118] In addition, intraabdominal CO_2 contributes to postoperative pain by decreasing intraperitoneal pH and causing irritation of the phrenic nerve.[119]

Management of postoperative pain in laparoscopy patients is complex and involves a multimodal approach that includes opioids, nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and local anesthetics. The multimodal approach has been found to improve patient satisfaction, decrease opioid requirements, and decrease the incidence of postoperative complications including PONV and unplanned hospital admission.[86,120]

NSAIDs have proven to be of value in managing postoperative laparoscopic pain. Several types of NSAIDs have been used including the cyclooxygenase-2 (COX-2) inhibitors, ketorolac, and acetaminophen, and their efficacy has been repeatedly studied. Although NSAIDs are not potent enough as a sole analgesic for managing laparoscopic pain, they have been shown to act synergistically leading to decreased opioid use. A double-blinded, placebo-controlled, randomized study of 80 American Society of Anesthesiologists (ASA) class I to III patients undergoing outpatient laparoscopy showed that short-term use of celecoxib decreased postoperative pain and postoperative opioid-containing analgesic requirements, while improving the quality of recovery.[121] In addition, multiple NSAIDs are being combined to optimize their effectiveness. A retrospective comparative study examining the efficacy of preemptive administration of pregabalin, acetaminophen, and celecoxib for the management of perioperative pain after robotic-assisted laparoscopic radical prostatectomy showed a decrease in both intraoperative and postoperative opioid use.[122]

Glucocorticoids also have been used successfully for the management of post-laparoscopy pain. In addition to possessing antiemetic properties, glucocorticoids have antiinflammatory and analgesic properties that make them useful in the management of visceral pain. The exact mechanism is not fully understood, but it is known that glucocorticoids reduce prostaglandin synthesis by inhibiting phospholipase enzyme and cyclooxygenase type II. In addition, they modulate the inflammatory response by inhibiting major cytokines including C-reactive protein, tumor necrosis factor, and several interleukins.[123,124] In a randomized controlled trial, the efficacy of dexamethasone administration in decreasing perioperative opioid consumption was evaluated.[120] The study showed that preemptive administration of glucocorticoids decreased total opioid consumption in the first 24 hours after laparoscopic hysterectomy. In addition, it was not associated with an increase in adverse effects.

The effectiveness of peripherally administered local anesthetics in the management of postoperative laparoscopy pain is a complicated question because research evidence remains mixed. A systematic review conducted by Mouton et al.[125] in 1999 evaluated 41 randomized controlled trials that studied pain control using local anesthesia in intraperitoneal and port-site infiltration, as well as mesosalpinx and fallopian-tube blocks.[125] The authors concluded that local infiltration and mesosalpinx and fallopian-tube blockade offered little benefit in the management of postoperative pain. Evaluation of studies of intraperitoneal local anesthesia injection showed that the technique improved overall pain scores but questioned the clinical significance of the treatment effect. In contrast, a recent meta-analysis of five randomized trials evaluated the efficacy of intraperitoneal local anesthetic for pain reduction after laparoscopic gastric procedures.[86] The analysis revealed an overall reduction in abdominal pain intensity, reduced incidence of shoulder pain, and decreased opioid use without adverse effects in patients managed using the block. Other techniques, such as ultrasound-guided rectus sheath block, are also proving to be effective in the management of post-laparoscopy pain by blocking the terminal branches of the lower intercostal nerves in a T8 to L1 dermatomal distribution.[126-128]

THE FUTURE OF LAPAROSCOPIC SURGERY

Minimally invasive surgery has become the norm over the last 20 years, prompting major advances in laparoscopic techniques. Recent innovations in technology include the development of robotic-assisted surgical systems such as the DaVinci Surgical System, which provide for greater surgical precision, decreased

postoperative pain, and shorter lengths of hospital stay.[129,130] (see Chapter 29) In addition, efforts have been made to eliminate the need for pneumoperitoneum through the development of "gasless" laparoscopic systems. The gasless laparoscopy technique creates a working space for the surgeon by inserting a fan-shaped device into the abdomen to lift the abdominal wall away from the viscera, eliminating the need for CO_2 insufflation. Current research shows much promise for this technique. Compared with conventional laparoscopy, gasless laparoscopy was associated with lower intraoperative blood loss, decreased postoperative pain, and less postoperative inflammation.[131-133]

Standard laparoscopic techniques are limited in several ways. They provide only two-dimensional depth perception, and control of standard laparoscopic instruments is counterintuitive. To move an instrument within a patient on the screen in one direction, the operator is required to move his or her hand in the opposite direction.[134] This creates a steeper learning curve for training. Newer technologies allow surgeons to operate laparoscopic equipment far more intuitively and with much greater dexterity than standard laparoscopic techniques.

The development of robotic-assisted laparoscopic surgery has allowed surgeons to overcome some of the limitations imposed by standard laparoscopic technology.[129,130] A surgeon using robotic-assisted technology controls surgical instruments from a control console that may be immediately adjacent to the patient, within the operative suite, or at a site hundreds of miles away from the operating room. An important advantage of robotic technology is the incorporation of three-dimensional (stereoptic) imaging, which permits superior depth perception. The surgeon manipulates the robotic arms from the control console, which then simulate the motion of the human wrist and fingers in the surgical field. These motions are also scaled down so that larger movements by the surgeon are translated into finer movements of the instruments. Robotic-assisted surgery offers the surgeon improved ergonomics, superior dexterity, and the ability to use traditional open surgical skills for laparoscopic operations. Robotic-assisted surgical techniques have been used in all types of procedures—cardiac, general, gynecologic, and urologic surgical specialties.[135]

Anesthetic management of robotic-assisted laparoscopic surgery is similar to standard laparoscopic surgery with a view caveats. Robotic-assisted radical prostatectomy and gynecologic procedures are performed in the steep Trendelenburg position (30-45 degree head-down position); this places the patient at risk for tracheal tube displacement, brachial plexus injury, and posterior ischemic optic neuropathy.[48,136,137] Careful positioning and attention to tube position and fluid management is essential. Another potential issue surrounds the prolonged set-up of robotic equipment and limited patient access during robotic procedures. Because of the potential for limited access to patients undergoing robotic-assisted surgery, especially pediatric patients, careful contingency plans should be made by the surgical team in case an intraoperative crisis call for immediate access to the patient is needed.[138]

SUMMARY

As technology advances, laparoscopic surgical techniques will be employed in increasingly more complicated procedures and patient populations. Providing safe and effective anesthetic care demands that the anesthetist understand the unique challenges of laparoscopic surgery, with particular attention to the physiologic effects of carbon dioxide insufflation and pneumoperitoneum.

Musculoskeletal System Anatomy, Physiology, Pathophysiology, and Anesthesia Management

CHAPTER 32

◆ *Mary C. Karlet and Terri M. Cahoon*

Somatic musculature is broadly classified into three compartments—skeletal, cardiac, or smooth—based on the muscles' anatomic and functional roles. Force generated by all these muscle types depends on the transient elevation of intracellular calcium (Ca^{2+}) and activation of actin and myosin filaments. Skeletal muscle is under voluntary control and is striated in appearance. Smooth muscle is found in most internal organs (except the heart), is under involuntary autonomic control, and is nonstriated. Cardiac muscle is striated in appearance and under control of an intrinsic pacemaker modulated by the autonomic nervous system.[1] The focus of this chapter is skeletal muscle, its function, and its neurologic control.

Skeletal muscle tissue includes muscles of the tongue and the soft palate, the extrinsic eye muscles, the muscles that move the scalp, all muscles attached to the skeleton, and the muscles in the pharynx and the upper third of the esophagus. Some skeletal muscles, such as those of the lips and the anus, serve as sphincters. Skeletal muscle is innervated by myelinated efferent motor nerve fibers called *alpha (α) motor neurons*. These fast-conducting somatic fibers arise from cell bodies located in the ventral horn of the spinal cord gray matter (Figure 32-1).

The motor nerve axon exits through the spinal cord ventral root and travels uninterrupted to the muscle through a mixed peripheral nerve. Inputs to the ventral horn motor nerve cell body are both excitatory and inhibitory. The inputs include neurons from the brain, neurons from other spinal cord segments, and afferent neurons from various sensory receptors. A motor neuron fires an action potential when the sum of the excitatory and inhibitory inputs depolarizes the nerve cell body to its critical threshold potential. Threshold depolarization of the cell body produces local electrical currents that spread to adjoining regions of the nerve membrane, leading to depolarization and action potential propagation down the axon.

At the muscle, each motor nerve divides into branches that enter the muscle and end on individual muscle cells called *muscle fibers*. A single motor neuron and all the muscle fibers it innervates are collectively called a *motor unit* (Figure 32-2). When a motor nerve fires, all the fibers within a single motor unit contract simultaneously.

Motor units exhibit considerable variability, and each unit usually contains between 100 and 200 muscle fibers. However, the motor unit may contain as few as two muscle fibers for fine, delicate movements or as many as a thousand for coarse movements.[1,2]

The strength of a muscle contraction is determined in large part by the number of motor units stimulated and the frequency of the stimulation. A minimal stimulus applied to a muscle may cause only a few muscle units to contract, with a weak overall response. As the stimulus is increased, more units are recruited, and a greater contraction of the muscle occurs.

OVERVIEW OF NEUROMUSCULAR TRANSMISSION

Skeletal muscles are normally relaxed and do not contract without nervous stimulation. At rest, the electrical potential difference across the muscle membrane is approximately −90 mV (inside negative). There is a high potassium ion (K^+) concentration inside the muscle cell and a high sodium ion (Na^+) concentration outside the cell.

The process of muscle contraction begins when the electrical activity of a *presynaptic* motor neuron communicates across a *junctional cleft*, or *synaptic gap*, to *postsynaptic* skeletal muscle fibers. The specialized conduction area, or *synapse*, where the axon of a motor neuron ends on a skeletal muscle fiber is called the *neuromuscular junction*, or *myoneural junction*. Each skeletal muscle fiber usually has only one neuromuscular junction, a notable exception being extraocular muscles that have multiple innervations per cell. The mediator substance that chemically transduces the axon's electrical message across the synaptic gap to the muscle is the neurotransmitter *acetylcholine* (ACh).[1-3]

Muscle contraction develops when the propagated action potential of the presynaptic motor neuron induces expulsion of the chemical mediator ACh into the junctional cleft. ACh binds to specialized receptors on the postsynaptic muscle membrane. If released from the axon nerve ending in sufficient quantity, ACh-receptor (AChR) occupation induces a transient change in the electrical property of the skeletal muscle membrane, and an action potential and muscle contraction follow.[2]

In the overall process of neuromuscular transmission, an action potential in the motor neuron induces the release of ACh into the junctional cleft, which evokes an action potential in the muscle. As described in greater detail in the following sections, the end result of muscle membrane depolarization is muscle contraction.

Neuromuscular Junction

Motor nerve endings develop in intimate and precise proximity to skeletal muscle fibers. The motor axon terminal is separated from the muscle cell it innervates by a synaptic gap of only 20 to 30 nm.[2] The demyelinated distal portion of the motor axon is essentially surrounded by a terminal Schwann cell that reinforces the connection of nerve and muscle.[4] This anatomic alliance increases the likelihood for prompt receptor activation after transmitter release.[2,4,5]

The synaptic gap is contiguous with the extracellular fluid, which provides a route for drugs or toxins to gain access to the neuromuscular junction. Botulinum toxin, for example, gains access to the junction through the extracellular fluid and produces its depressive neuromuscular effects by inhibiting ACh release from the nerve ending.[2,6,7]

Both sides of the neuromuscular junction, the presynaptic motor axon and the postsynaptic muscle cell, serve specialized functions. As it nears the neuromuscular junction, the motor

nerve axon loses its myelin sheath and divides into many smaller nerve fibers, which terminate as *end-feet*.

The motor nerve end-foot is distinct from the rest of the nerve. It is rich in mitochondria and the materials and support structures necessary for the synthesis, storage, mobilization, and release of the neurotransmitter ACh. Small, clear vesicles or granules are particularly numerous in the part of the nerve ending closest to the junctional gap, approximately 300,000 normally in a single end plate.[2] Each of these vesicles contains a small packet, or *quantum*, of ACh molecules. The ACh vesicles concentrate along the junctional surface of the nerve end-feet in areas called "active zones."[6,8]

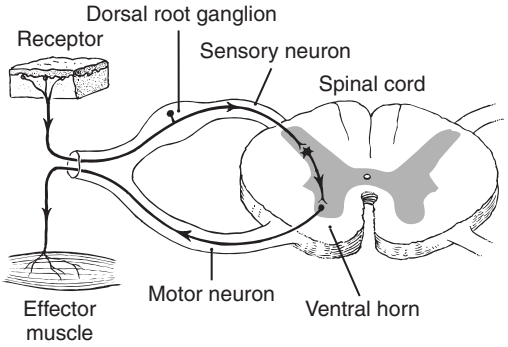

FIGURE **32-1** Spinal reflex arc. Sensory information from the skin is relayed to the motor neuron in the ventral horn of the spinal cord gray matter.

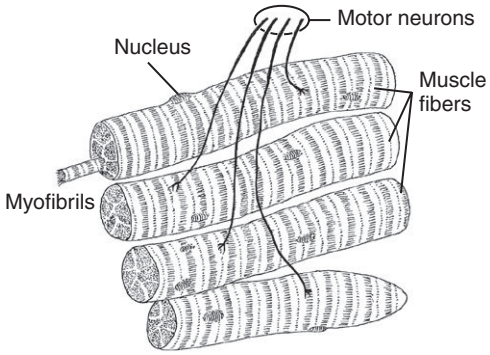

FIGURE **32-2** A motor unit. One motor neuron can synapse with several muscle fibers, which contract as a unit.

At the neuromuscular junction, each motor nerve ending closely approximates with a thickened and highly convoluted portion of the postsynaptic membrane called the *motor end plate*. The motor end plate is physically and functionally demarcated from the surrounding muscle membrane. The many membrane convolutions at the end plate are known as *junctional folds*. Both the primary and secondary folds expand the surface area of the postsynaptic membrane.[2,4] ACh receptors are concentrated near the shoulders of the junctional folds, lying near the ACh release sites. The close approximation of ACh release site and target receptor site ensures little transmitter waste and direct coupling of nerve signal and muscle response.[4,9] Figure 32-3 summarizes the anatomy and dynamic function of the neuromuscular junction.

Acetylcholine Release

Physiologic transmission of the nerve message to the muscle begins with a Ca^{2+}-dependent mechanism for ACh release from the nerve terminal. When a nerve impulse arrives at a motor nerve ending, the action potential causes a transient increase in Ca^{2+} conductance across the nerve membrane by activating voltage-dependent Ca^{2+} channels. Both "fast" and "slow" Ca^{2+} channels appear to open, but it is primarily the fast ("N-type" and "P/Q-type") Ca^{2+} channels that are involved in depolarization-induced transmitter release.[6,9] Calcium enters the nerve terminal, flowing down its electrochemical gradient. The influx of Ca^{2+} causes ACh vesicles to fuse with the nerve plasma membrane and then expel their content into the synaptic cleft.[4,6,10] The amount of ACh released is influenced by the amount of Ca^{2+} that enters the nerve terminal during nerve stimulation. The more Ca^{2+} that enters the nerve terminal, the greater the amount of ACh released.

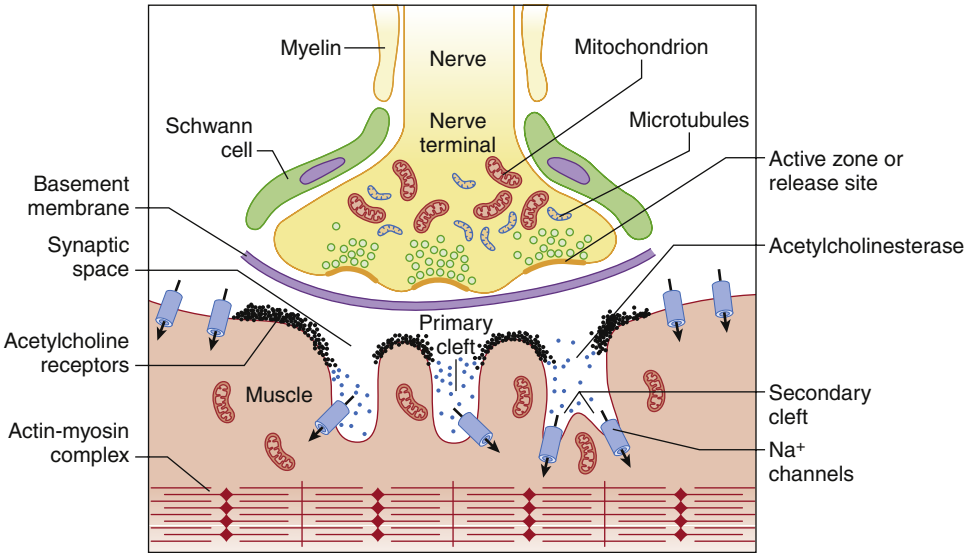

FIGURE **32-3** Structure of the adult neuromuscular junction showing the motor neuron, muscle fiber, and Schwann cell. The nerve terminal, covered by a Schwann cell, has vesicles positioned near the active zones on the membrane toward the synapse. The synaptic cleft is between the nerve and the muscle. The muscle surface has folds with dense areas on the shoulders of each fold containing acetylcholine receptors. The acetylcholinesterase are present in the synaptic clefts. (From Miller RD et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

About 150 to 200 ACh vesicles, or quanta, are released with each nerve impulse. Each quantum in turn contains about 10,000 molecules of the neurotransmitter.[2,11] This amount of ACh and the normal abundance of postjunctional receptors at each neuromuscular junction readily ensure muscle activation. A considerable safety margin exists in the synaptic transmission. With each nerve impulse, excess ACh is released, and excess ACh receptors are available for occupation.[9,11-13]

Small concentrations of other divalent cations can compete with and limit Ca^{2+} influx into the nerve ending, decreasing ACh release and impairing neuromuscular transmission. When administered intravenously, magnesium sulfate, for example, can interfere with Ca^{2+} influx and produce muscle weakness by inhibiting ACh release.[3,12]

Certain antibiotics, particularly the aminoglycosides, inhibit ACh release from the nerve terminal and can enhance neuromuscular blockade when administered concomitant with clinical dosages of neuromuscular blocking agents.[3,11,12]

Calcium channel–blocking drugs used for the treatment of dysrhythmias and hypertension block Ca^{2+} conductance through so-called "slow" ("L-type") channels. Their primary action is on the slow Ca^{2+} channels of the heart and blood vessels, but they can inhibit prejunctional Ca^{2+} influx. The large safety margin inherent in normal neuromuscular transmission obscures any clinically detectable effect these drugs may have on neuromuscular transmission. However, with disorders associated with impaired neuromuscular transmission, such as myasthenic syndrome, the Ca^{2+} channel blocker's prejunctional attenuation of ACh release may be unmasked, and neuromuscular transmission may be further weakened.[10,12,14]

Acetylcholine Synthesis

Neurons that release the neurotransmitter ACh are called *cholinergic neurons*. Active cholinergic motor neurons replenish their ACh stores by continually resynthesizing the neurotransmitter. Many enzymes and other proteins needed by the nerve ending to synthesize, store, and release ACh are made in the motor nerve cell body and are transported distally to the nerve ending by a process called *axonal transport*.

In the axoplasm of the motor nerve ending, the enzyme *choline acetyltransferase* (CAT) catalyzes the reaction of two substrates, *acetyl coenzyme A* (acetyl CoA) and *choline*, to form ACh, as seen in the following equation.

$$\text{Choline} + \text{Acetyl CoA} \rightarrow \text{Ach} + \text{CoA}$$

Choline is obtained locally by a Na^+-linked uptake into the cholinergic nerve ending. Acetyl CoA is synthesized from pyruvate in neuronal mitochondria. Mitochondria and other metabolic machinery used to synthesize ACh are abundant in the nerve ending (Figure 32-4).

About 80% of the newly synthesized ACh is stored within synaptic vesicles in the nerve terminal, positioned for release. Each nerve ending contains more than 300,000 of these vesicles. The remainder of the ACh is stored in a nonvesicular axoplasmic reserve.[2,4]

The ACh vesicles are released through exocytosis in response to action potential stimulation, but only a small fraction of the available vesicles is used to send each signal.[2,4]

Postjunctional End Plate

There is a distinction between the postjunctional cation channels of the muscle end plate and other cation channels of nerve and muscle membranes. Motor end-plate cation channels are *ligand-gated*, that is, they are opened or closed by the action of a chemical. Cation channels of nerve axons, on the other hand, are *voltage-gated* by electrical changes in the membrane.[5]

The binding of ACh molecules to postsynaptic receptor proteins causes a transient increase in conductance in ligand (ACh)-gated cation channels at the postjunctional motor endplate. The cation flow at the end plate produces a net inward Na^+ current and a net outward K^+ current. The previously polarized end-plate membrane (resting membrane potential of approximately −90 mV) becomes transiently "depolarized." The resulting postjunctional membrane voltage change is called the *end-plate potential* (EPP).[5] The EPP does not begin until 0.5 millisecond after the arrival of the action potential at the presynaptic nerve ending. This *synaptic delay* arises from the relatively slow liberation and diffusion of ACh across the junctional cleft.[2,5]

EPPs vary in strength according to the quantity of ACh released. The more ACh released, the greater the postsynaptic end-plate voltage change. In other words, EPPs do not adhere to the "all-or-none" principle. EPPs can be summed, and their magnitude depends on the strength of the summed stimuli of ACh molecules.

Perijunctional Area

The postjunctional end-plate membrane does not fire action potentials. After it is depolarized by ACh-receptor occupation, the current sink created by the local EPP depolarizes the *adjacent* muscle membrane. If the depolarizing input is great enough and reaches threshold potential, action potentials are fired from either side of the end plate in both directions along the muscle fiber (Figure 32-5).[5]

The transition zone where the potential developed at the end plate is converted to an action potential is called the *perijunctional area*. A demarcation exists between the chemically sensitive AChR channels of the end plate and the chemically insensitive but electrically sensitive Na^+ channels in the perijunctional area of the muscle membrane. The membrane in the perijunctional area is rich in Na^+ channels, and this feature enhances its capacity to respond to an EPP and transform it to an action potential.

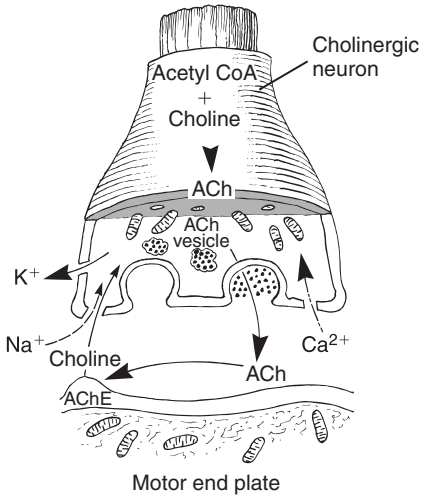

FIGURE 32-4 Acetylcholine (ACh) synthesis from choline and acetyl coenzyme A (acetyl CoA) in the motor nerve ending. Calcium ion entry into the nerve ending causes the ACh vesicles to release their contents. Acetylcholinesterase (AChE) on the postjunctional membrane destroys ACh. Choline is recycled into the nerve ending by a sodium ion–linked transport mechanism.

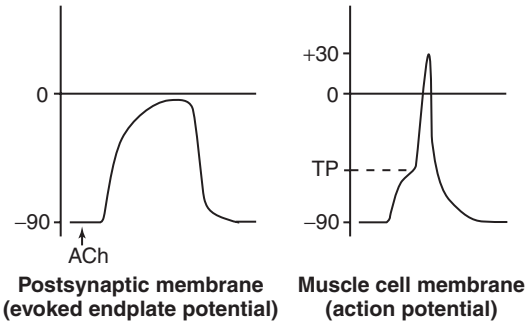

FIGURE **32-5** Depiction of the depolarization characteristics (the endplate potential) at the postsynaptic membrane in response to acetylcholine (ACh) and the depolarization and action-potential response at the adjacent, electrically excitable muscle membrane. *TP*, Threshold potential.

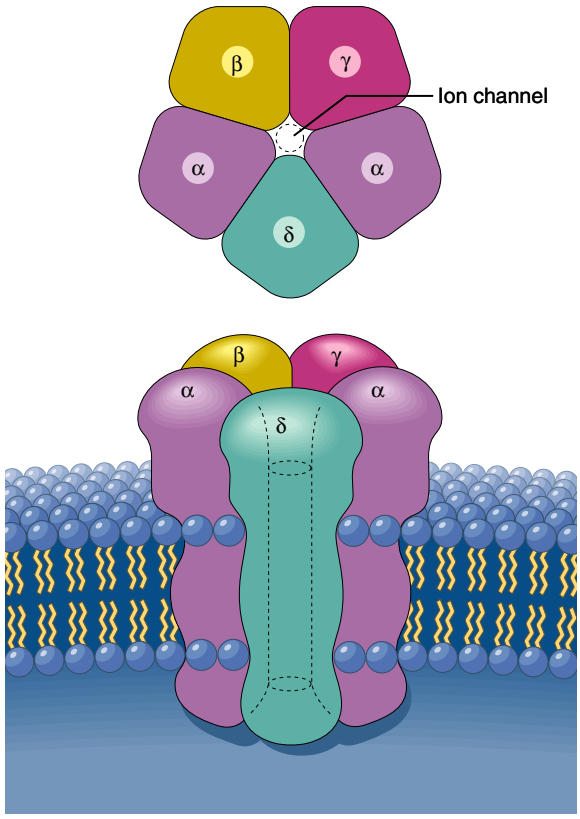

FIGURE **32-6** The fetal acetylcholine (ACh) receptor. (From Taylor P. Are neuromuscular blocking agents more efficacious in pairs? *Anesthesiology*. 1985;63:1-3.)

With a typical motor neuron's action potential, the EPP produced at the muscle end plate is usually sufficient to create an action potential at the muscle membrane, and muscle contraction is regularly produced.

Acetylcholine Receptor

Postjunctional neuromuscular ACh receptors have been extensively purified and studied in detail.[4,15] An estimated 50 million tightly packed nicotinic AChR sites are at each neuromuscular junction.

In fetal muscle, the ACh nicotinic receptor is a protein composed of five polypeptide subunits: two identical alpha (α) subunits, a beta (β) subunit, a gamma (γ) subunit, and a delta (δ) subunit. Figure 32-6 shows the receptor subunits organized in a pentagonal array around a central ion channel. Without ACh occupation, the central channel is closed; when open, small cations (Na^+ and K^+) are allowed to pass through the channel down their electrochemical gradients.[5]

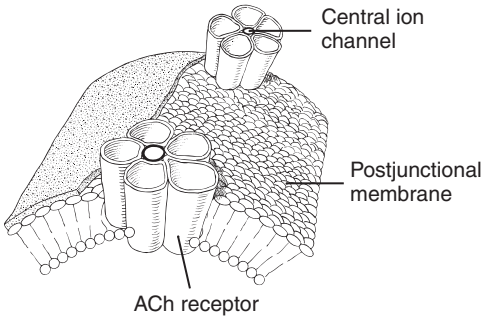

FIGURE **32-7** Two acetylcholine (ACh) receptors embedded in the postjunctional membrane.

In adults, the AChR protein structure is similar, except that the fetal γ subunit is replaced by an epsilon (ε) subunit.[3,16] The change produces an adult cholinergic postjunctional receptor that has an increased cation conductance and a shortened open time.

As noted earlier, the ACh receptors are located at the crests of the motor end-plate junctional folds, which directly approximate with nerve terminal release sites. In active adults, only the end-plate region of the muscle contains ACh receptors. As little as 200 μm away from the end plate, the muscle membrane becomes practically devoid of receptors.

The ACh receptors are synthesized in the muscle cells and then incorporated into the end-plate membrane as integral membrane proteins. The extracellular or junctional face of the receptor protrudes from the surface of the end-plate membrane, whereas the cytoplasmic surface of the receptor is more flush to the plasma membrane surface (Figure 32-7).

Activation of the postjunctional AChR and opening of the cation channel requires simultaneous ACh occupation at each of the two α-receptor subunits. The binding of two ACh molecules causes a conformational change in the α polypeptides, and the protein conformational change causes the central ion channel to open.[2] If only one α subunit site is occupied by the agonist, the channel remains closed. As described earlier, the open channel increases the conductance to positively charged ions, particularly Na^+, an effect that produces the net depolarizing potential, the EPP. When even one ACh molecule leaves an α subunit, the channel snaps shut and the current stops.

The α subunits are the sites of competition between the cholinergic agonist ACh and receptor antagonists, such as nondepolarizing neuromuscular blocking agents. The outcome of the competition, neuromuscular transmission or neuromuscular blockade, depends on the concentration of ACh and the relative concentration and binding properties of the antagonist involved.[3,12] Nondepolarizing muscle relaxants produce neuromuscular blockade, in part because they bind to one or both α subunit sites and, in so doing, prevent ACh from binding to both sites and opening the channel.

Prejunctional Receptors

Cholinergic receptors are also present at the prejunctional motor nerve ending. It is postulated that in addition to mediating nerve transmission at postjunctional receptor sites, ACh also acts on prejunctional receptors to enhance transmitter mobilization and release. Prejunctional cholinergic receptor occupation may transform the ACh pool from a reserve store to a readily releasable store so that transmitter output can keep pace with transmitter demand.[10]

All the nondepolarizing muscle relaxants used in anesthesia practice compete with ACh for postjunctional cholinergic receptor sites to produce neuromuscular blockade. Receptor antagonist effects at prejunctional receptors may augment nondepolarizing blockade by diminishing ACh output as well. Herein also lies an explanation for the *fade* that is observed with neuromuscular blockade monitoring of nondepolarizing muscle relaxers. Fade of tetanic and train-of-four stimulation may reflect the blockade of prejunctional ACh receptors by the muscle relaxant and failure of ACh release to keep pace with rapid stimulation.[12]

Acetylcholinesterase

As noted earlier, the combination of ACh with its muscle end-plate receptor causes a transitory depolarization of the end plate. The EPP is short lived because soon after binding, ACh is rapidly destroyed by hydrolysis, and its depolarizing action halts.[5] Paradoxically, the rapid destruction and removal of ACh from the junctional cleft is critical for continued muscle contractile response. The ACh molecule must be off the muscle end-plate receptor for the perijunctional muscle membrane to repolarize, or "reset," in anticipation of further activation.

The hydrolysis of ACh to choline and acetate is rapid and efficient. Most ACh is destroyed within a few milliseconds after it is released into the junctional cleft.[2] The enzyme *acetylcholinesterase* (AChE), also known as *true* or *tissue cholinesterase*, catalyzes the hydrolysis.

$$\text{Acetylcholine} \xrightarrow{\text{Acetylcholinesterase}} \text{Choline + Acetate}$$

Much of the choline by-product released by hydrolysis is efficiently drawn back within the prejunctional nerve terminal for use in the synthesis of new ACh. Acetylcholinesterase is present in high concentrations on the external surface of the postjunctional muscle membranes. The enzyme resembles a balloon-like structure and is loosely connected to the muscle end-plate membrane by thin stalks of collagen.

Without AChE, the concentration of ACh would become extremely high in the junctional cleft. Under these circumstances, ACh would maintain the muscle end plate in a state of persistent depolarization as ligand-gated cation channels remained open, yet the muscle itself would be paralyzed.[12] The reason for this seemingly illogical behavior (ACh-receptor occupation, end-plate depolarization, yet no muscle contraction) is that in the face of persistent end-plate depolarization, the Na^+ channels of the perijunctional muscle membrane do not reactivate or reset; these voltage-gated ion channels remain closed, impeding further muscle membrane depolarization. Thus, even with persistent end-plate depolarization, muscle contraction is prevented, and clinical weakness follows. A cyclic muscle membrane depolarization/repolarization sequence is necessary for normal muscle contraction to occur.

The mechanism of depolarizing muscle relaxants can, at least in part, be explained by a similar mechanism. Depolarizing muscle relaxants, such as succinylcholine, activate the muscle end plate in a manner similar to that of ACh, but they have a more protracted end-plate depolarizing response because they are less rapidly metabolized. AChR occupation by a depolarizing muscle relaxant causes a prolonged depolarization of the end plate, prohibits activation of perijunctional channels, and produces a depolarizing block.[3,17]

Reversal of a nondepolarizing neuromuscular block may be accomplished by the use of cholinesterase inhibitors. Anticholinesterase agents inhibit the breakdown of ACh and, in so doing, increase the amount of ACh at the neuromuscular junction. The abundance of ACh in the synaptic gap changes the agonist-antagonist ratio and enables the agonist (ACh) to bind to the ACh receptor with greater frequency than the antagonist (nondepolarizing muscle relaxant). Hence, a higher ACh concentration can overcome the receptor occupation by the muscle relaxant, and neuromuscular transmission can be restored (see Chapter 12).

Various other esterases, in addition to AChE, are present throughout the body. One that is found in the plasma is *pseudocholinesterase*, or *nonspecific cholinesterase*. Like AChE, pseudocholinesterase is capable of hydrolyzing ACh, but it also has properties separate from those of AChE. One distinction particularly relevant to anesthesia practice is the ability of pseudocholinesterase to metabolize ester local anesthetics and the depolarizing muscle relaxant succinylcholine.

Extrajunctional Receptors

In utero, before muscle innervation occurs, the muscle cells of a fetus synthesize *extrajunctional receptors*. These fetal receptors (γAChR) as well as receptors made up of five $\alpha 7$ subunits are inserted over the entire length of the muscle cell. As the fetal neuromuscular junction develops, increasing motor nerve activity appears to have a trophic effect in restricting the ACh receptors specifically to the neuromuscular junction.[12] By the age of 2 years, the nerve-muscle contact is fully mature and active, and the extrajunctional receptors disappear from the peripheral part of the muscle. If neural activity is reduced or abolished and the neural trophic influence is lost, the muscle resorts to fetal-like synthesis of γAChR and $\alpha 7$ receptors.[6,7,12,18]

Several situations, including stroke, spinal cord transection, thermal trauma, direct muscle damage, and prolonged immobility, have been associated with the accelerated spread of both γAChR and $\alpha 7$ receptors from the end-plate region to large areas of the skeletal muscle membrane.[6,7,18,19] These so-called *denervation injuries* result in an abnormal excitability of the muscle and an increase in muscle sensitivity to ACh, a condition that is called *denervation hypersensitivity*.[1,20] The extrajunctional receptors may develop within 48 hours after diminution of nerve activity. Eventually, the number of aberrant receptors per muscle fiber may increase 5- to 32-fold.[20] These receptors disappear and muscle sensitivity returns to normal if neural input is reestablished. Extrajunctional and end-plate cholinergic receptors are similar in many ways, but an important distinction pertinent to anesthesia practice is their differing response to receptor agonists and antagonists.

Clinically, extrajunctional receptors demonstrate a resistance to nondepolarizing muscle relaxants. Hence, larger doses of nondepolarizing relaxants may be necessary to induce neuromuscular blockade—for example, in an immobilized limb or in parts of the body affected by a stroke.[3,4,7,12] Monitoring a nondepolarizing neuromuscular block with a peripheral nerve stimulator in a paretic limb may result in an underestimation of the magnitude of neuromuscular blockade in nonparetic muscles.

Conversely, extrajunctional receptors are more easily activated by agonists (e.g., ACh, succinylcholine) than junctional receptors. Moreover, each extrajunctional channel stays open about four times longer than junctional receptors, allowing more ions to flow (primarily Na^+ into the muscle cell and K^+ out) in response to agonist-induced depolarization.[3]

The clinical significance of denervation injuries and the proliferation of extrajunctional receptors becomes evident with the administration of succinylcholine, which can produce alarmingly high levels of plasma K^+ in these patients.[12,21] Succinylcholine-induced hyperkalemia reflects the extensive proliferation of extrajunctional receptors along the entire muscle membrane and their

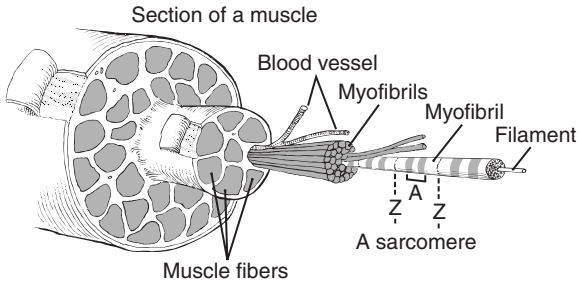

FIGURE **32-8** The structural arrangement and organization at each level of the muscle assembly. The skeletal muscle is composed of muscle fibers that contain long, cylindrical myofibrils. Each myofibril is made up of precisely arranged thick and thin filaments that form repeating dark and light bands called *sarcomeres*.

prolonged and exaggerated depolarization response to agonists. Succinylcholine stimulates the aberrant cholinergic receptors and triggers a protracted opening of the cation channels, allowing excess Na^+ movement into the cell and excess K^+ movement out, down their respective gradients.

Dangerous levels of succinylcholine-induced hyperkalemia have been observed within 4 days of denervation injury with doses of succinylcholine as low as 20 mg.[21] The pronounced release of K^+ in response to succinylcholine cannot be circumvented by the prior administration of nonparalyzing doses of nondepolarizing muscle relaxants.

MUSCLE PHYSIOLOGY

Skeletal muscle constitutes the greatest mass of somatic musculature. Skeletal muscle is composed of bundles of multinucleated, long, cylindrical cells. Muscle fibers typically extend the entire length of a muscle.[2] Because their length is much greater than their width, these cells are called *muscle fibers*. Each muscle fiber is a single cell surrounded by an electrically polarized cell membrane called the *sarcolemma*. The sarcolemma separates the extracellular space from the *myoplasm*, the muscle-fiber intracellular space. Dystrophin is a large protein that is located on the intracellular side of the sarcolemma and serves to stabilize the muscle membrane during contraction.[1]

Individual skeletal muscle cells are parallel to the muscle body and have no anatomic or functional bridges between them. The parallel arrangement helps maximize shortening capacity and velocity. The cells function independently so that the force of contraction of the total muscle is equal to the sum of individual fibers. This contrasts with smooth and cardiac muscle, in which the muscle cells are interdependent and are mechanically coupled to adjacent cells.[1,2]

Bundles of cylindrical filaments called *myofibrils* run along the axis of the muscle fiber. Each skeletal muscle fiber contains several hundred to several thousand myofibrils. The myofibrils are composed of contractile proteins that impart a striking, repetitive, light-and-dark banding pattern along the entire fiber length. The repeating unit, called a *sarcomere*, is the basic contractile unit of skeletal muscle. The alternating light-and-dark banding pattern is responsible for the classification called *striated muscle*. Cardiac muscle is also classified as striated muscle because it too has the repetitive pattern of light and dark bands.[1,2] The arrangement of the muscle fibers, myofibrils, and sarcomeres is shown in Figure 32-8.

Most skeletal muscles bridge two skeletal attachment points and are recruited to generate force and movement in voluntary actions ranging from chewing to walking. A muscle contraction that involves shortening of the muscle length to perform work

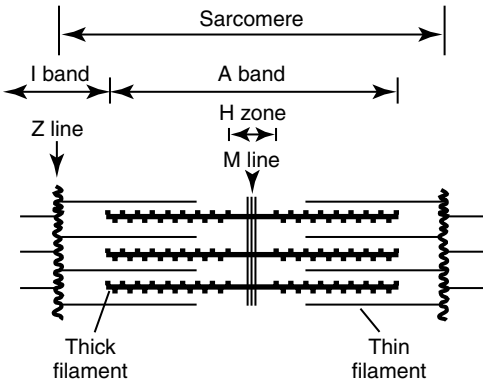

FIGURE **32-9** Longitudinal diagram of a sarcomere showing the arrangement of the thick filaments (myosin) and the thin filaments (primarily actin).

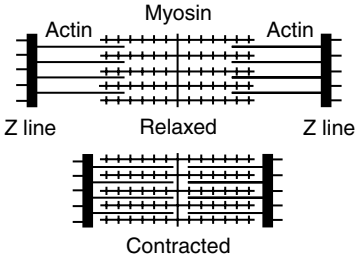

FIGURE **32-10** Actin filament sliding over myosin filament during muscle contraction.

is an *isotonic contraction*. A muscle contraction that produces increased tension but no appreciable decrease in length is an *isometric contraction*.

Structure of the Contractile Apparatus

The repeating, striated arrangement of the myofibril arises from the contractile filaments that compose the sarcomere: the *thick filaments* and the *thin filaments*.

The thick filaments, which are composed primarily of the protein myosin, are in the central region of the sarcomere in a dark-colored area termed the *A band*. A densely staining *M line* in the middle of the A band contains proteins that link the thick filaments. The thin filaments are about half the diameter of the thick filaments and are composed of the proteins actin, troponin, and tropomyosin. The less dense areas of the sarcomere, which contain only thin filaments, are referred to as *I bands*. Thin filaments, connected to *Z lines* or *Z disks*, partially interdigitate with the thick filaments in the relaxed muscle. With muscle contraction, force is generated by interaction and further overlap of thick and thin filaments. Two adjacent Z lines delimit each repeating sarcomere unit. The diagram of the sarcomere units in Figure 32-9 may merit careful study.

Cross sections of the myofibril reveal that each thick filament is surrounded by a hexagonal arrangement of thin filaments. The myosin and actin filaments are arranged to slide over one another, overlap, and create shortening of the sarcomere and the muscle during contraction[2] (Figure 32-10).

Thin Filament

The three major proteins that compose the thin filament—actin, tropomyosin, and troponin—each play a different role in the contractile process. Each thin filament includes two beadlike chains of polymerized *actin* twisted into a helix. *Tropomyosin* molecules are

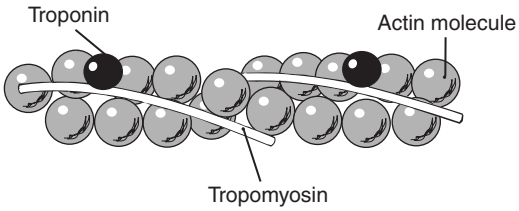

FIGURE **32-11** A thin filament. Globular actin molecules polymerize into a two-stranded, twisted filament. Rod-shaped tropomyosin molecules occupy the grooves between the two actin chains. The regulatory protein troponin binds to the tropomyosin component.

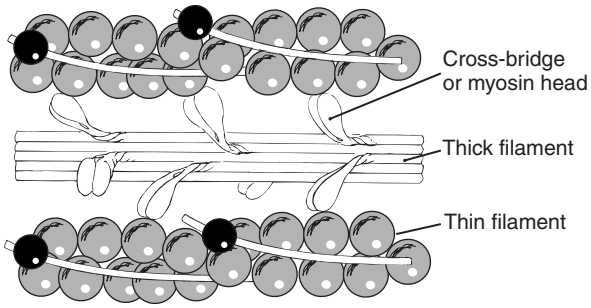

FIGURE **32-12** The tail regions of many myosin molecules intertwine to form a thick filament. The myosin heads, or cross-bridges, project out laterally toward the actin in the surrounding thin filaments.

located along the groove between the two actin chains. Each rod-shaped tropomyosin molecule covers about six or seven individual actin proteins. The most important protein in the regulation of the contractile process is *troponin*.[1] As depicted in Figure 32-11, troponin is attached intermittently to tropomyosin molecules.

Thick Filament

Myosin, the primary protein component of the thick filament, is a very large protein containing three pairs of polypeptides: one pair of heavy chains and two pairs of light chains. The six different polypeptides assemble to form the myosin protein. Each myosin protein contains a long tail with two globular heads.

The tail regions of several hundred myosin molecules aggregate to form one thick filament. The globular heads project out laterally from the thick filament at regular intervals toward the thin filaments surrounding it. In the relaxed muscle, the myosin heads are oriented toward but not attached to the thin filaments. The thick filament's globular projections are termed *cross-bridges* because they can link the thick and thin filaments. The cross-bridges in each half of the sarcomere are oriented in opposite directions away from the midpoint of the filament, which is important for their functional role in sarcomere shortening and muscle contraction.[1] The cross-bridge components are arranged as shown in Figure 32-12.

The myosin head and tail have a hingelike attachment, permitting a certain degree of movement. When muscle contraction is activated and myosin and actin link, the ability of the myosin head to swivel enables the attached actin filaments to slide over the thick myosin filaments (Figure 32-13).

Cross-Bridge Interaction and Cycling

Sliding Filament Theory

Physiologic contraction of striated muscle occurs when muscle fibers are depolarized to a threshold for action-potential formation. The depolarizing wave initiated by AChR occupation at the motor end plate is carried along the muscle membrane surface from one Na^+ channel to the next. Action potential depolarization of the

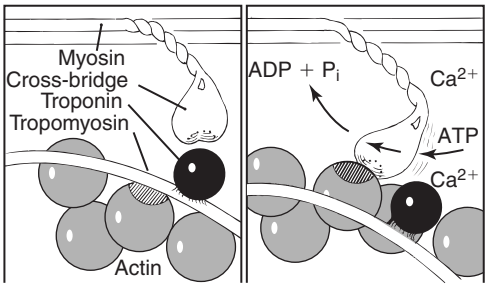

FIGURE **32-13** Formation of the actomyosin complex. Hydrolysis of adenosine triphosphate (ATP) leads to tipping of the myosin heads. *ADP,* Adenosine diphosphate; P_i, high-energy phosphate.

sarcolemma spreads rapidly to the muscle cell's interior through a reticular network of intracellular tubules that are contiguous with the cell membrane.

This network, composed of *transverse tubules*, or *T tubules*, forms a grid around the intracellular myofibrils and closely associates with the intracellular sarcoplasmic reticular membranes. The T tubules rapidly transmit the action potential from the sarcolemma to the myoplasm.

The *sarcoplasmic reticulum* is an irregular, closed membrane structure that weaves throughout the myoplasm of the muscle cell and contains large amounts of Ca^{2+}. The sarcoplasmic reticular membrane is active in sequestering Ca^{2+} by way of numerous high-affinity Ca^{2+} active-transport carriers in its membrane. These pumps maintain a high sarcoplasmic reticular store of Ca^{2+} and a very low resting myoplasmic Ca^{2+} concentration.[1,9]

The transit of an action potential along the sarcolemma and into the T-tubule system is detected by intracellular voltage sensors that trigger Ca^{2+} efflux from the sarcoplasmic reticular stores. The major Ca^{2+} release channels located on the sarcoplasmic reticulum are called *ryanodine receptors*. These channels are commonly called "receptors" because they bind the alkaloid ryanodine.[1] In response to action potential stimulation, the myoplasmic Ca^{2+} concentration rises several-fold from a resting value of less than 0.1 mmol. The overall effect is the discharge of Ca^{2+} from the sarcoplasmic reticulum into the myoplasm by the transit of an action potential into the muscle cell.[9]

The Ca^{2+} released into the myoplasm binds to troponin, which acts as a switch that changes the conformation of the tropomyosin to which it is bound. The conformational change in the rod-shaped tropomyosin exposes myosin binding sites on the underlying actin. The myosin heads react by binding to the exposed thin filament sites, forming a reversible complex with actin—the *actomyosin complex*. The process of myosin-actin binding in response to elevated myoplasmic Ca^{2+} is termed *cross-bridge formation*.

The myosin filaments' heads contain not only an actin-binding site but also a catalytic adenosine triphosphatase (ATPase) site that hydrolyzes the breakdown of ATP to adenosine diphosphate (ADP) and phosphate. ATP is essential for the sliding of the filaments and for muscle contraction. The energy yielded by the ATP hydrolysis is harnessed to tilt the myosin heads, in a "cocked" spring position. When the myosin heads bind to the actin site, the heads use the energy stored in the myosin heads to drag the actin filaments towards the center of the sarcomere. The pull of the actin filaments accentuates the overlap of the thick and thin filaments, causing shortening of the sarcomere and culminating in muscle contraction (Figure 32-14). Cross-bridge cycling and the associated movement of actin is called the *sliding filament theory*.

The actomyosin complex is stable and can be broken only by a renewed binding of ATP to each myosin head. With the binding

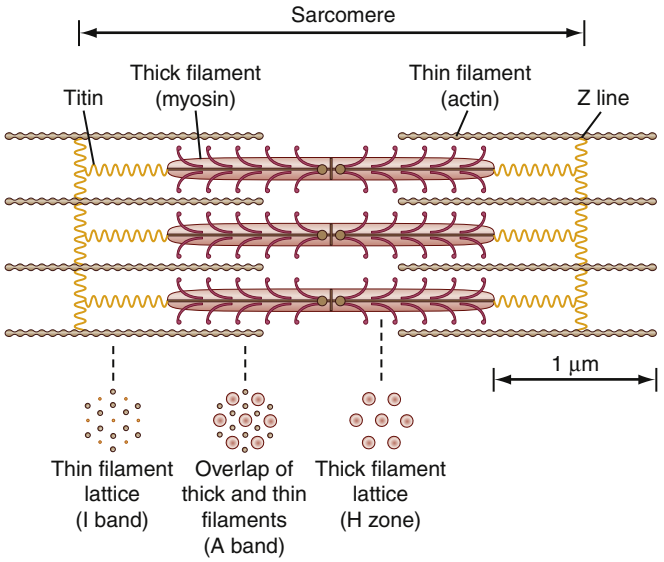

FIGURE **32-14** Organization of the proteins within a single sarcomere. The cross-sectional arrangement of the proteins is also illustrated. (From Koeppen BM, Stanton BA. *Berne & Levy Physiology*. 6th ed. Philadelphia: Mosby; 2010.)

of ATP, the actomyosin cross-bridge dissociates, and the myosin heads are repositioned for another round of cross-bridge formation. If the intracellular Ca^{2+} concentration is still sufficiently high, which mainly depends on the frequency of incoming action potentials, the cycle begins again: myosin links to actin, swivels, detaches, and reconnects at the next actin site.

A single sliding cycle or myosin "power stroke" shortens the length of the sarcomere by about 1%, causing the entire muscle fiber, which consists of a serial arrangement of sarcomeres, to also shorten by 1%. The sliding cycle has to be repeated about 50 times for full shortening of the muscle. The cycle continues until it is interrupted by the active removal of Ca^{2+} from the myoplasm or until the ATP is exhausted. Active Ca^{2+} removal from the cytoplasm back into the sarcoplasmic reticulum causes troponin, tropomyosin, and actin to return to a configuration that prohibits myosin-actin binding, and the muscle relaxes.

The overall process by which depolarization of the muscle fiber causes Ca^{2+} release from the sarcoplasmic reticulum into the myoplasm to cause cross-bridge cycling and muscle contraction is called *excitation-contraction coupling*.[9]

Box 32-1 summarizes the excitation-contraction coupling events. Box 32-2 summarizes the events leading to skeletal muscle relaxation.

Grading Contractile Force

Two major mechanisms grade skeletal muscle contractile force. One determining factor of muscle force is the number of motor units activated or recruited. With increasing voluntary effort, more and more motor units are recruited, and an increasing muscle force develops.

The other mechanism by which skeletal muscle tension is graded is by varying the frequency of the action potential discharge to the muscle. A single action potential invariably liberates sufficient Ca^{2+} ions to activate skeletal muscle contraction. However, the Ca^{2+} ions are rapidly transported back into the sarcoplasmic reticulum before the muscle has time to develop maximal tension. The brief contraction that results from transit of a single action potential is called a *twitch*.[2]

BOX 32-1

Steps of Neurohumoral Transmission and Excitation-Contraction Coupling

An action potential reaches the motor nerve ending when:

1. Ca^{2+} enters the nerve ending; ACh is released into the synaptic cleft.
2. ACh binds to a postsynaptic cholinergic receptor at the motor end plate.
3. The motor end-plate membrane depolarizes (the EPP).
4. An action potential is generated at the perijunctional muscle membrane.
5. The action potential spreads along the muscle membrane and inward to the transverse tubules.
6. Depolarization of the T tubules causes Ca^{2+} release from the sarcoplasmic reticulum.
7. Ca^{2+} triggers actomyosin complex cross-bridge formation; the sarcomere shortens; the muscle contracts.

ACh, Acetylcholine; *EPP*, end-plate potential; *T*, transverse.

BOX 32-2

Steps of Skeletal Muscle Relaxation

1. ACh is hydrolyzed by AChE in the synaptic cleft.
2. The end plate and muscle membrane repolarize to their resting potentials.
3. Ca^{2+} is actively pumped back into the sarcoplasmic reticulum.
4. Myoplasmic Ca^{2+} concentration returns to a normal low level.
5. The muscle relaxes.

ACh, Acetylcholine; *AChE*, acetylcholinesterase; *Ca^{2+}*, calcium ion.

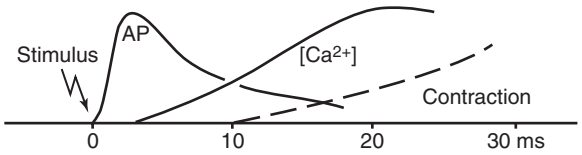

FIGURE **32-15** The electrical, ionic, and mechanical responses of a skeletal muscle to a single maximal stimulus. *AP*, Action potential.

Unlike cardiac muscle, skeletal muscle does not have a refractory period. Because of this property, rapidly repeated electrical impulses can cause summation of contractions and greatly increase the muscle tension. Repetitive action potentials maintain a high Ca^{2+} concentration in the myoplasm. The greater the myoplasmic Ca^{2+} concentration, the more cross-bridge sites are exposed, and the stronger the force of the contraction. Maximal and sustained muscle tension without relaxation—produced by the fusion and summation of successive twitch responses—is called *tetanus*.[9]

Figure 32-15 shows the time course and relationship between a single action potential, the myoplasmic Ca^{2+} rise, and the resulting twitch response. The action potential lasts about 2 to 4 milliseconds. The twitch begins about 2 milliseconds after the start of the muscle membrane depolarization. The duration of the twitch varies with the type of muscle stimulated.

Slow Versus Fast Muscle

Skeletal muscle fibers are classified as type I ("slow fibers") or type II ("fast fibers"), based on different myosin isoenzymes that distinguish the two types. The two fiber types differ in their metabolic

demands, their myosin ATPase activity, and their cross-bridge cycling rates. Muscles usually contain a mixture of both types of fibers, but one type often predominates.[1,22,23]

Slow (type I) muscle fibers are adapted for sustained movements, such as maintaining posture, and are resistant to fatigue. They have slow twitch durations, depend on oxidative metabolism for energy, have extensive blood supplies, and have rich concentrations of mitochondria.[1,22,23] An example of a type I muscle is the soleus muscle of the leg, an important muscle used for maintaining posture and walking. Type I muscle is called "red" muscle because its high myoglobin content imparts a dark, rubrous color.

Fast (type II) muscle fibers usually predominate in "white" muscle and are primarily concerned with rapid or powerful movement. They have short twitch durations, depend on glycolytic pathways for energy, and are easily fatigued.[1,23] Muscles specialized for fine, skilled movement, such as extraocular muscles, and some muscles of the hand are in this category.

The diaphragm is engaged in continuous rhythmic activity and so the muscle fibers must be resistant to fatigue. Infants have a greater tendency toward respiratory failure in part because at birth only 25% of their diaphragm is composed of type I fatigue-resistant fibers, compared with 55% in the adult. Before 27 weeks' gestational age, type I slow fibers make up less than 10% of the total diaphragm muscle content.[22]

Energy Sources for Skeletal Muscle

Muscle contraction requires a continual supply of energy at a rate proportionate to its energy consumption. The energy consumed by skeletal muscle is used for (1) cross-bridge cycling during muscle contraction, (2) sarcoplasmic reticular resequestration of Ca^{2+} during muscle relaxation, (3) rephosphorylation of creatine to replenish creatine phosphate energy stores, (4) activation of the Na^+/K^+ pump to restore proper membrane polarization, and (5) resynthesis of muscle glycogen.[2]

The amount of ATP present in the muscles is sufficient to sustain maximal muscle power for only about 3 seconds. For this reason, actively contracting muscles must continually form new ATP. There are three metabolic systems that provide a continuous supply of ATP in muscle cells: (1) the phosphocreatine-creatine system, (2) the glycogen-lactic acid system, and (3) the aerobic system.[23]

Phosphocreatine—Creatine System

The energy-rich phosphate bonds in muscle *phosphocreatine* (also called *creatine phosphate*) supply a limited amount of energy to produce ATP in skeletal muscle. The hydrolysis of creatine phosphate to creatine and phosphate is an extremely rapid reaction that releases large amounts of energy for the conversion of ADP to ATP. Creatine phosphate provides a stored source of energy that is used for short bursts of muscle power or for use at the very beginning of muscle contraction while other, more sustainable, energy-regenerating systems are being turned on.[2]

Glycogen—Lactic Acid System

Skeletal muscle stores glucose as energy-rich glycogen. With brief, intense muscle exertion, muscles meet their energy demands from the breakdown of glycogen to glucose (*glycogenolysis*) and the metabolism of glucose to pyruvate and lactate (*glycolysis*). Glycolysis occurs without the consumption of oxygen in the cytoplasm of the muscle cell. The energy released from the breakdown of glucose to pyruvate or lactate is used to convert ADP to ATP for short to moderate periods of muscle contraction.[23]

Aerobic System

When oxygen is plentiful, the skeletal muscle takes up products of the glycolytic pathway and other substrates, such as amino acids, fatty acids, or ketone bodies, and efficiently oxidizes them to CO_2 and water in the muscle fiber mitochondria. This energy-yielding process is called *oxidative metabolism*. The oxidation of products of the glycolytic pathway and free fatty acids is a slow process, but it is usually sufficient to meet the continual but more modest energy demands of the most frequently used skeletal muscle. The aerobic system is the primary source of energy for muscle cells during prolonged exercise and for steady-state requirements.[23]

MUSCULOSKELETAL PATHOPHYSIOLOGY AND ANESTHESIA

Musculoskeletal diseases have a wide variety of causes, ranging from autoimmune destruction of tissue, to genetically determined defects in muscle membrane proteins, to pharmacologically induced alterations in Ca^{2+} metabolism. Musculoskeletal defects may reside in the neuromuscular junction, the muscle infrastructure, or the skeletal support structures.

Myasthenia Gravis

Myasthenia gravis (MG), a chronic disease of the neuromuscular junction, is manifested by increasing skeletal muscle weakness, fatigability on effort, and at least partial restoration of function after rest.

Incidence

Myasthenia gravis is the most prevalent neuromuscular disorder. With variability depending on country and time of study, a recent incidence rate ranged from 3 to 30 people in every 1,000,000 with myasthenia gravis.[24] In individuals younger than 50 years, the ratio of women to men with the disease is 3 to 2; however, in those older than 50 years, the disease is equally distributed between the sexes. Myasthenia gravis can begin spontaneously at any age, but it occurs most often in women between the ages of 30 and 40 years and in men between the ages of 50 and 60 years.[11,25] The onset may be abrupt or insidious, and the course is fluctuating, marked by periods of exacerbation and remission.[26] Spontaneous remissions that do occur sometimes persist for years.

Pathophysiology

Electron microscopic examination of the neuromuscular junction of the patient with myasthenia gravis shows a decrease in the number of functional postsynaptic ACh receptors (Figure 32-16). The AChR lesion appears to be caused by immune-mediated destruction, blockage, or inactivation. The prejunctional ACh pool is normal.[11]

Myasthenia gravis is an autoimmune disease with two distinct forms. In the most prevalent form, circulating antibodies react with myoneural AChR proteins, leading to varying degrees of dysfunction. Anti-AChR antibodies (AChR-Ab) are found in the sera of 80% to 85% of patients with myasthenia gravis, but the antibody level does not necessarily correlate with the severity of the disease.[27-30]

A subset of AChR-Ab-seronegative myasthenia gravis patients have muscle-specific kinase (MuSK) antibodies. MuSK-MG patients have more bulbar muscle involvement and are at increased risk for aspiration. Up to 50% of these patients are likely to experience myasthenia crisis requiring mechanical ventilation.[27-31] Serum concentration of MuSK-MG correlates with severity of symptoms.[27] Evidence from case series have demonstrated increased prevalence in people living closer to the equator.[28,32]

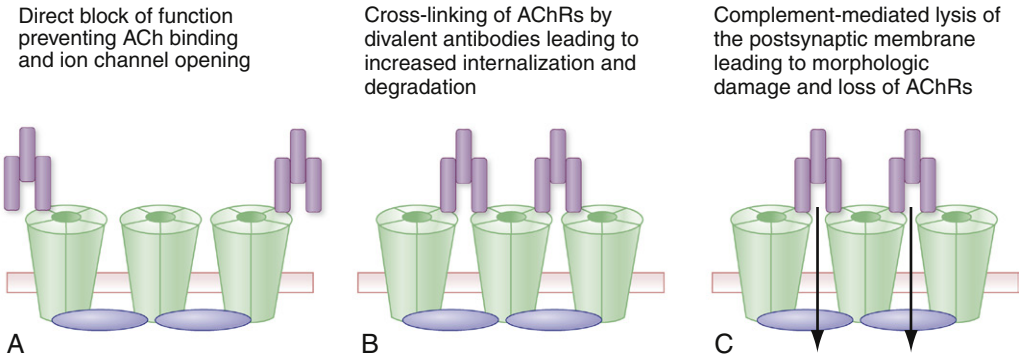

FIGURE **32-16** Mechanisms of loss of the acetylcholine receptor (AChR) at the neuromuscular junction. Antibodies can act **(A)** by directly blocking ACh binding or ion channel function; **(B)** by cross-linking the AChRs in the membrane, thereby leading to increased internalization and degradation; or **(C)** by complement-dependent lysis of the AChR-containing postsynaptic membrane. In myasthenia gravis, complement-dependent lysis is likely to be the most important mechanism overall. Interestingly, there is no evidence of complement-dependent mechanisms in either the Lambert-Eaton myasthenic syndrome or acquired neuromyotonia, in which cross-linking of the respective ion channels with increased internalization seems to be the main mechanism. (From Goldman L, Schafer AI. *Goldman's Cecil Medicine*. 24th ed. Philadelphia: Saunders; 2012.)

The initiating stimulus for the production of IgE antibodies against AChR or MuSK is unclear. The antibodies are T cell–dependent. The thymus gland seems to play a central role in the pathogenesis.[11,28,29] The thymus produces autoantibodies that cross-react to antigens in the neuromuscular junction.[28,33,34] The thymus is hyperplastic in approximately 65% and abnormal in about 75%. Thymomas, thymic tumors, are present in an additional 10%. Thymectomy is a viable treatment option for such patients.[11,28] Thymectomy improves symptoms, but is not curative, suggesting that antibodies are also produced elsewhere.[34]

Pregnancy exacerbates the symptoms of myasthenia gravis in 33% of pregnant women with the disease; however, other patients with the disease experience remission or no change in symptoms during pregnancy.[35] Anti-AChR antibodies that pass across the placenta may produce transitory symptoms of weakness in less than 20% of infants born to mothers with myasthenia gravis. Neonatal MG signs of weakness (e.g., difficulty with swallowing, sucking and breathing, ptosis, facial weakness) in the affected infant are usually present within the first few hours after birth. Spontaneous remission usually occurs within 2 to 4 weeks.[34,36] Neonatal MG has been linked to both AChR and MuSK antibodies.[28]

Clinical Manifestations

The clinical hallmarks of myasthenia gravis include generalized muscle weakness, which improves with rest, and an inability to sustain or repeat muscular contractions. Enhanced and repetitive effort produces enhanced weakness. The severity of myasthenia gravis can range from mild (slight ptosis only) to severe (respiratory failure). Environmental, physical, and emotional factors seem to affect the disease process, although unpredictably.[11]

Mouth, eyes, pharynx, proximal limb, and shoulder girdle musculature are most often affected. Visual symptoms (ptosis and diplopia) from extraocular muscle weakness occur in more than 50% of patients with myasthenia gravis.[28,37] The disease is restricted to the extraocular muscles in 20% of patients. Sensation and cognition are not affected by the disease process.[38]

Thymus gland abnormalities are detectable in about 75% of patients with myasthenia gravis.[11,37] Other autoimmune disorders, such as thyroid disease, collagen vascular diseases, polymyositis, and rheumatoid arthritis, occur more often in patients with myasthenia gravis.[36-38]

Myocarditis may complicate myasthenia gravis, especially in patients with thymomas. Microscopic lesions of myasthenic cardiac muscles are similar to skeletal muscle lesions, indicating a common pathogenesis. The myocardial inflammation produces dysrhythmias, particularly atrial fibrillation and atrioventricular block.[39]

Treatment

Therapy for patients with myasthenia gravis is directed toward improving neuromuscular transmission and includes cholinesterase inhibitors, corticosteroids and other immunosuppressants, plasmapheresis, intravenous immunoglobulin, and thymectomy.[40-42]

Treatment with cholinesterase inhibitors can dramatically reduce the symptoms of myasthenia gravis by inhibiting the hydrolysis of ACh and therefore increasing the neurotransmitter's concentration at the neuromuscular junction. Increasing the synaptic concentration of ACh enhances the possibility of postsynaptic AChR occupation, which is critical for the production of a threshold-reaching EPP for muscle contraction. Anticholinesterase treatment is particularly successful in patients with milder disease.[11,37,42] The most commonly used anticholinesterase agent in the United States is oral pyridostigmine.[42] An oral dose of 60 mg pyridostigmine lasts 3 to 6 hours and is equivalent to an intramuscular or intravenous dose of 2 mg pyridostigmine or 1 mg neostigmine.[36] The dosage is patient dependent with the average dose of 600 mg daily. Timing of administration should correlate to periods of highest activity.[34]

Titration of the anticholinesterase dose is challenging. Underdosing does not sufficiently retard the muscle weakness and can result in *myasthenic crisis*, a severe exacerbation of myasthenic symptoms resulting in respiratory distress. Overmedicating with a cholinesterase inhibitor can produce a surplus of ACh at the myoneural junction, causing a depolarizing-like block and augmenting skeletal muscle weakness. This situation is called *cholinergic crisis*. Muscarinic side effects (e.g., abdominal cramping, diarrhea, salivation, bradycardia, respiratory distress, and miosis) predominate in a cholinergic crisis.

Corticosteroid therapy produces an 80% remission rate in patients with myasthenia gravis, in part by reducing AChR antibody levels.[42] Glucocorticoid therapy is often used in combination with other agents. Use is limited by the side effects (e.g., osteoporosis, gastrointestinal bleeding, suppression of endogenous

cortisol release, cataracts, increased susceptibility to acute infections, hypertension, and glucose intolerance) observed with long-term administration.

In patients with more debilitating, widespread disease, immunosuppressive drugs such as azathioprine (Imuran) and cyclosporine may induce remission by interfering with the production of AChR antibodies. Side effects of azathioprine include severe hemopoietic depression and liver dysfunction. Cyclosporine side effects include hypertension and nephrotoxicity.[11,37,42,43]

Excision of the thymus gland is recommended for adults with generalized disease and for patients with thymomas, thymus gland hyperplasia, or drug-resistant myasthenia gravis.[11,38,42] Thymectomy effectively arrests or reverses the myasthenic process by removing a major source of antibody production. Clinical improvement of myasthenic symptoms is seen in 85% of patients within weeks to months after surgery; almost 35% of these patients go into remission requiring no medications.[11] Early evidence is suggestive that MuSK-MG patients respond less well to thymectomy.[11,42]

Plasmapheresis (plasma exchange) arrests severe refractive myasthenia gravis by reducing the concentration of circulating antibodies. It is used primarily as a short-term treatment because the improvement that it produces in symptoms is generally short lived.[44] Intravenous immunoglobulin also may be used for short-term control of symptoms prior to surgery.[11,37,42,44]

Anesthetic Implications

Several days before the operation and again immediately prior to surgery, the surgical candidate with myasthenia gravis should be evaluated for disease control and, if applicable, for stabilization of anticholinesterase dose.

The use of anticholinesterase medication in the immediate preoperative period is controversial.[12,37,40,41,45,46] Some experts feel that an awareness of drug mechanisms can enable anticholinesterase therapy to be safely continued into the preoperative period, especially in patients who depend on this therapy for their well-being. Others recommend discontinuing or tapering anticholinesterase medication before surgery to avoid complicating the anesthetic management. Patients with mild myasthenia gravis can usually tolerate the temporary disruption in treatment.[41,46]

The presence of cholinesterase inhibitors may potentiate vagal responses and beclouds both the intraoperative administration of muscle relaxants and the differential diagnosis and treatment of postoperative muscle weakness.

Emotional stress and surgery may precipitate or worsen skeletal muscle weakness. Pharyngeal and laryngeal muscle weakness, difficulty in eliminating oral secretions, and the risk of pulmonary aspiration should be considered in the anesthesia plan of care.[36] Swallowing and respiratory muscle dysfunction account for much of the morbidity and potential mortality in patients with myasthenia gravis.[41,47]

Regional and local anesthesia with careful monitoring are the preferred anesthetic techniques when appropriate. If general anesthesia is indicated, the respiratory depressant effects of sedatives, narcotics, and volatile anesthetic agents, compounded by the presence of an already weakened respiratory system, must be carefully considered.[40,41.48,49]

In many patients, the relaxant effects of a volatile anesthetic in combination with the patient's preexisting skeletal muscle weakness are sufficient to facilitate intubation of the trachea.[46,48,50] Enhanced muscle relaxation may be seen with the administration of all the potent volatile anesthetics.[40,41]

Small doses of succinylcholine may be used to facilitate tracheal intubation, but the response may be unpredictable.[36] Untreated patients with myasthenia gravis appear to be two to three times more resistant to succinylcholine. Normal dosages of succinylcholine may not effectively depolarize the end plate because of the deficiency of viable AChRs. For rapid-sequence induction, the dose of succinylcholine should be increased to 1.5 to 2 mg/kg.[12,40,41] On the other hand, patients treated with cholinesterase inhibitors exhibit a normal or prolonged response to succinylcholine. Cholinesterase inhibitors block the effects of plasma cholinesterase, as well as those of true cholinesterase; hence, succinylcholine and other medications metabolized by plasma cholinesterase (e.g., ester local anesthetics) may have a delayed hydrolysis and a prolonged duration of action.[12,46] The ester hydrolysis of atracurium and cisatracurium is independent of plasma cholinesterase activity.

The deficient number of functioning AChRs in patients with myasthenia gravis produces an extraordinary sensitivity to nondepolarizing muscle relaxants. Small doses of nondepolarizing agents can produce a profound block with a prolonged effect, even in patients being treated with cholinergic drugs.[37,40,41] One study showed that myasthenia gravis patients with a preanesthetic train-of-four ratio of less than 0.9 had a significantly lower ED_{95} (effective dose, 95%) of atracurium than myasthenia patients with no fade or nonmyasthenic patients.[50] Some patients require no medication at all for surgical muscle relaxation.[48,49,51]

Generally, muscle relaxant requirements are widely variable in patients with myasthenia gravis, a characteristic that makes neuromuscular blockade monitoring an essential and integral part of the anesthetic management. The orbicularis oculi muscle may overestimate the degree of muscle relaxation in patients with myasthenia gravis.[52] This site may be the most ideal site to monitor neuromuscular blockade to avoid the possibility of undetected residual muscle weakness. When needed, the use of smaller doses (half to two thirds the normal dose) of shorter-acting nondepolarizing relaxants is the prudent choice.[36,37,40,41,53]

Reversal of neuromuscular blockade with an AChE inhibitor should be performed cautiously in patients with myasthenia gravis. Overtreatment with an anticholinesterase agent can precipitate a cholinergic crisis and aggravate rather than reverse the muscle weakness. In many circumstances, the neuromuscular block can be titrated to allow complete spontaneous recovery, avoiding the use of reversal.

Case reports have reported effective use of sugammadex for reversal of neuromuscular blockade in myasthenia gravis patients.[54,55] In both cases a rapid and complete recovery from rocuronium was achieved without the use of anticholinesterase agents.

Complete, sustained return of muscle strength must be demonstrated before extubation and resumption of spontaneous ventilation. The patient should be informed that postoperative tracheal intubation and ventilatory support may be required. Skeletal muscle strength may appear to be adequate shortly after surgery but may deteriorate a few hours later. A higher likelihood for postoperative ventilation can be predicted for patients undergoing transsternal thymectomy, duration of the disease longer than 6 years, a daily pyridostigmine dose greater than 750 mg, the presence of chronic obstructive pulmonary disease, and a preoperative vital capacity less than 2.9 L.[46] Postoperative ventilation related to myasthenia crisis can be predicted for patients after transsternal thymectomy by the preoperative bulbar symptoms, history of preoperative crisis, preoperative serum AChR antibody greater than 100 nmol/L and intraoperative blood loss greater than 1000 mL, severity of preoperative muscle weakness, and major postoperative complications.[56,57]

Lambert-Eaton Myasthenic Syndrome

Incidence

Lambert-Eaton myasthenic syndrome (LEMS) is a rare autoimmune disease that classically occurs in patients with malignant disease, particularly small-cell carcinoma of the bronchi. One third to one half of patients, however, have no evidence of carcinoma.[10,58,59] Most patients with myasthenic syndrome are men between the ages of 50 and 70 years.

Pathophysiology

The predominant defect associated with LEMS appears to be an autoantibody-mediated derangement in presynaptic P/Q-type voltage-gated Ca^{2+} channels (VGCC) leading to a reduction in Ca^{2+}-mediated exocytosis of ACh at neuromuscular and autonomic nerve terminals.[10,58,60,61] The decreased release of ACh quanta from the cholinergic nerve endings produces a reduced postjunctional response. Unlike in myasthenia gravis, the number and quality of postjunctional AChRs remain unaltered, and the end-plate sensitivity is normal. The neuromuscular junction abnormality of LEMS is similar in location to that of Mg^{2+} intoxication or botulism poisoning, in which the release of presynaptic ACh is attenuated.

Clinical Manifestations and Treatment

Muscle weakness, fatigue, hyporeflexia, and proximal limb muscle aches are the dominant features of LEMS. The diaphragm and other respiratory muscles are also involved. Autonomic nervous system dysfunction is often present and is manifested as impaired gastric motility, orthostatic hypotension, and urinary retention.

Patients with LEMS experience a brief increase in muscle strength with voluntary contraction, distinguishing it from myasthenia gravis. Tetanic stimulation results in a progressive augmentation in muscle strength as the frequency of the stimulation is increased. Posttetanic potentiation is also enhanced.

There is no cure for LEMS. Treatment is aimed at improving muscle strength and reversing autonomic deficits.[11,36,40,60] 3,4-Diaminopyridine improves muscle strength in some patients by promoting presynaptic Ca^{2+} influx and increasing the number of ACh quanta that are liberated by a single nerve action potential. Plasmapheresis, corticosteroids, intravenous immunoglobulin, and immunosuppressive drugs provide improvement for some patients with LEMS. Unlike the effective use in myasthenia gravis, anticholinesterase drugs do not provide improvement for patients with LEMS.[36]

Anesthetic Implications

An index of suspicion for LEMS should be maintained in surgical patients with a history of muscle weakness and suspected or diagnosed carcinoma of the lung. Patients with LEMS are extremely sensitive to the relaxant effects of both depolarizing and nondepolarizing muscle relaxants.[12,36,37] Inhalational anesthetics alone may provide adequate relaxation, but if muscle relaxants are required, their dosages should be reduced and the neuromuscular blockade closely monitored.[37,62] Neuromuscular reversal with an anticholinesterase agent may be used. Prolonged ventilatory assistance may be required postoperatively.

Duchenne Muscular Dystrophy

Muscular dystrophy is a heterogeneous set of diseases that includes fascioscapulohumeral dystrophy, limb-girdle dystrophy, Becker muscular dystrophy (BMD), Duchenne muscular dystrophy, and others. *Duchenne muscular dystrophy* is the most common of these and has the most severe clinical course.[63]

Incidence

Duchenne muscular dystrophy (DMD), described by G.B. Duchenne in 1861, is an inherited, sex-linked, recessive disease that presents in early childhood at between 3 and 5 years of age. It is clinically evident in males and has an incidence of approximately 1 in 3500 live-born males.[64] Females are generally unaffected but are carriers of the disorder. Mental retardation of varying degrees occurs in about 30% of patients with DMD.[64] There is no cure for the disease. Corticosteroid therapy improves muscle strength, reduces the risk of scoliosis, and may slow disease progression in some patients.[65-67] Death often occurs in early adulthood and is usually caused by progressive cardiomyopathy or pneumonia.[63-65]

Pathophysiology

Patients with DMD experience an infiltration of fibrous and fatty tissue into the muscle, followed by a progressive and painless degeneration and necrosis of muscle fibers. The disease affects skeletal muscle, cardiac muscle, and smooth muscle. Muscle weakness ends with muscle destruction.

In 1987 the abnormal gene responsible for DMD was identified. This gene is located on the X chromosome and is errant in coding for the vital muscle protein *dystrophin*. Dystrophin is normally bound to a complex of glycoproteins as a transmembrane structural component of the muscle fiber sarcolemma.[68] Patients with DMD have an absence or a severe deficiency of the dystrophin protein, which alters sarcolemma integrity and stability.[67,69] The protein is present in low amounts or is structurally altered in Becker muscular dystrophy, a similar but rarer disorder that follows a milder and less progressive course than the Duchenne type.[68,69]

In the early stages of DMD, increased permeability of the sarcolemma and skeletal muscle necrosis are mirrored by elevated serum levels of the enzyme creatine kinase (CK). Serum CK levels are often 20 to 100 times normal levels (normal level, 40 to 150 units/L), but as muscle is lost to the destructive process, CK levels decrease.[64]

Clinical Manifestations

Duchenne muscular dystrophy is characterized by an unremitting weakness and a steady deterioration of the proximal muscle groups of the pelvis and shoulders. The child exhibits a clumsy, waddling gait and falls frequently. Weakness of the pelvic girdle leads to the classic finding of *Gowers sign*, in which patients use their hands to climb up their legs to arise from the floor. A steady deterioration of muscle strength forces most of these boys to be wheelchair bound by the age of 12 years.[64]

Skeletal muscle atrophy is usually preceded by fat and fibrous tissue infiltration, resulting in pseudohypertrophy. The infiltrative process is most apparent in the calf muscles, which become particularly enlarged.

Degeneration of respiratory muscles (diaphragm, intercostal, accessory muscles) occurs and leads to a restrictive type of ventilatory impairment. Unopposed action by healthy, nondystrophic axial muscles predisposes these patients to kyphoscoliosis, which further decreases the pulmonary reserve. Decreasing muscle strength also results in ineffective cough, impaired swallowing, and inability to mobilize secretions.[70,71]

More progressive forms of the disease affect not only skeletal muscle but also smooth muscle of the alimentary tract and cardiac muscle. Alimentary tract involvement can lead to intestinal hypomotility, delayed gastric emptying, and gastric dilation.[72,73]

Myocardial involvement occurs in almost all patients with progressive disease and includes cardiomyopathy, ventricular dysrhythmias, and mitral regurgitation.[46,64,65,74] Preclinical cardiac

involvement can be detected in up to 62% of boys between the ages of 6 and 10 years. Cardiomyopathy can be evident at 10 years of age and is present in nearly all patients over the age of 20 years.[75,76] In a study by Duboc et al.,[77] left ventricular ejection fraction was shown to be depressed in 25% of the patients with DMD before the age of 13 years. Angiotensin-converting enzyme inhibitors and β-adrenergic blockers may be used to slow the deterioration of cardiac function.[65,76-78] Typical electrocardiographic (ECG) changes include tall R waves in the right precordial leads and deep Q waves in the left precordial leads.[64]

Although often severe, compromised cardiac and respiratory conditions may be masked by the limited activity imposed by the patient's skeletal myopathy. Added stress, such as that produced by surgery and anesthesia, may suddenly increase cardiorespiratory demand and uncover the weakened cardiac and respiratory states.[79,80]

Anesthetic Implications

Patients with DMD are susceptible to untoward anesthesia-related complications. When possible, local or regional anesthesia should be considered.[80,81] For the patient on chronic corticosteroid treatment, consideration needs to be given to steroid coverage over the period of surgery.

Generalized muscle weakness, especially in the advanced stages of DMD, makes these patients exquisitely sensitive to the respiratory depressant properties of opioids, sedatives, and general anesthetic agents. Preoperative sedation should be omitted or minimal, and the smallest possible amounts of anesthetic agents should be used.

Preoperative and postoperative respiratory therapy can help maximize the patient's pulmonary condition.[46,80] In patients with more advanced disease, arterial blood gas determinations and preoperative pulmonary function studies may elucidate the extent of respiratory involvement and the amount of respiratory reserve. A preoperative forced vital capacity (FVC) less than 50% of predicted places the patient at increased risk for respiratory complications when undergoing general anesthesia or procedural sedation. Patients with a FVC greater than 35% of predicted have a high risk for pulmonary complications.[80] In one series, aggressive preoperative chest physiotherapy and incorporation of postoperative noninvasive positive pressure ventilation (NPPV) enabled patients with preoperative FVC levels of 30% and below to successfully undergo corrective spinal surgery.[82] Extubation directly to NPPV should be considered for DMD patients with baseline FVC less than 50% of predicted and is strongly recommended for patients with a FVC less than 30% of predicted.[80,83] Assiduous attention to respiratory function must be continued into the postoperative period. Delayed pulmonary insufficiency, as late as 36 hours after surgery, has been reported.[46,72]

The effects of nondepolarizing muscle relaxants must be scrupulously monitored. There is enhanced muscle relaxant sensitivity, and recovery may be prolonged three to six times the normal duration in patients with DMD.[84] If surgical muscle relaxation is required, a short-acting nondepolarizing muscle relaxant that is carefully titrated with the use of a nerve stimulator is recommended.

Cardiomyopathy and decreased cardiac reserve makes these patients sensitive to the myocardial depressant effects of general anesthetic agents, sedatives, and narcotics.[85,86] A preoperative consultation with a cardiologist is advised before anesthesia.[80] Echocardiography is recommended for operative patients to evaluate left ventricular (LV) function, but it cannot exclude the development of congestive heart failure (CHF) during surgery.[46,65,79,87] A carefully titrated intravenous "balanced" technique may help provide a smoother cardiovascular course. Ketamine has been used successfully for anesthesia during diagnostic muscle biopsy in patients with DMD. Judicious administration of intravenous fluids is warranted. The sudden occurrence of hypotension and tachycardia during anesthesia may herald heart failure.[79]

The potential for delayed gastric emptying, plus the presence of weak laryngeal reflexes, dictates that the anesthesia plan of care include measures for guarding against aspiration of stomach contents. Gastrokinetic agents and the prophylactic use of a nasogastric tube are recommended for patients with gastrointestinal dysmotility.[73,80]

Succinylcholine is contraindicated in patients with DMD.[65] The altered sarcolemma can lead to rhabdomyolysis and myoglobin efflux with succinylcholine administration. The resultant massive breakdown of the diseased muscle fibers produces a profound hyperkalemia that requires extensive and tenacious treatment with hyperventilation, calcium chloride, sodium bicarbonate, and glucose and insulin. Ventricular fibrillation and intractable cardiac arrest have been associated with succinylcholine administration to patients with diagnosed and undiagnosed muscular dystrophy.[88,89]

Rhabdomyolysis, hyperkalemia, hyperthermia, unexplained tachycardia, and cardiac arrest also have been reported after the administration of potent inhalation anesthetics to DMD patients without the use of succinylcholine.[85,86,90-92] These "malignant hyperthermia-like" reactions may be due to the destabilizing effect of inhalational agents on an already unstable and frail muscle membrane.[93] The term associated with DMD rhabdomyolysis in response to succinylcholine and/or potent inhalational agents is "anesthesia-induced rhabdomyolysis" (AIR).[86]

Although only a small proportion of DMD patients develop AIR in response to succinylcholine and inhalational anesthetics, given the availabilities of safe anesthesia alternatives, the anesthetist should consider a "trigger-free" total intravenous anesthesia (TIVA) or regional anesthetic for patients with DMD.[65,80,83,92-94] In addition to the strict contraindication of succinylcholine, this includes when feasible avoiding potent volatile inhalational agents or using them for the absolute shortest period possible.[83,93]

Despite the increased risk for "MH-like events" in patients with DMD, malignant hyperthermia (MH) and DMD are genetically distinct diseases. Current evidence indicates that DMD and BMD are not among the myopathies that are genetically associated with malignant hyperthermia and that patients with DMD and BMD do not have an increased risk of MH.[80,93,94]

Malignant Hyperthermia

Epidemiology/Incidence

Malignant hyperthermia (MH) is an uncommon, life-threatening, hypermetabolic disorder of skeletal muscle, triggered in susceptible individuals by potent inhalation agents, including sevoflurane, desflurane, and isoflurane and the depolarizing muscle relaxant succinylcholine.[95,96] A review of MH cases in New York State by Brady et al.[97] reported an estimated prevalence of MH in males 2.5 to 4.5 times the rate for females.[97] The exact incidence of MH is unknown, but the rate of occurrence has been estimated to be between 1:5000 to 1:50,000 general anesthetics.[95,96] The highest incidence of MH is in young people, with a mean age of 18.3 years.[95] High-incidence areas in the United States include Wisconsin, Nebraska, West Virginia, and Michigan.[98]

Susceptibility to MH is inherited as an autosomal-dominant pattern.[95,96] If a parent is identified as MH-susceptible (MHS), then each of the parent's siblings have a 50% chance of also being MHS.[95,96] MH has been associated with at least 23 genetic

mutations, and in many cases, the genetic defects have not been established.[98]

The first formal case report of MH was of an Australian family, described by Denborough et al.[99] over 40 years ago in the journal *Lancet*.[99] Since that time, a great deal has been learned about the biochemical and physiologic components of the disease. Nonetheless, many questions remain regarding the pathophysiology, diagnosis, and significance of some clinical manifestations.

Pathophysiology

Although the cause(s) of MH are not yet known with certainty, it is generally agreed that MH is an inherited disorder of skeletal muscle. In susceptible patients, a defect in calcium regulation is expressed by exposure to specific anesthetic triggers, the volatile inhalational anesthetic agents or succinylcholine. An uncontrolled rise in myoplasmic calcium results. The ryanodine receptor (RYR1) is the major calcium release channel of the sarcoplasmic reticulum, and much attention has been focused on RYR1 as the site of the MH defect.[1,96,100] The channel is called a "receptor" because it binds the plant alkaloid ryanodine. The calcium release defect involves skeletal muscle, and there is no evidence for a primary defect in cardiac or smooth muscle cells.

Malignant hyperthermia is initiated in MHS patients when specific anesthetic-triggering agents induce enhanced calcium release from the sarcoplasmic reticulum in myocytes. The enhanced intracellular calcium results in muscle contraction. Energy-dependent reuptake mechanisms attempt to remove excess calcium from the myoplasm, increasing muscle metabolism two- to three-fold. The accelerated cellular processes increase oxygen consumption, augment carbon dioxide and heat production, deplete ATP stores, and generate lactic acid.[95] Acidosis, hyperthermia, and ATP depletion cause sarcolemma destruction, producing a marked egress of potassium, myoglobin, and creatine kinase to the extracellular fluid.[98] Skeletal muscle constitutes 40% to 50% of our body mass, so relatively small changes in muscle metabolism may produce the dramatic systemic biochemical changes observed with MH.

Clinical Manifestations

Not all cases of MH are fulminant, but rather there is a spectrum or continuum of severity, ranging from an insidious onset with mild complications to an explosive response with pronounced rigidity, temperature rise, arrhythmias, and death.[95,96,101]

Although MH may present in several ways, a typical MH episode begins while the patient is under general anesthesia (GA) with a volatile anesthetic. Succinylcholine may or may not precede the MH episode.[95] The onset of MH symptoms may occur immediately after induction of anesthesia or several hours into the surgery.[101] Succinylcholine appears to accelerate the onset and increase the severity of the MH episode.[95,96] Desflurane and sevoflurane have been associated with more delayed onset of MH, as long as 6 hours after induction of anesthesia.[101-104] Although an uncommon event, MH can occur in the recovery room, usually within 1 hour after general anesthesia.[105]

The clinical features of MH are not uniform and the time course between onset of initial signs and fulminant MH is variable. Overall clinical manifestations of MH reflect increased intracellular muscle Ca^{2+} concentration and greatly increased body metabolism (Box 32-3). The most sensitive and an early indicator of MH is an unanticipated increase in end-tidal carbon dioxide ($ETCO_2$) levels out of proportion to minute ventilation.[96,106] The increased $ETCO_2$ may be abrupt or it may rise gradually over the course of the anesthetic. Common signs of MH include tachycardia, tachypnea, skin mottling, cyanosis, and total body or jaw muscle rigidity. Muscle rigidity is clinically apparent in 75% of cases. Hyperthermia, which may climb at a rate of 1° to 2° C every 5 minutes and averages 39.3° C (102.7° F), is often a late but confirming sign of MH.[95,106,107]

BOX 32-3

Clinical Events and Laboratory Findings During Malignant Hyperthermia

Clinical Events During MH

- Unexplained, sudden rise in end-tidal CO_2 (greater than 55 mmHg)
- Unexplained tachycardia, tachypnea, labile blood pressure, or arrhythmias
- Masseter muscle or generalized muscle rigidity
- Unanticipated respiratory or metabolic acidosis
- Rising patient temperature
- Cola-colored urine (myoglobinuria)
- Mottled, cyanotic skin
- Decreased Sa_{O_2}

Laboratory Findings Consistent with MH

- Arterial blood gases: Pa_{CO_2} greater than 60 mmHg, base excess more negative than −8 mEq/L, pH less than 7.25
- Serum potassium greater than 6 mEq/L
- Creatine kinase greater than 20,000 units/L
- Serum myoglobin greater than 170 mcg/L
- Urine myoglobin greater than 60 mcg/L

MH, Malignant hyperthermia; Pa_{CO_2}, partial pressure of carbon dioxide in alveolar gas; Sa_{O_2}, % of oxygen saturation.

The combination of acidosis, hyperkalemia, and hyperthermia leads to cardiac irritability, a labile blood pressure, and arrhythmias that can rapidly progress to cardiac arrest. Laboratory findings mirror the muscle breakdown and include myoglobinuria and increased serum potassium and CK. Myoglobin appears in the plasma within minutes of the hypermetabolic muscle response. Arterial and venous blood gas analysis reveals decreased oxygen tension and mixed metabolic and respiratory acidosis. Late complications may include cerebral edema, myoglobinuric renal failure, consumptive coagulopathy, hepatic dysfunction, and pulmonary edema.[95,107]

The variable time course and nonspecific clinical features and laboratory findings can make the diagnosis of MH difficult. Insufficient anesthetic depth, hypoxia, neuroleptic malignant syndrome, propofol infusion syndrome, thyrotoxicosis, pheochromocytoma, and sepsis can share several characteristics with MH, making the clinical picture ambiguous and the differential diagnosis challenging to even the most experienced practitioner[95,108,109] (Box 32-4). The average time between the onset of the first adverse sign indicating MH and the administration of dantrolene is 35 minutes.[107] Surgical procedures performed of necessity in a darkened operating room can further compromise the practitioner's diagnostic acumen.

Preoperative Assessment and Prevention

Patients who are MH susceptible are usually phenotypically normal, otherwise healthy, and completely unaware of their risk until exposed to a triggering anesthetic.[95,110] Furthermore, not everyone who has the MH gene develops an MH episode upon each exposure to triggering anesthetics. An MH-susceptible patient may be anesthetized multiple times before experiencing an MH

BOX **32-4**

Manifestations That Mimic Malignant Hyperthermia—Signs and Symptoms

Tachycardia
- Hypoxia
- Hypercarbia
- Hypovolemia
- Insufficient anesthetic depth
- Anticholinergics, sympathomimetics, cocaine, amphetamine
- Pheochromocytoma

Hyperpyrexia
- Heatstroke
- Blood transfusion reaction
- Infection
- Drug reaction
- Neuroleptic malignant syndrome
- Serotonin syndrome
- Hypermetabolic states (sepsis, thyroid storm, pheochromocytoma)
- Iatrogenic overheating

Tachypnea, Hypercapnia
- Congestive heart failure, pulmonary edema
- Hypermetabolic states
- Intraperitoneal carbon dioxide insufflation
- Airway obstruction, pneumothorax
- Excess dead space, low minute volume

Masseter Muscle Rigidity
- Insufficient neuromuscular blockade
- Temporomandibular joint syndrome
- Neuroleptic malignant syndrome
- Myotonia

event. Although MH susceptibility cannot be ruled out by history alone, every surgical patient should be questioned about:
- Family history of unexpected intraoperative complications or deaths
- Family or personal history of MH, muscle rigidity/stiffness, and/or high fever under anesthesia
- Personal history of dark or cola-colored urine after surgery or exercise
- Personal history or family history of high temperature or death during exercise

Because MH is an inherited disorder, all members of a family in which MH has occurred must be considered MHS unless proven otherwise.[98] Moreover, the absence of a positive family history does not preclude MH susceptibility.

Patients with a variety of neuromuscular disorders may exhibit one or more clinical features of MH in the perioperative period. There are a limited number of relatively rare disease entities that have a strong clinical and/or genetic link to MH susceptibility. These include *central core disease*, *King Denborough syndrome*, and *multiminicore disease*.[98,111-113] There is no risk for MH over the general population in patients with Duchenne or Becker muscular dystrophy, neuroleptic malignant syndrome, myotonia congenita, and myotonic dystrophy.[96,106,112]

All patients given general anesthesia for more than 20 to 30 minutes should have core temperature monitoring.[95,96] Pulmonary artery, distal esophageal, nasopharyngeal, and tympanic membrane temperature monitors are the gold standards for core temperature measurement. Intermediate temperature monitoring sites include mouth, axilla, rectum, and bladder. Skin temperature may not accurately reflect core temperature during an MH event.[98]

Weglinski et al.[114] reported that 50% of patients with unexplained CK elevation test positive for MH on biopsy. However, as a screening test for MH, CK levels are imprecise and nonspecific.

Heat stroke and strenuous exercise have been implicated as causal factors of MH in some patients. It is unclear whether these factors cause, exacerbate, or have no effect on MH triggering in humans.[106,115,116] It may be advisable to provide a trigger-free anesthetic to patients with unexplained exertional heat illness or exertional rhabdomyolysis until definitive MH testing can be performed.[115]

Management

Enhanced patient monitoring, earlier diagnosis and treatment, and the introduction of dantrolene are responsible for the dramatic decrease in mortality from nearly 80% 30 years ago to less than 5% today.[95,106,107] In a review of the North American MH Registry from 1987 to 2006, cardiac arrest and patient death occurred more often in patients with muscular builds and was associated with the development of disseminated intravascular coagulation.[107]

In 1979, dantrolene sodium was introduced as a treatment for MH. Since that time, dantrolene has been the cornerstone of treatment and has contributed greatly to the dramatic decline in death and disability associated with MH. Dantrolene is a unique muscle relaxant that does not work at the neuromuscular junction as do standard neuromuscular blocking drugs. Rather, it works by reducing calcium efflux from the sarcoplasmic reticulum, counteracting the abnormal intracellular calcium levels accompanying MH.[96,117,118] At clinical concentrations, dantrolene does not render the muscle totally flaccid and without tone, but it may cause significant muscle weakness and respiratory insufficiency, especially in patients with preexisting muscle disease.

Dantrolene administration with calcium channel blockers may induce life-threatening myocardial depression and hyperkalemia.[96,118] Dantrolene may cause significant muscle weakness in patients with preexisting muscle disease.[98]

Once MH is recognized, it is critical to discontinue the inhalation agent, hyperventilate with 100% O_2, administer dantrolene, cool the patient, and treat symptoms.[96] The Malignant Hyperthermia Association of the United States (MHAUS) provides an "Emergency Therapy for MH" poster that should be posted in every surgical site. The following treatment sequence is recommended for an acute MH episode:
- Discontinue the volatile anesthetic and succinylcholine.
- Call for help and alert the surgeon to conclude the procedure promptly.
- Hyperventilate with 100% oxygen at high flows (at least 10 L/min) to improve tissue oxygenation and eliminate CO_2.
- Administer 2.5 mg/kg dantrolene IV bolus and repeat as necessary every 5 to 10 minutes until symptoms abate. Occasionally, a total dose greater than 10 mg/kg may be needed, but if greater than 20 mg/kg is given without reversal of symptoms, the diagnosis should be reassessed. The alkaline solution is highly irritating to vessels and should be administered through the largest vein possible.[98,118]
- Monitor core temperature. If fever is present, initiate cooling by lavage (orogastric, bladder, open cavities), administration of chilled intravenous normal saline, and surface cooling (e.g., hypothermia blanket; ice packs to the groin, axilla, and neck). Stop cooling measures at 38° C to avoid hypothermia.
- Dysrhythmias will usually respond to treatment of acidosis or hyperkalemia. Treat persistent or life-threatening arrhythmias

with standard antiarrhythmic agents. Do not administer calcium channel blockers with dantrolene.
- Determine arterial blood gases, serum electrolytes, and blood glucose every 15 minutes until the syndrome stabilizes. Correct severe metabolic acidosis with sodium bicarbonate, 1 to 2 mEq/kg, guided by pH and base deficit. Coagulation profile, CK, blood and urine myoglobin, and liver enzyme levels should be established.
- Treat hyperkalemia with hyperventilation, bicarbonate, and intravenous insulin and glucose.
- Maintain urine output greater than 2 mL/kg/hr with hydration, furosemide (0.5 to 1.0 mg/kg), and mannitol as needed. Large losses of intravascular volume should be anticipated. Evaluate need for invasive hemodynamic monitoring.[95,96]

Each 20-mg vial of dantrolene must be reconstituted with 60 mL of sterile water for injection United States Pharmacopeia (USP) (with no bacteriostatic agent). The initial dantrolene dose of 2.5 mg/kg equates to 9 vials of dantrolene for a 70-kg patient. The poor water solubility of dantrolene makes it very time consuming to mix and administer the requisite doses. Although a newer dantrolene formulation is reportedly easier to reconstitute, during an MH emergency, the full-time efforts of additional medical personnel should be enlisted to assist with the labor-intensive preparation. A warmed diluent fluid stored at 37° to 39° C may expedite dantrolene preparation.[98,119,120]

Documentation of an MH episode should include patient responses, personnel involved, medications, interventions, and patient outcomes.

Anesthesia for the Malignant Hyperthermia–Susceptible Patient

Patients known or suspected of having MH should be assessed well before their date of surgery so that anesthesia records and MH testing center reports (if available) can be collected to corroborate the history.

Standard intraoperative monitoring for the MHS surgical patient includes blood pressure, ECG, pulse oximetry, capnography, and continuous measurement of core body temperature. A cooling water mattress should be placed under the MHS patient at the start of the procedure. Dantrolene pretreatment for the MHS surgical patient is not routine.[118]

If the surgical site permits, a regional or local anesthetic technique is preferable for the MHS patient. Local anesthetics (both amide and ester) are nontriggering drugs. Preoperative administration of anxiolytics followed by a nontriggering general anesthetic also can be administered safely in concert with close monitoring of appropriate vital functions. The list of "nontriggering" anesthetic agents is comprehensive enough to meet most anesthetic requirements (Box 32-5). All potent volatile inhalation agents and succinylcholine are MH triggers and should not be administered to the MHS patient. Nitrous oxide is not a MH trigger.

Not all drugs have been thoroughly screened as potential MH triggers, but it is clear that the vast majority of prescription and nonprescription drugs are safe, including antibiotics, antihypertensive agents, and drugs used in the treatment of gastrointestinal disorders. Keys to successful perioperative outcome for the MHS patient include the following[96]:
- Preoperative care in a relaxed and quiet environment with premedication anxiolysis as appropriate
- Avoidance of MH-triggering medications
- Preparation of an anesthesia machine by changing the carbon dioxide absorbent and removing or inactivating vaporizers. The anesthesia machine and ventilators should be flushed with oxygen set at 10 L/min. Newer anesthesia machines may require up to 150 minutes for the anesthesia machine to be "cleaned" of volatile agents with oxygen flush. Older anesthesia machines require only 20 minutes for adequate preparation.[96,121-123] An activated charcoal filter placed in the inspiratory limb of the circuit may speed the removal of potent inhalational anesthetics from the anesthesia workstation.[124]
- An MH kit or cart in the OR
- Assiduous perioperative observation for signs of MH, including continuous intraoperative monitoring of the patient's $ETCO_2$, arterial oxygen saturation, and core temperature
- A full appreciation of a preestablished treatment protocol by all perioperative medical personnel
- Ready availability of ice and the ability to crush it
- Ready availability of at least 3000 mL of cold intravenous solution

Surgery in an ambulatory surgical center can be safely performed for the MHS patient with appropriate planning and if proper safety precautions are regarded.[124-126] A preoperative evaluation and consultation with the surgeon will help determine the best location to perform the needed surgery. Appropriate monitoring, including end-tidal CO_2 and core temperature, must be in place and an adequate supply of dantrolene available.[96,127] A "trigger-free" anesthetic must be administered. Yentis et al.[128] reviewed the medical records of 303 children labeled as MHS who underwent surgery with nontriggering anesthetics between 1981 and 1990. None of the children developed MH, and on the basis of their retrospective analysis, the authors concluded that admission to the hospital solely on the basis of the MHS label is not warranted.[128]

For the MHS patient who has undergone an uneventful surgical course, close observation and monitoring should continue for at least 2.5 hours in the postanesthesia care unit (PACU). Malignant hyperthermia can first manifest in the recovery room after uneventful surgery and anesthesia. The MHS patient may be discharged on the day of surgery if the anesthetic has been uneventful.[98]

All locations where general anesthesia is administered should contain a fully stocked MH cart with drugs and supplies, including 36 vials of dantrolene and preservative-free sterile water for injection. Dantrolene has a shelf life of 30 months. Each minute

BOX 32-5

Malignant Hyperthermia: Triggering and Nontriggering Agents

Triggering Agents
- All volatile inhalation anesthetics (desflurane, isoflurane, sevoflurane)
- Succinylcholine

Nontriggering Agents
- Local anesthetics
- Opioids
- Nitrous oxide
- Barbiturates, propofol, ketamine, etomidate
- Benzodiazepines
- Nondepolarizing skeletal muscle relaxants (vecuronium, atracurium, cisatracurium, pancuronium, rocuronium)
- Digoxin, tricyclic antidepressants, magnesium
- Anticholinesterase agents
- Anticholinergic agents

is critical in an MH emergency, so a dantrolene supply should not be shared with a nearby facility. Dantrolene should be kept in or very close to the operating room so it is available immediately if MH occurs.[96]

Diagnostic Testing

The most accurate and commonly accepted test available for determining MH susceptibility is the caffeine halothane contracture test (CHCT). This test involves taking a biopsy of skeletal muscle from the patient and measuring its contractile response to caffeine, halothane, or both. Normal muscle contracts in response to caffeine or halothane, but this is augmented in the patient with MH. The test is available at four medical centers in North America.[96] Because it must be completed within hours after muscle biopsy, the patient must travel to the testing site. Patients who have survived an unequivocal episode of MH are considered MHS. The CHCT is indicated for family members of an MHS patient or for patients who have had a previous suspicious but undiagnosed reaction to anesthesia.

An alternative to the caffeine halothane contracture test for confirmation of MH susceptibility is genetic testing and DNA-based mutation analysis.[129,130] Intensive investigations have focused on identifying the gene or genes responsible for MH. Most of the focus has been on searching for mutations in genes that encode the ryanodine receptor (RYR1), the dihydropyridine receptor, and associated proteins on chromosome 19. Currently, only about 25% of the people at risk for MH are reliably detected by genetic testing.[130,131] For other MHS patients, the molecular genetic basis for the disease may be more heterogeneous, involving mutations at various sites on different chromosomes.[100,132,133]

Postoperative Care

The patient who has experienced an acute MH episode should be admitted to and monitored in an intensive care unit (ICU) for at least 36 hours. For surgery performed outside a hospital setting, a transfer protocol to a hospital must be available. Intravenous dantrolene should be continued for a minimum of 24 hours, at approximately 1 mg/kg every 4 to 6 hours as a bolus dose or continuous infusion.[98] Recrudescence of an intraoperative episode may occur in 20% to 25% of cases.[95,134,135] In a review by Burkman et al.[135] of 63 cases of recrudescence after a MH reaction, the mean time from the initial reaction to recrudescence was 13 hours. Patients who experience recrudescence are more likely to have a muscular body type and to have had greater than 150 minutes transpire from induction to MH reaction.[98,135,136]

Masseter Muscle Rigidity

Masseter muscle rigidity (MMR), or trismus, is a sustained and forceful contracture of the masseter muscle. The contracture may be severe enough to make opening the jaw impossible ("jaws of steel"). A mild increase in masseter muscle tone or incomplete jaw relaxation after succinylcholine administration is fairly common and may be a normal response. However, if the patient experiences severe jaw tightness that interferes with jaw opening or generalized muscle rigidity after succinylcholine administration, the clinician should assume this is an MH event and immediately begin MH treatment.[95,96]

Clinical signs of MH appear in about 20% of cases of MMR.[98] Because MMR after succinylcholine administration may be a harbinger of MH, many authorities recommend discontinuing the anesthetic after MMR and postponing elective surgery until the patient is evaluated for MH.[95,96] For emergency procedures, the anesthesia may be cautiously continued with nontriggering agents, while assiduously monitoring for rhabdomyolysis and signs and symptoms of MH.[96]

Because of the likelihood of MH and/or rhabdomyolysis, the surgical patient should remain in the hospital and be observed for at least 24 hours in an ICU after marked jaw rigidity.[98] Myoglobinuria may be apparent following MMR, and inducing a brisk urine output is important to lessen the risk of myoglobinuric renal damage. Patients who have experienced MMR should be counseled concerning the possibility that they are MHS and should be referred to a well-informed primary or specialty care physician or genetic counselor for further investigation.

Information Resources

A clinical grading scale may be used to retrospectively determine whether a patient who responded abnormally to anesthesia is likely to have had an MH episode.[137] The Malignant Hyperthermia Association of the United States (MHAUS) provides educational and technical information to patients and healthcare providers. Information is available via fax-on-demand (1-800-440-9990) or on the World Wide Web at http://www.mhaus.org. An MH hotline may be accessed for MH emergencies 24 hours a day at 1-800-MH-HYPER (1-800-644-9737). Healthcare providers are encouraged to report MH episodes to the North American MH Registry of MHAUS.

Myotonic Dystrophy

The myotonia are a group of hereditary skeletal muscle diseases that include myotonic dystrophy, myotonia congenita, myotonia fluctuans, and paramyotonia congenita. A symptom common to all myotonias is the inability of skeletal muscles to relax after chemical or physical stimulation.

Myotonic dystrophy (dystrophia myotonica) is composed of at least two clinical disorders, type 1 (DM1) and type 2 (DM2), with overlapping phenotypes and distinct genetic defects. *Myotonic dystrophy, type 1*, also known as *Steinert's disease*, is the most severe and the most common, accounting for 98% of all cases of myotonic dystrophy.[138] DM1 and DM2 are characterized by skeletal muscles that are hypoplastic, dystrophic, and weak yet prone to persistent contraction. Although muscles are primarily affected, myotonic dystrophy is distinguished from nondystrophic myotonias by being a multisystem disease.[64,139]

Incidence

Myotonic dystrophy is inherited as an autosomal dominant trait. In most cases, an affected person has one affected parent. The onset of symptoms can occur at any age, but usually occurs in the second to third decade of life. A slow, progressive deterioration of skeletal, cardiac, and smooth muscle occurs, resulting in death due to skeletal muscle wasting and cardiac conduction defects.[140] Particularly with DM1, the severity of clinical symptoms increases with transmission to subsequent generations (*genetic anticipation*).[141] An estimated 1 to 4 in 20,000 people worldwide have myotonic dystrophy, with an equal occurrence in males and females.[76,138] Myotonic dystrophy is the most common and severe inherited muscular dystrophy that begins in adulthood.[138]

Pathophysiology and Treatment

Myotonia is a condition of muscle membrane excitability that results in self-sustaining muscle contraction. Skeletal muscle chloride and sodium channel dysfunction is implicated in aspects of myotonia.[76,140] Therapeutic agents used to treat the myotonic contractures include phenytoin, procainamide, tocainide, and mexiletine. These agents delay the return of membrane excitation

by blocking rapid Na^+ influx into muscle cells. Regional anesthesia and nondepolarizing muscle relaxants do not prevent or relieve the recalcitrant contraction.[46] No treatment is available for the muscle weakness that develops with myotonic dystrophy.

Clinical Manifestations

A wide variety of symptoms are characteristic of myotonic dystrophy. Facial weakness ("expressionless facies"), ptosis, and sternocleidomastoid muscle and distal limb weakness are prominent features.[64] Frontal balding, cataracts, and testicular atrophy in males form a frequently recognized triad of characteristics. Endocrine abnormalities, such as insulin resistance, occur with a greater frequency in this patient group than in the general population.[64]

Myotonia occurs in most symptomatic patients and may be worsened by pressure, touch, cold, or shivering.[46,64] Insidious muscle atrophy, particularly of the face, neck, pharynx, and distal limbs, causes severe muscle debility in the later stages of the disease.[64] Myotonic symptoms usually precede the atrophy and weakness.

Cardiac disturbances occur in most patients with myotonic dystrophy, often manifesting as conduction defects and arrhythmias.[64] Conduction defects were present in over 50% of the patients in one series.[142] First-degree atrioventricular block is the most common finding, but greater degrees of heart block are also seen.[64,143] Arrhythmias include sinus bradycardia, atrial flutter or fibrillation, and ventricular extrasystole.[64,142-144] Complete heart block and sudden cardiac death can occur.[64,143] Structural cardiac abnormalities increase with age, and include left ventricular systolic dysfunction, mitral valve prolapse, and regional wall motion abnormality.[145]

Weakening of the thoracic muscles, including the diaphragm and intercostal muscles, reduces the respiratory reserve and the vital capacity. A restrictive type of ventilatory impairment develops with progression of the disease. Central sleep apnea and hypersomnolence cause hypoventilation and decreased ventilatory response to carbon dioxide.

Anesthetic Implications

Any drug that has the potential to depolarize skeletal muscle may produce an exaggerated contraction in patients with myotonic dystrophy. Succinylcholine is avoided, because administration can produce an intense generalized myotonic contracture for several minutes, making ventilation and intubation difficult or impossible. Agents associated with myoclonus such as etomidate have the potential to produce similar effects.[46]

Nondepolarizing muscle relaxants may be used in these patients, as long as the degree of muscle wasting and weakness is appreciated.[140] The dose of the nondepolarizer should be reduced according to the degree of muscle impairment, and the neuromuscular block should be monitored closely with a peripheral nerve stimulator.

Reversal of neuromuscular blockade with anticholinesterase agents may theoretically precipitate skeletal muscle contraction by producing an ACh-induced depolarizing block.[36,46] Shorter-acting nondepolarizing muscle relaxants have the obvious advantage of being less likely to require reversal. The anesthetist should be mindful that peripheral nerve stimulation may induce an exaggerated muscle contraction and be misinterpreted as sustained tetanus.

An abnormal swallowing mechanism resulting from palatal, pharyngeal, and esophageal muscle involvement and gastrointestinal hypomotility renders myotonic dystrophy patients vulnerable to pulmonary aspiration of gastric contents.[46,146]

Hypothermia and shivering should be avoided by raising the room temperature, warming inhaled gases and intravenous fluids, and active warming with thermal warming devices.

Underestimating the severity of respiratory compromise is not uncommon in these patients. Pulmonary function results may serve as useful baselines in the patient with advanced disease. The respiratory depressant effects of barbiturates, opioids, and volatile anesthetics may compromise already weakened respiratory musculature and lead to unexpected decompensation.[46,147] In the patient with a history of hypersomnolence, even small doses of short-acting anesthetic agents may be associated with an exaggerated and prolonged anesthetic effect.[46] Speedy[148] reported on a typical case in which a 31-year-old man with myotonic dystrophy remained unconscious and unable to maintain a patent airway for 4 hours after receiving an anesthetic that consisted of 50 mg of propofol, 0.5% isoflurane, and 50% nitrous oxide in oxygen. Completely uneventful responses to general anesthesia in myotonic patients have also been reported. Regional anesthesia may be a prudent choice for anesthesia when appropriate.[46]

Diligent monitoring of cardiovascular parameters should be maintained intraoperatively and postoperatively. Cardiac function that was clinically normal preoperatively may become unacceptably depressed when general anesthetic agents are administered. The patient should be questioned preoperatively about syncope, and the ECG should be examined closely for advanced conduction blocks. It may be wise to assume that even asymptomatic patients have some degree of cardiac involvement. Transthoracic pacing should be readily available.[46]

Pregnancy may exacerbate the symptoms of myotonic dystrophy. Uterine atony, postpartum hemorrhage, and retained placenta have accompanied delivery in patients with myotonic dystrophy. Increased progesterone levels are linked to the deleterious effects.[149]

The risk of MH in patients with myotonic dystrophy is no greater than in the general population.[140] Although succinylcholine is avoided due to the risk of sustained muscle contraction, halogenated inhalational agents can be safely used in patients with myotonia dystrophy.[93]

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory polyarthropathy with myriad degrees of systemic involvement. The disease is multifactorial, and the clinical picture varies widely in severity, extent of involvement, and symptoms. The capricious course of the disease may be persistent and debilitating or relapsing and remitting.[150] With each successive exacerbation, new joints may become involved.

Incidence

Rheumatoid arthritis is the most common form of inflammatory arthritis, affecting 0.8% of the U.S. population. The onset of RA can occur at any age, but most cases are diagnosed in patients between the ages of 25 and 55 years. RA is two to three times more likely to develop in women than in men. The life expectancy of patients with RA may be reduced by 3 to 7 years.[36,150,151] Because RA patients are living longer due to improved treatments and understanding of the pathophysiology and more elderly patients are being diagnosed, the age of greatest prevalence of RA is increasing. One third of patients with RA are older than 60 years.[150-152]

Etiology

The exact cause of RA remains elusive, but heredity may contribute up to 50% of the risk for a person's susceptibility.[150,151]

Impaired immunity, stress, and other environmental factors may precipitate or aggravate the disease.[36,150]

A viral or a bacterial infection that alters the immune system in a genetically susceptible host may play a role in the etiology.[150] The invading microbe may produce a protein similar to those in the body's own tissue, particularly joint tissue *(molecular mimicry)*. To destroy the antigen, the immune system may mount an autoimmune response and mistakenly direct its attack against its own tissue. Circulating autoantibodies called *rheumatoid factors* are detectable in up to 90% of patients with RA.[36,150,151] Another antibody found in 34% of RA patients is one that attacks citrullinated proteins (CCP). This anti-CCP antibody found in inflamed joints may be useful as a biomarker for RA because it can be detected in the blood prior to onset of RA symptoms.[150,153]

Clinical Manifestations

Joint Involvement. Inflammation and destruction of synovial tissues are responsible for most of the symptoms and chronic disability associated with RA. One contributor to the inflammatory process is the overproduction of pro-inflammatory cytokines, tumor necrosis factor (TNF), caused by interactions between T and B lymphocytes, synovial-like fibroblasts, osteoclasts, and macrophages.[151,154] Joint involvement progresses in three main stages: (1) inflammation of the joint synovial membrane and infiltration by polymorphonuclear leukocytes; (2) rapid division and growth of cells in the joint (synovial proliferation and pannus formation); and (3) liberation of osteolytic enzymes, proteases, and collagenases, which damage small blood vessels, cartilage, ligaments, tendons, and bones. Collapse of normal cortical and medullary architecture leads to erosion and dislocation of bone that is contiguous with the inflammatory cell mass.[150,153]

The onset of symptoms is most often insidious, evolving over a period of weeks to months.[36,150] The most common sites of onset are the hands, wrists, and feet. There is often symmetric joint involvement. Swelling, warmth, and pain in the affected joints are caused by the inflammatory process. Morning stiffness, weight loss, and fatigue are noted early in the disease course.

Dissolution of bone and disuse atrophy of bone (osteoporosis) are found in all seriously affected areas. Pain, inflammation, and erosion of bone and tissue may permanently limit the joint's full range of motion. Later stages of the disease are characterized by severe pain, joint instability, loss of physical function, and crippling deformities.[150,154]

Nerve entrapment may occur at any site where peripheral nerves pass near the inflamed joint. Carpal tunnel syndrome is a common peripheral neuropathy.

Synovitis in the temporomandibular joint may limit jaw motion. An estimated 45% to 75% of patients with RA have involvement of the temporomandibular joint.[153] As the disease progresses, flexion contractures and soft-tissue swelling may lead to a marked limitation in the patient's ability to open the jaw.

Although the thoracic and lumbar spine are usually spared, involvement of the cervical spine may be extensive and can lead to limited movement or deformity of the neck and to severe laryngeal deviation.[36,150,155] The most common site of cervical spine synovitis is C1-C2 (Figure 32-17). Atlantoaxial (C1-C2) instability results from erosion and collapse of bone and from destruction of supporting cervical ligaments. Symptoms occur when excessive motion between C1 and C2 exerts pressure on the spinal cord (Figure 32-18). Additionally, separation of the atlanto-odontoid articulation may allow the odontoid process of the axis to impinge on the spinal cord, leading to neurologic damage. The atlantoaxial subluxation, which contributes to 66% of cervical spine disorders related to RA, may also exert pressure and impair blood flow through the vertebral arteries[156] (Figure 32-19).

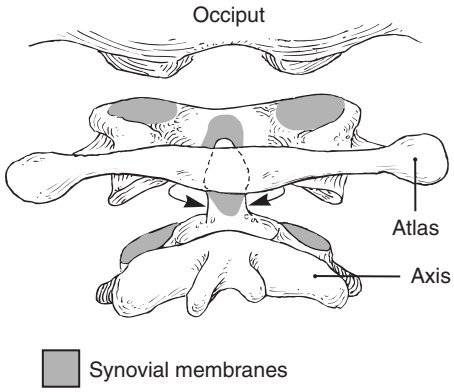

FIGURE **32-17** The relationship between the occiput, the atlas (C1), and the axis (C2). The atlas supports the head and rotates about the odontoid process of the axis. The occipitoatlantoaxial articulations are lined by synovial membranes and are firmly supported by surrounding ligaments (not shown).

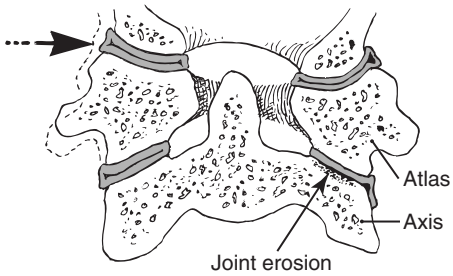

FIGURE **32-18** Erosion and collapse of C1 and C2 articular surfaces can lead to a shifting of the atlas over the axis. If the subluxation is pronounced, spinal cord compression may occur.

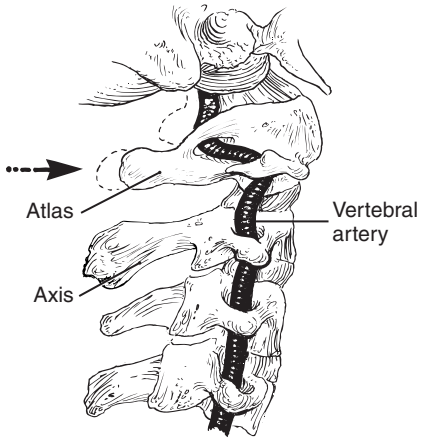

FIGURE **32-19** Vertebral artery compression may result from atlantoaxial subluxation.

Arthritis extends to the cricoarytenoid joint of the larynx in 26% to 86% of patients with severe RA.[157] The joint may become swollen, inflamed, and fixed in a position that obstructs airflow. Vocal cord nodules and polyps also may be present. Symptoms of cricoarytenoid arthritis include tenderness over the larynx, hoarseness, pain on swallowing, with radiation to the ear, and dyspnea or stridor. Patients with no overt clinical symptoms also may have significant laryngeal disease.

Systemic Involvement. Although the effects of RA are most clearly seen in joints, the disease is systemic. The immune-mediated destructive process affects a wide variety of organs, including the heart, lungs, muscle, vasculature, and eyes. The occurrence of extraarticular manifestations is usually associated with more active, erosive articular disease.

Firm, painless subcutaneous nodules occur in approximately 30% to 40% of patients with RA.[150] The nodules usually occur over pressure points, such as the occiput, the sacrum, the ulna, or the Achilles tendon, and may be associated with pressure ulcerations. Rheumatoid nodules also can occur in most visceral organs, including the lungs and the heart. Dural nodules can cause spinal cord compression and neurologic complications.

Pericarditis and pericardial effusion may accompany severe progressive RA and impair cardiac performance. Mitral regurgitation may occur related to cardiac valve fibrosis, and aortitis may cause aortic regurgitation.[36] Although rare, rheumatoid nodules have been isolated from the cardiac conduction system and may be associated with conduction defects.[36,150,151]

Pulmonary involvement manifests as pleural effusion, pneumonitis, pulmonary nodules, or interstitial fibrosis.[36,150,151,158] Decreased lung volume, diffusion capacity, and vital capacity may result from the lung alterations. Decreased arterial oxygenation may result from increased ventilation-perfusion mismatch.[158]

Rheumatoid myositis, which is characterized by muscle weakness and eventual muscle necrosis and atrophy, may accompany RA. Inflamed, painful, and underused joints contribute to the skeletal muscle atrophy.

Lacrimal duct and salivary gland destruction may result in dryness of the eyes and the mouth (Sjögren syndrome) in about 10% of patients with rheumatoid arthritis.[36,150]

Treatment

There is no cure for rheumatoid arthritis, and all treatment interventions are palliative. Medical therapy is directed toward relief of pain, nonspecific suppression of the inflammatory process, immunosuppression, prevention and correction of deformity, and control of systemic involvement.

Most patients, including those with mild to moderate disease, obtain some relief of symptoms with rest, joint immobilization, and use of nonsteroidal antiinflammatory drugs (NSAIDs). NSAIDs relieve joint pain, stiffness, heat, and swelling, in part by blocking cyclooxygenase and inhibiting prostaglandin, thromboxane, and prostacyclin synthesis. Despite their potent antiinflammatory properties, they do not alter the underlying disease process.[36,150,151]

Corticosteroids are potent antiinflammatory drugs that suppress many symptoms of RA. Long-term side effects (e.g., osteoporosis, predisposition to infection, suppression of endogenous cortisol release, cataracts, gastrointestinal bleeding, hypertension, and hyperglycemia), however, limit their use to isolated flares of the disease or to adjunctive rather than primary treatment.

Disease-modifying antirheumatic drugs (DMARDs), the primary treatment for RA, can slow the progressive damage and arrest the underlying disease process.[151] The antimetabolite methotrexate (Rheumatrex) is widely used as an effective DMARD for patients with aggressive RA. It stimulates adenosine release, which has an antiinflammatory effect. Bone marrow suppression, oral ulcerations, pneumonitis, and hepatic damage are potential side effects of methotrexate.[151] Gold salts, sulfasalazine, antimalarial drugs, and penicillamine are effective DMARDs used when more conservative, less toxic measures fail to retard symptoms.

Biologic DMARDs have been used to attach cytokines and cell-surface molecules. Agents such as the anticytokines etanercept (Enbrel), adalimumab (Humira), and infliximab (Remicade) work by interfering with the proinflammatory cytokine, tumor necrosis factor.[151,152] TNF inhibitors cause significant improvement in functional ability and alteration in disease progression. Notably, due to the immunosuppressive effect, these drugs increase the risk of developing serious infection, such as tuberculosis, especially when combined with corticosteroids. Increased risk includes bacterial to fungal to viral infections.[159-161]

Biologic agents such as interleukin-1 receptor antagonists offer the potential for more effective treatment of RA.[150,162] Leflunomide (Arava) is a DMARD that inhibits the proliferation of T lymphocytes and slows disease progression. The major side effect of leflunomide is liver-enzyme elevation and liver disease.[150] Agents target other pathogenetic molecules. Rituximab (Rituxan) is an anti-CD20 monoclonal antibody and works to deplete B cells. Abatacept (Orencia) alters T-cell activation. Tocilizumab (Actemra) is an interleukin-6 receptor antagonist. These are effective in some patients who do not respond to methotrexate treatment alone.[150,162]

Immunosuppressive drugs such as cyclophosphamide (Cytoxan) and cyclosporine (Sandimmune) and antimetabolites such as azathioprine (Imuran) are agents generally reserved for more refractory cases.[150]

Surgical interventions for relief of pain or correction or prevention of deformities include total joint replacement, synovectomy, and tenolysis.

Anesthetic Management

Overall, no individual anesthetic agent or mode of anesthesia is substantially safer than another for the patient with RA. Preoperative examination of an individual patient's disease course and medication history are likely to reveal specific features that affect the anesthesia or surgical course.

NSAID ingestion may result in platelet dysfunction. Mild anemia, a common finding in patients with RA, may be secondary either to the disease process or to drug therapy. Long-term NSAID therapy may exert harmful effects on the liver or kidney and exacerbate allergic rhinitis or asthma; these effects may influence the choice of anesthesia.

Patients receiving long-term corticosteroid therapy may develop hypophyseal-pituitary axis suppression, which may require perioperative steroid supplementation. Long-term administration of corticosteroids may increase the patient's susceptibility to infection by inhibiting normal host defense mechanisms. The tumor necrosis factor inhibitors are also associated with serious infections, mandating close attention to sterile techniques.

A thorough preoperative assessment of the airway is essential. Particular attention should be directed to the temporomandibular joints, cervical spine, and cricoarytenoid joints.

Range of motion of the temporomandibular joint must be assessed before anesthesia is induced. Patients with severe temporomandibular joint involvement may be unable to open their mouths more than 1 to 2 cm. In such cases, the use of a flexible fiberoptic bronchoscope or other optically guided instruments for tracheal intubation are of proven value.[36] Awake intubation with the aid of a intubating laryngeal mask airway using a superior laryngeal nerve block is an alternative.[157]

A thorough neurologic assessment and a radiographic evaluation of the cervical spine should be performed, especially for patients with advanced disease.[163] Atlantoaxial subluxation is radiographically confirmed as the distance from the anterior arch of the atlas to the odontoid process exceeding 3 mm.[36] Some patients with significant radiographic evidence of atlantoaxial or subaxial instability may be entirely asymptomatic.[150,163,164]

Neck pain is an early symptom of cervical spine instability. Paresthesias into the shoulders and arms, muscle weakness, paresis, and bowel or bladder dysfunction are some of the clinical manifestations of spinal cord compression secondary to atlantoaxial or subaxial subluxation. Compression on the vertebral arteries (see Figure 32-19), with interruption of vertebral artery blood flow, may cause symptoms including nausea, vomiting, dysarthria, dysphagia, blurred vision, or transient loss of consciousness. However, absence of preoperative symptoms does not guarantee cervical spine stability and safety.[156]

Altered cervical spine anatomy or laryngeal deviation can make intubation of the trachea an extreme challenge. Flexion deformity as well as cervical stiffness may interfere with positioning of the patient and the ability to perform direct laryngoscopy. Deviation of the larynx often can be detected preoperatively by palpating the location of the larynx in relation to the sternal notch. Anterior subluxation is enhanced by cervical flexion.[156] Flexion, extension, and rotation of the neck must be avoided in the presence of cervical instability. Such circumstances dictate alternative airway management such as fiberoptic-guided intubation of the trachea in the awake patient.

Hoarseness in a patient with RA should alert the anesthetist to possible cricoarytenoid joint involvement. Narrowing of the glottic opening may call for a smaller endotracheal tube. Laryngoscopy can assess normal cord motion and glottic patency. The vocal cords may be edematous and erythematous.[36] The patient should be observed closely for signs of airway obstruction after extubation.

Generalized demineralization of bone may increase the risk of fractures in patients with RA. Glucocorticoid therapy may aggravate the osteopenia. Proper patient positioning and padding of pressure points prevent nerve palsies, skin ulcerations, and further structural damage to the joints.

The spread of sensory spinal anesthesia is higher in RA patients. Epidural nodules and synovitis in the thoracolumbar spine may cause narrowing of the subarachnoid space and decrease the cerebrospinal fluid (CSF). The reduced dilution of the local anesthetic may contribute to the sensory effect averaging 1.5 dermatomes higher in a RA patient. The clinician should weigh the benefit of decreasing the dose of local anesthetic administered to a RA patient for a subarachnoid block with the risk of a insufficient block leading to conversion to general anesthesia.[165]

SUMMARY

Understanding the pathophysiologic characteristics, clinical presentation, and supporting laboratory studies of patients with musculoskeletal abnormalities is essential for safe and effective anesthetic management. A thorough preoperative assessment of this patient helps determine the extent of muscle, respiratory, and cardiac reserve and aids in anesthetic selection and planning for postoperative care.

Management of cases involving musculoskeletal pathology must take into account preoperative drug therapy for the disease and the potential effect this drug therapy may have on anesthetic agents and muscle relaxants. An anesthetic agent's margin of safety is often reduced in such patients; therefore fixed dosage regimens should be avoided.

CHAPTER 33

The Endocrine System and Anesthesia

◆ *Mary C. Karlet and David N. Fort*

GENERAL PRINCIPLES OF ENDOCRINE PHYSIOLOGY

Body homeostasis is controlled by two major regulating systems: the nervous system and the endocrine or hormonal system.[1,2] Both of these systems communicate, integrate, and organize the body's response to a changing internal or external environment.[1,3]

Organs that secrete hormones are called *endocrine glands*; collectively, these glands make up the *endocrine system*. The purpose of the endocrine system is regulation of behavior, growth, metabolism, fluid and electrolyte status, development, and reproduction. To accomplish these complex processes, multiple hormones interact to produce precise biochemical and physiologic responses.

Endocrine glands secrete their hormone products directly into the surrounding extracellular fluid. This distinguishes them from *exocrine glands*, such as salivary or sweat glands, whose products are discharged through ducts. Important endocrine glands include the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreas, ovaries and testes, and placenta.

Hormones

Endocrine function is mediated by hormones. Hormones are the signaling molecules or chemical messengers that transport information from one set of cells (endocrine cells) to another (target cells). Hormones are released from endocrine glands into body fluids in minute quantities but exert powerful control over most metabolic functions.[1,4]

Transmission of a hormonal signal through the bloodstream to a distant target cell (e.g., pituitary gland to the adrenal gland) is called an *endocrine function*. If a hormone signal acts on a neighboring cell of a different type (e.g., pancreas α cells to pancreas β cells), the interaction is termed a *paracrine function*. If the secreted hormone acts on the producer cell itself or on neighboring identical cells, the interaction is called an *autocrine function*.[1,2]

Types of Hormones

Hormones can be classified into three major categories: (1) proteins or peptides, (2) amines or amino acid derivatives, and (3) steroids.

Peptide or Protein Hormones. Most hormones have a peptide or protein structure. This group of hormones includes insulin, growth hormone, vasopressin (antidiuretic hormone), angiotensin, prolactin, erythropoietin, calcitonin, somatostatin, adrenocorticotropic hormone, oxytocin, glucagon, and parathyroid hormone. Peptide hormones are synthesized in endocrine cells as prehormones and prohormones. They are processed by the cell and stored in secretory granules within the endocrine gland.[1,2] The proper stimulus to secretion causes exocytosis of the peptide or protein hormone into the extracellular fluid.

Protein hormones, such as insulin, erythropoietin, and growth hormone, can now be synthesized for therapeutic purposes by recombinant deoxyribonucleic acid (DNA) techniques.

Amine- or Amino Acid–Derivative Hormones. Several hormones are amino acid or amine compound derivatives. Serotonin, important for its central nervous system effects, is synthesized from the naturally occurring amino acid tryptophan.[2] Thyroid hormones and catecholamine hormones (dopamine, epinephrine, and norepinephrine) are derived from the amino acid tyrosine. Thyroid hormones and catecholamine hormones are stored in the thyroid gland and adrenal medulla, respectively, and are released by the appropriate stimulation.[1]

Steroid Hormones. All steroid hormones are lipid soluble derived from cholesterol or have a chemical structure similar to that of cholesterol.[4] Common steroid hormones include hormones of the adrenal cortex (e.g., cortisol, aldosterone) and reproductive hormones (e.g., estrogen, progesterone, testosterone). Active metabolites of vitamin D are also steroid hormones.[1] In contrast to most other hormones, steroid hormones are not stored in discrete secretory granules but are compartmentalized within the endocrine cell and released into the extracellular fluid by simple diffusion through the cell membrane.[1,2]

Circulating steroid and thyroid hormones are bound to *transport proteins*, whereas circulating catecholamine hormones and most protein hormones are not bound to carriers. Plasma protein binding protects hormones from metabolism and renal clearance.[2] The circulating half-life of steroid and thyroid hormones is therefore typically longer than that of peptide and catecholamine hormones. For example, the thyroid hormone thyroxine, which is 99.95% protein bound, has a plasma half-life of 6 days, whereas insulin, which has essentially no plasma protein binding, has a half-life of about 7 minutes.[1]

The major sites of hormone degradation and elimination are the liver and the kidneys. Some hormone degradation also occurs at target-cell sites.[1,2,4]

Hormone Receptors

Binding to a specific target-cell receptor is the primary event that initiates a hormone response.[2] The hormone receptor displays high specificity and affinity for the proper hormone ligand, and the location of the receptor directs the hormone to the specific target organ or target-cell site.[3] Some hormones, such as insulin and growth hormone, act on widespread target sites; others, such as thyroid-stimulating hormone, act on one target tissue.[1] After binding, the hormone-receptor complex induces a cascade of intracellular events that produce specific physiologic responses in the target cell.[2]

Hormone Receptor Activation. Hormone receptors are located either on the surface of cells or inside cells.[4] Receptors for protein, peptide, and catecholamine hormones are located in or on the surface of the target-cell membrane. Hormone binding to a cell membrane receptor triggers a response by activating

enzyme systems in or near the plasma membrane bilayer. The activated enzymes generate intracellular signals, called *second messengers*, which carry the hormone's message within the intracellular space.

Several different second-messenger systems operate in response to cell membrane receptor-hormone binding. Probably the most widely described second-messenger system is the *cyclic adenosine monophosphate (cAMP) system*. This hormone transduction mechanism is initiated when receptor occupation activates the plasma membrane enzyme *adenyl cyclase*. The membrane-bound adenyl cyclase then catalyzes the intracellular conversion of adenosine triphosphate (ATP) to cAMP; cAMP in turn becomes the hormone's intracellular messenger, activating intracellular enzymes, modifying cell-membrane permeability or transport, and altering cellular gene expression.[1] The enzyme phosphodiesterase catalyzes the hydrolysis of cAMP and terminates its intracellular actions. Hormones that use cAMP as their second messenger include thyroid-stimulating hormone, vasopressin, parathyroid hormone, glucagon, some catecholamines, corticotropin, follicle-stimulating hormone, and luteinizing hormone.

Other intracellular second messengers include calcium, diacylglycerol, inositol triphosphate, and cyclic guanosine monophosphate. The primary intracellular messenger has not been identified for many hormones.

In contrast to peptide and catecholamine hormones, thyroid and steroid hormones produce the desired target-cell response chiefly by interacting with specific intracellular hormone receptors.[1] Thyroid and steroid hormones are small lipophilic molecules that enter target cells by simple diffusion or by special transport mechanisms. Once within the cell, these hormones occupy specific intracellular receptors.[2] In combination with their receptors, the hormones interact with DNA in the cell nucleus to enhance or suppress gene transcription or translation.[1,2]

Thyroid and steroid hormones enable the cell to alter gene expression, protein formation, and cell activity in response to environmental and developmental stimuli.[2] Every hormone has a specific onset and duration of action.[4] Hormones that act by binding to cell membrane receptors (peptide, protein, and catecholamine hormones) usually generate a hormonal effect in seconds to minutes. Hormones that bind to intracellular receptors and activate the transcription processes of specific genes (thyroid and steroid hormones) may require several hours or even days to generate a hormonal response.[1,4]

Hormone Receptor Regulation. Receptors are dynamic molecules that are constantly being destroyed and replaced. The receptor for insulin, for example, has a normal half-life of only about 7 hours.[2] Hormone receptor destruction may be part of a normal endocrine response or part of an acquired or genetic disease state.

In many instances, the hormone receptor number is inversely related to the concentration of the circulating hormone. A sustained elevation of the plasma level of a given hormone may cause the target site to decrease the number of receptors per cell. This *down-regulation* of receptor number serves to decrease the responsiveness of a target cell to hormone excess.[1] The insulin resistance observed in obesity and type 2 diabetes mellitus may be partly explained by down-regulation of the insulin receptors in response to chronically high levels of circulating insulin.[2]

Conversely, a low circulating hormone concentration may cause the target gland to increase the number of hormone receptors per cell.[2] This *up-regulation* of hormone receptor number amplifies the cell's sensitivity to hormone stimulation.[1,2]

The number of receptors in a target cell usually changes from day to day.[4] Regulation of receptor turnover, and thus hormone receptor number, is a mechanism by which hormone activity can be precisely modulated.[1]

Regulation of Hormone Secretion. The synthesis and secretion of hormones by endocrine glands are regulated by three general control mechanisms: neural controls, biorhythms, and feedback mechanisms.

Neural control can evoke or suppress hormone secretion. Pain, emotion, smell, touch, injury, stress, sight, and taste can alter hormone release through neural mechanisms.[5] Glucagon, cortisol, antidiuretic hormone, and catecholamines, for example, are all stimulated by the stress response to anesthesia, surgery, and trauma.

The secretion of many hormones is governed by genetically encoded or acquired *biorhythms*. These intrinsic hormonal oscillations may be circadian (e.g., the daily variability in glucocorticoid secretion), weekly (e.g., the menstrual cycle), or seasonal (e.g., thyroxine production).[3,5] The biorhythms also may vary at different stages of development and life (e.g., growth hormone secretion).[6]

Feedback control is another sophisticated mechanism through which a hormonal response is controlled. Many endocrine disorders arise from the breakdown of feedback loops.[2] *Negative feedback* acts to limit or terminate the production and secretion of a given hormone once the appropriate response has occurred. Negative feedback of a target-cell product to the hormone producer (the endocrine gland) limits or prevents hormone excess. When concentrations of the product are low, feedback inhibition to the endocrine gland is lessened and hormone secretion enhanced.

Virtually all hormones are controlled by some type of *negative feedback* mechanism.[3,6] For example, parathyroid hormone is controlled by calcium, insulin and glucagon are controlled by glucose, and vasopressin is controlled by serum osmolarity.[5] The negative feedback mechanism is a very important factor in the regulation of hormones of the hypothalamus and pituitary gland. Hypothalamic hormones stimulate the release of pituitary hormones from the pituitary gland. The pituitary hormones in turn may stimulate an output of product from peripheral target cells. Product from peripheral target tissues may then initiate feedback to the pituitary gland or the hypothalamus to inhibit pituitary or hypothalamic hormone synthesis and discharge.[2,5]

Positive feedback is a less common hormone-regulating mechanism in which a given hormone response initiates signals amplifying hormone release. The surge in luteinizing hormone (LH) that precedes ovulation is stimulated by LH; this is an example of positive feedback.[2]

PITUITARY GLAND

Relationship Between Pituitary Gland and Hypothalamus

The *pituitary gland*, or *hypophysis*, is known as the "master endocrine gland."[7] It secretes hormones that have far-reaching effects on various homeostatic, developmental, metabolic, and reproductive functions of the body. The pituitary is a small endocrine gland (only 500 mg in weight and about the size of a pea) centrally located at the base of the brain. It is enclosed within a bony cavity of the sphenoid bone called the *sella turcica*.[5,6] The pituitary gland is connected to the overlying hypothalamus by the *hypophyseal stalk (pituitary stalk)*. The hypothalamus is located below the thalamus, behind the optic chiasm and between the optic tracts. The pituitary, hypothalamus, and some of the surrounding structures are shown in Figure 33-1.

The brain, via the hypothalamus, is an important regulator of pituitary gland secretion. The hypothalamus collects and

FIGURE **33-2** Major target sites for anterior pituitary hormones. *ACTH,* Adrenocorticotropic hormone.

integrates information (e.g., pain, emotions, energy needs, water balance, olfactory sensations, electrolyte concentrations) from almost all parts of the body and uses this information to control the secretion of vital pituitary hormones.[5,6] Pituitary hormone secretion also is regulated by feedback control from peripheral target-organ hormones or other target-organ products.[6] The pituitary gland and hypothalamus have virtually no blood-brain barrier, allowing feedback products to exert potent effects.[8,9]

Functionally and histologically, the pituitary gland is divided into two distinct portions: the *anterior lobe (adenohypophysis)* and the *posterior lobe (neurohypophysis)*.[5,6] The anterior pituitary lobe is embryologically derived from an upward invagination of pharyngeal epithelial cells. The posterior pituitary lobe develops from a downward outpouching of ectoderm from the brain. Blood supply to the pituitary is from the superior and inferior hypophyseal arteries.[5,7]

Anterior Pituitary Lobe

The anterior pituitary lobe, which constitutes about 80% of the pituitary gland by weight, secretes six primary hormones.[6] Target sites for the anterior pituitary hormones are shown in Figure 33-2.

1. *Growth hormone (GH, somatotropin)* promotes skeletal development and body growth and regulates protein and carbohydrate metabolism.
2. *Adrenocorticotropic hormone (ACTH)* regulates the growth of the adrenal cortex and the release of cortisol and androgenic hormones from the adrenal gland. ACTH possesses mild melanocyte-stimulating properties, resulting in skin pigmentation at high levels.
3. *Thyroid-stimulating hormone (thyrotropin* or *TSH)* controls the growth and metabolism of the thyroid gland and the secretion of thyroid hormones, which regulate the rates of most chemical reactions in the body.[5,6]
4. *Follicle-stimulating hormone (FSH)* stimulates ovarian follicle development in females and spermatogenesis in males.
5. *Luteinizing hormone (LH)* induces ovulation and corpus luteum development in females and stimulates the testes to produce testosterone in males.
6. *Prolactin* promotes mammary gland development and milk production (lactogenesis) by the breasts. Prolactin also exerts an effect on reproductive function by inhibiting the synthesis and secretion of LH and FSH. Prolactin synthesis is markedly increased during pregnancy.[5]

Several other less important or less well-defined hormones also are secreted from the anterior pituitary lobe.[6]

Anterior pituitary hormones are synthesized and secreted by five distinct endocrine cell types within the gland: *somatotrophs* synthesize GH; *gonadotrophs* synthesize the two gonadotropic hormones, LH and FSH; *thyrotrophs* synthesize TSH; *corticotrophs* synthesize ACTH; and *lactotrophs (mammotrophs)* synthesize prolactin. About 40% to 50% of the anterior pituitary cells are somatotrophs and about 20% are corticotrophs.[5]

Control of Anterior Pituitary Hormone Secretion

Synthesis of anterior pituitary hormones is controlled by signals from the hypothalamus. Neurosecretory cells in various hypothalamic nuclei respond to input from the body by synthesizing specific neurohormones that have corresponding anterior pituitary target-cell types.[6]

Hypothalamic neurohormones are released into a capillary bed of the hypothalamus in an area called the *median eminence*. The hypothalamic hormones travel from the capillary plexus of the median eminence, down the pituitary stalk, in a specialized vascular system called the *hypothalamic-hypophyseal portal vessels*. At the anterior pituitary lobe, the hypothalamic hormones are released in high concentrations into capillary sinuses located among the glandular cells.[6] The hypothalamic hormones then locate and bind to their specific target-cell type.

Specific hypothalamic hormones have either an inhibitory or a stimulatory effect on their corresponding anterior pituitary target cells. Synthesis and release of most anterior pituitary hormones depend on a positive stimulatory signal from a given hypothalamic hormone. Some anterior pituitary cells are subject to both inhibitory and stimulatory control by more than one hypothalamic neurohormone.[5]

Synthesis of prolactin from anterior pituitary lactotroph cells is unique in that it is tonically restrained by an inhibitory hormonal signal (dopamine) from the hypothalamus. In essence, dopamine serves as a "physiologic brake" for lactotroph growth and prolactin synthesis. The inhibitory effect of dopamine agonists, such as bromocriptine, is exploited therapeutically for suppressing pathologic production of prolactin from pituitary tumors.[5,7] Table 33-1 outlines the major hypothalamic releasing or inhibiting hormones and their corresponding anterior pituitary target sites.

TABLE 33-1 Hypothalamic Hormones and Corresponding Anterior Pituitary Hormones

Hypothalamic Releasing/ Inhibiting Hormones	Anterior Pituitary Target-Cell Type	Anterior Pituitary Hormone Produced	Hormone Target Site	Primary Peripheral Hormone Involved in Negative Feedback
Thyrotropin-releasing hormone	Thyrotroph	Thyroid-stimulating hormone (TSH, thyrotropin)	Thyroid gland	Triiodothyronine
Corticotropin-releasing hormone	Corticotroph	Adrenocorticotropic hormone (ACTH, corticotropin)	Zona fasciculata and zona reticularis of adrenal cortex	Cortisol
Gonadotropin-releasing hormone	Gonadotroph	Follicle-stimulating hormone Luteinizing hormone	Gonads (testes, ovaries)	Estrogen, progesterone, testosterone
Prolactin-releasing factor	Lactotroph (mammotroph)	Prolactin	Breasts	None
Prolactin-inhibitory factor (dopamine, PIF)	Lactotroph			None
Growth hormone–releasing hormone	Somatotroph	Growth hormone	All tissues	Growth hormone, insulin growth factor-1
Growth hormone–inhibitory factor (somatostatin)	Somatotroph	Growth hormone	All tissues	Growth hormone, insulin growth factor-1

Anterior Pituitary Disorders

Disorders involving the anterior pituitary system may be due to a defect at the peripheral endocrine gland (primary disorder), the pituitary gland (secondary disorder), or the hypothalamus (tertiary disorder).[5] Pituitary tumors account for 15% of all intracranial tumors.[10] Most pituitary tumors, both functional and nonfunctional, are benign adenomas. Pituitary carcinoma is exceedingly rare.[7,10]

Hyposecretion. Anterior pituitary hyposecretion may occur when large nonfunctional pituitary tumors (e.g., chromophobe adenoma, craniopharyngioma, Rathke's pouch cysts) compress and destroy normal anterior pituitary cells. Postpartum shock (Sheehan syndrome), irradiation, trauma, infiltrative disorders (e.g., sarcoidosis, amyloidosis) and hypophysectomy are other causes of pituitary hormone deficiency states. Generalized pituitary hypofunction *(panhypopituitarism)* is more common than reduced output of a single anterior pituitary hormone.[7,11]

Important effects of panhypopituitarism include a decrease in thyroid function due to reduction in levels of TSH, depression of glucocorticoid production by the adrenal cortex due to the lowering of ACTH levels, and suppression of sexual development and reproductive function due to deficient gonadotropic hormone secretion.[6] In addition, large pituitary tumors (macroadenomas greater than 1 cm) may extend into or compress the surrounding brain tissue, producing diplopia, visual loss, facial numbness, facial pain, or seizures.[12]

Surgical intervention may be implemented to control bleeding or for decompression or removal of the pituitary tumor. Surgical patients with hypopituitary disorders may require thyroid hormone replacement and glucocorticoid coverage in the perioperative period.[13] Because of the possibility of diabetes insipidus after removal of the tumor, vasopressin should also be available.

Hypersecretion. Most pituitary tumors are benign hypersecreting pituitary adenomas.[12] The three most common hypersecreting pituitary tumors are those that produce prolactin, ACTH, or GH. Tumors that secrete gonadotropin and thyrotropin hormones are rare. Pituitary tumors also may be inherited as part of multiple endocrine neoplasia (MEN) type 1.[10,14]

Preparation of the patient awaiting pituitary surgery is guided in part by the results of preoperative endocrine tests. Hypersecreting pituitary tumors may become so large that they compress and destroy normal anterior pituitary cells, producing a deficiency in some anterior pituitary hormones.

Prolactin-secreting tumors commonly produce symptoms of galactorrhea, amenorrhea, and infertility in women and decreased libido and impotence in men.[7] The dopamine agonist bromocriptine is used to control prolactin levels, decrease tumor size, and restore normal gonadal function. Patients who have a suboptimal response to medical therapy benefit from microsurgical removal of the pituitary tumor.[7]

Specific anesthetic management implications for patients with excess ACTH (Cushing disease) and excess GH (acromegaly) are described in this chapter.

Growth Hormone

Growth hormone (somatotropin) is synthesized and secreted by somatotroph cells of the anterior pituitary lobe and is under dual control by the hypothalamus.[6] Growth hormone–releasing hormone stimulates GH release, and growth hormone–inhibiting hormone *(somatostatin)* is a powerful inhibitor of GH release. Pulsatile fluctuations of the hypothalamic releasing and inhibiting hormones regulate somatotroph activity throughout the day.[5]

The GH secretion rate is generally increased in childhood, followed by a further increase in adolescence, a plateau in adulthood, and declining values in old age. The normal physical decline associated with aging may in part be due to the age-related decline in GH production.[5,6] In addition, GH secretion is stimulated by stress (including anesthesia and surgery), hypoglycemia, exercise, and deep sleep.[5]

Unlike the other anterior pituitary hormones, GH does not exert its principal effects through a specific target gland but functions through all or almost all tissues of the body; it promotes the growth and development of most tissues capable of growing.[6] A major target of GH is the liver, where it stimulates the production of insulin-like growth factor type 1 (IGF-1), a hormone that mediates many of GH's effects.[6,10] Skeletal muscle, the heart, skin, and visceral organs undergo hypertrophy and hyperplasia in response to GH and IGF-1.[10,15]

The most obvious effect of GH is on the skeletal frame. It produces linear bone growth by stimulating the epiphyseal cartilage or

growth plate at the ends of long bones.[5,6] Throughout childhood, under the influence of GH, bones elongate at the epiphyseal plate, and the skeletal frame enlarges. After puberty, the growth plates unite with the shaft of the bone, bone lengthening stops, and GH has no further capacity to increase bone length.[6]

GH and IGF-1 support growth by increasing amino acid transport into cells and enhancing protein synthesis in the cell. GH also decreases the catabolism of existing proteins by stimulating lipolysis and mobilizing free fatty acids for energy use, a protein-sparing effect.[6] In addition to its growth-promoting activities, GH is said to be a "diabetogenic hormone." It increases blood glucose levels by decreasing the sensitivity of cells to insulin and inhibiting glucose uptake into cells.[6]

As is true of other anterior pituitary hormones, GH secretion is subject to negative feedback control. The primary negative feedback controller of the pituitary somatotrope is IGF-1. GH itself, as well as IGF-1, exert negative feedback control on the hypothalamus. GH release is also inhibited by hyperglycemia and increased plasma free fatty acids.[5]

Hyposecretion. Deficient GH production in childhood can result in insufficient bone maturation and short stature, a condition known as *dwarfism*. Mild obesity, decreased lean body mass, and hypoglycemia are common in GH-deficient dwarfs. Puberty usually is delayed. Symptoms of GH deficiency may be the result of hypothalamic dysfunction, pituitary disease, failure to generate normal insulin growth factor hormones, or GH-receptor defects.[6,7]

The biosynthesis of human GH by recombinant DNA techniques has enhanced the outlook for patients with GH deficiency. Treatment of these patients with GH leads to a positive nitrogen balance, accretion of lean body mass, and an improvement in metabolic homeostasis.[7]

Hypersecretion. Hypersecretion of GH, usually caused by a growth hormone–secreting pituitary adenoma (99% of cases), can produce a highly distinctive syndrome in adults called *acromegaly*. Acromegaly is produced by sustained hypersecretion of GH after adolescence. The condition occurs with equal frequency in both sexes.[12] If hypersecretion of GH occurs before puberty—that is, before closure of the growth plates—the individual grows very tall (8 to 9 feet), a rare condition known as *gigantism*.

Because growth plates close with adolescence, the excessive production of GH associated with acromegaly does not induce bone lengthening but rather enhances the growth of periosteal bone by the stimulatory effects of GH on bone osteoblasts (bone forming cells). Periosteal growth causes new bone to be deposited on the surface of existing bone.[6] The unrestrained bone growth in patients with acromegaly produces bones that are massive in size and thickness. Bones of the hands and feet *(acral)* become particularly large. Overgrowth of vertebrae may cause kyphoscoliosis and osteoarthritis.

Soft-tissue changes are also prominent with GH hypersecretion. The patient develops coarsened facial features *(acromegalic facies)* that include a large, bulbous nose, supraorbital ridge overgrowth, dental malocclusion, and a prominent prognathic mandible.[10,16] The changes in appearance are insidious, and many patients do not seek treatment until the diagnosis is obvious and the disease course advanced.[10,16,17]

Overgrowth of internal organs is less apparent clinically but no less serious. The liver, heart, spleen, and kidneys become enlarged. Pulmonary function tests are consistent with increased lung volumes and extrathoracic obstruction, but gas exchange is usually not grossly abnormal.[17] Exercise tolerance may be limited due to increased body mass and skeletal muscle weakness.[7]

BOX 33-1

Common Features of Acromegaly

- Skeletal overgrowth (enlarged hands and feet, prominent prognathic mandible)
- Soft-tissue overgrowth (enlarged lips, tongue, and epiglottis; distortion of facial features)
- Visceromegaly
- Osteoarthritis
- Glucose intolerance
- Peripheral neuropathy
- Skeletal muscle weakness
- Extrasellar tumor extension (headache, visual field defects)

Cardiomyopathy and hypertension in patients with acromegaly can lead to symptomatic cardiac disease (e.g., diastolic dysfunction, congestive heart failure, arrhythmias).[13,17,18] Bi-ventricular concentric hypertrophy manifests early in the disease course.[7,10]

The insulin-antagonistic effect of GH produces glucose intolerance in most patients and frank diabetes in up to 25% of patients with acromegaly.[7]

Clinical manifestations resulting from the local effects of the expanding tumor may include headaches (55%), papilledema, and visual field defects (19%), which are caused by compression of the optic nerves and chiasm. Significant increases in intracranial pressure are uncommon. Compression or destruction of normal pituitary tissue by the tumor may eventually lead to panhypopituitarism.[7] Common features of acromegaly are summarized in Box 33-1.

Life expectancy in patients with acromegaly is decreased on average by about 10 years.[10] Most patients die of cardiovascular causes. Hormonal control has a definite impact on survival. Lowering serum GH to less than 2.5 mcg/L results in reduction of the mortality rate to levels comparable with the general population.[19,20]

Treatment for acromegaly is aimed at restoring normal GH levels. The preferred initial therapy for active acromegaly is microsurgical removal of the pituitary tumor, with preservation of the gland.[12] Surgery achieves biochemical cure (normalization of IGF-1 and a glucose-suppressed GH of less than 2 mcg/L) in about 70% to 90% of microadenomas (less than 1 cm). Cure rates for macroadenomas by surgery are much lower (about 50%).[7,10,21]

Surgical approach to the pituitary tumor most often is via the endonasal transsphenoidal route, and this route is generally well tolerated by most patients.[8,10,13] A transcranial approach may be used for very large tumors with suprasellar extension.[13]

For transsphenoidal pituitary surgery, the head of the bed is typically elevated 15 degrees to improve venous drainage.[13,22] The anesthetist should consider monitoring for venous air embolism, especially if cavernous sinus invasion by the tumor is suspected and the patient is positioned in a steep head-up tilt.[12] Infrequently, the approach and exposure of the tumor are associated with significant blood loss. The use of submucosal injection of epinephrine-containing solutions or topical vasoconstrictors to assist in hemostasis may result in large blood pressure increases.[23] An anesthetic technique that incorporates muscle relaxation and allows for smooth extubation and rapid neurologic assessment is desirable.[12] Nitrous oxide should be omitted from the anesthetic plan if air is injected surgically to aid with tumor visualization. Preparing the patient preoperatively for awakening with nasal

packing is a consideration for some cases. Surgical complications are not common, but may include epistaxis, transient diabetes insipidus, cranial nerve damage, symptomatic hyponatremia, and cerebral spinal fluid leaks.[22]

Surgical ablation is usually successful in rapidly reducing tumor size, inhibiting GH secretion, and alleviating some symptoms.[7,24]

Administration of octreotide or lanreotide (long-acting somatostatin analogs), pegvisomant (a GH-receptor antagonist), and gland irradiation are adjunctive treatments for tumor regression or treatment options for patients who are not surgical candidates.[10,18,21]

Anesthetic Implications of Acromegaly. Preanesthetic assessment of patients with acromegaly should include a careful examination of the airway. Facial deformities and the large nose may hamper adequate fitting of an anesthesia mask. Endotracheal intubation may be a challenge because of the patient's large and thick tongue (macroglossia), prognathism, enlarged thyroid gland, obstructive teeth, hypertrophy and distortion of the epiglottis, and general soft-tissue overgrowth in the upper airway.[8,13,17,25-27] Subglottic narrowing and vocal-cord enlargement may dictate the use of a smaller-diameter endotracheal tube. Nasotracheal intubation should be approached cautiously because of possible turbinate enlargement.[11] The occurrence of Mallampati III and IV grades is higher in patients with acromegaly, and the incidence of difficult intubations may be four to five times higher than patients without acromegaly.[24,26] Preoperative dyspnea, stridor, or hoarseness should alert the anesthetist to airway involvement.[11] Indirect laryngoscopy, computed tomography (CT) scan of the neck, and neck radiography may be performed for thorough assessment. If difficulties in maintaining an adequate airway are anticipated, optically guided intubation or fiberoptic-guided intubation in an awake patient is of proven value.[12,13,17] Equipment for tracheostomy should be available if airway changes are advanced.[12] The endotracheal tube should remain in place until the patient is fully awake and has total return of reflexes.

More than 60% of patients with acromegaly have a history of sleep apnea associated with upper airway obstruction.[13,17] Sleep apnea and the predisposition to airway obstruction in these patients makes assiduous perioperative monitoring of the patient's respiratory status an absolute precaution.[12,18]

The frequent occurrence of cardiac arrhythmias, coronary artery disease, and hypertension in acromegalic patients warrants a thorough preanesthetic cardiac evaluation. Hyperglycemia may complicate the perioperative period, mandating careful perioperative monitoring of blood glucose and electrolyte levels.[17,18]

If preoperative assessment reveals impairment of the adrenal or thyroid axis, stress-level glucocorticoid therapy and thyroid replacement should be implemented in the perioperative period.

Entrapment neuropathies, such as carpal tunnel syndrome, are common in patients with acromegaly.[7] If arterial access is required, an Allen test should be performed before placement of a radial artery catheter; hypertrophy of the carpal ligament may cause inadequate ulnar artery flow. Alternatively, catheterization of other arterial sites should be considered.[11]

Posterior Pituitary Lobe

The posterior pituitary lobe secretes two important peptide hormones: *antidiuretic hormone (arginine vasopressin* or *ADH)* and *oxytocin*. Oxytocin and ADH are structurally very similar, but they have quite different actions. ADH controls water excretion and reabsorption in the kidney and is a major regulator of serum

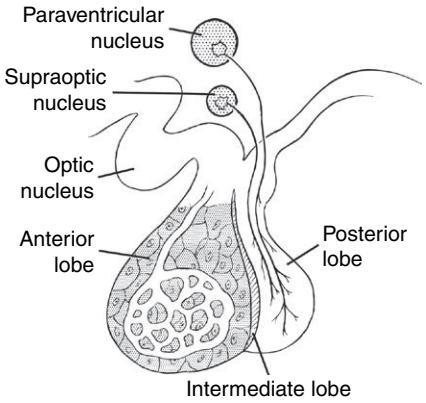

FIGURE **33-3** Nerve fibers arising from the supraoptic nucleus and the paraventricular nucleus transport antidiuretic hormone and oxytocin to the posterior pituitary.

osmolarity. Oxytocin stimulates contraction of myoepithelial cells of the breast for milk ejection during lactation. It also powerfully stimulates uterine smooth muscle contraction.[5] Oxytocin and its derivatives are used clinically for inducing labor and decreasing postpartum bleeding.

In contrast to the anterior pituitary lobe, which communicates with the hypothalamus via a vascular system, the posterior pituitary lobe communicates with the hypothalamus through a neural pathway. Unlike anterior pituitary hormones, posterior pituitary hormones are not synthesized within the pituitary gland itself but rather within two large nuclei of the hypothalamus, the *supraoptic nucleus* and the *paraventricular nucleus*. ADH is chiefly synthesized in the supraoptic nucleus and oxytocin in the paraventricular nucleus.[5,6] As shown in Figure 33-3, nerve fibers arising from these hypothalamic nuclei transport ADH and oxytocin down the pituitary stalk by axoplasmic flow to the posterior pituitary lobe. There, the hormones are stored in secretory granules at the nerve terminals. With proper excitation, nerve impulses originating in the cell bodies of the supraoptic or paraventricular nucleus are transmitted down the pituitary stalk and stimulate the release of ADH or oxytocin from the posterior pituitary lobe. The hormones then diffuse into nearby blood vessels and are transported to their distant target sites.

Three types of vasopressin receptors have been identified: V1, V2, and V3. Activation of receptor V1 mediates vasoconstriction. V2 receptors mediate water reabsorption in the renal collecting ducts. V3 receptors are found within the central nervous system and their stimulation modulates corticotrophin secretion.[9]

Antidiuretic Hormone

ADH is the body's principal preserver of water balance. It acts on V2 receptors on renal collecting ducts to increase the absorption of solute-free water through water channels called *aquaporins*. The integrated role of thirst, vasopressin, and renal response conserve water in the body and support normal body-fluid osmolarity. Plasma osmolarity is physiologically controlled within a small range (285 to 290 mOsm/L).[9] Without ADH, the collecting ducts are impermeable to water reabsorption; in this setting, water loss in the urine is excessive, and serious dehydration is provoked.[6]

ADH acts primarily to increase urine osmolarity, decrease serum osmolarity, and increase blood volume.[6] Additionally, high levels of ADH stimulate V1 receptors and cause potent systemic

vasoconstriction, especially in coronary, splanchnic, and renal vascular beds. ADH-induced vasoconstriction of vascular beds has been exploited therapeutically for the control of vasodilatory shock, hemorrhage, and sepsis.[9] Current advanced cardiac life support protocols recommend vasopressin as an adrenergic alternative to epinephrine for promoting the return of spontaneous circulation after cardiac arrest. Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]), a synthetic arginine analog of ADH, increases circulating levels of von Willebrand factor and factor VIII, and is used to reverse coagulopathy associated with platelet adhesion defects.[9]

Consonant with its role of maintaining normal fluid homeostasis, ADH is secreted in response to an increase in plasma osmolarity or plasma sodium ion concentration, a decrease in blood volume, or a decrease in blood pressure.[6]

The osmolarity of body fluids is the main variable controlling ADH secretion. Serum osmolarity changes are sensed by hypothalamic *osmoreceptors*, which in turn alter ADH synthesis and secretion.[5] The plasma *osmotic threshold* for ADH release is only 2% to 4% higher than normal plasma osmolarity.[5,28] When the plasma tonicity increases even subtly, healthy individuals release ADH into the blood.

The interplay between ADH and water is controlled by a delicate negative feedback loop. Water deprivation (increased plasma osmolarity) initiates signals in the hypothalamic osmoreceptors that cause ADH release from the pituitary gland to increase three- to five-fold. ADH, in turn, enhances renal tubular water reabsorption, dilutes the extracellular fluid, and restores normal osmotic composition.[6] Conversely, water ingestion (decreased plasma osmolarity) suppresses the osmoreceptor signal for ADH release.

A 10% to 20% decrease in blood volume or blood pressure also provokes ADH release.[28] Changes in blood volume are sensed in peripheral baroreceptors (especially the great veins and pulmonary vessels) and atrial stretch receptors. When these baroreceptors sense underfilling (volume depletion), they transmit afferent signals through vagal and glossopharyngeal nerves to the hypothalamus.[5,28] The hypothalamus responds by increasing ADH synthesis and stimulating ADH release.

The perioperative period is characterized by enhanced ADH secretion.[29,30] Pain, emotional stress, nausea, hemorrhage, and various drugs can be potent stimuli to ADH release. Positive-pressure ventilation enhances ADH release by reducing central blood volume.[8] The mild hyponatremia sometimes observed postoperatively may be at least partly explained on the basis of ADH action. Box 33-2 lists factors that stimulate ADH release or enhance the action of ADH at the renal tubules.[11]

Thirst provides a second line of defense of water balance. The *thirst threshold* is set about 5% higher than the osmotic threshold for ADH.[6,28]

Deficient Antidiuretic Hormone and Anesthetic Implications. Inadequate ADH secretion from the posterior pituitary lobe or the inability of renal collecting duct receptors to respond to ADH (impaired receptor sensitivity) results in a disorder called *diabetes insipidus (DI)*. Decreased ADH release produces *neurogenic or central DI*, and renal tubular resistance to vasopressin is termed *nephrogenic DI*.[28]

Common causes of neurogenic DI include severe head trauma, neurosurgical procedures (e.g., trauma to the median eminence, pituitary surgery), infiltrating pituitary lesions, and brain tumors.[28] Neurogenic DI that develops after pituitary surgery is usually transient and often resolves in 5 to 7 days.[8,13]

BOX 33-2

Stimulators of Antidiuretic Hormone Enhancement or Release

- Increased plasma sodium ion concentration
- Increased serum osmolarity
- Decreased blood volume
- Decreased blood pressure
- Smoking (nicotine)
- Stress
- Pain
- Nausea
- Vasovagal reaction
- Various medications (chlorpropamide, clofibrate, thiazide diuretics, carbamazepine, nicotine, cyclophosphamide, vincristine, morphine, high-dose oxytocin)
- Angiotensin II
- Positive-pressure ventilation

Nephrogenic DI may occur in association with genetic mutations, hypercalcemia, hypokalemia, and medication-induced nephrotoxicity.[28] Ethanol, demeclocycline, phenytoin, chlorpromazine, and lithium all inhibit the action of ADH or its release.[8]

The hallmark of DI is polyuria. The inability to produce a concentrated urine results in dehydration and hypernatremia. The syndrome is characterized by a low urine osmolarity (less than 300 mOsm/L), urine specific gravity less than 1.010, and urine volumes greater than 2 mL/kg/hr.[28] The tremendous urinary water loss produces serum osmolarities greater than 290 mOsm/L and serum sodium concentrations greater than 145 mEq/L. Neurologic symptoms of hypernatremia and neuronal dehydration may be present and include hyperreflexia, weakness, lethargy, seizures, and coma.[28]

The thirst mechanism assumes a primary role in maintaining water balance in awake patients with DI. Ingestion of large volumes of water prevents serious hyperosmolarity and life-threatening dehydration.[8]

Treatment protocols for DI depend on the degree of ADH deficiency. Most patients have incomplete DI and retain some capacity to concentrate their urine and conserve water. Mild cases (incomplete DI) may be treated with medications that either augment the release of ADH or increase the receptor response to ADH. These drugs may include chlorpropamide (sulfonylurea hypoglycemic agent), carbamazepine (anticonvulsant), and clofibrate (hypolipidemic agent).

Significant deficiency (plasma osmolarity levels greater than 290 mOsm/L) may be treated with various ADH preparations. Desmopressin (DDAVP), a selective V2 agonist, is often a preferred agent because it has less vasopressor activity, a prolonged duration of action (8 to 12 hours), and enhanced antidiuretic properties.[9,28] DDAVP may be administered nasally, intravenously, subcutaneously, and orally. Dosages for nasal application range from 5 to 40 mcg/day. Subcutaneous dosages are 0.5 to 2 mcg twice daily.

Perioperative administration of vasopressin is usually not necessary in the patient with partial DI, because the stress of surgery causes enhanced ADH release.[8,30] The surgical patient with a total lack of ADH (complete DI) may be managed with desmopressin (1 mcg subcutaneously) or aqueous vasopressin (an intravenous bolus of 0.1 unit, followed by a continuous intravenous infusion of

TABLE 33-2 Syndrome of Inappropriate Antidiuretic Hormone (SIADH) and Diabetes Insipidus (DI)

	SIADH	DI
Serum osmolarity	Less than 270 mOsm/L	Greater than 290 mOsm/L
Serum sodium	Less than 130 mEq/L	Greater than 145 mEq/L
Urine volume	Low	High (greater than 2 mL/kg/hour)
Urine osmolarity	Hypertonic urine relative to plasma	Hypotonic urine relative to plasma

DDAVP, 1-deamino-8-D-arginine vasopression.

vasopressin at 0.1 to 0.2 unit/hr).[8] Caution is advised when administering these drugs to patients with coronary artery disease or hypertension because of the arterial constrictive action of ADH.[28]

Plasma osmolarity, urine output, and serum sodium concentration should be measured hourly during surgery and in the immediate postoperative period.[8]

Isotonic fluids can generally be administered safely during the intraoperative period. If, however, the plasma osmolarity rises above 290 mOsm/L, hypotonic fluids should be considered and the vasopressin infusion increased above 0.2 unit/hr.[8]

Preoperative assessment of the patient with DI includes careful appraisal of plasma electrolytes (especially serum sodium), renal function, and plasma osmolarity. Dehydration will make these patients especially sensitive to the hypotensive effects of anesthesia agents. Intravascular volume should slowly be restored preoperatively over a period of at least 24 to 48 hours.

Hypersecretion of Antidiuretic Hormone and Anesthetic Implications. The *syndrome of inappropriate antidiuretic hormone (SIADH)* secretion is a disorder characterized by a high circulating vasopressin level relative to plasma osmolarity and serum sodium concentration. With SIADH, the kidneys, under ADH stimulation, continue to reabsorb water from the renal tubules despite the presence of hyponatremia and plasma hypotonicity. [8] Hormone-induced water reabsorption causes expansion of intracellular and extracellular fluid volumes, hemodilution, and weight gain. The urine is hypertonic relative to the plasma, and urine output is typically low. Table 33-2 compares SIADH and DI.

Clinical features of SIADH reflect water intoxication, dilutional hyponatremia, and resulting brain edema.[28] The swelling of brain cells may cause lethargy, headache, nausea, mental confusion, seizures, and coma. Hypertension and peripheral edema are not common. The severity of symptoms is related to the degree of hyponatremia and the rate of decrease of serum sodium.[31]

Inappropriate hypersecretion of ADH can result from various pathologic processes, including hypothyroidism, pulmonary infection or carcinoma, head trauma, intracranial tumors, and after pituitary surgery.[11] Secretion of ADH by neoplasms, especially small-cell carcinomas of the lung, is a common cause of SIADH.[8] The ectopic ADH produced by these tumors is identical to the ADH of hypothalamic origin. Certain drugs are associated with enhanced ADH secretion or response; these include carbamazepine, tricyclic antidepressants, chlorpropamide, cyclophosphamide, oxytocin, nicotine, and clofibrate.[28]

The patient with mild SIADH not associated with symptoms of hyponatremia is often managed effectively with fluid restriction of 800 to 1000 mL/day with 0.9% normal saline.[13,32] Patients with acute severe hyponatremia (plasma Na^+ less than 115-120 mEq/L) or acute neurologic symptoms may require more aggressive treatment with an intravenous infusion of hypertonic (3%) saline, with or without a loop diuretic.[28,32,33] To prevent acute loss of brain water and possible permanent neurologic damage (*central pontine demyelination syndrome*), the plasma sodium concentration must be corrected slowly. Many investigators recommend that acute hyponatremia be corrected at a rate not to exceed 1 to 2 mEq/L/hr or 6 to 8 mEq/L in 24 hours.[11,12] An intravenous infusion of hypertonic (3%) saline at a rate of 70 mL/70 kg/hr will increase the serum sodium level by approximately 1 mEq/L/hr.[31,33] Serum sodium levels should be measured at least every 2 hours during treatment.[28]

Demeclocycline, a tetracycline antibiotic, has been used to treat chronic SIADH by antagonizing the effects of vasopressin on the renal tubules.[8,28] Definitive treatment for SIADH is directed at the underlying disorder.

Clinical assessment of the patient's volume status is an essential part of the preoperative evaluation. Perioperative fluid management of the surgical patient with SIADH can usually be accomplished with fluid restriction that involves the use of isotonic solutions.[8] Estimating central volume status on the basis of central venous pressure measurements can help guide fluid replacement. Frequent determinations of urine output, urine osmolarity, plasma osmolarity, and serum sodium concentrations also can help direct fluid management. Nausea should be prevented, because it is a potent stimulus of ADH release.[28]

PARATHYROID GLAND

The parathyroid glands are small (approximately 3 × 6 × 2 mm) oval bodies located on the posterior surface of the thyroid gland. Most individuals have four parathyroid glands, one on each pole of the thyroid, but approximately 6% of individuals have five glands and 13% have only three. Blood supply to the parathyroid glands is via the inferior thyroid arteries.[34]

Calcium Regulation

The adult human body contains about 1 to 2 kg of the divalent cation calcium. Approximately 99% of the calcium exists in the bony skeleton, and only about 1% is in the extracellular space and soft tissues.[34-36] Bone therefore serves as a large reservoir that can store or release calcium as needed. Intracellular calcium is 10,000 times lower than ionized calcium concentration in the extracellular fluid.[35,36]

The concentration of the total serum calcium is tightly regulated within a range of about 8.6 to 10.6 mg/dL.[37] Serum calcium exists in three different forms (Figure 33-4):

1. Approximately 9% exists in a nonionized, chelated form. This calcium is bound to diffusible anions such as citrate, bicarbonate, and phosphate.
2. Approximately 41% is combined with plasma proteins (primarily albumin) in a nonionized, nondiffusible complex.
3. Approximately 50% exists in an ionized and diffusible form (normal level 4.7 to 5.2 mg/dL).

Only the free, ionized form of calcium exerts physiologic effects, hence measurement of serum ionized calcium levels provides the most clinically relevant determination.[34,35] Ionized calcium

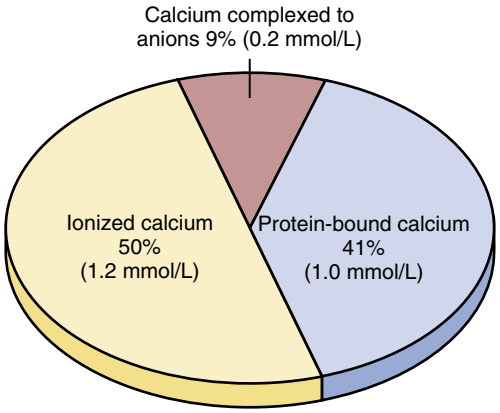

FIGURE **33-4** Serum calcium exists in three different forms: ionized, bound to serum proteins, and bound to diffusible anions. Only the ionized form of calcium exerts physiologic effects. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:956.)

performs a wide range of vital physiologic functions, including hemostasis (platelet aggregation, blood coagulation), muscle contraction, neurotransmission, bone formation, cell division, and many other aspects of cell function. Even small changes in calcium levels can cause extreme and immediate physiologic effects.[34]

Total blood calcium levels may not always reflect the ionized calcium status. Changes in serum protein levels can alter total blood calcium levels without altering ionized calcium values. Changes in total calcium levels parallel the serum albumin.[35] A decrease in serum albumin causes an associated decrease in total serum calcium levels.

Alterations in the pH of blood affect ionized calcium levels. Plasma proteins are more ionized in an alkaline pH, providing an increase in the number of anion-binding sites for the positively charged calcium. Alkalosis decreases ionized serum calcium by increasing protein-calcium binding. Acidosis, on the other hand, increases ionized serum calcium by decreasing calcium-protein binding.[35,36]

Two principal hormones, vitamin D and parathyroid hormone (PTH), operate in concert to regulate the plasma concentration of calcium. Both vitamin D and PTH raise serum calcium levels, but of the two, PTH has by far the strongest effect.

Vitamin D

Vitamin D compounds ingested from food or formed by the action of ultraviolet light on the skin are inactive prohormones.[35,37] Inactive vitamin D, called *cholecalciferol*, is converted by a series of reactions in the liver and kidneys to an active metabolite. The final step in the conversion of vitamin D to an active form is controlled in the kidneys by PTH.[37] The in vivo conversion of inactive vitamin D to the final active product, *1,25-dihydroxycholecalciferol*, is shown in Figure 33-5.

Active vitamin D increases plasma calcium, magnesium, and phosphate ion concentrations by promoting their absorption across the intestinal epithelium to the extracellular fluid.

Inadequate vitamin D intake or absorption, or insufficient exposure to sunlight, can lead to poor intestinal absorption of calcium and phosphate. In children, the resulting calcium and phosphate deficiency leads to defective mineralization of bone, a condition known as *rickets*.[34,35] In adults, vitamin D deficiency results in impaired bone mineralization, a condition known as *osteomalacia*.[34,36]

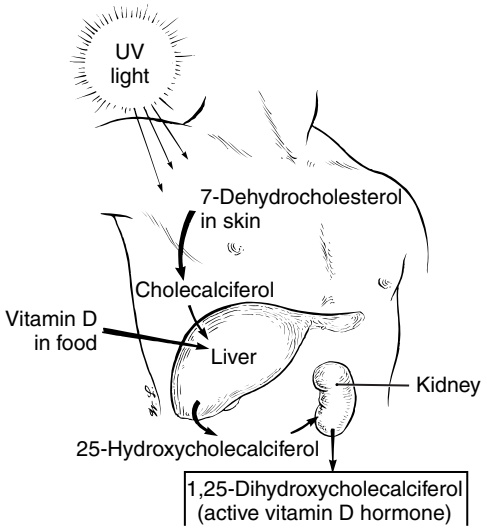

FIGURE **33-5** Conversion of cholecalciferol or vitamin D to an active form (1,25-dihydroxycholecalciferol) involves hydroxylation in the liver and kidneys. Active vitamin D is important in transporting calcium across the gastrointestinal tract. *UV,* Ultraviolet.

Parathyroid Hormone

PTH is secreted from *chief cells* of the parathyroid gland in response to low serum ionized calcium concentrations. Hyperphosphatemia (indirect effect) and acute hypomagnesemia also stimulate PTH secretion.[36]

PTH is the body's major hormonal regulator of calcium and phosphate metabolism. In PTH, the body possesses an extremely potent negative feedback agent for controlling serum calcium levels. In general, PTH increases the extracellular calcium concentration and decreases the extracellular phosphate concentration.[37] A small decline in the level of circulating ionized calcium produces a rapid increase in PTH secretion from the parathyroid glands. A sustained deficit in serum calcium levels (e.g., lactation, pregnancy) produces hypertrophy of the parathyroid glands, sometimes five-fold or greater, in order to maintain adequate PTH output.[34,36]

An elevation in serum calcium ion concentration produces an abrupt decline in PTH synthesis and output. Conditions associated with chronic elevations of serum calcium (e.g., immobility, malignancy, Paget disease) provoke a blunted PTH output and a diminution in gland size. In contrast to *acute* magnesium deficiency, parathyroid gland function and PTH secretion are inhibited by severe and *chronic* hypomagnesemia.[36,37]

The increase in serum calcium level in response to PTH secretion is the result of the hormone's direct effect on bone and the kidney and its indirect effect on the intestinal tract (Figure 33-6).

Effect on Bone. Bone is a living tissue that is constantly being remodeled.[35] In the healthy adult, bone-forming cells called *osteoblasts* are balanced by bone-destroying cells called *osteoclasts*.[34] Exchangeable calcium salts in bone serve as a large, rapid buffer that play a vital role in extracellular fluid calcium homeostasis. In addition to calcium, bone also provides an important reservoir for other ions such as magnesium and phosphorus.[34,36]

The most pronounced immediate control of blood calcium is due to PTH effects on bone.[37] When ionized serum calcium levels decline, PTH is released and acts directly on bone to mobilize skeletal calcium stores.[35] PTH promotes the activation and proliferation of osteoclasts, stimulating rapid absorption of calcium (and phosphate) from bone tissue to the extracellular fluid. Over time, abnormally high levels of circulating PTH can produce extensive absorption of calcium from the bone matrix.[34,37]

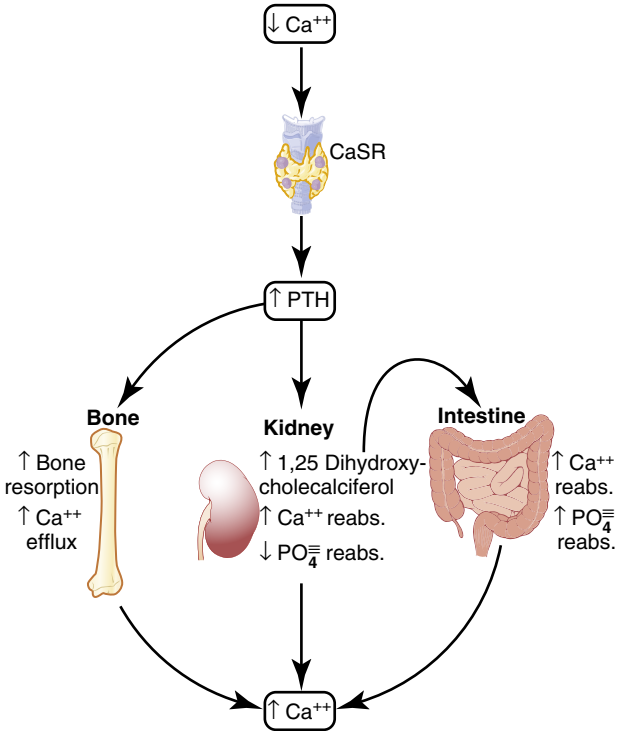

FIGURE **33-6** Summary of the effects of parathyroid hormone (PTH) on bone, the kidneys, and the intestine. CaSR, Calcium-sensitive receptor. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:956.)

The reservoir of calcium in bone is about 1000 times greater than the amount of calcium in the extracellular fluid. Only after sustained PTH activation, therefore, does bone erosion and destruction become apparent. With protracted PTH stimulation, however, the bones eventually become severely depleted of calcium.[34]

An increase in extracellular fluid calcium causes PTH levels to decline. Decreased PTH levels stimulate rapid deposition of calcium and phosphate bone salts, an effect that lowers serum calcium levels back to normal.

Effect on the Intestinal Tract. Parathyroid hormone indirectly enhances both calcium and phosphate absorption from the intestines by promoting formation of 1,25-dihydroxycholecalciferol, the active form of vitamin D. When the plasma calcium level is low, PTH stimulates 1α-hydroxylase, an enzyme in the kidney necessary for the formation of 1,25-dihydroxycholecalciferol. Active vitamin D in turn increases intestinal absorption of calcium and phosphate.[35]

In the absence of PTH, or in the presence of severe kidney disease, 1,25-dihydroxycholecalciferol is not formed, and the effect of vitamin D on calcium and phosphate regulation is lost. Patients with chronic renal failure often suffer from hypocalcemia, in part because the diseased kidneys lose their ability to form active vitamin D. Consequently, these patients are unable to absorb a sufficient amount of calcium from the gastrointestinal tract.[37]

Effect on the Kidney. PTH has two major effects on the kidney: it increases calcium reabsorption, and it increases phosphate excretion. PTH elevates serum calcium by augmenting the reabsorption of calcium from nephron tubules to the extracellular fluid. The major site of PTH-mediated calcium reabsorption is the distal convoluted tubule.[34,37]

Accompanying calcium reabsorption is enhanced phosphate excretion. PTH promotes phosphaturia by reducing phosphate ion reabsorption from the proximal convoluted tubule. The PTH-mediated phosphate loss from the kidney is generally strong enough to overcome the PTH-induced phosphate absorption from bone and intestines.[34]

Calcitonin

Calcitonin is a hormone secreted from the thyroid *parafollicular cells*, or C *cells*, in response to elevated serum ionized calcium.[35] It has an effect opposite that of the PTH system, lowering the serum ionized calcium concentration. Calcium levels are reduced by a calcitonin-mediated inhibition of bone osteoclasts, which shifts the balance toward osteoblasts and bone deposition.[35,37]

The serum calcium–lowering effect of calcitonin is weak. Its effect in lowering serum calcium is rapidly outweighed by the more powerful activity of PTH.[34] The rather weak effect of calcitonin is demonstrated by the observation that removal of the thyroid gland causes no significant alterations in bone density or long-term serum calcium levels.[34,35,37]

Parathyroid Gland Dysfunction

Hypoparathyroidism

Hypoparathyroidism may be a hereditary or acquired disorder characterized by inadequate secretion of PTH or a peripheral resistance to its effect.[37] Patients with hypoparathyroidism typically have low plasma calcium levels (ionized calcium less than 4.5 mg/dL and total calcium less than 8.6 mg/dL).[11] The blood phosphate concentration may be elevated because of the decreased renal excretion of phosphate.

Hereditary hypoparathyroidism, inadvertent surgical removal of parathyroid tissue, parathyroid gland injury from irradiation, and chronic severe magnesium deficiency (e.g., alcohol abuse, poor nutrition, malabsorption) are possible causes of hypoparathyroidism. Clinical signs of hypoparathyroidism reflect the degree of hypocalcemia and the rapidity of calcium decline. A sudden drop in ionized calcium usually produces more severe symptoms than a slow decline.[36,37] Treatment of chronic hypoparathyroidism includes vitamin D and calcium supplementation.

The decreased serum calcium ion concentration accompanying hypoparathyroidism produces hyperexcitability of nerve and muscle cells by lowering the threshold potential of excitable membranes. Cardinal features of neuromuscular excitability are muscle spasms and spontaneous nerve discharge. Symptoms vary in severity and may take the form of muscle cramps, perioral paresthesias, numbness in the feet and toes, or hyperactive deep tendon reflexes. The patient may feel restless or hyperirritable. Life-threatening laryngeal muscle spasm may occur, producing stridor, labored respirations, and asphyxia.[34,37] Tetany occurs when the blood calcium falls to about 6 mg/dL.[34]

Two classic manifestations of latent hypocalcemic tetany are *Chvostek sign* and *Trousseau sign*. Chvostek sign is a contracture or twitching of ipsilateral facial muscles produced when the facial nerve is tapped at the angle of the jaw. Trousseau sign is elicited by the inflation of a blood pressure cuff slightly above the systolic level for a few minutes. The resultant ischemia enhances muscle irritability in hypocalcemic states and causes flexion of the wrist and thumb with extension of the fingers *(carpopedal spasm)*.[23] Figure 33-7 illustrates some of the clinical manifestations of hypoparathyroidism and hypocalcemia.

Anesthesia Implications for Hypoparathyroidism. Temporary hypocalcemia often is observed after successful parathyroid surgery for hyperparathyroidism.[37] This may occur within a few hours to a few days after surgery.[37] The transient postoperative hypocalcemia is the result of parathyroid gland suppression

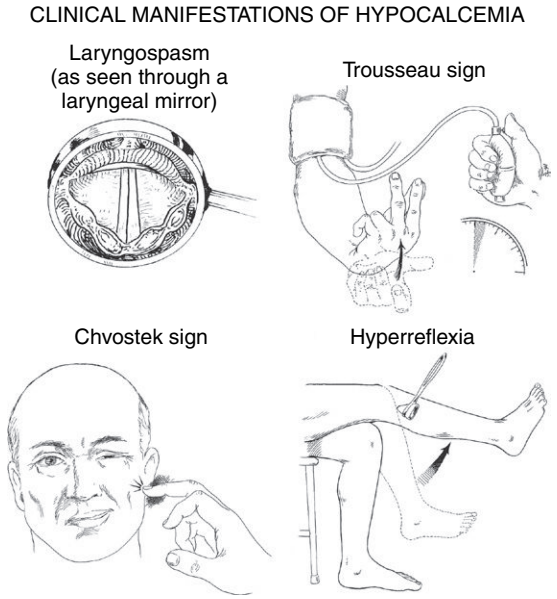

FIGURE **33-7** Hypocalcemia produces hyperexcitability of nerve and muscle cells. Chvostek sign and Trousseau sign are two classic manifestations of hypocalcemic tetany. Deep tendon reflexes may be hyperactive. Laryngeal muscles are sensitive to tetanic spasm.

(by preoperative hypercalcemia) and rapid bone uptake of calcium ("hungry bone syndrome").[36] Inadvertent removal of all parathyroid gland tissue induces a marked decline in total serum calcium concentration from normal levels to 6 to 7 mg/dL. Even a small amount of remaining parathyroid tissue usually is capable of sufficient hypertrophy to preserve normal calcium-phosphate balance.[34]

After parathyroid surgery, meticulous observation for signs of musculoskeletal irritability should be performed. The threshold for the development of signs of hypocalcemia is variable; however, manifestations of neuromuscular compromise often are observed at total serum calcium levels of 6 to 7 mg/dL.[34]

Laryngeal muscles are especially sensitive to tetanic spasm, and laryngospasm may cause life-threatening airway compromise in the hypocalcemic patient.[34] Respiratory distress following parathyroid surgery may be secondary to laryngeal muscle spasm, edema or bleeding in the neck, or bilateral recurrent laryngeal nerve injury. Unilateral recurrent laryngeal nerve injury produces hoarseness and usually requires only close observation. Bilateral recurrent laryngeal nerve injury causes aphonia and requires immediate airway support and intubation.[34]

Hypocalcemia may be apparent on electrocardiographic tracings as a prolonged QT interval, reflecting delayed ventricular repolarization.[11] Cardiac dysrhythmias, decreased cardiac contractility, and hypotension may occur, and congestive heart failure (although rare) is a danger.[36,38]

In addition to parathyroid surgery, circulating levels of ionized calcium can decline from other causes in the perioperative period. Precipitous increases in circulating levels of anions such as bicarbonate, phosphate, and citrate lower ionized calcium levels.[36] The rapid transfusion of citrated blood, or the rapid administration of bicarbonate may induce overt tetany in a previously asymptomatic hypocalcemic patient. Hyperventilation and alkalosis decrease ionized calcium levels by increasing calcium binding to proteins.[37] Vigorous diuresis can also augment calcium loss.

Patients with confirmed symptomatic hypocalcemia require prompt therapy. Acute hypocalcemia may be treated with an initial intravenous bolus of 10 mL of 10% calcium chloride or calcium gluconate administered over 10 minutes, followed by an infusion of 0.5 to 2 mg Ca^{+2}/kg/h.[36,37] Calcium, magnesium, phosphate, potassium, and creatinine levels should be monitored diligently during calcium replacement. Chronic magnesium deficiency impairs the secretion of PTH and should be corrected.[35]

Hyperparathyroidism

Primary hyperparathyroidism is characterized and diagnosed by the presence of elevated serum PTH levels despite high serum calcium levels. It may result from a parathyroid adenoma, gland hyperplasia, or parathyroid cancer.[27] In approximately 80% of cases, primary hyperparathyroidism is caused by hypersecretion of a single parathyroid adenoma.[36-39] Hyperplasia of one or more parathyroid glands accounts for about 15% of cases. Hereditary hyperparathyroidism may exist as part of a multiple endocrine neoplastic syndrome (MEN-1, MEN-2A).[36,37] Carcinoma of the parathyroid gland is found in less than 1% of patients and is associated with particularly high serum calcium levels.[39]

The incidence of primary hyperparathyroidism in the United States is approximately 0.1% to 0.5%, with a higher occurrence in females and a peak incidence between the third and fifth decades.[2,37] Stimulation of the parathyroid gland during pregnancy or lactation, prior neck irradiation, and a family history of parathyroid disease are predisposing etiologic factors.[37]

There are many causes of hypercalcemia, but hyperparathyroidism and cancer account for 90% of all cases.[37] Primary hyperparathyroidism is the most common cause of hypercalcemia in the general population.[11] Sustained overactivity of the parathyroid glands leads to hypercalcemia and hypophosphatemia. Most patients remain asymptomatic until the total serum calcium level rises above 12 mg/dL.[37] Severe hypercalcemia, generally defined as greater than 14 mg/dL, may be life threatening and demands immediate attention.[37,38]

With the development of sensitive laboratory assays for calcium and PTH, today more than half of patients with hyperparathyroidism are asymptomatic at diagnosis. Over time, sustained high levels of PTH lead to exaggerated osteoclast activity in bone, resulting in diffuse osteopenia, subperiosteal erosions, and elevated extracellular calcium levels. As osteoblasts attempt to reconstruct the ravaged bone, they secrete large amounts of the enzyme *alkaline phosphatase*.[34,35] A heightened serum alkaline phosphatase level, therefore, is a diagnostic feature of hyperparathyroidism.[39] Despite an increased mobilization of phosphorus from bone, serum phosphate concentration usually remains normal or low as a result of increased urinary excretion.

The effect of hyperparathyroidism on bone becomes clinically apparent when osteoclastic absorption of bone overwhelms osteoblastic deposition. With severe and protracted disease, the weakened bones become filled with decalcified cavities, making them painful and susceptible to fracture. Owing to early diagnosis, the destructive bone disease associated with hyperparathyroidism, *osteitis fibrosa cystica*, is rare today.

Many of the nonskeletal manifestations of primary hyperparathyroidism are related to the accompanying hypercalcemia.[39] Sustained and marked hypercalcemia may produce calcifications and other deleterious effects in the pancreas (pancreatitis), kidney (nephrolithiasis, nephrocalcinosis, polyuria), blood vessels (hypertension), heart (shortened ventricular refractory period, increased ventricular excitability, bradyarrhythmias), and acid-producing areas of the stomach (peptic ulcer).[38-40] The mnemonic "stones, bones, and groans" summarizes renal, skeletal, and gastrointestinal features of advanced hyperparathyroidism. Hypercalcemia raises

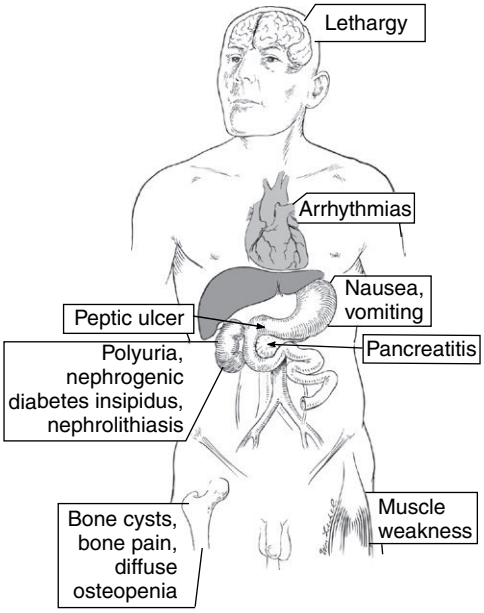

FIGURE **33-8** The patient with hyperparathyroidism exhibits manifestations of hypercalcemia. With severe, protracted disease, skeletal destruction becomes evident.

TABLE **33-3** Clinical Features of Hyperparathyroidism and Hypoparathyroidism

System	Hyperparathyroidism	Hypoparathyroidism
Cardiovascular	Hypertension, cardiac conduction disturbances, shortened QT interval	Prolonged QT interval, hypotension, decreased cardiac contractility
Musculoskeletal	Bone pain, pathologic fractures, muscle weakness, muscle atrophy	Neuromuscular excitability
Neurologic	Somnolence, cognitive impairment, depression, hypotonia	Tetany, paresthesias, numbness in fingers and toes, seizures
Gastrointestinal	Anorexia, nausea, vomiting, constipation, abdominal pain, pancreatitis, peptic ulcer	None significant
Renal	Tubular absorption defects, diminished renal function, kidney stones, polyuria	None significant

the threshold of excitable cells and causes progressive depression of the nervous system.[34] Depressive effects of hypercalcemia begin to appear in many patients when blood calcium levels rise above about 12 mg/dL. Profound muscle weakness, confusion, nausea, vomiting, and lethargy are additional features of the disorder. Figure 33-8 illustrates some of the clinical manifestations of hyperparathyroidism.

Secondary hyperparathyroidism develops in patients with chronically low levels of serum calcium, such as those with chronic renal failure, vitamin D deficiency, and gastrointestinal malabsorption. A compensatory parathyroid rise develops in response to the hypocalcemia. The clinical course is marked by the same PTH-mediated skeletal assault seen in the primary form of the disorder, but because it is an adaptive response, secondary hyperparathyroidism is seldom associated with hypercalcemia. The bone disease seen in patients with secondary hyperparathyroidism associated with chronic kidney disease is termed *renal osteodystrophy*.[37]

Hypercalcemia due to malignancy occurs in as many as 20% of cancer patients. Malignancy is the second most common cause of hypercalcemia in adults.[37] The hypercalcemia may be due to local invasion of bone by cancer cells, but many cases are due to elaboration of a PTH-like peptide (parathyroid hormone–related peptide, PTHrP) from tumor cells.[37] The overproduction of PTHrP by cancer cells mimics the effects of PTH, including bone destruction, hypophosphatemia, and hypercalcemia.

Table 33-3 compares common clinical features of hyperparathyroidism and hypoparathyroidism.

Anesthesia Implications for Hyperparathyroidism. The usual treatment for symptomatic primary hyperparathyroidism is surgical removal of abnormal parathyroid tissue. Surgical treatment for asymptomatic hyperparathyroidism is more controversial.[7] Parathyroidectomy may be performed with bilateral neck exploration under general anesthesia, but *minimally invasive parathyroidectomy* using cervical plexus block anesthesia and monitored anesthesia care is increasingly used, especially for excision of a single adenoma.[40-43]

Parathyroid tissue resembles brown fat, and this can occasionally make it difficult for the surgeon to locate. Further, parathyroid tissue is sometimes footloose and can be found in such ectopic places as the deep recesses of the mediastinum, pericardium, or the thymus gland.[35-37] The 5-minute half-life of PTH allows it to serve as a useful intraoperative marker.[43] Increasingly, surgeons use periodic intraoperative determinations of serum PTH and ionized calcium levels to help guide surgical resection.[40,41]

Blood loss from parathyroid surgery is usually minimal, and advanced monitoring is not required based on the surgical procedure. Serum calcium, magnesium, and phosphorus levels should be monitored in the postoperative period until stable. In most cases, serum calcium levels start to decline within 24 hours and return to normal within 3 to 4 days after successful surgery.[11]

With current methods of detection, most patients with hyperparathyroidism are asymptomatic. However, erosive effects of elevated PTH on bone and the systemic effects of chronic hypercalcemia should be considered in the anesthetic plan for patients with severe untreated disease.

Mild hypercalcemia (less than 12 mg/dL) can be managed by saline infusion (150 mL/hr).[11,37] Severe or symptomatic hypercalcemia (greater than 13 to 16 mg/dL) is treated aggressively. Isotonic saline hydration and loop diuretics (furosemide, 40 to 80 mg IV every 2-4 hours) can rapidly decrease serum calcium levels by hemodilution, increased glomerular filtration, and enhanced excretion.[8,11,38] Less frequently, intravenous bisphosphonates (pamidronate, zoledronate, etidronate) or calcitonin are used to lower serum calcium by inhibiting osteoclastic bone resorption.[8,11,37,38]

The hypercalcemic patient may be dehydrated because of anorexia, vomiting, and the impaired ability of the kidneys to concentrate urine.[37] In these patients, hydration with non–calcium-containing solutions should be maintained throughout the perioperative period to dilute serum calcium, maintain adequate glomerular filtration and calcium clearance, and ensure adequate intravascular volume. Vigorous hydration dictates the use of bladder catheterization, central venous pressure monitoring, and frequent determinations of serum electrolytes.

Elevated calcium levels may depress the central and peripheral nervous systems.[34] The use of preoperative sedatives in the

hypercalcemic patient who appears lethargic or confused should be avoided. General anesthetic requirements may be decreased as well in the patient with preoperative somnolence.[11]

Careful review of the patient's renal status is especially crucial in patients with secondary hyperparathyroidism. Associated complications of renal impairment (e.g., volume overload, anemia, electrolyte derangements) may affect anesthetic medication dosages and selection.[24,32]

Cardiac conduction disturbances and a shortened QT interval and a prolonged PR interval on the electrocardiogram are observed with hypercalcemia.[11]

Awareness of the effects of pH on the ionized portion of plasma calcium is important. Alkalosis shifts ionized calcium to the protein-bound form and decreases serum levels.

The response to neuromuscular blockade may be unpredictable.[11] Muscle weakness, hypotonia, and muscle atrophy may increase the patient's sensitivity to nondepolarizing skeletal muscle relaxants. Careful titration of muscle relaxants with use of a peripheral nerve stimulator is prudent.[11]

Patients with clinically significant bone disease are susceptible to fractures, and care must be exercised in positioning and padding.[7]

Hyperparathyroid patients are prone to postoperative nausea and vomiting.[44] Prophylactic antiemetic medications are advisable.

PANCREAS

The *pancreas* is a flattened, elongated, retroperitoneal organ that has both exocrine and endocrine functions. *Acinar cells*, which make up the exocrine portion of the pancreas, account for about 98% of the gland's weight. Digestive enzymes and bicarbonate are synthesized in acinar cells and secreted into the pancreatic ducts to aid the digestive process.

Islets of Langerhans

The *islets of Langerhans*, which make up 1% to 2% of the pancreas's weight, constitute the endocrine pancreas. The islets are microscopic collections of cells scattered throughout the gland. They produce hormones that do not enter ducts but rather are secreted directly into capillary blood vessels. Each islet cell has an abundant blood supply. Venous blood from the islets drains into the hepatic portal vein and then into the general circulation.[45]

At least four distinct cell types are found in the islets of Langerhans, identified as α (alpha), β (beta), δ (delta), and PP (pancreatic polypeptide) cells. Each cell type secretes a different peptide hormone. The β *cells* account for 60% to 70% of the islet mass and secrete the hormone *insulin*. They also secrete *amylin*, which can inhibit insulin secretion.[46] The α *cells* constitute about 25% of the islet cells and secrete the hormone *glucagon*. The δ *cells* represent about 10% of total cells and secrete the hormone *somatostatin*.[46]

Insulin and glucagon are crucial in regulating carbohydrate, fat, and protein metabolism. Their secretion is part of a hormonal regulatory system that accommodates repeated periods of feast and fasting throughout the day. Somatostatin may play a role in regulating gastrointestinal function by restraining the rate at which nutrients are digested and absorbed. It also inhibits the secretion of both insulin and glucagon.[46] Somatostatin also is distributed throughout the central nervous system and, as noted earlier in this chapter, is a hypothalamic inhibitor of anterior pituitary GH release. Pancreatic peptide inhibits exocrine pancreatic secretion.

Energy Balance

Glucose is the body's most abundant circulating fuel. The breakdown of glucose into simpler compounds releases energy the body uses for cellular metabolism. The energy-yielding breakdown of glucose to pyruvate or lactate is called *glycolysis* or the *Embden-Meyerhof pathway*.

Despite daily fluctuations between feeding and fasting states, plasma glucose concentration is maintained within an amazingly narrow range. This is accomplished by the counterbalancing effect of multiple hormones that control the storage of glucose and other nutrient fuels after meals and regulate fuel mobilization between meals. In most healthy individuals, the liver stores enough glycogen to maintain a normal plasma glucose during 8 to 12 hours of fasting.[47] An overnight fast usually lowers the blood glucose to 80 to 90 mg/dL. The blood glucose concentration increases briefly to 120 to 140 mg/dL after a meal before returning to control levels.[46] In a person with impaired glucose tolerance, the fasting plasma glucose (FPG) level is above 100 mg/dL, and in the diabetic patient, the FPG is equal to or greater than 126 mg/dL.[46,48]

Certain metabolic processes ensure the efficient storage of nutrients so they can be available for later use. *Glycogenesis*, or the storage of glucose as glycogen, occurs primarily in the liver and muscle. *Lipogenesis*, which represents the formation and storage of fat as triglycerides, occurs primarily in adipose tissue.

Other metabolic processes work in the opposite direction, providing adequate energy sources during times of fasting. *Gluconeogenesis* is the formation of glucose from lactate, pyruvate, amino acids, and glycerol; it is an important hepatic glucose production mechanism during fasting and starvation. *Glycogenolysis*, the breakdown of glycogen into glucose, occurs primarily in the liver. *Lipolysis*, the breakdown of stored triglycerides to free fatty acids and glycerol, is stimulated by the enzyme *hormone-sensitive lipase*.

The rates of glycogenesis, lipogenesis, gluconeogenesis, glycogenolysis, and lipolysis are determined largely by the actions of insulin and the opposing actions of so-called "counterregulatory hormones" (GH, cortisol, epinephrine, and glucagon). Insulin plays an important role as an *anabolic hormone*. It promotes growth and the constructive phase of metabolism. The potent anabolic effects of insulin are balanced by the opposing *catabolic actions* of the counterregulatory hormones. These hormones mobilize fuel substrates from protein, carbohydrate, and fat stores to meet the energy demands of various tissues.[45]

The "push and pull" effect of these two hormone systems helps maintain normal glucose concentrations in the healthy individual. In diabetes, when insulin concentrations are low or absent, the unopposed counterregulatory hormones begin to exert more prominent metabolic effects.

Obligate Versus Facultative Tissue

Different tissues have different glucose requirements, and some tissues are able to adapt to alternative sources of fuel when glucose is scarce. Muscle and most other tissues in the body are said to be *facultative* glucose organs. They use glucose for energy when it is available, but they can also shift to alternative sources of fuel (amino acids or fat) in the absence of glucose.

The brain is unique in that it is one of the few organs that uses only glucose for energy. It is said to be an *obligate* glucose organ. Erythrocytes and the adrenal medulla also depend on glucose as their sole source of energy. Unlike most other tissues, such as muscle, obligate glucose organs cannot immediately switch to alternative fuels when glucose levels fall. The brain's absolute, uninterrupted requirement for glucose dictates that the blood glucose concentration be maintained above a critical level. The central nervous system accounts for about 70% of total body glucose utilization, and normal cerebral function requires the delivery of

about 125 to 150 g of glucose per day. During prolonged starvation, ketone bodies can substitute for glucose as cerebral fuel.

Insulin

Of the hormones secreted from the islet cells, insulin is of greatest physiologic importance. In 1922, Banting and Best first isolated this critical hormone from the pancreas in its pure form. The clinical importance of this event is demonstrated by insulin's history of lifesaving effects in those with diabetes mellitus (DM), a previously uniformly fatal disease.

Insulin was the first mammalian peptide hormone produced with the use of recombinant DNA techniques. Genetically engineered insulin does not differ in biologic or chemical characteristics from pancreatic human insulin.

Storage and Release

Insulin is synthesized within the β cells of the pancreas, and it is packaged and stored in membrane-lined vesicles within the β-cell cytoplasm. About 200 units of insulin are stored in the pancreas in this form. With stimulation, insulin is released via exocytosis from the β cell to the surrounding capillaries, where it enters the portal circulation. In the first pass through the hepatic circulation, the liver removes 50% of the insulin delivered to it. Total daily insulin secretion is estimated to be about 60 units, but the total daily peripheral delivery is about 30 units.[45]

Insulin circulates unbound to any carrier protein. The circulating half-life of insulin is only 5 to 8 minutes, and the biologic half-life is about 20 minutes.[45] Almost all tissues in the body can metabolize insulin, but the major sites of hormone degradation are the liver and the kidney.[46] Very little insulin is excreted unchanged in the urine.

Effects of Insulin

Insulin is a hormone of energy or fuel storage. It is important to many cellular mechanisms related to growth, and it is intimately involved in the regulation of carbohydrate, fat, and protein metabolism.

Following ingestion of a meal, insulin levels increase sharply in response to stimulation by abundant circulating nutrient substrates. Insulin promotes the storage of carbohydrate, fat, and protein for future use when substrate supply is low.[46] Figure 33-9 outlines the effects of insulin on nutrient substrates.

The peripheral effects of insulin are initiated by a reversible binding to specific cell-membrane insulin receptors. Most cells in the body have insulin receptors, but the major targets of insulin action are the liver, muscle, and adipose tissue.[45]

Effects on Carbohydrate Metabolism. Insulin is the body's key hormone controlling glucose removal from the plasma. It facilitates the transport of glucose by stimulating its uptake into liver, muscle, and adipose tissue. The brain is one of the few tissues in the body that does not require insulin for glucose transport into its cells.[46]

In the liver, and to a lesser extent in muscle cells, insulin promotes the efficient storage of excess glucose in the form of glycogen (glycogenesis).[45] Under normal circumstances, about 60% of the glucose ingested with a meal is stored in the liver as glycogen. In addition to promoting hepatic glucose storage, insulin limits hepatic glucose output by inhibiting enzymes responsible for gluconeogenesis.[45,46]

Between meals, when the blood glucose and blood insulin levels decrease, the stored glucose can be released back into the blood (through gluconeogenesis and glycogenolysis) and be made available for local energy use or delivery to the central nervous system.

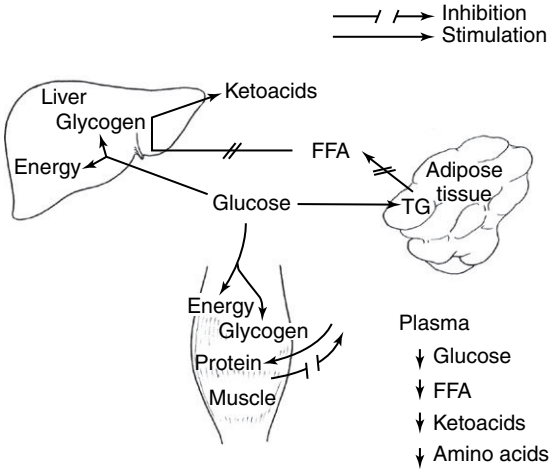

FIGURE **33-9** The effect of insulin on the overall flow of metabolic substrates. Insulin promotes the uptake of glucose into insulin-responsive tissue to meet energy needs. In the liver and skeletal muscle, insulin promotes the storage of excess glucose as glycogen. In adipose tissue, excess glucose is stored as triglyceride (TG). Insulin inhibits the breakdown of triglyceride into glycerol and free fatty acids (FFA). Amino acid uptake into muscle is increased for protein synthesis, and protein breakdown is inhibited.

Effects on Protein Metabolism. The actions of insulin on protein metabolism are also directed toward nutrient storage and growth (anabolism). Insulin stimulates the uptake of amino acids from the extracellular fluid to the cell. Once inside the cell, it promotes the synthesis of specific proteins. Insulin also conserves amino acids in existing proteins by inhibiting the breakdown of protein stores. Because insulin is required for protein synthesis, it is firmly established as an essential hormone for normal development and maintenance of healthy tissues.[46]

Effects on Fat Metabolism. The acute effects of insulin on fat metabolism are not as readily apparent as the effects on carbohydrate metabolism, but in the long run they are no less important.

Insulin favors fat storage. After a meal, carbohydrates not used for energy or stored as glycogen are converted, under the direction of insulin, to fatty acids and glycerol. These two substances combine in adipose tissue to form triglyceride, the storage form of fat. Insulin not only stimulates triglyceride storage in adipose tissue but also strongly inhibits the breakdown of stored triglyceride to free fatty acids and glycerol. Insulin blocks triglyceride hydrolysis and the liberation of free fatty acids into the circulating blood by suppressing the enzyme *hormone-sensitive lipase*. Increased free fatty acid release decreases insulin sensitivity in both muscle and liver and may also play a role in the pathology associated with type 2 DM.[49] Under ordinary conditions, insulin continually exerts a "braking" effect on free fatty acid release. A major consequence of lower concentrations of circulating free fatty acids is the decreased use of fatty acids for fuel.[45] Insulin suppresses fatty acid mobilization in the fed state when glucose is readily available to meet energy needs.

In the fasted state, when insulin levels are low, free fatty acid release is accelerated to provide metabolic fuel. The oxidation of fatty acids for energy during fasting spares glucose use.[45,46] Organic acids called *ketoacids* or *ketone bodies* are generated in the liver from fatty acid oxidation. Ketoacid production is increased in the fasted state when insulin levels are low, and it is markedly reduced when insulin levels are high. Insulin is the body's major antiketogenic hormone.[46-48]

Effects on Ion Transport. Insulin stimulates the translocation of vital electrolytes from the extracellular compartment into cells.

BOX **33-3**

Factors That Influence Insulin Release

Stimulators
- Glucose, mannose, fructose
- Amino acids
- Gastrointestinal hormones
- Acetylcholine (parasympathetic stimulation)
- β-Adrenergic stimulation

Inhibitors
- Hypoglycemia
- Somatostatin
- Glucagon, cortisol, growth hormone
- α-Adrenergic stimulation

Potassium, phosphate, and magnesium uptake into cells is mediated by an insulin mechanism.[45] Exogenous insulin administration may appreciably lower serum potassium, phosphate, and magnesium levels. The precipitation of hypokalemia secondary to vigorous insulin treatment can be of great clinical significance.

Insulin's actions are complex and wide ranging. Overall, insulin promotes the formation of complex molecules for nutrient storage and growth and fosters glucose use, instead of fat or protein, for energy.

Control of Insulin Secretion

Insulin synthesis and secretion are stimulated by "feast" or energy abundance. Ingestion of a meal (fuel excess) increases the rate of insulin secretion four- to five-fold.[48] Plasma insulin levels rise, reaching peak values 30 to 60 minutes after eating is initiated.[45] High insulin levels in turn direct nutrients to appropriate storage sites.

Between meals, insulin levels drift downward, the storage process is reversed, and metabolic substrates are mobilized in the form of glucose, free fatty acids, and amino acids. Plasma glucose is by far the most important stimulator of insulin release. Elevated plasma glucose levels directly activate β cells of the pancreas, stimulating insulin synthesis and secretion. Low plasma glucose concentrations inhibit this response. A maximal insulin response occurs at blood glucose levels of about 300 mg/dL.[45] Very little insulin, known as basal insulin secretion, is secreted at plasma glucose levels of 50 mg/dL and below.[45,49]

Amino acids also are potent stimulators of insulin release, although the β-cell response to amino acids is not as pronounced as the response to glucose. Fat has little if any stimulating effect on insulin release.[45]

Both adrenergic and cholinergic fibers of the autonomic nervous system innervate the islets. Parasympathetic vagal activity and β-adrenergic receptor stimulation increase insulin release. A general sympathetic discharge has a suppressive effect on insulin release through α-adrenergic receptor stimulation.[8] Pancreatic insulin secretion, however, does not *require* intact autonomic innervation; appropriate secretion responses occur in the transplanted pancreas as well.

Gastrointestinal hormones that accompany the digestive process potentiate insulin secretion. Food ingestion seems to send an "anticipatory" signal to the pancreas to discharge insulin in preparation for the absorption of glucose and amino acids.[46] Box 33-3 lists some of the factors that influence insulin secretion.

Glucagon

Glucagon is a linear polypeptide hormone produced by the α cells of the pancreatic islets as a biologic antagonist to insulin.[45,46] The most important role of glucagon is to enhance hepatic glucose output and increase plasma glucose. A decrease in blood glucose concentration below 90 mg/dL increases the plasma glucagon level by several-fold. Hyperglycemia, on the other hand, decreases glucagon release from the α cells.

Insulin and glucagon have opposing biologic actions. Whereas insulin is considered a hormone of energy storage, glucagon is considered a hormone of energy release.[46] Between meals, when blood glucose levels are low, the concentration of glucagon increases to maintain fuel production at a level that meets the energy needs of the individual. Special priority for glucose delivery is given to the brain.

Glucagon works in concert with the counterregulatory hormones epinephrine, GH, and cortisol. These hormones are strong defenders against hypoglycemia and are critical in restoring normal glucose levels during periods of hypoglycemic stress. They also are secreted in response to various other stresses such as infection, toxemia, severe injury, and surgery.[45] Nondiabetic surgical patients experience an increased plasma blood glucose, as much as 60 mg/dL above their preoperative levels, in response to surgical stress.[50]

DIABETES MELLITUS

Diabetes mellitus is a complex metabolic derangement caused by relative or absolute insulin deficiency. Diabetes has been called "starvation in a sea of food." Glucose is present in abundance, but because of insulin lack or insulin resistance, it is unable to reach cells for energy provision. Guidelines for diagnosing diabetes include an FPG level of 126 mg/dL or greater or a random glucose level above 200 mg/dL. The FPG diagnostic level was reduced from a previous value of 140 mg/dL based on findings that patients with an FPG of 126 mg/dL are at risk for diabetes-related complications.[51]

The incidence of diabetes has increased dramatically over the last 40 years. Today it affects nearly 26 million Americans or 8.3% of our population.[52] Diabetes is the leading cause of renal failure, blindness, and nontraumatic lower limb amputations.[52,53] Additionally, prediabetes, a condition in which blood glucose is higher than normal but below the criteria for a diabetic diagnosis, affects an estimated 79 million Americans.[52]

The rise can be attributed to a combination of three factors: (1) an overweight population, (2) more sedentary lifestyles, and (3) a rise in the elderly population.[53] As more of our population advances in age into the decades in which most cases of diabetes occur, the effect of the disease will become even more alarming. As outlined in Figure 33-10, many pathophysiologic features of DM are directly attributable to a lack of the normal effects of insulin on carbohydrate, fat, and protein metabolism.

Type 1 Diabetes Mellitus

About 5% to 10% of diabetic patients have *type 1 DM*. [52,53] This type of diabetes was formerly known as *insulin-dependent diabetes* or *juvenile-onset diabetes*. Individuals with type 1 DM have an absolute deficiency of insulin and are therefore entirely dependent on exogenous insulin therapy. In the absence of sufficient exogenous insulin, the disease course may be complicated by periods of ketosis and acidosis.

In most cases, type 1 DM is caused by an unusually vigorous autoimmune destruction of the β cells of the pancreatic islets. Environmental factors such as infection or exposure to specific antigenic proteins are cited as possible initiators of the immune assault.[54] Type 1 DM patients are also more likely to have other autoimmune diseases such as thyroid disease or Addison's disease.[55,56] A genetic predisposition for development of the disease also is involved.[48]

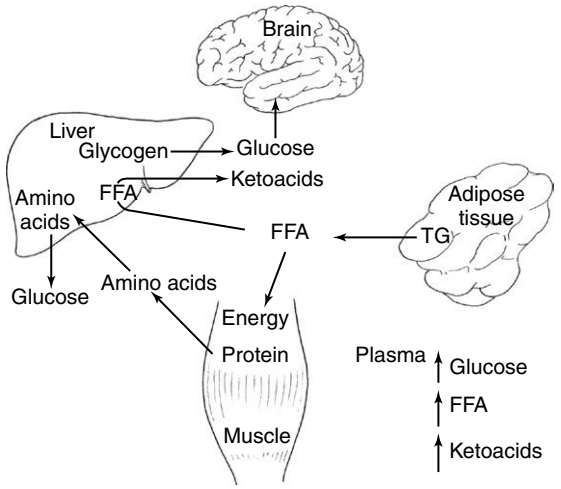

FIGURE **33-10** The pattern of substrate flow in the diabetic state. Lack of insulin enhances hepatic glucose production because of increased gluconeogenesis and glycogenolysis. The diabetic state promotes protein breakdown, and the released amino acids are converted to glucose in the liver (gluconeogenesis). Lipolysis is augmented, and this increases free fatty acid supply to the liver, resulting in enhanced ketogenesis. Free fatty acids provide an energy source to muscle and other facultative tissue. Glucose uptake by the brain is sustained. *FFA*, Free fatty acids; *TG*, triglyceride.

Type 1 DM usually develops before the age of 30 years, but it can develop at any age.[48] The classic symptoms of type 1 DM appear only when at least 80% of the β cells are destroyed.[48] The remaining β cells usually are eliminated inexorably over 2 or 3 years. In patients with type 1 DM, daily exogenous insulin therapy is essential for life. Some type 1 DM patients may be candidates for pancreatic transplant. The transplantation of isolated pancreatic islets has been plagued by graft survival and islet isolation setbacks, but it holds out promise for a future cure.

Type 2 Diabetes Mellitus

About 90% to 95% of the patients with diabetes have *type 2 DM*.[52] Type 2 DM is characterized by impaired insulin secretion, peripheral insulin resistance (a decreased number of insulin receptors or an insulin receptor or postreceptor defect), abnormal fat metabolism, and excessive hepatic glucose production.[48] Obesity is strongly associated with type 2 DM with over 80% of type 2 DM patients considered obese, primarily of the visceral or central type.[48] Type 2 DM was formerly known as *non–insulin-dependent diabetes* or *maturity-onset diabetes*.

Type 2 DM occurs in patients who have some degree of endogenous insulin production but produce quantities insufficient for sustaining normal carbohydrate homeostasis. Early in the disease process, insulin resistance contributes to an increase in insulin secretion and subsequent hyperinsulinemia. The exact mechanism causing insulin resistance remains unclear, although it is present in a number of metabolic abnormalities classified as metabolic syndrome. Eventually a decline in insulin secretion occurs, which leads to an increase in hepatic glucose production and ultimately a hyperglycemic state. Insulin levels may be low, normal, or even elevated, but a *relative* insulin deficiency exists. Typically, type 2 DM occurs in patients who are older than 30 years, obese (80%), and with a family history of the disease.[48] Type 2 DM has an insidious onset; indeed, it is estimated that half of those who have type 2 DM are not even aware of it. The disease course is rarely associated with ketosis or acidosis, but it may be complicated by a nonketotic, hyperosmolar, hyperglycemic state.

Treatment for this class of diabetes consists primarily of oral hypoglycemic agents, exercise, and diet therapy. Weight reduction in the obese diabetic patient improves tissue responsiveness to endogenous insulin and often restores normoglycemia.

The distinction between *insulin-treated* diabetics and *insulin-dependent* diabetics is important. Some type 2 diabetics may benefit from exogenously administered insulin, especially during times of illness or stress. Type 1 diabetics, on the other hand, are insulin-dependent and require exogenous insulin daily to live.

Diabetes Associated with Other Conditions

Diabetes may result from other conditions such as pancreatectomy, cystic fibrosis, or severe pancreatitis. Certain endocrine conditions, including Cushing syndrome, glucagonoma, pheochromocytoma, and acromegaly also may be associated with a diabetic state. Steroid-induced diabetes may occur in the patient taking supraphysiologic doses of glucocorticoids. Gestational diabetes occurs in approximately 2% to 10% of pregnancies in the United States.[48,52] Women who have had gestational DM have a 35% to 60% chance of developing type 2 DM 10 to 20 years postpartum.[52,53]

Insulin Deficiency

Effect of Insulin Deficiency on Carbohydrates

Insulin deficiency results in a decreased uptake and use of glucose by insulin-sensitive cells. Glycogen storage is decreased, and gluconeogenesis is uninhibited with insulin lack, causing the liver to increase its glucose output. This produces an intracellular deficit and an extracellular surplus of glucose.[45]

The hyperglycemia produced by insulin lack has immediate adverse consequences. When the blood glucose concentration increases to a threshold level (about 180 to 200 mg/dL), the amount of glucose filtered at the kidney glomerulus cannot be totally reabsorbed. The excess filtered glucose spills into the urine *(glucosuria)* and acts as an osmotic diuretic, pulling water with it. The increased urine output *(polyuria)* contributes to extracellular dehydration and electrolyte depletion. Intracellular dehydration also occurs because of the osmotic transfer of water out of cells and into the hypertonic extracellular fluid. In an attempt to compensate for the hypovolemia, the diabetic patient may drink large quantities of water *(polydipsia)*.[45,46,48]

Effect of Insulin Deficiency on Fat

As the diabetic state evolves, glucose-deprived cells meet their energy requirements by drawing on fat and protein reserves. Fat breakdown occurs normally between meals, when insulin levels are low, but it is enhanced greatly in diabetes. The lack of insulin activates hormone-sensitive lipase, which causes uninhibited lipolysis of stored triglycerides to free fatty acids and glycerol. This fat mobilization increases circulating lipids and may contribute to the atherosclerotic and angiopathic changes that complicate the disease course.[46]

Insulin deficiency produces a shift from carbohydrate to fat metabolism. Free fatty acids become the main energy substrate for essentially all tissues (the brain excluded). With uncontrolled diabetes, the excess free fatty acids are converted in the liver to ketone bodies (*acetoacetic acid*, *β-hydroxybutyric acid*, and *acetone*). This ultimately leads to greater circulating levels of ketoacids and an elevated hydrogen ion concentration in body fluids. The ketone body acetone is a volatile acid and is excreted via the lungs. Consequently, one can frequently identify ketonemia in uncontrolled diabetes by detecting a fruity "acetone breath."

Effect of Insulin Deficiency on Protein

The insulin deficiency of diabetes causes protein storage to halt and catabolism to ensue. When insulin levels are low or absent, the plasma amino acid concentration increases, and the excess circulating amino acids are converted in the liver to glucose (gluconeogenesis). The protein-wasting effects accompanying diabetes lead to weight loss, weakness, and widespread organ dysfunction. The diabetic may attempt to compensate for the protein loss and caloric drain by increasing food intake *(polyphagia)*.

Many proteins, including hemoglobin and structural tissue proteins, become glycosylated in the presence of high circulating blood glucose levels. Glucose adducts can alter protein function and may contribute to the organ damage and functional derangements observed in individuals with longstanding diabetes.[45]

Long-Term Diabetic Complications

Diabetic patients are subject to long-term complications that confer substantial morbidity and premature mortality. These complications include extensive arterial disease, cataracts, sensory and motor neuropathy, infection, and autonomic nervous system dysfunction.

Arterial thrombotic lesions in the diabetic population are widely distributed in the extremities, kidneys, eyes, skeletal muscle, myocardium, and nervous system. Owing to these diffuse lesions, diabetes carries a serious risk for the development of microvascular (e.g., nephropathy, retinopathy, neuropathy) and macrovascular (e.g., atherosclerosis, stroke, coronary artery disease) complications.[57,58] Cardiovascular disease is markedly increased in patients with DM and responsible for the cause of death in 80% of diabetic patients.[58] According to data from the Centers for Disease Control, the incidence of circulatory insufficiency to the legs and feet is four-fold to seven-fold greater in diabetic men and women compared with their nondiabetic counterparts. Gangrene is 17-fold more common in the diabetic than in the nondiabetic individual.[52,53,60] Not surprisingly, lower-extremity bypass grafting and amputations are common surgical procedures in the diabetic population. Heart disease is the leading cause of diabetes-related deaths. Cardiomyopathy in diabetic patients is independent of coronary artery disease and valvular heart disease and often progresses to impaired myocardial relaxation and ultimately diastolic dysfunction.[61] Adults with diabetes have heart disease death rates about two to four times higher than adults without diabetes.[52,53] Systolic dysfunction, decreased ejection fraction, and congestive heart failure may occur with severe and longstanding disease. Guidelines for perioperative cardiovascular evaluation, published by The American College of Cardiology/American Heart Association, list diabetes as an intermediate clinical predictor of cardiovascular risk.[62]

Further, more than 70% of diabetic individuals have a medical history of hypertension, a rate of occurrence two- to three-fold that for nondiabetic people. In many of these patients, the hypertension is uncontrolled. The risk of stroke is two to four times higher in people with diabetes, and their recovery rate after a stroke is poor.[63] Glucose-induced vasodilation further complicates an organ's ability to defend against an increase in systemic blood pressure.

The eyes are vulnerable to vascular disease because of the dense network of capillary vessels in the retina. Individuals with DM are 25 times more likely to be legally blind than individuals without DM.[48] Diabetic retinopathy is characterized by microaneurysm formation, swelling and narrowing of retinal blood vessels, and neovascularization. These vascular lesions may result in vitreous hemorrhage and retinal scarring or detachment. Loss of vision from diabetic retinopathy is the leading cause of new cases of blindness in people aged 20 to 74 years in the United States.[52,63]

Diabetic renal disease is the leading cause of end-stage renal disease in the United States.[48,60] The nephropathy may be caused by hemodynamic alterations, inflammation, and thickening of the glomerular capillary basement membrane and other structural changes in the glomerulus.[48] Renal insufficiency or chronic renal failure is often the end result. Diabetics commonly are candidates for kidney transplantation.

The diabetic process also interferes with normal nerve function. Diabetic neuropathy occurs in over 50% of individuals with longstanding disease.[48,52,53] Both the peripheral and autonomic nervous systems may be involved. Vagal denervation may occur early in the course of the disease. Dysfunction of the cardiac vagus nerve may be manifested as resting tachycardia, cardiac dysrhythmias, and the absence of heart-rate variability with deep breathing. Postural hypotension may occur in the diabetic with autonomic neuropathy as a result of dysfunctional sympathetic nervous system vasoconstrictive processes. Manifestations of orthostatic hypotension may include postural syncope, dizziness, and lightheadedness.

Diabetic patients with autonomic neuropathy are at increased risk for developing painless myocardial ischemia. The possibility of a myocardial infarction should be considered in the presence of unexplained hypotension in these patients.[64,65]

Other signs of autonomic neuropathy in the diabetic patient include early satiety, lack of sweating, impotence, and nocturnal diarrhea.[8] The patient with diabetic autonomic neuropathy has impaired gastric emptying and is at risk for aspiration of stomach contents in the perioperative period. Box 33-4 summarizes major chronic complications of DM.

There is a strong relationship between the hyperglycemia of diabetes and end-organ diseases. Sustained hyperglycemia seems to be prerequisite for significant nephropathy, retinopathy, and neuropathy to occur in type 1 and type 2 diabetes.[66,67] Other factors—genetic, environmental, or both—may have roles in determining end-organ complications. The hemoglobin A1c test, or glycosylated hemoglobin level, provides an estimate of the patient's overall plasma glucose control during the past 2 to 3 months. A value less than 7.0% suggests adequate blood glucose control.[48]

BOX 33-4

Chronic Complications of Diabetes Mellitus

Microvascular
- Retinopathy
- Neuropathy (sensory, autonomic, motor)
- Nephropathy

Macrovascular
- Coronary artery disease
- Peripheral vascular disease
- Cerebrovascular disease

Other
- Infection
- Cataracts
- Stiff joint syndrome
- Glaucoma
- Poor wound healing

Anesthetic Management of the Diabetic Patient

Diabetes is the most common endocrine disorder encountered in surgical patients. Long-standing diabetes predisposes the patient to many diseases that require surgical intervention. Cataract extraction, kidney transplantation, ulcer debridement, and vascular repair are some of the operations frequently performed on diabetic patients.

Diabetic patients have higher morbidity and mortality in the perioperative period compared with nondiabetics of similar age. Increased complications are not because of the disease itself but primarily because of organ damage associated with long-term disease.[8] Ischemic heart disease is the most common cause of perioperative mortality in the diabetic patient.[11]

Preoperative Considerations

The diabetic patient may come to the operating room with a spectrum of metabolic aberrations and end-organ complications that warrant careful preanesthetic assessment.

Cardiovascular complications account for most of the surgical deaths in diabetic patients.[8] The presence of hypertension, coronary artery disease, or autonomic nervous system dysfunctions can result in a labile cardiovascular course during anesthesia. It is essential that the cardiovascular and volume status of the patient be thoroughly evaluated before surgery. Preoperative electrocardiography is advised for all adult diabetic patients because of the high incidence of cardiac disease.

Autonomic nervous system dysfunction may result in delayed gastric emptying, making these patients prone to aspiration, nausea and vomiting, and abdominal distention. Preoperative aspiration prophylaxis with H_2-receptor blockers, gastroprokinetic agents, and/or preinduction antacids are recommended for patients with a prolonged history of poor glycemic control.[8,59,67] Intubation during general anesthesia is a logical choice for the patient with gastroparesis.

Patients with significant autonomic neuropathy may have an impaired respiratory response to hypoxia. These patients are especially sensitive to the respiratory-depressant effects of sedatives and anesthetics and require particular vigilance in the perioperative period.[8,11] Autonomic neuropathy contributes to a diminished thermoregulatory response to hypothermia requiring careful monitoring of core temperature.[59] Peripheral neuropathies (e.g., paresthesias, numbness in the hands and feet) should be adequately documented in the preanesthetic evaluation. Their presence may affect the decision to use regional anesthesia. Neuraxial blockade may exacerbate neural deficits in patients with diabetic polyneuropathy.[68]

Glycosylation of tissue proteins may produce a stiff-joint syndrome in diabetics. An estimated 30% to 40% of type 1 diabetics demonstrate restricted joint mobility.[11] Limited motion of the atlantooccipital joint can make endotracheal intubation in diabetic patients more difficult compared with nondiabetic patients.[69-71] Demonstration of the "prayer sign," an inability to approximate the palms of the hands and fingers, may help identify patients with tissue protein glycosylation and potentially difficult airways.

Evidence of kidney disease should be sought, and basic tests of renal function (e.g., urinalysis, serum creatinine, blood urea nitrogen) evaluated preoperatively. The presence of renal impairment may influence the choice and dosage of anesthetic agents, and potentially nephrotoxic drugs should be avoided. Patients should be well hydrated after radiocontrast dye exposure.

The anesthetist should examine the patient's history of glycemic control, including a fasting blood sugar on the morning of surgery, to ensure preoperative optimization of the patient's metabolic state. It is not clear what level of glycemic control is associated with the best risk/benefit ratio in the perioperative period, but a recommended target blood glucose range is 80 to 180 mg/dL.[72,73] Sustained hyperglycemia with attendant osmotic diuresis should alert the anesthetist to possible fluid deficits and electrolyte depletion. Preoperative electrolyte levels should be evaluated. Lactate-containing intravenous solutions are generally avoided because lactate conversion to glucose may contribute to hyperglycemia.

An important part of the preoperative evaluation is a review of oral hypoglycemic and insulin regimens.

Oral Glucose-Lowering Agents. Oral glucose-lowering agents and insulin are used as adjuncts to diet therapy and exercise for treating type 2 DM. Currently available oral hypoglycemic agents fall into the following classifications: (1) sulfonylureas, (2) nonsulfonylurea secretagogues, (3) α-glucosidase inhibitors, (4) thiazolidinediones, (5) biguanides, (6) DPP-4 inhibitors, (7) GLP-1 agonists, and (8) others. Often patients are on a combination of therapeutic agents. Table 33-4 lists medications commonly used to treat type 2 diabetes.

Sulfonylurea agents increase the secretion of insulin from the pancreas and thus require the presence of functioning β cells. These agents are not effective in patients with type 1 DM. Persistent and severe hypoglycemia is a possible adverse effect of sulfonylureas. The syndrome of inappropriate ADH secretion and hyponatremia has been associated with chlorpropamide, a first-generation sulfonylurea.

Newer nonsulfonylurea secretagogues such as the *meglitinides* (repaglinide) and *D-phenylalanine* (nateglinide) increase insulin production by pancreatic β cells in a manner similar to the sulfonylureas.[48,74] Caution must be used in patients with liver disease because these drugs are metabolized by the CYP34A enzyme pathway.

Acarbose (Precose) and miglitol (Glyset) are *α-glucosidase inhibitors*. These medications block the intestinal enzymes that digest starches into absorbable monosaccharides, resulting in a slower and lower rise in postprandial plasma glucose.

Rosiglitazone (Avandia) and pioglitazone (Actos) are *thiazolidinedione derivatives*. Thiazolidinediones decrease hepatic glucose output and reduce insulin resistance in the type 2 DM patient by sensitizing the insulin receptor for glucose uptake.[74] Liver enzymes must be monitored closely with these agents. The thiazolidinedione troglitazone (Rezulin) was withdrawn from the U.S. market for serious liver complications associated with the drug. In August 2007, the U.S. Food and Drug Administration (FDA) issued a "black box" warning on the drugs Avandia, Actos, and combination drugs that include these agents because of a significant increased risk of heart failure. As of November 2011, rosiglitazone has restricted availability in the United States.

Metformin, a *biguanide*, decreases hepatic glucose production and increases peripheral insulin use. Lactic acidosis, a rare but potentially fatal problem, has been reported with biguanides. Lactic acidosis is precipitated by drug accumulation; therefore, even mild renal impairment or nephrotoxicity is a contraindication to metformin therapy. Metformin is also not prescribed to patients with conditions that predispose to acidosis (e.g., liver disease, congestive heart failure).[75,76]

Sitagliptin phosphate (Januvia) is the first in a new class of oral glucose-lowering drugs known as *DPP-4 (dipeptidyl peptidase-4) inhibitors*. This class of drugs enhances insulin release from the pancreas in response to hyperglycemia. Two other DPP-4 inhibitors include saxgliptin (Onglyza) and linagliptin (Tradjenta).[74]

Exenatide (Byetta), and liraglutide (Victoza) are part of the newer class of drugs called GLP-1 (*glucagon-like polypeptide 1*) agonists also referred to as *incretin mimetics*. These drugs are approved as alternatives to starting insulin in type 2 DM and are only available via subcutaneous injection. Exenatide is derived from the saliva of the gila monster, with an amino acid sequence similar to that of human glucagon-like peptide. In the presence of glucose, the drug stimulates insulin release and lowers serum glucagon levels.[74]

Pramlintide (Symlin) is an injected antihyperglycemic medication for use in patients with type 2 or type 1 diabetes treated

TABLE 33-4 Oral Drugs for Type 2 Diabetes

Drug	Usual Daily Dosage
DPP-4 Inhibitor	
Sitagliptin (Januvia)	100 mg once
Saxgliptin (Onglyza)	2.5-5 mg once
Linagliptin (Tradjenta)	5 mg once
Sulfonylurea: First Generation	
Chlorpropamide (Diabinese)	250 to 375 mg once
Tolazamide (Tolinase)	250 to 500 mg once or divided
Tolbutamide (Orinase)	1000 to 2000 mg divided
Sulfonylurea: Second Generation	
Glimepiride (Amaryl)	1 to 4 mg once
Glipizide (Glucotrol)	10 to 20 mg once or divided
(Glucotrol XL sustained-release tablets)	5 to 20 mg once
Glyburide (DiaBeta, Micronase)	5 to 20 mg once or divided
(Glynase micronized tablets—Glynase Prestab)	1.5 to 12 mg once or divided
Alpha-glucosidase Inhibitors	
Acarbose (Precose)	50 to 100 mg tid with meals
Miglitol (Glyset)	50 to 100 mg tid with meals
Thiazolidinediones	
Rosiglitazone (Avandia) (restricted availability after November 18, 2011)	4 to 8 mg once or divided
Pioglitazone (Actos)	15 to 45 mg once
Biguanides	
Metformin (Glucophage)	1500 to 2550 mg divided
(Glucophage XR)	1500 to 2000 mg once
Glumetza (sustained release)	500-2000 mg once
Fortamet (sustained release)	1500-2500 mg once
Riomet (liquid)	1500-2550 mg divided
Nonsulfonylurea Secretagogues	
Repaglinide (Prandin)	1 to 4 mg tid before meals
Nateglinide (Starlix)	60 to 120 mg tid before meals
GLP-1 Agonists	
Exenatide (Byetta)	5 or 10 mcg subcut bid before breakfast and dinner
Liraglutide (Victoza)	1.2 or 1.8 mg subcut once
Amylin Analog	
Pramlintide (Symlin)	60-120 mcg subcut tid before main meals
Combination Drugs	
Metformin/glyburide (Glucovance)	500 mg/5 mg bid
Metformin/rosiglitazone (Avandamet)	500 mg/2 mg bid
Metformin/glipizide (Metaglip)	500 mg/2.5 mg bid
Metformin/pioglitazone (Actoplus Met)	500 mg/15 mg bid
(Actoplus Met XR sustained release)	1000 mg/15 mg once
Metformin/repaglinide (Prandimet)	500 mg/1-2 mg bid-tid
Metformin/sitagliptin (Janumet)	500 mg/50 mg bid
Metformin/saxagliptin (Kombiglyze XR)	1000-2000 mg/5 mg once
Glimepiride/rosiglitazone (Avandaryl)	4 mg/4 mg bid
Glimepiride/pioglitazone (Duetact)	4 mg/30 mg once

DPP-4 inhibitor, Dipeptidyl-peptidase-4 inhibitor; *GLP-1*, glucagon-like peptide; *subcut*, subcutaneous.

with mealtime insulin. It is a synthetic analog of human amylin, a naturally occurring hormone synthesized from pancreatic β cells that contributes to glucose control during the postprandial period. Amylin, similar to insulin, is absent or deficient in patients with diabetes.[74]

Insulin Preparations. Insulin preparations are generated today by DNA recombinant technology, mimicking the amino acid sequence of human insulin. All insulin formulations in the United States are prepared as U-100 (100 units/mL).

Insulin preparations differ in onset and duration after subcutaneous administration. In addition to subcutaneous injections, insulin delivery devices (e.g., implantable pumps, mechanical syringes) are used to facilitate exogenous administration. The greatest risk with all forms of insulin is hypoglycemia. Table 33-5 identifies major classes of exogenous insulin: rapid acting, short-acting regular, intermediate-acting, long-acting, and premixed.

It is imperative to know the surgical patient's normal insulin dosage regimen and treatment compliance. Some diabetic patients are on a fixed regimen that consists of a mixture of rapid- and intermediate-acting insulins taken before breakfast and again at the evening meal.[11] Other patients are on multiple injection regimens designed to provide more physiologic glycemic control.[48]

Insulin glargine (Lantus) and insulin detemir (Levemir) are biosynthetic human insulin analogs taken once a day. These insulins have delayed absorption from subcutaneous tissue, which prolongs their effects. Unlike neutral protamine Hagedorn and Lente, they have no peak effects, but rather provide steady plasma concentrations.[77]

Continuous subcutaneous insulin infusion is increasingly used by motivated patients desiring an optimal physiologic regimen.[78] Sophisticated infusion devices deliver small doses (microliters/min) of rapid-acting insulin lispro or insulin aspart at various programmable delivery rates. The pumps may be discontinued and a continuous insulin infusion implemented for the perioperative period. Alternatively, if continued into the perioperative period, the pump can be programmed to deliver a basal insulin dose supplemented with dextrose and potassium as needed, with rate adjustment based on serial blood-glucose measurements.[48,79,80]

Intraoperative Management

The diabetic surgical patient's operation should be scheduled early in the day if possible to minimize disruptions in treatment and nutrition regimens. Surgery produces a catabolic stress response and elevates stress-induced counterregulatory hormones.[11] In the diabetic patient, the hyperglycemic, ketogenic, and lipolytic effects of the counterregulatory hormones compound the state of insulin deficiency. For this reason, perioperative hyperglycemia and other metabolic aberrations are common in the surgical diabetic patient.

No specific anesthetic technique is superior overall for diabetic patients. Both general anesthesia and regional anesthesia have been used safely. General anesthesia, however, has been shown to

TABLE 33-5 Pharmacokinetics of Insulin Preparations

Insulin Type	Onset	Peak	Duration	Route
Long-Acting				
Insulin detemir—Levemir (Novo Nordisk)	1-4 hr	Relatively flat	12-20 hr	subcut
Insulin glargine—Lantus (Sanofi-Aventis)	1-4 hr	No peak	22-24 hr	subcut
Rapid-Acting				
Insulin aspart—Novolog (Novo Nordisk)	10-30 min	30 min to 3 hr	3-5 hr	subcut
Insulin lispro—Humalog (Lilly)	10-30 min	30 min to 3 hr	3-5 hr	subcut
Insulin glulisine—Apidra (Sanofi-Aventis)	10-30 min	30 min to 3 hr	3-5 hr	subcut
Short-Acting Regular Insulin				
Humulin R (Lilly)	30-60 min	2½-5 hr	4-12 hr	IV, subcut, IM
Novolin R (Novo Nordisk)	30-60 min	2½-5 hr	4-12 hr	IV, subcut, IM
Intermediate-Acting				
NPH				
Humulin N	1-2 hr	4-8 hr	10-20 hr	subcut
Novolin N	1-2 hr	4-8 hr	10-20 hr	subcut
Premixed Analogs				
Novolin 70/30 (Novo Nordisk) (70% NPH, human insulin isophane susp and 30% regular human insulin)	30-60 min	2-12 hr	18-24 hr	subcut
Novolog 70/30 (Novo Nordisk) (70% insulin aspart protamine susp and 30% insulin aspart injection)	10-20 min	1-4 hr	18-24 hr	subcut
Humalog Mix 75/25 (Lilly) (75% insulin lispro protamine susp and 25% insulin lispro)	10-30 min	1-6½ hr	14-24 hr	subcut

induce hormonal changes that accentuate glycogenolysis and gluconeogenesis, compounding the diabetic patient's hyperglycemic state. Regional anesthesia may produce fewer deleterious changes in glucose homeostasis.[73]

Cardiovascular autonomic neuropathy contributes to hemodynamic instability and may complicate the anesthetic course. Indeed, the compensatory mechanisms to anesthesia-induced vasodilation may be impaired, requiring the use of vasoactive drugs.[64] Withholding angiotensin-converting enzyme inhibitors preoperatively is gaining acceptance in an effort to avoid intraoperative hypotension.[61]

Special care must be taken in positioning and padding the diabetic patient on the operating table. Decreased tissue perfusion and peripheral sympathetic neuropathy may contribute to the development of skin breakdown and ulceration.

Diabetic patients represent a heterogeneous group requiring individualized perioperative care. The specific approach to metabolic management depends on the type of diabetes (type 1 or type 2), the history of glycemic control, and the type of surgery being performed. Frequent blood glucose determinations are an integral part of any diabetic management technique. A glucose meter or other accurate and rapid means of monitoring blood glucose levels should be available. During a long surgical procedure or for major surgery, at least hourly intraoperative blood glucose measurement is the prudent course for the brittle diabetic patient.

Strict control of even short-term elevations in blood glucose improves perioperative morbidity.[81,82] Persistent hyperglycemia has been shown to impair wound healing and wound strength.[83] In addition, reports suggest that postoperative infection is more prevalent in diabetic patients with uncontrolled blood sugar levels.[84,85] Studies also provide evidence that hyperglycemia worsens the neurologic outcome after ischemic brain injury.[86-88] Avoiding perioperative hyperglycemia is advisable, especially in patients at risk for acute neurologic insult (e.g., carotid endarterectomy, intracranial surgery, cardiopulmonary bypass).

Various regimens have been tendered on how to best manage the metabolic changes that occur in the surgical diabetic patient.[8,89-93] Experts differ on optimal protocols for case management and precisely defined target glucose levels. Current debate centers on the risk/benefit ratio of intensive or "tight" blood glucose control versus "nontight" control during surgery. The universal goal with all techniques is to avoid hypoglycemia and minimize metabolic derangements. Patients under anesthesia are generally maintained with a mild transient hyperglycemia to avoid the potentially catastrophic effects of hypoglycemia.[8,72] Frequent blood glucose determinations during surgery and in the immediate postoperative period are central to safe practice.[11]

Following are three different approaches to the metabolic management of the adult surgical diabetic patient, but the reader should note that there are numerous variations.

Intermediate-Acting Insulin Use. This is a traditional nontight method of managing the surgical diabetic patient and involves less intensive control of plasma glucose but aims to avoid marked hyperglycemia and dangerous hypoglycemia. Variations of this technique are used for stable diabetics undergoing elective operative procedures.[8,11]

1. On the morning of surgery, fasting blood sugar level is measured.
2. An intravenous (IV) infusion containing 5% dextrose is started at 100 to 150 mL/hr.

3. After the IV infusion is started, half of the patient's normal morning intermediate- or long-acting insulin dose is administered subcutaneously.
4. The glucose-containing IV infusion is continued throughout surgery. Additional fluid requirements are met with the administration of a second glucose-free infusate.
5. Blood glucose levels are checked every 1 to 2 hours during surgery.
6. If the blood glucose level exceeds an established maximum level, commonly 180 mg/dL, regular insulin is administered according to an established "sliding scale." Insulin sensitivity varies markedly from one patient to the next, but on the average, 1 unit of regular insulin can be expected to decrease the blood glucose level 40 to 50 mg/dL.[94] This time-tested regimen is easy to implement, and it is usually successful in preventing significant hypo- or hyperglycemia.[8,95,96]

The disadvantages of this technique are as follows:

1. Absorption of preoperatively administered subcutaneous insulin is unpredictable and erratic in the surgical patient because of blood pressure, blood flow, and temperature variations that occur with anesthesia.
2. The onset and peak effect of the preoperative intermediate-acting insulin may not correspond to the time of surgical stress, especially if the operation is delayed or prolonged.
3. The half-life of regular insulin is short, and a "rollercoaster" glucose profile may occur. Plasma glucose levels will vary considerably.

Insulin Infusion. An insulin intravenous infusion management technique may be used to maintain the blood glucose concentration within relatively narrow boundaries. Intensive perioperative regulation of blood glucose prevents hyperglycemia, but it carries the risk of hypoglycemia, and therefore necessitates more frequent blood glucose assays.[8,73,81] Regular insulin infusion may range from 0.5 to 5 units/hr, depending on the clinical situation and insulin resistance.[48] Intraoperative insulin infusion may be considered for the type 1 diabetic having major or prolonged surgery, the poorly controlled diabetic, the pregnant diabetic, the diabetic undergoing coronary artery bypass grafting, and the diabetic with serious concurrent illness.[8] An example of this regimen would be as follows:

1. On the morning of surgery, a fasting blood glucose level is measured.
2. An infusion of 5% dextrose (D_5W, 5% dextrose in water) is started at a rate of 50 mL/hr per 70-kg body weight.
3. A regular insulin infusion is begun, piggy-backed to the glucose infusion. The insulin infusion rate is set at insulin (units/hr) = last plasma glucose (mg/dL) ÷ 150. (If the patient is obese, has infection, or is on corticosteroids, the divisor is changed to 100.)
4. Blood glucose levels are measured every hour during insulin infusion and potassium levels checked after the first hour of the infusion.
5. Additional fluid requirements are met with the administration of a second glucose-free infusate.

Blood glucose levels less than 80 mg/dL may be treated with $D_{50}W$ and remeasured in 30 minutes. In a 70-kg patient, 15 mL of $D_{50}W$ can be expected to raise the blood glucose concentration by about 30 mg/dL. Surgical patients undergoing renal transplantation or coronary artery bypass graft procedures, obese and septic patients, and patients on steroid therapy usually have higher insulin-infusion requirements.[8,92,97]

The advantages of tight glucose management in the perioperative period are as follows:

1. The insulin infusion can be finely regulated to correspond to hourly variations in blood glucose levels.
2. Periods of hyperglycemia are less likely. Deleterious effects of hyperglycemia (e.g., hyperosmolarity, osmotic diuresis, impaired wound healing, infection) may be prevented.
3. The insulin-glucose infusion can be continued into the postoperative period until the patient is ready to eat, at which time subcutaneous insulin or an oral hypoglycemic agent can be reinstated.

Type 2 Diabetes and Oral Hypoglycemic Agents. Patients treated with oral hypoglycemic agents demand the same individualized perioperative management as those with type 1 diabetes. The duration of action of the patient's oral agent must be noted.

For the well-controlled surgical patient with type 2 diabetes who is scheduled for minor to moderate surgery, the patient's short-acting oral hypoglycemic agent may be continued until the evening before surgery. Discontinuing long-acting agents 2 to 3 days before surgery and converting to shorter-acting agents or insulin affords better perioperative glucose control.[97] Metformin should be discontinued 2 days or more before surgery because the surgical risks of hypotension and renal hypoperfusion place patients on this drug at increased risk for lactic acidosis.[75,76]

Glucose-containing fluids may be administered intraoperatively to protect against possible residual effects of oral hypoglycemic agents. Other experts adhere to a "no glucose, no insulin" technique for well-controlled type 2 diabetic patients. Regardless of the technique chosen, plasma glucose should be measured regularly throughout the procedure and hyperglycemia treated with insulin on a "sliding" scale.[95,96]

Acute Derangements in Glucose Homeostasis

Hypoglycemia

Hypoglycemia is encountered more often in the diabetic patient than in the healthy adult, and it can develop insidiously during the perioperative period.

Medications (e.g., insulin, sulfonylureas, β-adrenergic receptor blocking agents) and toxins (e.g., ethanol) are common causes of hypoglycemia. Severe liver disease (impaired hepatic glucose output), the altered physiology associated with gastric bypass surgery, sepsis, or an insulin-secreting tumor of the islets of Langerhans (an insulinoma) are conditions that are often complicated by hypoglycemia.

The blood glucose concentration at which signs and symptoms of hypoglycemia appear varies widely from one person to the next, but blood glucose levels in the range of 45 to 50 mg/dL commonly produce mild symptoms in the otherwise healthy patient. Because the brain is the predominant organ of glucose consumption, it is most sensitive to glucose deprivation.[46,47,98] Manifestations of impaired cerebral function (e.g., confusion, dizziness, headache, weakness) are associated with glucose lack. As the blood sugar level declines below 50 mg/dL, aberrant behavior, seizures, and loss of consciousness may occur. Other signs of hypoglycemia (e.g., tachycardia, diaphoresis, anxiety, tremors, piloerection, pupillary dilation, and vasoconstriction) reflect sympathetic-adrenal hyperactivity.[46] Acute treatment for the hypoglycemic surgical patient is the intravenous administration of 25 to 50 mL of 50% dextrose, followed by a continuous infusion of 5% dextrose.[11,48] Unless prompt glucose therapy is provided, irreversible brain damage may result.

Hypoglycemia is potentially catastrophic during surgery because most of the neural indications of glucose lack are masked by general anesthesia. Signs of sympathetic adrenal discharge also may be blunted by general anesthesia or severe diabetic autonomic neuropathy, making the diagnosis of hypoglycemia extremely difficult. β-Adrenergic receptor blocking agents can reduce the hyperglycemic effects of epinephrine, in addition to diminishing the

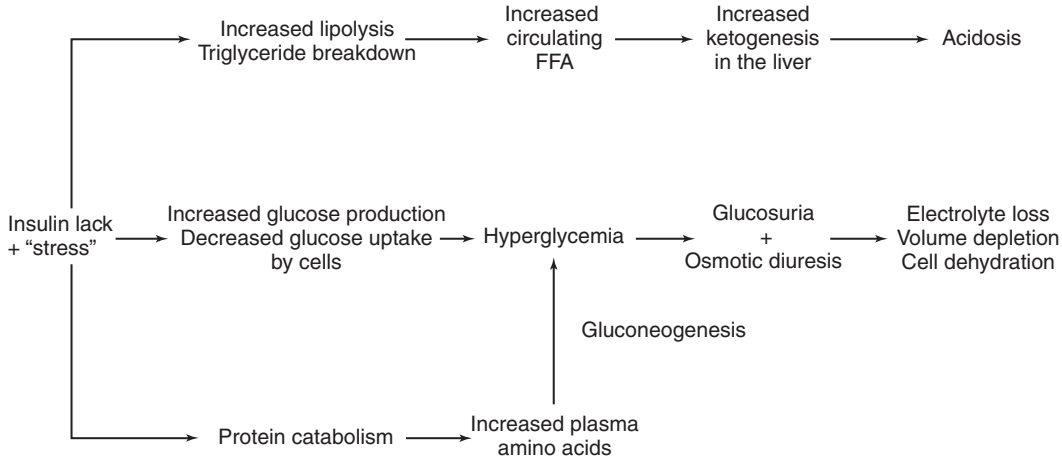

FIGURE **33-11** Substrate flow with diabetic ketoacidosis. *FFA*, Free fatty acid.

symptomatic warning signs of hypoglycemia.[48,98] Frequent blood glucose determinations, maintenance of mild hyperglycemia, and diligent monitoring help to avoid this serious complication during anesthesia.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is a medical emergency with a mortality rate of 5% to 10% (National Diabetes Information Clearinghouse [NDIC], 2011). DKA is triggered by a hyperglycemic event, usually in a patient with type 1 DM. Treatment errors, critical illnesses (e.g., myocardial infarction, trauma, cerebral vascular accident, burns), and infections are common precipitants of DKA.[99,100,101]

Stressful events stimulate the release of hyperglycemic counterregulatory hormones (e.g., glucagon, GH, epinephrine, cortisol).[46,48] The insulin-dependent diabetic is unable to secrete insulin to counterbalance the serum elevations of glucose, free fatty acids, and ketone bodies produced by these stress-induced hormones. Unless exogenous insulin is provided, the glycemic event may progress to severe ketoacidosis, dehydration, and acute metabolic decompensation.

DKA usually develops over 24 hours. Major signs and symptoms include hyperglycemia, volume depletion (average fluid deficit 5 L), tachycardia, metabolic acidosis, a calculated anion gap greater than 10, electrolyte depletion, hyperosmolarity (greater than 300 mOsm/L), nausea and vomiting, abdominal pain, and lethargy.[48,99] Blood levels of ketone bodies are elevated to above 5 mEq/L, and the patient's breath may have a fruity odor from excess acetone production. The respiratory center is typically stimulated by the low plasma pH, resulting in rapid, deep breathing (*Kussmaul respiration*). Acidosis, hyperosmolarity, and dehydration may depress consciousness to the point of coma.[48,99,100] Hypotension, hyperkalemia, and tissue catabolism also may be present. Figure 33-11 outlines the pathophysiologic events leading to diabetic ketoacidosis.

Gangrene and infection of an ischemic lower extremity are common surgical conditions associated with DKA. Preoperative management of the surgical patient with DKA requires an aggressive approach to restore intravascular volume, correct electrolyte abnormalities, improve acid-base balance, and reduce blood glucose levels with intravenous insulin.[48,99,100] The airway must be protected in the obtunded patient. Once the surgical problem that initiated DKA has resolved, medical management often is more effective.[8,101]

TABLE 33-6 Features of Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar Syndrome (HHS)

	DKA	HHS
Plasma glucose	Greater than 250 mg/dL	Greater than 600 mg/dL
pH	Less than 7.3	Greater than 7.3
Serum bicarbonate	Less than 18 mmol/L	Greater than 15 mmol/L
Serum osmolarity	+	++
Ketonemia	++	Normal or slight +
Mental obtundation	Variable	Present
Hypovolemia	Present	Present
Serum potassium	Normal or slight +	Normal

+, Increase; ++, large increase.

Hyperglycemic Hyperosmolar State

Hyperglycemic hyperosmolar state (HHS) is a life-threatening hyperosmolar condition triggered by a hyperglycemic event. This syndrome commonly occurs in elderly patients with type 2 DM, but it also develops in patients with no history of diabetes. Patients generally have some endogenous insulin secretion, but the hyperglycemic episode overwhelms the pancreas and produces severe hyperglycemia and glucosuria.[48,99,100] The amount of insulin secreted is usually sufficient to prevent lipolysis and ketone production. Therefore, unlike DKA, this syndrome usually is not associated with acidosis or significant ketogenesis. Table 33-6 compares common features of diabetic ketoacidosis and HHS.

Common precipitating factors of HHS include infection, sepsis, pneumonia, stroke, and myocardial infarction.[48,99,100]

A spectrum of symptoms is associated with HHS, culminating in mental confusion, lethargy, and coma.[48,99,100] Profound dehydration is present, resulting in hypotension and tachycardia. Laboratory evaluation may reveal a biochemical profile of marked hyperglycemia, normal arterial pH, absent or minimal ketonemia, and hyperosmolarity (greater than 330 mOsm/L).[48,99,100] Despite depleted total body potassium stores, the serum potassium levels at presentation may be normal or elevated due to acidosis and insulin-lack.[48,99,100] Even with appropriate treatment, the mortality figures for HHS are substantially higher (15%) than

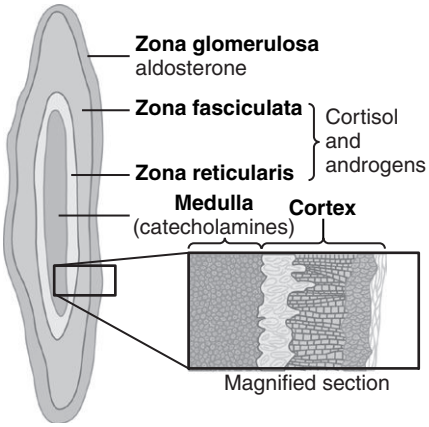

FIGURE **33-12** Secretion of adrenocortical hormones by the different zones of the adrenal cortex and secretion of catecholamines by the adrenal medulla. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011:921.)

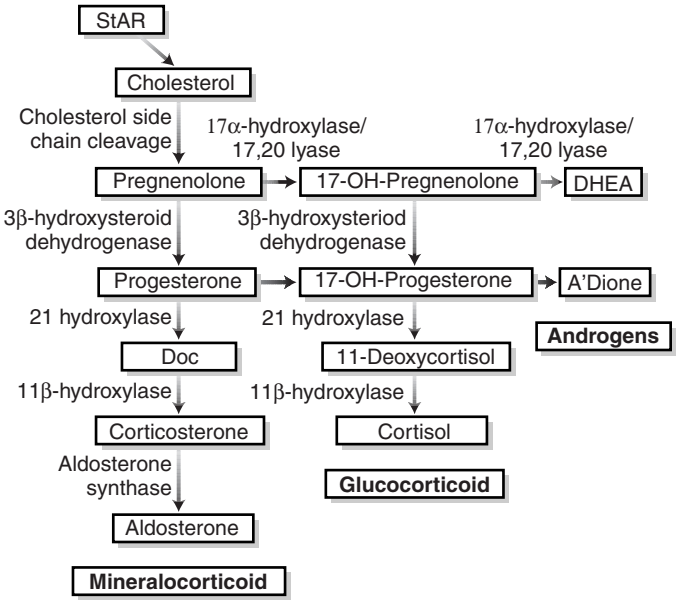

FIGURE **33-13** Adrenal steroidogenesis. Aldosterone, cortisol, and adrenal androgens are synthesized by a series of steroidogenic enzymes in a zone-specific fashion. *A'Dione,* Androstenedione; *DHEA,* dehydroepiandrosterone; *Doc,* deoxycorticosterone. those for DKA (less than 5%), in part because HHS commonly affects an older patient population, often with accompanying comorbidities.[11,48,99,100]

Treatment goals are similar to those for DKA and include identification and management of the precipitating problem, vigorous isotonic rehydration (average total body water deficit 9 L), correction of hyperglycemia, and electrolyte replacement.[48,99,100] An IV insulin infusion is necessary to reduce elevated serum glucose levels. The hazards inherent in aggressive fluid administration in the elderly patient dictate central hemodynamic monitoring during treatment.

ADRENAL GLANDS

The adrenal glands are located at the superior poles of each kidney and consist of two distinct anatomic and physiologic entities, the adrenal cortex and the adrenal medulla. The *adrenal medulla* comprises the central 20% of the adrenal gland and secretes the hormones epinephrine and norepinephrine. The *adrenal cortex* constitutes the outer part of the adrenal gland and secretes three main types of hormones: mineralocorticoids (e.g., aldosterone), glucocorticoids (e.g., cortisol), and androgenic hormones (e.g., dehydroepiandrosterone).[102]

Adrenal Cortex

The adrenal cortex is composed of three layers, each having distinct properties. The *zona glomerulosa* is the outermost tissue of the cortex; it secretes mineralocorticoid hormones. The *zona fasciculata* is the middle layer; it secretes primarily cortisol and other glucocorticoid hormones. The *zona reticularis* is the innermost layer of the adrenal cortex; it secretes primarily adrenal androgenic hormones[102,103] (Figure 33-12).

Hormones Secreted from the Adrenal Cortex

The adrenal cortex synthesizes more than 30 types of steroid hormones. All hormones secreted from the adrenal cortex have a steroidal structure and share a common cholesterol backbone. As a group, these hormones are termed *corticosteroids*. Corticosteroids have similar chemical structures but widely diverse functions.

Glucocorticoid and adrenal androgenic hormone production and release is controlled in major part by ACTH from the anterior pituitary gland. ACTH stimulates glucocorticoid hormone synthesis by activating the *P450 side chain cleavage enzyme* (P450ssc or *desmolase*). P450scc catalyzes the conversion of cholesterol to pregnenolone, the first step in corticosteroid hormone synthesis (Figure 33-13). The adrenal androgens, of which dehydroepiandrosterone is the most important, have effects similar to the male sex hormone testosterone and account for secondary sexual characteristics in females.[102] The glucocorticoids and mineralocorticoids are discussed in more detail in the following sections.

Glucocorticoids. Cortisol (hydrocortisone) is the prototypical glucocorticoid, and it accounts for 95% of the glucocorticoids released from the adrenal cortex.[103] Cortisol secretion is largely controlled by ACTH or corticotrophin. In turn, cortisol is the most potent regulator of ACTH. Cortisol has a direct negative feedback effect on the hypothalamus, inhibiting the release of corticotropin-releasing hormone (CRH), and on the anterior lobe of the pituitary gland, decreasing ACTH synthesis and release. When cortisol concentration is high, the feedback system reduces ACTH production. Figure 33-14 summarizes the mechanisms regulating cortisol release. Secretion rates of CRH, ACTH, and cortisol follow a circadian rhythm: levels are elevated in the early morning and decrease in the evening.[102,103]

The daily cortisol production is 15 to 30 mg, and most of this is produced and released in the morning.[102-104] Physical and mental stress increase the secretion of CRH, ACTH, and cortisol (Box 33-5). Stress, including surgery, typically raises cortisol production levels to more than 100 mg/day.[11,102,103,105] The normal cortisol blood concentration averages 12 mcg/dL, and this may increase to 30 to 50 mcg/dL during and after major surgery.[8,11]

After release from the adrenal cortex, cortisol circulates in the blood as free cortisol (the physiologically active form) or bound to cortisol-binding globulin (transcortin) or albumin. Approximately 90% to 95% of cortisol is transported in the bound form, and 6% is free. Cortisol is cleared from the blood in 1 to 2 hours but has a prolonged end-organ effect. Like other steroid hormones, cortisol exerts its effects by binding to target cell nuclear receptors and altering gene transcription and translation. Most of the metabolic effects of cortisol are therefore not immediate, but may take several

Inhibition
- Elevated plasma cortisol
- Opioids

ACTH, Adrenocorticotropic hormone.

hours to fully develop. Cortisol is inactivated mainly in the kidney and liver and excreted in the urine as 17-hydroxycorticosteroids.[103]

Cortisol Actions. Glucocorticoids have effects in virtually all cells in the body.[102] They are needed for the proper use of proteins, carbohydrates, and fats by the body. Glucocorticoids permit catecholamine synthesis and help mediate their effects on the heart and vasculature. Cortisol is central to the body's response to physical and mental stress.[102,103] Almost any stress, psychologic or physical, causes an immediate and marked increase in ACTH and cortisol secretion. Important perioperative stressors may include pain, anxiety, trauma, infection, intense heat or cold, and surgery. Inadequate cortisol during critical illness and surgery can lead to hypotension, shock, and death.[102,104]

Glucocorticoids have some mineralocorticoid and androgenic effects that may become especially apparent with hormone excess or supraphysiologic replacement dosages.

Effect on Carbohydrate Metabolism. Overall, glucocorticoids enhance the production of high-energy fuel for metabolic needs.[102] A key function is their ability to stimulate gluconeogenesis in the liver. The rate of gluconeogenesis increases 6- to 10-fold in the presence of cortisol.[103] Further, cortisol mobilizes amino acids from extrahepatic tissues (mainly muscle), making them available for gluconeogenesis and glycogenesis in the liver.[103] In extrahepatic tissues, cortisol moderately decreases the rate of glucose uptake and use. Cortisol is called "diabetogenic" because it increases blood glucose concentrations.

Effect on Protein Metabolism. Cortisol decreases protein synthesis and increases protein catabolism in essentially all body cells except those of the liver.[103] In the presence of sustained cortisol excess, the catabolic effects are marked. This is especially apparent in skeletal muscles, which become weak and atrophic.

Effect on Fat Metabolism. Plasma free fatty acids are mobilized from adipose tissue under cortisol's effect. Cortisol also enhances oxidation of fatty acids in the cells. In times of starvation or other stress, these two effects help shift metabolic systems to the use of fatty acids instead of glucose for energy. Excess cortisol results in a distinctive obesity, with chest, abdominal, interscapular, and facial fat expansion, leading to a "buffalo-like" torso and "moon facies."[102-104]

Effect on Inflammation and Immunity. Cortisol can diminish the body's inflammatory responses by suppressing proinflammatory cytokines. Migration of white blood cells into the inflamed area is also decreased. At pharmacologic doses, cortisol stabilizes lysosomal membranes and decreases antibody production.[102] These effects are the basis for therapeutic use of corticosteroids to reduce inflammatory responses associated with asthma, allergic reactions, and other inflammatory disorders.

Cortisol decreases the number of eosinophils and lymphocytes in the blood. T lymphocyte and antibody output are decreased from the atrophy of lymphoid tissue. As a result, with pharmacologic doses of cortisol, the level of immunity to foreign invaders of the body is reduced, and infection may ensue from infection that would otherwise not be pathologic. The ability of cortisol and other glucocorticoids to suppress immunity makes exogenous administration of these hormones useful in preventing the immunologic rejection of transplanted organs and in treating several autoimmune disorders.

Mineralocorticoids. *Mineralocorticoids* are required for life. They play a major role in the regulation of extracellular sodium and potassium ion concentrations and total body fluid balance. *Aldosterone* is the body's principal mineralocorticoid, accounting for 90% of all mineralocorticoid activity.[103] It is secreted from the zona glomerulosa, the thin zone of cells on the surface of the adrenal cortex. In large part, this zone functions autonomously of the other two adrenal cortex zones. Most distinctly, control of aldosterone secretion from the zona glomerulosa is largely independent of ACTH control (Figure 33-15). After secretion from the adrenal cortex, aldosterone circulates 60% bound to serum proteins. It has a relatively short half-life of about 20 minutes.[103]

The four main physiologic stimulants of aldosterone release are as follows, in order of importance[103]:

1. Hyperkalemia
2. Angiotensin II (activation of the renin-angiotensin system)
3. Hyponatremia
4. ACTH

With a total loss of mineralocorticoid secretion, death would ensue within days without treatment.[103,104]

Aldosterone Functions. One of our body's most significant protectors of volume status is the renin-angiotensin-aldosterone system. Renin is a proteolytic enzyme released from the *juxtaglomerular cells* of the kidney afferent arteriole in response to hypovolemia, sympathetic nervous system stimulation, hypotension, or hyponatremia.[106,107] Renin acts on the plasma protein

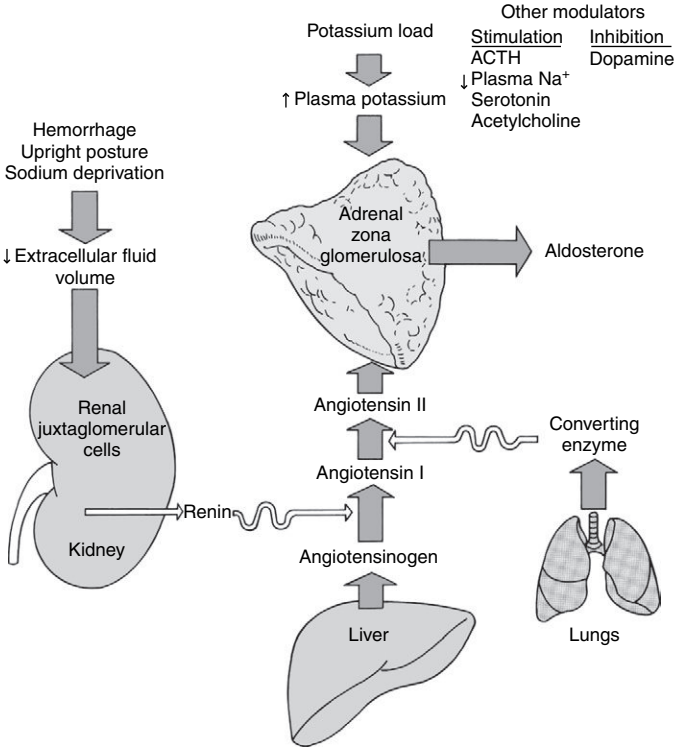

FIGURE **33-15** Regulation of aldosterone secretion. Hyperkalemia and activation of the renin-angiotensin system in response to hypovolemia are the predominant stimuli to aldosterone production. Adrenocorticotropin hormone (ACTH) has only a minor tonic stimulatory effect. (From Berne RM, et al, eds. *Physiology.* 5th ed. St Louis: Mosby; 2004:905.)

angiotensinogen to form angiotensin I (a 10–amino acid peptide), which is acted on by *angiotensin-converting enzyme* (primarily in the lung) to form angiotensin II (an 8–amino acid peptide). Angiotensin II is an extremely powerful vasoconstrictor and a potent stimulus of aldosterone synthesis and release.[102]

Aldosterone's primary target cells are *principal cells*, located in the kidney distal convoluted tubules and cortical collecting ducts. Here, aldosterone causes the reabsorption of Na^+ from the tubular fluid and in exchange, secretion of K^+ into the tubular fluid for excretion. Aldosterone's effect on the extracellular sodium ion *concentration* is limited because simultaneous with the Na^+ absorption is absorption of nearly equivalent amounts of water. Sodium and water reabsorption expands the extracellular fluid volume and elevates arterial blood pressure.[103]

Aldosterone's action on sweat and salivary glands is similar to that on renal tubules. The effect on sweat glands is important in hot environments, where body salt conservation is needed.

Disorders Associated with the Adrenal Cortex

An excess or deficiency of corticosteroids is associated with distinctive clinical syndromes.

Primary Aldosteronism. J.W. Conn described the first case of primary mineralocorticoid excess in 1954, a year after the biochemical composition of aldosterone was identified.[108] *Conn's syndrome* results from hypersecretion of aldosterone from an adrenal adenoma independent of stimulus. Primary aldosteronism also may be caused by adrenocortical hyperplasia or, rarely, carcinoma.[102] An increase in the plasma concentration of aldosterone and an increase in the urinary excretion of potassium with coexisting hypokalemia are pathognomonic of hyperaldosteronism.[102]

Manifestations of the syndrome reflect the exaggerated effects of aldosterone. Aldosterone's action of promoting renal excretion of K^+ (or hydrogen $[H^+]$) in exchange for Na^+ results in hypokalemic metabolic alkalosis. Hypertension associated with mineralocorticoid excess results from aldosterone-induced sodium retention and subsequent increase in extracellular fluid volume. Sodium levels tend to be normal due to concurrent fluid retention.[102,106,107] Primary aldosteronism accounts for less than 1% of all cases of hypertension.[11]

Primary aldosteronism is associated with low renin levels, a result of the elevated blood pressure's negative feedback to the juxtaglomerular cells. With *secondary hyperaldosteronism* the stimulus of excess aldosterone resides outside of the adrenal gland and is often associated with an increase in circulating renin levels.[102]

Treatment. Treatment of primary aldosteronism involves surgical removal of the adenoma or medical management. Surgical intervention is more successful for primary aldosteronism caused by adrenocortical adenoma than for gland hyperplasia because adenomas are almost always unilateral. When the affected adrenal gland is removed, the patient is cured in most cases. For patients with adrenal hyperplasia, pharmacologic antagonism of the mineralocorticoid receptor with spironolactone or eplerenone has been used successfully.[102,109]

Management of Anesthesia. Preoperative management of the patient with Conn's syndrome includes correcting electrolyte and blood glucose levels and managing hypertension.[8,11] Potassium should be replaced slowly to allow for equilibration of intracellular and extracellular potassium stores. Severe hypokalemia may produce muscle weakness and enhance nondepolarizing muscle relaxant responses, making peripheral nerve stimulation monitoring especially valuable. Electrocardiographic signs of potassium depletion include prominent U waves and arrhythmias. Plasma electrolyte concentrations and acid-base status should be checked often during the perioperative period. Inadvertent hyperventilation may further decrease plasma potassium concentration.

Hypertension may be controlled preoperatively with sodium restriction and aldosterone antagonists such as spironolactone.[110,111] Spironolactone, 25 to 100 mg every 8 hours, slowly increases potassium levels by inhibiting the action of aldosterone on the distal convoluted tubule. Patients with primary aldosteronism have a higher incidence of left ventricular hypertrophy, albuminuria, and stroke than patients with essential hypertension.[102,110,111] Measurement of cardiac filling pressures may be needed to assess fluid volume status in the perioperative period.[11]

Laparoscopic adrenalectomy is advocated as the operation of choice for surgically remediable mineralocorticoid excess. Compared with open laparotomy, patients who undergo laparoscopic adrenalectomy have similar improvement in blood pressure control and correction of hypokalemia.[112,113]

Glucocorticoid Excess (Cushing's Syndrome). *Cushing's syndrome* is a diverse complex of symptoms, signs, and biochemical abnormalities caused by excess glucocorticoid hormone. Clinical features reflect cortisol excess, either from overproduction of the adrenal cortex or exogenously administered glucocorticoid (Box 33-6). The catabolic effects of cortisol result in muscle atrophy and skin that is thin, atrophic, and unable to withstand the stresses of normal activity. The clinical picture includes central obesity with thin extremities, glucose intolerance, plethoric facies, purplish striae, muscle weakness, easy bruising, and osteopenia.[102,103] Mineralocorticoid effects include fluid retention and hypokalemic alkalosis. Most patients are hypertensive. Women manifest a degree of masculinization (e.g., hirsutism, hair thinning, acne, amenorrhea), and men manifest a degree of feminization (e.g.,

gynecomastia, impotence) due to androgenic effects of glucocorticoid excess.[102,103]

Causes of Cushing's syndrome can be ACTH-dependent (e.g., pituitary adenoma, ectopic secretion of ACTH by nonpituitary tumor), ACTH-independent (e.g., adrenal tumor, adrenal carcinoma), or iatrogenic (e.g., administration of supraphysiologic doses of glucocorticoids for conditions such as arthritis, allergies, and asthma). Overall, the most common cause of Cushing's syndrome today is the pharmacologic administration of glucocorticoids for various autoimmune and inflammatory conditions.[102]

Cushing's disease, first described by Harvey Cushing in 1932, specifically denotes an anterior pituitary tumor cause of the syndrome, and it accounts for 75% of all cases of endogenous Cushing's syndrome. The pituitary tumor produces excessive amounts of ACTH and is associated with bilateral adrenal hyperplasia.[102] Patients often develop skin pigmentation as a result of the melanocyte-stimulating properties of ACTH.

Ectopic Cushing's syndrome results from autonomous ACTH production by extrapituitary malignancies. Bronchial, thymic, or pancreatic carcinoid tumors account for most of these cases.[114] Small cell lung cancer and medullary carcinoma of the thyroid also can cause ectopic production of ACTH.[102,115]

About 5% to 10% of the cases of endogenous Cushing's syndrome are caused by autonomous cortisol production (ACTH-independent) by an adrenal tumor, usually an adenoma, and most often unilateral.[102] This form of hyperadrenalism is associated with suppressed plasma ACTH levels.[102-104] Adrenal tumors that are malignant are usually large by the time Cushing's syndrome becomes manifest.

Diagnosis. A widely used test for the diagnosis of hyperadrenocorticism is measurement of the plasma cortisol concentration in the morning after a dose of dexamethasone.[114] Dexamethasone suppresses CRH, ACTH, and plasma cortisol secretion in normal patients but not in those with endogenous hyperadrenocorticism. Diagnosis of Cushing's syndrome also may be based on elevated levels of salivary cortisol and urinary free cortisol.[102,114]

Treatment. Treatment for Cushing's syndrome depends on the cause. For Cushing's disease, selective removal of the pituitary corticotrope tumor (microadenomectomy), usually by a transsphenoidal approach is the primary treatment option.[114,116] Complications occur in less than 5% of patients and include diabetes insipidus (usually transient) and cerebrospinal fluid rhinorrhea.[99]

Management of Cushing's syndrome caused by an adrenal tumor consists of surgical removal. For smaller adrenal adenomas, a minimally invasive laparoscopic approach can be employed.[114,117] For larger tumors or those suspected of malignancy, an open laparotomy is preferred.[102] Because the contralateral adrenal gland is preoperatively suppressed, glucocorticoid replacement may be necessary for several months after surgery until adrenal function returns.[102,118]

The treatment of choice for an ectopic ACTH-secreting tumor is surgical removal, but this may not always be feasible because of the nature of the underlying process (e.g., metastatic carcinoma).[115] Ketoconazole, an antifungal drug that blocks the early stages of steroid synthesis, or metyrapone, an 11-β-hydroxylase inhibitor may be used to help normalize cortisol levels. Mitotane, an agent that blocks steroidogenesis at several levels, is used to treat cancer of the adrenal gland that cannot be treated with surgery.[102]

Management of Anesthesia. Important perioperative considerations for the patient with Cushing's syndrome include normalizing blood pressure, blood glucose levels, intravascular fluid volume, and electrolyte concentrations.[8,11] The aldosterone antagonist spironolactone effectively decreases extracellular fluid volume and corrects hypokalemia under these conditions.

Osteopenia is an important consideration in positioning the patient for the operative procedure.[8] Special attention must be given to the patient's skin, which can easily be abraded by tape or minor trauma. Glucocorticoids are lympholytic and immunosuppressive, placing the patient at increased risk for infection and mandating particular enforcement of aseptic techniques as indicated.[8,102]

The choice of drugs for induction and maintenance of anesthesia is not specifically influenced by the presence of hyperadrenocorticism.[8,11] Muscle relaxants may have a more exaggerated effect in patients with hypokalemia and preexisting myopathy, and a conservative approach to dosing is warranted when significant skeletal muscle weakness is present.

If adrenal resection or microadenomectomy is planned, glucocorticoids may be indicated postresection, administered at doses equivalent to adrenal output for maximum stress (hydrocortisone, 100 mg, IV, over 24 hours).[11]

Thromboembolic phenomena occur more often in patients with Cushing's syndrome, with an 11% incidence of deep venous thrombosis and a 2% to 3% incidence of pulmonary embolus postoperatively. The thromboembolic events are believed to be secondary to the prevalence of obesity, hypertension, elevated hematocrit, and increased factor VIII levels.

Primary Adrenocortical Insufficiency (Addison's Disease). In 1855, an English physician, Dr. Thomas Addison, first described a relatively rare clinical syndrome characterized by wasting and skin hyperpigmentation and identified its cause as destruction of the adrenal glands. *Primary adrenocortical insufficiency (Addison's disease)* becomes apparent when 90% of the gland is destroyed. Tuberculosis is a common cause of primary adrenocortical insufficiency worldwide, but in the United States, most cases are the result of autoimmune destruction.[102,119] Less commonly, primary adrenal insufficiency is congenital or caused by infection, adrenal hemorrhage, malignancy, or trauma.[102] Human immunodeficiency virus infection is the most common infectious cause of primary adrenal insufficiency in the United States.[120]

Clinical symptoms of Addison's disease reflect destruction of all cortical zones, resulting in adrenal androgen, glucocorticoid, and mineralocorticoid hormone deficiency[105,120] (Box 33-7). Weakness and fatigue are cardinal features. Reduced appetite with weight loss, vomiting, abdominal pain, and diarrhea are frequently reported. Hypoglycemia is often present.[121] Volume depletion is a common feature of the disease and may be manifested by orthostatic hypotension. Hyponatremia and mild acidosis are commonly revealed by laboratory screening.

BOX **33-6**

Clinical Features of Glucocorticoid Excess (Cushing Syndrome)

- Hyperglycemia
- Hypertension
- Weight gain; central obesity; fat pad on back of neck ("buffalo hump"); moon face
- Increased susceptibility to infection; increased leukocyte count
- Hypokalemia
- Alkalosis
- Hirsutism; acne
- Osteopenia
- Muscle weakness
- Skin stria; ecchymoses; facial plethora
- Mood disorders

Hyperkalemia may be evident, and is associated with serious cardiac toxicity and dysrhythmias.[103,121]

The adrenal-pituitary axis is intact in primary adrenal insufficiency, and ACTH concentrations are elevated as a result of the reduced production of cortisol. Increased melanin formation in the skin and hyperpigmentation of the knuckles of the fingers and toes, knees, elbows, lips, and buccal mucosa are distinguishing features.

Treatment. Treatment for adrenal insufficiency aims to replace both glucocorticoid and mineralocorticoid deficiency.[102] Normal adults secrete about 15 to 30 mg of cortisol (hydrocortisone) and about 100 to 150 mcg of aldosterone per day. Corticosteroids used for therapy aim to replace physiologic mineralocorticoid and glucocorticoid effects (Table 33-7).[11,102,104,119,120] Patients with Addison's disease are highly susceptible to the deteriorating effects of stress and require supplementation of standard replacement dosages[103,105,119] (see Perioperative Steroid Replacement).

Secondary Adrenocortical Insufficiency. Secondary adrenocortical insufficiency is caused by ACTH deficiency from two primary etiologies: (1) iatrogenic hypothalamic-pituitary-adrenal (HPA) axis suppression after exogenous glucocorticoid therapy, or (2) ACTH deficiency secondary to hypothalamic or pituitary gland dysfunction (e.g., tumor, infection, surgical or radiologic ablation).

Iatrogenic suppression of the HPA axis may follow long-term treatment with glucocorticoids, resulting in negative feedback to the hypothalamus and pituitary, decreased ACTH output, and eventual adrenal cortex atrophy.[11,120,121] The longer the duration of glucocorticoid administration, the greater the likelihood of suppression.[122] Sustained and clinically important adrenal suppression usually does not occur with treatment of 5 mg/day or less of prednisone or steroid treatment for periods less than 14 days.[120,123] Treatment periods long enough to provoke signs of Cushing's syndrome are usually associated with adrenal suppression of clinical importance.[121,124]

Clinical manifestations of secondary adrenal insufficiency resemble the primary disease, except secondary insufficiency is less likely to be associated with severe hypovolemia, hyperkalemia, or hyponatremia because mineralocorticoid secretion is usually preserved.[11,124] Hyperpigmentation is absent because ACTH levels are low.

Acute Adrenal Crisis. Acute adrenal crisis is a sudden exacerbation or onset of severe adrenal insufficiency. It is a rare event associated with high morbidity and mortality if allowed to progress unrecognized.[125,126] A patient with chronic adrenal insufficiency may deteriorate rapidly into an acute insufficiency state as a result of some superimposed stress, such as infection, acute illness, or sepsis. The stress of surgery or trauma in the patient with inadequate adrenal reserves can precipitate acute adrenal crisis in the perioperative period.[8,125,126]

Symptoms of adrenal crisis reflect acute deficiency of corticosteroids and include severe weakness, nausea, hypotension, fever, and decreasing mental status. In the surgical setting, hemodynamic instability or cardiovascular collapse may herald adrenal crisis. The index of suspicion for adrenal crisis should be particularly high if the patient has hyperpigmentation, hyponatremia, and/or hyperkalemia; a history of autoimmune disease (hypothyroidism, diabetes); or recent prior use of exogenous steroids.[121,124] The anesthetist should be mindful of the adrenal suppressive effects of etomidate.[119,127] Even a single dose of etomidate for induction of anesthesia can cause acute adrenocortical insufficiency and should be avoided in patients susceptible to adrenal insufficiency.[127,128]

Acute adrenal crisis is a medical emergency requiring aggressive treatment of the steroid insufficiency and associated hypoglycemia, electrolyte imbalance, and volume depletion. Early recognition and intervention are crucial steps in altering the course of acute adrenal insufficiency. Initial therapy begins with rapid intravenous administration of a physiologic saline solution with continuous cardiac monitoring.[102,119,125,126] If the patient is hemodynamically unstable, inotropic support may be necessary. Steroid

BOX 33-7

Clinical Features of Primary Adrenocortical Insufficiency

- Hypoglycemia
- Hypotension
- Anorexia, weight loss
- Nausea; vomiting; abdominal pain

*Glucocorticoid and mineralocorticoid activities of the steroids are relative to cortisol, with cortisol being 1.0.

replacement therapy begins with hydrocortisone, 100 mg IV, followed by hydrocortisone, 100 to 200 mg IV over 24 hours.[102,119] Mineralocorticoid effects are present at these doses.[102]

Perioperative Steroid Replacement. Case reports of perioperative cardiovascular collapse in surgical patients on pharmacologic doses of glucocorticoids were first reported in 1952.[122,129] These reports and subsequent knowledge regarding the stress response associated with surgery and the suppression of the HPA axis with supraphysiologic doses of corticosteroids has led to the practice of administering perioperative glucocorticoids to patients who have taken steroids in the preoperative period.

Synthesis and secretion of cortisol can increase 5- to 10-fold under conditions of severe stress, such as surgery, trauma, or infection.[8,120] In general, major surgery of long duration produces a greater adrenal output response than minor surgery of short duration.[122] For the adult patient who has received supraphysiologic doses of glucocorticoids (oral, topical, or inhaled), it may take 6 to 12 months from the time of discontinuation of steroids for the adrenal gland to recover full function.[11,120,130]

Debate exists regarding who should receive perioperative steroid coverage and what the appropriate steroid dose should be.[105,120,131] Many experts suggest that patients are at risk for adrenal insufficiency (AI) and therefore require steroid supplementation if the following have occurred[8,11]:

1. They have taken pharmacologic doses of glucocorticoids greater than 5 mg prednisone equivalent per day (5 mg prednisone is approximately bioequivalent to 20 mg hydrocortisone).
2. The period of treatment was for 2 to 3 weeks or longer.
3. The treatment occurred during the immediate 12 months before surgery.

Under these conditions, supplemental intravenous administration of hydrocortisone is advocated to compensate for the amount the body may be unable to produce in response to maximal stress.[11,122] The precise amount of glucocorticoids required for adequate supplementation has not been established. Therapeutic aims are to tailor the steroid dose considering the length and severity of surgical stress, while administering the minimal dose that will fully protect the patient.[105,120,124] A common perioperative protocol for steroid supplementation is included in Table 33-8. If the surgical patient is undergoing treatment with glucocorticoids at the time of surgery, supplemental doses are administered in addition to the patient's daily maintenance dose.[8,11,105,120]

The benefits of perioperative steroid supplementation are tempered by the potentially negative effects of decreased glucose tolerance, induction of stress ulcers, immunosuppression, and impaired wound healing.[120] Because acute adrenal crisis is life threatening, most clinicians believe that the potential risks associated with short-term glucocorticoid administration are outweighed by the benefits.[8,11,105]

Adrenal Medulla

The adrenal medulla is a catecholamine-producing endocrine gland that is derived embryologically from neuroectodermal cells. The gland is enervated by preganglionic cholinergic fibers of the sympathetic nervous system and can be thought of as analogous to a postganglionic neuron. Preganglionic fibers bypass the paravertebral ganglia and run directly from the spinal cord to the adrenal medulla. Epinephrine accounts for approximately 80% of the hormone secreted by the adrenal medulla, and norepinephrine accounts for 20%. The majority of norepinephrine synthesized in the adrenal medulla is converted to epinephrine by the enzyme *phenylethanolamine-N-methyltransferase (PNMT)*. The ability of the adrenal medulla to synthesize epinephrine is probably influenced by the flow of glucocorticoid-rich blood from the cortex through the medulla because high concentrations of glucocorticoids stimulate the enzyme PNMT (Figure 33-16).

Catecholamines in the adrenal medulla are stored in chromaffin granules.[132,133] Stimulation of the sympathetic nerves to the adrenal medulla causes large quantities of epinephrine and norepinephrine to be released into the circulation. The effects of circulating epinephrine and norepinephrine are similar to the effects of direct sympathetic stimulation but last 5 to 10 times longer because of the slow removal of these hormones from the blood. Norepinephrine and epinephrine are metabolized in the liver and kidney by the enzyme *catechol-O-methyltransferase*. The byproducts of metabolism, vanillylmandelic acid (VMA) and metanephrines, and free unchanged catecholamines are excreted in the urine[132,133] (Figure 33-17).

Norepinephrine stimulates α- and β-adrenergic receptors. It causes constriction of most blood vessels of the body, increasing total peripheral resistance. High circulating norepinephrine levels increase the heart's activity, inhibit gastrointestinal function, and dilate the pupils. Epinephrine has a greater affinity for β-adrenergic receptors. Its actions are seen primarily in the heart, producing chronotropic and inotropic effects. Epinephrine causes less constriction of blood vessels than norepinephrine. Norepinephrine and epinephrine release from the adrenal medulla can increase the metabolic rate of the body by as much as 100% above normal.

Pheochromocytoma

In 1905 the term *pheochromocytoma* was first used to describe the appearance of a tumor noted during autopsy resection to be a dusky *(pheo)* color *(chromo)*. Cesar Roux of Lausanne, Switzerland, and Charles Mayo of the United States were the first surgeons to successfully remove a pheochromocytoma.

Pheochromocytomas are catecholamine-secreting tumors derived most commonly from adrenomedullary chromaffin cells. The tumors synthesize, store, and secrete catecholamines, mostly norepinephrine and epinephrine. Unlike a normal adrenal medulla, most of these tumors predominantly secrete norepinephrine. In the majority of cases, however, it is impossible to predict the precise catecholamine secretion from the clinical features. The tumors are not innervated, and neural stimulation does not stimulate hormone release.[134]

TABLE 33-8 Guidelines for Perioperative Adrenal Supplementation Therapy

Type of Surgery	Hydrocortisone Dose
Superficial Surgery	
Dental Biopsies	None
Minor Surgery	
Inguinal hernia Colonoscopy	25 mg IV
Moderate Surgery	
Nonlaparoscopic cholecystectomy Colon resection Total abdominal hysterectomy Total joint replacement	50-75 mg IV, taper over 1 to 2 days
Major Surgery	
Cardiovascular Thoracic Liver	100-150 mg IV, taper over 1 to 2 days

Pheochromocytomas are sometimes broadly defined as following the "rule of 10s." They involve both adrenal glands in approximately 10% of adult patients with the tumor, 10% of the tumors arise from extraadrenal chromaffin cells, and 10% of the tumors are malignant (Table 33-9). Malignant pheochromocytomas are primarily extraadrenal and secrete norepinephrine exclusively.[135] Metastasis usually proceeds through venous and lymphatic channels to the liver.[134]

Biochemical testing and subsequent diagnosis of a catecholamine tumor is based on findings of elevated urinary or plasma catecholamines and their methylated metabolites, VMA, metanephrine, and normetanephrine (Table 33-10).[134,136-138]

Incidence and Associated Diseases. Pheochromocytomas are rare, occurring in approximately 0.1% of hypertensive patients.[134] Approximately 25% of tumors primarily arise from three inherited genetic syndromes that develop from germ-line mutations. These are von Hippel-Lindau (VHL) syndrome, multiple endocrine neoplasia type 2 (MEN 2), and Recklinghausen's disease.[14,139] Approximately 50% of patients with MEN type 2A or 2B develop pheochromocytomas[140] (Table 33-11). It is recommended that

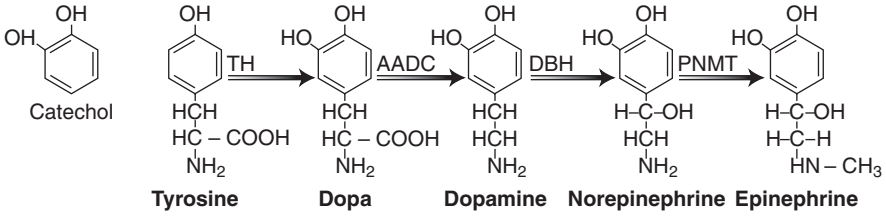

FIGURE **33-16** Biosynthetic pathway for catecholamines. The term *catecholamines* comes from the catechol (ortho-dihydroxybenzene) structure and a side chain with an amino group—the "catechol nucleus" *(left)*. Tyrosine is converted to 3,4-dihydroxphenylanine (dopa) (rate-limiting step) by tyrosine hydroxylase (TH); TH inhibitor, α-methyl-para-tyrosine (metyrosine). Aromatic L-amino acid decarboxylase (AADC) converts dopa to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β-hydroxylase (DBH). Norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT); cortisol serves as a cofactor for PNMT, which is why epinephrine-secreting pheochromocytomas are almost exclusively localized to the adrenal medulla. (From Melmed S, et al, eds. *Williams Textbook of Endocrinology*. 12th ed. Philadelphia: Saunders; 2011:546.)

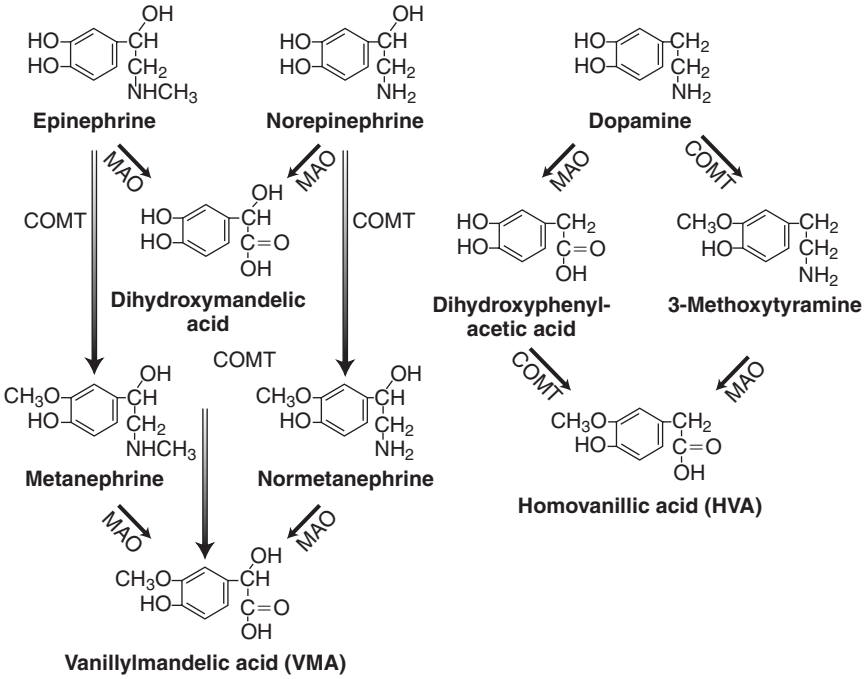

FIGURE **33-17** Catecholamine metabolism. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and converts norepinephrine to normetanephrine by meta-*O*-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by COMT to VMA. Dopamine is also metabolized by MAO and COMT to the final metabolite homovanillic acid (HVA). (Modified and redrawn from Young WF. Endocrine hypertension. In: Melmed S, et al, eds. *Williams Textbook of Endocrinology*. 12th ed. Philadelphia: Saunders; 2011:548.)

patients with a family history of MEN syndrome be regularly screened for pheochromocytoma.

Pheochromocytomas can occur at any age, but usually occur within the third to the fifth decade of life, with equal frequency in both sexes in adults.[133,141]

Clinical Manifestations. Manifestations of a pheochromocytoma reflect massive catecholamine release and include hypertension, diaphoresis, headache, tremors, and palpitations.[142] Hypertension may be paroxysmal or sustained.[134] The combination of paroxysmal diaphoresis, tachycardia, and headache in the hypertensive patient is a recognized triad of symptoms for pheochromocytoma.[8,11,133,139] Increasingly, patients are being diagnosed based on incidental radiographic findings or by having established familial syndromes.[134,140,143]

A catecholamine-mediated paroxysm typically consists of a sudden and alarming increase in blood pressure, a severe throbbing headache, profuse sweating, palpitations, tachycardia, a sense of doom, anxiety, pallor (or flushing), and nausea.[134] Orthostatic hypotension may result from plasma volume deficit or a lack of tone in the postural reflexes that defend upright blood pressure, due to the sustained excesses of catecholamines. Paroxysmal symptoms may last several minutes to days and are often followed by physical exhaustion. Clinical symptoms associated with pheochromocytoma are outlined in Table 33-12.

A paroxysm may be triggered by abdominal palpation, defecation, or any event that provokes pressure on the tumor.[134] Micturition may trigger symptoms if the pheochromocytoma is present in the urinary bladder wall. In some patients, no clearly defined precipitating factor can be found. Mental or psychologic stress does not usually initiate a crisis.[134]

Owing to the predominance of norepinephrine secretion, the symptoms associated with a pheochromocytoma reflect α-adrenergic activity over β-adrenergic effects. As a result of α-adrenergic inhibition of insulin and enhanced hepatic glucose output, hyperglycemia may be present. The cardiac output and heart rate may be significantly increased. An overall increase in metabolism accelerates oxygen consumption and can cause hyperthermia. Vasoconstriction in the extremities may produce pain, paresthesias, intermittent claudication, or ischemia.[134]

Hypertension is the most common symptom, occurring in more than 90% of patients.[133,134,136] Severe paroxysmal hypertension is present in approximately 40% of patients and is a distinctive manifestation of the disease.[133,134] Sustained hypertension is often resistant to conventional treatment. When pheochromocytomas are predominantly epinephrine secreting, hypertension can alternate with periods of hypotension associated with syncope. Hypotension reflects surges of epinephrine, causing disproportionate β-adrenergic stimulation with vasodilation in the presence of a contracted vascular space.

A catecholamine-induced increase in myocardial oxygen consumption, hypertension, and coronary artery spasm can precipitate myocardial infarction or congestive heart failure even in the absence of coronary artery disease.[11,134] Electrocardiogram (ECG) changes are common. Nonspecific ST-segment and T-wave changes and prominent U waves may be seen. Sinus tachycardia, supraventricular tachycardias, and premature ventricular contractions are commonly noted. Right and left bundle branch blocks and ventricular strain sometimes occur. Ventricular tachycardia also has been reported.[133,134]

Some pheochromocytomas may first present as a hypermetabolic state during anesthesia for unrelated surgery. The hypertension, tachycardia, hyperthermia, and respiratory acidosis of a pheochromocytoma may mimic light anesthesia, thyroid crisis, malignant hyperthermia, or sepsis.[142]

Preoperative Management. The pharmacologic effects of released catecholamines present major anesthetic challenges. Medical management prior to tumor excision aims to reverse the

TABLE 33-11 Manifestations of Multiple Endocrine Neoplasia*

Syndrome	Manifestations
MEN type 1 (Wermer syndrome)	Hyperparathyroidism, pituitary adenomas, pancreatic islet-cell tumors
MEN type 2A (Sipple syndrome)	Medullary thyroid cancer, hyperparathyroidism, pheochromocytoma
MEN type 2B (mucosal neuroma syndrome)	Medullary thyroid tumor, pheochromocytoma, neuromas of the oral mucosa, marfanoid habitus

*Multiple endocrine neoplasia (MEN) is a group of rare diseases caused by genetic defects that lead to hyperplasia and hyperfunction of two or more components of the endocrine system.

TABLE 33-9 Locations of Pheochromocytomas

Location	Percentage
Solitary adrenal	80
Extraadrenal	10
Bilateral adrenal	10

TABLE 33-10 Values for Catecholamines and Catecholamine Metabolites

Hormone/Metabolite	Normal Value
Vanillylmandelic acid, urine	2-7 mg/24 hr
Metanephrines, urine	Less than 1.3 mg/24 hr
Norepinephrine, urine	Less than 100 mcg/24 hr
Norepinephrine, plasma	150-450 pg/mL
Epinephrine, plasma	Less than 35 pg/mL
Catecholamines, free urinary	Less than 110 mcg/24 hr

TABLE 33-12 Frequency of Symptoms in Patients with Pheochromocytoma

Symptom	%	Symptom	%
Headache	80	Chest pain	19
Excessive perspiration	71	Dyspnea	19
Palpitation (with or without tachycardia)	64	Flushing or warmth	18
Pallor	42	Numbness or paresthesia	11
Nausea (with or without vomiting)	42	Blurring of vision	11
Tremor or trembling	31	Tightness of throat	8
Weakness or exhaustion	28	Dizziness or faintness	8
Nervousness or anxiety	22	Convulsions	5
Epigastric pain	22	Neck-shoulder pain	5
		Extremity pain	4
		Flank pain	4

TABLE 33-13 Drugs Used in the Management of Pheochromocytoma

Drug	Action	Pressor Crisis	Preoperative Blood Pressure Control	Comment
Phentolamine	α-Blocker	IV 2-5 mg	—	Rapid onset, short-acting; bolus every 5 min or infuse initially 1 mg/min
Phenoxybenzamine	α-Blocker	—	Oral 30 mg/day, increasing daily dosage by 30 mg	Long half-life; may accumulate; administer two or three times daily
Doxazosin	Selective α_1 antagonist	1 mg/day PO up to 8 mg/day PO	—	First-dose phenomenon; may cause syncope
Propranolol	β-Blocker	IV 1-mg bolus to total of 10 mg	Oral 40 mg bid; increase to 480 mg/day	Should not be administered without first creating α blockade
Atenolol	β-Blocker	—	Oral 50 mg/day initially; may increase to 100 mg/day	Long-acting, selective β_1 antagonist eliminated unchanged by kidney
Esmolol	β-Blocker	IV 500 mcg/kg/min loading followed by maintenance infusion	—	Ultrashort-acting selective β_1 antagonist; may be used during anesthesia
Labetalol	α- and β-Blocker	IV 10-mg bolus to 150 mg	Oral 200 mg tid	A much weaker α-blocker than β-blocker; may cause pressor response in pheochromocytoma
Nitroprusside	Vasodilator	IV infusion initially 0.5-1.5 mcg/kg/min	—	Powerful vasodilator; short-acting; may be used during anesthesia
Magnesium sulfate	Vasodilator	Initial loading dose of 50 mg/kg over 10 minutes followed by 15 mg/kg/hr	—	May potentiate neuromuscular blockade
Nicardipine	Calcium channel blocker	IV 2-6 mcg/kg/min	—	Better vasodilator than diltiazem
α-Methyl-tyrosine	Inhibitor of biosynthesis of catecholamines	—	Oral 1-4 g/day	Suitable for patients not amenable to surgery; may be nephrotoxic
Dexmedetomidine	Selective alpha 2 adrenergic receptor agonist	IV infusion: initially 1 mcg/kg over 10 minutes, then 0.5 mcg/kg/hr

effects of excessive adrenergic stimulation. Preoperative antihypertensive therapy and volume replacement have helped to decrease the surgical mortality rate from about 50% to the current 1% to 3%.[8] The preoperative use of α-adrenergic antagonists in concert with reexpansion of the intravascular fluid compartment greatly improves cardiovascular stability intraoperatively. Table 33-13 outlines drugs used in the management of pheochromocytoma.

α-Adrenergic Receptor Blockade. Phenoxybenzamine (Dibenzyline) remains the most commonly used drug for preoperative α-adrenergic blockade and blood pressure stabilization. It is a noncompetitive presynaptic (α_2) and postsynaptic (α_1) adrenergic receptor antagonist of long duration (24 to 48 hours).[133] Most patients with pheochromocytoma require an oral dose between 60 and 250 mg/day.[8,134]

Typically, patients require 10 to 14 days of α-adrenergic antagonist therapy to stabilize blood pressure, restore fluid volume, and decrease symptoms. Establishing normotension facilitates reexpansion of the intravascular fluid compartment. Satisfactory α-adrenergic blockade is implied if the hematocrit decreases by 5% during treatment.[11] Half to two thirds of the normal oral phenoxybenzamine dose may be given the morning of surgery.[8]

Prazosin (Minipress), a postsynaptic α_1-adrenergic receptor antagonist, also has been used successfully to treat the hypertension of pheochromocytoma preoperatively. The rising appeal of this selective α1-receptor antagonist is that, in theory, it leaves the α2-receptor intact, thereby inhibiting the release of norepinephrine and allowing a more effective management of blood pressure and heart rate.[144,145] Labetalol (Trandate, Normodyne), a mixed α- and β-receptor antagonist, has not been as effective as a first-line drug in controlling the blood pressure response, but it may be used as an adjunctive agent.[11,133,146]

β-Adrenergic Receptor Blockade. A β-adrenergic receptor antagonist is usually introduced in the preoperative period for control of tachycardia, hypertension, and catecholamine-induced supraventricular dysrhythmias. An important caveat is that β-adrenergic receptor antagonists should not be administered until after α-adrenergic blockade is established. Blocking β-receptor–mediated vasodilation in skeletal muscle without prior α-adrenergic blockade can increase the blood pressure even further in the patient with pheochromocytoma.[142] A helpful mnemonic for the reader is "a before b."

Other Treatment Regimens. Calcium channel blockers and magnesium sulfate infusion have been used with variable success as monotherapy for the perioperative management of pheochromocytoma. Some regimens use these agents in conjunction with adrenergic blocking drugs.[147]

To date, no specific preoperative management technique has been shown to be superior in terms of clinically significant outcomes.[147,148] The following criteria are proposed as end-points for the patient awaiting surgery for pheochromocytoma resection.[8,148]

1. No in-hospital blood pressure reading higher than 160/90 mmHg 24 hours prior to surgery
2. No blood pressure on standing lower than 80/45 mmHg
3. No ST-segment or T-wave abnormality on the ECG that cannot be attributed to a permanent defect
4. No marked symptoms of catecholamine excess; no more than one premature ventricular contraction every 5 minutes

Anesthetic Management. Effective anesthetic management is based on (1) selecting drugs that do not stimulate catecholamine release and (2) implementing monitoring techniques that facilitate early and appropriate intervention when catecholamine-induced changes in cardiovascular function occur.

The use of selective α2-receptor agonists such as clonidine and dexmedetomidine may be useful in managing blood pressure and heart rate.[149] Activating α2-receptors results in sympathetic inhibition and has been shown to reduce the release of catecholamines resulting in decreased blood pressure and heart rate.[150-153]

Pheochromocytomas are excised by open laparotomy or laparoscopy.[147,154-156] Laparoscopic resection is considered the gold standard for resection over the open approach due to better perioperative outcomes, less analgesia use, and a faster recovery period.[156-159] However, during pneumoperitoneum for laparoscopy, significant catecholamine release has been reported and should be anticipated by the anesthetist.[160]

A number of drugs and conditions can precipitate hypertension in the surgical patient with pheochromocytoma. Dopamine antagonists (metoclopramide, droperidol), radiographic contrast media, indirect-acting amines (ephedrine, methyldopa), drugs that block neuronal catecholamine reuptake (tricyclic antidepressants, cocaine), histamine, and glucagon may enhance the physiologic effect of tumor product.[11,134]

Pheochromocytomas are vascular tumors. Large-bore intravenous lines and a peripheral arterial catheter should be established preoperatively. Central venous pressure monitoring will help guide fluid management and intervention with inotropes or vasoactive drugs.[11,133] Arterial blood gases, electrolyte concentrations, and blood glucose levels should be assessed regularly during the anesthetic.

Critical intraoperative junctures are (1) during induction and intubation of the trachea, (2) during surgical manipulation of the tumor, and (3) after ligation of the tumor's venous drainage. Anesthesia induction may be accomplished with barbiturates, etomidate, or propofol. Anesthetic depth can be enhanced by mask ventilation of the lungs with a volatile anesthetic prior to laryngoscopy and intubation. Lidocaine (1 to 2 mg/kg IV) administered 1 minute prior to intubation may help attenuate the hemodynamic response to laryngoscopy. Short-acting opioids administered prior to intubation also may help blunt the blood pressure responses to intubation. Morphine sulfate should be avoided because of its propensity for histamine release. Rapid-acting vasodilating drugs such as nitroprusside should be readily available to treat hypertension.[11]

Sevoflurane and short-acting opioids provide cardiovascular stability and possess the ability to rapidly change anesthetic depth—attractive features in the anesthetic management of the patient with pheochromocytoma.[8,11,133,161] The tachycardia and increased sympathetic stimulation associated with desflurane makes it a less desirable choice for these cases.

The use of succinylcholine has been questioned because compression of an abdominal tumor by drug-induced skeletal muscle fasciculations may provoke catecholamine release. However, a predictable adverse effect of succinylcholine has not been supported clinically when administered to patients with pheochromocytoma. Skeletal muscle paralysis with a nondepolarizing muscle relaxant devoid of vagolytic or histamine-releasing effects is desirable. Pancuronium should be avoided for its known chronotropic effect.[8,11,133]

The anesthetist should anticipate a labile cardiovascular course during surgery. Hypertension can be treated with intravenous nitroprusside and high concentrations of inhaled anesthetic.[8,11,133] Lidocaine, labetalol, or esmolol may be given intravenously to decrease tachydysrhythmias. β-adrenergic receptor antagonists must be used cautiously in patients with catecholamine-induced cardiomyopathy because even minimal β-adrenergic blockade can accentuate left ventricular dysfunction.[11,133] The short half-life of esmolol makes it the preferred choice for β-adrenergic blockade. Dysrhythmias associated with hypertension may be resolved by simply lowering an abnormally high blood pressure. Indirect-acting sympathomimetics have an unpredictable pressor effect in these patients and should be avoided.

After surgical ligation of the veins that drain a pheochromocytoma, the rapid decrease in circulating catecholamines and the associated downregulation of adrenergic receptors may precipitate a decrease in blood pressure.[161] Intravenous administration of phenylephrine hydrochloride (Neo-Synephrine) or dopamine may be needed until the peripheral vasculature can adapt to the decreased level of endogenous α-stimulation. Hyperglycemia is common before excision of the pheochromocytoma. With tumor removal, the sudden withdrawal of catecholamine stimulation can result in hypoglycemia. Blood glucose levels should be monitored at frequent intervals intraoperatively and postoperatively.

Postoperative Management. Fluid shifts, pain, hypoxia, hypercapnia, autonomic instability, urinary retention, or residual tumor are all causes of postoperative hypertension. Invasive monitoring is indicated during the initial postoperative period to assess blood pressure changes and cardiac status. Fifty percent of patients remain hypertensive during the immediate postanesthesia recovery period, despite removal of the pheochromocytoma.[11,148] Postoperative catecholamine levels decrease to normal over several days. In 75% of patients, normal blood pressure returns within 14 days postsurgery.[134]

THYROID GLAND

The thyroid gland is an endocrine gland located anterior to the trachea between the cricoid cartilage and suprasternal notch. It produces and secretes two important thyroid hormones: 3,5,3-triiodothyronine (T_3) and thyroxine (T_4). The vascular supply to the gland is derived from the superior and inferior thyroid arteries. Blood flow is equivalent to about five times the weight of the gland, which is a blood supply as rich as almost any tissue in the body. The gland consists of two lobes and an isthmus. The recurrent laryngeal nerves run along the lateral borders of each thyroid lobe.[162]

Microscopically, the thyroid is divided into lobules, each of which is composed of 20 to 40 follicles. The follicles are the functional units of the thyroid gland. They are lined by epithelial cells that surround central deposits of a proteinaceous substance called *colloid*. The major constituent of the colloid is a large glycoprotein called *thyroglobulin*, which serves as the backbone for the synthesis and storage of thyroid hormones.[162]

Synthesis of Thyroid Hormones

Iodide Trapping

Approximately 1 mg of ingested iodine is required each week to form normal quantities of thyroid hormones. Dietary iodine is then reduced in the gastrointestinal tract to *iodide*. Common table salt is iodized with sodium iodide for the prevention of iodine deficiency.

The first stage of thyroid hormone formation is the transport of iodides from the extracellular fluid into the thyroid cells and follicles. About one fifth of the circulating iodide is removed from the blood by the thyroid cells and used for the synthesis of thyroid hormones, a process called *iodide trapping*. The iodide pump normally concentrates the iodide to about 30 times its concentration in the blood. Iodide trapping is the rate-limiting step in thyroid hormone synthesis and is under the control of TSH from the anterior pituitary. Once inside the thyroid gland, iodide ions are oxidized back to iodine.[162]

Thyroid Hormone Formation

Thyroid hormones are formed in the follicles of the thyroid gland under the control of TSH. Thyroglobulin contains the amino acid tyrosine, which combines with iodine to form various iodotyrosines, including the two major thyroid hormones. Thyroxine and triiodothyronine remain part of the thyroglobulin molecule, stored as colloid within the thyroid follicle until release. Enough hormone is synthesized and stored under basal conditions to supply the body with its normal hormone requirements for 2 to 3 months. As a result, if complete thyroid hormone synthesis ceases, the physiologic effects are not seen for several months.[162,163]

Although iodine is required for hormone synthesis, paradoxically, excess iodine can cause the gland to recede and inhibit production of thyroid hormone.

Release of Thyroxine and Triiodothyronine

TSH controls the release of hormones from the thyroid gland. On release, T_4 and T_3 are cleaved from the thyroglobulin molecule and secreted into the circulating blood. Thyroglobulin remains within the colloid.[162]

Under normal conditions, about 93% of the hormone released from the thyroid gland is T_4 and 7% is T_3.[162] The secretion of T_4 from the thyroid gland is 80 to 100 mcg/day. When thyroid hormones reach their target tissues, most of the T_4 is deiodinated to T_3—T_4 serving mostly as a hormone precursor. Triiodothyronine is more potent and less protein bound than T_4 and is the primary metabolically active hormone that stimulates target tissues.[163]

Transport of Thyroxine and Triiodothyronine to Tissues

Thyroid hormone exists in circulation in both free and bound forms. The amount of free hormone, which is the metabolically active fraction, is extremely small, less than 0.03% of total circulating T_4 and 0.3% of total circulating T_3. The majority of circulating hormone (99.9%) is bound to plasma proteins. Most of the thyroid hormones bind to the circulating proteins *thyroxine-binding globulin*, *transthyrotin*, and *albumin*.[164]

Because of the very high affinity of the plasma-binding proteins for thyroid hormones, the hormones are released to the tissue cells very slowly. The half-life of T_4 in the circulation is 6 to 7 days, and the half-life of T_3 is about 24 hours.[162,163]

Functions of Thyroid Hormones

Increased Cellular Metabolic Activity

Thyroid hormones initiate protein formation in virtually all cells of the body. Consequently, the level of enzymes, structural proteins, transport proteins, and other substances increases considerably under the direction of T_4 and especially T_3. The net result is a generalized increase in metabolic activity, heat production, and oxygen consumption of all or almost all tissues in the body.[164] The basal metabolic rate can increase by as much as 60% to 100% above normal when large quantities of thyroid hormones are secreted.[161] The rate and depth of respiration increase due to the enhanced metabolic rate and increased oxygen use and carbon dioxide formation by cells. The use of energy substrates is greatly accelerated. Protein synthesis is increased; however, protein catabolism also is increased. When the quantity of thyroid hormone is slightly increased, the muscles react with vigor; however, when the quantity is excessive, muscles become weakened from excess protein catabolism.

Effect of Thyroid Hormone on Growth

Thyroid hormones are necessary for normal growth in infants and children. In a hypothyroid state, the rate of tissue growth is greatly reduced. Thyroid hormone is required for normal growth and development of the brain during fetal life and for the first few years of postnatal life.[161,162]

Effect of Thyroid Hormone on Specific Systems

Thyroid hormones have direct and indirect effects on the excitability of the heart. The heart rate and the force of contraction are augmented with increasing thyroid hormone production. Vasodilation occurs from increased cellular oxygen consumption and results in increased blood flow to most tissues.[161,162]

Thyroid hormones increase the rate of hormone secretion from most endocrine glands, especially the pancreas. The heightened cellular requirement for glucose mandates higher insulin secretion. Thyroid hormones also enhance the secretion of digestive juices and the motility of the gastrointestinal tract, in addition to increasing an individual's appetite and food intake. In adults, thyroid hormones enhance the rapidity of cerebration.[161]

Regulation of Thyroid Hormone Secretion

Specific feedback mechanisms operate through the hypothalamus and anterior pituitary gland to precisely control the rate of thyroid secretion. Thyrotropin-releasing hormone (TRH) from the hypothalamus causes cells of the anterior pituitary lobe to produce and secrete TSH. Potent stimuli to TRH and TSH release include low levels of T_3 and T_4, stress, and exposure to cold.[161] TSH increases all known activities of thyroid gland cells, resulting in increased gland size and vascularity and increased hormone synthesis and release. High circulating levels of primarily T_3, and to a lesser extent T_4, inhibit the secretion of TRH and TSH through a negative feedback effect on the hypothalamus and anterior pituitary. Figure 33-18 summarizes the regulation of thyroid secretion.

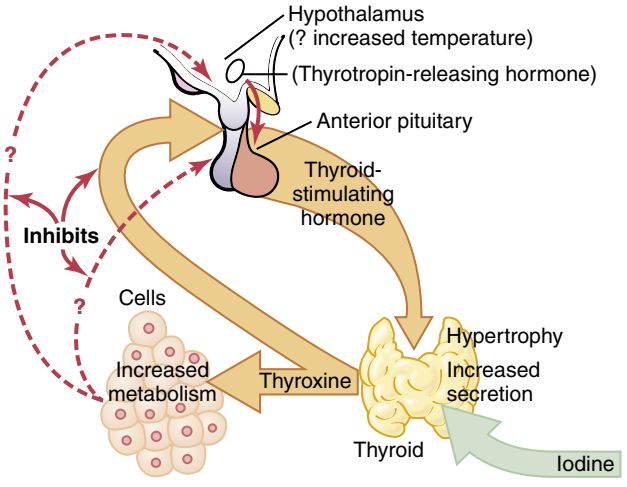

FIGURE **33-18** Regulation of thyroid secretion. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:915.)

Thyroid Gland Disorders

Thyrotoxicosis and Graves' Disease

Hyperthyroidism is defined as thyroid gland hyperactivity. *Thyrotoxicosis* is more specifically defined as a state of thyroid hormone excess.[164] The most common cause of thyrotoxicosis in the United States is *Graves' disease*, affecting approximately 0.5% of the population and accounting for 60% to 80% of thyrotoxicosis cases.[164,165] Graves' disease is an autoimmune disease in which TSH-receptor antibodies bind to and stimulate the thyroid gland, causing excessive production and secretion of T_4 and T_3.[164,165] Immunoglobulin G (IgG) autoantibodies mimic the action of TSH, but their effects are longer, lasting up to 12 hours compared with 1 hour for normal TSH.[162] Graves' disease occurs most often in women (prevalence 1% to 3% in women; 0.1% in men). The peak incidence occurs between 40 and 60 years of age.[165]

Thyrotoxicosis also can be caused by benign follicular adenomas that secrete large quantities of thyroid hormone. Thyroid adenomas are not believed to have an autoimmune etiology. Exogenous iodine excess (radiocontrast agents or angiography dye) or the administration of thyroid hormones may induce iatrogenic thyrotoxicosis. The antiarrhythmic agent amiodarone is iodine rich and may cause either hypo- or hyperthyroidism.[165] Toxic multinodular goiter, subacute viral thyroiditis, TSH-secreting pituitary tumors, and thyroid cancer are less common causes of thyrotoxicosis. There is a three-fold increase in Graves' disease in the postpartum period.[164]

Signs and Symptoms. Clinical manifestations associated with thyrotoxicosis reflect the widespread hypermetabolic effects of excess thyroid hormones. Physical manifestations include tachycardia, tremor, and muscle weakness. The thyroid gland is usually enlarged two to three times normal with Graves' disease. Sleep is often difficult. Weight loss (despite increased food consumption), anxiety, fatigue, and increased thermogenesis and oxygen consumption are clinical findings of thyrotoxicosis.[164,165]

The aberrant immunologic response associated with Graves' disease targets primarily the thyroid gland but also other tissues, including extraocular muscles and skin. Ophthalmopathy is observed in 30% to 50% of patients with Graves' disease.[164,165] Thyroid-associated ophthalmopathy may cause exophthalmos, eye redness, and periorbital edema. Papilledema and loss of visual acuity rarely occurs. Graves' ophthalmopathy results from autoimmune-mediated inflammation and swelling of the periorbital connective tissue and extraocular muscles.[164,165]

The blood volume increases slightly under the influence of excess thyroid hormone, a result of vasodilation. Mean arterial pressure usually remains unchanged, but the pulse pressure increases.[166] The systolic blood pressure is typically elevated 10 to 15 mmHg, and the diastolic pressure is reduced. Blood flow to the skin increases in response to the increased need for heat elimination.[166]

The effects of thyrotoxicosis on the heart are pronounced. Thyroid hormones have a direct effect on the excitability of the heart by increasing the number of β-adrenergic receptors. Palpitations, tachycardia, and cardiac dysrhythmias affect most patients.[166] About 10% of thyrotoxic patients have atrial fibrillation. The cardiac output increases with thyrotoxicosis, sometimes to 50% or more above normal.[166] Mitral valve prolapse is more common in patients with Graves' disease than in the general population.[166] With protracted high thyroid hormone levels, heart muscle strength may become depressed because of protein catabolism. Diagnosis of thyrotoxicosis is more difficult in the elderly because many of the hyperkinetic manifestations of hyperthyroidism are absent.[167] Elderly patients may initially present with myocardial failure or atrial fibrillation.[164,165,167]

The hyperthyroid individual may feel constant fatigue from the exhausting effect of thyroid hormone on the musculature and the central nervous system.

Diagnosis. The diagnosis of primary hyperthyroidism is established in most cases by the combined findings of an abnormally high unbound serum T_4 assay and depressed TSH levels. With Graves' disease, the diagnosis may be supported by the presence of thyroid-stimulating immunoglobulins.[164,168] Serum alkaline phosphatase and calcium concentrations are elevated in approximately 20% of patients with Graves' disease and reflect bone turnover.[164]

Other autoimmune diseases such as myasthenia gravis, rheumatoid arthritis, systemic lupus erythematosus, and DM are more common in patients with Graves' disease.

Treatment. A variety of treatment options are available for patients with Graves' disease. The three primary treatment options for thyrotoxicosis are radioactive gland ablation, surgery, and antithyroid drug therapy.[166,169,170]

Radioactive Iodine. A common therapy for Graves' disease in the United States is ablation of the thyroid gland with radioactive iodine ($Na^{131}I$). Two to four months is needed to reverse the hyperthyroidism with this approach. Hypothyroidism is common after treatment. Use of $Na^{131}I$ is contraindicated during pregnancy and breast feeding.

Thyroidectomy. Surgery for treatment of Graves' disease is an option when antithyroid drugs are ineffective, if radioiodine treatment is refused, in children or pregnant women, or if the thyroid goiter is exceptionally large. Patients should be treated preoperatively with antithyroid medication and rendered euthyroid prior to surgery. Complications associated with thyroid surgery occur in less than 1% of cases and include damage to the recurrent laryngeal nerve (RLN), hypoparathyroidism, and neck hematoma. Various nerve integrity monitors may be used during thyroid surgery to help the surgeon identify the RLN and avoid injury and vocal cord paralysis.[172-175]

Thyroidectomy is usually performed under general anesthesia, but local anesthesia with a bilateral cervical plexus block can be used for those patients who pose a general anesthesia risk.[176]

Antithyroid Drugs and β-Adrenergic Receptor Blockade. The main class of antithyroid medications is the *thionamides*, which include propylthiouracil (PTU), methimazole, and carbimazole. All thionamides inhibit thyroid hormone synthesis by interfering with the incorporation of iodine into tyrosine residues of thyroglobulin. PTU also inhibits conversion of T_4 to T_3. A euthyroid state is usually obtained in 6 to 7 weeks. Hepatitis and agranulocytosis are the most serious side effects of these drugs.[171]

About 10 days before surgery, oral potassium iodide (saturated solution of potassium iodide [SSKI], Lugol solution) may be added to the course of therapy to decrease gland size and vascularity and block hormone synthesis and release. Propranolol also may be added to the antithyroid regimen to reduce cardiovascular symptoms and inhibit the peripheral conversion of T_4 to T_3.[169,171]

Preoperative Assessment—Hyperthyroidism. The key to successful preoperative preparation of the hyperthyroid surgical patient is a careful assessment of the extent of thyrotoxicosis and the severity of end-organ manifestations. Thyrotoxicosis is associated with increased operative risk, so elective surgery should not proceed until the patient has been rendered euthyroid by medical management.[8,11,164] Antithyroid medications should be continued through the morning of surgery.[8]

Hyperthyroid patients have increased blood volume, decreased peripheral resistance, and a wide pulse pressure. The cardiac

output, heart rate, and systolic blood pressure may be increased. Appropriate corrections of the patient's fluid volume and electrolyte status should be accomplished before surgery.

A careful preoperative evaluation of the airway is mandatory in all hyperthyroid patients undergoing surgery. Thyroid gland enlargement can cause tracheal deviation and tracheoesophageal compression.[165] Although an enlarged thyroid gland is not in itself a predictor of a difficult intubation, a cancerous goiter is a major factor predicting difficult endotracheal intubation.[177,178] A patient with a large goiter and an obstructed airway poses the same challenge as any other patient in whom airway management is problematic. An awake fiberoptic intubation with topical anesthesia is of proven value under these conditions. Computed tomography, magnetic resonance imaging, or ultrasonography of the neck may be required.[165] Tracheomalacia weakens thyroid cartilage from chronic pressure, and its presence may necessitate a more prolonged intubation and vigilant observation after surgery. Hoarseness, sore throat, a feeling of pressure in the neck, coughing, or dyspnea suggests tracheal compression that can be caused by thyromegaly.

Only life-threatening emergency surgery should be performed in an untreated symptomatic hyperthyroid patient.[8,11] In an emergency situation, the otherwise healthy patient can be expeditiously prepared for surgery with the oral administration of potassium iodide (3 to 5 drops every 6 hours) and carefully titrated intravenous propranolol (1 to 10 mg) or esmolol (50 to 300 mcg/kg).[8] Elderly patients who require emergency surgery and have rapid ventricular rates require central pressure monitoring to guide therapy.

Intraoperative Management. A major goal of the perioperative management of the hyperthyroid patient is prevention of sympathetic nervous system stimulation. This is accomplished by providing sufficient anesthetic depth and avoiding medications that directly or indirectly stimulate the sympathetic nervous system.[8,11]

A preoperative anxiolytic medication is generally warranted. Atropine should be avoided as an antisialagogue because of its vagolytic effects and its ability to impair sweating.

Induction of anesthesia may be achieved with a number of intravenous medications. Ketamine should be avoided because it can stimulate the sympathetic nervous system. Pancuronium should be avoided because it has the potential to increase the heart rate.

Because of the increased incidence of myasthenia gravis and skeletal muscle weakness in the hyperthyroid patient, precaution dictates careful titration of muscle relaxant doses with use of a peripheral nerve stimulator. Respiratory failure has been described in surgical patients with uncontrolled hyperthyroidism.[179]

Isoflurane or sevoflurane are attractive choices for inhalation anesthetics because of their ability to offset sympathetic nervous system responses to surgical stimulation and because they do not sensitize the myocardium to catecholamines. Hyperthyroid patients do not generally require a higher minimum alveolar concentration (MAC) for inhalational anesthesia.[8,11] The increased cardiac output accompanying hyperthyroidism may accelerate the uptake of an inhaled anesthetic, resulting in the need to increase the delivered concentration, and this may be perceived clinically as an increased anesthetic requirement.[8,11]

Monitoring of the hyperthyroid patient should focus on early recognition of increased thyroid gland activity suggesting the onset of thyroid storm. Core body temperature should be monitored closely. The ECG should be assessed for tachycardia or dysrhythmias. Hypotension occurring during surgery is better treated with direct-acting vasopressors than with indirect-acting vasoactive drugs that stimulate the release of catecholamines. Hypercarbia and hypoxia should be stringently avoided because they stimulate the sympathoadrenal axis.

Meticulous care of the eyes is required. The patient with proptosis is at risk for corneal exposure and damage, so special care should be taken to lubricate and protect the eyes perioperatively. Box 33-8 summarizes key anesthesia implications for patients with hyperthyroidism.

BOX 33-8

Anesthesia Implications for the Hyperthyroid Patient

- Determine the extent of thyrotoxicosis and end-organ complications.
- Ensure a euthyroid state prior to surgery.
- Evaluate the airway closely.
- Avoid sympathetic nervous system activation and sympathomimetic drugs.
- Titrate muscle relaxants carefully, considering possible myopathy.
- Position carefully (decreased bone density and predisposition to osteoporosis).
- Monitor closely for early signs of thyroid storm.
- Pad and protect the eyes.

BOX 33-9

Clinical Manifestation of Thyroid Storm

- Fever greater than 38.5° C
- Tachycardia
- Confusion and agitation
- Dysrhythmias
- Nausea and vomiting
- Hypertension
- Congestive heart failure
- Abnormal liver function tests

Thyroid Storm. A feared complication in the hyperthyroid patient is *thyroid storm* or *thyrotoxic crisis*. Thyroid storm is an uncommon event that is caused by acute stress in the previously undiagnosed or incompletely treated hyperthyroid patient. Precipitating events may include trauma, surgery (especially thyroid surgery), the peripartum period, radioiodine treatment, acute illness, and infection.[180-181]

Thyroid storm is a life-threatening medical emergency that represents a severe exacerbation of hyperthyroid signs and symptoms. The clinical manifestations may include marked tachycardia, hyperthermia, hypertension, atrial fibrillation, sweating, tremor, vomiting, weakness, agitation, shock, and congestive heart failure (Box 33-9). Metabolic acidosis may be present secondary to increased lactate production from overactive metabolism. Similarities exist between the clinical features of thyroid storm and those of pheochromocytoma, neuroleptic malignant syndrome, light anesthesia, and malignant hyperthermia, making clinical diagnosis challenging in some cases.[180-182]

Thyroid storm associated with surgery may occur anytime in the perioperative period but is more likely to occur 6 to 18 hours after surgery.[182] To prevent substantial morbidity and mortality, treatment must be initiated as soon as the diagnosis is made. Mortality rates are as high as 20% to 30%, even with early diagnosis and management.[164] The high mortality associated with thyroid storm underscores the importance of achieving a euthyroid state before surgery.

Management of perioperative thyroid storm includes identifying and treating the precipitating cause, administering antithyroid medications, and providing hemodynamic support. Carefully titrated β-adrenergic receptor blockers blunt adrenergic manifestations. Antithyroid drugs (PTU or methimazole), administered via a nasogastric tube or rectally, block thyroid hormone synthesis.[171] Supplemental glucocorticoids should be administered because the turnover of endogenous steroids is accelerated by the hypermetabolism of thyrotoxicosis.

Supportive measures include intravenous hydration with glucose-containing crystalloid solutions, correction of electrolyte and acid-base imbalances, and management of hyperthermia. Salicylates may displace T_4 from its carrier protein; therefore, acetaminophen is the recommended antipyretic for lowering body temperature.[164] Adequate oxygenation is of paramount importance during thyroid storm. Vasoactive medications and advanced hemodynamic monitoring may be necessary to help manage the labile cardiovascular course.[164]

Hypothyroidism

Hypothyroidism is a state of thyroid gland hypofunction resulting in decreased circulating concentrations of thyroid hormones. Laboratory findings show decreased plasma T_4 concentrations and increased TSH levels in patients with primary hypothyroidism.[164] The clinical spectrum of thyroid hormone deficiency can range from the asymptomatic patient with no overt physical findings to the classic myxedematous patient with profound symptoms. Hypothyroidism is the most common disorder of thyroid function, occurring in 5% to 10% of women and 0.5% to 2% of men.[164]

Primary hypothyroidism accounts for 95% of all cases of hypothyroidism. An autoimmune-mediated inflammation and destruction of the thyroid gland, known as *Hashimoto thyroiditis*, is the most common form of hypothyroidism in the United States.[180] The disorder most often occurs in females of middle age and is associated with other autoimmune disorders such as myasthenia gravis, type 1 diabetes mellitus, and adrenal insufficiency.

In addition to autoimmune-mediated gland destruction, primary hypothyroidism also may be the result of severe iodine deficiency, nodular goiter, or iatrogenic causes (e.g., previous thyroid surgery, neck irradiation, radioiodine therapy).[164] The antiarrhythmic agent amiodarone is associated with hyper- and hypothyroidism.[166] Lithium inhibits the release of thyroid hormone and causes hypothyroidism in some patients.

Rarely, secondary hypothyroidism is the result of pituitary or hypothalamic disorders. Secondary hypothyroidism is associated with decreased concentrations of both thyroid hormones and TSH.[164] Regardless of the etiology, the clinical manifestations of hypothyroidism are similar.

Signs and Symptoms. Most cases of hypothyroidism are subclinical, with laboratory findings of increased plasma TSH but no overt signs. Patients with more significant disease develop signs and symptoms that reflect a slowed metabolism and impaired cellular functions. The thyroid gland usually is enlarged (goiter), nontender, and firm. A bruit over the gland reflects increased vascularity. Patients may have dry skin, cold intolerance, paresthesias, slow mental functioning, ataxia, puffy face, and constipation. The hair and nails frequently are brittle.[8,164,180] Lack of thyroid hormone causes the muscles to become weak. Patients with severe hypothyroidism may be hypersomnolent with a decreased ventilatory response to hypoxia and hypercarbia.[180]

The accumulation of proteinaceous fluid in serous body cavities is a well-recognized feature of hypothyroidism. The most common sites of effusions associated with hypothyroidism are the pleural, pericardial, and peritoneal cavities.[164,166] Inappropriate ADH secretion and impaired free water clearance can lead to hyponatremia. Accumulation of mucopolysaccharides and fluid imparts the characteristic edematous appearance called *myxedema*.[164]

Cardiovascular complications include sinus bradycardia, dysrhythmias, cardiomegaly, impaired contractility, congestive heart failure, and labile blood pressure.[166] Symptoms of low exercise tolerance and shortness of breath with exertion may be partially the result of decreased cardiac function. Chronic vasoconstriction produces diastolic hypertension and decreases the intravascular fluid volume.[164,166] The autonomic nervous system response is blunted, and there is a decrease in the sensitivity and number of β-receptors.[166,181-184]

Overt hypothyroidism is associated with a number of abnormalities in lipid metabolism that may predispose patients to accelerated coronary artery disease. Hypothyroidism is associated with anemia and decreased erythrocyte production of 2,3-diphosphoglycerate, leading to a leftward shift of the oxyhemoglobin dissociation curve.

These "classic" clinical features of hypothyroidism are often lacking in the elderly hypothyroid patient. In the older patient, thyroid status cannot always be predicted from clinical signs and symptoms, making the diagnosis of hypothyroidism more difficult.

Extreme hypothyroidism during fetal life, infancy, or childhood is termed *cretinism*. The condition is characterized by physical and mental growth retardation. In the newborn, unless cretinism is treated with adequate iodine or thyroxine within the first few weeks after birth, mental retardation remains permanent.[162-164] Neonatal screening (T_4 or TSH levels) has played a major role in preventing severe cretinism.

Treatment. Treatment of hypothyroidism requires replacement with thyroid hormone. The agent of choice is synthetic *levothyroxine sodium* (T_4) because of its long half-life (7 days) and its ability to attain physiologic levels of T_3. Replacement dosages range from 75 to 150 mcg/day, depending on the underlying autonomous thyroid function.[164]

An area of particular concern during thyroid hormone replacement is the effect on the cardiovascular system. Initiation of thyroid hormone replacement in a patient with coexisting angina pectoris or underlying risk factors for coronary artery disease is potentially hazardous and requires careful monitoring of both cardiovascular and thyroid status. Myocardial oxygen consumption is augmented by thyroid hormone, and a hypothyroid patient with deficient coronary artery circulation may not tolerate full replacement doses.

Anesthetic Management—Hypothyroidism. Patients with subclinical hypothyroidism have an overall low risk of complications when undergoing anesthesia and surgery. These patients should receive a careful preoperative evaluation and preoperative continuation of levothyroxine therapy.[8,11] Patients with overt or severe hypothyroidism are predisposed to multiple complications with anesthesia. Depression of myocardial function, abnormal baroreceptor function, and reduction in plasma volume may be present.[8,11] Slowed hepatic metabolism and renal clearance of injected drugs may prolong their effects, but MAC is not decreased significantly for inhaled agents.[8,11] Regional anesthesia is a prudent choice if the surgery permits it and there are no patient contraindications.[11] Elective surgical procedures should be postponed in the presence of severe or symptomatic hypothyroidism until normal thyroid status can be restored.[8,11]

All patients with hypothyroidism should undergo careful preoperative evaluation of the airway. A large goiter may cause airway compromise in the form of tracheal deviation or compression. In some patients with severe hypothyroidism, adequate air exchange

may be compromised by an enlarged tongue and myxedematous infiltration of the vocal cords.[8,11] Depression of the ventilatory responses to hypoxia and hypercarbia must be considered. Preoperative sedation should be avoided in the patient with macroglossia or preexisting hypoventilation. The risk of pulmonary aspiration is increased because of associated somatic obesity and delayed gastric emptying [8]

Hypothyroid patients may respond to opioids with increased central nervous and respiratory system depression. Potent inhalational agents may exacerbate hypotension and myocardial depression. Although ketamine has been proposed as the ideal induction agent, even ketamine can produce cardiovascular depression in the absence of a robust sympathetic nervous system.[11]

Intubation of the trachea may be facilitated by the administration of succinylcholine or a nondepolarizing muscle relaxant; however, hypothyroid patients may be more sensitive to standard doses of nondepolarizing muscle relaxants because of coexisting muscle weakness and decreased hepatic metabolism and renal elimination of these drugs.[8] Maintaining muscle paralysis with minimal doses of muscle relaxants is an appropriate goal.

Supplemental perioperative cortisol should be considered in the patient with symptomatic disease, because there exists a potential for adrenal insufficiency with stress.[8]

In hypothyroidism, the number of β-receptors is diminished, and responses to inotropic drugs and sympathetic stimulation may be influenced by the altered β-receptor pool.

Body temperature should be monitored closely in hypothyroid patients, and mechanisms for warming the patient should be used during surgery. Box 33-10 summarizes the anesthesia implications for the patient with hypothyroidism.

Myxedema Coma. Myxedema coma is a rare syndrome that reflects the end stage of untreated hypothyroidism. The presence of coma is a marker of the patient's clinical deterioration rather than a primary effect of hypothyroidism. A critical insult (e.g., infection, surgery, cerebrovascular accident, pneumonia, gastrointestinal bleeding, cold exposure) can precipitate myxedema coma in a patient with hypothyroidism.[164]

Generally the patient is elderly, has severe clinical features of hypothyroidism, and is hypothermic, hypoventilating, and hyponatremic. The response to hypoxia and hypercapnia is measurably decreased, and mechanical ventilation may be required. The patient is typically lethargic or stuporous. The skin often is pale as a result of cutaneous vasoconstriction.[164]

Myxedema coma is a medical emergency with a mortality rate greater than 50%.[11] Therapeutic attention should be paid to body temperature, shock, and ventilatory failure. Treatment consists of hemodynamic and ventilatory support and the intravenous administration of levothyroxine (300 to 500 mcg), with continuous ECG monitoring for myocardial ischemia.[8] Supplemental cortisol is appropriate because the myxedematous patient may have adrenal atrophy and decreased adrenal reserve.[164] Because these patients may be vulnerable to water intoxication and hyponatremia, meticulous fluid replacement is important. Only lifesaving surgery should proceed in a patient with myxedema coma.[8,11]

BOX 33-10

Anesthesia Implications for the Hypothyroid Patient

- Delay elective surgery for the patient with severe symptomatic disease.
- Evaluate the airway closely.
- Monitor for exaggerated central nervous system depression with anesthetic agents.
- Titrate muscle relaxants carefully, considering possible coexisting muscle weakness.
- Consider decreased hepatic metabolism and renal elimination when dosing medications.
- Maintain normothermia.
- Monitor ventilation closely, considering blunted ventilatory response to hypercarbia and hypoxia.

SUMMARY

The number and variety of patients with endocrine disorders presenting to surgery remains a consistent challenge for the practicing anesthesia provider. Our ability to diagnose and treat these disorders continues to evolve. Several advances in imaging and genetic profiling have yielded improved preoperative diagnostics. The increase in knowledge of the pathophysiology associated with each patient's individual condition will result in better anesthesia management.

34 CHAPTER Hematology and Anesthesia

◆ *Judith A. Franco and Mark H. Gabot*

When disruptions within the endothelial lining of blood vessels occur, the breach in vessel-wall integrity can be due to spontaneous plaque disruption, trauma, or iatrogenic reasons such as venous access or surgical intervention. Vessel-wall injury initiates an extraordinary chain of events that causes the cessation of bleeding with the formation of a clot, allowing the site of injury to heal. This event is followed by clot dissolution. *Hemostasis* is the process by which the body maintains the delicate balance between bleeding and clotting. Were it not for this balance, hemorrhage or thrombosis would ensue.

The focus of this chapter is to review the normal and abnormal processes of hemostasis, emphasizing: (1) the vessel wall, (2) platelets, (3) coagulation cascade, (4) emerging cell-based theory of coagulation, and (5) fibrinolytic system. An in-depth discussion surrounding the importance of hemostatic assessment and management during the perioperative period, with particular attention to transfusion practices and guidelines follows. A discussion concerning the patient with special hematologic circumstances concludes the chapter.

THE NORMAL VESSEL WALL

The normal blood vessel acts as a conduit to maintain a state of fluidity within the vascular system. Blood vessels are cylindrical and consist of three distinct layers—the intima, the media, and the adventitia (Figure 34-1).

The intima (the inner layer) is the lining separating the flowing blood from the vessel; it is made up primarily of endothelial cells. These endothelial cells play an important role in the modulation of hemostasis by synthesizing and secreting many procoagulants (initiators of coagulation), anticoagulants (inhibitors of coagulation), and fibrinolytics (to dissolve the clot) (Table 34-1). One of the important mediators, von Willebrand factor (vWF), is a necessary cofactor for the adherence of platelets to the subendothelial layer. Tissue factor (a cofactor from the coagulation cascade) activates the clotting cascade pathway when injury to the vessel occurs. Some mediators (e.g., thromboxane A_2, adenosine diphosphate [ADP]) control blood flow by influencing vasoconstriction. Other mediators (e.g., nitric oxide, prostacyclin) control blood flow by vasodilation of blood vessels. Endothelial cells also can suppress activation of the coagulation system by their expression of many coagulation inhibitors such as tissue factor pathway inhibitor.[1]

One of the most important yet simple functions of the endothelial lining is that of forming a barrier separating the fluid contents within the blood vessel (e.g., red blood cells, white blood cells, albumin, globulins, fibrinogen, platelets) from the highly thrombogenic material (e.g., collagen and procoagulants) that lies beneath, within the subendothelial space. The smooth endothelial lining physically repels the blood components away from the vessel wall, preventing activation of the clotting mechanism. When the endothelial wall is damaged, the above properties no longer apply.

The second layer of the vessel wall, the subendothelial layer, is extremely thrombogenic and very active. The subendothelial layer contains collagen, a potent and important stimulus for platelet attachment to the injured vessel wall. The subendothelial layer also contains fibronectin, which facilitates the anchoring of fibrin during the formation of a hemostatic plug.

The third layer, the adventitia, participates in the control of blood flow by influencing the vessel's degree of contraction. The endothelial cells produce nitric oxide and prostacyclin, which influence the adventitia. Nitric oxide affects platelet function by inhibiting platelet adhesion, aggregation, and the binding of fibrinogen between glycoprotein IIb/IIIa complex (GpIIb-IIIa) pseudopods. The ability of nitric oxide to influence and promote smooth-muscle relaxation results in vascular vasodilation. Once the vessel vasodilates, the increase in blood flow limits the activity of procoagulant mediators by simply washing the procoagulant mediators away. This metabolic reaction occurs within the endothelial lining (Figure 34-2). Under the influence of nitric oxide synthetase (NOS), L-arginine is converted to nitric oxide (NO). Nitric oxide then diffuses into the muscle cells and activates soluble guanylate cyclase, subsequently producing a second messenger, cyclic guanosine monophosphate, causing muscle relaxation.[1]

Prostacyclin is a lipid molecule produced in the endothelial cells from prostaglandin. A powerful vasodilator, prostacyclin also interferes with platelet formation and aggregation.

Platelets are an essential component of the thrombogenic response to bleeding. Platelets are round and disklike and circulate freely within the blood. They are formed in the bone marrow from megakaryocytes, maintain a concentration count of approximately 150,000 to 300,000/mm^3, and survive approximately 8 to 12 days.[2] Platelets are constantly working to "patch" thousands of minute vascular injuries that occur in perpetuity. Approximately 7.1×10^3 are used each day.[3]

The platelets flow along the vessel surface. Because they are smaller than some other constituents in fluid blood (e.g., red blood cells [RBCs], white blood cells [WBCs]), they tend to be pushed aside, strategically positioned near the vessel-wall surface where they can then "react" in the event of injury (Figure 34-3).

The membrane surface of the platelet serves as a physical barrier between platelet cytoplasm and the surrounding plasma. Platelets contain mitochondria in their cytoplasm, enabling them to participate in aerobic metabolism, and have glycogen stores that allow for anaerobic metabolism.[4] Platelets also contain contractile proteins, store large amounts of calcium and various enzymes, and require the use of their phospholipids' surface to promote cellular activity. Platelets contain alpha (α) granules that store proteins (e.g., vWF, fibrinogen, fibronectin, platelet factor 4, and platelet growth factor) and dense granules that store nonproteins (e.g., serotonin, ADP, adenosine triphosphate [ATP], histamine, and epinephrine).[2] Many of these granules synthesize

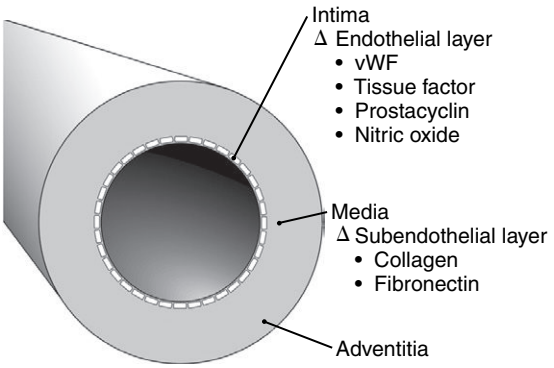

FIGURE **34-1** Schematic of vessel layers and some important mediators. *vWF*, Von Willebrand factor.

TABLE 34-1 Mediators Responsible for Procoagulant, Anticoagulant, and Fibrinolytic Activities

Property	Mediator	Function
Procoagulant	Coagulation factors	Coagulation
	Collagen	Tensile strength
	vWF	Adhesion
	Protein C	Degrades V and VII
	Protein S	Cofactor for protein C
	Fibronectin	Mediates cell adhesion
	Thrombomodulin	Regulates anticoagulant pathway
Anticoagulant	Antithrombin III	Degrades factors XII, XI, X, IX, & II
	Tissue pathway factor inhibitor	Inhibits tissue factor
Vasodilation	Nitric oxide	Vasodilates
	Prostacyclin	Vasodilates, inhibits aggregation
		Both promote smooth-muscle relaxation
Vasoconstriction	Thromboxane A_2	Vasoconstriction
	ADP	Vasoconstriction
	Serotonin	Vasoconstriction
Fibrinolytic	Plasminogen	Converts to plasmin
	tPA	Activates plasmin
	Urokinase	Activates plasmin
Antifibrinolytic	Plasminogen activator inhibitor	Inactivates tPa, urokinase
	α-Antiplasmin	Inhibits plasmin

ADP, Adenosine diphosphate; *tPA*, tissue plasminogen activator; *vWF*, vonWillebrand factor.

prostaglandins that enable the platelets to promote vascular and local tissue reactions.[2,4] Platelets also produce thrombin. In the platelet, thrombin's role is to activate some of the coagulation factors and to influence recruitment of platelets to the site of injury. All the contents in the cytoplasm of the platelet participate in regulating hemostasis. Platelets do not contain a nucleus, RNA (ribonucleic acid), or DNA (deoxyribonucleic acid), so they do not reproduce.[2]

Platelets are largely inactive unless they become activated as a result of vascular trauma. Adequate hemostasis is not possible in the absence of an adequate quality or quantity of activated platelets. It is important to note that platelets do not work independently to achieve hemostasis. They work in

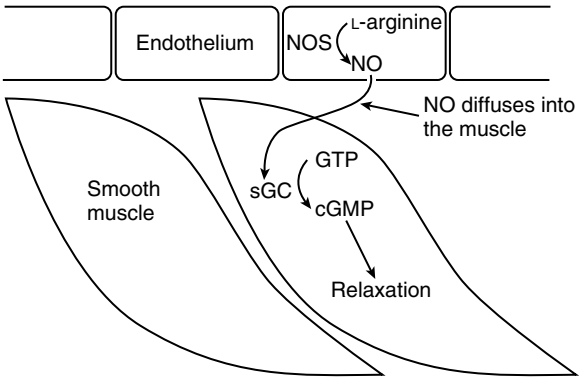

FIGURE **34-2** Nitric oxide influences vessel-wall vasodilation by causing muscle relaxation. *cGMP*, Cyclic guanosine monophosphate; *GTP*, guanosine triphosphate; *NO*, nitric oxide; *NOS*, nitric oxide synthetase; *sGC*, soluble guanylate cyclase.

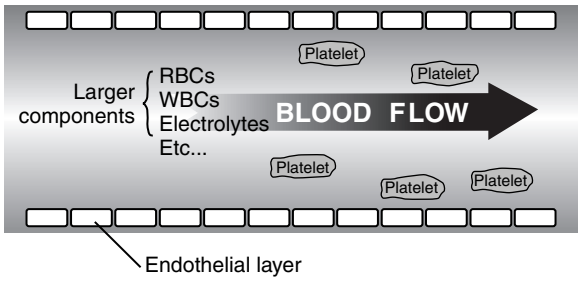

FIGURE **34-3** Position of platelets flowing in the blood vessel.

conjunction with plasma proteins of the coagulation cascade (see "Vessel Injury") to build a stable clot when injury to the vascular integrity occurs.

VESSEL INJURY

Clot formation in response to injury has traditionally been described to include the adherence of the platelet to the injured vessel wall and the response of the clotting cascade to form a stable clot and stop the progress of bleeding. When the endothelial lining is disrupted, as it might be by plaque dislodgement, surgical instrumentation, or trauma, an intricate process to maintain hemostasis and promote clot formation is initiated.

The vessel wall immediately contracts to cause a tamponade, decreasing blood flow. This contraction is a result of autonomic nervous system reflexes and the expression of thromboxane A_2 and ADP.[2,5] The area adjacent to the injury vasodilates and distributes blood to the surrounding organs and tissues. Contraction is followed by three separate stages in the formation of a primary plug: adhesion, activation, and aggregation.

In the adhesion stage, vWF mobilizes from within the endothelial cells and emerges from the endothelial lining. Glycoprotein Ib (GpIb) receptors emerge from the surface of the platelet (Figure 34-4). The purpose of GpIb is to attach to vWF and attract platelets to the endothelial lining; vWF makes platelets "sticky" and allows them to adhere to the site of injury.

Under the influence of tissue factor (a cofactor of the extrinsic clotting pathway), the platelet then undergoes a conformational transformation as it becomes activated (Figure 34-5). The once disklike structure swells and becomes oval and irregular. From the platelet surface, two other major glycoproteins, IIb and IIIa, project themselves outward. The purpose of the GpIIb-IIIa receptor complex is to link other activated platelets together in an effort to form a primary platelet plug. When this action is complete, the

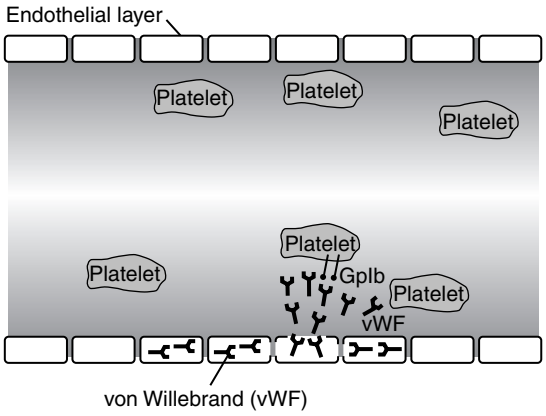

FIGURE **34-4** von Willebrand factor is responsible for adhesion of platelets.

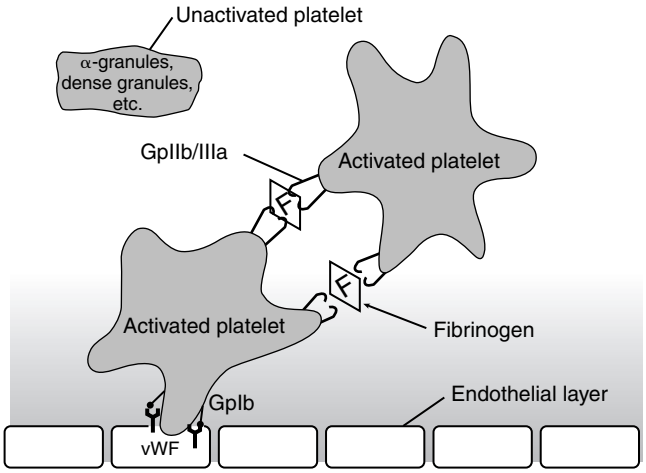

FIGURE **34-5** Glycoprotein IIb/IIIa complex (GpIIb-IIIa). Pseudopods link activated platelets together with fibrinogen to form a mound to "patch" injury to vessel walls. *VIII,* Factor VIII; *vWF,* von Willebrand factor.

platelets form a mound whose only goal is to seal and heal the site of injury within the blood vessel.

As platelets undergo this metamorphosis, they release the alpha and dense granules, the contractile granules, thrombin, and many important mediators into the blood in an effort to promote procoagulant activity. All these mediators are responsible for platelet aggregation to form a primary unstable clot. When injury is minute and less threatening, this primary plug is enough to maintain hemostasis. When the injury is large, activation of the coagulation clotting cascade is required for permanent repair to create and stabilize a secondary clot to cease bleeding.[2]

The coagulation cascade illustrates the activation of cofactors (also referred to as *zymogens*) and their role in this process of hemostasis. Most cofactors are enzymes, with some exceptions (e.g., factors V and VIII). The coagulation factors circulate as inactive cofactors until they are activated to assist in the process of coagulation (Table 34-2). Activation of cofactors results from either tissue or organ damage and sets in motion a process that terminates in stabilization of hemorrhagic conditions in the absence of pathology. The factors are identified with Roman numerals for ease of interpretation.

The clotting pathways are thought to be two separate and distinct pathways (extrinsic and intrinsic) that worked independently of each other but in conjunction with platelet activity and the common coagulation pathway (Figure 34-6). The extrinsic pathway (tissue factor pathway) became activated by the release of tissue factor when injury occurred outside the vessel wall (with organ trauma or crushing injuries). This section of the coagulation cascade consisted of factor III (tissue factor or thromboplastin) and factor VII (proconvertin).

When damage occurs outside of blood vessels, tissue factor (factor III) activates proconvertin (factor VII), changing it to activated (a) factor VII (VIIa). (When factor III activates factor VII, it is immediately inhibited by tissue factor pathway inhibitor, so only a predetermined amount of factor VII is activated.) Once factor VII is activated, it in turn activates factor X (Stuart-Prower) of the common pathway. Factor X forms a complex with factor V (proaccelerin, a prothrombinase complex), activating factor II (prothrombin), which when activated becomes factor IIa (thrombin). Thrombin in turn activates factor I (fibrinogen) to form activated factor I (Ia, fibrin).

The intrinsic pathway (contact activation pathway) is initiated when damage occurs to the blood vessels themselves. The intrinsic pathway is initiated by prekallikrein, high-molecular-weight kininogen (HMWK), and by the activation of factor XII (Hageman). With the help of calcium (factor IV), the coagulation pathway initiates a domino effect. Each factor, once activated, affects its subsequent factor. Factor XII (Hageman) activates factor XI (plasma thromboplastin antecedent), which activates factor IX (Christmas), which then activates factor VIII (antihemophiliac factor) and ultimately (similar to the extrinsic pathway) merges at the common pathway and activates factor X. The result is the generation of fibrin from the activation of prothrombin to thrombin.

Conversion of prothrombin to thrombin is an important reaction for both coagulation pathways. Thrombin assists in activating factors V, VIII, I, and XIII and influences the recruitment of platelets to the injured area. Enough thrombin must be present to activate adequate fibrin to form a stable clot.

Thrombin also behaves as an anticoagulant. It (1) prevents runaway clot formation by releasing tissue plasminogen activator (tPA) from endothelial cells, (2) stimulates protein C and protein S to inhibit clot formation, and (3) forms a relationship with antithrombin III to interfere with coagulation.[1] The common pathway is the terminal pathway of the coagulation cascade. In the common pathway, factor X has been activated by the intrinsic and extrinsic pathways. Factor X requires the help of factor V (proaccelerin) and calcium to convert factor II (prothrombin) to its active-state thrombin (IIa). Thrombin then activates factor I (fibrinogen) to its active form, Ia (fibrin). Factor XIII (fibrin-stabilizing factor) is required to ensure the platelet plug will hold. Factor XIII helps form a cross-linked mesh within the platelet plug, increasing its strength. Fibrin (factor Ia) in conjunction with factor XIII finally secures a stable secondary plug, and bleeding stops. Once a clot is made, it retracts, eliminating its serum. As it retracts, it weaves the edges of the vessel together, healing the site of injury.[2]

Most of the coagulation proteins are synthesized in the liver. Calcium, which is not a true factor, comes from diet; it is needed to "position" the coagulation factors on the surface of the platelet so clotting will ensue. Von Willebrand factor is synthesized in the endothelial cells, and factors II, VII, IX and X are dependent on vitamin K for utilization.

CELL-BASED THEORY OF COAGULATION

The cell-based theory is a newer concept for explaining the involvement of the platelet and clotting cascades in hemostasis. It hypothesizes *why* platelets and the extrinsic and intrinsic pathways of coagulation cascade do not work independently of one

TABLE 34-2 Coagulation Factors

Factor	Factor Name	Synthesized	Vitamin K Dependent	Action
I	Fibrinogen	Liver	No	Form a clot
II	Prothrombin	Liver	Yes	When in active form, activates I, V, VII, XIII, platelets, and protein C
III	Tissue factor or thromboplastin	Vascular wall and extravascular cell membranes; released from traumatized cells	—	Cofactor of VII
IV	Calcium	Diet	—	Promotes clotting reactions
V	Proaccelerin	Liver	No	Cofactor of X; forms a prothrombinase complex
VI	(Unassigned)	—	—	—
VII	Proconvertin	Liver	Yes	Activates IX and X
VIII	Antihemophiliac	Liver	No	Cofactor to IX
vWF	Von Willebrand	Endothelial cells	—	Mediates adhesion
IX	Christmas	Liver	Yes	Activates X
X	Stuart-Prower	Liver	Yes	Activates II, forms a prothrombinase complex with V
XI	Plasma thromboplastin antecedent	Liver	No	Activates IX
XII	Hageman	Liver	No	Activates XI
XIII	Fibrin stabilizing	Liver	No	Cross-links fibrin
Prekallikrein	Fletcher		—	Activates XII, cleaves HMWK
High-molecular-weight kininogen (HMWK)	Contact activation factor		—	Supports activation of prekallikrein, XII, XI

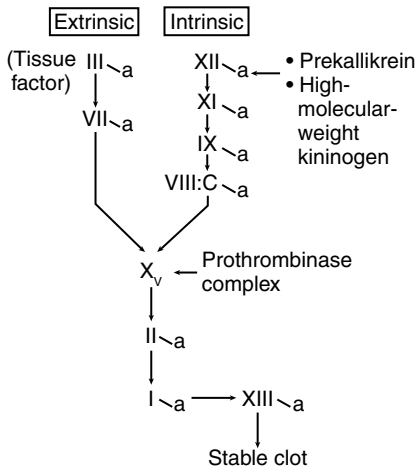

FIGURE **34-6** Schematic of the coagulation cascade (extrinsic, intrinsic, and common pathways). *a*, Active form.

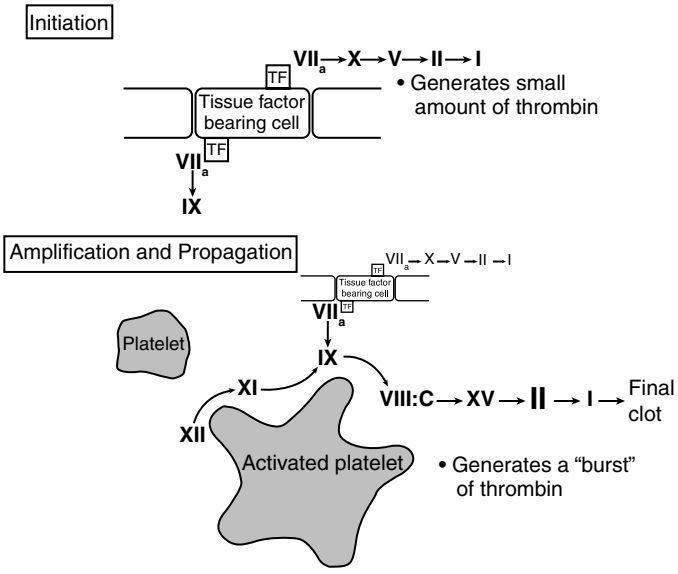

FIGURE **34-7** Cell-based theory of coagulation. (Adapted from Hoffman M, Monroe D. Coagulation 2006: a modern view of hemostasis. *Hematol Oncol Clin North Am.* 2007;21[1]:1-11.)

another but form a very interdependent relationship.[6] The theory posits that coagulation takes place on different "cell surfaces" that bear tissue factor (TF). These surfaces play a pivotal role in factor expression leading to hemostasis. The cell-based theory describes hemostasis as taking place in three phases: initiation, amplification, and propagation.

The initiation phase is triggered by injury to the endothelial surface (Figure 34-7). When injury occurs, TF is exposed at the site of injury. In its presence, the endothelial surface of the blood vessel changes, becoming acidic and making its phospholipid surface less repellent to platelets. TF down-regulates anticoagulants that reside in the subendothelial layer (e.g., antithrombin III, thrombomodulin) in an effort to promote coagulation.[7] This new medium enhances the many enzymatic processes that work to maintain hemostasis by encouraging aggregation and the activation of clotting factors to the site of injury. TF recruits platelets and activates factor VII.

In the cell-based theory, TF/VII reaction results in the activation of factors X (common pathway) *and* IX (intrinsic pathway). Factor X forms a complex with factor V, and together these two activated factors are able to generate a *small* amount of thrombin for clot formation.[8] Only a small amount of thrombin is created

because this reaction terminates almost immediately when tissue factor pathway inhibitor (TFPI) limits the amount of TF expressed. The activation of factor IX from the TF/VII complex does not participate in this initiation stage because IX does not act on TF-bearing cell surfaces.[7]

It is on the platelet cell surface that factor IX (generated from TF/VII) exerts its coagulation contribution to hemostasis. Factor IX attaches to the activated platelet cell surface and binds with a receptor, resulting in the activation of factor VIII, which in turn activates factor X. Additional thrombin is then produced.

As injury perpetuates and TF is expressed, platelets mobilize to the site of injury.[7] It is during the amplification phase that thrombin generation gains momentum, and acceleration and activation of clotting factors persists. Thrombin activates factors V, VIII, and IX.[6] Activated factor XI assists in generating even more factor IX on the platelet surface.[9] Von Willebrand factor promotes platelet aggregation through its adhesive properties with GpIb, and the expression of the GpIIb-IIIa pseudopods from the surface of platelets facilitates aggregation of additional platelets.

During the propagation phase, all coagulation factors are actively influencing one another, promoting coagulation and finally activating prothrombin, resulting in a large "*burst*" of thrombin. Remember, enough thrombin must be present to convert fibrinogen to fibrin to form a stable secondary hemostatic plug. This burst of thrombin does just that.

The cell-based theory is a means of providing a more thorough understanding and an innovative interpretation of coagulation. It explains how cell surfaces do not just express coagulation factors; these surfaces participate in conjunction with platelets and the coagulation cascade pathways to maintain hemostasis. This theory also explains why certain deficiencies fail to cause bleeding, despite changes in laboratory values such as the PT prothrombin time (PT) or activated partial thromboplastin time (aPTT), indicative of coagulation problems.[6]

FIBRINLOYTIC SYSTEM

Once a disrupted vessel is sealed, there is no longer a need for a hemostatic plug. A counterbalance mechanism, the fibrinolytic system, exists to degrade fibrin. Initially there is an increase in blood flow at the site of injury. This increase in blood flow washes away ADP and thromboxane A_2 and other procoagulant mediators, which were initially present to encourage hemostasis and limit the size of the clot. Thrombin, which initially behaved as a procoagulant, now acts as an anticoagulant and activates additional anticoagulant mediators. TFPI stops the action of TF. Protein C and protein S inhibit coagulation factors III, V, and VIII. Antithrombin III inhibits thrombin activity by sequestering factors XII, XI, IX, and X. Antithrombin III is a mediator that corrals some of the factors present in the clotting cascade and takes them out of the clotting equation (Figure 34-8). The clot manufactured is disrupted.

The process of fibrinolysis is highly regulated by plasma proteins (Figure 34-9). A clot is composed primarily of plasminogen, plasmin, fibrin, and fibrin degradation products. Plasminogen is an enzyme synthesized in the liver. It is stored like the clotting factors in an inactive form. While the clot is forming, plasminogen incorporates itself into the clot. With the assistance of the body's own tPA and urokinase, plasminogen is activated to plasmin. Plasmin then acts on the fibrin, causing fibrin to degrade into fibrin degradation products. The circulatory system removes the waste products of the clot. α-Antiplasmin and tissue plasminogen activator inhibitor are important fibrinolytic mediators that stop the process of fibrinolysis when the clot has been digested.

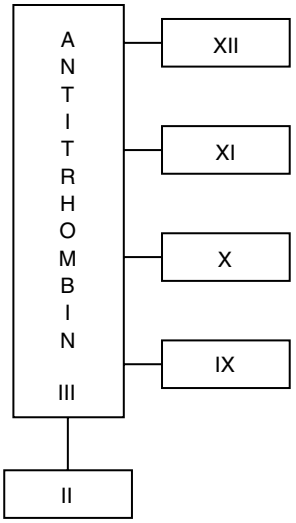

FIGURE **34-8** Antithrombin III corrals clotting factors XII, XI, IX, X. This influences factor II.

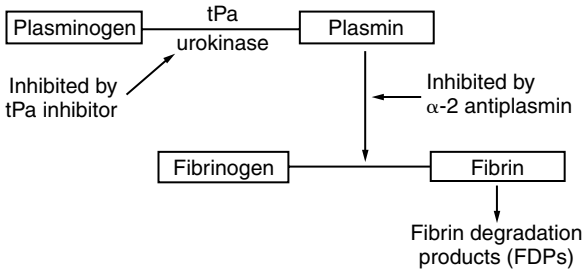

FIGURE **34-9** Schematic of the fibrinolytic system. *tPA*, Tissue plasminogen activator.

Platelets, coagulation cofactors, and the fibrinolytic systems are dependent on each other to ensure a person does not bleed to death or clot to death at any given moment. This system of checks and balances maintains hemostasis when a breach in vascular integrity occurs.

ANESTHETIC IMPLICATIONS

Preoperative Considerations

The preoperative interview is the ideal time for the anesthesia provider to gather detailed information regarding the patient's health status. A thorough history and physical is the best way to identify patients at risk for surgical bleeding or those patients with thrombopoietic tendencies.[10] It is also during the interview that additional laboratory tests can be ordered if necessary to identify potential defects in hemostasis and to guide the decision regarding whether to order and/or administer blood products.

During the preoperative interview, it is important to ask questions directly related to bleeding: (1) Does the patient experience unusual bleeding or bruising (e.g., bleeding gums, epistaxis, mucous membrane bleeding, bloody stools)? (2) Is there a history of previous bleeding with dental procedures? (3) Are there repeated spontaneous bleeding episodes or a history of excess bleeding that may have occurred after a minor procedure or childhood trauma? (4) Do familial bleeding tendencies exist? (5) Has there been a time when expected bleeding from a surgical procedure was more than anticipated?[4,11] These questions can reveal an undiagnosed inherited disorder of coagulation. Patients who have undiagnosed inherited coagulopathies may complain of hematomas, runaway bruising, and oozing, even after the most minor

injuries. An undetected preoperative bleeding tendency can lead to life-threatening blood loss during surgery.[4] Laboratory evaluation of platelets, coagulation, and fibrinolytic components can be screened with the commonly available coagulation tests.

When approaching the patient scheduled for surgery, a physical examination with a complete systems approach is necessary. The anesthesia provider must be alert to potential disruptions in hemostasis. Any overt physical sign of bleeding such as the appearance of bruising or petechial hemorrhages on the chest, abdomen, or upper extremities warrants further investigation. Small hemorrhages on the skin may indicate the presence of small hemorrhages on other organs as well. Remember, the questionable coagulopathy can be related to any number of disruptions in the hemostasis process: a platelet problem, a factor deficiency, an inherited disorder of coagulation, the presence of circulating anticoagulants, or a disturbance in the fibrinolytic system.

During the physical assessment, disorders of malnutrition or liver insufficiency suggesting a vitamin K deficiency may be revealed. These disorders can influence coagulation and explain increased bleeding, even for the simplest surgery. Vitamin K is created from bacteria in the gut and is necessary for the formation of factors II, VII, IX, and X. When illness such as liver insufficiency, cirrhosis, absorption problems, and failure to secrete bile are present, the patient will be unable to form and use these factors for effective coagulation.

Patients with preexisting inherited disorders of coagulation must undergo an adequate preoperative workup prior to surgery. Consultation with a hematologist or transfusion specialist is strongly recommended. Patients with preexisting coagulation disorders require considerable attention in the operating room. If general surgery is anticipated, special attention must be made to ensure no damage to soft tissues occurs. Damage to tissues may transpire during direct laryngoscopy, endotracheal intubation, peripheral or central line placement, and positioning or moving to and from the operating-room table.

The preoperative use of many medications—prescribed, over–the-counter, and herbal remedies—can interfere with normal platelet function and coagulation (Box 34-1). The anesthesia provider must ascertain whether the patient regularly ingests medications that might interfere with normal coagulation and when were the medications or herbals last taken. For example, many patients take aspirin for a number of reasons. Historically it has been recommended that aspirin be held for 7 to 10 days prior to surgery. Current recommendations are discussed in detail later in this chapter. Aspirin directly affects the life of the platelet by *irreversibly* inhibiting cyclooxygenase, resulting in decreased platelet function.[12] Nonsteroidal antiinflammatory drugs (NSAIDs) also inhibit cyclooxygenase, albeit *reversibly*, and the recommendation is to withhold NSAIDs for approximately 24 to 48 hours to avoid any bleeding effects in surgery[13,14] (Figure 34-10).

A preoperative discussion between the patient, surgeon, and anesthesia provider must occur regarding transfusion requirements during surgery. Informing patients about the safety, screening measures, and risks of blood administration cannot be ignored. A small percentage of patients will have to contend with the negative sequelae of transfusion therapy (e.g., hepatitis, human immunodeficiency virus, and bacterial transmission), despite careful screening and handling. In situations with emergent or trauma patients, many times a preoperative interview is unattainable, and the provider must rely purely on information supplied by family members (if present), physical assessment, and laboratory analysis.

Careful consideration must be given to the patient who refuses blood component therapy for personal or religious reasons.

BOX 34-1

Frequently Encountered Medications That Influence Coagulation

Anticoagulants
- Heparins
- Low-molecular-weight heparins
- Coumarin derivatives
- Direct thrombin inhibitors

Procoagulants
- Vitamin K

Antiplatelets
- Nonsteroidal antiinflammatory drugs
- Persantine
- Thienopyridine (Plavix and Ticlid)

Antifibrinolytics
- Amicar
- Tranexamic acid

Nonherbal Dietary
- Vitamin K
- Vitamin E
- Coenzyme Q10
- Zinc
- Omega-3 fatty acids

Herbal
- Garlic
- Ginger
- Ginkgo
- Feverfew
- Fish oil
- Flaxseed oil
- Black cohosh
- Cranberry

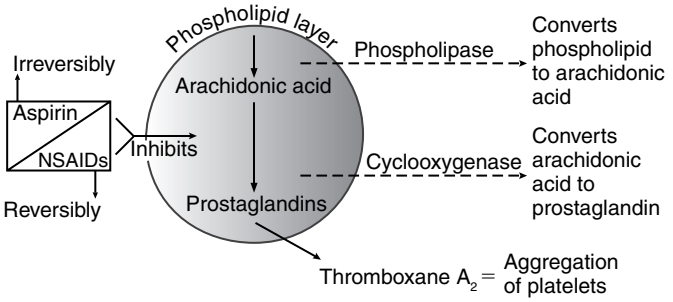

FIGURE **34-10** Schematic illustration depicting the mechanism and site of action of aspirin and nonsteroidal antiinflammatory drugs (NSAIDs).

This patient can be an ethical challenge to healthcare providers, especially when refusal may mean a greater chance for mortality because a high-risk procedure may incur greater blood loss. In these special situations, an inclusive discussion of potential or available options must be addressed. If the patient is a candidate, there are alternatives available such as erythropoietin administration, acute normovolemic hemodilution, cell salvage, recombinant factor VII or VIII, and topical coagulants. Pharmacologic alternatives (e.g., Amicar [aminocaproic acid], tranexamic acid) also can be a means of stabilizing coagulation when significant blood loss is anticipated.

Most anesthesia providers are familiar with the Jehovah Witness (JW's) population and their refusal of blood transfusion or derived components. However, it is important to consider that some JW's will accept certain fractions of primary blood components (e.g., albumin, leukocyte-depleted red cells, platelets, solvent-treated fresh frozen plasma [FFP], and recombinant products) or alternatives to allogenic transfusions, as long as blood remains continuous with the body.[15] Advice regarding available management options should be discussed, especially with high-risk blood-loss procedures.[16]

TABLE 34-3 Possible Causes and Treatment of Hemostatic Disorders

CLINICAL COAGULATION TESTS							
BL	**aPTT**	**PT**	**BT**	**PC**	**Fib**	**Possible Cause**	**Treatment**
	Abn					Factor VIII, heparin, "lupus anticoagulant," poor sample	No treatment
+	Abn					Factors XI, IX, VIII, heparin therapy	FFP, protamine
+	Abn	Abn				Factors V, X, II, dysfibrinogenemia, heparin, coumarins	FFP, cryoprecipitate, protamine
+		Abn				Factor VII	FFP
+	Abn		Abn			Von Willebrand disease	Desmopressin acetate, cryoprecipitate
+	Abn	Abn	Abn		Low	Hypofibrinogenemia	FFP, cryoprecipitate
+			Abn	Abn		Thrombocytopenia	Platelet concentrate (8-10 units)
+			Abn			Thrombocytopathy, aspirin, NSAIDs	Platelet concentrate
+	Abn	Abn	Abn	Abn	Abn	DIC, severe liver disease, dilutional coagulopathy	FFP, cryoprecipitate, platelet concentrate, whole blood

+, Increased clinical bleeding; *Abn*, abnormal result; *aPTT*, activated partial thromboplastin time; *BL*, bleeding; *BT*, bleeding time, *DIC*, disseminated intravascular coagulation; *FFP*, fresh frozen plasma; *Fib*, fibrinogen; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PC*, platelet count; *PT*, prothrombin time.

TABLE 34-4 Coagulation Tests

Laboratory Test	Value*	Description
Bleeding time	3-7 min	Measures platelet function: adhesion, aggregation Not considered a routine test Modest prolongations do not predict surgical bleeding Altered by aspirin and NSAIDs*
Platelet count	150,000-350,000 mm^3	Thrombocytopenic: <100,000 mm^3 Surgical risk: <50,000 mm^3 Spontaneous bleeding: <20,000 mm^3
Prothrombin time (PT)	Normal: Control Average Normal: 12-14 sec	Value is reagent dependent Prolonged with: • Extrinsic pathway disorder • Common pathway disorder Altered by coumarin derivatives*
Activated partial thromboplastin time (aPTT) (intrinsic and common pathway)	Average normal: 25-32 sec	Prolonged with: • Intrinsic pathway disorder • Common pathway disorder Altered by heparin and Lovenox*
Thrombin time (common pathway)	8-12 sec	Measures fibrinogen-to-fibrin reaction
Activated clotting time (ACT)	80-150 sec	Guides anticoagulation dosing
Fibrinogen	>150 mg/dL; 200-350 mg/mL	Measures fibrinogen level
Fibrinogen (degradation products)	<10 mcg/mL	Measures by-products from clot dissolution
D-Dimer	<500 mg/mL	Measures degradation products secondary to fibrinolysis
Thromboelastogram		Measures global hemostasis
Antithrombin III	80%-120%	Measures antithrombin III levels; decreased level may explain subtherapeutic heparin Severely depressed in DIC

*Values may vary among laboratories.
DIC, Disseminated intravascular coagulation; *NSAIDs*, nonsteroidal antiinflammatory drugs.

Laboratory Tests

Routine laboratory tests must be evaluated preoperatively. They serve to guide the clinician in determining whether a coagulation disorder exists (Table 34-3). Laboratory tests should be ordered on an individual basis, considering the patient's history and planned surgical procedure.

The most frequently assessed tests are the bleeding time, platelet count, PT, and aPTT (Table 34-4). Together, these tests evaluate vascular contraction, platelet function, coagulation, and the fibrinolytic system. Results of these routine tests must fall within the normal range. If they are outside normal range, there must be a reasonable explanation, and adequate measures must be taken to correct or control hemostasis before bringing the patient into the operating room. For example, if the patient requires surgery but not emergently, vitamin K can be administered 4 to 6 hours prior to surgery. If the risk of bleeding is moderate, a type and crossmatch may be preferred to a type and screen. If the patient requires surgery emergently, ordering blood components such as packed red blood cells, FFP, platelets, and cryoprecipitate may be advisable.

The bleeding time evaluates the capability of microvascular contraction and the function of platelets. When vascular injury occurs, the initial response from the blood vessels is to contract, and the response of the platelets is to adhere to the site of injury. If either of these two processes is compromised, prolonged bleeding will occur, resulting in inadequate hemostasis.

The bleeding time was once thought to be the best indicator of bleeding risk. The use of a bleeding time test, however, is open to much scrutiny, and there are many reasons to question its use and interpretation.[17] In the absence of drug ingestion, a prolonged bleeding time suggests primary hemostasis abnormality, and further investigation is recommended. Although the bleeding time is a means of evaluating vascular integrity and platelet function, it is important to appreciate that a prolonged bleeding time is not a good predictor of bleeding or a sign that an abnormality is present.[18] In addition, an isolated prolonged value is not a reason to cancel or delay a surgical procedure.

The platelet count is the actual number of platelets present in blood per cubic millimeter. A normal platelet count does not imply normal platelet function exists, only how many platelets are present in plasma. It is used to evaluate patients who present with petechiae or unexplained spontaneous bleeding and to monitor thrombocytopenia (low platelet count). The platelet's primary role is to maintain vascular integrity, aggregate when a plug is necessary to stop bleeding, and help initiate the clotting pathways. A normal platelet count is 150,000 to 300,000/mm^3.[2] Patients are considered thrombocytopenic at counts less than 100,000 mm^3. There are varying degrees of thrombocytopenia that must be considered preoperatively. Platelet counts greater than 100,000 are sufficient for hemostasis. When the platelet count declines to 50,000/mm^3, spontaneous bleeding rarely occurs, but one should suspect prolonged bleeding under surgical conditions.[19] A platelet count less than 20,000 is considered a critical level, and spontaneous bleeding is likely to occur.[20,21]

The PT is used to evaluate the efficiency of the extrinsic factors (III and VII) and common coagulation pathway (factors X, V, II, I) in generating enough thrombin to form fibrin to create a stable clot. The PT is specific to the extrinsic pathway of the clotting cascade. It is the most commonly used test to monitor oral anticoagulant therapy (e.g., the coumarin derivatives). The PT will be prolonged when patients have abnormalities or are deficient in factors specific to the extrinsic and common clotting pathways (III, VII, X, IX, II, I).[5]

Despite the frequent assessment of the PT value preoperatively, this laboratory value has drawbacks. The PT is not a very sensitive test. The PT also fails to identify the specific factor defect in the hemostatic system. It only identifies an existing problem that may or may not cause bleeding.

The international normalized ratio (INR) evaluates the extrinsic and common pathway independently of various reagents used in different laboratory settings and in different areas of the world. The normal INR is 1.5 to 2.5. Many institutions report both PT and INR values.

The aPTT is a test used to evaluate the efficiency of the intrinsic coagulation pathway (factors XII, XI, IX, and VIII) and the common coagulation pathway (factors X, V, II, I, and ultimately XIII) to form fibrin and eventually a stable clot. The aPTT can identify abnormalities in all factors except III and VII. It is also used to monitor anticoagulation status when heparin therapy is used. The aPTT can be prolonged by abnormalities, deficiencies, or inhibitors of any intrinsic or common pathway defect. Factor concentration must be decreased 30% before evidence of a prolonged PT or an aPTT can be appreciated.[1,19]

Any factor deficiency in either limb of the clotting cascade can alter the PT and/or aPTT, but this does not imply that any prediction of an individual patient risk of bleeding can be anticipated.[7] For example, a decrease in factor XII will demonstrate an increase in aPTT but will not cause bleeding.[6] A decrease in factor XI may or may not cause abnormal bleeding. However, a decrease in either factor VIII or IX will definitely cause bleeding with injury. This is seen in hemophilia.

The activated clotting time (ACT) is a simple, quick test that can be used in surgery to monitor the ability of blood to clot. The ACT is also used to regulate heparin therapy. The normal ACT is 90 to 150 seconds. The ACT is not, however, a sensitive test.

The thrombin time is a screening tool for assessing the ending phase of coagulation. Because fibrinogen can be assessed directly, analysis of the thrombin time is less emphasized.

The thromboelastogram (TEG) measures the process of clot formation over time. The benefit of this test is its ability to evaluate (1) platelet reactions, (2) coagulation, and (3) fibrinolysis. A blood specimen is collected and placed in a machine that measures the speed at which a clot forms. The results of the TEG provide an indication of (1) clot strength, (2) platelet number and function, (3) intrinsic pathway defects, (4) thrombin formation, and (5) the rate of fibrinolysis. The results of this test can be used to guide blood component therapy and possibly decrease the amount of transfusion products administered.[2]

Laboratory tests are only as good as the individual interpreting them and many times will not adequately reflect the potential to bleed or thrombose. The use of coagulation tests is best interpreted when patients are without pathology, are not on any medications that could disrupt the laboratory value measured, and are assessed in conjunction with physical assessment and clinical judgment. It is prudent to consult with a hematologist when there is any suspicion of the potential for abnormal bleeding in surgery or if a coagulation disorder exists. Coagulation tests can be performed in the operating room; however, lengthy delay in reporting their values during a time of critical volume loss and coagulopathic alterations can render the value ineffective. Coagulation tests initiated in the operating room may nevertheless serve as a guide.

Intraoperative Period

One main focus of the surgeon and the anesthesia practitioner in the operating room is to recognize and efficiently control blood loss. Frequent evaluation of the patient's clinical status, surgical site, sponges, canisters, and the operating room floor cannot be overemphasized.[19] The surgeon and anesthesia provider are equally responsible in communicating that persistent oozing or frank bleeding is occurring. It is this open communication that helps the surgical team recognize problems and rapidly intervene by having blood components in the room, rechecking ABO compatibility, and anticipating the need for coagulation-factor replacement if transfusion therapy is necessary.

There are many potential adverse effects associated with the administration of blood component therapy. Despite the presence of screening tests, hepatitis and human immunodeficiency virus (HIV) transmission continue to influence patients' decisions about whether they wish to receive blood components. But the incidence of hepatitis and HIV is low when compared with the frequency of other adverse reactions to blood component therapy. Transfusion therapy is also associated with acute hemolytic transfusion reactions, nonhemolytic reactions, viral transmission, transfusion-related acute lung injury, parasite transmission, and bacterial transmission.

The most commonly transfused blood components are red blood cells, platelets, fresh frozen plasma, and cryoprecipitate (Table 34-5). The major reasons for transfusion therapy in the operating room are to replace volume and coagulation factors and

TABLE 34-5 Blood Components

Blood Component	Definition	Surgical Indications	Dose
PRBC	Red blood cells anticoagulated in plasma	Bleeding Increase O_2-carrying capacity	1 unit increases Hgb by 1 g/dL and Hct by 3%
FFP (all factors)	Plasma separated from RBC and platelets Contains ALL clotting factors Contains naturally occurring inhibitors Source of antithrombin III One bag = 200-250 mL Expires 12 months post-donation	Microvascular bleeding Coagulopathy due to factor deficiency PT/aPTT >1.5 normal Massive blood transfusions Reversal of warfarin Acquired coagulopathy von Willebrand disease unresponsive to DDAVP Antithrombin deficiency	10-15 mL/kg
Platelets	Obtain from whole blood or plateletpheresis donations Contain platelets only One bag = random volume One bag pheresis = 250-300 mL	Massive blood transfusion Active bleeding: <5000 = spontaneous hemorrhage 10,000-50,000 = variable bleeding risk >50,000 = spontaneous bleeding unlikely due to platelets	1 unit/10 kg body weight 1 unit increases platelet level 5000-10,000/mm^3
Cryoprecipitate	Protein fraction taken off the top of FFP when being thawed Then refrozen up to 1 year Contains factors I, vWF, VIII, fibrinogen, XIII One bag = 10-20 mL	Microvascular bleeding von Willebrand disease unresponsive to DDAVP	1 bag/5 mg body weight 1 unit raises fibrinogen by 50 mg/dL

aPTT, Activated partial thromboplastin time; *DDAVP*, 1-deamino-8-D-arginine vasopressin (desmopressin acetate); *FFP,* fresh frozen plasma; *Hct*, hematocrit; *Hgb*, hemoglobin; *PRBC*, packed red blood cells; *PT,* prothrombin time; *vWF*, von Willebrand factor.

improve oxygen-carrying capacity.[22] Each component carries its own concerns.

Packed red blood cells (PRBCs) are transfused to improve tissue oxygenation. Although the oxygen-carrying capacity of red cells decreases with the length of storage, it improves when 2,3 diphosphoglycerate (2,3 DPG) is regenerated once transfused. Platelets are provided to patients when a deficit is appreciated or when massive transfusion is required. Platelets can be given as a single-donor plateletpheresis pack or collected and pooled from multiple donors (random-donor platelets).

The recommended dose for platelet replacement is one plateletpheresis pack per each 10 kg of patient weight. This dose should increase the platelet count by approximately 5000 to 10,000 mm^3.[5,19] Whereas the normal life span of a platelet is 7 to 10 days, the life span of a donated platelet is only 4 to 5 days.[9]

The Anesthesia Task Force recommends (1) the use of platelets in the operating room for microvascular bleeding, regardless of platelet count, and (2) the use of clinical judgment based on the risk of bleeding and the length of the surgery when the platelet count falls between 50,000 and 100,000/mm^3. Prophylactic administration of platelets may not be necessary, especially when the cause of thrombocytopenia is destruction of platelets (e.g., heparin-induced thrombocytopenia, idiopathic thrombocytopenia purpura, thrombotic thrombocytopenia purpura) or when the count is greater than 100,000.[19,22] Although there are varying degrees of thrombocytopenia, if persistent bleeding or oozing occurs in the operating room, a transfusion might be considered despite a platelet count greater than 50,000. Compatible plateletpheresis is recommended, but when matched platelets are unavailable, unmatched platelets can be given; however, this incompatibility shortens the life span of the platelet.[3,23] When pooled platelets are administered to women of childbearing age, Rh sensitization can occur, and administration of RH_O(D) immune globulin may be necessary prior to discharge.

Platelets carry the greatest risk of bacterial transmission.[23,24] Platelets are stored for 4 to 5 days at room temperature, providing an excellent medium for the growth and reproduction of bacteria. Standard protocols for blood banks and transfusion services require that a method be in place to detect bacterial contamination of platelets.[23,25]

Fresh frozen plasma is the fluid portion of whole blood, separated then frozen to preserve coagulation factors and subsequently thawed on use. FFP contains all the clotting factors and naturally occurring inhibitors.[26] It does not provide platelet replacement. The average volume in a unit of FFP is 200 to 250 mL. FFP must be ABO plasma compatible whenever possible.

FFP is transfused (1) for microvascular bleeding, (2) when the concentration of coagulation factors is deficient, (3) to patients with an inherited coagulopathy, (4) for the reversal of warfarin administration, and (5) for a deficiency resulting from a dilutional coagulopathy[19,21,26] (assuming the patient's preoperative laboratory values were normal). Dilutional coagulopathies increase when blood is diluted to at least 30% or when a patient loses more than one volume of blood, indicating only a third of the coagulation factors are present.[27] This deficit is reflected in laboratory values. Laboratory analysis will reveal the need for FFP by a PT and aPTT prolonged more than 1.5 times normal. The use of FFP for volume replacement is contraindicated. Safety screening for FFP is the same as for RBCs.

Cryoprecipitate is the precipitate collected off the top of FFP as it is thawed. Cryoprecipitate is then refrozen and thawed on use. It is rich in fibrinogen and contains factors VIII, XIII, and fibronectin. The current guidelines recommend cryoprecipitate for (1) microvascular bleeding in conjunction with FFP, (2) patients with von Willebrand disease or hemophilia when concentrates are unavailable, (3) suspected factor deficiencies, and (4) prophylaxis when a fibrinogen defect is present.[21] Despite cryoprecipitate's ability to decrease factor deficiencies, more studies are required to ascertain the effectiveness of cryoprecipitate in clinical outcome.

It is preferable to transfuse platelets, FFP, and cryoprecipitate with adherence to ABO compatibility to avoid hemolytic

reactions, but there are times when this practice is impractical. When massive transfusion occurs, one should be alert to the risk of hemolytic reaction. In addition to viral screening for donor units, the institution of solvent detergents, psoralen derivatives, and methylene blue are being evaluated as a means to decreasing emerging viral contaminations, especially when blood products are pooled. The effect of these additives on platelets, FFP, and cryoprecipitate is still under investigation.[23,25]

Despite policies, procedures, and screening modalities, there may never be a time when blood component therapy will be without risk.[23,28] New illnesses and viruses emerge as quickly as the old ones are controlled. Additionally, human error influences the incidence of transfusion reactions. Nevertheless, blood component therapy is still often necessary in the operating room.

Transfusion Guidelines

There is no magic number or an absolute transfusion "trigger" for blood-component administration. There are few if any fixed guidelines or practice standards for transfusion therapy. There are, however, many suggested guidelines and protocols that vary among individual institutions. Past literature recommends a hemoglobin of 10 g/dL as an indicator for red-blood-cell transfusion, but transfusion delivery based on one isolated laboratory value without regard to the patient's overall health status is irresponsible.[29] A hemoglobin value of 8 g/dL and even 6 g/dL may be acceptable when ischemia or risk factors for cardiovascular disease are not evident.[19,22]

There are also alternatives available to reduce or allay allogenic component replacement: preoperative autologous donation (PAD), acute normovolemic hemodilution (ANH), blood-cell salvage (BCS), and recombinant factor VII.[30-32]

Recombinant factor VII was approved by the U.S. Food and Drug Administration (FDA) in 1999 for hemophilia A (factor VIII) and B (factor IX), inhibitor disorders of factors VIII and IX, factor VII deficiency, and as a universal hemostatic agent.[8,33-35] Its off-label use has successfully treated coagulation insufficiencies associated with platelet dysfunction, intracranial hemorrhage, prostate surgery, and trauma.[36]

The exact mode of action of factor VII is undetermined. Both the classic coagulation cascade and the cell-based theory agree that factor VII enhances thrombin generation by augmenting TF/VII at the site of vessel injury and on the surface of the platelet.[6,33,34] Administration ultimately boosts thrombin to form fibrin for clot stabilization. The recommended dose of factor VII for hemophilia is 90 to 120 mcg/kg. There is no definitive dose for use in the operating room for patients without prior coagulation disorders, but 20 to 45 mcg/kg has been suggested.[8]

Factor VII will reverse prolonged INR, but it fails to replace all the clotting factors.[33] The anesthesia provider must remain vigilant intraoperatively, providing interventions that would prevent acidosis and hypothermia, both of which can interrupt the efficacy of the drug.[33,34,37] Patients have experienced cerebrovascular accidents, myocardial infarctions, pulmonary emboli, and arterial and venous thromboemboli. Factor VII should be used cautiously in any patient predisposed to thrombosis. The indications for the use of factor VII remain limited and the treatment is very expensive.[19,26,35,36,38] An extensive discussion of transfusion management practices can be found in Chapter 20.

Postoperative Management

Patients should be reassessed in the postanesthesia care unit and again within 24 hours of surgery. Unrecognized bleeding can thus be identified and corrected before the patient deteriorates. Evaluations of (1) the patient's color and mentation, (2) trends in vital signs (with specific attention to tachycardia or hypotension), (3) urine output, (4) hypothermia, (5) hemodynamic values such as central venous pressure (CVP), (6) laboratory values, and (7) dressings and/or drain volume must be judiciously monitored.

SPECIFIC DISORDERS

Bleeding diathesis can result from any number of deficiencies in coagulation. A few disorders encountered in practice are described here, as well as points to consider when dealing with a patient requiring anticoagulant therapy.

Von Willebrand Disease

Von Willebrand disease (vWD) has traditionally remained the most common inherited coagulation diathesis. Von Willebrand factor (vWF) is a heterogeneous multinumeric glycoprotein that serves two main functions: to facilitate platelet adhesion and to behave as a plasma carrier for factor VIII of the coagulation cascade.[39] Synthesis of vWF takes place in the endothelial cells and megakaryocytes.[40] An acquired form of vWD is seen with lymphomyeloproliferative or immunologic disease states secondary to antibodies against vWF.[41]

Similar to many coagulopathies, vWD has varying degrees of severity—mild, moderate, and severe. In the milder or moderate forms, regular or spontaneous bleeding is not evident but is likely after surgery or when trauma occurs.[10] In the more severe form of vWD, spontaneous epistaxis and oral, gastrointestinal, and genitourinary bleeding can be relentless.

Most patients with vWD exhibit a prolonged bleeding time, a deficiency in vWF and factor VIII, decreased vWF activity measured by a ristocetin (an antibiotic) cofactor (RCoF) assay, and decreased factor VIII coagulant activity (VIII:C). The recommended treatment for vWD is supplementation with recombinant factor VIII-vWF concentrate preoperatively and during surgery to raise the levels of circulating factor VIII and vWF. Cryoprecipitate is another means of acquiring factor VIII; however, there is attendant risk of viral transmission. Desmopressin acetate (1-deamino-8-d-arginine vasopressin [DDAVP]), a synthetic vasopressin, is an excellent option for the milder forms of vWD and should not be overlooked. DDAVP helps increase plasma levels of vWF and augment aggregation.[42]

Hemophilia

Hemophilia is an X-linked hematologic recessive disorder characterized by unpredictable bleeding patterns. Patients are either deficient in factor VIII (hemophilia A) or factor IX (hemophilia B). Hemophilia affects males almost exclusively, although females carry the gene for the disease. Patients with hemophilia A are grouped as mild (excessive bleeding after trauma or surgery), moderate (rarely have extensive, unprovoked bleeding), and severe (absence of factor VIII in the plasma). Hemophiliacs exhibit spontaneous bleeding, muscle hematomas, and pain at joint sites. Continued joint bleeding often results in decreased range of motion and progressive joint arthropathy and often requires orthopedic surgical intervention throughout life.[43]

In the past, the life expectancy for the hemophiliac was short. Because hemophiliacs were deficient in factors VIII and IX, they required blood-component transfusion to replace the deficient or missing factors. The only factor components available were FFP and cryoprecipitate. Screening tests for donated blood units were unavailable, and patient mortality was high. Many hemophiliacs contracted transmissible diseases such as hepatitis and HIV and ultimately died from sequelae of blood transfusion therapy.[43]

Furthermore, hemophiliacs were termed "high risk" for most surgical procedures and often turned down for many elective procedures. Today, blood components undergo extensive screening, and newer and safer treatment modalities exist. Most surgeries are available to hemophiliacs, with little risk of uncontrolled bleeding.[44]

For patients with hemophilia or a family history of hemophilia, a preoperative assessment of hemostasis is imperative. Preoperative laboratory tests should include a platelet count and function, a coagulation panel (PT, aPTT, factor VIII, factor IX, and fibrinogen), as well as an inhibitor test.[44] If the hemophiliac was given a test dose of factor VII preoperatively, the response to the test dose should be evaluated. The patient should be typed and crossmatched, because even a low-risk procedure can be catastrophic for the hemophiliac.

A clearly defined anesthesia plan is essential for the hemophiliac; uncontrolled bleeding is certainly a possibility. Factor VIII concentrate can be given prior to surgery. Factor VII is administered intraoperatively to augment thrombin generation and deter bleeding. The dose should be precalculated and vial availability confirmed prior to going into the operating room. Desmopressin (0.3 mcg/kg) also can be administered to increase plasma levels of factor VIII and vWF for mild to moderate hemophiliacs.[39,45] There is no risk for viral transmission when either of these drugs is initiated.

OTHER CONSIDERATIONS

Perioperative Management of Patients Taking Antithrombotic Drugs

The advent of new antithrombotic medications within the last decade has garnered increasing interest regarding the perioperative management of these potent medications. Antithrombotic medications can be categorized based on their respective method of altering the normal physiologic process of hemostasis: antiplatelet, anticoagulant, and fibrinolytic medications (Figure 34-11). See Table 34-6 for common antithrombotic medications.[46-50] Selection, dosing, and monitoring of antithrombotic therapy should be adjusted based on the patient's primary diagnosis, comorbidities, type of therapy (e.g., treatment or prophylaxis), and renal impairment.

The preoperative management of antithrombotic therapy is currently a controversial topic in that the risk of perioperative bleeding must be weighed against the risk of disease exacerbation. Excessive bleeding may occur if the anticoagulation medications are continued before surgery. This may lead to potentially serious intraoperative and postoperative complications or the need for transfusion of blood products. In contrast, abruptly withholding anticoagulant medications places the patient at increased risk for myocardial infarctions, cerebrovascular accidents, arterial or venous thromboembolism, pulmonary embolism, or death.[46-49] Situation-specific considerations are leading to new

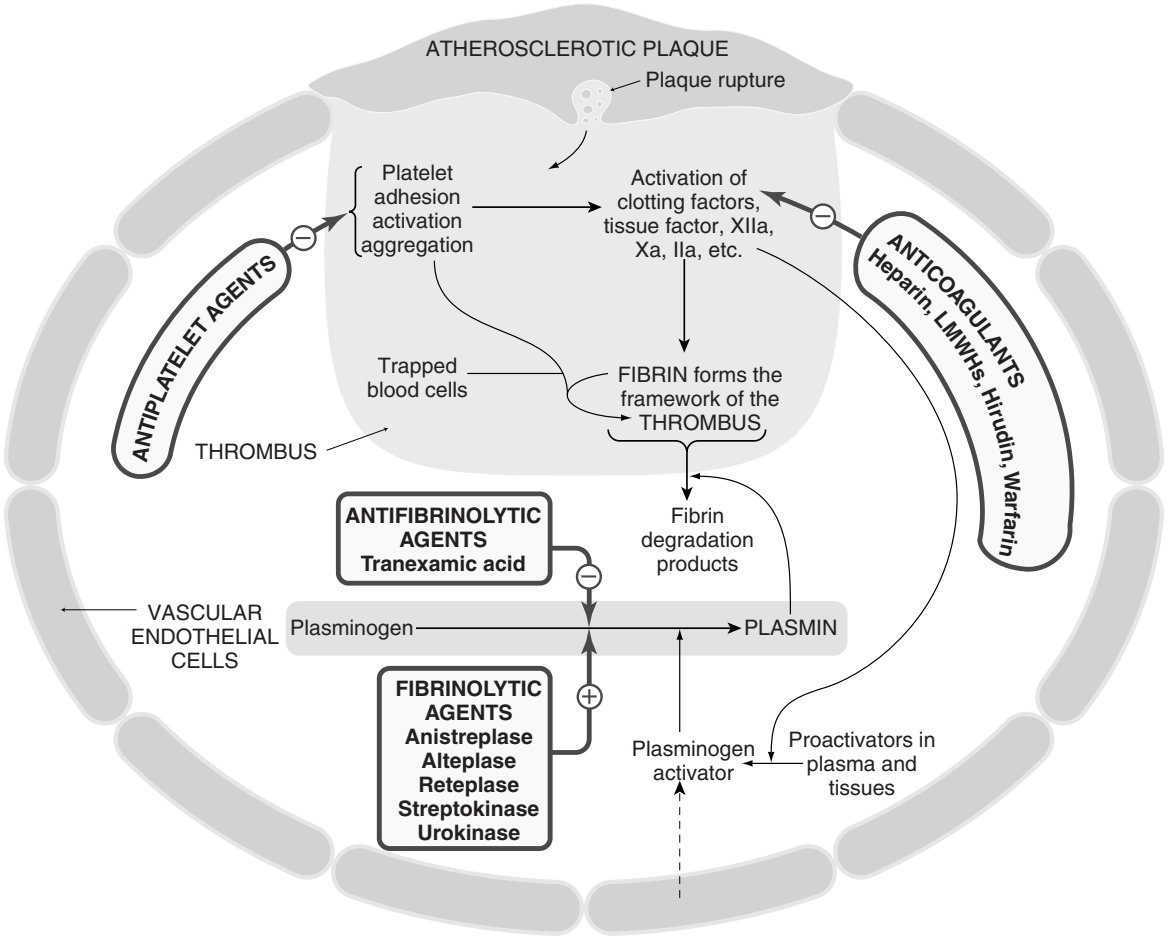

FIGURE **34-11** Pharmacodynamic properties of antithrombotic and antifibrinolytic medications. (From Rang HP, et al. *Rang and Dale's Pharmacology*. 7th ed. London: Churchill Livingstone; 2012:306.)

TABLE **34-6** Pharmacologic Properties of Common Antithrombotic Medications

Type	Name	Pharmacodynamic	Pharmacokinetic (Metabolism/ Plasma Half-life)	Clinical Indication(s)	Perioperative Management (Stop Before Procedure)	Reversal Methods
Antiplatelet	Aspirin	COX 1-2 inhibitor	Liver/20 min	Acute myocardial infarction and stroke	7 days	None
	NSAIDS (e.g., ketorolac and ibuprofen)	COX 1-2 inhibitor	Liver/2-7 hr	Pain and inflammation	24-48 hr	None
	Rofecoxib	COX 1 inhibitor	Liver/10-17 hr	Pain and inflammation	None	None
	Celecoxib	COX 1 inhibitor	Liver/10-17 hr	Pain and inflammation	None	None
	Clopidogrel	ADP receptor antagonist (pro-drug)	Liver/7 days	Coronary artery disease and peripheral vascular disease	7 days	None
	Ticlopidine	ADP receptor antagonist (pro-drug)	Liver/4 days	Coronary artery disease and peripheral vascular disease	7 days	None
	Prasugrel	ADP receptor antagonist	Liver/5 days	Acute coronary syndrome and percutaneous coronary intervention	2-3 days	None
	Ticagrelor	ADP receptor antagonist	Liver/2-3 days	Acute coronary syndrome and percutaneous coronary intervention	24-48 hr	None
	Dipyridamole	Inhibition of platelet uptake of adenosine diphosphate (e.g., phosphodiesterase antagonist)	Liver/40 min	Peripheral vascular disease	24-48 hr	None
	Abciximab	Glycoprotein IIb/IIIa receptor antagonist	Kidney/3 min	Acute coronary syndrome and percutaneous coronary intervention	72 hr	None
	Eptifibatide	Glycoprotein IIb/IIIa receptor antagonist	Kidney/2 hr	Acute coronary syndrome and percutaneous coronary intervention	24 hr	None
	Tirofiban	Glycoprotein IIb/IIIa receptor antagonist	Kidney/2 hr	Acute coronary syndrome	24 hr	Dialysis

BOX **34-2**

Procedures That May Be Performed Without Warfarin Discontinuation

Ophthalmic
- Cataract extractions
- Trabeculectomies

Dental
- Restorations
- Endodontics
- Prosthetics
- Uncomplicated extractions
- Dental hygiene treatment

Dermatologic
- Mohs micrographic surgery
- Simple excisions

Gastrointestinal
- Upper endoscopy and colonoscopy with or without biopsy
- Endoscopic retrograde cholangiopancreatography (ERCP) without sphincterotomy
- Biliary stent insertion without sphincterotomy
- Endosonography without fine needle aspiration
- Push enteroscopy

Orthopedic or Podiatric
- Joint and soft tissue aspirations and injections
- Nail avulsions
- Phenol matrixectomies

recommendations for perioperative management of patients on antithrombotic therapy.

A study by Dunn and Turpie demonstrates safety with uninterrupted administration of anticoagulant therapy, specifically warfarin, for *low*-risk procedures such as minor ophthalmic, dental, dermatologic, gastrointestinal, orthopedic, and podiatric procedures (Box 34-2). A thorough assessment of the patient history, diagnosis, and procedure must be made to weigh the risks of potential stroke, myocardial infarction, and thromboembolism for both cardiac and noncardiac surgeries. Complications of any kind translate into increased cost and prolonged hospitalizations.[11]

Antiplatelet Drugs and Noncardiac Surgery: Patients with Coronary Stents

Coronary stents are placed to improve coronary artery flow in patients with stable but symptomatic coronary artery disease or acute coronary syndromes, including unstable angina, non–Q wave myocardial infarction, and ST-elevation acute myocardial infarctions. Every year more than 2 million patients undergo percutaneous coronary intervention. Of these 2 million patients, greater than 90% will require at least one intracoronary stent. Furthermore, approximately 5% of these patients will undergo noncardiac surgery within the first year after stent placement, while many patients will continue to present for surgery thereafter.[47] The clinical efficacy of intracoronary stents is highly dependent on long-term antiplatelet therapy. As a result, anesthesia providers routinely manage patients with coronary artery disease who have had coronary stents placed and are typically receiving dual antiplatelet therapy with aspirin and thienopyridines (Figure 34-12).

There are two distinct complications associated with stent placement: acute stent thrombosis and in-stent restenosis. Acute

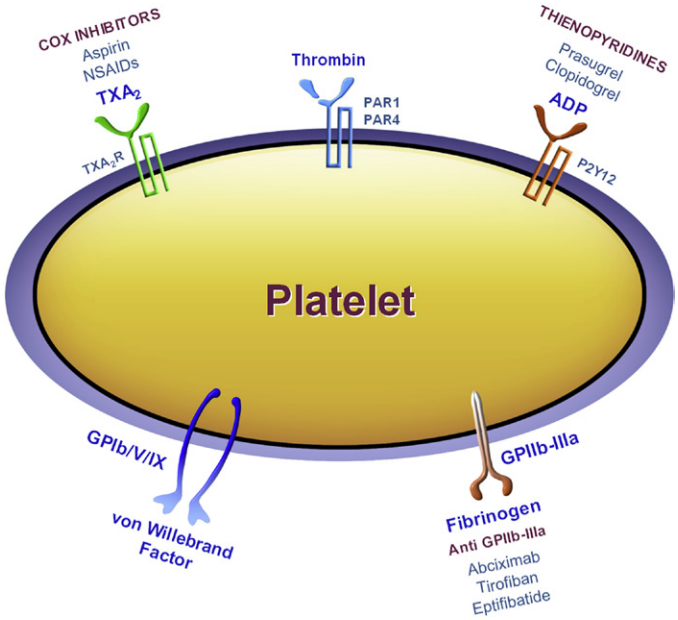

FIGURE **34-12** Main platelet receptors, glycoproteins, and common inhibitors. (From Albaladejo P, Samama CM. Patients under antiplatelet therapy. *Best Pract Res Clin Anaesthesiol.* 2010;24(1):41-50.)

stent *thrombosis* may lead to abrupt occlusion of the coronary artery and an acute coronary syndrome such as acute myocardial infarction. Acute stent thrombosis is a serious complication with a mortality rate of between 20% and 45%, or a myocardial infarction rate up to 64%. Stent thrombosis can occur anytime after stent implantation and anytime antiplatelet therapy is abruptly discontinued. Abrupt discontinuation of antiplatelet therapy can lead to a rebound effect, which is characterized by an inflammatory prothrombotic state. During this prothrombotic state there is increased platelet adhesion, platelet aggregation, and thromboxane A_2 activity.[49] Most events of acute stent thrombosis occur within the first 30 days after stent placement. In contrast, *restenosis* of a stent is a slowly developing occlusion directly related to excessive endothelial growth over time. In most cases, it peaks between 6 and 9 months after stent implantation. Symptoms of restenosis can be insidious and lead to symptoms of coronary insufficiency or be silent and lead to acute myocardial infarction.[46-48]

There are two types of stents available: bare-metal stents (BMS) and drug-eluting stents (DES). Bare-metal stents are made of a steel or cobalt alloy. Once the coronary stent is placed in the lumen of the coronary artery, the endothelialization process of the stent begins and takes approximately 2 to 4 weeks. For drug-eluting stents, the endothelialization process is significantly slower and in some cases may be incomplete. A polymer attached to the stent releases a drug designed to stop cell division and therefore excessive endothelial growth.[51] For both types of stent, patients typically receive dual antiplatelet therapy with aspirin and a thienopyridine (e.g., clopidogrel) to prevent acute stent thrombosis. The most common cause of acute stent thrombosis is premature discontinuation of dual antiplatelet therapy.[47] Current recommendations are to continue clopidogrel administration for 4 to 6 weeks for bare-metal stents and for at least 12 months for drug-eluting stents. Furthermore, aspirin is administered indefinitely. The risk of acute stent thrombosis is relatively low but may occur more commonly with DES because of the delayed or incomplete endothelialization process. Box 34-3 outlines additional risk factors for acute stent thrombosis. When considering discontinuing

BOX **34-3**

Additional Risk Factors for Acute Stent Thrombosis

Coronary Anatomy Factors
- Site of stent placement (e.g., bifurcation stenting, side branch occlusion)
- Left main coronary artery stent
- Long stent length (greater than 18 mm)
- Ostial stenting
- Overlapping stents
- Placement of multiple stents
- Small stent diameter (less than 3 mm)
- Suboptimal stent placement

Patient Risk Factors
- Advanced age
- Diabetes mellitus
- Gene polymorphism
- Hypercoagulable states (e.g., diabetes, malignancy, and surgery)
- Major cardiac adverse event within 30 days of percutaneous cardiac intervention
- Reduced left ventricular ejection fraction
- Prior brachytherapy
- Renal insufficiency

Stent Indication Factors
- Acute coronary syndrome
- Type C coronary lesion or total occlusion

Stent-Related Factors
- Type of stent placed
- Hypersensitivity to stent polymer

Pharmacologic Factors
- Abrupt discontinuation of antiplatelet therapy
- Diminished response or resistance to antiplatelet therapy

Adapted from Hall R, Mazer CD. Antiplatelet drugs: a review of their pharmacology and management in the perioperative period. *Anesth Analg.* 2011;112(2):292-318.

BOX **34-4**

Recommendations for Management of Patients with Drug-Eluting Stents

- Elective surgery with high risk of perioperative bleeding should be postponed until the appropriate course of thienopyridine therapy has been completed:
  - Bare-metal stent: 4-6 weeks
  - Drug-eluting stent: 12 months
- Elective noncardiac surgery is not recommended after stent placement when thienopyridine therapy or aspirin and thienopyridine therapy needs to be discontinued perioperatively. The prescribed period of thienopyridine therapy or aspirin and thienopyridine therapy is:
  - Bare-metal stent: 4-6 weeks
  - Drug-eluting stent: 12 months
- When surgery cannot be postponed and thienopyridine therapy must be interrupted, it is recommended that aspirin therapy be continued throughout the perioperative period and that thienopyridine therapy should be restarted as soon as possible after the procedure.
- Antiplatelet and anticoagulant medications with short half-lives may be used as perioperative bridging between discontinuation of antiplatelet therapy and surgery. In contrast, evidence is lacking in the use of warfarin, antithrombins, or glycoprotein IIb/IIIa agents as perioperative bridging after discontinuation of oral antiplatelet agents.
- Consideration should be given to the following patients:
  - Continuation of dual antiplatelet therapy beyond the recommended timeframe in patients at high risk for stent thrombosis
  - Continuation of aspirin antiplatelet therapy perioperatively in patients with drug-eluting stents

Modified from Grines CL, et al. Prevention of premature discontinuation of dual antiplatelet therapy in patients with coronary artery stents: a science advisory from the American Heart Association, American College of Cardiology, Society of Cardiovascular Angiography and Interventions, American College of Surgeons, and American Dental Association, with representation from the American College of Physicians. *J Am Coll Cardiol.* 2007;49(6):734-739.

or modifying antiplatelet therapy, it is prudent to involve a multidisciplinary team including a cardiologist, surgeon, and anesthetist for guidance regarding preoperative and postoperative management of antiplatelet therapy.

This patient population requires special attention preoperatively. Important information should include the date of stent implantation, the type of stent deployed, and antiplatelet therapy if applicable. Additional points to consider are the type of operation planned and the risk of bleeding. The current medication regimen must be assessed because many patients have discontinued their antiplatelet medications preoperatively, whereas others continue them at the request of their cardiologist. Surgery in which the risk of bleeding is low may not require discontinuation of antiplatelet therapy. Patients who require emergent surgery should be evaluated on a case-by-case basis, weighing the risks of bleeding against the risks of thrombosis. Due to the lack of prospective studies and guidelines, a wide variety of potential approaches to the perioperative management of BMS, DES, and antiplatelet therapy have been proposed. In 2007 the American Heart Association/American College of Cardiology (AHA/ACC) released their guidelines for management of patients with drug-eluting stents (Box 34-4).

Outpatients Requiring Noncardiac Surgery

The Eighth American College of Chest Physicians (ACCP) provides guidelines for the perioperative management of antithrombotic therapy and thromboembolism (Table 34-7).[52] When determining the perioperative management of anticoagulation therapy, consideration must be given to the risk of bleeding as related to the type of surgery (see Table 34-7), as well as the patient's risk for thromboembolism (Table 34-8). To date there lacks sufficient prospective, double-blind, randomized controlled studies to evaluate perioperative bridge therapies. Recent trials suggest that the bleeding risk using perioperative unfractionated heparin or low-molecular-weight heparin (LMWH) may be higher than previously thought. For these reasons, bridging anticoagulation should be approached cautiously, using patient input once risks and benefits have been discussed.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a systemic coagulation disorder characterized by activation of systemic inflammation and coagulation process as a result of an underlying pathologic condition. Clinical presentation of DIC may include thrombosis, hemorrhage, or both. Multiorgan system failure and hemorrhage is the result of widespread thrombotic microangiopathy and depletion of procoagulant factors (e.g., consumptive coagulopathy), respectively[53] (Figure 34-13).

The diagnosis of DIC is usually secondary to an underlying pathologic process (Box 34-5). Coagulation activation ranges from mild thrombocytopenia and prolongation of clotting times to acute DIC characterized by extensive bleeding and thrombosis.[54] Systemic activation of coagulation results in (1) intravascular deposition of fibrin, (2) thrombotic microangiopathy, (3)

TABLE 34-7 Bleeding Risk Associated with Invasive Procedures and Recommendations for Perioperative Management

Bleeding Risk (Category)	Invasive Procedures	Recommendations
High	Cardiac surgery, abdominal aortic aneurysm repair, neurosurgery, most cancer surgery, bilateral knee replacement, TURP, kidney biopsy	*Low-risk thromboembolism:* Stop warfarin 5 days before surgery and allow INR to return to near normal Restart warfarin 12-24 hr after surgery Use prophylactic dosages of LMWH or unfractionated heparin if procedure predisposes to thrombosis *Intermediate-risk thromboembolism:* Stop warfarin therapy 5 days before surgery Consider no bridging versus starting prophylactic LMWH or unfractionated heparin 2 to 3 days before surgery After surgery, restart warfarin and prophylactic LMWH or unfractionated heparin Alternatively follow bridge protocol *High-risk thromboembolism:* Follow bridge therapy protocol Await hemostasis before restarting LMWH; consider using therapeutic dosages of LMWH or unfractionated heparin
Intermediate (surgical)	Abdominal surgery, hemorrhoidal surgery, axillary node dissection dilation and curettage, hydrocele repair, orthopedic surgery, pacemaker insertion, internal cardiac defibrillator insertion, endarterectomy or carotid bypass surgery, noncataract eye surgery (complex lid, lacrimal, orbital), extensive dental surgery (multiple tooth extractions)	*Low-risk thromboembolism:* Stop warfarin 4 to 5 days before surgery and allow INR to return to near normal Restart warfarin after surgery Use prophylactic LMWH or unfractionated heparin if procedure predisposes to thrombosis *Intermediate-risk thromboembolism:* Stop warfarin 4 to 5 days before surgery Consider no bridging versus starting prophylactic LMWH or unfractionated heparin 2 to 3 days before surgery After surgery, restart warfarin and prophylactic LMWH or unfractionated heparin Alternatively follow bridge therapy protocol *High-risk thromboembolism:* Follow bridge therapy protocol Await hemostasis before restarting LMWH; consider using therapeutic dosages of LMWH or unfractionated heparin
Intermediate to low (nonsurgical)	Coronary angiography with or without percutaneous coronary intervention, noncoronary angiography, upper endoscopy with endosphincterotomy, colonoscopy with polypectomy, bronchoscopy with or without biopsy, biopsy (e.g., prostate, bladder, thyroid, breast, lymph node, pancreas)	*Low-risk thromboembolism:* Stop warfarin 5 days before surgery and allow INR to return to near normal Restart warfarin after surgery Use prophylactic dosages of LMWH or unfractionated heparin if procedure predisposes to thrombosis *Intermediate-risk thromboembolism:* Stop warfarin therapy 5 days before surgery Consider no bridging versus starting prophylactic LMWH or unfractionated heparin 2 to 3 days before surgery After surgery, restart warfarin within 12 to 24 hr, and/or prophylactic LMWH or unfractionated heparin Alternatively follow bridge protocol *High-risk thromboembolism:* Follow bridge therapy protocol Await hemostasis before restarting LMWH; consider using therapeutic dosages of LMWH or unfractionated heparin
Low to minimal	Arthrocentesis, general dental treatment (e.g., hygiene, restorations, endodontics, prosthetics, minor periodontal therapy, and uncomplicated extractions), ophthalmic procedures (e.g., cataract, trabeculectomy, vitreoretinal), TURP with laser surgery, upper and lower gastrointestinal endoscopy with or without mucosal biopsy	*All risks of thromboembolism:* Continue warfarin therapy Continue aspirin therapy Check INR the day of or the day before surgery to be sure not supratherapeutic

TABLE 34-8 Suggested Risk Stratification for Perioperative Thromboembolism

	INDICATION FOR VKA THERAPY		
Risk Stratum	**Mechanical Heart Valve**	**Atrial Fibrillation**	**VTE**
High	• Any mitral valve prosthesis • Any caged-ball or tilting disc aortic valve prosthesis • Recent (within 6 months) stroke or transient ischemic attack	• $CHADS_2$ score of 5 or 6 • Recent (within 3 months) stroke or transient ischemic attack • Rheumatic valvular heart disease	• Recent (within 3 months) VTE • Severe thrombophilia (e.g., deficiency of protein C, protein S, or antithrombin; antiphospholipid antibodies; multiple abnormalities)
Moderate	• Bileaflet aortic valve prosthesis and one or months of the of following risk factors: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age > 75 years	• $CHADS_2$ score of 3 or 4	• VTE within the past 3-12 months • Nonsevere thrombophilia (e.g., heterozygous factor V Leiden or prothrombin gene mutation) • Recurrent VTE • Active cancer (treated within 6 months or palliative)
Low	• Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	• $CHADS_2$ score of 0 to 2 (assuming no prior stroke or transient ischemic attack)	• VTE > 12 months previous and no other risk factors

$CHADS_2$ = congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, and stroke or transient ischemic attack; *VKA* vitamin K antagonist; VTE venous thromboembolism

Modified from Douketis JD, et al. Perioperative management of antithrombotic therapy: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest. 2012 Feb;141(2 Suppl):e326S-50S.

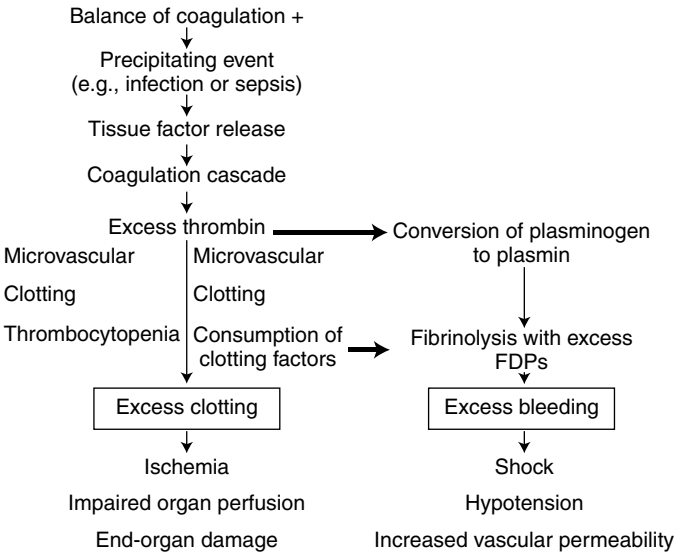

FIGURE 34-13 Pathophysiology of disseminated intravascular coagulation (DIC).

compromised blood supply to organs, and (4) multiorgan system failure. Systemic activation of coagulation also promotes the use and subsequent depletion of platelets and coagulation factors, which may induce severe bleeding from multiple sites.

Several factors play an important role in the pathogenesis of DIC. Tissue factor release is considered to play a central role in the development of hyperthrombinemia in DIC. Under normal conditions, mediators such as antithrombin and tissue factor pathway inhibitor (TFPI) regulate the process of coagulation. During specific conditions such as septicemia, liver impairment, capillary leakage, and the release of endotoxins and proinflammatory cytokines, the actions of these regulatory mediators are adversely altered. Experimental models of septicemia have shown increased fibrinolytic activity related to the acute release of tPA from the endothelium. The initial increased fibrinolytic activity is followed by the release of plasminogen activator inhibitor type 1 (PAI-1), which in turn impairs fibrinolysis and leads to accelerated thrombus formation in DIC. Finally, activated protein C mediates the release of inflammatory cytokines such as tumor necrosis factor and interleukins from endothelial cells. Complement activation and kinin generation increase the coagulation response, leading to subsequent vascular occlusion.[55]

Diagnosis of DIC is made by evaluation of the patient's clinical presentation in conjunction with laboratory tests such as platelet count, aPTT, PT, fibrin-related markers (e.g., fibrin degradation products, D-dimer), fibrinogen, and antithrombin. Additionally, a scoring system developed by the International Society of Thrombosis and Haemostasis (ISTH) assists with the diagnosis[56] (Box 34-6). Acute (overt) DIC is characterized by ecchymosis, petechiae, mucosal bleeding, depletion of platelets and clotting factors, and bleeding at puncture sites. A score of 5 or greater indicates overt DIC. Chronic (nonovert) DIC is characterized by thromboembolism accompanied by evidence of activation of the coagulation system. A score less than 5 suggests nonovert DIC.

The management and treatment of DIC depends on identification of the underlying pathologic condition. In obstetric catastrophes, DIC may resolve as a result of prompt delivery. Treatment of sepsis with antibiotic therapy may halt the progression of DIC. Restoration of physiologic anticoagulant pathways with activated protein C in the treatment of sepsis with overt DIC holds promise.[54] Activated protein C inactivates factors Va and VIIIa, resulting in decreased thrombin formation. Its use in treating DIC patients with severe sepsis has been approved by the FDA. For individuals requiring surgery who are bleeding or at risk for active bleeding, correction of coagulopathy with platelets, FFP, and/or cryoprecipitate must be used. Continued replacement of blood products should be based on the clinical presentation and reassessment of laboratory results.[5]

The use of antithrombotics for DIC remains controversial, especially in a patient who is prone to bleeding. Antithrombin III concentrates may prove effective in inhibiting coagulation; however, their use is still under investigation.[55]

Sickle Cell Disease. Sickle cell disease is a common hereditary hemoglobinopathy. Under normal circumstances, the beta-globin gene on chromosome 11 codes for the production of the beta-globin chains of the protein hemoglobin A. However, in

BOX 34-5

Clinical Conditions Associated with Disseminated Intravascular Coagulation

Respiratory
- Acute respiratory distress syndrome

Cardiovascular
- Fat embolism
- Hypovolemia
- Vascular disease
  - Kasabach-Merritt syndrome (i.e., giant hemangioma)
  - Large-vessel aneurysm (i.e., aortic aneurysm)

Neurologic
- Traumatic brain injury

Hematologic
- Hemolytic transfusion reaction
- Massive transfusion
- Thrombotic thrombocytopenic purpura

Gastrointestinal
- Fulminant hepatic failure

Pharmacologic
- Illicit drug use (i.e., methamphetamine overdose)

Other Considerations
- Immune-mediated disorders
  - Adult Still's disease
  - Allergic reactions
  - Lupus erythematosus
  - Transplant rejection
- Malignant disease
  - Cytotoxic chemotherapy
  - Myeloproliferative malignancy (i.e., acute promyelocytic leukemia)
  - Pancreatic carcinoma
  - Solid tumors (e.g., metastatic adenocarcinoma)
  - Trousseau syndrome (i.e., chronic compensated DIC)
  - Tumor lysis syndrome
- Massive trauma and shock states
  - Extensive burns
- Obstetric complications
  - Amniotic fluid embolism
  - HELLP syndrome (i.e., hemolysis, elevated liver function tests, and low platelets)
  - Placenta previa
  - Placental abruption
  - Retained dead fetus or products of conception syndrome
  - Septic miscarriage or abortion
- Sepsis
  - Fungal
  - Gram-negative and gram-positive bacteria
  - Helminthic
  - Malaria
  - Protozoan
  - Rocky Mountain spotted fever
  - Viral
- Systemic toxins
  - Snake venom

DIC, Disseminated intravascular coagulation.

BOX 34-6

International Society of Thrombosis and Haemostasis Scoring System for Disseminated Intravascular Coagulation

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?
   If yes, proceed; if no, do not use this algorithm.
2. Order global coagulation tests (e.g., platelet count, prothrombin time, fibrinogen, soluble fibrin monomers, or fibrin degradation products).
3. Score global coagulation test results.
   _____ Platelet count
   (>100, 0; <100, 1; <50, 2)
   _____ Elevated fibrin-related marker (e.g., soluble fibrin monomers/fibrin degradation products)
   (no increase, 0; moderate increase, 2; strong increase, 3)
   _____ Prolonged prothrombin time
   (<3 sec, 0; >3 sec but <6 sec, 1; >6 sec, 2)
   _____ Fibrinogen level
   (>1.0 g/L, 0; <1.0 g/L, 1)
4. Calculate score
5. If 5 or more, compatible with overt DIC; repeat scoring daily. If less than 5, suggestive (not affirmative) for nonovert DIC; repeat next 1 to 2 days.

Adapted from Bakhtiari K, et al. Prospective validation of the International Society of Thrombosis and Haemostasis scoring system for disseminated intravascular coagulation. *Crit Care Med*. 2004; 32(12):2416-2421.
DIC, Disseminated intravascular coagulation.

sickle cell disease, an autosomal recessive genetic abnormality of the beta-globin gene codes for the production of the variant hemoglobin, hemoglobin S. Patients may present with sickle cell trait or sickle cell disease. The sickle cell trait is a heterozygous disorder observed in 10% of African Americans.[39] Hemoglobin S levels are between 30% to 50% and erythrocyte sickling is observed with a P_{O_2} of 20 to 30 mmHg. In contrast, sickle cell disease is a homozygous disorder observed in 0.5% to 1.0% of African Americans. The majority of the hemoglobin molecule is hemoglobin S, and sickling is observed with a P_{O_2} of 30 to 40 mmHg. A sickle cell crisis may be triggered by a hypoxemia, hypothermia, infection, dehydration, venous stasis, and acidosis. Sickle cell crisis may be characterized by chronic hemolytic anemia, recurrent episodes of intermittent vasoocclusion, severe pain, and end-organ damage. Although previous studies of sickle cell disease cite a perioperative morbidity and mortality greater than 50%, perioperative mortality has diminished steadily, which is attributed with overall improvements in anesthetic care.[57] Suggestions for intraoperative management of patients with sickle cell disease are given in Box 34-7.

There is no universal method for caring for patients with a sickle cell disorder. The optimal percentage of hemoglobin S in patients receiving regular blood transfusions remains to be established, with clinical studies citing a range between 30% to 50%.[58,59] Providing preoperative transfusion supplementation always carries a risk of increasing the blood viscosity and causing end-organ damage. A conservative transfusion regimen has been shown to be as effective as an aggressive regimen in preventing perioperative complications and was associated with fewer transfusion-related adverse events.[8] Anesthesia management for a patient with sickle cell disease includes providing adequate hydration, promoting adequate oxygen saturation,

BOX **34-7**

Intraoperative Management of Patients with Sickle Cell Disease

- Standard monitors and invasive monitoring, as appropriate
- Selection of anesthetic technique appropriate for surgical procedure and clinical status of the patient
- Provide adequate hydration (e.g., monitor hemodynamic status, urine output, central venous pressures when available)
- Transfusion of cross-matched red blood cells to replace surgical blood loss (e.g., avoid increasing the Hgb greater than 10-11 g/dL)
- Avoid hypoxemia
- Maintain normothermia
- Maintain normal acid-base status
- Provide adequate perioperative pain management

From Firth PG. Anesthesia and hemoglobinopathies. *Anesthesiol Clin*. 2009;27(2):321-336.

ensuring normothermia, maintaining acid-base balance, and providing proper patient positioning, and supplying adequate analgesia may interrupt intraoperative and postoperative sickle cell crisis.[60]

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is recognized as the most important immunologic complication of heparin therapy and remains one of the few absolute contraindications for heparin use. Heparin continues to be used clinically because of its rapid onset, easy reversibility, and moderate therapeutic window with relatively few side effects. In the United States, approximately 30% of hospitalized patients or about 12 million people a year receive heparin. Approximately 5% of patients receiving heparin or low-molecular-weight heparin (LMWH) will develop immune reactions characteristic of HIT; of these patients approximately 50% or about 300,000 people will have clinically significant HIT thrombosis.[61]

The classic clinical presentation of HIT includes thrombocytopenia, resistance to heparin anticoagulation, thrombosis, and positive assay tests indicative of HIT. There are two classifications of HIT; Box 34-8 describes defining characteristics of each type. Of the two classifications, type II is associated with the greatest clinical morbidity and mortality. HIT type II is caused by the formation of immunoglobulin G antibodies directed against heparin-platelet factor 4 (H-PH4) immune complexes. The immunoglobulin G antibody fixes to complements with H-PH4 and subsequently activates platelets via the Fc receptor causing platelet aggregation[62] (Figure 34-14). Traditionally a 30% decrease in the platelet count was considered significant for HIT. Despite thrombocytopenia, patients clinically do not present with bleeding tendencies (e.g., spontaneous bleeding, hemorrhage, petechiae). Rather, HIT type II induces a clinically relevant hypercoagulable state with clotting and thrombus formation causing serious sequelae. Amputation and mortality associated with HIT type II is estimated to be 20% and 30%, respectively.[61]

Diagnosis and treatment of HIT should be based on clinical presentation and laboratory findings. Thrombocytopenia, cutaneous abnormalities (e.g., skin necrosis, ecchymosis, hematoma, purpura, blistering), and tachyphylaxis after heparin administration may indicate developing HIT. The use of physiologic testing (e.g., serotonin release assay, heparin-induced platelet aggregation assay) and antibody detection (e.g., enzyme-linked immunosorbent assay) has been used to confirm the diagnosis of HIT. Anesthesia providers are the primary providers of heparin perioperatively. During the preoperative period, it is imperative that the anesthesia provider review current laboratory tests and medications. If HIT is suspected after heparin administration, a hematologist should be consulted. Treatment of HIT includes discontinuation of all sources of heparin (e.g., medications, heparin-coated invasive lines), administration of direct thrombin inhibitors (e.g., argatroban or hirudin).[61] Arterial or venous thrombosis that compromises perfusion to distal sites may require prompt surgical intervention (e.g., embolectomy or vascular bypass).

BOX **34-8**

Heparin-Induced Thrombocytopenia (HIT) Type I and Type II

Type I

- Thrombocytopenia is mediated by direct heparin-induced platelet aggregation (e.g., nonimmune mediated)
- Onset is typically 1 to 4 days after start of heparin therapy
- Mild thrombocytopenia (e.g., less than 100,000 per microliter)
- Thrombocytopenia often resolves spontaneously even with continued administration of heparin
- Typically occurs with high-dose heparin administration
- Not associated with thrombosis and serious clinical sequelae

Type II

- Thrombocytopenia is mediated by the actions of the heparin, platelet factor 4, and immunoglobulin G expression (e.g., immune mediated)
- Onset is typically 5 to 14 days after start of heparin therapy
- Severe thrombocytopenia (e.g., less than 60,000 per microliter)
- Thrombocytopenia does not resolve spontaneously, therefore heparin administration must be discontinued
- Occurs with any heparin dose and route
- Associated with thrombosis and serious clinical sequelae

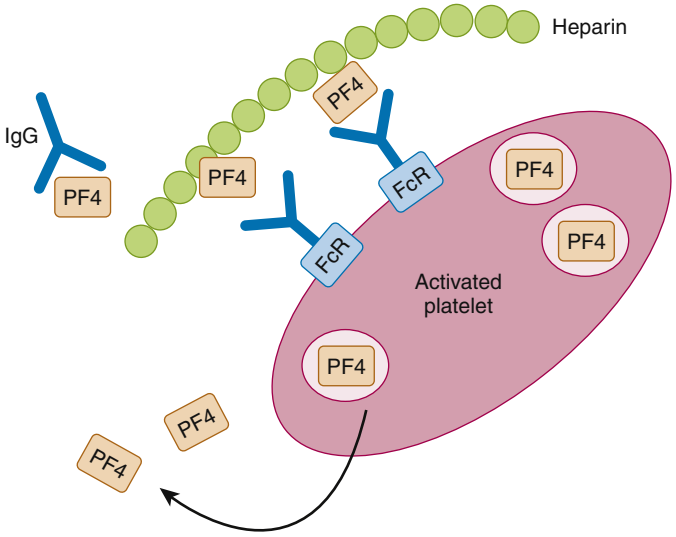

FIGURE **34-14** Pathophysiology of heparin-induced thrombocytopenia (HIT) type II.

SUMMARY

Each time patients consent to undergo a surgical or diagnostic procedure, the hemostatic system is challenged. An understanding of the normal hemostatic system, methods to prevent bleeding and decrease transfusion requirements, alternatives to blood transfusions, and an understanding of hemostatic pharmacology can only enhance patient care and safety when providing anesthesia care.

35 CHAPTER Thermal Injury and Anesthesia

◆ *Valdor L. Haglund*

The American Burn Association's National Burn Repository of 2011 estimates approximately 450,000 individuals a year with burn injuries visited emergency departments in the United States (between 2001 and 2009).[1] Of these, approximately 45,000 individuals were hospitalized for acute burn injuries and a little more than half were admitted to one of 126 specialized burn centers around the country. These burn centers undergo a rigorous review by the American Burn Association (ABA) and the American College of Surgeons (ACS) to become verified. The verification process insures the facility provides high-quality, specialized care of burned patients, maintaining the necessary resources and medical services mandated by ABA guidelines.[2]

There has been a decline in the incidence of burn injury the past 2 decades. This is in part due to an increased focus on burn prevention including increased use of smoke detectors, fire and burn prevention education, decreased smoking, water temperature regulations, and regulation of consumer products and occupational safety. An improvement in all aspects of medical care of these patients has played a major role in improving survival. These include increased access to emergency medical care, advanced ventilation and treatment of inhalation injuries, improved infection control practices, enhanced nutritional support, early burn wound excision and grafting, and the treatment of the hypermetabolic response. The development of evidence-based practice guidelines and multidisciplinary care models available at regional burn care centers have also contributed to improvements.[3]

Nonetheless, during the period 2001 to 2010 in the United States, more than 1.25 million people sustained burn injuries annually with 450,000 receiving medical treatment.[4] Approximately 3500 die from the burn injury—3000 from residential fires and 500 from motor vehicle or aircraft crashes.[5] Approximately 75% of deaths occur at the scene of the accident or during initial transport.[6] Roughly 35% of all burn victims are younger than 17 years of age, with more than 15,000 children requiring hospitalization as a result of their burn injuries. Scald injuries predominate among small children, with a progressive increase in the frequency of thermal-related burns in the elderly. Major causes of death in burn patients are multiple organ failure and infection. Major risk factors for death are older age and a higher total percentage of burned surface area, as well as chronic diseases. The main causes of early death (less than 48 hours after injury) are shock and inhalation injury. Multiorgan failure and sepsis were the most frequently reported causes of death. Death after a burn injury is not related to the toxic biologic effects of thermally injured skin but to shock associated with metabolic and infectious consequences of a large open wound, sepsis, inhalation injury, and extensive malnutrition, which cumulatively set the stage for life-threatening bacterial sepsis.[7,8]

CLASSIFICATION OF BURN INJURY

Burn injuries, regardless of their etiology, are classified according to the depth and extent of skin and tissue destruction, as well as the total body surface area (TBSA) involved. First-degree (superficial) burns are limited to the epidermis, the outermost layer of skin. The epidermis is thin and avascular, usually healing spontaneously and seldom requiring medical intervention. Second-degree burns, also known as deep and superficial *partial-thickness burns*, extend to the dermis. In contrast to the epidermis, the dermis is very vascular and contains numerous blood vessels and nerves. Thus severity of the type of burn varies, depending on the amount and depth of the dermal tissues involved. If the epithelial basement membrane of the dermis is intact, the skin will regenerate, and grafting may not be required. Third-degree burns, or *full-thickness burns*, extend to the subcutaneous tissue lying below the dermis. The entire skin thickness is destroyed with third-degree burns.[9] Skin grafting is required for these types of burns because the epithelium and the dermal appendages are destroyed. A fourth-degree burn classification is used by some to describe structures burned below the dermis, such as muscle, fascia, and bone. Table 35-1 classifies burns according to depth of skin layers affected, and Figure 35-1 illustrates the layers of burn injury.

The burn team assesses the extent of a burn and plans initial resuscitation efforts. Burn wounds can be readily quantified, but estimation of the burn size remains subjective and assessor related. The most widely used estimation is the "rule of nines," which was first described by Lund and Browder (Figure 35-2). The body is divided into regions that represent 9% or a multiple of 9% of the TBSA. Specific modifications apply to children because the surface areas of their heads and trunks are proportionally larger than their extremities.[10] The rule of nines is a quick method to visually estimate burn size; however, it may not be all inclusive. The extent of burn injury can be more specifically quantified using the Lund and Browder chart. Figure 35-3 demonstrates this method, which is more accurate in determining a burn victim's injury but is also more time-consuming to use. This method is often used when determining the extent of burn in the pediatric patient.

According to the ABA's injury severity grading system, a *major burn* is (1) a second-degree burn involving more than 10% of the TBSA in adults or 20% at extremes of age, (2) a third-degree burn involving more than 10% of the TBSA in adults, (3) any electrical burn, or (4) a burn complicated by smoke inhalation. Associated mortality estimates follow a burn formula derived from the National Burn Registry: if the age of the patient plus percentage TBSA of burn exceeds 115, the mortality is greater than 80%. Additionally, clinical observations estimate the mortality of a burn victim is doubled if inhalation injury is sustained in conjunction with a thermal burn.

ETIOLOGIES OF BURN INJURIES

On admission to a burn unit, the team determines the etiology of the burn injury and the circumstances surrounding the injury. This is especially important because specific pathophysiologic sequelae can be expected after an electrical burn, and still others after a thermal burn. An individual burned in a contained space, such as in a house fire, should be suspected of having an inhalation injury as well. There are four types of burn injuries: chemical, electrical, thermal/heat (also referred to as *flame* or *scald*), and inhalation. Chemical burns commonly occur in a laboratory setting or industrial environment. These chemical burns occur when a noxious chemical substance comes into contact with the skin. Tissue damage and destruction result from the reaction of the chemical with tissue proteins and cellular components. Skin disruption will continue until the chemical irritant is removed or neutralized. Initial treatment is application of copious amounts of water or normal saline irrigation. Chemical burns are uncommon in children.

Electrical burns can be the most damaging to skin and surrounding tissues. The extent of the burn depends on the amount of thermal energy conducted through the skin, based on the voltage and duration of contact with the electrical source. Significant tissue disruption can occur where electric current is most concentrated—at points of entry and exit, although two wounds are not always evident. Initially, the extensiveness of skin and underlying tissue involvement may be hard to diagnose, because surface damage may not reflect all tissue damage, and the entrance wounds may appear superficial. Electrical burns can cause severe damage to bones, blood vessels, muscle, and nerves. If the amount of muscle damaged from the conducted electric current is significant, myoglobin can be released into the circulation. Myoglobinemia places the patient with an electrical burn at great risk for developing renal failure secondary to myoglobinuria, which affects nephron and renal tubular function.

Thermal burns, or burns sustained from any heat source, commonly occur in and around the home. Approximately 70% of burns sustained by those up to the age of 4 years old are the result of scald injuries, whereas flame burns are the most common pattern among children 5 years and older. In general, younger children are at higher risk for sustaining burn injuries, and abuse or neglect may account for as much as 15% to 20% of these cases.[3]

Inhalation burn injuries often accompany thermal burns and should be suspected until aggressively ruled out.[11-13] Inhalation injury can be classified into three types, based on anatomic location. The first type includes upper-airway injuries caused primarily

TABLE 35-1 Degrees of Burn Injury

Classification	Tissue Level Involvement	Outcome and Treatment
First-degree burn (Superficial)	Epidermis	Skin appears red and slightly edematous; heals spontaneously; mild pain and no scarring; barrier preserved; sunburn or flash flame
Second-degree burn (Partial-thickness)		
Superficial dermal burn	Epidermis and upper dermis	Heals spontaneously; red and edematous; appears wet, hyperemic, and blistering; heals in 7-10 days; scar uncommon
Deep dermal burn	Epidermis and deep dermis	Requires excision and grafting for rapid return of function; heals in 2-8 weeks; probable scar without surgery
Third-degree burn (Full-thickness)	Destruction of epidermis and dermis	Epidermal and complete dermal loss; wound excision and grafting required; limitation of function and scar formation; waxy white leathery appearance; no pain due to nerve damage
Fourth-degree burn	Skeletal muscle, fascia, bone	Complete dermal loss with injury down to tendon or bone; complete excision, limited function; muscle necrosis; electrical injuries; limb loss common

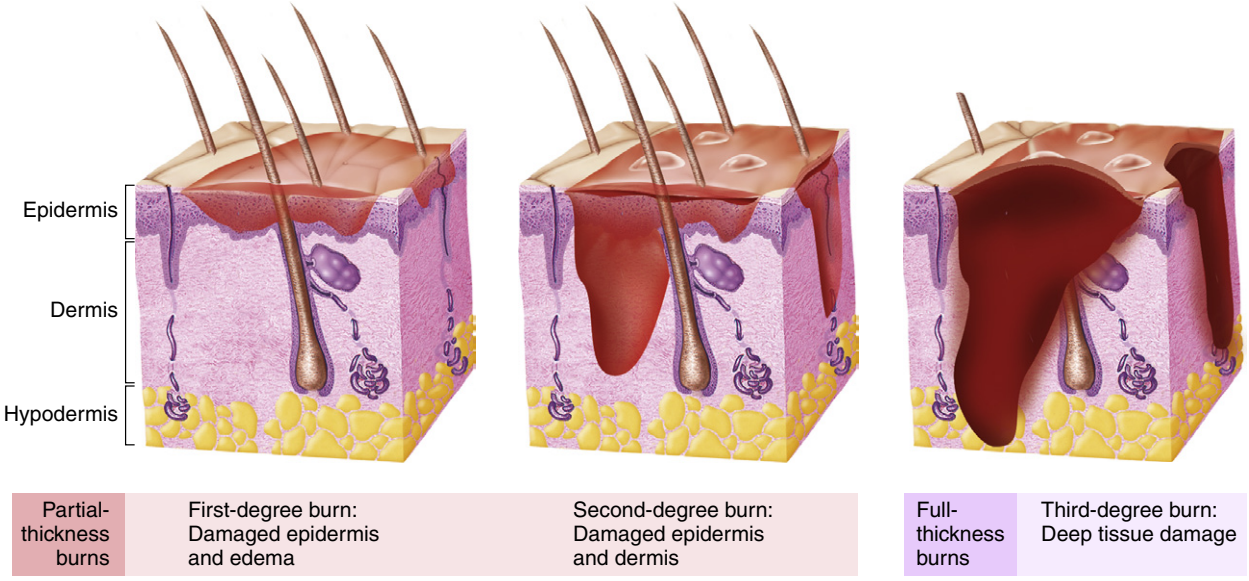

FIGURE 35-1 Classification of burns. Partial-thickness burns include first- and second-degree burns. Full-thickness burns include third-degree burns. Fourth-degree burns involve tissues under the skin, such as muscle or bone. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 8th ed. St. Louis: Mosby; 2013:193.)

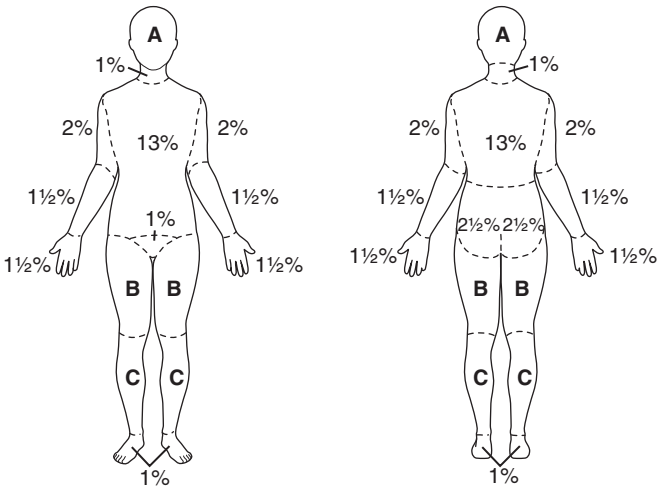
by thermal injury to the mouth, oropharynx, and larynx. The second type includes lower airway and parenchymal injuries to the trachea, bronchioles, and alveoli caused by chemical and particulate constituents of smoke. Inhalation injury usually means injuries of this type. The third type includes metabolic asphyxiation in which certain smoke constituents such as carbon monoxide or hydrogen cyanide impair oxygen delivery or use by the tissues. All three types may coexist in a given patient.

Damage to the airway can vary, depending on whether the upper airway or lower airway is affected. Upper airway injuries result from inhalation of superheated air or steam and toxic compounds found in smoke.[15] Brief exposure of the epiglottis or larynx to either dry air at 300° C or steam at 100° C can lead to massive edema and rapid airway obstruction.[16] The addition of an inhalation injury to a cutaneous burn doubles the mortality rate[17] and is a greater determinant of death than size of the burn wound. Inhalation of heated air can result in direct injury to the face, oropharynx, and upper trachea, while sparing the lower airway. It is speculated that heat entrained is readily dissipated in the upper airway, and there is reflex closure of the vocal cords effectively protecting the lower airway from heat-related injury. However, true thermal injury from exposure to live steam can occur in the lower respiratory tract because heat-exchange mechanisms of the airway are unable to cool the gas sufficiently as it is inhaled. Obstruction of the upper airway is due to excessive edema, macroglossia, and swelling of the pharyngeal soft tissue. Lower airway injuries more commonly arise from the inhalation of soot particles and/or chemicals produced by a fire. In the lower airway, inhaled toxins react with the airway mucosa forming acidic and alkali substances. Capillary permeability is increased. Extensive alveolar and epithelial damage can occur, with the trachea and bronchi becoming necrotic. Warning signs of respiratory injury include hoarseness, sore throat, dysphagia, hemoptysis, tachypnea, the use of accessory muscles, wheezing, carbonaceous sputum, and elevated carbon monoxide levels.[14,18,19]

Treatment of the burn patient involves three distinct phases: the resuscitative phase, debridement and grafting, and the



Area	Age 0	1	5	10	15	Adult
A - ½ of head	9½%	8½%	6½%	5½%	4½%	3½%
B - ½ of one thigh	2¾%	3¼%	4%	4¼%	4½%	4¼%
C - ½ of one leg	2½%	2½%	2¾%	3%	3¼%	3½%

reconstructive phase. Each phase has its own unique set of challenges the anesthesia provider must consider when developing an anesthetic plan.

TREATMENT OF THE BURN PATIENT

Resuscitative Phase

As with any trauma patient, initial treatment of the burn patient should involve attention to the airway, breathing, circulation, and coexisting trauma. All burn patients must be considered at risk for pulmonary compromise, especially if the percentage of TBSA involved is significant, and signs of inhalation injury are present.

Airway Injury

It is essential to aggressively rule out upper airway injury in patients at risk (e.g., involving a fire that occurred in a closed space or the development of unconsciousness or stupor that prevented the patient from protecting his or her airway). Diagnosis is made by history, the circumstances surrounding the burn injury, and physical examination. Above the oropharynx, thermal injury can produce significant inflammation, occluding the airway. Heat rarely causes damage below the vocal cords because it is effectively dissipated. The other components of smoke such as particulate materials, systemic toxins, and respiratory irritants trigger a cascade of events, resulting in pulmonary edema and a ventilation/perfusion $\dot{V}/\dot{Q}$ mismatch.[20] Airway examination is best accomplished by direct visualization of the airway with a laryngoscope or fiberoptic bronchoscopy.[21] Fiberoptic bronchoscopy is the gold standard for the diagnosis of the severity of inhalation injury. Table 35-2 has a commonly used classification of fiberoptic injury findings and associated mortality.[22] The chest radiograph is usually normal in the early phase of inhalation injury (unless aspiration of gastric or pharyngeal contents occurred during the accident), becoming abnormal once pulmonary edema or infiltration develops. Treatment of upper airway injury involves *early* endotracheal intubation, even if the burn patient is not yet demonstrating signs of airway decompensation. Even in the absence of an inhalation injury, the lungs are at risk for compromise if the burn area is large.

Thermal damage to soft tissues of the respiratory tract and trachea can make intubation an incredibly difficult task because of the malalignment of structures, swelling, and bleeding of the tissues involved. Intubation of the trachea is much easier to perform earlier rather than later, when there may be glottic or facial edema, which worsens after fluid resuscitation.[18-25] In the pediatric population, intubation should be performed with an uncuffed endotracheal tube, usually one size smaller than expected according to age and weight. Fiberoptic-assisted or laryngeal airway mask (LMA) guided intubation techniques are useful. The use of a retrograde wire, light wand, or GlideScope video-assisted techniques have all been used successfully.[26] Nasotracheal intubation in children may be preferred because it is better tolerated, and tube displacement with movement is less likely. Cuffed endotracheal tubes are traditionally used for pediatric patients younger than 8 years old. They are commonly used in pediatric burns because of the added flexibility of not requiring replacement that can be necessitated by decreasing edema and air leaks, which is the case with uncuffed tubes.[3,26]

In the absence of an airway abnormality, early tracheal intubation can usually be achieved using a rapid-sequence technique with an intravenous (IV) induction agent and a rapidly acting muscle relaxant. There is general agreement that succinylcholine administration to patients more than 24 hours after burn injury is unsafe,[27,28] although some authors extend this safe period to slightly longer.[29] Receptor up-regulation occurs after a burn injury, with proliferation of acetylcholine receptors throughout the muscle membrane. Succinylcholine can cause potassium (K^+) release from the entire muscle membrane rather than from discrete end-plate junctions, leading to hyperkalemia and possibly cardiac arrest.[30] The magnitude of K^+ elevation appears to be related to the size of the burn. This process of receptor up-regulation takes days to develop, allowing an initial 24-hour window of safety. It is wise to avoid the use of succinylcholine in a burn patient more than 24 hours after injury.[31]

Intubation with a nondepolarizing relaxant or without a relaxant via the techniques mentioned above allow for safe airway control. Several factors converge to produce an increased dose requirement of nondepolarizing relaxants in burn patients. These include up-regulation of acetylcholine receptors, massive fluid shifts producing significant changes in volume of distribution, and a qualitative decrease in receptor sensitivity. Plasma protein-binding alterations do not effect relaxants clinically because they are not highly bound. Rocuronium, for example, is only 30% protein bound. Both the dose administered and the serum concentrations required in the burn patient may be increased three- to five-fold to achieve the desired paralysis with a nondepolarizer.[32-34]

With an abnormal airway or upper airway obstruction, the safest way to secure the airway is with the patient awake. Key actions include effective topical anesthesia, patient positioning, and supplemental oxygenation. Incremental doses of ketamine or dexmedetomidine infusion along with topical anesthesia and avoiding relaxants allow the patients to continue to breath spontaneously with airway reflexes relatively intact while the airway is secured. Administration of sedatives may worsen airway obstruction and should be given judiciously. However, IV opioid administration may be appropriate for the alert patient in pain. Methods to secure the airway include flexible fiberoptic bronchoscopy, direct laryngoscopy, LMA-assisted intubation, blind nasal intubation, retrograde wire, light wand, or GlideScope video-assisted techniques. When the upper airway is badly damaged and endotracheal intubation is not possible, a direct surgical approach such as tracheotomy is indicated.

For the most part, after airway management, the burn patient is taken to the intensive care unit and placed on ventilatory support.[35] Inspired gases should be humidified to aid clearing of tracheobronchial debris and prevent drying of secretions. The endotracheal tube must be kept in place until the surrounding laryngeal edema has subsided. A progressive air leak around the endotracheal tube, especially in uncuffed pediatric sizes, may be an indication that edematous tissue is returning to normal.[14,18-20,36]

TABLE 35-2 Grading Scheme for Fiberoptic Bronchoscopy Findings in Inhalation Injury

Grade	Findings	Mortality (%)
0	Normal (no inhalation injury)	0
B	Positive based on biopsy only	0
1	Hyperemia	2
2	Severe edema and hyperemia	15
3	Severe injury: ulcerations and necrosis	62

Adapted from Chou SH, et al. Fiber-optic bronchoscopic classification of inhalation injury: prediction of acute lung injury. *Surg Endosc*. 2004;18(9):1377-1379; Cancio LC. Airway management and smoke inhalation injury in the burn patient. *Clin Plast Surg*. 2009, 36(4):555-567.

Administration of nebulized heparin and *N*-acetylcysteine with massive burn and smoke inhalation injury results in a decreased incidence of re-intubation for progressive pulmonary failure, decreased atelectasis, and reduced mortality. The Shriners Burns Hospital formula includes 5000 units of heparin and 3 mL of a 20% solution of *N*-acetylcysteine aerosolized every 4 hours for the first 7 days after the injury.[20]

Carbon Monoxide Poisoning

Any burn victim rescued from an enclosed-space fire should be considered at high risk for carbon monoxide poisoning. It is estimated that 50% to 60% of all fire victims die from carbon monoxide poisoning.[37] Symptoms depend on the carboxyhemoglobin level, although it is actually the tissue carbon monoxide level that determines the toxicity of carbon monoxide (Table 35-3).

Carbon monoxide binds to the hemoglobin molecule with 200 times greater affinity than oxygen, leading to a fall in oxyhemoglobin saturation as tissues become unable to extract oxygen.[14] The end result is a disruption in mitochondrial oxidative phosphorylation, which produces metabolic acidosis at the cellular level. Analysis of blood gases reveals a normal arterial oxygen tension but a decreased total oxygen content, indicating that the hemoglobin oxygen saturation is markedly reduced. Carbon monoxide increases the stability of the oxyhemoglobin molecule, decreasing the release of oxygen to the tissues and producing a leftward shift in the oxyhemoglobin curve (see Figure 17-6). Pulse oximeters do not detect carboxyhemoglobin (CoHgb) in blood and give falsely elevated readings for oxygen saturation in its presence. The diagnosis of carbon monoxide poisoning requires measurement of arterial CoHgb levels using a co-oximeter. The half-life of CoHgb is variable. In patients treated with 100% oxygen, it ranged from 26 to 148 minutes.[38] Treatment continues with 100% oxygen until the CoHgb level is less than 5% or for 6 hours.[39] A co-oximeter measures concentrations of all hemoglobin moieties (i.e., oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin).[40]

Hyperbaric oxygen therapy (HBOT) is an alternative treatment and may be helpful if the CoHgb level exceeds 25% or if clinical signs of toxicity are evident. Hyperbaric oxygen accelerates the clearance of carbon monoxide beyond that achieved using 100% oxygen at 1 atmosphere. The main rationale for its use is prevention of delayed neurocognitive syndrome. It can be difficult to transport and care for patients in the chamber, and debate continues over its effectiveness.[41]

TABLE 35-3 Carbon Monoxide Poisoning

Carboxyhemoglobin (%)	Symptoms
0-10	Normal
10-20	Headache, confusion
20-40	Disorientation, fatigue, nausea, visual changes
40-60	Hallucination, combativeness, convulsion, coma, shock state
60-70	Coma, convulsions, weak respiration and pulse
70-80	Decreasing respiration and stopping
80-90	Death in less than 1 hour
90-100	Death within a few minutes

Cyanide Poisoning

Hydrogen cyanide (HCN) poisoning is another toxicity seen with fires. It is produced by the combustion of materials such as plastics, foam, paints, wool, and silk. Cyanide poisoning produces tissue hypoxia by blocking the intracellular use of oxygen. Cyanide binds to the terminal cytochrome on the electron transport chain, causing hypoxia, lactic acidosis, and elevated mixed venous oxygen saturation. The half-life of HCN is approximately 1 hour. Signs and symptoms of poisoning include loss of consciousness, dilated pupils, seizures, hypotension, tachypnea followed by apnea, and high lactate levels. Cyanide has several antidotes, with differing mechanisms of action and diverse profiles. Hydroxocobalamin (vitamin B_{12}a) actively binds cyanide by forming cyanocobalamin, which is directly excreted via the kidney.

Hydroxocobalamin has a rapid onset of action, neutralizes cyanide without interfering with cellular oxygen use, and has a good safety profile. It is safe for use with smoke-inhalation victims, easy to administer, and is the preferred antidote to this type of cyanide poisoning. A hydroxocobalamin dose of 50 mg/kg is recommended. In addition, aggressive stabilization of cardiopulmonary function augments the hepatic clearance of cyanide via rhodanase, and can resolve cyanide poisoning (blood levels, 5.6-9 mg/L), without the use of antidotes.[14,20,42]

Hypovolemic Shock Associated with Thermal Injury

After the airway has been secured and other life-threatening injuries have been managed, the burn patient must be resuscitated with large volumes of fluid. Aggressive fluid administration and restoration of blood volume are critical for improving chances of patient survival and preventing renal failure. Burns cause a form of hypovolemic shock. These changes are reflected in loss of circulating plasma volume, hemoconcentration, massive edema formation, decreased urine output, and depressed cardiovascular function.[25,43] Fluid losses are greatest in the first 12 hours after burn injury and then begin to stabilize after 24 hours. Fluid losses occur secondary to direct transudation of plasma and plasma proteins from the wound and from diffuse capillary leakage that shift fluid from the intravascular space to the interstitium of unburned tissue. Capillary leak results from a loss of endothelial integrity and from reduction of intravascular oncotic pressure as plasma proteins are lost through the burn wound and incompetent capillary beds. The end result of changes in microvasculature caused by thermal injury is disruption of normal capillary barriers separating intravascular and interstitial compartments and rapid equilibration of these compartments. This causes severe depletion of plasma volume and a marked increase in extracellular fluid, clinically manifested as hypovolemia and burn-induced edema.[10,25,43]

Inflammatory mediators are released from burned tissues after injury, causing localized inflammation and burn-wound edema. Localized mediators include oxygen radicals, arachidonic acid metabolites, histamine, prostaglandins, leukotrienes, products of platelet activation, and the complement cascade.[23,37,44] Most edema occurs locally at the burn site and is maximal at 24 hours after injury. The edema itself results in tissue hypoxia and increased tissue pressure with circumferential injuries. Aggressive fluid therapy can correct the hypovolemia but will accentuate the edema process. In minor burns, the inflammatory process remains sequestered in the wound itself. However, in major burn insults, this local injury signals the release of systemic circulatory mediators resulting in a systemic response.

Fluid Resuscitation

Within seconds after an acute burn injury, massive fluid shifts begin to occur. Therefore, fluid resuscitation and airway management

are the hallmarks of initial therapy and should be instituted by the first-response emergency medical providers. There are many formulas for calculating a burn patient's initial fluid resuscitation requirements. Crystalloid resuscitation often provides substantial volumes of fluid, often in excess of that predicted by current formulas, resulting in numerous edema-related complications. This phenomenon is coined "fluid creep," and fluid therapy after the initial 24 hours is constantly being refined. In most centers, two formulas are accepted as guidelines for the resuscitation of severely burned patients, the Parkland and modified Brooke formulas.[45,46] The need for blood transfusion is usually not a major concern during the immediate resuscitation phase in acutely burned patients unless other coexisting trauma exists. Transfusion management is a prominent issue during subsequent surgical intervention.

The current ABA consensus formula for fluid resuscitation and urine output in burn patients is given in Box 35-1. Table 35-4 lists other suggested fluid protocols. Common to all of these formulas is the patient's weight in kilograms and the percentage of TBSA involved. The American College of Surgeons Committee on Trauma has advocated that only crystalloid formulas be used for all burn resuscitation. Colloid solutions are not advocated in the first 24 hours because capillary permeability remains enhanced, and colloids administered will not remain in the intravascular space. Isotonic crystalloid is the most commonly used fluid for resuscitation in U.S. burn centers. The most popular fluid resuscitation regimen, the Parkland formula, uses isotonic crystalloid solutions and estimates the fluid requirements in the first 24 hours to be 4 mL/kg/% TBSA burned. Crystalloid solutions generally provide adequate volume resuscitation, but the large volumes that are needed result in substantial tissue edema and hypoproteinemia. Consequently, complications of over-resuscitation, including abdominal compartment syndrome, pleural effusions, pulmonary edema, fasciotomies, and conversion of partial-thickness lesions to full-thickness lesions are more frequently observed.[46] It is important to remember that formulas for fluid guidelines are only that—guidelines. Individual factors also must be taken into account. It is crucial to resuscitate the patient with fluids according to patient response, hemodynamic variables, sensorium, and urinary output (0.5 to 1 mL/kg/hr in adults and 1 mL/kg/hr in children weighing less than 60 pounds),[44] instead of by a fixed formula.[23] Fluid resuscitation in children requires extreme precision, owing not only to their size but also their limited physiologic reserve. Because infants and small children have high volume-to-surface-area ratios, formulas that base fluid requirements on surface area burned and weight may underestimate need. The ABA recommends that to counteract the rapid use of glycogen stores and prevent the development of hypoglycemia, a dextrose-containing IV solution be administered for maintenance purposes in burned children in the immediate postburn period.[47,48] Some clinical criteria to indicate adequate fluid rescuscitation are noted in Box 35-2.

Intraabdominal hypertension (IAH) and abdominal compartment syndrome (ACS) are increasingly recognized as causes of significant morbidity and mortality in critically ill burn patients. These are the most dangerous and frequently reported adverse outcomes of fluid creep in massive burn resuscitation. IAH is a continuum of progressively worsening organ dysfunction, whereas ACS is an "all or none" phenomenon resulting when IAH remains either unrecognized or untreated. IAH and ACS impact end-organ function within not only the abdominal cavity (e.g., kidneys, liver, intestine) but also throughout the body (e.g., brain, lungs, heart). The most recent Consensus Guidelines define IAH as an intraabdominal pressure (obtained by transduction of bladder pressure) greater than or equal to 12 mmHg, and ACS as an intraabdominal pressure greater than 20 mmHg with evidence of new organ dysfunction. New organ dysfunction typically manifests as oliguria, impaired mechanical ventilation with high peak airway pressures, worsening metabolic acidosis, and hemodynamic instability. ACS is fatal without treatment. Treatment includes the use of neuromuscular relaxants and increased sedation in mechanically ventilated

BOX 35-1

Consensus Formula for Fluid Resuscitation and Urine Output in Burn Patients (American Burn Association)

Adults: Lactated Ringer's 2-4 mL × kg body weight × percent TBSA burned
Children: Ringer's lactate 3-4 mL × kg body weight × percent TBSA burned*†

Formulas for Minimum Urinary Output in Burn Patients
Adults: 0.5-1.0 mL/kg/hr
Children weighing less than 30 kg: 1 mL/kg/hr
Patients with high-voltage electrical injuries: 1-1.5 mL/kg/hr

From Pham TN, et al. American Burn Association practice guidelines burn shock resuscitation. *J Burn Care Res*. 2008;29(1):257-266.
*One half of the estimated volume of fluid should be administered in the first 8 hours after the burn. The remaining half should be administered over the subsequent 16 hours of the first postburn day.
†Infants and young children should receive fluid with 5% dextrose at a maintenance rate in addition to the resuscitation fluid noted above.

rhGH, Recombinant human growth hormone.

patients; extension of escharotomies on any anterior trunk burns, judicious use of diuretics, and decompressive laparotomy.[49,50-54]

Invasive hemodynamic monitoring (central venous pressure, pulmonary artery catheter) is indicated in patients who do not respond to fluid resuscitation, have preexisting cardiopulmonary disease, or are at risk of IAH and ACS. Catheters should be removed as quickly as possible to minimize the risk of local and systemic infection.

Hypermetabolic/Hyperhemodynamic Phase

Severe thermal injury with burns over 40% of a patient's total body surface area (TBSA) is followed by a pronounced hypermetabolic response that persists for up to 1 to 2 years. During this phase, there are significantly increased metabolic rates, multiorgan dysfunction, muscle protein degradation, blunted growth, insulin resistance, and increased risk for infection. The initial stress response to severe injury lasts for the first 2 to 3 days postburn. The subsequent phase is characterized by an increase in metabolism and hyperdynamic circulation. When left untreated, physiologic exhaustion ensues, and the injury becomes fatal.

Catecholamines and corticosteroids are the primary mediators of the hypermetabolic response after severe burns. There is a 10- to 50-fold surge of plasma catecholamine and corticosteroid levels that last up to 9 months postburn. Glucagon levels are also increased. Burn patients have increased resting energy expenditures, increased cardiac work, increased myocardial oxygen consumption, marked tachycardia, severe lipolysis, liver dysfunction, severe muscle catabolism, increased protein degradation, insulin resistance, and growth retardation.[55-57] Numerous efforts to control this response have been studied. Early burn wound excision and complete wound closure, prevention of sepsis, the maintenance of thermal neutrality for the patient by elevation of the ambient temperature, and graded resistance exercises during convalescence are simple, nonpharmacologic effective treatment goals. Several pharmacologic interventions and their efficacy are noted in Table 35-5.[55,58]

Pathophysiologic Changes

As with any disease entity, certain pathophysiologic alterations occur after an acute burn injury (Table 35-6). It is important for the anesthetist to understand the basis for these changes because many of these changes must be managed intraoperatively and reflected in the anesthetic plan.

Cardiovascular System. The cardiovascular system is greatly affected in the burn patient. Almost immediately after an acute burn injury, intravascular fluid losses begin. Etiologies for this include the loss of vascular and endothelial integrity and the release of circulating mediators described earlier. The loss of plasma proteins from within the intravascular compartment (due to disruption of the endothelium) persists for up to 36 hours after the initial burn injury. Hypovolemia results, with subsequent hypotension and circulatory compromise. The size and extent of the burn determine the magnitude of this development. Hence, burn victims can develop "burn shock" within the first 24 to 36 hours after an acute burn injury. A reduction in cardiac output is a hallmark of burn shock and appears to occur within minutes after the injury. It is initially preserved via catecholamine responses—tachycardia and vasoconstriction. However, with the progressive loss of intravascular fluids and proteins, left ventricular filling declines, leading to a reduction in cardiac output. Additionally, cardiac output is thought to be depressed from the release of myocardial depressant factor or proteins from burned tissues. The cardiovascular response to catecholamines is attenuated after burn injury as the result of reduced adrenergic-receptor affinity and decreased secondary-messenger production. Coronary blood flow can be reduced, further decreasing myocardial function. Systemic vascular resistance increases.

Aggressive fluid resuscitation administered over the first 24 to 36 hours aims to restore intravascular volume and cardiac function. What is seen is a systemic inflammatory response syndrome, characterized by increased cardiac output, tachycardia, and a reduction in systemic vascular resistance. The patient becomes hypermetabolic, with an increase in oxygen consumption and carbon dioxide production.[59]

Children with extensive burn injuries can become quite hypertensive weeks after their injury. Heart rate, cardiac output, and cardiac index remain significantly increased in burned children for up to 2 years when compared with normal ranges indicating vastly increased cardiac stress. Aggressive treatment of the hyperdynamic cardiac response may improve long-term morbidity.[60]

TABLE 35-6 Pathophysiologic Effects of Major Burns

System	Considerations
Respiratory	
Upper airway	Thermal damage to soft tissue and respiratory tract requires early endotracheal intubation Decreased chest wall compliance, functional residual capacity, and restricted chest wall expansion
Carbon monoxide poisoning	Considered in all victims of enclosed fires; treatment with 100% oxygen by mask, endotracheal intubation strongly advised until status can be evaluated
Neurologic	
Encephalopathy, seizures, increased intracranial pressure	Ongoing neurologic assessment mandatory because status frequently changes
Hematology	
Anemia, thrombocytopenia, and coagulopathies	Coagulopathies, transfusion reactions, and infection are common
Cardiac	
Burn shock phase (0 to 48 hr)	Hypovolemia is a major concern; fluid resuscitation mandatory; expect impaired cardiac contractility, initial myocardial depression, and decreased cardiac output
Hypermetabolic phase (after 48 hr)	Increased blood flow to organs and tissues; manifested by hyperthermia, tachypnea, tachycardia, increased oxygen consumption, and increased catabolism
Renal	
Early	
Reduced renal blood flow and glomerular filtration rate	Secondary to hypovolemia and decreased cardiac output; adequate fluid resuscitation and diuresis prevents renal failure; myoglobinuria and hemoglobinurea common, which alters urine-concentrating ability
Electrical burns and muscle necrosis damage renal tubules	Careful fluid resuscitation, renal function monitoring, and possible diuretic administration
Late	
Increased renal blood flow	Variable drug clearance
Nutrition	
Increased caloric requirements	Tight nutritional support mandatory
Hepatic	
Early	
Decreased function and drug clearance	Hepatomegaly; hypermetabolism and enzyme induction during hypermetabolic phase; sepsis common
Pharmacokinetics	
Decreased albumin	Altered volume of distribution, protein binding Highly protein-bound drugs have a higher free fraction and thus a larger volume of distribution
Increased α_1-acid glycoprotein	Usually minimal clinical effects of drugs in spite of the changes in protein levels
Denervation phenomenon with spreading of acetylcholine receptors	Succinylcholine avoided 24 hours after injury
Increased nicotinic acetylcholine receptors and decreased function	Requires a two-fold to three-fold increased concentration of nondepolarizer for paralysis
Skin Integrity	
Vulnerable to nosocomial infections	Strict adherence to aseptic individual patient rooms; wound care, including topical antimicrobial agents and early excision/grafting of the burn wound

Pulmonary System. Like the cardiovascular system, the pulmonary system can be significantly impacted in burn patients. Pulmonary function may decrease significantly even in the absence of inhalation injury. For example, functional residual capacity (FRC) is reduced, and lung and chest-wall compliance decrease, especially when the chest wall is circumferentially burned. With progressive fluid shift and interstitial edema formation in those with eschar formation, the inability to adequately expand the lungs impairs ventilation. In some cases, escharotomies are performed to alleviate the constrictive pressure in the tissues to improve oxygenation and ventilation. The oxygen gradient between alveoli and arterial blood increases with minute ventilation increasing to as much as 40 L/min from what is normally 6 L/min.

As previously mentioned, the lungs are at risk for compromise even without an inhalation injury. There are several mechanisms involved, including the effect of released mediators on the lung. In addition, plasma oncotic pressure is greatly reduced after burn injury, owing to the loss of plasma proteins in burned and nonburned tissues. Impaired vascular and capillary permeability, combined with the amount of fluid resuscitation necessary, sets the stage for pulmonary edema.

Mechanical ventilation is often required after major burn injury, especially when the patient has concomitant inhalation injury. The term "acute lung injury" (ALI) is used to designate the acute onset of impaired oxygen exchange that results from lung injury, and the condition is characterized by a Pa_{O_2}/Fi_{O_2} ratio of less than 300. Severe cases of ALI, categorized as acute respiratory distress syndrome (ARDS), are common as well. The risk for mortality from ALI and ARDS is due to respiratory failure and hypoxia, or may result from associated multisystem organ failure or ventilator-associated pneumonia. New strategies for mechanical ventilation are currently being used to support burn patients who have respiratory insufficiency, ALI, and ARDS. These strategies include changes in traditional mechanical ventilation paradigms (such as the use of low-tidal-volume ventilation) and the use of alternative modes of ventilation. Current practice is to use low-volume lung-protective ventilation to reduce overinflation and barotrauma.[61,62] This involves using tidal volumes of less than 7 mL/kg of measured ideal body weight and plateau pressures of less than 31 cm of water. Using ideal body weight is an important consideration in patients who have a major burn injury because they often have vast increases in body weight due to massive fluid

resuscitation. Modest permissive hypercapnia is allowed.[63] Several nonconventional modes of ventilation have been proposed for the treatment of severe ARDS in patients who have burn injury, including airway pressure release ventilation (APRV) and high-frequency oscillatory ventilation.[64,65]

Immune System. The burn-injured victim is particularly susceptible to infection. Because the normal protective function of the skin has been breached, the stage is set for microbial invasion. Within hours after an acute burn, altered immunologic responses are present. Leukocyte activity is depressed, as well as humoral and cellular responses. Burn eschar is a prime medium for bacterial growth. Colonization of gram-negative bacteria increases mortality. Patients often become septic and are vulnerable to pneumonia, particularly when prolonged endotracheal intubation is required. Strict asepsis is therefore required. Of those patients who die after sustaining a burn, infection is the leading cause of death in up to 100% of children and 75% of adults.[3,26,59]

Renal System. Renal function may decrease soon after burn injury as a result of myoglobinuria and hemoglobinuria. Myoglobinuria is most common after electrical injury, whereas hemoglobinurea is common after severe cutaneous burns of about 40% or greater. Acute kidney injury (AKI) is a common complication following major burn injuries and the incidence of maybe as high as 40%. The development is dependent on the size and severity of the burn and the presence of inhalation injury and is a poor prognostic indicator. AKI is divided into early and late categories. Early AKI was defined as occurring within 5 days of burn injury and results from hypotension and myoglobinuria. AKI occurring after 5 days of injury was defined as late and sepsis is the most common cause.[46] Patients may exhibit an inability to concentrate the urine. Elevated levels of stress hormones (e.g., aldosterone, angiotensin, catecholamines, and plasma renin) also contribute to renal dysfunction observed in the early post-burn period. Several burn centers are using the RIFLE criteria to assess the acute kidney injury (AKI). Rifle is an acronym for risk (R), injury (I), failure (F), loss (L), and end-stage kidney disease (E). (see Chapter 29). It is often used for patients with renal disease to identify the risk factors for occurrence of AKI, as well as to analyze the progression between stages of the RIFLE classification and the impact of progression of AKI on morbidity and mortality.[66,67]

Decreases in renal blood flow alter glomerular filtration. This is usually due to intravascular depletion, hypovolemia, decreased cardiac output, and increased levels of circulating plasma catecholamines. The renin-angiotensin-aldosterone system and the release of antidiuretic hormone are stimulated to conserve sodium and water.[68] Subsequently, alterations in electrolyte balance take place. Hourly urine output measurements remain the gold standard for assessing adequate fluid replacement and resuscitation (see Box 35-1). Delayed renal failure in children is rare.[69]

Gastrointestinal System/Nutrition. Aggressive nutrition support is mandatory after a severe burn injury. Metabolic rates may be increased up to twice normal secondary to the hypermetabolic state. Whole-body catabolism, muscle wasting, and severe cachexia occur with inadequate nutrition. Failure to meet the increased substrate requirements may result in impaired wound healing, multiorgan dysfunction, increased susceptibility to infection, and death.[70,71] In patients with extensive burns and a pronounced hypermetabolic response, carbohydrate is more effective than fat in maintaining body protein.[72] The burn-injured patient is resistant to the action of insulin in the liver and skeletal muscle, thus ongoing assessment of blood glucose, with administration of insulin in a tight control protocol, is necessary.

The necessity for continued adequate caloric intake during the preanesthetic evaluation period cannot be ignored. It is therefore unwise to arbitrarily discontinue enteral feedings the evening before a scheduled surgical procedure. This action can result in an excessive loss of calories, especially if the patient is to undergo extensive burn excision and debridement. Preoperative *nil-per-os* (NPO) guidelines must be considered at a safe minimum to prevent the patient from reverting to a catabolic state. For example, intubated patients do not need enteral feedings discontinued before surgery, whereas unintubated patients may remain on nutritional support up to 4 hours before a scheduled surgical procedure.[73] This practice maintains preoperative nutrition without increasing the risk for aspiration. Upon admission to the operating room, a non-intubated patient's nasogastric tube should be suctioned and general anesthesia induced to ensure rapid protection of the airway. If the patient is not receiving enteral feedings, but rather parenteral feedings through a central venous catheter, the parenteral nutrition line should not be used for administering fluids or drugs during the course of the anesthetic. Parenteral hyperalimentation and lipid infusions should be continued intraoperatively. Monitoring of glucose levels in these patients is advised. The use of infusions pumps is recommended in children to avoid over or under infusions.[26]

Burn patients also demonstrate a decrease in overall gastrointestinal function. When the percentage of TBSA involved is greater than 20%, the development of ileus is common.[74] Other gastrointestinal sequelae include acute ulcerations of the gastric and/or duodenal mucosa known as *Curling ulcers*. Treatment of these stress ulcers includes the administration of acid suppressive therapy (AST) including H_2 blockers, proton pump inhibitors, and antacids.[23] Fortunately, with the use of AST, these ulcers are rare.[75]

Hepatic effects of burn injury are variable. There may be an increase in liver function during the hypermetabolic phase followed by hypertrophy, hepatomegaly, and impairment in protein synthesis. Hepatic dysfunction also may result from drug toxicity, sepsis, or blood transfusions. Preoperative assessment of liver function is advised.[76,77]

Burn Management: Debridement and Grafting

The goal of burn therapy is to rapidly restore skin integrity. After thorough cleansing, the burn wound is typically treated with antimicrobial agents as early as possible to limit bacterial proliferation on the wound surface and to avoid bacterial wound invasion. Wounds have been shown to re-epithelialize more rapidly with less pain and inflammation when they are covered and a thin layer of wound fluid is maintained in contact with the surface. Subsequent treatment involves surgical procedures such as amputation, grafting, and multiple debridements.[78] Early removal and excision of the dead burn tissue with rapid closure of the burn wound has now become the standard in management of a severe burn. The early reestablishment of a physical skin barrier provides protection from bacteria, mechanical trauma, and insensible water loss and improves long-term outcomes.[79]

Because most patients with extensive burns require multiple procedures, limiting a single procedure to 20% excision of body surface has been suggested; however, larger areas may be excised depending on the patient's preoperative and perioperative hemodynamic stability and coagulation status. Other surgical end-points include a time of 2 to 3 hours if the patient's core temperature decreases to 35° C or if there has been blood loss requiring 10 units or more of packed red blood cells.[80] Generally, the burn patient may require surgical treatment every 2 to 3 days, with staging of

burn wound excisions until full grafting has been completed. Significant blood loss during burn surgery continues to be a challenge. Implementation of blood-conserving protocols can decrease blood component requirements. Several options include tumescent epinephrine, thrombin, fibrin, and other systemic hemostatic agents. The best hemostatic protocol must be individualized.[81]

In patients with extensive burns and limited donor sites, the wound coverage may require a combination of skin grafts, cultured skin, and skin substitutes. Several temporary and permanent skin substitutes are available.[82]

Anesthetic Implications

To facilitate a safe and effective anesthetic, a thorough preoperative plan must be developed in consultation with the entire burn team.

Preoperative Evaluation. The burn patient requires a thorough and complete preoperative assessment. Medical history, including laboratory studies, and physical examination with lung auscultation, assessment of chest compliance, and inspection of the neck and oral cavity to determine potential difficulties with airway management, should be implemented. In addition, the clinician should be aware of any underlying trauma, mechanism of burn (electrical, inhalation), percentage of TBSA injured, location of the burn sites, and the type and extent of the planned procedure. This information may impact the selection of agents, appropriate monitoring, positioning, vascular access, and blood-product requirements. A review of prior surgical procedures and anesthetics can be helpful in determining one's anesthetic plan. This is quite often possible as these patients tend to have multiple procedures.

The Set-Up and Preparation. A successful anesthetic that facilitates surgical excision and grafting of a burn wound requires planning and preparation of all necessary equipment (Box 35-3). There are specific anesthetic interventions that should be considered prior to patient arrival in the operating room. Perioperative challenges in the acute burn patient are noted in Box 35-4.

Intraoperative Management

Equipment and Monitoring. Burn patients require all standard monitors intraoperatively, although this otherwise routine consideration may be challenging. Electrocardiogram (ECG) leads are often difficult to place due to a lack of intact skin. Alternatives include stapling lead electrodes to the skin, use of needle electrodes or an atrial pacing-type esophageal stethoscope used for its ECG monitoring capability. Ideally, blood pressure cuffs should be placed on the unaffected limb or at a nonsurgical site. If the extent of surgical debridement is extensive or if movement of the patient's extremities intraoperatively limits accuracy of noninvasive cuff readings, the placement of an arterial line for blood pressure monitoring may be warranted, even in healthy patients. Large burns (i.e., greater than 20% to 30% TBSA) may necessitate invasive blood pressure monitoring after induction of anesthesia, if not in place preoperatively. Rapid and significant blood loss, potential for hemodynamic swings, and the need to verify intraoperative laboratory values more than validate this requirement.

Standard sites for monitoring pulse oximetry may not be available. Alternative sites include the nose, nasal alae or septum, ear, cheek, tongue, or toes. Any preexisting invasive monitors such as an arterial line, central venous catheter, or pulmonary artery catheter should be continued in the operating room. Noninvasive monitors for cardiac output, index, and stroke volume are also available.[83] Accurate temperature monitoring is essential because burn patients can become extremely hypothermic intraoperatively. Skin temperature devices are highly inaccurate in these patients, and there may not be a suitable area to apply them. Temperature measurements are obtained from a properly positioned esophageal stethoscope (i.e., distal third of the esophagus). Because many of these patients are in intensive care units, they may already be benefiting from a urinary drainage catheter that supports bladder temperature monitoring.

Critically ill burn patients are usually transported by the anesthesia provider directly to the operating room from the burn intensive care unit (and vice versa, postoperatively). These patients are typically intubated or have a tracheostomy, are on continuous infusions of pharmacologic agents, and have invasive lines in place. Astute monitoring of the patient's vital signs during transport is, of course, mandatory. Extreme care and diligence should be taken during transport so that any of these do not become dislodged. Portable oxygen delivery system is another component of required transport equipment. Careful handling and vigilant guarding of the airway is crucial. Amnestic and analgesic drugs should be administered as needed to facilitate moving the patient.

Airway Management. Acute airway problems are usually addressed immediately upon the patient's entry into the emergency department or once in the burn unit. In the nonintubated

BOX 35-3

Preoperative Anesthesia Planning for the Burn Patient

- Warm the operating room ahead of time (should not exceed 95° F).
- Check availability of blood products and order more if needed (based on preoperative hemoglobin value, the size of the burn, and extent of the planned debridement).
- Have blood products immediately available in the operating room as surgical debridement is initiated. This is particularly critical in the pediatric patient.
- Have at least one blood warmer primed, plugged in, and turned on. If the burn is large, have two.
- Make sure that you have adequate IV access before the surgeon begins debriding the burn.
- Have an adequate supply of narcotics and muscle relaxants.
- Know and plan ahead of time if invasive lines are needed.
- Plan for airway management and ventilation both intraoperatively and postoperatively as needed.
- Have a plan but be willing to modify it if necessary.

BOX 35-4

Perioperative Challenges in the Acute Burn Patient

- Compromised airway
- Pulmonary insufficiency
- Altered mental status
- Associated injuries
- Limited vascular access
- Rapid blood loss
- Impaired tissue perfusion due to:
  - Hypovolemia
  - Decreased myocardial contractility
  - Anemia
- Decreased colloid osmotic pressure
- Edema
- Dysrhythmia
- Impaired temperature regulation
- Altered drug response
- Renal insufficiency
- Immunosuppression
- Infection/sepsis

From Herndon DN. *Total Burn Care*. 4th ed. Edinburgh: Saunders; 2012:174.

patient without an inhalation injury and whose airway is essentially normal, induction and intubation of the airway can proceed as with any other anesthetic with the exception of avoiding succinylcholine as discussed previously. The use of a videolaryngoscope or the other airway methods discussed earlier may be considered if securing the airway is judged to be potentially difficult.

If the patient is already intubated, vigilance must be maintained to insure the trachea does not become accidentally extubated. Edema of airway structures may make re-intubation difficult, if not impossible. Thus securing an endotracheal tube in these patients can be most challenging because tape does not readily stick to burned skin. Some clinicians have used soft straps, nasal septal ties, or sutures to secure the endotracheal tube. Cloth ties encircling the patient's head are frequently used as well.

Temperature Regulation. Depending on the percentage of TBSA affected by a burn, temperature regulation can be problematic. There is a high risk for development of hypothermia secondary to evaporative heat loss and the body surface area exposed intraoperatively. The temperature in the operating room should be above 28° C.[37,84] Intravenous solutions and skin preparations should be warmed. All methods of heat conservation should be employed while the patient is in the operating room. The use of inline circuit heat moisture exchangers or lower gas flows will reduce evaporative respiratory tract heat loss. Forced-air warming blankets are effective, but their use can be limited. Over-body heating lamps have been used but need to be at a safe distance from the patient to prevent further burning. Plastic bags also can be helpful to insulate exposed body parts not requiring surgical access.

It has been suggested that keeping a patient warm is more beneficial than rewarming. When hypothermia ensues, deleterious effects of vasoconstriction occur, which may hinder any subsequent warming efforts. Moreover, slow rewarming in the postoperative period can lead to an increase in mortality.[85] If a patient becomes hypothermic despite efforts at prevention, the surgeon should be advised to conclude the procedure as quickly as possible.

Fluid and Blood Replacement. Surgical burn debridement procedures may be extraordinarily bloody operations. Surgical blood loss depends on the area to be excised (cm^2), time since injury, type of excision planned, and the presence of infection. Surgical wound management involves removal of the eschar layer until brisk bleeding of the dermis is observed. The surgical team may remove eschar so rapidly that it becomes difficult to replace blood and IV fluid in a manner that parallels the loss, giving way to hypovolemia and hypotension. Some institutions have suggested stopping the surgical procedure after 2 hours if more than two blood volumes have been lost or if the body temperature falls to 35° C or by greater than 1.5° C from baseline.

There are several formulae to approximate the extent of potential blood loss for a burn patient undergoing debridement. These vary from 200 to 400 mL of blood loss for each 1% of BSA excised and grafted to as high as 4% to 15% of the patient's blood volume for every percentage of skin debrided.[26,37] After excision and debridement, several hemostatic therapies may be used including tumescent epinephrine, phenylephrine thrombin, fibrin, and other systemic hemostatic agents. Gauze soaked in a vasoconstrictor preparation applied to the wounds may result in systemic absorption causing an undesired change in vital signs.[81] Table 35-7 lists a method for predicting surgical blood loss. A complete discussion of transfusion management can be found in Chapter 20.

Preoperative anemia is another indicator for transfusion and is commonly seen in thermally burned patients with greater than 10% TBSA involvment.[86-88] There are several reasons for its development. The inflammatory process gives way to destruction of red blood cells that accumulate in thrombosed microcirculation of burned tissues, leading to an erythrocyte loss up to 18% in full-thickness burns greater than 15% TBSA.[89] Thus bone-marrow suppression leads to a reduction in the production of erythropoietin after burn injury. Lastly, patients with extensive burns generally undergo numerous surgical procedures, resulting in blood loss and further anemia.

Adequate vascular access is critical before the initiation of surgical debridement. The size and extent of planned debridement will determine how much access is needed. One large-bore intravenous catheter is adequate for the induction of anesthesia in many burned patients, but at least two large-bore intravenous catheters are necessary before beginning a major excision. Obtaining sufficient IV access can be challenging and time consuming, depending on the extent and location of the burn. Critically ill patients or those with limited peripheral sites for IV access will often have a central venous catheter already in place. A large-bore catheter or a central line with multiple ports should be used whenever administration of large amounts of IV fluid and blood products is anticipated.

Availability of blood products should be confirmed before the patient is taken to anesthesia and operation. Ideally, blood products should have been checked and ready for administration at the outset of the procedure. This is particularly important in pediatric patients. Indeed, some clinicians initiate blood transfusion before the beginning of surgical debridement and apply compression dressings after excision and grafting.

Careful planning is essential when managing hemorrhage and potential complications associated with massive transfusion (e.g., citrate toxicity, loss of clotting factors) during debridement. Visual estimation of blood loss is subjective at best and prone to miscalculation. Surgical suction is often not used during debridements and surgical sponges are difficult to assess. Blood may leak onto the floor, be covered in the surgical drapes, or ooze beneath the patient. Thus proper monitoring of the patient's urinary output, hemoglobin, hematocrit, coagulation, and hemodynamic status is crucial during and after the surgical procedure.

The Anesthesia Management

Induction. No single agent is preferred for IV induction of general anesthesia in the burn patient. As with all anesthetics, plans should be individualized and based on the patient's preoperative status and medical history. The acutely burned patient seldom comes to the operating room immediately after injury; generally the patient is admitted and stabilized in the burn unit first. If the patient requires immediate surgery, he or she can be expected to be extremely labile within the first 24 hours of injury. The effects of the anesthetic agents can be exaggerated, especially if fluid resuscitation is not adequate or has not been fully completed. The loss of intravascular volume coupled with the potential for

TABLE 35-7 Calculation of Expected Blood Loss

Surgical Procedure	Predicted Blood Loss
<24 hr since burn injury	0.45 mL/cm^2 burn area
1-3 days since burn injury	0.65 mL/cm^2 burn area
2-16 days since burn injury	0.75 mL/cm^2 burn area
>16 days since burn injury	0.5-0.75 mL/cm^2 burn area
Infected wounds	1-1.25 mL/cm^2 burn area

From Woodsen LE, et al. Anesthesia for burned patients. In: Herndon DN, ed. *Total Burn Care*. 4th ed. Edinburgh: Saunders; 2012:175.

depressed myocardium can result in a hemodynamically unstable patient under general anesthesia. Careful, slow titration of anesthetic agents is vital. Appropriate premedication of stable patients with benzodiazepines or an opioid decreases anxiety and makes transfer to the operating room (OR) tolerable. Anxiety, depression, and pain are interrelated in patients with burns.[90,91] Induction of general anesthesia can be performed with the patient in the bed so that subsequent movement onto the OR table provokes little discomfort.

Regional anesthesia has been used for procedures confined to small areas, an extremity, or for surgery during the reconstructive phase. Advantages include prolonged postoperative analgesia, but variables in this patient population restrict its more general use. Performing a regional technique that requires passing a needle through burned tissue should be avoided due to the potential for spread of infection. The hypotension (hypovolemia) and vasodilation (with or without sepsis) that often accompanies spinal or epidural anesthesia makes this choice suspect until the burn wound has closed. In addition, coagulopathy and cardiorespiratory instability may be reasons to avoid a regional anesthetic technique. The greatest limitation to the use of regional anesthesia is the topographic extent of the surgical field where the anesthetized region must include both the area to be excised and the area to be harvested for skin graft.

In children, regional anesthesia is sometimes a viable option for postoperative analgesia. Caudal or epidural techniques have been used for debridements of the lower extremities or skin harvesting from the buttocks or thighs. Catheters can be used to extend the regional block for postoperative infusion analgesia.

All commonly used anesthetic induction drugs are acceptable. Propofol can be given if the patient is stable. Ketamine is an excellent alternative in unstable patients. Low doses of ketamine produce adequate amnesia and analgesia for the debridement of superficial burns; higher doses may be administered for more extensive procedures such as eschar excisions.[92] Postoperative emergence reactions can be minimized with the administration of benzodiazepines in small doses, and an anticholinergic prevents excessive pharyngeal and tracheobronchial secretions. In the pediatric burn patient, an inhalation induction with sevoflurane is certainly acceptable if the child does not have intravenous access prior to induction of general anesthesia and if the airway is otherwise normal.

Anesthesia in the burn patient can be maintained with an opioid and/or inhalation agents because the hemodynamic status of the patient permits. Volatile agents have been shown to be safe and effective, allowing rapid adjustment of anesthetic depth while permitting high oxygen concentrations. These patients may be sensitive to the cardiovascular depressant effects of inhaled anesthetics, especially if acute fluid resuscitation is incomplete. Inhaled agents do not provide analgesia in the postoperative period. Intubated burn patients who require intraoperative ventilation with specialized critical-care ventilators (e.g., percussive ventilators) where a standard anesthesia machine ventilators cannot be used, may require a total intravenous technique.[93]

As discussed previously, succinylcholine should be avoided after the first 24 hours. The patient will exhibit resistance to nondepolarizing muscle relaxants, and higher and more frequent redosing is usually necessary. Several factors including up-regulation of acetylcholine receptors, massive fluid shifts producing significant changes in volume of distribution, and a qualitative decrease in receptor sensitivity are responsible.[94]

Pain Management. The necessity of proper pain management is well understood because almost every patient encounter may be associated with psychologic distress and physical pain. Establishment of pain treatment protocols for burn patients that address their anxiolytic and analgesic needs is essential. Intravenous (patient-controlled analgesia) is preferred early in the course of burn care, because the absorption from intramuscular sites may be erratic or slow for rapid control of pain.

Opioids are an important adjunct in the care of burn patients. Pain from skin harvest sites frequently exceeds that from burned, debrided, and grafted areas. Morphine, fentanyl, and sufentanil all provide intra- and postoperative analgesia and are acceptable choices. Remifentanil, a short-acting opioid, may be used for dressing changes. Oftentimes, infusions of opioid will be used in the burn unit for pain control and/or sedation. One option is to continue these infusions during the operative procedure with bolus supplementation. Narcotic-based anesthetics provide the advantage of minimal cardiac depression. In addition, postoperative analgesia must be a vital constituent incorporated into the anesthetic plan.

Nonsteroidal antiinflammatory agents can be effective analgesics for smaller superficial burns. In larger burn injuries, the anticoagulant effects can lead to problems with hemostasis.

Painful procedures include dressing changes, debridements, nursing care, hydrotherapy, physiotherapy, and surgical procedures. The intensity of pain associated with treatments, together with the fact that they are inflicted repeatedly (sometimes twice a day or more) over long periods of time, explains the unique patient medication requirements in this population.[90,91]

Emergence from Anesthesia. The postoperative period should likewise be planned in advance. Critically ill and intubated burn patients should remain intubated postoperatively and transported directly to the burn unit. The anesthetist should safeguard the airway and be respectful of the patient's need for sedation and analgesia during this terminal phase of the anesthetic.

If extubation of the trachea is anticipated, opioids for postoperative analgesia can be titrated according to the need.

Reconstructive Phase

It is important to address the ongoing impact a burn injury can have on the individual. After numerous skin grafting and surgical procedures and some degree of healing has taken place, scarring may remain. To optimize function and prevent contractures and deformity, physical and occupational therapy are important considerations for these individuals. Months to years after hospital discharge, victims of major burns may return for reconstructive procedures to remove or reduce scar tissue. These procedures improve cosmetic and functional outcomes. Burn patients often experience anxiety, stress, and depression from prolonged hospital stays. The most important anesthetic concern is management of the airway, particularly if contractures of the face and neck are present. There are several options for airway management as mentioned previously from standard laryngoscopy, use of videolaryngoscope, or awake intubation using a fiberoptic technique.

Invisible scars may remain as well in the patient who has suffered a burn injury. Psychologic issues should be explored while the patient is still in-hospital. This is especially important when dealing with children. Recreational therapists can help them work through their feelings and fears. Once the child is home and physically healed, group settings such as burn camps can offer opportunities to be with other children who have suffered similar injuries. In such an environment, the child can experience freedom from judgment and not feel ashamed of their burn scars.

SUMMARY

Anesthetic implications for the burn patient are plentiful and can be extraordinarily challenging. As burn centers continue to evolve and improve in their ability to extend life after a severe burn injury, the likelihood of an anesthesia provider being involved in the care of a patient with thermal injury increases. Clinicians should remember these patients are challenged physically and emotionally. For many, the road to recovery is long and painful. As providers of anesthesia care and as patient advocates, it is important we take into account the unique aspects of the burn patient's overall care. As anesthetists, we can play a small but significant role in helping these patients in their difficult journey to recovery and healing. It is a role that comes with many rewards.

CHAPTER 36

Trauma Anesthesia

◆ *Matthew D'Angelo*

ETIOLOGY OF TRAUMATIC INJURY

Traumatic injury is a unique condition. Unlike other diseases that have a biologic basis, trauma is a result of an external force that ultimately disrupts normal structure and function of the body. In most situations, the initial cause of injury is not a result of genetics or environmental exposure, but circumstance and misfortune. Traumatic injury is a disease of human behavior. Although improvements to automobile safety and development of public policy have successfully reduced the annual number of traumatic injuries caused by motor vehicle collisions (MVCs), falls, and firearms by nearly a third, traumatic injury still remains the leading cause of death for Americans under the age of 40.[1] This translates to 180,000 deaths in the United States alone, or more simply put, one death every 3 minutes.[2] The mortality of injury is striking; however, it represents only a small fraction of those affected by trauma.

There is no absolute number that can precisely quantify the toll and cost of trauma. Although figures vary by author, it has been estimated that the cost for medical care and lost productivity in the United States was more than $400 billion in 2005—of that amount, nearly $100 billion resulted from MVC alone.[1,3] These figures, while staggering, account only for expenses and do not account for the burden that injury places on utilization of scarce medical resources.[2] Mortality is only the tip of the iceberg. Trauma accounts for nearly 30 million emergency care treatments per year in the United States, a tenth of which will require hospital admission and possibly surgical intervention.[2,3,4]

Some progress in improving these statistics has clearly been made in the United States, but prevention and treatment of trauma outside of the United States has lagged. Globally, injury is increasing in developing nations.[5] The World Health Organization (WHO) demonstrated in the year 2000 that 1.6 million people died as a result of trauma.[6] Although half of these deaths were a result of suicide, the remainder were due to homicide or combat-related violence.[6] The WHO estimates that injury will be the leading cause of death worldwide by 2020.[1] If the prediction is true, the morbidity and mortality of injury—a manmade illness—will far surpass that of infectious diseases. This change will represent a true paradigm shift in global health.

COORDINATED MANAGEMENT OF CARE

The acute management of a trauma patient presents unusual challenges. In many instances, trauma warrants immediate surgical intervention. Mechanism of action, multisystem injury, and preexisting medical conditions create complexities that are unusual when compared with routine perioperative management.

Time is a luxury and often a scarce resource when managing the critically unstable trauma patient. In many cases, surgical care cannot be postponed to acquire a battery of preoperative exams. Patient medical history may be unknown or incomplete at best. Patients are often unable to provide competent medical history. The patient's inability to provide a history may be a result of the injury or of concurrent acute intoxication. Regardless of the cause, this gap in information leaves many preoperative questions unanswered. Although every attempt should be made to ascertain a thorough history, it should not be done at the expense of delays in care.

Management of trauma in the United States has historically occurred at the municipal level, between the emergency medical system (EMS) and community hospital. Coordination between these stakeholders has varied widely across the United States, resulting in a range of outcomes. The evolution of modern trauma systems has challenged the community level care model—integrating prehospital, tertiary care providers, and public policy in the effort to direct trauma care—a multivariate phenomenon.

The implementation of the modern trauma system has resulted in significant improvement in patient outcomes. Pioneering examples of this paradigm shift can be seen throughout many cities in the United States and around the world; the impact of this shift on patient morbidity and mortality was formally recognized in 1998. The Skamania Symposium (Skamania Lodge, Oregon; Academic Symposium to Evaluate Evidence Regarding the Efficacy of Trauma Systems) was the first academic group to evaluate the efficacy of a trauma system.[7] This group systematically evaluated published data to determine the impact of trauma systems. Their findings were that care in a trauma center (versus a nontrauma center) was associated with fewer unnecessary deaths and less disability.[7,8] These findings have been supported by several other groups in the United States. Risk of death is considerably lower among patients who require early operative intervention if they are treated at a designated Level I trauma center. These outcomes are not a result of more rapid assessment and intervention alone, and emphasize the complex factors that contribute to the survival benefit of trauma center care. Studies in the United States show that mature, statewide trauma systems dramatically reduce unnecessary deaths from greater than 30% to less than 5%, compared with nontrauma system care.[9-12]

Organization of trauma systems varies across the United States. Even though systems are not the same and may vary widely, the American College of Surgeons (ACS) Committee on Trauma has developed standards to which all trauma systems must adhere to become accredited.[13] Through these standards, a level (Level I, Level II, etc.) can be assigned to a particular center that designates the resources the center can provide to care for an injured

The views expressed in this chapter are those of the author, and do not reflect the official policy or position of the Uniformed Services University of the Health Sciences, the Department of Defense, or the United States government.

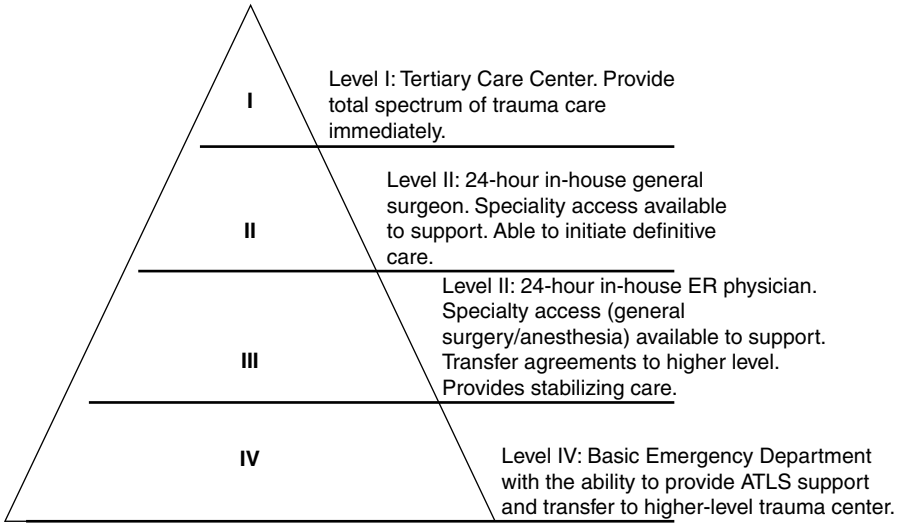

FIGURE **36-1** The levels of trauma care as described in Advanced Trauma Life Support. Lower echelons of care provide stabilizing measures, and care sophistication increases with increasing levels.

patient. Figure 36-1 describes the characteristics of the modern trauma system, its resources, and the levels of trauma care. What we can take away from the conclusions of the Skamania Symposium and guidance of the ACS Committee on Trauma is that positive outcomes in patient care are directly related to experience and development of a trauma system. Trauma can no longer be considered an *offshoot* skill where the paradigm involves massive fluid resuscitation, but a specific clinical expertise in which management and therapy directly impacts patient outcome. In short, experience and proficiency matter.

EARLY EVALUATION OF THE TRAUMA PATIENT AND COMMON INJURY PATTERNS

Immediate Admission of the Trauma Patient

The Advanced Trauma Life Support (ATLS) course developed by the American College of Surgeons provides a framework for the initial management and evaluation of the trauma patient from the prehospital setting through the hospital phase.

Prehospital

The prehospital management of trauma patients has a deliberate pathway. The primary goals revolve around ensuring a patent airway and adequate ventilation, as well as controlling external bleeding. Patients may be intubated in the field or treated with some other method of airway manipulation before arrival at the trauma center. There remains some controversy over the efficacy of rapid sequence induction in the prehospital setting; however, ensuring adequate oxygenation *is* essential. All patients should arrive at the hospital with some degree of supplemental oxygen in place.

In most cases, urgent airway management is not required in the prehospital setting. Occult hemorrhage and its ensuing pathology, on the other hand, is the greatest cause of early death from trauma.[14] Blood leaving the circulatory system can spill into cavities throughout the body (e.g., thorax, abdomen, retroperitoneum [the pelvis], or fascial planes of long bones) and/or bleed into the environment (i.e., the street). Classically, hemorrhage was met with intravenous (IV) access and volume resuscitation in the prehospital setting. This practice, however, is going through a renaissance of sorts in an effort to determine what is best practice and management.

As will be discussed later in the chapter, early fluid resuscitation in the absence of surgical hemostasis may not be beneficial because it will likely increase bleeding and may worsen patient outcome. Without hemostasis, mortality increases. The concept of "injury first" has been greatly developed in the wars in Iraq and Afghanistan. Tactical Combat Casualty Care has replaced the "ABC" acronym (airway-breathing-circulation) with "CABC" (catastrophic bleeding-airway-breathing-circulation), emphasizing the immediate application of direct pressure or tourniquets to control exsanguinating hemorrhage. The logic behind this change in priority is that if bleeding is not controlled, the patient will face certain death. Although civilian centers may not have to contend with the limited resources seen in austere environments, this change in approach exemplifies the important role hemorrhage control plays in hemorrhagic shock outcomes.

Primary Survey

Upon admission to the hospital or trauma center, ATLS guidelines provide a logical and sequential treatment strategy for rapidly assessing the patient. This process is commonly referred to as the *ABCDE's* of trauma care[15]:

*A*irway
*B*reathing
*C*irculation
*D*isability (neurologic status)
*E*nvironment/Exposure (undress the patient to fully assess)

The goal of the primary survey is to identify and rapidly manage life-threatening conditions or injuries. This sequence of events will be abbreviated and discussed individually from the anesthesia perspective shortly. Generally, however, the primary assessment involves a rapid assessment using physical examination techniques and American Society of Anesthesiologists (ASA) standard monitors. In addition, ultrasound and radiography are used to examine body cavities with the initial goal of determining the extent of injury. During this time, initial blood samples and IV access are obtained. All aspects of the primary survey are done simultaneously, thereby coordinating the efforts of surgical and anesthesia teams to prepare for potential surgical intervention. In the event the injuries are beyond the scope of the initial receiving facility, the primary survey provides the emergency team with enough information to stabilize and prepare the patient for transfer to a higher-level facility.

Secondary Survey

The secondary survey begins after the completion of the primary survey and resuscitative and stabilization efforts have been initiated. The secondary survey is a complete head-to-toe assessment that includes a neurologic examination.

BLUNT VERSUS PENETRATING TRAUMA

Blunt Trauma

Direct impact, deceleration, continuous pressure, shearing, and rotary forces may all contribute to the resulting *blunt trauma* a patient has incurred. These factors are associated with high levels of energy, and result from high-speed collisions and falls from substantial heights. Newton's first law can explain how most traumatic injuries occur: an object tends to remain in motion until it is affected by an outside force. Abrupt deceleration creates negative gravitational forces. When the outside "shell" of the human body decelerates abruptly, the internal organs, which in a sense are separate from the exterior of the body, continue forward at the original velocity and are torn from their attachments by way of rotary and shearing forces. These forces often cause disruption of connective tissue, blood vessels, and nerves.

Motor Vehicle Collision Trauma

Blunt trauma is most closely associated with motor vehicle collisions and falls. Blunt trauma tends to produce effects bodywide. The five types of *motor vehicle collisions* are classified as head-on, rear impact, side impact, rotational impact, and rollover. Injuries can be categorized as those above and those below the waist. The upper portion of the body may collide with the dashboard, steering wheel, or windshield, resulting in injuries of the head, neck, chest, abdomen, and upper extremities. Below the waist, injuries to the knees and femurs occur because of direct contact with the vehicle and lower dashboard. Acetabular fractures are typically a result of tensing the leg when bracing for impact. Blunt trauma rarely occurs in isolated body systems. As such, all blunt trauma victims, including those ultimately without high-risk mechanisms of cervical spine injury, should be suspected of and treated as if they have an unstable cervical spine until proven otherwise.[15]

Thoracic Trauma

Blunt chest trauma is the third leading result of injury—closely following traumatic brain injury and extremity trauma. Patients with blunt thoracic trauma present a unique series of concerns. These patients represent some of the most severely injured—with multisystem involvement—accounting for nearly 25% to 50% of all trauma deaths.[16,17] In developed nations, thoracic trauma is most often associated with motor vehicle collisions.

Blunt thoracic trauma often results when drivers who are not wearing safety belts impact the steering wheel during a motor vehicle collision. Penetrating and blunt trauma to the chest may injure several structures and thus compromise optimal resuscitation. Possibly injured structures include the chest wall, the lungs and airways, the heart and pericardium, and the great vessels of the thorax. Injuries to these structures also compromise anesthesia care by affecting gas exchange and cardiac output.

Pneumothoraces are present in as many as 40% of all blunt thoracic injuries.[16] The size and location of the pneumothorax may vary throughout the lung field. Although the etiology and management of pneumothoraces is somewhat commonplace to providers, the presence, or in many cases the assumed absence, of a pneumothorax should not be minimized. It is estimated that as many as 50% of pneumothoraces are not detected on initial radiography.[17] This occurrence presents several clinical intraoperative issues and may alter an anesthetic plan. Nitrous oxide should be avoided in patients with suspected thoracic trauma.

A number of life-threatening injuries, described below, require immediate interventions in patients with thoracic/chest trauma.

Tension Pneumothorax. *Tension pneumothorax* develops when the lung is punctured within the thoracic cavity, creating a one-way valve that traps air between the layers of the pleura. With each breath, more and more air becomes trapped in this space, increasing intrapleural pressure to the point that it eventually exceeds all other intrathoracic pressures. The enlarging pleural cavity then collapses the ipsilateral lung and shifts structures of the mediastinum (e.g., trachea, great vessels, heart) into the opposite hemithorax, thereby compressing the contralateral lung. The size of a pneumothorax will rapidly increase during positive-pressure ventilation, especially if nitrous oxide is used.

Patients with a pneumothorax often present with hypotension, subcutaneous emphysema of the neck or chest, unilateral decrease in breath sounds, diminished chest wall motion, hyperresonance to percussion of one hemithorax, distended neck veins, or tracheal shift. An upright expirational chest radiograph cam provide definitive information if the problem is significant.

Massive pneumothorax can result in reductions in cardiac output and ultimately cardiovascular collapse. Under emergent situations, a large-bore intravenous catheter (needle chest decompression) can be inserted into the second intercostal space just above the third rib, along the midclavicular line. Release of pressure should restore cardiac function. Initially, the catheter can be temporarily attached to an intravenous line extension tube and placed under water seal by putting it in a bottle of sterile water positioned beneath the level of the patient until proper chest tube thoracostomy can be performed. See Chapter 26 for a complete discussion of the diagnosis and management of a pneumothorax.

Pericardial Tamponade. *Pericardial tamponade* that restricts filling of the cardiac chambers during diastole and produces a fixed low cardiac output is also a life-threatening emergency that requires immediate correction with pericardiocentesis. Care should be taken when inducing anesthesia in patients with cardiac tamponade because cardiovascular collapse can occur. Ketamine has been recommended as an induction agent in these patients.

Massive Hemothorax. *Massive hemothorax*, which can be caused by bleeding from the heart and great vessels, is treated immediately. Adequate fluid resuscitation is accomplished before placement of chest tubes. Chest tubes allow drainage of blood from the pleural cavity but can lead to more extensive bleeding and hypotension.

Cardiac Rupture. Patients with *cardiac rupture* who are not treated with pericardial tamponade seldom survive because exsanguination is extremely rapid in this situation.

Traumatic Aortic Rupture. *Traumatic aortic rupture*, if complete, is usually fatal, but with an intimal tear with a dissecting aneurysm, the patient can be saved if the diagnosis and repair are performed promptly with concurrent well-managed fluid resuscitation and anesthesia care. Management of these cases requires rapid and accurate assessment and appropriate surgical and anesthesia intervention.

Tracheal Injuries. Airway injuries represent a devastating and potentially lethal event after blunt thoracic trauma. The relative infrequency of airway injury upon admission to a trauma center (0.2%-8.0%) is likely due to high victim mortality at the scene of injury.[16,17] *Partial disruption of the trachea or major bronchi* often is mangaged through securing of the airway (by intubation or tracheostomy) and surgical correction. *Total disruption of the trachea* is often fatal unless rapid surgical retrieval of the distal disrupted

airway segment is accomplished to allow lifesaving mechanical ventilation. The majority of thoracic airway injuries are found below the carina and are often visible only during bronchoscopy or computed tomography (CT) examination.

Penetrating Trauma

Penetrating injuries can range from a simple pinprick to high-velocity projectile injury. Damage depends on three interactive factors[18]:

1. The type of wounding instrument (e.g., knife; missile, such as a bullet; or fragment, such as a piece of shrapnel)
2. The velocity of the missile at time of impact
3. The characteristics of tissue through which it passes (e.g., bone, muscle, fat, blood vessels, nervous tissues, and organs)

Lower-velocity wounds (i.e., stab wound) inflict injury by lacerating and cutting tissue. Moderate- to high-velocity injuries (i.e., bullet) occur as a result of the deceleration of the object as it passes through tissue, causing kinetic energy to transfer to the surrounding tissue. In either situation, low- or high-velocity penetration, it ultimately results in disruption of normal anatomy and physiology. Velocity of the projectile is the most significant determinant of wound potential. In other words, penetrating bullet wounds have a greater potential to inflict serious injury when compared with a knife or other handheld projectile.

Damage Control Surgery

Surgical management for the severely traumatized patient is often a multistep process. In many cases, patients present to the trauma center with surgical emergencies. Early repair is often simply a life-saving measure and is not intended to be a definitive repair but rather a stabilizing measure, intended to reduce operating room (OR) time and morbidity.[19,20] After stabilization, patients will be transported for further evaluation (secondary survey) or additional resuscitation measures in the intensive care unit (ICU). Often patients will be returned to the OR several times because the surgical course involves several phases. This staged approach to surgical management is commonly known as *damage control surgery* (DCS).

Damage control surgery is a concept that developed in the early twentieth century. Its use fell in and out of favor until the 1970s and 1980s. Its utility in modern trauma care was rediscovered as advances in surgical technique, critical care medicine, and technology converged. DCS correlates with current concepts in trauma care that include damage control resuscitation with rapid surgical correction of bleeding and the prevention of the lethal triad of acidosis, hypothermia, and coagulopathy. It also involves limitation of crystalloid administration and application of high ratios of plasma and platelets to packed red blood cells.[21,22] DCS is used in various surgical disciplines, from packing the abdomen after abdominal trauma to using external fixators to set complex orthopedic injuries.[23]

Abdominal Trauma

Blunt abdominal trauma is a leading cause of morbidity and mortality among all age groups. Although diagnosis and treatment of penetrating trauma is easily determined, occult bleeding in blunt abdominal injury is often misdiagnosed.[24,25] Abdominal sonography, Focused Assessment with Sonography for Trauma (F.A.S.T.), computed tomography (CT) scan, magnetic resonance imaging (MRI), or angiography may help in the diagnosis of specific injuries and various treatment modalities. Extremely unstable patients, however, will require immediate surgery. It is essential that large-bore intravenous access be in place, above the diaphragm, prior to opening the abdomen in the event of massive hemorrhage as a result of liver or other organ injury.

THE ABCD'S OF TRAUMA ANESTHESIA

Although the ATLS curriculum provides an organized framework for the management of traumatic injury, it is not specific to any one discipline. The following sections discuss the implications of the *ABCD's* of trauma anesthesia and provide an approach to clinical management. It cannot be overstated; anesthesia must facilitate rapid surgical management. Trauma anesthesia and surgery is not elective. It should be the goal of the anesthesia team to rapidly move the patient to the OR. Perfusion of tissue (or lack thereof) is directly related to time.

Airway

Endotracheal intubation is a routine procedure of anesthesia practice. Despite its regular use during general anesthetics, intubation poses significant risk and may be extremely challenging when caring for the acutely injured patient. Difficult tracheal intubation is the third most common respiratory-related event leading to death and brain damage as reported in the ASA Closed Claims analysis.[26] Although certainly not all trauma patients will have a difficult airway, the anesthetist likely will not have the opportunity or time for a full airway examination because of several variables such as facial injuries and/or hypoventilation and apnea. As such, the provider must anticipate the worst-case scenario.

Emergent intubation in the trauma patient follows the general pathway of the ASA difficult airway algorithm.[27] Three assumptions should be made when approaching this type of patient. First, there is no turning back. Intubation is not routinely elective for these patients. Therefore, once induction begins the patient must end up with a controlled airway. In addition to requiring a secured airway, trauma patients are assumed to have delayed gastric emptying and a full stomach. As such, they are at increased risk for aspiration. Finally, any patient with blunt trauma or with penetrating injuries to the neck and face must be considered for cervical spine instability.

Rapid sequence intubation (RSI) is the standard method for traumatic airway management. This practice involves several steps often not used during standard induction. One of the greatest differences between routine induction and RSI is the use of a muscle relaxant before knowing whether the patient can be mask ventilated. Although daunting, and a deviation from the norm, muscle relaxation is associated with the highest overall rate of successful airway management and provides the greatest possibility for rapidly securing the airway.[28]

Steps to RSI

RSI begins with appropriate planning and team practice. Sufficient personnel must be on hand to (1) provide manual in-line stabilization of the cervical spine after removing the front of the cervical collar; (2) provide cricoid pressure (the Sellick maneuver); (3) oxygenate the patient with bag-valve-mask ventilation and then perform direct laryngoscopy; and (4) administer medications.

Direct laryngoscopy during manual in-line stabilization of the cervical spine is a safe and effective procedure in patients with potentially unstable necks.[29,30] Cricoid pressure is applied and intended to prevent both gastric insufflation during bag-valve-mask ventilation and passive reflux of gastric contents. Although caution is appropriate, both cervical spine injury and aspiration during intubation are moderately low-risk events when compared with the possible risks and injury from hypoxia. Therefore, it must be remembered that airway management is the priority. In-line

stabilization and cricoid pressure should be relaxed if they are interfering with successful intubation.

Whenever RSI is undertaken, the need for an emergent surgical airway is always a possibility; appropriate surgical resources should be immediately available in the event of the need for a surgical airway.

Common Indications for Airway Management

Patients with traumatic injury present in varying degrees of injury and may require emergent airway management. The most common indications for endotracheal intubation include: (1) inadequate oxygenation/ventilation; (2) loss of airway reflexes; (3) decreased level of consciousness (Glasgow Coma Scale [GCS] less than 8); and occasionally, (4) the need for pain management and the ability to safely provide deep sedation during painful procedures. Once it is deemed that the patient requires airway management, it should be done using RSI.

RSI is a procedure that is conducted to rapidly control a patient's airway, while reducing the likelihood of gastric aspiration. RSI consists of five primary components: (1) preoxygenation, (2) cricoid pressure, (3) induction/muscle relaxation, (4) apneic ventilation, and (5) direct laryngoscopy. Each of these steps is discussed in detail below.

Preoxygenation. Adequate preoxygenation is likely the best asset for the anesthetist managing a trauma patient. Preoxygenation provides the greatest amount of time before occurrence of hypoxemia. Preoxygenation is accomplished using 100% high-flow (10-15 L) oxygenation via a nonrebreather facemask or bag-valve facemask. Although there is some debate in the literature, four to eight tidal volume breaths appear to provide superior preoxygenation when compared with 3 minutes of tidal breathing.[31]

Preoxygenation is challenging in regard to patients who are unable to deep breathe or follow commands when obtunded. In these circumstances, it is appropriate to provide *controlled* positive pressure bag-valve-mask ventilation throughout induction. An increased oxygen reservoir in the lung will benefit the patient more than the (theoretic) increased risk of aspiration caused by ventilating through cricoid pressure.

Cricoid Pressure. Cricoid pressure was first described by Sellick in 1961.[32] The goal of this maneuver is to reduce the risk of pulmonary aspiration of gastric contents by compressing the esophagus with the continuous ring of the cricoid cartilage.[33] Cricoid pressure is maintained throughout the RSI and is not released until endotracheal tube (ETT) placement has been confirmed. Determining the appropriate pressure to apply to the cricoid ring has been the subject of debate. Vanner and Pryle[34] have determined that 30 Newtons (approximately 10 lbs of pressure) adequately occludes the esophagus.

Induction Agents. Anesthetic induction for RSI can be achieved by a variety of agents. At this time no literature is available to support the superiority of one agent over another. All induction agents will cause dose-dependent decreases in blood pressure in the hypovolemic, hemorrhaging patient. Dose-dependent hemodynamic instability can likely be attenuated by reductions in the induction dose. Although no formula can precisely predict the dose for a hemodynamically unstable patient, some authors suggest a dose that is one tenth to one half of the normal induction dose of propofol.[35] Ketamine can always be considered as an alternative trauma induction drug.[36,37] Etomidate use is discouraged due to the suppression of adrenal function. Recall during induction, an undesirable consequence, is a secondary concern when urgently managing an unstable trauma patient.

Succinylcholine (1.5 mg/kg) provides favorable and rapid muscle relaxation to facilitate intubation. It is generally the preferred agent for RSI for any patient who has no specific contraindication to its use. Succinylcholine administration may cause lethal hyperkalemia in patients with neurologic deficits from spinal cord injury, but not until 24 to 48 hours after injury.[38]

Rocuronium (1.2 mg/kg) and vecuronium (0.2 mg/kg) also can be used for RSI. The onset time for high-dose rocuronium (1.2 mg/kg) is similar to that for succinylcholine with only a slight delay in achieving complete relaxation.[39] Although these nondepolarizing agents may produce adequate intubating conditions, their use may influence what care can be provided. Prolonged paralysis will require sedation and will make any subsequent neurologic assessment more difficult.

Apneic Ventilation. Apneic ventilation is the concept of pulmonary ventilation using high-flow oxygen. Its purpose is to reduce the potential risk of gastric distension and pulmonary aspiration from positive pressure ventilation. The principle of apneic ventilation is based on Boyle's law in which gas leaves the facemask, fills the lungs, and exchanges in the lungs based upon the concentration gradient of gases in the alveoli. To work appropriately, apneic ventilation assumes that the airway is patent and that a high concentration of oxygen can be reliably administered.

Apneic ventilation remains controversial for practitioners. RSI for the trauma patient is intended to reduce the risk of aspiration in the case of a potentially full stomach, yet many trauma patients who present are unable to take a deep breath prior to induction, resulting in a reduced functional residual capacity and pulmonary reserve. Traditionally, with RSI, the practitioner is taught to refrain from positive pressure ventilation during induction. This practice, however, is commonly being modified by clinicians.

To avoid potential hypoxemia or in the event of an already hypoxemic patient, clinical modifications have been made to RSI that include bag-valve-mask ventilation through cricoid pressure—often termed "modified RSI." This method is actually the technique described by Sellick in 1961.[32,40] To date, there does not appear to be any increase in aspiration by bag-valve-mask ventilation through cricoid pressure.

Direct Laryngoscopy. No evidence indicates that a particular laryngoscope blade or size is optimal for RSI. The choice is likely provider dependent. The provider should use the equipment with which he or she is most comfortable.

Successful endotracheal tube placement is immediately confirmed by capnometry. If unsuccessful, a second direct laryngoscopy should be attempted, incorporating some change in technique (e.g., different laryngoscopist, blade, or patient position). There are a variety of adjunct tools available in the event of an unplanned difficult intubation. These include the basic and inexpensive, such as the intubating stylet or bougie, to the more advanced fiberoptic equipment.

If intubation is again unsuccessful (third attempt), the next step should be an airway adjunct to support oxygenation. These adjuncts range from the Combitube to the laryngeal mask airway (LMA). In the situation of "cannot intubate and inadequate facemask ventilation," LMA insertion should be the immediate next step.[41]

Airway Management of Cervical Spine Injuries

Cervical spine injury remains a significant concern when facing airway management of the trauma patient. The incidence of cervical spine injury after trauma is relatively rare at 2% to 3% of all trauma and approximately 6% to 10% for patients with traumatic brain injury.[42] Cervical spine injury should be assumed until proven otherwise. Immobilization of the neck is essential. To that

end, in-line stabilization is essential because it allows for removal of the front of the cervical collar, allowing more area for jaw and mouth movement, while limiting the risk for further injury.

The management and intubation of patients with suspected cervical spine injuries remains clinically controversial. Despite common belief, there is no evidence to suggest that fiberoptic intubation provides safer patient outcomes when compared with direct laryngoscopy with in-line stabilization.[43-45] As such, management of a cervical spine injury may be done so with the concepts of "emergent" which involves in line stabilization and RSI versus "controlled" which involves an awake fiberoptic technique. Figure 36-2 describes a logical management strategy for these two situations.

Breathing (and Ventilation)

Regardless of the need to manage the airway, the adequacy of breathing and ultimately patient oxygenation is essential to survival. Pulse oximetry is a commonly used noninvasive method to continuously monitor oxygen saturation. Pulse oximetry is often used as a surrogate measure of status. Although pulse oximetry provides a wealth of clinical information, it should be realized that this measurement is not ideal and that the data may provide a false sense of security. For instance, an otherwise healthy patient breathing room air oxygen (21%) will have a Pa_{O_2} level of approximately 100 mmHg and an Sa_{O_2} of 100%. If the patient is placed on a high-flow, nonrebreather mask of 100% oxygen, then the Pa_{O_2} could be expected to be approximately 500 mmHg and Sa_{O_2} would remain at 100%. Patients who experience declining pulmonary function will have a Sa_{O_2} of 100% over a wide range of Pa_{O_2} readings. It must be recognized that supplemental oxygen, although necessary, can mask pulmonary injury and in some cases respiratory decompensation. It should not be concluded that a saturation of 100% equates to a stable patient or the health of the pulmonary (breathing/ventilation) system.

Pulmonary contusions represent the most common lung injury. It is reported that as many as 70% of patients with blunt thoracic trauma present with some degree of pulmonary contusion.[17] Pulmonary contusions are injuries to the alveoli without gross disruption of pulmonary architecture. This injury is essentially a *bruise* to the lung tissue resulting in protein-rich fluid leaving ruptured pulmonary capillaries and settling into the alveolar membrane and interstitial space. Due to the widening of the pulmonary membrane, pulmonary contusions result in varying degrees of reduced gas diffusion that may be clinically relevant. Pulmonary contusions can develop or "blossom" over a range of time and ultimately may develop into acute respiratory distress syndrome (ARDS).

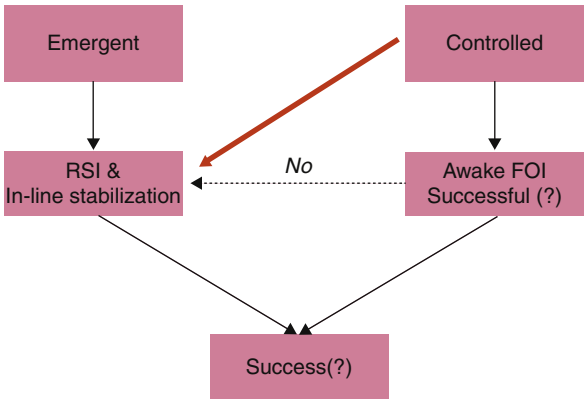

FIGURE **36-2** A logical management algorithm for controlled versus emergent airway management for a patient with a cervical spine injury. *RSI*, Rapid sequence induction; *FOI*, fiberoptic intubation.

ARDS is a common problem in trauma care. It may be a result of injury or the resuscitation of the patient. It has been estimated that between 10% and 40% of patients with traumatic injury will develop ARDS over their hospital course. Pathologically, ARDS is a result of protein-rich fluid leaving the pulmonary capillaries. As the disease progresses, the pulmonary capillary leakage is compounded by embolic events, which further increase intracapillary pressure and intensify interstitial leakage. ARDS culminates in hypoxia and decreased pulmonary compliance. Ventilating these patients is a challenge. Clinicians are often faced with the inability to appropriately oxygenate the patient without using high pressures to ventilate.[46] High pressures and decreased compliance sets the patient up for barotrauma and worsening pulmonary disease.

A variety of pulmonary techniques have been described for managing these patients. They range from high-frequency oscillation ventilation to cardiopulmonary bypass. At this time no one technique appears to be superior. It is widely accepted, however, that these patients should be ventilated using low tidal volumes to reduce peak pressures, and the plateau pressures should be maintained at less than 32 cm H_2O.[47,48] Although attempting to correct an Sa_{O_2} that is less than normal (less than 95%) by increasing the Fi_{O_2} may seem to be a desirable action, it would likely not be the best practice because of the toxic effects of oxygen over time, which can potentially worsen gas exchange.

Circulation

Up to thirty-five percent of trauma fatalities in the United States are due to hemorrhage and hemorrhagic shock.[49] A vast majority of patients that survive their initial injury and reach the hospital are coagulopathic when they die.[49,50] Hemorrhagic shock is the leading cause of early and late mortality after trauma.[51] Hemorrhagic shock is defined as a pathologic event that is triggered by the loss of circulating blood volume and results in a reduction in oxygen delivery to the tissue.

The physiologic response to hemorrhagic shock is a dynamic and complex process. Reductions in blood volume cause an immediate change in vascular tone and global systemic vascular resistance (SVR). Blood is shunted from low metabolic "ischemia-tolerant" vascular beds, such as skin and bone, to highly metabolic tissues (e.g., brain, heart, gut) with the intent of maintaining cellular perfusion and aerobic respiration. Early shunting compensates for relative hypovolemia. If short lived, compensated shock has very few long-term sequelae.

Unfortunately, uncontrolled hemorrhage is a likely event in major trauma. As the degree of blood loss worsens, vascular shunting increases. In this state, patients rapidly progress from a compensated state to decompensated shock. Vascular shunting continues during decompensated shock. Blood is directed away from lower metabolic organs, such as the kidneys and gut, in an attempt to maintain perfusion in higher metabolic structures. During decompensated shock, changes to SVR are less likely to adequately maintain perfusion. The body attempts to further compensate a dwindling stroke volume and cardiac output by increasing heart rate and contractility.

Unfortunately, compensatory mechanisms are imperfect. Prolonged reductions in perfusion will result in cellular injury. During protracted shock events, venous oxygen reserves are extracted and used as arterial oxygen supply declines. Metabolic imbalances between oxygen demand and delivery produce toxic metabolic by-products. As a result of this imbalance, cells are unable to

maintain vital metabolic functions. Energy production falls. Intracellular energy-dependent pumps fail, reducing cell wall integrity.

In an attempt to maintain energy production, cells transition from aerobic to anaerobic respiration. The conversion to anaerobic respiration is made at a significant cost to the cell. In addition to vast reductions in energy production, lactic acid and free radicals are produced. These toxic cellular by-products induce cellular injury, further reducing cellular function.

Despite vigorous resuscitation, hemorrhagic shock may result in patient death. The mortality rate for shock is approximately 50% if treatment is initiated at 30 minutes from the onset; the rate rises to 90% if 1 hour elapses before treatment is initiated.[52,53] This high mortality rate associated with the delayed treatment of hemorrhagic shock is the basis for the initiation of fluid resuscitation and hemostasis in the field. The "Golden Hour" was initially modeled from data collected from young, healthy males in military service during the Vietnam War. The Golden Hour represents a period of time (60 minutes) in which selected patients will likely survive hemorrhagic shock if perfusion is restored. This observation, however, cannot be extrapolated to the general population because, as stated, it was based on young, healthy men. It is likely, however, that when generalizing to the population at large, the Golden Hour is actually a nonspecific time that is age and health status dependent. The Golden Hour is likely an inverse relationship. As patients age, their ability to compensate during hemorrhagic shock decreases.

Hemorrhagic shock progresses through stages over time. Stage I of the three stages of shock is often called *nonprogressive shock* or *compensated shock*. A negative-feedback control mechanism of the circulation tries to return the cardiac output and arterial pressure to normal levels. This phenomenon is mediated through the baroreceptor reflexes, central nervous system (CNS) ischemic responses, contraction of blood vessels, release of vasopressin (antidiuretic hormone), formation of angiotensin, and compensation mechanisms that tend to return the blood volume back toward normal by mobilization of fluids from other spaces of the body.

Stage II of shock is also known as *progressive shock*. A positive-feedback mechanism comes into play with this phase of shock. When shock becomes severe enough, components of the cardiovascular system start to deteriorate. This deterioration is associated with cardiac depression caused by ischemia, vasomotor failure, thrombosis of small vessels, increased capillary permeability, release of endotoxins by ischemic tissues, and generalized cellular degeneration.

Stage III of shock is also called *irreversible shock*. This stage occurs when adenosine triphosphate reserves are depleted and toxic substances are released from apoptotic cells. Death follows as the natural consequence of not successfully halting progressive shock.

A successful resuscitation will often leave patients in a temporary hypermetabolic/hyperdynamic state. This is due to a "metabolic debt" for the period of ischemia. Patients often remain tachycardic despite appropriate resuscitation and sedation. Unfortunately, an apparent "successful" resuscitation does not mean survival. As such, morbidity as a result of hemorrhagic shock can be classified as early and late events. Acute irreversible shock presents as the classic massive hemorrhage and death. In this case, the resuscitation attempt does not match the blood loss. Ongoing hemorrhage and hypoperfusion worsens, leading to acidosis, coagulopathy, and death.

Subacute irreversible shock appears clinically opposite to acute irreversible shock. In this instance, fluid volume is restored, hemorrhage is controlled, but the patient has suffered a significant "dose" of shock and cellular ischemia that cannot be overcome. Ultimately, the "metabolic debit" is too great. Over time these patients succumb to multiorgan failure and related sequelae secondary to cellular hypoperfusion. Table 36-1 details ATLS classification of hemorrhagic shock.

Treatment of Hemorrhagic Shock

Patients admitted for care with a traumatic injury often present with obvious signs of blood loss and have the potential to be in compensated shock with an unknown degree of hypovolemia. Quantifying or estimating potential blood loss is a challenging issue. Routine monitors often are inadequate in detecting losses until the late stages of shock when physiologic compensation begins to fail. Patients may have large blood volume losses and yet appear at first to be relatively normovolemic.

Blood loss can be hidden in several locations in the body (e.g., the thorax, abdomen, pelvis, and lower extremities), thereby masking the blood loss and complicating the treatment plan. In addition, blood losses at the scene of injury are often not quantified. Blood loss to the environment (street) must be considered. The management of hemorrhagic shock from a traumatic injury follows a logical pathway as described in ATLS.[54]

Fluid Resuscitation. The balance between the appropriate amounts of fluid is one of the greatest challenges of successful trauma resuscitation. Resuscitation is commonly seen from one perspective, that of blood pressure. Fluid resuscitation, however, should not be viewed only in terms of blood pressure (i.e., perfusion) but also in terms of the degree and state of repair of the injury. For limited injuries with little or no active bleeding, ATLS resuscitation guidelines advise brisk isotonic crystalloid infusion (up to 2 liters) and component therapy for a larger resuscitation with greater blood loss.[15]

Unfortunately, therapy is not quite as simplistic in the case of ongoing or massive injury. The administration of fluid, in and

TABLE 36-1 Advanced Trauma Life Support Classification of Shock

	Class 1	Class 2	Class 3	Class 4
Blood loss (%)	<15	15-30	30-40	>40
Heart rate (beats/min)	<100	>100	>120	>140
SBP (mmHg)	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
RR (breaths/min)	14-20	20-30	30-40	>35
Mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic

of itself, may actually worsen the patient's clinical state if fluid administration is not timed appropriately. This necessary balance of body fluids is easily visualized when one considers a garden hose (vasculature), a water spigot (blood supply), and a sprinkler (perfusion). Imagine that a hose is connected to a water spigot and sprinkler. Water flows to the end of the hose and into the sprinkler in varying rates as the spigot is opened and closed causing variations of pressure. If the hose ruptures, water will move down the hose and exit at the tear. Depending on the rate of pressure, water may not reach the sprinkler at all. To maintain "normal" sprinkler function, water pressure would have to increase. Although this might seem advantageous, an increase in water pressure would also cause more water to exit at the tear in the hose. The additional loss of water or—in the case of a bleeding blood vessel—the additional loss of blood, would cause blood containing nutrients, coagulation factors, catecholamines, and oxygen-carrying capacity to be lost. This, of course, would be detrimental to the patient.

For these reasons, early resuscitative efforts (before surgical repair) and fluid administration should be done by hypotensive resuscitation. The concept of hypotensive resuscitation was first described in the early twentieth century. Hypotensive resuscitation is a clinical methodology that guides fluid resuscitation in a manner that avoids excessive bleeding by targeting fluid administration toward maintaining a lower than *normal* systolic blood pressure. Even though targets may vary, most clinician's target systolic blood pressure (SBP) at or near 85 to 90 mmHg.[55] This reduction in systolic pressure reduces bleeding and ultimately has been shown to reduce mortality.

This finding was most notably described by Bickell et al.[56] with a research project commonly referred to as the Houston Trial. The Houston Trial enrolled 598 patients with penetrating thoracoabdominal trauma. The subjects were randomized in the field to a fluid administration or no fluid administration group. The research protocol continued through the primary evaluation and ended as patients were transported to the operating room. The Houston Trial found that there was a significant difference in fluids administered between groups and that the resuscitation group had a higher mortality than the nonresuscitation group ($p = 0.04$). When possible, the initial fluid resuscitation should be minimized until hemostasis occurs and then administered only to avoid cardiovascular collapse. After hemorrhage has been controlled, a systolic blood pressure greater than 100 mmHg and heart rate less than 100 bpm can be the goal.

Intravenous Access. Appropriate intravenous access is a priority when managing a patient in hemorrhagic shock. The speed of intravenous fluid administration is directly related to the radial diameter of the catheter as described by *Poiseuille's law.* Larger catheters allow for increased flow by reducing turbulence. Patients should have access that has the least impediment to flow. In addition, catheter length should be minimized. As a rule of thumb, IV access should be "short and fat." Although central access is not necessary for resuscitation, patients suffering from significant hemorrhagic shock are often too vasoconstricted to cannulate large veins. Central venous access should be considered early in the management plan. Large-bore single- or double-lumen catheters should be used for central access.

In addition to size, location of the access is essential. IV access should be redundant, and placed in locations that will not deliver fluid directly to an injured area and that may not reach central circulation. For instance, a femoral catheter should not be used when major abdominal vascular or pelvic injury has occurred. Intravenous access above the diaphragm would provide the most assurance that the fluid would not "dump" into the abdomen or retroperitoneum. In general, there should always be access above the diaphragm.

Intravenous Fluids. Isotonic crystalloid infusions expand plasma volume, increase cardiac output, and ultimately cause an increase in blood pressure. In addition, they may reduce vasoconstriction, hemodilute the blood, and induce immune dysfunction. As discussed earlier, vigorous fluid resuscitation must be tempered with the understanding that fluid increases blood pressure and subsequently causes bleeding. Bleeding causes recurrent hypotension and begins a vicious cycle of fluid—bleeding—hypotension.

At the trauma center, red blood cells (RBCs) are replaced to provide adequate oxygen-carrying capacity. Shed blood is replaced with a 1:1 volume of packed RBCs and a 3:1 volume of crystalloids.

Serial electrolyte levels, hemoglobin and hematocrit levels, and arterial blood gas analysis are obtained approximately every hour in severely injured, unstable patients in surgery until the patient is stable. Additionally, coagulation parameters are observed closely in patients with signs of active bleeding. Colloids usually allow rapid restoration of intravascular volume but can contribute to a later episode of pulmonary edema and increased bleeding if hemostasis has not been achieved. Balanced electrolyte solutions (isotonic solutions) are given to help maintain perfusion.

Dextrose-containing solutions are generally undesirable for use in initial resuscitation fluid administration. Rapid determination of blood glucose levels is critical in patients with diabetes and in children. Traumatized infants and children in shock may rapidly consume their gluconeogenic substrate, allowing significant hypoglycemia to occur.[57] Although patients are more likely to become hyperglycemic than hypoglycemic after traumatic injury, hypoglycemia can occur. Significant hyperglycemia is associated with further neurologic injury.[58]

Traumatically induced hyperglycemia is so common that it is often called *diabetes of injury*.[59] Withholding glucose or giving it in moderate amounts in order to maintain blood glucose levels at less than 150 mg/dL is advisable if brain ischemia occurs, because data have shown that hyperglycemia existing before an ischemic or a hypoxic event increases ischemic damage.[60]

Coagulopathy and Trauma

A vast majority of patients that survive their initial injury and reach the hospital are coagulopathic when they die.[49,50] It is estimated that nearly a quarter of all trauma admissions present in varying degrees of coagulopathy on admission.[50]

Once coagulopathy develops, patient morbidity and mortality drastically increase. Coagulopathy is an independent predictor of mortality. In otherwise healthy patients, an elevated prothrombin time (PT) on admission indicates rapid hemorrhage, massive injury, and a steadily worsening perfusion state.[61] In addition to the loss of life; coagulopathy indirectly levies a burden on society and the healthcare system. As such, management strategies to reduce the morbidity and mortality of trauma-induced coagulopathy have become of particular interest.

Clot Formation. Hemostasis is a complex process involving proteins—cofactors and blood products that converge in a series of reactions intended to produce the fibrin and platelet network (with trapped red blood cells) that is a clot. Clot formation begins with an initial vascular insult. Tissue injury immediately causes the release of tissue factor (TF) from the endothelium. At the same time, vascular spasm causes platelets to migrate from the vascular lumen towards the site of injury. TF binds with activated, circulating factor VII (FVIIa). The interaction of FVIIa with TF begins the conversion of prothrombin (II) to activated thrombin (IIa) resulting in a "thrombin burst" on the surface of the platelet.

Conversion of thrombin completes the coagulation process yielding fibrin (I) connections that stabilize clot formation.[61,62] Under normal conditions, fibrinolytic pathways maintain appropriate clot size and location, limiting clot formation to the site of vascular injury.

Pathology and Causes of Coagulopathy. Massive injury can disrupt the clotting cascade at several points in the process, resulting in life-threatening consequences. Four mechanisms have been identified as primary causes of trauma-induced coagulopathy. These mechanisms are (1) dilution of factors; (2) hypothermia/acidosis; (3) severe traumatic brain injury (TBI); and (4) hemorrhagic shock.[49] Trauma-induced coagulopathy (TIC) has both endogenous and exogenous components. Endogenous acute traumatic coagulopathy is associated with shock and hypoperfusion. Exogenous coagulopathy arises from effects of dilution resulting from fluid resuscitation and consumption through bleeding and loss of coagulation factors. Coagulopathy is present in 10% to 34% of injured patients, depending on injury severity, acidosis, hypothermia, and hypoperfusion.[63]

Dilution. Traumatic injury often requires massive resuscitation to replace blood volume and restore perfusion. ATLS guidelines advocate fluid administration but do not provide clear guidance for the administration of procoagulant products such as plasma, cryoprecipitate (CRYO), and platelets.[15,64,65] Although required for initial resuscitation, crystalloid fluid administration dilutes coagulation factors and platelets and increases hydrostatic pressure. This ultimately leads to an inadequate clot and nonsurgical bleeding. Unfortunately, there does not appear to be any "magic concoction" to optimally resuscitate patients while maintaining the ability to form clots.

Resuscitation is a dynamic process. Treating one deficit, for instance anemia, with red blood cells will dilute coagulation factors and platelets leading to coagulopathy. The addition of crystalloid or nonblood colloids further exacerbates this tenuous situation.[63,66-68] Various authors advocate a balanced administration of RBCs, plasma, and platelets (1:1:1) for massive resuscitation. Balanced administration of blood products functionally represents whole blood. Figure 36-3 compares the balanced administration of blood products. This is supported by military data from Operation Iraqi Freedom.[69] Although it is an improvement, balanced component therapy falls short of the ideal whole blood replacement by virtue of (1) dilution with anticoagulant and nutritive solutions as blood is collected and processed, (2) losses due to centrifuging, separation, and readministration, and (3) losses over time in storage.

Establishing clinical end-points for correcting coagulopathy is challenging and historically has not been standardized. In an attempt to rectify this, a consensus statement of the College of American Pathologists, American Society of Anesthesiology, and European Task Force for Advanced Bleeding Care in Trauma recommends administering procoagulant products to maintain an international normalized ratio (INR) of less than or equal to 1.5 and a platelet count greater than 50,000.[64] Although these end-points are helpful in creating a standard methodology of care, and for replacement of factors in stable patients, it must be acknowledged that acute care based on laboratory data may be unrealistic. Laboratory analysis is time consuming and may not provide information rapidly enough in an actively bleeding patient. The clinician is frequently required to make decisions about transfusion in anticipation of the patient's course, which is why we recommend empiric 1:1:1 therapy until the situation is stable enough to guide therapy by laboratory values.

Hypothermia and Acidosis. Occult hypothermia is an uncommon event.[70-72] Less than 9% of trauma admissions are hypothermic on presentation.[73,74] Despite this, hypothermia remains an issue. Removal of clothing (**E**nvironment in ATLS management), muscle relaxation, cold intravenous fluid administration (resuscitation), and frequent examination (removal of blankets) contributes to heat loss. Hypothermia may result in significant coagulopathy. The vast majority of patient hypothermia can be attributed to radiant heat loss due to the gradient differences of patient and environmental temperature.[72]

Hypothermia induces a variety of physiologic changes. Although the precise mechanism is unclear, there is agreement that hypothermia alters platelet function and reduces fibrin enzyme

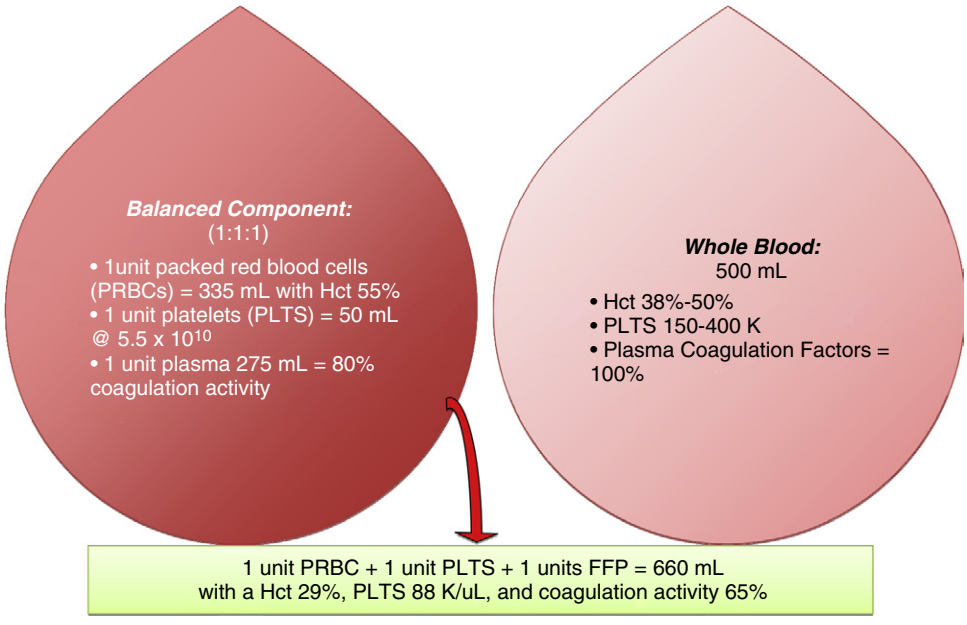

FIGURE **36-3** A comparison between whole blood administration and balanced component therapy. Balanced component therapy closely mimics whole blood. *Hct*, Hematocrit.

kinetics.[71,75] Hypothermia and acidosis compromise thrombin-generation kinetics via different mechanisms. Hypothermia primarily inhibits the initiation phase of thrombin generation. In addition, hypothermia inhibits fibrinogen synthesis, leading to a potential deficit in fibrinogen availability.[76] The clinical effect of hypothermia is a slowly formed and fragile clot that is unable to inhibit bleeding.[75]

Acidosis often accompanies massive injury, hemorrhage, and hypothermia. Acidosis, in and of itself, does not appear to have a significant impact on coagulation.[70,75] In the presence of hypothermia, however, acidosis can contribute to a potentially lethal triad of acidosis, hypothermia, and coagulopathy.[64,69] It is believed that acidosis impairs coagulation proteases and becomes clinically significant at pH less than 7.1.[69] Unfortunately, the administration of sodium bicarbonate to correct acidosis does not appear to be clinically effective to increase clotting function.[75]

The management of hypothermic and acidotic patients is fairly intuitive. The most efficacious management is to re-warm the patient and focus on returning perfusion to correct acidosis. Obviously, warming fluids as they are given and controlling the ambient room temperature of the resuscitation unit/operating room is essential. Hypothermia can be minimized when proper care is taken.

Activated Protein C Pathway. Trauma-induced coagulopathy is often thought of as a result of environmental or therapeutic interventions. Resuscitation necessitates large volumes of intravenous fluid to be administered causing hypothermia and dilution in the face of acidosis, leading to the lethal triad. In many ways, coagulopathy was a "cost of doing business." Recent research has challenged this belief.

The activated protein C (APC) pathway has been identified for decades. Although the role of the APC in fibrolytic pathways has been well established, its pathologic role in trauma-induced coagulopathy is only now emerging.[75] It is believed that the APC pathway is initiated when thrombin binds with thrombomodulin. The thrombin-thrombomodulin (T-T) complex is a normally occurring anticoagulant that develops as a negative feedback during clotting to limit clot to the area of injury.[77] APC is a vitamin K–dependent serine protease that induces anticoagulation by inhibiting factors V and VIII.[78] In a nonpathologic state, APC functions to limit clot propagation, ultimately maintaining blood flow in uninjured vessels. In the presence of damaged and hypoperfused tissue, however, it is believed that the APC pathway may lead to systemic coagulopathy.

Traumatic Brain Injury. Traumatic brain injury (TBI) in isolation is self-limiting, often producing very little blood loss. Despite this, TBI continues to be a significant cause of morbidity and mortality (25%-50%), often requiring neurosurgical intervention.[79-81] Although the mechanism is not fully understood, it is believed that TBI causes a local release of tissue factor (TF) from injured neurons, activating the protein C pathway and triggering the release of anticoagulant mediators.[80,81]

Early management of TBI should include rapid administration of plasma. The end-point of plasma administration should be to normalize the PT and INR. Because the plasma requirement needed to reverse TBI-induced coagulopathy is unpredictable, often requiring large quantities of plasma to reduce bleeding and normalize clot formation, administering plasma is recommended early, even before the initial PT or INR laboratory results return.[82]

Plasma administration may be time consuming and result in delays in surgical intervention. Because of this, several researchers advocate the early administration of recombinant factor VIIa (rFVIIa) for TBI-related coagulopathies. Although controversial, the use of rFVIIa in some studies has demonstrated an 80% reduction in blood product administration, reduced time to neurosurgical intervention, and decreased ICU admission for the treatment of patients with TBI.[82]

Shock. Research by Brohi et al.[83] suggests that hypoperfusion may be the sentinel step in trauma-induced coagulopathy. Like TBI, it is believed that hemorrhagic shock leads to activation of the protein C pathway, resulting in fibrinolytic coagulopathy.[77,82] Although the exact mechanism is unclear, it is believed that occult hemorrhage and hypoperfusion may increase T-T complexes, resulting in APC and clotting factor inactivation. This finding is consistent with observed clinical presentations. As previously noted, nearly half of all trauma fatalities are due to coagulopathic patients in hemorrhage and hemorrhagic shock who have no sign of TBI, hypothermia, or significant prehospital resuscitation.[49,77,83]

Management strategies for these patients should include a vigorous yet controlled resuscitation. In addition to ATLS guidelines, warm fluids, and early blood product administration, the goal of the resuscitation team should be to maintain perfusion while controlling blood pressure: not too low and not too high. Research has demonstrated that increased systolic blood pressures greater than 85 mmHg increases fluid/blood product administration and blood loss while having little impact on morbidity and mortality.[84,85]

Disability (Neurologic)

Neurologic assessment begins the moment the patient enters the hospital. Patient mentation, behavior, and response to stimuli all provide the clinician with a picture of any neurologic injury. A Glasgow Coma Scale (GCS) score is assigned during the primary or secondary survey and reassessed throughout the hospital course. Head injuries are classified grossly as blunt or penetrating, and the severity of the injury is based upon the GCS score.

The GCS evaluates the best eye response, best verbal response, and best motor response with a minimum score of 3 and maximum score of 15. A GCS of 13 or higher correlates with a mild brain injury, 9 to 12 a moderate injury, and 8 or less a severe brain injury.[85] See Table 19-5 for the Glasgow Coma Scale.

Head Injury

Patients with head injury may sustain primary traumatic brain injury (TBI) that cannot be anatomically corrected, only prevented. The goal of care is the prevention of secondary brain damage resulting from intracranial complications that are aggravated by intracranial bleeding, edema, and resultant increased intracranial pressure (ICP). Common extracranial causes of death in head-injured patients are hypoxia and shock. Anesthesia management of head-injured patients includes early control of the airway and maintenance of cardiovascular stability.

Management of neurologic injury follows a similar treatment pathway as that for other trauma patients. GCS of less than 8 necessitates endotracheal intubation. Goals for airway management should be to maintain Spo_2 greater than 90% with normoventilation to help reduce hypercarbia and hypoxemia, both of which contribute to elevated intracranial pressure. Judicious use of induction agents and neuromuscular blocking agents can facilitate a straightforward intubation. Attempts to perform an awake intubation in an obtunded, semicomatose, head-injured patient may promote coughing, bucking, and thrashing about, along with concomitant increases in the ICP that carry the risk of tentorial herniation. Nasal intubation may be problematic in the head-injured patient because of possible basilar skull fractures that can facilitate contamination and ultimate sepsis from nasal microorganisms introduced into the cranial vault. Late sepsis also can

occur from a sinus infection caused by prolonged nasal tracheal intubation. Gastric tubes are placed orally in head-injured patients for the same reasons.

Although hypotension is always a matter of concern, it is even more so for patients with neurologic injury. Cerebral perfusion pressure (CPP) describes the relationship of mean arterial pressure (blood pressure) and intracranial pressure. Systemic blood pressure directly affects cerebral blood flow. Hypoxemia in addition to hypotension is associated with a mortality of 75%.[86,87] As such, cardiopulmonary status must be maintained while controlling ICP.

Patients with a suspected open- or closed-head injury are placed in a head-up position to help promote venous drainage and reduce ICP. Management of ICP is a challenge. There is no exact treatment threshold; however, most experts support treatment for ICP greater than 20 to 25 mmHg. No one technique (total intravenous anesthesia [TIVA] vs. general anesthesia [GA]) has demonstrated superiority to another. Although some anesthetic agents may decrease cerebral metabolic demand, they also may reduce cerebral blood flow, which may not be a desired effect when trying to increase cerebral blood flow. Aggressive management of CPP has been correlated with improved patient outcome.[87] Patients with neurologic injury are more likely to die when their blood pressure falls below 90 mmHg. Clinical targets should be to maintain a mean arterial pressure at a minimum of 70 to 75 mmHg to maintain a CPP of at least 50 mmHg. This gross target should be maintained until ICP monitoring can be initiated.

ICP monitoring is indicated for many instances of moderate and severe brain injury. Current American Association of Neurological Surgeons (AANS) recommendations are for the placement of a ventriculostomy for ICP monitoring. It is the most accurate, cost-effective, and safe method for monitoring ICP.[87] Ventriculostomies allow for close monitoring of ICP as well as treatment of elevated ICP by drainage of cerebrospinal fluid (CSF). Anesthetists should be familiar with this equipment and how to safely calibrate the drainage system/close the system as indicated for the treatment of these patients.

The goal in treating intracranial hypertension is to promote adequate oxygenation and nutrient supply by maintaining CPP, oxygenation, and glucose supply without hyperglycemia.[88,89] Therapeutic maneuvers involve one or more of six treatment options: (1) decrease cerebral blood volume; (2) decrease CSF volume; (3) administer diuretics; (4) perform decompressive craniectomy; (5) resection of injured tissue; and (6) evacuate hematomas. Moderate short-term hyperventilation to a $Paco_2$ of 30 to 35 mmHg helps reduce increased ICP. However, excessive hyperventilation ($Paco_2$ of 25 mmHg) or less is not recommended. Hyperventilation is recommended as a temporizing measure for the reduction of elevated ICP and is avoided during the first 24 hours after injury when cerebral blood flow (CBF) is often critically reduced. If hyperventilation is used, jugular venous oxygen saturation ($SvjO_2$) measurement or brain tissue oxygen monitoring is recommended.[87] Prompt endotracheal intubation, administration of hyperosmotic diuretics, consideration of moderate short-term hyperventilation, and possible CSF drainage are considered for the reduction of cerebral swelling and the prevention of further brain injury.

Patients with significant head injury benefit from the placement of an arterial line in addition to the standard monitoring, which includes capnography and pulse oximetry. The placement of an ICP monitoring device facilitates the observation of changes in ICP dynamics that are influenced by drug administration and other manipulations. Intracranial hypertension exists when the ICP is at a sustained elevation of greater than 15 mmHg. Therapeutic maneuvers are aimed at maintaining CPP with a range of 50 to 70 mmHg and oxygen delivery Spo_2 of 90% or greater.[87]

The safety of isoflurane, desflurane, and sevoflurane has been demonstrated. Avoidance of nitrous oxide is recommended at least until the full extent of injuries is known because it may aggravate potential pneumocephalus and pneumothorax in the traumatized patient. In the head-injured patient, ketamine is generally avoided because it tends to increase the ICP. Temporary reduction of ICP is often achieved using small incremental doses of propofol, moderate levels of hyperventilation (short-term), mannitol and/or furosemide for diuresis, and elevation of the patient's head in relation to the heart for a beneficial gravitational influence. Etomidate has been advocated for use in trauma patients due to its minimal hemodynamic effects, but the resulting adrenal suppression is a disadvantage and it is not used for patients with TBI.[37] Although no significant clinical effects have been reported from single doses of etomidate, long-term use may be associated with increased mortality in multiple-trauma patients.[60,90-92] Approximately 50% of patients with moderate or severe TBI have at least transient adrenal insufficiency (AI). Younger age, greater injury severity, early ischemic insults, and the use of etomidate and metabolic suppressive agents are associated with AI. Lower cortisol levels are associated with lower blood pressure and higher vasopressor use.[93]

Blood pressure is monitored carefully to avoid hypotension (systolic blood pressure) less than 90 mmHg. Hyperosmolar therapy with mannitol 0.25 to 1 g/kg is effective for control of elevated ICP. Steroids have not been shown to improve outcome or reduce ICP.[94]

SPECIAL TOPICS IN TRAUMA ANESTHESIA

Spinal Cord Injury

Approximately 10,000 *spinal cord injuries* (SCIs) occur each year in the United States, and the median age at injury is 25 years. There are more than 250,000 spinal injury patients living in the United States. The leading cause of death in patients with SCI at the scene is respiratory failure from muscle weakness and aspiration. Most injuries occur in young males in the second and third decades of life. The SCI injuries are usually sustained from motor vehicle accidents, falls, assaults, diving injuries, and other sport injuries. Few severe injuries have as devastating physical and psychological effects as those caused by spinal cord trauma. Eventual outcome after an acute SCI depends on three factors: (1) the severity of the acute injury; (2) the prevention of exacerbation of the injury during rescue, transport, and hospitalization; and (3) the avoidance of hypoxia and systemic hypotension, which can further compromise neural function.[95-97] See Table 36-2 for the common mechanisms of spinal injuries.

Most SCIs occur in the cervical spine (55%) with other injuries fairly evenly divided among the thoracic, thoracolumbar, and lumbar regions. The most common resulting injuries are incomplete quadriplegia followed by complete paraplegia, complete quadriplegia, and incomplete paraplegia. SCIs can be categorized as complete or incomplete injuries. Complete injuries represent an absence of motor, sensory, bowel, and bladder function below the level of injury. There is some preservation of neurologic function with incomplete injuries.[98,99] Spinal cord injury should be ruled out in any traumatized individual. The nature of the accident should help guide the diagnosis. The mechanism of injury usually helps in the diagnosis of possible SCI. If an individual has been thrown from an automobile, a 1 in 13 chance exists that a cervical fracture has been sustained. If the victim remains in the car, the chances of such an injury improve to 1 in 436. Cervical SCI should be assumed to be present in any patient who has sustained trauma to the head or face, in any unconscious trauma patient,

TABLE 36-2 Classification of Spinal Injuries

Mechanism of Spinal Injury	Stability
Flexion	
Wedge fraction	Stable
Flexion teardrop fracture	Extremely unstable
Clay shoveler's fracture	Stable
Subluxation	Potentially unstable
Bilateral facet dislocation	Always unstable
Atlanto-occipital dislocation	Unstable
Anterior atlantoaxial dislocation with or without fracture	Unstable
Odontoid fracture with lateral displacement fracture	Unstable
Fracture of transverse process	Stable
Flexion-Rotation	
Unilateral facet dislocation	Stable
Rotary atlantoaxial dislocation	Unstable
Extension	
Posterior neural arch fracture (C1)	Unstable
Hangman's fracture (C2)	Unstable
Extension teardrop fracture	Usually stable in flexion; unstable in extension
Posterior atlantoaxial dislocation with or without fracture	Unstable
Vertical Compression	
Bursting fracture of vertebral body	Stable
Jefferson fracture (C1)	Extremely unstable
Isolated fractures of articular pillar and vertebral body	Stable

BOX 36-1

Six Signs and Symptoms Correlated with Spinal Cord Injuries

Paralysis
Inability to move the arms or legs should always raise suspicion of spinal cord injury.

Pain
Conscious patient may complain of pain localized at the site of the spinal injury.

Position
Patient holding the head upright or the neck with both hands may be indicating a Jefferson-type C1 fracture; the "hold-up" position (arms and hands held over the head as in a robbery) can indicate a C4, C5 fracture; the "prayer position" (arms folded across chest) indicates a possible C5, C6 fracture.

Paresthesias
Complaints of numbness, a "pins-and-needles" sensation, a burning sensation (dysesthesia), or a feeling of electric shock passing down the vertebral column or of water flowing down the back may indicate the presence of a spinal cord injury.

Ptosis
Drooping eyelid and myotic pupil, which are signs of Horner syndrome, may indicate a cervical spinal cord injury.

Priapism
Penile erection occurs in about 3% to 5% of spinal cord injuries. Its presence indicates that the sympathetic nervous system is involved.

and in any patient who complains of pain before or after careful palpation of the cervical spine. The clinician should be aware of the six conditions that are highly correlated with SCIs: paralysis, pain, position, paresthesias, ptosis, and priapism (Box 36-1). A comparison of cervical spine injuries and their acuity is noted in Table 36-2.

If SCI is suspected, care should be taken to prevent further extension of the injury. A properly fitted cervical collar should be carefully placed before the patient is moved or extricated.

Precautions should be taken for the prevention of further extension of actual or potential neurologic deficits. Spinal immobilization should be completed before the patient is moved. The head should be stabilized in neutral alignment with no extension, flexion, or rotation. Stabilization can be accomplished by placing a cervical collar on the patient, splinting, and/or sandbagging the head in neutral alignment. The patient should be placed on a long spinal back board before he or she is moved.[98]

All patients with suspected SCI must be assessed for adequacy of a patent airway. Care should be used to avoid extension, flexion, or rotation of the neck in the attempts to open the airway. A gentle "chin lift" maneuver may be adequate for securing a patent airway without disturbing the neutral neck position. Oxygen should be administered by mask immediately in the patient whose airway is secured at the scene. Hypoxia and hypercarbia can further accentuate the damage sustained with SCIs. These injuries at the C1 or C2 level result in complete respiratory paralysis. Death follows within a few minutes if artificial ventilation is not commenced rapidly. In such patients, a laryngeal mask airway (LMA) or a Combitube airway may be placed in the patient at the scene by paramedics. Although these devices initially may be adequate for allowing transport to a medical facility, they are replaced with an endotracheal tube as quickly as possible after the patient is admitted to a treatment facility.

If the patient with an SCI is breathing spontaneously on arrival at the treatment facility, the adequacy of ventilation should be immediately assessed. If the patient is not able to protect his or her airway (because he or she is unconscious or semiconscious; has an absent or diminished gag reflex or cough; or has intraoral or facial injuries with significant edema, or bleeding, or both), rapid intubation is needed. If ventilation appears to be reasonable, chest and cervical spine radiographic evaluation and neurologic examinations can be started while an arterial blood gas determination is completed. A lateral view of the cervical spine can be obtained quickly, and it reveals most unstable fractures. For a complete evaluation of the cervical spine, multiple films or CT scanning or MRI may be required. An adequate evaluation must include all seven cervical vertebrae; C7 is the most common site of injury.[99]

In children and uncooperative adults or in patients in whom awake intubation fails, a carefully selected dose of propofol and a neuromuscular blocking agent is used for inducing general anesthesia for the intubation.[100] Orotracheal intubation can be safely performed with neck immobilization and inline stabilization. Although there is debate in the literature, it is preferable to intubate these SCI patients orally. SCI patients have the best chance of recovery if hypoxia, hypercarbia, and hypotension are avoided or rapidly corrected if encountered. Arterial blood gas values

indicating that ventilation is suboptimal are corrected by intubation and mechanical ventilation. If there is a delay in establishing the airway, the patient is given ventilation by mask while cricoid pressure is maintained until the airway is secured. Severely traumatized patients who are hypoxic on arrival undergo ventilation by mask with application of cricoid pressure until the intubation is completed. This method prevents further hypoxic insults that can occur during the apneic period between the administration of a muscle relaxant and the completed intubation. Often, time does not allow the luxury of adequate preoxygenation in an already compromised hypoxic patient with respiratory inadequacy. To prevent further hypoxic insult and the resultant potential life-threatening dysrhythmias, these patients are continuously ventilated while cricoid pressure is applied. This measure helps maintain or improve oxygenation until laryngoscopy and intubation are completed.

Use of Muscle Relaxants in Patients with Spinal Cord Injury

As previously discussed, succinylcholine may precipitate cardiac arrest in patients with massive muscle injury or denervation, such as that seen in patients with SCIs, crush injuries of muscles, or burns. The basis for this problem involves supersensitivity and upregulation of the neuromuscular junction to the depolarizing effect of succinylcholine.[101] This phenomenon results in the release of large quantities of potassium during muscle contraction. Normal depolarization results in a small potassium flux across the muscle cell membrane. If a muscle is crushed, burned, or denervated, acetylcholine receptors proliferate around the injured cell, so that when the muscle is depolarized, the flux of potassium is increased significantly.[102] The problem is thought to develop in response to succinylcholine several days after the injury. Succinylcholine is not recommended for intubation of the patient with acute SCI because muscle fasciculation may exacerbate the SCI.[66] It is also contraindicated for routine use in children.[101,102] A conservative approach to caring for patients with SCI would be to avoid the use of succinylcholine by using a nondepolarizing muscle relaxant such as rocuronium or non-relaxant-assisted airway control techniques.[100]

Spinal Shock

A triad of *hypotension*, *bradycardia*, and *hypothermia* frequently results from a relative sympathectomy in SCI patients. The *spinal shock* is progressively intensified the more cephalad the SCI. Patients with SCIs at the T6 level or higher have severely impaired CNS function. Sympathetically mediated cardioaccelerator responses no longer oppose vagal innervation, allowing the heart rate to slow dramatically. Loss of sympathetic tone allows vasodilation, pooling of the peripheral circulation, and decreased venous return to the heart. This situation results in a decreased cardiac output and hypotension. The SCI also interrupts sympathetic pathways from the hypothalamus (temperature control center) to peripheral blood vessels. The patient in spinal shock is unable to constrict vessels or shiver in order to produce heat or to dilate vessels to dissipate heat. The patient's body temperature has a tendency to migrate toward the environmental level.

Treatment

Patients in spinal shock are hypotensive and bradycardic with warm, pink extremities. In contrast, patients in hemorrhagic shock tend to be hypotensive and tachycardic with cold, clammy skin. Use of invasive monitoring is critical for fluid resuscitation and appropriate intervention with vasoactive drugs—often norepinephrine infusion. An indwelling arterial catheter is mandatory in the acute phase of spinal shock. Moment-to-moment control of arterial blood pressure is essential for the replacement of fluids and for the use of vasoactive drug therapy. In addition, arterial blood gas assessments are facilitated by an indwelling arterial catheter.

The SCI patient is frequently unable to maintain adequate cardiac filling pressures. However, over-aggressive fluid therapy can precipitate pulmonary edema. For the maintenance of adequate arterial blood pressure and cord perfusion, pressor therapy may be initiated.

Other Considerations

Patients with SCI are extubated as quickly as possible after spinal stabilization surgery. If the patient requires intubation because of associated pulmonary injuries or dysfunction, then a weaning program is started when it can be tolerated by the patient. With frequent assessment of respiratory status, this weaning is usually begun within the first few days. Useful guidelines for assessing the adequacy of ventilation include measurement of the tidal volume (greater than 5 mL/kg), negative inspiratory force (−20 to 25 cm H_2O pressure—needed for adequate cough), and vital capacity (greater than 15 mg/kg). Patients with a high SCI often lose innervation of the intercostal and abdominal musculature.

For these reasons, continued assessment of adequate diaphragmatic innervation, a characteristic needed for the generation of adequate ventilation, is mandatory. Some patients require tracheostomies. Chest physiotherapy is initiated for all patients as soon as possible in order to reduce the risk of pulmonary congestion and infection. Oral or nasogastric tubes are placed for decompressing the stomach. This measure eases diaphragmatic excursion for improved ventilation and reduces the risk of aspiration. Peptic ulceration with loss of sympathetic innervation in the patient with a high SCI is a well-described complication, especially in patients receiving steroids.

Surgical Intervention and Anesthesia Approach

Although external immobilization devices, including a Halo vest, are sometimes used, many neurosurgeons believe that prolonged use of external fixation devices is contraindicated in patients with unsatisfactorily reduced spines. Frequently, spinal stabilization and/or decompression procedures are performed after initial resuscitation and diagnostic workup.

The neurosurgeon and anesthesia team document the current neurologic status and note any deficits before the start of anesthesia and intubation. In an awake intubation, the patient is assessed before and after endotracheal tube placement and after the patient is positioned for surgery.

Whether an anterior or a posterior surgical approach is used in cervical SCI depends on the nature of the injury. Internal fixation devices are commonly placed in the acute phase for stabilization of lower SCIs. At times, these procedures can be associated with significant surgical blood loss. Careful monitoring and replacement of blood loss are essential. Use of an autotransfusion device often saves considerable banked blood use in these procedures.

In patients deferred for elective spinal stabilization procedures, awake fiber optic intubations are performed. In controlled conditions, this measure allows the use of local, topical, and transtracheal anesthesia without the risk of pulmonary aspiration that is present in emergency procedures. Glycopyrrolate is commonly given before administering local anesthesia to the airway as an antisialagogue. Once moderate sedation is accomplished, superior laryngeal nerve block, topical oral pharyngeal, and transtracheal sprays are applied as necessary. At this point there are no data that suggest that nasal intubation is superior to oral intubation. It is preferable that endotracheal intubation be done orally if it can be accomplished safely. Anesthetic techniques that avoid

hypotension and provide good cardiovascular stability are recommended. Baseline analgesia is provided with opioids (generally fentanyl, sufentanil, or remifentanil). Muscle relaxation is provided with a nondepolarizing neuromuscular blocking agent to promote cardiovascular stability. Succinylcholine is avoided during the patient's remaining lifetime after a spinal cord injury with permanent neuromuscular deficits.

Nitrous oxide is avoided because many SCI patients may have a head injury or possible pneumothorax. Following head injury, nitrous oxide can cause a pneumocephalus to develop, with a subsequent rise in the intracranial pressure. Following injury to the chest wall, use of nitrous oxide with positive pressure can cause rapid expansion of a subclinical pneumothorax into a rapidly increasing and life-threatening pneumothorax with mediastinal shift.

Ketamine can be useful as an induction agent in unstable patients. Ketamine produces a transient increase in ICP; however, many clinicians consider this action secondary to maintaining stable vital signs, and consequently, it is often used in these situations.[103,104] Dexmedetomidine is also a useful adjunct.

Autonomic Hyperreflexia (Mass Reflex)

Trauma centers are chosen quite often to treat acute trauma patients during the initial hospitalization and also for future related surgery. In this setting, the anesthesia plan addresses the implications of *autonomic hyperreflexia,* which is a sudden massive sympathetic discharge resulting from stimulation below the level of spinal cord transection. Hyperreflexia is seen in 85% of SCI patients with lesions above T5 to T8. Signs of this condition include paroxysmal hypertension, bradycardia, and cardiac dysrhythmias in response to stimuli below the level of transection (such as bladder catheterization). Hyperreflexia is not observed until the spinal shock phase has passed. It is therefore usually seen when patients return to surgery for such procedures as cystoscopies, performed later in their recovery phase.

Autonomic hyperreflexia is caused by stimulation below the level of the lesion—typically caused by distention of the bladder or rectum that is caused by defecation, childbirth, and even cutaneous stimulation. It can occur intraoperatively with local, spinal, and nitrous oxide–opioid general anesthesia.

If autonomic hyperreflexia occurs, it is treated by removal of the stimulus, deepening anesthesia, and administration of direct-acting vasodilators. Untreated, the hypertension crisis may progress to seizures, intracranial hemorrhage, or myocardial infarction. No episodes have been reported with the use of potent inhalation anesthetics. Bradycardia is treated with atropine or glycopyrrolate.

Orthopedic Injury and Trauma Anesthesia

Although most *orthopedic injuries* are not usually immediately life threatening and are considered in the secondary evaluation of the trauma patient, they can be associated with significant hemorrhage and other extensive systemic physiologic derangements, such as shock, fat emboli, and thromboembolic hypoxic respiratory failure. Major hemorrhage associated with fractures requires massive intraoperative fluid resuscitation, although rapid exsanguination from major fractures is unlikely. Modern intramedullary rodding devices often allow patients to ambulate within 24 hours of surgery, drastically reducing the incidence of thrombophlebitis and its subsequent morbidity.[105]

Because the ideal time to repair open fractures operatively is within the first few hours after injury, all patients brought to the operating room for emergency surgical repairs are considered to have full stomachs and are anesthetized with techniques that are aimed at reducing the risk of aspiration. Certain secondary vascular injuries commonly occur with specific fracture sites because the sharp edges of fractured bones are forced into blood vessels and nerves in proximity to the fracture site.[106]

Massive hemorrhage can be associated with pelvic fractures. The displaced pelvic fragments can sever the arteries, veins, and nerves that exit the pelvis to the perineum and the lower extremities. This can result in major blood loss into the retroperitoneal space, with continued hemorrhage from movement of unstable fragments that shear away hemostatic elements that have formed in these ruptured blood vessels. Although blood loss from pelvic fractures involving the iliac artery is notorious, significant blood loss also can occur from fractures associated with disruption of the axillary, brachial, femoral, and popliteal arteries.

Severe shock can result from major bleeding into fracture sites, particularly in pelvic and long-bone fractures. Close monitoring and replacement of initial and ongoing blood loss are needed during the anesthetic management of these cases.

Hypoxic respiratory failure is a common sequela of long-bone fractures. The hypoxia results from continuous seeding of marrow fat into the venous circulation. All patients with major fractures, especially fractures of the lower extremities and pelvis, receive frequent assessment of arterial blood gases. Endotracheal intubation and mechanical ventilation are recommended for the treatment of fracture-induced hypoxia and the prevention of further lung damage. If patients are extubated immediately after fracture fixation, despite evidence of poor oxygenation and a large pulmonary venous admixture, they may develop acute respiratory distress syndrome and fat emboli syndrome. These patients benefit from continued mechanical ventilation and positive end-expiratory pressure (PEEP) that is titrated for the reduction of intrapulmonary shunting.[107]

Continuum of Care

Recovery from serious, traumatic injury is often a prolonged process. The practice of damage control surgery is to provide rapid, life-saving procedures and delay definitive repair until after the patient has been stabilized. Based on a variety of factors, patients may experience complications such as multiorgan failure, ARDS, prolonged mechanical ventilation, and infection as they convalesce. During this time, patients may require a variety of surgeries ranging from simple washouts of wounds to open reduction of the pelvis or to thoracic or abdominal surgeries. Patients may be transported to the operating room while intubated, or may be on vasoactive pressers, insulin, or total parenteral nutrition. Whether ICU therapy will be continued in the operating room is unclear; often this determination is provider/institution dependent.

Unfortunately there are currently very little anesthetic-ICU data that can quantify the positive or negative impact of anesthetic care on patient outcome. Many reasons could account for this gap. The particular injury and its degree of severity, coexisting disease, lack of ICU-anesthesia experience, and the amount of surgical time are likely just a few of the variables that cloud obvious anesthetic-related outcomes. It is important to recognize that actual anesthetic time is typically a fraction of the hospital course of critically injured patients. As such, the magnitude of the effect of anesthesia is largely unknown—or ignored.

Despite this general gap in clinical knowledge, it is logical to recognize the need to coordinate care throughout the surgical course of the trauma patient. The benefits of coordinated care have been demonstrated in some surgical–critical care literature; these include reducing hospital length of stay and reducing ventilator-associated sequela.[108,109] Recognition of the importance of maintaining the continuum of care from the ICU to the operating room

is paramount, and the anesthetic should always be tailored to the patient rather than tailoring the patient to a specific anesthetic.

SUMMARY

Traumatic injury is a leading cause of morbidity and mortality in the United States and around the world. Despite development, innovation, and changes to public policy, traumatic injury continues to pervade modern society. Consequently, a comprehensive understanding of trauma care is important for modern anesthesia practice. Trauma management has moved away from the community-based level and developed into a systems-based approach, coordinating prehospital care with larger centers, public policy, and a rational approach through use of ATLS. The organization of trauma care in the United States has substantially improved survival and quality of outcomes for severely injured patients.

Ideally, the anesthetist's involvement should begin as soon as the patient reaches the trauma facility. Care should follow the general algorithm developed in ATLS. Anesthesia providers and the trauma team should focus on ensuring an adequate airway and breathing while diagnosing and controlling injuries almost simultaneously. The principles of successful management of the trauma patient are based on organization and preparation, assessment of the patient's injuries, proper priority for therapeutic interventions, achievement and maintenance of a patent airway, fluid resuscitation, application of appropriate continuous invasive and noninvasive monitoring, correction of acid-base and electrolyte disturbances, and careful titration of anesthetic and adjunctive agents.

The degree of functional outcome of trauma patients is largely dependent on the early involvement of sound principles of anesthesia care in the resuscitation and overall anesthetic management during the perioperative period. In a well-managed team approach, assessment and treatment are carried out in rapid succession or even simultaneously.

CHAPTER 37

Outpatient Anesthesia

◆ *Rex A. Marley and Troy Calabrese*

The concept of outpatient anesthesia is not unique to the past three decades. It was introduced in dentists' offices with the administration of nitrous oxide. Physicians' offices were next to offer this type of service for superficial procedures that required at most the administration of local anesthesia. In 1909, Nicoll[1] first reported on 8988 outpatient surgical procedures performed at the Glasgow Royal Hospital for Sick Children. In 1916 in Sioux City, Iowa, Waters[2] opened the first freestanding unit designed for outpatient surgery.

The evolution of and demand for outpatient care have not slowed since first described by these pioneers. Surgical innovation, new anesthetic drugs and techniques, and changes in insurance carrier demands have increased the type and number of procedures performed at ambulatory care centers or traditional hospital operating rooms. Within the United States, outpatient procedures at freestanding centers increased nearly 300% between 1996 and 2006. An estimated 35 million outpatient surgical procedures were performed in 2006. The most common ambulatory procedures included myringotomy and tonsillectomy for patients under 15 years of age, large intestine endoscopy and therapeutic injection for patients aged 15 to 44 years, and intraocular lens extraction for patients 75 years or older. Currently, more than 62% of all elective procedures are performed on an outpatient basis.[3] In addition, difficult procedures performed even on patients with complex medical conditions are more routinely being performed on an outpatient basis. It is the responsibility of the attending anesthesia provider to ensure that these complex medical conditions are managed optimally before, during, and after the procedure.

It is expected that the patient will enter the outpatient surgical care facility, undergo the procedure, and then be released without needing an overnight stay. Outpatient surgery, in addition to office-based and free-standing ambulatory surgery centers, includes the "23-hour observation" patient, who may be admitted to the inpatient or overnight facility yet is discharged before staying in the hospital 24 hours. Surgical procedures requiring the expertise of an anesthesia provider in the office setting are becoming increasingly popular. Office-based surgery can be performed more efficiently and at lower cost than surgery performed in the hospital.[4] Presently, 12 million operations annually, representing about 10% of all outpatient procedures, are performed in an office-based setting.[5] Optimal anesthesia and surgical techniques for office-based surgery are similar to ambulatory procedures performed at traditional ambulatory surgical centers. Although office-based surgery can be performed safely, it is not without risk. Current issues of discussion include patient and procedure selection, recovery, complication management, perioperative management, and facility requirements.[6] Office-based anesthesia practice standards and guidelines have been developed by the American Association of Nurse Anesthetists (AANA),[7] the American Society of Anesthesiologists (ASA),[8] and the Joint Commission.[9]

FEATURES OF OUTPATIENT SURGERY

Advantages

Financial

An advantage of ambulatory surgical settings has been the economic benefit for consumers, third-party payers, and medical facilities. Patients may benefit not only from reduced medical cost but also from minimized costs of outside child care and from resumption of normal living activities at an earlier time. Third-party payers concerned about cost containment are increasingly identifying procedures that may be performed *only* in the outpatient setting. Cost savings exceeding 50% have been reported for selected surgeries (e.g., laparoscopic cholecystectomy) performed on an outpatient basis.[10] Ambulatory centers, secondary to their design, facility layout, and patient selection, tend to operate more efficiently than hospital-based operating theaters in regard to surgical volume.

Medical

One medical advantage of ambulatory surgery is the increased availability of hospital beds for patients requiring hospital admission. For patients who are susceptible to infection (e.g., children, immunosuppressed patients, cancer patients, and transplant recipients), minimizing time and contact in the inpatient hospital setting may decrease the risk of nosocomial infections.[11]

Patient Satisfaction

Patients report greater satisfaction with outpatient procedures because of shorter waiting times and lower costs.[12,13] Delays secondary to lack of available beds, as seen with inpatient facilities, are less likely to occur.

Social

Children benefit from outpatient surgery because it minimizes separation from parents and causes less disruption in a child's feeding schedule. The continued presence of and care offered by the parents are especially beneficial for children with mental or physical impairments.[14] Geriatric patients show better cognitive and physical capacity when separation from familiar surroundings and family is minimized. The elderly are better able to maintain their normal living routines (e.g., diet, medication, and sleep pattern). Postoperative confusion is decreased in geriatric patients undergoing outpatient procedures because they receive less medication and are returned to a familiar environment sooner than their inpatient counterparts.[15]

Staffing

The ambulatory surgery setting is more convenient than the inpatient surgery setting for the staff because it offers more efficient use of time, uniform work schedules, and more predictable surgical outcomes.

Disadvantages

The outpatient setting may have several disadvantages:

- The degree of patient privacy is less than that in the inpatient setting.
- The patient must make multiple trips to the physician's office or the ambulatory setting for evaluation and screening.
- Adequate home care must be ensured once the patient is discharged from the facility after surgery.
- Compliance and efficacy related to preoperative and postoperative instructions may not be as good as when the patient is admitted to the hospital before surgery.
- Because of the emphasis on efficiency, children have less time to adapt to the surgical setting than they would as inpatients.
- Observation time and monitoring for the occurrence of adverse events are decreased in the outpatient setting.
- Management of complications can be problematic at a freestanding or office-based facility secondary to a lack of resources.

Demographic Considerations

Patient Age

Patients of any age can receive outpatient anesthesia; age should not be a limiting factor when determining appropriateness for ambulatory procedures. Approximately 6% of outpatients are younger than 15 years, and more than 14% are at least 75 years of age.[3] More than 60% of all anesthesia administered for pediatric surgery is performed on an outpatient basis.[14]

Surgical Time

Earlier guidelines recommended limiting the amount of time of an outpatient surgery to less than 1.5 to 2 hours.[16] The reasoning was that the longer surgery lasts, the more likely patients will experience severe pain or vomiting.[17,18] Surgical time exceeding 2 hours was also thought to be a strong predictor for delayed discharge and unplanned hospital admission postoperatively.[19] However, other factors such as the skill of the surgeon, the type of surgery performed, the patient's condition, and the anesthetic technique used must be considered. Arbitrarily limiting the length of surgery to less than 2 hours is no longer considered necessary; procedures exceeding 4 hours are routinely performed without complications in ambulatory centers.

Suitable Procedures

The list of procedures suitable for the ambulatory setting is constantly evolving. Endoscopy of the large and small intestine is the most common type of outpatient procedure, and ophthalmologic surgery is the second most common.[3] The outpatient surgical procedure should not involve extensive blood loss or physiologic shifts of considerable fluid volumes because these processes necessitate protracted patient observation and hydration. In the past, the potential for blood transfusion implied the need for the procedure to be conducted at an inpatient facility. Now the increasing popularity of autologous blood donation for possible future transfusion has facilitated the application of transfusion during or after the outpatient surgery when needed.[20]

The list of surgical procedures deemed acceptable for outpatient surgery is ever expanding; routinely included are surgeries such as laparoscopic cholecystectomy,[21] lumbar laminectomy,[22] cervical laminectomy and fusion,[23] thyroidectomy,[24] hysterectomy,[25] and tonsillectomy.[26] The norm regarding suitable outpatient procedures continues to be challenged, with the addition of more potentially higher-risk procedures, that is, craniotomy for tumor,[27-29] adrenalectomy,[30] and gastric bypass surgery.[31] Facilities with a 23-hour observation area designed for extended patient assessment is often the desired location for procedures such as outpatient tonsillectomy and higher-risk procedures.

Procedures requiring prolonged immobilization are best conducted on an inpatient basis. For procedures associated with postoperative discomfort, arrangements for parenteral opioid therapy in the home may be made, provided that adequate pain relief can be achieved with safe doses of opioids.

PATIENT SELECTION

Proper patient selection minimizes the number of hospital admissions that follow outpatient surgery. Primary predictors of unanticipated hospital admission are related to the type of surgical procedure and subsequent complications, that is, nausea and vomiting, pain, or significant operative fluid shifts or blood loss. Evaluation of patients to determine who is appropriate for outpatient surgery and anesthesia requires consensus and cooperation between the surgical and anesthesia staff. Factors to consider in determining the suitability of a patient for outpatient surgery include the following:

- *The anticipated surgical procedure for the patient.* The proposed surgery should have an insignificant incidence of intraoperative and postoperative problems and should not require intense postoperative patient management.
- *The physical and psychosocial health of the patient.* The patient is ideally in his or her usual good health, or if ill, the condition should be well controlled. A reduction in postoperative complications has been shown if the patient's medical condition is stable for at least 3 months before surgery.[32] The patient and family should be receptive to the outpatient philosophy and the perioperative adaptations that will be required of them.
- *The surgeon's skills and cooperation.* Early referral to the anesthesia department for patients of questionable appropriateness helps streamline the outpatient process and minimize delays on the day of surgery.

Selection Criteria

Acute Substance Abuse

The patient with a history of substance abuse should be evaluated before the day of surgery. Counseling for such patients includes the warning that preoperative substance abuse will lead to cancellation of the surgery. A distinction between long-term and acute substance abuse must be made. A urinary drug screen should be performed in patients suspected of substance abuse. The patient with signs of acute substance intoxication is an inappropriate ambulatory surgery candidate because of the increased likelihood of impaired autonomic and cardiovascular responses. The surgery should be rescheduled after the patient is detoxified and treated. Patient management strategies should emphasize methods of minimizing postoperative pain, because substance abusers are typically intolerant to pain. Regional or local anesthetic techniques, if their use is suitable to the surgeon and appropriate for the type of operation being performed, may be used if the patient wishes to abstain from sedatives and opioids. Postoperatively, pain may be minimized by the use of local wound infiltration, regional techniques, and the prophylactic use of nonsteroidal analgesics. Placing a catheter in the wound and instilling local anesthesia, either continuously or intermittently, has been shown to prolong pain relief and improve patient satisfaction and should be considered for this patient population.[33]

Age

Patient age by itself should not be the deciding factor for outpatient suitability. Meridy[34] retrospectively examined the charts of

patients ranging in age from 9 months to 92 years and noted that most perioperative complications occurred in the 20- to 49-year age group. Patients older than 85 years, who required multiple hospitalizations within 6 months of the surgery, have been shown to have an increased risk of unanticipated hospitalization and death after outpatient surgery.[35] Although multiple medications and preexisting comorbidities are more likely in the elderly, there is a paucity of data supporting increased adverse outcome in these high-risk elderly patients.[36]

Premature Infant. The premature infant (gestational age of 37 weeks or less at birth) is an inappropriate candidate for outpatient surgery because of potential physiologic aberrations. The premature infant may:

- Exhibit anemia
- Not have fully developed gag reflexes (and thus be more prone to aspiration of liquid or solid food)
- Have immature temperature control and be susceptible to the effects of hypothermia, which could contribute to postoperative apnea
- Demonstrate immature brainstem functioning, which predisposes the infant to pathologic respiratory conditions

The infant with a hemoglobin value less than the predicted normal value for that age will require additional evaluation before surgery. Hemoglobin values in the premature infant may drop to between 7 and 8 g/100 mL, 1 to 3 months after birth.[37] The presence of anemia (hematocrit less than 30%) may increase the incidence of apnea in the newborn.[38] Some investigators have recommended delaying elective surgery until the hematocrit is increased to greater than 30% through supplementation of iron intake.[39]

In the perioperative period, the preterm infant is at greater risk for developing respiratory complications, including apnea, than is the full-term infant.[38] The preterm infant is susceptible to short apnea (6 to 15 seconds), prolonged apnea (greater than 15 seconds), or periodic breathing (three or more periods of apnea of 3 to 15 seconds separated by less than 20 seconds of normal respiration). Short or prolonged apnea and periodic breathing predispose the infant to hypoxemia and bradycardia. An obstructive component that leads to quicker oxyhemoglobin desaturation appears to be part of postoperative apnea in these infants.[40] These infants have developed prolonged apnea as late as 12 hours after surgery.[38]

The older the infant, the less likely that respiratory complications such as apnea will occur. In evaluating the suitability of a former preterm infant for outpatient surgery, conservative measures are best; inpatient status should be assigned if significant concerns exist. These patients benefit from the intensive monitoring available in the inpatient setting. Much discussion has been held as to the postgestational age (gestational age plus postnatal age) at which the former preterm infant may safely undergo outpatient anesthesia. Healthy former premature infants whose postgestational age is less than 50 to 60 weeks[41,42] should be admitted to the hospital for extended monitoring. Postoperative apnea has been described even in the full-term infant.[44] The ability to exactly predict the susceptibility of an infant to postoperative apnea is lacking.[45] Patients should be evaluated individually for appropriateness for outpatient surgery, and consideration should be given to growth and development, feeding problems, upper respiratory tract infections (URTIs), apneic history, and disorders of metabolic, endocrine, neurologic, or cardiac systems. All infants with a history of prematurity should be closely observed for signs of apnea and bradycardia. If any of these signs are evidenced in the postanesthesia care unit, patients should be admitted and observed. An infant with a history of apnea or bradycardia must be apnea free and without monitoring for at least 6 months to be considered for outpatient surgery.[43] Efforts should be made to schedule surgery for these patients as early in the day as possible to allow for extended observation time.

Beyond simply delaying surgery, attempts to minimize the likelihood of postoperative apnea in susceptible infants have been examined. Spinal anesthesia without sedation resulted in less prolonged apnea, oxyhemoglobin desaturation, and bradycardia than did general anesthesia or spinal anesthesia with ketamine sedation.[39] However, apnea and delayed respiratory failure have been reported in children who have had spinal or caudal anesthesia.[45] Infants treated with endotracheal intubation or mechanical ventilation (or both) for respiratory distress syndrome at birth have been shown to have abnormal arterial blood gas values and abnormal pulmonary function results as late as 1 year after treatment.[46] Infants exhibiting signs of bronchopulmonary dysplasia should not be considered for outpatient surgery.[47] Patients with a history of bronchopulmonary dysplasia are at risk for sudden infant death.[48]

Infants with a history of apneic events or who have siblings who developed sudden infant death syndrome (SIDS) are at risk for SIDS. The greatest at-risk age for the development of SIDS is between 1 month and 1 year of age.[49] In infants who have lost a sibling to SIDS, the risk of dying from the same syndrome is four to five times that of the general population.[50] Patients at risk for the development of SIDS should not be considered for outpatient surgical procedures until they are at least 6 months to 1 year old.[51]

Full-Term Infant. Healthy, full-term infants (older than 37 weeks' gestational age at birth) can be considered for minor outpatient surgery. Full-term infants with histories of apneic episodes, failure to thrive, and feeding difficulties are not suitable candidates for outpatient surgery. Infants with a history of respiratory difficulties at birth are not suitable outpatient candidates unless they are free of respiratory symptoms at the time of surgery and at the time of hospital discharge.[51] There are no formal practice guidelines from major anesthesia or pediatric organizations regarding outpatient surgery in infants. However, individual hospitals frequently establish a cutoff age of 50 to 56 weeks of postconceptual age in infants born before 37 weeks, and also consider factors such as anemia, prior apnea, and coexisting disease. Postoperative monitoring recommendations range from 12- to 24-hour admission for cardiorespiratory monitoring. Some facilities also restrict day surgery procedures for term infants to only those infants older than 44 to 46 weeks of postconceptual age, or the facilities require a longer observation period (e.g., 4 hours) in phase II recovery.[52] Some evidence-based suggested guidelines are listed in Box 37-1.

Geriatric Patient. The decision of whether to perform ambulatory surgery on a geriatric patient (age 65 years or older) should be individualized and based on physiologic age rather than on chronologic age. Existing medical problems are a concern when considering the geriatric patient for outpatient surgery. There are more concomitant age-related diseases that should be optimally treated preoperatively in this group of patients. Patient age exceeding 85 years is a predictor of hospital admissions after outpatient surgery.[35,53] Thoughtful preoperative planning for the elderly patient's post-discharge care is paramount to ensure a safe and successful outpatient experience. The elderly population presenting for outpatient surgery has increased dramatically and will continue to increase as the population ages.[54] Appropriate home care and transportation to and from the outpatient center with a responsible caregiver must be ensured.

Special Considerations

Convulsive Disorders. Surgery for patients with seizure disorders should be scheduled early in the day so patients can be observed

BOX **37-1**

Suggested Guidelines for Outpatient Surgery in Infants

- Appropriate short-acting anesthetic agents may facilitate emergence and discharge.
- Where possible, regional anesthetic techniques and nonopioid analgesics should be used instead of opioids.
- A loading dose of caffeine citrate 20 mg/kg may decrease postoperative apnea in former premature infants.
- If the surgical procedure is suitable, consider spinal anesthesia without sedation in former premature infants; however, postoperative monitoring is still recommended in the at-risk age range.
- Former premature infants should be admitted for observation unless they are over 54 to 56 weeks of postconceptual age (depending on degree of prematurity) and are without anemia, ongoing apnea, or other significant medical problems. Infants meeting these criteria also need to have had an uneventful anesthetic and recovery room course before consideration of discharge.
- Term infants are acceptable for outpatient procedures providing they are otherwise healthy, the procedure is not likely to result in significant physiologic changes or postoperative pain requiring opioid medications, and the anesthetic proceeds uneventfully. It may be prudent to monitor these patients in the recovery area for several hours postoperatively.
- All infants should be cared for in a facility with adequate and appropriately sized equipment, and medical and nursing staff with appropriate expertise and adequate ongoing experience in caring for this age group.

From Everett LL. How young is the youngest infant for output surgery. In: Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders; 2009:469-474.

for 4 to 8 hours after the operation before they are discharged. It is important to establish the patients' ability to maintain their schedule for anticonvulsant medications. Patients with uncontrolled seizure activity are not deemed appropriate for outpatient surgery by most institutions.

Cystic Fibrosis. The extent of pulmonary involvement is the primary determinant of appropriateness for ambulatory surgery in patients with cystic fibrosis. Such patients should be evaluated several days before the proposed surgery; patients with symptomatic respiratory distress are better treated in an inpatient setting, where appropriate respiratory-care management and hydration can be administered.[55] Protective airway measures should be instituted in the cystic fibrosis patient secondary to an increased risk of gastroesophageal reflux disease and pulmonary aspiration.[56]

Malignant Hyperthermia Susceptibility. Malignant hyperthermia susceptibility is impossible to predict because it occurs in phenotypically normal individuals.[57] A malignant hyperthermia (MH)–susceptible patient is defined as having one or more of the following[58-63]:

1. A previous episode of MH
2. Masseter muscle rigidity with previous anesthesia
3. A first-degree relative with history of an MH episode or positive muscle biopsy
4. Diseases with known mutations on chromosome 19; may include, but are not limited to, central core myopathy, King-Denborough syndrome, Native American myopathy, and hypokalemic periodic paralysis
5. Patients with heat-induced rhabdomyolysis

Diseases not associated with MH susceptibility include mitochondrial myopathies, Noonan syndrome, osteogenesis imperfect, and neuroleptic malignant syndrome.[57]

The MH-susceptible patient who has received a trigger-free uneventful anesthetic does not require overnight hospitalization based exclusively on being MH susceptible. The ambulatory facility should have the requisite monitoring and resuscitation capabilities, including a minimum of 36 vials of dantrolene, for managing the MH patient.[64] A point-of-care monitor (capable of measuring blood gases and electrolytes) and urinalysis with a dipstick (to detect myoglobinuria) are useful monitoring devices used in the free-standing ambulatory center.[65] The patient should be scheduled as early in the day as possible to allow for extended patient observation for at least 1 hour in the postanesthesia care unit (PACU) plus an additional hour in phase 2 recovery, and the lack of symptoms of MH should be ensured before discharge is considered.[66] A patient who exhibits marked rigidity of the jaw muscles should not be discharged. Overnight observation is required for temperature rise, myoglobinuria, elevated creatine kinase (CK) levels, or progression to an MH episode. Patients who experience milder increases in jaw tension should be observed for signs and symptoms of MH for at least 12 hours. If there is evidence of myoglobinuria (i.e., dark, cola-colored urine), elevated temperature and pulse rate, or abnormality of acid-base balance, the patient should be emergently transferred and admitted to the nearest full service facility and observed overnight.[66,67] Written discharge instructions should include: (1) how to monitor the patient's temperature at home, (2) how to recognize the signs and symptoms of MH, and (3) contact information if emergency medical advice is required.[68]

Morbid Obesity. The uncomplicated morbidly obese patient is an appropriate candidate for select outpatient surgery.[69] The morbidly obese patient with significant preexisting cardiac, hepatic, pulmonary, or renal disease has to be evaluated on an individual basis and may best be managed as an inpatient. Late problems are more likely to occur when the body mass index (BMI) reaches 35 to 40 kg/m^2; this was once considered to be the cutoff point for ambulatory surgery. With the introduction of select bariatric procedures into the outpatient setting, this exclusionary criterion has been reevaluated. A higher incidence of postoperative hypoxemia has been observed in patients with a BMI of 35 kg/m^2 or higher.[70] However, unanticipated hospital admission after ambulatory surgery was not increased in obese patients with an average BMI of 44 kg/m^2.[71] The laparoscopic adjustable gastric banding procedure has opened the door for bariatric surgery to be performed on an outpatient basis, because this procedure does not open the digestive tract.[72-74] Initial reports of outpatient laparoscopic Roux-en-Y procedures are being investigated for safety and appropriateness.[75] The ability to sufficiently manage postoperative pain and address postoperative ambulation should be discussed preoperatively by the surgeon and anesthesia provider. The morbidly obese patient is at risk for persistent hypoxemia in the PACU, which may necessitate overnight supplemental oxygen therapy.

Morbid obesity is associated with an increased risk of obstructive sleep apnea (OSA).[76] Preoperative airway evaluation (e.g., Mallampati classification, nuchal girth, redundant pharyngeal tissue) is important. A high Mallampati airway classification, reduced thyromental distance, and restricted mandibular mobility were predictive of difficult endotracheal intubation, yet an increasing BMI was not associated with difficulty.[77] An assessment of intubating conditions in the patient with OSA found a 22% incidence of difficult endotracheal intubation.[78] The likelihood of

a difficult airway has to be assessed preoperatively, and the ability to manage the difficult airway has to be ensured.

If continuous positive airway pressure (CPAP) is part of the patient's management of OSA, the patient, undergoing general anesthesia, should be instructed to bring his or her CPAP machine into the surgery center for use in the immediate postoperative recovery phase. Intraoperative benzodiazepine[79] and opioid usage, out of concern for worsening airway obstruction, should be minimized or avoided in these patients, and pain should be controlled with alternative techniques (e.g., nonopioid analgesics, regional anesthesia techniques, local wound infiltration with local anesthesia) when possible.[80] Moderate to severe OSA patients requiring postoperative opioids should not undergo ambulatory surgery.[81]

No increase in unanticipated hospitalizations has been shown in OSA patients who are deemed eligible to undergo ambulatory surgery.[82,83] The decision concerning whether to provide for the patient with OSA in the ambulatory setting should be contingent on certain criteria being met. The Society for Ambulatory Anesthesia has recently released a consensus statement on preoperative selection of adult patients with OSA scheduled for ambulatory surgery. Patients with a known diagnosis of OSA and optimized comorbid medical conditions can be considered for ambulatory surgery if they are able to use a continuous positive airway pressure device in the postoperative period. Patients with a presumed diagnosis of OSA, based on screening tools such as the STOP-Bang questionnaire, with optimized comorbid conditions can be considered for ambulatory surgery if postoperative pain can be managed predominantly with nonopioid analgesic techniques. On the other hand, OSA patients with nonoptimized comorbid medical conditions may not be good candidates for ambulatory surgery. All obese patients should be assessed with the STOP-Bang questionnaire as part of the preoperative evaluation (see Box 43-2). A score greater than 3 indicates a high suspicion for OSA. As noted above, unless the patient's comorbid conditions are optimized and they are able to use CPAP after discharge and achieve postoperative pain relief without opiates, they are not candidates for outpatient surgery (Box 37-2).[84] Strict adherence to preoperative eligibility requirements and home care protocols is essential.[85] Consideration should be given to scheduling these patients early in the day to allow for prolonged observation of an additional 3 hours prior to discharge.[86] Patients with obstructive sleep apnea may be considered for discharge home if they are without (1) signs of moderate to severe OSA, (2) recurring PACU respiratory issues, that is, apnea, bradypnea, oxyhemoglobin desaturation, and (3) potent postoperative opioids for analgesia.[87]

Reactive Airway Disease. Before surgery is performed, the severity of reactive airway disease must be assessed, and optimal disease management should be achieved. A chest radiograph is indicated only if the patient is suspected of having an acute infiltrative process or if deterioration in the patient's physical condition has occurred. Likewise, arterial blood gases are indicated when signs and symptoms of chronic respiratory insufficiency are suspected. The patient may be best managed as an inpatient if indications for a chest radiograph or arterial blood gases are met. Consultation with the patient's internist may help in formulating therapeutic modalities and establishing baseline conditions for this patient. Patients receiving long-term medication therapy should continue to take their medications until the time of surgery. All parties involved must anticipate the possibility of admitting the patient to the hospital if the symptoms of the disease become exacerbated.

Sickle Cell Disease. The possibility of sickle cell hemoglobinopathy should be considered in every African American when obtaining the preoperative medical history. If individual or family history is suggestive of the disease, a Sickledex may be obtained in children 6 months of age and older to determine the presence of sickle-shaped red blood cells.[88] The patient with sickle cell disease is at risk for crisis development if acidosis, dehydration, or hypoxia occur. These patients often present for cholecystectomy because cholelithiasis is a well-recognized complication of chronic hemolysis.[89]

The select patient diagnosed with sickle cell disease is an acceptable outpatient candidate, but this patient is not without risk.[90] Sickling of the red blood cells may occur when the patient with sickle cell trait is subjected to hypoxia.[91] If the patient with sickle cell anemia is to be cared for in the ambulatory setting, certain criteria must be satisfied:

1. The patient should have no major organ disease as a result of the sickle cell disease.
2. The patient should not have had a sickle cell crisis for at least 1 year.
3. The patient should be compliant with the prescribed medical care.
4. On discharge, the patient should be within 15 minutes' travel time to a facility prepared to care for the patient.
5. The patient should receive close follow-up postoperative care.

The procedure should not be a prolonged surgery that is associated with blood loss. The patient should arrive earlier than normal so adequate intravenous hydration can be established. The patient's surgery should be scheduled early in the day to allow for extended postoperative monitoring before the patient is discharged from the ambulatory center.

BOX **37-2**

The Society for Ambulatory Anesthesia Consensus Statement on Preoperative Selection of Adult Patients with Obstructive Sleep Apnea Scheduled for Ambulatory Surgery

- Patients with known OSA whose comorbid conditions are optimized and are who are able to use CPAP after discharge are candidates for ambulatory surgery.
- Patients with known OSA whose comorbid conditions are not optimized are not candidates for ambulatory surgery and may benefit from further treatment.
- Patients with a presumptive diagnosis of OSA, optimized comorbid conditions, and postoperative pain that can be managed with nonopioid analgesics are candidates for ambulatory surgery.
- Patients with a presumptive diagnosis of OSA and nonoptimized comorbid conditions are not candidates for ambulatory surgery and may benefit from further treatment.

All obese patients should be assessed via the STOP-Bang method for presumptive OSA (see Box 43-2).

Comorbid conditions include hypertension, arrhythmias, heart failure, cerebrovascular disease, and metabolic syndrome.

Adapted from Joshi GP, et al. Society for Ambulatory Anesthesia consensus statement on preoperative selection of adult patients with obstructive sleep apnea scheduled for ambulatory surgery. *Anesth Analg*. 2012: Aug 10. [Epub ahead of print].
OSA, Obstructive sleep apnea; *CPAP*, continuous positive airway pressure.

Social Considerations

Factors other than physical condition must be weighed in considering a patient for outpatient surgery (Box 37-3). The lack

BOX 37-3

Social Considerations in Ambulatory Surgery

- Patient compliance
- Presence of responsible caregiver
- Discharge accommodations
- Access to assistance
- Financial and insurance considerations

of appropriate home conditions and care makes the outpatient option less desirable.

Unacceptable Patient Conditions for Ambulatory Surgery

Certain situations make ambulatory surgery impractical. Each patient must be considered individually for acceptability as an outpatient surgical candidate. Patients believed to be at increased risk for outpatient surgery and to be unacceptable candidates for such surgery are those with any of the following[32]:

- Unstable ASA physical status classification III or IV (e.g., cardiac, renal, endocrine, pulmonary, hepatic, or cancer diagnoses)
- Active substance/alcohol abuse
- Psychosocial difficulties, that is, responsible caregiver not available to observe the patient the evening of surgery (see Box 37-3)
- Poorly controlled seizures
- Morbid obesity with significant comorbid conditions, that is, angina, asthma, OSA
- Previously unevaluated and poorly managed moderate to severe OSA
- Ex-premature infants younger than 60 weeks postconceptual age requiring general anesthesia with endotracheal intubation
- Uncontrolled diabetes
- Current sepsis or infectious disease necessitating separate isolation facilities
- Anticipated postoperative pain not expected to be controlled with oral analgesics or local anesthesia techniques

PATIENT EVALUATION AND PREPARATION

To recognize anesthetic risks and determine the patient's suitability for the planned procedure, preoperative evaluation is mandatory for all patients preparing to undergo outpatient anesthesia and surgery. Challenges for the outpatient team will be organizing and accomplishing all the necessary tests and evaluations while causing the least inconvenience to the patient and maintaining an expedient surgical process. The preoperative interview elicits pertinent patient information and clarifies risk factors that may affect surgery and outcome. Additionally, by obtaining a thorough current and past medical history—including a personal and family anesthetic history—the staff may determine what further patient workup is required before surgery. A formalized preanesthesia assessment clinic is the most comprehensive and cost-effective process for preoperative evaluation and preparation.[92] Preoperative screening also allows the staff to communicate what will be expected of the patient in the perioperative phases.

Consultations, laboratory tests, and diagnostic procedures should be performed based on clinical findings rather than on a preestablished regimen of "standard" tests. Without any discoveries from the medical history and physical examination, the probability of observing a significant abnormality is negligible in diagnostic procedures, including electrocardiogram, chest radiograph, and laboratory tests. Abnormal test results obtained from routine testing potentially alter patient care only 0.22% to 0.56% of the time.[93] Routine preoperative laboratory screening is neither cost-effective nor predictive of postoperative complications.[94-96]

Patient Interview

Patient screening should take place sufficiently in advance of the scheduled surgery to allow time for necessary risk assessment, preoperative testing, specialty consultations, and adjustments in patient care. Proper timing of the patient assessment, particularly for the patient with complex medical conditions, minimizes surgical delays and cancellations. The high-risk patient should be evaluated at least 1 week before the scheduled procedure. With respect to client convenience, the otherwise healthy individual who does not have the opportunity to visit the clinic can be evaluated on the day of surgery. In this circumstance, there is a higher potential for surgical postponement or cancellation with last-minute discovery (e.g., inappropriate fasting, suspected difficult airway).

Patient Orientation

The preoperative interview allows the staff to convey what is expected of the patient and what the patient can expect perioperatively. Providing instructions to the patient, verbally and in writing, results in improved patient compliance. An information packet given to the patient at the interview is beneficial. It should detail specific instructions and concerns related to the procedure (Box 37-4).

Patients and family members should have the opportunity to become acquainted with the ambulatory surgery facilities and the anticipated sequence of events. This includes orientation to the laboratory and procedure areas, changing areas, waiting room, play areas, and the short-stay area, where the patient remains after surgery until discharge. This orientation is designed to reduce patient and family fear by providing relevant perioperative information (e.g., directions, anticipated schedule, instructions for physiologic preparation of the child, expected postoperative course, and discharge instructions), offering reassurance, and enhancing coping skills through familiarity. A variety of techniques may be incorporated to prepare the child for the operative procedure. Children can be oriented to equipment that is commonly used in the perioperative setting (e.g., anesthetic mask, intravenous therapy equipment, the anesthesia machine and circuit, blood pressure cuff, thermometer, and postoperative oxygen therapy devices). Children can be told when and where they will be reunited with their parents after surgery.

History and Physical

Results of a thorough medical history and physical examination performed by a member of the medical staff should be available in the patient's chart before the surgery is performed. A separate anesthesia history should be incorporated into a questionnaire specifically designed for preanesthetic evaluation; the anesthesia provider should review this history with the patient.

Such a review may be accomplished in a written format and would include a general review of the major systems, history of allergies, current medications, past and present medical problems, laboratory and diagnostic test results, and patient and family response to previous anesthetics. Prior anesthesia records should be examined for complications, response to anesthesia, and postoperative course. Patient evaluation should be conducted within 30 days of the scheduled surgery for medically stable patients and within 72 hours of the scheduled surgery for high-risk patients. The clinician should determine whether any changes might have occurred since the original history and physical examination were

BOX **37-4**

Preoperative Patient Instructions

Preoperative Instructions
- Tell the patient when and where laboratory tests, consultations, and diagnostic procedures will be completed.
- Clarify the appropriate time for the patient to be without food and drink.

Registration on the Day of Surgery
- Tell the patient the time to report for surgery, and mention that a wait can normally be expected.
- Describe the location of the parking areas.
- Tell the patient where to report for surgery.

Ambulatory Center Policies
- Inform the patient and family about expected conduct.
- Explain the ambulatory facility policies to the patient and family.
- Describe the family waiting area and services (e.g., dining areas).
- Review advance-directive information as required by law in some states.
- Review the patient's right-to-privacy policies.
- Outline the facility's cancellation policies: late arrival, nonadherence to fasting guidelines, inappropriate transportation home, lack of responsible person to help patient postoperatively, interim changes in patient's health status (e.g., upper respiratory tract infection [URTI]).

Personal Considerations
- Tell patient to wear comfortable, loose-fitting clothing that may be easily stored.
- Instruct patient to wear no jewelry or makeup (remove nail polish from at least one nail).
- Instruct patient to bring personal toilet items (e.g., comb, brush, toothbrush) as required.
- Caution patient to leave valuables at home.
- Tell caregiver to bring child's favorite toy, comforter, or pacifier, or light reading material for the older patient.

Postoperative Considerations
- Inform patient and family of the discharge time, including the time spent in the postanesthesia care unit and the customary length of stay until discharge.
- Instruct patient in the manner of discharge, the appropriate transportation arrangements, and the necessity for the presence of a responsible caregiver.
- Give the patient postoperative instructions: no driving, alcohol, or major decisions postoperatively for at least 24 to 48 hours after anesthesia (see Box 37-13 for additional information)
- Inform the patient where, how, and to whom complications should be reported. Supply telephone numbers.
- Indicate the possibility of hospital admission.

Considerations if the Patient's Physical Condition Changes
- Tell the patient to contact the surgeon.
- Tell the patient to contact the anesthetist.
- Tell the patient to call regarding cancellations or physical condition changes (e.g., URTI).

performed, and an update note should be made on the day of the procedure. A review of current vital signs, laboratory test results, diagnostic reports, and fasting status should be made.

Laboratory Evaluation

Each ambulatory center should have a consensus regarding the minimum testing requirement for surgery. These testing criteria depend on the proposed surgical procedure, the patient's medication history, and the patient's physical condition. Some states and regions have established minimum testing requirements. However, conducting a battery of preoperative laboratory tests without specific indications that they are needed has not been shown to reduce patient morbidity,[94] is not cost effective, and may even place the patient at increased risk.[95] Discriminating laboratory testing, based on findings from the history and physical examination and primarily designed to evaluate a patient's comorbidities and surgical risk, seems to be indicated. Normal laboratory test and diagnostic procedure results are deemed current if the tests are performed within 6 months of surgery if the patient's physical condition remains stable.[96,97] Exceptions include serum potassium level determinations, which should be obtained within 7 days of surgery for patients receiving diuretics or digitalis, and blood glucose level determinations, which should be obtained on the same day of surgery for patients with diabetes controlled by medication. Physical conditions and systemic illnesses in which preoperative laboratory testing is appropriate are listed in Box 37-5.

Pregnancy Testing

The medical facility should have established guidelines delineating when testing for pregnancy is appropriate and informed consent must be obtained. Anesthetic concerns include the effect of surgery and anesthesia on the developing fetus and the potential to trigger preterm labor. If the medical history and physical examination indicate that the patient may be pregnant, or if pregnancy might complicate the surgery, then pregnancy testing should be performed. It is important that the patient be educated as to the potential risks of exposing a fetus to an anesthetic. Whenever possible, especially in the adolescent population, a female staff member should question the patient in the absence of family members.[98] Suggested pregnancy testing guidelines are given in Table 37-1.

Diagnostic Procedures

Chest Radiography. Performing routine preoperative chest radiography is not recommended without specific indications for the necessity of the test from the history and physical examination. Clinical findings obtained from the history and physical are as efficient as a chest radiograph. A chest radiograph should be considered preoperatively if the patient (1) presents with new pulmonary signs or symptoms, (2) has end-stage renal disease, or (3) has decompensated heart failure, and only if the test might change patient management or outcome. Patients with these symptoms might not be suitable candidates for ambulatory surgery, except for brief, minor procedures, for example, ophthalmologic surgery.[96]

Electrocardiography. Few data support the routine performance of 12-lead electrocardiographic screening before elective surgery, because it has not been shown to be cost effective, is a poor predictor of perioperative complications, and is of limited value in detecting ischemia in asymptomatic individuals. It has been proposed that routinely acquiring a preoperative electrocardiogram is not indicated in the patient undergoing ambulatory surgery.[97]

BOX **37-5**

Indications for Laboratory Testing

Complete Blood Count
- Hematologic disorder
- Vascular procedure
- Chemotherapy
- Unknown sickle cell syndrome status

Hemoglobin/Hematocrit
- Age less than 6 months (less than 1 year if born premature)
- Hematologic malignancy
- Recent radiation or chemotherapy
- Renal disease
- Anticoagulant therapy
- Procedure with moderate-to-high blood loss potential
- Coexisting systemic disorders (e.g., cystic fibrosis, prematurity, severe malnutrition, renal failure, liver disease, congenital heart disease)

White Blood Cell Count
- Leukemia and lymphomas
- Recent radiation or chemotherapy
- Suspected infection that would lead to cancellation of surgery
- Aplastic anemia
- Hypersplenism
- Autoimmune collagen vascular disease

Blood Glucose Level
- Diabetes mellitus
- Current corticosteroid use
- History of hypoglycemia
- Adrenal disease
- Cystic fibrosis

Serum Chemistry
- Renal disease
- Adrenal or thyroid disease
- Chemotherapy
- Pituitary or hypothalamic disease
- Body fluid loss or shifts (e.g., dehydration, bowel prep)
- Central nervous system disease

Potassium
- Digoxin therapy
- Diuretic therapy

Creatinine and Blood Urea Nitrogen
- Cardiovascular disease (e.g., hypertension)
- Renal disease
- Adrenal disease
- Diabetes mellitus
- Diuretic therapy
- Digoxin therapy
- Body fluid loss or shifts (e.g., dehydration, bowel prep)
- Procedure requiring radiocontrast

Liver Function Tests
- Hepatic disease
- Exposure to hepatitis
- Therapy with hepatotoxic agents

Coagulation Studies
Prothrombin Time and Activated Partial Thromboplastin Time
- Leukemia
- Hepatic disease
- Bleeding disorder
- Anticoagulant therapy
- Severe malnutrition or malabsorption

Platelet Count and Bleeding Time
- Bleeding disorder
- Abnormal hemorrhage, purpura, easy bruisability

Urinalysis
- Not indicated as a routine screening test

Pregnancy
- Possibility of pregnancy

Serum Medication Levels
- Monitor for medications (e.g., theophylline, phenytoin, digoxin, carbamazepine) if patient exhibits signs of ineffective therapy, potential drug side effects, poor drug compliance, or has recently changed medication therapy without documentation of drug level

TABLE **37-1** Recommendations for Preoperative Pregnancy Testing

Population Type	Recommendations
Menstruating females under 13 years of age	No pregnancy test unless history is either indicative of sexual activity or is inconclusive.
Patients of childbearing age (over 13 years of age until 1 year after last reported menses)	Preoperative pregnancy test should be offered to all patients regardless of history, except in patients with a history of hysterectomy or bilateral salpingo-oophorectomy.
Testing on the day of surgery	Urine pregnancy test is sufficient.
Testing within 1 week of surgery	Serum pregnancy test is preferable.
All patients	Well-documented informed consent must be obtained from patients or their guardians.
All patients	A thorough and detailed history should be obtained from all patients.

From Steffey TS, Twersky RS. Is routine preoperative pregnancy testing necessary. In: Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders; 2009:28-32.

Fasting Status and Aspiration Risk

Part of the preoperative evaluation process identifies patients at risk for aspirating gastric contents into the lungs and developing aspiration pneumonitis. Factors associated with an increased risk of pulmonary aspiration of gastric contents are listed in Box 37-6.[15,98,99] Recent ingestion of food and liquid before surgery contributes to an increased risk of aspiration. Solid foods must be digested to a bolus diameter of less than 2 mm before the food can pass through the pylorus. This process normally takes several hours for solids, whereas liquids pass through the pylorus in 1 to 2 hours. Historically, patients have been required to fast for extended periods in an attempt to ensure an empty stomach. However, sustained fasting does not ensure that the stomach will be empty at the time of surgery. The traditional policy of fasting after midnight fails to address several variables that influence gastric emptying for surgery:

- The time of the scheduled surgery
- The time at which the patient retired for the night
- The variability of gastric emptying for solids and fluids across individuals

Several problems have been associated with prolonged fasting:

- Dehydration
- Hypoglycemia
- Hypovolemia
- Increased irritability
- Enhanced preoperative anxiety
- Reduced compliance with preoperative fasting orders
- Thirst and related discomfort (e.g., hunger, headache, unhappiness)

Data suggest that liquids (e.g., clear apple juice, clear broth, coffee, gelatin, Popsicles, pulp-free orange juice, water, and weak tea) may be given to healthy, unpremedicated patients up to 2 hours before surgery without placing them at increased risk for aspiration. There is no increase in gastric volume, nor is there a decrease in gastric pH, at the time of elective surgery. The studies that allowed patients to consume clear liquids until 2 to 3 hours before surgery demonstrated that although the patients appeared to be at no greater risk of aspirating gastric contents, the pH of the stomach contents remained less than 2.5. In light of these findings, recommended fasting guidelines for the otherwise healthy individual have been liberalized (Table 37-2).[100]

BOX 37-6

Risk Factors for Pulmonary Aspiration

- Age extremes (younger than 1 year or older than 70 years)
- Anxiety
- Ascites
- Collagen vascular disease (e.g., scleroderma)
- Depression
- Esophageal surgery
- Exogenous medications (opioids or premedications [e.g., barbiturates] and anticholinergics)
- Failed intubation or difficult airway history
- Gastroesophageal junction dysfunction (e.g., hiatal hernia)
- Mechanical obstruction (e.g., pyloric stenosis, duodenal ulcer)
- Metabolic disorders (e.g., hypothyroidism, chronic diabetes, hepatic failure, hyperglycemia, obesity, renal failure, and uremia)
- Neurologic sequelae (e.g., developmental delays, head injury, hypotonia, seizures)
- Pain
- Pregnancy
- Prematurity with respiratory problems
- Smoking
- Type and composition of gastric contents (e.g., solid foods, milk products)

Special Considerations

Daily Medications

Patients should continue to take their prescribed cardiopulmonary medications on the morning of the surgery. The medications may be taken with a minimum of water (up to 150 mL in adults and up to 75 mL in children) up to 1 hour before anesthesia.

Warfarin Sodium. An early decision regarding whether the administration of warfarin sodium should be (1) continued, (2) discontinued, or (3) interrupted and bridging anticoagulation be accomplished with subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin be initiated must be made in consultation with the surgeon and the patient's internist. The question of whether the disadvantages of stopping the administration of this medication before surgery outweigh any advantage must be addressed. If the decision to withhold warfarin is made, the drug should be discontinued approximately 5 days before the scheduled surgery, and an international normalized ratio (INR) should be determined on the day of surgery. With adequate hemostasis, warfarin should be resumed 12 hours to 24 hours after surgery.[101] A complete discussion on the perioperative management of anticoagulants can be found in Chapter 34.

Diabetes

Recommended care for the diabetic patient who is undergoing ambulatory surgery is a subject of debate and lacks clear guidelines. The patient with diabetes is at increased risk for cardiovascular, pulmonary, and neurologic events and should receive an early and thorough preoperative evaluation, including electrocardiography, history

TABLE 37-2 Preoperative Fasting Recommendations

Ingested Materials	Minimum Fasting Period* (hr)
Clear liquids†	2
Breast milk	4
Infant formula	6
Non-human milk‡	6
Light meal§	6
Heavy meal; fried or fatty food	8

From American Society of Anesthesiologists Committee. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2011;114(3):495-511. These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying.

*The fasting periods noted above apply to all ages.

†Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

‡Because non-human milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

§A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

and physical examination, and indicated laboratory analysis. The patient with insulin-dependent diabetes whose diabetes is not well controlled and whose serum glucose levels are prone to wide fluctuations may be best treated in the inpatient setting depending upon the type of surgery. Considerations for care of the patient with diabetes who is undergoing ambulatory surgery include the following [102]:

- Schedule the patient's surgery for early in the day.
- Obtain baseline information regarding the patient's glycemic control.
  - Previous 3- to 4-month trend for blood glucose and glycosylated hemoglobin A1c (HbA1c), if available for review, to assess glycemic control
  - Type (e.g., oral antidiabetics and insulin), dose, and schedule of antidiabetic therapy
  - Hypoglycemic events: occurrence, frequency, manifestations, and blood glucose level when symptoms occur
  - Hospitalization history related to glycemic control issues
- Instruct the patient to have nothing to eat or drink after midnight the night before surgery if the procedure is scheduled for early in the day.
- Monitor the patient's blood or serum glucose levels on arrival to the ambulatory center by use of a capillary test strip or laboratory analysis.
- Prevent hypoglycemia while maintaining blood glucose levels at less than 180 mg/dL.
- Manage preoperative oral antidiabetic and noninsulin injectable therapy.
  - Continue usual routine prior to day of surgery
  - Withhold therapy on the day of surgery
- Manage preoperative insulin therapy (Table 37-3).
- Return the patient to preoperative activities of daily living (e.g., baseline activity status, nutrition habits) as soon as possible.
- Make the patient aware that admission to the hospital is likely if persistent nausea and vomiting prevent resumption of normal dietary intake.

Heart Murmur

The surgical patient with a heart murmur requires further workup if the condition was previously undetected. Heart murmurs are categorized as innocent or pathologic. Pathologic murmurs may be due to complex congenital malformations or heart disease and have accompanying physical dysfunction, whereas with innocent murmurs, the patient may be completely asymptomatic. Whether the murmur is benign, functional, or caused by organic heart disease, cardiologic assessment should be obtained before the induction of anesthesia.[103]

Rhinorrhea

From 20% to 30% of all children display symptoms of rhinorrhea a good portion of the year. Children younger than 2 years of age are prone to 5 to 10 viral respiratory infections annually.[104] For the child undergoing ambulatory surgery, individual patient evaluation is required for a runny nose. The history and physical examination are beneficial in determining the cause. The differential diagnosis of rhinorrhea should include the following:

- Allergic (seasonal) rhinitis
- Bacterial infection (early stages)
- Flu syndrome
- URTI
- Vasomotor rhinitis
- Nothing found

The clinician obtaining the patient history should try to ascertain the allergic or acute nature of the runny nose and determine whether it is normal for the child or an illness has recently developed and worsened. Recently acquired (within 12 to 24 hours of surgery) rhinorrhea or chronic rhinorrhea in the otherwise fit child is not a contraindication to surgery. The differentiation between a noninfectious and an infectious runny nose might influence the decision of whether the procedure should be delayed (Box 37-7). Surgery might be delayed for only 2 weeks in the child with localized infectious rhinorrhea.[105,106]

Considerations for Postponing Surgery

Lack of Drug Compliance

The patient with uncontrolled hypertension or diabetes who has wide swings in blood pressure or blood glucose levels may not be suitable for outpatient surgery; such conditions should be optimally managed before outpatient surgery and anesthesia are performed.

TABLE 37-3 Patient Instructions for Preoperative Insulin and Noninsulin Administration

Insulin Regimen	Day Before Surgery	Day of Surgery	Comments
Insulin pump	No change	No change	Use "sick day" or "sleep" basal rates
Long-acting, peakless insulins	No change	75%-100% of morning dose	Reduce nighttime dose if history of nocturnal or morning hypoglycemia; on the day of surgery, the morning dose of basal insulin may be administered on arrival to the ambulatory surgery facility
Intermediate-acting insulins	No change in the daytime dose; 75% of dose if taken in the evening	50%-75% of morning	See comments for long-acting insulins
Fixed combination insulins	No change	50%-75% of morning dose of intermediate-acting component	Lispro-protamine only available in combination; therefore use NPH instead, on day of surgery
Short- and rapid-acting insulin	No change	Hold the dose	
Noninsulin injectables	No change	Hold the dose

Scientific principles and clinical implications of perioperative glucose regulation and control. *Anesth Analg.* 2010;110(2):478-497.

Fasting Status

For safety reasons, the patient not adhering to the fasting guidelines should not undergo surgery, and the rationale of not eating before surgery should be reinforced.

Suspicion of Pregnancy

If the patient responds that she may be pregnant or if clinical signs are indicative of pregnancy, surgery should be delayed until determination of whether the patient is pregnant can be made. Decisions about whether surgery should be performed and what type of anesthesia should be used can be based on pregnancy test results.

Upper Respiratory Tract Infection

Acute respiratory infections are one of the leading medical causes for surgery cancellation in children. In patients with an acute infection, differentiating between a bacterial infection as causative of the upper respiratory tract infection (URI) or lower respiratory tract infection (LRI) and other causes—such as uncomplicated viral infection (afebrile, clear secretions) or allergic conditions—is important. Differentiating between a noninfectious process and an infectious process is paramount in the decision regarding whether the procedure should be performed. This differentiation may be difficult to make early in the course of the disease. Symptoms of URI include the following:

- Elevated white blood cell count (greater than 12,000 with a left shift)
- Mucopurulent nasal secretions
- Inflamed and reddened mucosa (nasopharyngeal and oropharyngeal) (with allergic rhinitis, e.g., nasal mucosa is ashen and boggy)
- Positive chest findings (e.g., congestion, rales)
- Temperature of 37.5° C to 37° C (greater than 37° C usually associated with lower respiratory tract involvement)
- Tonsillitis
- Viral ulcers in the oropharynx

Other accompanying symptoms may include conjunctivitis, coughing (nonproductive), fatigue, itching, laryngitis, malaise, myalgia, sneezing, and sore throat. Laboratory and diagnostic testing in children with suspected URI includes nasal or throat cultures if signs of an infectious process are observed. A chest radiograph is not warranted, especially if chest sounds are clear. Similarly, the value of obtaining a white blood cell count has been challenged because the results may be normal and typically do not influence whether to proceed with the surgery.[107]

BOX 37-7

Differential Diagnosis of Rhinorrhea

Noninfectious Runny Nose

- Allergic rhinitis
  - Seasonal
  - Perennial
- Vasomotor rhinitis
  - Emotional (crying)
  - Temperature

Infectious Runny Nose

- Viral infections
  - Nasopharyngitis (common cold)
  - Contagious disease (e.g., chickenpox, measles)
- Acute bacterial infections
  - Streptococcal tonsillitis
  - Meningitis

Anesthetizing the patient who has a URI or LRI has been shown to increase the incidence of respiratory-associated complications two- to seven-fold. Bronchial reactivity may persist for 6 to 8 weeks after a viral LRI .The anesthetized patient with a respiratory tract infection is more prone to experience breath holding, bronchospasm, coughing, hypoxemia, increased secretions, laryngospasm, pneumonia, atelectasis, croup, and stridor. Risk factors for the development of perioperative adverse respiratory events include endotracheal intubation (less than 5 years of age), history of prematurity, history of reactive airway disease, exposure to secondhand smoke, surgery involving the airway, the presence of copious secretions, and nasal congestion.

A minimum of 4 hours of postoperative observation is appropriate before the patient is considered for discharge from the ambulatory setting. Each case should be reviewed individually. The decision to operate frequently depends on the urgency of the surgery, the duration and complexity of the surgery, and the need for instrumentation of the airway. Children with uncomplicated respiratory infection may undergo elective procedures without significantly increasing anesthesia complications.[106-108] Further discussion on the management of children with respiratory infection is in Chapter 48. Guidelines for deciding whether surgery should be performed in children with respiratory infections are given in Box 48-1.

Each case has to be reviewed individually and consideration given to the urgency of the surgery, the duration and complexity of the surgery, the number of times the procedure has been canceled, and the wishes of the family and patient.

PREMEDICATION

Premedicating the ambulatory surgery patient with sedative agents is done on an individual basis and with minimally effective doses. The concern about giving anxiolytic and sedative medications is related to their potential to prolong the patient's stay. Prophylactic drugs for postoperative nausea and vomiting (PONV) are commonly used in patients at risk. Nonsteroidal antiinflammatory drugs (NSAIDs) given orally, when indicated for analgesia, should be considered preoperatively.[17] Preemptive analgesia may reduce postoperative pain by preventing surgically induced peripheral and central sensitization.[109] Lower postoperative pain scores and less opioid use have been seen when NSAIDs were given prior to surgery.[110] However, the use of premedication should not become routine; rather, the decision to administer these agents should be based on individual need and desired benefit.[111] Common indications for preoperative medication are as follows:

- To decrease patient anxiety and fear
- To facilitate smooth induction and emergence from anesthesia
- To supplement anesthesia and reduce the need for general anesthetic agents
- To reduce the volume and acidity of gastric contents
- Prophylaxis for postoperative nausea and vomiting
- To provide a more pleasant stay in the PACU

Pulmonary Aspiration Prophylaxis

Patients at higher risk for aspirating gastric contents should be given medications before surgery to raise gastric pH and lower gastric volume, with the hope of minimizing their risk for pulmonary aspiration. Pulmonary aspiration prophylaxis in the patient not at risk is not recommended.[100]

Antacids

The value of oral antacids lies in their ability to rapidly reduce gastric acidity; they are effective in raising pH in 15 to 20 minutes.[112]

This characteristic is useful in emergency situations, but it is of limited application in the ambulatory setting. Although oral antacids raise gastric pH, they have the disadvantage of increasing gastric volume. Clear, nonparticulate oral antacids (e.g., two tablets of Alka-Seltzer Gold in 30 mL of water; 30 mL [0.4 mL/kg pediatric dose] of 0.3 M sodium citrate [Bicitra]) are preferred over particulate antacids, such as Maalox or Mylanta, because particulate antacids may produce pulmonary injury if aspirated.[113]

Gastrokinetics

Reducing the volume of gastric fluid with the gastrokinetic agent metoclopramide (Reglan) helps minimize the risk of aspiration. Metoclopramide has been demonstrated to decrease gastric fluid volume by reducing gastric emptying time without increasing pH in adults and in children. Metoclopramide may also reduce the risk of pulmonary aspiration by increasing lower esophageal sphincter tone. It appears to exert a central antiemetic effect via dopamine receptor blockade of the chemoreceptor trigger zone.[114] The combination of metoclopramide with a histamine$_2$ (H_2)-receptor antagonist has been shown to be effective in raising gastric volume pH and decreasing gastric volume content.[115]

The intramuscular dose is 10 mg for adults (0.1 mg/kg for children) given at least 45 minutes before surgery. The intravenous dose is 10 to 20 mg (0.15 to 0.2 mg/kg) given over the course of 3 to 5 minutes at least 30 minutes to 45 minutes before surgery. These regimens allow sufficient time for the desired results to be achieved. The oral dose, 10 mg for adults (0.1 mg/kg for children), achieves peak plasma concentrations 40 to 120 minutes after administration.[32]

H_2-Receptor Antagonists

Selective and competitive H_2-receptor antagonists, such as cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid), block hydrogen ion release by gastric parietal cells. These drugs do not alter the pH of gastric fluid already present in the stomach. All are available over the counter. These medications may be administered the night before surgery, on the day of surgery, or both, to reduce gastric acidity. Famotidine and ranitidine have longer durations of action, are more potent, and exhibit a lower potential for side effects than cimetidine.[116]

Cimetidine. In one study, an intravenous adult cimetidine dose of 300 mg helped reduce the risk of pulmonary aspiration. The oral dose is 300 mg (3 to 4 mg/kg) for adults and 7.5 mg/kg for children, given from 1.5 to 3 hours before surgery. This is effective in reducing the risk of chemical pneumonitis if pulmonary aspiration occurs.[116]

Famotidine. The intravenous dose of famotidine is 20 mg for adults, given 15 to 30 minutes before surgery; this is effective in increasing gastric pH. When given electively, oral famotidine (40 mg) is given the night before surgery and on arising the morning of surgery. When compared with ranitidine, famotidine was slower in raising the gastric pH to safe levels.[117]

Ranitidine. The intravenous dose of ranitidine is 50 to 100 mg or 1 to 2.5 mg/kg. This drug decreases the risk associated with pulmonary aspiration. The oral dose of 150 to 300 mg for adults (2.5 mg/kg for children), given 1 to 3 hours before surgery, increases gastric pH, whereas gastric fluid volume may not be less than 25 mL. Comparable results were noted when ranitidine (150 mg) was given at bedtime and again on arising on the morning of surgery or when it was given orally 1 to 2 hours before surgery.[116]

Gastric Proton-Pump Inhibitors

Omeprazole. Omeprazole (Prilosec) causes dose-dependent intracellular inhibition of gastric acid secretion in humans without affecting gastric volume. Omeprazole has a longer duration of action than the H_2-receptor antagonist agents in suppressing gastric acid secretion and appears to cause no significant side effects.

The intravenous dose of omeprazole is 40 mg, administered after the induction of anesthesia. This is as effective as ranitidine in raising gastric pH above 2.5.

The oral dose is 80 mg, given the evening before surgery. This has increased mean gastric pH to 4.56, compared with the pH of 2.05 that was achieved with the administration of a placebo. Orally administered omeprazole 40 mg was not found to be as effective as either famotidine 40 mg or ranitidine 300 mg in protecting against pulmonary aspiration in parturients.[116]

Lansoprazole, Rabeprazole, and Esomeprazole. Orally administered lansoprazole (Prevacid), 30 mg, rabeprazole (Aciphex) 20 mg, or esomeprazole (Nexium) given the day prior to surgery and on the morning of surgery were not as effective in raising pH and lowering gastric volume as a single morning-of-surgery dose of ranitidine 150 mg. Intravenous preparations of esomeprazole 20 and 40 mg and lansoprazole 30 mg are available.[118]

Pantoprazole. Pantoprazole (Protonix) is marketed as an intravenous solution, and also as tablets, which may prove useful for perioperative use. Intravenously administered pantoprazole 40 mg was comparable with ranitidine 50 mg in increasing pH and reducing gastric fluid volume.[119]

ANESTHETIC CONSIDERATIONS

Anesthetic techniques suitable for outpatient surgery include general anesthesia, regional anesthesia, and monitored anesthesia care. The goals for outpatient anesthesia, regardless of the type administered, are listed in Box 37-8, and factors influencing the choice of anesthesia are shown in Box 37-9. The ideal anesthetic agent for ambulatory anesthesia—whether it is administered inhalationally, intravenously, locally, or regionally—is one with the appropriate pharmacokinetic traits (i.e., rapid onset and offset, short duration, inert metabolites, and insignificant side effects).

BOX 37-8

Goals of Outpatient Anesthesia

- Minimize the physiologic changes associated with anesthesia.
- Provide a fast, smooth onset of anesthetic action.
- Promote intraoperative amnesia and analgesia.
- Afford suitable operating circumstances.
- Minimize perioperative anesthetic side effects.
- Allow rapid offset of anesthetic influence while maintaining patient comfort.

BOX 37-9

Considerations for Choice of Anesthetic

- Surgical requirements
- Skill of anesthesia provider
- Patient choice
- Patient age
- American Society of Anesthesiologists physical status classification
- Level of care available once patient is discharged from outpatient facility
- Risk of postoperative nausea and vomiting
- Postoperative analgesia requirements

General Anesthesia

General anesthesia is the most widely used anesthetic technique for ambulatory surgery. General anesthesia should be achieved with the less-soluble inhalation agents or with short-acting intravenous agents that have the capability of reversal if required. A combination of potent rapid-onset and rapid-offset inhalation agents (e.g., desflurane, sevoflurane), along with intravenous agents (e.g., propofol, intravenous opioids, short-acting muscle relaxants, NSAIDs, and dexmedetomidine), comprise general anesthesia in contemporary practice. The popularity of general anesthesia in the ambulatory setting is related to its acceptance by the patient, the anesthesia provider, and the surgeon, and to the consistent pace that can be maintained with regard to achieving a satisfactory state of anesthesia.

Depth-of-Anesthesia Monitoring

Recent advances in depth-of-anesthesia monitoring technology have made their mark in ambulatory anesthesia. The data indicating that the routine use of bispectral index monitoring (BIS) during outpatient anesthesia improves outcomes is mixed. Some of the purported advantages of BIS monitoring in the outpatient setting include reducing the amount of anesthetic agent required, faster emergence from anesthesia, and a reduction in phase II vomiting.[120-125]

Airway Management

Issues regarding the use of general anesthesia with a facemask, a laryngeal mask airway (LMA), or an endotracheal tube in patients undergoing outpatient surgery are the same as those in patients undergoing inpatient surgery. The indications for intubating the trachea depend on the constraints of the surgery and the individual patient concerns (e.g., risk of regurgitation and aspiration, hypoventilation, access to the airway, use of muscle relaxants, and airway obstruction).

Drawbacks to endotracheal intubation specific to the outpatient setting must be considered. Irritation and trauma to the upper airway and trachea are a concern, especially in children. The development of postextubation croup is rare (0.1%), but the potential for its occurrence must be considered in the plan for discharging the patient.[126] Careful attention paid to minimizing intubating trauma, ensuring that an air leak is present at less than 40 cm H_2O, and avoiding large-diameter endotracheal tubes helps reduce the incidence of postextubation croup in children.[127]

The LMA has proven to be a popular and cost-effective airway management tool in the ambulatory setting. Patients tolerate LMAs at a lower dose of anesthetic than that needed for an endotracheal tube. Neuromuscular blocking agents are rarely necessary for airway management, and the incidence of airway morbidity such as coughing and sore throat is lower with LMAs than with endotracheal tubes. These advantages may facilitate faster recovery and earlier discharge of patients. Limitations include incomplete protection against aspiration of gastric contents and inadequate delivery of positive pressure ventilation.[128,129]

Intravenous Fluid Therapy

Debate exists over whether all patients undergoing brief (less than 15 minutes) anesthesia require intravenous cannulation for uncomplicated surgery in which rapid recovery is expected. If an intravenous catheter is not inserted in children undergoing general anesthesia, the equipment and personnel trained in intravenous line placement should be immediately available in case they are needed.

The optimum amount of perioperative fluid therapy remains unclear. The three common total fluid regimens include restrictive, liberal, and hemodynamic goal directed. Each technique has its proponents.[130-133] Benefits of liberal fluid therapy include less thirst postoperatively, a lower incidence of sore throat; and a lower incidence of dizziness, drowsiness, and faintness on standing compared with patients for whom fluids were withheld perioperatively. Less postoperative nausea and vomiting also has been reported.[134] Fluid restriction has been used as part of fast-track surgery to reduce the length of stay compared to application of liberal fluids.[133] Authors of a recent large-scale meta-analysis noted that outcomes favored a goal-directed therapy rather than liberal fluid therapy without hemodynamic goals. Whether goal-directed therapy is superior to a restrictive fluid strategy remains uncertain.[130]

Intravenous cannulation should be used, and perioperative fluid should be administered in the following situations:

1. *Procedures lasting longer than 30 minutes*. Longer surgical times increase the risk of hypothermia, increase the amount of anesthetics delivered to the patient, and result in a delay of resumption of normal diet.
2. *Procedures with an increased incidence of postoperative nausea and vomiting*. Intravenous access permits the administration of antiemetic medications and allows hydration.
3. *Procedures associated with postoperative discomfort*. If anticipated postoperative pain is unlikely to be controlled by nonintravenous means, an avenue should be established for the administration of intravenous analgesics.
4. *Prolonged fasting before surgery*. If the child has been fasting for more than 15 hours, intravenous hydration is desirable for the maintenance of fluid and glucose homeostasis.
5. *Procedures associated with intraoperative and postoperative bleeding*.
6. *Procedures associated with the use of perioperative antibiotics or patients who require the perioperative administration of antibiotics*.

Regional Anesthesia

The use of regional anesthesia in the ambulatory setting is well established. Regional anesthesia improves pain scores, decreases opiate use, and lowers the incidence of postoperative nausea and vomiting. Thus more patients can be discharged home in less time with high satisfaction.[135]

Local wound infiltration, peripheral nerve block, intravenous regional anesthesia, ophthalmic blocks (e.g., retrobulbar or periorbital), brachial plexus anesthesia, spinal anesthesia, and epidural anesthesia are all successfully used for outpatient surgery. The proper application of outpatient regional anesthesia requires knowledge of the anticipated surgical procedure, anesthesia requirements, length of procedure, and appropriate patient selection. The shortest-acting agent capable of providing satisfactory central neuraxial blockade should be used in the ambulatory setting if unreasonable delays in discharge are to be avoided. Peripheral nerve blockade with longer-acting local anesthetics can provide up to 24 hours of analgesia postoperatively. Although there are several advantages to regional techniques, there are potential disadvantages including whether the performance of these blocks requires more time than general anesthesia and the possibility they may reduce the overall efficiency of an outpatient unit. Regional techniques are not as reliable as general anesthesia and may further delay surgery. There is also the issue of postoperative complications including postspinal headache, transient neurologic symptoms (TNS) after spinal anesthesia, and urinary retention.[136] The advantages and disadvantages of the use of outpatient regional anesthesia are listed in Box 37-10.

Recommendations for the safe and effective use of regional anesthesia in outpatient surgery are noted in Box 37-11. Specific regional techniques are discussed in detail in Chapters 44 and 45.

POSTOPERATIVE CONSIDERATIONS

After the surgical procedure, care is provided in either the PACU (phase I) or the short-stay unit (phase II) until the patient is ready for discharge from the ambulatory setting. The location and the level of nursing care required vary according to the patient undergoing the procedure, the type of anesthesia used, and the surgical procedure. Properly addressing potential or realized complications in the most efficient manner possible expedites patient management and promotes a timely discharge process. Complications that might delay the patient's departure from the ambulatory facility include nausea, vomiting, and pain. Each outpatient facility has specific criteria for discharge that should be met before the patient is released from the facility.[137] A thorough discussion of the current practices in postanesthesia recovery is provided in Chapter 50.

BOX 37-10
Advantages and Disadvantages of Outpatient Regional Anesthesia

Advantages
- Recovery times are shorter than those of general anesthesia.
- Unanticipated admission to the hospital is reduced.
- Phase I recovery bypass (fast-track) eligibility is high.
- Provides excellent immediate postoperative pain relief.
- Results in better postoperative pain scores than general anesthesia.
- Common side effects associated with general anesthesia (e.g., airway trauma, dizziness, "hangover," myalgia, nausea and vomiting, pharyngitis) are minimized.
- The patient who fears general anesthesia or "loss of control" has a satisfactory alternative.

Disadvantages
- Cooperation of the patient and the surgeon is required.
- Regional anesthesia may require more time to provide than general anesthesia. In an ambulatory setting, where surgeries and patient stays tend to be of short duration, regional anesthesia may not be as well received. If a team approach is used, patient stays may be minimized by early placement of the proposed regional anesthetic if appropriate.
- Inherent problems associated with regional anesthesia, regardless of inpatient or outpatient status, include the sympathetic block associated with spinal and epidural anesthesia, which may complicate the discharge course if residual block results in orthostatic hypotension.

Postoperative Complications and Management

With today's standard of anesthesia care, major morbidity and mortality after ambulatory surgery are extremely rare; however, a variety of adverse postoperative events may lead to unplanned hospital admission (Box 37-12).[138] Postoperative nausea and vomiting and pain are the most common reasons for hospitalization after ambulatory surgery. Certain procedures (e.g., laparoscopic sterilization; laparoscopic inguinal herniorrhaphy; head and neck; ear, nose, and throat; urologic; orthopedic) are also associated with a higher incidence of unplanned hospital admissions. The hospital admission rate after ambulatory surgery is less than 2%.[139]

Nausea and Vomiting

Persistent nausea and vomiting are responsible for delays in discharge and for increases in patient cost and are a common factor in unanticipated hospital admission after outpatient surgery. The reported incidence of PONV is approximately 30% on average and as high as 80% in high-risk patients. Postdischarge nausea and vomiting (PDNV) has been reported to occur in up to 50% of patients. Up to 35% of these patients did not experience PONV.[140,141] Many anesthetic and nonanesthetic-related factors affect the susceptibility of patients to postoperative nausea and emesis.[142] Nonanesthetic-related factors contributing to increased episodes of emesis include the following[143-151]:

- *Age*. There is a higher incidence of postoperative vomiting in children, particularly in those between 3 and 12 years of age. A gradual decrease in the incidence of postoperative nausea and vomiting has been shown after 50 years of age.

BOX 37-11
Recommendations for the Use of Regional Anesthesia in Outpatient Surgery

- Local anesthesia is ideal and should be used whenever possible as the sole anesthetic regimen, or be included for postoperative analgesia after any technique.
- Peripheral nerve blockade is highly effective in providing postoperative analgesia and rapid discharge when used for upper or lower extremity surgical procedures. It is also effective for truncal operations such as hernia repair. The use of continuous catheter techniques provides maximum benefit.
- Performance of a block in a separate induction room may reduce the additional time otherwise required for regional anesthesia.
- If neuraxial blockade is chosen, spinal anesthesia has the advantages of rapid onset and high reliability. Unfortunately, there appears to be a persistent risk of transient neurologic symptoms (TNS) with the current agents. Low-dose bupivacaine (less than 6 mg) provides a low risk of TNS with the potential of a short discharge time, but with a high degree of variability and a limitation of adequate surgical anesthesia to the lower extremity and rectal area.
- Performance of an epidural anesthetic provides a more rapid discharge than with most of the current spinal techniques, and it provides the added advantage of flexibility in duration and extent of blockade if a catheter is placed.
- Excessive sedation must be avoided if the advantage of a high degree of alertness and rapid discharge is to be maintained.
- Discharge times after spinal anesthesia also require careful selection of drug and dose. The addition of epinephrine to subarachnoid local anesthetics increases the potential for urinary retention and for prolonged discharge times. The use of fentanyl may be a better choice for intensifying local anesthetic effect without prolonging discharge due to urinary retention.
- Urinary retention after a short-acting spinal anesthetic in low-risk patients is not any more frequent than with general anesthesia, and these patients can be discharged without mandatory voiding.

Adapted from Mulroy MF, Strodtbeck W. Is regional anesthesia appropriate for outpatient surgery. In: Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders; 2009:359-363.

- *Apprehension*. Preoperative anxiety may increase the likelihood of vomiting. Proposed mechanisms by which apprehension contributes to vomiting include swallowed air, with resultant abdominal distention, increased gastric volume, and increased catecholamine levels.
- *Gastroparesis*. Several pathologic conditions are associated with gastroparesis, such as ileus, bowel obstruction, diabetes mellitus, muscular dystrophies, collagen vascular disorders, uremia, raised intracranial pressure, and pregnancy. The accompanying delayed gastric emptying means a greater gastric content and thus a greater chance of vomiting.
- *Gender*. Emesis occurs in adult females more than in males. After 70 years of age, gender is no longer a distinction for developing postoperative nausea and vomiting.
- *Individual predisposition*. Patients relating a previous history of nausea and vomiting after anesthesia or a history of motion sickness are at increased risk for nausea and vomiting after subsequent anesthetics.
- *Food ingestion*. Recent ingestion of food before undergoing anesthesia increases the probability of vomiting, as does vomiting during the induction of anesthesia.
- *Nonsmoking status*. Cigarette smokers seem to experience less postoperative nausea and vomiting than nonsmokers.
- *Type of surgery*. Prolonged surgical times correspond to an increased risk of vomiting. Certain surgical procedures—for example, arthroscopy, laparoscopy, lithotripsy, intestinal operations, ovum retrieval, orchiopexy, otoplasty, retinal detachment, tonsillectomy with or without adenoidectomy, and strabismus—are associated with an increased incidence of postoperative vomiting.

Anesthetic-related factors contributing to emesis include the following:

- *Premedications*. Preoperatively administered opioid analgesics, primarily the longer-lasting agents, increase postoperative vomiting due to opiate-induced stimulation of the central chemoreceptor trigger zone.

BOX 37-12

Risk Factors for Unanticipated Hospital Admission

Surgical
- Pain
- Bleeding
- Extensive surgery
- Surgical complications
- Abdominal surgery
- ENT and urology surgery

Anesthesia
- Nausea and vomiting
- Somnolence
- Aspiration

Social
- Discharge without escort

Medical
- Medical complications related to DM, IHD, and sleep apnea
- Medication error

From Shnaider I, Chung F. Outcomes in day surgery. *Curr Opin Anaesthesiol*. 2006;19:622-629.
DM, Diabetes mellitus; *ENT*, otorhinolaryngology; *IHD*, ischemic heart disease.

- *Induction of anesthesia*. Inhalation induction may result in gastric distention from positive pressure ventilation via the anesthesia facemask and is known to increase postoperative vomiting. For intravenous induction of anesthesia, propofol is mildly antiemetic and etomidate and ketamine are emetic.
- *Maintenance of anesthesia*. Several variables are known to increase the incidence of postoperative vomiting:
  - Longer anesthesia times
  - General anesthesia when compared with regional or local anesthetic techniques
  - Volatile inhalation anesthetics when compared with intravenous hypnotic agents
  - Intraoperative opioid administration
  - Nitrous oxide

Postanesthetic-related factors contributing to emesis include the following:

- *Ambulation*. More commonly seen in phase II recovery when the patient is mobilized in preparation for discharge, especially in patients receiving opioid analgesics.
- *Postural hypotension*. Dizziness, syncope, and nausea may be a problem if there is a significant reduction in blood pressure on standing.
- *Uncontrolled pain*. Etiologic factors may include increased catecholamine concentrations, increased level of consciousness, or peripheral sensitization after direct tissue injury with the resultant release of endogenous nociceptor activators.
- *Postoperatively administered opioid analgesics*.
- *Oral intake*. Fluids given routinely to patients before discharge from phase II recovery results in a greater incidence of vomiting or prolonged phase II stay than do fluids given to patients only if they are requested.[152]
- *Lower inspired oxygen concentrations*. Higher concentrations (50% to 80%) of intraoperative and postoperative supplemental oxygen therapy have been suggested to reduce the incidence of PONV, although the results from studies have been mixed.[153-157]
- *Reversal agents*. Opioid and benzodiazepine receptor antagonists and neuromuscular reversal agents may increase nausea and vomiting. In regard to neuromuscular reversal, it appears that only higher doses of neostigmine (greater than 2.5 mg) may demonstrate emetic tendencies.[158]

Suggested management of nausea and vomiting involves preoperatively administered pharmacologic interventions.[159-162] However, evaluating the efficacy of these agents is difficult because the cause of nausea and vomiting is multifactorial. Oral fluids should be withheld, and intravenous fluid hydration can be maintained with normal saline or lactated Ringer's solution until the emesis is controlled. Patients at high risk for postoperative nausea and vomiting will benefit from prophylactic antiemetic therapy. Antiemetic drugs should be administered singularly or in combination, based on the number of identified risk factors. Patients at high risk will benefit from multimodal drug therapy. Combination therapy permits targeting multiple receptors, as well as administering agents with prolonged effects to complement medications with rapid-onset properties. When postoperative nausea and vomiting does occur in the postoperative phase, pharmacologic treatment should consist of medications from a pharmacologic class different than from the prophylaxis antiemetic administered. Antiemetic management strategies based on patient risk are noted in Figure 37-1.

Acupressure/Acupuncture. P6 acupoint stimulation can be effective in preventing or minimizing postoperative nausea and vomiting. The mechanism of action is uncertain, but endorphin release or serotonin changes have been suggested as possible causes.[147]

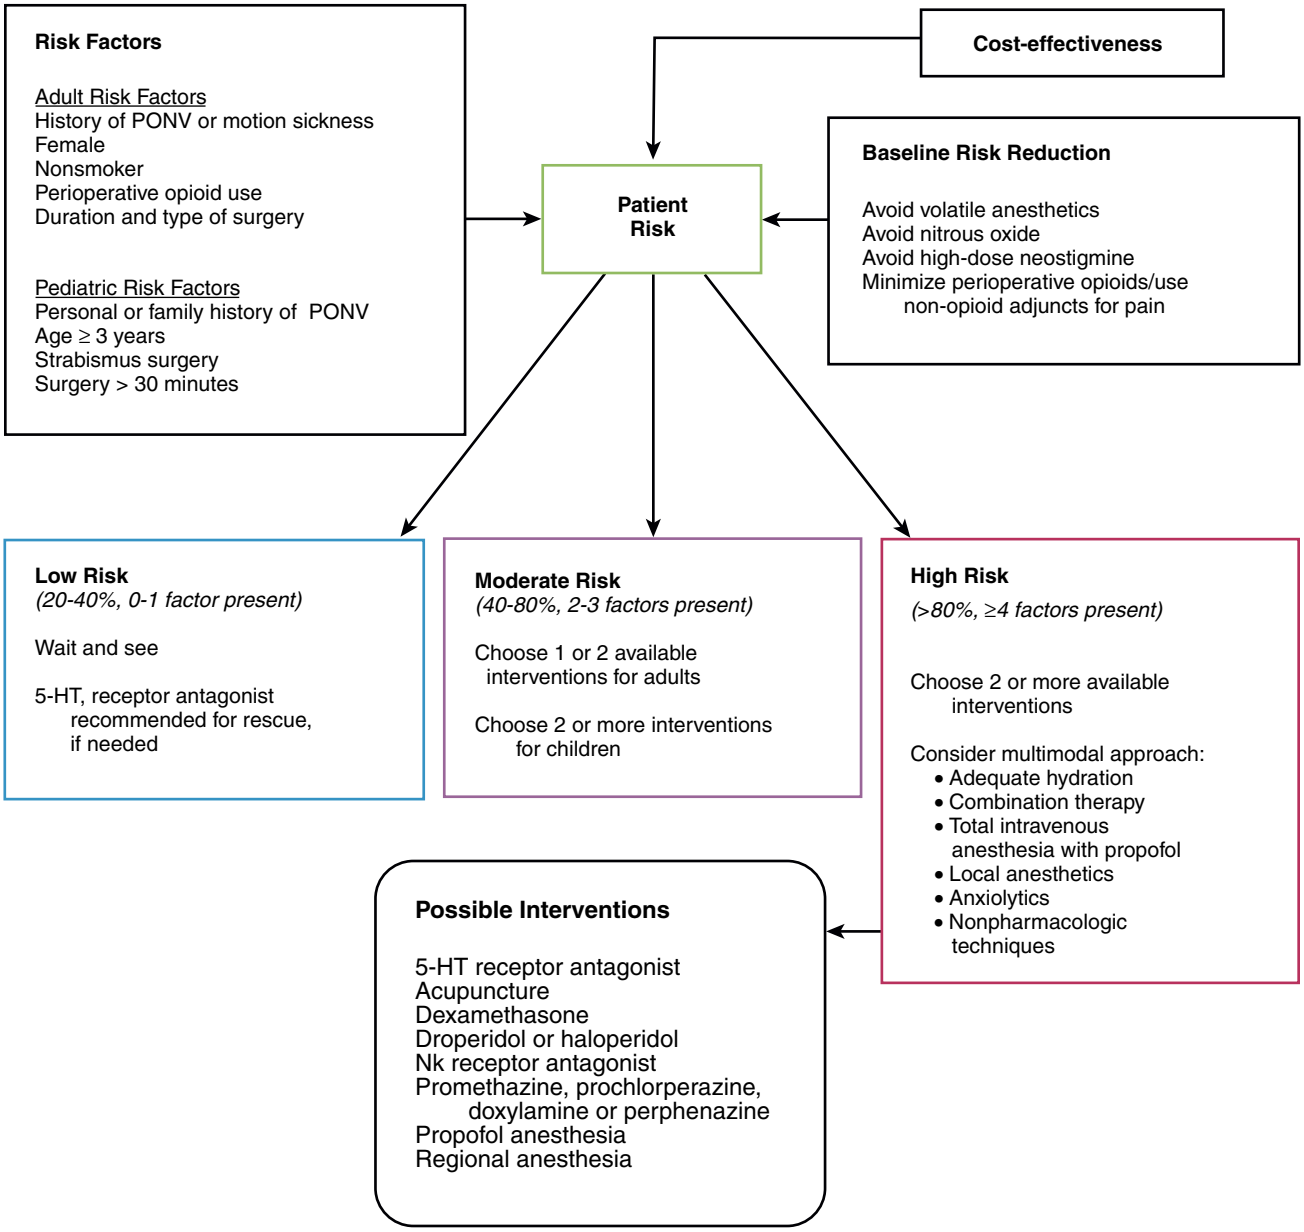

FIGURE **37-1** Antiemetic management strategies based on patient risk. (From Le TP, Gan TJ. Update on the management of postoperative nausea and vomiting and postdischarge nausea and vomiting in ambulatory surgery. *Anesthesiol Clin*. 2010;28[2]:225-249.) *PONV,* postoperative nausea and vomiting; *5-HT,* serotonin; *Nk,* neurokinin.

Aprepitant. Aprepitant (Emend) is a neurokinin-1 receptor antagonist. Oral administration of 40 to 80 mg within 3 hours of induction of anesthesia is recommended for high-risk, nonpregnant patients. Aprepitant has been shown to be more effective than ondansetron for preventing PONV and PDNV, especially in the first 48 hours.[163]

Dexamethasone. Studies have found dexamethasone to be effective in reducing the incidence of postoperative nausea and vomiting. For adults, dexamethasone 5 to 10 mg, given alone or in combination with other antiemetic agents, was effective in reducing postoperative vomiting.[164-165] In children, 0.0625 mg/kg was as effective as 1 mg/kg intravenously in preventing vomiting after tonsillectomy. Administering dexamethasone immediately after induction of anesthesia avoids the perineal pruritus seen when the drug is administered to an awake patient. Dexamethasone may be beneficial in the treatment of postoperative nausea and vomiting when used in combination therapy with other agents. The time until discharge from the phase II recovery area has been shortened after ambulatory surgery in patients receiving dexamethasone.[166,167] The incidence of vomiting in phase III is reduced if dexamethasone is administered during surgery.

This beneficial effect could be secondary to its long duration of action, with effects lasting as long as 24 hours. Adverse effects from a single dose of dexamethasone have not been reported.[168] The exact antiemetic mechanism is unknown; however, improvements in mood and sense of well-being, central inhibition of prostaglandin synthesis, inhibition of endogenous opioid release, and changes in the permeability of the blood-brain barrier to serum proteins have been suggested.[169] Blood glucose levels transiently increase after dexamethasone administration.[170]

Dolasetron. Dolasetron (a selective serotonin type 3 receptor antagonist), 12.5 mg given intravenously, is effective in preventing and treating postoperative vomiting. Dolasetron should be administered within 15 minutes before the end of anesthesia. A single oral dose of 100 mg of dolasetron given 1 to 2 hours before surgery is effective for the prevention of postoperative vomiting. One comparative study found 50 mg of dolasetron given intravenously to be as effective as 4 mg of ondansetron for the prevention of postoperative nausea and vomiting.[171]

Droperidol. Droperidol (Inapsine, a butyrophenone/dopamine receptor antagonist), 10 to 20 mcg/kg given intravenously, has been effective in reducing vomiting. Prophylactically administered droperidol, 20 mcg/kg given intravenously immediately after induction, was superior to metoclopramide, 5 or 10 mg orally, in reducing postoperative vomiting.[116] This dose appears to offer a compromise between reducing vomiting and extending the patient's stay owing to prolonged sedation.[172]

Caution should be exercised with the use of larger doses of droperidol (50 to 75 mcg/kg), because the occurrence of side effects (e.g., anxiety, dizziness, drowsiness, extrapyramidal symptoms, hypotension) and the potential to delay discharge may be increased. In 2001 the Food and Drug Administration (FDA) placed a "black box" advisory on the packaging label regarding the use of droperidol and risk of fatal dysrhythmias. The FDA recommends 12-lead electrocardiographic monitoring of patients for 2 to 3 hours after drug administration, which creates concerns over time efficiency in the ambulatory setting.[173] The FDA has recently agreed to reassess this issue, given that the overwhelming consensus among anesthesiologists and nurse anesthetists is that droperidol is safe when used in small doses as an antiemetic. Since the FDA-mandated advisory, the use of droperidol in anesthesia has decreased significantly.[174] A further discussion of the clinical use of droperidol can be found in Chapter 9.

Ephedrine. Ephedrine (an indirect-acting sympathomimetic agent), 0.5 mg/kg given intramuscularly at the end of surgery, was found to be as effective as droperidol, 40 mcg/kg given intramuscularly, in minimizing nausea and vomiting while producing less sedation. Similarly, ephedrine, 0.5 mg/kg given at the end of abdominal surgery, reduced the incidence of nausea and vomiting during the first 3 hours postoperatively. Ephedrine, 10 to 25 mg given intravenously, has been recommended for the treatment of nausea and vomiting associated with the postural hypotension of ambulation before the patient is discharged from the facility.[175]

Metoclopramide. Metoclopramide (a benzamide) exerts beneficial gastric effects by increasing lower esophageal sphincter tone, promoting gastric emptying by increasing gastric and small-bowel motility, presumably through cholinergic, antidopaminergic, and antiserotonin (at higher doses) receptor effecs.[176] Conflicting reports have been published about the efficacy of metoclopramide as an antiemetic. A review of placebo-controlled studies involving metoclopramide failed to find any clinically significant antinausea effect at low dosages.[177] Metoclopramide is ineffective as an antiemetic at lower dosages (e.g., 10 mg) in the adult population[178] unless used in combination with other antiemetics (e.g., dexamethasone).[179] Larger doses of metoclopramide (0.4 to 0.5 mg/kg or generic 50 mg IV) in the adult patient may offer some antinausea benefit individually and when used in conjunction with ondansetron or dexamethasone.[180,181] By itself, even at moderate doses of 0.5 mg/kg, metoclopramide is not as effective as ondansetron.[182] An advantage of metoclopramide is its lack of sedative traits; this quality reduces the potential for delaying patient discharge. The intravenous administration of 0.15 mg/kg of metoclopramide has been recommended for the treatment of nausea and vomiting in patients in the PACU who appear sedated.[183] Metoclopramide is not without side effects; extrapyramidal symptoms have been associated with its use.[184]

Ondansetron. Ondansetron (a selective serotonin type 3 receptor antagonist), 0.15 mg/kg given intravenously, is widely used as an antiemetic and rescue drug for PONV. In the adult patient, 4 mg of ondansetron appears to be as effective as 8 mg when it is administered intravenously in the PACU as a treatment for nausea and vomiting.[169]

Palonosetron. Palonosetron (Aloxi) is a second-generation serotonin type 3 receptor antagonist with a long duration of action. Intravenous doses of 0.025 to 0.075 mg are effective in preventing both PONV and PDNV.[185]

Scopolamine. Transdermal scopolamine has a 2- to 4-hour onset of action and should be applied before surgery (preferably the night prior). Timing of the patch placement may be challenging in the ambulatory setting. Side effects, including dry mouth, drowsiness, contact dermatitis, and visual disturbances, are generally mild. Toxic psychosis has been reported in pediatric and elderly populations.[186]

Postoperative Pain

Appropriate postoperative pain management helps minimize the stress of surgery, thereby fostering a quicker convalescence. Uncontrolled postoperative pain causes triggering of the stress response, patient uneasiness, and neurohumoral responses, and increases nausea and vomiting, psychologic distress, discharge delays, and unanticipated hospital admission. Pain management should begin with the use of wound infiltration with local anesthesia such as bupivacaine or bupivicaine liposomes (Exparel), the use of peripheral or regional nerve block, perineural, incisional, or intraarticular local anesthesia catheters, and the administration of opioid and nonopioid (i.e., NSAIDs) analgesics preoperatively or intraoperatively, particularly in procedures associated with discomfort after emergence from anesthesia. These practices decrease analgesic requirements in the immediate recovery period, resulting in reduced pain scores and decreased postoperative nausea and vomiting.[187]

The severity and onset of postoperative discomfort are influenced by previously administered analgesics. Immediate control of pain in the PACU can be achieved by incremental titration of small intravenous doses of a short-acting opioid analgesic such as fentanyl (12.5 to 75 mcg) or alfentanil (50 to 300 mcg) every 2 to 3 minutes until nociceptive pain relief has been achieved. Nonopioid analgesics should be considered to treat inflammatory pain or neuropathic pain. They have the advantage of improving overall analgesia, promoting early mobilization, and minimizing opioid-related side effects. Once patient discomfort has been controlled and the patient is tolerating oral fluids, early management of pain with oral analgesics (similar to those the patient will be taking after discharge) should be considered. This allows for evaluation of the analgesic's effect on pain alleviation, the patient's mental condition, and the patient's respiratory drive. The outpatient's analgesic medication should be safe and easily managed by the patient or caregiver once the patient is discharged from the facility.

Discharge Criteria

Before the patient is discharged from the ambulatory facility, he or she must meet certain criteria of recovery from the effects of surgery and anesthesia. A consistent method of evaluating the patient for discharge readiness offers the advantages of reproducibility, standardization, and objectivity; however, no single universally accepted standard exists for determining discharge readiness.

BOX **37-13**

Key Education Points for Discharge Instructions

Medications
- Detail the name, purpose, and dosage schedule for each medication. Emphasize the importance of following the directions on the label.
- The patient should resume medications taken before surgery per the physician's order.
- If pain medication is not prescribed, nonprescription, nonaspirin analgesics (e.g., acetaminophen, ibuprofen) may be effective to treat mild aches and pains.
- Additional pain medication may be ordered by the physician after surgery. The patient should take these medications as directed, preferably with food to prevent gastrointestinal upset.

Activity Restriction
- Caution the patient to take it easy for the remainder of the day following surgery. Postoperative dizziness or drowsiness is not unusual after surgery and anesthesia and may last several days.
- For the next 24 hours, the patient should not drive a vehicle, operate machinery or power tools, consume alcohol (including beer), make important personal or business decisions, or sign important documents.
- Describe the permissible activity level in specific behavioral terms (e.g., do not lift objects greater than 20 lb); describe any limitation of activities.

Diet
- Explain any dietary restrictions or instructions.
- If no dietary restriction, instruct the patient to progress as tolerated to a regular diet.

Surgical and Anesthesia Side Effects
- Anticipated sequelae of surgery, such as bleeding and pain, should be delineated.
- Common side effects associated with anesthesia include dizziness, drowsiness, myalgia, nausea and vomiting, and sore throat.

Possible Complications and Symptoms
- Instruct the patient and responsible caregiver in pertinent signs and symptoms that could be indicative of postoperative complications.
- The patient should call his or her physician if any of the following develop:
  - Fever greater than 38.3° C (greater than 101° F) orally
  - Persistent, atypical pain
  - Pain not relieved by pain medication
  - Bleeding that does not stop or prolonged, unexpected drainage from the wound
  - Extreme redness/swelling around the incision, drainage of pus
  - Urinary retention after 8 hours or as otherwise instructed
  - Unremitting nausea or vomiting

Treatment and Tests
- Procedures the patient or responsible caregiver are expected to perform, such as dressing changes or the application of warm, moist compresses, should be described in detail.
- A complete list of necessary supplies should be included.
- If any postoperative tests are to be conducted, instructions as to the date, time, test location, and any pre-visit preparation should be listed.

Access to Postdischarge Care
- Provide the telephone number of the responsible and available physician.
- Provide the telephone number of the ambulatory center and the hours of operation.
- Provide the name, address, and telephone number of the appropriate emergency care facility.

Follow-up Care
- Identify the date, time, and location of the patient's scheduled return visit to the clinic or surgeon.

Modified from Marley RA, Moline BM. Patient discharge from the ambulatory setting. *J Post Anesth Nurs*. 1996;11:41

For discharge to occur, the patient must be clinically stable and able to continue the recovery process at a remote recovery location. The decision to discharge is best made on objective criteria outlined in the policies of each ambulatory surgical facility. Distinct objective discharge criteria must be addressed when assessing home readiness of the patient. (*Note:* Before discharge from phase I, the patient's vital signs will be stable, there will be no respiratory impairment, protective reflexes of swallow and cough will be present, and the patient will be oriented to his or her preoperative level. It is assumed that the status of these parameters will not deteriorate during the patient's stay in phase I.) Individually, the following clinical markers should be evaluated in an organized, concise manner:

1. Vital signs should be stable and age appropriate.
2. The patient should be oriented to person, place, and time or at a level appropriate for the patient's developmental and preoperative status.
3. Ambulation can be affected by the surgical procedure and the patient's developmental level. If assistance to ambulate is required, the home caregiver must be capable of meeting this need.
4. There should be no respiratory distress.
5. Swallowing and coughing protective airway reflexes must be present.
6. Bleeding should be minimal or appropriate for the surgical procedure.
7. Pain should be minimal or controlled with an appropriate analgesic regimen.
8. Nausea and vomiting should be minimal.
9. Oral intake prior to discharge is not necessary unless crucial to the patient's continued convalescence at home (e.g., diabetic patient, patient requiring oral analgesics).[51]
10. Voiding is not mandatory before discharge, except for patients at high risk for postoperative urinary retention (e.g., history of postoperative urinary retention, pelvic or urologic surgery, perioperative catheterization).[51]
11. A responsible caregiver should be available.

A complete discussion of postanesthesia discharge criteria can be found in Chapter 50.

Discharge Considerations

During the preparatory phase, the availability of a responsible person who will oversee the patient's care once the patient is discharged should be ascertained before surgery. In some cases,

inpatient admission may be necessary if a responsible individual cannot be located. Postoperative care may be required for up to 48 hours in such cases, especially in elderly patients. The patient and responsible person should be provided with written instructions that are verbally reinforced before the patient is discharged. This information should include the physician's telephone numbers and steps to be taken if questions or complications arise. Once the patient has satisfied the criteria for discharge from the outpatient facility, certain discharge instructions should be reviewed to expedite and streamline the discharge process (Box 37-13).

The period of patient recovery after discharge from the ambulatory facility until resumption of normal activities is termed *phase III*. This is an important and often forgotten aspect of postoperative ambulatory care. Patient-care issues requiring attention continue to be important. It is important to convey to patients that it will take several days before they begin to feel as they did before surgery.

SUMMARY

The numbers and types of surgeries performed on an ambulatory basis will continue to increase, as will the ability of facilities to appropriately treat these patients. As anesthetic techniques and agents are refined, thereby increasing the safety and efficiency of patient care and discharge, new groups of patients will be evaluated for their appropriateness for outpatient surgery. These new groups will continue to challenge our resources for providing ambulatory anesthesia.

38 CHAPTER Anesthesia for Ear, Nose, Throat, and Maxillofacial Surgery

◆ *Gary D. Clark and Julie A. Stone*

The practice of anesthesia for the ear, nose, and throat (ENT) patient is both challenging and rewarding. The anesthesia practitioner is often required to make decisions regarding difficult airway management and must have the knowledge and skills to navigate abnormal and difficult anatomy. As a specialty, ENT presents specific concerns to the anesthetist in regard to the preparation and management of surgical procedures (Box 38-1). There are several essential goals when providing anesthesia for ENT and maxillofacial (i.e., plastics and dental) surgical procedures:

1. Possessing a thorough knowledge of the airway anatomy and function
2. Selecting and preparing for appropriate technique(s) and approach for airway management
3. Preventing and managing potential airway complications
4. Producing profound selective muscle relaxation during periods of extreme stimulation, yet maintaining the potential for rapid recovery (e.g., suspension laryngoscopy)
5. Maintaining cardiovascular stability during periods of intense surgical stimulation
6. Omitting neuromuscular relaxation for surgical procedures that require isolation of nerves
7. Preventing or containing airway fires
8. Minimizing intraoperative and postoperative blood loss
9. Preventing adverse respiratory and cardiac responses resulting from manipulation of the carotid sinus and body
10. Taking the appropriate postoperative measures to prevent and treat postsurgical airway obstruction
11. Avoiding or limiting the use of nitrous oxide during tympanoplasty or other closed-space grafting

Surgical intervention for ENT procedures uses a variety of specialty equipment, including lasers, endoscopes, and specialized endotracheal tubes (e.g., laser and microlaryngeal tube). The basis of many ENT and maxillofacial surgical procedures includes endoscopic examination of the sinuses; tissue tumors of the head, neck, and oral cavity; abscesses; surgery to the middle ear; papillomas of the airway; hypertrophic tonsils and adenoids; acute epiglottitis; thyroid disorders; and traumatic or congenital facial deformities. The majority of these procedures involve the nose, facial and frontal sinuses, larynx, oropharynx, nasopharynx, tongue, trachea, mandible, and maxilla, as well as other supporting structures of the head and neck. These procedures necessitate sharing the airway with the surgeon and may lead to a tenuous airway and significant challenges perioperatively. Airway compromise in ENT patients may be subtle and can take several forms. Therefore, good communication is essential in the preoperative period to ensure the safest approach to anesthesia.

This chapter describes the pertinent anatomy and physiology of the head and neck for the anesthetist, reviews specialized anesthetic considerations, reviews surgical and anesthesia equipment used during ENT procedures, analyzes some of the common pharmacologic agents used for ENT procedures, and discusses principles of anesthesia for ENT.

FUNCTIONAL ANATOMY OF THE HEAD AND NECK

A fundamental knowledge of the anatomic and physiologic function of the structures of the head and neck is essential for dealing with the myriad decisions arising perioperatively during these procedures. Commonly, the ENT surgical procedure is being performed because the anatomic structures are abnormal, distorted, or deviated. Having a working knowledge of the structures and their relationships before subjecting the patient to respiratory changes produced by anesthesia is imperative.

The anatomic structures of the head and neck and their relationships are complex (Figure 38-1). The sensory and motor supply of the upper airway originates from cranial nerves and includes the trigeminal, glossopharyngeal, facial, and vagus nerves. Understanding the sensory supply is required to provide sufficient local and regional anesthesia. Likewise, motor function evaluated during and after surgical procedures may indicate trauma or damage to muscles. A thorough knowledge of which nerves control muscle function is essential to preventing such trauma.

The relationships of the oropharynx, nasopharynx, nasal chambers, sinuses, esophagus, and lower airway structures such as the larynx, cricoid, thyroid, and vocal cords provide a basis for directing and providing care for the patient receiving ENT surgery. The nose is a major anatomic structure that is responsible for warming, filtering, and providing humidity to the air taken in during inspiration. The structures of the nose include the external nose, the nasal cavity, and frontal, maxillary, and ethmoid sinuses. The nares or nostrils are separated by the septum. The lateral margins of the nares are cartilaginous structures and extend posteriorly over the hard palate, leading to a confluence at the soft palate, oropharynx, and base of the tongue. The oropharynx rests superior to the epiglottis, vocal cords, larynx, and trachea.

The external nose is composed largely of cartilage supported primarily by soft connective tissue and delicate mucous membranes, as is the nasal septum. The nasal cavities are hollow structures formed by a floor, roof, lateral wall, and the septum. The lateral aspects of the nasal cavities contain concha, or turbinates. The turbinates are highly vascular and are divided into three separate compartments: the superior, middle, and inferior. The turbinates greatly increase the surface area of the nasal cavities, aiding in filtration and humidification of inspired gases.

The extensive vascular supply of the turbinates may lead to severe bleeding if the nasal airway or nasoendotracheal tube is not inserted along the superior margin of the hard palate. Congestion of the mucosal veins in the turbinates of the nose causes swelling of these tissues, reducing the size of the nasal cavity (most notably, the paranasal sinuses) and thus creating the feeling of "congestion" during respiration. Inadvertent palatine submucosal insertion of the nasoendotracheal tube can lead to severe bleeding

BOX 38-1

Special Considerations for ENT Procedures

- Use of specialized ventilation techniques
  - Insufflation
  - Intermittent apnea
  - Apneic oxygenation
- Prevention of endotracheal tube fire
- Shared airway
- Surgical field avoidance
- Restricted use of nitrous oxide
- Restricted use of muscle relaxants
- Use of specialized equipment
  - Laser
  - High-frequency jet ventilation (HFJV)
- High percentage of pediatric patients
- Minimizing blood loss

ENT, Ear, nose, and throat.

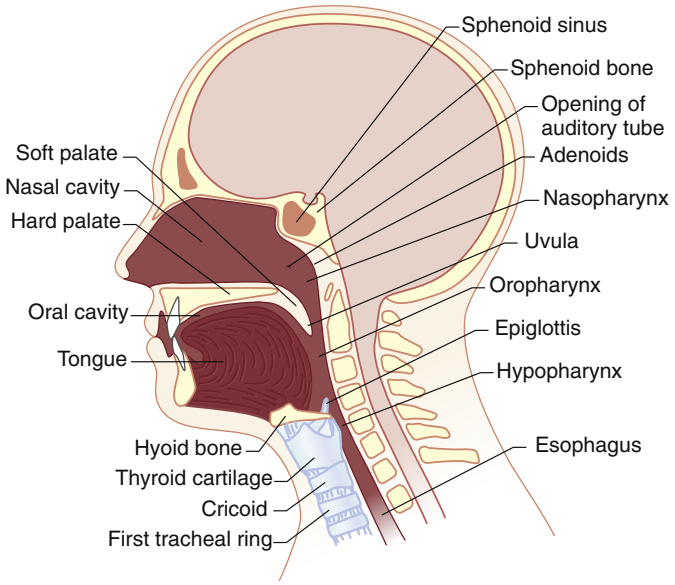

FIGURE **38-1** Anatomy of nasal cavity, oral cavity, nasopharynx, oropharynx, and hypopharynx. (From RD Miller, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2358.)

or infection in the perioperative period if entry of the tube is forced or tissues are engorged. These paired sinuses include the sphenoid, ethmoid, frontal, and maxillary sinuses. They not only serve as resonators for the voice but also filter, humidify, and warm the air during inspiration. These hollow structures are formed of low-density bone and are lined with a thin layer of mucous membranes, reducing the weight of the skull but making these bones more susceptible to fractures and cerebral spinal fluid leak secondary to facial trauma.[1-3]

The pharynx is composed of the terminal end of the nasopharynx, the oropharynx, and laryngopharynx or hypopharynx extending to the sixth cervical vertebra. The medulla inhibits respiration with swallowing; the pharynx then serves as a muscular tube that constricts, allowing the passage of food. The pharynx allows the smooth passage of air and functions as a modulator for the voice. The nasopharynx is continuous with the internal nasal cavities and extends to the soft palate. The nasopharynx communicates with the oropharynx and forms the posterior aspect of the throat. Major structures of the oropharynx include the base of the tongue, soft palate, uvula, and lymphatic structures (tonsils). The tonsils are the most sensitive areas of the oropharynx. Beginning with the anterior margin and progressing bilaterally and posteriorly, the oropharynx is defined by the soft palate, base of the tongue, uvula, palatine tonsils, and adenoids, forming Waldeyer's ring.[1-3]

Hypertrophy of the palatine and adenoid tonsils (exaggerated many times by chronic infection) and of the soft palate and uvula can pose serious airway compromise, particularly in young children. The generous blood supply to the tonsils from branches of the external carotid, maxillary, and facial arteries and their close proximity to the facial and internal arteries are matters of concern regarding potential bleeding during "routine and simple" tonsillectomy. The laryngopharynx includes the epiglottis, which provides protection for the vocal cords, and is the region shared by the esophageal orifice and larynx.

The complexity of the neuromuscular system, which controls the epiglottis, allows the isolation of the trachea from the esophagus during swallowing. Any interruption of this coordinated neuromuscular function of the epiglottis or of any other protective reflexes can provide a dangerous opportunity for the entrance of food or liquid into the larynx and lower airway. As food is squeezed posteriorly, an automatic swallowing reflex is initiated. The larynx is pulled superiorly, allowing the epiglottis to cover and protect the opening of the larynx.[1] The epiglottis does not operate as a movable lidlike structure that falls to close the larynx during swallowing, as is often claimed. Passage of food into the trachea can occur if the muscles and protective elevation of the larynx become rigid or are changed due to nerve interruption. A series of reflex and involuntary processes mediated by the superior laryngeal, recurrent laryngeal, and glossopharyngeal nerves coordinates and regulates glottic closure during swallowing.[1-3]

The larynx is a rigid organ composed of three paired and three unpaired cartilages (arytenoid, corniculate, and cuneiform and thyroid, cricoid, and epiglottis, respectively) and is supported by the hyoid bone. This hollow structure forms a reservoir distal to Waldeyer's ring and provides the connection of the oropharynx to the trachea (Figure 38-2). The primary functions of the larynx are vocalization and articulation; secondarily, it provides protection of the airway and allows respiration.[1] In the adult, the area of the vocal cords, or rima glottis, is the narrowest portion of the larynx. In children, the cricoid ring is the narrowest portion of the airway until approximately 10 years of age. Cuffed tubes are then generally recommended for those older than 8 to 10 years of age to allow for a better seal of the airway, prevent subglottic edema, and reduce the incidence of postoperative airway compromise.[4]

Specific nervous structures of the head and neck are worthy of note because of their superficial location or proximity to operative sites. Surgeons may use audible or visual nerve-locating devices to find these nerves and their appropriate branches. To accurately locate these nerves, neuromuscular blocking agents may be avoided during the maintenance of certain general anesthetics.

The facial nerve (VII) has six major branches: four anterior (temporal, zygomatic, buccal, and mandibular), one inferior (cervical), and one posterior (posterior auricular) branch. The facial nerve located at the tragus of the ear is the motor and sensory supply to the muscles for facial expressions. The zygomatic branch leaves the skull via the stylomastoid foramen and advances anteriorly over the maxilla. The corda tympani branch of the facial nerve conveys taste from the anterior two thirds of the tongue, and the more superficial tri-branched facial nerve controls facial expression. The trigeminal nerve begins at the gasserian ganglion and divides into three branches; they are the ophthalmic (the first division, V_1), maxillary

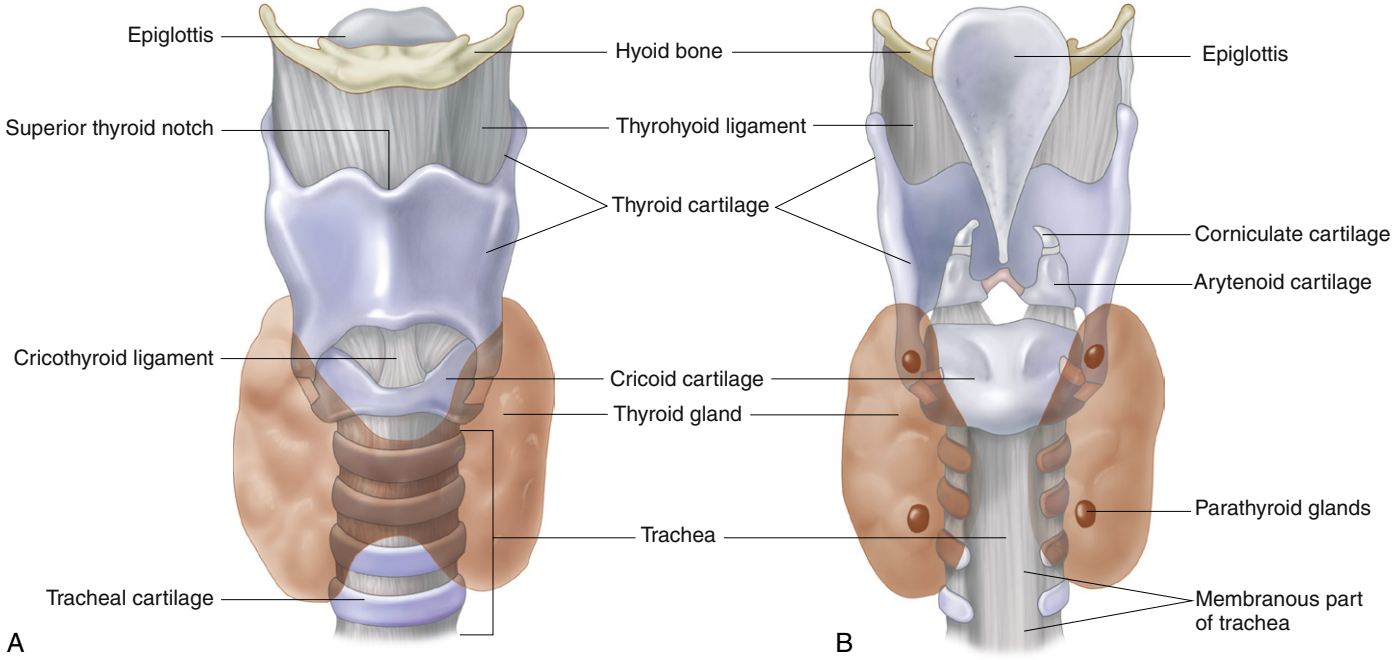

FIGURE **38-2** Laryngeal cartilages. Some softer tissues of the larynx and surrounding structures have been removed to make it possible to see the cartilages of the larynx. Note the position of the nearby thyroid gland. **A,** Anterior view. **B,** Posterior view. (From Patton KT, Thibodeau GA. *Anatomy & Physiology.* 8th ed. St. Louis: Mosby; 2013:804.)

(the second division, V_2), and mandibular (the third division, V_3). All three divisions provide sensory and motor innervation to the nose, sinuses, palate, and tongue. They aid in the motor control of the face and in mastication.[1-3]

The glossopharyngeal nerve provides motor and sensory innervation for the base of the tongue and nasopharynx and oropharynx. The glossopharyngeal nerve is responsible for eliciting the gag reflex during instrumentation of the posterior pharynx and vallecula.

The superior laryngeal and recurrent laryngeal nerves are both branches of the vagus (X). The superior laryngeal nerve descends to the hyoid bone and then branches into the internal laryngeal nerve, which passes through the thyrohyoid membrane, and the exterior laryngeal nerve, which descends over the lateral thyroid cartilage to the distal trachea. The recurrent laryngeal nerve ascends from the vagus up the distal trachea, passing through the cricothyroid ligament into the proximal trachea and vocal cords. The recurrent laryngeal nerve lies between the trachea and esophagus and supplies sensory innervation to the trachea and vocal cords. This branch of the vagus nerve also affects vocal cord closure and sensory function up to the inferior aspect of the epiglottis. Stimulation of the epiglottis with the tip of a straight laryngoscope, blades, suction catheters, and placement of an endotracheal tube in the trachea can produce a vagal response.[3] The paired and unpaired cartilages of the larynx are listed in Table 38-1. Nerve supply to the larynx is given in Table 38-2. The intrinsic muscles of the larynx, their nerve supply, and function are listed in Table 38-3. The extrinsic muscles of the larynx, their nerve supply, and function are listed in Table 38-4.[1-5]

TABLE 38-1 Paired and Unpaired Cartilages of the Larynx

Paired	Unpaired
Arytenoid	Thyroid
Corniculate	Cricoid
Cuneiform	Epiglottis

TABLE 38-2 Nerve Supply of the Larynx

Nerve	Innervation
Sensory Nerves	
Internal laryngeal (vagus)	Laryngeal mucosa above vocal cords (inferior epiglottis)
Recurrent laryngeal	Laryngeal mucosa below vocal cords
Glossopharyngeal	Superior aspect of epiglottis and base of tongue
Motor Nerves	
Recurrent laryngeal	All intrinsic muscles except cricothyroid
External laryngeal	Cricothyroid muscles

PREPARATION AND CONSIDERATIONS FOR EAR, NOSE, AND THROAT PROCEDURES

The Shared Airway and Considerations for Positioning

Operative procedures involving the airway, mouth, or bony structures of the face involve a true sharing of the airway between the surgeon and the anesthetist. Therefore, proper preparation requires planning and communication between the surgeon, surgical personnel, and the anesthetist prior to the surgical procedure. Sharing the airway with the surgeon also requires preparing and planning the use of the appropriate equipment. For example, during laryngoscopy the endotracheal tube may have to be smaller in diameter and moved to one side of the oropharynx to allow the surgeon to work around the tube and to facilitate the surgery. Many times the head of the table is rotated 90 to 180 degrees away from the anesthetist, resulting in a vulnerable airway to which the anesthetist may have little or no access. Of particular concern are

TABLE 38-3 Intrinsic Muscles of the Larynx

Muscle	Innervation	Function
Cricothyroid	Superior laryngeal nerve	Tension and elongates vocal cords
Thyroarytenoid	Recurrent laryngeal nerve	Relaxes vocal cords
Vocalis	Recurrent laryngeal nerve	Relaxes vocal cords
Posterior cricoarytenoid	Recurrent laryngeal nerve	Abducts vocal cords
Lateral cricoarytenoid	Recurrent laryngeal nerve	Adducts vocal cords
Transverse arytenoid	Recurrent laryngeal nerve	Adducts vocal cords
Aryepiglottic	Recurrent laryngeal nerve	Closes glottis
Oblique arytenoid	Recurrent laryngeal nerve	Closes glottis; approximates folds

TABLE 38-4 Extrinsic Muscles of the Larynx

Muscle	Innervation	Function
Sternohyoid	Cervical plexus; C1, C2, C3	Draws hyoid bone inferiorly
Sternothyroid	Cervical plexus; C1, C2, C3	Draws thyroid cartilage caudad
Thyrohyoid	Cervical plexus; hypoglossal nerve; C1 and C2	Pulls hyoid bone inferiorly
Thyroepiglottic	Recurrent laryngeal nerve	Inversion of aryepiglottic fold
Stylopharyngeus	Glossopharyngeal	Folds thyroid cartilage
Inferior pharyngeal constrictor	Pharyngeal plexus; vagus	Aids swallowing

the maintenance of adequate ventilation and patency of the anesthesia circuit and endotracheal tube. Extubation, disconnects, and leaks must be prevented. Adequacy of ventilation is constantly assessed by observing chest movement, auscultation, pulse oximetry, end-tidal CO_2, and blood gas analysis. A sudden loss of breath sounds, rising inspiratory pressures, or a reduction in end-tidal CO_2, particularly in the presence of a sharp reduction in inspiratory effort, may be due to a deflation of the endotracheal tube cuff, obstruction of the endotracheal tube, dislodgment of the endotracheal tube, a disconnection of the anesthesia circuit, or severing of the endotracheal tube during surgical dissection.[5] When coupled with vigilance, the precordial or esophageal stethoscopes are simple devices that should not be overlooked; these devices, in addition to more sophisticated mechanical devices, help the anesthetist maintain assessment of the airway.

Assessment of the airway prior to induction is critical in most ENT patients. Although the induction of anesthesia and securing of the airway are performed in the usual manner (with the anesthetist at the head of the table), the management of the airway can become questionable and difficult while at a distance. Obtaining a thorough history and performing an extensive evaluation of the airway for the ENT patient is crucial. A good examination of the airway will (1) allow for a careful and deliberate approach to airway management, (2) aid in evaluating the need for additional equipment and assistance, and (3) include alternative approaches for the difficult airway if the initial plan proves not to be successful. Once the induction is complete and the airway established, the anesthetist must be prepared to provide adequate ventilation, deliver necessary anesthetic and adjunct agents, place invasive lines, and safely monitor the patient while remaining at a distance and isolated from the airway.

Orchestrating how the patient is turned so that the patient's head is away from the anesthetist demands clear planning. The endotracheal tube should be secured with tape or suture to prevent removal. The invasive line tubing, intravenous access lines, monitoring devices, and breathing circuit require added length to extend to the patient without creating tension at the site before induction. The patient's entire head is frequently draped and prepped into the surgical field, limiting access to the endotracheal tube and breathing circuit connections (Figure 38-3).

FIGURE 38-3 Illustration of secured airway for a patient undergoing face, neck, or maxillofacial surgical procedures. Note that the tube is positioned to prevent pressure on the lip, nose, or forehead and secured with tape to prevent movement during surgery. The connection is covered by sterile surgical drapes and allows only limited access during the surgical procedure.

When repositioning of the head is necessary, communication between the surgeon and anesthetist is important to reduce the possibility of extubation, position change, or occlusion of the endotracheal tube. Signs of air leaks around the endotracheal tube (e.g., bubbling, the sound of air escaping, or the smell of anesthetic agent from the patient's mouth) may well be more sensitive indicators than mechanical airway monitors. Occlusion of the endotracheal tube is best prevented but can be determined by good auscultation, watching chest wall motion, and monitoring inspiratory pressures and morphology of CO_2 waveforms. The surgeon must communicate any changes in the surgical field, such as changing the position of a suspended or fixed laryngoscope, dark

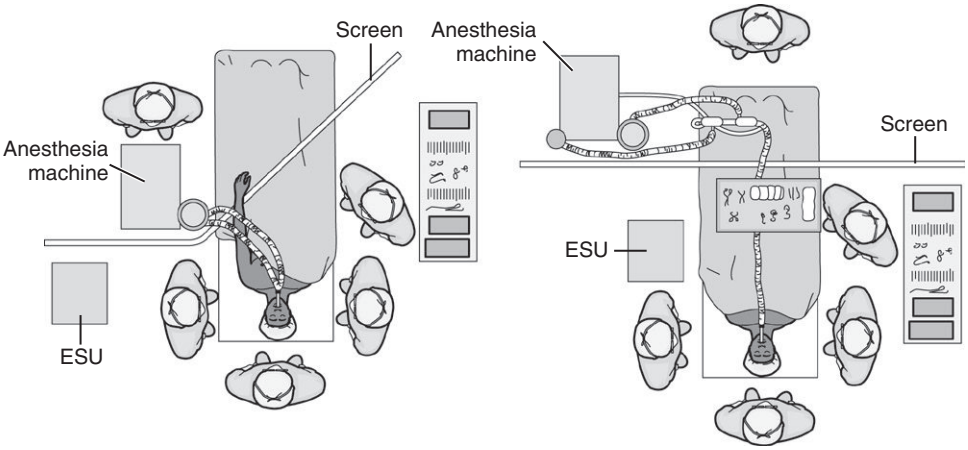

FIGURE **38-4** Position of the anesthetist for surgery of the head and neck. *Left*, The anesthetist is positioned at the side of the table and using a standard circle circuit. *Right*, The anesthetist is positioned at the foot of the bed and using a coaxial (Bain) circuit. *ESU,* Electrosurgical unit. (From Phillips N. *Berry & Kohn's Operating Room Technique*. 12th ed. St Louis: Mosby; 2013:873.)

blood, manipulation of carotid bodies, or the need for a change in the patient's head position.[6] Increased inspiratory pressures or a rapid loss of inspiratory pressure, decreased oxygen saturation, changes in end-tidal CO_2 measurements, or diminished breath sounds should, in turn, be communicated to the surgeon so that inspection of the airway and anesthesia circuit may be undertaken. If unable to arrive at a cause, undraping the patient may become necessary for a thorough examination of tube placement and connections or to find a leak in the anesthesia circuit that could compromise patient ventilation.

Procedures of the head and neck typically require access to all planes of the head by several members of the surgical team.[7] Because a number of problems can be encountered with the intubated patient during the surgical procedure, the surgeon may elect to perform a tracheostomy, then place and suture a flexible endotracheal tube in a fixed position during the procedure. A heightened state of vigilance must be maintained for occlusions from mucous plugs or blood, disconnects, endotracheal tube fires, and other problems that may arise during the anesthetic. During some ENT procedures, the surgical team also may need access to the chest and abdomen for securing grafts for the esophagus or oral cavity. Often this requires the anesthetist to take residence at either the side of the patient or at the foot of the operating table (Figure 38-4). Providing a smooth transition with protection of the established airway and prevention of hypoxia are the primary concerns during movement of an operating table with an anesthetized patient.

The anesthesia circuit and other monitors should be temporarily and briefly disconnected before the bed is turned. This will prevent undue tension on the circuit and other lines that could lead to traumatic extubation or loss of access. Ventilation of the patient with 100% oxygen and adequate tidal volumes for 3 to 5 minutes before disconnection will denitrogenate the functional residual volume and provide an extra reservoir of oxygen during the turn, preventing even a short period of hypoxia. However, if a volatile agent is the primary source of anesthesia, the addition of intravenous anesthesia during this preoxygenation is necessary to maintain an adequate level of anesthesia and/or amnesia during this period. A saturation of 100% is a reasonable goal before the disconnection and table movement.

The degree of table movement should be discussed with the surgeon before any interruption in the anesthesia or the breathing circuit takes place. Turning of the operating table should be a well-organized procedure, understood by all members of the surgical team, and one that takes the minimum amount of time. After relocking the bed, reconnection of the anesthesia circuit must be immediate to reestablish oxygenation and/or anesthesia. Reevaluation and assessment of the tube placement, breath sounds, chest expansion, oxygen saturation, anesthetic level, line and intravenous access, and end-tidal CO_2 should be performed *before* prepping and draping is begun and throughout the case. Once adequate ventilation is established, the use of an "artificial nose" or airway humidifier will help in preserving heat and moisture during long periods of anesthesia.

Attention to simple practical points may prevent airway mishaps. At least one large-bore intravenous line, as well as arterial and central venous pressure lines, should be started on the nonoperative side, if possible on the side of the patient that will be nearest to the anesthetist during the procedure. This will prevent obstruction of flow due to the surgical procedure, afford easier access for drug administration and blood sampling, facilitate the manipulation or maintenance of lines during surgery, and allow the surgeon easy access to the operative field. If such lines must be placed on extremities opposite the anesthetist, adequate extensions should be placed before a change in position of the table to reduce the chance of lines being removed, infiltrated, or disconnected during movement. The calf of the leg may be used for noninvasive blood pressure measurements to prevent dampening of intravenous fluid flows in the upper extremities. Care must be taken to ensure that the measurement of the blood pressure takes into account variations in table changes from the horizontal position to prevent hypotension to vital organs. Monitoring of neuromuscular relaxation may be performed at locations other than the adductor pollicis. Stimulation of the tibial nerve produces flexion of the big toe and is similar to that of the adductor pollicis.[8] Because ENT procedures may take more than 2 hours and can require significant fluid administration, monitoring urinary output with a Foley catheter may be included in the plan.

SPECIALIZED EQUIPMENT FOR EAR, NOSE, AND THROAT PROCEDURES

Endotracheal Tubes Designed for ENT Surgery

A number of endotracheal tubes are available for securing an airway. Standard endotracheal tubes equipped with flexible or

straight connectors are acceptable for many ENT procedures. The diameter and length of the endotracheal tube (ETT) will affect ventilation and seal of the airway. Using a small-diameter ETT in a large adult airway will not only lead to less ventilation through increased resistance but also will allow only a small portion of the cuff to contact the trachea. Using specialized tubes with small diameters allows more even distribution of the cuff over the trachea during inflation. Several of these specially designed ETTs have found wide acceptance in ENT anesthesia. A variety of designs are used to limit encroachment of the ETT into the surgical field, prevent kinking of the ETT when severe angles are necessary, prevent fires in the airway during laser therapy, and provide maximal patient ventilation and safety.[9]

A number of ETTs have been introduced for use in ENT anesthesia. The purpose for the evolution of these various types of ETT cuffs was to reduce cuff pressure on the tracheal wall and allow for improved tracheal perfusion, reduced tracheal injury, and more convenient airway access. Preformed right-angled ETTs, in cuffed and noncuffed types, are available for either oral or nasal intubation of adults or children. Oral Ring, Adair, and RAE tubes (named after inventors Ring, Adair, and Elwyn) are an excellent choice for cleft palate repair, tonsillectomy, uvulopalatopharyngoplasty, and procedures of the eye or upper face. Nasal RAE tubes are particularly well suited to maxillofacial surgery that does not allow for oral intubation. The nasal RAE can be used for cosmetic procedures of the face, surgical procedures of the oral cavity and mandible, or to correct malocclusion. However, although the preformed bend in the RAE tube prevents the ETT from kinking in many instances, it may be too distal or proximal for an individual patient's airways. This then allows the tip of the ETT to rest well below or above the carina. A careful check of the breath sounds and inspiratory pressures is imperative after intubation with the RAE to ensure proper positioning. Nasal intubation and placement of a nasogastric tube in the unconscious patient with facial trauma is best avoided to prevent possible penetration of the brain.[10,11]

Anode, armored, reinforced, and Kant Kink tubes all have an embedded coiled wire or plastic coil strand to produce a tube with greater flexibility and memory. Armored tubes for oral or nasal intubation resist kinking and retain their original integrity. They are useful when acute neck flexion or severe angles of the ETT are required, as in procedures involving the base of the skull or posterior aspect of the neck. However, several reports suggest that even the edentulous patient can on occasion occlude a reinforced ETT.[12] Several varieties of metal-impregnated tubes are available for use with laser surgery; these are designed to reduce the occurrence of an airway fire (Figures 38-5 and 38-6). The cuff of the laser tube is usually filled with saline to dampen or prevent the ignition. In addition, it is recommended that the cuff be filled with dyed saline so that a cuff perforation is readily apparent. Wrapping a standard ETT with reflective tape is not an adequate alternative to these commercially prepared tubes because the wrapped standard ETT will dry and lead to greater flammablility.[13]

Although not classified as an endotracheal tube, the laryngeal mask airway (LMA) and intubating laryngeal mask airway may be used to facilitate intubations as well as control the airway. The LMA does not produce tracheal stimulation, which can be a considerable advantage in ENT procedures. The incidence of coughing on emergence is lower with the LMA than with the endotracheal tube. Another advantage of the LMA is the ability to insert the device without the use of neuromuscular blocking agents or for airway rescue situations. Although LMA is contraindicated in some patients with laryngeal pathology, it is often the airway of choice when dealing with patients with pharyngeal

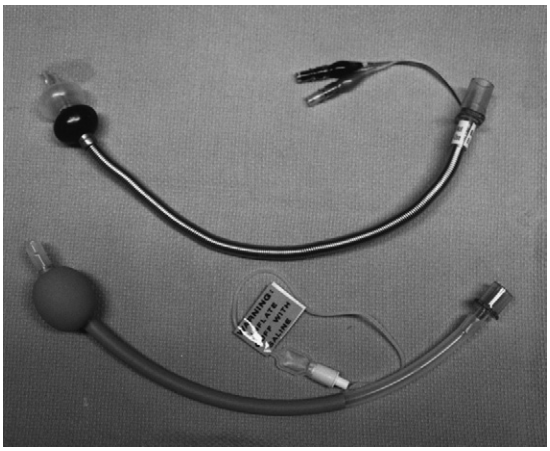

FIGURE **38-5** Endotracheal tubes for laser surgery of the airway.

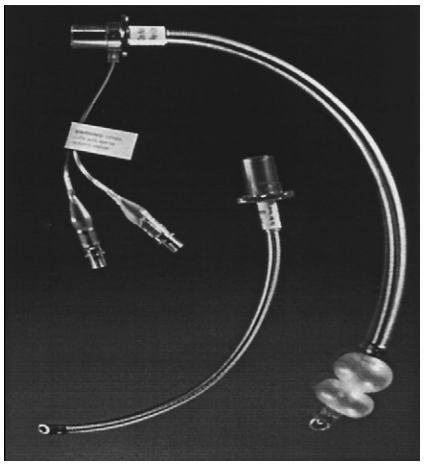

FIGURE **38-6** The Laser Flex endotracheal tube comes with a double cuff or no cuff. The double cuff is typically filled with normal saline. (Courtesy of Mallinckrodt Inc.)

pathology. Indications for LMA use in ENT surgery include a conduit for surgical access to the glottis and trachea, an aid to neurologic monitoring to avoid relaxant use, and as a means to isolate the glottis from bleeding from pharyngeal sources.[14]

SPECIAL CONSIDERATIONS FOR EAR, NOSE, AND THROAT PROCEDURES

Pharmacologic Considerations

The use of local anesthetics is particularly prevalent during nasal and sinus surgery. The most commonly used local anesthetics for ENT surgery include the amide-based drugs. Many procedures are performed using topical and local anesthesia as the sole agent, in combination or supplemented with monitored anesthesia care, intravenous sedation, or general anesthesia. Table 38-5 gives some topical local anesthetics commonly used in ENT surgery. Determination of doses of local anesthetics administered by injection and topically must be carefully calculated because more than one agent in various combinations are commonly used.

Additional information regarding local anesthetics for injection and topical use can be found in Tables 10-7, 10-8, and 10-9.

Vasoactive Drugs

The duration of action of a local anesthetic is proportional to the time the drug is in contact with nerve fibers. For this reason,

TABLE 38-5 Topical Anesthetic Drugs

Drug	Concentration	Dose	Notable Features
Cocaine	4%	3 mg/kg	Only local anesthetic with vasoconstrictive ability Blocks reuptake of norepinephrine and epinephrine at adrenergic nerve endings
Lidocaine	2% and 4% solution 2% viscous solution 10% aerosol 2.5% and 5% ointment 10%, 15%, 20%	4 mg/kg plain 7 mg/kg epinephrine 250-300 mg	Rapid onset Suitable for all areas of the tracheobronchial tree
Benzocaine	*Cetacaine contains:* 14% benzocaine, 2% butamben, and 2% tetracaine		Short duration of action (10 min) Can produce methemoglobinemia
Bupivacaine	0.25%, 0.5%, 0.75%	2.5 mg/kg plain	Slow hepatic clearance Long duration of action
Mepivacaine	1%, 2%	4 mg/kg	Intermediate potency with rapid onset
Dyclonine	0.5%, 1%	300 mg maximum	Topical spray or gargle Frequent use for laryngoscopy Absorbed through skin and mucous membranes

epinephrine in varying concentrations (1:200,000 or 5 mcg/mL; 1:100,000 or 10 mcg/mL; and 1:50,000 or 20 mcg/mL) may be added to local anesthetic solutions to produce vasoconstriction. Vasoconstriction limits systemic absorption and maintains a higher drug concentration in the vicinity of the nerve fibers to be anesthetized, thus extending the effects of the local anesthetic. Addition of epinephrine to a local anesthetic prolongs the duration of blockade and decreases systemic absorption and plasma concentrations, thus decreasing toxicity.[15]

It is estimated that in the United States, topical cocaine (4% to 10% solution) anesthesia is used in more than 50% of ENT procedures performed annually—specifically rhinolaryngology procedures.[16] Cocaine is a naturally occurring ester of benzoic acid that is hydrolyzed by plasma cholinesterase. Applied topically, it is an excellent local anesthetic and vasoconstrictor. The duration of action is approximately 45 minutes.[15] Cocaine produces vasoconstriction by blocking catecholamine reuptake into the adrenergic nerve ending, resulting in vasoconstriction and shrinking of the mucosa. Epinephrine is also injected for ENT procedures and is usually injected shortly after the application of cocaine. This combination of cocaine and epinephrine sets the stage for a significant interaction. Because cocaine that is absorbed into the plasma can block the uptake of epinephrine systemically, a toxic effect of epinephrine can result from the injection. This interaction can result in severe headaches, hypertension, tachycardia, and dysrhythmias.[17]

Anticholinergics

Anticholinergics were used liberally in the early days of anesthesia, predominantly because of the excessive secretions caused by older volatile inhalation agents. With the advent of newer anesthetic agents, excessive secretions are not an issue and the need for anticholinergics has diminished. The antisialagogue effects, however, may still be useful in certain intraoral procedures that require a drier operative field. Glycopyrrolate may be a better choice than atropine because it produces less tachycardia in comparison to atropine. Glycopyrrolate does not readily cross the blood-brain barrier and thus lacks sedative effects.

Corticosteroids

Glucocorticoids may be administered preoperatively and intraoperatively to decrease laryngeal edema formation, reduce nausea and vomiting, and prolong the analgesic effects of local anesthetics. They should be administered as early as possible in the perioperative period so as to reach their peak effect prior to initiating surgery. The use of steroids may reduce the nausea and vomiting experienced after surgery. Dexamethasone was also reported to prolong the analgesic effects of local anesthetics.[18] It has been postulated that prostaglandins, histamine, and other mediators increase the permeability of local vessels, changing nociception at the site of trauma and leading to the sensation of pain. Steroids inhibit the production of prostaglandins and therefore reduce pain. Although the use of steroids may be beneficial, they can also create sufficient immunosuppression to mask inflammation or infection.

Postoperative Nausea and Vomiting

All patients are at risk for postoperative nausea and vomiting (PONV). ENT procedures, particularly of the middle ear, are associated with a high incidence of PONV.[19] Patients experiencing PONV are uncomfortable after surgery, their discharge may be delayed from the postanesthesia care unit (PACU), or they may have an unscheduled hospital admission. The accumulation of blood in the posterior oropharynx, which may drain into the stomach or be swallowed during the postoperative period, can lead to PONV. This frequently occurs during throat procedures such as tonsillectomy. Packing the back of the throat with surgical packs during the procedure can prevent some drainage into the stomach. Care must be taken that the patient is awake, all surgical packs are removed, and suctioning of the airway precedes the extubation process, producing a clear airway and ensuring the control of protective airway reflexes. A multimodal approach is advocated to attenuate PONV in ENT patients.[20,21]

Special Anesthetic Techniques Associated with ENT Procedures

Deliberate Controlled Hypotension

Extensive dissection is required for many head and neck tumors, with operative times extending to 12 or more hours. Considerable fluid replacement, blood loss, electrolyte imbalances, and cardiovascular and respiratory changes may occur during surgery. The surgeon may request deliberate controlled hypotension to reduce blood loss. Patients must be individually evaluated prior to controlled hypotension to determine a safe mean pressure.

TABLE 38-6 Common Intravenous Agents for Hypotensive Techniques

Drug and Dosage	Advantages	Disadvantages
Sodium nitroprusside Variable age- and anesthetic-dependent effects *Young adults:* 1-5 mcg/kg/min *Children:* 6-8 mcg/kg/min	Potent; reliable; rapid onset and recovery; cardiac output well preserved	Reflex tachycardia; rebound hypertension; pulmonary shunting; cyanide toxicity possible
Esmolol 200 mcg/kg/min to achieve 15% reduction of mean arterial pressure	Particularly useful to control tachycardia	Potential for significant cardiac depression
Nitroglycerin *Adults:* 125-500 mcg/kg/min *Children:* 10 mcg/kg/min	Preserves myocardial blood flow; reduces preload; preserves tissue oxygenation	Increases intracranial pressure; highly variable dosage requirements
Nicardipine 5 mcg/kg/min	Ca^{++} channel blocker Preserves cerebral blood flow	
Remifentanil with propofol Remifentanil: 1 mcg/kg IV then continuous infusion 0.25-0.5 mcg/kg/min Propofol: 2.5 mg/kg IV then infusion of 50-100 mcg/kg/min	Remifentanil reduces middle ear blood flow, creating a dry surgical field for tympanoplasty Propofol may help reduce PONV	No analgesic effect once remifentanil infusion discontinued

Modified from DeGoute CS. Controlled hypotension: a guide to drug choice. *Drugs*. 2007; 67(7):1053-1076.
PONV, Postoperative nausea and vomiting.

The effects of common intravenous controlled hypotensive techniques are compared in Table 38-6.[22,23] The practice of controlled hypotension focuses on reducing the mean arterial pressure to some predetermined level related to the limits of cerebral and systemic autoregulation. The mean pressure is not usually allowed to fall below 60 mmHg, maintaining cerebral and renal autoregulation, as well as adequate coronary artery blood flow. Patients with chronic hypertension may require a higher mean pressure to maintain adequate perfusion.[23] Regardless of the technique or medication chosen, it is imperative that urine output, mean arterial blood pressure, cerebral and cardiac perfusion pressure, and arterial blood gases be closely monitored and maintained. When using hypotensive anesthesia, an arterial line is required. Hypotensive techniques are also used with endoscopic sinus surgery. It has been noted that better operating conditions are achieved when moderate hypotension is produced with a vasoconstrictor such as a beta blocker than when vasodilating agents are used.[24]

SELECT TECHNIQUES COMMONLY USED IN ENT PROCEDURES

Laser Surgery

Anesthesia and laser surgery is also discussed in Chapter 43; however, some specific issues concerning lasers are relevant to ENT surgery. Laser technology has been used in medicine for more than 30 years. The two most common lasers used in ENT surgery are the CO_2 and Nd:YAG (neodymium-doped yttrium aluminum garnet); recently the argon laser has become a popular choice as well.[25] Laser light is different from standard light. Whereas standard light has a variety of wavelengths, lasers have only one wavelength (monochromatic). Laser light oscillates in the same phase, or all the photons are moving in the same direction (coherent), and its beam is parallel (collimated). The wavelength of the Nd:YAG laser beam is shorter as it passes through the garnet than that of the CO_2 laser. The shorter wavelength allows less absorption by water and therefore less tissue penetration. For example, the shorter wavelength of the Nd:YAG allows the laser light to pass through the cornea, whereas the longer wavelength of the CO_2 laser would burn the cornea. Laser light emits a small amount of radiation and can be infrared, visible, and ultraviolet in the spectrum. Lasers enable very precise excision, produce minimal edema and bleeding, and are favored by surgeons for resection of tumors and other obstructions of the airway. For operations in and around the larynx, the CO_2 laser is frequently used because of its shallow depth of burn and extreme precision.[13] The CO_2 laser produces a beam with a relatively long wavelength that is absorbed almost entirely by the surface of these tissues, vaporizing cellular water. Intermittent bursts of the CO_2 laser produce intense, precisely directed energy that results in a clean cut through the target tissue with a minimal amount of penetration of surrounding tissue. A low-energy helium-neon laser is commonly used to aim or direct CO_2 laser beams.

The holmium:yttrium-aluminum-garnet (Ho:YAG) laser is a fairly new laser. The Ho:YAG laser has a pulsed infrared output with a wavelength of 2.1 mm. The laser has excellent absorption in water-rich tissues, and in otolaryngology, it has been used for nasal surgeries and for tonsillectomies.

Laser light beams are primarily used for their thermal effect and can be used to cut, coagulate, or vaporize tissues. The exact tissue interaction of a laser is dependent on several variables, including the types of tissues being irradiated, the wavelength of the emitted beam, and the power of the beam.

The majority of surgical fires occur during head and neck surgery. This is due to the presence of oxygen and the extensive use of lasers. The use of laser technology mandates taking measures to ensure the safety of the patient and operating room personnel (Box 38-2). Specific concerns include eye protection with appropriate colored glasses, avoidance of the dispersion of noxious fumes, and fire prevention. Stray or reflected beams of the Nd:YAG laser are capable of traversing the eye to the retina; therefore, green-lensed eye protection for all personnel is mandatory during use of the Nd:YAG laser. All persons in the operating room must wear goggles specifically designed to absorb Nd:YAG laser beams. The required protective eyewear for CO_2 lasers can be any clear glass or plastic that surrounds the face. Orange-red eye protection is required for the potassium-titanyl phosphate (KTP) laser, and orange glasses are required for the argon laser.

When tissues are cut by a laser, the smoke and vapors that are formed are called laser "plume." This plume is an environmental

BOX 38-2

General Safety Protocol for Surgical Lasers

- Post warning signs outside any operating area: "WARNING: LASER IN USE."
- Patient's eyes should be protected with appropriate colored glasses and/or wet gauze.
- Matte-finish (black) surgical instruments reduce beam reflection and dispersion.
- Use the lowest concentration of oxygen possible.
- Avoid using nitrous oxide (N_2O), because it supports combustion.
- Lasers should be placed in STANDBY mode when not in use.
- Use an endotracheal tube specifically prepared for use with lasers.
- Inflate cuff of laser tube with dyed saline so that a cuff perforation is readily apparent.
- All adjacent tissues should be shielded by wet gauze to prevent damage by reflected beams.
- Plume should be suctioned and evacuated from the surgical field.

concern and potentially toxic to operating room personnel. When the tissues vaporized by the laser are malignancies or viral papilloma, the concern arises as to whether these vapors are even more dangerous to operating room personnel if not removed from the environment. Because this issue remains under investigation, it is judicious to suction the laser plume and not allow it to circulate into the room.

The prevention of combustion within the airway is of primary concern. Fire in the airway is relatively uncommon (0.4%), and it is usually due to penetration of the laser through the ETT, which exposes the beam to a rich oxygen supply. Nitrous oxide, although not flammable, also supports combustion and can propagate the flame.[26] Positive pressure ventilation in the presence of intraluminal combustion produces a blowtorch effect that causes serious damage to the respiratory tract of the unfortunate patient.[27] Many important steps should be taken to minimize the risk of laser fires.[28] Box 38-3 lists safety measures for preventing fires during ENT procedures.[13] Operating room fires are discussed further in Chapters 42 and 53.

The "perfect" ETT for use with lasers remains a major discussion. However, several manufacturers have attempted to produce a laser-compatible ETT that allows for adequate ventilation during the laser procedure but reduces the risk of airway fire injury. A few generalizations can be made. The necessity of an inflatable cuff is a point of debate, although the ability to better ventilate the patient and keep the field free of combustible gases is an advantage. When filled with air, the cuff becomes a generous reservoir of combustion-supporting gas. If a cuffed tube is used, inflation with methylene blue–tinged normal saline is encouraged to make it possible to detect penetration. If a laser beam contacts the cuff, the colored liquid will absorb and disperse heat, alerting the operating team to the penetration; the liquid also will reduce combustion.[29]

Fire safety policies, procedures, and practice guidelines are now routine and observed in every modern operating room.[30]

Endoscopy

Endoscopic surgery includes panendoscopy, laryngoscopy, microlaryngoscopy (laryngoscopy aided by an operating microscope), esophagoscopy, and bronchoscopy. All of these procedures can be performed using a rigid or flexible endoscope. If the rigid

BOX 38-3

Safety Measures for Preventing Fires During Ear, Nose, and Throat Procedures

- Use only air for open delivery to the face if the patient can maintain a safe blood O_2 saturation without supplemental.
- If the patient cannot maintain a safe blood O_2 saturation without extra O_2, secure the airway with a laryngeal mask airway or tracheal tube.
  - *Exceptions:* When patient verbal responses may be required during surgery (e.g., carotid artery surgery, neurosurgery, pacemaker insertion) and when open O_2 delivery is required to keep the patient safe, do the following:
  - Deliver the minimum O_2 concentration necessary for adequate oxygenation at all times.
  - Begin with a 30% delivery O_2 concentration and increase as necessary.
  - For unavoidable open O_2 delivery above 30%, deliver 5 to 10 L/min of air under drapes to wash out excess O_2.
  - Stop supplemental O_2 at least 1 minute before and during use of electrosurgery, electrocautery, or laser, if possible. Surgical team communication is essential for this recommendation.
  - Use an adherent incise drape, if possible, to help isolate the incision from possible O_2-enriched atmospheres beneath the drapes.
  - Keep fenestration towel edges as far from the incision as possible.
  - Arrange drapes to minimize O_2 buildup underneath.
  - Coat head hair and facial hair (e.g., eyebrows, beard, moustache) within the fenestration with water-soluble surgical lubricating jelly to make it nonflammable.
  - For coagulation, use bipolar electrosurgery, not monopolar electrosurgery.

During Oropharyngeal Surgery (e.g., Tonsillectomy)

- Scavenge deep within the oropharynx with a metal suction cannula to catch leaking O_2 and nitrous oxide (N_2O).
- Moisten gauze or sponges and keep them moist, including those used with uncuffed tracheal tubes.

During Tracheostomy

- Do not use electrosurgery to cut into the trachea.

During Bronchoscopic Surgery

- If the patient requires supplemental O_2, keep the delivered O_2 below 30%. Use inhalation/exhalation gas monitoring (e.g., with an O_2 analyzer) to confirm the proper concentration.

From Sheinbein DS, Loeb RG. Laser surgery and fire hazards in ear, nose, and throat surgeries. *Anesthesiol Clin.* 2010;28(3):485-496.

laryngoscope is used, the laryngoscope may be suspended from an arching support anchored to the patient's abdomen/chest or from a Mayo stand over the patient. One of the most common endoscopic procedures performed is the endoscopic sinus surgery. Over 250,000 endoscopic sinus surgeries are performed yearly in the United States alone.[31,32] Endoscopic sinus surgery is often associated with multiple and seasonal allergies leading to polyps. Patients undergoing surgery are often also being evaluated for pathology responsible for hoarseness, stridor, or hemoptysis. Other possible reasons for endoscopic examination include foreign-body aspiration, papillomas, trauma, tracheal stenosis, obstructing tumors, or vocal cord dysfunction. Several complications can arise with endoscopic surgery: eye trauma, epistaxis, laryngospasm, and bronchospasm; excessive plasma levels of local anesthesia

and epinephrine have been reported as well. Preoperatively, the patient should be examined for any signs of airway obstruction and proper measures should be taken to ensure safe and controlled airway management. Knowledge of the location and size of a mass is important, and discussion with the surgeon about chest roentgenogram, magnetic resonance imaging (MRI), and computed tomography (CT) scan results can be invaluable.[33]

Light sedation is suggested for premedication because older children and adults may experience respiratory depression and worsening of airway obstruction. The airway must be protected from aspiration of gastric contents, especially during prolonged airway manipulation and deeper sedation. Premedication with an antisialagogue to dry secretions and a full regimen of acid aspiration prophylaxis in aspiration-prone patients may be indicated. An awake oral or nasal intubation with minimal sedation and topical anesthesia of the oral cavity, pharynx, larynx, and nasopharynx is common. For shorter ENT procedures, anesthesia should be maintained with short-acting inhalation and intravenous agents to (1) avoid patient movement and vocal cord movement and (2) control sympathetic nervous system response to brief periods of extreme stimulation, as in laryngoscopy.

Good muscle relaxation of the vocal cords is an essential part of anesthesia management for microsurgery of the larynx. A single-dose short-acting relaxant such as succinylcholine may be considered for brief cases. If the procedure is expected to last 30 minutes or more, use of an intermediate-duration neuromuscular-blocking drug such as vecuronium, cisatracurium, or rocuronium for the initial tracheal intubation allows the return of muscle strength and spontaneous respiration to meet extubation criteria at the end of the surgical procedure. Emergence should include adequate oropharyngeal suctioning, humidified oxygenation, and observation in the PACU for laryngeal spasm or postextubation croup or stridor.

One of the greatest management challenges during endoscopic procedures is that of sharing the airway continuously with the surgeon. Several methods have been used to provide oxygenation and ventilation during the procedures. One method is to control the airway by using a small cuffed ETT (5.0 to 6.0 mm for an adult). Because the 5.0- and 6.0-mm ETTs are designed for smaller patients, a better ETT selection might include the microlaryngeal endotracheal tube (MLT). The MLT in similar sizes (5.0 to 6.0 mm) has a cuff that is larger than the small standard ETTs (5.0 to 6.0 mm), allowing for a larger cuff distribution across the surface of the trachea and creating a wider field of pressure on the tracheal surface. Distinct advantages of an ETT include a secure airway with easily controlled ventilation, a cuff to protect the lower airway from debris, monitoring of end-tidal CO_2, and the ability to administer inhalational anesthetics. Several drawbacks include the potential for extubation and loss of airway, complications during laser surgery, and interference with the operative field by the ETT.

Intermittent apnea is also used as a technique to ventilate patients in this shared space. The anesthetist or the surgeon repeatedly removes the ETT, operates during a brief period of apnea, and then allows the anesthesia provider to reintubate and ventilate the patient. One advantage of the technique is that no special equipment is needed to ventilate the patient. Many patients undergoing these procedures have a long history of heavy smoking and alcohol use, which predisposes them to cardiovascular disease and labile vital signs. Some of the disadvantages of this approach include difficulty in reintubation and the time allotment between ventilations while preventing desaturations. The procedure must be interrupted frequently to ventilate the patient, and the airway is unprotected while the ETT is removed. During this technique, the blood pressure and heart rate tend to fluctuate widely. The procedure resembles a series of stress-filled laryngoscopies and intubations, separated by varying periods of minimal surgical stimulation. Intravenous administration or topical application of agents such as lidocaine; small doses of alfentanil, remifentanil, sufentanil, or fentanyl; and/or β-adrenergic receptor–blocking drugs such as esmolol may help moderate the sympathetic response.

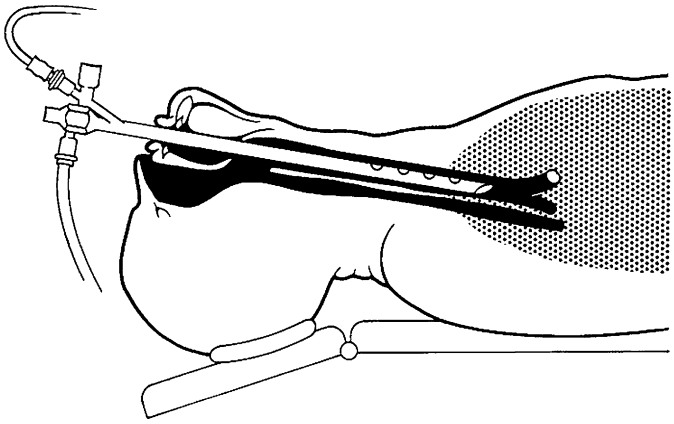

FIGURE **38-7** Rigid bronchoscope connected at its proximal end through an oblique side port to the jet line of the ventilator. (From Biro P. Jet ventilation for surgical interventions in the upper airway. *Anesthesiol Clin*. 2010;28[3]:397-409.)

Jet Ventilation

Jet ventilation has been used extensively for laryngeal surgery. When the trachea is not intubated, a metal needle mounted in the operating laryngoscope or passed through the cords can be used for jet ventilation. Jet ventilation may be performed manually, using a simple hand valve attached to an appropriate oxygen source, or together with various mechanical devices that allow for adjustment of rate and oxygen concentration. Because oxygen can support combustion, the lowest concentration of oxygen possible should be used. Many patients will tolerate an Fio_2 of 30% or less; however, oxygen requirements for each patient should be considered for his or her individual needs. Using lower levels of oxygen will decrease the likelihood of an airway fire.

High frequency is useful when access to the airway by the surgeon is limited by the endotracheal tube or the surgeon might interfere or ignite the tube. Jet ventilation does not require an endotracheal tube and requires only a narrow catheter with resistance to laser beams. There is no absolute contraindication to high-frequency jet ventilation (HFJV); however, it can be difficult maintaining oxygenation and/or CO_2 elimination in certain patients. These include patients who are morbidly obese, have a stiff thorax, or present with advanced forms of restrictive and/or obstructive lung disease, lung fibrosis, and reduced alveolar-capillary diffusion capacity, such as with pulmonary edema. Jet ventilation should be avoided in any situation in which an unprotected airway is a concern (e.g., full stomach, hiatal hernia, or trauma).[33]

Common types of HFJV include supraglottic, infraglottic, transtracheal, and via a rigid bronchoscope.[34] Figure 38-7 shows the commonly used rigid bronchoscope technique. HFJV was originally used as a technique to provide adequate oxygenation and alveolar ventilation for rigid bronchoscopy and laryngeal surgery. HFJV is typically ventilation at low tidal volumes with high respiratory rates. A needle connected to a high-pressure hose with a regulator to adjust rate and volume is used to deliver the ventilation. With the tip of the needle either above or below the

glottis, the anesthetist directs a high-velocity jet stream of oxygen into the airway lumen. The lungs are ventilated as the mixture of oxygen forces air into the lumen. Introduction of high-pressure (up to 60 psi) jet-injected oxygen entrains room air into the lung, allowing the jet stream of gases into the airway for ventilation.[35] Whereas inspiration is accomplished by HFJV pressurizing gas into the airway, the expiration is passive and adequate exhalation should be constantly assessed. Some pauses in ventilation may be necessary to provide adequate time for expiration, particularly in patients with severe respiratory disease.

If an airway mass lies above the level of delivery of the gas jet, it may be easy to force the gas down the trachea during inspiration, but the gases will be trapped during expiration. This air trapping can lead to increased airway pressure, subcutaneous emphysema, and pneumothorax, particularly in patients with bullae. The anesthetist or surgeon also may find it difficult to aim the jet into the airway lumen, leading to hypoxia. If the jet is not accurately aimed, gastric distention, subcutaneous emphysema, or barotrauma may result. Patients with decreased pulmonary compliance or increased airway resistance from bronchospasm, obesity, or chronic obstructive pulmonary disease (COPD) are at high risk for hypoventilation with jet techniques. Adequacy of ventilation is assessed by observing chest movement, auscultation with the precordial stethoscope, and a pulse oximeter. Intravenous anesthetic techniques are used with HFJV, because environmental contamination by leaking volatile agents is a concern.[34]

Foreign-Body Aspiration

Aspiration of foreign bodies is a common problem that carries high morbidity and mortality, particularly in children. Asphyxiation by an inhaled foreign body is a leading cause of accidental death among children younger than 4 years. Some common aspirants include peanuts, popcorn, jelly beans, coins, and bites of meat and hot dogs. The majority of aspirated items are food particles, with nuts and seeds being the most common. Aspiration of beads, pins, and parts of small toys are not unusual. A common site of foreign body aspiration is the right bronchus. If the patient is supine when the aspiration occurs, the object will most likely be found in the right upper lobe. If the patient is standing, the right lower lobe is most likely to be affected. Signs of aspiration include wheezing, choking, coughing, tachycardia, aphonia, and cyanosis. These signs indicate an obstructive severe irritation and swelling in the airway. As a result of the swelling, air may be trapped in the lungs, not allowing adequate expiration. Although rigid bronchoscopy is the traditional diagnostic "gold standard," the use of computerized tomography, virtual bronchoscopy, and flexible bronchoscopy is increasing. Reported mortality during bronchoscopy is 0.42%. Although asphyxia at presentation or initial emergency bronchoscopy causes some deaths, hypoxic cardiac arrest during retrieval of the object, bronchial rupture, and unspecified intraoperative complications in previously stable patients constitute the majority of in-hospital fatalities. Major complications include severe laryngeal edema or bronchospasm requiring tracheotomy or reintubation, pneumothorax, pneumomediastinum, cardiac arrest, tracheal or bronchial laceration, and hypoxic brain damage.[36]

Anesthetic management depends on the location of the airway obstruction, the size and location of the object, and the severity of the obstruction. If the foreign body is located at the level of the larynx, a simple laryngoscopy with Magill forceps should allow for easy removal of the object. Care must be taken not to dislodge the object and allow it to fall deeper into the airway. If the foreign body is located in the distal larynx or trachea, the patient should have an inhalation induction performed in the operating room, maintaining spontaneous respiration. With the patient spontaneously breathing, the surgeon will most likely use a rigid bronchoscope for extraction of the foreign body. Usually, a gentle mask induction without cricoid pressure or positive pressure ventilation is the preferred induction technique.[37] Attempts to assist respirations should not be made because that might cause the object to move farther into the airway and compromise ventilation with occlusion. Patients should be placed in the sitting position because it is known to produce the least adverse effect on airway symptoms. An antisialagogue, H_2 antagonist, and metoclopramide are often administered intravenously to decrease secretions and promote gastric emptying; the secretions may obscure the view through the bronchoscope. Patients with full stomachs who are induced with a rapid sequence must be prepared for complete occlusion of the airway.

Direct and sometimes rigid laryngoscopy is typically performed. A rigid bronchoscope is also used and passed through the vocal cords into the trachea. Ventilation is accomplished through a side port of the laryngoscope or bronchoscope that can be attached to the anesthesia circuit. If a foreign body is present, the telescope eyepiece within the bronchoscope is removed and optical forceps are inserted through the bronchoscope for retrieval of the item. When the telescopic eyepiece is being changed, a leak is present in the ventilation system, and protracted periods can lead to hypoxia. When an anesthesia gas machine circuit is used, high fresh gas flow rates, large tidal volumes, and high concentrations of inspired volatile anesthetic agents are often necessary to compensate for leaks around the ventilating bronchoscope. Coughing, bucking, or straining during instrumentation with the rigid bronchoscope may cause difficulty for the surgeon and result in damage to the patient's airway; these must be avoided. The best anesthesia technique for rigid laryngoscopy and bronchoscopy is total intravenous anesthesia, allowing greater control of cardiovascular stability and relaxation for short periods, as well as ventilation with 100% oxygen, allowing longer periods of hypoventilation without hypoxia.

A rigid bronchoscopy can lead to several complications, including damage to dentition, gums, and upper lips and chipped or damaged teeth, all of which can be prevented to some degree with the use of a mouth guard and vigilance. A good range of motion of the cervical vertebra is also evaluated and necessary for insertion of the rigid scopes. Vagal stimulation may be noted from the extreme head extension, and tracheal tears can occur with the introduction of the bronchoscope. Inadequate ventilation manifests as hypoxemia, hypercarbia, barotrauma, and dysrhythmias. The surgeon must be prepared to perform an emergency tracheotomy or cricothyrotomy if partial obstruction suddenly becomes complete.

At the conclusion of the procedure, patients can be intubated to provide ventilation until returning to consciousness. Allow the patient to return to consciousness as quickly as possible, with airway reflexes intact prior to extubation. Laryngeal and subglottic edema may occur for 24 hours after removal of a foreign body. To check for airway edema, the cuff of the ETT can be deflated if not contraindicated, and the lumen of the ETT should be occluded for one or two breaths during inspiration and expiration while listening for air movement around the tube. If there is no air escaping around the ETT, postoperative sedation and ventilation might be considered. Close observation and use of humidified oxygen are suggested during the recovery period. Some additional supportive measures that can alleviate some of the postoperative complications that occur include racemic epinephrine, bronchodilators, and steroids.

PROCEDURES INVOLVING THE FACE, EAR, HEAD, AND NECK

Some of the common surgical procedures for the ear and face include myringotomy with insertion of tubes, mastoidectomy,

acoustic neuroma, stapedectomy, and tympanoplasty. During ear surgery, the anesthetist must be concerned with four major issues: (1) nerve preservation, (2) the effect of nitrous oxide on the middle ear, (3) control of bleeding, and (4) PONV.

Nerve Preservation During Surgical Procedures

Surgical procedures of the ear and face require meticulous identification and preservation of the facial nerve and other cranial nerves, especially during resection of a glomus tumor or an acoustic neuroma. Intraoperative neuromonitoring is a relatively recent advance in electromyography (EMG) applied to head and neck surgery. Its purpose is to allow real-time identification and functional assessment of vulnerable nerves during surgery. The nerves most often monitored in head and neck surgery are the motor branch of the facial nerve (VII), the recurrent or inferior laryngeal nerves (X), the vagus nerve (X), and the spinal accessory nerve (XI), with other cranial lower nerves monitored less frequently. Morbidity from trauma to these nerves is significant and obvious, such as unilateral facial paresis. Although functional restorative surgery can be performed, the importance of preventing nerve injury in head and neck surgery is obvious.

The identification of these nerves requires the surgeon to isolate and verify function by means of an electrical stimulation. One method used for nerve isolation is the brainstem auditory evoked potential and electrocochleogram monitoring. Table 38-7 lists several types of intraoperative neurophysiologic monitoring used during ENT procedures and the effects of various anesthetic drugs on the monitoring modality.[38]

Patient movement during neck dissection and skull base surgery must be prevented, especially if a positioning device is used for craniotomy. Muscle relaxants should be used only at time of induction and intubation to prevent interference with the nerve monitors. The use of local anesthetics is also contraindicated because of their suppressant effects on muscle action potential amplitudes and muscle movement. Hemostasis during neck dissection is not as critical as during otologic or skull base neurosurgery, but the use of a short-acting opioid infusion such as remifentanil or sufentanil will help control blood pressure and aid hemostasis. The use of volatile anesthetic agents and nitrous oxide is acceptable only if the nitrous oxide is discontinued well before closing any cavity. Common anesthetic techniques include the use of remifentanil with short-acting volatile anesthetic agents with or without nitrous oxide. Midazolam preoperatively helps assure amnesia and rapid emergence. Selected use of deep extubation helps prevent straining during emergence; straining increases postoperative bleeding and may necessitate reexploration.[38]

Middle Ear Procedures

Middle ear procedures require a bloodless surgical field, specific head positioning, facial nerve monitoring, and management of postoperative nausea and vomiting. The term *middle ear* refers to the air-filled space between the tympanic membrane and the oval window. It is connected to the nasopharynx by the eustachian tube and is in close proximity to the temporal lobe, cerebellum, jugular bulb, and the labyrinth of the inner ear. The middle ear contains three ossicles—the malleus, incus, and stapes—which transmit sound vibration from the eardrum to the cochlea. This air-filled cavity is traversed by the facial nerve before it exits the skull via the stylomastoid foramen. The facial nerve provides motor innervation to the muscles of facial expression. Common surgeries in adults include tympanoplasty (reconstructive surgery for the tympanic membrane, or eardrum), stapedectomy or ossiculoplasty for otosclerosis, mastoidectomy for removal of infected air cells within the mastoid bone, and removal of a cholesteatoma. Common middle ear surgery in children includes tympanoplasty, mastoidectomy, myringotomy, grommet insertion, and cochlear implantation.[39]

Middle ear surgery can be done with either local or general anesthesia depending on the patient's ability to cooperate. Local anesthesia with sedation requires the patient to remain still under surgical drapes for extended periods. The main advantages of performing middle ear surgery under local anesthesia are the ability to test hearing during surgery and less bleeding. Most middle ear procedures can be performed as outpatient surgery; thus rapid recovery, good analgesia, and avoidance of nausea and vomiting are essential. Pain is a primary problem at the beginning of surgery when multiple injections of local anesthetic with epinephrine are given. The use of topical application of lidocaine and prilocaine (eutectic mixture of local anesthetics [EMLA]) may increase patient comfort. A bloodless surgical field is mandatory in microsurgery. A combination of physical and pharmacologic techniques is used to minimize bleeding. The patient's head is positioned to avoid venous obstruction and congestion.[40,41]

When general anesthesia is chosen, the airway can be maintained with a laryngeal mask airway (LMA) or endotracheal intubation. Intubation may be more appropriate if extreme neck extension or rotation is required. A nerve stimulator is often employed for intraoperative monitoring of evoked facial nerve electromyographic activity to aid preservation of the facial nerve. Muscle relaxants therefore are avoided after intubation. A smooth recovery without coughing or straining is important, especially in patients who have undergone reconstructive middle ear surgery to prevent prosthesis displacement.

Postoperative nausea and vomiting (PONV), a common problem after middle ear surgery, can be minimized by appropriate choice of anesthetic technique and antiemetic prophylaxis.[42] As noted above, a bloodless operative field is essential. Physical and pharmacologic techniques are used to minimize bleeding. They include a head-up tilt of 15 to 20 degrees, avoidance of venous obstruction, normocapnia, and controlled hypotension. An ideal blood pressure range is 80 to 90 mmHg or a reduction of mean arterial pressure to 30% of baseline in patients with hypertension. A slightly elevated position of the head reduces arterial and venous pressures in areas above the heart; however, it increases the risk of air embolism.

Pharmacologic agents used for controlled hypotension in ear, nose, and throat surgery include inhalation anesthetics, β-adrenoceptor antagonists (labetalol and esmolol), α_2-adrenergic agonists (dexmedetomidine), opioids (remifentanil), and more recently magnesium sulfate.[39,43] Dexmedetomidine has several advantages as an adjunct to lower blood pressure. It produces sedation, analgesia, and a modest reduction in heart rate and blood pressure without respiratory depression. Dexmedetomidine has been used successfully to lower blood pressure during general anesthesia or as the primary sedative with supplementary low-dose propofol and midazolam for intravenous sedation.[44,45] At the completion of the surgical procedure, the patient's head is lifted and usually wrapped with a bandage. The anesthetist will want to avoid excessive coughing and bucking of the patient during this period. Therefore, using a technique that limits coughing is desirable. Provided there are no contraindications, a deep extubation might be considered.

Nitrous Oxide and Middle Ear Surgery

Nitrous oxide (N_2O) is more soluble than nitrogen in blood and enters the middle ear cavity more rapidly than nitrogen leaves,

TABLE 38-7 Types of Intraoperative Neurophysiologic Monitoring and the Effects of Various Anesthetic Drugs

Type or Modality of Neurophysiologic Monitoring	Surgery Examples	Region	Volatile Agents (e.g., Isoflurane)	Neuromuscular Blocking Agents*	TOTAL INTRAVENOUS ANESTHESIA		Local Anesthetics*	Nitrous Oxide
					Opioids	Propofol		
Brainstem auditory evoked response	Acoustic neuroma, trigeminal neuralgia, facial nerve decompression, endolymphatic sac	Cerebellopontine angle, mastoid region, middle ear	1	0	0	1	0	0
Cortical somatosensory evoked potentials	Spinal fusion, tumor, decompression	Spine (posterior columns)	2 (affect amplitude and latency of waveforms)	0	0	0	2	1 Nitrous oxide (affects amplitude only)
Neuromuscular junction monitoring	Neuromuscular blockade in anesthesia	Ulnar nerve, facial nerve, posterior tibial nerve	0	2	0	0	2	0

From Dillon FX. Electromyographic (EMG) neuromonitoring with otolaryngology-head and neck surgery. *Anesthesiol Clin.* 2010;28(3):434-442.

Scale: 0 = insensitive; 1 = somewhat sensitive; 2 = very sensitive.

*The two classes of drug to be avoided during monitoring of facial, recurrent laryngeal, vagal, and other cranial motor nerves are neuromuscular blocking agents and local anesthetics. Both may increase latency, decrease amplitude, and increase stimulus threshold of the evoked response, or may decrease the sensitivity of EMG to nerve injury.

†A conventional balanced anesthetic (opioid, nitrous oxide/oxygen, volatile agent) is suitable for surgery using EMG and EEG.

BIS, Bispectral electroencephalogram; *EEG*, electroencephalogram; *EMG*, electromyogram; *IONM*, intraoperative nerve monitoring; *MEP*, motor evoked potentials.

causing an increase in middle ear pressure if the eustachian tube is obstructed. Normally, pressure increases in the middle ear are vented via the eustachian tube into the nasopharynx. Yawning and swallowing actively open the eustachian tubes, but these equalizing maneuvers cannot occur in anesthetized patients. Additionally, pressure also may be increased in the middle ear with positive pressure ventilation by forcing air into the compartment through the eustachian tubes. During tympanoplasty, the middle ear is open to the atmosphere; thus there is no build-up of pressure, but once a tympanic membrane graft is placed, the continued use of nitrous oxide might cause displacement of the graft. At the end of surgery, when nitrous oxide is discontinued, the remaining N_2O is rapidly absorbed, which may then result in negative pressure, also possibly resulting in graft dislodgement, serous otitis media, disarticulation of the stapes, or impaired hearing. Some clinicians feel that discontinuation of the N_2O at least 15 minutes before closure of the middle ear is sufficient to prevent these adverse effects. Because N_2O is only a supplement to general anesthesia, avoiding it altogether during tympanoplasty is more reasonable. Nitrous oxide also may increase PONV, and its use in middle ear surgery may further increase the incidence of PONV above that already associated with this type surgery.[39]

Myringotomy and Tube Placement

Most often, patients scheduled for myringotomy are young, healthy patients. A myringotomy allows the pressure to equalize between the middle ear and the atmosphere, reducing the pressure in the middle ear compartment. Simple tubes with a lumen (grommets) are placed through the patient's tympanic membrane to alleviate the pressure created in the middle ear usually seen with chronic serous otitis media or recurrent otitis media. Chronic otitis media is manifested as fluid in the middle ear. Recurrent otitis media, a common pediatric disorder, is defined as either three or more acute infections of the middle ear cleft in a 6-month period or at least four episodes in 1 year. Untreated otitis media may lead to permanent middle ear damage and hearing loss; therefore, appropriate treatment is necessary. Children with chronic otitis frequently have accompanying recurrent upper respiratory infections (URIs). Intervals between URIs may be brief, and the patient is usually on a regimen of antibiotics. Scheduling surgery during these interludes is often impractical. Frequently, the eradication of middle ear fluid and inflammation resolves the URI; therefore, surgery should not be delayed.

Bilateral myringotomies with tube insertions are typically very short operations. Sedative premedications may outlast the procedure and are usually not necessary. Mask or IV induction and maintenance using oxygen, nitrous oxide, and a volatile inhalation agent such as sevoflurane is routine. If IV access is established, it is usually done after mask induction in children and may include fluid therapy or an injection cap for temporary access and administration of drugs. IVs are not usually necessary unless another procedure is performed at the same time.[46,47] N_2O is often avoided in surgeries that involve the middle ear, but given that the myringotomy surgical procedure is relatively short, and a tube will be placed through the tympanic membrane into the middle ear to relieve pressure, the effects of N_2O are not relevant. For bilateral procedures, the inhalation anesthetic is discontinued during the second myringotomy to facilitate prompt emergence. N_2O is continued until the completion of the surgery. Intubation is performed only if airway difficulties are anticipated or encountered, but airway equipment is always prepared and available. The procedure is typically without much risk of bleeding, but the patient's head must be held still, particularly when the myringotomy knife is being used.

The patient is supine with the head turned to expose the ear to the microscope. An ear speculum is inserted into the ear canal, cerumen is removed, and an incision is made in the tympanic membrane. Fluid is sometimes suctioned from the middle ear, and then a tympanostomy tube is inserted through the incision into the middle ear, straddling the tympanic membrane. Antibiotic and steroid eardrops frequently are inserted into the external auditory canal and mild pain medications given rectally, orally, or intravenously are administered in the perioperative period. The surgeon moves to the other side of the table, the microscope is repositioned, the head is turned, and the procedure is repeated in the other ear.[48,49]

Tonsillectomy and Adenoidectomy

The frequency of adenotonsillectomy in the United States has declined recently, although it remains the most common pediatric surgery.[50] The lateral tonsils, tonsillar tissue at the base of the tongue, and adenoids form a tonsillar "ring" around the oropharynx that can lead to significant airway challenges after surgical intervention. An adenotonsillectomy, although often considered a simple procedure, has the potential for significant airway challenges. Considerations of airway obstruction, shared airway, mechanical suspension of the airway, management of intubation and extubation, pain management, and the desire for a rapid awakening are all subtleties of anesthesia for this procedure. In adult patients, a tonsillectomy may also accompany a uvulopalatopharyngoplasty (UPPP) for pickwickian syndrome or obstructive sleep apnea (OSA). OSA is typically seen with obesity and redundant pharyngeal tissue. OSA patients can also present with significant comorbid conditions.[51,52]

The patient undergoing a tonsillectomy and/or adenoidectomy will probably have a higher incidence of airway obstruction because of the hypertrophied tissues. Chronic obstruction and infections of the tonsils can lead to systemic involvement, producing additional cardiac and respiratory anomalies. In the case of suspected airway obstruction, the clinician must choose wisely among routine intravenous induction, inhalation induction, awake intubation, or fiberoptic-assisted intubation before induction. Adult patients with severe obstructive sleep apnea may require awake intubation before the induction of general anesthesia. Surgical approaches to tonsillectomy include coblation, cold steel, snare, monopolar cautery, and hot knife techniques. Techniques differ with respect to operative times, intraoperative blood losses, postoperative pain scores, or time to resumption of oral intake.[53]

In children, anesthesia is induced with propofol or sevoflurane, oxygen, and N_2O by mask depending on the age of the child and intravenous access. Some institutions allow parental presence in the operating room during induction to prevent separation anxiety in the child. Laryngeal mask airway and endotracheal tube both may be used depending on the experience of the operating team.[54] A recent review noted that the use of the LMA during pediatric tonsil surgery does not appear to have any major disadvantages compared with use of the ETT. Analysis of safety, comfort, complications, and postoperative problems suggests that LMA may be superior for some outcome variables such as coughing and gagging. Use of spontaneous ventilation is more common among LMA patients.[55]

A cuffed tube is recommended in those older than 8 to 10 years of age,[4] with continued attention given to inflation pressures of the cuff. A properly sized pediatric ETT should allow a leak at 20 cm H_2O airway pressure, which reduces the likelihood of postoperative croup and edema. After the airway is secured, the mouth gag is inserted by the surgeon. An adequate depth of anesthesia is

needed to facilitate gag insertion. The gag, designed to maintain an open mouth and tongue retraction, is equipped with a groove for the ETT or LMA to rest in (Figure 38-8). The airway should be reevaluated at the time the gag is placed to ensure that the tube has not been moved from its original position and that occlusion of the tube has not occurred as a result of compression from the gag. The table is frequently turned 45 to 90 degrees away from the anesthetist just prior to incision.

The choice of maintenance techniques for anesthesia varies. Several major goals need to be considered when choosing an anesthetic: (1) provide a depth of anesthesia adequate to blunt strong reflex activity elicited by the procedure, (2) a rapid return of protective reflexes, (3) good postoperative analgesia, (4) reduced postoperative bleeding, and (5) minimal PONV. The use of intermediate-acting muscle relaxants is acceptable; however, they are usually not necessary. Judicious narcotic supplementation will reduce the total amount of inhalation agent required and provide analgesia with minimal postoperative respiratory depression. Disadvantages of opiates include increased sensitivity and desaturation in sleep apnea patients and PONV. Suggested techniques include modest opioids and acetaminophen doses for analgesia, dexamethasone and ondansetron for antiemetic prophylaxis, and deep extubation of the trachea to minimize coughing and airway stimulation when prudent.[54] Although an increase in postoperative bleeding has been a concern with the use of nonsteroidal antiinflammatory drugs (NSAIDs), a Cochrane review found that NSAIDs did not cause any increase in bleeding and there was significantly less nausea and vomiting compared to use of alternative analgesics.[56,57]

Blood loss during tonsillectomy is difficult to assess but has been estimated to average 4 mL/kg or 5% of blood volume.[7] Average blood loss during UPPP is slightly higher because the procedure frequently is performed in conjunction with adenotonsillectomy. Although younger, healthier patients can tolerate greater volumes of blood loss, transfusion should be considered if blood loss, laboratory values, and patient factors indicate the need.

At the end of the surgical procedure, the surgeon may release tension on the mouth gag to ensure that all bleeding has been controlled. The insertion of an orogastric tube and some irrigation may be used to remove blood and secretions from the stomach and oropharynx. This is thought to reduce the incidence of postoperative nausea and vomiting. Suctioning of the oropharynx and nares should be done very gently and briefly, avoiding the surgical beds to prevent disruption and mucosal bleeding. Vigorous suctioning may induce laryngospasm and bronchospasm.

FIGURE **38-8** Superior view of the suspension technique for tonsillectomy using the Crowe-Davis mouth gag. Note use of preformed RAE orotracheal tube.

During emergence from anesthesia after tonsillectomy or UPPP, the anesthetist should ensure that all protective reflexes have returned, the airway is free of blood and debris, and an adequate breathing pattern is present before the removal of the ETT. A topical spray of 2% lidocaine (maximum 3 mg/kg) on the glottic and supraglottic areas before intubation prevents postextubation stridor and laryngospasm after adenotonsillectomy. This approach has proved as effective as administering lidocaine (1 mg/kg IV) before extubation but without higher sedation scores.[58]

The postoperative tonsillectomy patient should be transported to the recovery in the "tonsil position"—that is, on one side with the head slightly down. This allows blood or secretions to drain out of the mouth rather than flow back onto the vocal cords. Adults, however, frequently prefer a middle- or high-Fowler position after UPPP. This position aids in ventilation and lessens the feeling of asphyxiation in the immediate postoperative period. The patient must be awake enough to manage his or her own airway. To hydrate the airway, 100% oxygen with a high-humidity mist is given by facemask or face tent. The pharynx should be rechecked directly for bleeding and edema before discharge.

Routine tonsillectomy is generally performed as an outpatient procedure. A small subset of children are observed overnight if there are sufficient age, comorbidity, or perioperative concerns. Although postoperative bleeding is the most serious complication, persistent vomiting, poor oral intake, and persistent desaturation are the most common reasons for unscheduled overnight admission after ambulatory surgery. The incidence of postoperative nausea and vomiting can be as high as 70% during the first 24 hours after tonsillectomy.[59] This is due to swallowed blood, opioid administration, or pharyngeal stimulation, and significantly increases the risk of overnight admission, delayed oral intake, and lower patient satisfaction.[54,60,61] As discussed previously, it is important to develop anesthetic techniques that incorporate the use of antiemetics to minimize episodes of nausea and vomiting.

Bleeding Tonsil

Post-tonsillectomy hemorrhage (PTH) is the most common emergency pediatric airway surgery. PTH rates are between 0.5% and 7.5% and are most common in patients more than 15 years of age, boys, patients with frequent infectious tonsillitis, and after hot (electrocautery) versus cold (scalpel) techniques. Approximately 75% of the postoperative tonsillar hemorrhages that occur are within 6 hours of the surgical procedure. The remaining 25% of the postoperative bleeds occur within the first 24 hours of surgery, although bleeding may be noted up until the sixth postoperative day.[62] Slow oozing of the tonsillar bed is far more common than profuse bleeding. Patients may swallow large volumes of blood before bleeding is actually discovered. The patient may present with signs of hypovolemia evidenced by tachycardia, hypotension, and agitation. If the blood is swallowed, the patient may have nausea and vomiting. Appropriate laboratory tests including hemoglobin, hematocrit, and coagulation profile should be performed to determine patient status. Restoration of intravascular volume and/or blood based on the volume lost should precede induction. All patients should be assumed to have a significant amount of blood in the stomach and a rapid sequence induction is indicated. Care with laryngoscopy is necessary to prevent traumatic dislodgement of any clots. In some patients, an awake intubation to maintain reflexes may be necessary. At induction of anesthesia, an additional person should be available to provide suctioning of blood from the oropharynx. The patient should be placed

in a slight head-down position to protect the trachea and glottis from aspiration of blood. Gastric decompression is performed to assess for occult blood loss and decrease the risk of subsequent pulmonary aspiration. The induction agent selected is based on the hemodynamics and condition of the patient. Emergence and extubation of the trachea should occur after return of protective laryngeal reflexes.[54]

Thyroid Surgery

A thorough knowledge of the specific issues related to anesthesia case management for thyroidectomy is essential to provide high-quality care. Airway management may be difficult despite a normal airway examination because of impingement of a thyroid mass on the laryngeal and tracheal structures. Because sympathetic nervous system hyperactivity is associated with increased amounts of thyroid hormone, it is essential that all patients having an elective thyroidectomy be rendered euthyroid prior to surgery. There are multiple preoperative antithyroid medication regimens that effectively treat thyroid hormone hypersecretion. Although it is a rare event, thyroid storm can still occur during the perioperative period.

The thyroid gland is butterfly-shaped and composed of two lobes that are connected by a median tissue mass named the *thyroid isthmus*. It is located on the anterior and anterolateral aspect of the trachea immediately inferior to the larynx. The thyroid gland is the largest endocrine gland in the body, weighing 20 g in the healthy adult. Its major blood supply arises from the superior and inferior thyroid arteries, which are branches of the common carotid artery. Blood flow is approximately five times the weight of the gland, and therefore the thyroid receives one of the greatest blood supply per gram of tissue measures in the body.[63]

Motor function associated with movement of the intrinsic muscles of the larynx that abduct, adduct, and tense the vocal cords is supplied by the recurrent laryngeal nerve (RLN) and the external branch of the superior laryngeal nerve. These nerves lie in close proximity to the lateral lobes of the thyroid gland. During surgical resection, if these nerves are temporarily or permanently damaged, then vocal cord movement can be adversely affected and may result in airway compromise after extubation. Anatomic representation of the thyroid gland and its associated structures is presented in Figure 38-9.

Pathophysiology

Thyroid dysfunction can be treated medically or surgically. A thyroidectomy is performed as definitive treatment for thyrotoxicosis or malignancy. Thyrotoxicosis refers to a condition in which excessive amounts of thyroid hormone are present in a patient's system, whereas hyperthyroidism (the most common cause of thyrotoxicosis) describes states in which the excessive thyroid levels are due to a hyperactive thyroid gland.[64,65] Malignancies of the thyroid gland are the most common malignancies of the endocrine system and have been associated with prior exposure to radiation.[65,66] Thyrotoxicosis is a rare (2%) occurrence in thyroid malignancies.

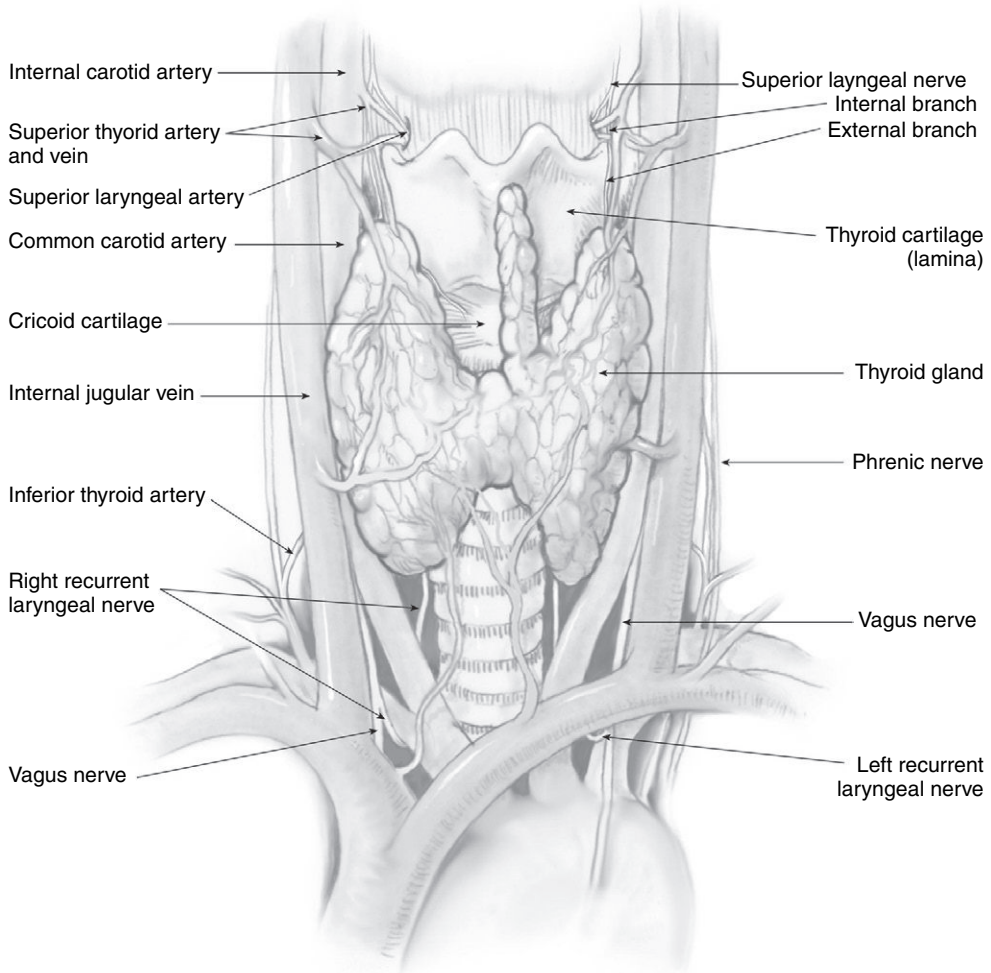

FIGURE **38-9** Thyroid gland and surrounding anatomic structures.

TABLE 38-8 Oral Drugs Used to Treat Hyperthyroidism

Drug	Daily Oral Adult Dose	Comments
Thionamides		
Methimazole (generic)	*Starting:* 10-40 mg once or divided *Maintenance:* 5-15 mg once or divided	Methimazole is preferred due to ease of dosing and a better side effect profile; continue up to the morning of surgery
Propylthiouracil (PTU) (generic)	*Starting:* 100-450 mg divided bid or tid *Maintenance:* 100-150 mg divided bid or tid	
Iodide		Iodide therapy added 1 week prior to surgery and continued through the day of surgery; decreases the production and release of thyroid hormone and reduces thyroid vascularity
SSKI	1-3 drops tid	
Lugol's solution	5 drops tid (dissolve in a full glass of water)	
Beta blockers		Beta blockers without intrinsic sympathomimetic activity are preferred; also used in emergency thyroid surgery for adrenergic suppression
Propranolol (generic)	20-40 mg qid	
Propranolol (Inderal)—long acting	80-160 mg once	
Atenolol (generic and Tenormin)	25-100 mg once or bid	
Metoprolol (generic and Lopressor)	50-200 mg divided bid or tid	

Adapted from Elisha S, et al. Anesthesia case management for thyroidectomy. *AANA J.* 2010;78(2):151-160.
bid, Twice a day; *tid*, three times a day; *qid*, four times a day; *SSKI*, saturated solution of potassium iodide.

Surgery is the principle treatment used to treat thyroid malignancies both for purposes of excision of the tumor as well as staging. Most thyroid malignancies (greater than 90%) are considered well differentiated and are categorized as papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC). PTC accounts for 70% to 80% of thyroid cancer, usually presents at an early stage, and has an excellent prognosis (greater than 95% 10-year survival). FTC accounts for 10% of thyroid cancer and tends to present at a later stage than PTC. The 10-year survival rate for FTC is 85%.[64]

Preoperative Assessment and Preparation

The primary goals during preoperative assessment are ensuring that the patient is euthyroid, assessing the degree of end-organ complications, and determining the extent of airway involvement. Thyroid tumors or large goiters can impinge upon the tracheal cartilages and esophageal tissues, resulting in tracheomalacia and airway compromise. Preoperatively, the patient will be taking a combination of antithyroid medications to decrease the synthesis and release of thyroid hormone and to treat the hyperdynamic state associated with hyperthyroidism. The patient may have taken or be currently taking glucocorticoids, and thus require the administration of a steroid stress dose preoperatively or intraoperatively. Patients should continue their regimen of antithyroid medications and beta blockade through the morning of surgery. Preoperative use of antithyroid drugs has greatly decreased morbidity from thyroid surgery and rendered thyroid storm a rare event. The aim of preoperative management is to restore a normal metabolic state prior to surgical interventions. Patients with hyperthyroidism have increased T_3 and T_4 values and decreased or normal thyroid-stimulating hormone (TSH) levels. Beta-blocking drugs are widely used as an adjunct to the antithyroid thionamides for symptomatic control. Beta blockers are generally continued throughout the surgical period and may be incrementally withdrawn postoperatively. Drugs that are used to treat hyperthyroidism are listed in Table 38-8.[67]

All routine airway assessments should be performed as well as a full visualization and palpation of the patient's neck for a thyroid goiter. The patient's airway should be assessed in the supine position. If there is any indication for the potential for airway compromise, a chest radiograph and a CT scan of the neck and chest should be performed. Routine preoperative testing should include an electrocardiogram. Additional testing is dictated by the individual patient condition. Patients with hyperthyroidism have a higher incidence of myasthenia gravis and may present with skeletal muscle weakness and an increased sensitivity to muscle relaxants.[67]

Intraoperative Anesthetic Management

General endotracheal anesthesia is the technique of choice for thyroidectomy, and the standard induction and maintenance drugs are used. Paralysis may inhibit the surgeon's ability to assess the integrity of the recurrent laryngeal nerve (RLN), and relaxation is avoided after intubation if nerve testing is planned. Succinylcholine is used for intubation due to its short duration. Intraoperative neural monitoring (IONM) during thyroid and parathyroid surgery has gained widespread acceptance as an adjunct to the gold standard of visual nerve identification. Neurophysiologic monitory modalities and the effects of anesthetic drugs are given in Table 38-7.

A special endotracheal tube, Medtronic nerve integrity monitor (NIM) EMG endotracheal tube (NIM-EMG ETT), is frequently used to assess recurrent laryngeal and vocal cord function during surgery.[68] Injury during surgical procedures can lead to hoarseness, aphonia, and (although rare) difficulty with ventilation as a result of permanent adduction of the cords. The major advantage of using the NIM-EMG ETT is that it allows the surgeon the capability of identifying the recurrent laryngeal nerve prior to traction or severing the nerve. The NIM-EMG ETT is a flexible silicone elastomer endotracheal tube with an inflatable cuff. The tube is fitted with four stainless steel wire electrodes (two pairs) that are embedded in the silicone of the main shaft of the endotracheal tube and exposed only for a short distance, slightly superior to the cuff. The electrodes are designed to make contact with the patient's vocal cords to facilitate electromyographic (EMG) monitoring of the recurrent laryngeal nerve

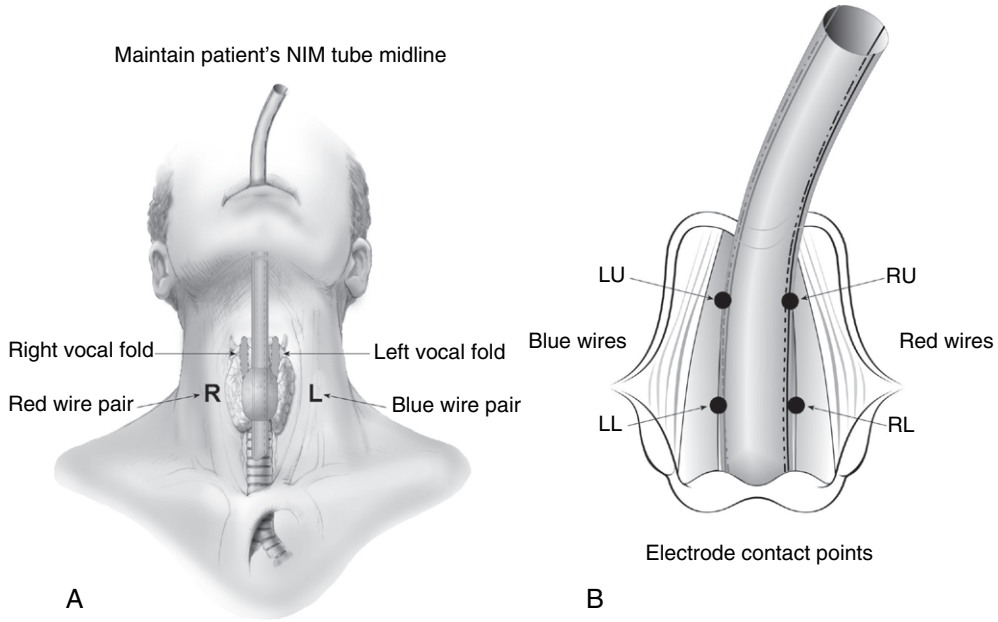

FIGURE **38-10** Nerve integrity monitor (NIM) endotracheal tube. **A,** Proper placement of the NIM endotracheal tube in relation to the thyroid gland. **B,** Four electrode contact points in relation to the vocal cords.

when connected to a multichannel EMG monitoring device. If monitoring correctly, the EMG should show a consistent sound signal and an action potential tracing. The red wire pair of the NIM tube should contact the anterior and posterior portion of the right true vocal cord, and the blue wire pair should contact the anterior and posterior portion of the left true vocal cord as shown in Figure 38-10. Paralysis and laryngeal tracheal anesthesia with lidocaine both inhibit accurate EMG readings. Research is ongoing regarding the efficacy of EMG; however, some studies have shown no statistically significant difference in outcome between a standard endotracheal tube and an NIM tube.[69,70]

Maintenance of anesthesia can be provided by inhalational anesthetics with or without nitrous oxide. A combined deep and superficial cervical plexus block can be considered for intraoperative and postoperative pain management.[71] The patient should be constantly monitored for an increase in core body temperature and hyperdynamic response. If hypotension occurs, it is best treated with a direct-acting vasopressor (phenylephrine) rather than an indirect-acting vasopressor (ephedrine), which stimulates the release of catecholamines.[67] The patient is positioned supine with the head elevated 30 degrees and the neck extended using a roll behind the neck and shoulders (Rose position). The arms are tucked at patient's sides with the ulnar nerves padded and protected. Hyperextension of the neck should be avoided in those patients with atlantoaxial joint instability and/or those with limited range of motion. Due to the limited access to the face, special care should be taken to protect the eyes from injury, especially in patients with exophthalmos.

Postoperative Management

The most common postoperative complications include hypocalcemia, recurrent laryngeal nerve damage, and hematoma at the surgical site. A complete list of the potential postoperative complications is presented in Box 38-4. Postoperative hypocalcemia can result from hypoparathyroidism. The four parathyroid glands are located on the posterior aspect of the thyroid gland and produce parathyroid hormone, which increases serum calcium. Inadequate release of parathyroid hormone is due to the inadvertent removal of the parathyroid glands during a total thyroidectomy. It can also occur secondary to parathyroid gland devascularization, injury, or "stunning" from dissection.[67,72]

Hypocalcemia causes neuronal excitability in sensory and motor nerves. Patients most commonly develop signs and symptoms associated with hypocalcemia 24 to 96 hours postoperatively. The degree of hypocalcemia coincides with the severity of the symptoms, which include perioral numbness and tingling, abdominal pain, paresthesias of the extremities, carpopedal spasm, tetany, laryngospasm, mental status changes, seizures, Q-T prolongation on the electrocardiogram, and cardiac arrest.[64,67,72] Neuromuscular irritability also can be confirmed by assessing for Chvostek's sign (i.e., facial contractions elicited by tapping the facial nerve in the periauricular area) and Trousseau's sign (i.e., carpal spasm on inflation of a blood pressure cuff). In addition, monitoring postoperative ionized calcium levels is recommended because these values are reflective of the physiologically active form of calcium.

Treatment for severe symptomatic hypocalcemia includes the administration of calcium gluconate or calcium chloride (10 milliliters of 10% solution) intravenously given over several minutes and followed by a continuous infusion (1-2 mg/kg/hr) until calcium levels normalize.[67]

Recurrent laryngeal nerve (RLN) damage is estimated to occur in 0% to 14% of cases. The surgical identification and preservation of the RLN is essential to avoid injury. RLN damage may be unilateral or bilateral; however, unilateral nerve injury is more common. Unilateral RLN damage causes the ipsilateral vocal cord to remain midline during inspiration, resulting in hoarseness. Bilateral RLN injury results in dysfunction of both vocal cords, which remain midline during inspiration. After extubation, biphasic stridor, respiratory distress, and aphonia occur due to unopposed adduction of the vocal cords and closure of the glottic aperture. Unlike unilateral nerve injury, bilateral nerve injury necessitates immediate intervention requiring emergent reintubation or tracheotomy.[67]

BOX **38-4**

Complications Associated with Thyroidectomy

- Hypocalcemia-hypoparathyroidism
- Recurrent laryngeal nerve injury—unilateral or bilateral
- Neck hematoma
- Thyroid storm
- Superior laryngeal nerve injury
- Infection
- Pneumothorax
- Tracheomalacia

Adapted from Elisha S, et al. Anesthesia case management for thyroidectomy. *AANA J*. 2010;78(2):151-160.

Postoperative bleeding of the surgical site results in a neck hematoma, which causes airway obstruction and asphyxiation. Common symptoms of neck hematoma include neck swelling, neck pain and pressure, dyspnea, and stridor. Initial treatment includes the emergent evacuation of the neck hematoma followed by airway management.[67,72]

Cleft Palate and Lip

Cleft Palate (Hard Palate and Soft Palate)

Cleft lip and palate is one of the most common craniofacial abnormalities, occurring in approximately 1:700 births.[73] During fetal development, the bones of the face develop between the fifth and ninth weeks and the growth of the palatal bones between the sixth and eleventh weeks. A cleft develops when the bones of the nasal and maxillary or the palatal bones fail to fuse. A fetus can develop both a cleft lip and palate or either alone. Up to 30% of these newborns have other congenital anomalies such as Down syndrome, Pierre Robin syndrome, and Treacher Collins syndrome.

The timing for surgery remains controversial. Generally, cleft lip repair with primary tip rhinoplasty is performed at age 3 months. This will enable the baby to feed and demonstrate normal facial expressions. The next repair involves closure of the posterior hard palate and the soft palate before the development of speech and is usually at 5 to 8 months of age depending on the exact defects. The patient's overall health status and the presence of other congenital anomalies are considerations as well. Widely followed preoperative guidelines include the rules of ten: weight at least 10 pounds, hemoglobin at least 10 g, white blood cell count less than 10,000/mm^3, and age more than 10 weeks. Others advocate for earlier repair, and in utero techniques are under investigation.[74,75]

Intubation may sometimes be difficult if the laryngoscope blade slips into the cleft. However, packing the cleft with gauze may prevent this from occurring. An oral RAE tube or flexible connector is used and secured at the midline of the lower lip. A specialized mouth gag is used to hold the mouth open and the ETT in place during cleft-palate surgery. All air bubbles should be carefully removed from IV lines to prevent air embolus, owing to the incidence of associated cardiac anomalies (e.g., atrioventricular defect [AVD]) that may lead to air crossing from the venous to the arterial circulation. Congenital heart disease may influence which drugs are selected for maintenance of anesthesia and infiltration of the operative site, particularly if epinephrine is selected. Care must be implemented to protect the child's eyes because accidental damage may occur during the surgical procedure. Before emergence, a suture is often placed through the tip of the tongue and taped to the cheek. This suture eliminates the need for an oral airway and prevents damage to the palatal repair. If soft-tissue obstruction occurs during emergence or recovery, traction on the suture can alleviate the problem. If edema occurs, a more aggressive and immediate airway management technique should be used. Copious secretions and blood may cause laryngospasm after extubation, and therefore a clear airway is imperative.

Cleft Lip

Management of unilateral cleft lip repair consists of routine induction followed by oral intubation using an RAE tube or a flexible connector. Secure the tube to the lower lip and midline via tape. To decrease tension on the surgical sutures at the end of the procedure, the surgeon may place a Logan bow across the upper lip of the patient.[76] When the Logan bow is placed, mask ventilation during emergence will become impaired or impossible. Extubation must be performed only with the patient fully awake and reflexes intact. The child's surgical site must also be protected from finger and hand manipulation. Some hospitals recommend the use of hand mittens or taping the extremities onto armboards during the postoperative period. Close monitoring of respiration should proceed into the postoperative period.

Dental Restoration Procedures

Dental restoration procedures are performed under general anesthesia for a multitude of reasons. These include rampant cavities, history of cerebral palsy or Down syndrome, and an uncooperative patient who would not be an appropriate candidate for local anesthetic and an office procedure.

Mentally disabled patients typically develop a close relationship with either a family member or their long-term health-care worker. It is often suggested that this individual accompany the patient to decrease anxiety and communicate a health history to the anesthesia provider. A thorough airway assessment should be performed before considering induction. Oral midazolam (0.5 mg/kg) or ketamine (3 to 4 mg/kg intramuscularly [IM]) is most effective in sedating children in the preoperative arena. Because many patients requiring dental restoration have congenital anomalies, it is not uncommon to find a small oropharynx, enlarged tonsils, a large tongue, and increased secretions. Atlantoaxial instability and congenital heart disease should also be considered in the preoperative preparation and anesthetic management.[77-79] Preparation and appropriate airway management must be planned and implemented for these patients. Patients who receive phenytoin to control seizures may have gingival hyperplasia. Because the gingiva is highly vascular, any surgical manipulation during restoration may lead to significant blood loss.

In patients with normal airways, a standard induction is appropriate, and a nasal intubation usually facilitates the dental procedure. The application of a topical vasoconstrictive nasal spray during the preoperative period reduces or prevents bleeding during the insertion of the nasotracheal tube. Following loss of consciousness, lubricated intranasal trumpets may be inserted into the most patent nasal airway. Starting with a smaller nasal trumpet, several are placed in increasing sizes to dilate the airway. When full dilation of the nares has occurred, a well-lubricated ETT is passed through the nose into the trachea, either blindly or assisted by Magill forceps under direct laryngoscopy. The nasal ETT is preferably placed on the side opposite where the surgeon will be working. The ETT is often sewn to the nasal septum by the surgeon. Throat packs may be placed to prevent blood from entering the stomach and causing nausea and vomiting; monitoring their removal is essential to preventing respiratory obstruction after extubation.

Sinus and Nasal Procedures

Nasal and sinus procedures for drainage of chronic sinusitis, polyp removal, repair of a deviated septum, or closed reduction of fractures

generally involves the young and healthy patient population. Many patients who undergo sinus and nasal surgery have chronic environmental and drug allergies; therefore, there is an increased incidence of reactive airway disease in these patients. Nasal polyp removal, for example, may be necessitated by Samter syndrome. A patient with Samter syndrome or triad presents with nasal polyps, asthma, and an aspirin allergy. The nasal polyps, if symptomatic, are removed surgically. The use of fiberoptics or functional endoscopic sinus surgery for nasal and sinus surgery has become a popular treatment for chronic sinusitis.

Nasal surgery may be successfully accomplished with local anesthesia, local combined with intravenous sedation, or general anesthesia. All three methods of anesthesia require vasoconstriction. The mucous membranes of the sinuses and nose are highly vascular, and blood loss may be significant if vasoconstriction is not used. The surgeon may select to control vasoconstriction with epinephrine or cocaine. Bizikas et al.[80] found when comparing cocaine and tetracaine that using tetracaine 2% with epinephrine produces superior anesthesia and vascular control for rhinoplasty. A hypotensive technique or slight head elevation (i.e., 10 to 20 degrees) may be used during the procedure. Using general anesthesia has been associated with increased blood loss, even with the use of an epinephrine injection. This exaggerated blood loss may be related to the vasodilatory properties of inhalation agents. Delivering general anesthesia for sinus surgery with propofol, as well as other intravenous anesthetic techniques for the maintenance of anesthesia, has been associated with less blood loss than occurs with the use of volatile agents for maintenance.[78] The placement of an oropharyngeal pack and light suctioning of the stomach at emergence may attenuate postoperative retching and vomiting. After all of the packing is removed, extubation should be performed on the awake patient who has regained control of protective reflexes.[79] The use of intravenous or topical lidocaine may reduce some of the coughing prior to extubation, leading to less bleeding in the postoperative period.
